
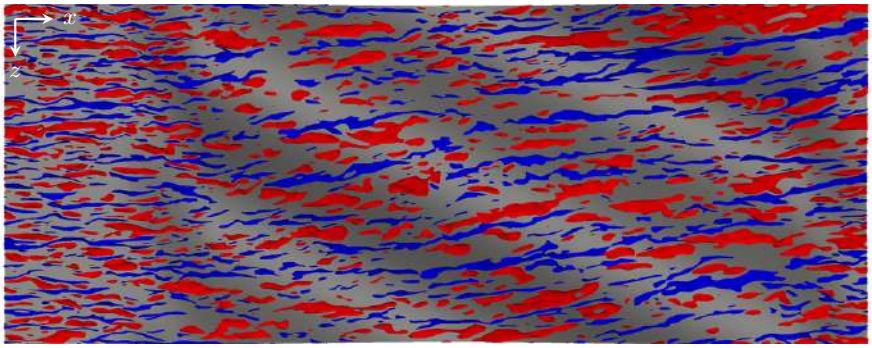

Figure 1: Contours of the random streamwise velocity fluctuations for $u''^{+} = -3$ (blue) and $u''^{+} = 3$ (red) in the streamwise interval $-20 \leq x \leq 145$ and in the near-wall region $0 < y^{+} < 20$ of the actuated upstream traveling wave case.

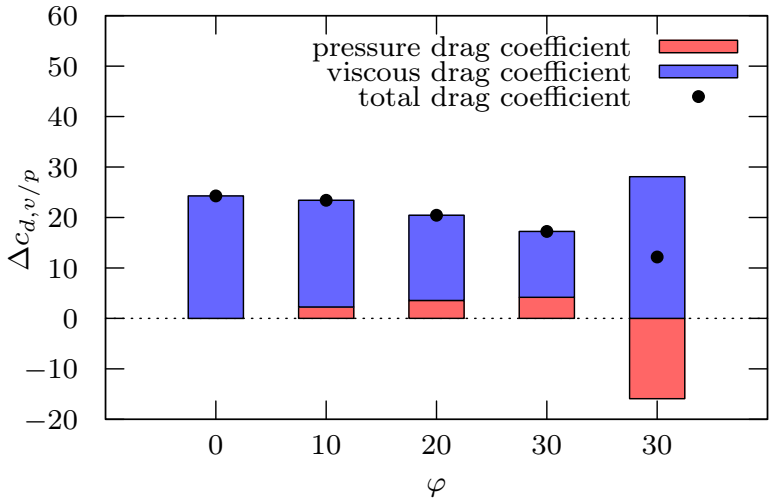

Figure 2: Variation of the viscous, pressure, and total drag coefficient.

represent increasing sweep angles for downstream traveling waves a decreasing viscous drag reduction and an additional favorable pressure drag contribution is observed. That is, the decrease of the overall drag reduction is damped since the pressure distribution generates thrust on the wavy surface. For the upstream traveling case, i.e., the fifth column, on the other hand a strong additional pressure drag diminishes the high viscous drag reduction such that the overall drag reduction is only moderate.

CONCLUSION

Large-eddy simulations of transversal traveling surface waves in turbulent boundary layer flow at a sweep angle were conducted. The results show a decrease of the overall drag reduction for non-zero angles. However, for small angles the effect is only on the order of a few percent since an additional positive pressure drag balances the decrease of the viscous drag reduction for downstream traveling waves. For upstream traveling waves the increased viscous drag reduction is diminished by a negative additional pressure drag. The detailed alterations of the turbulent flow field due to non-zero sweep angles will be presented at the conference.

PARTICLE IMAGE VELOCIMETRY BASED EVALUATION OF COHERENT STRUCTURES AND SKIN-FRICTION DRAG REDUCTION BY SPANWISE WALL OSCILLATIONS

Kushal Kempaiah[1], Fulvio Scarano[1], Gerrit E. Elsinga[2] and Bas W. Van Oudheusden[1]

Summary The reduction of turbulent skin-friction drag over a fully developed canonical zero-pressure gradient turbulent boundary layer (ZPGTBL) subjected to spanwise oscillation is measured using planar particle image velocimetry (PIV). The experiments are conducted at Re_θ of 1000, the chosen range of spanwise oscillation amplitude and frequency is around the optimum reported in earlier studies ($T^+_{osc} = 100 - 700$, $A^+_{osc} = 50 - 150$). A high-resolution planar PIV set-up is employed to determine the drag reduction directly from wall shear stress measurement over the oscillating wall. Drag reduction, of up to 15% are quantified. A pronounced drop of turbulence production in the range $y^+ = 5 - 100$ is observed. The vorticity analysis indicates a distortion from the well-known hairpin-packet arrangement, suggesting that the drag-reduction mechanism lies in the inhibition of the hairpin auto-generation.

Introduction

Turbulent skin-friction drag plays a major role in energy consumption in the 21st century. Many techniques have been developed to reduce its detrimental effects. Spanwise wall oscillation is one such technique with a potential of achieving a significant skin-friction reduction. Several numerical (Jung et al. 1992) and experimental campaigns (Choi et al. 1998) have been undertaken with reductions of 45% in skin friction (Quadrio and Ricco 2004) being reported at optimum conditions. Experiments on drag reduction by spanwise wall oscillations reported in the literature have widely employed hot wire anemometry (HWA), given the high accuracy, small probe size and the high temporal resolution. Single-probe HWA measurements do not provide complete information on the behaviour of the different components of the Reynolds stresses which is important to quantify the variation in velocity fluctuations in the streamwise and wall-normal directions of the boundary layer. In addition, turbulent kinetic energy (TKE) production, which is related to the shear stress, can also explain the effects of the wall oscillation. Measurements with planar-PIV provide quantitative information on some components of the Reynolds stress tensor and the spanwise component of the vorticity vector.
Concerning the drag reduction mechanism, it has been proposed that the imposed spanwise wall motion affects the orientation of the streamwise vortices, which leads to a disruption in the lift-up mechanism, and thereby the production of turbulence (Touber and Leschziner 2012). This directly corresponds to a reduction in the ejection and sweep events, which are the drivers for wall-normal momentum transport. These ejections are associated with the formation of hairpin or horseshoe vortices, which are known to occur in packets and travel with similar velocities. It is therefore of practical interest to visualize and quantify the changes in the hairpin packets behaviour under the action of spanwise oscillations.
The present study investigates the applicability of planar PIV to determine skin friction drag reduction over a spanwise oscillating wall. The drag estimates are obtained by measuring the near-wall velocity gradient yielding an estimate of the wall shear. The method and its inherent uncertainties are discussed and compared with existing data. Moreover, velocity and vorticity visualizations are used to infer the large-scale organization of the turbulent structures, with a focus on hairpin packets and the modifications incurring when spanwise oscillations induce drag reduction.

Experimental setup and procedure

The experiments were conducted in an open-return low-speed wind tunnel (W-tunnel) at the Aerospace Engineering laboratory of Delft University of Technology. The tunnel features a contraction ratio of 9:1 with exit cross-section of $40 \times 40 cm^2$. For the current experiment, the turbulence intensity at the edge of the boundary layer at $33 m/s$ is below 1.4%. The flow at the exit is confined within a rectangular channel $1.63m$ long and a flat plate is installed $0.13m$ above the channel floor. The oscillations were obtained using a slider-crank mechanism with the system reaching up to 15 Hz oscillation frequency and peak-to-peak amplitude of 0.02 m. System vibrations were minimised by using a counterweight. The test section was realised in Plexiglas providing optical access for PIV imaging. The measurements are performed at two streamwise locations: ahead (-0.075) and over (0.85) the oscillating plate, at the positions indicated in Figure 1,

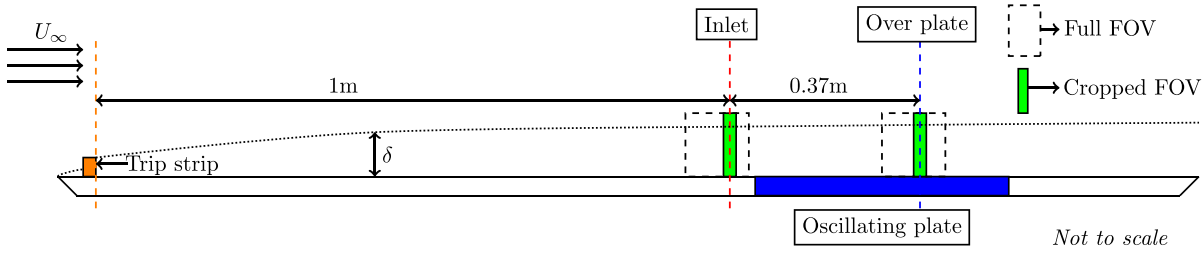

Figure 1: Schematic side-view of the plate with oscillating section. Regions of interest for the PIV measurements are highlighted in green

non-dimensionalization done with the length of the oscillating plate with its leading-edge as reference. For the near-wall measurements, the viscous sub-layer ($y^+ < 5$) is well resolved with 6 ($5y^+ = 0.5mm$) vectors, and data following a linear trend within a finite measurement interval.

Results

The slope $\left(\frac{\partial u}{\partial y}\right)_{y=0}$ at the wall is quantified and processed to provide the drag change with respect to the non-oscillating surface. Figure-2 depicts the boundary layer profile up to the wall, it can be seen clearly that the slope at the wall for the wall oscillated case is lower than that of the stationary wall. The results for the different experiments, with a varying value of the oscillation frequency and constant amplitude, are shown in Figure-3(Left). A peak reduction of 15% is obtained at $T^+_{osc} = 94$ and $A^+_{osc} = 100$ for $Re_\theta = 1000$. The non-dimensional wall velocity $(W^+_m = \pi A^+_{osc}/T^+_{osc})$ corresponding to the above case is $W^+_m = 3.34$ and the reported reduction from literature for a similar condition ($T^+_{osc} = 100$ and $W^+_m = 4.5$) is 17% from Quadrio and Ricco (2004).

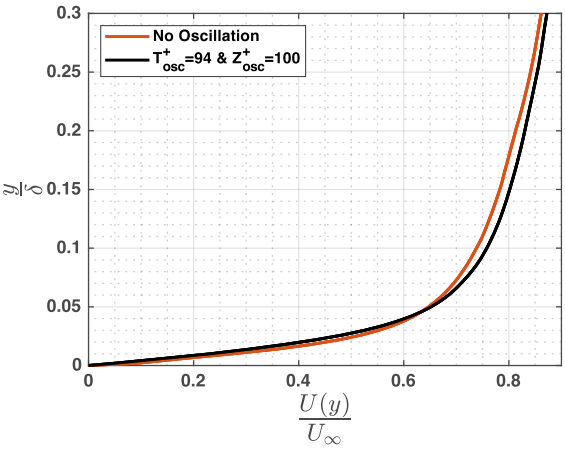

Figure 2:Scaled boundary layer profile

A hairpin packet signatures as described by Adrian (2007) features the presence of a packet of hairpin vortex heads aligned approximately along a 30-degree slope from the wall and separated by approximately 120-160 wall-units in the streamwise direction. They appear atop the low-speed streaks where they tend to auto-generate and lead to packets. For the stationary wall, hairpin packets of 2 to 4 vortices are most frequently observed; a marked difference from the case of the oscillating wall, where the range of organised structures varies between isolated hairpins and packets with more than 2 hairpins are only seldom observed. Figure-3 (Right) depicts this situation.

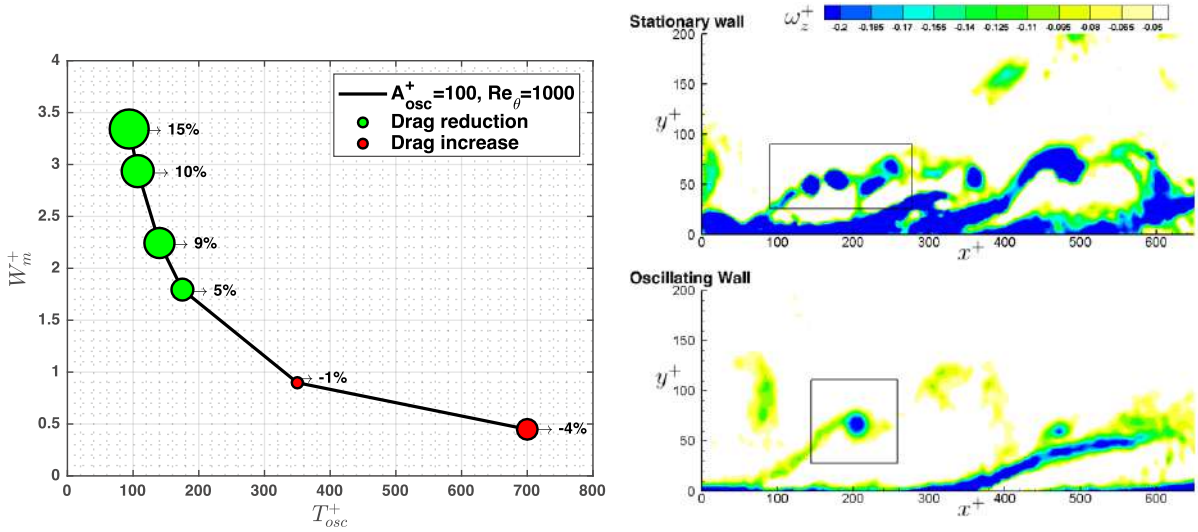

Figure 3: Drag reductions obtained from wall shear measurements(marker size represents magnitude(Left) and Vorticity fields(Right) with Hairpin packet signature (top) stationary wall (bottom) oscillating wall

INVESTIGATION OF THE FLOW STRUCTURE BEHIND THREE-DIMENSIONAL AND TWO-DIMENSIONAL ROUGHNESS ELEMENTS ON A MODEL OF A FLYING WING

Alexandr Pavlenko*[1], Valeriia Kaprilevskaia[1], Victor Kozlov [1] and Mikhail Katasonov [1]
[1] Laboratory of Aerophysical researches of subsonic flows, Khristianovich Institute of Theoretical and Applied Mechanics of SB RAS, Novosibirsk, Russia

Summary The paper is devoted to the experimental studies of the development of stationary perturbations and the transition to turbulence behind a localized three-dimensional roughness element and two-dimensional roughness in the negative and positive pressure gradient region of a flying wing model. Panoramic flow structure were carried out by means of liquid crystal thermography technique with a heated surface by halogen lamp and oily covering visualization (mixture of oil, kerosene and titanium dioxide powder). Using hot-wire anemometry, the spatial characteristics of stationary perturbations were studied, and also the spectra of velocity pulsations spectra were obtained. It was found that the application of an acoustic field of 1 kHz leads to an increase in the amplitude of stationary structures behind the two-dimensional roughness element.

INTRODUCTION

Nowadays unmanned aerial vehicles (UAV) and drones are very popular types of aircrafts. Intensive development of unmanned aircraft leads to competition for the characteristics of aircraft. The most important indicators are autonomy, the minimum effective scattering area in the framework of the application of stealth technology. These requirements are fully satisfied by the concept of "flying wing" (figure 1). Reduction of aerodynamic resistance of the UAV by flow laminarization over stream-lined surfaces looks promising. The investigation of the flow structure over curved surfaces is a difficult challenge of the researchers. This work was aimed on investigation of the development of stationary perturbations behind a localized three-dimensional roughness element and two-dimensional roughness and of physical mechanisms of laminar-turbulent transition on the flying wing in the negative and positive pressure gradient region.
This work was supported by the project of Russian Science Foundation № 16-19-10330.

EXPERIMENTAL SETUP

Experiments were carried out in the test section of the T-324 low-turbulent wind tunnel of the ITAM SB RAS. The degree of free-stream turbulence was 0.04% in the range of 5-10000 Hz. The flow velocity was selected from the range 7.2 - 20 m/s and was controlled using a Pitot-Prandtl nozzle connected to an electronic micromanometer using a pneumatic track with an accuracy of 1%. Reynolds number was in range from $1.8*10^5$ for $U_o = 7.2$ m/s to $5*10^5$ for $U_o = 20$ m/s. In this experiment the main method of free-stream flow structure visualization was liquid crystal thermography. Visualization was made by thin-film liquid crystal coating which were placed in the research area. Then the coating was heated over than performance range. When exposed to the free-stream the film got cool and it allowed seeing the structure of the flow. The temperature range of the liquid crystal film used in the experiment was 30 - 32 °C.
Oil film technique was chosen as a second visualization method. Use was made of titanium dioxide mixed with kerosene. Having been covered in solution the wing was placed in wind tunnel working part. Exposed to the free-stream the solution became dry. After the experiment pictures of the flow were taken. Visualization made by oil film technique is illustrative of limiting streamline on the wing surface.
Qualitative measurements of boundary layer structure and its characteristics were carried out by constant-temperature hot-wire anemometry. Multilayer cylindrical roughness elements, cones and ribs were placed on the surface of the wing for excitation of stationary disturbances. Multilayer structure was chosen to investigate how roughness height influences on the disturbances. Total height was varied from 0.44 to 10 mm.
Investigations were carried out on the windward and leeward side of the model. The angle of attack was varied from -5 to 18 degrees.

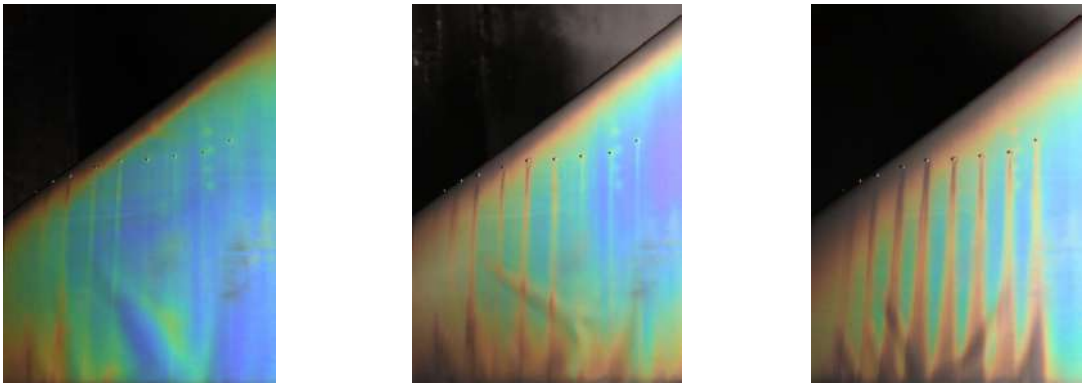
RESULTS AND DISCUSSIONS

The first series of experiments was devoted to the study of the flow over windward side of flying wing with disturbances' generators placed on its surface. These generators were made as three-dimensional (figure 2) and two-dimensional roughness elements, their height matching the boundary layer thickness. Visualization pictures of wall-adjacent flow were obtained in presence and absence of the three-dimensional roughness element by liquid crystal thermography. Using hot-wire it was possible to get quantitative data of boundary layer structure over a full range of speeds. It was shown that longitudinal structures are formed on the wing surface even in the absence of the roughness elements. These structures decrease in transverse size when free-stream velocity is increased. Influence of the three-dimensional roughness element height on the boundary layer structure was investigated. It was established that roughness greater than boundary layer thickness generates the most intensive longitudinal structure compared to minor roughnesses. Also area of the boundary layer maximum receptivity was found for the flying wing configuration. Being placed in this area roughness element leads to formation of the most intensive longitudinal structure. Location of this area is constant over a full range of free-stream velocity presented in this work. Visualizations of the flow behind three-dimensional roughness element (h_{3D} = 0.98 mm) were obtained in the area of maximum receptivity. It was found that longitudinal structure deflects and changes its form. Such form is probably a forepart of the general S-shaped form of the longitudinal structure moving downstream.



a) b) c)

Figure 2. Determination of the maximum susceptibility region: a) U_∞ = 7.2 m/s; b) U_∞ = 10.2 m/s; c) U_∞ = 15.1 m/s.

The second series of experiments was devoted to the study of the flow over leeward side of flying wing with cones and ribs on its surface. In the experiments performed on the model of a flying wing at low subsonic speeds, various flow options were found depending on the angle of attack. It is shown that the main types of flow around, previously known from experiments on the direct and sliding wings, are also realized on this type of wing. At small angles of attack, a laminar detachment bubble arises parallel to the leading edge, and with an increase in the angle of attack, a large-scale vortex flow gradually arises, which is characteristic of the case of flow around with a stall near the leading edge. It is shown that such a flow can be effectively controlled using cones and ribs near the leading edge of the wing (figure 3).

FLOW OVER SURFACES ROUGHENED BY CALCIUM CARBONATE DEPOSITION

T. A. Nascimento *[1], B. O. Temer[1], and J. B. R. Loureiro[1]
[1] Interdisciplinary Center for Fluid Dynamics (NIDF), Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Summary Scaling formation over the internal surfaces of ducts, valves or heat exchangers is the main reason for the loss of efficiency in many industrial applications. The present work investigates the flow dynamics of calcium carbonate deposition in circular pipe flows. An experimental campaign is carried out to measure the deposition rate of calcium carbonate for different Reynolds numbers and fixed saturation index. The fouling thickness along the pipe is measured and the deposits characterized by scanning electron microscope and x-ray diffraction. The paper discusses the separate contributions for pressure losses as a result of the increase of surface roughness and the decrease in effective pipe diameter. The type of roughness created by the deposition process is also investigated. The growth direction of the roughness elements is correlated with the Reynolds number.

INTRODUCTION

Scaling is a problem typically found in many industrial applications, ranging from biomedical to oil exploration and production. Although many works have been devoted to the subject, the existing intricate relations between the thermodynamic predictions, the kinetics of the chemical reactions and the flow dynamics are still poorly understood (Zhang et al. 2001). Most of the data available in literature were obtained from small mixing vessels or capillary pipe flow experiments. Typically, these experimental results bare no dynamical similarity with real industrial applications.

The predictive models used by the oil industry rely essentially on thermodynamics and capillary tube blockage tests. The persistent high number of equipment failures due to fouling, specially in carbonate reservoirs oil fields, establishes an urgent need for research and improved technological solutions.

EXPERIMENT

Experiments were conducted on the Multipurpose Flow Loop of the Interdisciplinary Center for Fluid Dynamics (NIDF/UFRJ). A 70 m long and 11 mm internal diameter plexiglass pipe was used to simulate fully developed turbulent pipe flow. Solutions of 0.05 mol/l calcium chloride ($CaCl_2.2H_2O$) and 0.05 mol/l sodium bicarbonate ($NaHCO_3$) were prepared in separate reservoirs and mixed at the entrance of the flow loop, which operates in open circuit, as a illustrated in Fig. 1. The inlet flow rates were measured by electromagnetic flow meters; a Coriolis flowmeter was positioned at the outlet, prior to the discharge tank. The fourth tank was used to store the cleaning solution.

Figure 1: Sketch of the flow loop.

Four different total flow rates were investigated: 300, 450, 600 and 750 litres per hour. Each experimental run lasted for 90 minutes, after which the test sections were dried at ambient temperature and the cleaning solution was pumped into the flow loop.

RESULTS

Figure 2a illustrate the rough structure created by the deposition of $CaCO_3$ over the smooth pipe wall. Fig. 2a shows a fractal growth pattern. The smallest unity has a cubic shape, typical of calcite, the most stable form of $CaCO_3$. The structure grows from the wall as dendrites, probably from a nucleation site. The growth angle was measured for each visible structure and mean values have been calculated for positions 8.20 m and 62.20 m of the pipe length for the different flow rates. The results, shown in Fig. 2b, indicate a relation between the growth angle and the Reynolds number.

Figures 3a,b shows the deposition rate and the effective diameter along the pipe. The deposition rate was estimated by weighting the test sections in the beginning and at the end of experiment. It shows an exponential decay since in the inlet the solution saturation is maximum. Once precipitation and deposition begins, ions are consumed to form the crystals so that saturation decreases along the pipe. This fact also explains the profile of the effective diameter, as the thickness of

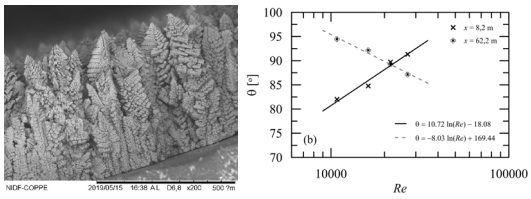

Figure 2: Illustration of the rough structures and the growth angle with respect to the pipe wall.

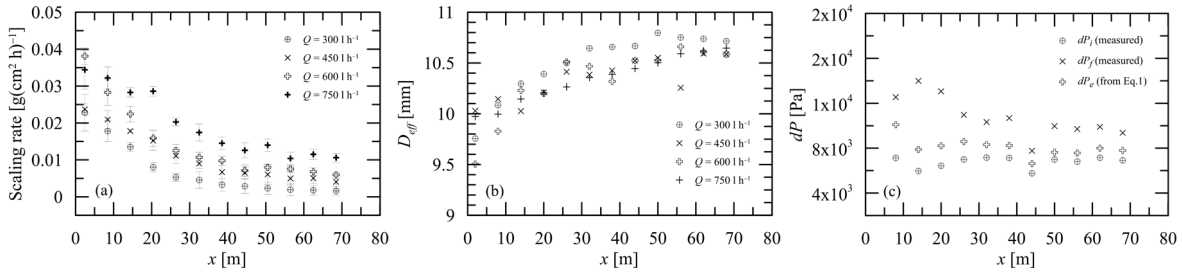

Figure 3: Deposition rate, effective diameter and differential pressure along the pipe.

fouling is higher in the entrance of the duct. The effective diameter reaches an almost constant value only at $x = 50$ m. It can also be noted that at the end of the test the inner wall of the pipe was fully covered by calcium carbonate.

The distribution of the differential pressure (dP) measurements for flow rate of $Q = 300$ lh^{-1} is shown in Fig. 3c, where dP_i denotes the values for the smooth pipe, measured at the beginning of the test, dP_f is the last measurement prior to the end of the run and dP_e was calculated from Eq. 1,

$$\frac{\Delta dP}{dP} = \frac{\Delta f}{f} - 5\frac{\Delta D}{D}, \tag{1}$$

where Δ denotes the changes between initial condition (subscript i, smooth pipe, D = 11 mm) and final condition (subscript f, roughened pipe, effective diameter shown in Fig. 3b).

Given a relative percentage change in the pipe diameter, this equation can be used to estimate dP for the final condition, considering that otherwise the inner wall would remain smooth (here denoted as dP_e). Figure 3c shows that the major contribution for the increase in pressure drop along the pipe is due to the surface roughness effects. The change in dP estimated from Eq. 1, due to the changes from nominal to effective diameter, is close to dP_i.

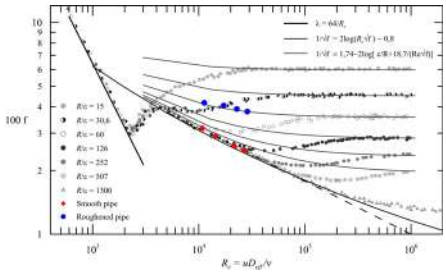

Figure 4: Moody chart illustrating the increase in drag caused by fouling.

The friction factor is shown in Fig. 4. At the start of the scaling experiments the pipe wall is smooth and f behaves as expected, following the Blasius equation. After 90 minutes, the inner surface has been fully covered by the $CaCO_3$ deposition; the blue dots represent the significant increase in wall friction due to pipe obstruction and, more importantly, due to increase in surface roughness.

EXPERIMENTAL INVESTIGATIONS OF BOUNDARY LAYER PERTURBATIONS GENERATED BY CONTROLLED LOCALIZED IMPACT OF THE ROUND MEMBRANE

Mikhail Katasonov*[1], Victor Kozlov[1], Alexandr Pavlenko[1] and Ivan Sadovskii[1]
[1] Laboratory of Aerophysical researches of subsonic flows, Khristianovich Institute of Theoretical and Applied Mechanics of the Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russia

Summary The spatial development of the flat plate boundary layer disturbances is experimentally investigated by the hot-wire anemometry. Controlled disturbances were introduced into the laminar flow by means of a membrane with a round form located on the surface of the model. The pulsed motion of a round membrane leads to the formation of longitudinal localized structures and wave packets in the boundary layer. Wave packets consist of a set of straight and oblique waves, differing in their propagation characteristics. The development of wave packets downstream is consistent with the linear theory of hydrodynamic stability.

INTRODUCTION

The laminar-turbulent transition in the boundary layer with an increased or moderate level of free-stream turbulence is associated with the development of disturbances generated by external flow perturbations [1]. It is known that the effect of large-amplitude incoming flow perturbations leads to the formation of longitudinally oriented localized structures (bands) in the boundary layer, consisting of regions with an excess and deficit of longitudinal velocity [2]. These structures are the primary instability and provide the necessary conditions for the development of high-frequency (secondary) wave disturbances, which under the favorable conditions evolve into turbulent spots. As recent studies have shown [3], the influence of incoming flow perturbations on the region of boundary layer incipience, in addition to streaky structures, can lead to the appearance of wave packets.

The present investigations are devoted to the study of the appearance and development of wave packets (precursors) and longitudinal localized structures. Wave packets form near the fronts of longitudinal localized structures where a sharp local change in the longitudinal velocity inside the boundary layer is observed.

EXPERIMENTAL TECHNIQUE

The measurements were carried out with a constant temperature hot-wire anemometer. The spatial structure of the studied disturbances was determined by the method of hot-wire anemometry visualization. Two-dimensional fields of the longitudinal components of the flow velocity were measured in various planes. Data collection was carried out synchronously with the moment of introduction of controlled disturbances. Artificial disturbances were generated in the boundary layer by means of high amplitude impulse deflection (0.3 mm) of a round membrane with a diameter of 18.7 mm, located on the surface of the model at a distance of 150 mm from its leading edge. As a model, we used a flat plate with a length of 1500, a width of 1000, and a thickness of 10 mm, on which a non-gradient Blasius flow was organized. The free-stream velocity was U_o = 21.5 m/s. The model was installed in a low-turbulent subsonic wind tunnel T-324 of ITAM SB RAS.

RESULTS

Papers in studies on the straight wing [4], the close attention of the experimenters to wave packets generated by localized action on the boundary layer attracted the fact of their rapid growth downstream. It turned out that the region of the unfavorable pressure gradient favors a strong increase in wave packets observed near the leading and trailing edges of longitudinal localized structures. An increase in the unfavorable gradient and further separation of the flow intensifies this process even more. In the region of a favorable pressure gradient, wave packets in the visualization patterns are not visible, since their intensity decreases here. In a nongradient flow, it was possible to increase wave packets downstream by increasing the Reynolds number to values greater than Re (δ^*)> 700. It was shown in [5] that if the frequencies of wave packets fall into an unstable region, they magnitude increase, that is, their behavior is consistent with the theory of hydrodynamic stability. A detailed study of the characteristics of wave packets [3] showed that they are very close to those observed for Tollmien-Schlichting wave packets.

These studies have established that the longitudinal structure arises due to local upward deviation of the model surface (membrane). Its length along the flow is determined by the time during which the membrane is in a deflected position. Wave packets occur during a short period of time when the membrane makes its movement up and back, down. The intensity of the localized longitudinal structure decreases downstream. Those observations are corresponds to the results of previous studies [2-5]. The amplitude of wave packets, in contrast, increases with increasing Reynolds number. It is experimentally shown that wave packets consist of straight and inclined waves. The straight waves increase faster than the inclined. The nature of their development is consistent with previous studies on the generation of wave packets by a point source on a plate [6], see figure 1.This figure shows the isocontours of the wave packet amplitude of present research in comparison with the isocontours of the amplitude of a typical wave train, obtained in

*Corresponding author. E-mail: mikhail@itam.nsc.ru.

[6]. The type of wave packets appeared as a result of the injection of a perturbation by the blowing-suction method and the method of controlled motion of the surface is fundamentally similar. The behavior of amplitude downstream of the wave packets is differing for the straight and oblique waves. The intensity of straight wave packets increases constantly downstream. At the same time, oblique wave packets grow sharply first and then their amplitude decreases.

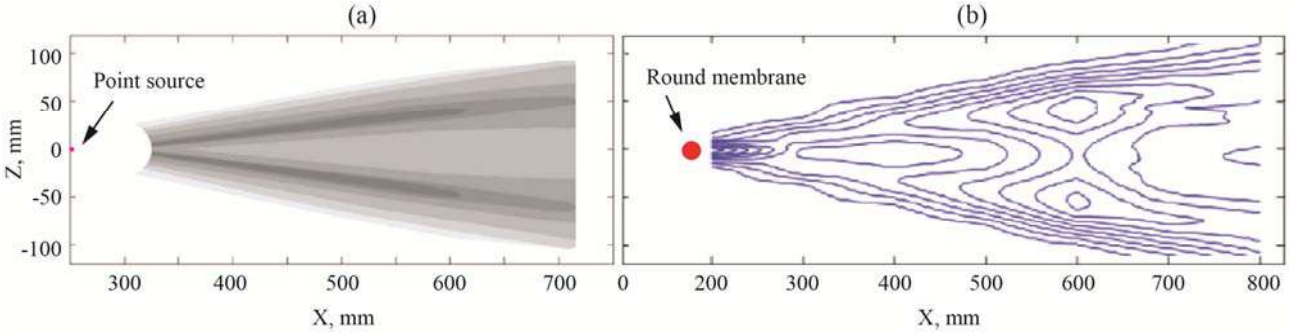

Figure 1. Isolines of the amplitude of the typical wave train generated by point source (a) and wave packet at the back front of the longitudinal localized disturbance (b) in the flat plate boundary layer.

CONCLUSIONS

Pulse movement of the round membrane with high amplitude in the boundary layer results in formation of disturbances of two types: longitudinal localized structures and wave packets near their fronts. Creating a source of modular perturbations allowed us to obtain data for high Reynolds numbers, where the wave packets become growing. Wave packets generated in this case consist of straight and oblique waves. The nature of their development is consistent with previous studies (generation of perturbations by a point source).

INVESTIGATION OF THE EFFECT OF ROUGHNESS ELEMENTS ON THE BOUNDARY LAYER FLOW STRUCTURE OVER THE SWEPT WING SURFACE

Valeriia Kaprilevskaia[1]*, Alexandr Pavlenko[1], and Victor Kozlov[1]
[1] Laboratory of Aerophysical Research of Subsonic Flow, Khristianovich Institute of Theoretical and Applied Mechanics SB RAS, Novosibirsk, Russia

Summary The paper given represents the investigation results of stationary and secondary disturbances development behind two-dimensional roughness element. The experiment was carried out using liquid-crystal thermography and hot-wire anemometry. Lying upstream three-dimensional roughness element induced the disturbances which were affected by two-dimensional roughness lying further downstream. In this case the two-dimensional roughness caused the appearance of stationary structures. Excited by acoustics secondary perturbations took place within frequency range different from the case of excitement by three-dimensional roughness. Hot-wire helped to show that longitudinal structures started to form on the leading edge of the two-dimensional roughness element. The position of secondary disturbances was connected to the inflection points of transverse velocity distribution.

INTRODUCTION

Use of swept wings is required for transonic flight. However comparing them to a straight wing, the swept one has an additional instability mechanism due to the presence of the cross-flow. Such a mechanism results in laminar-turbulent transition in the favourable pressure gradient region. If modern aircraft manufacturers design a laminarized aircraft, it will provide a 15% reduction in fuel consumption. However there are a lot of problems since even micron-sized roughness can cause a localized area of laminar-turbulent transition in the transverse direction.

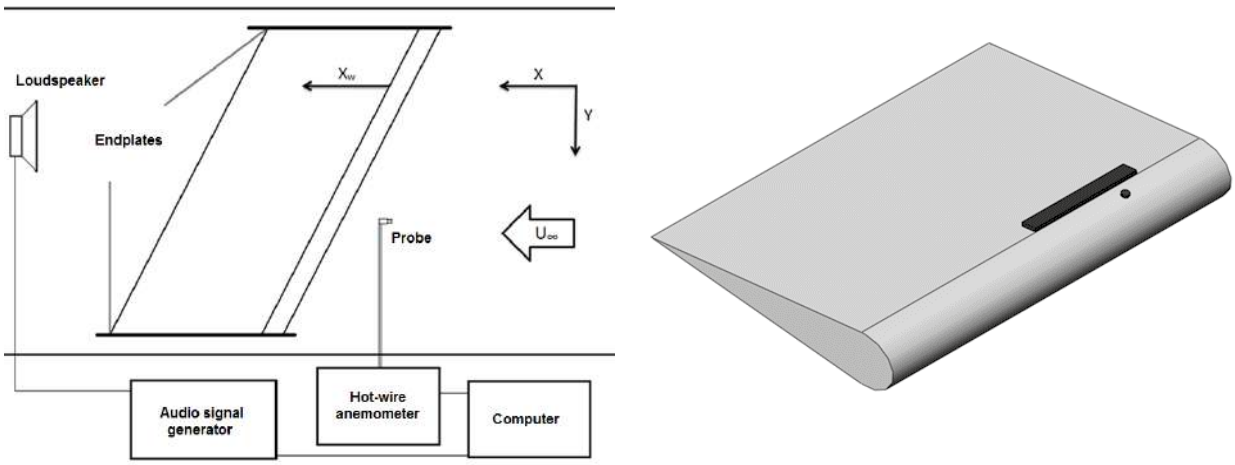
In [1 - 2], the investigations of transition caused by roughness were carried out in the neutral pressure gradient area. Single vortex forming on the edge of the roughness results in appearing of two modes of the secondary disturbances, followed by laminar-turbulent transition [1].

In paper [3] the investigations of the flow behind lengthy sticker are described. It was showed that the most destabilizing effect was caused by edges of the sticker led to stationary vortexes generation.

The variety of two- and three-dimensional roughness elements can be found on the surface of the modern wing: the joint of the slat is the perfect example of the two-dimensional roughness; natural surface roughness, vortex generators, insects and snow are considered as three-dimensional roughness elements.

EXPERIMENTAL SETUP

The experiment was carried out in the test section of the low-turbulent wind tunnel AT-324 of the ITAM SB RAS Figure1, (a). The test section parameters are 1000 × 1000 × 4000 mm. The free-stream velocity control was realized by the Pitot-Prandtl nozzle connected to an electronic manometer. Carrying out the experiment the values of free-stream velocity were 9.2 and 10.9 m/s.



a b

Figure 1. Experimental set up (a) and the model of the wing with two-dimensional and three-dimensional roughness elements on its leading edge (b)

*Corresponding author. E-mail: valeria.kaprilevskaya@gmail.com

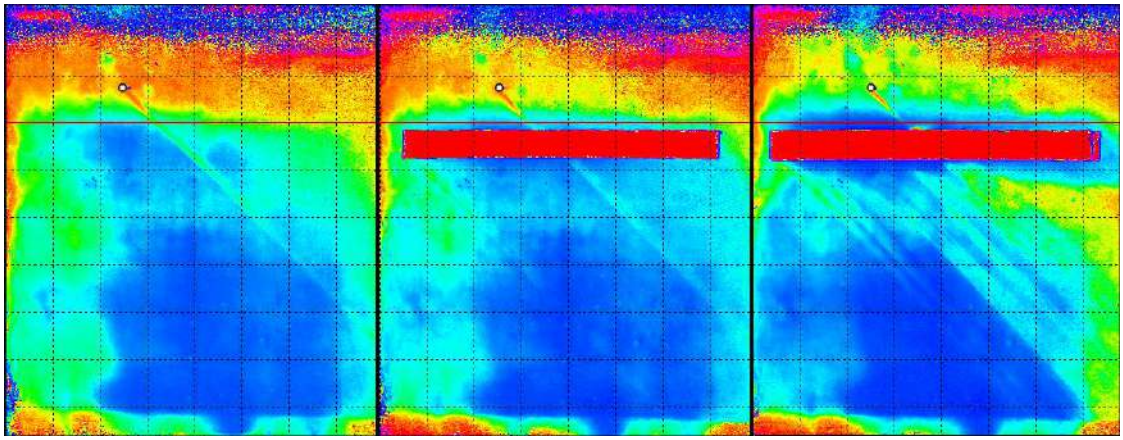
In the current work use was made of the wing formed by the cylinder with radius r = 40 mm and two converging planes Figure 1, (b). Chord is 400 mm and sweep angle is 45º. The angle of attack α = -12.3° was chosen to realize a favourable pressure gradient over the flat part of the wing profile.

Generation of the stationary disturbances was provided by three-dimensional cylindrical roughness element. The roughness involved had height of 0.8 mm and diameter of 1.6 mm. Two-dimensional roughness element was placed on the flat part of the wing; its width was 15 mm and length was 200 mm. It should be noted that two-dimensional roughness was multilayer and the thickness of the single layer was 0.13 mm. The total height could vary from 0 to 1.82 mm.

The secondary disturbances were excited by the loud speaker connected to the sound generator.

RESULTS

The results of the experiment were obtained using liquid-crystal thermography (LCT) and hot-wire anemometry. These techniques allowed receiving of qualitative and quantitative data of the flow over swept wing surface in presence of roughness elements. While carrying out the experiment, the two-dimensional roughness element was placed on the flat part of the wing. Figure 2 represents the influence of its height h_{2D} on the trace behind the cylindrical roughness element.



a b c

Figure 2. Visualization of the flow over wing's surface using LCT.
Height of the two-dimensional roughness element: a) 0mm; b) 0.52 mm; c) 1.56 mm

CONCLUSIONS

The two-dimensional roughness element destabilizes disturbances forming behind three-dimensional one and it also leads to decreasing of the boundary layer stability starting from h_{2D} = 0.52 mm. It was also found that two-dimensional roughness element generates stationary structures itself.

The acoustic influence significantly speeds up the development of the secondary disturbances. It causes the rapid growth of those disturbances and nonlinear development stage. The acoustics rebuilds the mean flow leading to multiplication and amplification of the stationary disturbances and increases the area of the turbulent flow regime too.

ABSENCE OF INERTIAL OVERLAP IN 2-D TURBULENT WALL JETS

Summary The wall jet flow comprises of universal inner and outer scaling layers termed as the wall layer and the full-free jet layer respectively. Starting with this two-layer structure, theoretical arguments suggest that the overlap of these universal layers leads to a non-universal (Re_τ -dependent) power-law profile for mean velocity in the overlap layer. We define an intermediate variable $\eta\sqrt{Re_\tau}$, which absorbs this Re_τ-dependence of the overlap layer leading to a universal power-law overlap profile. Data indicate that there is no inertial overlap between the inner and outer scaling regions for the range of Reynolds numbers considered here.

INTRODUCTION

Wall- jet is a special kind of wall- bounded flow characterized by a non-monotone mean velocity profile with a velocity maximum (U_{max}) occurring close to the test surface. On either side of this maximum, velocity decreases in the wall normal direction (z). The study of wall-jet flow started way back in 1960's [1]. Several studies suggest that a wall jet could be considered to be made up of either a half free jet on top of a turbulent boundary layer or a jet layer overlapping with the inner wall layer. In the former, the boundary layer is considered to have its own overlap layer [2,3] while the latter is expected to exhibit an overlap consisting of a near-wall mesolayer and an inertial overlap layer further out [4]. Here, we are presenting some insights into the structure of wall-jet flow with the help of our own experiments and data from the literature. In particular, we show that the data do not exhibit occurrence of an inertial overlap in wall jets.

DATA AND RESULTS

The wall jet setup is constructed at the Fluid Dynamics Laboratory (FDL), Indian Institute of Tropical Meteorology (IITM), Pune, India. Mean velocity profiles at different streamwise (x) and spanwise (y) stations are measured, using a single hotwire probe, for two nozzle Reynolds numbers $Re_j = U_j b/\nu = 10244\ and\ 21228$ (P1 and P2 respectively); $\nu = 1.5 * 10^{-5} m^2 s^{-1}$(fluid kinematic viscosity) , b is nozzle height and U_j is the nozzle exit velocity. Wall shear stress is measured using Oil Film Interferometry.

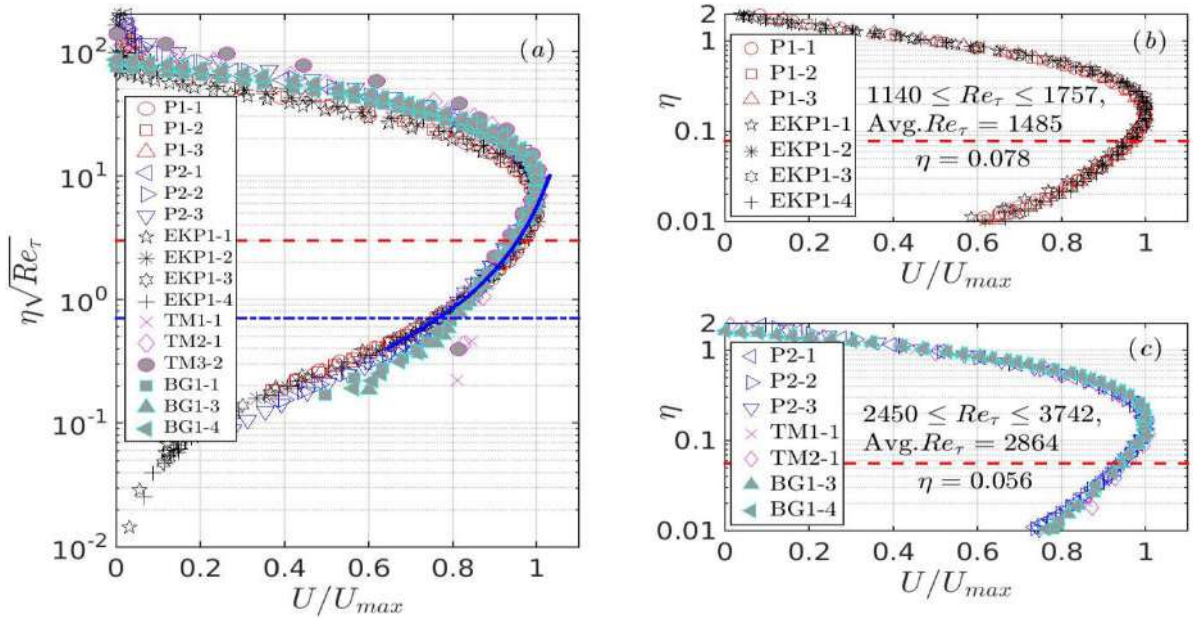

Fig 1: (a) Mean velocity profiles in the overlap layer scaling. Ordinate is the intermediate variable $\eta\sqrt{Re_\tau}$. Solid blue line is the least-squares curve fit of equation (1) to all data between the dashed and the dashed-dotted lines ($0.7 < \eta\sqrt{Re_\tau} < 3$). Our data is at $x/b =$ 49.5, 64.5 and 107. $Re_\tau = U_\tau * Z_T/\nu$ where, U_τ is the friction velocity, Z_T is the height from the wall above the velocity maximum where velocity equals $U_{max}/2$ and $\eta = z/Z_T$. (b) Outer scaling for high-Re wall jets with avg. $Re_\tau = 1485$ and (c) Outer scaling for high-Re wall jets with avg. $Re_\tau = 2864$.

*Corresponding author. E-mail: abhishek.gupta@tropmet.res.in

We have also included data from the literature such as Eriksson et al. 1998 (as EKP) [5], Bradshaw & Gee 1962 (as BG) [6] and Tailland & Mathieu 1967 (as TM) [7]. The detailed information about these datasets is given in their respective papers.

The wall jet flow comprises of universal inner and outer scaling layers termed as the wall layer and the full-free jet layer respectively. Starting with this classical inner and outer universal scaling (not shown), we have derived a universal overlap expression (derivation is not shown) in terms of an intermediate variable $\eta\sqrt{Re_\tau}$ of the form

$$\frac{U}{U_{max}} = K_o\left(\eta\sqrt{\mathrm{Re}_\tau}\right)^A - \frac{\beta}{U_{max}} \qquad (1)$$

where, K_o= −0.288, A = −0.535 and β/U_{max} = −1.115 are universal constants and obtained from the fitting of data used in fig-1(a) according to above equation .

All the data of fig-1(a) collapse remarkably well in the region where overlap is expected to occur. The collapse extends over the range $0.7 < \eta\sqrt{\mathrm{Re}_\tau} < 3$ i.e. approximately 40% of a decade in $\sqrt{\mathrm{Re}_\tau}$; the extent of this region is decided empirically by observation. Here, the position and extent of the mean-velocity overlap are fixed in $\eta\sqrt{\mathrm{Re}_\tau}$ and not in η or $z^+ = U_\tau * z/\nu$. In fact, with increasing Reynolds number, the position of the overlap layer is expected to shift towards the wall and its extent is expected to reduce in η coordinate; opposite is expected to be true for the z^+coordinate.

An interesting question that arises is whether there exists any inertial overlap layer between the inner and outer scaling regions. For this, we plot the mean velocity profile data by dividing it into two broad categories, low-Re_τ and high-Re_τ. Fig-1(b) and 1(c) are the plot with the average low-Re_τ= 1485 (for 1140 < Re_τ< 1757) and high-Re_τ= 2864 (for 2450 < Re_τ< 3742). From these plots, it is clear that beyond the outer limit (in η coordinate) of the mean-velocity overlap layer, data show remarkable collapse in outer scaling (up to η of 0.078 and 0.056 respectively). Exactly similar behavior is seen in inner scaling (not shown). This indicates that only the Re_τ-dependent (or mesolayer) mean velocity overlap of fig-1(a) exists in wall jets and the inertial overlap layer does not appear to exist, at least for the range of Reynolds numbers considered here. Also it may be noted that with increase in Reynolds number, the outer edge of the overlap layer in fig-1(c) shifts towards the wall in outer (η) coordinate as compared to fig-1(b). This indicates that the outer full-free jet flow progressively dominates the inner wall flow with increasing Reynolds number.

CONCLUSIONS

Experimental mean velocity data strongly support a two-layer structure of wall jets. An inner wall layer (scaling purely on wall variables) and an outer full free jet layer (scaling purely on outer variables). These scalings are universal i.e. independent of Re_τ. Analysis shows that these inner and outer descriptions lead to an Re_τ-dependent (non-universal) power-law velocity profile in the overlap layer of wall jets. An intermediate variable $\eta\sqrt{Re_\tau}$ absorbs this Re_τ-dependence and gives a universal power-law curve for approximately 40% of a decade in the intermediate variable over the range $0.7 < \eta\sqrt{Re_\tau} < 3$. Selective plotting of experimental data for low- and high-Re_τ ranges show that there is only Re_τ-dependent overlap between the universal inner and outer mean-velocity scaling descriptions; no inertial overlap appears to exist in wall jets for the range of Re_τ values presented here.

MEAN PARAMETERS OF TURBULENT BOUNDARY LAYER WITH ZERO PRESSURE GRADIENT ON THE WALL OF THE WIND TUNNEL AT VERY HIGH REYNOLDS NUMBERS

Anton Gorbushin*[1,2], Svetlana Osipova [1,2], and Vladimir Zametaev [1,2]
[1] Central Aerohydrodynamic Institute, Zhukovsky, Russia
[2] Moscow Institute of Physics and Technology, Dolgoprudny, Russia

Summary Mean parameters of incompressible turbulent boundary layer (TBL) on a wind tunnel wall were acquired in the TsAGI T-128 Wind Tunnel (WT) in the range of $Re_\theta = 5.3\times10^4 – 2.9\times10^5$. The maximum Reynolds number $Re_\theta = 2.9\times10^5$ was 4.8 times higher in comparison with similar WT wall data published in scientific literature. At the maximum Reynolds number the record-high von Kármán number $\delta^+\sim1\times10^5$ was reached whereas the log law was applicable up to $y^+\approx 1.3\times10^4$. It confirmed different authors' suggestions about the universal profile of speed in outer region of layer. The acquired results were compared with other researchers' data and with known semi-empiric/analytical dependencies as well. The agreement between the shape factor at high Reynolds numbers was within $\Delta H = \pm0.012$ (±1%), and the local skin friction coefficient was $\Delta c_f = \pm0.000025$ (±1.7%).

INTRODUCTION

Studies of turbulent boundary layers (TBLs) at very high Reynolds numbers draw attention for two reasons: (i) they are of practical use for design of large aircraft and ships; (ii) researchers have always wondered what would happen with turbulent boundary layer at $Re \to \infty$. Incompressible TBLs with zero pressure gradient are of most interest. Many studies have described this canonical case. They can be divided into three groups: (i) studies on a flat-plate in wind tunnels or water tunnels; (ii) measurements on wind tunnel walls; (iii) atmospheric TBLs. Mean parameters of boundary layer acquired in test facilities at very high Reynolds numbers are defined in [1-3]. According to [1] the maximum Reynolds number $Re_\theta = 2.35\times10^5$ ($Re_\tau = 7.2\times10^4$) was reached on a flat-plate in WT, where θ is the momentum thickness of the boundary layer, $Re_\tau=\delta^+= \delta_{0.99}U_\tau/\nu$ is the von Kármán number, $U_\tau=U_e(c_f/2)^{1/2}$, ν is the kinematic viscosity of the air, c_f is the local skin friction coefficient, U_e is the local exterior flow speed. In water tunnels $Re_\theta = 1.5\times10^5$ ($Re_\tau = 5\times10^4$) was reached on a flat-plate [2]. The maximum Reynolds number reached on a WT wall was acquired in [3] and made $Re_\theta = 6\times10^4$.

This study supplements existing TBL data at very high Reynolds numbers with the results obtained on the wall of TsAGI transonic WT in the range of $Re_\theta = 5.3\times10^4 – 2.9\times10^5$.

TEST DESCRIPTION

Figure 1. Wind tunnel nozzle and rake installed on its upper wall.

The experimental studies conducted in the TsAGI T-128 transonic WT, which is a continuous variable-density closed-circuit test facility equipped with the four-stage compressor and the main drive with the power of 100 MW. Mach number range is M=0.15–1.4, total pressure range is P_t = 20–400 kPa. The facility is equipped with a 12-m adjustable nozzle. The size of test section is 2.75 × 2.75 m. The nozzle sidewall shape (Fig. 1) was chosen so that the zero pressure gradient could be provided over the length of 4 meters until the nozzle exit. The pressure gradient made dCp/dx= -0.006 m^{-1}, which corresponds to the local streamwise pressure gradient parameter [1] $K_p = \nu/U_e^2 \times dU_e/dx \approx 7\times10^{-10}$. The parameters of boundary layer were measured with a 0.2-m rake equipped with 26 total pressure probes, installed on the upper wall near the nozzle exit (Fig.1). The studies were conducted at M=0.2 (U_e ≈ 69 m/s; P_t≈100; 200; 300; 380 kPa), M=0.25 (U_e ≈ 86 m/s; P_t≈380 kPa), M=0.4 (U_e ≈ 140 m/s; P_t≈320 kPa).

RESULTS AND CONCLUSION

Clauser chart technique was used, where the log law $u^+ = {}^1/_k \ln y^+ + B$ was fitted to the velocity profiles using the von Kármán constant k=0.384 and additive constant B=4.127 recommended in [4]. Figure 2 shows mean velocity profiles in inner coordinates and the log law. The profiles are shifted on Y-axis by ΔU^+=2.5. At the maximum Reynolds number, the record-high von Kármán number $\delta^+\sim1\times10^5$ was obtained whereas the log law was applicable until $y^+\approx$

*Corresponding author. E-mail: gorbushin@tsagi.ru.

1.3×10^4. Figure 3 shows the comparison of non-dimensional velocity profiles with other studies confirming the conclusion (see [3], for example) that mean velocity profiles in the outer region of boundary layer show similarity i.e. independence of Reynolds number. The authors have found an analytical solution of Navier-Stokes equation $U/U_e = e^{-y}\int_0^y \exp(\eta - e^{-\eta})d\eta$ with the help of asymptotic methods at Re→∞ [5] that is also in good agreement with the experiment data beginning with $y/\delta_{0.99} \approx 0.6$.

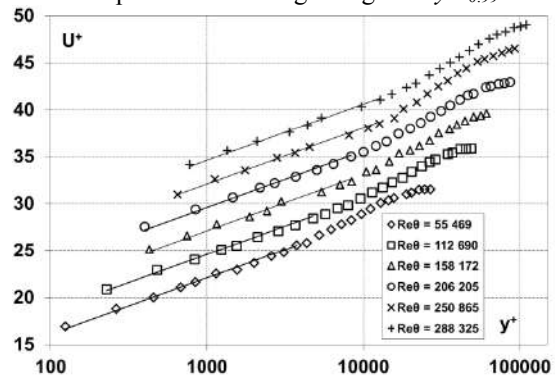

Figure 2. Mean velocity profiles in inner coordinates.

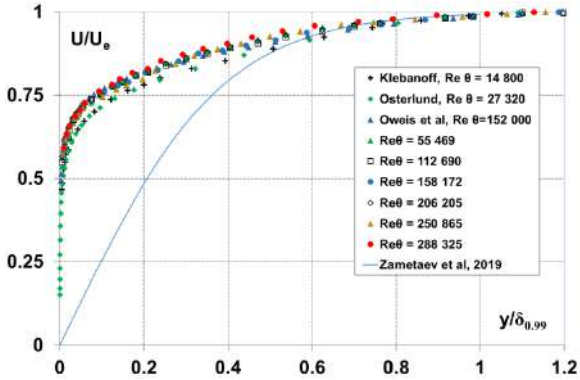

Figure 3. Comparison of non-dimensional velocity profiles with data of other studies.

Figure 4 shows the results as a dependency of the shape factor H on Re_θ in comparison with data of other studies. The agreement between the data at high Reynolds numbers is within $\Delta H = \pm0.012$ (±1%). The absolute value of derivative for this dependency considerably decreases beginning with $Re_\theta \approx 6\times10^4$. Figure 5 shows the results as a dependency of the friction coefficient c_f on Re_θ in comparison with data of other studies and known expressions defined by Schlichting, Coles-Fernholz, Falkner, Nikuradse, Prandtl-Kármán, Schultz-Grunow, Kármán-Schoenherr, Pirozzoli with constants recommended in [4]. The agreement between the skin friction coefficient at high Reynolds numbers is within $\Delta c_f = \pm0.000025$ (±1.7%). The relation between Re_θ and Re_x for these expressions was obtained basing on the analysis of study data published in scientific literature. Well known from literature compressibility corrections were applied to the shape factor in the form of multiplier 0.9775 (~2%) for M=0.25 and 0.946 (~5%) for M=0.4 and to the friction coefficient – 1.013 (~1%) for M=0.4.

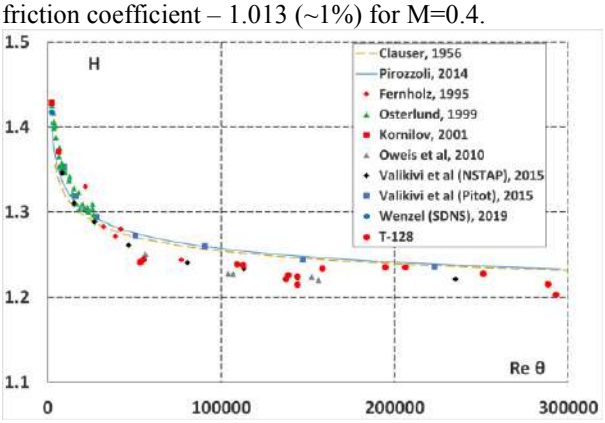

Figure 4. Shape factor H as a function of Re_θ.

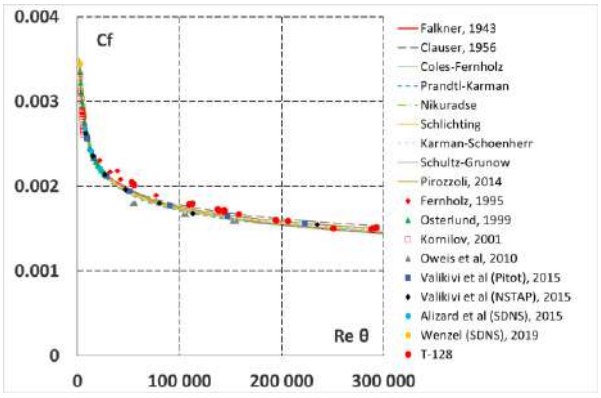

Figure 5. Skin friction coefficient c_f as a function of Re_θ.

The dependency $H = f(c_f)$ was compared with other authors' experimental results and with semi-empiric dependencies of Hama, Clauser and Pirozzoli. The change in the friction coefficient was shown for the same velocity profile with different values of the von Kármán constant published in scientific literature.

CONCEPT OF VELOCITY AND TEMPERATURE FIELDS COMPARISON AT HEAT TRANSFER DETERIORATION UNDER WATER SUPERCRITICAL CONDITIONS

Vladyslav Filonov[1,2], Yuliia Filonova[1,2], and Victor Razumovskiy[2]
[1] IPP-CENTRE Ltd, Kyiv, Ukraine
[2] NTUU 'Igor Sikorsky Kyiv Polytechnic Institute', Kyiv, Ukraine

Summary. This paper presents one of the stages of creating reliable engineering methods for predicting deterioration heat transfer phenomenon for supercritical water reactors (SCWR) concept. This is the main problem for this type of fourth-generation reactor concept because a limited set of experimental data, the complexity of experimental studies, as well as multifactor nonlinearity of the process significantly complicate reliability of predicting the deterioration area by existing methods. The most advanced way to analyze deterioration conditions and characteristics is based on DNS strategy. Despite significant progress in recent years, it is still difficult to apply DNS to the engineering problems. A huge number of various turbulence models tests on existing experimental data indicate the prospect of adapting two-parameter models to predict deteriorated heat transfer. In this work DNS heat equation (DNSHE) procedure is considered, which will help in better understanding the mutual influence of speed and temperature in the boundary layer, based on model velocity and pressure fields, as well as on experimental data on heating wall temperature axial distribution. Obtained results will help to estimate the perspectives in adapting the temperature wall-functions for reliable nonlinear heat transfer characteristics prediction.

BACKGROUND AND INTRODUCTION

Moving towards supercritical water parameters in fourth-generation SCW reactors requires the solution of the main thermophysical problem - reliable heat transfer in the core. It is important to accurately predict the thermal loads limits in which there is no deteriorated heat transfer [1]. The majority of degraded heat transfer modes are characterized by the principal non-linearity of thermohydraulic processes in the core flow part due to the sensitivity of water properties to temperature.

Existing methods for predicting deteriorated heat transfer can be divided into two categories: analytical and differential. Analytical calculation methods are based on the use of empirical dependencies, together with the main parameters and additional balance relations form a system of transcendental equations. Sometimes, instead of balance relations, a one-dimensional momentum transfer equation is used. Nowadays are known several dozen of generalizing dependencies that are used to estimate the heat transfer coefficient [2].

Since analytical correlations and estimations cannot give an idea of the heat transfer deterioration processes complexity, an alternative and more fundamental approach is the use of CFD (differential methods). Many test calculations indicate the perspective of the eddy viscosity turbulence models adaptation. By varying the turbulent Prandtl number [3], better agreement between calculation and experiment can be achieved. Near-wall temperature function adaptation is perspective in prediction the deteriorated heat transfer, based on results of estimating the supercritical water flow pressure drop in one- and three-rod assemblies [4], as well as good agreement with experimental data regardless of the heat transfer regime.

The DNS application to predict deteriorated heat transfer [5] allows us to evaluate the flow structure near the heating wall, the ratio of forces, as well as changes in turbulence characteristics. These results can be used to calibrate engineering approaches that can be applied to more complex geometry and large-scale problems. Authors are working on the creation of reliable procedures that allow the use of eddy viscosity turbulence models together with near-wall functions on dynamically adaptive grids near a pseudo phase transition. In this paper authors suggest the procedure of velocity and temperature fields relationship finding in pseudo phase transition region.

EXPERIMENTS

Many experimental studies have been carried out in NTUU “KPI” at various test sections, which are presented in Fig.1. Screws were used for spacing of the rods in 3R and 7R assemblies, in addition, they provided the flow spin. Also, NTUU “KPI” has performed experiments in smooth vertical 600-mm heated-length tube A of outer diameter (OD) 8.11 and inner diameter (ID) 6.28-mm and vertical 600-mm heated-length tube B of 12.28/9.50-mm OD/ID (Figure 1).

For study external flowing around the rods bundle the NTUU “KPI” has performed experiments in a vertical 3 or 7 - rod bundle simulator made of 485-mm heated-length tubes of 5.2-mm OD and 4.5-mm ID with four helical ribs of 0.6-mm height and 1-mm width that were wound over the tubes with a 400-mm pitch. The bundle rods touching each other with the ribs formed the cage of regular triangles (Figure 1). 1-mm gap between the element ribs and a shaped dielectric displacer was provided with calibrated stainless steel fins of 0.1-mm thickness welded to the cylindrical surface of the rods in 7 cross-sections at 125, 185, 245, 305, 365, 425, and 485 mm from the entrance into the bundle.

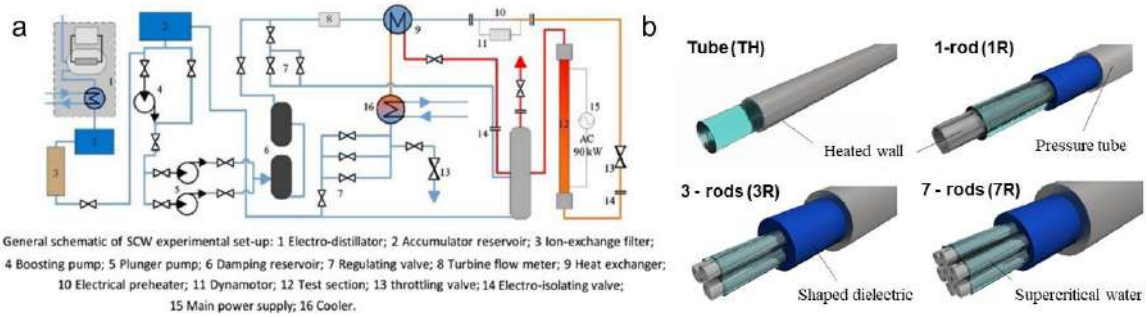

Figure 1. Scheme of the experimental set-up and test bundles.

DNSHE CONCEPTION

In a first approximation, the analysis of relationship between velocity- and temperature- near-wall functions can be carried out based on an energy equation numerical solution for the boundary layer (DNSHE). An axisymmetric formulation is considered (in the general case, an annular channel).

In this case, for representative modes with deteriorated heat transfer, model velocity and pressure fields are formed using CFD. The axial temperature distribution on the wall is formed as an interpolation function obtained based on experimental data. A numerical solution of the energy equation is carried out using FVM with a central differencing scheme in space on a locally adaptive Cartesian grid. The use of such meshes with wavelet algorithms makes it relatively easy to organize the mesh adaptation procedure near the pseudo phase transition point, as well as test various mesh refinement criteria. The general DNSHE concept is presented in Figure 2.

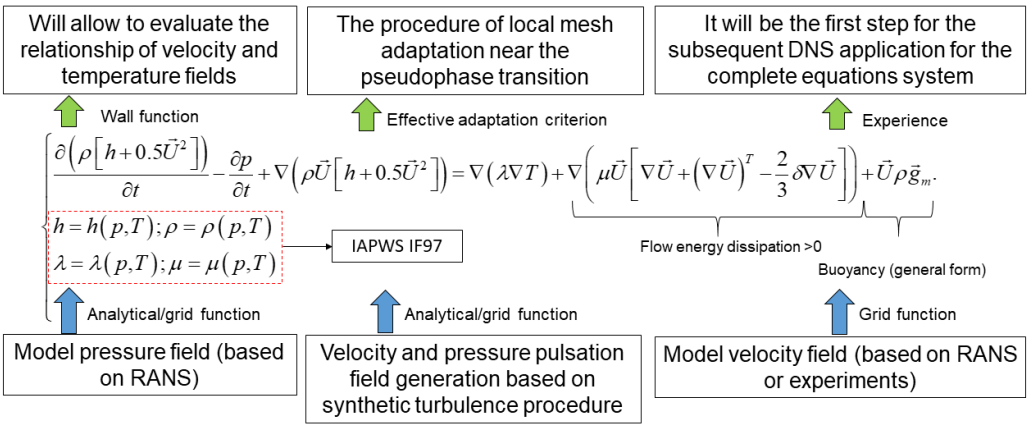

Figure 2. Chart of the DNSHE conception.

CONCLUSIONS

The application of DNSHE procedure together with the existing experimental data set for deteriorated heat transfer allow us to evaluate the relationship between the velocity- and temperature- fields in boundary layer. Also, this procedure is a great support to estimate the correctness of temperature near-wall functions adaptation for two-parameter turbulence models. In future works we will apply the experimental velocity fields instead of the modeling one, based on experimental instrumental measurements.

APPLICATION OF CORRUGATED SURFACE TO CONTROL SKIN FRICTION NEAR THE SEPARATION

Artur Dróżdż, Paweł Niegodajew, Mathias Romańczyk and Witold Elsner
Czestochowa University of Technology, Armii Krajowej 21 42-200. Czestochowa, Poland

Summary The paper is about experimental analysis of a new passive skin friction control method applied to a high Reynolds number turbulent boundary layer close to separation. A proposed approach is based on the mechanism of scale interaction observed in the wall bounded flows known as amplitude modulation of small scales by large-scale motion. Results show that the small waviness of the surface can be use in an efficient way to postpone the turbulent boundary layer separation for high Reynolds numbers, where other methods based on roughness fails. This method introduces asymmetry between sweep and ejection events in the flow which results in positive skewness of streamwise fluctuations and additionally increases the momentum near the wall. The momentum is increased only in the inner part of boundary layer.

INTRODUCTION

Development of TBL in APG is accompanied with decrease in the wall shear in the streamwise direction and the separation usually takes place when τ_w reaches zero [1]. So, an effective separation postponing method should allow either to increase the τw locally (when the separation is expected to occur) or to reduce its decreasing rate within entire APG area.

Available literature offers a variety of different approaches allowing for flow separation delay which are generally classified as active or passive. The former ones involve a number of diversified solutions as dilution of polymer additives in flowing liquids [2,3], gas injectors [4,5], heating and cooling processes [6], moving wall systems [7,8] or exposing the flow to the action of electromagnetic field [9]. These methods are usually effective on one hand, on the other hand they require a consider-able energy input, which leads to higher energy consumption and reduction in the total efficiency. Consequently, a widespread attention is paid to the passive methods as they do not require an external energy source. Such methods may include, distributed roughness, blowing and suction or vortex generators.

The recent progress in both measuring and computational techniques has allowed acquiring a valuable data which ensured a better understanding of processes occurring in TBL. Particularly interesting is discovering of the amplitude modulation phenomenon discovered by Mathis [10], which relays on interaction between large scale motion (LSM), located in the outer region, with small structures close the wall. For relatively large Reynolds number LSM causes sequentially increase and decrease of the flow velocity close the wall, what surprisingly leads to increased net convection velocity of small structures and to increased wall-shear stress [11,12]. As it was showed further by Agostini and Leschziner [13] the small scales rather than LSM have a dominant contribution to the wall-share stress, however this is done though the amplitude modulation.

In the present study we would like to present a conceptual passive method, which relies on modification of the wall topology by waviness which shape is inspired by amplitude modulation process. This geometry was designed in a way ensuring an enhancement the amplitude modulation process by increasing the activity of pseudo-induced LSM in high speed zones on the crests of waviness and thus strengthen convection velocity of the small scales. Consequently, increased wall-shear stress and postponing of TBL separation is achieved. In particular, the study is focussed on searching for the optimal geometry of the wall including amplitude to period ratio of wavy surface. Worthy to note is that the re-search undertaken in this work has a pioneering character as such an attempt aimed at postponing separation at high Reynolds number has not been undertaken before.

EXPERIMENTAL SETUP

The experiment was performed in an open-circuit wind tunnel, where the TBL was developed along a flat plate, which was 5035 mm long, what allows to reach boundary layer thickness, $\delta = 95$ mm at the inlet to the test section. The wavy wall of different length was mounted just after the inlet plane (shown in Fig. 1). The specially design diffuser shape test section with a length of 1.835 m equipped with a perforated movable upper wall allows to generate the turbulent boundary layer on the bottom wall which is at the verge of the separation. The velocity measurements were performed with hot-wire anemometry Dantec Dynamics Streamline Pro apparatus. A single hot-wire probe of a diameter $d = 3$ μm and length $l = 0.4$ mm was used. The hot-wire bridge was connected to a 16-bit A/D converter. To have the verified reference friction velocity u_τ along the flow the CCCM technique was applied introduced by Niegodajew et al. 2019 [12]. The wavy wall was manufactured from a high-density polyurethane material which ensures a hydraulic smoothness of the surface right after mechanical processing. The amplitude of the wavy wall is changing in the streamwise direction to have the fixed ratio to the boundary layer thickness.

Fig. 1 Wavy-wall geometry. Streamwise direction from left to right.

RESULTS

The measurements were performed for the high inlet Reynolds number based on friction velocity Re_τ equal to 4000. Several different wavy surfaces were used during step by step optimisation characterised by different amplitude, length and period of wavy wall. At each step the velocity profile was measured at the fixed distance from the inlet (x = 1000 mm). The study showed that the applied method, with appropriately selected geometrical parameters ($A^+/(\lambda/\delta_{99,in}) \approx 110$, $\lambda/\delta_{99,in} = 1.71$ in Fig. 2), allowed obtaining a 13% increase in wall shear stresses at sepation relating to the value at the ZPG inlet and thus ensuring a delay of turbulent detachment of boundary layer.
In order to assess how the corrugated wall affects the boundary layer, the mean and fluctuation velocity profiles as well as the skewness factor at the certain location downstream the modified surface has been analysed. The effect of increased momentum is assigned either to modulation of convection velocity or/and to production of turbulent kinetic energy (TKE) in the location preceding recirculation zone. It means that the most affected area is the near-wall region. For corrugated wall the increased *uu* variance value is observed in the wall vicinity.

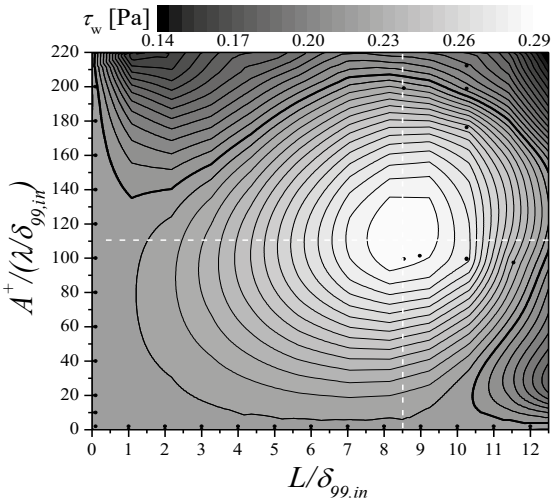

Figure 2. The wall shear stress at x = 1000 mm as a function of normalised both wave amplitude and length.

SUMMARY

It was demonstrated that for the specific amplitude, the period and the length of wavy wall the maximum of the skin friction value can be achieved when dealing with high Reynolds number turbulent boundary layer in adverse pressure gradient leading to separation. The undergoing results shows that the method can be used in an efficient way to postpone the turbulent boundary layer separation, where classical methods based on turbulizators fail. The optimized wavy wall shape substantially increases the momentum near the wall for high Reynolds number turbulent boundary layer and acts in similar way as the amplitude modulation mechanism leading to increase in convection velocity of turbulence. The significant increase of velocity is observed in the inner region of boundary layer (y<0.5δ), which coincides well with the area of the boundary layer where the effect of amplitude modulation is usually observed. Such reorganization of turbulence production introduces dominance of the sweep over the ejection. Increased sweep enhanced momentum transfer to the wall and cause the higher turbulence production downstream the flow.

ON THE SEPARATED STRUCTURES IN TURBULENT FLOW AROUND OVAL-TRENCH DIMPLES

Aleksei Chulyunin*[1], Aleksei Sinyavin[1]
[1] Lomonosov Moscow State University, Research Institute of Mechanics, Moscow, Russia

Summary The mechanisms that determine the structure of the separated turbulent flow of an incompressible fluid around an oval-trench dimple which located on a flat wall transverse to the rectangular channel are discussed. In the case of short oval-trench dimples, including a spherical dimple, there are three equilibrium states of Reynolds-averaged flow: one symmetric state and two reflective asymmetric single vortex states. As the length of dimple increases, the symmetric state of the flow stabilizes, and the possible asymmetric equilibrium states become unstable. Further increases in the length of the dimple lead to the structural topology of the internal flows in the dimple becomes complicated.

INTRODUCTION

Study of the interaction between fluid flows and irregular surfaces is a common and significant problem of modern mechanics. A special place among such researches has dimpled channels. In these channels, the increase in heat transfer can be ahead of a rise in hydraulic losses [1, 2]. Based on the value of parameter Δ, shallow ($\Delta < 0.125$), moderate ($0.125 < \Delta < 0.25$), and deep ($\Delta > 0.25$) dimples are nominally distinguished. In the shallow dimples, the flow is unseparated. In contrast, in the moderate dimples, the characteristic vortex structures appear in the form of asymmetric two-cell region of the recirculation flow. The corresponding flows are observed in experiments and are well reproduced by URANS computational technologies. At this time, the calculation of deep dimples is complicated because the separated flow around them may have ambiguous structure and may be unsteady.

In paper [3], using the URANS computational technology, it is shown that, in the transition range from the moderate to the deep dimple $0.2 < \Delta < 0.26$, the uniqueness of the resulting flow is broken. This is exhibited in the fact that, for the same values of Δ and other constitutive parameters of the problem, the steady separated flow can look like both symmetric two-cell vortex structure and asymmetric single vortex structure. A more detailed study [4] of the turbulent flow around the spherical dimple ($\Delta = 0.26$, $Re_D = 40\,000$) with the LES computation technology confirmed the formation of separated asymmetric structure. However, in contrast to the URANS predictions, these structures appear to be unstable, and the flow patterns obtained by averaging the numerical solution to the problem demonstrate the existence of two alternating single vortex structures declined with respect to the main external flow by angles ±45°. In the same time, the long-term averaging provides the symmetric flow pattern around the dimple [4].

Recently, more and more works are devoted to the study of the characteristics of oval-trench dimples. In [5] it was shown that the total heat transfer from a channel with a long oval-trench dimple more than three times exceeds the heat transfer from a channel with a spherical dimple with the same spot area. In [5] dimples of small depth and, as a result, with steady structures are studied.

At the present study, based on the numerical modelling and partially by the experiment, the structures of the flow in deep oval-trench dimples are examined.

COMPUTATIONAL SETUP

A rectangular channel with an oval-trench dimple is considered. The dimensions of the calculation domain corresponded to the geometry of the channel with the dimple at the lower wall. The height of the channel was 0.83D. The distance from the channel side wall to the nearest trench edge was 1.5D for all λ. The entry boundary of calculation domain was at a distance of 4.5D from the front edge of the trench whereas the exit boundary was at a distance of 4.5D downstream the rear edge. In this study, we used two approaches to modelling turbulent flows. The first is based on the use of Reynolds averaged Navier-Stokes equations, which are closure using the two-parameter SST turbulence model. The second approach uses a modification of the method of detached eddies IDDES (The Improved Delayed Detached Eddy Simulation).

The unstructured mesh of polyhedral form applied for the discretization of the numerical domain into the control volumes. The average linear dimension of the cells inside the trenches was equal to 7×10^{-3} D and the dimension inside the flow core was 5×10^{-2} D. The near-wall step was prescribed equally to 10^{-4} D. A grid stretching normal to the wall is used to provide the sufficient near-wall grid resolution with $y^+<1$. A stretching factor normal to the wall is chosen to place several grid points into the viscous sublayer. The total number of control volumes was from 18 to 25 million, depending on the value of parameter λ. At the channel inlet boundary, a uniform profile of velocity head q was assigned. At the outlet boundary, the open boundary conditions with constant pressure $p = p_{out}$ were set, whereas no-slip boundary conditions were set on all rigid inner boundaries.

RESULTS

The performed series of calculations show that with the increase of the length of the cylindrical part of the dimple from 0 to L = R, the flow stabilizes. Figure 1 presents the computer visualization of two characteristic states of the flow for $\lambda = 0.5$ with pronounced inclined single-core vortex structures beginning on the inner walls of trench end spherical rounding and emerging on the outer near-wall region of the flow near the opposite ends of the trench. Thus, the flow structure around the oval-trench dimple of small elongation is similar to the spherical dimple, but without a switch. The specific form of the steady-state flow structure depends on the initial conditions of the task. This result was obtained both numerically (URANS and DES technologies) and experimentally in the wind tunnel of the Research Institute of Mechanics of Lomonosov Moscow State University. As we move on to longer dimples, the pattern changes substantially. Instead of two equally possible asymmetric vortex structures (Figure 1, $\lambda = 0.5$), there remains a single symmetric two core structure beginning on the internal walls of end rounding and emerging in the outer flow through the central part above the rear edge of the trench (Figure 2a, $\lambda = 1.5$). The obtained flow in the trench of moderate length may be interpreted as the coincidence of two counter moving swirling jets flowing from the opposite ends of the trench.

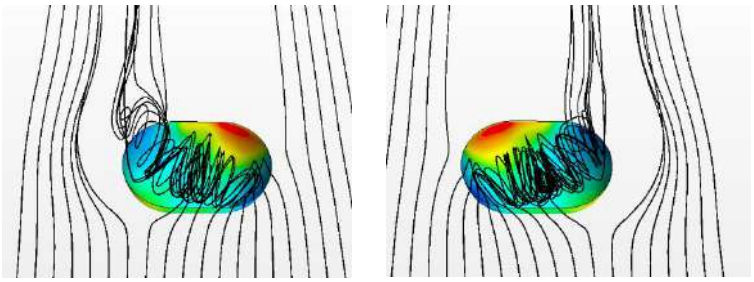

Figure 1. Single core asymmetric vortex structures of flow around a short trench at $\lambda = 0.5$.

An increase in parameter λ leads to the following qualitative variations in the structure of the flow around the oval-trench dimple (Figure 2b). The flow structure is symmetric but has qualitative differences from the previous case. Between the counter moving swirling jets propagating from the opposite ends of the trench, a buffer structure appears in the form of two secondary swirling jets propagating in different directions from the trench plane of symmetry. The flow rate in these secondary jets is fed from the external flow above the central part of the trench. Part of the shear layer turns back and enters in the trench, generating the vortex source in the trench plane of symmetry. As a result, the periphery swirling jets from the opposite ends of the trench come into collision not with each other, but with the countermoveing central jets. In the places of the collision of these jets at some distance to the left and the right from the trench plane of symmetry, they coalesce and turn back by 90° with the formation of two non-swirling jets flowing into the concurrent external flow.

SHOCK/BOUNDARY-LAYER INTERACTIONS: A COMPARISON BETWEEN SHOCK-CAPTURING AND SHOCK-FITTING SIMULATIONS

Alessia Assonitis *[1], Renato Paciorri[1], and Aldo Bonfiglioli[2]
[1] Department of Mechanical and Aerospace Engineering, Università La Sapienza, Roma, Italy
[2] Scuola di Ingegneria, Università degli Studi della Basilicata, Potenza, Italy

Summary Compressible viscous flows are often characterized by the interaction between shock-waves and boundary layers. The occurrence of shock/boundary-layer interactions (SBLI) within an high-speed flow can greatly affect the performance of a vehicle due to the presence of intense local heating and the loss of efficiency of the aerodynamic control surfaces. It is therefore of paramount importance to accurately predict the skin-friction and wall-heating distributions which, in turn, require the accurate modeling of the shock-waves. The proposed paper compares the reliability of two different numerical approaches which consist in modeling the shock-waves by either shock-capturing or shock-fitting, whereas in regions of smooth flow the governing PDEs are in both cases approximated using the same unstructured-grid CFD solver.

INTRODUCTION

Numerical models for compressible flows can be cast into two main categories: shock capturing (S-C) and shock-fitting (S-F). S-C methods, which are nowadays very popular due to their algorithmic simplicity, are built upon the integral, conservation-law form of the governing equations. No special treatment is required to handle the discontinuities, but these exhibit a finite thickness which is orders of magnitude larger than their physical one. Moreover, and, despite their great popularity, S-C schemes are known to be plagued by a variety of numerical problems that affect the accuracy and the quality of the computed solutions also downstream of the shocks [1].

The S-F technique, initially developed by Gino Moretti [2], relies on a different shock-modeling approach which consists in identifying and tracking the motion of the discontinuities, which are treated as internal boundaries of zero thickness that bound regions of the flow-field where a continuous solution of the governing PDEs exists. The motion of the discontinuities, and their upstream and downstream states, are computed by means of the Rankine-Hugoniot jump relations, whereas in the smooth-flow regions of the computational domain any gas-dynamic solver can be used to approximate either the conservation-law or non-conservative form of the governing PDEs [3].

The S-F approach overcomes most of the numerical troubles incurred by S-C methods, but it typically requires a major coding effort with respect to S-C algorithms.

In the proposed paper numerical simulations of different test-cases involving SBLIs have been performed using both the aforementioned approaches and, in particular, an improved version of S-F algorithm for unstructured grids proposed by Paciorri and Bonfiglioli [4]. The results will be mutually compared and also with experimental data available in the literature in order to highlight the different performance of the two shock-modeling practices.

RESULTS

A sample test-case that will be analyzed in the full paper consists in the oblique shock reflection on a flat plate, which was experimentally studied by Degrez et al. in [5]. Figures 1 and 2 show the density field computed using both the S-C and S-F approaches on nearly identical unstructured triangular grids; in particular, the S-F simulation is of an hybrid type, whereby only the strongest shocks are fitted and the remaining ones are captured. The comparison between the S-C simulation and the hybrid, S-F one clearly shows the advantages of the latter in terms of solution quality, particularly in the area where the SBLI takes place. Observe, in particular, that the captured shocks span several grid elements and are therefore characterized by a finite thickness, the size of which is comparable to the size of the recirculation region. In order to improve the quality of the S-C solution a much finer grid would be required, thus incurring in a higher computational cost.

More details about this simulation and other test-cases (e.g. transonic airfoil, hypersonic compression corner) will be discussed and analyzed in the full paper.

TURBULENCE SUPPRESSION VIA COMPLIANT LUBRICATING LAYER

Alessandro Monti*[1] and Marco Edoardo Rosti[1]
[1] Okinawa Institute of Science and Technology Graduate University, Onna, Kunigami, Okinawa, Japan

Summary We study the effect of a lubrication layer on a turbulent channel flow at nominal $Re_\tau = 300$, with two immiscible, homo-viscous flows separated by a thin interface. The problem at hand is tackled by means of direct numerical simulations and the multiphase nature of the flow is accounted through the volume of fluid method. The analysis is performed for several heights of the lubricating layer and multiple interface surface tensions, the latter governed by the Weber number We. We show that, in the selected parameters subset, the lubricating layer completely or partially laminarizes, bringing drag reduction benefits. A satisfactory explanation of the turbulence suppression mechanisms will be provided.

INTRODUCTION

The benefits of lubricating high-viscosity oil pipelines with water for increasing transport-efficiency are well-known and date back to the beginning of the 20th century [1]. The technology is based on the balance, in internal flows, between the pressure gradient needed to pump the liquid and the shear-stress at wall. When a centripetal acceleration is applied to the multiphase liquid, the water, having lower viscosity than oil, migrates towards the high-shear regions (i.e. the wall). In this way, the balance above reduces in effectively pumping water instead of crude, thus reducing the energy needed to transport the liquid. These flows are known as core-annular flows and the drag-reduction mechanisms is viscosity-driven [2]. Since the seminal work by Isaacs and Speeds [1], the topic has been heavily studied due to the critical impact that petroleum industry has had in the modern society. Comprehensive overviews on the topic are provided by Joseph *et al.* [2] and, more recently, by Ghosh *et al.* [3].

While the viscosity effects on the drag reduction mechanisms are well understood, the roles of the surface tension and of the size of the lubricating layer still lack a complete explanation. A first attempt to clarify the role of the surface tension has been carried out by Roccon *et al.* [4]. The authors analysed a turbulent channel flow with a thin lubricating layer ($\delta/H = 0.15$, being H the half-height of the channel) having the same viscosity of the carrier fluid. The analysis was tackled through direct numerical simulations. The work shows that the surface tension alone can bring drag reduction with higher savings than bi-viscous flows. The homo-viscosity lubricating layer relaminarises, with the surface tension suppressing the turbulence self-sustained mechanisms of the wall-cycle [4, 5]. This drag reduction mechanism (surface-tension-driven) has been characterised and distinguished by the typical viscosity-driven drag reduction [1, 4].

Inspired by this promising work, our study aims to unravel the mechanisms of the turbulence suppression. We further increase the parameter set tackled by acting on the size of the lubricating layer. The idea is to decouple the turbulence mechanisms found close to the wall and in the logarithmic region, in the fashion of a scales-separation effect seen in high-Reynolds number flows [6]. The size of the lubricating region, therefore, will span from the edge of the buffer layer to the core of the logarithmic region. Finally, the elasticity of the separating layer will also be modified to investigate the role of the surface tension.

This work aims to fullfil the gap in the literature from the fluid-mechanics point of view, by analysing the turbulence break-down mechanisms.

METHODOLOGY

We consider the flow of two incompressible Newtonian fluids, separated by an interface, in a turbulent channel flow at $Re_\tau = 300$. The two-fluid motion is governed by the incompressible Navier-Stokes equations and the interactions between the two fluids are tackled by enforcing the continuity of the velocity field and of the traction force at the interface,

$$u_i^{f1} = u_i^{f2} \quad \text{and} \quad \sigma_{ij}^{f1} n_j = \sigma_{ij}^{f2} + \sigma\kappa n_i \tag{1}$$

where the superscripts $f1$ and $f2$ indicate the two phases, σ_{ij} denotes the Cauchy stress tensor, n_i the normal vector at the interface, κ the interface curvature, and σ the uniform surface tension. The two-phase interaction is accounted by applying the volume of fluid method [7], where the extrema of an indicator function, $H \in [0, 1]$, identify the fluid phases. The function H, here, is reconstructed via the MTHINC method [7]. The indicator function is then updated through the transport equation,

$$\frac{\partial \phi}{\partial t} + \frac{\partial u_i H}{\partial x_i} = \phi \frac{\partial u_i}{\partial x_i}, \tag{2}$$

being u_i the local fluid velocity and ϕ the cell-average value of H. Once equation (2) is solved, the momentum equation can be rewritten with the one-continuum formulation [8],

$$\frac{\partial u_i}{\partial t} + \frac{\partial u_i u_j}{\partial x_j} = \frac{1}{\rho}\left(\frac{\sigma_{ij}}{\partial x_j} + f_i\right), \tag{3}$$

*Corresponding author. E-mail: ictam2020@aimgroup.eu.

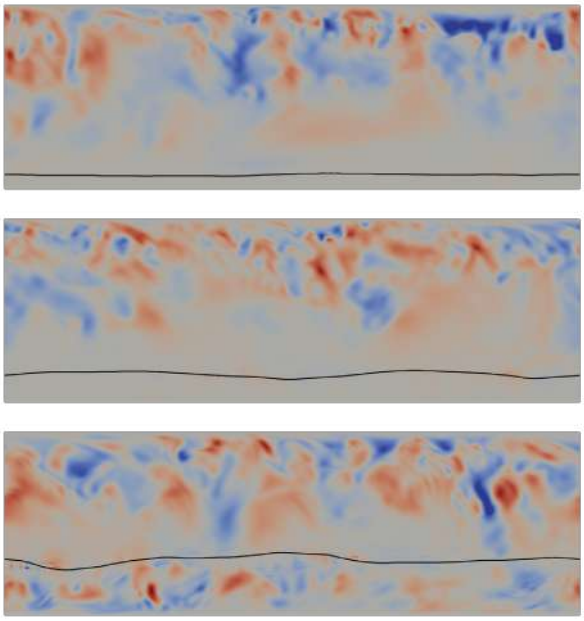

Figure 1: Contours of the wall-normal velocity normalised with the nominal friction velocity, u_τ, that gives $Re_\tau = 300$. The Weber number considered is $We_\tau = 0.5$. The x axis represents the streamwise direction, while the y axis the wall-normal one. Top panel: $\delta/H = 0.15$; Central panel: $\delta/H = 0.3$; Bottom panel: $\delta/H = 0.60$.

where ρ is the density, $f_i = \sigma\kappa n_i \delta$ (being δ the bell function used to single out the interface region) and $\sigma_{ij} = -p\delta_{ij} + 2\mu D_{ij}$ is the Newtonian stress, indicating p the pressure, δ_{ij} the Kronecker delta, μ the dynamic viscosity and D_{ij} the strain rate tensor, respectively. The two-phase fluid properties are accounted with a linear interpolation,

$$x = (1 - \phi)\, x^{f1} + \phi x^{f2} \tag{4}$$

where the function x can be replaced by ρ, μ and σ_{ij}. Finally, the Navier-Stokes equations with the modified momentum equation (3) are solved via a fractional-step method. Furher details of the methodology with the validation can be found in [9]

PRELIMINARY RESULTS

As the study is still ongoing, we present here some preliminary results. We used as initial condition a turbulent channel flow at $Re_\tau = 300$, in a $2\pi H \times 2H \times \pi H$ box, where H is the half-channel height, with periodic boundary conditions in the streamwise and spanwise directions, while a no-slip condition is applied at the walls. We then applied the volume of fluid method by placing an initially parallel-to-the-wall interface at $\delta/H = [0.15, 0.3, 0.6, 1]$, setting the surface tension by tuning the Weber number, $We_\tau = \rho u_\tau^2 H/\sigma = [0.5, 1, 1.5]$. Figure 1 shows that, for $We_\tau = 0.5$, the layer below the interface laminarises for the case $\delta/H = [0.15, 0.3]$, while partially laminarises when $\delta/H = 0.6$, i.e. when then interface is placed in the core of the logarithmic region, at $y^+ = 180$. The mechanisms of the turbulence break-down still need to be further investigated but the preliminary results are promising.

A RIGID BODY TRANSLATING IN A BOUNDARY LAYER

Ellen Jolley*[1], Frank T. Smith[1]
[1] Department of Mathematics, University College London, Gower Street, London, WC1E 6BT

Summary The study considers a slender, heavy body moving with streamwise velocity in a boundary layer. The application in mind is aircraft icing, in which small ice particles may adhere to the surface of an aircraft and interfere with its aerodynamics. Some such particles are small enough to enter the boundary layer of the aircraft, which results in substantially different dynamics from those outside the boundary layer due to the presence of incoming vorticity. A wide range of interesting solutions exist including 'crashes' (eventual collision with the wall), 'fly away' (escape to infinity), and 'bouncing' (repeated excursions far from the wall but with eventual return).

INTRODUCTION

The problem here is to determine the long term behaviour of a rigid body which moves due to its dynamic interaction with the surrounding fluid. This problem is of significant interest to industry due to its relevance to aircraft icing, in which small ice particles can adhere to aircraft wings, engines, or fuselages and deform the aerodynamic shape in such a way as to disrupt flight, in worst cases resulting in serious accidents [1]. In this work, we are considering a boundary layer setting and hence vorticity is present, but comparison can be made with the similar problems considered in [2, 3] which are both vorticity-free.

The flow is modelled as two-dimensional and incompressible, and we work in the streamwise rest frame of the body. The incoming boundary layer flow is first approximated as a linear profile, i.e. with constant incoming vorticity, which approximates the near-wall boundary layer flow. The body is small in both dimensions but is thin, so that its width (comparable to the boundary layer thickness) is much less than its length. Its angle of incidence is assumed to be small so that it is nearly aligned with the oncoming flow profile. The Reynolds numbers and Froude numbers of interest are large and hence the relevant force governing the body motion is the pressure force. The small vertical scale of the problem yields that pressure has no vertical dependency, and hence the pressure above the body is identified with the free-stream pressure to be zero. Hence the pressure beneath the body determines its motion. The boundary conditions consist of the kinematic conditions at the wall and the underbody surface, as well as the Kutta condition insisting on continuity of pressure at the trailing edge. The modelling assumption that the body density is significantly greater than the fluid density (appropriate for ice in air) yields that the flow is quasi-steady on the time scale of body motion, which allows significant analytic progress to be made.

RESULTS AND DISCUSSION

By making use of volume flux conservation and Bernoulli's principle, the velocity distribution and pressure can be determined in terms of the underbody curve for the entire flow region under the body. This reduces the system to a pair of non-linear integro-ODEs for the body height and angle (with height measured from its centre of mass, and its angle being the angle its chord line makes with the positive x-axis), which can be solved numerically to yield a wide-range of solutions, including 'crash' solutions (eventual collision with the wall), 'fly away' (escape to infinity), and 'bouncing' (repeated excursions far from the wall but with eventual return). The outcome depends sensitively on initial conditions as well as the incoming flow and body shape, but one predictor for whether a body will crash or not is its initial angle (positive angle making the body more inclined to a crash and negative angle inclining the body to fly away).

Crash solutions

Figure 1 shows the numerical results in a crash scenario, i.e. finite-time collision with the wall. Asymptotic analysis of the governing equations as the underbody curve approaches contact with the wall predicts that the height and angle are $O(T_0 - T)^{4/5}$,3where T is the scaled time variable and T_0 is the time of the crash. Since this predicts infinite velocity in the limit of the crash, consideration of a second time stage is required. In this second time stage, there is a small region of extremely high pressure surrounding the crash point which now forms the dominant component of the force on the body. The results, shown in Figure 2, yield constant velocity in the limit of the crash. This second stage result of constant velocity is in line with the findings of [2].

Fly away and bouncing solutions

A second category of solutions exists for which the body never collides with the wall. This can manifest as escape to infinity ('fly away') or as repeated excursions far from the wall with eventual return (termed 'bouncing', but there is no collision). In all cases, the body angle oscillates and all three can be understood by the same asymptotic regime in which the height is large and depends on a 'long' time variable while the angle remains of order unity and varies on 'short' time. This then yields a differential equation which can be solved to find the limit cycle for the body angle and predicts a parabolic solution for height with leading coefficient depending on the angle limit cycle. If this leading coefficient is positive, it leads to a parabolic height consistent with fly away solutions (Figure 3). If it is zero, we then consider a next-

*Corresponding author. E-mail: ellen.jolley.18@ucl.ac.uk

order adjustment to the height which adds an additional term to the resulting equations, accounting for the 'bouncing' behaviour, which consists of parabolic excursions with negative leading coefficient, followed by a region where the new term is most important causing a 'rebound' (Figure 4). There is a third type of solution not discussed here for which neither height nor angle depend on long time and both enter limit cycles, hence the body never collides with nor ventures far from the wall. All of these solutions with oscillating body angle are unique to flows with incoming vorticity, and thus are not found in [3] which considers a similar problem without incoming vorticity, due to a region of reverse flow occurring at the leading edge in flows with vorticity affecting the pressure distribution.

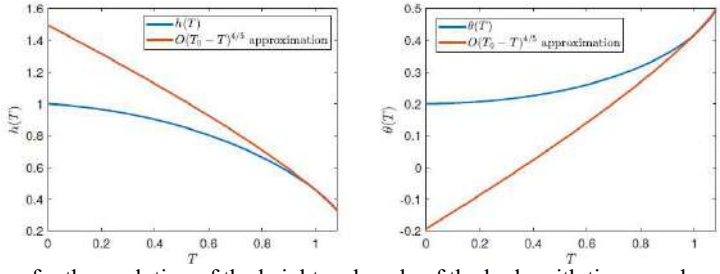

Figure 1. Numerical solutions for the evolution of the height and angle of the body with time are shown in blue and the asymptotic $(T_0 - T)^{4/5}$ approximation in red. The initial angle was positive and the body had initial downwards velocity.

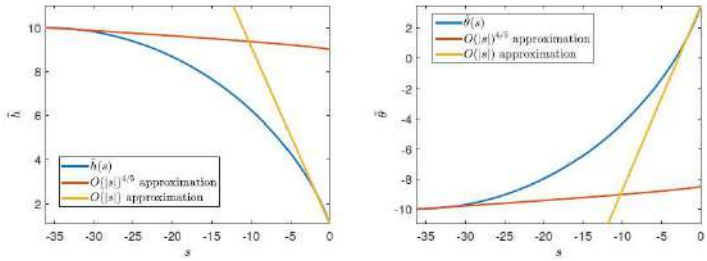

Figure 2. Numerical solutions for the time evolution of the re-scaled height and angle of the body are plotted against a re-scaled time variable in blue. The curve in red shows that the solution matches with the $(T_0 - T)^{4/5}$ approximation far from the wall, and yellow shows the linear velocity in the limit.

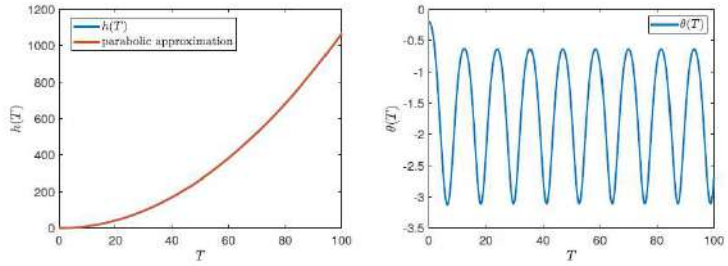

Figure 3. Numerical solutions for the evolution of body height and angle with time in a fly away case are shown in blue. The initial angle was negative and the initial velocity was zero. The curve for height overlaps closely with the parabolic approximation shown in red.

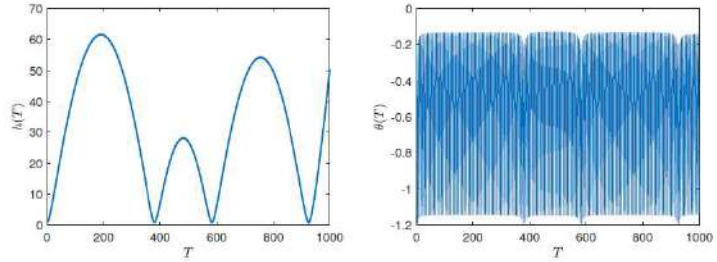

Figure 4. Numerical solutions for the evolution of body height and angle in a 'bouncing' case. Initial conditions were the same as in Figure 3 but with flow vorticity increased. Note here time ranges from 0 to 1000 rather than 0 to 100 as in Figure 3.

FORCED IGNITION OF BLUFF-BODY FLAME IN NITROGEN DILUTING COFLOW

Qiong Lan[1], Jian Zhang *[2], and Yangwei Liu[1]
[1] National Key laboratory of Science and Technology on Aero-Engine Aero-Thermodynamics, School of Energy and Power Engineering, Beihang University, Beijing, 100191, China

Summary The ignition process of non-premixed bluff-body flame in nitrogen diluting coflow has been performed using large-eddy simulations (LES) combined with the flamelet/progress variable approach. In the case of air-diluted coflow, the air was diluted by mixing nitrogen to keep the coflow momentum mostly identical to the case of air coflow. Therefore, We defined a $Damköhler$ (Da) number to quantify the effect of chemistry on the ignition sequence. Da number for the case of air coflow is about two times of the case of air-diluted coflow. Since the flow recirculated, the case of air coflow was easier and faster to successful ignition. And for the case of air-diluted coflow, the ignition source extinguished firstly, then a process similar to auto-ignition emerged, which demonstrated by formaldehyde (CH2O) enriched and arising of hydroxyl radical (OH) followed up.

INTRODUCTION

High efficiency and low pollutant emissions combustion technology has always been concerned in recent years. In many combustion facilities, exhaust gas recirculation (EGR) or flue gas recirculation (FGR) is often used to preheat and dilute jet reactants, which can improve the combustion efficiency and reduce the peak temperature of reactant zone and thus NO_x. Similar with this, moderate or intense low-oxygen dilution (MILD) combustion or named as flameless combustion (FLOX), highly preheated air combustion (HPAC), high temperature air combustion(HiTAC) or diluted combustion have been developed. Owing to different research organizations describe the characteristics of those technologies and emphasize differently, those technologies not fully identical, while they all operates on the reactant dilutions or high recirculation rates to enhance the uniform temperature distribution.

Bluff-body is often as a flame stabilizer resettled in pilot stage, especially in non-premixed combustor. As one of the target burner that Sydney bluff-body burner has been widely investigated. Large vortex structure in recirculation zone enhances the turbulent and mixing level to keep flame stable in bluff body wakes. Reactants dilution may directly influence the transport process of mixture and chemical mechanism. An intrinsic problem with dilution flame, especially for air dilution flame, is the ignition of fuel-air mixtures. The variation of chemical reaction composition may lead ignition difficult in dilution combustion.

This paper is mainly focus on the effect of diluting coflow for forced ignition in non-premixed bluff-body flames. With entire time sequence of force ignition for both of air-diluted coflow flame and air coflow flame at different ignition locations, we aimed to study the varying ignition regimes of bluff body in diluted environment.

MATHEMATICAL MODEL

The present simulations use Large eddy simulation (LES) combine with Flamelet progress variable (FPV) approach to solve turbulent reactive flows. The governing equations after Favre-filtered can be written as follows:

$$\tilde{D}_t\bar{\rho} = -\bar{\rho}\nabla\cdot\tilde{\mathbf{u}} \quad (1)$$

$$\bar{\rho}\tilde{D}_t\tilde{\mathbf{u}} = -\nabla\bar{p}+\nabla\cdot\bar{\underline{\underline{\sigma}}}+\nabla\cdot\bar{\underline{\underline{\sigma}}}^{res}+\bar{\rho}\mathbf{g} \quad (2)$$

$$\bar{\rho}\tilde{D}_t\tilde{Z} = -\nabla(\bar{\rho}\tilde{\alpha}\nabla\tilde{Z})+\nabla\cdot\bar{\tau}_Z^{res} \quad (3)$$

$$\bar{\rho}\tilde{D}_t\tilde{C} = -\nabla(\bar{\rho}\tilde{\alpha}\nabla\tilde{C})+\nabla\cdot\bar{\tau}_C^{res}+\bar{\rho}\tilde{\dot{\omega}}_C \quad (4)$$

$$\bar{\underline{\underline{\sigma}}} = 2\bar{\rho}\tilde{\nu}(\tilde{\underline{\underline{S}}}-\frac{1}{3}(\nabla\cdot\tilde{\mathbf{u}})\underline{\underline{I}}) \quad (5)$$

$$\bar{\underline{\underline{\sigma}}}^{res} = \bar{\rho}\tilde{\mathbf{u}}\tilde{\mathbf{u}}-\bar{\rho}\widetilde{\mathbf{u}\mathbf{u}} \quad (6)$$

$$\bar{\tau}_\psi^{res} = \bar{\rho}\tilde{\mathbf{u}}\tilde{\psi}-\bar{\rho}\widetilde{\mathbf{u}\psi} \quad (7)$$

In these equations, the superscript and represent Favre- and Reynolds-filter quantity, respectively. The subscripts $=$ represents tenor; substantial derivative $D_t=\partial_t+\mathbf{u}\cdot\nabla$; $\mathbf{u}$, $\mathbf{g}$, p, ρ, α represent velocity vector, gravity vector, pressure, density and molecular diffusivity, respectively. Mixture fraction Z and progress variable C are both scalars, ψ is generic scalar variable; In the Eq. (5), σ is viscous stress, ν is kinematic viscosity, S and I represent rate-of-strain tensor and identity matrix, respectively. Eqs. (6) and (7) are the residual stress tensor and residual scalar flux, respectively, where the superscript res represents subgrid residual quantity. The unclosed terms in the Favre-filtered equations are solved by a dynamic approach.

Table 1: Simulation parameters

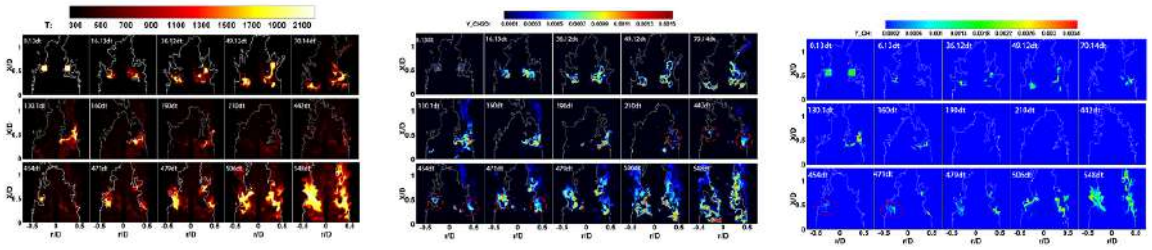

Figure 1: The instantaneous variation sequence of T, CH_2O, and OH for case of air-diluted coflow in the process of forced ignition.

COMPUTATIONAL SETUP

Numerical simulation was based on the Sydney bluff-body burner which consists of a cylindrical bluff-body with an orifice and is centered in a wind tunnel that supports a co-flowing air stream. The bluff-body diameter is $D = D_b = 50mm$ and the fuel jet diameter is $D_j = 3.6mm$. The central nozzle ejects a turbulent fuel jet at $Re = 15800$ which is composed of methane and hydrogen (1:1 by volume) with a stoichiometric mixture fraction $Z_{st} = 0.05$. U_e and U_j represent the fuel jet velocity and the external ambient coflow velocity, respectively.

The cases of simulation were listed in Table. 1. The HM1e flame is just the Sydney bluff-body HM1e flame. To compare with it, a nitrogen diluting coflow case was introduced in here. In this case, the nitrogen was used to dilute coflow air, and the mass fraction of oxygen was diluted from 23% to 20%, which led a different reacting process. Besides, the inlet velocities of fuel jet and coflow were also kept unchanged for both cases. Since the nitrogen has comparable density as air, the flow structures before flame established in both cases would be fairly similar, then we could focus on the role of the chemistry in flame ignition.

Before forced ignition source was placed, the flow of reactants was reached to a statistical stationary state without chemical reaction, which took dozens of flow-through-time in the computation. We called this state a cold flow. The forced ignition source was filled into a small and axisymmetric ring-shaped region in cold flow field. In that region, forced ignition source was numerically represented by adiabatic flame solution of steady flamelet equation.

RESULTS AND DISCUSSIONS

The burning performance parameters of bluff-body flames in air-diluted coflow and air coflow are obtained from the FPV approach. We introduced a $Damköhler$ (Da) number which is a dimensionless number represent the ratio of flow time to chemical reaction characteristic time to quantity the effect of chemistry on ignition process. It can be expressed as follows:

$$D_a = \frac{\tau_{Flow}}{\tau_{Chemistry}} = \frac{D_{ref}}{\Delta U}\frac{\dot{\omega}^*_{C,st}}{C^*_{st}} \tag{8}$$

Da number can directly quantity the chemical reaction rate. Larger Da means faster chemical reaction and easier successful ignition. The reduction of the Da number will be harmful for ignition, may result a failure of the ignition.

CONCLUSIONS

The forced ignition of non-premixed bluff-body flame in air coflow and nitrogen diluting coflow has been performed. The variation of coflow compositions nearly have almost no impact onflow structure, and the difference of ignition mainly caused by chemistry. With the nitrogen diluting coflow, Da number is about a half of the case of air coflow, ignition is relatively difficult in this condition. Corresponding to this, the ignition of case air-diluted coflow which putting ignition source at the outer edge of recirculation zone is failure. Coflow dilution led the ignition difficult and slower. A suitable ignition source position is vital for ignition. The flow recirculated can facilitate the ignition source propagated towards bluff-body and easier to successful ignition. And for the case of air-diluted coflow, stable flame also finally generated in ignition source put inside of the recirculation zone, while flame extinguished firstly, and then a process similarly auto-ignition appeared in this coflow environment.

CELLULAR FLAME DEFORMATION BY THE PASSAGE OF A SHOCK: REACTIVE RYCHTMYER-MESHKOV INSTABILITY

Hongxia Yang[1,2] and Matei I. Radulescu*[1]
[1] Department of Mechanical Engineering, University of Ottawa, Ottawa, Canada
[2] Fire & Explosion Protection Laboratory, Northeastern University, Shenyang, China

Summary We study experimentally, numerically and theoretically the head-on interaction of the shock with a cellular flame. We resolve the dynamics into four distinct stages. At times significantly less than the characteristic flame time, the flame front deforms non-linearly as an inert interface due to the Ricthmyer-Meshkov(RM) instability. At times comparable to the flame time, dilatation due to chemical energy release amplifies the growth rate of RM instability. This stage is abruptly terminated by the transverse burnout of the resulting flame funnels, followed by a longer front re-adjustment to a new cellular flame evolving on the cellular time scale of the flame. The flame evolution model obtained permits to predict the evolution of the flame geometry and burning rate for arbitrary shock strength and flame properties (burning velocity and expansion ratio).

INTRODUCTION

The interaction of shocks with flames is a fundamental problem of reactive compressible flows with applications to flame acceleration and flame control in propulsion applications. State of the art Large-Eddy-Simulations cannot descend to the scales of the flame, hence the flame enhancement by the interaction with the shock has to be modelled. In the present study, we address this fundamental problem of head-on interaction of a shock with a cellularly unstable flame experimentally, numerically and theoretically. We study the evolution of the flame surface, under the impulsive action of the shock wave leading to Ricthmyer-Meshkov(RM) instability. Numerical simulations are conducted to extend the observational time limited in the experiments.

FLAME EVOLUTION

In the experiments, a planar flame was initiated using a long tungsten wire inside a rectangular Hele-Shaw cell [1]. Through hydrodynamic instabilities, the flame acquired a cellular shape, as shown in Fig. 1a. A shock was generated at the other end of the channel, and it interacted with the flame head-on. Fig. 1a shows the evolution of the flame after the shock passage. The flame cusps reverse under the impulsive motion of the RM instability. In the experiments, the subsequent flame evolution is not available, since the shock reflects from the end wall, and re-interacts with the flame.

To extend the study of the flame evolution, we have conducted two-dimensional direct numerical simulations using a single Arrhenius model calibrated to recover the correct flame speed and gas expansion ratio. Fig. 1b provides the evolution of the flame obtained numerically, which was found in excellent agreement with experiment. Following the passage of the shock, the flame inverts and long funnels are created. These burn out after approximately 1 flame time t_f, defined as the laminar flame thickness divided by the laminar flame speed. The subsequent evolution is a re-distribution of the flame frontal curvature as the flame recovers its initial structure.

FLAME EVOLUTION STAGES

Figure 2 shows the evolution of the flame length obtained experimentally and numerically and the resulting burning rate. The evolution of the flame amplitude shows that there are four distinct stages after the reversion of the interface. The first stage can be recognized as the inert evolution of the interface, at times significantly less that the characteristic flame time t_f. The reactive and inert simulations are identical and in excellent agreement with experiments. During this stage, the evolution of the flame shape is well approximated by the non-linear growth rate of the Richtmyer-Meshkov instability in inert flow given by Mikaelian [2]:

$$\eta'_{Mik} = \frac{\eta'_0}{1 + 3\eta_0^+ kt\frac{(1+A_t)}{(3+A_t)}}, \tag{1}$$

where $\eta'_0 = \frac{1}{2}(\eta_0^- + \eta_0^+)[u]kA_t$ is the amplitude growth rate in the linear stage [3], $[u]$ is the velocity jump for the interface with the passage of the shock wave, η_0^- and η_0^+ are the amplitude before and immediately after the shock passage, and $A_t = {}^{(\rho_b-\rho_u)}/_{(\rho_b+\rho_u)}$ the Atwood number after the interaction, ρ_u and ρ_b are the unburned and burned gas density.

At times comparable to the flame time, the disturbed flame amplitude surpasses the inert model's prediction. On these time scales, energy release is no longer negligible. A correction to the inert non-linear growth rate model is to account for the volumetric expansion of the material crossing the flame, which lengthens the flame and increases its surface area .

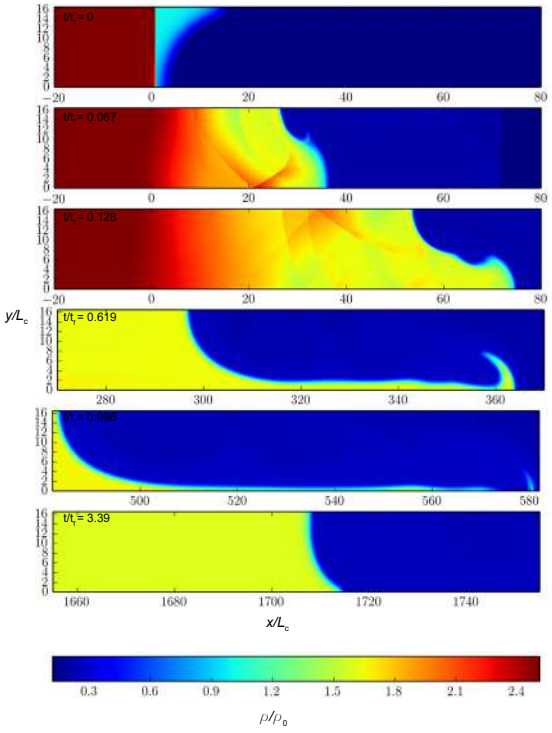
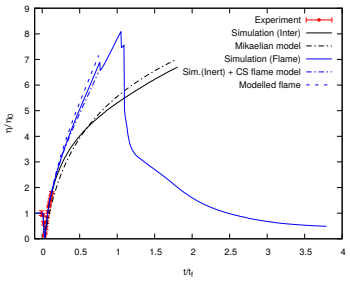
(a) Schlieren image sequence of the interaction. Time 0 corresponds to the beginning of the interaction.

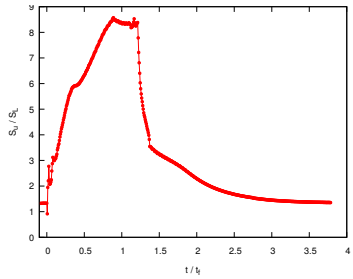


(b) Density profiles illustrating the flame evolution subsequent to the interaction. L_c refers to the characteristic length scale that gives the measure of the pre-heat zone thickness in the steady flame.

Figure 1: Experimental and simulation results of the interaction of a M=1.9 incident shock wave with stoichiometric hydrogen-air flame.



(a) Comparison of the time evolution for the experiment and the simulation of the reactive and non-reactive interaction.



(b) Time evolution of the burning velocity for the simulation.

Figure 2: Comparison of the interface amplitude as a function of time for the experiment and the simulation of the reactive and non-reactive interaction.

The growth rate of the flame length (and surface area) depends on the surface of the flame itself, yielding an exponential feedback. The growth rate in this second stage becomes:

$$\eta'_f = \eta'_{MIK} + \frac{2\rho_u A_F S_u}{\rho_b H}, \tag{2}$$

where A_F is the flame area, S_u is the laminar burning velocity, H is the channel width. We take $A_F \simeq \eta$.

The non-linear reactively enhanced growth of the flame terminates when the funnels created burn out by the transverse reaction fronts. This occurs on a time scale associated with the flame's displacement velocity and the transverse length scale of the cellular flame, $\frac{\rho_b H}{\rho_u S_u}$, which is close to the flame time itself t_f. The subsequent flame relaxation to a new cellular structure occurs on this same time scale. The model provides a simple way to estimate the flame burning rate increase upon passage of a shock and duration of this event.

DETAILED MECHANISM ON FLOW PATTERN SWITCHING UNDER THERMOACOUSTIC INSTABILITY FOR LOW-SWIRL H2 JET FLAMES

Takeshi Shoji*[1], Shigeru Tachibana[1], Terukazu Suzuki [2], Yoshihiro Nakazumi[2], and Takeshi Yokomori[2]

Summary This experimental study extensively explores newly observed flow pattern switching between divergent and convergent flows under thermoacoustic instability (TI) for lean-premixed H_2 turbulent jet flames in a low-swirl combustor (LSC) via time-resolved optical diagnostics. Under stable operation in the absence of TI, the mean radial profile of axial velocity at the injector exit contains double peaks surrounding a low velocity region, indicative of divergent flow typical in LSCs. Once TI occurs at a dominant frequency of 402 Hz, an atypical top hat-like axial velocity profile, corresponding to convergent flow, is observed. More interestingly, switching between divergent and convergent flows occurs during each TI cycle period. This unique switching is caused by the interaction between the jet's shear layer and large-scale vortex-induced radial flow toward the combustor axis.

BACKGROUND AND CONTEXT OF PRESENT STUDY

Thermoacoustic instabilities (TIs) have been a primary technical challenge in the development of low-emission swirl-stabilized combustors[1]. Recently, low-swirl combustors[2] (LSC) have begun to be used to explore TIs in order to establish a fundamental understanding of flame-turbulence interactions inside gas turbine combustors[3,4]. A fundamental feature in LSCs is a divergent flow, the so-called central divergence zone (CDZ), without any inner recirculation zone, which is created by the combination of an unswirled central flow and a surrounding swirled flow. In the CDZ, a freely propagating flame is aerodynamically stabilized at a location where the local velocity equals the burning velocity.

Earlier studies[3,4] on TIs inside LSCs showed that TIs are caused by the delayed ignition of unburned mixtures trapped inside ring vortices shed from the injector rim into the external shear layer. This delayed ignition leads to in-phase thermoacoustic coupling satisfying Rayleigh's criterion[5], corresponding to the growth of TI, and induces flapping flame motion in the shear layer while, on average, the flame behaves similarly to a lifted bowl shaped CH_4 flame and is attached to the injector rim in the case of a 0.9 H_2/0.1CH_4 flame[3,4]. Detailed studies by Therkelsen et al.[3] also show that axial stretch rate, essentially the spatial decay rate of axial velocity along the centreline, is always negative even under TI because of the presence of the typical divergent flow in the LSC flowfield. However, more recent studies by our group[6] have introduced a new pattern of flame/flow dynamics for a low-swirl H_2 jet flame under TI, involving a drastic flow pattern switching between the typical divergent flow and an atypical convergent flow during a TI cycle.

Our present study conducts an in-depth experimental investigation into the mechanism of the flow pattern switching that occurs under TI for a lean-premixed low-swirl H_2 jet flame utilizing extensive time-resolved optical diagnostics.

EXPERIMENTAL APPROACH AND SAMPLE RESULTS

Experiments are conducted in an LSC with a swirl number of 0.39 and an injector diameter of D = 35 mm, using simultaneous time-resolved 200 kHz pressure fluctuation measurements, 10 kHz OH* chemiluminescence imaging, and 40 kHz PIV measurements with an Nd:YAG laser (EdgeWave GX600-2-L). Details of the methods are as in our prior studies[6]. The spatial resolutions of the optical diagnostics are higher than previously, enabling more detailed investigations of flame/flow dynamics. The bulk velocity of mixtures of H_2 and air, with seeding of tracers, is initially set at V_m = 15 m/s, and the fuel flow rate is increased linearly over 5 s while maintaining a constant air flow rate. This achieves a gradual increase in the equivalence ratio from 0.25 to 0.33, and thus transition from stable to unstable LSC operation.

Representative results of time-resolved measurements during transition are shown in Figure 1. Figure 1a depicts time-series pressure fluctuations p' during a time interval of t = 0–5 s. The amplitude of p' clearly increases with t, or equivalently ϕ, and reaches its maximum value; the system evolves into a limit cycle. Note that the dominant frequency of the limit cycle oscillation f_{peak} is 402 Hz in the present study.

Figure 1b shows radial profiles of mean axial velocity V_z normalized by V_m which were extracted near the injector exit at z = 7 mm during t = 0–0.5 s (stable operation) and t = 4.5–5.0 s (limit cycle oscillation). Under stable operation, a low axial velocity region (around $r/D \sim 0$) induced by an unswirled flow is surrounded by double velocity peaks at $r/D \sim$ 3.5, which is a typical divergent flow profile[7,8]. Interestingly, once TI occurs during t = 4.5–5.0 s, an atypical top hat-like velocity profile is observed, suggesting a convergent flow. This unique trend was first observed in our prior studies[6].

Figure 1c presents normalized axial velocity fluctuations V'_{zc} at (r, z) = (0, 7) mm during t = 4.5–5.0 s with phase-averaging based on f_{peak}. A reference pressure fluctuation signal at the same frequency is also shown. Remarkably, there is a significantly large peak-to-peak velocity-oscillation amplitude of approximately 80% of the bulk velocity V_m. Such a large velocity oscillation can be realized without blow-off only by flames with fairly high burning velocity, e.g., an H_2 flame in the present study. The phase difference between the velocity and pressure oscillations is approximately 120°.

To characterize the flow pattern switching occurring under TI, phase-averaged radial profiles of axial velocity at z = 7 mm during t = 4.5–5.0 s are shown in fig. 1d. These phase instances correspond to those in fig. 1c; i.e., phase-averaging

*Corresponding author. E-mail: shoji.takeshi@jaxa.jp.

is applied with a phase resolution of 15° but results are plotted at every 60°. Phase-averaged velocity vectors superimposed on Abel-deconvoluted OH* chemiluminescence images are also shown in figs. 1e to 1j at corresponding phases to fig. 1d. From $\theta = 60^\circ$ to 120°, when the mean axial velocity increases and reaches its maximum, an origin of a large-scale vortex is generated (white circle in fig. 1f). This vortex is likely induced in the shear layer with a relatively large velocity gradient, as confirmed in fig. 1d. At $\theta = 180^\circ$ in fig. 1g, a radially wide flame region observed at $z/D \sim 1.1$ begins to disappear due to the termination of chemical reactions, and a new flame region is ignited at $z/D \sim 0.6$. Concurrently, the large-scale vortex following the ignited flame region convects downstream. At later phase instances (θ = 240°–360°) the vortex induces a strong radial flow in the negative r direction (white square in fig. 1h), which causes interaction between the vortex-induced flow and the jet's shear layer located at $r/D \sim 0.3$–0.4. Because such interaction leads to strong positive axial velocity along the shear layer, typical LSC-like axial velocity profiles are created at $\theta = 300^\circ$. Finally, the vortex-induced flow is more entrained into the jet toward the burner axis after a certain time delay, resulting in the flow pattern switching back to top hat-like velocity profiles at later phase instances θ = 360°–60°. Therefore, the formation of the unique convergent flow under TI is attributed to the entrainment of the vortex-induced flow which constricts the central flow region toward the burner axis. It is also worth noting that the location of the vortex visualized by velocity vector fields remarkably coincides with that of vortical flame structures situated beneath the radially flat flame region.

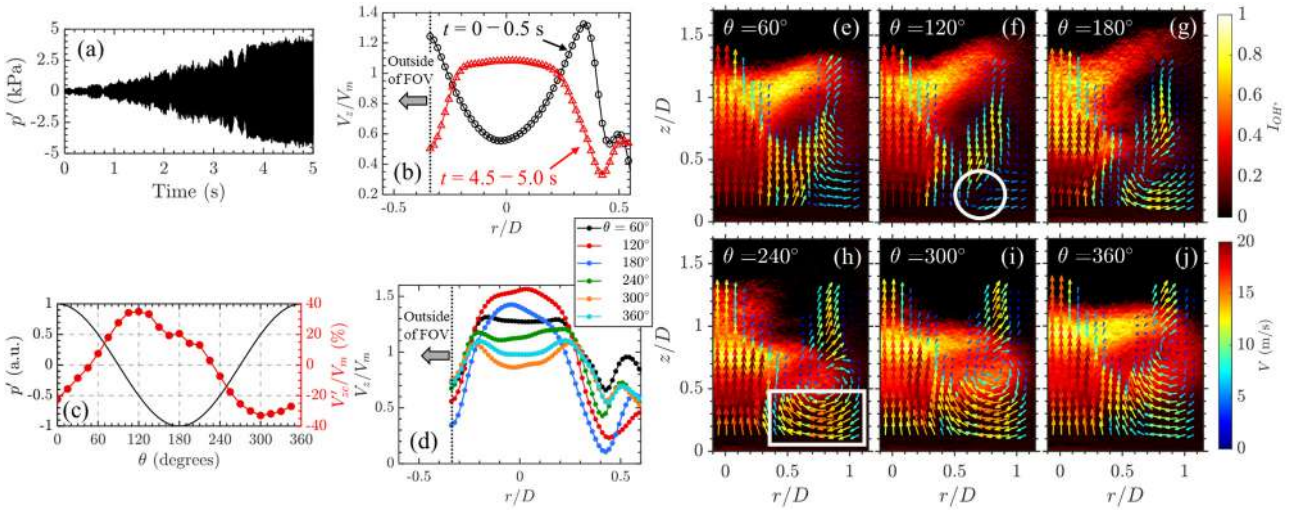

Figure 1. (a) Time-series pressure fluctuations p'. (b) Radial profiles of mean axial velocity V_z normalized by initial bulk mixture velocity (V_m = 15 m/s) taken at z = 7 mm during t = 0–0.5 s (stable operation) and t = 4.5–5.0 s (TI). Gray arrows represent the region outside the experiment field of view. (c) Reference pressure fluctuation signal at a dominant frequency of TI of 40 Hz (left ordinate axis) and phase-averaged normalized axial velocity fluctuations V'_{zc} at (r, z) = (0, 7) mm. Both plots are calculated during t = 4.5–5.0 s. (d) Phase-averaged normalized radial profiles of mean axial velocity V_z/V_m during t = 4.5–5.0 s. (e-j) Phase-averaged Abel-deconvoluted OH* chemiluminescence images with velocity vectors during t = 4.5–5.0 s. Color bar on top row shows normalized OH* chemiluminescent intensity using global maximum intensity, bottom row color bar shows velocity vector magnitude. Portions of velocity vectors corrupted by laser reflections from quartz duct are omitted.

The discussion above unveils the detailed mechanism of flow pattern switching under TI for a low-swirl H_2 jet flame. Nevertheless, as was also concluded in previous studies[3,4,6], further explorations in thermoacoustic coupling between unsteady heat release and pressure oscillations, stretch rate estimation to quantitatively characterize the flow pattern switching, and modal decomposition analyses to study relations between the switching and coherent flame/flow structures are needed for more in-depth clarification of this unique mechanism, as also presented in this study.

FORMATION OF ISOLATED FLAME CELLS PROPAGATING ACROSS ULTRA LEAN HYDROGEN MIXTURES IN NARROW GAPS

Summary Very lean hydrogen flames were thought to quench in narrow confined geometries. However, flames with very low fuel concentration undergo an isolated critically-sustained propagation in narrow gaps: H_2-air flames can overcome large heat losses and very lean conditions by breaking the reaction surface into isolated flame cells that locally enrich the mixture through differential diffusion over a curved front. These kernels travel steadily in straight lines or split cyclically in various unexpected patterns.

EXPERIMENTAL AND NUMERICAL CONFIGURATIONS

Morphology, stability and safety issues of ultra-lean confined hydrogen-air flames are studied in an experimental setup [2] in which two parallel flat plates, disposed vertically, are separated a small distance apart forming a narrow channel of height h. The reaction front is tracked using Schlieren techniques and high-speed imaging, with the path followed by the flames outlined by the trailing condensed water streaks formed just behind them [1] (Fig. 1). In addition, an in-house finite-element code has been used to analyze the processes [3]. Since the flow is laminar and the flame thickness $\delta_T \sim (0.5 - 1)$ mm is comparable to the gap size h, the propagation problem of the flame can be treated as quasi two-dimensional, considerably simplifying the simulations of lean hydrogen-air flames (Fig. 2).

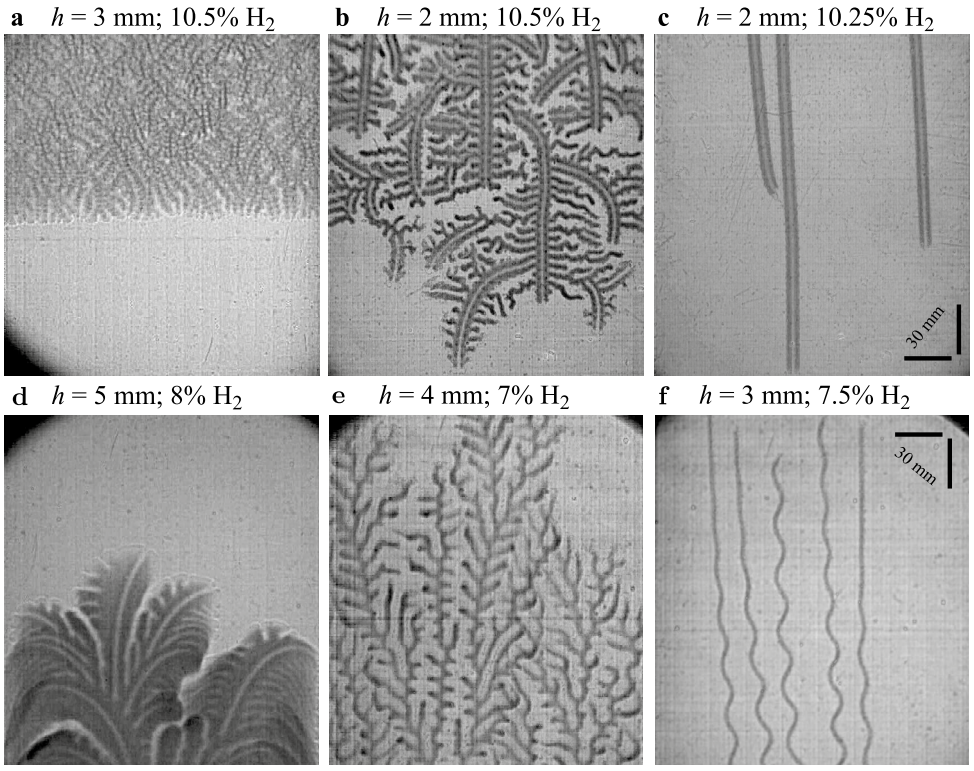

Figure 1: Different propagation modes of hydrogen flames. Downward propagation, **a** continuous flame front, **b** splitting cells and **c** several two-headed isolated steady flame cells. Upward propagation , **d** continuous flame front, **e** fractal-like propagation mode and **f** several one-headed isolated steady cells.

For sufficiently large values of h, the high mass diffusivity of hydrogen outlines a reactive front characterized by the formation of small wrinkles through thermodiffusive instabilities (Fig. 1**a** and **d**). In gaps narrower than $h < 6$ mm, the expected continuous flame front breaks into a set of small flame cells separated by cold, unburned gas, unveiling two

*Corresponding author. E-mail: ictam2020@aimgroup.eu.

regimes that only emerge in flames with low enough hydrogen concentration. In the first one, the flame front breaks into several unstable flame cells (Fig. 1**b** and **e**) that split continuously and propagate leaving a path that conforms a pattern that reminds of ferns and tree leaves. In the second regime, the flame front breaks into a few isolated stable flame cells (Fig. 1**c** and **e**) that move steadily delineating an almost straight trajectory that reminds of the fingering patterns found during smoldering combustion of thin solid materials [7].

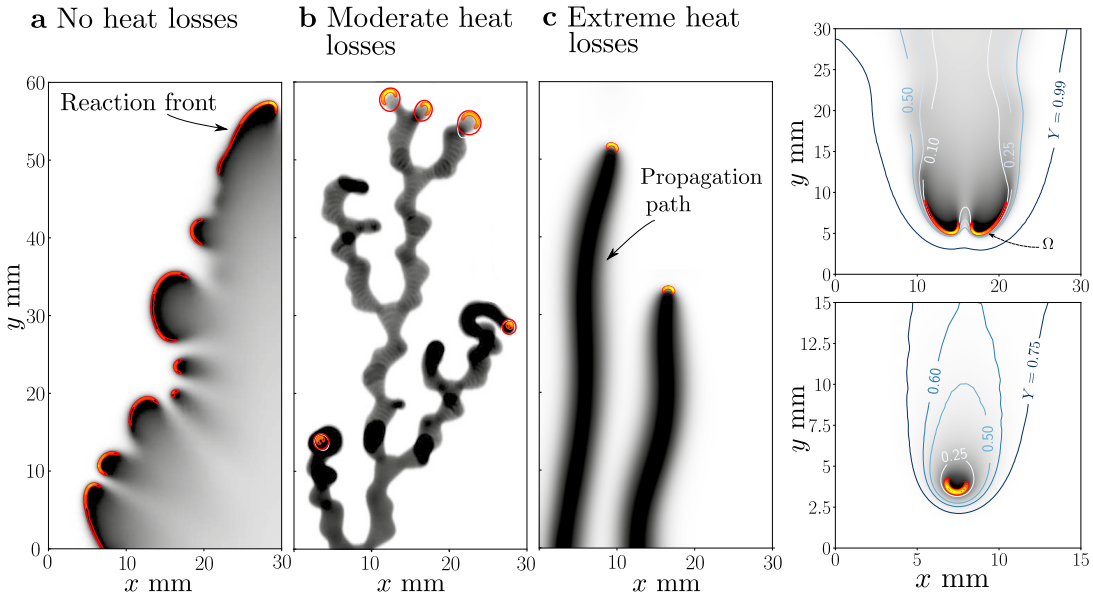

Figure 2: Numerical solutions of lean flames for increasing values of the heat-loss parameter, turning the propagation from a continuous front solution to splitting and isolated regimes. Inset detail of one and two-headed cells.

From the experimental results it is unclear both how the flame cells are formed and why hydrogen flames withstand more adverse conditions than heavier hydrocarbon fuels [6]. To investigate the causes that lead to the new propagation regimes identified experimentally, we modeled the propagation of the H_2-air flame including heat losses at the walls in an integrated averaged formulation in the transverse coordinate z. The aforementioned computations (Fig. 2) identified the intense heat losses at the walls and the high mass diffusivity of the fuel as the two main mechanisms controlling the emergence of the newly-discovered propagation modes

CONCLUSIONS

The discovery of the propagation regimes described above opens new research lines regarding near-limit hydrogen combustion in narrow geometries. Based on the experimental and numerical results and in the mathematical modelling of the problem, we appoint the conductive heat losses to the surrounding walls and the high diffusivity of hydrogen flames as the two physical mechanisms governing the onset of the two propagation regimes reported here. As the use of hydrogen in the near future is expected to increase [5, 4], we anticipate a raising concern about the safety of hydrogen-powered devices [2] that will motivate the exploration of interactions between different phenomena that may unveil unknown flame behaviours relevant in the development of safety measures.

MAXIMALLY AMPLIFIED PERTURBATIONS IN A LAMINAR PREMIXED FLAME, OBTAINED BY LINEAR ANALYSIS

Chuhan Wang *[1], Thomas Ludwig Kaiser[2], Lutz Lesshafft[1], and Kilian Oberleithner[2]
[1] Laboratoire d'Hydrodynamique, CNRS / Ecole Polytechnique / Institut Polytechnique de Paris, Palaiseau,France
[2] Laboratory for Flow Instabilities and Dynamics, Technische Universit at Berlin, Berlin, Germany

Summary The instability of flames, which leads to strong heat and pressure fluctuations in combustion chambers, still represents a major challenge for optimising combustion efficiency. We seek to identify the optimal perturbations, which are maximally amplified in a 2D laminar premixed slot flame, in order to describe the physical amplification mechanisms and find strategies for their control. The optimal velocity forcing and associated flow response are computed in a global framework, where both spatial dimensions are resolved. These optimal structures exhibit the signature of the "Orr mechanism", which amplifies perturbations through sheared convection.

GLOBAL INSTABILITY ANALYSIS OF LAMINAR FLAMES

The objective of our study is to investigate the amplification of small perturbations in a laminar slot flame through global linear analysis. While the unstable flame behaviours are observed and described in various flame configurations, the precise mechanisms of this process remain little explored, and quantitative modelling via linear tools has not yet made its way into the mainstream of flame research. In closely related fields, like shear flows and thermal convection, so-called global linear analysis tools have been widely applied with great success; be it in the context of self-excited non-parallel flow systems like cylinder wakes [1], externally driven systems like laminar jets [2], or even coherent structures in turbulent jets [3].

The applicability of global linear analysis to flame dynamics has indeed been demonstrated in several recent studies, either for the description of self-excited oscillations [4, 5, 6] or for the amplification of external excitation [6, 7, 8]. In both contexts, the linear flame transfer function (FTF) plays a crucial role, and the most recent studies indicate that the FTF can successfully be obtained through linear tools in a global framework. Such a framework must account for the strong non-parallelism of the flow, for chemical reaction, and for the coupling of acoustic and vortical perturbations. The chemistry modelling in particular presents a challenge in current calculations.

SCOPE AND METHODOLOGY

We present a linear analysis of the coupled multi-physics dynamics in a laminar slot flame that is fully resolved in two spatial dimensions. In the framework of *resolvent analysis* [2, 3, 8], we identify the specific type of "optimal" perturbation that is maximally amplified and thus leads to the strongest oscillation in the flame.

The premixed air-methane flame, fully attached to the outlet of a slot, at $Re = 728$ is simulated using the AVBP code from CERFACS. Here, the compressible Navier-Stokes equations for reacting flow are resolved, such that the coupling between flow dynamics, chemical reaction and species transport are included. The flame in this configuration is stable, and its steady velocity and species fields, which serve as a base state in our analysis, are shown in figures 1(a,b).

A *linearised* flame solver, based on the compressible reactive Navier-Stokes equations, is formulated and then discretised by a continuous Galerkin finite-element method on an unstructured mesh. Reaction is modelled with a two-step reduced analytical chemistry scheme involving five species. Computation of FTFs via this linearised solver allows to validate our system of equations against the nonlinear reference solver. The computation of optimal forcing, and its associated linear flame response, involves a singular value decomposition of the linear resolvent operator. For a given definition of an energy norm, the optimal *energy gain* between input and output is obtained as a function of excitation frequency.

CFD and DG data are retrieved from [6]. CG is the result from the present work. (b) Resolvent analysis of the target flame case. Optimal gain as a function of frequency. The five leading gain curves are presented.

CURRENT RESULTS

The linearised solver is first validated for the reference case of a premixed laminar flame with one-step global reaction [6], against nonlinear unsteady simulations. The FTF obtained via our linearised solver is presented in figure 3(a), in excellent agreement with that identified from nonlinear simulations. We then investigate the target flame case with two-step reaction, simulated with the AVBP code. The shape of the linear flame response to inflow forcing obtained in this way matches the result of nonlinear simulations, shown in figure 2.

Optimal forcing structures, in the sense of maximal amplification of kinetic fluctuation energy, at a frequency $f = 30$Hz, are shown in figures 1(c,d), alongside the linear flame response (figures 1e,f). In the spatial distribution of *optimal forcing*, tilted vortical structures are found in the slot boundary layer. These structures are indicative of the "Orr mechanism", which amplifies perturbations through sheared convection. The shape of the *flame response* to this forcing resembles that to inflow forcing in figure 2. The curves of gain in kinetic energy between input and output are shown in figure 3, which allows to identify the receptivity of the system at low frequencies.

COMBUSTION OF A PLANE HYDROGEN MICROJET AT SUBSONIC AND SUPERSONIC SPEEDS

Victor V. Kozlov[1]*, Maria V. Litvinenko[1], Yury A. Litvinenko[1], Andrey G. Shmakov[2]
[1] Khristianovich Institute of Theoretical and Applied Mechanics, Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russia
[2] Voevodsky Institute of Chemical Kinetics and Combustion, Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russia

Summary In this report, we presented the results of experimental studies of the diffusion combustion of a plain hydrogen microjet flowing from a slit micronozzle at subsonic and supersonic speeds. For the first time, four scenarios of diffusion combustion of a plain hydrogen microjet including supersonic combustion in the presence of supersonic cells in both air and hydrogen are presented. The stabilization of the subsonic combustion of a hydrogen microjet was established to be due to the presence of a "flame constriction region," while the stabilization of the supersonic combustion of a microjet was found to be associated with the presence of supersonic cells. The observed hysteresis of diffusion combustion of a plain hydrogen microjet depends on both the method of igniting the microjet (near or far from the nozzle exit) and the direction of change in the rate of its outflow.

INTRODUCTION

Experimental studies of the diffusion combustion of a circular hydrogen microjet [1–4] showed various scenarios for combustion proceeding depending on the increase in the microjet velocity at exit diameters ranging from 0.25 to 1 mm. The following scenarios of diffusion combustion of a circular hydrogen microjet were found: (1) combustion of a pure laminar microjet with a long-range laminar flame ($U0 \le 150$ m/s), (2) the occurrence of a spherical "flame constriction region" (FCR) with the presence of a laminar microjet and laminar flame with turbulization of a microjet and flame when a laminar microjet overcomes a narrow region of a gas density gradient ($U0 > 150$ m/s), (3) detachment of the turbulent flame from the FCR ($U0 > 200$ m/s), and (4) ceasing the combustion of the turbulent section of the microjet while maintaining the combustion in the FCR (moreover, in this situation, the combustion in the FCR is maintained up to the transonic speeds of its outflow, while there is such a phenomenon as "nozzle choking" [4–6] ($U0 > 331$ m/s); and (5) ceasing the combustion of a microjet ($U0 \approx 331$ m/s). It should be noted that "nozzle choking" occurred when the flow rate of the hydrogen microjet was close to the speed of sound in air ($U0 \approx 331$ m/s). In this case, the stabilization of the combustion of both a circular microjet [1–6] and a plain microjet [7] was provided by the presence of the FCR and the existence of combustion in it. However, we were unable to reach supersonic diffusion combustion of a hydrogen microjet due to "choking of the nozzle" by the FCR that heated the micronozzle exit and prevented the flame from cutting it off. One of the characteristics of supersonic combustion of a jet stream, along with a number of others, is the presence of supersonic cells in both the jet and the flame, but in a situation of flame detachment from the nozzle exit. This was demonstrated in detail when a circular hydrogen microjet was ignited far from the nozzle exit [8]. In this situation, it was possible to observe the presence of supersonic cells in the jet, as well as the flame separated from the nozzle exit. This study is aimed to study experimentally the features of the diffusion combustion of a plain hydrogen microjet flowing from a slit micronozzle and to determine various scenarios for this process depending on the rate of the microjet outflow. Special attention will be paid to the study of the characteristics of the microjet development at supersonic (relative to air at $U0 = 331$ m/s and hydrogen at $U0 = 1284$ m/s) speed of its flow and in the presence of supersonic cells. It should be noted that the study of the characteristics of the diffusion combustion of a plain microjet at supersonic speed will be carried out for the first time since, so far, hydrogen combustion has mainly been studied in circular microjets.

RESULTS AND DISCUSSION

Diffusion Combustion of a Plain Hydrogen Microjet (**Scenario no. 1**). Figure 1 shows the scheme of the experiment and the shadow pattern of the diffusion combustion of a plain hydrogen microjet at the rate of its outflow $U0 \le 150$ m/s.

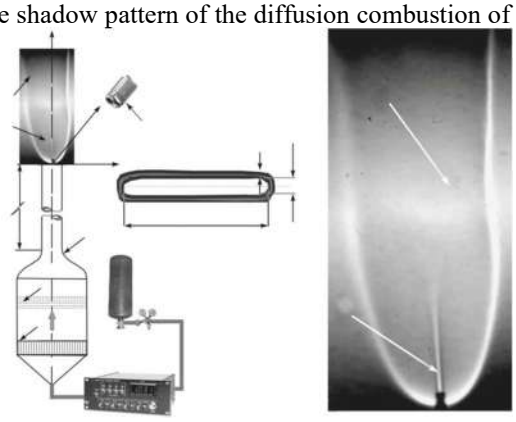

Figure 1.

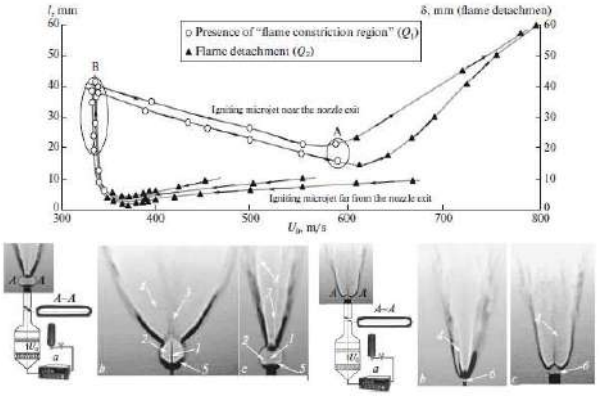

Figure 2.

---

*Corresponding author. E-mail: kozlov@ita.nsc.ru

A detailed description of the equipment used in the experiments and the research routine are presented in [11]. As seen in Fig. 1, II, the shadow pattern demonstrates the laminar combustion of a plain hydrogen microjet at the speed of its outflow $U_0 \leq 150$ m/s and in the presence of the laminar.

Scenario no. 2. At an increase in the flow rate of the microjet, it is possible to observe the emergence of the FCR, the combustion in which occurs up to the transonic velocity of the microjet outflow, but ultimately leads to "micronozzle choking" due to heating of the nozzle exit by the FCR. The range of outflow rates of a hydrogen microjet in the presence of the FCR depends on the method of its ignition: near or far from the nozzle exit. In this case, so-called hysteresis, which is clearly visible in Fig. 2, can be observed. Hysteresis of the development and disappearance of the FCR depending on the method of igniting a plain hydrogen microjet (far/close to the nozzle exit) and at a decrease or increase in its outflow rate. Based on the research results presented in [9], Fig. 2 shows a graph of development and disappearance of the FCR depending on the ignition method (near/far from the nozzle section), as well as the increase/decrease of the outflow rate of a plain hydrogen microjet. The graph clearly shows the presence of hysteresis in this process. When a microjet is ignited near the nozzle exit, the FCR heating the nozzle exit makes it possible for this region to exist until it disappears with flame detachment at a sufficiently high velocity of the microjet ($U_0 \approx 590$ m/s). However, when the microjet flow rate decreases, swapping the flame detachment for its attachment with the FCR appearance occurs at $U_0 \approx 333$ m/s. This correlates with the situation observed while igniting the hydrogen microjet far from the nozzle exit. Thus, in this case, you can observe the hysteresis cycle. Half-cycle A: the presence of the FCR, its disappearance, and flame detachment upon igniting the microjet near the nozzle exit and the increase of its outflow rate (position A). Half-cycle B: swapping the flame detachment for its attachment and the FCR appearance at a decrease in the outflow rate of the microjet while igniting it far from the nozzle exit (position B). It should also be noted that the flame detachment from the nozzle exit and the FCR disappearance, which prevent heating of the micronozzle exit and, therefore, "micronozzle choking," create conditions for the combustion of the hydrogen microjet to reach supersonic speeds.

Scenario no. 3. Supersonic combustion of a plain micro jet of hydrogen in the presence of supersonic cells relative to the speed of sound in air (331 m/s). The classical pattern of the subsonic combustion of a hydrogen microjet, in particular a plain microjet (a) studied in detail in [7]. Moreover, supersonic cells characteristic of supersonic combustion (relative to the speed of sound in air) of the circular hydrogen microjet studied in [10] can be observed in this situation.

Scenario no. 4. Supersonic combustion of a plain micro jet of hydrogen in the presence of supersonic cells relative to the speed of sound in hydrogen (1284 m/s). Figure 3 shows the shadow patterns of the diffusion combustion of a hydrogen microjet flowing from a plain micronozzle at an outflow rate of $U_0 \approx 1484$ m/s and a view of the narrow (I) and wide (II) sides of the micronozzle (a) without and (b) with combustion.

EVALUATION OF NANOPARTICLE POPULATION BALANCE MODELS IN FLAME SPRAY PYROLYSIS

Sebastian Klukas *[1], Marcus Giglmaier[1], and Nikolaus A. Adams[1]
[1] Chair of Fluid Mechanics and Aerodynamics, Technical University of Munich

Summary Flame spray pyrolysis (FSP) is a promising and innovative technique to fabricate versatile functional nanomaterials. Its inherent benefits include cost efficiency, a predicted scaling capability and an extensive range of applicable precursor solutions as well as an accordingly broad range of produced nanoparticles. The study at hand focuses on the formation of maghemite iron oxide nanoparticles (γ-Fe_2O_3) by application of low-cost nitrate-based precursors. The featured numerical method is able to incorporate multicomponent droplet evaporation, thermal decompositions, gaseous combustion as well as particle formation and growth. Three classes of nanoparticle population balance models (PBM) are employed and evaluated. Results show a similar spatial particle spreading for all applied models while deviations in particle size distribution become apparent.

INTRODUCTION

In general, FSP [1] can be divided into five physical subprocesses: primary and secondary spray atomization, precursor reaction, droplet evaporation, gaseous combustion as well as nanoparticle formation, coagulation and growth. These are schematically displayed in figure 1 and are, with the exception of primary atomization, reflected in the current numerical study. The FSP process is initiated by injection of a liquid fuel precursor solution. Since it is coaxially entrained by a fast gaseous flow, the emerging liquid jet is rapidly atomized into small droplets. These subsequently evaporate into a combustible gas mixture while simultaneously undergoing thermal precursor decomposition. A pilot flame and gaseous coflow provide the necessary thermal flow conditions for ignition and steady operation. The prevalent fluid properties at each inlet stream is summarized in table 1. The featured FSP burner corresponds to the laboratory scale "SpraySyn" burner as it is investigated by the German research foundation's priority program DFG-SPP 1980 [2].

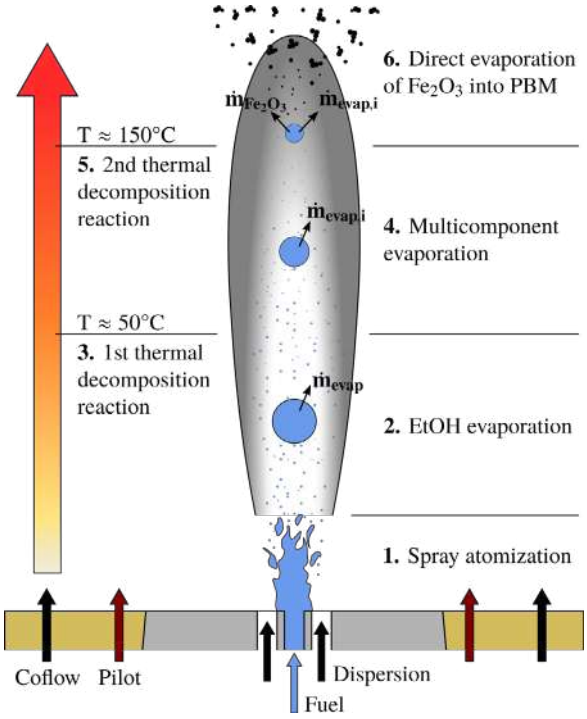

Figure 1: Schematic of the "SpraySyn" FSP burner.

Table 1: Applied inlet conditions.

	Fuel	Dispersion	Pilot	Coflow
Y_i [-]	EtOH + Precursor	O_2	CH_4 + O_2	O_2

Re [-]	78	6262	1067	1530

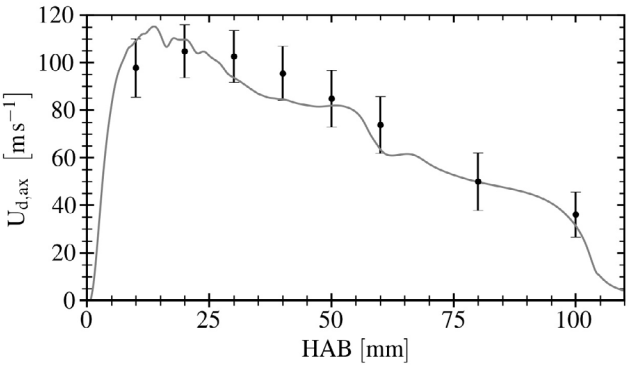

Figure 2: Instantaneous velocity compared to PDA data [2].

NUMERICAL METHOD

The challenge for the numerical method is to incorporate the considered FSP subprocesses while capturing their coupling and related time scales. In general, the reacting multiphase flow is resolved by an Eulerian-Lagrangian approach. Four-way coupling is achieved by transient source term adaptation as well as droplet breakup and collision models. Gas phase reactions are resolved by the steady laminar flamelet model (SLFM) utilizing one-dimensional non-premixed counterflow diffusion flames for thermochemical lookup table generation. The OpenFOAM software libraries are employed to solve the Reynolds-Averaged Navier-Stokes (RANS) equations.

A detailed analysis of FSP requires special attention to the liquid phase evolution. Firstly, multicomponent evaporation

*Corresponding author. E-mail: sebastian.klukas@tum.de

is prevalent since the droplets contain two or more species. Thus, the multi-species variant of the Abramzon-Sirignano model is incorporated into the solver [3]. To be consistent with the flamelet approach the evaporating species water and nitric acid are taken into account by additional species conservation equations. Therefore, both are considered to be neither fuel nor oxidizer and do not participate in any gaseous reaction. Secondly, thermal precursor decomposition is included in the Lagrangian phase and assessed by the following two-step chemical reaction of ferric nitrate [4]:

$$\mathrm{Fe(NO_3)_3 \cdot 9H_2O} \longrightarrow \mathrm{FeOH(NO_3)_2 \cdot 2H_2O + HNO_3 + 6H_2O}$$

$$\mathrm{2FeOH(NO_3)_2 \cdot 2H_2O} \longrightarrow \mathrm{Fe_2O_3 + 4HNO_3 + 3H_2O}$$

Due to their minute vapor pressure, the nucleating $\mathrm{Fe_2O_3}$ nanoparticles are assumed to evaporate instantly into the gas phase. Intermediate iron species are considered to not participate in any phase change processes. To account for the vast amount of nanoscale particles, their number concentration is conserved by PBM. The objective of this study is to assesses the performance of three different types of such models and evaluate their capability of predicting nanoparticle formation within the complex FSP process. The applied PBM are: A straightforward bimodal monodisperse model based on additional scalars for particle volume and concentration, a sectional model featuring a fixed number of particle classes in direct correlation to the number of particle molecules and a bimodal polydisperse model, which derives a particle size distribution by the method of moments.

RESULTS

Validation of the implemented numerical method is performed by comparison to experimental PDA measurements [2]. The corresponding axial profiles of droplet velocity are displayed in figure 2. The demonstrated agreement is repeated in a similar fashion for mean diameter, mean velocity as well as for radial profiles of these quantities. The results illustrate an increasing discrepancy between numerics and experiment with greater distance to the symmetry axis. Exemplary results for the bimodal monodisperse PBM are depicted in figure 3. A detailed comparison to models which take the particle size distribution into account is carried out.

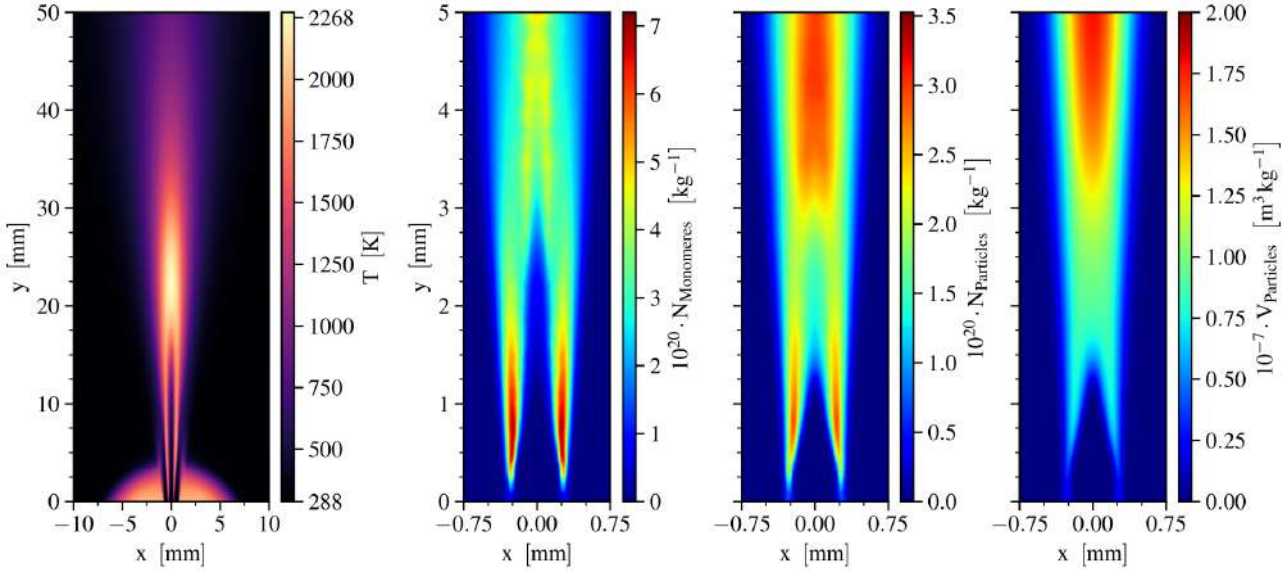

Figure 3: Results for the bimodal monodisperse particle model. Temperature, monomere and particle distributions are displayed.

CONCLUSIONS

The realized numerical method shows great promise to reflect the physical processes of nanoparticle formation in FSP in an efficient and accurate manner. Initial results for a bimodal monodisperese particle model are presented. A detailed comparison between three distinct PBM as well as a detailed experimental validation will be presented at the conference.

IMPACT OF HEAT LOSSES ON FREELY PROPAGATING PREMIXED FLAMES IN NARROW CHANNELS: FROM NON-SYMMETRIC TO SYMMETRIC FLAME SHAPES

Summary. The influence of heat losses on the structure of premixed flames freely propagating in narrow channels is investigated. It is shown that the flame shape depends on the channel width, the reactants mean flow rate and the heat losses. For very narrow channels only symmetric flames, with either mushroom or tulip shapes, are formed at any intensity of heat losses. For wider channels the flames are non-symmetric for adiabatic walls or for small heat losses, and become symmetric as heat losses increase.

We study by numerical simulations the effect of heat losses on the structure of premixed flames freely propagating in narrow channels of planar and circular cross sections, using kinetics of the Arrhenius type and assuming constant transport properties and unit Lewis number (see [1] for further details on the formulation). It is shown that in fairly narrow channels only symmetric flames are formed at any intensity of heat losses. The response curve (flame velocity versus heat losses) takes in this case a typical C-shaped form, as shown in Fig. 1 for a=5, where a is the channel width h scaled with the flame thermal thickness δ_T: there is a maximum critical value of the heat loss intensity above which flame propagation is impossible. This value depends also on the intensity of the mass flow rate in the channel m (Fig.1 corresponds to m=0).

The structure of the flame changes noticeably in wider channels. In these cases the flame results to be non-symmetric when heat losses are sufficiently small (or zero). Nevertheless it was found that with a gradual increase in heat losses the flame shape becomes symmetric again. This can be appreciated in Fig.1 for the cases with $a > 5$, and in Fig. 2 for a =10. As expected, for sufficiently wide channels (e.g. the case a=15 in Fig.1), flame extinction does not occur, not even for very large values of the heat losses parameter, which would correspond to isothermal (cold) walls. It is important to note that the critical quenching width depends on the intensity of the gas mass flow rate, and that near this critical value the flame remains symmetric. The detected symmetry of the flames near the critical value can facilitate the calculation of the critical extinction parameters, of importance for practical applications. We also want to note the appearance of multiplicity of steady-state regimes when flames with symmetric and non-symmetric shapes can coexist.

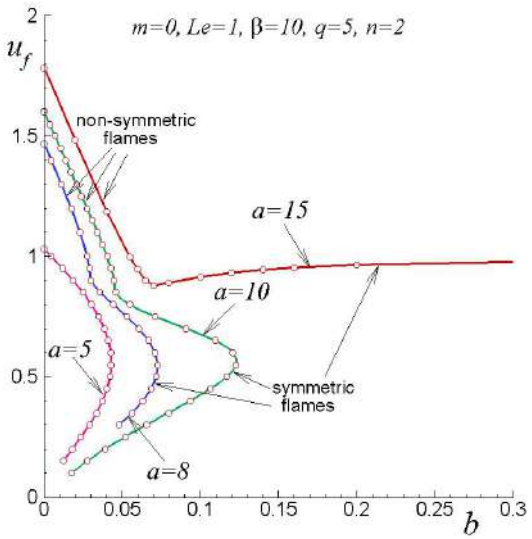

Figure 1. Computed flame velocity u_f (with respect to the wall and scaled with the laminar planar flame speed), calculated as a function of the heat-loss intensity $b = \frac{\lambda_w \delta_T}{\lambda_g h_w}$, with λ_w and λ_g the wall and gas thermal conductivities, δ_T the flame thickness and h_w the wall thickness in planar channels with reactants mass flow rate m=0.

CONCLUSIONS

We study in this paper the influence of heat losses in the flame shape and the quenching width when Le=1 flames propagate freely in narrow channels. These results may be useful for the design of micro combustion devices, and for safety issues in combustion systems, given that the flame propagation speed is closely related with its shape and surface.

STUDY OF THE DIRECT INITIATION OF SPHERICAL DETONATIONS

Paul Clavin *[1], Raúl Hernández Sánchez[1], and Bruno Denet[1]
[1] Aix Marseille Univ, CNRS, Centrale Marseille, IRPHE, Marseille, France

Summary An analysis of the direct initiation of gaseous detonations in spherical geometry is presented, for a Mach number close to unity (small heat release). In this limit, the evolution is described by a Burgers equation, modified by a reaction and a curvature term. The solutions of this equation are presented in a pulsating detonation case.

INTRODUCTION

The direct initiation of a spherical detonation has attracted a lot of attention, starting with the suggestion of Zeldovich that a successful initiation requires that the time to reach the Chapman Jouguet (CJ) velocity is larger than the reaction time. This criterion leads to a critical radius of the order of the detonation thickness of the planar CJ detonation. It was shown experimentally that this critical radius is much too small. A quasi-steady analysis by He and Clavin [1] (see also [2]), using a square wave model, showed that the curvature of the detonation leads to a turning point representative of a curvature-induced quenching; the spherical CJ velocity has a C-shaped curve (see Figure 1) and the quasi-steady solutions exist above a critical radius much larger than the detonation thickness. However the quasi-steady approximation is not fully satisfactory and cannot reproduce the behavior of DNS trajectories, especially near criticality [1],[2],[3]. A theoretical model with an inner structure more realistic than the square wave model, will be used to assess the role of the unsteady effects, in the case of successful initiations or failures.

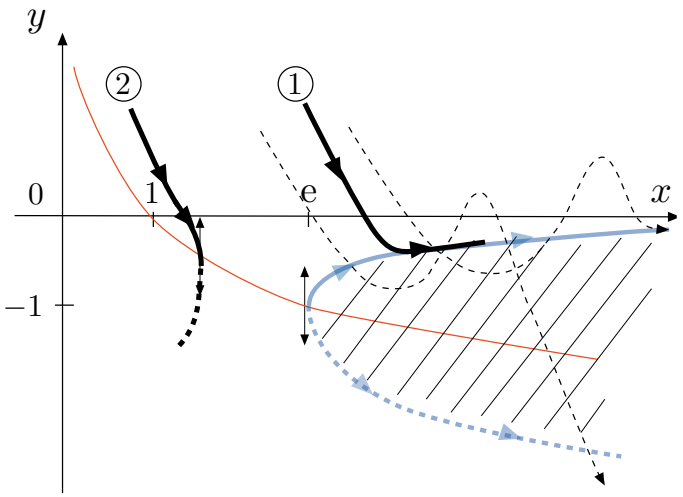

Figure 1: Sketch of the trajectories, x is proportional to the radius, y is proportional to the difference between the detonation velocity and the plane CJ velocity. Dotted lines represent schematically unsteady trajectories obtained by DNS. Solid lines are the quasi-steady trajectories.

MODEL AND RESULTS

In the limit of a small heat release, the full Euler equations reduce to a Burgers equation, modified by a reaction term and curvature term [5, 6]. This inner detonation structure has to be matched to a rarefaction wave. Sufficiently close to the Chapman-Jouguet solution, this Burgers equation can also be transformed in an integral equation [5], of the type recently used in the plane case by the authors in [7].

We present here solutions of the reactive Burgers equation with curvature [6]. For a small heat release, this equation can be written:

$$\frac{\partial \mu}{\partial \tau} + \left(\mu - \frac{y}{b}\right)\frac{\partial \mu}{\partial \xi} = \frac{1}{2}\omega(\xi, y(\tau)) - \frac{(1+\mu)}{\tilde{r}_f(\tau)}, \tag{1}$$

$$\xi = 0: \quad \mu = 1 + 2y(\tau)/b. \tag{2}$$

where μ is a reduced flow velocity in the laboratory frame, ω is the reaction term, the last term in the right hand side of (1) is a curvature term. Using the boundary condition at the shock (2), the reduced detonation velocity y can be obtained ($y = 0$ corresponds to the Chapman Jouguet velocity). An example of numerical integrations of this equation for different initial radii is shown in Figure 2.

*Corresponding author. E-mail: paul.clavin@univ-amu.fr

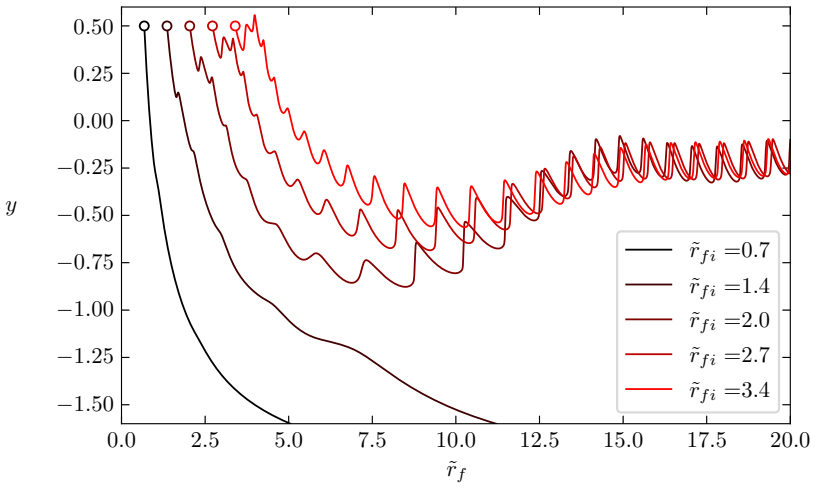

Figure 2: Examples of numerical integration of the reactive Burgers equation for a weakly unstable detonation $b = 2$. The failure occurs for initial radius small enough $\tilde{r}_{fi} < 1.5$ because of chemical-kinetics quenching.

CONCLUSIONS

For detonations close to the CJ velocity, it has been possible to simplify the full system of equations describing the spherical detonation to get a Burgers equation with reaction and curvature terms. Concerning the trajectories of the lead shock in direct initiation, the limit of small heat release is in qualitative agreement with direct numerical simulations, except for the overshoot during the re-acceleration phase which is sometimes observed in DNS.

TAYLOR DIPSERSION AND THE FLAME THERMODIFFUSIVE INSTABILITY

Joel Daou *
Department of Mathematics, University of Manchester, Manchester, UK

Summary We investigate the effect of Taylor dispersion on the thermo-diffusive instability of flames. This is a physically interesting and analytically tractable problem within a relatively unexplored class of problems pertaining to the interaction between Taylor dispersion (or flow-enhanced diffusion) and Turing-like instabilities in reaction-difusion systems. The analysis is carried out in the Hele-Shaw burner configuration and adopts a constant density approximation. Depth-averaged equations are first obtained which incorporate Taylor dispersion and show that diffusion is effectively anisotropic. A linear stability analysis of travelling wave solutions leads to a simple dispersion relation which allows stability-bifurcation diagrams to be drawn in the parameters space.

INTRODUCTION

There are two major intrinsic flame instabilities in premixed combustion. The first, known as the Darrieus-Landau or hydrodynamic instability, is the instability of an interface propagating towards a less dense medium [1]. The second instability, known as the thermo-diffusive instability [2], occurs in fuel-lean mixtures where the thermal diffusivity D_T and the fuel diffusion coefficient D_F are such that their ratio, the Lewis number $\boxed{\mathrm{Le} \equiv D_T/D_F}$, is sufficiently away from unity. The thermo-diffusive instability may be identified as a Turing-like instability [3] since it requires, as in the case of Turing instability in a reaction-diffusion system [4], two diffusive processes to have differing diffusion coefficients. Strictly speaking, however, the Turing and thermo-diffusive instabilities are quite different, not least because the former pertains to a spatially homogeneous steady state, while the latter to a travelling wave.

The rich topic of flame instabilities has been the subject of dedicated reviews e.g. [3, 5, 6]. A main objective of this paper is to complement the literature by addressing unexplored aspects of flame instability using an extension of our approach based on the *thick flame asymptotic limit* described in [7, 8]. The specific novel problem to be addressed in this paper is ***the influence of Taylor dispersion on the thermo-diffusive instability***, which is an interesting subproblem of the more general problem of ***flame instabilities in a Hele-Shaw cell under forced convection***. In fact, the Hele-Shaw configuration is ideal for investigating the instabilities of flames [9], at least in theoretical and numerical studies where heat-losses and density variations, which are difficult to ignore in practice, may be switched off or on, depending on our focus. Recent experiments on flames in Hele-Shaw cells have been conducted at the University of Aix-Marseille [10] and at the University of Southern California [11].

THEORETICAL RESULTS

As a configuration for the investigation we shall adopt that of the Marseilles experiment which is sketched in Figure 1 showing a flame propagating downwards. As described in [10], the burner's operation is briefly as follows. By opening the inlet valve at the bottom, a reactive mixture flows upwards to fill the cell and is ignited at the top of the burner where a flame parallel to the horizontal x-direction is formed and remains anchored thanks to a flow velocity exceeding on average the flame speed U_L. Closing the valve, the flow is stopped and the downwards flame propagation is recorded. It is important to point out that the effect of the flow, or forced convection, on the propagation and stability of the flame has not been addressed. Although this seems to be a simple ingredient to incorporate, it has a profound influence. Specifically, by considering flame propagation against a vertical flow, say given in the unburnt-gas by $\mathbf{u} = u_0(1 - y^2/a^2)\hat{\mathbf{z}}$ where a is the channel half-width and $\hat{\mathbf{z}}$ a unit vector in the z-direction, it is possible to investigate theoretically the effect of Taylor dispersion [12, 13] on flame propagation and stability. Indeed, Taylor dispersion modifies the effective diffusion coefficients of heat and mass in the flow direction (z-direction), which modifies the effective Lewis number $\mathrm{Le}_{\mathrm{eff}}$. In fact, the results of our publication [8] indicate that $\boxed{\dfrac{\mathrm{Le}_{\mathrm{eff}}}{\mathrm{Le}} = \dfrac{1+\gamma(1-\alpha)^2\mathrm{Pe}^2}{1+\gamma(1-\alpha)^2\mathrm{Pe}^2\mathrm{Le}^2}}$, where $\mathrm{Pe} = au_0/D_T$ is the Peclet number, $\gamma = 8/945$ a numerical coefficient, and α the gas expansion parameter defined in terms of the unburnt gas and burnt gas densities ρ_u and ρ_b by $\alpha = 1 - \rho_b/\rho_u$. The formula shows that $\mathrm{Le}_{\mathrm{eff}} \sim \mathrm{Le}$ as $\mathrm{Pe} \to 0$ and $\mathrm{Le}_{\mathrm{eff}} \sim \mathrm{Le}^{-1}$ as $\mathrm{Pe} \to \infty$. This suggests that Taylor dispersion may have significant influence, worth exploring, on the thermo-diffusive instability which critically depends on $\mathrm{Le}_{\mathrm{eff}}$. This is a highly original investigation which is best initiated by adopting first

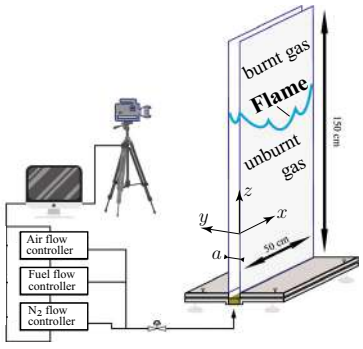

Figure 1: Hele-Shaw burner, adapted from [10]

*Corresponding author. E-mail: joel.daou@manchester.ac.uk.

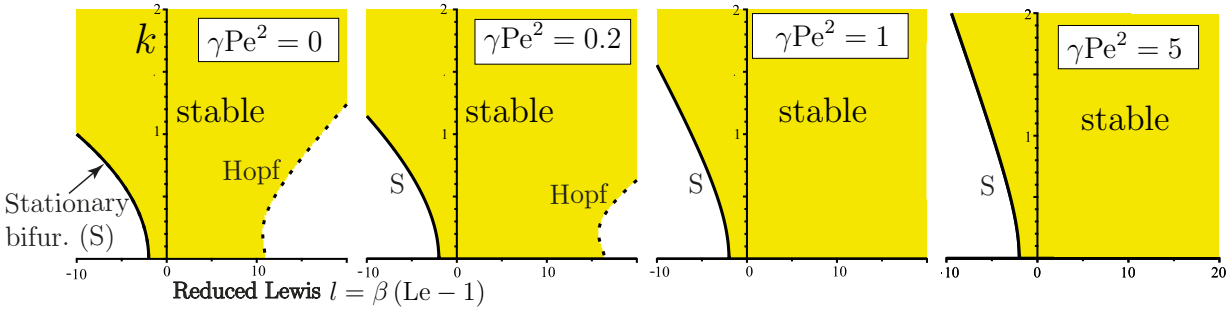

Figure 2: Stability region and bifurcations in the l-k plane for selected values of the parameter $\gamma \mathrm{Pe}^2$; l is the reduced Lewis number and k is the perturbation wave number.

the constant density approximation ($\alpha = 0$) and addressing the stability of a planar flame (parallel to the x-axis) propagating downwards against the flow. The problem has however a crucial complication: enhanced diffusion, which leads to the formula for $\mathrm{Le}_{\mathrm{eff}}$ above, is applicable in the longitudinal z-direction; in the transverse x-direction diffusion is unaffected by the flow. Therefore, the stability problem in the x-z plane (obtained by y-averaging the governing equations), is one involving ***anisotropic diffusion***. Accordingly, the classical approach of tackling the problem, using familiar jump conditions applicable at inner reaction layers needs significant revision. This revision and related aspects are addressed in this work. The main outcome is the derivation of a dispersion relation describing the linear stability of the flame to perturbations proportional to $\exp(ikx + st)$ with wave number k and growth rate s. The dispersion relation is found to be given by

$$2\Gamma^2(\Gamma - 1) + \frac{l}{1 + \gamma \mathrm{Pe}^2}\left[(\Gamma - 1 - 2s)(1 - \gamma \mathrm{Pe}^2) + 4\gamma \mathrm{Pe}^2 k^2\right] = 0\,,$$

where $l = \beta(\mathrm{Le} - 1)$ is the so-called reduced Lewis number involving the Zeldovich number β and $\Gamma = \sqrt{1 + 4s + 4k^2}$.

.

CONCLUDING REMARKS

We note that the dispersion relation incoroprates the effect of Taylor dispersion and the resulting anisotropy of diffusion. A sample of the results implied by the dispersion relation are illustrated in figure 2 for selected values of the parameter $\gamma \mathrm{Pe}^2$. When $\gamma \mathrm{Pe}^2 = 0$ we recover the classical results with a stationary bifurcation curve for small values of l and a Hopf bifurcation curve for larger values. As $\gamma \mathrm{Pe}^2$ is increased the Hopf bifurcation curve is displaced to the right and disappears for $\gamma \mathrm{Pe}^2 > 1$. Thus a sufficiently strong flow impedes the oscillatory flame instability. Also, the size of the stability domain in the left half-plane (delimited from the left by the stationary bifurcation curve) is reduced by an increase in $\gamma \mathrm{Pe}^2$ which indicates that the flow may somewhat promote the cellular instability. In any case, the results demonstrate the ability of Taylor dispersion to significantly affect Turing-like instabilities.

VIBRATION INSTABILTY OF PREMIXED FLAMES

Christophe Almarcha *[1] and Basile Radisson[1]
[1] Aix Marseille Univ., CNRS, Centrale Marseille, IRPHE, Marseille, France

Summary We present a new combustion instability that arises when a premixed flame is propagating in a Hele-Shaw burner. In such a configuration, the wall deformations of the burner are strongly coupled to the flame shape and heat release. We demonstrate that it is possible to take advantage of this coupling for either triggering oscillatory instabilities or for studying the response of premixed flames to oscillating flows.

INTRODUCTION

A premixed flame propagating freely in a burner eventually induces pressure and flow oscillatory instabilities. Usually these two are selected by the acoustic modes of the burner. A canonical experiment was performed in a vertical tube, open at the top and closed at the bottom[1] and exhibited two parametric instabilities. A first one flattening the flame shape and a more intense second one inducing wrinkles on the flame shape. The frequency of the oscillations corresponds to a fundamental acoustic frequency of the burner, with the height of the tube corresponding to a quarter wavelength of the acoustic mode. Recent experiments of premixed flames propagating in Hele-Shaw burners have exhibited either similar [2, 3] behaviors or a totally different one: As remarked by [4], the oscillations appearing in their experiment are not corresponding to the fundamental acoustic mode, indicating that the coupling with the burner seems to be different. We demonstrate here that it is possible to trigger oscillating instabilities in a wide range of frequency by playing with the burner wall thickness, material and dimensions. We show that the new combustion instability results from the coupling between the flame and the vibration modes of the walls. The sensitivity to instability of propane-air mixtures and methane-air mixtures are tested. Finally we use the new vibro-acoustic coupling exhibited for studying the flame response to forced flow oscillations.

INSTABILITY

The vertical Hele-Shaw cell used here is 1500mm high, 500mm large, and the gap between the walls is $5mm$. It is open at the top and closed at the bottom where the supply line is situated. The walls of the Hele-Shaw burner are either of glass or of PMMA. The thickness is varied between 2mm and 19mm in order to explore a wide range of bending stiffness [5]. Thanks to mass flow controllers, the desired mixture is injected in the cell. When the upward flow inside the cell is stopped, a premixed flame can propagate inside [6]. Electret microphones are distributed inside the burner and record the pressure fluctuations. As reported on Fig.1, a lean premixed methane-air flame propagatin in a Hele-Shaw burner with a $8mm$ thick PMMA wall is unstable and exhibits a $8.5Hz$ pressure oscillation. Such a frequency cannot be related to an acoustic mode. The acoustic wavelength would be around $40m$ wich is much bigger than the burner size. When playing with the material and the thickness of the burner walls, and keeping the other dimensions constant, the range of the instability frequency appears between $5Hz$ and $200Hz$. We demonstrate that the bending stiffness of the burner walls is controlling the instability frequency.

VIBRATION RESONANCE OF THE BURNER

The coupling between the flame and the walls vibration, that is necessary for the emergence of the instability described in the preceding section, can be used to study the response of a premixed flame to imposed flow oscillations. In particular, the thresholds of primary and secondary acoustic instabilities can be examined when forcing a wall with an electromagnetic shaker. In that case, the flow oscillations inside the burner are imposed by the vibration eigenmodes of the walls. An example of the velocity induced by the first four eigenmodes of the plates in reported on Fig. 2. On the same figure, the modifications of the flame shape when it crosses nodes or antinodes is also reported. Such spatiotemporal diagrams can be used to study the thresholds of destabilization and restabilization of premixed flames. In particular, the dependance of the Markstein number on the oscillating frequency can be investigated.

CONCLUSIONS

We studied the emergence of a new kind of combustion instability where the coupling between the flame and the vibrations of the burner walls appears to be of prime importance. We demonstrate that contrary to the classical acoustic combustion instability, the frequency and mode shape of the oscillatory instability in Hele-Shaw cells can be ruled by the bending stiffness of the burner walls. As a consequence, oscillatory instabilities with frequencies as low as $8.5Hz$ have been obtained in this metric-size burner. Such finding may be of prime importance when studying burner with such geometries.

EARLY DETECTION OF THERMOACOUSTIC COMBUSTION OSCILLATIONS IN A MULTI-SECTOR STAGED COMBUSTOR FOR AERO ENGINES USING MACHINE LEARNING

Yuhei Shinchi[1], Sena Kishiya*[1],Chinami Aoki[1], Naohiro Takeda[1] , Hiroshi Gotoda [1], Takeshi Shoji [2], and Seiji Yoshida [2]
[1] Department of Mechanical Engineering, Tokyo University of Science, 6-3-1 Niijuku, Katsushika-ku, Tokyo, 128-8585, Japan
[2] Japan Aerospace Exploration Agency, 7-44-1 Jindaiji-Higashimachi, Chofu-shi, Tokyo, 182-8522, Japan

Summary : We conduct an experimental study on an early detection of combustion oscillations in a multi-sector staged combustor using a new methodology combining dynamical systems theory and machine learning. The determinism of recurrence plots and the joint dimensional vicinity are useful measures for capturing a transition to well-developed combustion oscillations. The feature space obtained by a support vector machine has potential use for detecting a precursor of combustion oscillations.

Thermoacoustic combustion oscillations as a result of various mechanisms of nonlinear coupling of acoustic waves to heat-release rate fluctuations lead to serious structural damage in practical combustors. Detection methodologies for thermoacoustic combustion oscillations and the characterization of a rich variety of dynamic behavior have become of much interest in the fields of combustion physics and related branches of nonlinear science. Time series analyses inspired by symbolic dynamics [1] and complex networks [2, 3] have been adopted as promising detectors of combustion oscillations for various types of confined turbulent combustors. Machine learning inspired by information processing in the brain has widespread applications in technologies covering all scientific disciplines. Gotoda and co-workers [4, 5] have recently shown the applicability of methodologies combining complex networks, statistical complexity, and machine learning for an early detection of combustion oscillations. Our main interest in this study is to examine if machine learning is valid for detecting a precursor of combustion oscillations in an aircraft engine model combustor. In this study, we propose a new methodology that integrates dynamical systems, symbolic dynamics, and machine learning for detecting a precursor of combustion oscillations in a multi-sector staged combustor.

The multi-sector combustor, which was developed by JAXA green engine technology program, mainly consists of three lean staged fuel nozzles (LSF) and three emission control fuel nozzle (ECF) [6]. LSF has a pilot fuel injector for diffusion combustion at the center of the fuel nozzle and a main fuel–air mixer for lean premixed combustion around the pilot. All the experiments are conducted using the high-pressure and high-temperature combustion test facility at JAXA. The pressure fluctuations p' are measured by a pressure transducer. The sampling frequency of p' is set to 50 kHz.

As shown in Eqs. (1)-(3), we use a new index [7], namely, the joint dimensional vicinity J, to capture a precursor of combustion oscillations. It considers the correlation entropy [8] and the joint recurrence plots [9]. Note that ${R_R}^D$ represents the density of recurrence plots and J ranges from 0 to 1. We adopt a support vector machine as one of the machine learning technologies for J and the determinism D_E [9] in recurrence plots. The details of the support vector machine are described in Refs. [4] and [5].

$$J = \frac{S - {R_R}^D}{1 - {R_R}^D} \tag{1}$$

$$S = \frac{\frac{1}{\left(N_{sp} - 1\right)^2} \sum_{i=1}^{Nsp-1} \mathbf{JR}_{ij}^{D,D+1}}{{R_R}^D} \tag{2}$$

$${R_R}^D = \frac{1}{N^2} \sum_{i,j=1}^{N} \mathbf{R}_{i,j}^{D} \tag{3}$$

Figure 1 shows the relationship between J and D_E in terms of the amount of main fuel w_{fm}. The location of (J, D_E) moves from left to right on the J-D_E plane with an increase in w_{fm}, forming a parabolic-like shape. This indicates that the two-dimensional plane consisting of the determinism in recurrence plots and the joint dimensional vicinity can capture a transition from stable combustion state to well-developed combustion oscillations which occurs with increasing the amount of main fuel, while maintaining the amount of pilot fuel. Figure 2 (A) shows the feature space consisting of J and D_E obtained by a support vector machine. The combustion state is clearly classified into three regions on the feature space: stable combustion state (blue), combustion oscillations (red), and the transition from stable combustion state to combustion oscillations (yellow). We here increase w_{fm} over about 10 seconds so as to induce combustion oscillations (see Fig. 2(B)). The black plots are drawn on the feature space with increasing time. The combustion state changes back and forth between stable combustion state and the transition state at around 16 s $\leqslant t \leqslant$ 19 s, and well-developed combustion oscillations finally appear at approximately t = 20 s. This clearly shows that the feature space obtained by the

support vector machine allows us to detect a precursor of combustion oscillations. We will present additional results in the poster session.

COMBUSTION OF A ROUND HYDROGEN MICROJET IN A CO-FLOW

Iurii A. Litvinenko[1], Genrich R. Grek[1], Victor V. Kozlov [1], Maria V. Litvinenko[1], Alexander S. Tambovtsev[1] and Andrey G. Schmakov [2]
[1] *Khristianovich Institute of Theoretical and Applied Mechanics, Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russia*
[2] *Voevodsky Institute of Chemical Kinetics and Combustion, Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russia*

Summary Experimental data on the diffusion combustion of round hydrogen microjet in coaxial co-flows are presented. The effects on combustion of the co-current of air and that of air premixed with nanopowder of TiO_2 are of interest. The hydrogen jet flows from a round micronozzle which is surrounded by a coaxial slit to produce the co-flow. In a subsonic range, the so-called "bottleneck-flame" region is generated close to the nozzle exit, while in high-speed conditions the flame separates from the nozzle. At increasing velocity of both the hydrogen microjet and the co-flow, the "bottleneck-flame" region is still found and the combustion becomes more intense. The "bottleneck-flame" region is suppressed at the microjet velocity approaching transonic values.

INTRODUCTION

Stabilization of the diffusion combustion process is an important problem, especially when using miniature burner devices. An increase of the flow rate at maintaining the diffusion combustion process is possible up to certain values. The rate of separation of the diffusion flame, for example, hydrogen is two orders of magnitude higher, while the flame temperature reaches 1600-1800C. Such conditions can be used for hardening or spraying nanoparticles. In this case, particles can be entered through a coaxial nozzle. Co-current oxidizing jet can also stabilize the burner at high hydrocarbon gas flow rates.

EXPERIMENTAL SETUP

The Experimental set-up is shown in Fig. 1. To generate a burning microjet, the nozzle section of the test facility was supplied with hydrogen from a vessel at 100atm. pressure; a co-current air flow emanated from a coaxial slit through injection of compressed air as is shown in Figure 1. In conditions of the co-current air flow seeded with nanoparticles, micronozzle with round coaxial slit and centre hole was used. Hydrogen was supplied to the central hole and a co-current with TiO_2 particles to the coaxial gap.

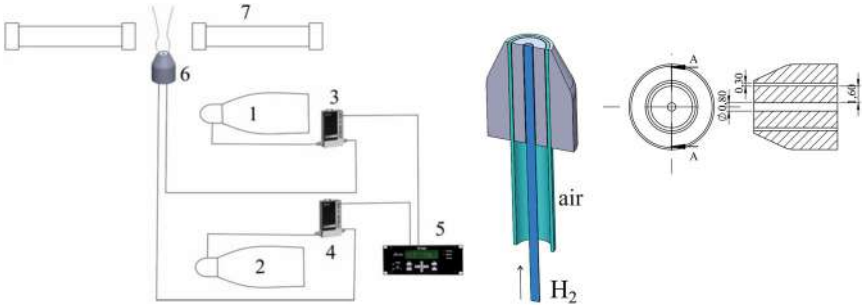

Figure.1. Experimental sketch: 1- hydrogen, 2 – air flow, 3, 4 – flow-meter valve, 5 – flow-meter controller, 6 – nozzle section, 7 – Schlieren device; cross-section of the nozzle is shown on the right

Diffusion combustion of the hydrogen microjet, occurring with and without the concurrent flow, was recorded by a digital camera and examined at acquisition of its shadow images using a Schlieren method and a digital camera providing a resolution of 24 Mpix. The volume flow rate Q (sm^3/s) was controlled by precision flow meters from MKS Instruments (USA) with an accuracy of 0.7 %. Microjet velocity was calculated as $U = Q/S$ where S stands for the cross section of the round nozzle of hydrogen microjet or that of the coaxial slit generating the concurrent flow. Note that the above formula is not appropriate in supersonic conditions as far as it does not take into account a set of parameters, particularly, gas compressibility.

RESULTS

Combustion of round hydrogen microjet in a co-current air flow in subsonic conditions

Shadow images of the microjet combustion at variation of the hydrogen velocity (U_1, m/s) and of the coaxial air microjet (U_2, m/s) are presented in Figure 2. At increasing velocity of the co-current air flow, the "bottleneck-flame" region shrinks similarly to that at acceleration of the hydrogen microjet which was observed in Refs. [1-5]. One can see in Figure 2 (a-d) that the turbulent combustion is intensified downstream of the "bottleneck-flame" region at the speed

[1] Corresponding author. E-mail: litur@itam.nsc.ru

of axial air jet getting higher. The main features of subsonic diffusion combustion of a hydrogen microjet surrounded by a co-current air jet are similar to those we observed earlier in hydrogen microjets [1-5].

Combustion of round hydrogen microjet in the co-current flow of air with nanopowder in subsonic conditions

Shadow images of the diffusion combustion of round hydrogen microjet without concurrent air jet and with are presented in Figure 2 (e-f). In a case of co-current air jet with nanopowder (see figure 2f), picture illustrates the interaction of both jets at their combustion visualized by radiation.

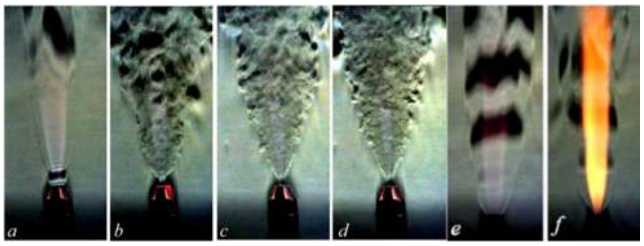

Figure 2. Shadow images of the hydrogen combustion modulated by the coaxial air jet at U_1 = 204 m/s and at variation of U_2 (m/s) as 0 (*a*), 9 (*b*), 18 (*c*), 26 (*d*); and without of coaxial jet U_1= 158m/s (*e*) and with U_1=158 m/s, U_2= 37.5 m/s (*f*)

CONCLUSION

Two options were considered including the concurrent flow of air and that of air seeded with nanoparticles. In the first case, the flame configuration is distinguished by the origination of "bottleneck-flame region" close to the nozzle exit. At variation of flow velocity, the spherically-shaped "bottleneck-flame region" turns into a cylindrical one. In conditions of supersonic combustion, the supersonic cells are generated both in the lifted hydrogen microjet and in the concurrent air flow.

In the other case of concurrent air flow premixed with nanopowder, the experimental data are also obtained at subsonic and transonic flow velocities. It was founded, that the scenarios of diffusion combustion in conditions of the concurrent flow are similar to those of the isolated hydrogen microjet. The origination of "bottleneck-flame" region at the nozzle exit is observed as well as the flame lift-off at increasing velocity of hydrogen. At the regime of "bottleneck-flame" region, the flame becomes deformed both in the center of microjet and in the concurrent flow. As it seen in figure 2f, the nanoparticles emanating from the coaxial slit are heated most of all in central area of hydrogen flow.

NUMERICAL RESEARCH ON DETONATION INITIATION FOR LOW-VOLATILITY LIQUID FUEL

Xiongbin Jia, Ningbo Zhao *,Xiao Liu, and Shizheng Liu
College of Power and Energy Engineering, Harbin Engineering University, Harbin, 150001, China

Summary Numerical analysis has been performed to characterize the detonation initiation for low-volatility liquid fuel with small diameter. Comparative analysis versus equivalent gaseous mixtures points out that the evaporation content of liquid fuel ahead of the flame plays a critical role at flame acceleration stage. Furthermore, detailed discussion on the flow field shows that several local detonations contribute a lot to the final stage of detonation transition. Results in present study provide theoretical guidance and explanation for future experiments.

INTRODUCTION

Tons of paper has been published to investigate the detonation initiation in gaseous system by theoretical, numerical and experimental methods in the past decades. However, the study of liquid-fueled detonation, which is believed more attractive for applications due to its high energy density per volume and easy storage, is still in its infancy due to the fact that the governing parameters of two-phase mixtures are far more than that of gaseous mixtures. In fact, apart from the chemical composition and initial pressure and temperature of the mixtures, particle parameters (e.g. particle size, shape and distribution) and complex multiple-phiysical processes including atomization, droplet breakup, partial vaporization before fuel burning are all important factors effecting the chracteristics of liquid-fueled detonation. Therefore, systematic study on liquid-fueled detonation only takes place in about 1950s. Since then, many pioneering researches have made unremarkable breakthroughs in two-phase detonation field [1].

It is now generally accepted that the detonation for high-volatile liquid fuel is premily similar to the hehavior in the equivalent gaseous system when the fuel droplet size is fine enough (smaller than 10μm). However, large-scale droplets will bring about large cell size and long reaction zone. On the one hand, large droplets inevitably increase the difficulty in initiation since the critical initiation energy increase proportionally to the third power of the cell width [2]; on the orther hand, long reaction zone may lead to detonation failure due to heat losses to the wall and incomplete combustion. Majority of previous researches focus on the characteristics of self-sustaining detonation wave, however, the liquid fueled detonation initiation mechanism still remains unclear, especially for low-volatility fuel.

Present numerical study aims to characterize the low volatility liquid-fueled detonation initiation. Perticularly, influencing factor of flame acceleration is researched and detonation transition process is analyzed in detail.

MODEL INTRODUCTION

1.5m long and 0.04m width obstructed channel with a blockage ratio of 0.35 filled with stoichoimetric gaseous air and liquid decane droplets are calculated by Eulerian and Lagrangian approach on the FLUENT platform under initial condition of 300K and 0.1Mpa. Assume that the droplets are all 20μm diameters and evenly distributed in the channel, and the initial laminar flame is ignited by a low energy input. In addition, one-step reduced reaction kinetic mode is used to predict the combustion, RANS based *k-ω* shear-stress transition model is employed to solve the turbulent flow. Especially, low speed flow is treated by PISO solver. The outlet boundary is set as pressure-outlet of 0.1MPa, and the remaining boundaries are adiabatic and no-slip boundary condition.

RESULTS ANALYSIS

Figure 1 shows the comparison of the time-dependent pressure variations of the monitoring point between the experiment [3] and present simulation with liquid fuel of n-heptanes due to the easily experimental availability. It can be seen that the deviation of pressure peak does not exceed 8.5%, validating the feasibility of current numerical strategy.

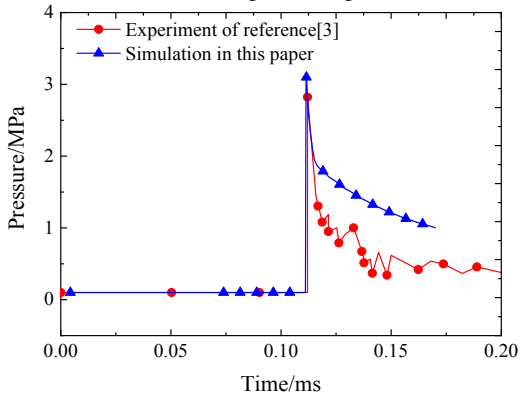

Figure 1. Comparison between experiment and simulation

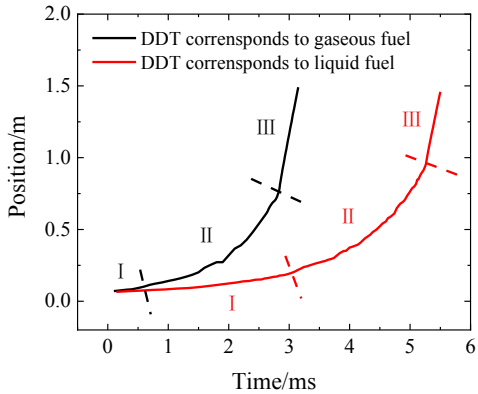

Figure 2. Time-dependent position variations of flame tip

*Corresponding author. E-mail: zhaoningboheu@126.com.

Figure 2 shows the position variations of the leading edge of flame with time of gaseous versus liquid decane system in the whole detonation initiation process, which can be divided into three stage consisting of (Ⅰ) liner flame development, (Ⅱ) exponential flame growth and (Ⅲ) stable detonation propagation stages according to the flame characteristics. Obviously, the biggest difference between two systems mainly comes from the first stage, where flame acceleration in liquid-fueled system looks much lower, and the exploration of the reason will be presented in Fig. 3.
Three frames in Fig. 3 represent the typical flame shapes (white line) with the corresponding n-decane vapor content in different stages as marked in Fig. 2, O_i represents the ith obstacle. Although the flame has been stretched into a turbulent state at the first stage, the majority of the n-decane vapor accumulates tightly around the flame surface, indicating that energy released from combustion are mainly used to break and heat the fuel droplets, which consequently restricts the flame development. On the contrary, plenty fuel droplets have been converted into vapor ahead of the flame under the action of strong shocks at the second stage, making the flame acceleration much analogous to that in the gas-phase system. Especially, the higher mass fraction of fuel vapor near the flame tip means a better compression of the evaporative mixtures, which could create larger energy density to greatly promote the exponential flame development. In the last stage, although there is almost no evaporative fuel before detonation wave since no shocks sweep over, detonation wave is strong enough to convert the droplet into vapor and simultaneously ignite it in an extremely short time.

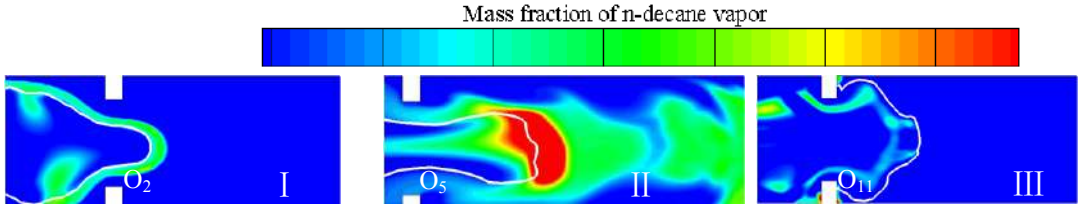

Figure 3. Mass fraction of evaporative n-decane

Figure 4 shows the typical process of liquid-fueled detonation transition. At 5232μs, the strong leading shock waves focus at the corner of the lower obstacle, triggering a local detonation (LD_1). This LD_1 quickly quenches when propagating at the narrow gap between the obstacle and oncoming flame due to insufficient fresh reactants supply, nonetheless, the flame is significantly enhanced. Similar, another local detonation (LD_2) appears at the corner of the upper obstacle and quenches just like LD1, see 5240μs. At 5260μs, the interaction of the flame and wall contributes to the formation of the LD_3. Unlike the former two, LD_3 quickly merges into the main flame, consequently, triggering an overdriven detonation coupled by leading shock and flame near the tenth obstacle at 5276μs, consistent with the classical Zeldovich gradient mechanism [4]. The OD, on the one hand, travels into the products as a retonation and decays into deflagration gradually; on the other hand, propagates forwards the reactants and attenuates into CJ detonation wave with a structure of triple-waves intersection including incident wave, Mach stem and transverse wave, see 5300μs.

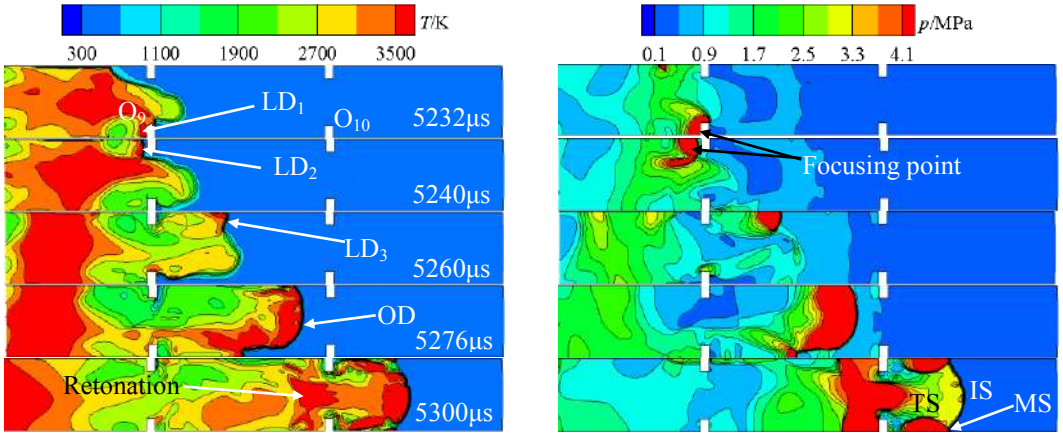

Figure 4. Flow field variations in detonation transition process

CONCLUTION

Detonation initiation for low-volatility liquid fuel is chracterized by numerical simulation in present study. Results show that the evaporation content of liquid fuel ahead of the flame plays a key role at flame acceleration stage and several local detonations contribute a lot to the final stage of detonation transition.

REALIZATION OF THE FILTERED TURBULENT FLAMELET MODEL ON DIFFUSION FLAME

Chi Zhang[1], Lipo Wang *[1], Jian Zhang[2], and Qun Hu[1]
[1] UM-SJTU Joint Institute, Shanghai Jiao Tong University, Shanghai, China
[2] Institute for Aero Engine, Tsinghua University, Beijing, China

Summary The interaction between flame and turbulence keep raising the challenges to the understanding of flame dynamics and performing simulations. In this project, a noval filtered flamelet model is proposed and examined in the framework of large eddy simulations (LES). The general methods of the simulation are developed, including the properties of the filtered flame equations and a four-dimensional flamelet tabulation, that incorporated with the LES subgrid models. Simulations are performed to justify the applicability of the modeling. Because of the involved flame model parameters can be directly calculated at the filter grid size level, and also crosspond to the solutions of the one-dimensional filtered governing equations, this model has the characteristic to reduce the unfounded uncertainty of the diffusion flame.

INTRODUCTION

In studying the structure of the filtered non-premixed turbulent flame at different filtering scale levels, Wang [1] derived a so-called filtered turbulent flamelet equation, where the differential relation between the filtered species mass fractions and the filtered mixture fraction is built. The objective of the current project is to develop and validate a new modeling idea based on the turbulent flamelet equation. First, the theoretical part is elaborated. Then the filtered flame structured is resolved and analyzed for the flamelet tabulation. Based on these setup, a turbulent jet flame is numerically investigated and preliminary results are presented.

FILTERED FLAMELET TABULATION

The governing equation for the filtered mixture fraction $\widetilde{Z}$ expressed:

$$\frac{\partial \bar{\rho}\widetilde{Z}}{\partial t}+\nabla\cdot(\bar{\rho}\widetilde{Z}\widetilde{\vec{u}})=\nabla\cdot[\bar{\rho}(D+D_T)\nabla\widetilde{Z}]=\nabla\cdot[\bar{\rho}\mathfrak{D}_T\nabla\widetilde{Z}], \tag{1}$$

and for the filtered species concentration $\widetilde{Y}_i$.

$$\frac{\partial \bar{\rho}\widetilde{Y}_i}{\partial t}+\nabla\cdot(\bar{\rho}\widetilde{Y}_i\widetilde{\vec{u}})=\nabla\cdot[\bar{\rho}(D_i+D_{T,i})\nabla\widetilde{Y}_i]+\overline{\omega_i}=\nabla\cdot[\bar{\rho}\mathfrak{D}_{T,i}\nabla\widetilde{Y}_i]+\overline{\omega_i} \tag{2}$$

Here $\bar{\cdot}$ and $\widetilde{\cdot}$ denote the filtered and density-weighted filtered quantities, respectively. Similar as the laminar flamelet, the turbulent scalar dissipation χ is defined as

$$\chi=2D_T\left(\frac{\partial\widetilde{Z}}{\partial n}\right)^2 \tag{3}$$

The one-dimensional counter flame structure is solved via Cantera [2] in physical space for the flamelet tabulation. Specifically, the fuel stream consists of methane and hydrogen with 1:1 volume ratio and the air stream functions as the oxidizer. The one-dimensional form of Eq. (1) and Eq. (2) together with the temperature equation

$$\bar{\rho}\frac{\partial\widetilde{T}}{\partial t}+\bar{\rho}\widetilde{u}\frac{\partial\widetilde{T}}{\partial x}=\frac{\partial}{\partial x}[\bar{\rho}(D+D_t)\frac{\partial\widetilde{T}}{\partial x}]-\sum_i W_i\widetilde{\omega}_i h_i \tag{4}$$

are numerically solved. The GRI-Mech 3.0 detailed mechanism is used as the chemical sources for the temperature and species equations. Specifically, the numerical procedure for the tabulation consists of the following steps.

1. For the counter flow flame with a preset strain rate a, first calculate the solution vector, from which the filtered source terms can be obtained at any filter length σ.
2. For a particular combination of the sub-filter diffusivity D_t and the filter length σ, calculate the coefficients of each term, e.g. $\widetilde{\rho}$, $\widetilde{\rho u}$, of the filtered temperature, mixture fraction and species equations. The mixture fraction can also be calculated from the species concentration using the Bilger formula.
3. Solve the linear system to obtain the filtered temperature $\widetilde{T}$, filtered species concentration $\widetilde{Y}_i$ and filtered mixture fraction $\widetilde{Z}$ at each grid point.
4. Loop over all preset D_t , σ and all possible a. (corresponding to maximum temperature T_{max} from 1750K to 2250K) and restore the solutions of all the cases in the physical space.

*Corresponding author. E-mail: Lipo.Wang@sjtu.edu.cn

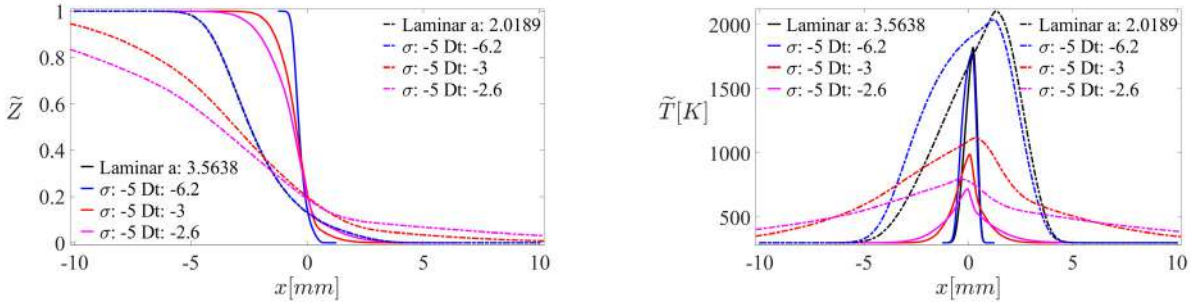

Figure 1: The effects of D_t on the filtered mixture faction $\tilde{Z}$ and the filtered flame temperature $\tilde{T}$ at different strain rate a. Here the values of D_t, σ and a are expressed in the base-10 logarithmic scale.

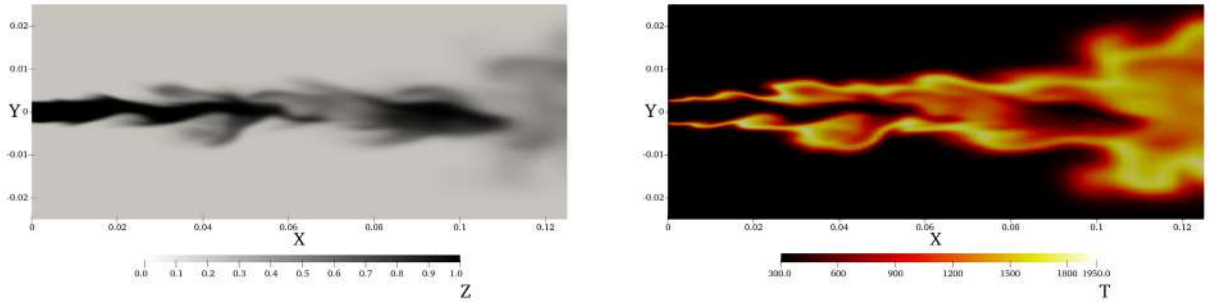

Figure 2: Contours of the calculated species fields: mixture faction $\tilde{Z}$ and the temperature temperature $\tilde{T}$

Once done, the flame solution will then be mapped into the lower dimensional space with the following involved parameters: the filtered mixture fraction $\tilde{Z}$, turbulent scalar dissipatoin χ, D_t and σ. In the post-processing code:
1. Calculate the turbulent scalar dissipation χ according to Eq. (3) at each point.
2. Mapping the filtered temperature $\widetilde{T}$, filtered species concentration $\widetilde{Y}_i$ and filtered density $\widetilde{\rho}$ to the four-dimensional look-up table.
3. The extremely large and small χ cases can be extrapolated from the existing solutions to fill up the flamelet table.

Figure 1 shows the filtered mixture faction and the temperature profile in the one-dimensional space. It can be seen that D_t have strong influences to the results. Overall, D_t and σ lead to the similar changes of the temperature profile. For a given strain rate, when D_t increases, the flame zones becomes thicker with the lower maximum temperature.

SIMULATION AND CONCLUSIONS

An open-source, finite-volume based OpenFOAM framework is used for the demonstrate simulation of a hot-jet. The pressure-based combustion solver *rhoReactingFoam* is chosen as the baseline code. This solver applies the hybrid algorithm, PIMPLE, for the pressure-velocity coupling. The density is directly calculated from the ideal gas state equation. We modified the code that the mixture fraction equation was implemented, and the species and energy equations were replaced by the lookup method described above. To perform the large eddy simulation, the subgrid stresses are closed by the standard k-equation subgrid-scale model [3]. The preliminary results are showed in Figure 2, which justify the promising potential for further improvements in turbulent combustion modeling and simulation. More quantitative and statisitical results, also the comparisons with the experiments, will be presented at the time of meeting.

This project aims to demonstrate the possibility of the numerical realization of the turbulent filtered flamelet model proposed by [1]. In the framework of large eddy simulations (LES), the general principles of the simulation have been developed. From the solutions of the filtered flame equation in the physical space, a four-dimensional flamelet tabulation was constructed and incorporated with the LES sub-grid models. The method was successfully implmented in the OpenFOAM framework, and stable results were obtained.

AN OPTIMIZATION ALGORITHM FOR OBTAINING GLOBAL KINETICS PARAMETERS BY USING FLAME DATA FROM SIMPLIFIED KINETICS

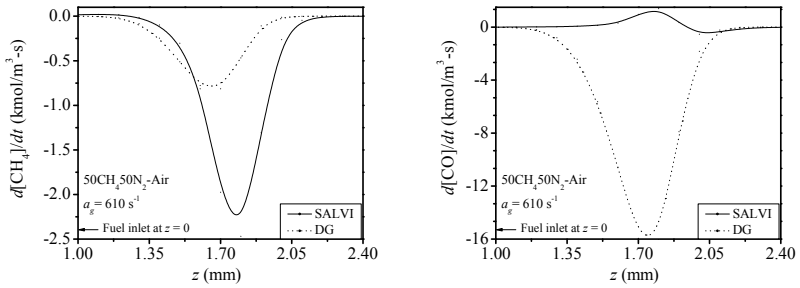
S M Ali *[1] and S Debnath[2]
[1] Department of Aerospace Engineering, Indian Institute of Technology, Madras, India
[2] Group Digital Transformation Office, Vedanta Limited, India

Summary The current work proposes an optimization algorithm for obtaining global kinetics parameters by performing a linear regression analysis on the flame data obtained from simplified kinetics. A two-step methane global kinetic model (DG) is optimized using this algorithm to demonstrate its applicability. A two-step methane global model (DG) is optimized using this algorithm for non-premixed flames data obtained from the simplified kinetic model (SALVI). The results showed that the optimized DG model (DG-Opt) has accurately captured the overall CH_4 and CO overall reaction rates in comparison to the simplified SALVI model.

BACKGROUND

Detailed or simplified kinetic mechanisms are developed to capture all the elementary processes and generally capable of capturing characteristics of both premixed and non-premixed flames. But, due to large number of species and reactions involved in their development, the direct use of these mechanisms in practical combustors is computationally expensive. On the other hand, global kinetic models are target-specific involving only few reactions and species, hence, require lesser computational time in comparison to detailed/simplified kinetics. This work focuses on the development of the optimization approach for obtaining global kinetic parameters by using flame data from simplified kinetics.

Figures 1a and 1b show the comparison CH_4 and CO overall reaction rates from DG global (Dryer & Glassman, 1973) and SALVI simplified (Slavinskaya et al., 2008) kinetic models near extinction of $50CH_450N_2$-air non-premixed flames. The data clearly show that the reaction rates of CH_4 and CO are not accurately captured from the two-step global kinetic model (DG). Hence, the DG model (Rxn1- $CH_4+O_2 \rightarrow CO+2H_2O$ & Rxn2- $CO+0.5O_2 \rightarrow CO_2$) has scope for optimization. The next sections describes the optimization process.



(a) CH_4 reaction rate (b) CO reaction rate

Figure 1: Comparison pf CH_4 and CO overall reaction rates from global (DG) and simplified (SALVI) kinetic model near extinction

OPTIMIZATION ALGORITHM

Figure 2 shows the flowchart for the algorithm used to perform optimization of global kinetic parameters. The concentration, temperature and reaction rates data in the flame region obtained from simplified kinetics are used to train a linear fit model for global kinetics. For model optimization, the initialized global parameters are varied to obtain an error matrix. The minimum root mean square error (RMSE) and maximum R-square (R2) is located to obtain the optimized parameters. These initial optimized models (R2 or RMSE) are improved further by removing outliers beyond 95 % prediction interval. To test the applicability, a two-step global methane kinetic model is optimized using this algorithm The subsequent section shows results of this optimization.

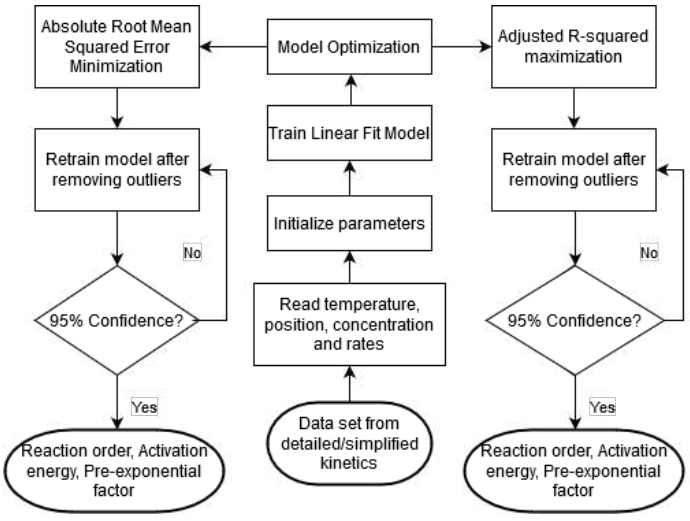


Figure 2: Flowchart for the optimization algorithm

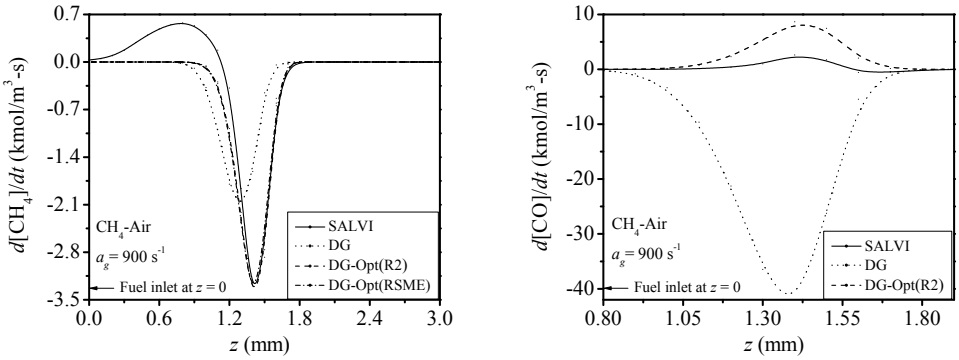
*Corresponding author. E-mail: smughees.ali@gmail.com

RESULTS AND DISCUSSION

Figures 3a and 3b show the comparison of CH_4 and CO overall reaction rates from unoptimized (DG) and optimized (DG-Opt) with simplified (SALVI) kinetic model near extinction of CH_4-air non-premixed flame. The data show that consumption reaction rates for CH_4 and CO are accurately captured by the optimized kinetic model (DG-Opt).



(a) CH_4 reaction rate (b) CO reaction rate

Figure 3: Comparison of CH_4 and CO overall reaction rates from unoptimized (DG) and optimized (DG-Opt) with simplified (SALVI) kinetic model near extinction of $100CH_4$-air non-premixed flame

The data from the simplified kinetics model (SALVI) show production of CH_4 on the fuel-rich side of the flame. This might be due to reverse CH_4 reaction accelerated by diffusion of radicals from the stoichiometric flame region. As the DG-Opt model is developed to capture only the forward reaction rates, its results deviate from the simplified kinetics (SALVI) in fuel rich region. But, the forward rates are accurately captured. For CO reactions, DG-Opt model has accurately capture the reaction rate trends for simplified model. The global parameters of the optimized model are compiled in the Table 1.

Table 1: Global kinetic rate parameters and reaction order for the optimized kinetic model (DG-Opt)

Model	A	n	E_a	Reaction order	A	n	E_a	Reaction order
	R2				RMSE			
$CH_4 + O_2 \rightarrow 2H_2O + CO$	$10^{14.91\pm0.33}$	0	269715±10627	$[CH_4]^{0.2}[O_2]^{1.6}$	$10^{11.81\pm0.36}$	0	253641±11320	$[CH_4]^{0.1}[O_2]^{1.0}$
$CO + 0.5O_2 \rightarrow CO_2$	$10^{11.93\pm0.29}$	0	230502±9091	$[CO]^{0.1}[O_2]^{1.1}[H_2O]^{0.1}$	$10^{10.48\pm0.33}$	1	219212±10444	$[CO]^{0.1}[O_2]^{0.8}[H_2O]^{0.1}$

Units in J, kmol, m^3, s and K.

CONCLUSIONS

The comparison of the global (DG) kinetic model with simplified (SALVI) kinetic model has shown that DG does not accurately capture the rates of CH_4 and CO oxidation. This is due to the use of specific conditions (T ~1100-1400 K; ϕ ~0.05-0.5) for construction of DG model from Plug Flow Reactor (PFR) data. In the case of non-premixed flame, the conditions for fuel oxidation are different from PFR. Hence, the DG model optimized using the data generated from the simplified model under non-premixed flames conditions improved the predictions. This conclusion related to non-premixed flames is also supported by the recent studies of Ali and Varunkumar (2019,2020). The accurate reaction rates prediction from the DG-Opt model has demonstrated the effectiveness of the proposed optimization algorithm. Future work involves the use of this algorithm for obtaining global parameters for other fuel-oxidizer combinations.

COMBINED PHYSICS AND DATA-DRIVEN MODAL DECOMPOSITION OF COMPLEX COMPRESSIBLE FLOWFIELDS

Datta V. Gaitonde *[1] and S. Unnikrishnan[2]
[1] Mechanical and Aerospace Engineering, The Ohio State University, Columbus, OH
[2] Aero-Propulsion, Mechatronics and Energy, Florida State University, Tallahassee, FL

Summary High-fidelity simulations can provide all pertinent details of compressible turbulent fluctuations in complex flowfields. However, comprehending the driving physics remains a major challenge, and motivates the development and implementation of new innovative analysis techniques. Here, we summarize a powerful methodology that integrates physics-based and data-driven decompositions. The former, performed with Doak's method, yields an exact splitting of a carefully chosen vector fluctuation quantity into its hydrodynamic, acoustic and thermal components. In addition to extracting insights into driving mechanisms, these components are also superior inputs to data-driven techniques such as Dynamic Mode Decomposition and Spectral Proper Orthogonal Decomposition. 3-D results on jet noise and hypersonic transition databases illustrate the power of this combined approach.

DECOMPOSITION OF COMPRESSIBLE FLUCTUATIONS

The analysis of turbulent fluctuations has typically taken recourse to data-driven statistical techniques, which include different types of space-time correlations and modal decompositions such as variants of Dynamic Mode Decomposition (DMD) and Proper Orthogonal Decomposition (POD), all of which are agnostic of the underlying physics. The variables subjected to such approaches are often the primitive variables, or combinations of their local derivatives. Physics insights are then extracted in the context of larger scale dynamics such as different types of instabilities or energy transfer mechanisms. The results are often interpreted in a physics-based, or fluid-thermodynamic (FT), framework that has its origin in Kovásznay's decomposition [1] comprised of hydrodynamic (H), acoustic (A) and thermal (T) content and their interactions with each other.

Though conceptually powerful, the direct use of Kovásznay's method has been constrained by the difficulty in extension to non-linear fluctuations or non-uniform mean flows. The method of Doak [2] lifts these constraints using a very different approach applicable to any turbulent flow. The key distinction is that whereas Kovásznay's method associates a particular variable with each FT component (fluctuating vorticity ω' with H, pressure p' with A and entropy s' with T), Doak's method decomposes a single, carefully selected variable consistently and exactly into its three FT components, where H is rotational (solenoidal), A is irrotational-isentropic and T is irrotational-isobaric. The decomposed variable is the vector "momentum density", $\rho(\boldsymbol{x},t)\boldsymbol{u}(\boldsymbol{x},t)$, chosen because the continuity equation is naturally linear in this composite variable. This avoids the difficulty arising from associating p' solely with A, since p' also has H content. Doak's procedure then splits $(\rho\boldsymbol{u})' = (\rho\boldsymbol{u})'_H + (\rho\boldsymbol{u})'_T + (\rho\boldsymbol{u})'_A$. This requires the solution of Poisson equations; for example, $(\rho\boldsymbol{u})'_A = -\bigtriangledown\psi'_A$ where ψ'_A is obtained from $\bigtriangledown^2\psi'_A = \frac{1}{c^2}\frac{\partial p'}{\partial t}$. Computational implementation details for Large Eddy Simulation (LES) databases, with boundary treatments, are discussed in [3]. A second crucial aspect of Doak's formulation follows from its foundation in the full Navier-Stokes equations: specifically, in the non-linear turbulent region of any flow, the sources/sinks in the three FT components due to the fluctuating Lamb vector, viscous and entropic interactions can be explicitly delineated through the budget of the total fluctuating enthalpy, TFE $= (h + 0.5\boldsymbol{u}\cdot\boldsymbol{u})'$. This provides insight into various causal mechanisms, including intermittency, that can be obscured with typical statistical techniques.

Although the exact FT decomposition provides a powerful new method to analyze compressible fluctuations, substantial additional advantages accrue from applying data-driven techniques such as DMD or POD to the FT variables, as opposed to directly obtained variables such as p' or ω'. This is now illustrated in two problems, jet noise and hypersonic transition, where a Kovásznay-type viewpoint arises naturally and illustrates the dynamics in a very revealing fashion.

RESULTS

Jet noise: The following LES-based results are representative of jets at subsonic as well as supersonic Mach numbers. Figure 1(a) shows the multi-scale nature of the turbulence in typical turbulent jets, together with the radiation field (variables plotted and conditions are noted in the figure). Even though the acoustic energy is only a small fraction of the overall energy, its dynamics are crucial because of their relatively large impact on humans and structures. Representative $A_x = (\rho u)'_A$ and pressure (p') iso-levels are shown in (b); the key point to note is the compact and highly-organized wavepacket nature of the former, which should be representable with a low-ranked model. Indeed, the spectral POD decomposition of A_x in (c) confirms this postulate: the first three modes contain $\sim 75\%$ of the energy for A_x, but only $\sim 45\%$ for p'. This has profound consequences on the advantages of using A_x instead of p', two of which are shown. First, the sources to ψ'_A (performed through a TFE analysis) are restricted to $r \leq 1D$ from the jet axis. Thus, using A_x at a surface as close as $r = 1.5D$ as input to a simple wave-propagator provides an excellent prediction of the farfield noise: in this region of no significant acoustic energy production, it can be shown that ψ'_A and p' satisfy a simple scaling relationship. This close propagator surface placement is a major accuracy and efficiency benefit to LES, since it facilitates

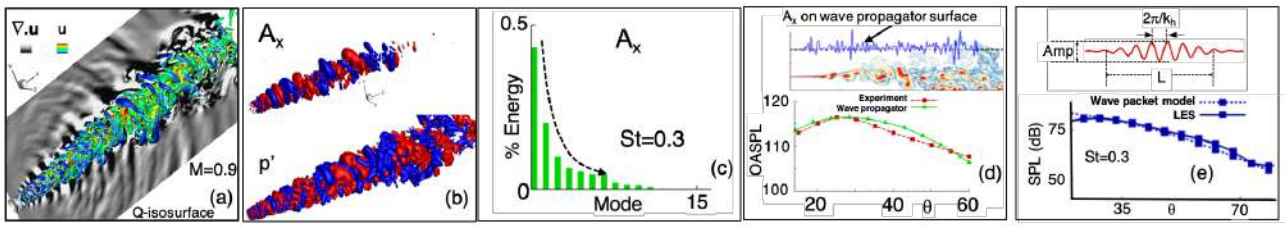

Figure 1: Combined FT and SPOD for superior far field and wavepacket modeling

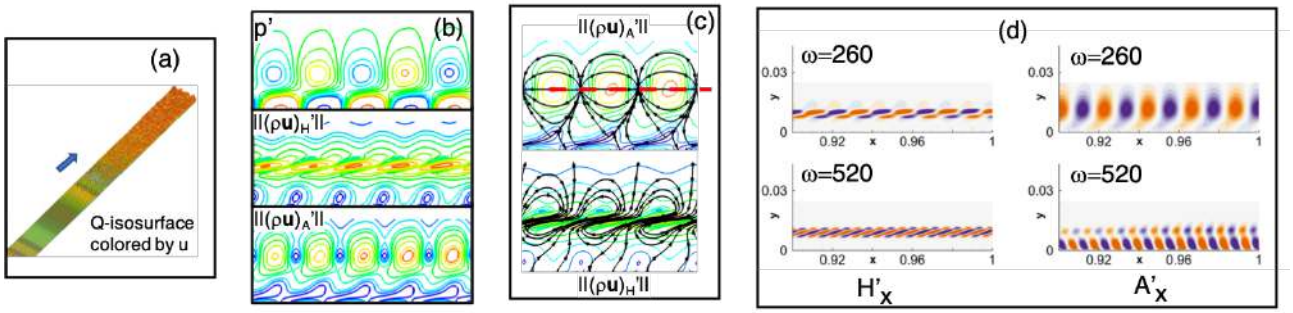

Figure 2: Combined FT and DMD for hypersonic transition

a substantial reduction to the simulation domain. Second, the fact that unlike p', ψ'_A is free from hydrodynamic content greatly improves its utility in developing wavepacket models. (e) shows how parameters such as k_h, Amplitude (Amp) and L, when extracted from A_x provide accurate noise prediction even for subsonic flows, where the use of p' requires empirical adjustment.

Hypersonic transition and breakdown: The second (or Mack) mode that emerges in hypersonic transition is especially suited for analysis with FT decomposition because of the crucial importance of acoustic energy [4], and here too, sequential application of physics-based and data-driven techniques provides a richer perspective. Figure 2(a) shows a qualitative picture of the breakdown, starting from regular imposed perturbations that grow linearly and induce transition and breakdown. (b) shows the crucial distinctions between the primitive and FT variables using the p', $||\,(\rho\boldsymbol{u})'_H\,||$ and $||\,(\rho\boldsymbol{u})'_A\,||$ fields. As in the jet case, there is only a superficial similarity between p' and A, especially in the crucial near-wall region. Their respective flux lines in (c) show that the A field exhibits trapped behavior between the critical layer and the wall, but the H field does not. Further quantitative analysis shows that although A is much smaller than H or T, its rate of amplification dominates 2nd mode growth – this crucial feature is masked by traditional variables. Furthermore, since T is also a trapped component[5], the 2nd mode is very sensitive to small changes in temperature or wall heating. This has consequences on control: the acoustic component can be used to guide actuator development. The exact nature of the FT decomposition makes it amenable for application in the non-linear breakdown region downstream as well. Here, the appearance of harmonics can be described by performing (data-driven) DMD on the individual FT fields. The results, (d), show clearly that the first superharmonic of $H_x = (\rho u)'_H$ has spatial support near the critical layer, while that for A_x appears near the wall. When combined with the more rapid growth of the latter, the evidence clearly suggests that the near-wall dynamics is more crucial than that near the critical layer.

CONCLUSIONS

There is considerable benefit to analyzing high-fidelity compressible turbulent simulations by first decomposing fluctuations into their acoustic, hydrodynamic and thermal components, and then subjecting these to data-driven statistical techniques. The form of the Navier-Stokes equation allows for a precise decomposition of $\rho\boldsymbol{u}$ (but not any arbitrary variable) in this fashion, and also provides means, through total fluctuating enthalpy budgets, to gain insight into sources and sinks of FT components. Results from two complex 3-D problems illustrate these benefits in combination with SPOD and DMD. The jet noise data was provided courtesy of G. Brés (Cascade Technologies).

FLOW MECHANICS OF DUAL-PULSE LASER-INDUCED BREAKDOWNS AND EFFECT ON IGNITION

Jonathan M. Wang *[1] and Jonathan B. Freund[1,2]
[1] Department of Mechanical Science and Engineering, University of Illinois at Urbana–Champaign, USA
[2] Department of Aerospace Engineering, University of Illinois at Urbana–Champaign, USA

Summary A focused laser can cause optical breakdown of gas into a nearly opaque plasma that efficiently absorbs subsequent laser energy. The rapid heating produces a blast wave and intricate hydrodynamic interactions that depend on the distribution of deposited energy. How subtle alterations in the hot-spot shape lead to pronounced changes in the later hydrodynamics, how multiple depositions interact to augment vorticity generating mechanisms, and how these flow characteristics ultimately mediate ignition of a combustible mixture are all investigated.

INTRODUCTION

Laser-induced breakdown offers an attractive approach for ignition systems because it provides a versatile means of depositing both energy and radical species [3]. The energy deposition drives complex local flow, which can couple with the ignition process. For some conditions gas is ejected from the focal region [1, 2], which distributes energy, creates strains on nascent flames, and increases the kernel surface area. Multiple such breakdowns can enhance ignition probability [5, 6]; the fluid mechanics underlying this are investigated.

Detailed simulations are used to analyze the post-breakdown flow, particularly the mechanisms of vorticity generation, for both single and dual-pulse cases. A secondary pulse can be used to access a broad range of hydrodynamic responses by exploiting energy otherwise lost in the shock and accentuating asymmetries associated with single-pulse ejections. The burning rate of the flame kernel in a lean H_2–O_2 mixture can be increased by controlling configuration parameters.

METHODS

The axisymmetric Navier–Stokes equations, initialized with a kernel length $L = 2\,\mathrm{mm}$, ambient speed of sound a_∞, density ρ_∞, and viscosity μ, are solved with high-order methods for a perfect gas with constant transport properties, specific heat ratio $\gamma = 1.4$, and Reynolds number $\mathrm{Re} \equiv \rho_\infty a_\infty / \mu = 4.4 \cdot 10^4$ corresponding to air at $p_\infty = 1\,\mathrm{atm}$ and $T_\infty = 298\,\mathrm{K}$. These modeling choices void complexity of the true plasma characteristics yet are sufficient to reproduce key flow features for single-pulse breakdowns [4].

RESULTS

With its kinetic energy only a small fraction of the total deposited energy, the breakdown-induced flow can be sensitive to even small alterations in the early-time kernel geometry, particularly asymmetries during the kernel's rapid expansion [4]. The dynamics of the resultant vorticity, generated baroclinically by this expansion, determine the ultimate ejection pattern, which varies markedly with subtle changes to the kernel and in some cases reverses direction.

The flow is significantly altered by a nearby secondary kernel, as shown in figure 1. This small simultaneous deposition produces low-density gas that promotes the expansion of the primary kernel, leading to generation of positive vorticity that suppresses the ejection otherwise produced by the primary kernel alone.

A time delay τ and spatial offset d broadens the range of hydrodynamic responses (figure 2). These follow from three effects: (1) passage of kernel II's shock through kernel I, (2) biased expansion of kernel II near kernel I, and (3) evolution of kernel II in the post-shock rarefaction of kernel I. The second effect is shown in figure 3 for the figure 2(d) case. The leftward protrusion of kernel II near $r = 0$, an artifact of its expansion towards the low-density remnants of kernel I, leads to pronounced flow into the narrowed inter-kernel gap. The flow diverges at a stagnation point in this dense fluid (figure 3b), and the ensuing rightward flow near $r = 0$ (figure 3c), absent in the single-pulse case, opposes the concurrent leftward flow in kernel II. This effect leads to kernel II's suppressed ejection in figure 2(d) as well as the ejections in opposite directions in figure 2(c).

These effects occur in tandem with baroclinic generation of vorticity that would produce a leftward ejection for a single pulse [4]. The curious $d \lessgtr 0$ asymmetry can be traced to the kernels' own asymmetry: the leftward ejection of kernel I is augmented by kernel II's shock for $d > 0$ and suppressed for $d < 0$, while that of kernel II is augmented by the post-shock rarefaction of kernel I for $d > 0$ and suppressed for $d < 0$.

In corresponding simulations of ignition in a lean H_2–O_2 mixture (not shown), the figure 2(c) configuration produces H_2O 47% faster than that of figure 2(a) and 2.2 times faster than a single pulse of equal energy, due to the broad distribution of hot gas.

Summary The aim of the present work is to contribute to a better understanding of the physical mechanism causing the low frequency oscillations of the Shock Wave Boundary-Layer Interaction (SWBLI) by analyzing data from highly resolved unsteady numerical simulations. Results show that the low frequency reflected shock-wave motion is mainly driven by the low frequency breathing of the separation bubble that comes from a modulation of the successive enlargements and shrinkages of the separated zone (medium frequency flapping of the shear-layer); the oscillations of the reflected shocks foot being in phase with the motion of the separation point.

INTRODUCTION

The Shock-Wave Boundary-Layer Interaction (SWBLI) is a recurrent physical phenomenon present in aeronautical and space systems. If the shock wave is strong enough, the subsequent adverse pressure gradient can lead to a separation of the boundary layer. A separation bubble is then created surrounded by a complex system of shock waves. The highly 3-D separation bubble leads to a steep increase of the drag force, heat fluxes and pressure fluctuations at the wall. Previous studies have additionally shown that the recirculation bubble as well as the reflected shock wave are subjected to a low frequency streamwise motion called the unsteadiness of the SWBLI. This unsteadiness subjects structures to oscillating loads that can damage their integrity, justifying the importance of a careful study of SWBLIs and particularly its low frequency unsteadiness.

Even if this phenomenon is well known, the mechanism leading to the SWBLI unsteadiness is still not well understood. Mainly two kind of mechanisms have been referred to in order to explain the existence of the SWBLI unsteadiness [1]. The first one consists in an excitation of the SWBLI by the large scales of the incoming turbulent boundary layer. The second one is provoke by the dynamics of the recirculation zone that drives the unsteadiness of the whole SWBLI system. Despite arguments in favor of each mechanism, no definitive explanation have been yet provided. The aim of the present work is then to perform well resolved DNS of SWBLIs and analyze results in order to contribute to a better understanding of the SWBLI unsteadiness and the physical mechanism causing these low frequency oscillations. To this end, the canonical configuration of an oblique shock wave impinging a boundary layer developing on a flat plate is considered.

NUMERICAL APPROACH

The Navier-Stokes equations are solved by using a high order finite volume approach on cartesian meshes. The Euler part is discretized by means of a high-order one-step Monotonicity Preserving scheme, namely the OSMP7 scheme [2], based on a Lax-Wendroff approach, which ensures a 7th-order accuracy in both time and space in the regular regions. Monotonicity-Preserving (MP) constraints, first developed by Suresh and Huynh [3] and further extended in [2], are applied; they locally relax the TVD constraints near extrema. The resulting OSMP7 scheme recovers the 7th-order accuracy in both time and space everywhere, except near discontinuities where the scheme is Monotonicity-Preserving. Besides, the discretization of the diffusive fluxes is obtained by means of a classical centered 2nd-order scheme. These numerical schemes are implemented in the in-house parallel (MPI) Finite Volume DNS solver (code CHORUS) that has been developed at LIMSI-CNRS. This numerical tool has intensively been validated on the simulation of high Reynolds number turbulent and shocked flows [5]. Results demonstrate the correct accuracy of the numerical approach to predict turbulent features and the great efficiency of the MP procedure to capture discontinuities without spoiling the solution at an almost negligible additional cost (at most 2.5 %).

RESULTS ON SWBLI CONFIGURATIONS

In order to better understand the mechanisms leading to the unsteadiness of the SWBLI, it has been chosen to first perform a SWBLI simulation suppressing one of the two suspected mechanisms leading to the unsteadiness. By simulating the interaction between a *laminar* boundary layer and an incident oblique shock wave, the suspected influence of the large scale turbulent structures within the incoming boundary layer on the SWBLI unsteadiness has been suppressed. The only remaining suspected cause of the unsteadiness would be the dynamics of the separation bubble.

Shock-Wave Laminar Boundary-Layer Interaction:

We first chose to simulate a 3-D test-case similar to the one designed by Degrez *et al.* [4] ($M_\infty = 2.15$; $Re_{x_{sh}} = 10^5$) with however a higher shock angle ($\sigma = 33.8°$) to recover an unsteady behavior of the recirculation bubble that exhibits 3-D flow patterns. Results (Fig. 1-left) have shown that the separation point of the recirculation bubble and the foot of the reflected shock wave have a fixed location along time. This result shows that, in this configuration, the SWBLI unsteadiness has not been observed. Analyses of the dynamics of the recirculation bubble has been performed. Two

*Present address: DynFluid, Arts & Métiers ParisTech, 151 Bd de l'Hôpital, 75013 Paris, France
†Corresponding author. E-mail: Christian.Tenaud@limsi.fr

regions have been identified in the recirculation bubble: the first part of the separation, upstream of the incident shock wave impingement and the second part downstream of the impingement. Although SWBLI unsteadiness has not been observed (no motion of the reflected shock wave), the characteristic low frequency of the SWBLI unsteadiness has however been recorded that characterizes the dynamics of the whole recirculation bubble: low frequency breathing ($St_L \simeq 0.03 - 0.04$) of the recirculation bubble and medium frequency flapping ($St_L \simeq 0.12 - 0.15$) of the shear layer in whole of the bubble, in addition to higher frequencies ($St_L \simeq 0.5 - 0.6$) characterizing the vortex shedding from the shear layer in the second part of the recirculation bubble. In particular, the reattachment location is sensitive to the instabilities of the recirculation bubble, namely the breathing, the flapping and the Kelvin-Helmholtz frequencies. Even though present in the first part, the low frequency activity is not intense enough to provoke the oscillations of the separation point and the subsequent oscillations of the reflected shock foot.

Shock-Wave Turbulent Boundary-Layer Interaction:

In order to reproduce and analyze the SWBLI unsteadiness, the simulation of the interaction between a incident shock wave and a *turbulent* boundary layer has secondly been undertaken (Fig. 1-right). In this context, the accurate simulation of a turbulent compressible incoming boundary layer is of great importance. A Synthetic Eddy Method (SEM) (Jarrin et al. [2006]) that we adapted to compressible flows, has efficiently been employed at the inlet boundary to generate a fully developed flat plate turbulent boundary layer ($M_\infty = 2.33$; $Re_\theta = 2539$) upstream of the impingement of the oblique shock-wave without a prohibitive additional computational cost. In the turbulent case, the SWBLI unsteadiness has clearly been recorded. The frequencies characterizing motion of the reattachment point are characteristic of the low ($St_L \simeq 0.03 - 0.04$) and medium frequency flapping ($St_L \simeq 0.12 - 0.15$) of the separation zone, while the frequencies of the separation point are characteristic of the low frequency flapping of the separation zone. Besides, the foot of the reflected shock wave oscillates in phase with the separation point. Motions of separation and reattachment points are mainly in opposite phase indicating successive enlargements and shrinkages of the recirculation bubble; the shrinkage phase being associated with a shedding of a large amount of fluid from the separated zone to downstream. This medium frequency flapping have been shown to be irregular in time; the maximum size of the recirculation bubble being submitted to discrepancies between successive cycles. This behavior of the separation bubble is responsible for the low frequency temporal modulation of the amplitude of the separation and reattachment points and thus to the low frequency breathing of the separation bubble.

CONCLUSION

We here show that the reflected shock-wave is passive and the SWBLI unsteadiness is related to the low frequency breathing of the recirculation bubble (and not the large scales of the incoming turbulent boundary layer); the oscillations of the reflected shocks foot being in phase with the motion of the separation point. This low frequency activity of the recirculation bubble also seems to be at play in the laminar case. Although in the laminar case the behavior in the second part of the recirculation bubble is the same as in the turbulent case, the low frequency activity in the laminar regime is counter-currently damped towards the first part of the bubble as the length of the bubble is much greater than in the turbulent case. It is then not intense enough to excite, in the first part of the bubble, the separation point and the subsequent oscillations of the reflected shock foot.

Figure 1: Q criterion colored by the magnitude of the longitudinal velocity. Shock waves are highlighted by isosurfaces of $\nabla \cdot \mathbf{u}$: laminar case on the left, turbulent case on the right.

NOISE REDUCTION AND SHOCK LEAKAGE IN BEVELLED PLANAR JETS

De-Jun Sun *[1], Chuang-Chao Ye [1], Peng-Jun-Yi Zhang [1], and Zhen-Hua Wan[1]
[1] Department of Modern Mechanics, University of Science and Technology of China, Hefei 230027, China

Summary Rectangular supersonic jets exist widely in propulsion system of modern and new design concept aircrafts, due to their advantages in design simplicity, thrust-vectoring capabilities and flexibility with integration into the frame of aircraft. However, in underexpanded supersonic jets, the upstream travelling waves referred to as screech tones can cause structural fatigue failure of nozzle. In this work, high fidelity numerical simulations are employed to investigate the effects of asymmetric lips of nozzle on shock screech. The simulation results present the phenomenon of shock leakage [1]. Compared to the symmetric planar jet, the asymmetric lips change the shock structures and intensity of shear layer oscillations. The noise level of screech decreases with increasing the length difference of two lips, and the maximum 7 dB drop is found when this difference reaches the hight of the nozzle. Dynamic mode decomposition (DMD) is further utilized to analysis the jet oscillations. DMD results show that the asymmetric nozzle mainly suppresses the most energetic DMD mode, corresponding to the dominant frequency of shock screech. In short, the oscillations of shear layer and shock leakage are suppressed when the nozzle is bevelled. The study can be used as a reference for the supersonic thrust-vectoring engine design and control of high level screech noise.

NUMERICAL METHODS AND CONFIGURATIONS

The flow development of the underexpanded jet with fully expanded jet Mach number $M_j = 1.55$ is investigated by high fidelity numerical simulations. The in-house solver HiResX is used to perform all the simulations, which solves compressible Navier-Stokes equations with the fifth order HWCNS scheme on a curvilinear coordinate system. Figure 1 shows the model of bevelled planar jets, and three models with L/H=0, 0.5 and 1.0 are studied. A similar configuration can also be found in the work of Berland *et al.* [2]. The total numbers of grid point of the computational domains are around 67.7 million, and a finer grid of symmetric nozzle model with 90 million grid points is used for convergence test. For all cases, the solutions of 250 non-dimensional time units are stored for statistics after the jets are fully developed. Two probes $P^{\pm}$ are set at the points outside of the plates $y = \pm 0.85H$ and $0.4H$ away from the planar leading edge, as shown in Figure 1.

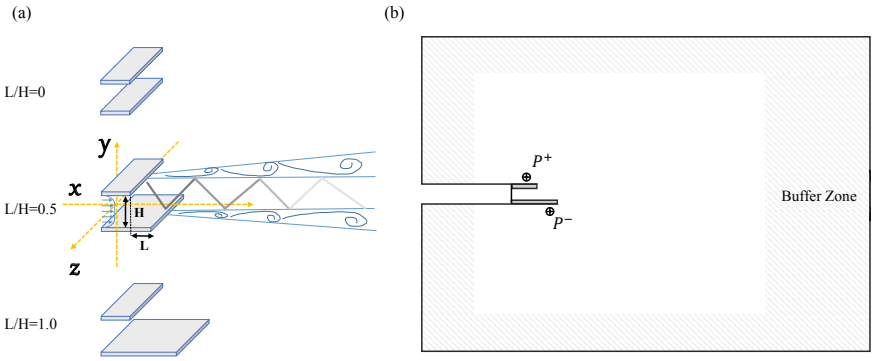

Figure 1: Schematics of the configurations of supersonic planar jets (a) and the set-up of computational domain (b).

RESULTS

Figure 2 shows the numerical schlieren with spanwise vorticity in the spanwsie middle plane. It is clear that the asymmetric nozzles change the shock structure significantly. The mainstream direction of bevelled jets bias to the side of shorter planar, with 6.2° and 9° declination in Cases L/H=0.5 and L/H=1.0, respectively. Mach waves and shock screeches are detected. Present results indicate that the screech waves may come from shock leakage near the saddle point of vorticity in the shear layer.

Compared to symmetric nozzle, bevelled nozzles decrease the shock intensity and weaken the oscillation of shear layers. Table 1 shows the overall sound pressure level (OASPL) at the probes. It is found that the OASPLs are decreased in Cases L/H=0.5 and L/H=1.0, respectively. Dynamic mode decomposition (DMD) is performed,

*Corresponding author. E-mail: dsun@ustc.edu.cn.

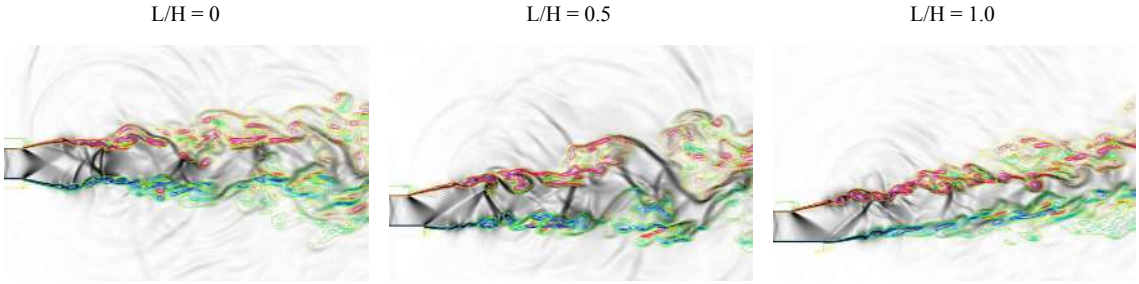

Figure 2: Numerical schlieren with spanwise vorticity in the spanwsie middle plane.

which further reveals that the bevelled nozzles suppress the first DMD mode efficiently. The frequency of the first DMD mode is corresponding to the dominant frequency of shock screech. Moreover, the power spectra density (PSD) of pressure fluctuations at probes P^+ and P^- is shown in Figure 3, the PSD is dominated by the frequency of shock screech f_s and its harmonic frequencies in the Cases L/H=0.0 and L/H=0.5. The high frequency noise in the lower plate is lower than the upper plate, especially for Case L/H=1.0, because the shock and turbulence interactions are stronger.

	$L/H=0$	$L/H=0.5$	$L/H=1.0$
Dominant St (P^+/P^-)	0.0945/0.0945	0.0925/0.0925	0.0984/0.0984
1^{st} DMD mode St	0.0946	0.0925	0.0986
OASPL/dB (P^+/P^-)	161.5/161.5	160.4/160.4	154.5/155.2

Table 1: Comparison of bevelled jets and symmetric jet

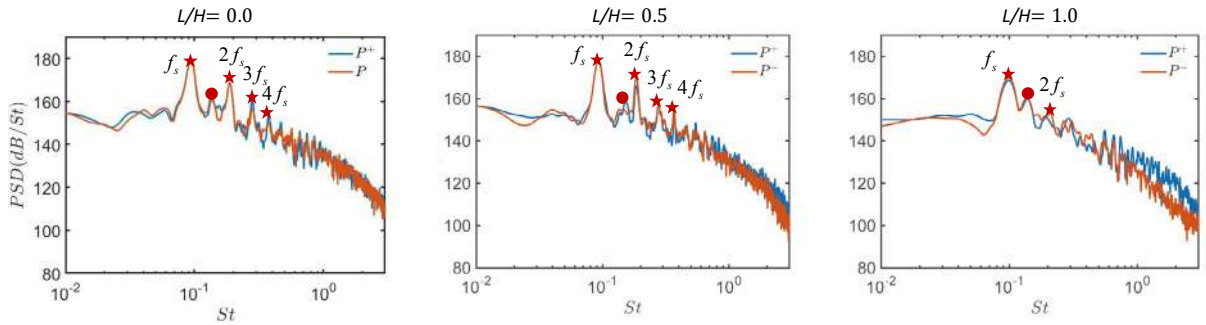

Figure 3: Power spectra density of the pressure fluctuations for probes P^+ and P^- as a function of the Strouhal number $St = fh/U_j$.

CONCLUSIONS

The effect of asymmetric nozzles for supersonic planar jets on screech is investigated with high-fidelity numerical simulations. The bevelled nozzles present the potential of thrust-vectoring. The phenomenon of shock leakage can be found in present jets. The numerical results show that the amplitudes of screech tones are also weakened with bevelled nozzles.

ON THE CAUSALITY OF THE SHOCK-WAVE/TURBULENT BOUNDARY-LAYER INTERACTION

Kenzo Sasaki *[1], André V. G. Cavalieri[1], Diogo Camello Barros[2], and Lionel Larchevêque[2]
[1] Instituto TecnolÓgico de Aeronáutica (ITA), Aerodynamics Department, São José dos Campos, Brazil
[2] Aix Marseille Université, CNRS, IUSTI, Marseille, France

Summary The present work aims to investigate the unsteady behaviour of an impinging oblique shock wave and its interaction with a Mach 2 turbulent boundary layer by exploiting the large-eddy simulation (LES) data presented in Jiang *et al.* 2017 [1]. The main objective is to identify the mechanisms at the origin of the low-frequency unsteadiness within the interaction zone. Our approach consists in isolating the quasi two-dimensional dynamics by performing a spanwise averaging of the pressure and velocity fields. Then, data-driven methods such as single/multiple-input transfer functions, the Hilbert transform and the spectral proper orthogonal decomposition (SPOD) are applied to the resulting flow field. Preliminary results indicate that a feedback mechanism between downstream propagation of fluctuations within the mixing layer and upstream acoustic disturbances corresponds to the driving mechanism for such phenomenon, complementing previous studies for this configuration.

INTRODUCTION

Shock wave/turbulent boundary layer interaction (STBLI) is of great relevance for the aerospace industry, as it is present in a large number of practical external and internal flow problems such as in airfoil design, turbomachinery, overexpanded nozzles and supersonic inlets [2]. When interacting with a wall, an impinging shock gives rise to an adverse pressure gradient in the boundary layer responsible for flow separation. The resulting separation bubble produces an expansion fan, followed by reattachment compression waves, associated to a highly unsteady reflected shock [3].

The frequency associated to reflected shock dynamics is known to be several orders of magnitude lower than the characteristic frequencies of the incoming turbulent boundary layer, and the driving mechanism of such motion remains unclear. Some works try to relate the shock motion to the upstream turbulent boundary layer [4], while other authors argue that this flow unsteadiness is intrinsically associated to the flow dynamics downstream of the shock [5]. The objective of the current work is to shed further light on this mechanism.

PRELIMINARY RESULTS

The flow field under study is a Mach 2 plane-shock interaction, with a low-frequency characteristic Strouhal number $St \sim 0.03$ for the shock motion and $St \sim \mathcal{O}(1)$ for the turbulent boundary layer. Quantities are nondimensionalized using the interaction length and speed of sound. The origin of the streamwise coordinate system is placed at the averaged shock location on the wall. Figure 1 presents the mean streamwise velocity and its premultiplied spectrum at the shock foot.

Our goal here is to use frequency and time-domain, single and multiple-input transfer functions, which are built from the application of system identification methods directly to LES data. This method has been successfully applied for modeling the dynamics of a turbulent boundary layer [6]. These models are built directly from temporal data, and enable considerable flexibility in terms of input and output definitions. Furthermore, they allow us to extract physical information regarding the system, such as the causality relationship between quantities.

Figure 2 presents an example of the application of the method for this problem; the output position was defined as the average position of the shock foot and the input position was varied along the wall-normal and streamwise directions.

Figure 3: SPOD modes for the streamwise velocity fluctuations at a frequency corresponding to the shock motion and the turbulence scales; the arrows depict the approximate direction of propagation of the fluctuation.

The streamwise velocity fluctuation was considered as the measured quantity and a spanwise averaging was performed to isolate the quasi 2D dynamics. The fluctuations were also low-pass filtered to isolate the shock motion. The index (P) computed via the Hilbert transform was defined to quantify the causal relationship between input/output quantities. $P = 1$ indicates that the defined input is driving the output behaviour in a perfectly causal manner. The results of figure 2, with high correlations near the reattachment point $(x, y) = (1, 0)$ and nearly perfect causality, indicate that downstream fluctuations are driving the low-frequency behaviour of the shock and permit an accurate prediction of its motion.

To further understand the effects at play here, spectral proper orthogonal decomposition (SPOD) modes were computed at the shock frequency and at the frequency corresponding to the turbulent scales. SPOD modes are used to isolate the most energetic structures at a given frequency and have been used in other works to extract information about the flow for modeling and control applications. These results are presented in figure 3. An evaluation of the phase together with the flow animation indicate an upstream traveling motion for the low-frequencies which is complementary to the results of the transfer function analysis and previous studies [5].

CONCLUSIONS & PERSPECTIVES

The preliminary analysis performed here highlights the presence of a feedback mechanism which appears to drive the low-frequency shock oscillations. For the final version of this work, we plan to extend the transfer function (including the case with more input quantities) and SPOD analysis along with a theoretical evaluation via linear stability theory. More details regarding the implementation of these tools will be considered along with a more complete overview of STBLI configuration.

A LATTICE BOLTZMANN FRAMEWORK FOR COMPRESSIBLE FLOW SIMULATIONS

Mohammad Hossein Saadat[1], Benedikt Dorschner[1], and Ilya V. Karlin *[1]
[1] Department of Mechanical and Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

Summary We propose a numerical framework based on the lattice Boltzmann method (LBM) for simulation of compressible flows up to moderately supersonic regime. The framework is based on a compressible LB model which retains the simplicity and efficiency of the standard lattices, and is solved on irregular unstructured meshes. The promising results of the proposed algorithm pave the way for numerical simulations of realistic engineering problems.

INTRODUCTION

The development of accurate and efficient numerical schemes for the simulation of compressible fluid flows remains an active research field due to its importance in many engineering applications. The presence of shock waves in compressible flows adds another level of complexity to the computations, as this requires the scheme to not only be able to accurately resolve the small scale structures of the flow, but also to have enough dissipation to remain stable at shock jumps and avoid the Gibbs oscillations. The lattice Boltzmann method (LBM) as a kinetic theory approach to computational fluid dynamics (CFD) is now a well-established tool for the simulation of complex fluid flows. In the LBM, populations $f_i(\boldsymbol{x}, t)$ associated with a set of discrete velocities $\boldsymbol{c}_i, i = 0, ..., Q-1$, are designed to recover the target equations of continuum mechanics in the hydrodynamic limit. The evolution of populations is based on simple rules of propagation along the discrete velocities, and relaxation to a local equilibrium. This makes the LBM a simple and efficient alternative for conventional CFD solvers and an attractive candidate for simulation of flows in realistic applications.

It is, however, well known that most LB models using the standard lattices ($D2Q9$ in two dimensions and $D3Q27$ in three dimensions, where $DdQn$ model refers to d dimension model with n discrete velocities), are limited to low-speed incompressible applications up to Mach number $Ma < 0.3$, as they suffer from a limited Galilean invariance and lack of isotropy at high-speed flows. The reason is that the number of discrete velocities of the standard lattices is too low to reproduce all of the symmetries required for obtaining the full compressible Navier-Stokes-Fourier (NSF) equations. While increasing the number of discrete velocities (high-order lattice) is a systematic way to go beyond incompressible regime and simulate high-speed compressible flows, it comes at the price of drastically increasing the computational costs, which eventually makes large scale simulations unfeasible.

The present study addresses these issues with the aim of developing a compressible LB framework, while retaining the simplicity and efficiency of the standard lattices. Such a LB model would enable high fidelity simulations of fundamental and engineering applications in the compressible regime.

KINETIC MODEL DEVELOPMENT

The main idea of developing a compressible LB model on standard lattices is to employ a two-population model (one population f_i responsible for the mass and momentum conservation, and the other one g_i for the energy conservation) and introduce correction terms into the kinetic equations to eliminate the spurious terms in the momentum and energy equations resulting from the above mentioned constraints of the standard lattices. The kinetic equations can, therefore, be written in the conventional propagation-collision form as follows [1]

$$f_i(\boldsymbol{x}, t) - f_i(\boldsymbol{x} - \boldsymbol{c}_i\delta t, t - \delta t) = \Omega_{f,i} + \delta t\phi_i, \tag{1}$$

$$g_i(\boldsymbol{x}, t) - g_i(\boldsymbol{x} - \boldsymbol{c}_i\delta t, t - \delta t) = \Omega_{g,i}, \tag{2}$$

where f_i and g_i are populations of discrete velocities c_i at point $\boldsymbol{x}$ and time t, $\Omega_{f,i}$ and $\Omega_{g,i}$ are collision terms and ϕ_i are correction terms. The derivation of correction terms ϕ_i is based on the Chapman-Enskog analysis of the kinetic equations (1) and (2) (see [1] for the full derivation).

NUMERICAL METHOD

The numerical implementation involves propagation along the discrete velocities and local collision (see Eqs. (1), (2)). Here, we perform propagation on unstructured irregular mesh. This allows us to employ body conforming meshes, which give more flexibility in handling complex geometries and are more efficient in capturing small scale structures of the flow near the wall. The computational domain is therefore discretized into an irregular mesh. Then, in order to perform propagation step at each grid node, populations at its corresponding departure point $\boldsymbol{x} - \delta t\boldsymbol{c}_i$ are reconstructed using the second-order accurate finite-element interpolation scheme [2]. After propagation, the post-collision populations are computed. The Grad approximation is used for implementing the wall boundary conditions [3].

RESULTS AND DISCUSSION

The proposed compressible LB model gives a unified flow solver which covers from subsonic to moderately supersonic regime with shock waves, while still using the simple $D2Q9$ lattice model. Figure 1-a shows the results of supersonic flow over NACA0012 airfoil at $Ma = 1.5$ and $Re = 10000$. It is observed that the present model can accurately simulate problems which were only possible before by employing high-order lattice ($D2Q49$).

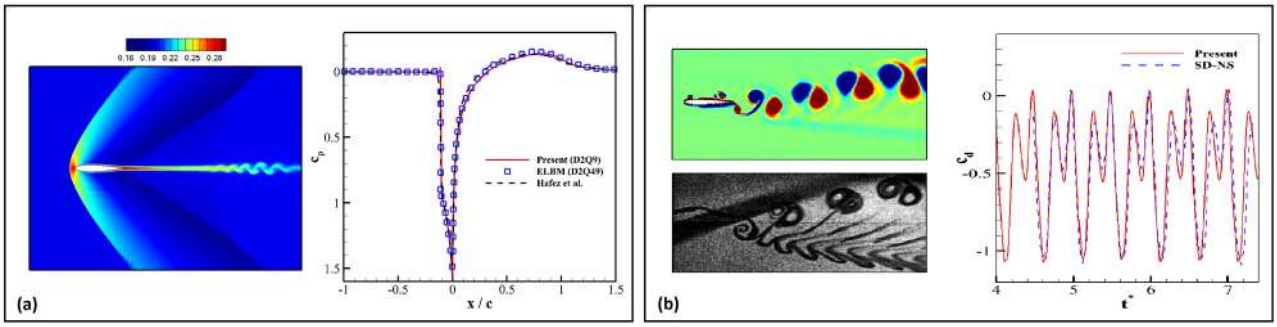

Figure 1: Flow over NACA0012 airfoil: (a) supersonic flow over airfoil, temperature contour (left) and the distribution of pressure coefficient over airfoil surface (right), (b) compressible flow over plunging airfoil, vorticity contour in comparison with the experimental results reported by [5] (left) and the time evolution of drag coefficient in comparison with numerical results of [4] (right).

An extension to a moving mesh approach makes the present model a suitable candidate for simulation of flows with deformable moving bodies and fluid-solid interaction (FSI) applications. This is achieved by employing the so-called arbitrary Lagrangian-Eulerian (ALE) technique. The preliminary results of compressible flow over an airfoil undergoing sinusoidal plunging motion are shown in Fig. 1-b. The comparison with the numerical [4] and experimental [5] results, show excellent agreement.

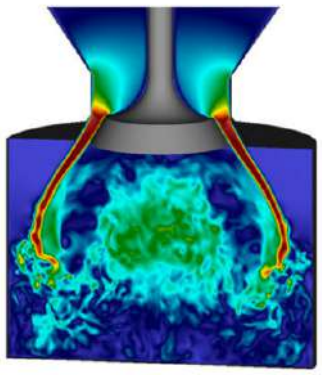

Figure 2: Simulation of valve-moving piston setup [6].

The promising results of the proposed model open interesting prospects toward the numerical simulation of engineering problems with realistic complexity such as flow in internal combustion engine (Fig. 2), compressible turbulence and shock turbulence interaction.

THE INTERACTION OF A TURBULENT CYLINDER WAKE WITH AN OBLIQUE SHOCK WAVE

Sean McCreton*[1], Manuj Awasthi[1], Danielle Moreau [1] and Con Doolan[1]
[1] School of Mechanical and Manufacturing Engineering, The University of New South Wales, Sydney, Australia

The interaction of the turbulent wake of a cylinder with an oblique shock wave is explored using high-speed schlieren imaging. Cylinders are placed in a Mach 3 flow at Reynolds numbers of 0.6 and 0.75 × 10^6 to produce turbulent wakes that pass through oblique shock waves of varying strengths. Spectral Proper Orthogonal Decomposition (SPOD) of the schlieren light intensity fluctuations reveals that the turbulent structures in the wake are modified as they pass through the shock wave. The final manuscript will present additional experimental results to further characterise the wake-shock interaction as well as a comparison to theoretical models and other studies.

Introduction

The interaction of turbulent flow with a shock wave is a complex physical problem with significant implications for high-speed flow applications. The behaviour of this phenomena and its impact on the mean flow and turbulence characteristics are of great importance in understanding the aeroacoustic loading within a supersonic combustion ramjet (scramjet). Many studies explore the behaviour of shock turbulence interaction, presenting theoretical [1]–[3], experimental [4], [5] and numerical [6], [7] results.

Linear Interaction Analysis (LIA), first proposed by Kovasznay [8], is commonly used to predict turbulence characteristics downstream of shock turbulence interaction by linearising and decomposing upstream turbulence into small and simple waves. Ribner [1], [2] and Moore [3] applied the technique to plane waves interacting with normal shock waves, reconstructing the downstream waves to produce the desired downstream turbulence quantities. When compared to LIA predictions, experimental and numerical simulations produce widely varied results. Agui et al. [4] and Braun et al. [6] observed a similar disagreement to the predicted amplification in turbulence at higher shock Mach numbers, while Barre et al. [5] and Ryu and Livescu [7] observed amplifications similar to those predicted by LIA.

Based on previous work, we have a good understanding of how homogeneous and isotropic turbulence interacts with a shock wave, but few studies explore non-homogeneous or anisotropic cases. Hence, this study aims to investigate the interaction of a highly turbulent cylinder wake with an oblique shock wave and compare the turbulent characteristics downstream of a shock wave to LIA predictions as well as experimental and computational work.

Experimental Setup

Measurements have been performed in UNSW's Mach 3 wind tunnel, a blowdown facility that produces up to 20 seconds of sustained supersonic flow [9]. A 2-dimensional converging diverging nozzle accelerates the flow to Mach 3 into a rectangular test-section with a cross-section measuring 142.6 × 101.6 mm and length of 700 mm. Stagnation pressures range between 450 kPa and 650 kPa and stagnation temperatures range between 278 K and 300 K, producing Reynolds numbers ranging from 40-50 × 10^6 m^{-1}.

The experimental figure is shown in Figure 1. Aluminium cylinders with diameters (d) of 12 mm and 15 mm were installed across the width of the tunnel (101.6 mm) at half the height of the test-section. The test Reynolds numbers based on these diameters are 0.6 and 0.75 × 10^6 respectively. A 10° wedge was installed on the floor of the tunnel to generate an oblique shock wave which crossed the turbulent cylinder wake 2.5 to 4.5 diameters downstream of the cylinder. A schlieren system in a typical z-type arrangement was used to observe the wake-shock interaction through a set of BK-7 viewing windows with their upstream edge positioned 10.5mm downstream of the centre of the cylinder. Schlieren images were recorded at 50,000 and 100,000 frames per second (fps) in monochrome using a Memrecam HX-7s high-speed camera.

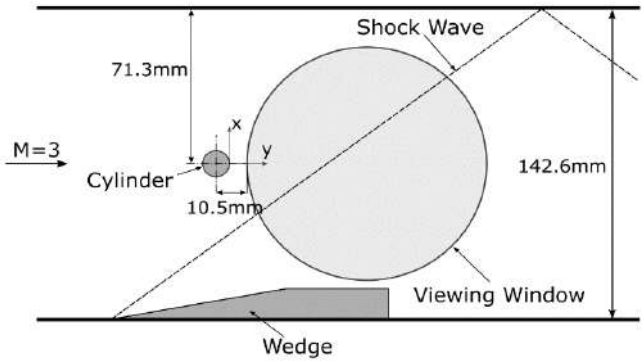

Figure 1. Schematic of the experimental setup

Results

The pixel intensities of the schlieren images are used to analyse the flow by calculating the power spectral density and performing dynamic mode decomposition and SPOD using code adapted from Towne et al. [9]. The mean and variance of the pixel intensities for the 12 mm cylinder with 10° wedge can be seen in Figure 2 (coloured to assist with visualisation), with edge detection shown by black lines indicating sharp gradients with key flow features identified. Figure 3 displays the results for the first SPOD mode, including spectral energy (a) and resulting pixel modal energies for subsets of the imaging region (b-c). For the first time, we can observe the interaction of a highly turbulent cylinder wake with a shock wave and the modification to turbulence characteristics downstream of the shock.

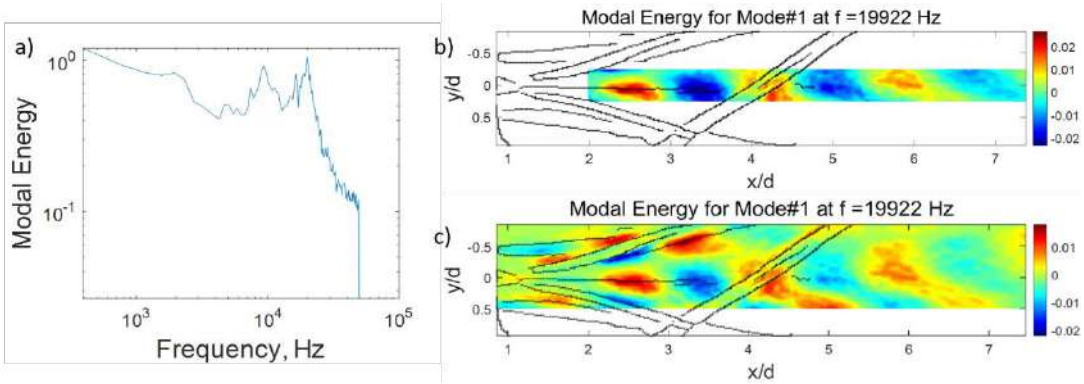

Figure 3. First SPOD mode for cylinder wake-shock interaction: a) spectral energy, b) and c) SPOD modes at 19.2 kHz for reduced domains

CONCLUSIONS

This study observes the interaction of a highly turbulent cylinder wake with an oblique shock wave in a Mach 3 wind tunnel using high-speed schlieren imaging. Numerous post-processing techniques are applied to analyse the fluctuating schlieren light intensities in the viewing region to analyse the behaviour of the wake-shock interaction. The full paper will present further experimental cases and characteristics of the turbulence modification through the shock wave to compare to LIA predictions and other experimental and computational work.

AN ACCURATE NUMERICAL SCHEME TO SOLVE COMPRESSIBLE MULTISPECIES REACTING FLOW

Luc Lecointre *[1,2,3], Etienne Studer[1], Serguey Kudriakov[1], Ronan Vicquelin[2], and Christian Tenaud[3]

[3] Université Paris Saclay, CNRS, LIMSI, 91400, Orsay, France

Summary We propose a numerical scheme for an accurate resolution of equilibrium compressible multispecies flows. This scheme minimises numerical diffusion and is robust enough to capture discontinuities and interfaces. It can be used for configurations where we observe interactions between shock wave and turbulence with important variation of temperature like in atmospheric reentry problem or in detonation phenomenon. To solve Euler equations, we extend the Roe's approximate Riemann solver to multispecies flows and use a Lax Wendroff approach to obtain high order one-step scheme coupled to a monotonicity preserving criterion to capture discontinuities. A splitting operator is used to compute viscous and reactive part of the Navier-Stokes equations. Moreover, we apply an adaptive grid refinement technique to refine the mesh at characteristic local scales to be fully resolved numerically.

DESCRIPTION OF THE NUMERICAL SCHEME

The simulation of severe flow conditions, such as unsteady reactive supersonic flows, requires robust accurate numerical methods. They have to deal with multi-scale phenomena, their numerical diffusion must be limited and they have to be robust enough to capture dicontinuities and interfaces such as shock-wave, contact discontinuity or flame front. They also have to combine complex chemical kinetics with physical process and then be able to treat large variations of temperature and density.

We developed here a high order scheme to solve the Navier-Stokes equations for compressible reacting multispecies flow. We describe in the following the different steps to extend the Roe's approximate Riemann solver to a robust high order scheme in order to solve the Euler part of the equations for multispecies flow with temperature dependant heat capacities. Then we present the implementation of the viscous and the reactive part and the adaptive grid refinement techniques.

Extended Roe Solver for Multispecies flow

The Roe's approximate Riemann solver is used to deal with equilibrium gases with temperature dependant heat capacities. It involves the definition of a Roe average state described by a series of thermodynamic variables. In particular, some pressure derivatives allow to compute the sound speed $\tilde{c}_s$ at the average state. Contrary to the perfect gas case, this Roe average state is not uniquely defined. The properties of the Roe solver [1] impose relations between the thermodynamic variables of the average state but are not sufficient to uniquely define all of them. Some approximations must also be made such as realised by VINOKUR and MONTAGNÉ in [2]. A comparison of different formulations to compute these thermodynamic variables can be found in [3], but the authors did not conclude on the superiority of any method.

We extend the existing approximate Riemann solver to a N-species flow by defining the corresponding Jacobian matrix and Roe average state. We compute the approximation of the Roe average state by an analogous approach to the monospecies case in particulary by using projection of the N approximated pressure derivatives variables on the N-1-subspace defined by the mass conservation condition.

In addition to the Roe solver we use an adapted Lax Wendroff approach to obtain a high order one-step scheme coupled with a monotonicity-preserving (MP) criterion to accurately capture discontinuities such as described in [4] for the perfect gas case. We succeeded to express the high order final numerical flux for the multispecies flow with only $\tilde{c}_s$ as unknown parameter. The use of this single parameter in the expression of the high order terms and in the flux limiter criterion allow to get a robust scheme and discriminate more precisely than in [3] the approximations of the Roe average state.

Resolution of the Navier Stokes equations

To solve the Navier Stokes equations, we use a 2nd-order Strang splitting scheme to complete Euler equations with viscous and reactive part [5]. The viscous part, which also take into account the diffusion of the species, is solved using a 2nd-order Runge-Kutta time integration coupled with a 2nd-order centered scheme. In order to deal with multiscale phenomena and not to limit the time step with the stiff reaction term, the reactive part is treated with a Radau5 implicit scheme.

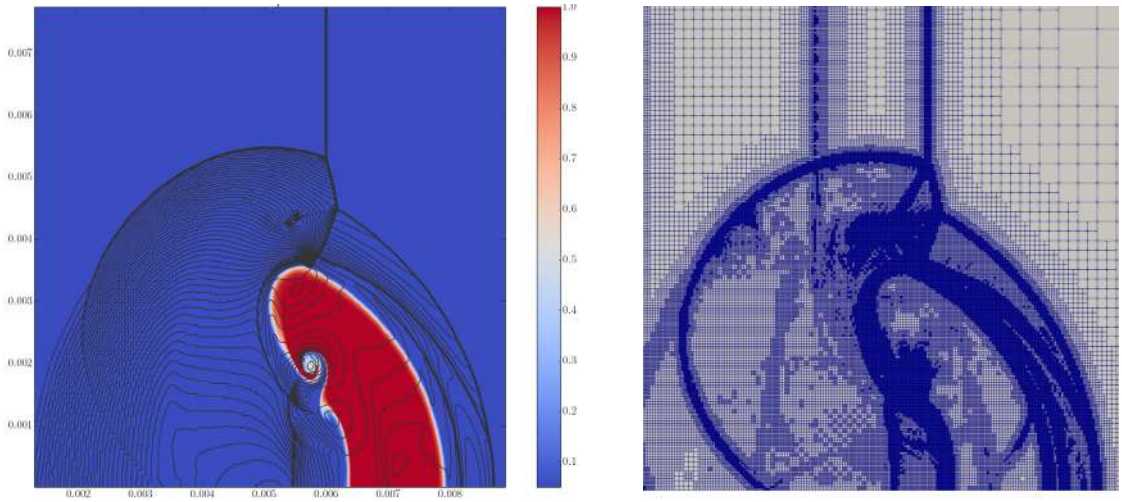

Figure 1: Interaction between a shock at Mach 2 and a hydrogen bubble according to the test case presented in [8] after $4\mu s$. Pressure isolines and hydrogen mass fraction isocontours (left) and corresponding refined mesh (right)

Grid refinement

For several configurations, in particular problems involving detonations problems, characteristic time and space scales span over several orders of magnitude, typically between the size of the system and the flame thickness. In order to solve the relevant scales and save CPU time and memory usage, we use an adaptive multiresolution procedure described in [6] to refine the mesh by using a graded tree data structure that evolve in time. Through an error estimate, a threshold parameter ϵ drives the efficiency of the grid refinement and limits local loss of accuracy.

NUMERICAL RESULTS

We illustrate our method with 1D and 2D academic test cases by using the above presented high order extension of the Roe solver for multispecies flows. For the well documented test cases with shock-bubble interations in gas-gas flows, the quality and the accuracy of our prediction of pressure and temperature improve the capture of the shock bubble interaction phenomena (see fig. 1). In particular, the instabilities around the bubble are better capture than in [7] for the same grid level. The different approximations for the Roe average state are evaluated with the high order scheme and show the best results with the VINOKUR-MONTAGNÉ's method [2].

We will also propose reactive configurations, we are planning to present at the Congress the result of a 2D premixed flame propagation in hydrogen explosions with a fifth order numerical scheme with the test case presented in [9].

CONCLUSIONS

We developed a high order scheme using an extension of the Roe solver for multispecies flow associated with a splitting scheme to treat viscous part and complex chemistry. This numerical scheme is able to accurately capture compressible phenomena inside a multispecies flow and account for configurations as detonation or atmospheric reentry problem. We finally apply adaptive grid refinement to compute the flow with a significant CPU time reduction without loss of accuracy. The numerical applications demonstrate the abilities of this new scheme in transonic and supersonic multispecies flow.

EMERGENCE OF INTERMITTENCY AND ASYMPTOTIC STATES IN SOLENOIDALLY FORCED COMPRESSIBLE TURBULENCE

Sualeh Khurshid *[1] and Diego Donzis[1]
[1] Department of Aerospace Engineering, Texas A&M University, Texas, USA

Summary We use a large database of highly resolved direct numerical simulations of compressible isotropic turbulence to show that intermittency in the solenoidal field is well represented by scaling laws predicted for incompressible turbulence. We also show that similar to incompressible turbulence, the solenoidal field transitions from Gaussian statistics to anomalous asymptotic scaling at $R_\lambda \approx 10$, much lower than needed for establishing an inertial range. We also show that compressibility can affect the transition Reynolds number.

INTRODUCTION AND MOTIVATION

The notion of small scale universality, in some quanititave sense, has been the been the staple of turbulence theory and modelling approaches. A universal behavior is often predicted for an asymptotic relevant parameter, for example Reynolds number (R_λ), Schmidt number, Mach number. A quantitative measure of the asymptotic parameter value is, however, often missing in the description. It is therefore difficult to assess the validity of the asymptotic state predictions, if one exists, or departures from it when the asymptotic parameter value is ambiguous. Therefore, developing a quantitative understanding of asymptotic states is of obvious fundamental importance but has implications for important engineering problems. For example, computational design techniques such as large eddy simulations (LES) are based on the existence of this asymptotic universal state. Recently [1] it was shown that incompressible turbulence transitions from a low R_λ state to a universal so-called anomalous asymptotic scaling regime at $R_\lambda \approx 10$, much lower than previously believed. The universal behavior in the velocity field, for example, previously had largely been attributed to the establishment of an inertial range, which emerges only at R_λ at least an order magnitude larger than this transition R_λ. However, it was shown that scaling in the inertial range itself could be predicted from the scaling and transition of velocity gradients at $R_\lambda \sim O(10)$. This suggests that universal behavior observed in incompressible turbulent flows and features of fully developed turbulence are not a consequence of inertial range dynamics or available only at extremely large values of Reynolds number.

Flows in a wide range of natural and engineering applications, for example astrophysics, reacting flows and high speed flight, are compressible. The presence of a coupled velocity and thermodynamic field leads to more complicated physics and a wider range of parameter space than just the Reynolds number. It is therefore important to explore and characterize universal features and their emergence in compressible turbulence. In this paper, we show that compressible turbulence, analogous to incompressible flows, exhibits a transition from a low-R_λ state to fully developed turbulence and that this transition is altered by compressible motions, characterized here by the turbulent Mach number (M_t).

INTERMITTENCY AND UNIVERSAL SCALING

A well known characteristic of fully developed turbulence is presence of strongly localized large fluctuations in instantaneous quantities such as velocity gradients, enstrophy (Ω) and dissipation (ϵ). The large fluctuations lead to departures of scaling predictions for higher order moments based on Kolmogorov's 1941 theory (K41). This so-called anomalous scaling due to intermittency has historically been seen as a high-R_λ feature. It has recently been suggested that anomalous scaling, observed as an algebraic growth of velocity gradients and dissipation with Reynolds number, is achieved at $R_\lambda \sim O(10)$ [1, 2, 3, 4]. A schematic of the underlying formalism is shown in Fig. 1a. At low-R_λ the velocity gradients $(M_p = \langle(\partial u/\partial x)^p\rangle/\langle(\partial u/\partial x)^2\rangle^{p/2})$ exhibit Gaussian statistics $(Y_{2p} = (2p-1)!!)$ As R_λ increases, perturbations in the field become unstable beyond a critical Reynolds number (resembling a Landau transition) and grow such that the statistics obey algebraic scaling laws with respect to R_λ. Higher order moments transition at lower Reynolds numbers than lower order moments. Therefore, the most extreme events show signatures of fully developed turbulence earlier in R_λ. All the transitions for velocity gradients are complete at $R_\lambda \sim 10$ and the flow can then be considered fully turbulent. If the transition Reynolds is known, the scaling exponents (ρ_{2n}) can be predicted by matching the asymptotic states: Gaussian at low R_λ and algebraic scaling at high R_λ [2]. These allow for accurate calculations of scaling exponents of velocity structure functions as well.

Intermittency in compressible turbulence is modified by fluctuations in thermodynamic variables which can be strongly coupled with the velocity field [5] giving rise to new phenomena. For example, it has been suggested that the most dissipative structures in compressible turbulence concentrate in sheets instead of filaments as in incompressible turbulence [6]. In addition, small localized shocks in dilatational components, termed shocklets, alter intermittent behavior. This seems to be confined to the dilatational component of velocity as structure functions of the solenoidal velocity have been shown to scale similar to incompressible counterparts with small compressibility effects [8]. Therefore, one can expect

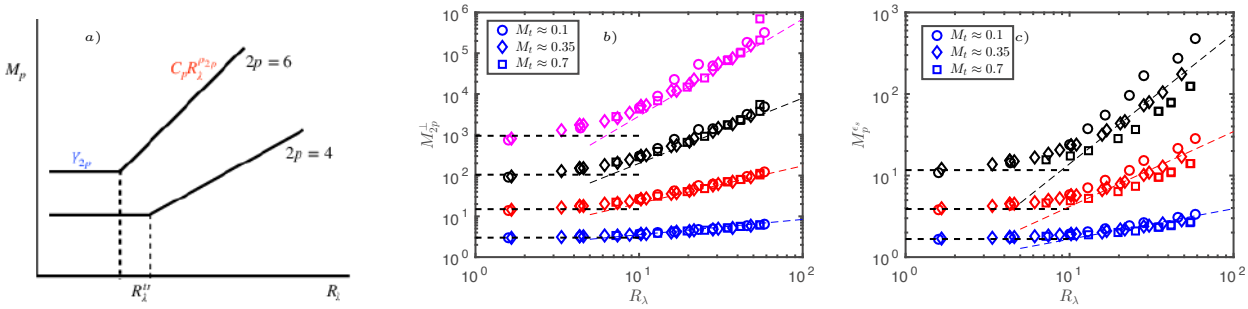

Figure 1: a) A schematic showing transition of velocity gradients from a low-R_λ Gaussian state to high-R_λ anomalous scaling. Moments of (b) transverse velocity gradients ($2p = 4, 6, 8, 10$) and (c) solenoidal dissipation ($p = 2, 3, 4$) for different M_t.

the incompressible analysis of Yakhot & Donzis [1] to apply to solenoidal variables. In Fig. 1b we plot the normalized moments of transverse velocity gradient $(\partial u/\partial y)$ at three different turbulent Mach numbers from solenoidally forced isotropic turbulence simulations. The numerical scheme is 10-th order compact in space with RK3 discretization in time. The small scale resolution (Δx) is between 1 and 2 times the mean Kolmogorov scale with a CFL of 0.3. We observe behavior similar to incompressible turbulence. At low-R_λ, the velocity gradient statistics are Gaussian (horizontal dashed lines) with a transition to anomalous scaling beyond $R_\lambda \sim 10$. The dashed scaling lines correspond to analytical results computed by Yakhot & Donzis for incompressible turbulence [2]. The excellent agreement of the data at all M_t with these predictions shows that the solenoidal velocity field in compressible turbulence indeed obeys the same scaling as incompressible turbulence with no discernible compressibility effects. Further, similar to incompressible turbulence, the asymptotic scaling is achieved in flows with no inertial range and is an emergent phenomenon from a transition. We also show the moments of solenoidal dissipation ($\epsilon_s = \mu\omega_i\omega_i$, $M_p^{\epsilon_s} = \langle\epsilon_s^p\rangle/\langle\epsilon_s\rangle^p$) in Fig. 1c for $p = 2, 3, 4$. Moments of solenoidal dissipation are related to the moments of velocity gradients as $\langle\epsilon_s^p\rangle \sim \langle(\partial u/\partial y)^{2p}\rangle$. Solenoidal dissipation then is composed of three velocity gradients, each of which exhibit Gaussian statistics at low-R_λ. The solenoidal dissipation field then should exhibit χ^2 statistics with 3 degrees of freedom if components area in fact independent. This is what we observe at low R_λ in Fig. 1c, where χ_3^2 moments are plotted as dashed horizontal lines and agree well with DNS data. Beyond $R_\lambda \sim 10$, the solenoidal dissipation moments grow algebraically and agree well with scaling observed and predicted for incompressible turbulence (dashed colored lines). However, here we see a monotonic decrease in moments with increase in turbulent Mach number. The decrease in intermittency in solenoidal dissipation field is consistent with the literature [7, 6]. This is also consistent with the assumption that dissipation intermittency within highly compressible flows occurs in sheet like structures rather than filaments. The scaling with respect to R_λ appears to be preserved even at higher M_t. The weakened moments appear to be a consequence of delayed transition with respect to R_λ at higher M_t

CONCLUSIONS

We use high-resolution direct numerical simulations of compressible isotropic turbulence to study the emergence of intermittency in transverse velocity gradients and solenoidal dissipation. We show that at low-R_λ, velocity gradients obey Gaussian statistics and transition to an anomalous scaling when R_λ increases beyond $O(10)$. The gradients do not have a statistically significant trend with respect to turbulent Mach number. We also show that moments of solenoidal dissipation obey scaling laws similar to incompressible turbulence with respect to the Reynolds number. The magnitude of the moments decreases with an increase in turbulent mach number or, equivalently, the compressibility of the flow. Anomalous scaling is observed at a much lower R_λ than is needed for the development of an inertial range. The observed scaling of the velocity gradients implies the scaling of inertial range structure functions for the solenoidal field is the same as their incompressible counterpart, as reported previously in the literature from high-R_λ simulations. We show these exponents can be computed from much lower-R_λ data than is needed for establishing a wide enough inertial range to measure the exponents reliably. Therefore, information about high-R_λ turbulence is already present at low R_λ and can be studied using highly-resoled low-R_λ simulations. Our data also suggest that the transition to fully developed turbulence with respect to Reynolds number in compressible flows can be delayed with an increase in turbulent Mach number.

EXPERIMENTAL INVESTIGATION OF A FLOW THROUGH A LINEAR TURBINE CASCADE

Idalia Jagodzińska *[1], Bartosz Olszański[1], Konrad Gumowski[1], and Sławomir Kubacki[1]
[1] Warsaw University of Technology, Faculty of Power and Aeronautical Engineering, Institute of Aeronautics and Applied Mechanics, Nowowiejska 24, 00-665, Warsaw, Poland

Summary The paper discusses experimental investigation of flow through a linear transonic Low Pressure Turbine cascade in VKI LS-59 arrangement using the Particle Image Velocimetry technique. Experiments are performed for chord Reynolds number of $Re_{c2} = 6,87 \cdot 10^5$, isentropic Mach numbers at cascade outlet of $M_{2is} = 0,777$ and $M_{2is} = 0,975$, and the freestream turbulence level, $Tu = 2.5\%$. The analysis of the boundary layer transition in transonic flow regimes, shock wave - boundary layer interaction (SWBLI), shock-induced separation and the turbulence generation in wake behind the blade is performed. The obtained flow field data allow to evaluate the standard $k - \omega$ model by Wilcox (2008) and the algebraic transition model by Kubacki and Dick (2016). The aim was to verify, if the database is well suited for testing and development of the RANS-based techniques.

OVERVIEW

Next to a research on transonic flow over a flat plate or airfoil, the eligible test case is the flow in turbomachinery blading in transonic regime, which often encourages the fundamental phenomena like laminar-to-turbulent transition, shock wave-boundary layer interaction and shock-induced separation. For years, the Computational Fluid Dynamics (CFD) techniques, in most industrial applications, have been treated as fully-turbulent approaches thus neglected the details of flow coming from laminar and transitional boundary layers. The new transition models can be adjusted to turbomachinery flows. It provokes to their evaluation with the experimental results acquired with expanded set of the measurement techniques.

The interaction of the shock wave with the boundary layer in transonic flow regimes is mostly investigated for flat plates or airfoils. A comprehensive description of the shock wave turbulent boundary layer interaction has been done by Delery and Marvin [2]. The up-to-date review of SWBLI phenomenon has been also done by Babinsky and Holger [1]. In the transonic blade cascade the shocks generated at the blade trailing edge propagate downstream and impact the BL on the adjacent blades. Moreover, the flow over the turbine blades experiences a strong streamwise curvature making the transition prediction very challenging task. The shock wave may directly induce the BL separation. Alternatively, it may also lead to BL thickening, enhancement of the adverse-pressure-gradient (APG) effect and BL separation near to the blade trailing edge. The velocity field measurements in the wake of the blades with classical measurement techniques such as wake traverse probes as well as the blade surface pressure measurements have been done by Kiock et al. [3]. A comparison of experimental data with numerical results, obtained with various turbulence and transition models (see [4]), calls for improvement of the RANS-based approaches. The present work aims at providing the database for validation/development of the RANS-based techniques. For that purpose, the pressure measurements on blade surface were performed, and the flow characteristics in the wake region behind the blade were analysed using the non-intrusive PIV method.

EXPERIMENTAL APPARATUS AND MEASURING TECHNIQUES

The experiments have been done in the open circuit intermittent, in-draft (suction) type wind tunnel. The model of the low-pressure turbine (LPT) linear cascade, consisting of 8 blades in VKI LS-59 arrangement, was placed in the wind tunnel test section. The flow two-dimensionality was ensured. The Reynolds numbers were between $Re_{c1} = 2,59 \cdot 10^5$ upstream from the cascade up to $Re_{c2} = 6,87 \cdot 10^5$ downstream the cascade. The inlet and outlet conditions, in terms of the static pressure, static temperature, inlet turbulence level were provided. The air humidity was controlled. The pressure measurements on the blade surface were done for the pressure tappings in the mid-span plane of the blade. The PIV was performed using the Nd:YAG 200mJ Litron laser and LaVision DaVis software. The laser sheet covers the downstream region of the cascade including rear part of the blades suction side.

RESULTS

The surface Mach number distribution was compared with the data obtained in four European wind tunnels [3] for comparable outlet flow conditions, $Ma_{2is} = 0,803$ and $Ma_{2is} = 0,996$. The obtained data were also compared with numerical results obtained with the fully-turbulent model by Wilcox (2008), and with the algebraic transition model by Kubacki and Dick (2016b). For the subsonic case both models show a good agreement with experiments. For the transonic case the shock wave boundary layer interaction is visible at streamwise distance $x/c = 0.6$ (c is the blade chord). The main difference between the models is visible in the rear part of the blade (results not shown). The algebraic transition

model shows a better correspondence between measured and predicted Mach number distribution in vicinity of the blade trailing edge. The fully-turbulent $k - \omega$ model produces a thicker turbulent boundary layer, which result in a too abrupt change on the surface Mach number distribution in the vicinity of the shock wave.

The Particle Image Velocimetry measurements of the mean and fluctuating velocity components for two flow conditions, $Ma_{2is} = 0,777$ and $Ma_{2is} = 0,975$, were performed. In subsonic case, $Ma_{2is} = 0,777$, a good correspondence between measured and predicted mean velocity profiles was reported (results not shown). In transonic case, $Ma_{2is} = 0,975$ (see Figures 1 and 2), somewhat lower mean velocity is reproduced in simulation, compared to measurement, at $1,2c_{ax}$ (c_{ax} is the axial chord) downstream the cascade (Fig. 2, left). Much higher differences are reported between predicted, using the standard $k-\omega$ model, and the measured turbulent kinetic energy profiles (Fig. 2, right). The algebraic model shows better correspondence with measurements. This is due to a stronger turbulent kinetic energy production in the separated boundary layer on the blade surface, compared to the production observed with the fully-turbulent approach (without the boundary layer separation). Both models show higher differences farther away from the blade trailing edge (results not showed). This shows that further closure models is necessary. Thus, the obtained experimental results can serve as database for improvement of modelling techniques.

CONCLUSIONS

By the SWBLI existance the turbomachinery transonic flow is intricate for experimental investigation. The use of PIV technique allows for verification of flow characteristics in wake behind the blades. The RANS models show deficiencies in capturing the mean and fluctuating velocity characteristics in the transonic flow regime. The differences are due to a too weak mixing reproduced with RANS in the wake region behind the blade.

CHARACTERIZATION OF THE SHEAR LAYER IN SEPARATED SHOCK/TURBULENT BOUNDARY LAYER INTERACTIONS

Clara M. Helm[1] and M. Pino Martín *[1]
[1] Department of Aerospace Engineering, University of Maryland, College Park, MD 20742, USA

Summary We present a thorough characterization of the shear layer that exists in large eddy simulation data of three separated, compression ramp-generated shock/turbulent boundary layer interactions. Flow conditions include freestream Mach numbers of 2.9, 7.2, and 9.1 producing shear layers with convective Mach numbers of 1.0, 1.9, and 2.0 respectively. We will show that these shear layers share many properties with canonical compressible mixing layers. For example, in each shear layer is found a region where the mean profiles can be scaled to collapse to an approximate similarity profile. Peak turbulence quantities are consistent with compressible mixing layer theory. The conservative and dissipative turbulence energy exchange mechanisms are consistent with those found in canonical mixing layers, and the spreading rate and turbulence anisotropy both decrease with increasing M_c. The signature and structure of the large shear layer vortices will also be presented including a direct measurement of the vortex convection velocity.

BACKGROUND

The mixing layer is one of the most fundamental shear flows in the study of compressible turbulence. Despite its conceptual simplicity, the compressible mixing layer exhibits certain properties that are difficult to explain physically resulting in an inability to develop precise scaling laws and robust models. One of the most documented features of the compressible mixing layer is a significant decrease in spreading rate with increased compressibility (Among many references see [1, 2, 3, 4].), however, the cause of this decrease is still not entirely understood. Complicating our understanding further is the fact that compressibility can significantly alter the development and dynamics of the Kelvin-Helmholtz vortices, causing them to become more three-dimensional and less coherent with increasing convective M_c (Among many references see [5, 6]). A major obstacle in the study of compressible mixing layers is the lack of reliable and detailed data, particularly for turbulence statistics, at elevated convective Mach number ($M_c > 1$).

OVERVIEW OF RESULTS

High convective Mach number conditions occur naturally in the Shock/Turbulent Boundary Layer Interaction (STBLI) shear layer. In this research we employ our Large Eddy Simulation (LES) database of compression ramp-generated STBLI to analyze for the first time the properties of mixing layers in hypersonic separated flow including free-stream Mach number ranging from 3 to 10 and convective Mach number from 1 to 2. All three flows are of a flat plate boundary layer over a two-dimensional wedge and are assumed to be homogeneous in the spanwise direction. All three flows are fully separated in the mean producing counter-current shear layers. Details of the database are listed in Table 1 where M_e is freestream Mach number, δ is boundary layer thickness, ϕ is the ramp angle, Re_θ is Reynolds number based on momentum thickness, Re_τ is the friction Reynolds number, and L_{sep} is the mean separation length. Grid outer dimensions in streamwise, spanwise, and wall-normal directions are listed as L_x, L_y, and L_z respectively. Also included in Table 1 is the convective Mach number $M_c = (U_1 - U_2)/(a_1 + a_2)$ where U is streamwise velocity and a the local speed of sound. The subscript 1 refers to the high-speed side of the shear layer and 2 the low-speed side. For further details on the LES method and its application to hypersonic STBLI flows, please see Helm & Martin [7] and the references within.

In Figure 1, the time- and spanwise-averaged mean turbulent kinetic energy (TKE $= \rho u_i' u_i' / 2U_e^2$) field in the M10 ramp flow highlights the region of shear behind the shock front (black line) and above the separation bubble (magenta line). A coordinate system labeled (x', z') is selected to define the similarity variable $\zeta = z'/x'$. The dashed lines in the contour plot of Figure 1 indicate the range in x' for which ζ collapses the mean flow to the profiles shown to the right. The spreading rate, convective Mach number, and peak turbulence levels can be determined from these collapsed profiles. We will show that the trends we observe are consistent with existing compressible mixing layer theory. Turbulent kinetic energy and Reynolds stress budgets show that STBLI shear layers have a much greater streamwise turbulence production rate than is observed in compressible mixing layer data, however, both the transfer of turbulence energy by the pressure-strain and the energy drain by viscosity show similar behavior to canonical mixing layer data at matching M_c (Figure 2).

Case	M_e	ϕ	δ (mm)	$(L_x \times L_y \times L_z)/\delta$	Re_θ	Re_τ	L_{sep}/δ	M_c
M3	2.92	24^o	7.0	$14 \times 4 \times 4.5$	3220	360	3.4	1.03
M7	7.17	33^o	5.0	$22.5 \times 10 \times 8$	3720	210	5.6	1.89
M10	9.05	34^o	18.0	$19.6 \times 10 \times 7$	8280	520	3.6	1.99

Table 1: LES Database Summary

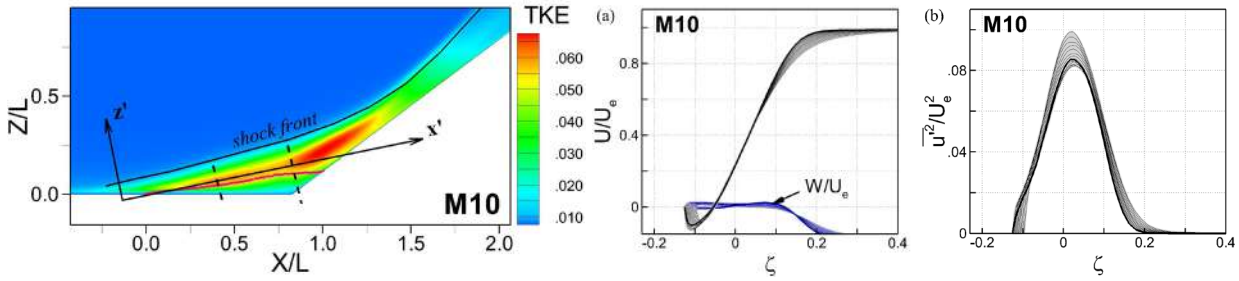

Figure 1: Shear layer similarity in Mach 10 flow.

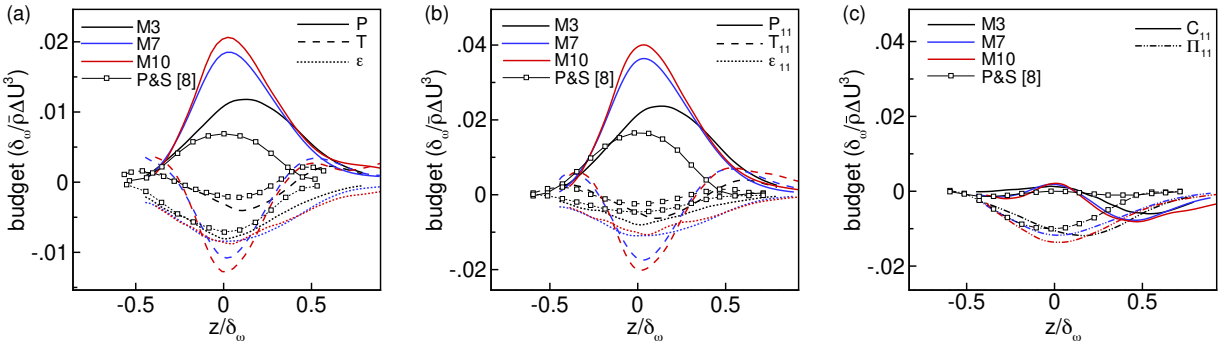

Figure 2: TKE (a) and streamwise Reynolds stress (b-c) budgets compared to data of Pantano & Sarkar[8].

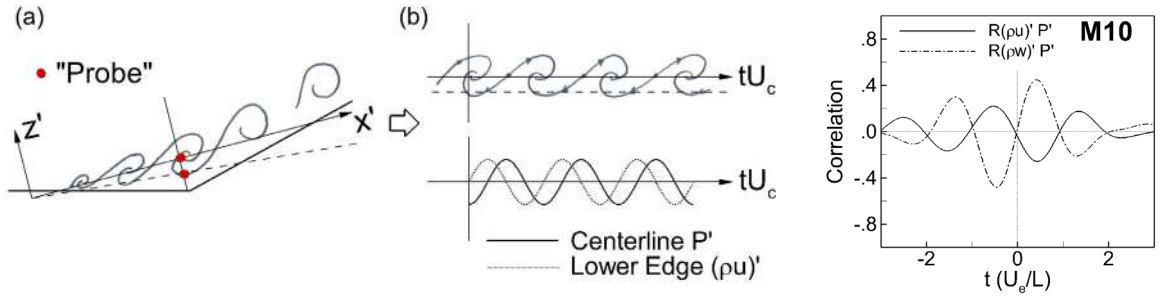

Figure 3: Conditionally averaged vortex time signature in Mach 10 flow.

As a result, the spreading rate and turbulence anisotropy decrease with increasing M_c. We will also show the averaged signature of the large shear layer vortices can be determined by taking time signals from within the similarity region and transforming them to spatial "frozen" vortices using Taylor's hypothesis as drawn schematically in Figure 3. We developed a sophisticated method of filtering and conditionally averaging the time signals to produce clean signatures of the mixing layer vortices (Figure 3), and which also allows us to accurately measure the convection velocity, a quantity that is essential for accurate interpretation of the theoretical comparison.

IS THERE UNIVERSALITY IN COMPRESSIBLE TURBULENCE?

Diego Donzis *[1]
[1] Department of Aerospace Engineering, Texas A&M University, College Station, USA

Summary Compressible turbulence presents a much richer behavior that its incompressible counterpart. While universal scaling laws have been widely and successfully utilized to understand the latter, much less is known about the former. Here we argue that the lack of universal laws and disagreements across flows found in the literature, can be reconcile when the set of governing parameters is supplemented with a non-dimensional variable based on dilatational motions. Using specific analytical limits of the governing equations, we identify the correct governing parameters, show that they can indeed collapse all data in the literature, and provide a framework for further understanding and more realistic physics-based turbulence models.

INTRODUCTION AND MOTIVATION

Most flows in natural and engineered systems are turbulent exhibiting fluctuations in all hydrodynamic and thermodynamic variables which describe the state of the fluid and flow. In a number of situations one can assume the fluid to be incompressible which implies constant density fields and fluid elements that preserve their volume. This results in a great simplification of the problem as hydrodynamics decouples from thermodynamics reducing greatly the complexity of the problem. However, this is not the case in the general case which includes astrophysical phenomena, aerodynamics, reacting flows, and geophysical phenomena, among many others. In such flows hydrodynamics is coupled with thermodynamics leading to much more complex spatio-temporal behavior and a much larger parameter space than in incompressible flows. Thus it is not surprising that much less is known about the former.

Universal scaling laws have been of great value to the fundamental understanding and practical description of a number of physical phenomena including incompressible turbulence. Universal scaling laws for incompressible turbulence have been at the center of our understanding of these flows [1, 2] which are typically cast in terms of the single non-dimensional parameter, namely the Reynolds number. A widely used definition of this parameter is based on the so-called Taylor microscale λ which can be written as $R_\lambda = \langle\rho\rangle u_{rms}\lambda/\mu$ where $\langle\rho\rangle$ is the (constant) density, u_{rms} is the root-mean-square velocity, and μ is the (constant) dynamic viscosity. Universal scaling laws are important because it allows us to characterize the behavior of a system not only at different conditions (Reynolds numbers), but perhaps more importantly, across different flows and at different conditions. This is central element in turbulence modeling.

Universality in the case of compressible turbulence, on the other hand, has been more elusive, in part, due to the lack of a set of parameters that can define the state of the flow uniquely for a range of conditions. Typically, the degree of compressibility is measured by the turbulent Mach number $M_t = \langle|\mathbf{u}|\rangle/c$ where $\mathbf{u}$ is the velocity vector, c the mean speed of sound and angular brackets are a suitably defined average. Significant work has been devoted to find universal scaling laws in terms of M_t to characterize compressibility effects. However, as we show here, data from well-resolved simulations as well as specific theoretical limits of the governing equations show that this is fundamentally flawed, explaining thus the disagreement between data and the limited success in finding theoretically sound models of wide applicability.

We argue that this is due to an incomplete set of parameters to characterize the state of the flow. Furthermore, using specific asymptotic limits we show that universal scaling laws are indeed observed when the parameter space is extended to include internally generated dilatational motions regardless of the mechanisms used to drive turbulent fluctuations [3]. We support our results with a massive database of highly-resolved direct numerical simulations (DNS), along with all data available in the literature.

SIMILARITY SCALING AND GOVERNING PARAMETERS

In incompressible flows, one can use a characteristic length and velocity ($\mathcal{L}$ and $\mathcal{U}$, respectively) to normalize the governing equations. This leads to a single non-dimensional parameter, the Reynolds number, $R_\mathcal{L} = \rho\mathcal{U}\mathcal{L}/\mu$. A central theme in understanding, characterizing and modeling turbulence has been the scaling of a large number of statistics on the Reynolds number, typically the Taylor Reynolds number for convenience [1, 2]. As noted above this has been complemented with M_t as a measure of compressibility to describe fully the statistical state of the flow [4, 5]. The limitations of this approach can be readily seen in Fig. 1(left, top) where we show the normalized pressure rms for a very large database of isotropic flows with a range of forcing schemes as well as homogeneous shear layers. The present simulations and the studies from the literature are described in more detail in [3]. There is clearly no collapse of the data showing the inadequacy of M_t to scale pressure fluctuations. However, if one considers the limiting behaviors at low and high compressibility levels for which well known theoretical results can be established one can find $p^2_{rms}/\langle p\rangle^2/(M_d\gamma)^2 \approx A^2\mathcal{D}^{-2} + 1$. where $\mathcal{D} = \delta\sqrt{\delta^2+1}/M_t$, $M_d = M_t\delta/\sqrt{\delta^2+1}$, and A is a constant of $\mathcal{O}(1)$ which may depend weakly on the flow geometry. In this formulation, we see a new parameter $\delta \equiv u_{d,rms}/u_{s,rms}$ ($u_{d,rms}$ and $u_{s,rms}$ are the rms of

*Corresponding author. E-mail: donzis@tamu.edu

the dilatational and solenoidal components in a Helmholtz decomposition of $\mathbf{u}$) emerge naturally with M_t, as the proper similarity variables to describe the state of turbulence. Indeed, in Fig. 1(left, bottom) we see an excellent collapse of all the data (including isotropic and shear flows) defining two regimes: the low-compressibility regime at $\mathcal{D} \lesssim 0.5$ where pressure behaves as in incompressible turbulence and a high-compressibility regime with $\mathcal{D} \gtrsim 0.5$ where pressure attains equipartition with $\mathbf{u}_d$ [6].

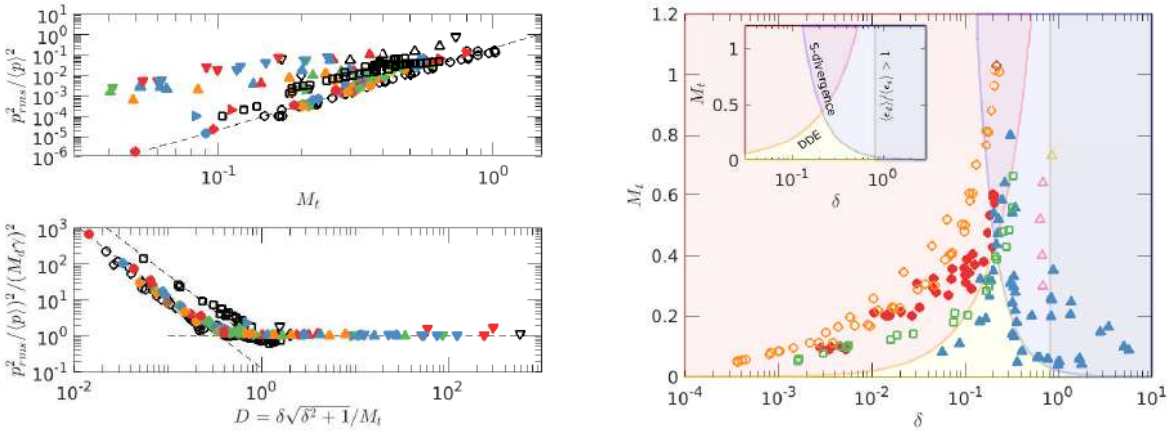

Figure 1: Left: Scaling of pressure variance in terms of M_t (top) and the new scaling parameter $D = \delta\sqrt{\delta^2+1}/M_t$ (bottom) from our DNS database [3] (symbols in colors) and the literature (black symbols) which includes isotropic flows as well as shear layers Right: database of simulations in the δ-M_t plane with different regimes (DDE: dilatationally-dominated equipartition; S-divergence: departure of velocity skewness gradient from well-known incompressible value; $\langle \epsilon_d \rangle / \langle \epsilon_s \rangle > 1$: region where dilatational dissipation dominates) in colors. (adapted from [3]).

Similar observation can be made about the so-called dilatational dissipation $\langle \epsilon_d \rangle \equiv \langle \mu (\nabla \cdot \mathbf{u})^2 \rangle$ which has been studied in a number of flows as it is critical to the general dynamics of the flow, especially its dilatational motions. A number of models have been proposed of the form $\langle \epsilon_d \rangle / \langle \epsilon_s \rangle \sim M_t^\alpha$ where $\langle \epsilon_s \rangle = \langle \mu |\boldsymbol{\omega}|^2 \rangle$ is the solenoidal dissipation, and α takes different values depending on model adopted and the difference assumptions [6]. Here we also show that this form cannot describe adequately the available data but we show that δ can. Another example of the inability of M_t to collapse the data but the success of the combination of M_t and δ, is the skewness of velocity gradients, a measure of the non-linearity in the flow and the production of vortical motions. The conclusion from these observations based on a large number of studies, is that universality does seem to emerge in compressible turbulence but only when an additional parameter including dilatational motions is included.

THE BROAD PICTURE

Universal scaling laws provide a basis for characterization, deeper understanding and modeling of complex physical phenomena. While tremendous advances in incompressible turbulence have been built on this basis, universal scaling laws for compressible turbulence have been much more elusive. We argue here that a main reason for this state of affairs is the incorrect identification of non-dimensional groups to characterize completely the statistical state of the turbulence. By including a new parameter $\delta = u_{d,rms}/u_{s,rms}$, we show that it is possible to collapse all data available for isotropic and homogeneous shear flows. Thus, we argue that the state of the turbulence ought to be identified in a δ-M_t plane as shown in Fig. 1(right). Depending the specific values of M_t and δ turbulence may exhibit fundamentally different behaviors as depicted with the different shaded regions [3]. This clearly highlights the reason why M_t alone is insufficient to characterize these flows, even in isotropic setups. The analysis also provides evidence for an ultimate regime at high Mach numbers, based on statistical mechanics and renormalization group, that leads to equipartition between solenoidal and dilatational components of the velocity field. Overall, this work provides a new view on how to seek universality in compressible turbulence, leading to new venues for better models and deeper understanding.

IMPACT OF FREESTREAM TUNNEL NOISE ON THE MACH 6 FLOWINTERACTING WITH A 35 DEGREE COMPRESSION RAMP

Fabian Dettenrieder, Bryson Sullivan, and Daniel J. Bodony *
Department of Aerospace Engineering, University of Illinois, Urbana, Illinois, U.S.A.

Summary Conventional blow down wind tunnels generate acoustic fields from their boundary layers that impinge on the test article. At supersonic speeds, the model's bow shock distorts the sound and generates vortical and entropy waves that also impact the model. These disturbances affect the model's boundary layers and alter their transition and separation, subsequently affecting global properties of the flowfield. We study this process for a Mach 6 flow approaching a 35 degree compression ramp mounted on a flat plate with a sharp leading edge using direct numerical simulation. The conditions and model geometry match experiments conducted in the NASA Langley 20-inch Mach 6 tunnel. The incoming sound field is constructed from tunnel characterization data and included in the DNS. Comparisons of the flat plate–compression ramp flows are made between the quiet and sound-laden freestreams.

INTRODUCTION

High-speed flight is characterized, in part, by the dynamic interaction of the flow field around the inner and outer mold lines of the vehicle with the surface material and its underlying structure. Deflected vehicle control surfaces are especially prone to fluid-thermal-structure interaction (FTSI) and motivate the problem considered here (left panel of Fig. 1). Studying the FTSI of a deflected control surface with a high-speed flow is an important component of ensuring that engineering models used for vehicle design are sufficiently accurate so that vehicle integrity can be assured without the weight increase of over-design.

An ongoing, joint computational-experimental investigation between the authors and Professor Stuart Laurence (University of Maryland) is examining the shock wave–boundary layer interaction (SWBLI) of a Mach 6 flow approaching a 35 degree ramp fitted with a compliant insert, as shown in the right panel of Fig. 1. The experiments are being conducted in the NASA Langley Research Center 20-inch Mach 6 conventional blow down tunnel (see insert of Fig. 1). The 35 degree compression ramp is mounted on a 280 mm wide by 711 mm long flat plate with a sharp leading edge and exposed to the Mach 6 flow for approximately 5 seconds. Low- and high unit (per meter) Reynolds numbers of 6.6×10^6 and 23.6×10^6 were tested, resulting in ramp-approaching boundary layers that were transitional or turbulent, respectively. No measurements are available to document the boundary layer development along the flat plate. The freestream static pressure, temperature, and density values are 1,990 Pa, 63 K, and 0.11 kg/m^3. The tunnel stagnation temperature is approximately 516 K. More details can be found in [1].

The NASA LaRC 20-inch Mach 6 tunnel is conventional in the sense that tunnel wall boundary layers are turbulent and generate noise. It is well known in boundary layer transition studies that tunnel noise lowers the Reynolds number at which turbulence is observed. It is less well known how tunnel noise alters the details of the compression ramp SWBLI flow of interest and, more importantly, how it impacts validating computational models against the experimental data. The objective of this work is to evaluate the impact of tunnel noise on the details of the ramp SWBLI and, ultimately, how it affects the dynamic response of a compliant panel fitted on the ramp.

RESULTS

Two DNS of the flat plate–compression ramp model are used to examine how the tunnel freestream sound impacts the SWBLI described in the Introduction. The equations of continuity, momentum, and total energy for a compressible, viscous, perfect gas in curvilinear coordinates are solved using a high-order WENO spatial scheme and fourth order Runge-Kutta for time advancement. MPI and OpenMP are used for parallelization, and parallel HDF5 is used for input/output. The ghost cell approach is used for all computational boundaries. All solid surfaces are modeled as no-slip, isothermal walls with 300 K as the fixed temperature. The higher unit Reynolds number condition was studied. The simulations start from a uniform Mach 6 flow and are allowed to reach steady state. The simulation domain encompasses the entire flat plate, starting upstream of the leading edge, the compression ramp, and a portion of the region downstream of the ramp. The spanwise width of the domain is 60 mm and assumed to be periodic. The grid size is $5900 \times 500 \times 1080$ in the streamwise, wall normal, and spanwise directions. A grid convergence study (not shown) has confirmed robustness of the quantities of interest to further grid size increases.

DNS with a quiet freestream

A side-view of the DNS with a quiet freestream is shown in Fig. 2. The boundary layer is laminar just downstream of the leading edge and experiences laminar separation within 10% of the flat panel length. The separated boundary layer quickly transitions to turbulence and becomes an extensive shear layer that impinges the ramp more than half way up from the corner and forms the upper boundary of a large separation zone. The size of the separation bubble and location of the shear layer impact on the ramp exceed those found in the experimental data [1].

DNS with a sound-laden freestream

Rufer & Berridge [2] conducted a freestream noise survey of the NASA LaRC 20-inch Mach 6 tunnel using PCB and Kulite transducers. A sample power spectral density is shown in Fig. 1 for four different Reynolds numbers. At the highest unit Reynolds number, the incident pressure fluctuation root mean square is 1% of the freestream pressure.

The highest Reynolds number spectrum from Fig. 1 was used to estimate the freestream sound field. Several assumptions were necessary, including: (1) the rectangular tunnel walls contributed equally to the radiated sound from the turbulent boundary layers as measured by the probes, (2) the probes measured the post-shock pressure fluctuations, (3) the probe tip shock was normal to the freestream, (4) the phase of the sound field was random, and (5) the freestream sound was planar. Assumptions (1)–(5) can be used to estimate the freestream sound $p'(\vec{x},t)$, $\vec{u}'(\vec{x},t)$ and $\rho'(\vec{x},t)$ which must be added to the otherwise constant freestream pressure p_∞, velocity U_∞, and density ρ_∞. The DNS with the incident sound will be presented and compared with the quiet DNS results.

SCALING OF DECAYING TURBULENT KINETIC ENERGY IN COMPRESSIBLE TURBULENT MIXING

Eunhye An[1] and Eric Johnsen *[1]
[1] Department of Mechanical Engineering, University of Michigan, Ann Arbor, USA

Classical Kolmogorov theory is restricted to incompressible and homogeneous flow of a single fluid. However, compressible turbulent mixing involves compressibility effects and inhomogeneities, for which the classical theory is not directly applicable. In this work, we present a scaling for the rate of decay of turbulent kinetic energy in compressible turbulent mixing, in which an inhomogeneity in turbulent intensity gradients is imposed. We explain the compressible turbulent mixing at the interface by considering dilatation of turbulent kinetic energy in turbulent energy balance equation. This scaling law is compared with DNS results, with good agreement.

INTRODUCTION

Kolmogorov theory applies to incompressible, homogeneous flows of a single fluid. However, for compressible, inhomogeneous flows of multi-material fluids, the turbulence phenomenology is less well understood. Such situations can be found in engineering and nature. Turbulent mixing at gradients in turbulent intensity plays an important role in a variety of oceanic, atmospheric and astrophysical flows. For example, in the oceans, intensity gradients originate from wind along the surface or internal-wave breaking where energy cascades into smaller scales, thus leading to turbulent mixing. Additionally, in astrophysics, the turbulence in the interstellar medium (ISM) is compressible [1], with mixing between hotter and cooler regions. To understand these phenomena, it is essential to investigate the mechanism of turbulent mixing under different conditions and determine the parameters controlling the turbulent mixing process.

Previous studies of multi-component and/or compressible turbulent mixing have been carried out. Tordella and Iovieno [2] investigated the effects of difference in spectral energy with integral length scale gradients in incompressible turbulent mixing and observed both self-similarity and intermittency. Movahed and Johnsen [3] considered fluids with different densities, but the same kinematic viscosities, to understand the role of density gradients alone. However, the effect of other variables such as turbulent kinetic energy (TKE) intensity and the scaling of the mixing region growth have not been explored in detail. In this study, we introduce a scaling for the rate of decaying TKE and the mixing region growth in turbulent mixing between turbulent flows of different initial intensities.

NUMERICAL SETUP

Direct Numerical Simulation (DNS) of the compressible Navier-Stokes equations are performed for a binary system of ideal gases. The discretization scheme is based on explicit sixth-order central differences and fourth-order Runge-Kutta time marching. To simulate decaying turbulence more efficiently, a new initialization procedure was developed [4], in which a surrogate simulation is started and rescaled appropriately to the desired initial conditions. The corresponding initial velocity fields consist of fully developed turbulence initiated from a Batchelor spectrum with desired properties from the beginning.

We juxtapose two cubes where turbulent diffusion occurs at the interface and used the same fluid with different turbulent intensities. The root-mean-square velocity and the corresponding Reynolds number are varied, but all other variables such as density, viscosity, and Taylor micro-scale, are kept the same. Zero-gradient and periodic boundary conditions are applied in the inhomogeneous and spanwise directions, respectively.

SCALING

Under no forcing, the volume averaged TKE decays only by dissipation.

$$\frac{dk}{dt} = -\varepsilon \qquad (1)$$

When equation (1) is scaled by a single, constant eddy turnover time, τ, which is defined as Taylor micro-scale over the root-mean-square velocity, the TKE is shown to decay exponentially. When comparing results for a single fluid in a periodic domain for different time scales and Reynolds numbers, the TKE still exhibits exponential decay with the same exponent. However, for inhomogeneous flow like turbulent mixing, the relationship between the rate of TKE decay and dissipation is more complicated.

To address this issue, we start by considering the energy transfer term, $\frac{\partial u_i u_i u_j}{\partial x_j}$ [5] and decompose it in non-conservative form with two terms: dilatation and advection of TKE. In compressible flow, the dilatation of TKE is expected to be much larger than the advection term, so we take only the dilatational term into account. Integrating the resulting equation, a conservation law for TKE is obtained as follows, in which TKE is defined as exponential function whose argument has two terms:

*Corresponding author. E-mail: ejohnsen@umich.edu

$$k/k_0 = exp\left[-\left(c_1\, t/\tau + c_2 \int \sqrt{\Delta} dt\right)\right] \qquad (2)$$

RESULTS

For inhomogeneous flow, energy transfer at the interface is important. To understand the mixing behavior, we divide the volume into three regions: the mixing region and the regions left/right of the mixing region (referred as region 1 and region 2 below). Then, total TKE can be predicted as the sum of TKE, possibly with different coefficients in each region:

$$\langle k \rangle_{total} = a_1 \langle k \rangle_1 + a_m \langle k \rangle_{mix} + a_2 \langle k \rangle_2 \qquad (3)$$

Time scales are also likely different in each region due to the different root-mean-square velocities. The TKE averaged in region 1, in the mixing region, and in region 2 with respect to time scaled according to the different regions are presented in Figure 1. All cases with different intensity ratios have the same decay rate, while the TKE scaled only by a single, eddy turnover time decay with different rates. In regions 1 and 2, it is necessary to consider the dilatational time corresponding to this scaling. However, in the mixing region, the TKE decays only with eddy turnover time. This behavior occurs because compressibility (e.g., acoustic waves) has little effect on mixing region and only large-scale eddies are responsible for mixing. Furthermore, coefficients a_1, a_m, and a_2 in eq (3) can be determined by the mixing region extent. The mixing region is captured by the mass fraction of scalar [6]. We found that the mixing region grows as a power-law with an exponent close to 0.4. Also, the left and the right interfaces evolve with the same exponent. Thus, all coefficients in eq (3) are defined as power-law relations. As a result, a final formation of decaying TKE is obtained as follows:

$$\langle k \rangle_{total} = \sum_{n=1,m,2} a_n \langle k \rangle_n \qquad (4)$$

$$a_n \langle k \rangle_n = f(\Delta, u_{rms}, h_0, t) = \begin{bmatrix} \left(\frac{1}{2} - \frac{h_L}{L_t}\right) k_{r1,0} exp\left[-\frac{c_\varepsilon}{\pi}\left(\frac{t \cdot u_{rms1,0}}{\lambda_0} + \frac{1}{(2\pi)^2}\int \sqrt{\Delta^2} dt\right)\right] \\ \left(\frac{h}{L_t}\right) k_{m,0} exp\left[-\frac{c_\varepsilon}{\pi}\left(\frac{t \cdot u_{rmsm,0}}{\lambda_0}\right)\right] \\ \left(\frac{1}{2} - \frac{h_R}{L_t}\right) k_{r2,0} exp\left[-\frac{c_\varepsilon}{\pi}\left(\frac{t \cdot u_{rms2,0}}{\lambda_0} + \frac{1}{(2\pi)^2}\int \sqrt{\Delta^2} dt\right)\right] \end{bmatrix}$$

where Δ is the dilatation, c_ε the dissipation quantity, and h the mixing region width. Results from DNS and the scaling agree well. Our scaling thus predicts the decay of TKE as well as turbulent mixing with turbulent intensity gradients.

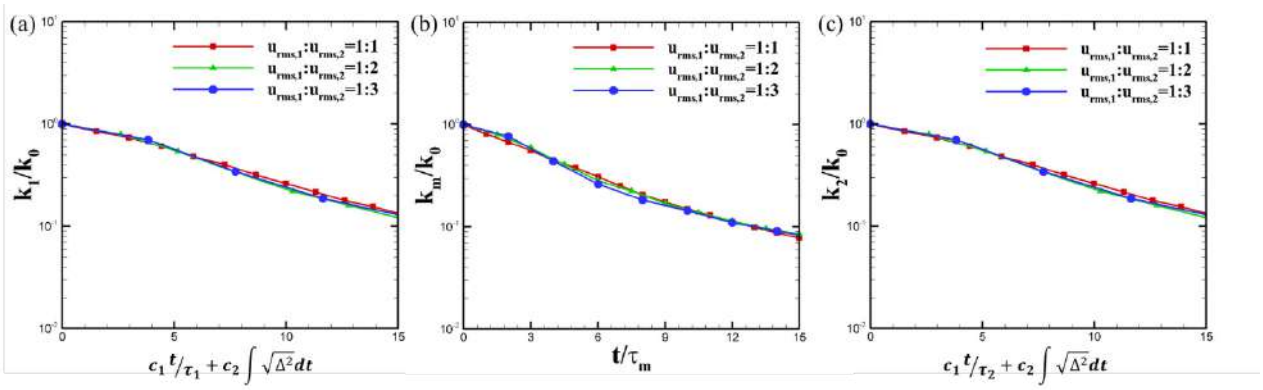

Figure 1. Turbulent kinetic energy averaged in (a) the left side, (b) mixing region and (c) the right side based on the mixing region as a function of the scaled time scale.

CONCLUSIONS

We present a scaling for the mixing region growth and TKE decay in compressible and inhomogeneous turbulent flow. Due to the inhomogeneity, the energy flux through interface plays a significant role in the compressible transport of TKE. Total TKE can be divided into the sum of TKE from the different regions separated by mixing region interfaces. The TKE decay agrees well with the proposed scaling. In the future, coefficients of the scaling will be parameterized and the formation of mixing region growth and decaying TKE completed.

SHOCK-LIKE STRUCTURES IN A SONIC VENTURI NOZZLE

B. Zebrowski *[1], P. Jordan[1], V. Jaunet[1], G. Lehnasch[1], R. Maury[2], and M. A. Lambert[2]

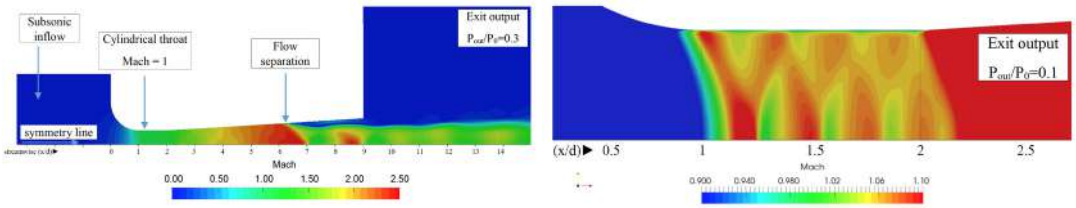
Summary A duct acoustic analysis is performed in the cylindrical throat of a sonic venturi nozzle, in order to understand shock-like structures observed in numerical simulations. The cylindrical throat is considered as an infinitely extended hard-walled duct, in which the flow is circulating at critical condition (Mach around 1). The analysis shows that a simple analytic model, depending only on the Mach number, is able to capture the periodic flow pattern observed in the simulations.

INTRODUCTION

Critical flow venturi nozzles are devices widely used for gas flow-rate measurement. From one-dimensional Euler equations, it is straightforward to show that the mass flow-rate only depends on the stagnation quantities of the incoming flow, the nozzle critical section and the gas thermodynamic properties. These devices are defined by international standard ISO9300 [1], which includes an empirical correction factor, the discharge coefficient C_d, that account for viscous and three-dimensional effects.

A recent investigation of cylindrical-throat Venturi nozzles has highlighted a flow topology in the cylindrical section of the venturi nozzle, in which a periodic flow pattern appears (Figure 1b) [2] .



(a) Overview (b) Throat region

Figure 1: Mach contour obtained via RANS simulation of ISO9300 standard cylindrical-throat Venturi nozzles. Throat diameter 10mm.

The present work is motivated by the understanding of the origin and the modeling of this flow pattern. Indeed, the successive compression/expansion of the flow may result in a specific behavior of the boundary layer growth, that may need to be accounted for in the modeling of the nozzle discharge coefficient C_d.

METHODOLOGY

The problem is considered using a duct-acoustics model. The configuration considered involves an inviscid, isentropic plug flow in an infinitely extended hard-walled cylindrical duct flow. Using the Reynolds decomposition and assuming that the pressure fluctuation can be described by a normal mode-ansatz

$$p'(x,r,\theta,t) = \hat{p}(r)e^{i(kx+m\theta-\omega t)}, \tag{1}$$

the linearized Euler equations around the base flow reduce to one equation for the pressure fluctuation [3] :

$$\hat{p}'' + \frac{1}{r}\hat{p}' + \left((\omega - Mk)^2 - k^2 - \frac{m^2}{r^2}\right)\hat{p} = 0, \tag{2}$$

where k is the wave number, m the azimuthal wave number, ω the frequency, r the dimensionless duct radius and M the Mach number in the throat. Solution to Equation (2) can be written in form of Bessel functions $\hat{p} = J_m(r\alpha)$, where $\alpha^2 = (\omega - Mk)^2 - k^2$ is the dispersion relation.

The flow pattern observed is assumed independent of time, we thus consider $\omega = 0$. The azimuthal wave number chosen for the study is $m = 0$. Introducing the wave length $\lambda = \frac{2\pi}{k}$ in the dispersion relation gives :

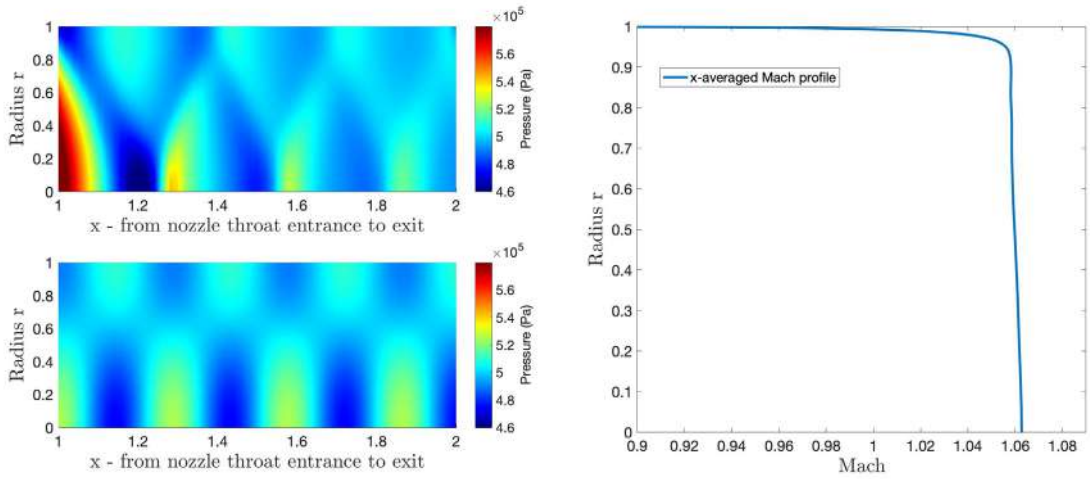
*Corresponding author. E-mail: bruno.zebrowski@ensma.fr.

$$\lambda_n = \frac{2\pi\sqrt{(M^2-1)}}{\alpha_n} \tag{3}$$

where values of α_n are found by imposing a Neumann boundary condition at the duct wall $\frac{\partial p}{\partial r}\Big|_{r=1} = J_0'(\alpha_n) = 0$, with n being the n$^{\text{th}}$ root of J_0'. Equation (3) is also known as Prandtl-Pack [4] shock cell model, which was first introduced to describe shock cells wave-length in jets. The difference is that, in the jet, a different pressure boundary condition is imposed to solve Equation (2).

RESULTS

A modelled flow field is obtained by superposing a uniform flow field, at the mean Mach number (averaged along the cylindrical throat region) of the simulated flow, and a the normal mode ansatz (1) for k at $n = 1$ and arbitrary amplitude. A comparison between the modelled flow field and the simulated one is given in Figure 2a.



(a) (b)

Figure 2: (a) Pressure in the cylindrical throat region. Top : RANS simulation (NPR = 10) - Bottom : first mode from duct-acoustics model for M = 1.06 (b) x-averaged Mach profile from RANS simulation in the throat region

As the flow pattern can only appear if the Mach number of the base flow is supersonic, this implies that the flow computed by the RANS simulation in the throat region is not sonic as we expect but slightly supersonic. This is illustrated in Figure 2b, where the spatially averaged Mach profile inside the throat is plotted. The Mach number is greater than 1.0 in the region of uniform flow, which is the result of the small inlet radius of curvature. Similar analysis has been done for several nozzle pressure ratio ($\frac{P_{in}}{P_0}$), the same conclusion is drawn from these results.

CONCLUSIONS

A duct acoustics analysis has been used to describe shock-cell patterns observed in RANS simulations of the ISO9300 standard cylindrical throat venturi nozzle. The results show good agreement between duct acoustics model and the RANS simulations. This information will be useful for the improvement of models of the discharge coefficient of cylindrical venturi nozzles.

CHARACTERISTICS OF ENTROPY LAYER FOR CONES AND CYLINDERS IN SUPERSONIC FLOWS

WANG Gang*, Xie Zhu-xuan, Yang Yan-guang
China Aerodynamics Research and Development Center, Mianyang 621000, China

Abstract: An analytic method is presented to study the distribution of vorticity downstream the shock wave and the characteristics of the entropy layer for various cones and cylinders in supersonic flows. The relations of shock-shape, the distribution character of various parameters within the shock layer, and the entropy increment were combined to obtain the characteristics of vorticity and the entropy gradient. Numerical simulation are performed at the Mach number of 3, 5 and 10. The results indicate that the distribution of entropy and vorticity is connected with shock shape directly. Due to the differences of the shape of shock, the vorticity and the extreme value of entropy gradient for blunt-nosed cylinders are both larger than the cases for flat cylinders. As the shock-shape of flat-nosed cylinders is more liable to be affected than blunt-nosed cylinders with increasing Mach number, the position of the extreme value moves to the surface as the Mach number increases for flat-nosed cylinders, while it remains the identical value for blunt-nosed cylinders. The vorticity is regarded as the criterion of the edge of entropy layer in the normal direction, and two methods are proposed and discussed to estimate the edge.

Keywords: Entropy layer; Vorticity distribution; Supersonic flows; Blunt-nosed cylinder.

Methods

Entropy gradient as the streamlines just flow across the shock wave:

$$\frac{\mathrm{d}s}{\mathrm{d}\bar{y}} = f(M_\infty, \overline{R_c}, \bar{y}, \beta) \tag{1}$$

$\mathrm{d}s/\mathrm{d}\bar{y}$ is relatively complicated which may occupy the space, but it is not difficult to illustrate the expression. In particular, for a calorically perfect gas within the shock layer, the specific heats at constant pressure c_p is constant as

$$c_\mathrm{p} = \frac{\gamma}{\gamma - 1} R_\mathrm{con} \tag{2}$$

Then, Eq.(1) is to be written as

$$\frac{\mathrm{d}s}{\mathrm{d}\bar{y}} = -\frac{4\gamma \overline{R_\mathrm{c}}^2 R_\mathrm{con} cos^4\theta}{\sin^2\theta} \frac{(M_\infty^2 \sin^2\theta - 1)^2}{(2\gamma M_\infty^2 \sin^2\theta - \gamma + 1)[(\gamma - 1)M_\infty^2 \sin^2\theta + 2]} \tag{3}$$

Entropy distribution behind the shock wave

$$\delta s = s - s_\infty = \int c_\mathrm{p} \frac{\mathrm{d}T}{T} - R_\mathrm{con} ln \frac{p}{p_\infty} \tag{4}$$

s is the entropy at a given temperature T and pressure p, and s_∞ is the entropy of incoming flow.

The entropy layer introduces a large amount of rotationality into inviscid flows over bodies, as can be quantitatively obtained from Crocco's theorem, which could be written as follows

$$\frac{\partial \vec{u}}{\partial t} - T\nabla s + \vec{w} \times \vec{u} + \nabla h_0 = 0 \tag{5}$$

In Eq.(5), $\vec{u}$ is the local velocity vector along the streamline; h_0 is the total enthalpy. For steady and adiabatic flows, h_0 is constant, and hence $\nabla h_0 = 0$. The vorticity $\vec{w}$ is related to the entropy gradient ∇s normal to a streamline

$$T\nabla s = \vec{w} \times \vec{u} \tag{6}$$

In Eq.(6), $\nabla s = \frac{\mathrm{d}s}{\mathrm{d}n}\vec{n}$, in which $\vec{n}$ is perpendicular to the local surface, hence

$$\frac{\mathrm{d}s}{\mathrm{d}n} = \frac{1}{\cos\alpha}\frac{\mathrm{d}s}{\mathrm{d}\bar{y}} \tag{7}$$

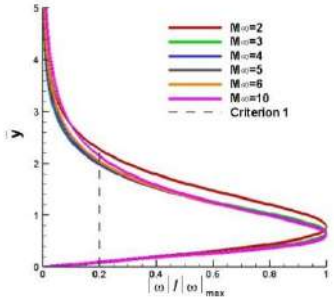

Fig.6 Distribution of $|\omega|/|\omega|_{max}$ for blunt-nosed cylinder

Conclusion

An method for estimating the distribution of entropy and vorticity for blunt-nosed cones and flat-nosed cylinders has been developed. The distribution of entropy increase, entropy gradient, and the vorticity are all related to the shape of shock waves directly. As the shock-shape of flat-nosed cylinders is more liable to be influenced than blunt-nosed cylinders with increasing Mach number, the position of the extremum moves to the surface as the Mach number increases for flat-nosed cylinders, while it nearly remains the identical value for blunt-nosed cylinders. Two hypotheses to define the edge of the entropy layer in the normal direction are proposed and the results have been discussed in detail. Although the method for defining the edge of the entropy layer is still open, it should be on the basis of the distribution of vorticity. What is more, the distribution of the entropy gradient and also the distribution of vorticity decreases slightly as the cone angle increases.

NUMERICAL INVESTIGATIONS OF HIGH MACH NUMBER SHOCK / VORTEX INTERACTION

Wang Conglei
HONGGUANG AIRBORNE EQUIPMENT CO., LTD., Nanjing, China

Summary The effect of shock Mach number from 1.2 to 3.0, on the interaction between shock wave and vortex has been numerically investigated using seventh order weighted essentially non-oscillation finite difference scheme. Because of the increasing of the shock wave strength, the higher Mach number shock interacted with vortex produces larger local supersonic area and more shear layers. Results show that the counter rotating vortex moving downward after interacted with shock. When shock Mach number increases enough, there is a new vortex generated by the escaped shock appeared up to the original vortex core and disappeared at last. Furthermore, double two-layer Lamb vector divergence structures exist in the higher shock Mach number cases and only one in the lower Mach number cases, which indicate shear layers appear in these positions.

The interaction between shock and turbulence is an important phenomenon in supersonic flow, and the interaction between shock and vortex is an important part of the interaction between shock and turbulence, which exists widely in high-speed compressible flows. The aerospace field has a wide range of application backgrounds, such as applications such as supersonic engines, supersonic aircraft and rapid inflation of inflatable structures. To date, a wide range of experimental studies [1,2], theoretical analysis [3,4], and numerical simulations [5,6] have been carried out for the problem of shock wave and vortex interaction. The related research on the mechanism of shock wave and vortex train and the interaction between shock wave and strong vortex [7,8]. Although there have been many studies on the interaction between shock waves and vortices, little attention has been paid to the interaction between high Mach number shock waves and strong vortices. The flying Mach number is mostly greater than 2.0. Therefore, in this paper, the interaction between shocks with Mach number 1.2-3.0 and strong vortex with Mach number 1.2 is studied and analysed. The changes of the strong vortex structure under the action of shocks with different Mach numbers are demonstrated. The motion and deformation of vortex and the change of vorticity under shock are researched and analysed, and the important influence of shock intensity on vorticity generation and transportation is revealed. Furthermore, the flow mechanism of vortex motion and deformation under shock of different Mach numbers is discussed.

Mathematical formulation and numerical method

Euler equation in conservative form can be expressed as:

$$\frac{\partial \boldsymbol{Q}}{\partial t}+\frac{\partial \boldsymbol{F}}{\partial x}+\frac{\partial \boldsymbol{G}}{\partial y}-\frac{1}{Re}\left(\frac{\partial \boldsymbol{F}_v}{\partial x}+\frac{\partial \boldsymbol{G}_v}{\partial y}\right)=0 \tag{1}$$

Where, $\boldsymbol{Q}$ is the conservation variables. $\boldsymbol{F},\boldsymbol{G},\boldsymbol{F}_v,\boldsymbol{G}_v$ are conservation fluxes. Re is the Reynolds number. x and y are the coordinates. t is time. These equations are numerically solved by a seventh-order weighted essentially non-oscillatory scheme for the convective terms and sixth-order central difference scheme for the viscous terms. The temporal integration is performed using a fourth-order Runge-Kutta algorithm.

Results and discussion

In this section, computational results for the cases including both the subsonic vortex case and supersonic vortex case are presented. The shock structure and its relation with the shock and vortex strengths are discussed.

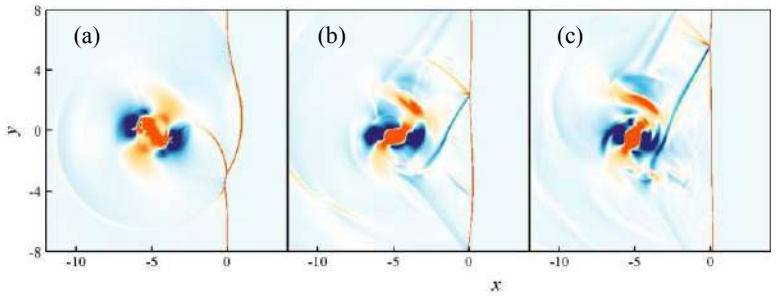

Fig. 1 Vortical structures by iso contours of the Q-criterion in different cases

To exhibit the coherent structures in the flow field, Fig. 1 shows instantaneous snapshots of the flow field depicted by iso-surface of the Q criterion. The deformation of the vortex structure is smaller than that under high Mach number shock conditions. As shown in Fig. 2, with the increase of the Mach number of the shock wave, the vorticity increases when passing through the shock wave is larger, and the vortex amount decreases after leaving the shock wave. Comparing the interaction of shocks and vortices with different Mach numbers, when the shock Mach number is less than 1.6, there are two double-layered structures connecting the vortex and shock above the vortex center. When the shock Mach number is higher than 1.6, a three-layer structure connecting the lower edge of the vortex and the shock appears, indicating that,

the momentum transport mechanism is obviously different from the momentum transport mechanism under the condition of shock wave of small Mach number. It can be found that the vorticity transport mechanism changed significantly when the shock Mach number was greater than 1.6. As shown in Fig. 5, that under the action of low and medium Mach number shocks, only one shear layer appears here. Under the action of shock waves with Mach number greater than 1.6, multiple shear layers appear here.

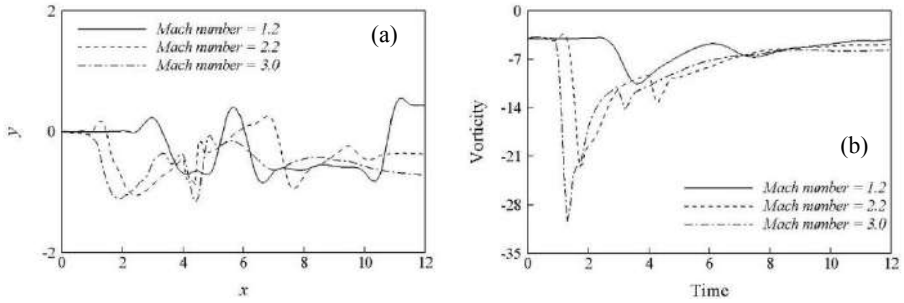

Fig. 2 Trajectory of vortex core and vorticity variation

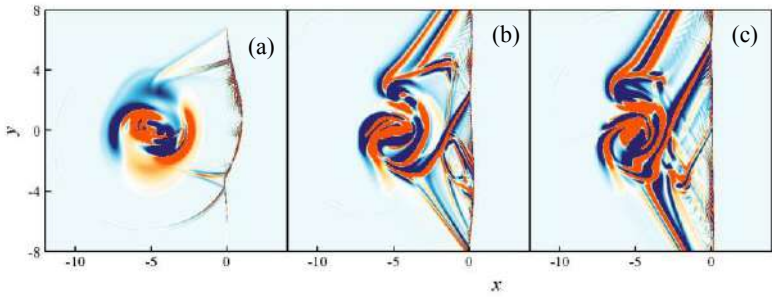

Fig. 3 Variables distribution of flow field in different cases at dimensionless time 0.25

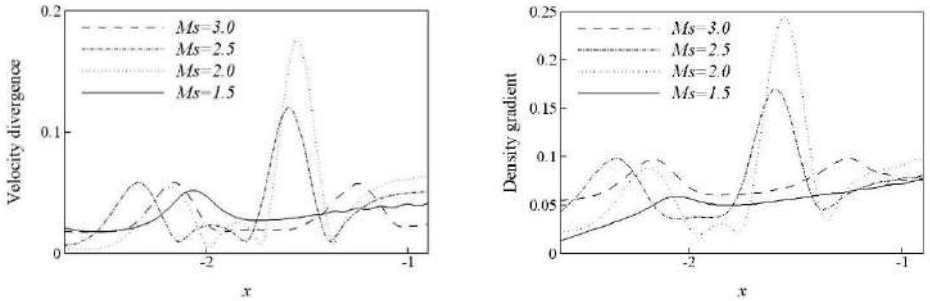

Fig. 5 Velocity divergence and density gradient distribution

CONCLUSIONS

In this paper, a direct numerical simulation method based on the 7th-order WENO algorithm based on eigen decomposition is used to study the interaction between shocks with different Mach numbers and vortices. The flow field appears significantly different from the flow structure under the condition of the interaction between the low Mach number shock and the vortex. Increasing the shock Mach number will increase the vortex core oscillation and increase the vorticity dissipation. When the shock Mach is higher than 1.6, after the vortex interacts with the shock wave, a small vortex will be induced due to the generated shock wave different from the shock condition of the low Mach number shock wave. And in the process of high Mach number shock and vortex, a three-layer structure of Lamb vector divergence and vorticity will appear.

ENTROPY GROWTH IN VISCOUS BINARY MIXTURE SHOCK WAVE

Damir Madjarević[1] and Srboljub Simić *[2]
[1] Department of Mechanics, Faculty of Technical Sciences, University of Novi Sad, Novi Sad, Serbia
[2] Department of Mathematics and Informatics, Faculty of Sciences, University of Novi Sad, Novi Sad, Serbia

Summary Entropy growth across the shock wave appears as jump when the shock waves are modelled as singular surfaces. When the dissipation is included in the model, jumps of field variables are smoothed out into a continuous shock structure. However, in contrast with expectations, classical Navier-Stokes-Fourier model of gas dynamics exhibits non-monotonic growth of entropy density along the shock profile. The present study investigates the entropy growth in a dissipative model of binary mixture. It shows that internal viscous and thermal dissipation within constituents is insufficient to keep monotonic growth of entropy density, as it was in a single-component gas, but has to be further enhanced.

INTRODUCTION

Shock waves in classical gas dynamics are regarded as propagating singular surfaces on which jumps of the field variables occur. They are related to the speed of propagation of the shock wave through Rankine-Hugoniot relations—localized consequences of the governing conservation laws. It is well-known that Rankine-Hugoniot relations admit multiple solutions for the same value of the shock speed in supersonic, as well as in subsonic regime. Under these circumstances one must have an additional selection rule that distinguishes physically admissible solutions from the ones that are not. The entropy growth condition is one of the accepted criteria that selects supersonic jumps as admissible ones.

When the dissipation is included in the model, e.g. viscous dissipation of Navier-Stokes kind and thermal dissipation of Fourier kind, the jumps of field variables are smoothed out and transformed into a continuous shock structure (shock profile) asymptotically connecting the equilibrium states determined by the Rankine-Hugoniot relations. It is then expected that smoothed entropy profile grows monotonically along the shock structure. However, in contrast with expectations, classical Navier-Stokes-Fourier (NSF) model of gas dynamics exhibits non-monotonic growth of entropy density along the shock profile [1]. This result had been proved to be consistent with the basic modelling assumptions of classical irreversible thermodynamics [2].

Recent studies of the aforementioned unexpected behaviour suggested a possible resolution to the problem [3]. Instead of using the classical equilibrium entropy density, compatible with classical assumption of local thermodynamic equilibrium, it is proposed to exploit the kinetic entropy (as suggested in the kinetic theory of monatomic gases) and to determine its approximate macroscopic form using Grad's approximation and NSF constitutive relations. Such an entropy density increases monotonically along the shock profile.

This study is a part of the ongoing project in which we analyze the entropy growth across the shock wave for different dissipative models of gas dynamics. So far, it was shown [4] that in the multi-velocity and multi-temperature mixture of Euler fluids, a properly defined entropy grows monotonically. The purpose of this study is to extend the model with internal viscous and thermal dissipation and analyze the entropy growth across the shock wave

THE MODEL OF THE MIXTURE

The multi-temperature model of the mixture is built up within the framework of Rational Extended Thermodynamics [5] and consists of balance laws of mass, momentum and energy for each constituent. The state variables of the $n-$component mixture are the density ρ_α, the velocity $\mathbf{v}_\alpha$ and the temperature T_α of each constituent, $\alpha = 1, \ldots, n$. It will be assumed that constituents are not chemically reacting, so that mass of each constituent is conserved. The balance laws of momentum and energy contain the source terms that describe the mutual interaction between the constituents, i.e. exchange of momentum and energy. They present the source of dissipation, and determine the entropy production rate in the case of Euler fluids. Such a system is hyperbolic in the whole state space.

Concerning the model, few remarks are in order [6]: (a) closure of the model is achieved by the application of the entropy principle and Liu's procedure; (b) no prior assumption about local equilibrium was made; (c) entropy density of the mixture is sum of the partial entropy densities, $\rho S = \sum_\alpha \rho_\alpha S_\alpha$; (d) partial specific entropies satisfy partial Gibbs' relations (for constituents), $T_\alpha \mathrm{d}S_\alpha = \mathrm{d}\varepsilon_\alpha + p_\alpha \mathrm{d}(1/\rho_\alpha)$.

This model, even when restricted to Euler fluids, is capable of capturing highly non-equilibrium behaviour through the constituent-related velocity and temperature state variables. In previous studies [7] it was shown that shock structure in binary mixture of Euler fluids exhibits the behaviour that is qualitatively in agreement with the results of kinetic theory of mixtures: in the case of insufficient energy exchange between the constituents, there appears a temperature overshoot of the heavier constituent. Recent study [4], concerned with the entropy growth and entropy production rate in binary mixture shock waves, revealed that mixture entropy density grows monotonically across the shock wave, whereas entropy densities of the constituents may have non-monotonic profiles.

*Corresponding author. E-mail: ssimic@uns.ac.rs.

In this study we enhance the model of binary multi-temperature mixture by taking into account internal viscous and thermal dissipation, and analyze the entropy growth across the plane shock wave. Constitutive relations for viscous stresses and heat fluxes are taken in the classical NSF form for each constituent [8]. The entropy density is also enhanced in the spirit of [3], starting from generalized Grad's velocity distribution for mixtures and incorporating non-equilibrium terms—viscous stresses σ_α and heat fluxes q_α [9]:

$$\rho S = (\rho S)_{\mathrm{Eul}} - \sum_\alpha \left(\frac{3}{8 p_\alpha T_\alpha} \sigma_\alpha^2 + \frac{\rho_\alpha}{5 p_\alpha^2 T_\alpha} q_\alpha^2 \right), \tag{1}$$

where $(\rho S)_{\mathrm{Eul}}$ is the entropy density for mixture of Euler fluids.

PRELIMINARY RESULTS AND DISCUSSION

Shock profiles are numerically computed assuming the travelling wave profile, reducing the model to a system of ordinary differential equations. The solutions asymptotically connect upstream and downstream equilibrium states, related through Rankine-Hugoniot equations for the mixture.

Numerical computations are performed for two particular cases, that differ in the values of upstream Mach number—$M_0 = 1.3$ (Figure 1, graphs (a) and (b)) and $M_0 = 1.6$ (Figure 1, graphs (c) and (d))—while the equilibrium mass concentration of the lighter constituent $c_0 = 0.25$, and the mass ratio of the constituents $\mu = 0.1$, are the same. On graphs (a) and (c), T_1 and T_2 are the dimensionless temperatures of lighter and heavier constituent, respectively, while T is the average dimensionless temperature. For the purpose of comparison, the profiles are presented both for inviscid (mixture of Euler fluids, curves indicated by 1) and for viscous case (curves indicated by 1). In the inviscid case, the entropy density for the mixture of Euler fluids increases monotonically. However, in the viscous case both Eulerian and non-equilibrium entropy density (1), based upon Grad's distribution, have non-monotonic profiles.

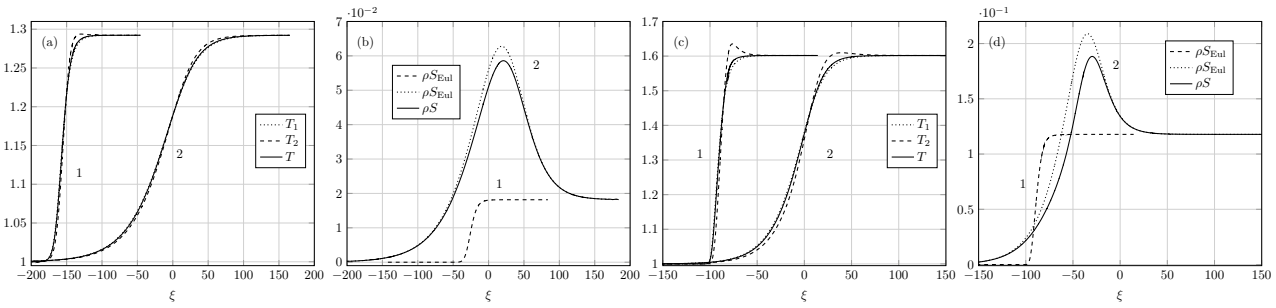

Figure 1: (a) Temperature profiles for inviscid (1) and viscous (2) case, $M_0 = 1.3$; (b) Entropy density profiles for inviscid (1) and viscous (2) case, $M_0 = 1.3$; (c) Temperature profiles for inviscid (1) and viscous (2) case, $M_0 = 1.6$; (d) Entropy density profiles for inviscid (1) and viscous (2) case, $M_0 = 1.6$.

The results of this study show that internal dissipation is insufficient to bring monotonicity to the entropy density within the shock structure, although such a simple extension of the model showed remarkable agreement with the profiles of state variables obtained by the kinetic theory of mixtures [10]. They also suggest that the method proposed in [3] cannot be extended by an *ad-hoc* procedure to mixtures, although it is physically motivated. Instead, it has to be put into broader context that will take into account mutual influences of the constituents on the partial fluxes of momenta and energy. This delineates the framework of our ongoing research.

LES OF H2/N2 TRANSCRITICAL COAXIAL INJECTION

Raffaele Olmeda *[1] and Christian Stemmer[1]
[1] Lehrstuhl für Aerodynamik und Strömungsmechanik, Technische Universität München , Boltzmannstr. 15, 85748 Garching b. München

Summary In modern rocket engine applications, propellant and oxidizer are injected in the combustion chamber at high pressures and low temperatures often close to their critical conditions. The prediction of the flow thermodynamic behaviour close to the injector plate is challenging due to the difficulties associated to produce reliable experiments and simulations for these scenarios. In particular, when the oxidizer enters the combustion chamber in a subcritical state, two-phase thermodynamic states must be taken into account. In the present work 3D LES simulations will be carried out to study the coaxial injection of gaseous hydrogen and subcritical nitrogen. The focus of the work will be on the density evolution of the flow in direction parallel and perpendicular to the injection. The influence of two-phase thermodynamic on the flow behaviour will be evaluated.

INTRODUCTION

To run CFD simulations of transcritical injection, several challanges need to be tackled. Since propellant and oxydizer are close to the critical point, Van der Waals forces become relevant and a real-gas Equation of State is necessary. Furthermore, the schemes used to numerically solve the governing equations must be robust enough to compute the huge gradients typical for the region close to the critical point. In particular, the pressure coefficient shows a peak along the pseudo-boiling line that exponentially increases the thermal fluxes in the shear layer between the two substances. Moreover, during the simulation the hypothesis of equilibrium of the mixture may not hold anymore in some points. In this case, a two-phase thermodynamic state must be considered, risking otherwise to misrepresent the density development right after the injector. LES simulations of a two-species jet are performed in order to study the behaviour of transcritical mixing. The computations are carried out in the attempt to correctly represent the shape of the jet and the density evolution downstream of the injector.

SETUP

The case analysed is described by Oschwald [1] (see Fig. 1). A reservoire initially contains nitrogen at 4 MP and 298 K. Nitrogen and hydrogen are injected through a coaxial injector. In the inner element, nitrogen is injected at 118 K, below its pseudo-boiling point. Hydrogen is injected from the external anulus at 270 K. The evolution of the jet has been studied experimentally by means of 2D-Raman density measurements. The choice of N2 and H2 attempts to recreate the condition of an operating rocket engine. O2 has been substituted with N2, which is close in atomic weight, to avoid chemical reactions and focus on the aspect of transcritical mixing. Preliminary simulations are run with a splitter plate setup. A 2D mesh is expanded in the third cartesian direction with a periodic boundary condition. In a second phase, simulations are performed in a full 3D domain.

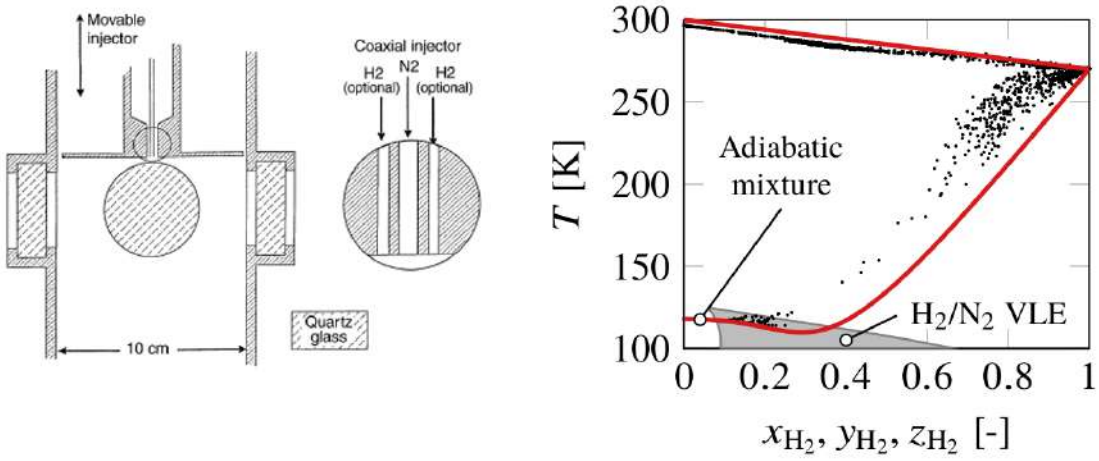

Figure 1: Experimental setup of Oschwald (left) and scatter plot of molar fraction/temperature for the mixture (right).

*Corresponding author. E-mail: raffaele.olmeda@tum.de.

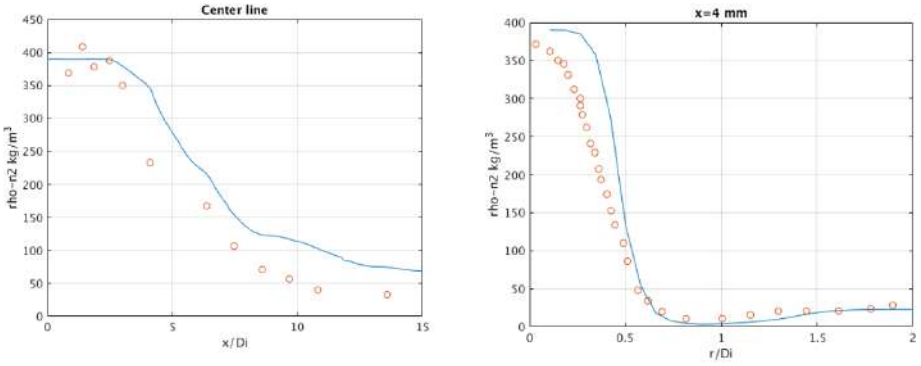

Figure 2: Nitrogen partial density profile along the central injector line (left) and in radial direction for x= 4 mm (right).

NUMERICAL METHODS

LES simulations are performed with the software CATUM [2], an in-house code developed in the Chair of Aerodynamic of the Technical University of Munich. It solves a finite volume form of the Navier-Stokes equations. A second-order scheme is used for the diffusive fluxes. Central difference or upwind are used for the convective fluxes depending on the local stability of the flow. The Peng-Robinson cubic equation of state is used to represent real-gas thermodynamics. It has been tested against the Soave Redlich Kwon EoS and proven to be superior for this test case. Since nitrogen is injected at a subcritical state, a two-phase subroutine is also necessary. As can be seen in Fig. 1, the scatter plot of of mass fraction versus temperature shows points in the two-phase region of the diagram. A Vapor-Liquid Equilibrium (VLE) method is adopted in order to correctly compute the points in this region.

PRELIMINARY RESULTS

Simulations have already been carried out with the mesh of the splitter setup. The results obtained have been compared with the experimental data and can be seen in Fig. 2. For the profile of nitrogen partial density in longitudinal direction, very good accuracy has already been obtained close to the injector. Going further downstream, there is a divergence from the experimental data which is expected to diminish increasing the mesh resolution and using the full 3D setup. For the profile in the radial direction instead, excellent accordance is found for $r/D > 0.5$. Close to the center of the injector the results are less precise. Is believed the error is caused from a delayed mixing of inner nitrogen core with the outer hydrogen layer. Also in this case, the results are expected to improve with a mesh convergence study and full 3D representation, which will compute correctly the turbulent fluctuations of the jet, accelerating the mixing.

SELF-INDUCED OSCILLATIONS OF THE SHOCK STRUCTURES IN A HYPERSONIC FLOW OVER DOUBLE WEDGE

Gaurav Kumar and Ashoke De *
Department of Aerospace Engineering, Indian Institute of Technology, Kanpur, UP, India - 208016

Summary This study investigates the presence of self-induced oscillations of shock structure in a hypersonic flow over a double wedge. Previously, this flow configuration has been numerically studied for inviscid flow with variations such as inflow Mach number (M_∞), wedge angles and wedge lengths. The current work seeks out to investigate this unsteady viscous self-induced periodic oscillations of shock structure in a low enthalpy, M_∞=7 viscous flow over a double wedge which has a fore wedge angle of 30°. A numerical error controlled fluid solver is used to investigate the double wedge flow. The current findings are in accordance with the previously published results for these parameters as the flow structures do not settle down to a steady-state in the long term. However, a more resolved study has revealed a broader bandwidth of frequency associated with the higher harmonics.

INTRODUCTION

Due to shock-shock and shock-boundary layer interaction, an enormous amount of mechanical and thermal load can be generated in hypersonic flows over surfaces containing corners which is dangerous for the structural integrity of the vehicle. Such configurations are ubiquitous in various internal as well as external flows such as control surfaces of aircraft and rockets and scramjet intakes. A comprehensive study of such shock-shock interactions for inviscid diatomic perfect gas ($\gamma = 1.4$) over double wedge at Mach number(M_∞)=9, fore to aft wedge length ratio(L_1/L_2)=1, fore angle of the wedge(θ_1) =15° and a varying range of second wedge angle(θ_2) is available in ref.[1]. The study shows the transition of shock-shock interaction type from type VI → V → IV → IVr as θ_2 increases from 35° to 60°. The study reveals a many-fold increase in pressure load as the type of shock interaction varies. In ref.[2], the same configuration is shown to exhibit a self-induced oscillation of the shock system in a range of $42 < \theta_2 < 43$ where L_1/L_2=2 is used. A high resolution numerical study was performed in ref.[3], where $M_\infty = 7$ and 9 was simulated over a double wedge with $\theta_1 = 15°$ and L_1/L_2=2. They have considered the variation of γ with temperature, but the flow was still assumed to be inviscid. A difference in θ_2 was observed compared to ref.[2] where self-induced oscillations occur, and it was demonstrated that the difference was due to the difference of gas model used and not due to the numerical resolutions or schemes. A viscous dissipation was expected to damp down such oscillations due to change in flow topology, but no detailed viscous computations were carried out due to numerical difficulties.

In ref.[4], a fully viscous computation was performed on double wedge configuration at M_∞=7, θ_1=30°, L_1/L_2=2 and $45° < \theta_2 < 60°$ with temperature-dependent gas model. This simulation was in accordance with the experimental setup in ref.[5] and a good agreement of thermal loading on the wedges was obtained. A long-time transient simulation had revealed the presence of time-periodic shock configuration in the range of $\theta_2 > 47°$. For the computations performed in ref.[4], a density-based compressible flow solver called *rhoCentralFoam*[6] was used in OpenFOAM[7] framework which is second-order accurate in space and first-order accurate in time. Also, it has been observed that rhoCentralFoam produces oscillatory solutions for not very small CFL number (>0.2). Due to this, a new improved *rhoCentralFoam* solver called *kanpurCentralFoam* (so named because code developed at IIT Kanpur) is developed which has eliminated such instability up to CFL=1.0. This solver uses a third-order TVD Runge-Kutta time integration method with the spatial discretization of *rhoCentralFoam*. Also, an improved operator-splitting method has been utilized here instead of the sequential operator-splitting method used in *rhoCentralFoam*, which further adds to the stability of the solution. Numerical methods used are briefly summarized in the next section.

NUMERICAL METHODS

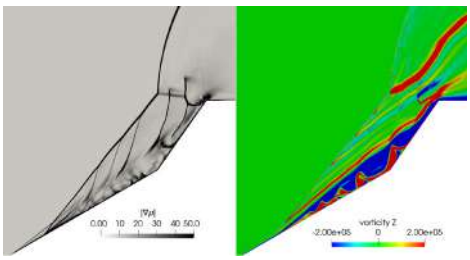
The conservation equations for mass, momentum, and energy for a fluid control volume $d\Omega$ enclosed by surface $\partial\Omega$ is given by eq. (1), where $\vec{W} = [\rho \quad \rho\vec{u} \quad \rho E]^T$ represents mass density, linear momentum and total energy of the control volume. Here, $\vec{F_c}$ and $\vec{F_\nu}$ are convective flux and diffusive flux, respectively. A thermally perfect gas relation, $p = \rho RT$ is used for state equation. The calorical properties of the gas is assumed to be temperature dependent and the variation with temperature is accounted using JANAF tables[8]. The Sutherland relation is used to account for the variation of diffusion parameters (μ and κ).

$$\frac{\partial}{\partial t}\int_\Omega \vec{W} d\Omega + \oint_{\partial\Omega} (\vec{F_c} - \vec{F_\nu}) dS = 0 \tag{1}$$

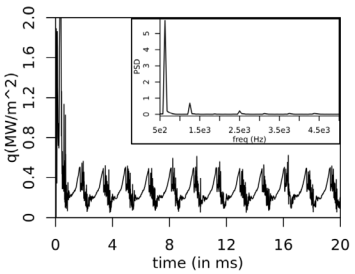
*Corresponding author. E-mail: ashoke@iitk.ac.in.

RESULTS

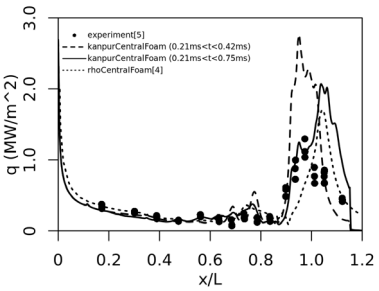
The new solver developed has been validated extensively for a wide range of flow conditions to demonstrate good time accuracy, dispersion and dissipation properties. But, for the brevity of the paper only simulation of double wedge configuration of ref.[4] at $M_\infty = 7$, $L_1 = 50.8$ mm, $\theta_1 = 30^\circ$ and $\theta_2 = 55^\circ$ is shown here. The domain is chosen in accordance with ref.[4, 5]. For removing any obstruction created by the outlet boundaries, the top boundary is placed at a distance of $1.5L_1$ above the wedge, and the right outflow boundary at $0.75L_1$ and a non-reflecting boundary condition is applied. A fixed velocity, pressure and temperature condition is provided at the inlet as used in ref. [4, 5]. A no-slip isothermal wall boundary condition is applied at both the wedge surfaces with wall temperature ($T_w = 300$K). A high resolution structured grid is finalized based on systematic grid comparison study with first cell size normal to the wall (Δy_w) $= 5\ \mu m$ and cells near shock-shock interaction region (Δ) $= 0.127$ mm. The simulations are run at a CFL no. 1.0 ($\Delta t \approx 2$ ns) for 20 ms, which is much longer than the experimental time and long enough after the flow becomes periodic.



(a) Density gradient and span-wise vorticity contours at t=11.8 ms



(b) Time history and PSD of wall heat flux (Middle of 2^{nd} wedge)



(c) Averaged wall heat flux

Figure 1: Computed results of double wedge flow, $M_\infty = 7$, $\theta_1 = 30^\circ$, $\theta_2 = 55^\circ$.

Figure 1 shows the simulated results for the above case. In fig. 1a, density gradient and span-wise vorticity field are plotted for t = 11.8 ms where all the shock interaction pattern can be seen along with a large separation region at the wedge corner. A seven shock structure is formed at the end of the second wedge. However, the overall shock structure is deformed and transient due to the interaction with shocklets originating from the separation region. Fig. 1b shows the unsteady wall heat flux at the middle of the 2^{nd} wedge surface, which becomes periodic after 1 ms and has been visually observed through flow contours as well. Due to the higher-order time integration method used, high-frequency oscillations are also resolved. Fig. 1c shows the variation of average wall heat flux along the wedge surfaces, and it has been compared with the experimental results of ref.[5] and numerical results of ref.[4]. A good match with the experimental data is observed except at the location of the peak value of wall heat flux. The location of the peak from ref.[4] is also seen to have mismatch compared to the experiment[5]. This is due to the difference in the time window for averaging, which cannot be matched with the experiment as the flow does not become steady with time and experiments were conducted for a small time window.

CONCLUSIONS

A new solver developed in OpenFOAM framework called *kanpurCentralFoam* is designed to be stable and accurate for an application in hypersonic flow calculations. It is capable of providing more accurate results to its predecessor *rhoCentralFoam*. An accurate simulation carried out in this study reveals the presence of time-periodic self-induced shock oscillation as predicted earlier. A high order time integration method has revealed a larger band of frequency near the impingement point, which was lost in the previous numerical studies.

EFFECT OF SURFACE CONDITION ON OBLIQUE SHOCK REFLECTION

Susumu Kobayashi[1] and Takashi Adachi [1]
[1] Department of Mechanical Engineering, Saitama Institute of Technology, Saitama, Japan

Summary To investigate the effect of surface condition (permeability and surface roughness), a series of experiment using a shock tube has been performed. We used a sintered metal plate as porous material. To compare the effect of permeability and that of surface roughness, we also carried out the experiment using wedge models with surface roughness. The incident shock Mach number was 1.30 and the reflecting wedge angle was 36 deg. The results for surface roughness of #240 are almost the same with those for smooth surface, and dynamic transition was not apparent. However, as to the results for surface roughness #30, dynamic transition was observed. In the case of reflection over a sintered metal plate, it was demonstrated that the effect of permeability was added to that of surface roughness.

INTRODUCTION

When a plane shock wave impinges on a plane solid slope, oblique shock reflection phenomenon occurs. The reflection configuration is roughly classified into two, i.e., regular reflection (RR) and Mach reflection (MR). Regular reflection is composed of two shock waves, the incident shock wave and the reflected shock wave. Mach reflection is composed of three shock waves, the incident shock wave, the reflected shock wave and the Mach stem. These three shocks have an intersection called triple point. From the triple point, there appears a slipstream (velocity discontinuity).

In the analysis of the phenomenon, von Neumann presumed 2-D steady inviscid non-heat-conducting uniform flow divided by discontinuities (shock waves and a slipstream). To make the system steady, he took the coordinate system with respect to some reference point. In the case of RR, a reflection point, where the incident shock touches the slope, is taken as the reference point, and his theory is called two-shock theory, since only two shock waves are concerned. While, in the case of MR, the triple point is taken as the reference point, and the theory is called three-shock theory since three shock waves are involved.

After von Neumann's theoretical study, oblique shock reflection phenomena have been investigated so much both numerically and experimentally. In the absence of viscosity and heat-conductivity (transport properties), the system of the phenomenon involves no characteristic length, and so it is considered to be self-similar. As a result, the reflection configuration does not change during the propagation of incident shock wave. For a fixed incident shock Mach number M_i, there exists some slope angle θ_{tr} which borders RR and MR, and below this angle the reflection is MR and above this angle RR. This angle is called transition wedge angle [1].

The authors' past research revealed that for the wedge angle θ_w slightly below θ_{tr}, transition from RR to MR occurs during the incident shock propagation [2]. This is evidently the case when the self-similarity does not hold. This means that the transport properties of fluid play an important role. In fact, the oblique shock reflection under low-pressure atmosphere exhibits this phenomenon [3]. This is because the effect of viscosity is enhanced when the pressure is low (high kinematic viscosity).

In the present paper, the authors' interest lies in the effect of surface condition over the dynamic transition. In von Neumann's two-shock theory, he assumed that the velocity behind the reflected wave is parallel to the reflection surface. This is reasonable when the slope material is not a deformable material. However, when the material is porous, the fluid can pass through it, and thus the velocity component perpendicular to the surface is allowed. We utilized a sintered metal (bronze) plate as reflection surface. Porous material has intrinsically surface roughness, and it was proved by our past experiment that the surface roughness acts to delay the dynamic transition [4]. We also performed experiments with models with surface roughness, and compared the results to investigate the effect of permeability.

EXPERIMENTS

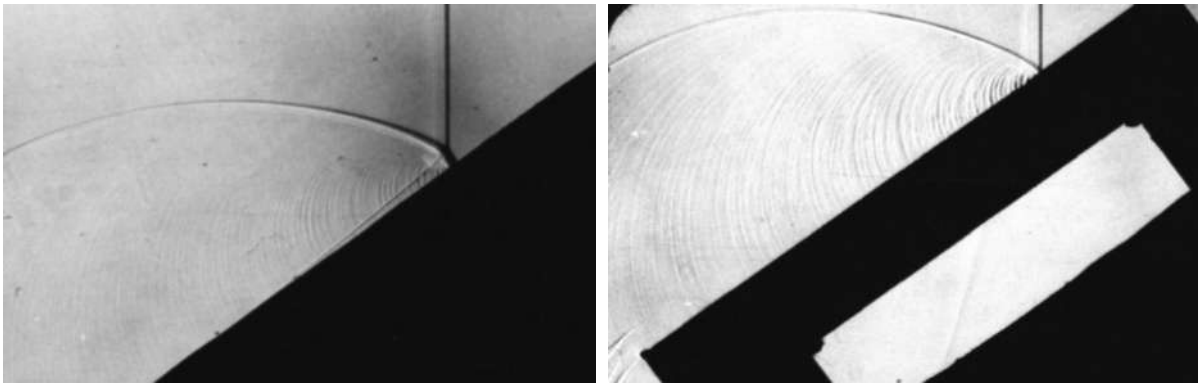
A series of experiment has been performed using a shock tube in our institute. Wedge models are made of brass and their surface were polished with #2000 sandpapers. For the porous plate, a C-shaped attachment was prepared to observe transmitted wave behaviour as a bi-product of the present investigation. The thickness of the sintered plate was 9 mm and its length was about 62 mm. The sintered metal was made of bronze spherical particles whose diameter ranges roughly from 500 μm to 710 μm, and the surface roughness corresponds to #30 sandpaper. The porosity ranges from 25 to 43%. To compare the effect of permeability with that of surface roughness, we prepared wedge models with surface roughness by pasting a sheet of sandpaper (#240 and #30). The incident shock Mach number M_i was 1.30, meaning that all the utilized data is in the range of $1.295 \leq M_i < 1.305$. The reflecting wedge angle θ_w was 36°.

Wave configuration was visualized by shadowgraphy. Light source was a xenon flash lamp with the pulse width of 180 ns. Two pressure gauges (300 mm apart) are installed ahead of the test section to estimate the incident shock Mach number. The output from the gauge nearer the test section triggers the light source via a delay circuit. By regulating the delay timer, we can obtain images at various instant. In measurement, the origin O is taken as the tip of reflection surface, and along the surface the ξ-axis is taken and the η-axis is taken perpendicular to it. Location (ξ, η) of reflection point P and triple point T was measured by using a profile projector (V-12, Nikon) from negative films. Both points are defined by the intersection of the high-pressure edge of the visualized incident shock and the low-pressure edge of the reflected wave. Accordingly, due to the thickness of visualized wave front, η can be positive even if reflection is regular.

RESULTS

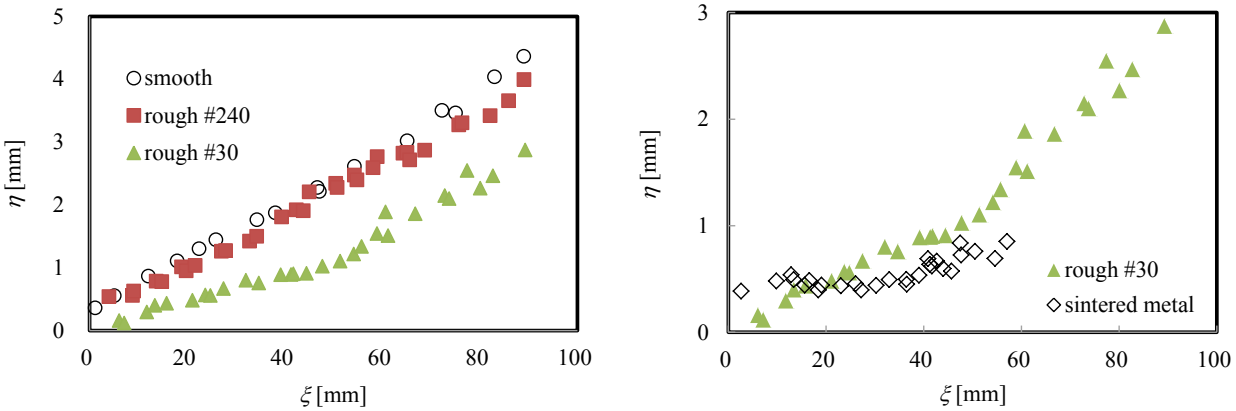
Figure 1 compares the visualized wave configuration for rough surface (#240) and sintered bronze plate at about the same distance of the triple point from the tip. Both reflections are Mach type, and the Mach stem height is larger for rough surface. In Fig. 1 (b), a transmitted wave through the sintered bronze plate can be barely observed in a cavity. This wave is a weak compression wave and propagates at sound speed.

Figure 2 (a) compares the effect of surface roughness over the location of reflection point (RR) and triple point (MR). In the case of surface roughness #240, the trajectory almost overlaps that for smooth surface (#2000). Although the surface roughness of #240 (roughness height about 0.1 mm) exceeds hydraulically smooth condition (0.0517 mm) [5], it does not seem to be effective in this case. On the contrary, the surface roughness of #30 is more effective than #240. Figure 2 (b) compares the effect of surface roughness and permeability. Compared with rough surface (#30), in the case of sintered bronze, the height of reflection point P stays about 0.4 mm at $0 < \xi < 40$ mm. Hereafter, the transition to MR occurs, but the slipstream is obscured by wavelets from the surface. Figure 2 (b) shows also that the effect of permeability is added to that of surface roughness in the case of porous surface.



(a) Reflection over a rough surface (#240, $\xi = 50.5$ mm), (b) Reflection over a sintered bronze plate ($\xi = 47.6$ mm)

Figure 1. Comparison of visualized wave configuration ($M_i = 1.30$, $\theta_w = 36^\circ$).



(a) Comparison of roughness, (b) Effect of permeability

Figure 2. Comparison of triple-point location ($M_i = 1.30$, $\theta_w = 36^\circ$).

CONCLUSIONS

To investigate the effect of surface condition (roughness and permeability), a series of shock tube experiment has been carried out using a sintered bronze plate. Surface roughness of #240 is not so effective as that of #30. The surface roughness surely delays the dynamic transition to MR. In the case of sintered bronze plate, it was demonstrated that the effect of permeability is added to that of surface roughness.

PREDICTION OF THE COMPRESSION WAVE PROPAGATING ALONG A HIGH-SPEED RAILWAY TUNNEL

Rohit Sankaran Iyer[1], Tae Ho Kim[1] and Heuy Dong Kim *[1]
[1] Department of Mechanical Engineering, Andong National University, Andong, Korea Republic.

Summary High-speed train ingress in a railway tunnel generates a high-pressure compression wave due to the piston effect. This compression wave propagates along the tunnel at the local speed of sound. Tunnel wall friction and blockage ratio are a key part in determining the magnitude of a compression wave during the propagation process. In this study, a 3-D computational fluid dynamics (CFD) analysis has been undertaken in order to understand the effect of steady and unsteady friction parameters on a propagating compression wave. Compressible, Euler equations with friction source terms were solved on five different blockage ratio cases (0.1, 0.2, 0.25, 0.3 and 0.4). With the increment in steady friction factor, the attenuation rate of the compression wave in propagation is affected substantially, while the unsteady friction factor has a significant effect on the distortion rate.

BACKGROUND

A distinct compression wave starts to develop near the entrance section as a high-speed enters a tunnel. According to Aero-acoustic theory [1], the train speed and blockage ratio play a major role in determining the magnitude of this entry compression wave. Thereafter, this compression wave propagates along the tunnel at the local speed of sound and eventually emits from the exit as a micro-pressure wave (MPW). It is conjectured from previous studies [2-6] that compression wave propagating along the tunnel could either steepen due to the dominance of non-linear effect over viscous dissipation or could attenuate and spread due to viscous dissipation being dominant in certain cases. In reality, both these effects collaboratively play a major role in deciding the fate of a propagating compression wave. Amongst many other parameters, the major factors that have known to considerably affect the attenuation and distortion of the propagating compression wave are tunnel wall skin friction and blockage ratio. Since Zielke's [3] introduction of the frequency dependent friction in unsteady flows, the unsteady friction term has been incorporated in many compression wave propagation studies [4-6] along with the applicable governing equations. In the past, Matsuo et al. [5] used one-dimensional Euler equations augmented with friction source terms to study on slab track tunnels and concluded that with increasing train speed, the compression waveform tends to become steeper. Also, a one-dimensional study using Fukuda et al.'s [2] model to estimate the effect of friction terms on propagating wave in tunnels with acoustic absorbers was studied by Stefan Adami et al. [6]. Although till date there have been few analytical studies using one dimensional Euler equations with friction terms augmented into it, but a 3-D CFD study on the effects of steady and unsteady friction parameter has not been performed. Hence, a 3-D computational study using Euler equations with friction source terms have been used here to perform simulations on five different blockage ratio cases 0.1,0.2,0.25,0.3 and 0.4. At different blockage ratios, using two different values of λ_s the distinctive effects of both the friction terms have been explored on the propagating compression wave.

METHODOLOGY

Assuming ideal gas behaviour with fluid friction on wall, the Euler equations that are used to carry out the current CFD simulations can be written as follows:

$$\frac{\partial U}{\partial t} + \frac{\partial F}{\partial n} + S = 0$$

$$U = \begin{pmatrix} \rho \\ \rho u \\ e \end{pmatrix} \quad F = \begin{pmatrix} \rho u \\ p + \rho u^2 \\ (e+p)u \end{pmatrix} \quad S = \begin{pmatrix} 0 \\ f \\ 0 \end{pmatrix}$$

$$f = f_s + f_{us}$$

where 'n' is the normal vector(for 2-D; n=x, y), t being time, ρ density of fluid, u is the fluid velocity, p pressure, e being internal energy and 'f' is the source term which is the summation of steady and unsteady friction parameters. The fluid friction term f_s and f_{us} could be written as follows, stated in [2]:

$$f_s = \frac{\boldsymbol{\lambda_s}.\rho(u+c)^2}{2d_h}$$

$$f_{us} = \boldsymbol{\varepsilon_{us}}.\int_0^t W(\tau).\frac{\partial u}{\partial \tau}.d\tau$$

Where $W(\tau)$ is the weighting function as stated in [3]:

*Corresponding author. E-mail: kimhd@anu.ac.kr

$$W(\tau) = 3e^{-26.37\tau} + e^{-70.85\tau} + e^{-135.02\tau} + e^{-218.92\tau} + e^{-322.55\tau} + e^{-445.93\tau} + e^{-589.04\tau}$$

'λ_s' and 'ε_{us}' are the steady and unsteady friction factors as mentioned above.

RESULTS AND DISCUSSION

For a 'λ_s' value of 0.5 and 0.9 and 'ε_{us}' values of 10, the attenuation and distortion rate for blockage ratios varying from 0.1 to 0.4 has been shown in Fig.1(a) to Fig.1(d).

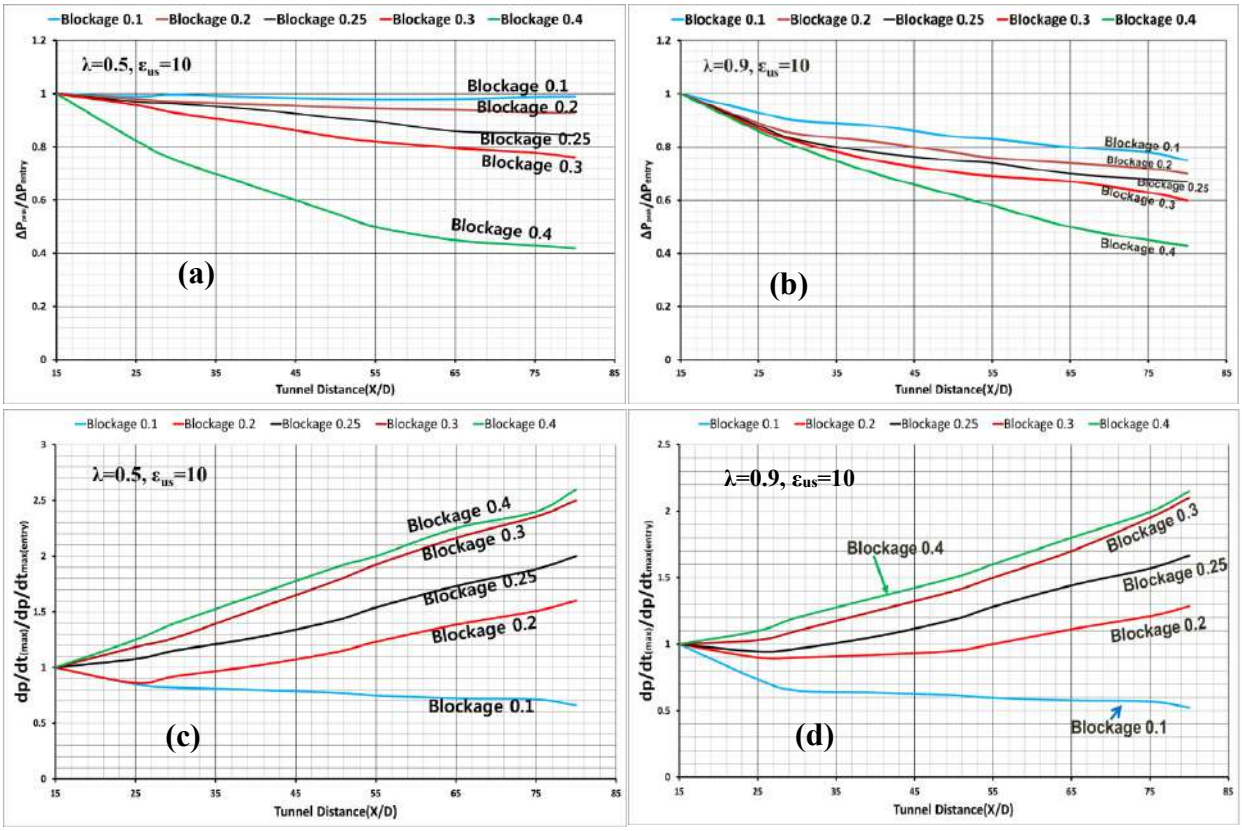

Figure 1(a): Attenuation of compression wave in tunnel for λ_s=0.5 and ε_{us}=10; (b): Attenuation rate for λ_s=0.5 and ε_{us}=10; (c): Distortion rate of compression wave λ_s=0.5 and ε_{us}=10; (d): Distortion rate of compression wave λ_s=0.9 and ε_{us}=10.

The effect of wall steady friction factor λ_s has been predominantly found more significant on the attenuation rate of compression wave for high blockage ratios and has negligible effect as the λ_s value was changed from 0.5 to 0.9 on the distortion rate. This could be attributed to the increase in wall shear forces inside the tunnel thereby reducing the strength of the compression wave as it propagates along the tunnel.

CONCLUSIONS

From the current numerical results, it could be inferred that the strength of the compression wave tends to be decreased as the steady friction factor is increased from 0.5 to 0.9.

EFFECT OF FUEL MASS FRACTION HETEROGENEITY ON THE DETONATION PROPAGATION SPEED

Alberto Cuadra-Lara, César Huete *, and Marcos Vera
Grupo de Mecánica de Fluidos, Universidad Carlos III de Madrid, Leganés, Spain

Summary We present the asymptotic linear theory describing the propagation of a planar detonation front through a heterogeneous mixture of reactive gases consisting of random fluctuations in the fuel mass fraction. The study begins with the derivation of the transfer functions that relate the upstream fuel-mass-fraction inhomogeneities with the burnt-gas perturbation variables via normal-mode analysis. The results are then used in a Fourier analysis of the detonation interaction with two- and three-dimensional isotropic heterogeneous fields to provide integral formulae for the turbulent kinetic energy, sonic energy and averaged vorticity and entropy production rates. Second-order corrections for the averaged Rankine-Hugoniot conditions are provided, along with analytical expressions for the deviation of the detonation propagation velocity with respect to that of the equivalent homogeneous mixture. Upstream inhomogeneities are found to speed up the detonation front, with a velocity amplification factor that depends on the properties of the fuel-air equivalence ratio, which translates into variations of the density and the heat release with the fuel mass fraction.

INTRODUCTION

Detonation waves have been explored extensively for propulsion applications given their theoretical advantage over deflagrative pre-mixed combustion. For instance, rotating detonation engines, which do not operate under the Brayton Cycle, benefit from the additional work extraction from the cycle and a decrease in the physical size of the combustor [1]. However, many challenges must be surmounted before detonation-based engines could be presented as a competitive alternative. Some hurdles include the incomplete fuel-air mixing at the molecular level, the stability of the detonation, and the strong noise generated by the system even in highly idealized configurations [2]. It has been found that upstream heterogeneities play a pivotal role in the detonation dynamics [3, 4].

The interaction of a strong detonation with inhomogeneous entropic and vortical fields have been analyzed in previous works [5, 6]. The motivation was there to improve descriptions of the influences of compressible turbulence on detonation propagation and, in particular, to determine how passage of a planar detonation modifies the turbulence. By employing the same mathematical description as in the pioneering work of Ribner [7] and the analysis of Jackson *et al.* [8], this work [9] complements these fundamental studies by placing the focus on the mixture imperfections, which adds another type of convective perturbation associated to the mixture equivalence ratio, *i.e.*, local heat of combustion of the mixture. The linear-interaction analysis predicts a second-order propagation velocity augmentation for weakly overdriven detonations independently of the type of perturbations generated by the equivalence ratio fluctuations, *i.e.*, positive or negative perturbations in the upstream density and/or heat of combustion fields. For strongly overdriven detonations, a weak deficit in the propagation speed is found only when upstream perturbations in the equivalence ratio are dominated by heat release perturbations.

PROBLEM DESCRIPTION

It is considered a planar detonation front that propagates through a heterogeneous gaseous mixture, as depicted in Fig. 1(a). It is assumed that the deviation of the local fuel mass fraction Y_u with respect to its mean value $\langle Y_u \rangle$ is sufficiently small for linear theory to be applicable, namely, $|\delta Y_u| = |Y_u - \langle Y_u \rangle| \ll 1$. Assuming that there is no privileged direction in the upstream flow, the spectrum of the fuel mass fraction perturbation $\delta Y_u(k)$ is taken to be homogeneous and isotropic. The function k refers to the wave number amplitude characterizing the size of the fuel mass fraction deviations.

Anticipating that the heterogeneous mixture is dominantly static, isobaric and isothermal, the variations of the fuel mass fraction are solely associated to density and heat of combustion changes. Taking a generic air-fuel mixture, for fuels heavier than air positive values of δY_u are associated to positive deviations of density in the upstream flow $\delta \rho_u$, and vice-versa. By knowing that the maximum of the heat release of a given mixture occurs in slightly richer conditions, the sign of the heat release deviations respect to the mean values can be also anticipated. Therefore, positive values of δY_u leads to negative deviations of the heat release δq_u in sufficiently rich environments, while the contrary applies in lean mixtures. Figure 1(b) shows the variation of density and heat release with the fuel mass fraction for different gases. The small parameter δY_u is employed to write the perturbed density and potential heat of combustion fields

$$\rho_u = \langle \rho_u \rangle + \delta \rho_u = \langle \rho_u \rangle (1 + \delta Y_u W) \quad \text{and} \quad q_u = \langle q_u \rangle + \delta q_u = \langle q_u \rangle (1 + \delta Y_u H), \tag{1}$$

where the parameters W and H relate to the local slope of the $\rho_u - Y_u$ curve and the $q_u - Y_u$ curve, respectively. Accurate values of q_u can be obtained with either numerical codes or experimental data.

For sufficiently weak perturbations, the heterogeneous mixture can be approximated with the linear superposition of independent modes, each of them being characterized by the wavenumber $\vec{k}$, so that $\delta Y_u(\vec{x}_l) = \epsilon(k) e^{\mathrm{i}\vec{k}\cdot\vec{x}_l}$, where $\vec{x}_l$ is the

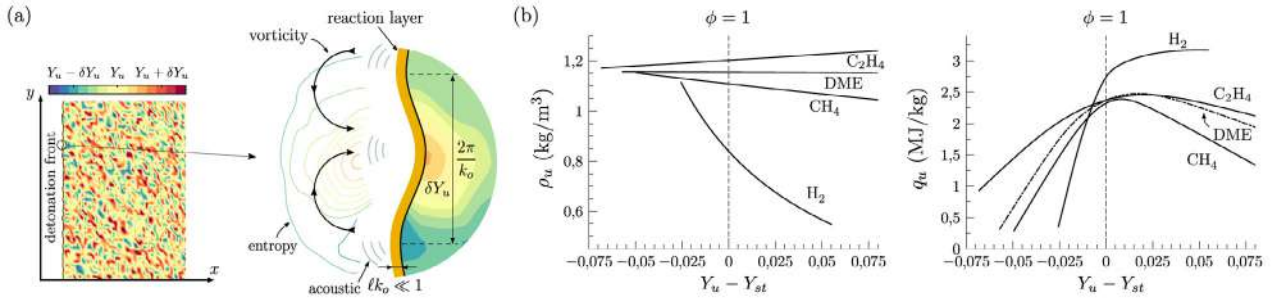

Figure 1: (a) Sketch of the corrugated detonation front through a heterogeneous gaseous mixture, where $|\delta Y_u| = |Y_u - \langle Y_u \rangle| \ll 1$. The detonation length ℓ is assumed to be much smaller than the characteristic upstream length k_o^{-1}. (b) Variation of density and heat release with the fuel mass fraction for representative fuel-air mixtures. The dashed line represents the stoichiometric condition given by $Y_u = Y_{st}(\phi = 1)$ Computations are given for hydrogen, methane, ethylene and dimethyl ether (DME) at 300 K and 10^5 Pa in fresh conditions. See Ref.[9] for further details.

vector defining the position in a reference frame comoving with upstream flow and $\epsilon(k)$ represents the amplitude of the perturbation for a given wavenumber vector amplitude $\vec{k}$.

For the interaction with a single-frequency perturbation field, the long-time amplitude of the perturbations can be written in terms of the characteristic oscillation frequency of the detonation front. Neutral conditions associated with the absence of pressure perturbations at the oscillating detonation or fully planar propagating detonations occur for distinguished conditions of reactive mixture associated to the density and heat release variations, W and H, respectively. Fourier superposition for two- and three-dimensional isotropic fields is used to obtain integral formulae for the amplification of the kinetic energy, enstrophy, and density fluctuations in the burnt gas. The effects of the propagation Mach number, overdrive, and mixture properties through W and H are identified, and the later plays a key role in the intensity of the turbulence generation. Regarding the type of upstream mixture, density perturbations dominate the turbulence generation for moderate-to-high overdrives, while heat release variations become relevant for weak overdrives. As a direct result, heat-release variations make the acoustic contribution the same order as the rotational and entropic perturbations. Aside from the fact that viscosity and molecular diffusion are not accounted for in the model, in which case the spectra would become time-dependent functions after the passage of the detonation, the small-scale regime must be taken with caution as the thin-detonation hypothesis may not be fulfilled. Properties of the turbulent flow behind the detonation front predicted by the linear interaction theory should be further extended to include the effects of finite reaction lengths.

CONCLUSIONS

This work aims to shed further light, from a theoretical framework, on the hydrodynamical aspects that contribute to the modification of detonation velocity when it propagates through a non-uniform mixture of reactive gases. The linear analysis shows how a non-uniform fresh mixture that exhibits weak fuel mass fraction deviations perturbs the detonation front surface, thereby creating additional disturbances in the burnt gas. The deposition of rotational/acoustic velocity perturbations in the downstream flow along with the amplification of the entropic fluctuations comes with a price in the overall RH relations. In particular, changes are expected in the jump conditions given the averaged downstream magnitudes with respect to the case of uniform mixtures with the same averaged upstream properties. As a direct consequence, the averaged propagation speed of the detonation wave will also be affected, as previously noted for inert shocks [10]. The second-order correction to the propagation speed is determined by the type of turbulence generated downstream. For overdriven detonations, the downstream acoustic contribution plays a subdominant role in favour of rotational-entropic disturbances, while the contrary applies for weakly overdriven detonations, for which the effect of upstream heat-release variations is of utmost importance.

EXAMINING THE THERMAL BOUNDARY LAYER IN TRANSCRITICAL TURBULENT CHANNEL FLOWS

Jack Guo *[1] and Matthias Ihme[1]
[1] Department of Mechanical Engineering, Stanford University, Stanford, California, USA

Summary Flows at supercritical conditions play an important role for practical applications including chemical processing, propulsion, and geophysical flows. These applications motivate the study of wall-bounded variable-density turbulent heat transfer. We investigate a series of transcritical turbulent channels with density ratios up to $O(10)$. The density ratio is controlled by imposing a temperature gradient between the hot and cold walls of the channels. Analysis of the boundary layer structure shows that the temperature law of the wall is clearly visible with noticeable differences between the hot and cold walls. When compared to other methods, semi-local scaling performs best when matched with existing correlations.

INTRODUCTION AND MOTIVATION

At pressures above the critical point, a "supercritical pseudotransition" is observed as the fluid transitions between liquid-like and gas-like states despite the absence of a classical phase transition. Macroscopically, this pseudotransition is characterized by a distinct peak in specific heat capacity and by sharp gradients in density, thermal conductivity, and dynamic viscosity. These characteristics contribute to well-documented difficulties in accurately describing the thermodynamic state [1]. Neither current experimental techniques nor engineering simulation tools adequately perform in turbulent flows at transcritical conditions, specifically suffering from insufficient characterization of the near-wall turbulent heat transfer dynamics [1, 2]. Thus, direct numerical simulations have been employed for studying this flow regime.

In variable-density wall-bounded flows, a majority of previous work focuses on viscous boundary layer structure with results including the law of the wall, similarity scaling via wall-units and semi-local units, the van Driest transformation, and the Trettel-Larsson transformation [1, 3]. In this study, we turn our attention to thermally-derived statistics, specifically the temperature law of the wall as a thermal analogy of the celebrated velocity law of the wall. When appropriately scaled, the mean temperature differential, $\overline{\theta} = \overline{(T - T_w)}$, follows a linear profile with respect to the wall-normal distance y in the near-wall regime in the thermal sublayer and a logarithmic dependence on the wall-normal distance further away in the logarithmic layer. The temperature law of the wall was proposed as an algebraic correlation by Kader [4] – hereafter, we denote this Kader temperature law of the wall as KLOW. While there has since been significant analysis in the constant-property regime [5], the variable-property regime has received limited investigation and is confined to small density ratios of $O(1)$ and to simplified thermodynamics. Lee *et al.* [6] numerically investigated an incompressible turbulent boundary layer with temperature-dependent viscosity; they modify KLOW by specifying a constant value for the slope in the logarithmic layer. Patel, Boersma & Pecnik [7] later analyze variable-density turbulent channels with imposed constitutive relations for density, viscosity, and thermal conductivity as a function of temperature but with constant specific heat. They found that using a van Driest-transformed temperature profile results in improved matching with KLOW, while the Lee *et al.* modification has mixed success and fails to consider effects of property variations in the logarithmic layer. To address inadequacies in analysis completed thus far, we perform DNS calculations of transcritical turbulent channels with 1) a fully-compressible formulation, 2) thermodynamic variables specified as functions of two independent, intensive properties, and 3) density variations of up to $O(10)$.

METHODS AND APPROACHES

For the computational domain, we use a streamwise- and spanwise-periodic plane channel with isothermal and no-slip wall boundary conditions. The working fluid is molecular nitrogen (N_2) with critical pressure $p_c = 3.3958$ MPa, critical temperature $T_c = 126.19$ K, and critical density $\rho_c = 312.31\ kg/m^3$. The working fluid is set at a bulk pressure of $p_0 = \int pdV / \int dV = 3.87$ MPa, corresponding to a reduced pressure of $p_r = p_0/p_c = 1.14$. Other details of the setup are found in [1]; the only modification to the setup was to the value of the hot wall temperature boundary condition.

Our calculation uses the finite-volume compressible code CharLES$^{\text{X}}$, with an additional entropy-stable double-flux model [8] specifically designed for transcritical flows. For further details for the solver and for documentation of its previous use in turbulent flow calculations, refer to [1] and the references therein.

RESULTS

Figures 1 and 2 illustrate the mean reduced temperature and mean reduced density, respectively, averaged across homogeneous directions and in time. Four cases are presented, constructed by modifying the hot wall temperature, while the cold wall temperature is kept constant at $T_{w1} = 100$ K for all cases. A broad range of density ratios is considered; the cases with hot wall temperature $T_{w2} = \{125, 140, 190, 300\}$ K correspond to density ratios of $\overline{\rho}_{hot}/\overline{\rho}_{min} = \{1.63, 5.26, 10.10, 17.84\}$, respectively.

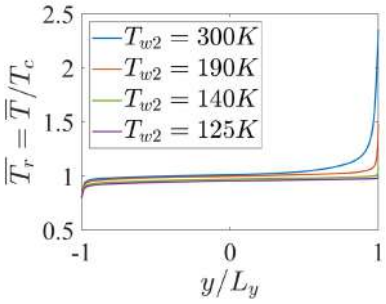

Figure 1: Mean reduced temperature profiles, plotted against channel width.

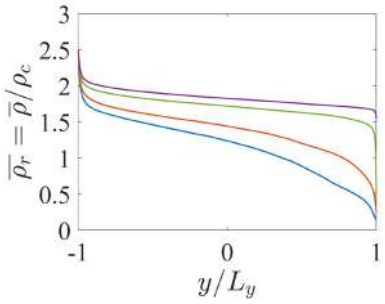

Figure 2: Mean reduced density profiles, plotted against channel width.

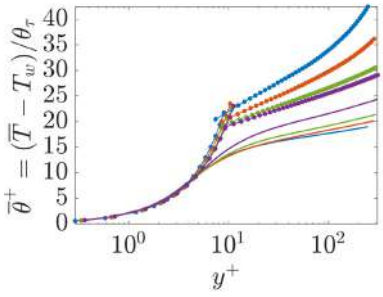

Figure 3: $\overline{\theta}^+$ profiles for cold wall; KLOW shown in lines with filled circles.

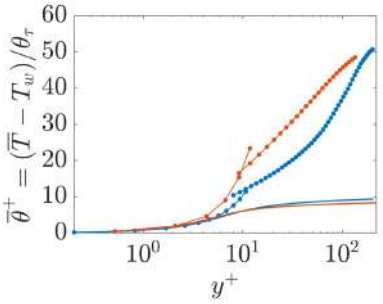

Figure 4: $\overline{\theta}^+$ profiles for hot wall; see Figure 3 for plot legend.

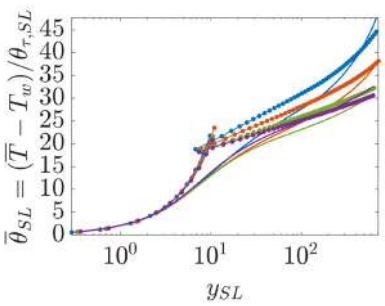

Figure 5: Semi-locally-scaled mean temperature differential profiles at cold wall.

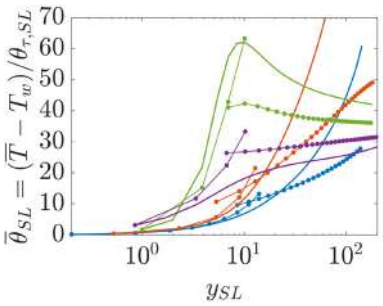

Figure 6: Semi-locally-scaled mean temperature differential profiles at hot wall.

Figures 3 and 4 show the mean temperature differential profiles along with KLOW for the cold and hot wall cases, respectively. Here, the friction temperature used for normalization is defined as $\theta_\tau = q_w/\left(\rho_w c_{p,w} u_\tau\right)$, where q_w is the heat flux at the wall. As done in [6] and [7], the constant Prandtl number in the original KLOW is replaced by a local averaged Prandtl number, $Pr(y)$. We see that as $\Delta T = T_{w,2} - T_{w,1}$ decreases, the agreement for the cold wall improves, while the performance of KLOW at the hot wall is unsatisfactory. Figure 4 includes only two of the cases to simplify visualization; as ΔT decreases, KLOW actually increases in magnitude and performs worse compared with the DNS profiles. Comparison with the Lee correlation [6] and transformation via a van-Driest integral $\int_0^{\overline{\theta}/\theta_\tau} \sqrt{\overline{\rho}/\rho_w} d(\overline{\theta}/\theta_\tau)$ as done in [7] are not shown here since neither provided noticeable improvement. Instead, significant improvement is made when both y and θ are normalized by local quantities, with $\overline{\rho}(y), \overline{\mu}(y)$ and $\overline{c_p}(y)$ being used to obtain semi-local coordinate y_{SL} and semi-locally-scaled temperature differential $\overline{\theta}_{SL}$. Results for the cold and hot walls are shown in Figures 5 and 6, respectively. Interestingly, the complex interaction of variable properties causes the semi-locally-scaled $\overline{\theta}$ to no longer exhibit a logarithmic profile in certain cases, a phenomenon requiring future investigation.

CONCLUSIONS

We have provided results of a DNS calculation of transcritical turbulent channels with density ratios up to $O(10)$, along with analysis of the thermal boundary layer structure. Current correlations for the mean temperature differential are matched poorly using existing scalings because the effects of thermodynamic gradients are not fully accounted for. However, use of semi-local scaling yields significant improvement by more fully capturing the local flow behavior.

STUDY OF TURBULENT KINETIC EQUATION IN CONVERGING SPHERICAL SHOCK-TURBULENCE INTERACTION

Chen Boxuan[1], Fu Song *[1], and Yan Bowen[1]
[1] Department of Engineering Mechanics, Tsinghua University, Beijing, China

Summary Simulations of interaction between converging spherical shock wave and compressible isotropic turbulence are carried out. Mean fields of these flow are showed in this paper. Turbulent kinetic energy equation is used to study these flow. The turbulent kinetic energy of these flow is not fit standard k-ε turbulent model. Reynold stress is better to use realizable k-ε model, not Boussinesq eddy viscosity model. Terms in turbulent kinetic energy equation related to viscosity, like dissipation, is not important in these flow. Terms in turbulent kinetic energy equation related to pressure, like pressure-dilatation and pressure-diffusion, is important in these flow.

SHOCK-TURBULENCE INTERACTION

The flow is solved by BGK method. This method is based on kinetic molecular theory.

The calculate domain is a block in 3 dimension with side length 2π. In this region, there is isotropic compressible turbulence flow. To avoid the reflect of shock, there is a buffer area outside. Due to the study of Ankit Bhagatwala and Sanjiva K. Lele, it is enough to simulate these flow on 256^3 grids.

The isotropic compressible turbulence is generated using the result of isotropic compressible decay turbulence. It lets the isotropic compressible turbulence develop to a state where the nonlinear energy transfer mechanism is fully active. The methodology to calculate isotropic compressible decay turbulence is proposed by Ristorcelli and Blaisdell. The Taylor scale Reynolds number of the flow Re_λ is 45, and the turbulent Mach number M_t is 0.4.

The converging shock is launched by a spherical interface. There is low density and low pressure inside while high density and high pressure outside. In typical shock tube problem, there will be shock wave, expansion wave and contact surface. However, the contact surface should be avoided so the ratio of density and pressure is determined only by the Mach number M_s of the shock. This paper shows the result of the case which Mach number M_s equals 2.4.

Vorticity field can show the turbulence clearly, and dilatation field can show the shock clearly. Figure 1 gives the vorticity result where the black line is the shock wave displayed by dilatation. The vorticity structure outside the shock is smaller than the vorticity inside the shock. This is because of the compression of the shock. Shock provides anisotropic in radius direction to turbulence flow. Due to the turbulence, the fluctuating shock can be seen as a spherical shock and many "shocklets" integrated together. The "shocklets" are much stronger than usual. It explains why the turbulent kinetic equation in this flow is different with purely turbulence.

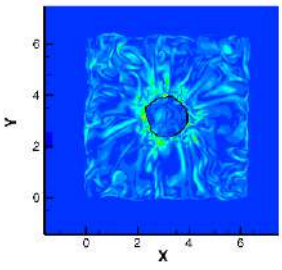

Figure 1. Vorticity field of turbulence, and black line show the shock.

The flow is spherically symmetric so the mean field can be written as a function of radius r. The data values within a shell were averaged and this gave the mean field of the flow. Turbulent kinetic equation is calculated in this way.

TURBULENT KINETIC EQUATION

Turbulent kinetic equation assumes the following form:

$$\bar{\rho}\frac{DK}{Dt} = -\overline{\rho u_m'' u_n''}\frac{\partial \widetilde{u_m}}{\partial x_n} + \frac{\partial}{\partial x_n}\left(\overline{t_{mn}'' u_m''} - \overline{\rho u_n''\frac{1}{2}u_m'' u_m''} - \overline{p' u_n''}\right) + \overline{u_m''}\left(\frac{\partial \widetilde{t_{mn}}}{\partial x_n} - \frac{\partial \bar{p}}{\partial x_m}\right) + \overline{p'\frac{\partial u_m''}{\partial x_m}} - \overline{t_{mn}''\frac{\partial u_m''}{\partial x_n}}$$

where t_{mn} is viscosity stress, and the right hand side of equation is production, diffusion, mass-flux, pressure-dilatation and dissipation.

Turbulent kinetic equation provides Reynolds stress. Production term in turbulent kinetic equation also needs Reynolds stress to calculate. Using Boussinesq approximation to calculate Reynolds stress would have unrealistic results: Reynolds stress may be negative or too big. The way to avoid it is to use realizable k-ε(RKE) eddy viscosity model. Figure 2(a) shows the results of Reynolds stress calculate by simulation and RKE model. Figure 2(b) shows the results of production in turbulent kinetic equation calculate by simulation and RKE model.

*Corresponding author. E-mail: fs-dem@mail.tsinghua.edu.cn.

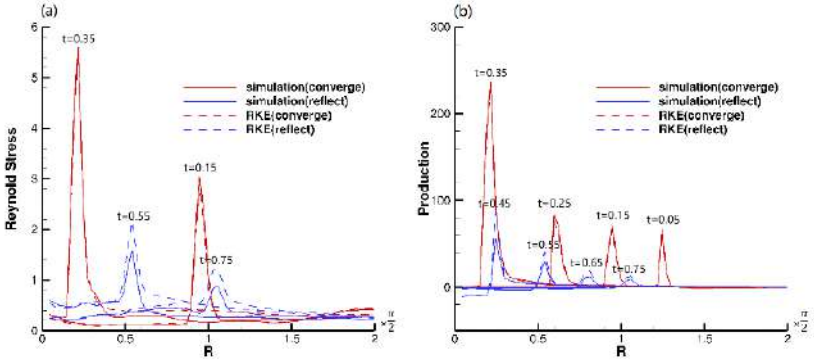

Figure 2. Reynold stress (a) and production term (b) calculate by simulation and RKE model.

The part in brackets of diffusion term is what we care about. Molecular diffusion $\overline{t''_{mn}u''_m}$ is too small so it doesn't need study in this case. Pressure diffusion $-\overline{p'u''_n}3$is bigger than turbulent diffusion $-\overline{\rho u''_n \frac{1}{2}u''_m u''_m}$, while pressure diffusion $-\overline{p'u''_n}3$ is usually neglected under normal conditions. There was a relation we found which can be approximated as:

$$-\overline{p'u''_n} \sim \nu_t \frac{\partial \bar{p}}{\partial x_n}$$

Figure 3(a) shows this.

Pressure-dilatation $\overline{p'\frac{\partial u''_m}{\partial x_m}}$ can be simplified by adding $\frac{\partial}{\partial x_m}(-\overline{p'u''_m})$. It gives $-\frac{\partial}{\partial x_m}\overline{p'u''_m} + \overline{p'\frac{\partial u''_m}{\partial x_m}} = -\overline{u''_m \frac{\partial p'}{\partial x_m}}$. There was a relation we found which can be approximated as:

$$-\overline{u''_m \frac{\partial p'}{\partial x_m}} \sim \nu_t \Delta \bar{p}$$

where Δ is Laplace operator. Figure 3(b) shows this.

For mass-flux $\overline{u''_m}\left(\frac{\partial \bar{t}_{mn}}{\partial x_n} - \frac{\partial \bar{p}}{\partial x_m}\right)$, viscosity work $\overline{u''_m \frac{\partial \widetilde{t_{mn}}}{\partial x_n}}$ is very small so we only consider pressure work $-\overline{u''_m}\frac{\partial \bar{p}}{\partial x_m}$. Zeman and Ristorcelli have found a relation between $\overline{u''_m}$ and mean flow, so $-\overline{u''_m}\frac{\partial \bar{p}}{\partial x_m}$ can be approximated as:

$$-\overline{u''_m}\frac{\partial \bar{p}}{\partial x_m} \sim -\frac{\nu_t}{\bar{\rho}}\frac{\partial \bar{\rho}}{\partial x_m}\frac{\partial \bar{p}}{\partial x_m}$$

Figure 3(c) shows this.

For all of the above, coefficients are relate to M_t and M_s, and it needs further study.

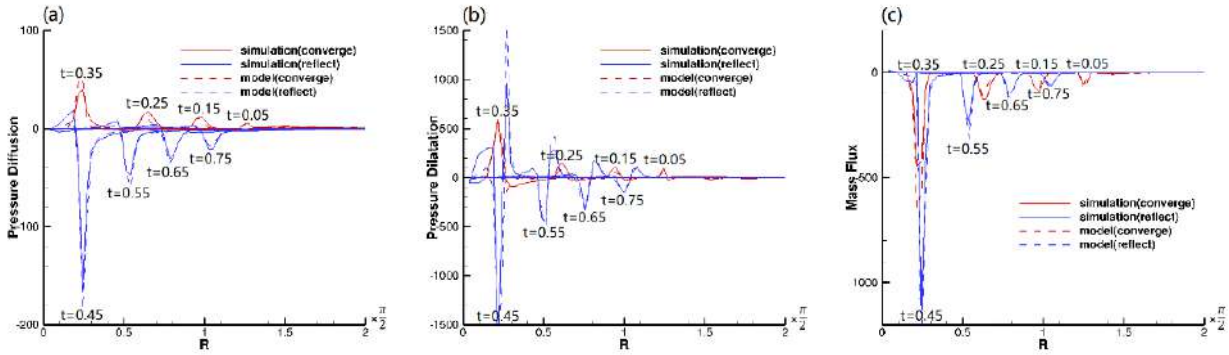

Figure 3. Pressure diffusion term (a), pressure dilatation term (b) and mass flux term (c) calculate by simulation and model.

EFFECT OF CO-FLOW ON COUNTER ROTATING VORTEX RING FORMATION IN A MODERATELY UNDER-EXPANDED JET

Haroon Ahmad[1], Nadeem Hasan[2], and Sajeev Sanghi [1]
[1] Department of Applied Mechanics, Indian Institute of Technology, Hauz Khas, New-Delhi, India
[2] Department of Mechanical Engineering, Aligarh Muslim University, Aligarh, U.P., India

Summary Axisymmetric *DNS* is done for a moderately under-expanded jet at exit-Reynolds number $Re_j = 5 \times 10^4$, exit-Mach number $M_j = 1.5$ and pressure ratio $p_j/p_a = 1.5$, respectively. The effect of co-flow ratio (V_a/V_j) at three different magnitudes, *i.e.* $V_a/V_j = 0$, 0.15 & 0.3, is explored. The increase in co-flow ratio suppresses the formation of counter rotating vortex ring (*CRVR*). The *CRVR* formation occurs earlier in time with increasing V_a/V_j.

INTRODUCTION & METHODOLOGY

A counter rotating vortex ring (*CRVR*) having circulation opposite to that of the primary vortex ring (*PVR*), is formed on the *PVR* periphery in the under-expanded jets [1]. The main cause behind the *CRVR* formation is the rolling-up of the slip-streams emanating from the triple points of Mach-reflection between oblique intercepting shocks and embedded shock, respectively [1]. This rolling up has been attributed to the effect of Kelvin-Helmholtz instability [1]. The *velocity ratio* or *co-flow ratio* ($\frac{V_a}{V_j}$) is the ratio of the ambient fluid speed (V_a) to the jet fluid speed the nozzle exit (V_j). Lovaraju & Rathakrishnan [2] experimentally studied the effect of co-flow on subsonic, correctly-expanded and under-expanded jets. They observed that co-flow retarded the mixing which caused potential core elongation.

An initially axisymmetric and laminar jet of calorically and thermally perfect gas, issuing from a circular nozzle/orifice is considered. The compressible Navier-Stokes equations are formulated in the cylindrical-polar coordinate system that causes an inherent polar-coordinate singularity in the governing equations. This is handled by introducing a new user-defined coordinate system ($\tilde{r}$,$\tilde{\theta}$) in place of (r,θ). The concept has been adapted from Mohseni & Colonius [3]. The domain varies from $(-R, R)$ and $(0, \pi)$ in $\tilde{r}$, $\tilde{\theta}$ coordinates. For non-dimensionalisation, $U_j - U_a$ is the velocity scale, jet-diameter (D_j) is the length scale, ambient temperature and ambient density as the scales for temperature and density, respectively. The axisymmetric form of the compressible Navier-Stokes equations in the new user-defined coordinate system has been solved using the modified version of the *PVUM+* scheme proposed by Hasan et al. [4]. The algebraic Euler characteristic boundary conditions are used [5]. Hat shaped velocity profile for axial-velocity at the nozzle-exit has been used as the initial condition. Initially, density & temperature are fixed at their respective ambient values. The domain spans upto $27D$ longitudinally and it radially spans about $\pm 10D$. The jet emanates from the nozzle whose opening lies just behind the domain face and its dimension ranges from $-0.5 \leq \tilde{r} \leq 0.5$ (see Fig. 1).

RESULTS

Axisymmetric *DNS* simulations were performed for three different co-flow ratios *i.e.* $V_a/V_j = 0$, 0.15 & 0.3 for a starting under-expanded jet at exit-Reynolds number $Re_j = 5 \times 10^4$, exit-Mach number $M_j = 1.5$ and pressure ratio $p_j/p_a = 1.5$, respectively. Figure 1 shows the instantaneous numerical-schlieren snapshots for these jets at different V_a/V_j. With increasing V_a/V_j, Mach reflection occurs earlier in time and its life-span also reduces due to relatively faster propagation of *PVR*. At high co-flow ratio magnitude *i.e.* $V_a/V_j = 0.3$, Mach reflection becomes quite weak due to which the slip-streams cease to emanate in absence of triple-points. Figure 1 also shows that with increasing V_a/V_j, the formation of *CRVR* also occurs earlier in time but about 15% increase in V_a/V_j results in a single *CRVR* pair in contrast to multiple *CRVR*s formed in absence of any co-flow. This shows that increasing V_a/V_j results in the suppression of *K-H instability* that rolls up the slip-stream in form of a *CRVR*. Again, at $V_a/V_j = 0.3$ there is no *CRVR* formation due to the absence of proper Mach reflection. In agreement with [2], it is seen that increasing V_a/V_j elongates the developing inviscid core of the starting jet while, the radial elongation of the *PVR* reduces due to the reduced entrainment of the ambient fluid into the *PVR*. With increasing V_a/V_j, the onset of instability inside the *PVR* and the shock-shear layer-vortex interaction occur earlier in time. But the life-span of hock-shear layer-vortex interaction gets reduced.

STABILITY OF EXPANDING ACCRETION SHOCKS IN REACTIVE MEDIA

César Huete*[1], Andrés Calvo[1], Daniel Martínez-Ruiz[2], and Alexander L. Velilkovich[3]
[1] Grupo de Mecánica de Fluidos, Universidad Carlos III de Madrid, Leganés, Spain
[2] ETSIAE, Universidad Politécnica de Madrid, Madrid, Spain
[3] Plasma Physics Division, Naval Research Laboratory, Washington, DC 20375, USA

Summary Stagnation of a cold material streaming to the center or axis of symmetry via an expanding accretion shock wave is a phenomenon of paramount importance in high-energy-density physics. The examples range from plasma flows in x-ray-generating Z pinches, impact ignition in Inertial Confinement Fusion, and core-collapse supernovae in astrophysics. We present a theoretical analysis for the case of stagnation that does not involve a rarefaction wave behind the expanding shock front. The dispersion equation that determines the eigenvalues of the problem and the explicit formulas for the eigenfunction profiles corresponding to these eigenvalues are presented for strong shock waves propagating in reactive media. Non-adiabatic transformations as dissociation, ionization and global chemical reaction are analyzed. The boundaries of stability are explicitly determined.

INTRODUCTION

In the high-energy-density context, non-adiabatic shocks can develop in a wide range of phenomena, including thermonuclear detonations formed in thermonuclear supernovae. Further examples can be found in the so-called core-collapse supernovae (CCSNe), a type of supernovae powered by stellar core collapse. The shock wave evolves through a phase of accretion shock, in which it becomes endothermic due to the nuclear dissociation process taking place across the shock. A distinctive common feature of these two fronts is that energy variations (either exothermic and endothermic) may likely depend on thermodynamical absolute values, and thus on the shock intensity. A clear example is found in the energy lost by radiation in the so-called radiative shocks. Under the ICF/HEDP experimental conditions [1, 2], the mechanism of plasma stagnation via the expanding shock is roughly similar, although the gravity does not play a significant role.

To study the stability of the expanding shock, a linear perturbation analysis is carried out [3], which is applicable under the following assumptions [4]: the non-adiabatic transformations of the fluid particles occur in a very thin layer right behind the shock for the whole supersonic front to be considered a fluid discontinuity. Besides, pressure, density and temperature are related through the perfect gas equation of state in the perturbation variables in the equilibrium states. The name non-adiabatic comprises any type of energy gain or loss across the shock, *e.g.,* reactive, dissociating, radiating or ionizing, along with the associated molecule structure changes.

PROBLEM DESCRIPTION

The initial conditions for the Noh problem are $\rho_1(r, t = 0) = \rho_0$, $p_1(r, t = 0) = p_0$ and $\boldsymbol{v}_1(r, t = 0) = -v_0\boldsymbol{e}_r$, where ρ_0 and p_0 are the initial density and pressure, and $v_0 > 0$ is the uniform initial radial velocity, and $\boldsymbol{e}_r$ is a unit vector in the positive radial direction. The subscript 1 refers to variable conditions in the whole domain ahead of the shock front while the subscript 0 to the initial conditions. The evolution of the upstream flow can be derived by employing the self-similar coordinate $\xi = r/(v_0 t)$. The singularity is resolved by the expanding shock that moves at constant speed $\dot{r}_s$ emerges at $t > 0^+$ and puts the downstream flow at rest. The linear, small-amplitude stability analysis covers the general case of 3D perturbations of the classic Noh solution for spherical geometry, with small-amplitude distortion of the expanding shock front proportional to the spherical harmonic, $Y_l^m(\theta, \phi)$ and the particular filamentation 2D perturbation $\sim \exp(im\theta)$ for cylindrical geometry. For the above two cases, our perturbation problem is solved analytically, resulting in an explicit dispersion equation for the eigenvalues determining the time evolution of the solutions, as well as explicit formulas for the corresponding eigenfunctions.

For a spherical geometry, the perturbed shock front position is written in terms of spherical harmonics, *i.e.*,

$$\frac{r_s(\theta, \phi, t)}{\dot{r}_s t} - 1 = \epsilon \sum_{l,m} \left(\frac{t}{t_0}\right)^{\sigma} Y_l^m(\theta, \phi), \tag{1}$$

where $\dot{r}_s t$ corresponds to the unperturbed radial position of the shock. The term proportional to the small-amplitude parameter ϵ includes $Y_l^m(\theta, \phi) = P_l^m(\cos\theta)e^{im\phi}$, where P_l^m is the associated (generalized) Legendre function and l and $m \leq l$ correspond to the integer mode numbers. The deviation from the unperturbed position $\delta r_s = r_s - \dot{r}_s t$ depends on time as well as the polar $\theta \in [0, \pi]$ and azimuthal $\phi \in [0, 2\pi]$ angles, see scheme in Fig.1. The lack of scales dictates the power-law dependence $(t/t_0)^{\sigma}$, where the t_0 is an arbitrary temporal parameter used to provide of dimensional consistency. The eigenvalue $\sigma = \sigma_{\mathrm{R}} + i\sigma_{\mathrm{I}}$ is a complex parameter to be determined and whose properties describe the shock dynamics: the oscillation frequency will be dictated by the value of σ_{I} while the real part will determine if the shock is stable ($\sigma_{\mathrm{R}} \leq 0$) or unstable ($\sigma_{\mathrm{R}} > 0$).

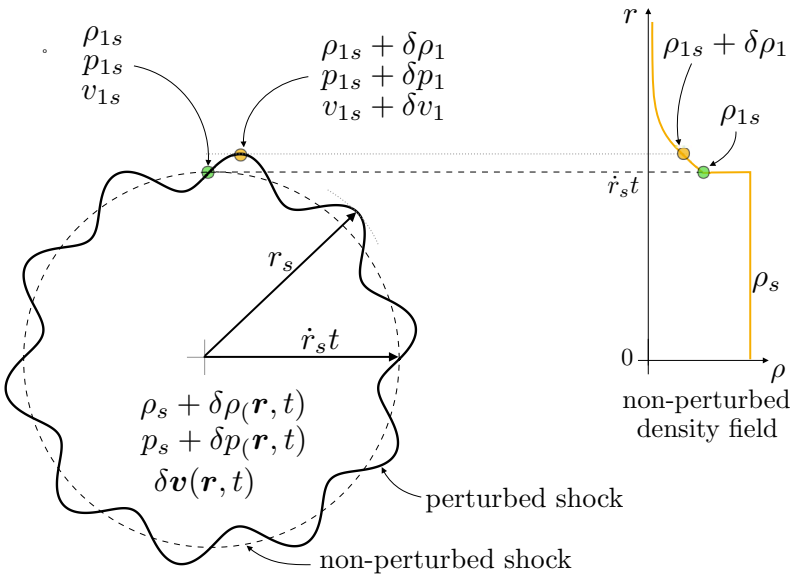

Figure 1: Sketch of the perturbed shock moving through the non-uniform upstream flow. Representation for the cylindrical geometry with $m = 10$.

The problem formulation includes the perturbation of the flow variables downstream in term of the corresponding eigenfunctions and the eigenvalue σ. The inviscid Euler equations are solved with the aid of the linearized Rankine-Hugoniot equations, which finally render the dispersion relationship

$$\begin{aligned}&\{(\sigma+\nu-1)\left[\mathcal{R}_s(\nu-1)-\sigma-\nu\right]+\mathcal{R}_s j(j+\nu-2)\}(1+h)F_{1s}^{+}\\&+\left[2(\sigma+\nu)-\mathcal{R}_s(\nu-1)\left(1+h_1\right)\right](\sigma+\nu+j-1)F_{1s}^{-}=0\end{aligned}\tag{2}$$

that determines the eigenvalue σ as a function of the geometry factor ν, the mode number j, the mass compression ratio $\mathcal{R}_s$, and the functions h and h_1. The factor h is recognized as the D'yakov-Kontorovich parameter that measures the slope of the Rankine-Hugoniot curve relative to the Rayleigh–Mickelson line. The parameter h_1 is an independent coefficient accounting for the influence in the post-shock values due to the change of pre-shock properties. The functions F_{1s}^{+} and F_{1s}^{-} refer to the hypergeometric functions evaluated at the shock front that can be defined conjointly as

$$F_{1s}^{\pm}={}_2F_1\left(\frac{j-\sigma}{2},\frac{j\pm1-\sigma}{2};j+\frac{\nu}{2};\eta^2=\mathcal{M}_s^2\right),\tag{3}$$

where $\mathcal{M}_s$ is the post-shock Mach number. As discussed in [3], there exits a infinite set of complex eigenvalues for any mode number j, which are the mathematical manifestation of the acoustic reverberations between the shock and geometrical center. Each of those exhibit a different temporal power-law decay, when stable.

CONCLUSIONS

The linear stability analysis of the expanding accretion non-adiabatic shock is performed, on condition that reactive processes occur in a negligible thickness layer behind the shock. The model, that allows the inclusion of any phenomenon that may alter the energy balance across the shock, is applied to different contexts of interest in high-energy-density physics, as they are ionization, dissociation, and global exothermic reactions. The boundaries of stability are explicitly determined. Numerical simulations are carried out to include non-linear interactions and finite-length effect contributions.

BISTABILITY AND SEPARATION HYSTERESIS OF SHOCK WAVE BOUNDARY LAYER INTERACTION

Summary The bistability and separation hysteresis of shock wave boundary layer interaction flows are observed and investigated numerically, using curved compression ramp geometrical configuration. The occurrence of this new phenomenon indicates that the boundary layer's state (attachment/separation) depends on its evolutionary history even for the same free-stream and boundary conditions. Specifically, beginning with an attachment state, the boundary layer remains attached as the angle of attack (AOA) increases slowly and suddenly separates once AOA reaches a marginal angle. However, if AOA is decreased back from this angle, the boundary layer will not attach and remain separated until AOA reaches a small enough angle. The mechanism of the separation hysteresis is expounded using three characteristic adverse pressure gradients.

INTRODUCTION

Hysteresis is a general property of multistable systems manifested as the dependence of a system on its evolutionary history, which is ubiquitous in aerospace flow systems, such as aerodynamic hysteresis (subsonic external flow hysteresis) [1], and shock wave reflection hysteresis (supersonic internal flow hysteresis) [2,3]. However, for supersonic external flows, as far as we know, even though hysteresis phenomenon has been proposed theoretically [4], it has not yet been observed experimentally or numerically. In this paper, we report the separation hysteresis in curved compression ramp flows (SHCCR) induced by AOA-variation, which is observed for the first time. The features of CCR flows with the laminar boundary layer are presented, and the mechanism of SHCCR is discussed.

BISTABILITY OF CURVED COMPRESSION RAMP FLOW

The bistability of curved compression ramp flow is studied thorough three dimensional Direct numerical simulations (DNS) []. As shown in figure 1, the streamwise and spanwise regions are $-82mm \leq x \leq 107.2mm$ and $0mm \leq z \leq 40mm$, respectively. The turning angle is $\phi = 18°$. The curvature radius of the concave region is $R = L/\tan(\phi/2)$, where $L = 25mm$ is the distance from the original point of the curved wall to $(0,0)$. The free-stream Mach number is fixed at 6.0 and other flow parameters are consistent with our previous work [6]. The incoming boundary layers are both laminar on the flat plate and will become turbulent downstream. It can be seen that there are two different flow states, (a) attachment and (b) separation, for the same free-stream and boundary conditions, and both simulations of these two states are convergent. The reason of the existence of the bistability is as follows. When L is large, the adverse pressure gradient (APG) is small and the flow tend to be attaching. If L is small enough, the flow should separate induced by strong APG. For an appropriate L, the flow may be attached or separated, which is determined by the evolution process.

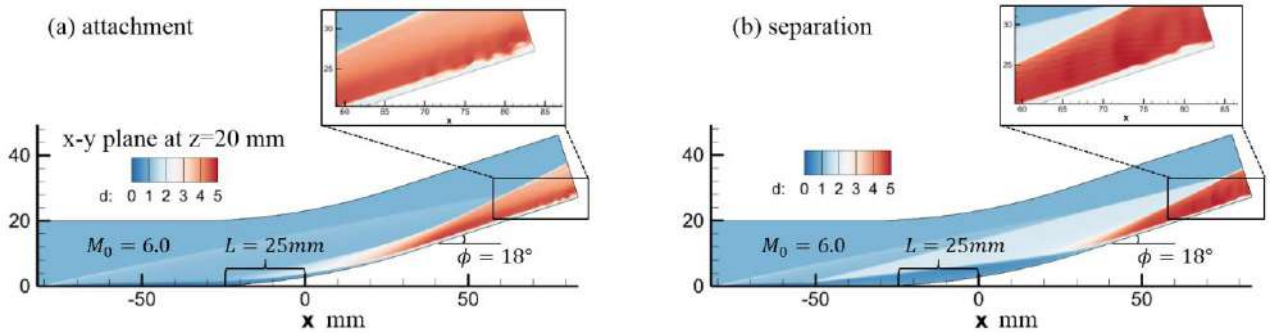

Figure 1. bistablitiy of the curved compression ramp flow.

SEPARATION HYSTERESIS OF CURVED COMPRESSION RAMP FLOW

The separation hysteresis is expected to occur by tunning the AOA. As shown in figure 2, the simulation begins with $\alpha = 0°$ corresponding to an attachment state (state 1). As AOA increases $\alpha = 21°$ in state 4), the attachment state is maintained. However, when AOA is large enough ($21° < \alpha < 22°$), the separation arises suddenly. Since the flow in the separation bubble is subsonic at a low speed, we can distinguish the separation state with an obvious blue area representing M < 1 on the curved wall. If AOA decreases gradually from $\alpha = 22°$ (state 3) back to $\alpha = 0°$ (state 5), the separation state persists ($\alpha = 21°$ in state 4). Note that for the same free-stream conditions (states 1 and 5, 2 and 4), there are two

*Corresponding author. E-mail: yanchaohu@pku.edu.cn

steady states (attachment and separation). Furthermore, if we decrease AOA from $\alpha = 0°$ (state 5) to $\alpha = -4°$ (state 6), the leading edge shock transits to an expansion fan, and the separation region becomes smaller. As AOA continues to decrease, the separation shrinks gradually and the boundary layer attaches again when $-5° < \alpha < -4°$. Finally, as AOA increases from $-5°$ back to $0°$, the flow maintains the attachment state (states 7 and 8). The process from state 1 to state 8 constitutes a new flow hysteresis phenomenon, i.e., SHCCR induced by AOA-variation.

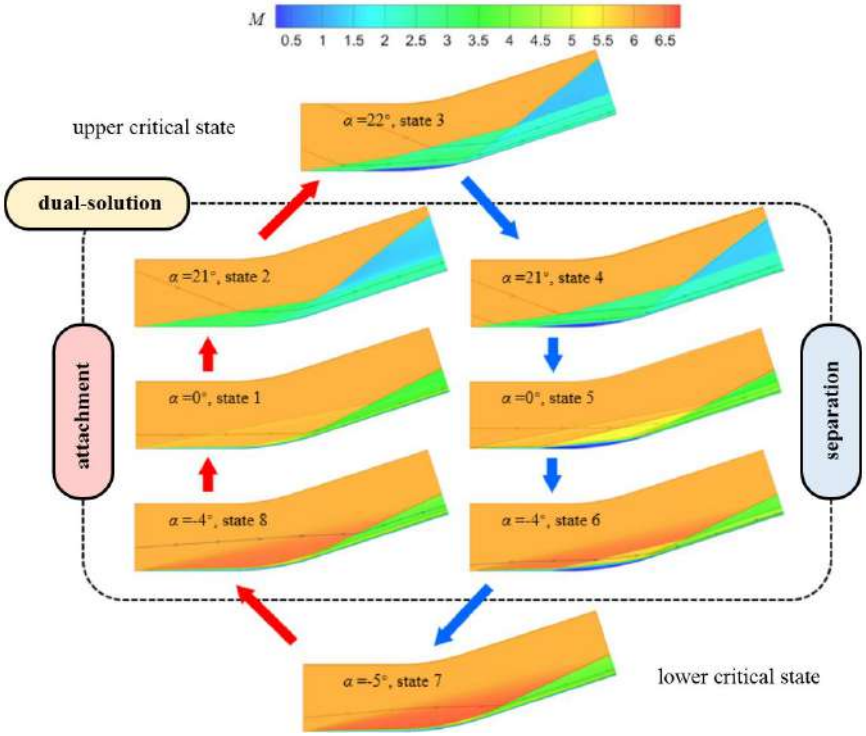

Figure 2. Separation hysteresis of the curved compression ramp flow.

THE MECHANISM OF SEPARATION HYSTERESIS

Here, the relative magnitude of APG induced by separation and curved wall should be further emphasized. We denote the resistance of the boundary layer to APG as I_b, and the maximum APG induced by the curved wall in attachment states as I_{cw}. If the boundary layer cannot resist the APG induced by the curved wall, i.e., $I_b < I_{cw}$, a separation bubble will occur and form a "virtual ramp" inducing a stronger APG, whose maximum value is denoted as I_{sb}. Generally, as mentioned above, near the separation point, APG induced by the virtual ramp ($R \to 0$) is larger than that induced by the curved wall, i.e., $I_{sb} > I_{cw}$. Therefore, the boundary layer must be attached when $I_b > I_{sb}$. However, by changing the inflow or boundary conditions (such as tunning the AOA), I_b may locate in $[I_{cw}, I_{sb}]$, where both attachment and separation are theoretically possible. In this region ($I_{cw} < I_b < I_{sb}$), a separation hysteresis could occur induced by the variation of some flow parameter, which is just the new phenomenon we have discussed above.

CONCLUSIONS

In this paper, SHCCR induced by AOA-variation is observed numerically. Starting from an attachment state, the boundary layer keeps attaching with increasing AOA and suddenly separates when the AOA reaches the upper marginal angle, with the separation bubble covering the curved ramp and forming a virtual ramp. While AOA decreases back gradually, the separation bubble seems to be frozen and the boundary layer will not attach until AOA is small enough. The mechanism of the separation hysteresis is expounded.

SELF-SUSTAINED BIPHASIC CATALYTIC PARTICLE TURBULENCE

Ziqi Wang[1], Varghese Mathai[2], and Chao Sun *[1]
[1] Center for Combustion Energy, Key Laboratory for Thermal Science and Power Engineering of Ministry of Education, Department of Energy and Power Engineering, Tsinghua University, 100084 Beijing, China
[2] School of Engineering, Brown University, Providence, Rhode Island, 02912, USA

Summary Turbulence is known for its ability to vigorously mix fluid and transport heat. While over a century of research for enhancing heat transport, few have exceeded the inherent limits posed by turbulent-mixing. Here we have conceptualized a kind of "active particle" turbulence machine: we find that by adding a minute concentration ($\phi_v \sim 1\%$) of a heavy liquid (hydrofluoroether) to a water-based turbulent convection system, remarkably, high efficient biphasic dynamics is born, which supersedes turbulent heat transport by up to 500%. The system is unique in that it operates on a self-sustained dynamically equilibrated cycle of a "catalyst-like" species, and exploits several heat-carrier agents including pseudo-turbulence, latent heat and bidirectional wake capture. We find that the heat transfer enhancement is dominated by the kinematics of the active elements and their induced-agitation [1]. The present finding opens the door towards the establishment of tunable, ultra-high efficiency heat transfer/mixing systems.

INTRODUCTION

In the global context of energy exchange, thermal turbulence holds a central place as a major driver in many natural and industrial processes [2]. The primary heat transporters of thermal turbulence are the "plumes" (a form of coherent turbulent structure), and they form an essential component in ocean currents, atmospheric and mantle convection, volcanic eruptions, bio-chemical and combustion reactions, as well as in the sustenance of thermonuclear phenomena in the sun, the stars, and other galactic powerhouses[3]. A remarkable property of these coherent plume structures is their ability to mix initially distinct constituents across multi-decadal length and time scales, yielding extremely efficient (super-diffusive) transport of scalars[4], which are typically orders of magnitude faster than those achievable by molecular diffusion alone. The same characteristics of the plumes have become to be exploited in design of efficient heat exchangers and mixing networks. From a fundamental perspective, a central question for any heating or cooling device is to establish a robust relationship between an applied temperature difference and the corresponding heat flux[3]. The vast majority of recent explorations for marginal to moderate heat flux enhancements underlines the need for fundamentally new concepts of heat transport in closed-system heat exchangers.

EXPERIMENTS

We begin with a classical (water-based) thermal convection system (aspect ratio 0.5, with a heated bottom plate ($T_b \approx 35°C$) and a cooled top plate ($T_t \approx 5°C$) at atmospheric pressure p_0. To this, we introduce a minute fraction ($\phi_v \sim 1\%$) of a low conductivity liquid (hydrofluoroether (HFE-7000)), through which a highly efficient active particle turbulence is born (Fig. 1(a). The active species enters a dynamic boiling condensation cycle, thereby creating self-sustained biphasic catalytic heat-carrier elements (see insets (b)-(d)) and supplanting the plumes (classical coherent structures) of thermal turbulence (insets (e)-(f)).

RESULTS

The collective dynamics of the vapor-liquid elements gives rise to even stronger coherent structures than in thermal turbulence. We report heat flux enhancements of up to 500% (green-shaded half of Fig. 1(g)). When the bottom plate temperature T_b is raised above a critical value T_{cr}, the heat transfer (Nu/Nu_0) increases almost linearly (Fig. 1(g)), where Nu_0 is the heat exchange possible due to convective turbulence alone. This occurs as a consequence of increased activity of the biphasic particles (see insets Fig. 1(b)-(d)). Remarkably, the five fold enhancement in heat flux is attained with only a 1.3% (by volume) activity of the biphasic species (inset to Fig. 1(g)). The HFE-7000 liquid boils to form vapor bubbles and the vapor bubbles will detach from the bottom plate and rise; at the meantime of rising through the bulk of the cell the vapor will condense into liquid; so the bubbles become biphasic with more and more liquid fraction, and consequently more and more heavier until they reach the top plate, where they condense totally into liquid droplets. The liquid droplets will fall and return the bottom plate. These processes are self-sustained. The biphasic particles appear from the bottom plate with a lower density (positive buoyancy) as compared to water, and after releasing heat in the bulk and near the top plate, they increase their overall density (gain negative buoyancy) and move downward to recover their initial state. Thus the role of the biphasic species to the thermal convection system holds a close analogy to that of a "catalyst". We also investigate the detailed mechanism of drastic heat transfer enhancement the active biphasic particles. The effective heat transfer gain (up to 500%) of biphasic turbulence is believed to result from the combined contributions of (a) the kinematics of the active particles (see the blue shaded part in Fig. 2), and (b) their induced liquid agitation (see the blue shaded part in Fig. 2).

Insets (b)-(d) show novel heat carriers of the system: (b) biphasic risers, (c) settlers, and (d) plumes. Insets (e)-(f) show shadowgraphy images of the classical heat transporters of thermal turbulence, namely (e) hot and (f) cold thermal plumes. Inset scale bars: 6 mm. (g) Heat flux enhancement expressed as the ratio of Nusselt numbers $\mathrm{Nu}/\mathrm{Nu}_0$ vs temperature difference $T_b - T_{cr}$. Here Nu is the Nusselt number of the current system, Nu_0 is the Nusselt number of classical thermal turbulence, T_b is the bottom plate temperature, and T_{cr} is the boiling point of HFE-7000 liquid above which the dynamic evaporation-condensation cycles begin. Inset shows the vapor phase of the biphasic species volume fraction α.

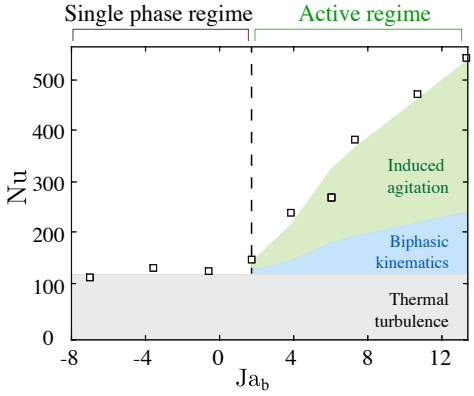

Figure 2: Nusselt number for increasing Jakob number Ja_b. The shaded areas show different contributions to the total heat transfer enhancement, namely thermal turbulence (gray), biphasic particle kinematics (blue) and induced liquid agitation (green).

CONCLUSIONS

In summary, we have created an efficient class of active biphasic thermal turbulence by the addition of a minute quantity ($\sim 1\%$) of a low boiling point liquid, which provides sustained heat transport enhancements (by up to 500%) that well-surpasses the limits achievable by classical thermal turbulence. The drastic enhancement is found to be the kinematics of the active particles and their induced liquid agitation. The biphasic particle system attains this state through minimal operational modifications to the existing thermal turbulence system, which may revolutionize future industrial designs. Remarkably, the system shows regimes of linear scalings of heat exchange with temperature change (for independent changes in bottom and top plate temperatures), and for aspect ratio changes, suggesting robust predictability and heat transfer control in both heating and cooling applications. The biphasic transport here is efficient, self-sustained and dynamically equilibrated, and requires minimal operational modifications to existing closed-system heat exchangers. Furthermore, the biphasic species (HFE-7000) is non-corrosive, non-flammable, and non-ozone depleting (ODP 0), and hence holds promise as a safe and highly effective "catalyst-like" additive in contemporary clinical, biochemical, and nuclear engineering settings.

RAYLEIGH–BÉNARD CONVECTION IN CYLINDRICAL CONTAINERS WITH RING-SHAPED ROUGHNESS OF THE PLATES

Mohammad Emran and Olga Shishkina *[1]
[1] Max Planck Institute for Dynamics and Self-Organization, Am Fassberg 17, 37077 Göttingen, Germany

Summary We investigate the influence of the regular roughness of the heated and cooled plates on the mean heat transport in a cylindrical Rayleigh–Bénard convection (RBC) cell of the aspect ratio one, by means of three-dimensional direct numerical simulations (DNS; totally 115 different cases). The roughness is introduced by a set of isothermal obstacles, which are attached to both plates and have a form of concentric rings of the same width. The considered Prandtl number is $\mathrm{Pr} = 1$, the Rayleigh number Ra varies from 10^6 to 10^8, the number of the rings on each plate is up to 10, the height of the rings is varied from 3% to 80% of the cylinder radius and the gap between the rings is varied from 3% to 37.6% of the cell radius. Our DNS show that by small Ra and wide roughness rings, a small reduction of the mean heat transport (the Nusselt number Nu) is possible, but in general, the presence of the heated and cooled obstacles leads to an increase of Nu, compared to the case of classical RBC with smooth plates. For very tall obstacle rings and sufficiently wide gaps between them, the effective mean heat flux can be several times larger than in the smooth case. For any prescribed roughness geometry, the scaling exponent in the Nu vs. Ra scaling first increases with growing Ra, up to approximately 0.5, but then smoothly decreases back towards the exponent in the no-obstacle case.

INTRODUCTION

In classical RBC [1] the heating and cooling plates are assumed to be smooth, while in most applications this assumption is not fulfilled. Roughness of the plates or the presence of the heated and cooled obstacles, which are attached to the corresponding plates, can influence significantly the mean heat and momentum transport in the system, which are represented by the Nusselt number Nu and Reynolds number Re, respectively. Moreover, the scaling relations of Nu and Re on the main input parameters of the system, which are the Rayleigh number Ra and Prandtl number Pr, are also affected by the wall roughness. Thus, it was reported that, compared to the case of smooth plates, the exponent γ in the scaling relation $\mathrm{Nu} \sim \mathrm{Ra}^{\gamma}$ can be larger (e.g., [5, 7, 13]) and/or the pre-factor in this relation can be increased (e.g., [6, 9]). For moderate Ra up to 10^8, 3D DNS [12] in a cubical container with a fixed rectangular roughness showed that γ first increases with growing Ra, but then saturates back to the smooth-wall value. Similar results were obtained in 2D DNS [14], for a broad Pr-range and Ra up to 10^{10}. 2D simulations based on the immersed boundary method (IBM) [16] for Ra up to 10^{12} showed that at $\mathrm{Ra} \approx 3 \times 10^9$ there is a transition from one scaling regime with $\gamma \approx 1/2$ for smaller Ra to another regime with $\gamma \approx 1/3$ for larger Ra. Therefore the regime with $\gamma \approx 1/2$ can be interpreted neither as the ultimate regime for extremely high Ra nor as a transition to it, but rather as an intermediate regime triggered by the regular roughness. Similar results were obtained also in experiments [8]. In [2], it was obtained experimentally that γ increases for non-regular (power-law distributed) roughness, while for regular (periodic) roughness it is unaffected. This supported a theoretical model [11] that proposes a relation between the increase of γ and the surface's fractal dimension, for the case when the spectrum of the typical roughness length scales is sufficiently broad.

To address the question, whether the number of the roughness scales influences the Ra-range with increased γ, in [17] the effect of the multi-scale roughness in 2D IBM simulations, for Ra up to 10^{12}, was studied. A sinusoidally shaped roughness, represented by 3 different length scales, lead to the enhanced heat transport with $\gamma \approx 1/2$, which was observed for more than 3 decades of Ra. Note that for a single-scale roughness, this regime was restricted to only one and half decades of Ra [16]. Therefore, the more roughness scales means the broader Ra-range, where the increased γ can be observed. With an infinite spectrum of the roughness length scales, such that for any distance to the plate there exists a roughness scale which is smaller than this distance, one can anticipate a scaling regime with an increased γ that extends to extremely large Ra and thus is indistinguishable from the ultimate regime.

One should mention also that the plate roughness can not only increase but also can decrease Nu. This was obtained first in 2D DNS [10] and then confirmed in [15] and [4]. The reduction of Nu happens when the fluid stagnates in the gaps between the roughness elements and this leads in general to thicker thermal boundary layers (BLs) and smaller overall heat transport in the system, compared to the case of the smooth plates. The effect of Nu reduction happens at small roughness heights and this critical roughness height decreases very rapidly with growing Ra [15].

RESULTS

In this study we investigate the effect of the regularly distributed isothermal roughness obstacles in a cylindrical domain of the aspect ratio 1, which are attached to the heated bottom and cooled top plates and have the temperatures of the corresponding plates. The effect of the plate roughness is not modelled but instead, 3D DNS, using a direct Poisson solver, are conducted for Ra from 10^6 to 10^8, $\mathrm{Pr} = 1$ and various types of the concentric ring-shaped obstacles – on total 115 different cases [3]. The choice of the geometry is motivated mainly by the following reason: In cylindrical domains

with ring-shaped roughness elements, the turbulent wind, or the large-scale circulation (LSC) that develops in RBC cells for sufficiently large Ra, unavoidably goes across the roughness elements, independently from the LSC orientation. The full system of the governing equations under Oberbeck–Boussinesq approximation is considered. The effective quantities $\mathrm{Ra}_{\mathrm{eff}}$, $\mathrm{Re}_{\mathrm{eff}}$, $\mathrm{Nu}_{\mathrm{eff}}$ are based on the effective cell height H_{eff} which is determined by the fluid volume (the cylinder volume minus the volume of all obstacles) divided by the area of the horizontal cross-section of the cylinder.

The obtained results show that in the most cases the regular roughness leads to an increase of Nu. Only for small Ra and relatively small gaps between the obstacles, a reduction of Nu is possible, compared to the smooth-plate case, which, therefore, becomes irrelevant for high Ra. Our DNS confirm that the effect of the roughness comes out when the obstacle height is larger than the thickness of the thermal BL. In this case, the width of the gaps between the obstacles (a) and obstacle height (h) become important: for large gaps and tall obstacles, the mean heat flow can increase by several times, compared to the smooth-plate case. When the cavities between the obstacles are only partly washed out by the convective flow, the scaling exponent γ can increase up to $\approx 1/2$, but with further increase of Ra, the exponent slowly decreases and tends to that in the smooth-plate case. Larger number of the ring-shaped obstacles of sufficiently large heights and gaps between them, usually means a stronger heat transport in the system, since the additional heat flux in that case is proportional to the additional covering area of the heated/cooled surfaces.

Interesting funding is also that the destruction, or a complete re-organisation of a single-big-roll LSC, which is usually observed in classical RBC with smooth plates, can also lead to an increase of the global heat transport. Thus, by extremely tall obstacles, for a sufficiently large gaps between them, the LSC is transformed into a set of smaller rolls, each of which is located in a gap between two neighbouring obstacles of the same temperature and extends from the very bottom to the very top of the cell. This is similar to the phenomenon of Nu increase in classical RBC, affected by the cell confinement.

For any Ra, there exists an optimal configuration of the ring-shaped obstacles that provides the maximal Nu. Deeper investigation of this problem and also the dependence of the optimal configuration on Pr needs to be addressed in the future studies. From our present study, however, for $\mathrm{Pr} = 1$ and cylindrical container of the aspect ratio one, we can conclude the following. For a fixed effective Rayleigh number, $\mathrm{Ra}_{\mathrm{eff}}$, an increase of $\mathrm{Nu}_{\mathrm{eff}}$ due to the roughness can be obtained if both, the gap between the roughness elements, a, and the roughness height, h, are larger than the thicknesses of the thermal BL, δ_θ, in the smooth-plate case. An increase of the gap in the interval up to $a_{\mathrm{cr}} \approx 4\delta_\theta$, leads to a significant increase of the effective Nusselt number, $\mathrm{Nu}_{\mathrm{eff}}$. Further increase of a does not influence much the value of $\mathrm{Nu}_{\mathrm{eff}}$. Furthermore, for $a > \delta_\theta$, and $h > \delta_\theta$, the mean heat flux increases almost linearly with the roughness elements height, or with the additional area of the heated/cooled surfaces. Thus, the largest heat transport in the system is anticipated for thin and extremely tall roughness elements, where the gap between them equals $a = a_{\mathrm{cr}}$.

Summary We employ linear stability analysis as well as DNS simulations to investigate double diffusion when the unstably stratified scalar contributing to the density field settles with respect to the fluid. The linear stability analysis identifies a new, settling-driven instability mode that competes with the traditional double-diffusive mode. DNS simulations demonstrate the formation of layers in regions of parameter space where they do not occur for non-sedimentary systems. In a different regime, DNS simulations demonstrate the formation of gravity waves in regions of parameter space where they do not occur for non-sedimentary systems. A mean-field analysis clarifies the role of settling on both γ- and collective instability mechanisms.

INTRODUCTION

Stably stratified fluids whose density is a function of two scalar fields can give rise to double-diffusive instabilities, provided these two scalars diffuse at different rates and one of them is unstably stratified while the other one is not. An important example concerns the world's oceans, as heat diffuses about one hundred times more rapidly than salt. When warm, salty water overlies cooler, fresher water, so that the more slowly diffusing scalar is unstably stratified, we commonly observe an exponentially growing instability called salt fingering. By contrast, if the cold and fresh water is on top, the evolving instability is oscillatory in nature. In both cases, the resulting instability can contribute significantly to vertical transport. Other environments in which double-diffusion plays an important role include magmas, metals and stellar interiors. A comprehensive review of the field is given in the beautiful, recent book by Radko (2013).

In the present work, we aim to understand how the traditional picture of double-diffusion is modified if the unstably stratified scalar is a particulate phase with a Stokes settling velocity. A number of laboratory flow visualization experiments demonstrate that thermal or compositional density gradients can dramatically alter the effective settling velocity of the particles by driving double-diffusive instabilities or settling-driven convection. We provide a detailed quantitative understanding of double-diffusive instabilities involving a sediment phase, with implications for a wide range of processes, among them the outflow of sediment from buoyant river plumes into colder lakes or the saline ocean, the dynamics of certain classes of clouds, as well as ecological, astrophysical and engineering applications.

BASIC INSTABILITY MECHANISM

We conduct a linear stability analysis for a base state with constant gradients of temperature (or salt) and sediments. We find that the settling velocity generates a phase shift between the perturbation fields of the two scalars, which gives rise to a novel, settling-driven instability mode. This instability mechanism favors the growth of waves that are inclined with respect to the horizontal. It is active for all density and diffusivity ratios, including cases in which the two scalars diffuse at identical rates. If the scalars have unequal diffusivities, the new settling-driven instability mode competes with the elevator modes of the classical double-diffusive fingering instability. We present detailed linear stability results as a function of the governing dimensionless parameters, including cases involving lateral gradients of the base state density fields that result in predominantly horizontal intrusion instabilities (figure 1).

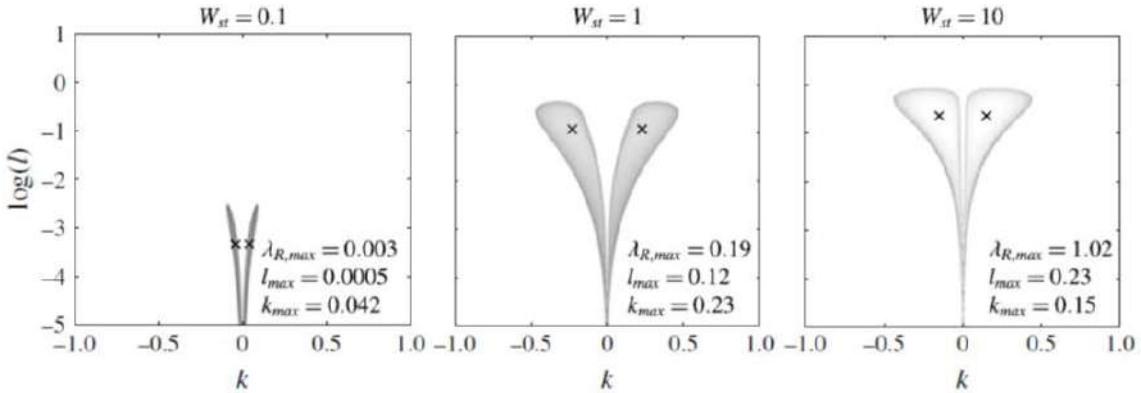

Figure 1. Linear stability results: maximum real part of the growth rate, as a function of the vertical (k) and horizontal (l) wavenumbers, for three different values of the settling velocity (from Alsinan et al. 2017).

LAYER FORMATION

Highly resolved two- and three-dimensional DNS results of the above systems serve to illustrate the nonlinear competition of the various instabilities in different parameter regimes. In particular, we find evidence for layer formation in sedimentary fingering convection in regions of parameter space where it does not occur for non-sedimentary systems (Reali et al. 2017, figure 2). This is due to two complementary effects. Sedimentation affects the turbulent fluxes and broadens the region of parameter space unstable to the γ-instability (Radko 2003) to include systems at larger density ratios. It also gives rise to a new layering instability that exists in γ-stable regimes. The former is likely quite ubiquitous in geophysical systems for sufficiently large settling velocities, while the latter probably grows too slowly to be relevant, at least in the context of sediments in water. Similarly, we also find that sedimentation broadens the range of parameter space where the basic instability gives rise to the spontaneous excitation of large-scale gravity waves (Ouillon et al. 2020), for the same two complementary reasons: the modification of the turbulent fluxes renders the flow unstable to the traditional collective instability (Stern 1969, Traxler et al. 2011), while settling gives rise to a new pathway towards instability. We finally note that layers induced by the γ-instability can form in the absence of gravity waves, further validating Radko's theory of layering (Radko 2003).

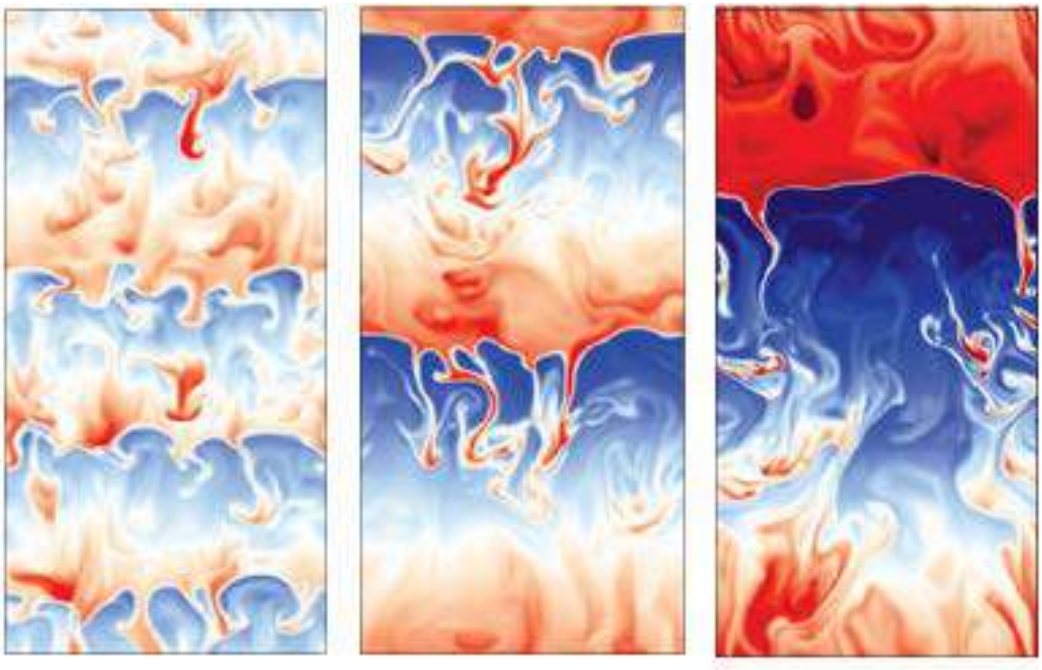

Figure 2. DNS simulation of layer formation in double-diffusive sedimentation (from Reali et al. 2017).

CONVECTIVELY-TRIGGERED MIXING OF A SHEARED INTERNAL WAVE

C. J. Howland[1], J. R. Taylor[1], and C. P. Caulfield [2]
[1] DAMTP, University of Cambridge, Cambridge, UK
[2] DAMTP & BP Institute, University of Cambridge, Cambridge, UK

Summary We use direct numerical simulations to investigate the turbulent mixing that arises due to the interaction of a sinusoidal shear flow and an internal gravity wave. Although the flow is in principle susceptible to shear instabilities, quasi-exponential growth of perturbations is only observed when the flow becomes sufficiently statically unstable, in the sense that a locally-defined Rayleigh number exceeds a critical value. This dynamical behaviour has significant implications for the ensuing irreversible mixing.

INTRODUCTION

Turbulent mixing exerts a vital influence on the transport of tracers such as heat, carbon and nutrients throughout the ocean. This mixing is especially important in the thermocline, where strong stratification inhibits vertical transport and turbulence can enhance diapycnal mixing (across density surfaces). Due to the strong stratification, turbulence in the thermocline is highly intermittent in both space and time, with sporadic, highly energetic 'mixing events' commonly attributed to the breaking of internal waves.

Near-inertial internal waves, whose dynamics are controlled by the Earth's rotation, introduce vertical shear and can break at sufficiently large amplitude through shear instabilities. By contrast, higher frequency internal gravity waves introduce vertical motion and strain into the density field, which can lead to breaking via a combination of shear and convectively-driven instabilities. Observations in the thermocline [1] reveal that local overturns in density profiles, associated with mixing, can be produced in regions where both shear and wave-induced strain contribute significantly to the flow dynamics.

Understanding how the interaction of internal gravity waves and near-inertial shear leads to turbulent mixing is thus vital in constraining diapycnal fluxes in the ocean interior. This study aims to identify whether turbulence is primarily induced by shear-driven instabilities or convectively-driven instabilities in such flows and pinpoint how these instabilities depend on the relative amplitude of the gravity waves compared to the shear. We also aim to quantify mixing, appropriately defined as the irreversible transfer of available potential energy to background potential energy, in these flows and test how well simple parameterisations can describe their energetics.

METHOD

Motivated by the observations of [1] in the ocean thermocline, we consider an initial value problem where the shear flow $\overline{u} = \sin(z)$, with a minimum gradient Richardson number of 1, is superimposed on a finite-amplitude internal gravity wave with wave vector $\mathbf{k} = (1/4, 0, 3)$. We perform the simulations in a triply-periodic domain at Reynolds numbers of 5000 and 8000, and vary the initial wave steepness s to investigate the relevant breaking mechanisms in different flow scenarios. The equations of motion are solved subject to the Boussinesq approximation and a uniform background stratification.

We extend the definitions of available potential energy from [2] and [3] for use in our triply-periodic computational domain, and compare the 'true' rate of irreversible turbulent mixing

$$\phi_d = \frac{Ri_0}{RePr} \left\langle \frac{\partial z_*}{\partial \theta} |\nabla \theta|^2 \right\rangle, \tag{1}$$

to the dissipation rate of scalar variance χ commonly used to infer mixing rates in stratified turbulence.

RESULTS

The initial dynamics of all our numerical simulations involve the shear flow distorting the internal wave in a similar fashion to how waves are refracted in weakly nonlinear ray tracing calculations. Perturbation length scales increase in regions associated with positive shear, whereas in regions of negative shear these scales decrease. For the larger values of initial wave steepness (e.g. $s = 1$) this quickly leads to regions with statically unstable density profiles, and a build-up of available potential energy. As shown in figure 1a, convective plumes develop locally in the region of negative shear (close to $z = \pi$), introducing spanwise variation to the initially two-dimensional flow. Only at later times do local shear instabilities develop, leading to the 'trains' of turbulent billow structures seen in figure 1b.

The energy associated with the spanwise velocity component grows exponentially in every simulation once a local Rayleigh number of $Ra = O(1000)$ exists somewhere in the domain, as seen from the orange curves (and dashed lines) in

*Corresponding author. E-mail: cpc12@cam.ac.uk

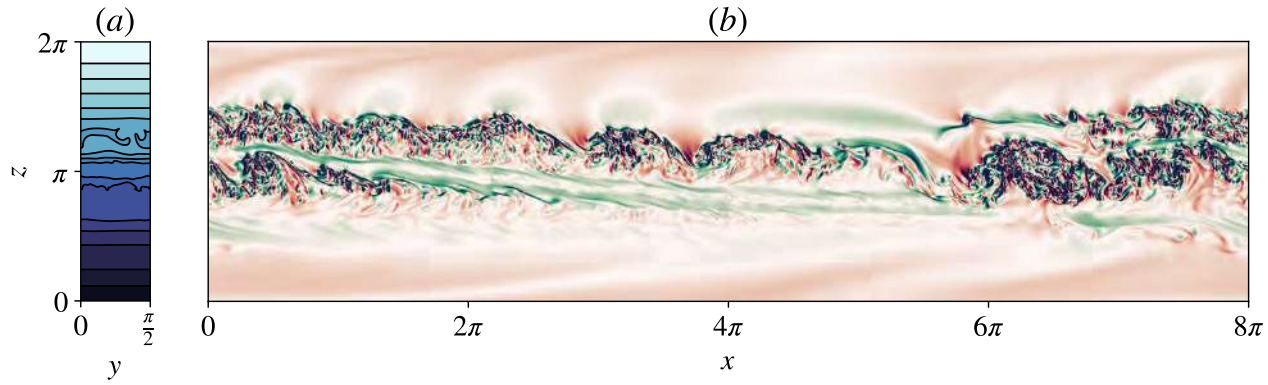

Figure 1: (a) Snapshot of density field contours in a spanwise-vertical plane at time $Nt = 26$. (b) Snapshot of the spanwise vorticity component in a streamwise-vertical plane at time $Nt = 32$. Both snapshots are taken from the simulation with initial wave steepness $s = 1$ at $Re = 5000$.

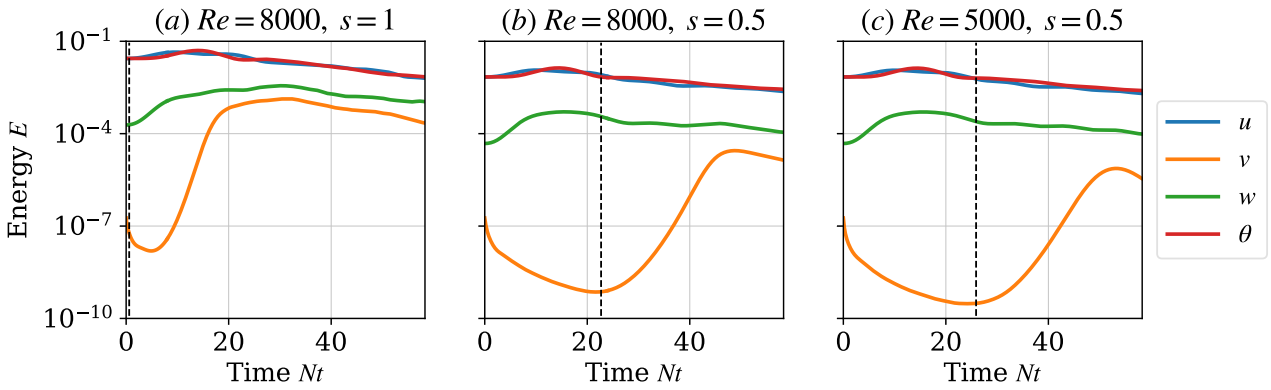

Figure 2: Time series of the perturbation energy associated with individual components of velocity $\mathbf{u}$ and the scalar field θ, plotted on a logarithmic scale. Dashed lines mark the first time when the maximum local $Ra \geq 2000$.

figure 2. We can deduce that a linear convective instability plays the key role in the early development of three-dimensional motion in these flows. Figure 2 also shows that the onset time of this exponential growth depends strongly on the initial wave steepness s, but not so much on the Reynolds number of the flow. The difference in the peak values of the spanwise energy in figures 2b and 2c highlights that smaller Re does however affect the nonlinear saturation of the instability.

As well as providing the apparently dominant mechanism for the generation of small scales, this local convection significantly modifies the density profile on which the turbulent structures seen in figure 1b develop. Locally this leads to strong variations in the correlations between the viscous dissipation rate ε and the irreversible mixing rate ϕ_d. Highly turbulent regions associated with high values of ε coincide with regions of both weak stratification and strong stratification, leading to extreme variations in the local instantaneous mixing efficiency. The ensuing changes in the local mixing rates may furthermore lead to significant changes in the inferred values of both the global mixing efficiency and the total diapycnal flux associated with these wave breaking events, demonstrating the central importance of convection, even in (apparently) statically stable shear-driven flows.

REDUCED FLOW REVERSALS IN TURBULENT RAYLEIGH-BÉNARD CONVECTION IN THE ABSENCE OF CORNER VORTICES

Heng-Dong Xi *[1], Xin Chen[1], and Dong-Pu Wang[1]
[1] School of aeronautics, Northwestern Polytechnical University, Xi'an, China

Summary We report a comparative experimental study of the reversal of the large-scale circulation in turbulent Rayleigh-Bénard convection in quasi-two dimensional (2D) cell with and without corner vortices. It is found that the reversal frequency (f) is greatly reduced in the corner-less cell. The reduction of the reversal frequency is more significant, in terms of both the amplitude and the scaling exponent, in the high Ra regime. Our results reveal that the role of corner vortices is to destabilize the main vortex thus increase the reversal frequency, especially in the high Ra regime. In addition, we classified the reversals into main-vortex-led (MVL) and corner-vortex-led (CVL). The frequency of MVL reversal in normal cell is found in excellent agreement with the frequency of reversals in corner-less cell where all the reversals should be MVL.

INTRODUCTION

Thermal convection is ubiquitous in nature and many engineering applications. Rayleigh-Bénard convection (RBC) is a model system for the study of the thermal convection problem [1-4]. In RBC, a well known coherent flow structure called large-scale circulation (LSC) had been studied extensively for last two decades. A fascinating feature of the LSC is the spontaneous and random reversal of its flow direction. The reversal of the LSC is of general interest for its putative connection to similar reversals in the atmosphere, and in the outer core of the earth. In the studies of the reversal of the LSC very often the (quasi-) two-dimensional (2D) rectangular convection cells are used and in such (quasi-) 2D geometry, the LSC consists of a big main vortex of a tilted-ellipse shape and two small corner vortices diagonally opposite to each other. It was found that the reversal of the LSC is accomplished as following: the corner vortices grow both in size and amplitude, squeeze and eventually break up the main vortex, then connect to each other to form a new big single-roll vortex again, but with a reversed circulating direction [5]. In this picture the corner vortices play a crucial role in the reversal process. However, it was recently found in a vertical thin circular cell where the corner vortices are absent that the reversal of the LSC could still occur [6]. It was also found that the scaling of the reversal frequency on Ra is controlled by the stability of main vortex [7]. To unlock the intricate dynamics behind these seemingly contradictory results a comparative study of the reversals in cells with and without the corner vortices becomes essential.

In this paper we report a comparative experimental study of the reversals of the LSC in a corner-less and a normal convection cell. It is found that in the corner-less cell the reversal of LSC still happens, and the reversal frequency decreases with Ra, and is divided into slow and fast decrease regimes. The transition of the reversal frequency in this corner-less cell is very similar to that in the normal cell, while the reversal frequency in the corner-less cell is greatly reduced. The reduction of the reversal frequency is more significant, in terms of both the amplitude and the scaling exponent, in the high Ra regime. Our results reveal, for the first time, the quantitative role of the corner vortices in the occurrence of the reversals of the LSC.

RESULTS AND DISCUSSION

We first compare the flow topology in the normal and the corner-less cells. The upper-right and lower-left insets of Figure 1 show the time averaged velocity field captured in the normal and the corner-less cells at similar Ra (7.94×10^8 and 7.56×10^8 respectively) for $Pr = 7.0$, and during the 2 hours average time, no reversal occurs. From the two velocity maps, one can see that the typical flow pattern in the normal cell, *i.e.* a main vortex in the shape of tilted ellipse and two small corner vortices sitting at the up-left and down-right corners. For the corner-less cell the flow pattern is totally different, due to the existence of the screens the main vortex feels no corners, thus it is in a circular shape. The fluid in the corner is trapped by the screen, forms a fixed-size small vortex at each corner. And those four fixed-size small vortices are restricted by the screens thus have no direct interaction with the main vortex. With the addition of the four screens a LSC without (the effects of) the corner vortices is indeed achieved.

We then examine the reversal frequency f in the normal cell and corner-less cell where f is defined as the averaged number of reversal events per second. In Figure 1, the measured reversal frequency f as a function of Ra for both corner-less and normal cell are plotted. As shown in the figure, similar to the normal cell case [7], it is found that in the corner-less cell the reversal frequency exhibits a slow decrease followed by a fast decrease with increasing Rayleigh number Ra, separated by a transitional Ra ($Ra_{t,r}$). Besides, the data from the corner-less cell also falls on the top of each other with two distinct scaling regimes being $f \cdot t_E \sim Ra^{-1.53\pm0.12}$ and $f \cdot t_E \sim Ra^{-5.05\pm0.18}$. The existence of the transition for both cases, with and without the corner vortices, confirms that the transition is originated from the stability of the main vortex [7].

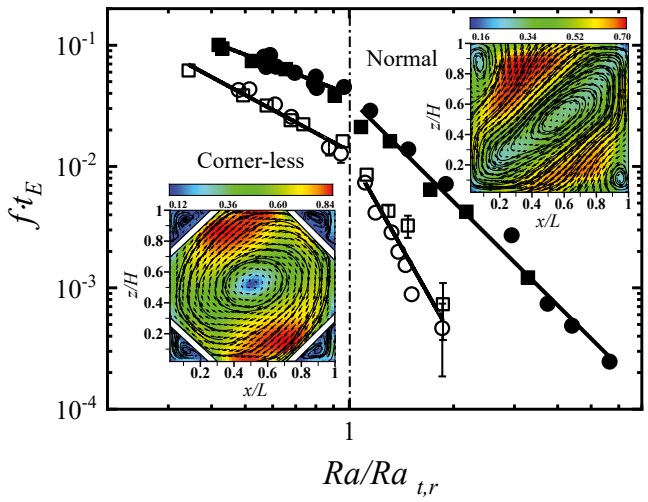

Figure 1: Flow reversal frequency f (normalized by $1/t_E$) as a function of Ra (normalized by transitional Ra ($Ra_{t,r}$)) for $Pr = 5.7$ (circles) and $Pr = 7.0$ (squares), where t_E is the turnover time of the LSC. The solid and open symbols are the data measured from normal cell and corner-less cell respectively. The solid lines are the power-law fits to the data. The two insets are the long time averaged PIV velocity maps with streamlines measured from the normal cell at $Ra = 7.94 \times 10^8$ (upper right) and the corner-less cell at $Ra = 7.56 \times 10^8$ (lower left), both at $Pr = 7.0$. The velocity is coded with both colour and vector length in units of cm/s.

Compared to that in the normal cell, f in the corner-less cell is greatly reduced. Moreover, one can see that the slope in $Ra < Ra_{t,r}$ regime does not change as much as that in $Ra > Ra_{t,r}$ regime. The reason is understandable: when $Ra < Ra_{t,r}$ the LSC is in the abnormal-single-roll-state (ASRS) where the interior of the main vortex is already broken into two small vortices [7], thus is very unstable, the reversal is mainly induced by the instability of the main vortex, the corner-vortex does not play a significant role. Thus when the corner-vortices are eliminated, the decay rate of the reversal frequency does not change much. While when $Ra > Ra_{t,r}$ the flow is in the single-roll-state (SRS), the main vortex is very stable and it is very hard for the reversal to occur if there are no corner vortices to drain energy from, and weaken and break the main vortex. In this regime the corner vortices are significant to the occurrence of the reversal, thus once the corner-vortices are eliminated, the reversal frequency is greatly reduced. Our results reveal that although the corner vortices are not necessary for the reversal, the presence of the corner vortices greatly increase the reversal frequency through destabilizing the main vortex, especially in the high Ra regime.

Summary We apply the weak formalism on the Boussinesq equations, to characterize scaling properties of the mean and the standard deviation of the potential, kinetic and viscous energy flux in very well-resolved numerical simulations. We investigate the scale-by-scale averaged terms of the weak equations, which are a generalization of the Kármán-Howarth-Monin and Yaglom equations. We have not found the classical Bolgiano-Oboukhov (BO) picture, but evidence of a mixture of BO and Kolmogorov scalings. All the energy fluxes are compatible with a BO local Hölder exponent for the temperature and a Kolmogorov 41 for the velocity. This behaviour may be related to anisotropy and to the strong heterogeneity of the convective flow, reflected in the wide distribution of BO local scales. We then investigate the properties of extremes events finding a way to characterise plumes in the core of the flow.

INTRODUCTION

According to the prediction based on a generalization of the Kolmogorov theory for turbulent fluids, first suggested for stably stratified flows (2; 7), the velocity and temperature increments scale like $\delta u_\ell \sim \ell^{1/5}$, $\delta T_\ell \sim \ell^{3/5}$ above the BO length, L_{BO}, resulting in a constant flux of potential energy towards small scale. In contrast, for scale $\ell < L_{BO}$, the kinetic energy flux is constant, so that $\delta u_\ell \sim \ell^{1/3}$. Unfortunately, several issues make difficult the measurement of the BO scaling in a closed domain (6). In particular, L_{BO} has been found to be globally of the order of the entire volume of the box, and the anisotropy could make also ambiguous to discern between the BO scaling and other shear-scaling (1). Moreover, the similarity argument does not take into account intermittency effect, produced by large fluctuations of velocity gradients or temperature gradients. Indeed, it is well known that both velocity and temperature are highly intermittent random fields, and therefore local dynamics or local energy exchange may be subject to intense fluctuations and strong inhomogeneity. The purpose of the present work is to put forward an approach capable to capture the full complexity of local energy fluxes and exchanges.

METHODS

We have carried out a very high-resolved DNS analysis of the small-scale properties of turbulent Rayleigh-Bénard convection in a cubic cell at $Pr = 1$. The unusually accurate resolution allows to go well below the Kolmogorov length. We have used two simulations at $Ra = 10^7$ and $Ra = 10^8$.
To compute the local inter-scale energy transfer and viscous dissipation in numerical data, we use the weak solution formulation generalization of the Kármán-Howarth-Monin equation (3). We present the local energy budget of Boussinesq equations, which relies on weak formulation of the equations (4) and has been derived in a recent work (5) for the case of stable-stratified flows. The local budget involves filtered or coarse-grained observable $\widetilde{o}_\ell$ defined as $\widetilde{o}_\ell(x,t) \equiv \int d^d r G_\ell(r) o(x+r,t)$, where the subscript ℓ refers to the scale dependence introduced by the filtering.

RESULTS

We have not found evidence of a standard BO scaling, which would mean $h_u = 3/5$, $h_T = 1/5$. Instead, our numerical experiment points out that only the temperature follows this BO scaling, so that buoyancy effects are found to be dominant on the temperature variance budget at small scales. Yet the velocity follows the Kolmogorov 41 scaling $h_u = 1/3$, at least in the available range of scales.

We will present also some results about instantaneous fluctuating budgets to highlight the link between plumes and extreme events in the flow. In figure 1, we show an example of instantaneous extreme event of inertial energy dissipation at $Ra = 10^8$ (left plot), and its corresponding temperature field (right plot). A clear connection between the two fields is visible.

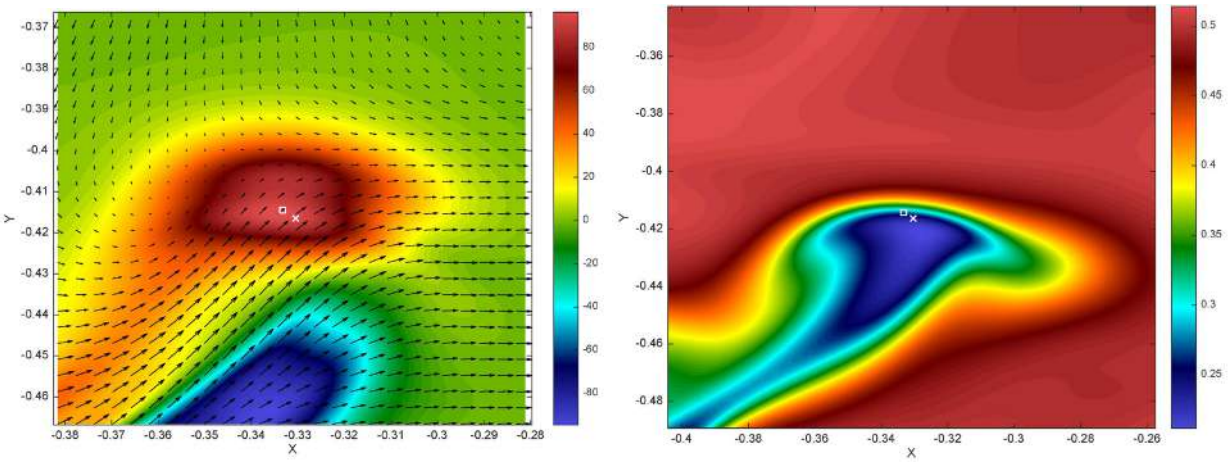

Figure 1: Instantaneous extreme event of inertial energy dissipation (left), and corresponding temperature field (right plot) at $Ra = 10^8$. The snapshots are plotted on an horizontal slice at half height of the cell.

CONCLUSIONS

From the analysis of the scale by scale averaged terms of the weak form of the Karman-Howarth-Monin equations we have observed a mixture of BO scaling for the temperature and Kolmogorov scaling for the velocity. Such peculiar behavior can be explained by removing the isotropic condition, and consider that the horizontal velocity increments and the vertical velocity increment scale with a different exponent, respectively h_u^H and h_u^V. In such a case, it is easy to see that the scaling exponent $\mathcal{D}$, $\mathcal{D}^T$, $\mathcal{D}^\nu$, $\mathcal{D}^\kappa$ will be respectively $\min(3h_u^H - 1, 3h_u^V - 1)$, $\min(h_u^H + 2h_T, h_u^V + 2h_T)$, $\min(2h_u^H - 2, 2h_u^V - 2)$, $2h_T - 2$. If we take $h_u^H = 1/3$, $h_u^V = 3/5$ and $h_T = 1/5$, we thus get the theoretical results.

SECONDARY FLOW AND HEAT TRANSFER IN TURBULENT FLOW OVER STREAMWISE RIDGES

Alexander Stroh*[1], Kay Schäfer[1], Pourya Forooghi[2], and Bettina Frohnapfel[1]
[1] Institute of Fluid Mechanics, Karlsruhe Institute of Technology, Karlsruhe, Germany
[2] Department of Engineering, Aarhus University, Aarhus, Denmark

Summary Surface structuring in form of streamwise-aligned triangular ridges is investigated in the framework of a fully developed turbulent channel flow with constant wall temperatures of different values prescribed on the upper and lower walls at $\mathrm{Re}_b = 18000$. Two arrangements of the ridges on both channel walls are considered – a symmetrical arrangement and a staggered arrangement with a spanwise shift of the upper wall structure by a half ridge-to-ridge separation. The ridges generate a strong large-scale secondary motion and hence enhance momentum and heat transfer in the channel by approximately 30% relatively to the smooth channel. In spite of the fact that both arrangements translate into very similar global flow properties, the composition of skin friction coefficient and Stanton number significantly differs. The componental split-up of the friction coefficient reveals that the enhancement of momentum transfer mainly originates from the dispersive component linked to the secondary flows. For the Stanton number, however, the enhancement arises not only from the dispersive component, but also from a strong modification of the turbulent flow properties.

INTRODUCTION

Secondary flows of Prantl's second kind are known to be generated in turbulent boundary layer flows subjected to a spanwise inhomogeneity of the near-wall flow field [1]. The spanwise inhomogeneity alters local turbulent properties of the flow and introduces distinct gradients into the Reynolds stress distribution, which eventually manifests in the presence of large-scale vortex pairs occupying the entire boundary layer thickness and can significantly modify the mean velocity profile.The presence of secondary flow translates into an enhancement of momentum and heat transfer, which is of great interest from atmospherical, geological and technical point of view [2]. In technical applications, the spanwise inhomogeneity of the near-wall flow field can be introduced by various means of intentional surface structuring or unintentional local surface roughening through e.g. erosion or deposition during device operation. The present contribution presents a detailed analysis of the secondary flow generated in a channel with streamwise ridges and the related heat transfer.

METHODOLOGY

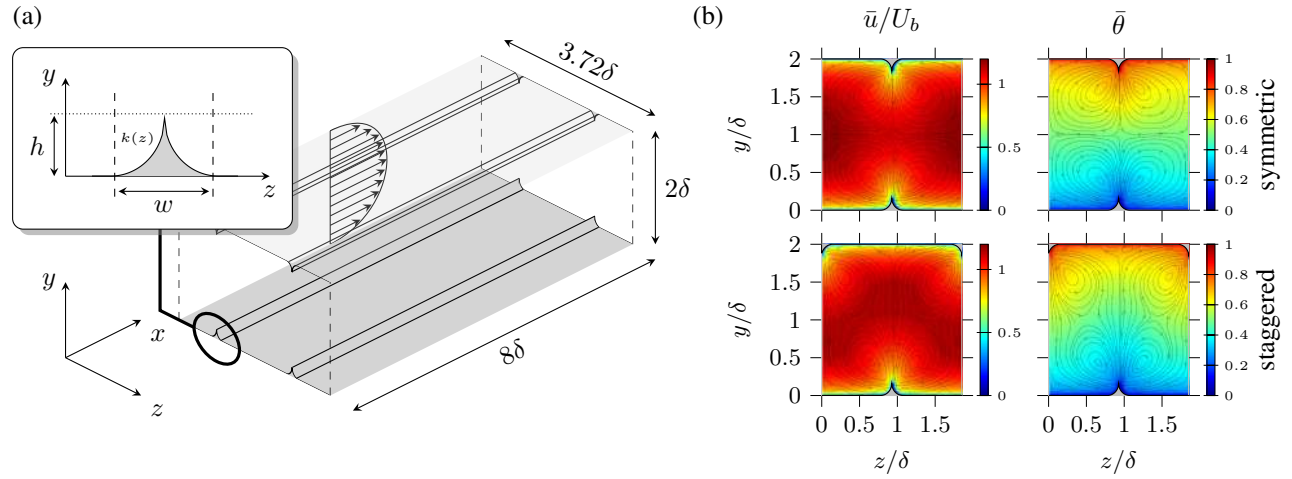

Figure 1: (a) Schematic of the simulation domain with ridge geometry and (b) mean velocity and temperature fields overlayed with secondary motion patterns for symmetric and staggered arrangement. [3]

The analysis is carried out using flow fields produced by a direct numerical simulation (DNS) in a fully developed turbulent channel flow driven at a constant flow rate (CFR) fixed to $Re_b = 2U_b\delta/\nu = 18000$ for all considered simulations. Periodic boundary conditions are applied for velocity field in the streamwise and spanwise directions, while the wall-normal extension of the domain is bounded by no-slip boundary conditions at the lower and upper domain wall ($y = 0, 2\delta$). Temperature is treated as a passive scalar with periodic boundary conditions applied for the thermal field in x- and z-directions, while a constant temperature on lower and upper wall is applied (T_l and T_u). This results in a fixed heat flux in the wall-normal direction. The Prandtl number is chosen to be Pr = 0.71, assuming air as the working fluid. The schematic of the numerical domain is depicted in Figure 1(a). The domain is discretized with $768 \times 385 \times 384$ grid nodes.

The wall structuring is modeled by an immersed boundary method (IBM) through introduction of external volume force field to the Navier-Stokes equations [4]. The surface geometry of a streamwise-elongated triangular ridge is formed by two converging arcs with $r = 0.16\delta$ resulting in a height distribution $k(z)$ (see Figure 1 a). The elevated structures are placed on both channel walls in symmetric or staggered arrangement, where the structures on the upper wall are shifted in spanwise direction by half the element separation. The spanwise spacing between the ridges is given by $S = 1.86\delta$.

Table 1: Integral flow properties and decomposition of the skin friction coefficient and Stanton number.

RESULTS

The topology of the secondary flow, its influence on the streamwise mean velocity distribution and the related temperature distribution are shown in Figure 1(b) for the two considered configurations. Table 1 summarizes the integral properties of the three considered flow configurations. An increase of skin friction coefficient by 34% and 36% and an enhancement of Stanton number by 29% and 31% are estimated for the symmetrical and staggered arrangement in comparison to the smooth case, respectively. In spite of the fact that the two different arrangements yield very similar global behavior in terms of friction coefficient and Stanton number, the composition of these flow properties differs significantly. The triple decomposition [5] and FIK-identity split-up [6] (see Table 1) with laminar part ($\cdot^L$), a turbulent fluctuation part ($\cdot^T$), a dispersive fluctuation part ($\cdot^D$) and an IBM-related contribution ($\cdot^F$) for skin friction coefficient, $C_f = C_f^L + C_f^T + C_f^D + C_f^F$ and Stanton number, $\mathrm{St} = \mathrm{St}^L + \mathrm{St}^T + \mathrm{St}^D + \mathrm{St}^F$, reveal the fact that the augmentation of skin friction coefficient is governed by the additional dispersive component originating from the generated secondary motion. The dispersive component is more dominant in the staggered arrangement. As for the Stanton number, it is evident that its augmentation also emerges mainly from the dispersive contribution in the staggered arrangement. The symmetric arrangement demonstrates a weaker dispersive contribution in combination with a significant enhancement of the turbulent contribution in the outer flow region. The wall-normal distribution of the individual contributions to C_f and St are shown in Figure 2(a) and (b), respectively. The figure reveals that the local componential contribution is linked to the secondary flow topology. In the staggered arrangement the secondary flow is allowed to expand more freely into the opposite channel half, while in the symmetric arrangement the wall-normal jets on the ridge-tips oppose each other and confine the topology of the secondary motion (see Figure 1,b). This translates into the enhancement of turbulent heat flux for the symmetric case, while only a slight enhancement can be observed close to the centerline of the channel in staggered arrangement.

CONCLUSION

A DNS study of a turbulent fully-developed flow over structured surfaces in two configurations (symmetric and staggered arrangement) is performed and compared to the smooth channel case. We find that the introduction of the ridges results in a generation of strong large-scale secondary motion with a local magnitude up to $6.6\%U_b$. The presence of secondary motion significantly affects momentum and heat transfer properties of the flow. In spite of the fact that the two different arrangements yield very similar global behavior in terms of friction coefficient and Stanton number, the composition of these flow properties differs significantly. The results suggest that both dispersive and turbulent contributions are mutually affected by the secondary flow topology, which are in turn controlled by the arrangement of the surface structures. This indicates the possibility to manipulate the mechanisms involved in momentum and heat transfer by varying the surface structure. The study also confirms an alteration of turbulent properties away from the wall through generation of large-scale secondary motions introduced by wall structuring.

Summary We present our efforts on the development of direct numerical simulations of Rayleigh-Bénard convection towards the ultimate regime. In particular, we present new simulation results for simulation up to $Ra = 10^{13}$ and $Pr = 0.7$ in a $\Gamma = 1/2$ cell. A one-to-one comparison with the Göttingen measurements shows excellent agreement between experiments and simulations, both for the overall heat transfer and measurements of local flow quantities. The Göttingen measurements reveal that the transition to the ultimate regime takes place around $Ra \approx 2 \times 10^{13}$, so our simulations are close to reaching this. Furthermore, results for $Ra = 10^{14}$, $Pr = 0.7$ in a $\Gamma = 0.23$ cell will be discussed. These simulations are in good agreement with measurements by Roche et al., New J. Phys. 12, 085014 (2010).

INTRODUCTION

Rayleigh-Bénard (RB) convection, the flow in a box heated from below and cooled from above, is the model system used to study thermal convection. The main control parameters are the Prandtl number $Pr = \nu/\kappa$, the ratio of viscosity to diffusivity, and the Ra number $Ra = \beta g \Delta L^3/\kappa\nu$, which measures the strength of thermal driving. Here, β is the thermal expansion coefficient, g the gravitational acceleration, Δ the temperature difference between two plates, and L the height of the sample. Both in experiments and simulations of RB convection, it is a major challenge to reach the ultimate regime in which the boundary layers transition from laminar to turbulent [1]. Figure 1a shows that for not too high Ra, i.e. $Ra = 5 \times 10^{11}$, all experiments and simulations on the heat transport agree very well. For higher Ra, in the ultimate regime, the scaling exponent γ in the relation $Nu \sim Ra^{\gamma}$, where Nusselt Nu is the dimensionless heat transport, increases. This figure also shows that there are two facilities (in Grenoble), which show an increased Nusselt number already around $Ra = 5 \times 10^{11}$, while other experiments (in Göttingen) [2] show this transitions around $Ra \approx 2 \times 10^{13}$. The observation of the ultimate regime in the Göttingen experiments are in agreement with the unifying theory for thermal convection [3], according to which the ultimate regime should set in when the shear Reynolds numbers at the boundaries is sufficiently high. There is no clear explanation for the mentioned disagreement. However, it is conjectured that unavoidable variations of the Pr number, finite conductivity of the horizontal plates and sidewall, non-Oberbeck-Boussinesq effects, i.e., the dependence of the fluid properties on the temperature, and even wall roughness and temperature conditions outside the cell might play a role. So far, the highest Ra obtained in direct numerical simulations is $Ra = 2 \times 10^{12}$ for aspect ratio $\Gamma = 0.5$ [4].

MAIN RESULTS

A major challenge in obtaining a high Ra number in direct numerical simulations is the required grid resolution to resolve all physical flow scales. An estimate of the computational resources needed for direct numerical simulation of turbulent RB convection is obtained by evaluating the number of nodes that is required. The basic assumption is that the flow can be divided into bulk and boundary layer regions, the former discretized by a mesh of the same size as the smallest between the Kolmogorov and Batchelor scales and the latter with the resolution criteria suggested by [5]. We further assume that the rectangular box has a size $W \times W \times L$ discretized in Cartesian coordinates, while the cylinder has a diameter D and a height L discretized in cylindrical coordinates. For the ease of discussion, we will restrict to $Pr = 1$, keeping in mind that as the Prandtl number deviates substantially from unity. The simulation becomes more demanding either because the velocity field develops finer scales than the temperature ($Pr \ll 1$) or vice versa ($Pr \gg 1$). For the mean Kolmogorov scale η we can easily write $\eta/L \approx (RaNu)^{1/4}$ that with a fit $Nu = ARa^{\beta}$ ($A \simeq 0.05$ and $\beta = 1/3$ from the high end of Ra in figure 1) yields a number of nodes per unit length in the bulk $N_{bu} = 0.473Ra^{1/3}$. For the resolution of each boundary layer we rely on the correlation derived by [5] which suggest a number of nodes $N_{bl} \approx 0.35Ra^{0.15}$. Within these figures, the total number of nodes for the rectangular domain reads $N_{Car} = \Gamma^2(0.105Ra + 0.156Ra^{0.816})$. For the cylindrical case this gives $N_{Cyl} = 0.5\pi\Gamma^2(0.105Ra + 0.156Ra^{0.816}) + \pi\Gamma(0.223Ra^{0.816} + 0.116Ra^{0.633})$. Dissipation spectra of turbulence [6] show a peak of around 10η, which implies that also a mesh of size 1.5–2η is sufficient to resolve

*Corresponding author. E-mail: r.j.a.m.stevens@utwente.nl.

most of the dissipation. In agreement with this view, numerical experiments show the simulation results convergence when we use about $1/8$ of the number of grid points given by the above estimates [8].

We will present a comparison between the Göttingen experiments and direct numerical simulations up to $Ra = 10^{13}$ [7, 9]. We find perfect agreement between experiments and simulations, both for the heat transfer, see figure 1a, and for the mean and temperature variance profiles close to the sidewall, see figure 1b and figure 1c. In addition, we discuss simulations for $\Gamma = 0.23$ up to $Ra = 10^{14}$, which are performed on grids with almost 100×10^9 nodes. The preliminary results from these simulations are in good agreement with measurements by Roche et al. [10].

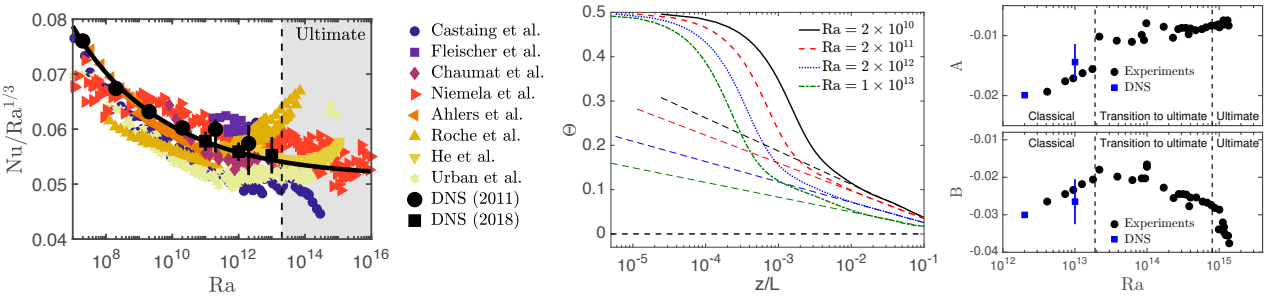

Figure 1: (a) Nu versus Ra for various experiments and simulations; detailed reference information can be found in Ref. [11]. (b) Logarithmic temperature profiles as function of height close to the sidewall at $(R - r)/L = 0.0045$ measured in the simulations. Panel (c) shows that excellent agreement is obtained for the coefficients A and B of the observed logarithmic temperature profiles $\Theta(z) = A \ln z/L + B$ shown in panel b, see Ref. [2]. The data for $Ra = 10^{13}$ is preliminary analysis of a simulation with $Pr = 0.7$ in a $\Gamma = 0.5$ cell performed on a computational grid with $6144 \times 1536 \times 6144$ nodes in the azimuthal, radial, and axial direction, respectively.

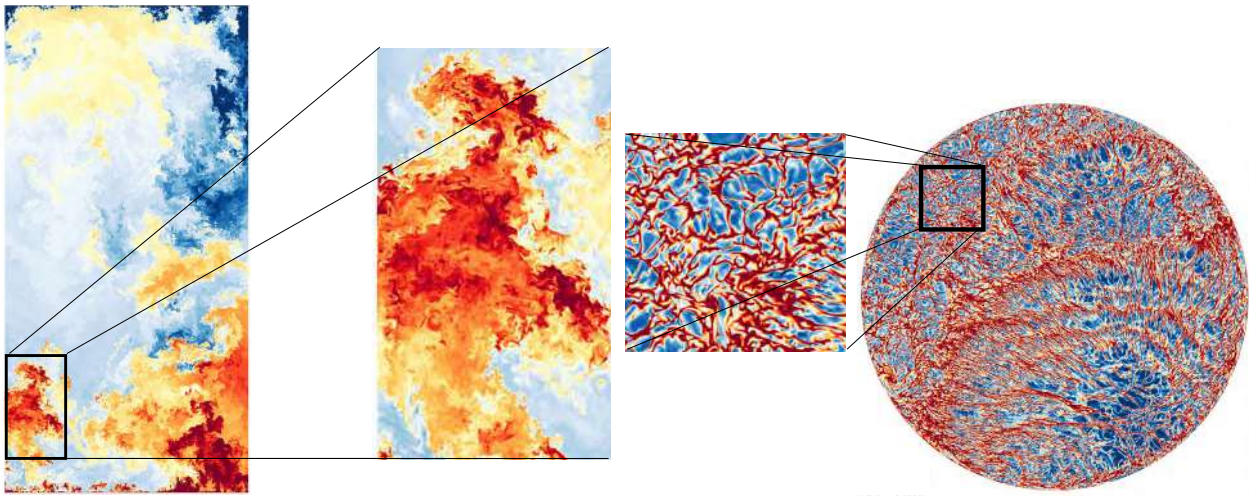

Figure 2: (left) Visualization of RB convection in a $\Gamma = 1/2$ cell at $Ra = 10^{13}$ for $Pr = 0.7$, which is close to the onset of the ultimate regime in corresponding measurements performed in Göttingen. (right) Snapshots of the temperature field at boundary layer height just above the hot bottom plate, which is at about 0.02% of the domain height of the cylinder.

ROTATING RAYLEIGH-BENARD CONVECTION WITH A MELTING BOUNDARY

S. Ravichandran *[1] and J. S. Wettlaufer [1,2]
[1] Nordita, KTH Royal Institute of Technology and Stockholm University, Stockholm, Sweden

Summary We study numerically the convection of fluid heated from below in a rotating container when the solid upper boundary can melt. The solid is composed of the same (pure) substance as the liquid. We examine the morphology of the phase boundary as a function of the Rayleigh, Rossby, Prandtl and Stefan numbers. In particular, we report here the influence of the Prandtl number. The effects are mediated through the columnar vortex state, typical of rotating Rayleigh-Benard convection. For the Rayleigh number $\mathcal{O}\left(10^7\right)$ considered here, columnar vortices with larger vertical velocities form for higher Prandtl numbers. Since these columnar vortices carry hot fluid from the heated boundary, the solid boundary melts in a pattern reflecting the size and number of columnar vortices.

INTRODUCTION

Rotating convecting systems that involve solidification or melting are common in astrophysical and geophysical fluid dynamics. Here, we study the dynamics of a single-component system with solid and liquid phases heated from below. Initially the lower half of the container is molten, and the upper half is solid. The vertical motion due to thermal buoyancy brings the heat necessary for phase change to the upper boundary. Thus, the Stefan problem associated with the melting of the solid and the movement of the solid-liquid interface has to be solved, in addition to that of fluid convection. The morphology of the melting solid is a result of the nonlinear interactions between convection and melting at the solid-liquid interface.

SETUP

The rigid container is of size $L \times L \times (A \times L)$, with gravity g along the $-z$ direction, and rotating about the $+z$ axis with an angular velocity Ω. The aspect ratio is taken to be $A = 0.5$ here. We assume that the solid and liquid have the same density ρ and heat capacity C_p, with possibly different thermal diffusivities κ_s and κ_l. The latent heat of fusion is λ. The lower boundary is hotter than the melting temperature T_m by an amount ΔT which is also taken to be the scale of temperature differences. The enthalpy H and the temperature T are nondimensionalised in terms of these quantities, giving

$$\phi = \frac{H - H_0}{C_p \Delta T}, \tag{1}$$

$$\theta = \frac{T - T_m}{C_p \Delta T}, \tag{2}$$

$$\tag{3}$$

where H_0 is the enthalpy of the solid at T_m. The equation of state relating θ to ϕ is

$$\theta = \begin{cases} \phi & \text{solid} \\ \phi - St^{-1} & \text{liquid,} \end{cases} \tag{4}$$

where $St = C_p \Delta T / \lambda$ is the Stefan number.

The length scale is the dimension of the container L, and the buoyancy velocity $U_b = (g\alpha \Delta T L)^{1/2}$ is the velocity scale (α is the coefficient of thermal expansion). Using these scales, the equations governing the motion can be nondimensionalised and become

$$\frac{D\mathbf{u}}{Dt} = -\frac{\nabla p}{\rho} + \frac{1}{Re}\nabla^2 \mathbf{u} + \mathbf{e}_z \theta - 2Ro^{-1}\mathbf{e}_z \times \mathbf{u}, \tag{5}$$

$$\nabla \cdot \mathbf{u} = 0 \tag{6}$$

$$\frac{D\phi}{Dt} = \frac{1}{RePr}\nabla \cdot (\hat{\kappa} \nabla \theta), \tag{7}$$

where $Re = U_b L/\nu$ is the Reynolds number, $Pr = \nu/\kappa_l$ is the Prandtl number, $Ro = U_b/(\Omega L)$ is the Rossby number, and $\hat{\kappa} = \kappa/\kappa_l$ is the ratio of local thermal diffusivity to the diffusivity in the liquid.. The Rayleigh number $Ra = Re^2 Pr/A^3$. In the solid, $\mathbf{u} = 0$ in equations (5-7).

*Corresponding author. E-mail: ravichandran@su.se

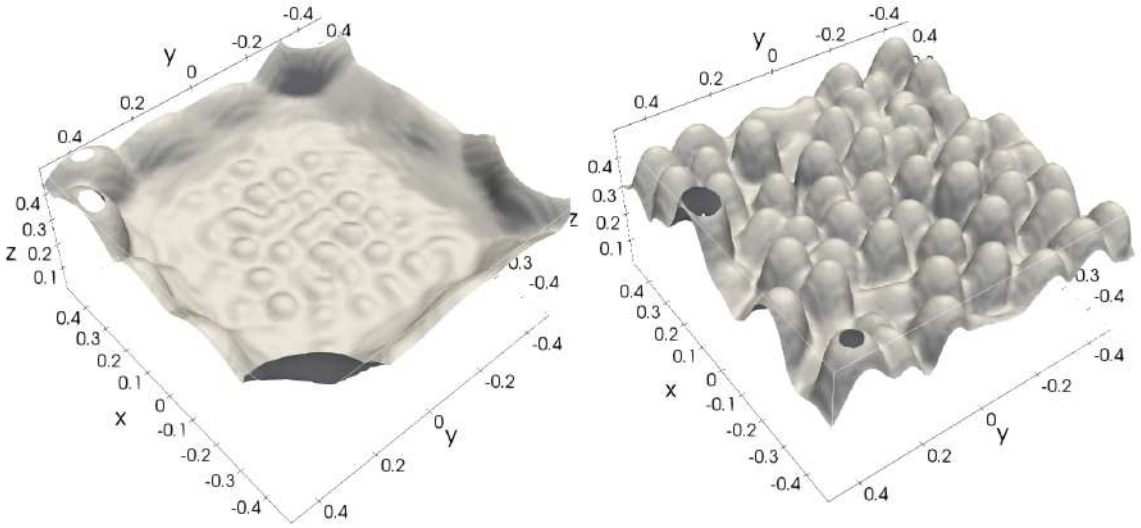

Figure 1: The solid-liquid interface at $t = 120$ for cases with $Pr = 1$ (left) and $Pr = 5$ (right). In the former, the flow is predominantly a peripheral streaming flow, with the result that more melting occurs around the periphery than near the axis. In stark contrast, for $Pr = 5$, the resultant melting forms inverted lobes, with the characteristic number and size of the columnar vortices for the given parameters reflected in the morphology of the interface. The solid-liquid interface shown is the iso-surface $\chi = 0.5$ (Eq. 8).

At $t = 0$, the bottom half of the domain is liquid, with enthalpy $\phi = St^{-1}$; the top half has enthalpy $\phi = 0$. The upper and lower boundaries are held at temperatures $\theta = -p$ and $\theta = 1$ respectively (p is a small number, taken to be $p = 0$ here). The lateral boundaries are insulating, no-slip walls. No-slip conditions are also applied at the solid-liquid interface, which is of an arbitrary shape and has a temperature $\theta = 0$. The lower wall has a constant temperature and free-slip.

Equations 5 - 7 are solved using a finite volume solver. The enthalpy method [1] is used to track the moving interface. The requisite velocity conditions in the resulting arbitrarily shaped solid region are applied using the volume-penalisation method [2] wherein the solid is modelled as a porous medium with vanishing porosity. This amounts to adding a term $-\frac{\chi}{\eta}\mathbf{u}$ to the right hand side of equation (5), where $\eta \ll 1$ is the penalisation parameter and χ is a phase-field identifying the solid region. χ can be related to the enthalpy ϕ as

$$\chi = 1 - \max\left(0, \min\left(1, St\phi\right)\right). \tag{8}$$

RESULTS

We present results for the case $St = 1$, with $Re = 5000$, $Ro = 0.2$ and two Prandtl numbers $Pr = 1$ and $Pr = 5$, with $\hat{\kappa} = 1$ for simplicity. The initial conditions are such that the entire system is at $\theta = 0$. The flow, we note, is in the rapidly rotating regime. For the parameters considered, the flow takes the form of columnar vortices spanning the entire liquid height for $Pr = 5$. For $Pr = 1$, on the other hand, a peripheral cyclonic streaming flow of alternating up- and downwelling regions results. These structures impinge on the solid in the upper half of the container, where the heat transported by them melts the solid in patterns reflecting the characteristics of the flow. Figure 1 shows the resultant solid-liquid interface at $t = 120$. When columnar vortices are present, the solid melts in an array of inverted lobes, the number of which corresponds to the number of columnar vortices.

CONCLUSIONS

The Stefan problem in a rotating convecting system has been studied using the enthalpy method, with the solid region simulated using a volume-penalisation method. This combination of numerical methods is straightforward to incorporate into an existing numerical solver. The influence of the Prandtl number on the characteristics of the flow, and thence on the melting of the solid, is demonstrated. The roles of the Rayleigh, Rossby and Stefan numbers, and the influence of other boundary conditions are explored in detail in a publication currently under review ([3]).

ULTIMATE HEAT TRANSFER IN 'WALL-BOUNDED' CONVECTIVE TURBULENCE

Shingo Motoki *[1], Kouki Kawano[1], Masaki Shimizu[1], and Genta Kawahara[1]
[1] Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka, Japan

Summary Direct numerical simulations have been performed for turbulent thermal convection between two horizontal no-slip, permeable plates with the distance H and the temperature difference ΔT. On the no-slip plate surfaces $z = 0, H$ the wall-normal transpiration velocity is assumed to be proportional to the local pressure fluctuation, i.e., $w = -\beta p'/\rho, +\beta p'/\rho$ (Jiménez *et al.* 2001). The permeability parameter is fixed at $\beta(g\alpha\Delta T H)^{1/2} = 3$, and the Prandtl number is set to unity, where $(g\alpha\Delta T H)^{1/2}$ represents the buoyancy-induced terminal velocity. At lower Rayleigh number Ra, the Nusselt number Nu scales with Ra as $Nu \sim Ra^{1/3}$, as commonly observed in turbulent Rayleigh–Bénard convection. At higher Ra, on the other hand, the ultimate scaling $Nu \sim Ra^{1/2}$ is observed. We shall discuss the reason why the ultimate scaling can be achieved in this 'wall-bounded' system.

INTRODUCTION

Rayleigh–Bénard convection is one of the most canonical turbulent flows. It is thermal convection driven by buoyancy, and dimensionless parameters in this system are the Rayleigh number Ra and the Prandtl number Pr. At low Ra wall-to-wall heat flux is given by thermal conduction. When Ra is increased, thermal convection arises and eventually convective turbulence appears to drastically enhance the heat flux. The dimensionless wall-to-wall heat flux normalized with the thermal conduction heat flux is the Nusselt number Nu. A large number of experiments and numerical simulations have been performed, and the scaling law $Nu \sim Ra^{0.31}$ have been commonly observed at $Ra \sim 10^8 - 10^{11}$ (see e.g. He *et al.* 2012). Grossmann & Lohse (2000) have proposed the scaling theory of Nu with Ra and Pr. Their theory gives us the scaling $Nu \sim Ra^{1/3}$ in the high-Ra range $Ra \sim 10^8 - 10^{14}$ for $Pr \sim 1$.

It has long been anticipated that at extremely high Ra, both thermal and kinetic energy dissipation ϵ are dominated by the bulk region rather than the thermal and kinetic boundary layers, leading to the so-called ultimate scaling $Nu \sim Ra^{1/2}$ (Kraichnan 1962; Grossmann & Lohse 2000). However, the ultimate scaling has not been observed even at very high Ra as yet. Even in convective turbulence with surface roughness, it is still an open question whether or not the ultimate scaling can be achieved (Zhu *et al.* 2017, 2019).

In this study we investigate turbulent thermal convection between horizontal no-slip, permeable plates heated from below and cooled from above by numerically solving the Boussinesq equation (Kawano *et al.* 2020). We have found that wall permeability brings about the ultimate scaling $Nu \sim Ra^{1/2}$.

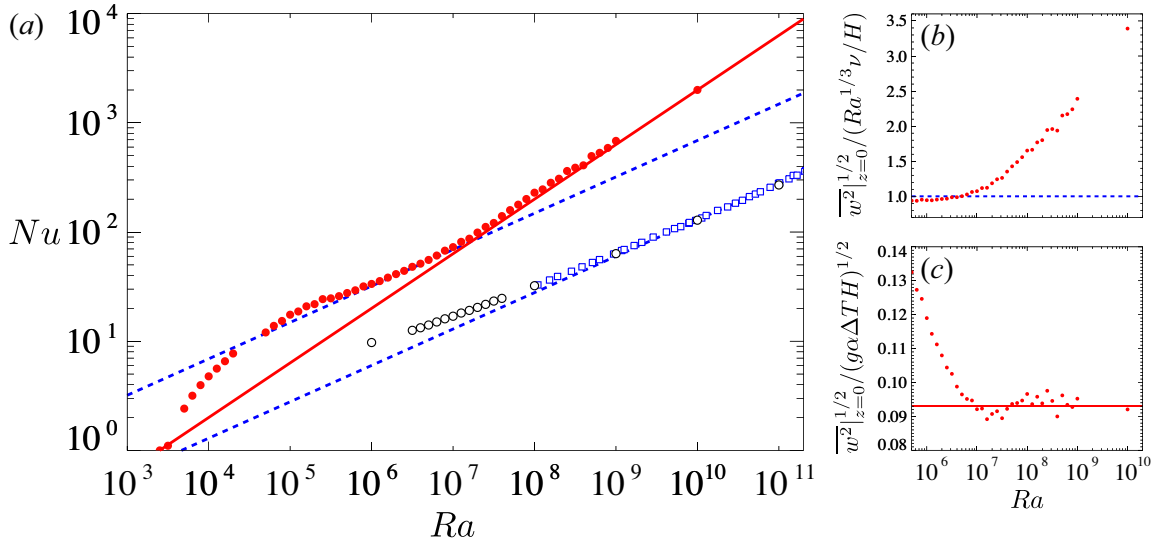

Figure 1: (*a*) Nusselt number Nu as a function of the Rayleigh number Ra. (*b,c*) Root-mean-square vertical velocity at the wall normalized by (*b*) $Ra^{1/3}\nu/H$ and (*c*) $(g\alpha\Delta T H)^{1/2}$. The closed red circles and the open black circles respectively represent the permeable case $\beta(g\alpha\Delta T H)^{1/2} = 3$ and the impermeable case $\beta(g\alpha\Delta T H)^{1/2} = 0$ for the Prandtl number $Pr = 1$. The blue open squares indicate experimental turbulent data from Niemela & Sreenivasan 2006 (cylindrical container). The solid red line and the dashed blue line stand for the scalings $Nu \sim Ra^{1/2}$ and $Nu \sim Ra^{1/3}$, respectively.

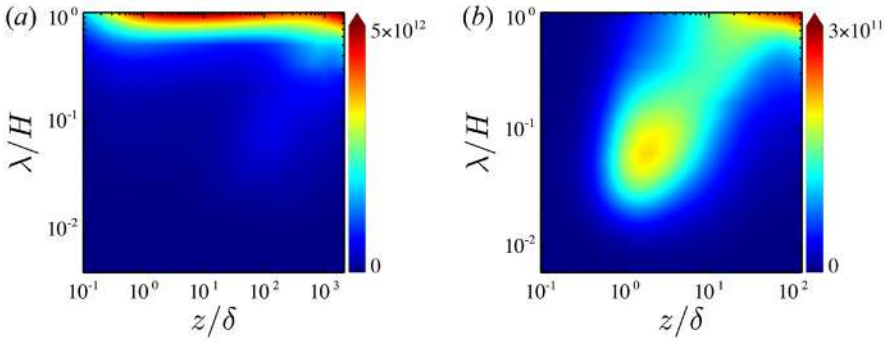

Figure 2: Premultiplied spectra of buoyancy power $g\alpha Tw$ as a function of the horizontal wavelength λ and the distance to the lower wall z in (a) the permeable case $\beta(g\alpha\Delta TH)^{1/2} = 3$ and (b) the impermeable case $\beta(g\alpha\Delta TH)^{1/2} = 0$ at $Ra = 10^{10}$ for $Pr = 1$. $\delta = \Delta T/\mathrm{d}\overline{T}/\mathrm{d}z|_{z=0}$ represents the thermal conduction length.

SCALING OF THE NUSSELT NUMBER WITH THE RAYLEIGH NUMBER

We perform direct numerical simulations for convective turbulence between the horizontal plates with the distance H and the temperature difference ΔT using a Fourier–Chebyshev spectral method. The no-slip, permeable conditions, $u = v = 0$ and $w = -\beta p'/\rho$, $+\beta p'/\rho$ (Jiménez *et al.* 2001), are imposed on the plate surfaces $z = 0$, H. The permeability parameter is fixed at $\beta(g\alpha\Delta TH)^{1/2} = 0$ (impermeable case), 3 (permeable case), where $(g\alpha\Delta TH)^{1/2}$ denotes the buoyancy-induced terminal velocity. The Prandtl number is set to unity, and both horizontal periods, L_x and L_y, are taken to be H.

Figure 1(a) shows the Nusselt number Nu as a function of the Rayleigh number $Ra = g\alpha\Delta TH^3/(\nu\kappa)$. In the impermeable case $\beta(g\alpha\Delta TH)^{1/2} = 0$, at high $Ra \sim 10^8 - 10^{10}$ the Nusselt number can be seen to scale with the Rayleigh number as $Nu \sim Ra^{1/3}$, nearly consistent with the well-known turbulent scaling law $Nu \sim Ra^{0.31}$ (see e.g. He *et al.* 2012). In the permeable case $\beta(g\alpha\Delta TH)^{1/2} = 3$, on the other hand, the ultimate scaling $Nu \sim Ra^{1/2}$ can be observed undoubtedly at higher $Ra = 10^8 - 10^{10}$, whereas the ordinary scaling $Nu \sim Ra^{1/3}$ is confirmed at lower $Ra \sim 10^6$. It is worthy of note that the scaling property of Nu critically changes at $Ra \sim 10^7$ from $Nu \sim Ra^{1/3}$ to $Nu \sim Ra^{1/2}$ with increasing Ra. Even in the permeable case, at lower $Ra \sim 10^6$ we have not observed significant wall-normal transpiration velocity (figure 1b) in the near-wall region, implying that the ultimate scaling cannot be achieved.

DISCUSSION ON ULTIMATE SCALING

Premultiplied spectra of buoyancy power $g\alpha Tw$ are shown in figure 2 as a function of the horizontal wavelength λ and the distance to the lower wall z in the permeable case $\beta(g\alpha\Delta TH)^{1/2} = 3$ and the impermeable case $\beta(g\alpha\Delta TH)^{1/2} = 0$ at $Ra = 10^{10}$ for which the ultimate scaling has been observed in the permeable case (see figure 1a). In the impermeable case the significant buoyancy power can be seen for small-horizontal-scale motion, i.e. near-wall plumes, in the vicinity of the wall $z/\delta \sim 10^0$. In the permeable case, on the other hand, even in the the vicinity of the wall $z/\delta \sim 10^0$ the large-horizontal-scale motion can be induced by buoyancy.

Let us discuss this remarkable difference in the near-wall length scale between the permeable and the impermeable case, leading to difference in the Nu scaling. In the permeable case at higher $Ra \sim 10^8 - 10^{10}$ significant wall-normal transpiration velocity is induced even in the near-wall region (figure 1c). Therefore, although the thermal conduction layer still exists on the wall, there is no near-wall layer of the wall-normal (vertical) velocity in the higher-Ra permeable case, suggesting that there would not appear small-scale vertical motion in the near-wall region where the effects of the viscosity on the vertical velocity is negligible. The vertical motion should exhibit the length scale comparable with H anywhere, and thus the balance between the dominant buoyancy and inertial terms in the vertical Boussinesq equation gives us the velocity scale of the order of the buoyancy-induced terminal velocity $(g\alpha\Delta TH)^{1/2}$. Then the energy budget equation, including pressure power on the permeable plates (being an energy sink and comparable with ϵ), provides us with the Taylor's dissipation law $\epsilon \sim (g\alpha\Delta TH)^{3/2}/H$ as well as the ultimate scaling $Nu \sim Ra^{1/2}$ in the higher-Ra permeable case.

Summary Numerical simulations for 2D Rayleigh-Bénard convection with regular obstacles with varying density, mimicking different porosity ϕ, are performed, in order to reveal the transition from the traditional RB convection to Darcy-type porous-media convection. The heat transfer $Nu(\phi)$ is surprisingly found to vary non-monotonously: With decreasing ϕ, it first increases, before it decreases for ϕ approaching 0. The non-monotonous behavior originates from two competing effects of the porous structure on the heat transfer, which we identify, based on both global and local analysis of the flow: On the one hand, the flow coherence is enhanced in the porous media, which is beneficial for the heat transfer. On the other hand, the convection is slowed down by the enhanced resistance due to the porous structure, leading to heat transfer reduction.

INTRODUCTION

One of the paradigms for thermal convection studies is Rayleigh-Bénard (RB) convection, i.e., convection in a box heated from below and cooled from above, and it has been studied extensively over the last decades [1–3]. Also the related problem of convection in a fluid-saturated porous medium has received increasing attention, owing to its importance in a wide range of natural and industrial processes, such as geothermal energy recovery and geological sequestration of carbon dioxide [4, 5]. When a porous medium is present in a convection cell, the convection is blocked and the flow is stabilized. The strength of the stabilizing effect can be quantified by the porosity ϕ. On first sight the stabilizing effect is stronger for more blockage, i.e., for smaller porosity ϕ. In thermal convection, however, in general the interplay between stabilizing and driving forces can result in surprising effects. Chong *et al.* [6] found that for thermally driven flows stabilized in various ways the appropriate strength of the stabilizing force can lead to significant heat transfer *enhancement* due to increased flow coherence, in particular, revealing an universal mechanism of the turbulent transport enhancement in the presence of stabilizing forces. Obviously, when the stabilizing force gets even stronger, the flow motion is eventually suppressed, leading to heat transfer reduction. Consequently, the heat transport varies non-monotonously with the strength of the stabilizing force.

The objective of this study is to find out whether such a non-monotonic behavior also exists for thermally driven flow stabilized by porosity, i.e., to find out whether the (dimensionless) heat transfer $Nu(\phi)$ is non-monotonic, to clarify the connection of this system to other stabilizing-destabilizing flows, and to understand the local flow structure. Surprisingly, although both the traditional RB convection without the porous structure and the Darcy-type porous-media convection have been studied extensively, hardly any studies have been done to reveal the physics of the transition process between these two extreme cases.

METHOD

We perform a numerical study of a representative porous medium model, namely two-dimensional (2D) RB convection in regular porous media. Circular, solid obstacles with diameter l are spaced uniformly on a square lattice. In such a pore-scale model, the detailed flow in the pores is resolved and the interaction between the porous medium and various flow structures of convection is faithfully captured, which are essential to connect the macroscopic properties with the microscale mechanisms. As Prandtl number, we take $Pr = 4.3$ for water.

RESULTS AND DISCUSSION

Figure 1a shows the effect of the porosity ϕ on the (dimensionless) heat transfer Nu for $Ra = 10^7$ and 10^8. It is observed that $Nu(\phi)$ varies non-monotonously as ϕ is decreased from 1 (full porosity, so no obstacles included). First, when ϕ is slightly decreased, the heat transfer is enhanced, and then when ϕ is sufficiently small, it is reduced as compared to the $\phi = 1$ case. Correspondingly, there is an optimum porosity for the heat transfer, which dependents on Ra. The non-monotonic behavior of $Nu(\phi)$ is indeed reminiscent of the influence of other stabilizing forces on turbulent transport through coherent structure manipulation [6]. The reason for the non-monotonic behavior is that the obstacle array has two

Thematic Session FM

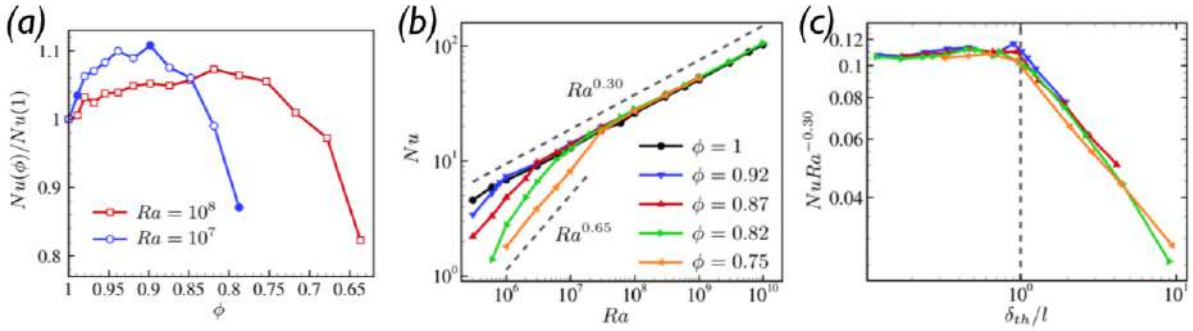

Figure 1: Global transport quantities: (a) $Nu(\phi)$ for two different Rayleigh numbers Ra, (b) $Nu(Ra)$ for different porosities ϕ, (c) The compensated Nusselt number $Nu/Ra^{0.30}$ vs the thermal boundary layer thickness δ_{th} (in terms of the obstacle diameter l) shows universal behavior.

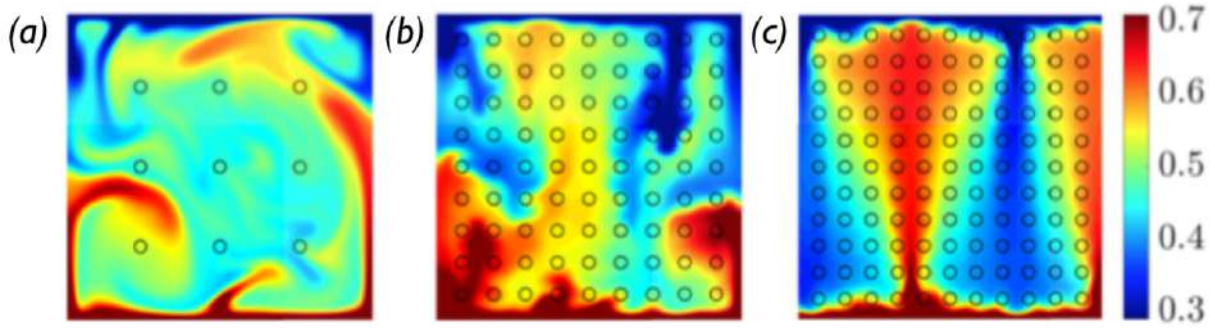

Figure 2: Local flow properties: Snapshots of the instantaneous temperature field at $Ra = 10^7$ and different porosities ϕ, corresponding to the three filled symbols in figure 1a. (a) $\phi = 0.99$, (b) $\phi = 0.90$, (c) $\phi = 0.85$.

competing effects on the heat transfer. On the one hand, the flow becomes more coherent with the correlation between temperature fluctuation and vertical velocity being enhanced, leading to heat transfer enhancement. On the other hand, the convection strength is reduced due the impedance of the obstacle array, leading to heat transfer reduction. This interpretation is supported by the local snapshot of the flow (figure 2).

The influence of porosity on flow properties depends on Ra, and two different heat transfer regimes are observed at fixed ϕ, see figure 1b. In the small-Ra regime where viscosity dominates, Nu is decreased as compared to the $\phi = 1$ case with a steep effective power law $Nu \sim Ra^{0.65}$, while in the large-Ra regime Nu is increased as compared to $\phi = 1$ with the classical power law $Nu \sim Ra^{0.30}$. The scaling crossover occurs when the thickness δ_{th} of the thermal boundary layer δ_{th} is comparable to the pore scale l – implying an universal curve $Nu(\phi)$ vs δ_{th}/l, see figure 1c. In both scaling regimes the $Nu(Ra)$ dependence can be estimated in the spirit of the unifying theory of refs. [7], in which the energy dissipation rate and the thermal dissipation rate and their distributions between bulk and boundary layer play the central role.

OUTLOOK

Presently, we have restricted us to the heat transfer and flow structure of 2D RB convection in regular rectangular porous media. In the future, we will extend the study to the 3D case, to allow for a one-to-one comparison to experiment, and to different regular and disordered obstacle arrangements.

TURBULENT ROTATING CONVECTION TO THE EXTREME

Matteo Madonia[1], Andrés Aguirre Guzmán[1], Jonathan Cheng[2], Herman Clercx[1], and Rudie Kunnen *[1]
[1] Fluids and Flows group, Department of Applied Physics, Eindhoven University of Technology, Eindhoven, The Netherlands

Summary We study turbulent rotating convection in the so-called geostrophic regime; a state where rotation strongly shapes the flow but buoyant forcing is strong enough to enforce vigorous turbulence. The geostrophic regime is believed to be descriptive of geophysical and astrophysical flows. We report heat transfer and flow measurements from dedicated large-scale experiments of geostrophically constrained convection, a unique foray into this scarcely accessed but eminently relevant flow regime.

Introduction

Planetary-scale buoyancy-driven flows abound in nature, where the interplay between buoyant forcing and the rotation of the celestial body is decisive in the shaping of these flows. We study this interplay in a model system: rotating Rayleigh–Bénard convection (RRBC), the flow between two rotating horizontal plates driven by heating from below and cooling from above. The strength of the thermal forcing is quantified by the Rayleigh number $Ra = g\alpha\Delta T H^3/\nu\kappa$, where g is the gravitational acceleration, H the vertical separation of the plates and ΔT the applied temperature difference, and α, ν and κ are the thermal expansion coefficient, kinematic viscosity and thermal diffusivity of the fluid, respectively. The Prandtl number $\sigma = \nu/\kappa$ characterizes the fluid. Finally, to quantify rotation we use the Ekman number $E = \nu/2\Omega H^2$ with Ω the rotation rate.

Due to the sheer size of natural flows, we are faced with extreme parameter values: the Rayleigh number, with its cubic dependence on size, can take large values $Ra \sim 10^{20} - 10^{25}$, while the Ekman number, scaling as H^{-2}, is small, $E \sim 10^{-15} - 10^{-12}$. The flow behaviour at these extreme parameters is considerably different from that at moderate parameter values; the so-called geostrophic regime of rotating convection, named after the dominant geostrophic balance of pressure gradient and Coriolis force, is expected to be descriptive of these natural flows. However, to study this regime in a laboratory setting, to get to extreme parameter values, poses quite some challenges.

Figure 1: TROCONVEX at 4 m height.

TROCONVEX: a unique laboratory setup

It is clear that the height H of the convection volume is a crucial parameter for reaching extreme values for Ra and E [1]. This is the starting point of the design of TROCONVEX (Turbulent ROtating CONVection to the EXtreme), a 4 m tall cylindrical vessel for the study of RRBC in water (figure 1). A convenient coincidence is that strong rotational constraint (small E) reduces the typical horizontal scale considerably; it follows the length scale of convective onset $L_C \sim E^{1/3}$ [2, 3]. That is why our slender container (diameter 0.39 m) still captures at least ten horizontal length scales L_C. The cylinder consists of four sections, so that we can also use smaller H when desired. The setup can perform heat transfer measurements and is equipped with active thermal insulation on bottom and sidewall, where temperature-regulated heat shields prevent losses. Additionally, thermistors at several vertical positions in the sidewall can be used for diagnostics.

Results: flow structure and heat transfer

To check the feasibility of replicating the various flow features expected in the geostrophic regime based on asymptotically reduced models [2], we have visualised the flow with rheoscopic fluid extracted from shaving cream [4]. Figure 2 displays some examples, where we indeed find the expected flow features of (rotating) convection. The various degrees of axial organisation at different ratios of buoyancy and rotation is striking: starting from a strong vertical coherence as rotation dominates (columns; fig. 2c), as the thermal forcing is increased, columns turn into plumes with some wavy vertical variation (fig. 2d); then on to geostrophic turbulence (fig. 2e) where small-scale coherence is mostly lost and a fluctuating bulk is observed; finally on to rotationally-influenced turbulence (fig. 2f) where buoyancy is strong enough to mostly overcome the restrictions imposed by rotation.

These visualisations can be used in the interpretation of the heat transfer data, compiled in figure 3 (left panel). We report the Nusselt number $Nu = qH/k\Delta T$, where q is the heat flux density and k the thermal conductivity of the fluid, the total heat flux normalised by the conductive flux. From convective onset, we find a series of scaling ranges with different slopes [1], approaching the nonrotating heat transfer at higher Ra as expected when buoyancy dominates over rotation.

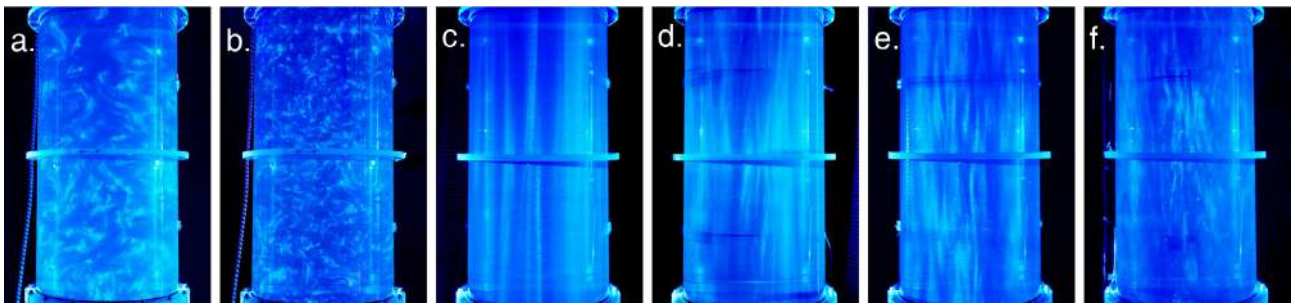

Figure 2: Visualisations of (rotating) convection. Nonrotating convection at (a) $Ra = 1.4 \times 10^{11}$, (b) $Ra = 2.2 \times 10^{12}$. Rotating convection at $E = 5 \times 10^{8}$ and (c) $Ra = 9.6 \times 10^{10}$ (convective Taylor columns), (d) $Ra = 8.6 \times 10^{11}$ (plumes), (e) $Ra = 1.6 \times 10^{12}$ (geostrophic turbulence), (f) $Ra = 3.3 \times 10^{12}$ (rotationally-influenced turbulence).

However, regime boundaries (dotted and dashed vertical lines) are not quite conclusively identified by considering only the heat transfer.

That is why we turn to the sidewall temperature statistics. The vertical profile of temperature $\overline{T}(z)$ displays a mean bulk gradient in RRBC [2], in contrast to the vanishing slope of nonrotating convection. We determine the mid-height temperature gradient $-\partial_z \overline{T}|_{z=0.5}$ and plot it in figure 3 (right panel) for the measurements at $E = 3 \times 10^{-7}$ (other E omitted for clarity). A clear, non-monotic dependence on Ra can be observed, where the scaling inversions do align nicely with predicted transitions between flow states. We thus have a potent diagnostic for the delineation of the flow phenomenology that is more pronounced than just the heat transfer.

Conclusion and outlook

TROCONVEX is a dedicated experimental tool to map the convective heat transfer and the corresponding flow structures in the geostrophic regime of RRBC in detail. There is solid agreement between experiments and accompanying direct numerical simulations; however, the latter can only probe the flow at reduced parameter values. For exploration of the flow statistics in geostrophic convection the experimental approach is more feasible. That is why we are currently implementing a transparent section for extension to stereo-particle image velocimetry, to get quantitative flow data. The first results will be presented at this conference.

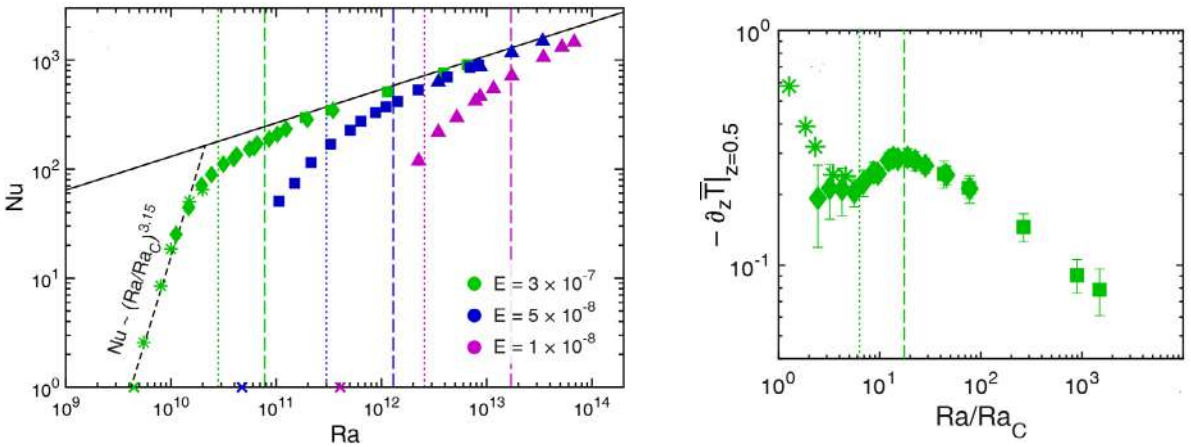

Figure 3: Left panel: Heat transfer data from TROCONVEX. Symbol shape indicates tank height H: 0.8 m (diamonds), 2 m (squares), 4 m (triangles). Asterisks are results from accompanying direct numerical simulations. Crosses indicate the critical Ra_C for onset of convection [3]. The solid line in the left panel is the best-fit trend $Nu = 0.11 Ra^{0.308}$ to our datapoints for nonrotating convection (not shown here); dotted lines indicate the predicted transition from columns to plumes, vertial dashed lines the predicted transition from geostrophic to rotationally-influenced turbulence. Right panel: corresponding measurements of the mid-height temperature gradient at $E = 3 \times 10^{-7}$.

CONTROL OF THE VERTICAL SPEED OF BUOYANCY-DRIVEN FINGERS BY DIFFERENTIAL DIFFUSION EFFECTS

S. S. Gopalakrishnan [1], B. Knaepen[1], and A. De Wit *[1]
[1] Université libre de Bruxelles (ULB), CP231, 1050 Brussels, Belgium

Summary A miscible horizontal interface separating two solutions of different solutes in the gravity field can deform into convective finger-like structures due to buoyancy-driven instabilities like the classical Rayleigh–Taylor (RT) instability or the double-diffusive (DD) and diffusive-layer-convection (DLC) instabilities, triggered by differential diffusion of the solutes in the solutions. We show that, in two-species stratifications, the vertical speed of the fingers induced by these various instabilities scale as the dynamic density jump triggered by differential diffusion effects.

FINGERING IN PRESENCE OF DIFFERENTIAL DIFFUSION

In the gravity field, a stratification between two solutions of different compositions can become unstable because of various buoyancy-driven instabilities. The Rayleigh–Taylor (RT) instability develops at the interface when a denser solution overlies a less dense one in the gravitational field deforming it into finger-like structures [1]. When a less dense solution overlies a denser one, differential diffusion effects can destabilize the miscible interface if at least two different solutes contribute to change the density. When the denser lower solution contains a solute diffusing faster than the solute in the upper less dense zone, a double-diffusive (DD) instability can induce a fingered deformation of the interface [1]. Such a double-diffusive instability has been extensively studied in the context of salt fingers that form in oceans where thermohaline convection is triggered by the differential diffusion of salt and heat. When the solute in the upper solution is the one that diffuses faster, an unstable scenario arises due to the formation of an accumulation zone below the interface and a depletion zone above it. The formation of a locally unstable density stratification on either sides of the interface drives locally convective motions that propagate independently through the solutions. This instability mechanism is referred to as diffusive-layer convection (DLC) [1].

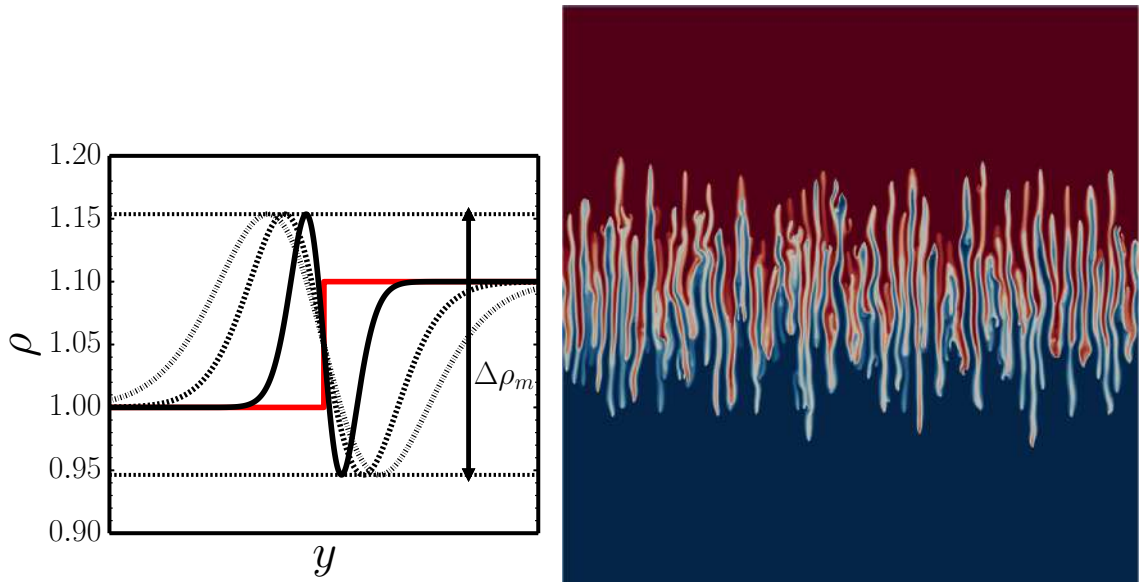

Figure 1: (Left) In presence of differential diffusion, the density profile becomes non-monotonic and features a dynamic density jump $\Delta\rho_m$ that can be larger than the initial density difference $\Delta\rho_0$ (here in red) between the two solutions. (Right) Rayleigh-Taylor fingering in presence of differential diffusion. The vertical speed of the fingers scales linearly with $\Delta\rho_m$.

We show numerically that, in presence of differential diffusion, a non-monotonic density profile can develop for these various instabilities, in which the dynamic density jump $\Delta\rho_m$ between the two extrema can be larger than the initial density difference $\Delta\rho_0$ between the two solutions (Fig.1). When buoyancy-driven fingers develop due to RT, DD or DLC modes, the vertical speed of the fingers observed (see Fig.1 for an example of RT [2]) is found to scale linearly with $\Delta\rho_m$ when $\Delta\rho_m > \Delta\rho_0$ (Fig.2). We classify the various scalings in the parameter space spanned by the two parameters of the problem: the buoyancy ratio R which is related to the ratio of the densities of the two solutions and δ the ratio of diffusion coefficients of the two solutes involved [3].

*Corresponding author. E-mail: adewit@ulb.ac.be

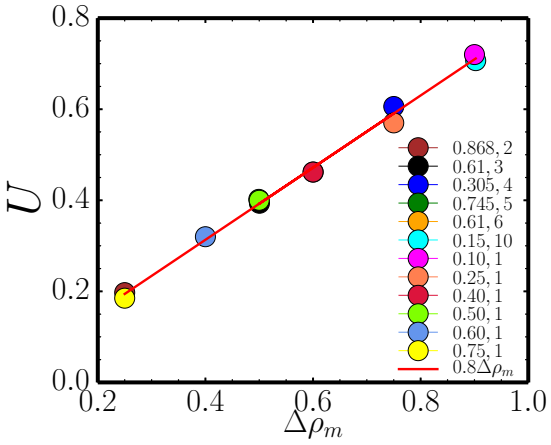

Figure 2: The vertical speed U of the fingers scales as the dynamic density jump $\Delta\rho_m$ for different couple of (R, δ) values.

CONCLUSIONS

In two-species stratifications, the fact that the two different solutes influencing density diffuse at different rates can induce non-monotonic density profiles. If the adverse dynamic density jump $\Delta\rho_m$ developing in this case is larger than the initial density difference $\Delta\rho_0$ between the two solutions, the vertical speed of the fingers scales linearly with $\Delta\rho_m$. This paves the way to differential diffusion control of the mixing between two solutions by a careful choice of the solutes at hand [3].

BI-DIMENSIONAL SOLUTAL PLUME GENERATED FROM AN EXTENDED SOURCE

Niloy De *[1], Patrice Meunier[2], Yves Méheust[3], and François Nadal[1]
[1] Wolfson school of Mechanical and Electrical Engineering, Loughborough University, Loughborough, UK
[2] IRPHE, CNRS, Aix-Marseille University, France
[3] Laboratoire GéoScience, Université de Rennes, France

Summary Experiments and numerical calculations are performed to study the dynamics of a single 2D plume generated from an extended source. A water-filled Hele-Shaw cell is placed vertically in a pressure chamber and pressurized with carbon dioxide. The CO_2-enriched layer that builds underneath the surface destabilizes into a plume that pours down to the bottom of the cell. At moderate Rayleigh numbers, the transverse concentration profile is reasonably fitted by a function of the form $c(x) = A[\cosh(x/l)]^2$, where both the amplitude A and the width l are functions of the altitude. The scaling laws observed in the numerical simulations for the dimensionless plume width l and vertical velocity w are close to the theoretical scaling laws obtained from mass conservation: $l \sim Ra^{1/2}$ and $w \sim 1$ for $Ra < Da^{-1}$; $l \sim Ra^{3/4}Da^{1/4}$ and $w \sim (RaDa)^{1/2}$ for $Ra > Da^{-1}$.

INTRODUCTION

In the current context of global warming, the mitigation of greenhouse gas emission is the utmost concern. In this context, geological storage of carbon dioxide (CO_2) appears a promising solution. Upon injection, supercritical CO_2 rises up to the top caprock and immediately starts dissolving at the water/brine interface, leading to a CO_2-enriched layer of brine that happens to be heavier that the underlying pure brine. After a diffusion stage, this (gravitationally) unstable configuration triggers a gravitational instability where convective plumes are generated and pour downwards to the bottom of the aquifer. In such a convective regime, the dissolution rate of CO_2- that is the efficiency of the CO_2-trapping - is greatly enhanced.

At the laboratory scale, such gravitational instability can be reproduced by means of CO_2-pressurized Hele-Shaw cells [2] and visualized with pH -sensitive color indicators - since CO_2-dissolution increases the acidity of aqueous solutions. Amongst all the available pH indicators, Bromocresol purple (BP) has a pH range between 6.8 and 4.8, which is suitable for changes in pH induced by moderate partial pressures of carbon dioxide. A theory based procedure is then used to convert the pH -map into a CO_2-concentration field. In the present work, we have used BP to experimentally study the dynamics of a single plume in a Hele-Shaw cell generated from an laterally extended source. We have explored the plume dynamics for a partial pressure of CO_2 ranging from 0.5 to 5 bar, and a source size lying in the range $2 \rightarrow 8$ mm. 2D numerical calculations have been performed to complement the experimental results and confirm the scaling laws predicted by mass conservation considerations over a wide range of Rayleigh and Darcy numbers.

EXPERIMENTAL CONFIGURATION AND METHOD

Mechanical and optical set up

The experimental set up consist of a Hele-Shaw cell filled with the solution of pH indicator (BP) and placed at the centre of a pressure chamber initially filled with nitrogen. The chamber is connected to a CO_2-filled reservoir by a ball valve

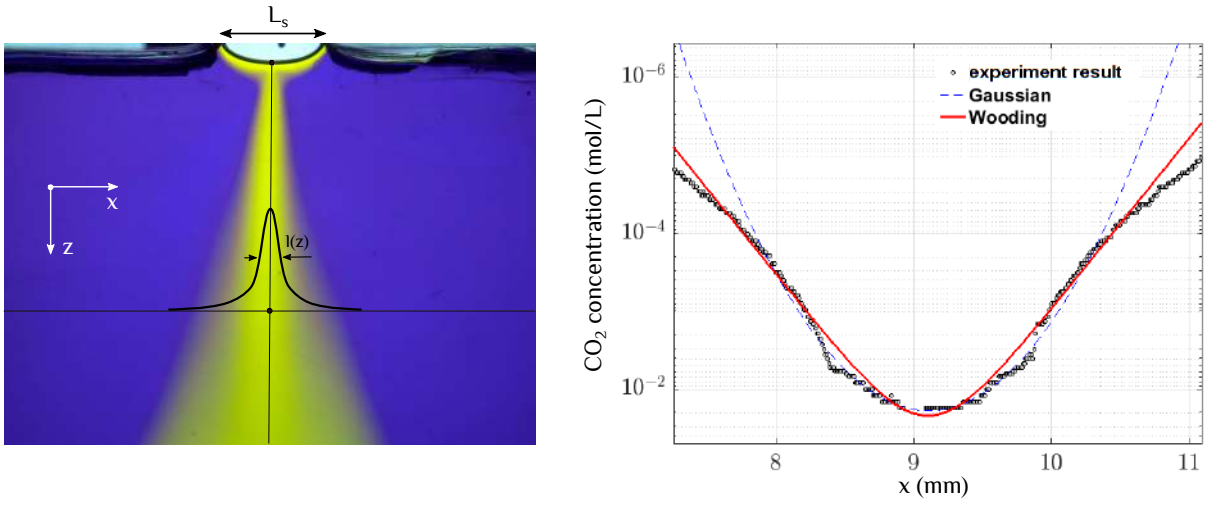

Figure 1: Left: raw picture of the CO_2-plume generated by an extended source visualized by means of bromocresol purple (partial pressure of $CO_2$is $P_{CO_2} = 4$ bar, $L_s = 8$ mm and Hele-Shaw cell thickness is 1 mm) ; Right: transverse concentration profile inferred from the RGB map at an altitude $z = 25$ mm.

*Corresponding author. E-mail: N.De@lboro.ac.uk

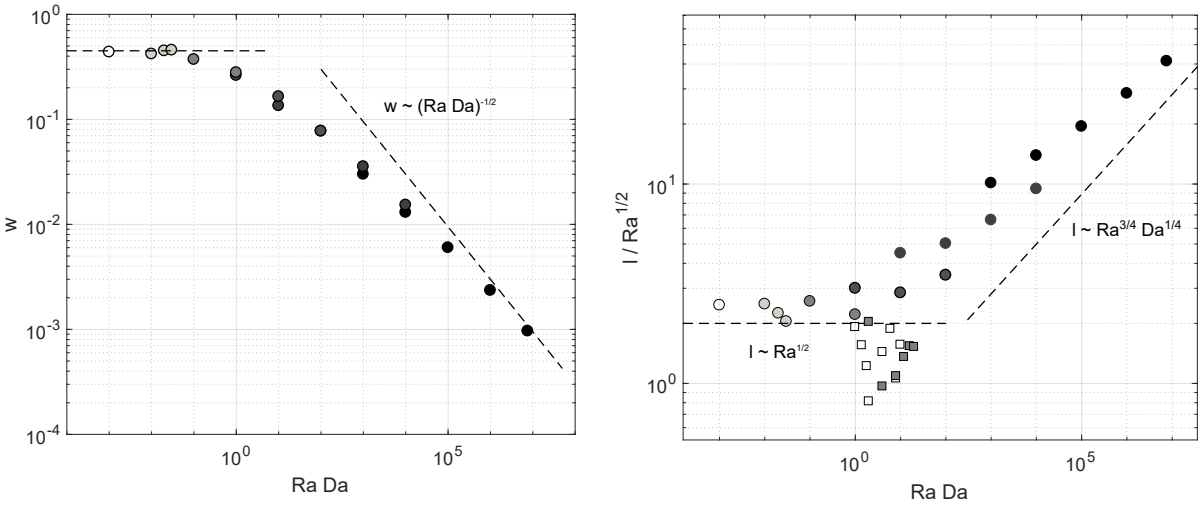

Figure 2: Left: dimensionless vertical velocity w measured at the plume neck (where the plume width l is minimum) as a function of the dimensionless parameter $Ra\,Da$; Right: dimensionless plume width l (multiplied by the square root of the Rayleigh number) as a function of $RaDa$. Numerical and experimental results are plotted in with circles and squares respectiveley.

(the chamber-reservoir combination was required to perform experiments isothermally at the highest pressures) which, once opened ensured a mixing time which is much smaller than the growth time of the onset time of the gravitational plume. A single plume is then generated by partially blocking the open surface of the Hele-Shaw cell in order to obtain an extended source (dissolution interface) of lateral size L_s (see Fig.1).

Governing Equations and non-dimensional parameters

The dimensionless forms of the Navier-Stokes and advection-diffusion equation used in the numerical calculations can be written as follow [2]

$$\frac{1}{Sc}\left[\frac{\partial \boldsymbol{u}}{\partial t}+(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}\right]=-\boldsymbol{\nabla}p+\boldsymbol{\nabla}^2\boldsymbol{u}-\frac{1}{DaRa^2}c\,\boldsymbol{z},\quad\text{and}\quad\frac{\partial c}{\partial t}+(\boldsymbol{u}\cdot\boldsymbol{\nabla})\,c=\boldsymbol{\nabla}^2 c, \tag{1}$$

where $\boldsymbol{u}$, p and c are the velocity, pressure and CO_2-concentration fields. The Rayleigh, Darcy and Schmidt numbers are defined as $Ra=\Delta\rho g\kappa L_s/\mu D$ and $Da=\kappa/L_s^2$ and $Sc=\rho\,D/\mu$. In the expressions of the dimensionless groups, κ, μ, ρ, and D denote the permeability of the Hele-Shaw cell, the viscosity and density of the solution and the diffusivity of the carbon dioxide. The density difference to pure water at saturation CO_2-concentration is referred to as $\Delta\rho$.

RESULTS AND PRELIMINARY CONCLUSIONS

Far from the source, the transverse profile of concentration in the plume is reasonably rendered by a function of the form $c(x)=A\,[\cosh(x/l)]^2$ (Wooding's solution [1]) - as expected as long as the extended nature of the source can be ignored - where both the plume width l and the maximum amplitude of the concentration profile are functions of the altitude z that are connected by mass conservation. The numerical results are in fairly good agreement with the scaling law coming from the mass flux conservation at the neck of the plume (balance between lateral and vertical mass fluxes). The width of the concentration transverse profile (measured at the plume neck) is proportional to the square root of the Rayleigh number ($l\sim Ra^{1/2}$) at low Rayleigh numbers ($Ra<Da^{-1}$) and scales as $Ra^{3/4}Da^{1/4}$ at large Rayleigh numbers ($Ra>Da^{-1}$). The vertical velocity w plateaus at low Rayleigh numbers and scales as $(Ra\,Da)^{-1/2}$ at large Rayleigh numbers. In the quite narrow range of parameters where experiments can be performed (one order of magnitude in $Ra\,Da$), the experimental results are currently overestimated by almost a factor 2 by the numerical calculations. This could be due to the effect of the meniscus in the experimental configuration, which accelerates the flow and consequently reduces the plume width (see Fig.2).

BOUNDARY LAYER PROFILES AND HEAT TRANSPORT IN TURBULENT RAYLEIGH-BE NARD CONVECTION: A THEORETICAL STUDY

Emily S.C. Ching *[1], N.C. Tai[1], Lukas Zwirner[2], and Olga Shishkina[2]

[2] Max Planck Institute for Dynamics and Self-Organization, Am Fassberg 17, 37077 Göttingen, Germany

Summary In turbulent Rayleigh-Bénard convection, the boundary layers are unsteady with fluctuations, the time-averaged large-scale circulating velocity vanishes far away from the top and bottom plates, and the motion arises from buoyancy. We have derived the full set of boundary layer equations for both the temperature and velocity fields from the Boussinesq equations for a quasi-two-dimensional flow above a heated plate, taking into account all the above effects. By solving these boundary layer equations, we obtain theoretical results for the time-averaged temperature and velocity boundary layer profiles and the Nusselt number which measures the heat transport.

INTRODUCTION

For a container with a given geometry, the dynamics of Rayleigh–Bénard convection (RBC) system is determined by two dimensionless parameters, the Rayleigh number $\mathrm{Ra} = \alpha g \Delta L^3/(\kappa\nu)$ and the Prandtl number $\mathrm{Pr} = \nu/\kappa$, where α denotes the isobaric thermal expansion coefficient, ν the kinematic viscosity and κ the thermal diffusivity of the fluid, g the acceleration due to gravity, Δ the temperature difference between the bottom and top plates, and L the height of the container. In turbulent RBC, boundary layers (BLs) develop and play a crucial role in turbulent transport. The BLs are unsteady with fluctuations, the time-averaged velocity along the direction of the large-scale circulation vanishes far away from the plates, and the motion of the fluid is not forced but arises from buoyancy. We have recently derived the full set of BL equations for both the temperature and velocity fields for general Pr from the quasi-2D Boussinesq equations, accounting for all these physical effects [1, 2], which have not been successfully incorporated in any prior existing BL theory. Solving these BL equations, we obtain theoretical results for the time-averaged temperature and velocity BL profiles and the Nusselt number (Nu).

THEORY

We consider a quasi-2D fluid flow above a semi-infinite horizontal heated plate in RBC. The velocity field is $\mathbf{u}(x,z,t) \equiv u(x,z,t)\,\hat{x} + v(x,z,t)\,\hat{z}$ with the vertical direction $\hat{z}$ and the horizontal direction $\hat{x}$ and the temperature field is $T(x,z,t)$. The governing Boussinesq equations are the continuity equation $\nabla\cdot\mathbf{u} = 0$ and

$$\partial_t \mathbf{u} + \mathbf{u}\cdot\nabla\mathbf{u} = -\nabla p/\rho + \nu\nabla^2\mathbf{u} + \alpha g(T - T_h)\hat{z}, \quad (1)$$

$$\partial_t T + \mathbf{u}\cdot\nabla T = \kappa\nabla^2 T, \quad (2)$$

where $p(x,z,t)$ is the hydrodynamic pressure, ρ the density, and T_h is the temperature of the heated plate situated at $z = 0$. We perform the Reynolds decomposition: $u = U + u'$, $v = V + v'$, $T_h - T = \Theta + \theta'$ and $p = P + p'$, average (1) and (2) over time and define the space-dependent eddy viscosity $\nu_t(x,z)$ and eddy thermal diffusivity $\kappa_t(x,z)$ by $\langle u'v'\rangle_t \equiv -\nu_t\partial_z U$ and $\langle v'\theta'\rangle_t \equiv -\kappa_t\partial_z\Theta$ to obtain

$$U\partial_x U + (V - \partial_z\nu_t)\partial_z U = (\nu + \nu_t)\partial_z^2 U - \mathcal{H}_B\rho^{-1}\partial_x P, \quad (3)$$

$$U\partial_x\Theta + (V - \partial_z\kappa_t)\partial_z\Theta = (\kappa + \kappa_t)\partial_z^2\Theta. \quad (4)$$

We have taken the BL approximation that partial derivatives of flow quantities along the plate are much smaller than those away from the plate and assumed that the convection-diffusion terms in the vertical direction are negligible compared to the buoyancy term, which is then balanced by the pressure gradient. This balance implies $P \sim B\rho U^2$ with $B \equiv \mathrm{Ra}/(2\mathrm{PrRe}^{5/2})$ where Re is the Reynolds number that measures the time-averaged velocity of the large-scale circulation. Thus the problem is divided into two classes: (1) $\mathcal{H}_B = 1$ when B is at least of order 1 such that the horizontal pressure gradient $\partial_x P$ plays a direct role and (2) $\mathcal{H}_B = 0$ where $B \ll 1$ such that $\partial_x P$ is negligible and buoyancy effect is manifested indirectly via the velocity boundary condition. We introduce the stream function Ψ with $U = \partial_z\Psi$ and $V = -\partial_x\Psi$ and define the similarity variable $\xi \equiv \mathrm{Pr}^a\mathrm{Ra}^b(z/L)(x/L)^c$, the dimensionless functions $\psi(\xi)$, $F(\xi)$ and $\theta(\xi)$ by $\Psi \equiv \mathrm{Pr}^a\mathrm{Ra}^b\nu(x/L)^{c+1}\psi(\xi)$, $P \equiv \mathrm{Pr}^{-(1+a)}\mathrm{Ra}^{1-b}(\rho\nu^2/2L^2)(x/L)^{-c}F(\xi)$, $\Theta \equiv (\Delta/2)\theta(\xi)$. Using ideas of Prandtl's mixing length model, we propose a closure model extending our previous idea [3] $\nu_t/\nu \approx k_1 G$ and $\kappa_t/\kappa \approx k_2 G$, where $G \equiv \int_0^\xi \psi(p)dp$ and k_1, k_2 are positive constants, to account for fluctuations. We look for nontrivial similarity solution and further require the equations to be independent of Ra. This gives $b = -a = 1/5$, $c = -2/5$ for $\mathcal{H}_B = 1$ and $c = -3/4 + k_1/8$ with $0 \le k_1 < 2$ for $\mathcal{H}_B = 0$. We define the velocity BL thickness $\delta(x)$ as the distance at

*Corresponding author. E-mail: ching@phy.cuhk.edu.hk

which $U(x,z)$ attains its maximum value and show that $\delta(x)$ is approximately inversely proportional to $\sqrt{\mathrm{Re}}$ albeit with a different x-dependence from that of the Prandtl-Blasius theory: $\delta(x)/L = [\psi_\xi(\xi_m)/2(c+1)\mathrm{Re}]^{1/2}\xi_m(x/L)^{-c}$, where ψ attains its maximum value at $\xi = \xi_m$. The full set of BL equations for $\psi = G_\xi$ and $\theta = -F_\xi$ are obtained:

$$\mathcal{H}_B = 1: \quad 5(1+k_1G)G_{\xi\xi\xi\xi} + (5k_1+3)G_\xi G_{\xi\xi\xi}] - (G_{\xi\xi})^2 - F + \xi F_\xi = 0 \tag{5}$$

$$5(1+k_2G)F_{\xi\xi\xi} + (3\mathrm{Pr}+5k_2)G_\xi F_{\xi\xi} = 0 \tag{6}$$

$$\mathcal{H}_B = 0: \quad 8(1+k_1G)G_{\xi\xi\xi\xi} + (2+9k_1)G_\xi G_{\xi\xi\xi} + 2(2-k_1)(G_{\xi\xi})^2 = 0 \tag{7}$$

$$8(1+k_2G)\theta_{\xi\xi} + [\mathrm{Pr}(2+k_1)+8k_2]G_\xi\theta_\xi = 0 \tag{8}$$

The boundary conditions are $G(0) = G_\xi(0) = G_{\xi\xi}(0) = 0$, $G_{\xi\xi}(\infty) = G_{\xi\xi\xi}(\infty) = 0$, $\theta(0) = 0$ and $\theta(\infty) = 1$. Hence solving these BL equations, we obtain the time-averaged temperature and velocity BL profiles, $\theta(\xi)$ and $\psi_\xi(\xi)/\psi_\xi(\xi_m)$. We have shown that the normalized time-averaged temperature BL profiles at high Pr ($\mathrm{Pr} = 4.38$ and $\mathrm{Pr} = 2547.9$) [2] and the time-averaged temperature and velocity BL profiles at low Pr ($\mathrm{Pr} = 0.1$) [1] obtained in direct numerical simulation (DNS) are well described by our theoretical results. We can further obtain theoretical results for Nu and Re:

$$\mathcal{H}_B = 1: \quad \mathrm{Nu} = \frac{5}{6}\theta_\xi(0)\mathrm{Pr}^{-1/5}\mathrm{Ra}^{1/5}; \qquad \mathrm{Re} = \frac{5}{6}\psi_\xi(\xi_m)\mathrm{Pr}^{-2/5}\mathrm{Ra}^{2/5}, \tag{9}$$

$$\mathcal{H}_B = 0: \quad \mathrm{Nu} = \frac{2}{\sqrt{2+k_1}}\frac{\theta_\xi(0)}{\sqrt{\psi_\xi(\xi_m)}}\mathrm{Re}^{1/2}. \tag{10}$$

Data obtained from DNS show that B decreases as Pr decreases at fixed Ra, and decreases as Ra increases at fixed Pr [1]. Thus the class $\mathcal{H}_B = 0$ is expected to be reached at a sufficiently high Pr for a fluid with any given Pr. For the class $\mathcal{H}_B = 0$, using the BL equations (7) and (8), we derive analytical results for ξ_m, $\psi_\xi(\xi_m)$ and $\theta_\xi(0)$ and, as a result, obtain the dependence of Nu on Re and Pr in the high-Pr [$\mathrm{Pr} \gg 1$ and $\mathrm{Pr}(2+k_1)/(8k_2) \gg 1$ with $B \ll 1$] and low-Pr ($\mathrm{Pr} \ll 1$) limits:

$$\mathrm{Nu} = F_1(k_1)\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3} = \frac{3^{1/2}}{2^{2/3}\Gamma(1/3)}\left(\frac{2-k_1}{2+k_1}\right)^{\frac{1}{6}}\left[1+\frac{(7k_1-2)}{4(2-k_1)}\right]^{\frac{2+k_1}{2(7k_1-2)}}\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3} \text{ (high-Pr limit)}, \tag{11}$$

$$\mathrm{Nu} \to \frac{1}{\sqrt{\pi}}\mathrm{Re}^{1/2}\mathrm{Pr}^{1/2} \quad \text{(low-Pr limit)}. \tag{12}$$

These results reveal a close resemblance of the scaling dependencies of Nu in turbulent RBC and in steady forced convection where temperature is passive as described by the Prandtl-Blasius-Polhausen (PBP) theory. This surprising finding is nontrivial as the velocity BL equations in the two theories are different and fluctuations play a significant role in turbulent RBC. DNS results in a cylindrical container of the diameter-to-height aspect ratio 1 for $10^4 \le \mathrm{Ra} \le 10^{10}$ and $0.005 \le \mathrm{Pr} \le 300$ show that $\mathrm{NuRe}^{-1/2}$ scales as $\mathrm{Pr}^{1/2}$ when Pr is small ($\mathrm{Pr} < 1$) and as $\mathrm{Pr}^{1/3}$ when Pr is large ($30 < \mathrm{Pr} < 100$) provided $B < 1$, which are in good agreement with the theoretical results.

CONCLUSIONS

We have derived the full set of BL equations for both the velocity and temperature fields in turbulent RBC from the quasi-2D Boussinesq equations. Our theory takes into account various physical effects that were not included in existing BL theories. By solving the BL equations, we have obtained theoretical results for the time-averaged velocity and temperature BL profiles and Nu. In the regime $\mathcal{H}_B = 0$ which is expected to be reached at sufficiently high Ra, we have found a close resemblance of the scaling dependencies of Nu on Re and Pr in turbulent RBC and in steady forced convection where temperature is passive as described by the PBP theory.

STATISTICAL PROPERTIES OF THERMAL PLUMES IN TURBULENT RAYLEIGH-BENARD CONVECTION WITH A ROUGH PLATE

Summary A comparative study of the plume dynamics near the rough and smooth horizontal plates of a water-filled asymmetric Rayleigh-Bénard cell is presented. Direct numerical simulations are performed over a large range of Rayleigh numbers (from 10^5 to 10^{10}) in order to cover the three heat transfer regimes. Several techniques of plume feature description are used to highlight how roughness changes the dynamics of plume emission and the energetic content of plumes.

MOTIVATION

In a real thermal system, the underlying surfaces involve specific topographies or small-scale roughness which have a significant impact on the heat transfer. Particularly, in the case of turbulent convection, the addition of wall roughness results in a global heat transfer enhancement and in some cases, in an increase of the exponent of the heat transfer scaling law ($Nu \sim Ra^{\beta}$, Nu Nusselt number, Ra Rayleigh number) [1, 2]. It is commonly admitted that the heat transfer enhancement originates from an intensification of the thermal plume emission at the tips of roughness elements [3].

In classic turbulent Rayleigh-Bénard convection, previous studies have shown the role of thermal plumes in the heat transport within the cavity [4]. Several techniques of plumes description have been proposed to characterize plumes in terms of geometry, number, intensity or velocity. They can be based on the post-processing of a temperature field determined from thermochromic liquid crystal microspheres [5], on the identification of temperature threshold in numerical snapshots [6], on the analysis of cliff-ramp structures in local time series [7], or on shadowgraph treatment [8].

In the present numerical study, we consider convection over a regularly roughened plate in a Rayleigh-Bénard cell. The three successive heat transfer regimes, previously observed in this kind of configuration (see for example [1]), are modelled from inactive roughness (regime I) to a regime (called III) where the relative heat transfer increase is larger than the relative surface increase induced by roughness addition. The objective of this work is to identify how roughness changes the plume features and their dynamics, depending on the regime.

NUMERICAL SET-UP

We study the fluid flow occurring in an asymmetric 3D Rayleigh-Bénard rectangular cell filled with water. The cell is heated from below by an isothermal rough plate, modeled by a set of square-based obstacles as sketched on figure 1. Sizes of the roughness elements share some common geometric features with the Lyon's experiments [9, 2] such as aspect ratios or distribution, but we retain a larger roughness height ($H_r/H = 0.03$, H cavity height) in order to trigger the first transition between the heat transfer regimes I and II to a lower Ra.

The Navier-Stokes equations are solved under the Boussinesq approximation. The parallel numerical solver (SUNFLUIDH code) uses a finite volume discretization on staggered grids. The time marching is treated by a semi-implicit scheme combined with a prediction - correction scheme for the velocity - pressure coupling, with a global second-order accuracy. The code has been validated for the classic turbulent Rayleigh-Bénard convection by comparison with the DNS data [10]. Numerical simulations are performed for a large range of Rayleigh numbers in order to cover the three heat transfer regimes ($10^5 \leq Ra \leq 10^{10}$). We use meshes from $1.3 \cdot 10^6$ to $5 \cdot 10^8$ cells in order to ensure a sufficient space resolution. The computational domain is decomposed into 256 to 2048 subdomains depending on the considered Ra number. The convergence in space and time has been *a posteriori* checked by testing the convergence of several formulations of the time-averaged Nusselt number.

RESULTS

Taking advantage of the cavity asymmetry, we conduct a comparative study of the plume dynamics near the rough and smooth horizontal plates within the same Rayleigh-Bénard cavity for the three regimes of heat transfer.

First, we consider more specifically three particular Ra numbers, each belonging to a different regime (figure 1). The time monitoring of a set of probes recording temperature or vertical velocity, and located near the rough and smooth plates, shows how roughness alters the statistical properties of thermal plumes. In agreement with the experiments (see for example [3, 4, 9]), intense temperature fluctuations are observed more frequently near the rough plate than near the smooth plate, especially in the intermediate regime II. Concurrently, the largest vertical velocity fluctuations are found near the smooth plate rather than around the rough one. In addition, instantaneous characteristics of thermal plumes such as amplitude (in terms of local increment) or width (equivalent to a transit time) can also be calculated from the time series, following the [7] methodology. As expected, log normal distributions are generally recognized in the PDFs of the plume features. However, a noticeable change is observed in regime II, with a more frequent detachment of high energy plumes close to the rough plate, both in terms of potential and kinetic energy.

Finally, we make use of space-time diagrams [8] to quantify the spatio-temporal dynamics of the thermal plumes. An increase of the plume number with Ra is observed on both sides of the cavity for all regimes. Although a similar plume distribution near the smooth and rough plates is found in regime I and III, we show that a strong asymmetry between the two horizontal plates is established in regime II with a significant increase of the number of plumes close to the roughness. Moreover, we note in this regime the presence of highly dissipative structures not only near roughness but also within the bulk of the cavity (as seen on figure 1).

Summary In recent decades great interest has been expressed in thermal convection structures (TCS), also called thermals, in the atmospheric boundary layer (ABL) and its characteristic manifestations. The new method of acoustic sounding data treatment for detecting these structures has been obtained. The structures have been measured under different wind and temperature conditions over arid-steppe zones of Rostov region and of the Caspian lowland in the eastern part of Kalmykia Republic, Russia in summer time of years 2007, 2016, 2018, 2019. The duration of over-limit vertical velocity, the maximum velocity in this interval and the horizontal scale have been calculated. The statistical distribution was proved to be close to Rayleigh distribution.

INTRODUCTION

In studying thermal convection structures (TCS) in the atmospheric boundary layer (ABL) a large number of theoretical physico-mathematical models have been created. However, numerical solution of the thermohydrodynamics equations are difficult for calculating, analysis and understanding the results. Exact analytic solutions are found only in some case studies. Consequently, the statistic methods retain its relevance and significance and continue to develop [Petenko I. and Bezverkhnii V., 1999; Petenko I. and Shurygin E., 1999]. In addition, it should be pointed out that the Maxwell distribution for ensemble of the TCS was received in the paper [Vulfson A. and Borodin O., 2018].

EXPERIMENTAL DATA

TCS and their characteristic manifestations in the ABL were investigated using acoustic sounding. The multiple-frequency Doppler sodars LATAN-3M [Kouznetsov R, 2009] with a vertical resolution of 20 and 10 m, a pulse emission interval of 5 and 3 s, an altitude range of 600 and 350 m and a basic carrier frequency of 2 kHz and 4 kHz had measured the profiles of the wind velocity components. These profiles were used for calculating the scale of TCS. Experimental data were being obtained during the field campaigns organized by the A.M. Obukhov Institute of Atmospheric Physics RAS over semi-arid zones of the Caspian lowland in the eastern part of Kalmykia Republic, Russia, and in Rostov region, Russia in summer time of years 2007, 2016, 2018, 2019. The structures were investigated under weak wind conditions. The convection was well-developed during all these case studies.

RESULTS AND DISCUSSION

An original method of the acoustic sounding data treatment for extracting TCS has been developed. The episodes of the vertical velocities above limit values at which TCS aroused hypothetically were considered. A moving rectangular filter was used for averaging the original data of the horizontal and vertical wind-velocity components. The duration of vertical velocity excess over the threshold, the maximum velocity within this interval and the horizontal scale were calculated. It is assumed that TCS move forward during any relatively small time step with some averaged velocity (Taylor's hypothesis). This time step has been taken empirically and amounted to 10 minutes. In this case, the spatial distribution of velocity field and its time variations have been adequately reproduced. As the threshold, a few alternatives were used: 0.3 m/s, 0.6 m/s and 1.2 m/s.

The statistical distribution of calculated characteristics was close to Rayleigh distribution [Kurgansky M., 2000] (see example for 23d of July, 2016, in Figure 1):

$$\rho(U) = \frac{2U}{{U_0}^2}\exp\left(\frac{{U_m}^2-U^2}{{U_0}^2}\right),$$

where ${U_0}^2 = \left[\langle U^2\rangle - {U_m}^2\right]$, $\langle U^2\rangle$ is the mean-square vertical velocity of TCS, and U_m – the threshold for vertical velocity.

*Corresponding author. E-mail: vazaevanv@ifaran.ru.

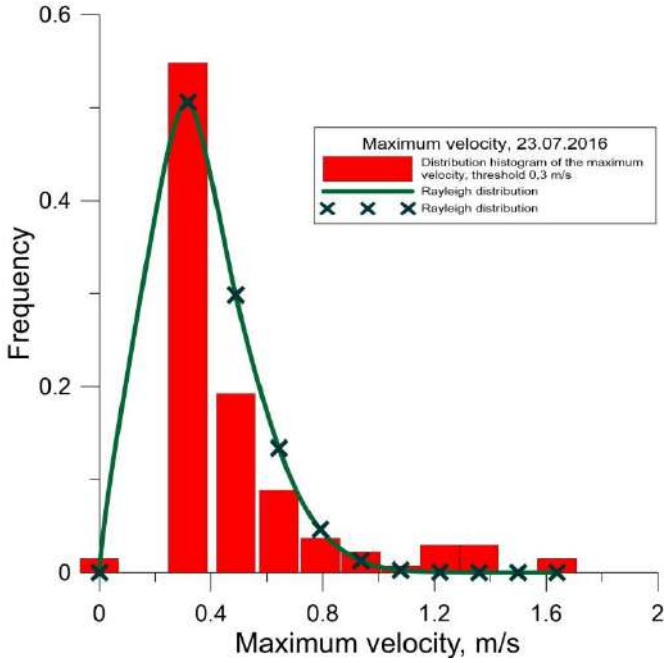

Figure 1. Distribution histogram of the maximum vertical velocity, and Rayleigh distribution, Kalmykia, 23d July, 2016.

This fact can be implemented in the parameterization, forecast of TCS, and can facilitate the understanding of the processes in the so-called "grey-zone" of numerical simulation. Note that Rayleigh distribution is universe and can be applied, for example, to the statistics of the intense moist convective vortices and also of the height of the ocean waves.

STRAIN RATE SIGNATURES OF PLUMES IN RAYLEIGH BE NARD CONVECTION

Prafulla P. Shevkar *[1], R. Vishnu[2], Sanal K. Mohanan[1], and Baburaj A. Puthenveettil[1]

Summary We present a new criteria to detect thermal plumes from the velocity field in a horizontal plane that pass from the local boundary layer to the plume close to the hot plate in turbulent Rayleigh Bénard convection. Based on the characteristics of deformation of fluid elements, we propose that the negative dominant eigenvalues of the 2D strain rate picks up the thermal plume regions. We also show that the areas identified by this criteria match the areas identified by the horizontal divergence criteria $\bar{\nabla}_H.\bar{u} < 0$ proposed by Vipin and Puthenveettil [4].

Thermal plumes play major role in transporting heat [1, 7] from the hot plate in turbulent Rayleigh Bénard convection (RBC), and hence, detecting them and understanding their dynamics is important to understand the phenomenology of RBC. There are several temperature based criteria [2, 6] to identify thermal plumes. However detecting plumes from the velocity field near the hot plate is hard since their velocity or strain signatures are not known. Such detection, in addition to being important experimentally, since velocity fields are easily available from PIV, also give insights into the kinematics of plumes in RBC. In this paper, we arrive at a criteria to identify thermal plumes near the hot plate using the eigenvalues of the 2D strain rate tensor S in a plane close to the hot plate.

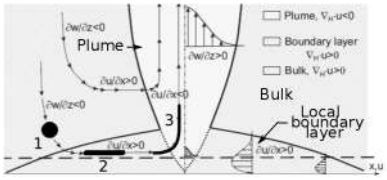

Figure 1: Schematic of the deformation of a fluid element near the hot plate in RBC.

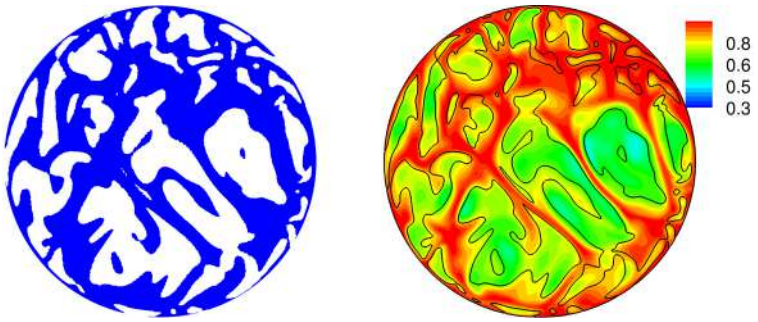
Cases	λ_1	λ_2	$\lvert\lambda_1/\lambda_2\rvert$	$\nabla_H.\bar{u}$	Region
1	+	+	> 1	> 0	non-plume
2	+	-	> 1	> 0	non-plume
3	+	-	< 1	< 0	plume
4	-	-	< 1	< 0	plume

Table 1: Possible values of eigenvalues at each point and the region corresponding to those points.



(a) (b)

Figure 2: (a), Dominant negative eigenvalues of S in a horizontal plane at a height of $0.006H$ from the hot surface and; (b), T overlaid with the $w = 0$ contour line at $Ra = 2 \times 10^8$ and $Pr = 1$, both obtained computationally.

Eigenvalues of the two dimensional strain rate tensor S, due to the 2 horizontal components of velocity in a plane, describe the deformation charcteristics of fluid elements in the form of extension or compression strains occurring at a points in the plane [3]. These eigenvalues at a point take positive or negative signs, corresponding to the extension and compression strains along the principal axes, with the associated eigenvectors giving the lines of action of the elemental deformations at that point. Figure 1 shows a schematic of the change in shape of a spherical fluid element at three different positions along it's path near the hot plate in RBC. The spherical fluid element is initially in the bulk (location 1) which then moves into the boundary layer (location 2), and finally becomes a part of the plume (location 3) [7]. Inside the boundary layer, due to the horizontal shear forces present, the fluid element undergoes predominantly horizontal stretching, implying that the extensional strain dominates in the horizontal direction within the boundary layer; the dominant eigenvalue of S in a horizontal plane is then expected to take a positive sign at location 2. As the fluid element reaches location 3, inside the plume, it gets further stretched in the vertical direction. The extensional strain then dominates in the vertical direction inside the plume resulting in a compressive strain in the horizontal direction to conserve mass. The dominant eigenvalue of S is then expected to take negative signs within plumes. Such a displacement and deformation of a fluid volume can be inferred from the visualization experiments in a vertical plane using passive markers [5].

We construct an instantaneous S at every spatial point in a horizontal plane close to the hot plate from experimental and computational data. The ordered eigenvalues λ_1 and λ_2 of S at each point so that $\lambda_1 > \lambda_2$, which provide the local principal strain rates, are calculated from,

$$\lambda_{1,2} = \frac{1}{2}\left(u_x + v_y \pm \sqrt{(u_x - v_y)^2 + (u_y + v_x)^2}\right) \tag{1}$$

where, u and v are the velocities in the x and y directions and subscripts x and y denote the derivatives in these directions. The dominant eigenvalue at a point is λ_1, if $|\lambda_1/\lambda_2| > 1$ and is λ_2, if $|\lambda_1/\lambda_2| < 1$. Figure 2(a) shows the dominant negative eigenvalues calculated numerically in a plane close to the hot plate in RBC; figure 2(b) shows the corresponding dimensionless temperature field T overlaid with the vertical velocity $w = 0$ contour line. $T = (\theta - \theta_c)/(\theta_h - \theta_c)$ where, θ is dimensional temperature and subscripts c and h denotes the cold and hot plate temperatures. From figures 2(a) and 2(b), it is clear that the regions with negative dominant eigenvalues are the regions in which w is positive and T is mostly > 0.75, making these regions most likely to be the thermal plumes [2]. Thus, we expect that, close to the hot plate in RBC, regions with negative dominant λ's are the thermal plumes while the remaining regions are the boundary layers.

Figure 3(a) shows the distribution of the dominant eigenvalues and the corresponding eigenvectors calculated from the velocity field obtained by PIV in a convection cell from a central 84.10×73.76 mm^2 region near the hot surface in a horizontal plane within the Prandtl-Blasius and the natural convection boundary layer thicknesses. The negative dominant eigenvalues fall in the plume region with the eigenvectors being normal to the plumes in regions with weak shear (mainly seen at low Ra), while in the shear dominant regions, the eigenvectors are likely to be inclined at a small angle to the plumes. Vipin and Puthenveettil [4] proposed a velocity based criteria to identify thermal plumes, the criteria identifies negative horizontal divergence ($\bar{\nabla}_H.\bar{u} < 0$) regions as plumes; this criteria was used by Shevkar et al. [3] to find the scaling of mean plume spacing with shear in RBC. Since $u_x + v_y = \bar{\nabla}_H.\bar{u}$ in (1), regions with negative values of $\bar{\nabla}_H.\bar{u}$ are also the regions with the negative dominant eigenvalues. Hence, regions with negative $\bar{\nabla}_H.\bar{u}$ shown in figure 3(b), match with the regions of negative dominant eigenvalues of S, shown in figure 3(a). Table 1 summarises the various combinations of λ, and their occurrence in plume and non-plume regions, close to the hot plate in RBC. Case 1, with both positive eigenvalues, corresponds to the local impingement regions on the hot plate, where fluid elements get stretched in all the horizontal directions.

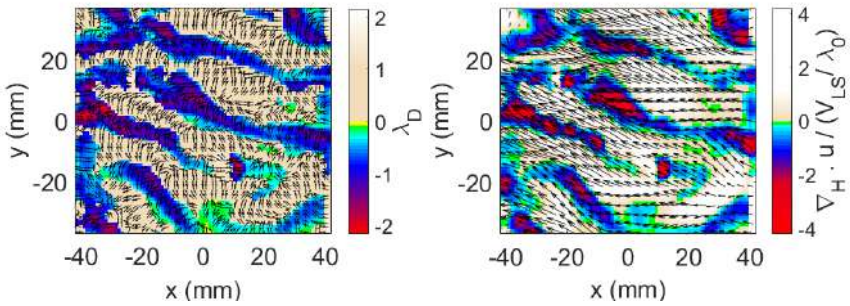

Figure 3: (a), Dominant eigenvalues of the 2D strain rate tensor S, overlaid over the corresponding eigenvectors in a horizontal plane at a height of 1.3 mm from the hot plate calculated from PIV and; (b), the corresponding dimensionless horizontal divergence field, overlaid over the horizontal velocity vector field at $Ra = 1.2 \times 10^9$ and $Pr = 5.09$.

In conclusion, in a horizontal plane close to the hot plate, regions with negative dominant eigenvalues of S, i.e. $|\lambda_1/\lambda_2| < 1$ where, λ's are ordered eigenvalues pick up plume regions, on which also fall the negative $\bar{\nabla}_H.\bar{u} < 0$ regions [4]. Regions identified by this criteria as thermal plumes consist mostly larger temperatures than background regions and positive values of w; they are also line like, similar to the plumes on the hot plate[1]. Hence we conclude that in a horizontal plane in the plume regions, the compressive strain dominates the extensional strain.

EFFECT OF THERMAL RADIATION ON HEAT TRANSFER EFFICIENCY IN TURBULENT RAYLEIGH-B NARD CONVECTION

Pavel Urban[1]*, Tomáš Králík[1], Pavel Haznelka[1], Věra Musilová[1], Tomáš Věžník[1], David Schmoranzer[2], and Ladislav Skrbek[2]

Summary We examine the effect of thermal radiation and its influence on the measured efficiency of convective heat transport in Rayleigh-Bénard convection (RBC) experiments performed at room and cryogenic temperatures. We present a detailed analysis of conventional far-field radiative heat transport occurring in selected, well-documented, RBC experiments with transparent gaseous working fluids. Our findings reveal that while the effect of thermal radiation across transparent fluids is negligibly small at cryogenic temperatures, it generally cannot be neglected in large-scale high Rayleigh number experiments performed at room temperatures without further analysis. Additionally, we discuss experiments with radiatively participating (absorbing thermal radiation) working fluids and show that their analysis needs special attention.

Rayleigh-Bénard Convection (RBC) is a physical model used for study of thermally-generated convection between two infinite parallel horizontal plates mutually displaced by distance L. The convective flow is generated by the temperature difference ΔT between the bottom hot plate (T_b) and the top cold plate (T_t). RBC in the Oberbeck-Boussinesq working fluid is fully characterized by two dimensionless control parameters expressing physical similarity of the convective flow: the Rayleigh number, $Ra = (g\alpha\Delta TL^3)/\nu\kappa$, and the Prandtl number, $Pr = \nu/\kappa$, where g, α, ν and κ denote respectively the acceleration due to gravity, isobaric thermal expansion coefficient, kinematic viscosity, and thermal diffusivity. The aspect ratio $\Gamma = D/L$ is the third dimensionless parameter characterising RBC, when the experiment is conducted in a vertical cylindrical cell with the diameter D.

The basic problem in RBC study is to find the efficiency of heat transfer, which is defined by the dimensionless Nusselt number, Nu, via $Nu = Nu(Ra; Pr; \Gamma)$ scaling. The classical theories [1] predict scaling law of $Nu \sim Ra^{1/3}$ under the assumption that the heat transfer in turbulent RBC is controlled by the heat conduction of marginally stable thermal boundary layers, although the bulk between them is turbulent. In this model, the convective heat transport does not depend on the height L and all of the temperature difference ΔT is spread over the top and bottom boundary layers with thickness $l = L/(2Nu)$, which are thin in comparison with L in turbulent RBC.

Standard interpretation of RBC experiments does not consider heat transfer via thermal radiation. At room temperature, the effect of radiation can be significant, as the heat flux by thermal radiation increases with the fourth power of absolute temperature T. To assess the role of thermal radiation in RBC, we have analysed selected experiments performed in cylindrical cells of various aspect ratio Γ with gaseous working fluids at room (helium, nitrogen and sulphur hexafluoride) and cryogenic temperatures (helium) [2]. For fully transparent working fluids, we show that in some turbulent high Ra experiments the radiative heat transfer ought to be taken into account, as it affects the Nu numbers and also appreciably changes $Nu(Ra)$ scaling relation. Since the thermal radiation does not directly affect the working fluid in this case, the measured value of Nu may be simply corrected by adjusting the value of the convective heat flux [2].

On the other hand, in the case of radiatively participating fluids, radiation is absorbed in the fluid at least partly and can affect the convective flow significantly. For example, in room temperature experiments on heat transfer efficiency with CO_2 [3], the delayed onset of convection and decrease in Nu number by 20 % at Ra up to 10^4 (in comparison with transparent air) were observed. The authors attributed both these observations to the stabilizing effect of the gas thermal radiation on RBC [3]. Influence of radiation on the character of the $Nu(Ra)$ dependence was also demonstrated in water experiments [4]. The working fluid was homogeneous mixture of water with a tuneable density of dye for absorption of visible light incoming from an external source below the transparent bottom plate. Tuning the dye density varied depth of penetration of radiation from the boundary layer to the turbulent bulk. When the radiation was absorbed in the region of the boundary layer close to the bottom plate, similarly as in standard RBC, 1/3 $Nu(Ra)$ scaling law was observed (Ra up to 10^9). On the other hand, when also the turbulent bulk was heated, a steeper 1/2 scaling law was observed, signifying a more efficient heat transport (Ra up to 10^8).

A natural question is, how the Nu number can be affected by thermal radiation in room temperature experiments when a radiatively participating fluid is used, specifically at very high Ra number experiments with water (Ra up to 10^{12}) and SF_6 gas (Ra up to 10^{15}). The radiative part of heat transfer in this case cannot be simply corrected as in the case of transparent fluids. We have used spectral absorption coefficients [5, 6] for these two fluids and calculated absorption of the thermal radiation emitted by the bottom plate with temperature $T_b = 293$ K over the 1 m thick layers of SF_6 (Figure 1) and water (Figure 2). The absorption was calculated for two values of density of SF6 (6 kg/m3 and 160 kg/m3), corresponding to atmospheric pressure and elevated pressure of 20 bar realized in the Göttingen experiments [7]. The distance z of 1 m corresponds to the height of the RBC cell, while the boundary layer thickness z is of the order 1 mm and less. For both atmospheric and elevated pressure, most of radiation power emitted by the bottom plate is absorbed in the gas outside the boundary layer. The absorption was calculated for the forward and omnidirectional thermal radiation from the bottom plate. Thermal radiation of the gas was omitted in this calculation. In Göttingen SF_6 experiment [7] the transferred heat flux varied from ~4 W/m^2 to ~500 W/m^2 at Ra numbers from ~10^{11} to 10^{14}. For example, the bottom plate

with emissivity $e = 0.05$ at $T_b = 295$ K emits a heat flux of 22 W/m^2 which is especially significant at lower *Ra* numbers with respect to the measured transferred heat flux.

Regarding absorption in water, all the heat emitted by the bottom plate is absorbed within very thin layer with $z < 10^{-4}$ m, in stark contrast to SF6.

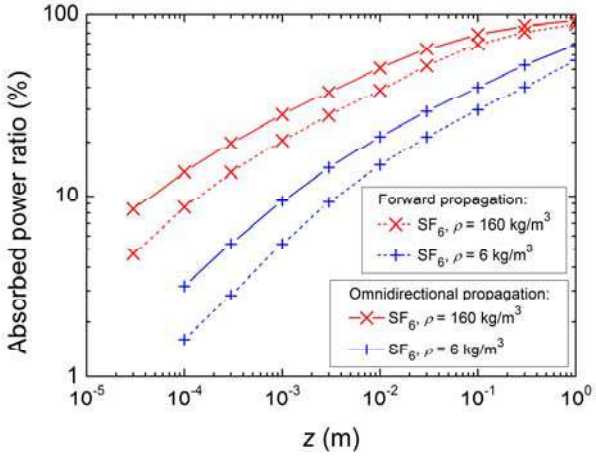

Figure 1. Radiative power absorbed in SF_6 gas layer (ratio with respect to the heat power emitted by the bottom plate with temperature $T_b = 295$ K) plotted versus distance z from the emitting plate. Densities 6 kg/m^3 and 160 kg/m^3 of SF_6 gas correspond to atmospheric pressure and elevated pressure of 20 bar realised in the Göttingen experiments [7].

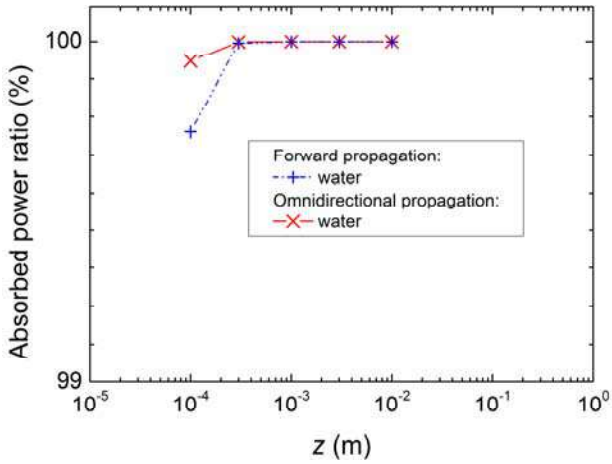

Figure 2. Radiative power absorbed in water layer (ratio with respect to the heat power emitted by the bottom plate with temperature $T_b = 295$ K) plotted versus distance z from the emitting plate.

In conclusion, for fully transparent working fluids at room temperature, we show that the radiative heat transfer could affect the *Nu* number appreciably and can be corrected. Experiments utilizing fluids absorbing thermal radiation require special care and thermal radiation as well as its absorption inside the RBC cell ought to be taken into account. On the contrary, in the cryogenic experiments (at temperatures of a few K) with gaseous or liquid helium, the radiative heat transport contributes to the total heat transport through the cell by a negligibly small amount [2].

Summary We present an innovative sine-helicoidal channel geometry which allows, due to the alternation of centrifugal forces, the perturbation of the Dean cells, and consecutively the obtention of chaotic advection. Numerical investigations have been carried out to study the laminar flow patterns in the sine-helicoidal channel. Its thermal efficiency is compared to the one given by a classical helicoidal channel for a thermal Dirichlet boundary condition. Results showed that the sine-helicoidal geometry improves the mixing and heat transfer significantly. One might thus envision the use of such device for applications in which the lack of mixing is a limiting factor.

INTRODUCTION

Flows in curved channels are often used for many industrial operations: heat transfer, chemical reaction, filtration, separation, dispersion, etc. (1). The particularity of the flow in a curved channel is to develop, due to the centrifugal force and to the viscous drag along the walls, two symmetrical vortex cells in the flow cross section. This leads to helicoidal Lagrangian trajectories. The flow is characterized by the dimensionless Dean number ($\mathrm{Dn} = \mathrm{Re}\sqrt{a/R}$ where Re is the Reynolds number and a characteristic length of the cross-section). These Dean cells appear from $\mathrm{Dn} \simeq 0$ until large values of Dn where they subsist as coherent structures in the turbulent flow. Their intensity will be stronger if the radius of curvature R is smaller (*i.e.* stronger curvature k). If the length of the curved channel is increased, it is necessary to give it a certain torsion. We then obtain a helicoidal channel. Dean's vortex cells are slightly modified by this channel torsion, the plane of curvature separating the two vortices is just rotated to match the torsion angle. The particle trajectories are always toroidal and there is no fluid exchange between the two vortex regions. However, if we twist two consecutive portions of toroidal channel, we can break the flow symmetry and obtain complex trajectories of so-called chaotic advection. This chaotic advection flow within twisted channels was first numerically evidenced by Jones *et al.* in 1989 (2) and experimental confirmation given by Le Guer and Peerhossaini in 1991 (3). Numerous studies have then proven the effectiveness of this geometry with twisted curved channels to improve mixing, heat and mass transfer and reactive transfer. In the following sections we present an original geometry of channel arranged in a sine-helicoidal shape and some numerical results of flow patterns and heat transfer efficiencies compared to those given by the flow in a helicoidal channel.

GEOMETRY AND PARAMETERIZATION

The wavy square channel is parametrized by a sine-helicoidal smooth analytical curve winding around a circular cylinder. The two geometries are shown in Fig. 1 (a). The two channels have the same length. They are equipped with identical straight sections at inlet and outlet. The difference between the two channels is how the curvature is organized around the cylinder. The curvature of the sine-helicoidal channel periodically changes while revolving around the cylinder surface (of radius R) through two opposite curvature extrema (up and down). The radius of curvature of the helicoid is unique and equal to the one of the cylinder (*i.e.* $R_h = R$) when the radius of curvature of the sinusoid R_s is variable and can be obtained by considering the sinusoid flattened on a (X, Y) plane (the flattened cylinder surface):

$$Y(X) = cR\sin\left(bX\frac{2\pi}{L}\right) + pX\ , \tag{1}$$

with $L = 2\pi R$, R the radius of the helicoid, p the vertical step, c a coefficient, $c\,R$ the amplitude of the sinusoid, and b the number of sinusoids per revolution. The relationship between the two radii of curvature depends strongly on the choice of the number of sinusoids per revolution b (quadratic dependence) and the coefficient of the amplitude of the sinusoid c. We introduce two Dean numbers, the first one is related to R_h, the curvature of the cylinder $\mathrm{Dn}_h = \mathrm{Re}\sqrt{a/R_h}$ and the second one is related to R_s, the curvature of the sinusoid $\mathrm{Dn}_s = \mathrm{Re}\sqrt{a/R_s}$ with the Reynolds number $\mathrm{Re} = Ua/\nu$. We can therefore show that $\mathrm{Dn}_h = \mathrm{Re}\sqrt{a/(b^2c\,R_s)} = \mathrm{Dn}_s/(b\sqrt{c})$.

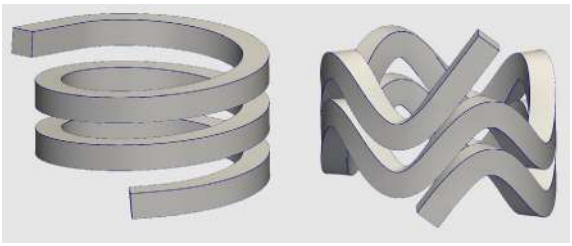
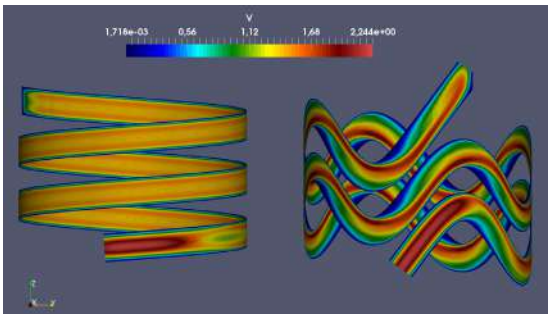
RESULTS

The fluid is Newtonian. The flow is steady, incompressible and laminar. The fluid temperature at the wall is chosen with a certain deviation from the fluid temperature at the inlet. The Prandtl number is close to that of water, $\mathrm{Pr} = 10$. The helicoidal and the sine-helicoidal channel lengths are identical. Both mesh sizes are also approximately the same, with 3×10^6 cells. In Fig. 1 (b) are shown the results for $\mathrm{Re} = 400$ for a fluid with a Prandtl number $\mathrm{Pr} = 10$. It is observed that the flow reaches rapidly ($\theta \approx \pi/2$ from the inlet channel) a hydrodynamically fully developed state in the case of the helicoidal configuration. Correlatively, the thermal field reaches a thermally fully developed state, but with a longer length (not shown here). This is not the case for the sine-helicoidal configuration for which the velocity field exhibits a strong periodic modulation along the channel, which results in the creation of a thermal strange eigenmode pattern for the thermal field observed at periodic locations along the channel (4). The results shown in the figure clearly evidence that the sine-helicoidal geometry offers an additional degree of freedom allowing a modulation of the velocity field that makes the fluid mixing more efficient.



(a)



(b)

Figure 1: (a) The helicoidal and sine-helicoidal channel geometries and (b) Module of the velocity field in a cylindrical slice coinciding with the curved plane passing through the middle of the channel section with the Reynolds number $\mathrm{Re} = 400$.

In order to evaluate the heat transfer performance for the two flows, three different mixing indicators are considered, which can be monitored throughout the evolution of the fluid in the channels: mean temperature T_m of the fluid, which represents the energy extracted from the walls, the coefficient of variation CoV of the fluid temperature, which accounts for the level of homogenization of the scalar temperature inside a cross-section and finally the overall Nusselt number which characterizes the parietal heat transfer along the channels. With $\mathrm{Re} = 400$ ($\mathrm{Dn}_h \simeq 253$ and $\mathrm{Dn}_s \simeq 506$) and a constant wall temperature, the sine-helicoidal channel configuration gives always better results in terms of the mean temperature T_m (increase) and its homogenization in the cross section (decrease of CoV) and also for the parietal Nusselt number (increase of 18%). The results are given in table 1.

Table 1: Mean temperature T_m on the cross-section and its coefficient of variation CoV for the helicoidal and sine-helicoidal flows after a quarter turn in the channel ($\theta = \pi/2$). The overall parietal Nusselt number is also given.

Geometry	T_m	CoV	Nu
Helicoidal	0.33	0.958	5.11
Sine-helicoidal	0.364	0.681	6.03
Relative enhancement (%)	10	29	18

We have also conducted a parametric study in order to found the optimal Reynolds number for which the geometry considered here is the most efficient for thermal mixing.

CONCLUSION

The potentiality of the sine-helicoidal flow has been proven to enhance thermal mixing by chaotic advection. This mathematically parameterizable geometry offers potential for the search of optimal geometries for the design of innovative and highly efficient mixers, heat exchangers and reactors.

STABILITY OF MIXED BAROCLINIC CONVECTION IN A NEARLY SEMI-CYLINDRICAL CAVITY

Abhishek Kumar *[1] and Alban Pothérat[1]
[1] Centre for Fluid and Complex Systems, Coventry University, Coventry CV1 5FB, United Kingdom

Summary In this work, we are seeking the critical conditions for the oscillatory instability that arises in a nearly semi-cylindrical cavity fed in with hot fluid at the upper boundary, bounded by a cold, porous semi-circular boundary at the bottom, and infinitely extended in the third direction. In this geometry, the flow is driven by an unusual type of mixed convection, which is the combination of the buoyancy indirectly caused by the shape of the boundaries and the through-flow. Linear stability analysis and direct numerical simulations are performed, using the spectral element method to identify observable states. Our analysis reveals that the unstable modes are three-dimensional. They show oscillatory or non-oscillatory behaviour depending upon the strength of through-flow. The nature of the bifurcation is determined through Stuart–Landau analysis.

We study the convective patterns that arise in cavities with curved isothermal boundaries and permeated by a through-flow (see Fig. 1(a)). This generic configuration is representative of numerous problems where solid materials are melted, for instance, metallurgical casting processes [1]. In this configuration, despite the stable stratification, the pressure gradient and the temperature gradient form an angle, which is maximum near the upper corners. This results in a buoyancy force that cannot be opposed by pressure and leads to a baroclinic imbalance, which drives the base flow [2].

The non-dimensional equations governing stratified flows under Boussinesq approximation are

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla)\mathbf{u} + \nabla p = RaPrT\mathbf{e}_y + Pr\nabla^2\mathbf{u}, \quad (1)$$

$$\frac{\partial T}{\partial t} + (\mathbf{u}\cdot\nabla)T = \nabla^2 T, \quad (2)$$

$$\nabla\cdot\mathbf{u} = 0, \quad (3)$$

where $\mathbf{u}$ is the velocity field, p the pressure field, t is the time, and T is the temperature field. The flow is characterised by three non-dimensional parameters, the Rayleigh number Ra (which is the ratio of buoyancy force to dissipative force), the Prandtl number Pr (which is the ratio of kinematic viscosity to thermal diffusivity), and the Reynolds number Re based on the dimensional feeding velocity u_0. In all simulations, we fixed Pr to 0.02, a value typical of liquid metals in continuous casting processes. Equations (1)-(3) are solved using the spectral element method. We impose a free-slip and a no-slip boundary conditions for the velocity field at the upper free surface and at the front wall respectively. For the temperature field, we impose a conducting boundary condition at both the upper free surface and at the front wall. We apply a no-slip boundary condition for the velocity field and an insulating boundary condition for the temperature field at the right and left side- walls. To satisfy the uniform inflow and outflow, we set vertical velocity to $-u_0$ at the upper free surface and the front wall.

We perform three different types of numerical computations using the open source-code NEKTAR++ [3]. First, we obtain a two-dimensional steady base flow using direct numerical simulation (DNS). Second, we perform linear stability analysis (LSA) of three-dimensional perturbations on the two-dimensional base flow by solving the linearised governing equations (see [2] for details). Third, three-dimensional (3D) DNS are performed in weakly sub- and supercritical regimes

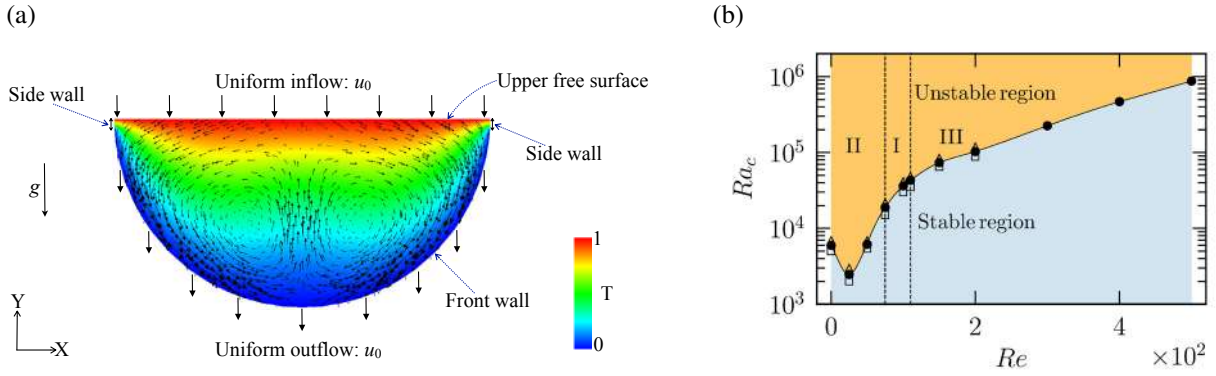

Figure 1: (a) Two-dimensional base flow at $Pr = 0.02$. $Ra = 10^4$, and $Re = 50$. Colours represent the temperature field and arrows represent the velocity vector $\mathbf{u}$. (b) Critical Rayleigh number Ra_c as a function of Re. Blue (orange) regions below (above) the curve represents flow regimes that are linearly stable (unstable) to two or three-dimensional perturbations.

(a) LSA (b) DNS

Figure 2: For $Re = 0$ and $Ra = 7 \times 10^3$: (a) Vorticity perturbation along the homogeneous direction. Out-of-plane vorticity component ζ_z' computed from the linear stability analysis (LSA) at $z = 0$ plane for $k = 6$; (b) ζ_z' computed from the direct numerical simulation (DNS) in the $z = 0$ plane.

to assess the relevance of the linear stability results and to find the nature of the bifurcation by computing the parameters of the Stuart–Landau model [4].

The two-dimensional (2D) base flow is driven by baroclinic imbalance and produces two counter-rotating rolls (see Fig. 1(a) for example). This 2D base flow becomes linearly unstable to three different types of mode, depending on Re at a sufficiently high Rayleigh number. Fig. 1(b) displays the estimate of the critical Rayleigh number Ra_c, at which this transition occurs for a stable state to an unstable state, as a function of Re. When Re is increased from 0, the critical Rayleigh number $Ra_c(Re)$ initially decreases up to $Re = 25$ and then increases. Thus the through-flow has a stabilising influence as soon as the Reynolds number Re exceeds 25. Figure 2 shows the vorticity distributions in a weakly supercritical case for $Re = 0$ and $Ra = 7 \times 10^3$. The snapshots of the topologies of the perturbation from LSA and DNS are presented Fig. 2(a) and Fig. 2(b) respectively, and they match very well. We also find an excellent agreement in the estimate of the growthrate, frequency and the dominant wavenumber between LSA and DNS. Thus the 3D DNS confirm the relevance of the linear stability analysis.

In this study, we observe that the base flow is susceptible to three distinct types of infinitesimal perturbations. For $Re \leq 75$ the most unstable mode corresponds to Branch II as obtained from the linear stability analysis. The three-dimensional DNS show that the most unstable mode is a wave travelling in the $\mathbf{e}_z$ direction. DNS for $100 \leq Re \leq 110$ shows that the instability sets in as a standing oscillation (type I mode), while for $Re \leq 150$ the most unstable mode is non-oscillatory and corresponds to Branch III. Further, from the 3D DNS data, we determined the nature of the bifurcations points through Stuart–Landau analysis for completeness. DNS data revealed that the nature of the bifurcation associated to the three modes varies too. Modes corresponding the branch II and III shows *supercritical* bifurcation, whereas the onset of mode I is *subcritical*.

EFFECT OF ROTATION ON THERMAL VIBRATIONAL CONVECTION IN HORIZONTAL PLANE LAYER

Victor Kozlov*[1], Kirill Rysin[1], Aleksei Vjatkin[1]
[1]Laboratory of vibrational hydromechanics, Perm State Humanitarian Pedagogical University, Perm, Russia

Summary. We study the thermal vibrational convection of liquid in a rotating horizontal plane layer with isothermal boundaries of different temperatures. Vibrational convection is excited by circular cavity vibrations in the horizontal plane under the stable fluid stratification in the gravity - the layer is heated from above. In the absence of rotation, vibrational convection manifests itself in the form of two-dimensional rolls upon reaching the threshold value of the vibrational parameter. Under rotation, the vibroconvective patterns take the form of cells. With growth of the dimensionless rotation rate, the critical value of the vibrational parameter increases and the size of the vibroconvective cells decreases. The results are analyzed in the space of governing dimensionless parameters, the vibrational and gravitational Rayleigh numbers and dimensionless rotation rate.

EXPERIMENTAL METHODICS AND RESULTS

Thermal vibrational convection is an averaged convection of a non-isothermal fluid excited by the oscillating force fields, for example, the inertial force field in a vibrating cavity [1]. Rotation has a significant effect on vibrational thermal convection, since the Coriolis force affects not only the averaged flows, but also directly acts on the oscillating component of the velocity – the generator of vibrational convection [2]. A special case is represented by force field rotating in the reference frame of the cavity. It could be excited by circular vibrations of the cavity, or by external static fields (in the case of the cavity rotation). Not speaking about the weightlessness conditions, the circular vibrations can cause intense averaged thermal convection even under the conditions of a strong stabilizing effect of other convective mechanisms, for example, in a flat layer heated from above [3].

The objective of this work is to study the effect of rotation on the excitation threshold of vibrational thermal convection in a horizontal plane layer. To exclude the gravitational mechanism of convection, the layer is heated from above, at this the gravitational force plays an exclusively stabilizing role.

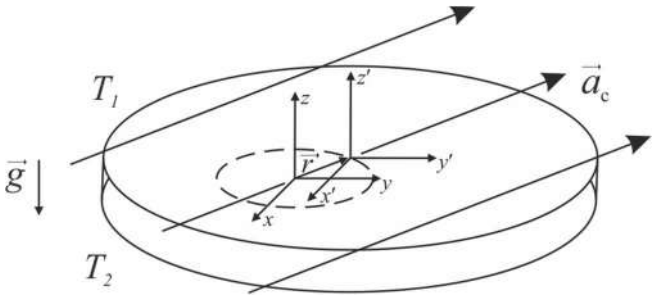

Figure 1. The problem statement

In this case, the thermal vibrational convection is determined by the following dimensionless parameters: the Prandtl number $Pr = \nu/\chi$, the vibrational parameter $R_v = \left(b\Omega_v\beta\Theta h\right)^2/2\nu\chi$, gravitational Rayleigh number $Ra = g\beta\Theta h^3/\nu\chi$ and dimensionless rotation rate $\omega \equiv \Omega h^2/\nu$. Here b and Ω_v – are the amplitude and the radian frequency of circular cavity vibration, which excite the rotating inertial force field $\vec{a}_c$ (Figure 1), Ω – cavity rotation rate, Θ and h – temperature difference and layer thickness, β,χ,ν – coefficients of volume expansion, thermal diffusivity, and kinematic viscosity of fluid. In the experiments the rotation rate was relatively low $\Omega << \Omega_v$.

The experimental procedure is as follows. For a given temperature difference Θ and rotation rate Ω, the frequency of circular vibrations at definite amplitude b monotonically increases. At this, the heat transfer through the layer is measured and the structure of convective flows is studied. For this purpose, the photochromic film is pasted on the lower cold boundary of the working layer, whose color varies depending on temperature. The temperature of the upper boundary of the layer is set by a transparent heat exchanger through which the photographic recording of convective flows is carried out.

The experiments show that with an increase of intensity of the layer vibration, the regular convective structures develop in a threshold way (Fig. 2), which is accompanied by a significant increase in the heat flux. The rotation has a stabilizing effect on the threshold of excitation of vibrational convection.

*Corresponding author. E-mail: kozlov@pspu.ru

The threshold of convective stability increases with a dimensionless frequency (Fig. 3); at various values of Ra the points are consistent with each other. Here R_v^* is the stability threshold at a given Ra in the absence of rotation.

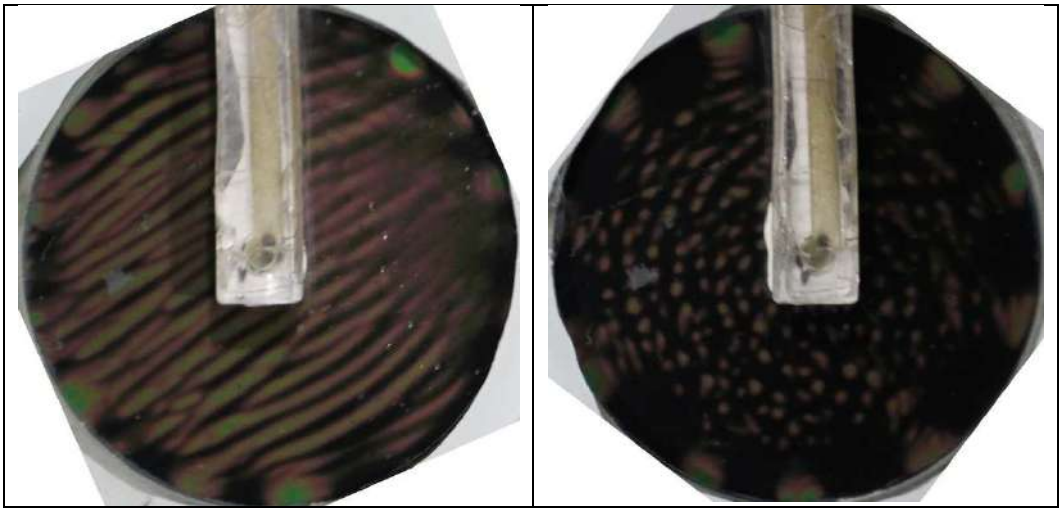

Figure 2. Photos of vibroconvective structures in the supercritical region, $Ra = -1.11 \cdot 10^5$, $R_v = 2.03 \cdot 10^5$: left – in the absence of rotation; right – under rotation, $\omega = 20.2$

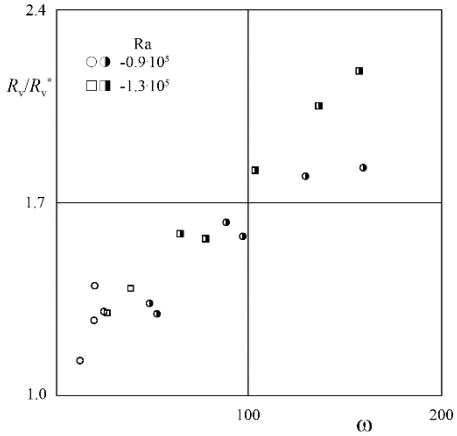

Figure 3. The threshold of vibrational convection excitation at various values of the gravitational Rayleigh number versus the dimensionless rotation rate

CONCLUSIONS

The vibrational thermal convection in a horizontal plane layer rotating around a vertical axis is experimentally investigated. The convection is excited by a high-frequency circular oscillations of the cavity in the horizontal plane. The fluid is stably stratified in the field of gravity – the layer is heated from above. It is found that in the absence of rotation the vibrational convection appears in the form of two-dimensional rolls, the excitation threshold is in good agreement with the theoretical expectation. Experiments demonstrate that under rotation the vibroconvective patterns have the form of cells. With increase of the dimensionless rotation rate, the critical value of the vibrational parameter (at a definite Rayleigh number) grows, and the size of the vibroconvective cells decreases. The effect of rotation on the thermo-vibrational convective mechanism is similar to the effect of rotation on natural convection in a horizontal plane layer.

STOCHASTIC MODELING OF TRANSIENT BOUNDARY LAYERS IN HIGH-RAYLEIGH-NUMBER THERMAL CONVECTION

Marten Klein*[1], Alan R. Kerstein[2], and Heiko Schmidt[1]
[1] Department of Numerical Fluid and Gas Dynamics, Brandenburg University of Technology (BTU Cottbus-Senftenberg, Cottbus, Germany
[2] Consultant, Danville, California, U.S.A.

Summary One-dimensional turbulence (ODT) modeling is used to investigate the boundary layer in high-Rayleigh-number thermal convection for a notionally infinite horizontal layer of fluid. The model formulation distinguishes between turbulent advection, which is modeled by a stochastic process, and deterministic molecular diffusion to capture relevant vertical transport processes (including counter-gradient fluxes). For this study, statistical homogenization is applied to the two horizontal dimensions so that we use ODT as stand-alone tool. We show that the model yields mean and fluctuation temperature profiles that are in several respects consistent with available reference data. Furthermore, the profile of a surrogate for the fluctuation velocity is reminiscent of canonical wall turbulence.

INTRODUCTION

Turbulent thermal convection manifests itself by irregular fluid motions on a range of scales, which are the results of a nonlinear interplay of buoyancy, inertial, and viscous forces as well as thermal diffusion. The fluid-surface coupling is achieved by shallow boundary layers so that it is mandatory to accurately capture their dynamical properties in numerical simulations if one wishes to quantitatively predict, for instance, the heat transfer or the induced flow velocities. For typical control parameters found in applications, the resolution requirements are far too high as direct numerical simulation (DNS) would be possible in the foreseeable future (e.g. [1]). Unfortunately, widely used and economical gradient-diffusion closures for modeling the sub-filter scale dynamics will not be sufficient to be predictive (e.g. [2]). We address this dilemma by utilizing the stochastic one-dimensional turbulence (ODT) model [3] for the simulation of nonstationary boundary layers in thermal convection problems. The objective is to investigate the turbulent boundary layer properties up to very high Rayleigh numbers with a physics-based but feasible numerical model.

In the following we, first, describe the flow configuration and model application. After that, we present some key results for the temperature and velocity statistics including a surrogate analysis. Finally, we close with our main conclusions and an outlook to what will be presented at the conference.

OVERVIEW OF THE FLOW CONFIGURATION AND MODEL FORMULATION

Figure 1(a) shows a sketch of the canonical Rayleigh–Bénard set-up investigated together with the ODT computational domain (ODT line). A Boussinesq fluid is confined between two smooth horizontal isothermal no-slip walls that are located at $z = 0$ and $z = L$. The heated and cooled walls have prescribed temperatures T_{hw} and T_{cw}, respectively, with constant difference $\Delta T = T_{\mathrm{hw}} - T_{\mathrm{cw}}$. The flow properties are governed by the Rayleigh number, $Ra = g\,\beta\,\Delta T\,L^3/(\nu\kappa)$, and Prandtl number $Pr = \nu/\kappa$, where g is the background gravity and β, κ, ν denote the fluid's thermal expansion coefficient, thermal diffusivity, and kinematic viscosity, respectively.

Figure 1(b) shows statistically representative vertical profiles of the temperature, $T(z,t)$, and a horizontal velocity component, $u(z,t)$ (inset). Deterministic molecular diffusion is directly resolved along the ODT line whereas the effects of turbulent advection are modeled by a stochastic process. The computational domain is thus a single vertical line along which flow profiles are evolved in time as described in [3, 4, 5, 6]. In contrast to the original model formulation [3, 4], we incorporate the vector velocity, $\boldsymbol{u} = (u, v, w)^{\mathrm{T}}$ as in [5, 6].

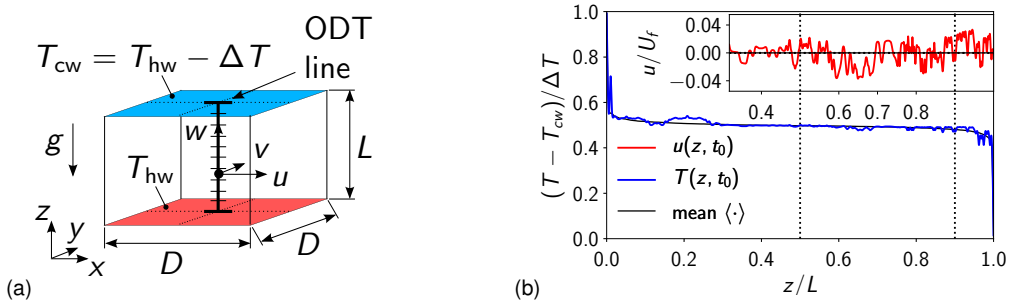

Figure 1: (a) Sketch of the Rayleigh–Bénard configuration investigated. Here, the vertical spacing, L, is fixed, whereas the horizontal dimension, D, is taken to infinity ($D \to \infty$). A stochastic ODT simulation aims to capture the nonstationary vertical transport and is carried out on a one-dimensional computational domain (ODT line). (b) Representative instantaneous and time-averaged vertical profiles of the temperature, T, and a horizontal velocity component, u, for $Ra = 10^{10}$, $Pr = 0.7$ (air). The velocity reference scale is the free-fall velocity, $U_f = \sqrt{g\,\beta\,\Delta T\,L}$.

*Corresponding author. E-mail: marten.klein@b-tu.de.

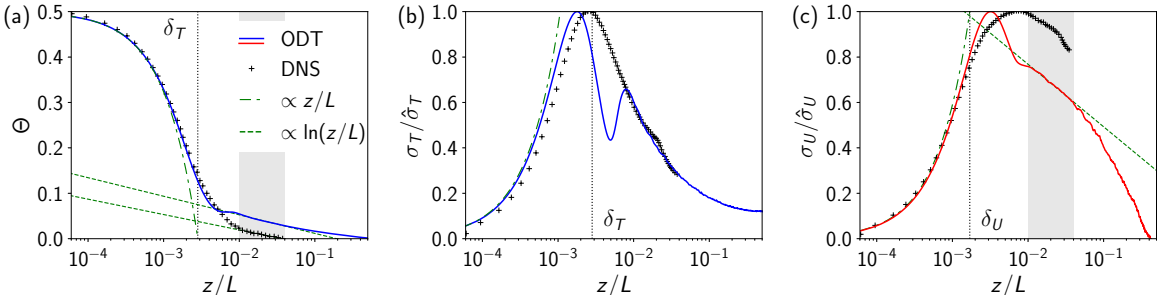

Figure 2: Boundary layer profiles over the heated wall for $Ra = 3 \times 10^{10}$ and $Pr = 0.7$ from ODT together with reference DNS data from [7] for the axis of a cylindrical set-up of aspect ratio one. (a) Normalized mean temperature, Θ; (b) normalized standard deviation of the fluctuation temperature, $\sigma_T/\hat{\sigma}_T$; and (c) normalized standard deviation of the fluctuation horizontal velocity, $\sigma_U/\hat{\sigma}_U$. The cap $\hat{(\cdot)}$ denotes the maximum value. In ODT, a 'mean boundary-layer downstream velocity', $\langle u_\mathrm{d} \rangle$, is used as a surrogate for the fluctuation velocity, σ_U, that is, we take $\langle u_\mathrm{d} \rangle \sim \sigma_U$. Linear and logarithmic regions, as well as the thermal, δ_T, and viscous, δ_U, boundary-layer thicknesses (slope method) are indicated. Logarithmic profiles have been fitted across $10^{-2} \leq z/L \leq 4 \times 10^{-2}$ (shaded region).

KEY RESULTS

Figure 2(a) shows the normalized mean temperature, $\Theta = (\langle T \rangle - T_\mathrm{b})/\Delta T$, where $T_\mathrm{b} = (T_\mathrm{hw} + T_\mathrm{cw})/2$ is the bulk temperature and $\langle \cdot \rangle$ a conventional temporal average. ODT reproduces the near-wall structure, but Θ departs from the reference data towards the bulk. It is remarkable that the present ODT results suggest the onset of a logarithmic region, $\Theta(z) = A \ln(z/L) + B$, which is in general consistent with [8]. The ODT solution exhibits approximately the same prefactor, A, as the reference data but a larger additive constant, B, due to the earlier departure from the sublayer.

Next, figure 2(b) shows profiles of the standard deviation of the fluctuation temperature, $\sigma_T = \sqrt{\langle T^2 \rangle - \langle T \rangle^2}$. Reasonable agreement between ODT and the reference data is observed close to and far from the wall. However, an unphysical bimodal structure can be discerned around $z \approx \delta_T$, which is precisely where Θ departs from the linear sublayer. This structure is presumably of the same origin as a similar one in the ODT fluctuation velocity observed in turbulent channels [5]. Here, the responsible modeling error manifests itself primarily in the driving Boussinesq temperature.

At last, we consider a surrogate analysis for the fluctuation velocity since ODT exhibits zero-mean velocity (see figure 1(b)). This differs from available reference data, which exhibits a large-scale circulation (e.g. [7]). We therefore consider a synthetic 'boundary-layer downstream velocity', $u_\mathrm{d}(z,t) = \boldsymbol{u}(z,t) \cdot \boldsymbol{e}_\mathrm{d}(t) \geq 0$, which is a projection of the vector velocity, $\boldsymbol{u}$, on an instantaneous 'boundary-layer downstream direction', $\boldsymbol{e}_\mathrm{d} = [\boldsymbol{e}_x(\partial_z u)_\mathrm{hw} + \boldsymbol{e}_y(\partial_z v)_\mathrm{hw}]/[(\partial_z u)^2_\mathrm{hw} + (\partial_z v)^2_\mathrm{hw}]^{1/2}$. The temporal mean, $\langle u_\mathrm{d} \rangle$, of instantaneous positive semi-definite $u_\mathrm{d}(z,t)$ profiles is used as surrogate for the positive semi-definite horizontal fluctuation velocity, $\sigma_U = \sqrt{\langle U^2 \rangle - \langle U \rangle^2}$, where $U = \sqrt{u^2 + v^2}|_\mathrm{axis}$ is evaluated at the axis of a cylindrical set-up [7]. Figure 2(c) shows profiles of the reference horizontal fluctuation velocity, σ_U, in comparison to the ODT surrogate, $\langle u_\mathrm{d} \rangle$. There is good qualitative agreement between both quantities and there is no bimodal structure in $\langle u_\mathrm{d} \rangle$ obtained by ODT. Furthermore, the profile of $\langle u_\mathrm{d} \rangle$ is reminiscent of the streamwise fluctuation velocity in canonical wall turbulence (e.g. [9]). Note that the profile seems to exhibit the onset of a logarithmic region but the vertical extend is small which suggests further analysis at higher Ra numbers.

CONCLUDING REMARKS AND OUTLOOK

The capabilities for economical but also reasonably accurate and robust modeling of transient boundary layers in turbulent thermal convection have been addressed by utilizing the stochastic one-dimensional turbulence (ODT) model. We have shown that point-wise temperature and velocity statistics (at least up to second order) exhibit reasonable agreement with available reference data. We have furthermore suggested a 'boundary-layer downstream velocity' surrogate for the fluctuation velocity. Vertical profiles of this surrogate are reminiscent of the streamwise fluctuation velocity in wall turbulence which is currently further investigated.

In the talk, we will outline the model formulation. After that, we will discuss the boundary-layer properties. At last, we will address the Ra number dependence and scaling properties by making use of the model's predictive capabilities.

EXPERIMENTS ON FLOWS IN A CHANNEL WITH SURFACE CORRUGATION AND PERIODIC HEATING

Ayumu Inasawa*[1], Kanato Hara[1], and Jerzy M. Floryan [2]
[1] Department of Aeronautics and Astronautics, Tokyo Metropolitan University, Hino, Tokyo, Japan
[2] Department of Mechanical and Materials Engineering, University of Western Ontario, London, ON, Canada

Summary Flows in a channel with surface corrugations and periodic heating were examined experimentally to demonstrate the formation of the thermal drift phenomenon. The lower wall had a sinusoidal surface corrugation with an amplitude of 10% of the channel half-width and a non-dimensional wavenumber of 1. This wall was exposed to periodic heating with the same wave number. The heating and groove patterns were misaligned with a phase difference of $\pm\pi/2$. The upper smooth wall was kept isothermal with its temperature equal to the mean temperature of the lower wall. The results show that a pair of counter-rotating stationary rolls created by the periodic heating lead to the formation of a net horizontal flow whose direction is dictated by the phase difference. The volumetric flow rate carried by this flow increases monotonically with the heating intensity.

INTRODUCTION

Thermal convection is a canonical problem in fluid dynamics. In general, convection is driven either by vertical temperature gradients, assuming that the critical stability conditions are met, or by horizontal temperature gradients, which lead to horizontal density variations and convection regardless of the magnitude of these gradients. A representative example of the former is the classical Rayleigh-Bénard (RB) convection, and an example of the latter is horizontal convection [1]. Recent theoretical analyses of RB convection at subcritical Rayleigh numbers have revealed that stationary convection is possible between isothermal walls with geometrical surface irregularities [2]. A systematic way to create horizontal convection involves the use of spatially patterned heating [3], which generates stationary buoyancy-driven rolls over a wide range of Rayleigh numbers, offering the potential for the development of novel drag-reducing methodologies [3-4]. Additional flow phenomena were predicted analytically when either a proper combination of patterns of heating were used at the upper and lower walls [5] or a combination of surface corrugation and patterned heating were employed [6], both of which were able either to create net horizontal forces between the bounding walls or to induce net horizontal flow. This effect is referred to as thermal drift [5-6]. A significant advantage of using patterned heating for flow control is that it does not require placing mechanical devices in the flow. Although the characteristics of such flows were determined analytically, no experimental observations are available to confirm their existence. In the present study, flows in a channel with periodic surface corrugations and periodic heating are examined experimentally to confirm the existence of net horizontal flows driven by the thermal drift effect. This problem can be viewed as a pattern interaction problem with the global flow created through an interaction between the properly placed heating and topography patterns.

EXPERIMENTAL SETUP

The experiment was conducted in a horizontal rectangular open conduit whose width, height and length were 400mm, 20mm (=2h) and 749mm, respectively, giving an aspect ratio (the ratio of width to height) of 20 (Fig. 1a). The lower wall with a sinusoidal surface corrugation with amplitude of 0.1h was heated periodically by supplying hot/cold water to the embedded aluminium pipes (see Fig. 1b), while the upper smooth wall was kept isothermal at T_0=293K, by supplying water with a fixed temperature to embedded pipes. The spatial distribution of the grooves and the heating were characterized by the same wavelength of λ=62.8mm, giving a non-dimensional wavenumber of $\alpha=2\pi h/\lambda = 1$. The phase difference between the heating and corrugation patterns could be changed from $\Omega = +\pi/2$ to $\Omega = -\pi/2$. The periodic Rayleigh number Ra_p measuring the intensity of the periodic heating was defined as $Ra_p=g\beta h^3\Delta T_p/(\nu\kappa)$, where ΔT_p denotes the peak-to-peak amplitude of the absolute temperature along the lower wall, g stands for the gravitational acceleration, β is the thermal expansion coefficient and κ denotes thermal diffusivity. The experiments were carried out for Ra_p=750-3000. Properties of the fluid (air) at the upper wall temperature were used as the reference quantities. Special plates were installed at the exits of the conduit to eliminate thermal plumes. A particle image velocimetry (PIV) system (Dantec) consisting of a double-pulsed Nd:Yag laser and a CCD camera of 2048 × 2048 pixels was used to obtain instantaneous velocity fields. The surface temperature was measured using a combination of thermography and thermocouples.

RESULTS

Figures 2(a) and (b) display the time-averaged flow field expressed in terms of a map of the horizontal velocity U and streamlines for Ra_p=1500. In the case of $\Omega=\pi/2$, shown in Fig. 2(a), pairs of counter-rotating stationary rolls whose upward and downward motions occur above the hot spots ($x/h \approx 39, 45$) and cold spots ($x/h \approx 36, 42$), respectively, were formed and aligned periodically in x. The upward motion was much stronger than the downward motion, resulting in the centers of the rolls being attracted to the upwash zone. A stream tube meandering between the convection rolls and carrying net horizontal mass flow is clearly visible. The direction of flow in this stream tube is such that the fluid passing above the

*Corresponding author. E-mail: ainasawa@tmu.ac.jp

hot spots moves upwards while it is directed downwards above the cold spots on the corrugated surface. The flow direction is reversed when the phase difference between the heating and the grooves is shifted by π, as shown in Fig. 2(b). Figure 3 illustrates the Rayleigh number dependency of the volumetric flow rate of the net horizontal flow, calculated by integrating the horizontal velocity profile at the corrugation peak (x/h=37.7). It can be seen that the flow rate increases monotonically with the heating intensity up to Ra_p=3000 regardless of the phase difference between the heating and corrugation patterns, indicating that a proper combination of corrugation and heating patterns can drive net flow in either of the horizontal directions.

CONCLUSIONS AND OUTLOOK

Flows in a channel with surface corrugations and periodic heating were examined experimentally. The results show that periodic heating creates pairs of counter-rotating stationary rolls which generate a net horizontal flow, thus confirming the existence of the theoretically predicted thermal drift. The direction of the net horizontal flow is reversed when the phase of the heating is shifted by π with respect to the corrugation. The volumetric flow rate carried by this flow is found to increase monotonically with the heating intensity. In the presentation, properties of the flow fields will be discussed and compared with the theoretical predictions.

DENDRITE PREVENTION IN BATERRIES USING FLOW

Oles Dubrovski[1] and Ofer Manor *[2]

[2] Department of Chemical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary: We study the inhibiting effect of flow on dendritic growth. Our system is a flow battery chamber recharging an entering electrolyte with concentration C_{Li} and at velocity U_0. The reaction takes place at the cathode, where an initial sinusoidal distribution of dendrites is present. A concentration boundary layer develops at the surface of the cathode. We solve asymptotically the governing equations, coupled with the limiting current boundary condition. Our results indicate a smoothing effect that the flow has on the flux of ions to the dendrites, which inhibits dendritic growth.

INTRODUCTION

Dendrites pose a significant safety concern for commercial batteries. Vast research is taking place today to prevent the formation of dendrites and especially to render Lithium-metal batteries chargeable. Usually, the focus is on using new materials for electrodes and adopting new kinds of electrolytes [1,2]. Theoretical studies have been considering only the surface tension and deformation stresses in the solid cathode as growth-inhibiting mechanisms [3,4,5]. However, it has been known for a long time that flow in electrochemical cells may inhibit the growth of dendrites [6,7]. We develop a theoretical model for the description of dendritic growth under the influence of flow in a concentration boundary layer, where we employ the limiting current conditions to account for the ion mass flux between the electrodes in the electrochemical cell.

THEORY

The system configuration is given in Figure 1. We consider a recharge process of a flow battery. An electrolyte containing lithium ions with concentration C_{Li} enters at velocity U_0 into a battery chamber containing an anode and a cathode. On the cathode lithium ions deposit according to the limiting current conditions. The punctured line indicates a sinusoidal deformation of the cathode characterized by the wavenumber k due to an initial presence of dendrites along the surface. The Reynolds number is small, and the Peclet number is large. Therefore a concentration boundary layer develops at the surface of the cathode with the leading-edge region at the forefront. Our model includes an asymptotic analysis of the ion concentration in the bulk electrolyte, the leading edge of the electrode, and the boundary layer regions.

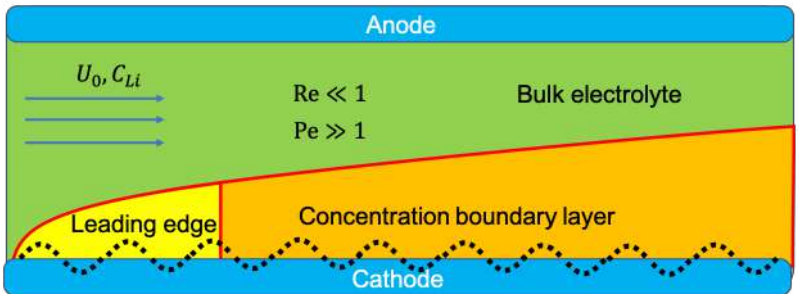

Figure 1. **Dendritic growth in a flow battery system configuration.** The electrolyte enters the chamber with concentration C_{Li} and at velocity U_0. A leading edge and concentration boundary layer regions develop at the surface of the reacting cathode. The initial sinusoidal dendrite distribution on the cathode is depicted by the dashed line.

RESULTS AND CONCLUSIONS

The initial presence of the dendrites serves as a hotspot for the depositing lithium ions, which without any inhibiting mechanism, will grow indefinitely. Our results indicate that the flow has a smoothing effect on the lithium-ion flux distribution along the cathode, essentially canceling the dendritic growth hotspots at large enough k. The smoothing effect originates from the advective transport of ions in the electrolyte.

CONVECTION AND ELECTROVORTEX FLOW IN LIQUID METAL BATTERIES

Jonathan S. Cheng *[1], Ibrahim Mohammed[1], Gerrit M. Horstmann[2], and Douglas H. Kelley[1]
[1] Department of Mechanical Engineering, University of Rochester, Rochester, USA
[2] Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany

Summary We study thermal convection and electrovortex flow (EVF) in series of liquid gallium laboratory experiments. These two forces notably interact in liquid metal batteries (LMBs), a promising technology suited for grid-scale energy storage: convection occurs due to the presence of internal heating while EVF is driven by diverging current densities. Though these forces have potential to both help and hinder the batteries' operation, flow structures and scaling properties in this context remain largely unknown. To this end, we present a suite of velocity measurements which reveal the dominant flow modes and typical flow speeds over broad ranges of convective forcing, EVF forcing, and container shape. These data are compared to predictions from both the EVF and convection literature.

Introduction

As renewable energy sources such as wind and solar power become increasingly relevant, so too do the unique challenges associated with their implementation. Some of these sources are intermittent and unpredictable, and therefore require our electrical grids to be capable of storing large amounts of energy. A variety of technologies are in development to address this challenge. Among them, liquid metal batteries (LMBs) – galvanic cells where the cathode, anode, and electrolyte material are each composed of a different fluid (Fig. 1a) – stand out due to their potential to be remarkably cost-effective.

The LMB system is inherently stably stratified, with density gradients naturally separating each fluid layer. However, the combination of heat production and electromagnetic forces caused by the flow of ions ensures that vigorous flows manifest [4]. Two of the most prominent flows that occur within a single layer of an LMB are thermal convection and electrovortex flow (EVF). Convection is caused by heating of the electrolyte layer during operation, which creates significant adverse temperature gradients. EVF emerges when a divergent current density interacts with its own induced magnetic field [2], and occurs in liquid metal battery setups due to the size difference between positive and negative current collectors.

These flows have a host of effects on the viability of an LMB, from enhancing mixing within the cathode or anode layer (leading to even greater efficiency), to disrupting the middle electrolyte layer (leading to direct contact between cathode and anode material and failure of the battery). However, while significant literatures exist for each effect independently, their interaction within the LMB context remains largely unexplored. In this study, we tackle this issue using a large experimental survey of convection and EVF interactions, in a broad range of forcings and geometries relevant to liquid metal batteries.

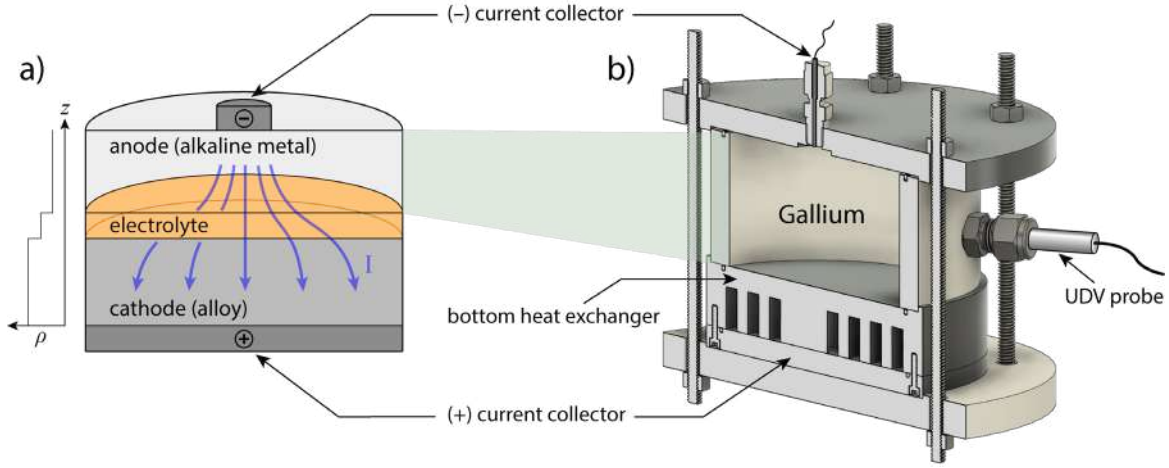

Figure 1: a) Diagram of a liquid metal battery cell modified from [4], showing the current density during the discharge process, and b) Cross section view of the design drawing of the experimental setup. Current collectors connect to a power supply and induce EVF while heat exchangers connect to thermal baths to induce convection. The top heat exchanger (not pictured) is a double wound copper spiral attached above the gallium layer.

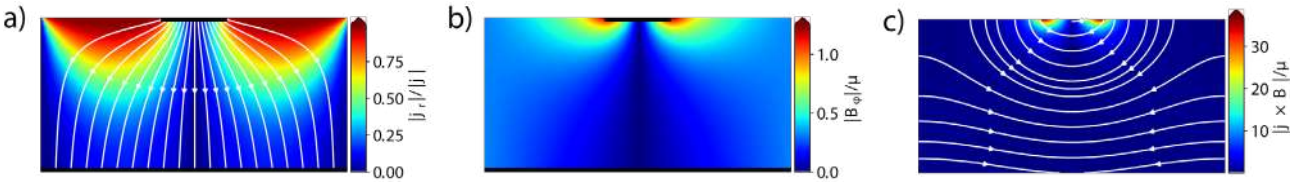

Figure 2: Analytic solutions for a) the current density, b) the magnetic field, and c) the Lorentz force distribution for an aspect ratio $\Gamma = 2$ layer.

Experiment

The experimental apparatus (Fig. 1b) is a closed cylindrical cell of fixed diameter $D = 12$ cm and interchangeable heights ranging from $H = 3$ cm (aspect ratio $\Gamma = D/H = 4$) to $H = 12$ cm ($\Gamma = 1$). Previous studies and linear theory predict that the onset modes for both EVF and convection are dependent on container shape, a somewhat free parameter in LMBs. The working fluid is liquid gallium, which has physical properties resembling LMB materials but melts near room temperature. We induce convection with cold and hot heat exchangers attached to the top and bottom boundaries of the cell, respectively. We induce EVF by passing an axisymmetric vertical current through the system; the top current collector is much narrower than the bottom, leading to a strong divergence in the current density. The flexibility of this setup allows us to access broad ranges of the governing parameters: the Rayleigh number Ra, describing the strength of convective forcing, reaches values as high as $\sim 10^7$ in our device. The EVF parameter S, likewise describing the EVF forcing, reaches values as high as $\sim 10^5$. In addition, we are able to impart a stabilizing temperature gradient to the system. This occurs in the cathode of the LMB during operation, and the combination of stable density stratification and EVF is an important phenomenon that has not been previously addressed.

Data are acquired using several ultrasonic doppler velocimetry probes positioned at different locations in the sidewall and ceiling of the cell. The probes measure flow velocities along the line of the emitted beam, in the direction of said beam. By examining measurements from multiple probes, flow structures can be deduced.

Phase diagram

We present our velocity data in the form of phase diagrams describing the transitions between different dominant flow structures and velocity scalings, as the experiment scans over ranges of convective forcing (Ra), EVF (S), and aspect ratio (Γ). Linear theory is used to predict the onset modes of EVF in different tank dimensions (see Fig. 2). Combining this with previous theoretical arguments and experimental/numerical results, an array of predictions for exclusively convection or exclusively EVF are plotted in the (Ra, S, Γ) phase space. The predictions serve as a benchmark for our experiments.

In most cylindrical geometries, convection leads to a poloidal, torus-shaped roll with the upward flow at the central axis. EVF is predicted to produce a similar structure, but with downward flow at the central axis instead. In the presence of an external B-field (very likely to be present in practical LMB arrays), EVF manifests as a container-scale horizontal swirling flow beyond some S. These different modes inevitably interfere with each other depending on the degree of each forcing, leading to changes in their onset values, velocities and overall structure in time and space. The analysis of [3], though in a different geometry and applied to vacuum arc remelting, predicts the crossover between convection-dominated and EVF-dominated flows. Ashour *et al.* [1] make a similar but more reduced prediction in the cylindrical geometry, and both analyses are incorporated in the phase diagram for comparison with experimental results.

Conclusion

We employ a novel experimental device to explore the flow regimes driven by convection and EVF in liquid gallium, laying the groundwork for future LMB design. Velocities measured via ultrasonic doppler velocimetry are used to produce a phase diagram which predicts the types of flows that emerge from convection and EVF for a given LMB setup. In an actual three-layer system, these flows will have a significant effect on the efficiency and viability of the battery.

LINEAR STABILITY OF MIXED CONVECTION UNDER SORET AND VISCOUS HEATING EFFECTS

K. Ali amar *, S. C. Hirata, and M. N. Ouarzazi
Univ. Lille, EA 7512 - Unité de Mécanique de Lille - Joseph Boussinesq (UML), F-59000 Lille, France

Summary The aim of this work is to investigate analytically and numerically the Soret effect on the linear stability of mixed convection due to viscous dissipation in a horizontal channel of infinite lateral extention filled with a binary fluid mixture. No external temperature difference is imposed on the layer. Thus, the sole cause of thermal instability is the flow rate, through the volumetric heating induced by the viscous dissipation. A linear stability analysis suggests that the most unstable perturbations are in the form of longitudinal rolls. Positive as well as negative separation ratios are analyzed which revealed that for $\psi > 0$ the system undergoes a "Pitchfork" bifurcation, while for $\psi < 0$ the system loses its stability via a "Hopf" bifurcation. Afterwards, the thresholds for the appearance of the monocellular flow are derived analytically using the parallel flow approximation.

INTRODUCTION

In shear flows, the heat generated by viscous friction between adjacent fluid layers may produce a local temperature increase, which can lead to unstable temperature gradients within the fluid. In the last decades, a series of papers proved that viscous heating (or viscous dissipation) effects should not be neglected when considering the stability of shear flows of highly viscous fluids [1].

The aim of the present paper is to extend the linear analysis of Barletta et al. [2] to the case of a binary fluid. As it is well-known, a temperature gradient applied to a binary fluid mixture induces a mass fraction gradient. This phenomenon is known as thermodiffusion, or the Soret effect. We recall that the Soret separation ratio ψ, being proportional to the strength of the Soret effect, can be either positive or negative. In the case of a positive ψ, the lighter component of the fluid mixture is driven into the direction of higher temperatures, thus further enhancing the density gradient. For negative ψ, the opposite situation occurs.

In this work, we investigate the linear stability of the Poiseuille flow of binary fluids by taking into account the effects of viscous heating and thermodiffusion. As in [2, 3], no external temperature difference is prescribed over the layer: the upper boundary is considered isothermal and the lower one is adiabatic. Positive as well as negative separation ratios are analyzed. Differently from [4], in our case the Squire transformation cannot be used. Therefore, the full three-dimensional linear eigenvalue problem is solved in order to determine the thresholds for the onset of the different convective structures (transverse, oblique, or longitudinal modes).

RESULTS AND DISCUSSION

A linear stability analysis has been carried out by solving numerically the eigenvalue problem for arbitrarily oriented convection rolls. The influence of the Prandtl number, Pr, the Lewis number, Le, and the inclination angle of the rolls, ϕ, on the neutral stability condition have been investigated. The neutral stability curves have been represented by tracing the functional dependence of $\Lambda = GePe^2$ on the wave number k of the normal-mode disturbance, where the Péclet Pe and Gebhart Ge numbers can be seen as measures of the main flow intensity and viscous dissipation effects, respectively. The most relevant results obtained are described in the following.

(i) The minimum of the neutral stability curve $\Lambda(k)$, i.e. the critical point (k_c, Λ_c), is at its lowest when the inclination angle of the wave-like disturbance roll is $\phi = \dfrac{\pi}{2}$, as can be seen in figure 1. This means that the most unstable disturbances are the longitudinal rolls and justifies the use of Λ as an appropriate parameter for describing the transition to the instability;

(ii) Frames (a)–(c) of figure 2 shows the critical values of Λ_c, k_c and ω_c for the onset of longitudinal rolls versus the separation ratio ψ . The behaviour displayed in figure 2 reveals that for positive separation ratios, we observe the appearance of a stationary convective structure characterized by a zero frequency $\omega = 0$. The critical wave number vanishes when ψ exceeds a particular value ψ_{mono}, thereby indicating that the primary instability is structured in the form of a single-cell flow (monocellular flow). For negative separation ratios, the flow crosses a new bifurcation threshold called Hopf bifurcation at ψ^*, i.e. the codimension-2 bifurcation point where two modes becomes simultaniously convectively unstable, constituting a new convective state macroscopically different from the previous one, in the form of oscillating rolls with finite amplitudes and smaller wavelengths to increase the evacuation of the inherent heat of the system;

(iii) By using the parallel flow approximation along the y-direction for $\psi > \psi_{mono}$, the critical value of the onset of convection is readily obtained as $\Lambda_c = \dfrac{120}{Le\ \psi}$.

Finally, based on the obtained results we propose a protocol to estimate the Soret coefficient.

OBLIQUE IMPINGING JET MECHANISM IN TURBULENT RAYLEIGH-B ENARD CONVECTION

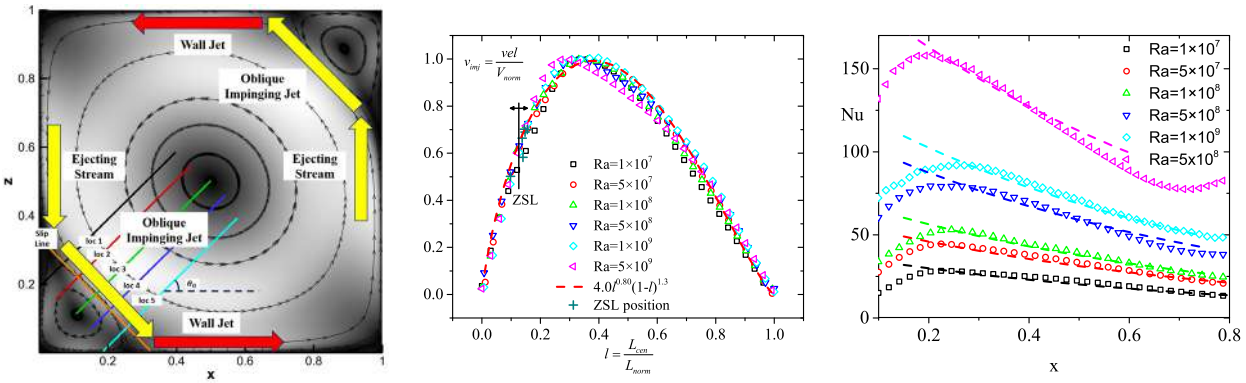
Wen-Feng Zhou*[1,2], Jun Chen[2], Yan-Chao Hu[1], and Yan-Guang Yang[3]
[1] Hypervelocity Aerodynamics Institute, China Aerodynamics Research and Development Centre, Mianyang, China
[2] State Key Laboratory for Turbulence and Complex Systems, College of Engineering, Peking University, Beijing, China
[3] China Aerodynamics Research and Development Centre, Mianyang, China

Summary The oblique impinging jet (OIJ) Mechanism is found to play a key role in heat transfer near the plate in Rayleigh-Bénard (RB) convection. The OIJ is induced by the large scale circulation impinging onto the horizontal plate, and then develops into a wall jet. The OIJ demonstrates the conservation in space and similarity for various Rayleigh (Ra) numbers. The local heat transfer Nu distribution $Nu_{loc} = Nu_m exp[-(x - x_{rea})/(L_x - x_{rea})]$ is derived theoretically by similarity analysis of wall jet equation, where x_{rea} is the location of reattachment, L_x is the length of the cell and Nu_m is the local Nu at reattachment point obtained through an impinging-jet-based model. Both the scaling and distribution of Nu_loc agree with the DNS. The same heat transfer scaling for both the impinging region and the cell reveals that the OIJ dominates the near wall flow at moderate Ra.

INTRODUCTION

Enormous phenomenon in nature such as convection in the earth's mantle, cloud formation, and large-scale circulation (LSC) in the ocean are mainly driven by the convection. A fluid in a confinement heated from the bottom at high temperature and cooled from the top is popularly known as the Rayleigh-Bénard (RB) convection [1, 2]. The heat transport in a confinement of width L_x and height L_z filled with a fluid is often determined by three dimensionless parameters, namely, the Rayleigh number $Ra = g\beta\Delta T L_z^3/(\nu\kappa)$, the Prandtl number $Pr = \nu/\kappa$, and the aspect ratio $\Gamma_x = L_x/L_z$. Here, ΔT is the temperature difference between the top and bottom plates, g the acceleration due to gravity, β the thermal expansion coefficient, ν the kinematic viscosity, and κ the thermal diffusivity, L_y the depth of the container, respectively.

The heat and momentum transfer ability related to those three parameter is the most important issue in this system. Much attention is pay on the property of the boundary-layer like flow near the wall. It has been found that a local Nu (defined as $Nu_{loc} = \frac{\partial T/\partial z}{\kappa\Delta/L_z}$) reaches the maximum in the region between LSC and corner-roll (CR) and drops along the streamwise direction [3], which seems to be counter-intuitive with the view of BL development. The mechanism of heat transfer inspired us to understand the flow and heat transport influenced by LSC and CR.



(a) (b) (c)

Figure 1: (a)The distribution of average velocity on xz-plane at $\mathrm{Ra} = 1 \times 10^8$; (b) Normalized velocity distributions of different Ra along the line from CR center to LSC center; (c)Nu distribution from DNS and theoritical work.

OBLIQUE IMPINGING JET PROCESS

Our study is based on the DNS data in a slim rectangular box with the spanwise aspect ratio $\Gamma_y = L_y/L_z = 1/6$ and $\Gamma_x = 1$ [3, 4]. Ra ranges from 10^7 to 5×10^9 and $Pr = 0.7$. The LSC motion near CR and along the horizontal plate is analogy with the oblique impinging jet [5] and corresponding attaching wall jet. The magnitude of time-spanwise average velocity $vel = \sqrt{U^2 + W^2}$ on xz-plane is shown in Fig.1(a). The OIJ corresponds to separated down/up stream of LSC, which originates from the deflected flow in the plume-emission region. This stream goes along with the shear layer of CR and impinges onto the bottom/top plate, then reattaches. The OIJ induced by LSC transports more momentum to the near-wall region and correspondingly carries more heat flux from the plate than the downstream shear flow. After impinging, the flow reattaches and develops on the horizontal plate, which corresponds to a WJ.

*Corresponding author. E-mail: wenfeng_zhou@pku.edu.cn

The streamwise and Ra similarity properties are found in the OIJ. The velocity magnitude profile of OIJ at different positions on the zero streamline (ZSL) separating the corner-roll and LSC (e.g., $loc1$ to $loc5$ in Fig.1(a)) collapse together, indicating streamwise similarity and a good conservation of the 'jet' like flow without obvious diffusion behavior. For Ra similarity, we show the normalized vel profile with different Ras in Fig.1(b). vel are scaled by the maximum magnitude V_m, and the length are scaled by the distance of two centers L_c : $v_{imj} = \frac{vel}{V_m}, l = \frac{l_{cr}}{L_c}$, where l_{cr} is the distance to the CR's center, L_c is the length of center of CR to the center of LSC. vel profiles collapse together, demonstrating a Ra-similarity of OIJ process, and can be empirically described by a beta function $v_{imj} = 4.0l^{0.80}(1-l)^{1.30}$.

As the normalized vel distributions collapse, V_m and L_c should be appropriate scales to characterize the OIJ process. Re_{vimj}, defined by the above two scales with viscosity ν fulfill the Ra scaling $Re_{vimj} = \frac{V_m L_c}{\nu} \sim Ra^{0.50}$.This scaling is consistent with the previous Re-scaling [6] defined by large-scale motion and scale indicating that the OIJ is mainly dominated by wind of LSC, as a result of interaction process between LSC and CR.

NUSSELT DISTRIBUTION IN THE IMPINGING REGION

The distribution of the heat transport on the plate is well described by

$$Nu_{loc} = Nu_m e^{-(x-x_{rea})/(L_x-x_{rea})}, \tag{1}$$

where Nu_m is the local Nusselt number at the reattachment point, x_{rea} is the location of the reattachment point. The above correlation fits the present data for the WJ region to within 15% as shown in Figure 1(c). The exponential decay in x direction near the reattachment points is compatible with the similarity analysis of Navier-Stokes equations by Cantwell [7] and Shishkina *et al.*[8]. This formula is similar to the empirical formula proposed by Goldstein *et al.*in the study of OIJ [5].

The perspective of OIJ makes it possible to understand the Nu_{loc} distribution. Fig.1(c) shows that Nu decreases in the wind direction, which seems to conflict with the view of traditional forced convection BL flow. For BL, the heat flux correlate to the shear positively. As the flow develops, the shearing is strengthened thus Nu_{loc} increases. However, for the WJ induced by OIJ, the high heat transfer induced by impinging concentrates on the reattachment point, which dominates heat transfer more than the shear.

Equation (1) shows that the heat transfer for different Ra is characterized by the stagnation heat transfer Nu_m. The relation between $\mathrm{Nu_m}$ and Ra number is derived by using scale analysis of the temperature equation for OIJ: $\mathcal{U}\Delta/\mathcal{L}_x \sim \kappa\Delta/\mathcal{L}_z^2$. The right side of the above equation is the diffusion term with the scale of thermal BL: $\mathcal{L}_z \sim \lambda_\theta$. The left side of the equation is convection term. The velocity in this term is the characteristic velocity of OIJ, which is the same scale as the bulk velocity of LSC; the length scale is similar to the scale of CR. Based on this fact, we have

$$Nu = \frac{L_z}{2\lambda_\theta} \sim \frac{1}{\sqrt{2}} \mathrm{Re}_{\mathrm{lsc}}^{1/2} \mathrm{Pr}^{1/2} (r_{\mathrm{cr}}/L_z)^{-1/2} \sim \mathrm{Ra}^{0.2925} \tag{2}$$

The LSC Reynolds number $\mathrm{Re_{lsc}}$ can be estimated as Re_{vimj} and have $\mathrm{Re_{lsc}} \sim \mathrm{Ra}^{0.50}$. One the other hand, $r_{\mathrm{cr}}/L_z \sim \mathrm{Ra}^{-0.085}$ is provided in Ref.[4]. It is noted that the relation between Nu and Re with regards to the scale of CR gives an effective exponent 0.585 larger than 0.5 , but smaller than the impinging jet (0.7) [5] and that of TBL (0.8). This indicates that within the range of the Rayleigh number in this work, the impinging jet is under developing.

CONCLUSION

In this paper, an oblique impinging jet (OIJ) process is proposed to analyze to momentum and heat transfer in Rayleigh-Bénard convection. The OIJ originates from the plume-emission region and contains abundant cold/warm fluid and carried by LSC. When the impinging occurs, the well-mixing enhances the heat transfer, leading to a local heat maximum. This OIJ process and the corresponding wall jet (WJ) process impact a quite large region in RB cell. Nu_{loc} decay exponentially in x-direction while the maximum Nu fulfill $Nu_m \sim Ra^{0.2925}$ is derived from the impinging jet model and consistent with the DNS result. A close Nu scaling of wall jet heat transport (0.2925) and the global Nu (scaling exponent 0.30) reveals that the OIJ mechanism provides a new angle of view to understand the local inhomogeneous heat transport and has important relevance to global heat transport.

ON THE EFFECTIVE HORIZONTAL BUOYANCY IN TURBULENT THERMAL CONVECTION

Summary A misalignment between the global temperature gradient and the gravity in thermal convection will produce an effective horizontal buoyancy. It breaks the reflection symmetry of the system and results in an overall horizontal heat transfer. Experimentally, a condition of increasing horizontal Rayleigh number (Ra_H) under fixed vertical Rayleigh number (Ra_V) is achieved by tilting the convection cell and simultaneously increasing the imposed temperature difference. We find that, with increasing buoyancy ratio ($\Lambda = Ra_H/Ra_V$), the overall heat transfer features a monotonic increase of the vertical component (Nu_V) as well as an increase in the horizontal component (Nu_H). The effect of Prandtl number (Pr) is also studied numerically. Finally, we extend the Grossmann-Lohse theory to the present case, the result of which is successful in predicting $Nu_V(Ra_V, \Lambda, Pr)$.

INTRODUCTION

Thermal convection is of crucial importance for understanding many thermally-driven fluid flows in nature, for example, ocean circulation, mantle convection and convections in celestial bodies. In certain circumstances involving convective flows, either the imposed temperature gradient has a non-parallel component with respect to the gravity or the gravitational field itself is altered, resulting in an effective horizontal buoyancy with respect to the temperature gradient which makes the problem even more complicated. For example, mantle convection near the subduction zone, convection in binary star systems and atmospheric circulation with wide latitude scales. A simple implementation of the effective horizontal buoyancy is to tilt the regular Rayleigh-Bénard convection (RBC) setup by an angle β.

To explore the effect of horizontal buoyancy separately, unlike in most previous studies of tilted RBC [1, 2, 3], we use $\tau = \sqrt{H/(\alpha \Delta g \cos\beta)}$ as the typical time scale (the free fall time for a fluid parcel to travel from the top plate to the bottom plate when the cell is tilted by an angle β), instead of $\tau = \sqrt{H/(\alpha \Delta g)}$ (the conventional free fall time), together with the cell height H, the temperature difference between the two plates Δ, to normalize the governing equations, which yields:

$$\frac{\partial \tilde{\boldsymbol{u}}}{\partial \tilde{t}} + \tilde{\boldsymbol{u}} \cdot \nabla \tilde{\boldsymbol{u}} = -\nabla \tilde{p} + \sqrt{\frac{Pr}{Ra_V}} \nabla^2 \tilde{\boldsymbol{u}} + \tilde{T}\hat{\boldsymbol{z}} + \frac{Ra_H}{Ra_V}\tilde{T}\hat{\boldsymbol{x}}, \tag{1}$$

where $Ra_V = \alpha g \cos\beta \Delta H^3/(\nu\kappa)$ is the vertical Rayleigh number, $Ra_H = \alpha g \sin\beta \Delta H^3/(\nu\kappa)$ is the horizontal Rayleigh number and $Pr = \nu/\kappa$ is the Prandtl number. For simplicity, we define $\Lambda = Ra_H/Ra_V = \tan\beta$ as the buoyancy ratio. In this study, we fix the vertical thermal driving strength while varying the effective horizontal buoyancy over the vertical one (see figure 1). Experimentally, this is achieved by tilting the convection cell with respect to the gravity by an angle β and simultaneously raise the temperature difference Δ across the conducting plates accordingly.

For classical RBC, the governing equations satisfy the K_x reflection symmetry ($u_x \to -u_x, x \to -x$). In other words, if (T, u_x, u_y, u_z) is a solution, so is $(T', u_x', u_y', u_z')(x, y, z) = K_x(T, u_x, u_y, u_z)(x, y, z) = (T, -u_x, u_y, u_z)(-x, y, z)$. However, the presence of an effective horizontal buoyancy (i.e. the last term on the r.h.s. of Eq. 1) breaks the K_x symmetry, which results in a global horizontal Nusselt number:

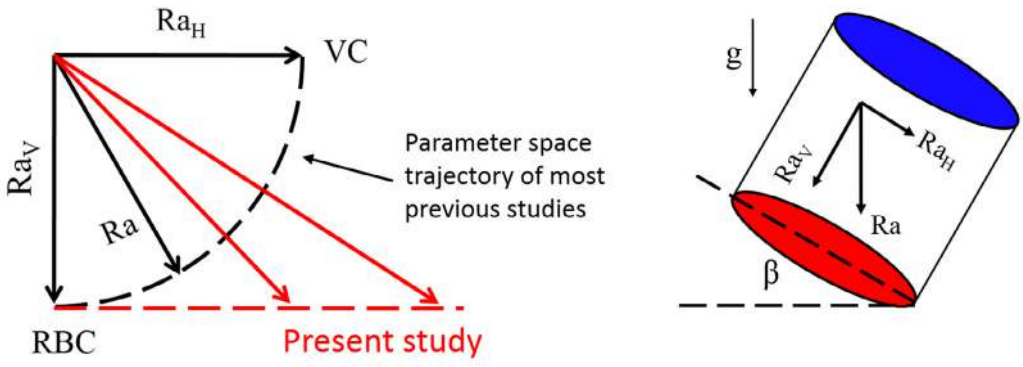

Figure 1: Comparison between the parameter space trajectory explored in the present study (red dashed line) and that by simply tilting the cell (black dashed curve, which is the case in most of the previous studies). Ra_V is the vertical Rayleigh number and Ra_H is the horizontal Rayleigh number. Here RBC stands for 'leveled' Rayleigh–Bénard convection, and VC stands for vertical convection.

*Corresponding author. E-mail: xiakq@sustech.edu.cn.

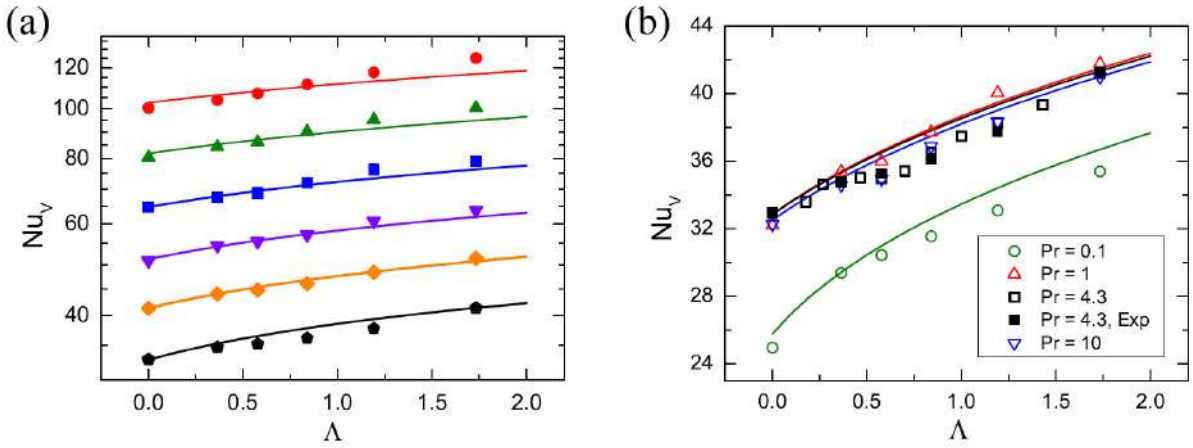

Figure 2: Vertical Nusselt number as function of the buoyancy ratio. Solid symbols are the experimental data, open symbols are the DNS data, and the solid lines show the predictions of the generalized theory. (a) From top to bottom, $Ra_V = 4.6 \times 10^9$, 2.2×10^9, 1.0×10^9, 4.6×10^8, 2.2×10^8, 1.0×10^8. The Prandtl number is fixed at $Pr = 4.3$. (b) $Nu_V - \Lambda$ for different Prandtl numbers, the vertical Rayleigh number is fixed at $Ra_V = 10^8$.

$$Nu_H = \frac{1}{V}\left(\int_{z=0} x\frac{\partial T}{\partial z}dS - \int_{z=H} x\frac{\partial T}{\partial z}dS\right)/(\Delta/H). \tag{2}$$

The horizontal Nusselt number, together with the vertical Nusselt number (Nu_V) and the Reynolds number (Re), are the three response parameters of the system. In leveled RBC, the horizontal Nusselt is always zero and can be viewed as a conservative quantity corresponding to the K_x symmetry.

RESULTS

Figure 2 shows the vertical Nusselt number as function of the buoyancy ratio for (a) different vertical Rayleigh number and (b) different Prandtl numbers. Solid symbols are the experiment data and open symbols are from DNS. It is seen that for fixed vertical Rayleigh number, the vertical heat transfer increase monotonically with the buoyancy ratio, and the relative increase in Nu_V is insensitive to the change in Ra_V for $Pr = 4.3$. The Prandtl number dependence seems more complicated, the enhancement in Nu_V is larger for low Prandtl number. On the other hand, for fixed buoyancy ratio Λ, the highest vertical Nusselt occurs around $Pr = 1$, further increase in Prandtl results in a small reduction of Nu_V.

To explain the intricate $Nu_V(Ra_V, \Lambda, Pr)$ behavior in Figure 2, we developed a generalized Grossmann-Lohse theory [4]. The central idea of the generalized theory is to write the contribution from horizontal Nusselt number in the exact relation for the balance between viscous dissipation and global transfer, i.e., the second term on the r.h.s of:

$$\epsilon_u = \frac{\nu^3}{H^4}Ra_V Pr^{-2}(Nu_V - 1) + \frac{\nu^3}{H^4}\Lambda Ra_V Pr^{-2}\left(Nu_H + \langle\frac{\partial\tilde{T}}{\partial\tilde{x}}\rangle_V\right), \tag{3}$$

as a smooth function connecting two limiting cases with extreme high and low Prandtl numbers:

$$c_5\frac{\Lambda Ra_V Pr^{-1}Re}{4Nu_V}f(6aNu_V Re^{-1/2}), \tag{4}$$

where $f(x) = (1+x^4)^{-1/4}$ and c_5 is a constant determined using the experimental data. The predictions of the generalized theory are plotted in Figure 2 as solid lines, which not only captures the general feature of the buoyancy ratio dependence, but also the intricate Pr effect.

TERMINAL EXTENSIONAL VISCOSITY OF DILUTE POLYMER SOLUTION USING CABER-DOS SYSTEM

Daiki Yamada[1], Andres Franco-Gomez[1] and Yoshiyuki Tagawa *[1]
[1] Department of Mechanical Systems Engineering, Tokyo University of Agriculture and Technology, Tokyo, Japan

Summary Understanding the behaviour of extending polymer fluids is of great importance for various applications such as inkjet printing and microfluidic devices. Imaging of ultra-high spatial resolution (0.5 μm/pixel) enable us to observe a behaviour of a viscoelastic fluid before pinch-off. The results using Capillary Breakup Extensional Rheometer Dripping onto Substrate (CaBER-DoS) show that the extensional viscosity is almost constant in high Hencky strain region. After showing a terminal extensional viscosity, a very thin liquid thread becomes unstable due to the effect of surface tension and forms a beads-on-a-string and pinch-off.

INTRODUCTION

Liquid jets are applied to printing technologies such as inkjet printers. In inkjet printers, a small amount of polymer is added to the ink. This method minimizes the formation of satellites and secondary droplets, which is essential for print quality. Fluids containing polymers have viscoelastic properties and a significantly increased resistance to elongational flow. When the polymer fluid stretches in a uniaxial-like extensional flow, the fluid forms a thread, leading to the delay of the thread breakup. The thread thinning dynamics is a very important research topic for controlling the volume of the liquid.

In recent years, Capillary Breakup Extensional Rheometer Dripping onto Substrate (CaBER-DoS) has been reported as a new method for stretching rheological measurement [1][2]. Sur *et al.* [2] observed the thread thinning dynamics of viscoelastic fluid using CaBER-DoS system and reported that the temporal evolution of necking radius, which is the representative length of the liquid thread, agree with the exponential decay model. In contrast, before pinch-off, the model does not agree with the result.

In this paper, the O (10^1) μm of liquid thread is measured with an improved spatial resolution of the camera. The results suggest that the polymer reaches the extensibility limit before pinch-off, and there is a transition from elastic to viscous dominance.

METHOD

Figure 1(a) shows the experimental setup. The liquid flows from the nozzle tip (Nozzle diameter and radius $D_0 = 2R_0 = 1.27$ mm) and dropped onto a glass substrate (S2112, Matsunami, spreading parameter $S < 0$) placed under the nozzle at distance H from the substrate, with the aspect ratio (H / D_0) is around 3. As soon as the dripping fluid touches the substrate, the contact area increases, and a liquid bridge is formed between the substrate and the nozzle. We use two fast cameras (Photron, FASTCAM SA-X), one is to secure a shooting area that can capture the entire thread (spatial resolution is 3 μm/pixel), and the other is to capture liquid threads of O (10^1) μm under shooting conditions with improved spatial resolution (spatial resolution is 0.5 μm/pixel). In this experiment, semi-dilute polymer solutions of polyacrylamide (PAM) solutions are prepared in a mixture of glycerin / water (70 / 30 %).

RESULT AND DISCUSSION

The continuous images obtained by the experiment are shown in Figure 1 (b, c). The liquid becomes thinner with time maintaining a cylindrical shape, and from Figure 1 (c), in a very thin liquid thread, (iii) an instability due to slight disturbance at the liquid thread interface propagates by the effect of surface tension, (iv) forming beads-on-a-string [3] and (v) pinch-off.

The necking process is captured by estimating the minimum length R of the liquid thread using Matlab image analysis. The figure shows the necking radius R as a function of time t. The model of viscoelastic fluid is FENE-P dumbbell model [4]. The necking radius decays exponentially with time due to the balance between capillary force and elasticity of the polymer chains (Elasto-capillary regime, EC regime), expressed by

$$\frac{R}{R_0} \approx \left(\frac{GR_0}{2\sigma}\right)^{\frac{1}{3}} \exp\left(-\frac{t}{3\lambda}\right),$$

where G is the elastic modulus of the fluid, σ is the surface tension, and λ is the extension relaxation time. The dashed line in the figure represents the theoretical line fitted by measuring the physical properties of the solution. The strain rate under the condition of extensional flow expressed by,

$$\dot{\varepsilon} = -2\frac{d\ln R}{dt} = -\frac{2}{R}\frac{dR}{dt},$$

*Corresponding author. E-mail: tagawayo@cc.tuat.ac.jp

where dR/dt is the rate of change of the necking radius. In the EC regime, the Weissenberg number, which is a dimensionless number that compares elastic to viscous force in a flow, is constant ($Wi = \lambda\dot{\varepsilon} = 2/3$). The calculated relaxation time of the three solutions are 190 ms (0.4 wt%), 394 ms (0.6 wt%), and 494 ms (0.8 wt%), respectively. The results show that the necking radius before pinch-off does not match the line of the EC model.

To understand the behaviour, it is necessary to consider extensional viscosity and Hencky strain. Extensional viscosity is characterized as the resistance to the extensional flow, while Hencky strain is the integral of the strain rate with respect to time t.

$$\eta_E = \frac{\sigma}{\dot{\varepsilon}R} = \frac{\sigma}{-2dR/dt}, \qquad \varepsilon = 2\ln\frac{R_0}{R},$$

Figure 2 (b) shows the extensional viscosity as a function of Hencky strain. The extensional viscosity of the three liquids increases with increasing Hencky strain, except in the high Hencky strain region ($\varepsilon \geq 3$), it tends to an asymptotic value. Under the extensional flow, the randomly arranged polymer chains begin to orient in the stretching direction. In the EC regime, this phenomenon becomes prominent and dominant the liquid thread thinning. However, polymer chains have finite extensibility. In the high strain region, the polymer chain exceeds the finite extensibility, necking like a Newtonian behavior. Finally, a very thin liquid thread becomes unstable due to the effect of surface tension induced by a slight disturbance and forms a beads-on-a-string and pinch-off.

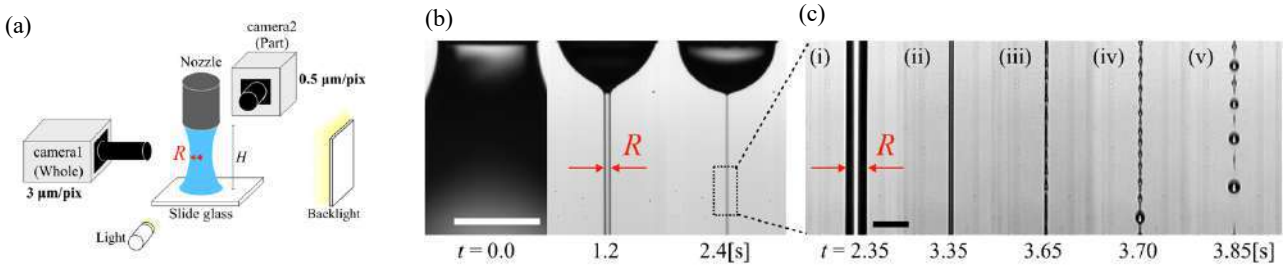

Figure 1 (a) Schematic view of an experimental setup. (b) Continuous images of the thread (0.6 %PAM solution in glycerin/water (70/30 %)) filmed by camera 1(Whole). The white bar is 1 mm. (c) Detail images of the thread filmed by camera 2(Part). The black bar is 50 μm.

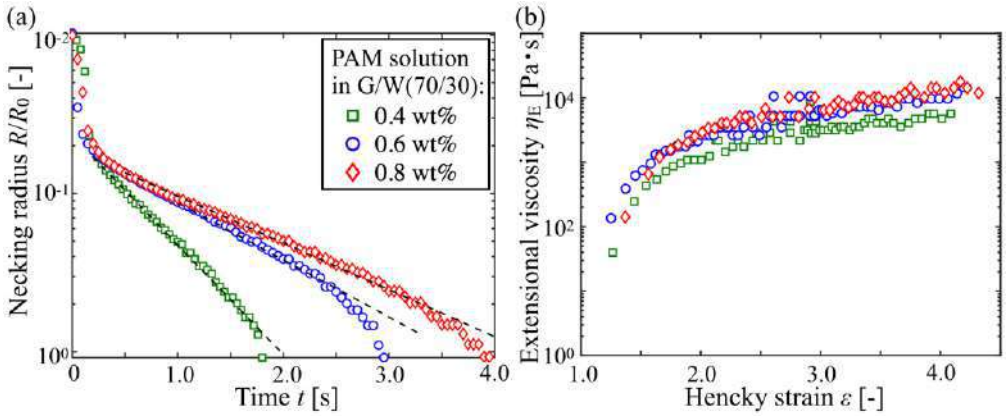

Figure 2 (a) Dimensionless necking radius R/R_0 as a function of time t analysed by the image filmed by camera 1(Whole). The dashed lines show the fitted region that can be described by the equation shown and corresponds to constant strain rate region. (b) Extensional viscosity η_E as a function of hencky strain ε. The plot of $\varepsilon \leq 3$ was calculated from the image of camera 1(Whole), and $\varepsilon \geq 3$ was calculated from the image of camera 2 (from (i) to (ii) in Figure 1. (c)).

CONCLUSIONS

In this paper, the thread thinning dynamics is experimentally investigated using CaBER-DoS. The spatial resolution of images is improved to film the thread of O (10^1) μm. The results suggest that the polymer fluid, which normally should be elastic, necks like the behavior of a Newtonian fluid before pinch-off. A very thin liquid thread becomes unstable due to the effect of surface tension induced by a slight disturbance and forms a beads-on-a-string and pinch-off.

DROP FRAGMENTATION BY LASER-PULSE IMPACT

Alexander L. Klein[1], Dmitry Kurilovich[2], Henri Lhuissier[3], Oscar O. Versolato[2], Detlef Lohse[1], Emmanuel Villermaux[3,4], and Hanneke Gelderblom *[5]

Summary The impact of a laser pulse onto an opaque liquid drop induces a violent fluid-dynamic response: due to plasma formation and local boiling the drop gets propelled forward and deforms into a thin, radially expanding sheet. This sheet destabilizes through the expulsion of radial ligaments and the nucleation of holes, and eventually breaks up into tiny fragments. We reveal the dynamics of these processes via high-speed and stroboscopic imaging complemented with analytical modelling. By combining experimental data from two vastly different liquid systems, we show how the early-time laser-matter interaction controls the late-time fragmentation.

INTRODUCTION

The impact of a nanosecond laser-pulse onto a free-falling opaque liquid drop induces a strong deformation and eventually fragmentation of the liquid [1, 2]. As shown in Figure 1, the laser impact causes the spherical drop to deform into a thin sheet that destabilizes into a fine web of ligaments and smaller droplets. Control of the fragmentation of liquid tin drops upon laser impact is of direct importance to extreme ultraviolet light sources used in nanolithography [1, 4]. Drop fragmentation upon impact onto a solid object has been widely studied. While there are some similarities between these cases and laser-impacted drops, there are also strong differences due the the fundamentally different impact mechanisms involved [5]. Hence, how a drop fragments as the result of a laser impact is still an open question.

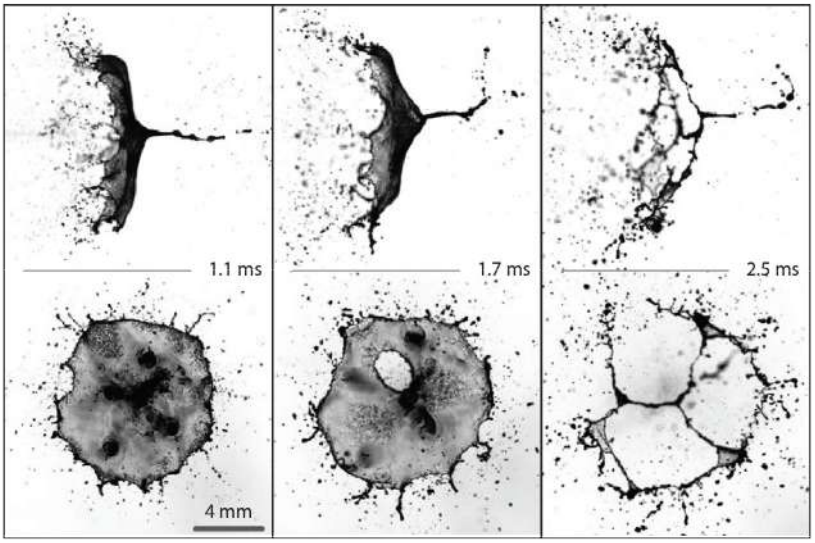

Figure 1: Deformation and fragmentation of a dyed solvent drop at different times after the impact of a nanosecond laser pulse, in side-view (top row, laser pulse coming from the left) and back-view (bottom row, laser pulse pointing into the paper). The initially spherical 0.9-mm sized drop deforms into a thin sheet bordered by a rim. This rim destabilizes through the radial expulsion of ligaments, which subsequently break up into droplets. On the expanding sheet corrugations appear that eventually pierce holes close to the rim (at t = 1.1 ms), and close to the centre of the sheet (t = 1.7 ms). A final web of ligaments is shown for t=2.5 ms. Taken from [2].

METHODOLOGY

We study laser-induced fragmentation experimentally using two different liquid systems: millimeter-sized dyed solvent (methyl-ethyl-ketone) drops and micrometer-sized liquid tin drops. The combination of the two systems allow us to explore a broad range of parameters and study the effect of differences in the laser-matter interaction: the solvent drops are propelled by rapid vaporization, while the tin drops are driven by plasma-recoil.

The response of the drops to a 10-ns Nd:YAG laser pulse is recorded by stroboscopic imaging in side- and back-view (Figure 1). Details of the experimental setups are described in [3] for the solvent drops and [4] for the tin drops. Experimental observations are complemented by an analytical model for the deformation of the drop into an expanding sheet [5, 2], as well as a theoretical analysis of the fluid dynamic instabilities at play [2].

RESULTS

In both the solvent and the tin drops, two types of breakup contribute to the fragmentation, as shown in Figure 1: the radial expulsion of ligaments from the rim of the sheet formed by the expanding drop and the nucleation of holes on the thin sheet itself. We identify two Rayleigh-Taylor instabilities that are triggered by accelerations of the drop in two orthogonal planes as the cause of these breakups. We present theoretical models predicting the growth rate and preferred wavelength of the instabilities, which are in agreement with our experimental observations.

On top of the random nature of these instabilities, the laser-induced hole nucleation shows strong deterministic features, as illustrated in Figure 2. These features result from variations in the sheet thickness caused by the global drop deformation dynamics and the laser-beam profile. The random hole nucleation caused by the instability therefore gets convoluted by a deterministic thickness profile. The resulting web of ligaments shows a complex distribution in ligament thickness. At least five different processing leading to ligamentation are identified, which give rise to a broad drop-size distribution.

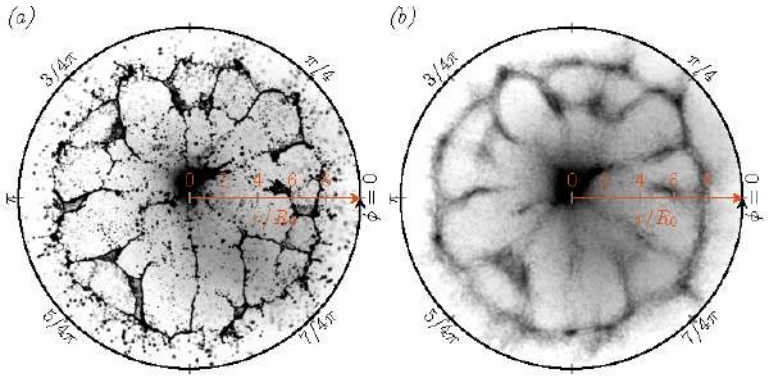

Figure 2: (a) Back-view of a web of ligaments formed by the fragmentation of a solvent drop. (b) Image overlay of 31 different experiments recorded under the same conditions as in (a), revealing the highly deterministic nature of the final web of ligaments. Taken from [2].

CONCLUSIONS

We studied the fragmentation of a drop that is propelled by a laser-induced phase change. Two liquid systems have been considered, which differ not only in length scale but also in propulsion mechanism: millimetre-sized vapour-driven drops of dyed solvent and micron-sized plasma-driven tin drops. In both systems, two types of Rayleigh-Taylor instabilities induced by the rapid acceleration of the drop have been identified, which cause the formation of ligaments that eventually break into droplets. The final web of ligaments and spray of droplets result from a subtle interplay between these instabilities and deterministic fluctuations in the sheet thickness caused by the laser-beam profile and drop dynamics.

EFFECTS OF INJECTION ANGLE ON LIQUID JET PRIMARY ATOMIZATION IN SUPERSONIC CROSSFLOW

Feng Xiao[1], Chi-Bing Shen *[1], Yi-Heng Tong[2], Sen Lin[1], and Shao-Kang Peng[1]
[1] Science and Technology on Scramjet Laboratory, National University of Defense Technology, Changsha, 410073, China
[2] Department of Aerospace Science and Technology, Space Engineering University, Beijing, 101416, China

Summary In this paper, the primary atomization process of the liquid jet injected into supersonic flow from the flat wall at different angles are simulated using an interface tracking method. The simulated liquid jet injected at different angles demonstrate substantially different primary atomization morphology and shock structures. The growth of liquid jet penetration as injection angles increases is correctly predicted by the present two-phase flow solver in comparison with the experimental measurements. The liquid jet injected at the angle of 120° produces a more efficient atomization process, which can promote the mixing between the liquid fuel and the supersonic air flow in a Scramjet engine.

INTRODUCTION

In order to achieve reliable engine starting and high combustion efficiency in a liquid-fueled supersonic combustion ramjet (Scramjet) engine, the liquid fuel jet must atomize efficiently in the supersonic air flow for sufficient fuel/air mixing. Since the fuel is typically injected into the supersonic air flow from the wall in the combustion chamber, extensive experimental studies of liquid jet atomization in supersonic gas crossflow have been carried out. However, the majority of these studies focus on the atomization of liquid jet injected perpendicularly into the air flow, and the atomization of liquid jet injected in other angles has been rarely investigated though the angled fuel injection could improve the atomization performance. Further understanding of the injection angle effects on liquid jet primary breakup is desired, and this subject is investigated here using both numerical and experimental methods.

NUMERICAL METHODS

In the developed two-phase flow solver, a coupled Level set and Volume of Fluid method (CLSVOF) method is implemented to capture the liquid/gas interface. The liquid flow is solved by an incompressible flow solver using a finite volume method while the gas flow is solved by a compressible flow solver using a finite difference method. The coupling of the gas flow solver and the liquid flow solver is achieved by specifying boundary conditions for each other at the interface. Specifically, the gas variables are used to provide pressure boundary conditions for the liquid flow solver; the liquid variables are used to provide velocity boundary conditions for the gas flow solver (see [**?**] for details).

RESULTS

The experiments were carried out, and High-Speed schlieren photography was used. Fig. 1 shows the photos of the liquid jet primary atomization in a Mach 1.86 air crossflow at three different injection angles: $\alpha = 60°$, $\alpha = 90°$, and $\alpha = 120°$.

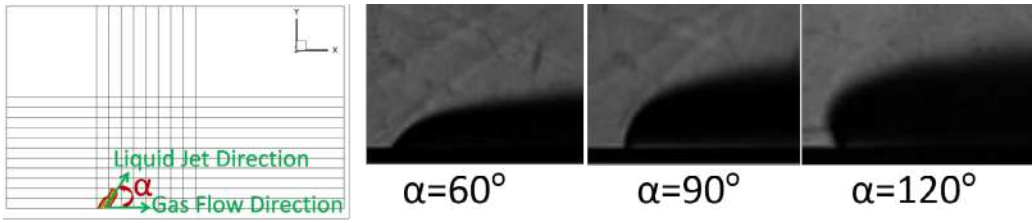

Figure 1: Schlieren photos of liquid jet primary atomization in supersonic air crossflow at different injection angles

In the simulated test cases, the liquid jet diameter D is $0.2mm$. Liquid jet velocity V_L and freestream air velocity U_G are $23.24m/s$ and $517.6m/s$ respectively. The Mach number of the air flow is 2. Figure 2 presents instantaneous primary atomization morphology of liquid jet in the supersonic crossflow at the three different injection angles. Significant differences in liquid column breakup morphology at different injection angles are observed. At $\alpha = 60°$ and $\alpha = 90°$, the predicted liquid column first moves in the liquid injection direction, and then bends in the gas crossflow direction. When the liquid jet is injected at an angle of 120°, the liquid column first moves upstream; as the liquid velocity component in

*Corresponding author. E-mail: 285403264@qq.com

the direction opposite to the crossflow reduces to 0 due to drag forces from the gas, the liquid column reaches the utmost upstream position, and then the liquid column starts to bend in the crossflow direction. These predicted liquid column behaviours are consistent with schlieren photos in Fig. 1 at all three injection angles. It is demonstrated in Figs. 2 that the liquid jet disintegrates more progressively as α increases. When the injection angle is $120°$, the liquid ligaments and droplets arising from liquid jet primary atomization are generally smaller than those at $\alpha = 60°$ and $\alpha = 90°$. And the resulting liquid structures are observed to scatter more widely in the vertical (y) and spanwise (z) directions at $\alpha = 120°$, indicating that liquid fuel inject at the angle of $120°$ is likely to result in more efficient mixing between the fuel and the supersonic air crossflow than at the two smaller injection angles. The contours of the nondimensionalized pressure $P^* = P/(\rho_G U_G^2)$ in slice z=0 are also included in Figs. 2 to show the shocks. When the liquid is injected at an angle of $60°$, an oblique shock is formed in front of the liquid jet. As the injection angle grows, the angle of the predicted shock ahead of the liquid jet increases, and a strong normal shock is formed at $\alpha = 120°$. These agree well with the experimental observation of the shock structures illustrated in Fig. 1.

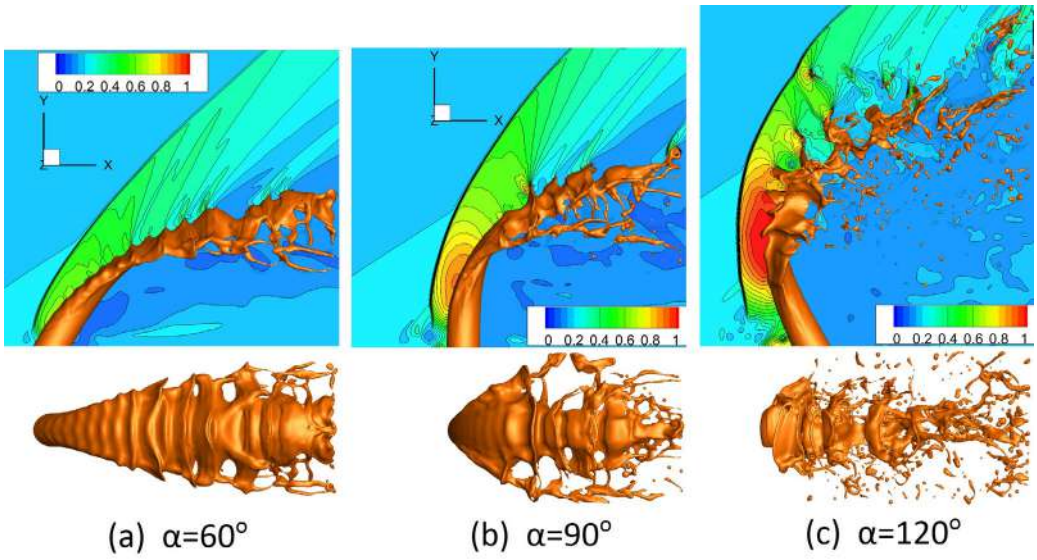

Figure 2: Primary atomization morphology of liquid jet in the Mach 2 crossflow at $\alpha = 60°$ from a front view (upper figure) and top view (lower figure) with P^* contours in slice z=0

The liquid jet penetration in supersonic gas crossflow predicted by simulations at different injection angles are measured and compared with the experimental measurements in Fig. 3. The liquid jet penetration predicted on Grid A and Grid B differs slightly by 5%, implying that the liquid column deformation and breakup can be properly resolved on the current grid resolution. The liquid jet penetration at the injection angles of $60°$ and $120°$ agrees well with the experimental measurements while the liquid jet penetration at the injection angle of $90°$ is slightly underestimated. The tendency that the liquid jet penetration increases as the injection angle grows is well reproduced by the current two-phase flow simulation methodology.

BUBBLE TYPES EJECTED FROM COAXIAL NOZZLES

Ewout Zuiderduin[1], Bart van der Vaart[1], Stefano Coco[1], Kees Venner[1], and Claas Willem Visser *[1]
[1] Department of Thermal and Fluid Engineering, Faculty of Engineering Technology, University of Twente

Summary Gas bubbles ejected from core-shell nozzles were recently applied as building blocks for tailored polymer foams (Visser et al., Adv. Mater. 31(46), 2019). Here we study the bubble ejection regime as a function of the liquid flow, the gas pressure, and the nozzle geometry. Different ejection regimes including jetting, monodisperse bubbles, bidisperse bubbles, and spraying are reproduced and classified. Their incidence could be reasonably collapsed on a single master graph, providing engineers a tool for predictive design of core-shell nozzles.

Ejecting a gas and a liquid from a core-shell nozzle into ambient air or gas results in rapid production of gas-filled bubbles. These "flying bubbles" have been fabricated with shells of water [1], tin [1], copper [2], gold [2], and polymers [2]–[4], and find application in laser target generation[5] and fabrication of scaffolds in tissue engineering[3]. Recently, we used this method for "*direct bubble writing*", in which the resulting bubbles are stacked into 3D-printed polymer foams with locally controlled gradients in the cell size and cell interconnectivity [4]. Here, the foam's cell size, cell size distribution, and density directly result from the ejected bubble size, their consistency, and the relative thickness of the liquid shell, respectively. Therefore, understanding and predicting the ejection regime of gas-filled bubbles from core-shell nozzles is essential for fabrication of foams with new ink formulations or nozzle geometries.

It is well-known that the ejection of bubbles into air can occur in different regimes that depend on the liquid flow rate and gas pressure applied to the core-shell nozzle[3], [6]–[10]. Figure 1 shows the nozzle design (a-c) as well as the observed regimes, including pure-liquid dripping (d) or jetting (f), the formation of a large blob of bubbles at the nozzle (e), various coherent bubble ejection regimes (g-i), and ejection of less-controlled sprays (j). In our recent work[4] we hypothesized that the Weber number $\mathrm{We} = \rho D V^2/\sigma > 1$ is a prerequisite for ejection in the form of a coherent stream (Figure 1f-j). Here, $\rho, \sigma, D,$ and V denote the liquid's density and surface tension, the outer nozzle diameter, and the estimated ejection velocity $V = Q/(1/4\pi D^2)$, respectively. Furthermore we assumed that gas is only entrained (Figure 1e,g-j) if the gas pressure exceeds the sum of the liquid-induced, inertial, viscous, and capillary pressures at the inner nozzle tip: $P_{tot} = P_I + P_\mu + P_\sigma$; for details we refer to [4]. This abstract provides first results of systematic tests of these hypotheses.

Here, we designed and 3D-printed core-shell nozzles with inner diameters $0.6\mathrm{m} < D_i < 1.5\mathrm{mm}$, outer diameters $0.6\mathrm{m} < D < 1.5\mathrm{mm}$, and heights $1\mathrm{mm} < H < 1.4\mathrm{mm}$, as shown in Figure 1a-c. Subsequently, gas (air) and liquid (water with 0.4% Tween-80 surfactant) were fed to the shell and the core of the nozzle, respectively. The liquid flow rate was controlled with metal syringes that were driven a syringe pump, whereas a pressure controller was used to set the gas pressure.

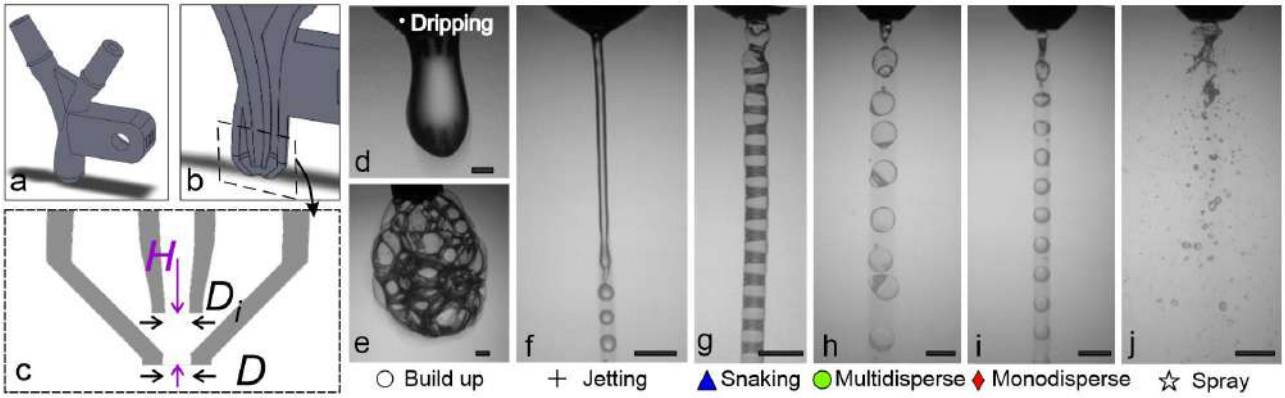

Figure 1: Ejection regimes from core-shell nozzles. (a) Visualized 3D model of the nozzle. (b) Cross section of the nozzle tip. (c) Schematic cross section, indicating geometrical control parameters. (d-j) Ejection regimes in the dripping mode (d), Build-up (e), pure-liquid jetting (f), snaking (g), bidisperse bubble ejection (h), monodisperse bubble ejection (i), and spraying (j).

The resulting ejection regimes are shown and named in figure 1d-j. Each regime is plotted as a function of the liquid flow rate and the gas pressure in figure 2. For the dripping regimes observed at low flow rates $Q \leq 12\mathrm{ml/min}$ without (d) and with (e) gas ejection, gravity eventually pulls the droplet from the nozzle. At higher flow rates, pure-liquid jetting is observed up to a certain threshold gas pressure, for which air-containing regimes (figure 1g-i) are observed. This threshold increases with increasing flow rates. The red line displays the predicted threshold for gas entrainment $P = P_{tot}$ [4]. Here, both viscous pressure build-up in the nozzle and the inertial pressure exerted by the liquid are overcome by the gas pressure.

To test this prediction over a wider range of the control parameters, in Figure 3 we plot the ejection regime data for 16 nozzle geometries as a function of the dimensionless pressure P/P_{tot} and the dimensionless flow rate (the Weber number). A reasonable collapse is observed. At $\mathrm{We} \approx 4$, the transition from pure-liquid dripping to jetting is consistently

*Corresponding author. E-mail: **c.visser@utwente.nl**.

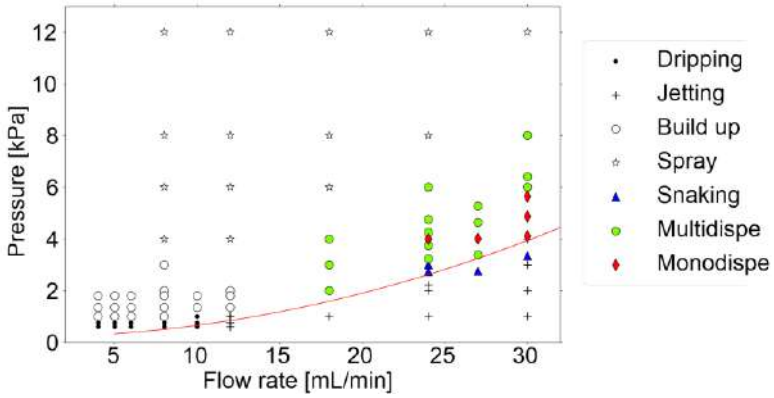

Figure 2: Ejection regimes as a function of the gas pressure and the liquid flow rate. The solid line indicates $P = 0.8P_{tot}$, which corresponds reasonably well with the transition from pure-liquid to gas-containing ejection regimes.

observed, as expected [11]. The equivalent transition from gas-containing dripping droplets to coherent trains of bubbles occurs at higher Weber number for $P \approx P_{tot}$, possibly because multiple thin liquid-gas interfaces can "stick" to the nozzle surface which will increase their adhesion. However, details of this transition remain to be investigated. Furthermore, we observe controlled bubble ejection (the most useful window for applications, indicated by coloured markers) only in a window between pure-liquid ejection at low pressures and spraying at high pressures. This window narrows for increased flow rates, where the most interesting domain (monodisperse bubbling) is observed. The mechanisms behind the regime transitions, as well as design changes to broaden the useful range of control parameters, will be subject of future studies.

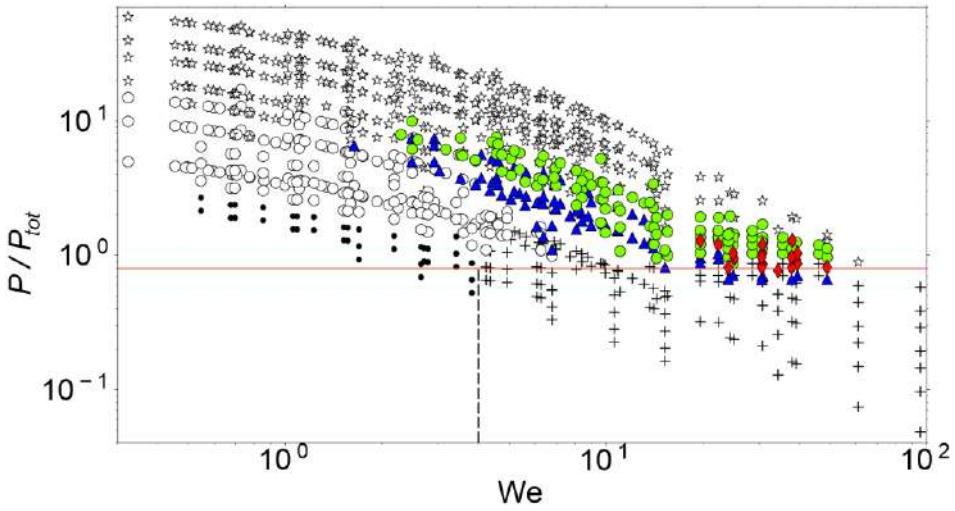

Figure 3: Ejection regimes as a function of the normalized pressure and the Weber number. The red line indicates $P = 0.8P_{tot}$; the vertical dashed lined indicate the expected and observed transition from jetting to dripping at We = 4.

In conclusion, various ejection regimes from core-shell nozzles were observed. Their incidence was quantitively measured as a function of the liquid flow rate and the gas pressure. Non-dimensionalizing these parameters revealed that controlled bubble ejection is expected in a narrow regime within $3 < \mathrm{We} < 50$, and $0.7 < P/P_{tot} < 7$. This result may already benefit predictive (rather than trial-and-error) nozzle designs. In the future, we aim to improve our understanding of the observed transitions and to widen the operation window for direct bubble writing [4].

ABSORPTION OF A LIQUID DROP BY SWELLING FIBERS

Pierre Van de Velde[1], Suzie Protière [2] , and Camille Duprat *[1]
[1] LadHyX, Ecole polytechnique, Palaiseau, France

Summary The present work describes the imbibition dynamics of a drop placed on one or multiple swelling fibers. Several timescales are observed during the absorption of a drop on a single fiber. The drop and fiber geometries are described experimentally and help rationalizing the imbibition dynamics. When placed on two parallel fibers, a drop is able to deform the fibers leading to the transition from a bridge to a collapsed state. This swelling induced transition can drastically reduce the absorption time.

INTRODUCTION

Many examples of drops interacting with fibers can be found both in nature and industry, from wet dog hair or bird feathers to drying or coloring of fabrics or the fabrication of paper. The dynamics of drops on fibers can be counterintuitive. For example, a wetting drop placed on a cone will spontaneously move towards the region of higher curvature and thus away from the tip [1]. Placed on an array of elastic fibers, the drop exerts a capillary force on the fibers that can cause large deformations of the fibers, drop motion and a significant change in droplet shape [2]. On a larger scale, localized wetting and swelling of a fibrous material such as paper may cause large macroscopic deformations [3]. Understanding the swelling behavior of individual fibers is crucial to predict the mechanical response of larger fibrous networks.

In the present work, we aim at predicting the time taken by a fibrous medium to absorb a given volume of fluid. We thus study the dynamics of a drop placed on one or several deformable fibers in the presence of swelling. We find that the geometry of the drop plays an important role on the observed imbibition and wetting dynamics. We link the drop geometry to the observed dynamics by examining the drop shape on non-swelling fibers.

EXPERIMENTAL SETUP

Elastomer PVS (polyvinylsiloxane, Zhermack Elite double 32) fibers of various radii (r_{fiber} from 200 to 500µm) are molded and clamped at their ends. A drop of silicon oil (viscosity of 2 cPa.s) is deposited of the fiber using a micropipette. The shape of the drop is then followed in time using two digital cameras placed above and in front of the fiber respectively. Images are analyzed with a custom image treatment code.

DROPS PLACED ON A SINGLE FIBER

We first investigate the case of a single drop placed on a swelling fiber. Figure 1 presents the evolution of the droplet height with time for different initial volumes. We observe three different regimes with different timescales.

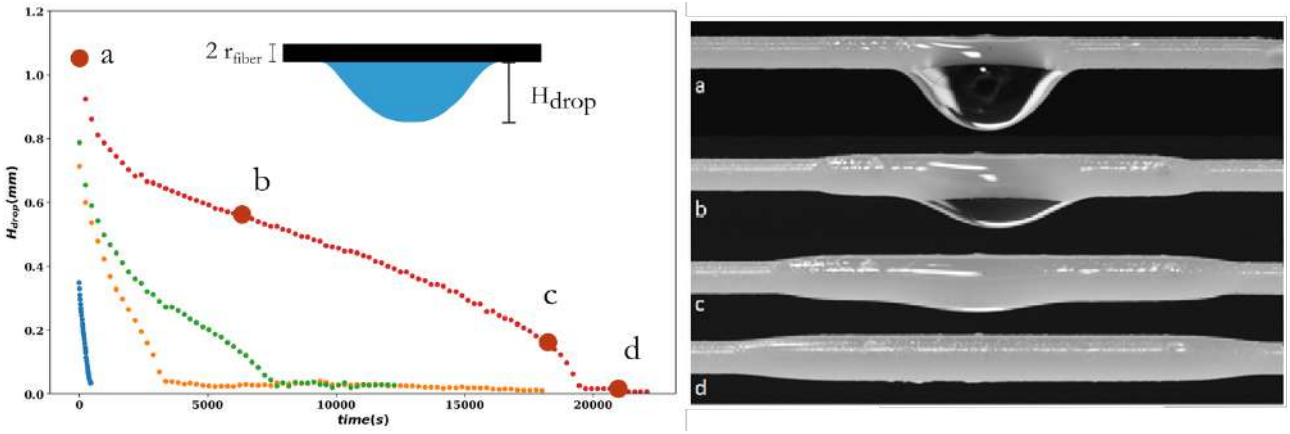

Figure 1 Experimental evolution of the drop height H_{drop} with time (silicon oil with 2 cPa viscosity) on a PVS fiber (radius = 250 µm) during the swelling process.

In the first regime (a), we observe a fast initial imbibition with a characteristic time (t_{swell}) that does not depend on the initial volume. This corresponds to the time needed for the fluid to diffuse from the drop towards the center of the fiber in the radial direction. Additional experiments with completely immersed fibers confirm that this time depends only on the initial fiber radius. In a second regime (b-c), when the maximum swollen radius is reached, the drop rests on

*Corresponding author. E-mail: camille.duprat@ladhyx.polytechnique.fr

a saturated zone of the fiber leading to a deceleration of the imbibition governed by diffusion in the axial direction. This regime is only observed for volumes large enough to reach local saturation at the position of the drop. In the third regime (c-d), once most of the drop is absorbed within the fiber, the remaining drop volume is sufficiently small for it to roll up and spread around the fiber leading to a reacceleration of the absorption of all the liquid by the fiber. Here the geometries of the drop and the fiber play a crucial role in the imbibition dynamics at all stages.

We thus study the shape of the drop on non-swelling nylon fibers for various radii and explain the origin of the different regimes shown before. The minimal volume necessary for the appearance of the second regime can be directly estimated from the drop geometry on the fiber.

DROPS PLACED ON TWO PARALLEL FIBERS

We now investigate the swelling of two fibers when a drop is placed between them. We focus on two parallel stretched fibers. When placed between two parallel and elastic fibers, a drop can either stay compact and bridge the fibers or spread over a long distance, sticking the two fibers together (zipped state) [4]. The spacing between the fibers and the resulting drop geometry play a crucial role in determining if the zipped state can be reached. In the case of swelling PVS fibers, the drop modifies the geometry locally and is under specific conditions able to bring the fibers closer together, leading to a spontaneous zipping of the fibers (i.e. they come in contact as they collapse) as shown in Figure 2. The zipping can drastically decrease the total absorption time of a given volume compared to the case of a single fiber, since the spreading of the drop at the zipping transition allows it to be absorbed in a much larger region of the fiber without saturating the fiber locally.

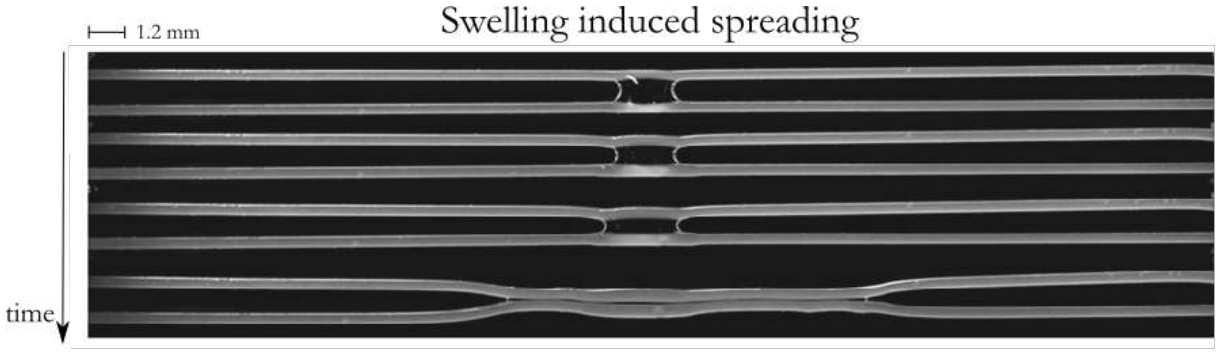

Figure 1 Evolution of a drop placed between two parallel streched PVS fibers. The drop swells the fibers locally bringing them close enough to cause the zipping transition. (2 min between pictures)

We investigate the parameters determining the zipping transition and link them to the swelling of a single fiber. We construct a phase diagram to identify the different possible morphologies after swelling. From experiments on this model system, we can start rationalizing the effect of swelling during the imbibition of fibrous networks.

SURFACTANT-LADEN DROPLETS ON SUPERHYDROPHOBIC SURFACES

Ahmed Aldhaleai, Peichun Amy Tsai *

Summary We experimentally and theoretically examine the influence of a double chain cationic surfactant, didodecyldimethylammonium bromide (DDAB), on the wetting states and contact angles on superhydrophobic (SH) surfaces made of regular hydrophobic microstructures. We use two types of hydrophobic micro-patterns of different surface roughness r and packing fraction ϕ and vary nine surfactant concentrations (C_S) in the experiments. At low C_S, some of the droplets are in a gas-trapping, Cassie-Baxter (CB) state on the high-roughness microstructures, whereas some droplets are in a completely wetting Wenzel (W) state on the low-roughness microtextures. We found that the contact angle of CB drops can be well predicted using a thermodynamic model considering surfactant adsorption at the liquid-vapor (LV) and solid-liquid (SL) interfaces. At high C_S, however, all drops wetting on W mode. Based on a Gibbsian thermodynamic analysis, we find that for the two types of superhydrophobic surfaces used, Wenzel state has a lowest thermodynamic energy and thus is more favorable theoretically. The CB state, however, is metastable at low C_S due to a thermodynamic energy barrier and becomes more stable on the SH microtextures with greater ϕ and r, in an agreement with our experimental observations.

INTRODUCTION

The wetting and spreading characteristics of pure liquids on solid surfaces is of significant interest in several engineering and industrial applications, including droplet-based microfluidics, coating, inkjet or electrohydrodynamic jet printing, and membranes technology, especially for oil-water separation. In particular, droplet wetting on low-energy surfaces as so-called ultrahydrophobic or superhydrophobic (SH) surfaces with water contact angle (CA) ($\theta \geq 150°$) and small contact angle hysteresis (CAH) has received a great interest due to their promising applications for friction control, anti-icing, anti-fouling, self-cleaning, and improving corrosion resistance. Such SH surfaces allow the drop to sit on the top of the surface textures with air trapped underneath with a partial gas-liquid interface, as the so-called Cassie-Baxter (CB) or "Fakir" wetting state. The presence of a gas layer minimizes the interfacial energy by reducing the contact between the liquid and solid-surface area, thereby making the CB state is more favorable. However, the long-term stability of the preferred CB state on SH surfaces is still challenging and can be lost through an irreversible wetting transition to Wenzel (W) state, where the liquid fills in the surface cavities. To date, the wetting properties of SH surfaces have been extensively investigated, but mostly limited to pure liquids. Amphiphilic aqueous surfactant solutions, on the other hand, were investigated to a less extent, and there are only few experimental studies reported CB-W transition of surfactant-laden drops on SH surfaces. Here we investigate experimentally and theoretically how a cationic surfactant and its concentration (C_S) change the contact angle (CA) and wetting state of droplet on ulatra-hydrophobic microstructures of different solid-fraction (ϕ) and surface roughness (r). Systematic measurements were conducted to record both CA and wetting state for nine DDAB surfactant concentration solutions. We fit our experimental results to a thermodynamic model based on surfactant adsorption at interfaces to examine C_S-dependent CA. Using Gibbsian thermodynamic analysis, we also elucidate theoretically the probability and the stability of the experimentally observed CB state at low C_S.

RESULTS AND DISCUSSION

C_S-dependent contact angles

Fig. 1 shows the experimental and predicted results for the C_S-dependent CAs of CB and W drops on S1 (◆) and S2 surfaces for the last 10 s recording period. For the CB wetting state, there is a good agreement between our experimental data (filled symbols) and the predictions (solid lines) of the C_S-dependent CAs of CB drops, and the prediction is match better our measurement on S2. This may attributed to the smaller solid fraction (lower ϕ) and hence less pinning of the contact line. Both measured and predicted CB CAs on S2 (lower ϕ) are greater compared to S1 (higher ϕ) due to a greater liquid-air contact with smaller ϕ. However, the poorly predicted C_S-dependent CAs of modified W equation can be assisted through the use of newly modified W models that incorporate the pinning effect for W drops.

Free energy analysis for the stability and metastability of the wetting states

To explain the occurrence of different wetting states depending on the C_S on the different microstructures, we carried out an analysis starting from the Gibbsian thermodynamics (1; 2), following the recent published work by Shardt(**?**), and analytically solved the free energy (E) of our composite system of DDAB-laden surfactant droplets sitting on each microstrucuted surface. The derived free energy equation, $E - E_0$, with respect to the assumed reference state has the form of Shardt et al.(3) free energy:$E - E_0 = \gamma_{LV}\pi R^2(2 - 3\cos\theta + \cos^3\theta) - 4\pi\gamma_{LV}R_0^2$, where E_0 is the reference free energy, defined as the free energy of a spherical drop with no SL contact; R is the spherical cap radius of curvature; R_0 is the initial radius of a spherical drop of 10 μl; $\cos\theta = f\cos\theta_Y(C_S) - f_1$. Here, f is the ratio of the SL surface area (pillar-top area) to the total (SL and LV) areas and f_1 is the ratio of the LV interfatial area to the total projected area beneath the drop. Fig.2c shows that there is a free energy barrier between the CB and W states, $E_{max} - E_{CB} > 0$, for C_S from 0 to ~ 0.25 on

*Corresponding author. E-mail: peichun.amy.tsai@ualberta.ca.

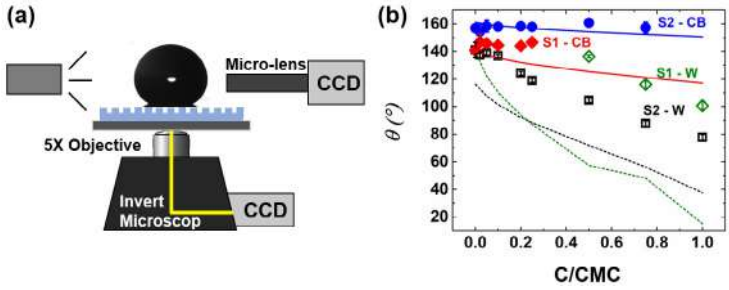

Figure 1: (a) Schematics of experimental setup, and (b) measured and predicted contact angles for DDAB droplets at concentrations between 0 and 1 CMC on two SH microstructures, high-r S1 (◆,◇) and low-r S2 (●,□) in a Cassie-Baxter (CB) (◆,●) and a Wenzel (W) (◇,□) wetting state during the last 10 secs in a time period of 100 s. The error bars represent the standard deviations of ten drops. Theoretical prediction of the CB and W contact angles considering surfactant adsorption, are also plotted for S1 (—,- - -) and S2 (—,- - -), respectively.

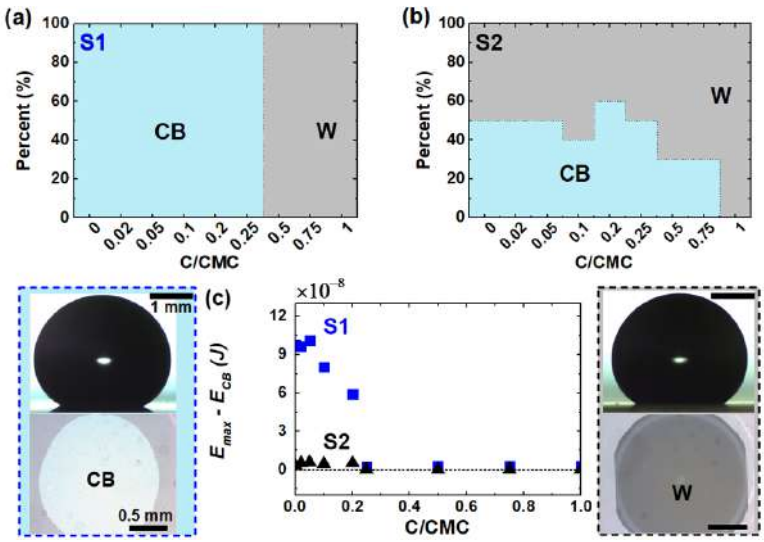

Figure 2: Percentage of experimental droplets in a Cassie-Baxter (CB) and Wenzel (W) states vs. surfactant concentration for (a) S1 and (b) S2, based on an average of 10 independent droplets at each DDAB surfactant concentration (C_S). (c) The free energy barrier, $E_{max} - E_{CB}$, as a function of C_S for S1 (■) and S2 (▲). Side and bottom-view snapshots showed a Stable CB (Left) and Stable W (Right) drops.

both surfaces S1 and S2. By comparing the calculated free energy barrier on S1 (higher ϕ and r; ■) with the percentage of CB drops experimentally observed as a function of C_S, the CB state was observed for droplets with ≤ 0.25. This can be attributed to the presence of high energy barrier at these concentrations. Either CB state for C_S from 0 to 0.75 CMC before the transition occurs at 1 CMC or W state was observed for all C_S on S2 (lower ϕ and r; ▲) due to the lower energy barrier than that of S1. On both surfaces, at high C_S, W state was more frequently observed.

In conclusion, we experimentally measured the contact angles and wetting states of DDAB surfactant-laden drops for nine different concentrations on two superhydrophobic microstructured surfaces of different packing-fraction (ϕ) and surface roughness (r). A model considering surfactant adsorption at the LV and SL interfaces has been derived and compared to the experimental data of the contact angles and wetting states of the surfactant drops on the superhydrophobic microtextures. The experiments and the theoretical predictions of the CB contact angles were in a good agreement. We further consider thermodynamic surface energies to predict the stability or metastability of the wetting states depending on C_S. We found that the Wenzel state is thermodynamically favorable for both surfaces at all DDAB concentrations, but there is a free energy barrier between the CB and W states for $C_S \leq 0.25$ for our SH surfaces. This thermodynamic analysis implies that the CB state is metastable at these concentrations and, moreover, this metastable CB state becomes more stable on surfaces with greater ϕ and r.

MEAN FLOWREVERSAL IN VIBRATED SESSILE DROPS

Dong Luo, Binxu Wang, and Jianjun Tao *
SKLTCS, CAPT, Department of Mechanics and Engineering Science, College of Engineering, Peking University, Beijing, 100871, P. R. China

Summary Three-dimensional simulations of vibrated sessile drops with pinned contact lines are carried out, and a flow reversal phenomenon is revealed: the direction of the mean flow around the drop axis can be reversed by changing the exerted vibration frequency or acceleration amplitude. The regions for the upward and the downward axis mean flows in the vibration frequency-amplitude space are distinguished from each other by systematic simulations for both the hydrophilic and the hydrophobic cases. Based on a dynamic model, the analytical relation among the vibration frequency, the acceleration amplitude, and the resonance frequency is derived for the marginal states between the upward and the downward mean-flow regions and is confirmed by the numerical simulations, indicating that the reversal phenomenon is intrinsically determined by the oscillating kinetic energy.

INTRODUCTION

The dynamic behavior of an oscillating drop is of great importance for the crystal growth, spray coating, condensation, microfluidic mixing, and atomization processes. Under the assumption of zero gravity, the dynamics of an oscillating unsupported inviscid drop was studied by Rayleigh [1]. Because of the nonlinear effect, an internal mean flow may be generated by periodic oscillations. At low oscillating frequencies (less than 1kHz), a downward mean flow along the symmetry axis was observed experimentally and numerically by tracing tracer particles and was explained in terms of Stokes drift driven by capillary waves originated from the oscillating contact line [2, 3]. On the contrary, an upward mean flow starting from the bottom center of a droplet along the symmetric axis was reported in other experiments, where the sessile water droplets were vibrated by the oscillating hydrophobic substrates and the contact lines either oscillated [4, 5] or were not oscillatory [6]. Therefore, the factors determining the direction of the axis mean flows need to be clarified.

METHODS AND RESULTS

We consider a sessile water drop of density $\rho_1 = 1000\, kg \cdot m^{-3}$ and viscosity $\mu_1 = 10^{-3}\, Pa \cdot s$ with a pinned circular contact line on a vibrated flat support in the ambient gas of density $\rho_2 = 1.25\, kg \cdot m^{-3}$ and viscosity $\mu_2 = 10^{-5}\, Pa \cdot s$ as shown in Fig. 1. The x and z coordinates are fixed on the support surface and the vibration corresponds to an oscillating body force in the vertical direction $a = Asin(2\pi ft)$, where A is the acceleration amplitude, and f is the vibration frequency. In the simulations, the surface tension coefficient is $72mN/m$ and Volume of Fluid (VOF) method is applied to catch the interface. The computational domain (L_x, L_y, L_z), the drop's volume V, and the drop's bottom radius R are $(6mm, 3mm, 6mm)$, $20\mu l$, and $2.5mm$ for the hydrophilic substrate, and $(6mm, 3mm, 6mm)$, $5\mu l$, and $1.138mm$ for the hydrophobic substrate, respectively. It was found that different vibration frequencies lead to different oscillating (m, n) modes, where n is the azimuthal wave number and $(m - n)/2 + 1$ is the number of layers of polar wave peaks or troughs observable from the side views. We have checked that the oscillating modes obtained with the uniform mesh (n_x, n_y, n_z)=(128,64,128) at different frequencies are consistent with the experimental observations [7].

In the following simulations, we focus on the oscillating $(2, 0)$ mode, an axisymmetric mode, and hence its mean flow is shown in the meridian plane. The mean flow has a dominating inner vortex ring, which is responsible for the position of the saddle point (the blue point in Fig. 1) and corresponds to an upward or downward drift flow along the drop axis. More importantly, a flow reversal phenomenon is found, i.e. the direction of the dominating mean flow along the axis may be changed by varying either the acceleration amplitude (Fig. 1) or the frequency of the vibration. The regions for the upward (red delta) and the downward (green gradient) axis mean flows in the $f - A$ space are determined numerically and are shown in Fig. 2(a) for the hydrophilic and in Fig. 2(b) for the hydrophobic substrates, respectively.

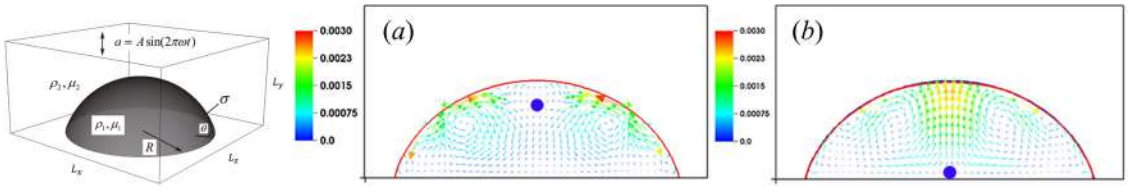

Figure 1: Computation configuration and the mean flows of the oscillating mode (2,0) at $(a) f = 80Hz,\ A = 5m/s^2$ and $(b) f = 80Hz,\ A = 15m/s^2$. The color indicates the velocity amplitude.

*Corresponding author. E-mail: jjtao@pku.edu.cn

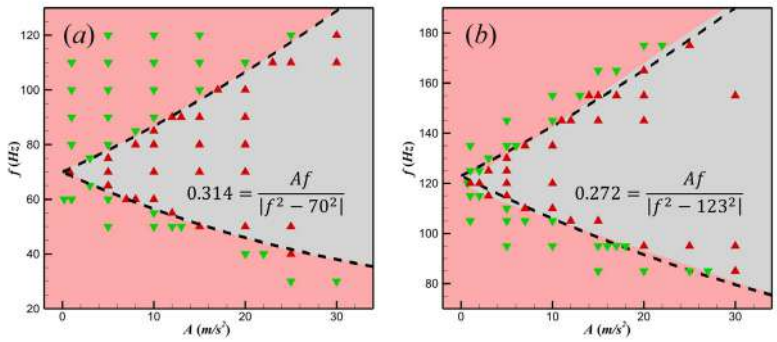

Figure 2: The direction of the axis mean flow in the $f - A$ space for (a) the hydrophilic and (b)the hydrophobic cases, where the static contact angles are $70°$ and $115°$, respectively. The symbols indicate the numerical results, and the black dashed lines represent the reversal boundaries defined by the dynamic model.

The reversal mechanism is explained as follows. The vibrated drop surface has two layers in the vertical direction for mode (2,0). The top point of the drop has largest oscillation amplitude and hence the top layer causes an upward axis mean flow according to the nonlinear theory for the standing water wave [8], while the influence of the bottom layer on the axis mean flow is mainly determined by the downward or inward flow near the node circle. When the vibration becomes stronger, e.g. the vibrational acceleration amplitude increases from $5m/s^2$ to $15m/s^2$ as shown in Fig. 1, the oscillation at the drop top is more enhanced than the bottom layer and hence the top layer's effect becomes dominant. Consequently, there should be a kinetic energy threshold, above which the downward axis mean flow turns to be upward. It is known that drops have their intrinsic oscillating frequency f_0 [1], and the resonance occurs when the vibrated frequency $f = f_0$. Based on the Navier-Stokes equations, a dynamic model is built and the total kinetic energy is derived to be proportional to $\frac{\rho_1 V(Af)^2}{(f^2-f_0^2)^2}$. Therefore, we may assume that the energy threshold for the mean flow reversal as $E_c = \frac{C_0\rho_1 V(Af)^2}{(f^2-f_0^2)^2}$, where C_0 is a coefficient, or at the reversal boundary in the $f - A$ space we have

$$\frac{Af}{|f^2 - f_0^2|} = \sqrt{\frac{E_c}{C_0\rho_1 V}} = C. \tag{1}$$

The intrinsic frequencies f_0 for the present hydrophilic and hydrophobic cases are 70 Hz and 123Hz, respectively. It is shown in Fig. 2 that when $C = 0.314m/s$ and $0.272m/s$, the reversal boundaries predicted by the dynamic model agree with the numerical simulations very well.

CONCLUSIONS

In this paper, the flow fields of vibrated sessile drops are simulated numerically with the VOF method, and it is found that the axis mean flow may change its direction with the increase or decrease of the vibration frequency and the acceleration amplitude. The mean-flow reversal results directly from the competition between the nonlinear upward axis mean flow caused by the standing wave at the upper layer and the downward axis drift flow related to the bottom layer. A dynamic model is proposed to define the kinetic energy threshold for the mean flow reversal, whose dependencies on the vibration frequency and the acceleration amplitude are shown in Eq. (1) and are confirmed quantitatively by the numerical simulations for both the hydrophilic and the hydrophobic cases.

ON THE BEHAVIOR OF MICROBUBBLE CLUSTERS IN ULTRASOUND FIELD

Hironobu Matsuzaki[1], Yunqiao Liu[2], Kazuyasu Sugiyama[3] and Shu Takagi*[1]

Summary In the present study, the behaviour of microbubble clusters is analysed under the presence of ultrasound field. From the experimental observation, it is shown that there exists the maximum size of microbubble clusters which can be captured in the focal region of focused ultrasound. This maximum size depends on the ultrasound frequency and the behaviour of bubble cluster is qualitatively well-predicted by introducing the classical theory for resonant frequency of bubble-clusters (Omta (1987)[1]). The present experimental results show quantitatively some deviation from this theory. Here, we discuss the effect of bubble number density and surface-coated shell characteristics on the bubble cluster behaviour.

INTRODUCTION

Microbubbles of a few μm diameter have been clinically used as contrast agents for ultrasound imaging. They are also expected to be used for the drug delivery system (DDS). In case of DDS, a vesicle containing microbubbles can be used to deliver the drag under the ultrasound irradiation to control the location and break-up the vesicle for the release of drag at the target region. These techniques can be further utilized to bring some chemical reaction at some specific timing and the location. For these purposes, manipulation of microbubble using ultrasound field is an important research target to investigate. For the manipulation of microbubbles, Bjerknes force [2] is utilized. Especially, primary Bjerknes force is often used to manipulate the bubble positions. Primary Bjerknes force F_{B1} is expressed using time-dependent bubble volume $V(t)$ and pressure $P(r,t)$ as $F_{B1} = -\langle V(t)\nabla P(r,t)\rangle$. Due to this force, small bubbles which have the natural frequency higher than the imposed ultrasound frequency stay at the anti-node, and large bubbles of lower natural frequency stay at the node in standing wave. This effect is also observable in the focused ultrasound experiment. In the case of the focused ultrasound, focal region becomes anti-node and small microbubbles are attracted in the focal region, forming bubble clusters. Here in the present study, this phenomenon is analyzed in detail.

METHODS

Schematic figure of experimental setup is shown in Fig.1. The ultrasound transducer is set at the top. The focused ultrasound is irradiated toward the bottom of container filled with polyacrylamide gel, where the water with microbubbles are confined in the small volume around the bottom of the gel to avoid the effect of acoustic streaming. Focal region of the ultrasound appears in this small confined region filled with water and the microbubbles are moving toward this region. Ultrasound frequency is varied from 0.3MHz to 5.5MHz. Bubble cluster formation is observed from the bottom using inverted microscope (TE2000-E, Nikon Corp.) with high speed camera(MotionPro X3, IDT Inc.). Observed bubble clusters are shown in Fig.2.

In addition to the above experiment, we also conducted theoretical estimation for bubble cluster formation, using the technique developed by Ref. [3], [4] and [5]. Takahira et al.[3] used multipole expansion technique to analyse the multi-bubble interaction problems and Ilinskii et al. [4] introduced Lagrangian and Hamiltonian mechanics in the similar problem and Liu et al. [5] extended Takahira's method by introducing Toroidal-Poloidal field theory for hyperelastic membrane model of the surface-coated microbubbles. Here, we combine these techniques to analyse the natural frequency of a surface-coated-bubble cluster.

RESULTS AND DISCUSSION

From the Omta's theory[2], the following relation is hold for the natural frequency of bubble cloud and its size under the assumption of dilute bubble concentration with potential flow theory, denoting α :volume fraction of bubble and γ :effective polytropic index.

$$\frac{D_c}{D_b} = \frac{2\alpha^{\frac{1}{6}}}{\pi}\sqrt{\frac{3}{\gamma}}\left(\frac{\omega_c}{\omega_b}\right)^{-1}$$, where D_c and D_b are the diameter of the bubble cloud and each bubble, ω_c and ω_b are the natural frequency of them, respectively.

*Corresponding author. E-mail: takagi@mech.t.u-tokyo.ac.jp

This relation indicates that the natural frequency of bubble cloud is inversely proportional to the diameter of bubble cloud, if the same size mono-dispersed bubbles are used in experiment. In the present experiment, bubbles are attracted toward the focal point of focused ultrasound and start forming the bubble cluster. The bubble cluster becomes larger and larger by taking more microbubbles in it. This process continues gradually until the bubble cluster suddenly disappear from the focal point. This phenomena can be explained by the primary Bjerknes force theory and the natural frequency of bubble cloud (cluster). That is, growth of a bubble cluster size gives the reduction of natural frequency of bubble cluster and the focal point becomes unstable region beyond a certain critical size of bubble cluster, when the natural frequency of a bubble cloud becomes lower than the imposed ultrasound frequency. This critical size cluster is expected to have the natural frequency which is the same as the imposed ultrasound frequency. The experimental results are shown in Fig. 3. It is shown that there is a simple well-correlated tendency and that the cluster diameter when they escape from the focal point is roughly inversely proportional to the imposed ultrasound frequency.

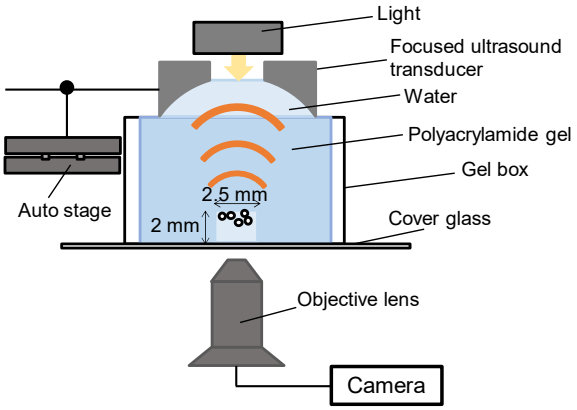

Figure 1. Experimental setup for bubble cluster observation

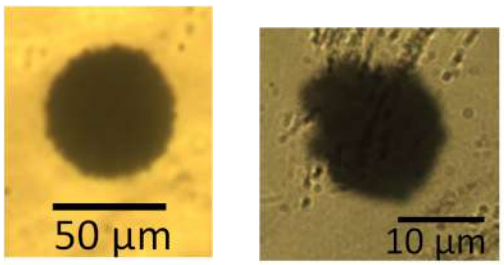

(a) 0.4 MHz (b) 2 MHz
Figure 2. Photos of captured bubble clusters (Captured by (a) 0.4MHz Ultrasound, (b) 2 MHz)

CONCLUSIONS

The maximum size of bubble clusters captured by focused ultrasound was investigated. Given the imposed ultrasound frequency, microbubbles accumulate in the focal region of focused ultrasound and forming a bubble cluster. This bubble cluster continues growing until it reaches the maximum size, beyond which the cluster escapes from the focal region. This maximum size is explained using the theories of the Bjerknes force[2] and resonant frequency of bubble cloud[1] and the behaviour is well-predicted qualitatively. Compared with the prediction by Omta's theory, surface-coated-microbubble clusters captured by focused ultrasound shows quantitatively different behaviours. The present bubble clusters behave to have larger natural frequency than the theoretical prediction for the same size free-surface-bubble cloud.

THERMALLY-DRIVEN BUBBLE OSCILLATION IN AN IMPACTING DROP

Masaki Kato, Takahiro Okabe and Minori Shirota*[1]
Graduate School of Science and Technology, Hirosaki University, Hirosaki, Japan

Summary We experimentally observed a unique circular subcooled boiling for the first time in an impacting water drop on a heated solid surface: bubbles at the front of the circular boiling region perform violent volume oscillations which helps to rapidly enlarge the boiling area in the spreading drop. Observation through a high-speed camera revealed that the collapse of the bubble was closely related to the dry-out of the microlayer formed in between the bubble and the solid. After the analysis with a spherical bubble growth model, we clarified that the evaporation of microlayer and the condensation on the subcooled liquid play important roles to determine the bubble dynamics.

INTRODUCTION

Spray cooling is a promising heat reduction technology for further development in high-performance electro devices such as microchips. Such a high cooling heat flux as 1000 W/cm^2 can be achieved with spray cooling probably due to the bubble dynamics in impacting drops on heated solids. The importance of bubble motion in pool boiling has been widely studied. However, bubble dynamics, mainly driven by phase change, in an impacting drop is yet to be investigated.

The characteristics of the boiling in an impacting drop can be summarized as follows: while bubbles nucleate and grow on the heated solid surface the bulk liquid above the solid is kept cold during the impacting process of typically several milli-seconds. The situation causes a high temperature gradient in the thermal boundary layer in the liquid surrounding the bubble. Under certain conditions, the high temperature gradient might cause subcooled boiling with violent bubble collapses, which has been well studied in pool boiling triggered with MEMS technology [1].

In the present study we focus on subcooled boiling in impacting drops of water. By employing a high-speed imaging technique, we explore the bubble dynamics in both the drop-size and the bubble-size scales. We also construct a theoretical model for thermally driven bubble oscillation in a thermal boundary layer with the development of the microlayer in between a bubble and a heated solid.

EXPERIMENTAL METHOD AND THEORETICAL MODELLING

Room temperature water drops were gently released from a needle to a sapphire plate heated at about 170 °C. The transparent sapphire plate enabled us to observe bubble formation process from below through a mirror using a high-speed camera (Photron SA-Z or Shimadzu HPV-X2 with frame rate up to 500 000 fps) with an LED backlight.

We constructed a theoretical model for the bubble growth and shrink in an impacting drop on a heated wall; the overview of the model is shown in Fig. 1. The bubble was assumed to be a spherical cap whose time change in radius followed Rayleigh-Plesset equation [2]. The bubble started to grow several milli-seconds after the drop contacted the wall. The surrounding liquid of the bubble therefore had a temperature gradient in the direction normal to the solid. In such thermal boundary layer, heat Q_l conducted through the bubble surface in both directions, i.e., toward the bubble from a superheated region and toward the surrounding liquid in subcooled region.

In the modelling, we also examined the effect of microlayer evaporation on the bubble growth. Here we assumed the heat conduction through the microlayer Q_{ml} was determined by Fourier's law. We also took into account the enthalpy

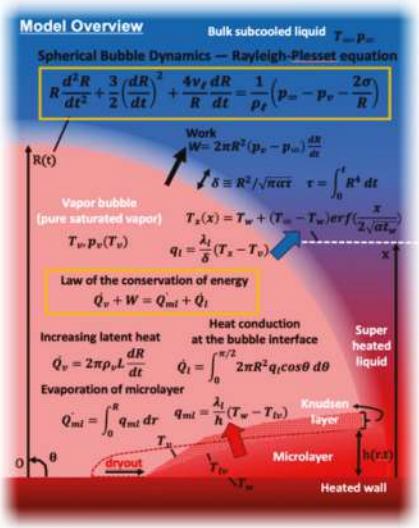

Fig. 1 Overview of bubble growth model.

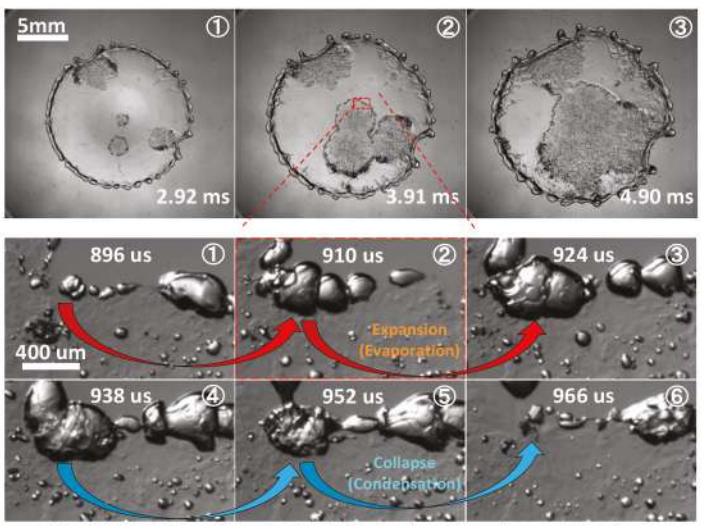

Fig. 2 Circular subcooled boiling region in an impacting drop.

*Corresponding author. E-mail: mshirota@hirosaki-u.ac.jp

change of vapor inside the bubble due to the evaporation and condensation on the bubble surface Q_v. The conservation of energy therefore reads $Q_v + W = Q_{ml} + Q_l$.

RESULTS AND DISCUSSION

Typical images of subcooled boiling in an impacting drop is shown in Fig. 2. We see from this figure that at about 3 ms after the contact of the drop with the heated solid four circular boiling regions started to grow and fully covered the spreading drop in about 4 ms. A close observation of the circular boiling region revealed that bubbles continued violent expansion and collapse at the front while inside the circle the bubble motions were very gentle.

The circular boiling region originated from a single bubble collapse which is clearly shown in Fig. 3. In this figure, the boundary between a microlayer and a dry-out region can be observed with backlighting as the boundary has a large difference in refractive index and the curvature. We can also observe the formation of a droplet ring from the residue of the microlayer. We also revealed from the observations that bubbles collapse soon after the microlayer was dried out. Interestingly, if we increased the initial drop temperature, the violent bubble oscillation disappeared. Therefore, we conclude the bubble growth is mainly driven by the heat supply from microlayer. The shrink should be then occurred when the heat release to the subcooled surrounding liquid exceeds the heat supply.

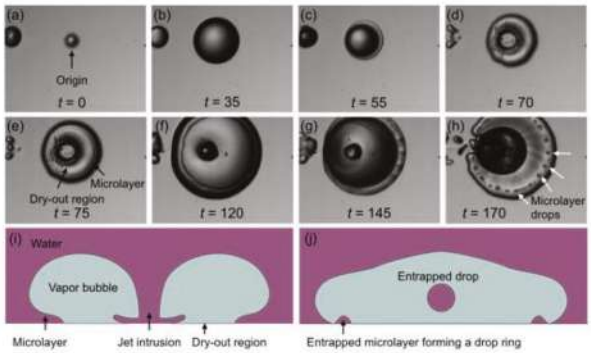

Fig.3 Images of the onset of circular boiling region (a-h) and schematic drawings showing the formation of microlayer (i) and microlayer drop ring (j).

In order to evaluate the validity of our model and to investigate the effect of microlayer and the temperature distribution in the thermal boundary layer developed on the heated solid, we first compare in Fig. 4 our experimental results on the time change in bubble radius with that of model predictions without microlayer for different drop temperatures T_∞. Note here that we used the same initial conditions for all the model predictions. Figure 4 clearly shows that without the microlayer the bubble cannot grow enough with the experimental condition, i.e., the initial drop temperature $T_\infty = 25$ °C.

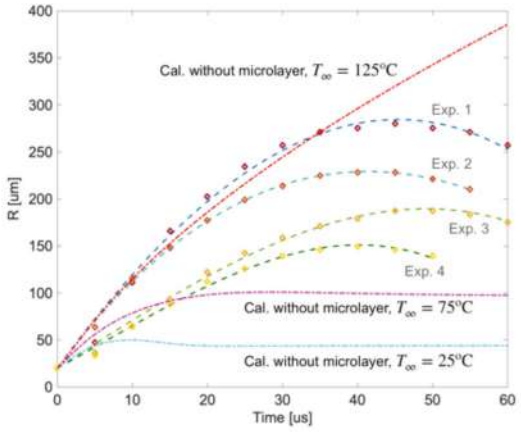

Fig.4 Comparison on the bubble radius between experimental value and model prediction without microlayer.

We therefore conclude that both the microlayer and the thermal boundary layer play crucial roles in the evolution of subcooled boiling in an impacting drop. To investigate the contributions more specifically, we look into the energy budget to confirm the assumption in our model, i.e., bubble starts to shrink when the microlayer is dried out and the heat release to the surrounding subcooled liquid exceeds the heat supply. To proceed the analysis, we have to know $Q_{ml}(t)$ for given $R(t)$. The difficulty in this problem arises from the fact that to apply the Fourier's law for the heat conduction in microlayer we have to specify the temperature at the interface between the Kunudsen layer and the bulk vapor, T_{lv}, see Fig. 1. In the present analysis, ewe adopted a kinetic boundary condition [3] to obtain T_{lv}.

By giving experimentally obtained $R(t)$ and its derivatives, we evaluated the energy budget as shown in Fig. 5. We find in this figure that in case of $T_\infty = 25$ °C, $dQ_{ml} \approx W + dQ_v - dQ_l$. This evidence confirms that our assumption in the modeling does not lose the essence of the physics regardless of its simplicity.

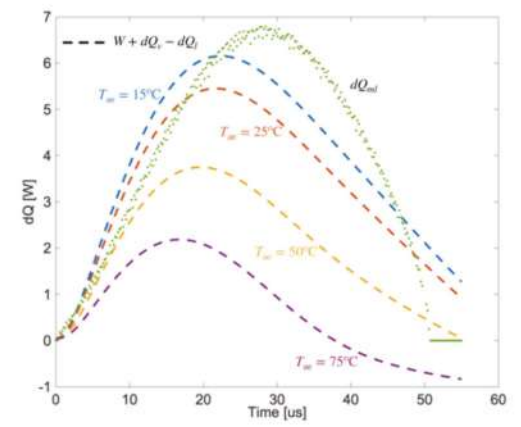

Fig.5 Energy budget estimated by the model prediction with experimentally obtained bubble radius $R(t)$ and its derivatives.

RAYDROP : A UNIVERSAL DROPLET GENERATOR BASED ON A NON-EMBEDDED "CO-FLOW-FOCUSING"

Adrien Dewandre[1], Javier Rivero-Rodriguez[1], Youen Vitry[1], Benjamin Sobac[1], and Benoit Scheid*[1]
[1] TIPs Lab, Université libre de Bruxelles, Brussels, Belgium

Summary We present a new configuration based on the alignment of two capillaries immersed in a pressurized chamber containing a continuous phase. The dispersed phase exits one of the capillary through a 3D-printed nozzle, placed in front of the extraction capillary for collecting the droplets. This non-embedded and co-flowing implementation of an axisymmetric flow-focusing is referred to as the Raydrop device. Experimental results demonstrate the universality of the Raydrop in terms of the variety of fluids that can be emulsified, as well as the range of droplet radii that can be obtained, without neither the need of surfactant nor coating. Numerical computations of the Navier-Stokes equations based on the quasi-steadiness assumption are shown to correctly predict the droplet radius in the dripping regime, as well as the dripping-jetting transition, when varying the geometrical and fluid parameters.

THE RAYDROP DEVICE

Most commercial microfluidics droplet generators rely on the planar flow-focusing configuration implemented in polymer or glass chips. The planar geometry, however, suffers from many limitations and drawbacks, such as the need of specific coatings or the use of dedicated surfactants, depending on the fluids in play. On the contrary, and thanks to their axisymmetric geometry, glass capillary-based droplet generators are a priori not fluid-dependent. Nevertheless, they have never reached the market because their assembly requires art-dependent and not scalable fabrication techniques.

The device presented in this paper relies on the alignment of two glass capillaries inside a pressurized chamber, forcing by flow-focusing the tip-streaming regime as presented by Evangelio *et al.* [1]. A 3D-printed micro-nozzle is additionally connected at the tip of the injection capillary (see Fig. 1(d)), enforcing the dripping of small droplets as in embedded axisymmetric co-flow (see Utada *et al.* [2]). Therefore, our non-embedded design presents both the characteristics of

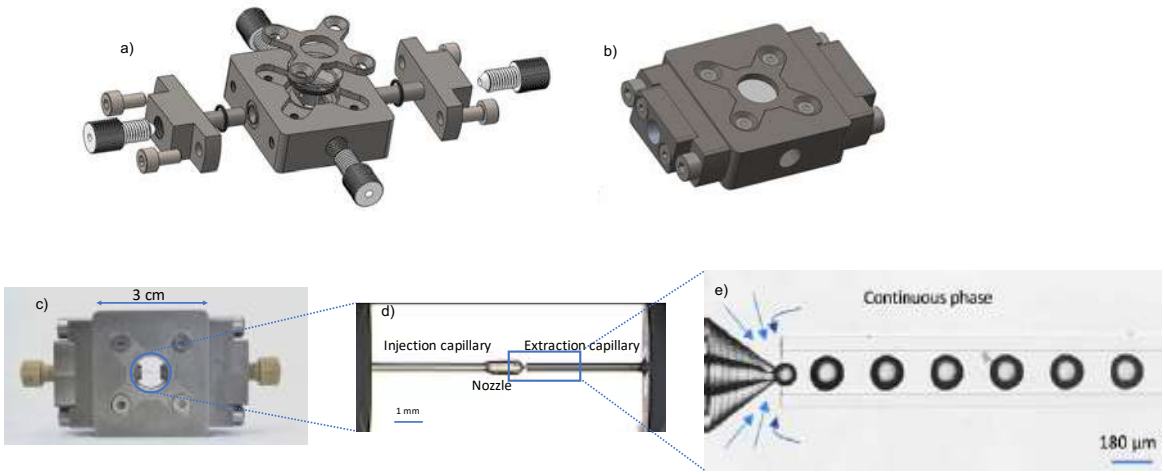

Figure 1: (a) Exploded view and (b) assembled view of the Raydrop. (c) The Raydrop with the injection and extraction glass capillaries. (d) Zoom through the top window of the two capillaries aligned in the chamber filled with the continuous phase. (e) Zoom on the droplet generation area. The 3D-printed nozzle connected to the injection capillary carries the dispersed phase while the extraction capillary collects droplets of the dispersed phase entrained by the continuous phase. At the entrance of the extraction capillary, the continuous phase is dramatically accelerated because of the change of section and squeezes the dispersed phase, resulting in the droplets formation.

a co-flow (axisymmetric geometry) and a flow-focusing (dramatic local accelerations of the continuous phase), and is thereby called non-embedded "co-flow-focusing". The technological breakthrough of this design is two-folds. Firstly, it enables high-throughput generation of mono-disperse droplets, intrinsic to the dripping regime, for a wide variety of fluids, thanks to the fact that the continuous phase is not confined before entering the extraction capillary, allowing for flushing very viscous continuous phases. Secondly, it takes benefit of specific fabrication techniques and materials compatible with a large-scale production of the device, while ensuring a very precise and reproducible alignment of the two capillaries in the chamber. Additionally, the device is made plug-and-play thanks to the standard connections and the possibility to easily assemble and disassemble all parts for cleaning.

EXPERIMENTAL AND NUMERICAL RESULTS

Excellent agreement between droplet radius measured experimentally and predicted by transient modeling, as shown in Fig. 2, confirms that the droplet generation essentially depends on the geometrical parameters as well as on the flow-rate of the continuous phase, and shows little sensitivity to the flow rate of the dispersed phase. This little sensitivity

*Corresponding author. E-mail: bscheid@ulb.ac.be

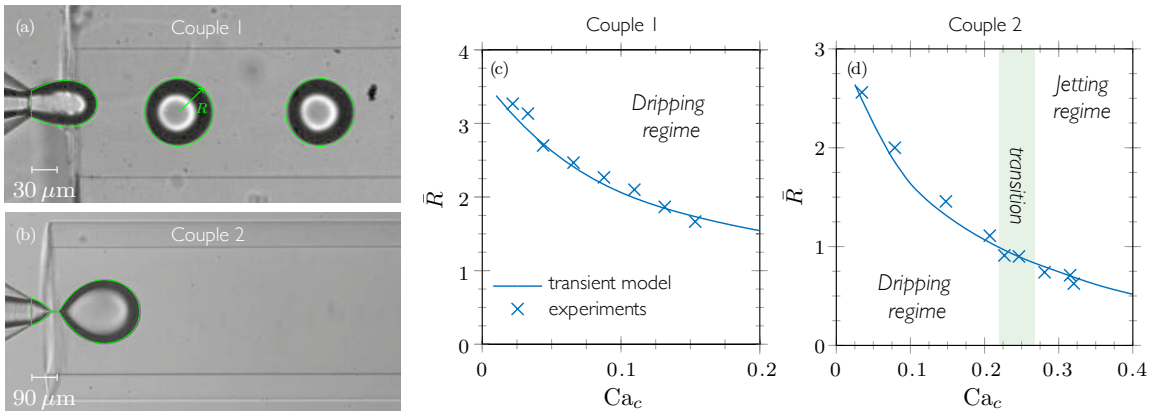

Figure 2: (a-b) Comparison between transient simulations (green lines) and experimental pictures for the formation of water drops in mineral oil for two geometries referred to "Couple" 1 and 2; (c-d) comparisons of dimensionless droplet radius for various values of the capillary number of the continuous phase, Ca_c. The shaded area in (d) shows the experimental dripping-jetting transition.

allows to consider a quasi-static (QS) model for which the dispersed flow rate tends to zero, recovering a system very analog to the pendent droplet, provided the gravity force is replaced by viscous forces. And as in the pendent droplet problem, the dripping mechanism can be associated to the bifurcation point in terms of droplet volume for which viscous forces are not balanced anymore by surface tension forces. This bifurcation point depends on the capillary number of the continuous phase Ca_c and it is shown to disappear at a transition Ca_c^* above which force equilibrium remains possible, which then corresponds to the jetting mode in the quasi-static limit, precursor of the tip-streaming regime. Figure 3 shows the dripping-jetting transition as predicted in the quasi-static limit in function of the viscosity ratio λ between the dispersed and the continuous phase. The influence of inertia has also been studied, as quantified by the Laplace number

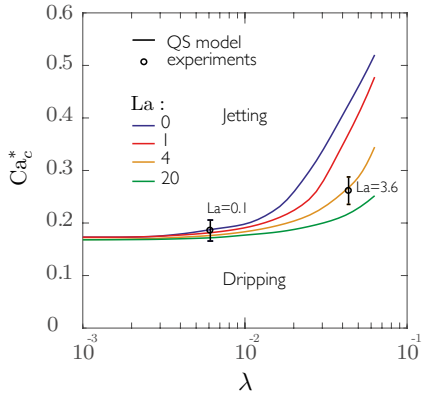

Figure 3: Influence of λ on the dripping-jetting transition at Ca_c^* in the quasi-static dripping regime for different values of the Laplace number La gauging the role of inertia. The geometry of "couple" 2 has been used. The point for $La = 3.6$ corresponds to the experimental transition identified in Fig. 2(d) and show an excellent agreement.

La (which corresponds to the Reynolds number defined with the capillary-viscous velocity). We found that, thought the drop size prediction is essentially independent on inertia, the prediction of the dripping-jetting transition does. Actually, it enhances the dripping-jetting transition, i.e. Ca_c^* decreases with increasing La for a fixed λ, and this enhancement is more pronounced as λ increases. On the contrary, inertia plays almost no role in the inviscid limit, i.e. for $\lambda \to 0$.

CONCLUSIONS

The present paper shows the ability of the Raydrop device to produce droplets with diameters in the range from 20 to 400 μm and with various fluids (water, oil, organic solvent, polymer resin, air). The monodispersity ensured by the dripping regime, the robustness of the fabrication technique, the universality of the axisymmetric configuration, and the optimization capabilities from the numerical modeling relying on the quasi-static assumption, confer to the Raydrop device a very high potential in the race towards high-throughput droplet generation processes through parallelization.

EFFECT OF SUBSTRATE STIFFNESS ON THE MAGNETOWETTING DYNAMICS OF SESSILE FERROFLUID DROPLETS

Bhaskarjyoti Sarma *, Dipankar N. Basu, and Amaresh Dalal
Department of Mechanical Engineering, Indian Institute of Technology Guwahati, Assam, India-781039

Summary Magnetic field mediated wetting of paramagnetic sessile droplets has been studied extensively. However, the wetting dynamics and shape evolution of a ferrofluid droplet are substantially altered by the substrate compliance, as elucidated in the present experimental study. For example, the rigid surfaces offer less resistance to the droplet contact-line motion, while the softest substrate pins the contact line. Next, we find that both wetting time and the wettability increases with the decrease in the stiffness of the underlying substrate. Further, the non-uniform magnetic field was able to split the parent droplet into a secondary droplet, which size increases with the increasing softness of the substrate. The study is fundamentally essential for paving building blocks for futuristic applications involving elasto-magnetocapillary interactions.

INTRODUCTION

The wetting nature of ferrofluid droplets in a uniform or non-uniform magnetic field has received considerable attention in the last few decades owing to its unmatched applicability in many industrial processes, which involves mechanical sealing and acoustics [1], tissue engineering [2], magnetic self- assembly [3], etc. to name a few. Apart from these dynamical systems, the static deformation of a paramagnetic droplet has also been one of the prime subjects of investigations in the recent past [4,5]. Interestingly, the aforementioned static magnetowetting studies haven't taken the stiffness and wettability of the underlying substrate into account.

Here, we experimentally elucidate the wetting dynamics of ferrofluid (FF)droplets on substrates of different stiffness and wettability. Our prime intention is to co-relate the change in apparent dynamic contact angle and the motion of the air-liquid-solid three-phase contact line to the substrate compliance. We believe this study will shed light on the previously unexplored magneto-elastocapillary regime, a potential host for cutting edge applications in the future.

EXPERIMENTAL DETAILS

Figure 1*a* shows the schematic of the experimental set-up for this study, wherein a ferrofluid (EMG 408, Ferrotec, USA) droplet is dispensed atop a solid substrate with the help of a micropipette and subsequently a permanent magnet (Rectangular rare earth neodymium magnets (N52); dimensions: 10 mm $\times$ 20 mm $\times$ 2 mm) is placed atop the droplet to create a non-uniform magnetic field in the vertical (z-axis) direction (refer to figure 1*b*). The solid substrates are chosen to get a range of substrates stiffness, including rigid glass substrate to thin PDMS film-coated glass substrates. We mix PDMS (polydimethylsiloxane, Sylgard 184) and cross-linker (both purchased from Dow Corning, Wiesbaden, Germany) in three different ratios, namely 10:1, 30:1 and 50:1 resulting in substrates with elastic modulus, E = 1.5, 0.06, and 0.02 respectively. The thickness of the aforementioned PDMS coated surfaces ranges from 2 to 4 μm, while the surface roughness is approximately 2 $\pm$ 0.3 nm. The magnet is attached to a vertically movable frame, thereby facilitating the generation of a desired magnetic field. Here we have experimentally investigated the spatiotemporal evolution of a 3 μL FF droplet when the magnet is placed above at a distance, H = 4.71 mm (measured from the surface of the substrate), resulting in a magnetic field, B_z = 450 mT.

We have employed a continuous videography method after evaluating the temporal scale of deformations. The videos are recorded with a Sony camcorder at a rate of 25 frames per second, while the background is illuminated with a white LED light giving a sharp contrast to the snapshots recovered. The image analysis is done by ImageJ [6] software.

RESULTS AND DISCUSSIONS

In this study we evaluate the temporal variations in droplet dynamic contact angle, (θ_d or θ_d^*) and contact radius (r_d or r_d^*), as a measure of the deformation of the FF droplet in the presence of a magnetic non-uniform magnetic field in axial direction. Figure 2(*a-i*) exhibits a brief overview of the droplet deformation process in the magnetic environment. Briefly, the initially hemispherical droplet (t =0) experiences a pull in the vertical portion, resulting in elongation of the apex as well as the movement of the contact line along the surface. The droplet after reaching its maximum elongation splits into two parts as soon as magnetic force overcomes the surface tension force as seen in the final snapshot.

As the droplet elongates the θ_d (or θ_d^*) and r_d (or r_d^*) is also modified depending upon the stiffness of the underlying substrate as shown in figure 2(*j-k*). Here we have non-dimensionalized the time with the splitting time (t_s), defined as the time period from t = 0 to the instant of droplet splitting and the r_d and θ_d with their initial equilibrium values. It can be discerned that the contact line gradually decreases from its maximum to a lower value until the droplet is fragmented except for a rigid glass surface. For the rigid glass surface, the contact angle initially decreases to a lower value, beyond

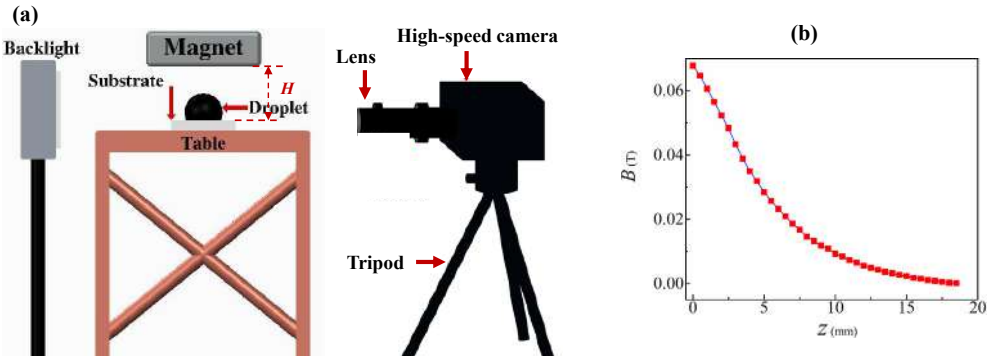

Figure 1: (a) Schematic of the experimental set-up. (b)Magnetic flux density (B) as a function of the vertical gap (H) between the magnet and the bottom substrate.

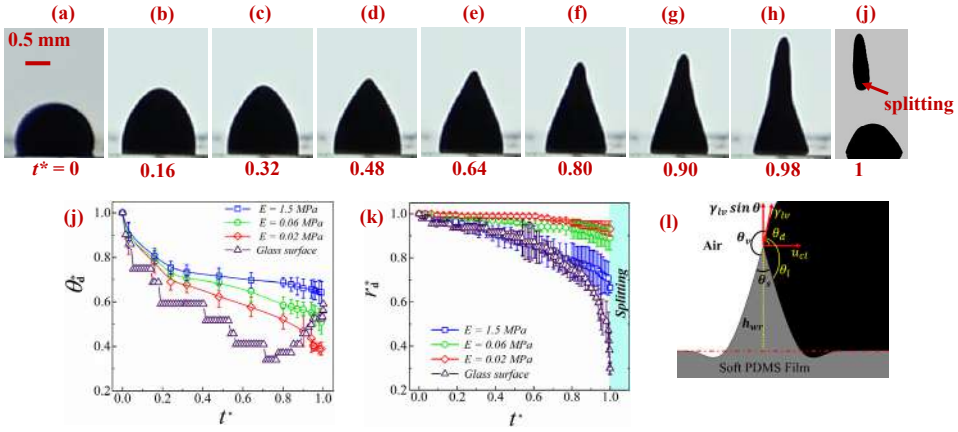

Figure 2: (a)-(i) Shape evolution of a FF droplet on a 10:1 PDMS surface. (j) and (k) variations in θ_d^* and r_d^* with time for all the substrates of this study. (l) schematic of wetting ridge formation on soft substrate (30:1 and 50:1 PDMS surface).

which it increases. In contrast, the contact radius, r_d^*, decreases approximately by 80 % for the rigid glass surface, whereas for the soft viscoelastic surfaces, the radius nearly remains constant for the whole deformation cycle. For example, for the softest PDMS surface (50:1), the change in radius is approximately 4 % till the instant of breakup of the droplet.

The anomalous behavior of the θ_d^* on a glass surface can be attributed to the higher wettability of the water-based FF on the former. While a spherical cap approximation can approximate the droplet on the PDMS based hydrophobic surfaces, the droplet takes the shape of the elliptical lens on the glass surface before the application of the magnetic field. Further, the near pinning behaviour of the contact radius on the soft substrate can be attributed to the formation of wetting ridges at the contact line [7]. The softer the substrate, the larger the wetting ridge and hence higher the pinning. Due to the absence of pinning the contact radius can move freely on a rigid surface like glass during magnetowetting. Furthermore, the secondary droplet size also depends on substrate stiffness which couldn't be shown due to page limitation.

CONCLUSIONS

A sessile FF droplet experiences sever deformation leading to the splitting in a non-uniform magnetic filed. The change in contact angle and radius during deformation depends strongly on softness of the underlying substrate. Soft substrates favours formation of large wetting ridge and promotes pinning of the contact line.

ASYMMETRIC BUBBLE PINCH-OFF IN TURBULENCE

Daniel J. Ruth[1], Wouter Mostert[1], Stephane Perrard[1,2], and Luc Deike *[1]
[1] Department of Mechanical and Aerospace Engineering, Princeton University, Princeton, United States
[2] Departement de Physique, Ecole Normale Superieure, PSL (Paris Sorbonne Lettres) Research University, Paris, France

Summary We study the pinch-off of a bubble surrounded by a turbulent flow, in which the turbulence initially deforms the bubble and sets a complex bubble shape that prescribes the dynamics of the inertial collapse. The mean power-law behavior remains similar to that expected for an axisymmetric bubble in a quiescent fluid, but the turbulent deformations introduce shape asymmetries which persist through the collapse [1]. Specifically, the bubble's size relative to the scale at which turbulence is balanced by surface tension controls the appearance of a kink-like structure in the neck. Here, we analyze the spatial asymmetries in the neck collapse by contrasting the motions of four separate points on the neck, each imaged with a high-speed camera, with the mean collapse dynamics, finding greater variability than would be inferred by just considering the mean behavior.

BACKGROUND

In recent decades, much theoretical and experimental effort has been put into understanding the process by which an axisymmetric bubble or droplet splits into multiple "child" pieces. The final part of this process involves the "pinch-off" of the neck of fluid separating the two lobes by the surrounding fluid. During this phase, the mean radius of the neck $\overline{r}$ shrinks as a power law collapse $\overline{r} \sim (t_0 - t)^\alpha$, where t_0 is the pinch-off time and α is the similarity exponent. When dominated by the inertia of the continuous phase (as is the case for an air bubble breaking apart under water), α is a slowly-varying exponent approaching $1/2$ [2]. In industrial and environmental processes in which bubbles break apart, though, surrounding turbulence will prevent the bubble's initial condition from being axisymmetric, instead introducing a deformed initial condition for the pinch-off. We aim to describe bubble pinch-off in these realistic conditions in which multi-scale perturbations are present.

TURBULENT DEFORMATIONS AND FREEZING

In this study, we investigate the pinch-off of a bubble underwater that is surrounded by a homogeneous and isotropic turbulent flow in the continuous phase. The turbulence deforming the bubble is characterized by its energy dissipation rate ϵ, while the surface tension σ of the air-water interface acts to minimize the surface area of the bubble. With these parameters and the water density ρ, we can construct the Hinze length scale $d_\mathrm{H} = (\sigma/\rho)^{3/5}\epsilon^{-2/5}/2$, which is the length scale at which turbulent stresses are balanced by surface tension [3]. When the bubble, whose size is comparable to the diameter of the needle through which it is injected d_n, is much smaller than d_H, surface tension is able to counteract the turbulent stresses, and the bubble shape is not significantly deformed compared to the quiescent case. When $d_\mathrm{n} > d_\mathrm{H}$, however, the turbulent stresses dominate, and the bubble is significantly deformed by the turbulence as the neck pinches off.

With a power-law collapse given by $\overline{r} = r_\tau[(t_0 - t)/\tau]^\alpha \equiv c(t_0 - t)^\alpha$, where the neck has a radius r_τ at a time τ before pinch-off, the relative speed of two opposing points on the neck is $2\overline{v}_\mathrm{col} = 2\alpha c(t_0 - t)^{\alpha-1}$. Expressed as a function of the mean neck size, $2\overline{v}_\mathrm{col} = 2\alpha c^{1/\alpha}\overline{r}^{1-1/\alpha}$. This permits a comparison to the typical velocity difference between two points separated by a distance $2\overline{r}$ in the turbulence, which is $v_\mathrm{turb} = 2^{5/6}(\epsilon\overline{r})^{1/3}$ in the inertial subrange of the turbulence. The ratio of the two speeds is $2v_\mathrm{col}/v_\mathrm{turb} = \alpha c^{1/\alpha}\epsilon^{-1/3}\overline{r}^{2/3-1/\alpha}/2^{1/3}$. So long as $\alpha < 3/2$, the collapse rate becomes much greater than the local turbulent velocity scale once $\overline{r}$ shrinks beyond

$$r_\mathrm{freeze} = \left(2^{1/6}\epsilon^{1/3}c^{-1/\alpha}\alpha^{-1}\right)^{3\alpha/(2\alpha-3)},$$

so for $\overline{r} \ll r_\mathrm{freeze}$ we expect an inertial collapse controlled by the initial and boundary conditions set by the turbulent field, no longer with any direct interaction between turbulent eddies and the shrinking neck. In a recent paper [1], we showed that on average, the neck collapse in such a scenario does follow the $\alpha \approx 1/2$ behavior characteristic of an inertial collapse. On a case-by-case basis, however, we observed rich dynamics in the form of neck shape modulations and deformation-induced "kinking" of the fluid neck, which are attributed to the turbulent stresses overcoming the bubble's restoring surface tension to deform the initial shape of the bubble. As $d_\mathrm{n}/d_\mathrm{H}$ increases, a kink is more likely to occur during the collapse, and it is more likely to happen earlier on, when the neck width is larger [1]. Prior to any kink, though, the neck collapse can still exhibit asymmetries while the azimuthal-averaged dynamics suggest an inertial collapse, a result of collapse having memory of its initial conditions [4]. Here, we expand on those results by investigating further the azimuthal asymmetries induced by the turbulence.

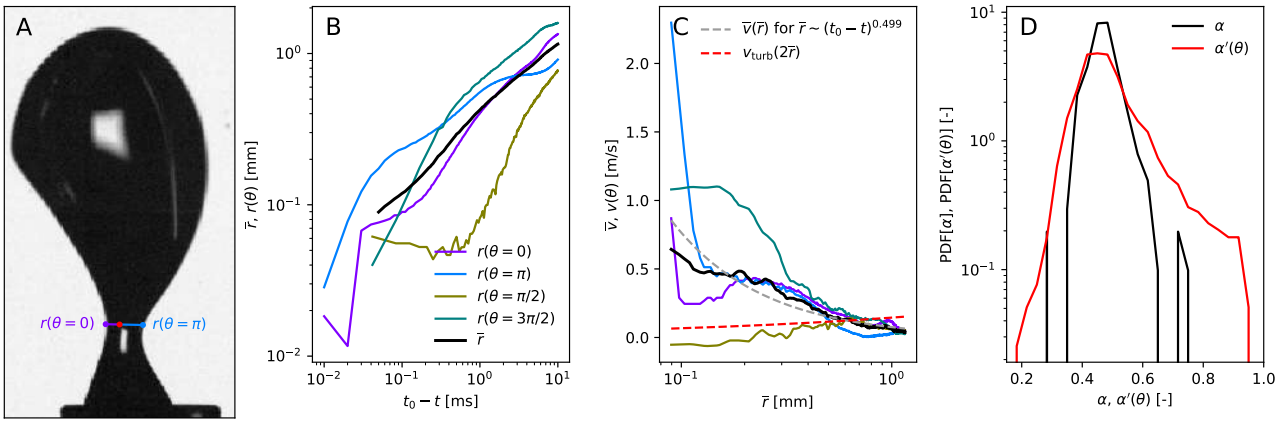

Figure 1: The pinch-off of a bubble rising into a turbulent field. (A) The bubble at $0.5\,\mathrm{ms}$ before pinch-off. Lines showing two of the four measured points on the neck $r(\theta)$ are shown in purple and blue, each measured from the pinch-off point, shown in red. (B) The distances between the pinch-off point and four imaged points on the neck $r(\theta)$, as well as the average neck size $\overline{r}$. (C) The collapse rate of the four sides of the neck $v(\theta,t) = -\partial r(\theta,t)/\partial t$, showing that the four sides of the neck collapse with different behavior. The mean collapse rate $\overline{v}$ and a power-law fit to it with $\alpha = 0.499$ are shown as the solid black and dashed gray lines, respectively. The dashed red line shows the turbulent velocity scale $v_{\mathrm{turb}} = 2^{5/6}(\epsilon\overline{r})^{1/3}$, which becomes much slower than the collapse velocities once the neck is very small. (D) The distribution of scaling exponents fit to the mean collapse curves from ~ 300 experiments, in black, and that of the exponents fit to the collapses of each of the four points measured on the neck, in red.

RESULTS AND DISCUSSION

Experimentally, we use two high-speed cameras viewing an air bubble rising from a needle into a turbulent water flow from 90° angles to track the collapse of the four resolved points on the neck (that is, the left and right side of the neck in each orthogonal view). This gives $r(\theta,t)$ for $\theta = 0, \pi/2, \pi$, and $3\pi/2$, where θ is the azimuthal angle around the neck cross-section, and each curve $r(\theta,t)$ measures the distance between the bubble interface and the eventual pinch-off point.

One of the two cameras' views is shown, along with the two distances corresponding to $r(\theta = 0)$ and $r(\theta = \pi)$, in Figure 1 a). The four collapse curves are shown along with the average collapse $\overline{r}$ in b), and the corresponding collapse velocities of the four points are shown in c) as a function of the mean neck size $\overline{r}$. The mean collapse rate is compared with a power-law collapse $\overline{v}_{\mathrm{col}} = a\overline{r}^{1-1/\alpha}$, with α and a fit to the data shown as the dashed gray line. Finding α in this manner, as opposed to with a fit to $\overline{r} \sim (t_0 - t)^{\alpha}$, alleviates the issue caused by the kink appearance modifying the pinch-off time. It is apparent that the close agreement between the experimentally-measured $\overline{v}$ curve, for which $\alpha = 0.499$, and that predicted for an inertial collapse, $\alpha \approx 1/2$, masks the complexities of the neck's collapse, which are evidenced by the differently-behaved $r(\theta,t)$ and $v(\theta,\overline{r})$ curves. Finally, the characteristic turbulent velocity over the neck scale, $v_{\mathrm{turb}}(2\overline{r}) = 2^{5/6}(\epsilon\overline{r})^{1/3}$, is shown as the dashed red line in Figure 1 c), showing that it is only comparable to the collapse velocities when the neck is relatively large.

For the ~ 300 cases of bubbles pinching off in turbulence with $0.27 \leq d_{\mathrm{n}}/d_{\mathrm{H}} \leq 1.63$ initially presented in ref. [1], we now perform the power-law fit to obtain the scaling exponent α describing the mean collapse for each case. Additionally, we fit $v(\theta) \sim \overline{r}^{1-1/\alpha'(\theta)}$ to find the power-law exponent $\alpha'(\theta)$ describing the motion of each of the four imaged points on the neck in each case. The distributions of α and α' are given in Figure 1 d). Each is centered near $1/2$, but there is a much wider variability in the local exponent $\alpha'(\theta)$ than the mean exponent α. Results from all cases with turbulence are included in this plot, but binning the results by $d_{\mathrm{n}}/d_{\mathrm{H}}$ reveals that the spread of $\alpha'(\theta)$ increases with increasing turbulence.

These results complement recent findings [1] by introducing a new metric, the local collapse exponent $\alpha'(\theta)$, as a measure of the local collapse dynamics. The wide distribution of $\alpha'(\theta)$ provides further evidence that while the mean dynamics of bubble collapse in turbulence may resemble the scaling expected for symmetric collapse in a quiescent fluid, the turbulence-induced deformations to the bubble's initial shape yield changes to the entirety of the collapse, even beyond the finite scales of the turbulence.

A UNIFIED EULERIAN MULTIPHASE FRAMEWORK FOR FLUID-STRUCTURE INTERACTION PROBLEMS INCLUDING CAVITATION

Mauro Rodriguez *[1], Spencer Bryngelson[1], Shunxiang Cao[1], and Tim Colonius[1]

Summary Understanding the impact load mechanisms from cavitation bubbles and shocks emitted by their collapse in and near solid deformable media is important for engineering and biomedical applications. In such flows, transient pressure fluctuations can lead to a cloud of small vapor bubbles near the solid object. A unified Eulerian framework for fluid-structure interaction problems including cavitation is developed to incorporate numerically unresolved and resolved bubbles and the solid material elasticity. The numerical model uses interface-capturing techniques for the fluid-structure coupling with phase change. The method is based on a high-order accurate weighted essentially non-oscillatory shock and interface capturing scheme. Studies of single bubble and cloud dynamics near a solid/compliant structure relevant to therapeutic ultrasound applications are presented.

INTRODUCTION

Understanding the bubble dynamics in or near compliant or hard matter is important for engineering and biomedical applications, particularly in the context of cavitation-induced damage. Biomedical applications include therapeutic ultrasound tools with ultrasound waves of amplitudes and frequencies ranging from -25 to 100 MPa and 100 kHz to MHz, respectively, to treat pathogenic tissues (soft) and stones (hard). Two examples of these tools are extracorporeal shockwave and burst wave lithotripsy, therapeutic ultrasound treatments using 4 to 40 MPa peak positive and -25 MPa peak negative pressure amplitudes and 100 kHz to MHz frequencies ultrasound waves, respectively, to break urinary stones (e.g., kidney and gall bladder stones). In burst wave lithotripsy, an array of ultrasound transducers emit focused ultrasounds waves that effectively fractionate larger stones due to the incident wave reflecting off the distal side of the stone switching sign and focusing to a maximum tensile stress. The negative pressure in the wave may lead to the generation of bubbles near the surface of the stone. The gas bubbles then respond to the burst wave by oscillating in volume, coalesce and forming larger bubbles, and/or collapse emitting shocks into the surroundings. The small stones have been shown to be most effective at eroding the stone.

To study these fluid-structure interaction problems, the challenge is to numerically simulate: (i) growth and coalescence of small bubbles in the bubble cloud to larger, resolvable bubbles and (ii) wave dynamics in the fluid(s) and nearby solid. During the oscillations, vapor can condense, gases can dissolve into the liquid, and vice versa across the bubble interface and affect the bubble dynamics. Unlike resolving a single bubble, resolving a population of bubbles in the bubble cloud is computationally unfeasible. These flows are typically modeled using a sub-grid model in an Eulerian framework [3, 4]. However, it is not well understood how to appropriately transition from a region in a bubble cloud where the unresolved (sub-grid) bubbles are sufficiently large to be resolved. Unlike the gas bubbles and surrounding liquid that lend themselves to an Eulerian framework, the nearby solid undergoes infinitely small to finite deformations that are well-suited to be captured in a Lagrangian framework. However, algorithmic complexity increases significantly with two separate solvers and coupling between them. Of the two current Eulerian approaches (i.e., hyperelastic (Godunov-based) and hypoelastic (conventional)) used to study wave dynamics and deformations in solids [2], the hypoelastic approach's algorithm is well-suited to incorporate elasticity to existing multiphase/multi-component numerical solvers [5]. Thus, we leverage the Eulerian numerical framework in the open-source Multi-component Flow Code (MFC) [1, 3, 8] in conjunction with (i) the heat and mass transfer relaxation approaches of [6, 7] and (ii) the hypoelastic numerical model of [5] to develop a numerical model and framework to solve multi-component fluid-structure interaction problems including multi-scale cavitation ranging from resolved singular bubbles to unresolved bubbles in a bubble cloud.

NUMERICAL MODEL AND METHODS

The open-source MFC solver, an Eulerian numerical shock- and interface-capturing method, is used to develop a unified numerical solver to solve 3D fluid-structure interaction problems with multi-scale cavitation. The solution is evolved in time using Runga-Kutta schemes. Approximate Riemann solvers (e.g., Harten-van Leer-Lax and contact, HLLC) in conjunction with a high-order accurate weighted essentially non-oscillatory schemes are used for upwinding the solution [1]. Bubble cloud model is an Eulerian-Eulerian sub-grid model [3] that resolves the cavitation bubble dynamics directly or models them via phase averaging, depending upon the characteristic length sizes and bubble number. The 6-equation numerical model of [6, 7] and associated relaxation procedures are solved to include heat and mass transfer (including phase change) at the material interfaces. As proposed by [5], evolution equations of the elastic contribution of the Cauchy stress tensor are solved to incorporate elasticity for material solid in the Eulerian numerical framework.

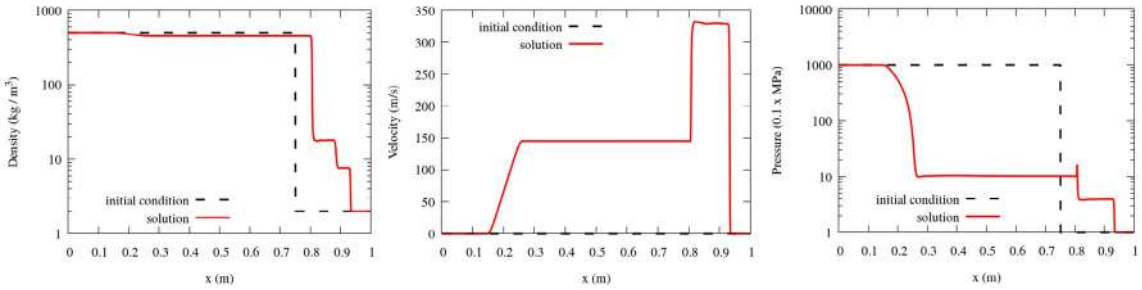

Figure 2: Dodecane liquid-vapor shock tube with mass transfer solved with MFC. The initial (black line) and numerical solution (red line) at $t = 400$ μs are shown.

RESULTS

A unified Eulerian numerical model and multiphase/multi-component framework for fluid-structure problems involving multi-scale cavitation has been developed using MFC. Figure 1 shows cavitation bubble dynamics simulations, the first two subfigures by MFC and third by the similar numerical framework of [5]. MFC has been validated for resolved, single spherical bubble dynamics (growth and collapse) with comparison to the numerical solution of the Keller-Miksis equation (see Fig. 1a) [8]. Numerical simulations of focused, burst wave lithotripsy experiments interacting with a bubble cloud at the surface of a cylindrical model kidney stone (represented by a stiff liquid) have been conducted in MFC to study the wave dynamics and damage mechanisms in the stone (see Fig. 1b) [4]. The numerical multiphase interface- and shock-capturing hypoelastic model of [5] and similar to MFC has been used to study the shock-induced single bubble collapse near a model spherical kidney stone (see Fig. 1c). The figure shows the transmission and internal reflection of the incident shock inside of the stone generating a focused region of tension (highlighted in red) inside of the stone as the bubble begins to collapse. Figure 2 shows the result of the dodecane liquid-vapor shock tube problem with mass transfer solved with MFC. The initial and numerical solutions at $t = 400$ μs are shown. A similar numerical solution of the density, showing the rarefaction, evaporation, contact and shock waves, velocity and pressure is also obtained by [7]. In addition to validation results, numerical simulations of fluid-structure problems involving the growth and collapse of a single bubble and/or bubble clouds with gas and vapor, undergoing phase change, in a liquid near a compliant or hard solid to understand the bubble and wave dynamics and associated damage mechanisms are also presented.

Summary We study the break-up of a gas bubble in a much denser turbulent flow, a crucial problem for bubble mediated gas transfer at the ocean-atmosphere interface, by performing ensembles of direct numerical simulations (DNS). We investigate the effect of the Weber number, We, defined as the ratio of turbulent and surface tension forces, on the bubble life time, the number of children and their size distribution. We confirm that life time is given by the eddy turnover time at its scale, with a much broader distribution in the vicinity of the critical We below which bubbles are stable. The number of children increases with We along with a wider distribution of radius. We propose a scaling law for the children number as a function of the mother We and the time elapsed since the mother break-up. We adapt a model for the size distribution, valid for binary break-up and all investigated We.

INTRODUCTION

The description of bubbles generated by breaking waves is of strong interest in the understanding of the interactions between the atmosphere and oceans [1], bubbles having a dramatic effect on gas transfer [2]. The smallest bubbles tend to dissolve in water whereas larger ones rise to the surface and collapse. The bursting of bubbles at the surface produces sea spray aerosols, that can be transported in the atmosphere and evaporate, playing a role in the thermodynamics of the atmosphere. As a consequence, improving the accuracy of climate models requires a better description of air entrainment and bubble statistics under breaking waves and a better understanding of the dynamics of bubbles in a turbulent flow. Moreover, bubbles in turbulence appear in other contexts, such as by air entrainment by ships and submarines, and they have practical implications in petroleum engineering for transportation in pipe flows [3].

The size distribution of bubbles under a breaking wave has been studied both experimentally [4] and numerically [5] and a model for the size distribution has been developed [6] for bubbles above a critical scale, the Hinze scale, which balances surface tension and deformation induced by turbulence. However, for bubbles below this critical scale, the statistics remains poorly characterized and the formation mechanisms are still to be determined [5]. The critical Hinze scale is equivalent to a critical Weber number, of order unity, W_{e_c}, and reads $d_H = C_\epsilon^{2/5}\epsilon^{-2/5}\sigma^{3/5}\rho^{-3/5}$, where ϵ is the turbulent dissipation rate, ρ the density of the liquid, σ the surface tension and $C_\epsilon \approx 2$ is a numerical coefficient. For bubbles initially close to the Hinze scale, binary break-up has been described and various models have been proposed for the size of the child bubble and the break-up time [7]. However, for Weber numbers far from the critical conditions, little quantitative information is available. In this study, we explore the physics of bubble break-up at various Weber numbers, and describe the resulting size distribution.

ENSEMBLE OF STATIONARY STATE SIMULATIONS AT VARIOUS WEBER NUMBER

We perform direct numerical simulation (DNS) of the two-phase, three-dimensional, incompressible Navier-Stokes equations with surface tension. We use the free software Basilisk, which is based on an spatial adaptive quad/octree grid allowing to save computational time while resolving the different length scales of the problem, combined with a geometric volume-of-fluid reconstruction of the interface [8]. As discussed in the recent review of Elghobashi [3], direct numerical simulations of two-phase turbulent flow are challenging, and so far bubble breakup in turbulence has only been studied using diffusive interface techniques.

The simulations are performed in a two-step process. First, we perform a precursor simulation and create an homogeneous and isotropic turbulent flow in a cubic box using forcing in real space as proposed by Rosales and Meneveau [9], and obtain a statistically stationary state, characterized by the Reynolds number Re_λ. Second, a bubble is injected in the box at a given time and we follow the bubble deformation and break-ups, the initial bubble being characterized by the Weber number W_e. Figure 1 shows a sequence of snapshot extracted from a numerical simulation performed at $Re_\lambda = 37$ and $W_e = 2$ in which two successives binary break-ups occur. We observe that the same numerical parameters but different instantaneous flow states lead to a variable bubble number and child size distribution, due to the chaotic nature of the velocity and pressure fluctuations. To account for the sensitivity to the initial conditions we follow a statistical approach, and perform an ensemble of simulations (between 20 to 40) for each set of parameters by considering different times in the precursor. Each simulation runs until a stationary state in terms of number of bubbles is reached: all child bubbles that could break have broken. We perform ensembles at $Re_\lambda = 37$ spanning various Weber numbers, $W_e \in \{2, 5, 10, 15\}$ and investigate sensitivity to Reynolds number with two more ensembles at $Re_\lambda = 76$ and $W_e \in \{2, 5\}$. The values of Reynolds number reached are typical of what is accessible in two-phase simulations of turbulent flow [3]. Mesh size

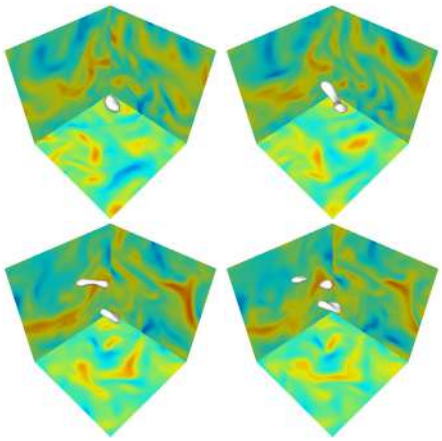

Figure 1: Snapshots of bubble break-up in turbulence from DNS of the two-phase Navier-Stokes equations using the solver Basilisk. Each background plane shows one component of the velocity. Bubbles interfaces are represented in white. Parameters are $R_{e_\lambda} = 37$ and $W_e = 2$. We observe two successive binary breakups leading to the creation of three child bubbles.

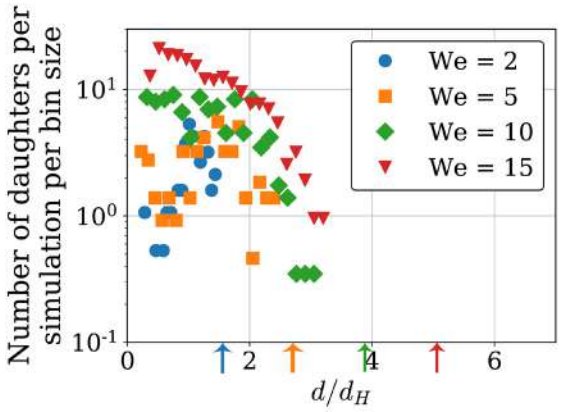

Figure 2: Child bubble size distribution for various initial Weber number for $R_{e_\lambda} = 37$, the diameter is made dimensionless by using the Hinze lengthscale d_H. The arrows represent the initial injection sizes for each ensemble. More bubbles of smaller sizes compared to the injection size are created when We increases.

convergence tests, as well as sensitivity tests to the adaptive mesh refinement criteria have been performed to ensure the physical accuracy of the results.

From this extensive data set, we analyze the final size distribution of child bubbles after multiple break-up events as a function of the initial Weber number. At low initial Weber number, $W_e = 2$ close from the critical Weber number, the majority of the break-ups are binary, with two child bubbles of similar sizes, just below the Hinze scale, as shown by the final averaged size distribution in fig. 2. This corresponds to a classic break-up scenario close to critical conditions, and described in previous studies [7]. At higher initial Weber number, $W_e > 10$, more bubbles are formed, with a broader distribution of sizes, with bubbles up to an order of magnitude smaller than the initial bubble, as shown in fig. 2.

Next, we analyze each break-up individually and characterize the life time of the bubbles as well as the number of bubbles being formed in a given time, for various instantaneous mother Weber numbers We^M. The life time of bubbles depends primarily on their Weber number and scales with t_c the eddy turnover time at the scale of the initial bubble, with the distribution of life times broadening for Weber number close to critical conditions. As multiple break-up events occur, we characterize the average number of bubbles, $\bar{N}$, created during a given observation time after the first break-up Δt, the first break-up defining the mother Weber number W_e^M. We obtain an empirical functional form $\bar{N} = f(W_e^M, \Delta t)$ which describe the entire range of Weber numbers that we explore and a duration time in the range $\Delta t \in [0, 9t_c]$. Finally we characterize the child bubble distribution when considering every break-up independently, depending on the Weber number of the mother, W_e^M, by modifying existing models in the literature [7]; which accounts for binary break-up and is valid at all Weber number.

In this work we have quantified how bubble break-up in turbulence is controlled by the relative strength between the turbulent fluctuations and the bubble cohesion due to surface tension. We have described both the statistical and the dynamical properties through the analysis of the bubble life time, the children size distribution at infinite and short times, and the number of child bubbles. This work paves the way for further theoretical description of bubble break-up in turbulence.

Summary We consider centimetric disks that float at the water-air interface as a result of the equilibrium between the disk's weight, the hydrostatic force and the surface tension force. We first show that the water surface reaction can be approximated by a linear spring force if the disk radius is much larger than the capillary length. We then overview recent experimental and theoretical work on the frictional force experienced by a disk in motion and the capillary attraction force between two disks, and show that these forces are adequately captured by relatively simple analyses.

INTRODUCTION

A solid body can be supported at the water-air interface by virtue of the equilibrium between its weight $m\vec{g}$, surface tension force $\vec{F}_\sigma$ and hydrostatic force $\vec{F}_h$ (fig.1(a)) [1]. Here we consider cylindrical disks with radius R that deform the underlying interface by a displacement δ. The interface is pinned to the bottom perimeter of the disks.
We report our recent work on three forces experienced by these capillary disks: the vertical force that results from hydrostatic pressure and surface tension; the horizontal friction force experienced by a disk in sliding motion [2]; the horizontal attractive capillary force between two disks [3].

VERTICAL FORCE AS A LINEAR SPRING

The vertical force balance [4] on a disk yields

$$mg = \pi R^2 \rho g \delta + 2\pi R \sigma \sin\theta. \tag{1}$$

where σ is the surface tension, ρ the liquid density and θ the angle formed by the interface with the disk contour. The relevant length scale in this problem is the capillary length $l_c = \sqrt{\sigma/\rho g}$, which for water at room temperature is $l_c \approx 2.7$ mm. Assuming $\delta \ll l_c$ and $R \gg l_c$ one can show that the liquid profile is described to leading order by $u(r) = -\delta\, \mathrm{e}^{-(r-R)/l_c}$ [5], which yields $(\mathrm{d}u/\mathrm{d}r)_{r=R} = \delta/l_c = \tan\theta \approx \sin\theta \approx \theta$. As a result, equation 1 can be rewritten as $mg = k\delta$, which highlights the fact that the combination of hydrostatic and surface tension forces in equation 1 act as a linear spring with effective spring constant

$$k = \pi\sigma(Bo + 2\sqrt{Bo}), \tag{2}$$

where $Bo = \rho g R^2/\sigma = (R/l_c)^2$ is the Bond number. We compare our approximation to numerical solutions of the non-linear Young-Laplace equation (fig. 1(b)). Our result remains a very good approximation even for $\delta \sim l_c$, provided that $R \gg l_c$, thus extending the regime of validity of the linear spring constant in equation 2.

HORIZONTAL FRICTION FORCE

A disk sliding on the water-air interface (*slider*) experiences a friction force that is principally dominated by skin friction [2] (fig.1(c)). Skin friction results from the viscous boundary layer that forms underneath the disk. Interestingly, an analytical expression of this friction force can be obtained when the boundary layer can be considered as quasi-static. This occurs when the typical time scale for the boundary layer to develop [6] $t_{BL} = R/v$ is small compared to the typical time scale of acceleration (or deceleration) of the disk $t_D = m/\rho\sqrt{\nu v R^3}$, where v is the instantaneous body speed and ν the liquid kinematic viscosity. t_{BL} is obtained by balancing fluid inertia and viscous stress and t_D by balancing the disk's inertia and viscous stress. The ratio t_{BL}/t_D yields the dimensionless *sliding number*

$$S_l = \frac{\rho}{m}\sqrt{\frac{R^5\nu}{v}}, \tag{3}$$

which can also be obtained as the ratio between fluid inertia and body inertia. When $S_l \ll 1$ the boundary layer is quasi-static and the Blasius boundary layer theory [7] can be applied, yielding an expression for the friction force

$$F_D = \alpha\rho\sqrt{\nu}R^{3/2}v^{3/2}, \tag{4}$$

where $\alpha = 1.64$. In figure 1(d) we show a number of experimental data sets collapsed by this analysis.

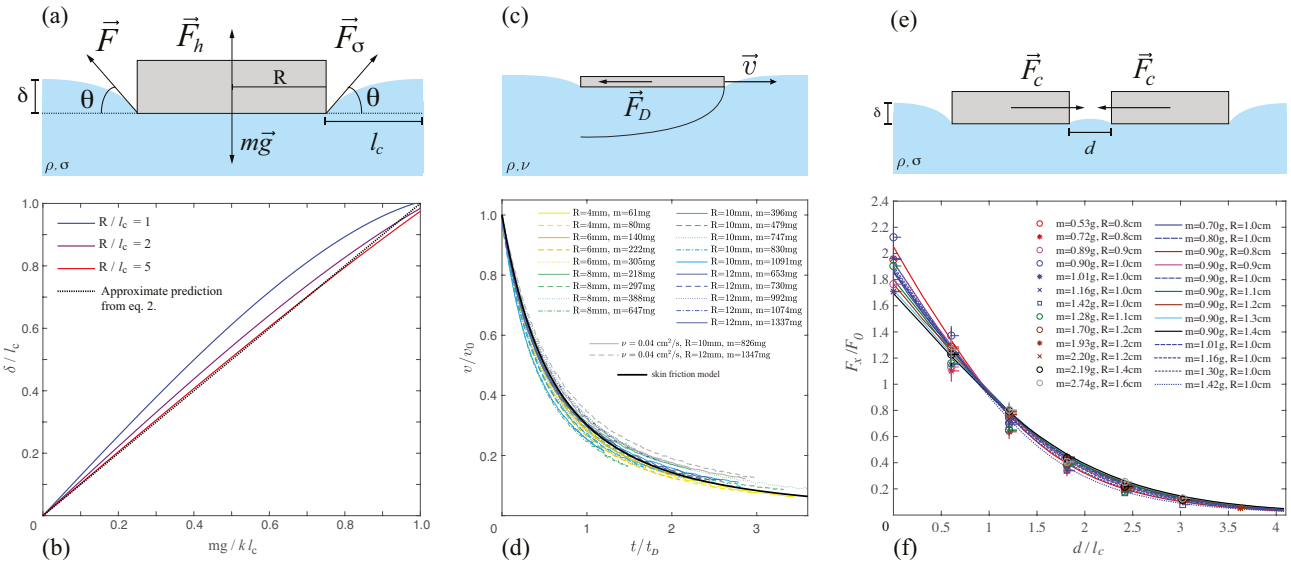

Figure 1: (a) Side view schematic of a disk resting on a water-air interface. (b) Comparison of numerical solutions of the Young-Laplace equation (continuous lines) to the prediction obtained in the limit $\delta \ll l_c$ and $R \gg l_c$ (dotted line). (c) Side view schematic of a sliding disk and the boundary layer in the underlying fluid (not to scale). (d) Collapse of deceleration data. The black line is $v(t)/v_0 = 1/(1+\alpha t/t_D)^2$ as derived from the quasi-static boundary layer theory. (e) Side view schematic of the capillary attraction between two disks. (f) Collapse of data of the capillary attraction force. In all figures, R is the disk(s) radius, m the mass and ν the liquid kinematic viscosity. Unless otherwise specified, $\nu = 0.01$ cm^2/s.

HORIZONTAL CAPILLARY FORCE

We now consider the interaction force between two disks resting at the water-air interface [3] (fig.1(e)). It is well known that two particles trapped at a fluid interface may interact due to the deformation they induce on the free surface [8], but only a few direct measurements of the capillary attraction force between macroscopic floating bodies have been reported [9]. We performed direct measurements of the force between centimetric disks floating at an air-water interface. We developed a custom experimental setup which uses a magnetic force to balance the capillary attraction force and characterised how the attraction force depends on the disk mass, diameter and relative spacing. Experimental results are captured by numerical simulations that take into account the disk's vertical displacement and spontaneous inward tilt, highlighting the significance of the latter. Moreover, a relatively simple scaling analysis can be developed assuming small deformations $\delta \ll l_c$, large disk size $R \gg l_c$ and nearby disks $d \ll l_c$, where d is the distance between the disks (fig.1(e)). In these limits, the hydrostatic component of the attractive force is small relative to the contribution from surface tension, and the capillary attraction scales with

$$F_0 = \sigma \frac{\delta^2 R^{1/2}}{l_c^{3/2}}, \tag{5}$$

where δ can be derived from eq. 1. In figure 1(f) we show a number of experimental and numerical data sets collapsed by this scaling analysis.

CONCLUSIONS

We have summarised recent comprehensive work on the vertical, horizontal, and interaction forces experienced by capillary disks at the water-air interface. Quantifying the forces these bodies experience is relevant to the understanding of the motion of living organisms at the water-air interface [10] and may inform the design of aerial-aquatic microrobots for environmental exploration and monitoring [11].

NUMERICAL STUDY OF DROP BOUNCING ON A FLUID-FLUID INTERFACE

Jean-Lou Pierson[1]
[1] IFP Energies Nouvelles, Rond-point de l'echangeur de Solaize, 69360 Solaize, France

Summary We investigate numerically the motion of an axisymmetric drop toward a fluid-fluid interface. This free boundary problem is solved by a Volume of Fluid method. Thanks to an Adaptative Mesh Refinement technique the thin film located between the drop and the interface can be resolved. Particular attention is given on the influence of each dimensionless parameters driving the problem dynamics. When viscous and inertia effects have comparable orders of magnitude the drop velocity decreases monotonously to zero as it approaches the interface. When inertia effects are larger than viscous effects a strikingly different behaviour is observed : the drop bounces back from the fluid-fluid interface. We identify the underlying mechanisms necessary for bouncing and discuss them in connection with several other canonical situations such as the bouncing of a solid sphere or a drop on a wall.

INTRODUCTION

In the chemical industry, fluid-fluid separators are frequently used to separate a dispersed phase from a surrounding fluid. Different kinds of processes exist such as hydrocyclone, flotation and gravity separator. For the latter the main separation mechanism is the buoyancy force due to the density difference between the two phases. The speed at which the drops can rise and coalesce is often a key factor in the efficiency of such a process. The aim of the present study is to investigate the rise of an axisymmetric droplet toward a fluid-fluid interface as an idealisation of the full process.

Many researchers have focused on the film drainage problem when the film present between the drop and the interface becomes sufficiently thin to allows a lubrication type analysis (see for instance [1] for a review). Very few papers have investigated the full dynamics of the drop when it is released far form the interface. Chi & Leal [2] have performed a numerical investigation of a drop rising towards a fluid interface in the Stokes regime. They showed that the decrease of the film thickness is dramatically affected by the viscosity ratio. Mohamed-Kassim & Longmire [6] have investigated experimentally the impact of a drop on a fluid-fluid interface in inertial regimes. They showed that the drop can bounce at the interface. To better understand the characteristic mechanisms leading to bouncing, we carry out an extensive numerical investigation of this problem.

NUMERICAL METHODOLOGY AND PROBLEM DEFINITION

Computations are carried out by solving the full Navier-Stokes equations using the Volume of Fluid approach implemented in the Basilisk code [7] (see also basilisk.fr). The corresponding finite-volume spatial discretization schemes make use of a graded quadtree partitioning. An Adaptative Mesh Refinement technique is used to accurately catch the dynamics of the thin film. This technique enables us to accurately describe the film up to the minimal thickness of $5 \times 10^{-3} D$ where D is the initial drop diameter. The simulations are stopped once this criterion is reached.

The problem is governed by 4 dimensionless parameters : the Archimedes number (Ar) which can be seen as Reynolds number based on gravitational velocity, the Bond number (Bo), which compares buoyancy and surface tension forces, the viscosity ratio (λ) and the density (ζ) ratio. The Archimedes number is varied by 1 order of magnitude, the Bond number and viscosity ratio by 3 orders and the density ratio is fixed to 0.9. Depending on the value of these parameters, a variety of flow regimes, rising velocity, decrease of the film thickness and bouncing are observed. In this talk we shall focus on the main mechanisms governing the appearance of the bouncing regime.

BOUNCING MECHANISMS

Figure 1 (a) reveals the strong dependence of the terminal velocity (which can be observed for $z/D \leq -2$) on the viscosity ratio when $Ar = 4$. For the range of Bond numbers presented in figure 1 (a), the terminal velocity is almost insensitive to the Bond number. When $Ar = 40$ (figure 1 (b)) a much stronger dependence of the steady velocity on the Bond number is observed. The most striking difference bewteen figure (a) and (b) is the presence of bouncing (negative velocity) when the drop reaches the interface for $Ar = 40$. Why is the rebound promoted by larger inertia effect ? The explanation lies in the value of the Stokes number which characterizes the particle inertia relative to viscous force, and scales as ζAr. This compares well to the bouncing of a solid sphere on a wall [3]: when the Stokes number is smaller than a critical value, viscous effect dissipates all the surface energy stored by the small deformation of the particle and as a results it does not bounce.

During the bouncing of a drop at high Bond number important deformations, of both the drop and the interface are observed (figure 2). By comparing figure 2 (a) and (b) it appears that the shape of the drop does not change much when the drop approach the interface, whereas the interface undergoes more pronounced deformations. As first shown by [6], the interface deformation appears sooner than drop deformation because surface tension effect are larger within the drop. In figure 2 (c), the drop takes a hemi-spherical shape while the interface follows closely the drop shape. The drop upper

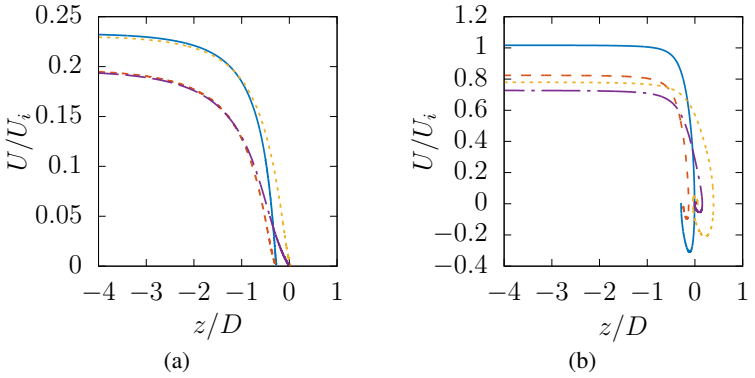

Figure 1: Rising velocity as function of the drop position with respect to the initial position of the horizontal interface. — $\{Bo = 1, \lambda = 1\}$, – – $\{Bo = 1, \lambda = 10\}$, -- $\{Bo = 10, \lambda = 1\}$, –·– $\{Bo = 10, \lambda = 10\}$. (a) $Ar = 4$, (b) $Ar = 40$.

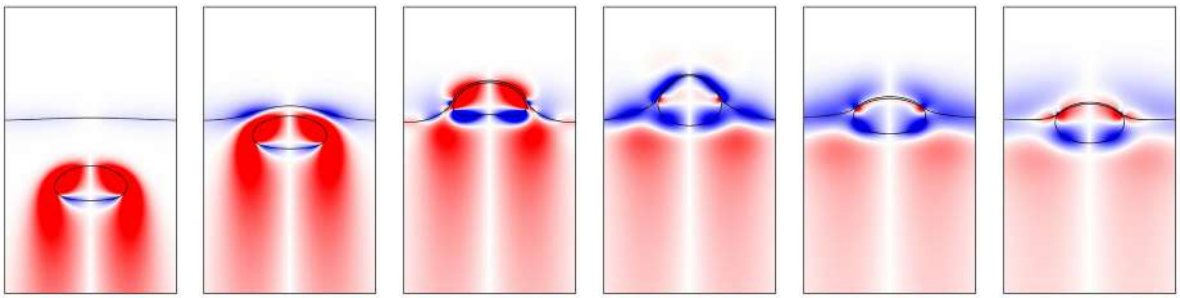

Figure 2: Drop rising toward a fluid-fluid interface, $Ar = 40$, $Bo = 10$, $\lambda = 1$. The time interval between each frame is $t = 1.2t_i$ where t_i is the inertial time scale. Colors refer to the magnitude and sign of the azimuthal vorticity.

part keeps an upward velocity as evidenced by the positive (red) vorticity contours. Due to this velocity the maximum height reached by the drop is increased in figure 2 (d). The drop is surrounded by negative vorticity contours which means that the drop and the interface undergo a downward motion. This bouncing behaviour has two possible candidates : the first one is based on the surface energy due to the deformation of the drop as evidenced by [5] when studying a drop bouncing on a wall. However in the present configuration this is not a convincing explanation since the surface tension force is negligible ($Bo = 10$). The privileged explanatation relies on the downward oriented buoyancy force, induced by the interface deformation, which acts on the drop [4].

CONCLUSION

A computational investigation of the rise of a drop toward a horizontal fluid-fluid interface allowed us to identify the key ingredients for bouncing. In particular, when the Stokes number associated with the drop is of order 1 the drop velocity decreases monotonously to zero, while for larger value of the Stokes number bouncing of the drop is observed. For high Bond and high Archimedes numbers the deformation of both the interface and the drop are important during the impact. We showed that the bouncing in this regime is mainly explained by the interface deformation.

A DROP DOES NOT FALL IN A STRAIGHT LINE: A RATIONALE FOR THE WIDTH OF STALAGMITES

J. Parmentier *[1], S. Lejeune[1], M. Maréchal[2], F. Bourges[3], D. Genty[4], V. Terrapon[1], J.-C. Maréchal[2], and T. Gilet[1]

Summary Drops loaded in calcium ions detach from stalactites and impact the underlying stalagmites, thereby allowing these latter to grow through calcite precipitation. Nevertheless, little is known about the influence of the drop free fall and splash dynamics on stalagmite shape and width. Through high-speed imaging of impacting drops on stalagmites from several caves, we observed that the impact point position of the drops is scattered, sometimes over several centimetres. We show that this dispersal has no external cause and must, therefore, be self-induced. Using a Langevin-like equation, to describe the free fall in response to gravity and aerodynamic forces, we then propose a prediction of the impact point dispersal as a function of the falling height travelled by the drops. We finally show that measured stalagmite widths are correlated to the impact point dispersal of the drop.

INTRODUCTION

Beyond their outstanding beauty, stalagmites help to understand past climate and hydrology. Measuring e.g. the size variations of the annual laminae seen in vertical cross sections of stalagmites give information on the precipitation history in regions where ice or sediment cores cannot be used [1]. While the chemical reactions underlying the slow growth of the stalagmites is fairly well understood, little is known about the fluid dynamics at play during their formation. The calcite is brought by drops detaching from the stalactite. The drops fall and impact a very thin film of water that covers the stalagmite. For most stalagmites, the drop velocity is sufficient to generate a splash, with the formation of a corona and secondary droplets (Figure 1).

In previous models of stalagmite growth, it was commonly accepted that drops fall on a straight vertical line from the stalactite, thereby feeding the stalagmite film from one central point [2]. However, our high-speed movies revealed that the impact points of drops originating from a single stalactite are scattered, sometimes over several centimeters (Figure 2).

MATERIALS AND METHODS

We have taken high-speed movies of drops splashing on a wide variety of stalagmites as well as still pictures of stalagmites only, in seven different caves of the south of France. The radius, velocity and impact point of the drop, along with the radius of the spreading lamella formed at impact and the stalagmite width, were measured by image processing. Additional data were also taken in a more controlled lab setting, for a drop radius similar to that encountered in natural conditions.

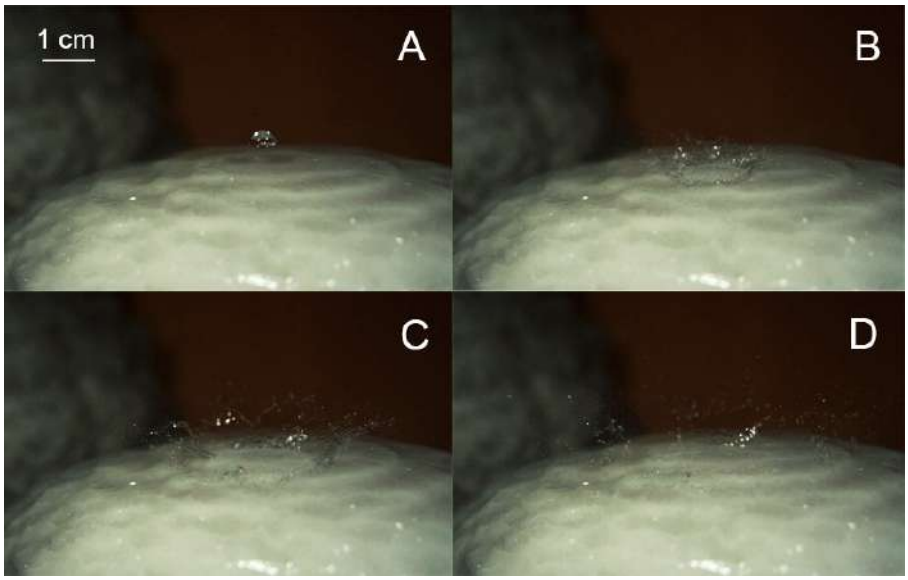

Figure 1: (A-D) Time sequence of the impact of a drop on a stalagmite (Orgnac cave, South of France), with lamella spreading and crown formation. All frames A-D are separated by 1.9 ms. (A) The drop of radius 2.61 mm at most 625 μs before the impact. (B) Formation of the crown at least 625 μs after the drop crushed on the stalagmite. (C) Spreading of the lamella in the water residual film and ejection of secondary droplets. (D) Fragmentation of the crown. The lamella has reached the stationary value $r = 2.3$ cm, around 7 ms after the initial impact.

RESULTS

Our measurements show that drops falling from the ceiling of caves all have the same radius and that the size of the fluid lamella formed by their impact on the stalagmite is weakly dependent on the drop velocity. On the other hand, drops falling from higher ceilings are faster and more dispersed. We postulate that drops do not fall straight, but rather follow a wavy trajectory owing to their aerodynamic interaction with the surrounding air. This hypothesis does not come out of the blue; the same phenomenon is also observed in a controlled lab environment, where the falling drops are protected from parasitic air currents. Furthermore, the airflow measured in caves could only cause a deviation of a few millimeters at most.

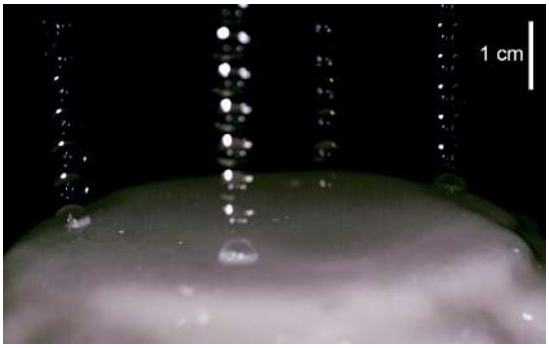

Figure 2: Drops coming from the same stalactite fall in different locations on the stalagmite below (Orgnac cave, South of France). This image was obtained by superimposing frames showing the trajectories followed by four drops landing on this stalagmite. For each drop the frames are separated by 625 μs, from the moment the drop appears in the field of view, up to right before impact.

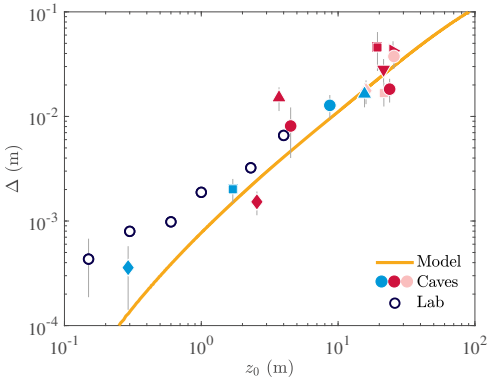

Figure 3: Standard deviation Δ of impact point position as a function of the falling height z_0. The solid curve is obtained by solving numerically the recurrence relations obtained for the drop position and velocity. Hollow symbols correspond to data from a lab setting, and solid symbols to in situ measurements, both obtained with high-speed videos. (Credit: The Royal Society 2019 [3])

The aerodynamic force acting on a drop considered spherical, can be formulated as follows:

$$\mathbf{F} = -C_d \frac{\rho_a S \left|\dot{\mathbf{X}}\right|}{2} \dot{\mathbf{X}} - C_l \frac{\rho_a S \left|\dot{\mathbf{X}}\right|}{2} \mathbf{e}_r \times \dot{\mathbf{X}} \tag{1}$$

where ρ_a is the air density, S is the cross-sectional area of the drop perpendicular to its motion, $\mathbf{e}_r$ is a unit vector of random direction in the plane perpendicular to the velocity vector of the drop, $\dot{\mathbf{X}}$, and C_D and C_L are the drag and lift coefficients, respectively. The first contribution of this force, the drag, is responsible for the saturation velocity reached by drops falling from very high ceilings ($z_0 > 20$ m). The second term of the equation represents a lift force which originates from the wake of the drop. Above a Reynolds value of around 212, which is still laminar though, the break of symmetry in the wake of the drop induces the shedding of randomly oriented vortices at a frequency increasing with the drop velocity. It is assumed that each of these vortices pushes the drop in a direction opposed to that of its emission, therefore deviating the drop from its original position and creating a random walk-like trajectory.

Integrating the horizontal projection of Newton's equation over one vortex shedding period yields two discrete equations for the position and velocity of the drop. An ensemble average over many falling successive drops allows to estimate the horizontal dispersal as a function of the falling height of the drop (comparison with lab and cave measurements in Figure 3).

The width of several dozens of stalagmites is finally related to the size reached by the liquid lamella formed at impact and to the impact point dispersal. For small falling heights, the stalagmite width is mostly set by the maximum spreading of the lamella, while for large falling heights, the stalagmite radius increases proportionally to the impact point dispersal.

CONCLUSION

We show that there is a strong positive correlation between the falling height, the impact point dispersal and the stalagmite width. We propose a theoretical model of the fall of the drop that includes aerodynamic forces. Owing to some lift of random direction that represents the effect of vortex shedding, the drop experiences a random walk, and its impact point on the stalagmite is scattered.

COLLIDING MERGING OF BINARY IMMISCIBLE DROPLETS

Chu-Po Huang[1], and Kuo-Long Pan *[1]
[1] Department of Mechanical Engineering, National Taiwan University, Taipei, Taiwan, R.O.C.

Summary Two types of merging between immiscible drops in collision are studied. Depending on the interfacial tensions among the three media, including air and two liquids at equilibrium with negligible motions, partial and complete engulfing between the drops can be identified. With impact inertia, it may yield adhesive merging, where two drops adhere to each other, or encapsulation, where the softer drop engulfs the harder one. Based on two parameters, a Weber number and an impact parameter, we have created a regime diagram that indicates the parametric conditions of various outcomes. While the contact result between two drops at rest can be analyzed by a free-energy approach, those with substantial motions need to consider the impact energy. Via an analysis based on the conservation of energy, a model is built to predict the critical Weber number of transition between two regimes of merging.

INTRODUCTION

There has been considerable research aiming to understand the fundamentals of binary droplet collisions. Depending on the collision Weber number (We) and the impact parameter (B), which characterize, respectively, the ratio of impact inertia to surface tension and the relative directions of the colliding drops, two identical droplets may coalesce permanently, rebound, coalesce temporarily followed by creation of satellite droplets, or coalesce temporarily followed by rotational/stretching separation when the impact trajectories of the drops are sufficiently off-centered.

Previous studies have been mostly concerned with identical liquids and thus show a symmetric pattern of two identical drops during head-on impact. An intriguing topic of considerable relevance, but much less considered, is the collision between droplets of diverse properties [1], particularly when they are immiscible. Specifically, it was found in [2] that a droplet can merge (macroscopically) with another droplet made of immiscible liquid, instead of bouncing as would be expected. This suggests a different form of coalescence which is distinct from the general one caused by miscibility at a microscale level. Depending on various factors to be explored, the 'soft' drop with lower surface tension may attach to the hard drop with higher surface tension, with the interior liquid either exposed non-uniformly to the surroundings, or totally encapsulated, as shown in Fig. 1. To realize the behaviors and transformation, the key factors such as the effects of fluid material properties (disparities in surface tension and viscosity, molecular formulation), the geometrical conditions of the drops (size and volume ratio) and kinematic conditions (impact inertia and colliding path orientation) are studied to understand anisotropic droplet collisions.

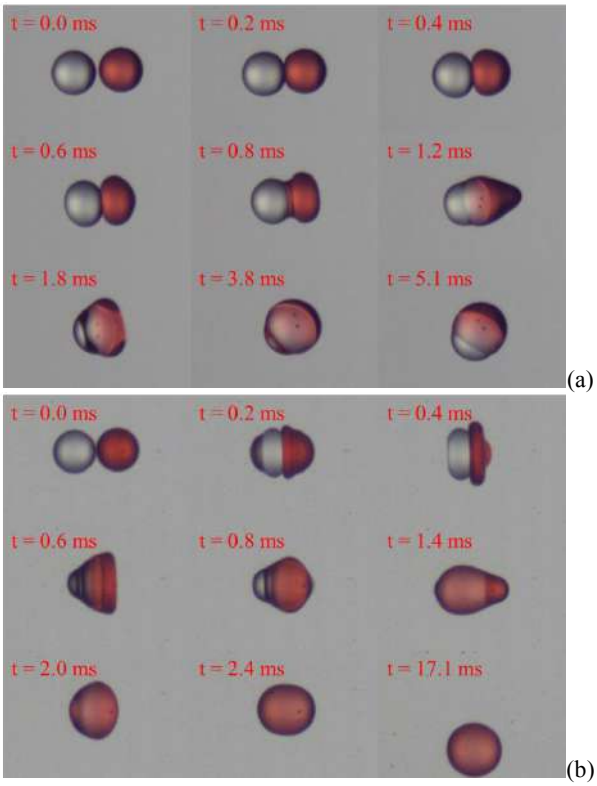

Figure 1. Collisions between a water droplet and another made of (a) heptadecane showing adhesive merging and (b) hexadecane showing encapsulation.

EXPERIMENTAL SETUP

The experimental setup was similar to that described in [3]. Two identical droplets were generated by nozzles that were triggered by the vibration of piezoelectric plates. They were made to impinge onto each other with adjusted angles of the colliding path. Time-resolved images were either taken through stroboscopy synchronized with the droplet generation circuit or recorded by a high-speed CMOS digital camera, which supported a maximum resolution of 512×512 pixels with 5100 frames per second (fps). The shutter of the high-speed camera was synchronized with a LED lamp that can support the shortest duration of 1 μs, so as to capture images with sufficiently small exposure and adequate light intensity while avoiding slurring due to background scattering.

RESULTS AND DISCUSSION

In this work, the regime diagrams for the impact between two immiscible droplets have been obtained for the first time. For the conditions at low or moderate We, the collision outcomes basically follow that of static cases which can be predicted by using the free-energy analysis [4]. For the impact of two drops made of immiscible liquids, based on the

*Corresponding author. E-mail: panpeter@ntu.edu.tw.

interfacial tensions between each pair of the three phases, the contact outcome of immiscible drops follows the minimization of free energy at equilibrium, as indicated by Fig. 2.5. Here the spreading parameters are defined as

$$S_1 = \sigma_{23} - (\sigma_{12} + \sigma_{13}),\ S_2 = \sigma_{13} - (\sigma_{23} + \sigma_{12}),\ S_3 = \sigma_{12} - (\sigma_{13} + \sigma_{23}).$$

While not shown herein, in the situations of weak impact inertia, the experimental results basically agree with that predicted for the static cases in terms of equilibrium evaluation, whereas some variations shall be concerned, such as evaporation of volatile liquids which would change surface tension due to ambient conditions like temperature or Marangoni effects due to spatial gradients of surface tension, particularly when the predicted values are near the thresholds. This gives a demonstration for extension and application following similar tracks of droplet interaction such as synthesis of biological materials or medicines. On the other hand, one of the motives for this research is to understand why most studies have reported encapsulation but not adhesive coalescence [5]. Indeed, by using the present approach, it is found that while adhesive coalescence is expected to occur at static situation, with substantial impact inertia, insertive motion can be created and lead to encapsulation spanning for a noticeable range of Weber number as seen in Fig. 2.

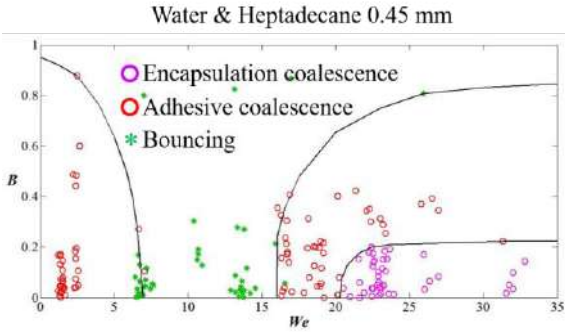

Figure 2. Regime diagram of H_2O-$C_{17}H_{36}$ collision in terms of *We* and *B*.

To predict the parametric conditions of transition from adhesive coalescence to encapsulation with increasing inertia relative to surface tension, we have derived a criterion based on the conservation of energy.

$$\frac{1}{2} * (\rho_1 + \rho_2) * \frac{1}{6}\pi D^3 \left(\frac{1}{2}U\right)^2 + \pi D^2 * (\sigma_1 + \sigma_2) = \pi D^2 * \left(2^{\frac{2}{3}} * \sigma_2 + \sigma_3\right) + \mu * \frac{U^2}{D^2} * \pi D^3 * Z * t$$

This is further reduced to $A \times \sigma_2 D^2 + C \times \rho_2 U^2 D^3 = Z \times G \times \mu_2 D U^2 \times \tau$, where *A*, *C*, and *G* are the coefficients to be fit for surface energy, kinetic energy, and viscous dissipation, respectively. They express $(\sigma^* + 1) - \left(2^{\frac{2}{3}} + \sigma_3/\sigma_2\right)$, $(\rho^* + 1)/48$, and $(\mu^* + 1)$, respectively, where $\sigma^* = \sigma_1/\sigma_2$, $\rho^* = \rho_1/\rho_2$, and $\mu^* = \mu_1/\mu_2$. By using the modified characteristic time of oscillation: $\tau = \frac{\pi}{4}\sqrt{\frac{2\rho_1 D^3}{\sigma_1}}$, the relation between *We* and *Oh* which indicates the transformation boundary can be obtained as:

$$We = 1/\left(\frac{Z}{A} \times G \times Oh \times \frac{\pi}{4} \times \sqrt{\frac{2\rho^*}{\sigma^*}} - \frac{C}{A}\right),$$

where $We = \frac{\rho_2 D U^2}{\sigma_2}$ and $Oh = \frac{\mu_2}{\sqrt{\sigma_2 \rho_2 D}}$. This transition from adhesive coalescence to encapsulation with increasing *We* only occurs for fluids that allow for formation of partial encapsulation, thus being observed in the present experiments of water-hexadecane and water-heptadecane. In a comparison, it is seen in Fig. 3 that the theoretical model basically predicts the experimental results. Furthermore, the experimental results of [2] that show encapsulation are indeed located in the area above the theoretical curve. More data and refinement would be investigated to improve the model.

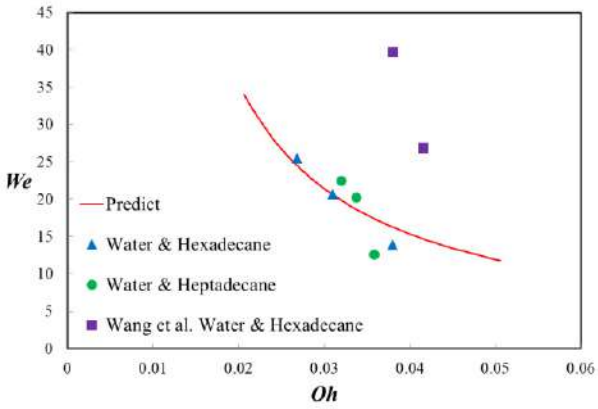

Figure 3. The transition boundary between adhesive coalescence and encapsulation given by the model and experimental results.

CONCLUSIONS

Regime diagrams are obtained by using techniques for generating controlled droplets with high accuracy in binary droplet collision of immiscible liquids. Two types of coalescence, adhesive and encapsulation, are analyzed by using a free energy analysis for near equilibrium configuration. Impact dynamics can change adhesive coalescence to encapsulation, but not the other way around. A phenomenological model is built to identify the transitional trend. While the consequences of tested liquids mostly follow the analysis, some need delicate concerns due to property variations such as surface tension/temperature (water-hexadecane) and surfactant/Marangoni effect (water-octanol).

DROPLET GENERATION IN ENSEMBLES OF RANDOMLY CORRUGATED LIGAMENTS

Sagar Pal *, Marco Crialesi-Esposito, Daniel Fuster, and Stéphane Zaleski
Institut Jean le Rond d'Alembert, Sorbonne Université and CNRS, Paris, France

Summary This study focuses on a description of droplet sizes, created as a result of capillary-induced breakup of ligaments. Direct numerical simulations of air-water systems are employed by solving the two-phase Navier-Stokes equations with surface tension. The breakup of individual ligaments are triggered by initial surface corrugations, the subsequent evolution of which is governed by deterministic dynamics. Stochasticity is introduced in the mix by conducting an ensemble of numerical simulations of slender corrugated ligaments, each realization corresponding to a random but unique initial configuration. Probability density functions of the droplet sizes are computed using different ensemble sizes. These results combining the effects of stochasticity with the capillarity-driven non-linear dynamics facilitate our understanding of the nature of drop size distributions encountered in realistic and complex fluid fragmentation scenarios.

INTRODUCTION & METHODOLOGY

Ligaments constitute the penultimate stage in the complex sequence of capillary-driven topological changes that are typical of liquid fragmentation processes, finally resulting in the generation of polydisperse collections of drops. There are several hypotheses in existing literature [1] that attempt to explain the physical mechanisms responsible for the selection of droplet size. A popular model [2] asserts that the polydispersity in the droplet sizes is strongly correlated to the corrugations initially present in the ligaments from which the drops originate. But so far, neither experimental nor numerical studies have been conducted with the aim of improving our understanding of how droplet size distributions are influenced by the corrugation-coalescence driven mechanism. In the present study, we have developed a numerical experiment that grants us precise control over both quantitative and qualitative aspects of such random corrugations, and its subsequent influence on the resulting droplet sizes. We perform direct numerical simulations of the two-phase Navier-Stokes equations under the incompressible framework. Material properties correspond to that of air-water systems at 20 degrees Celsius. Simulations are carried out in the axi-symmetric framework, therefore excluding the existence of azimuthal modes with respect to the central axis of the ligament. The ligaments are initially at rest, but rapidly destabilize and evolve into droplets due to the initial surface corrugation (large potential energies). We perform many such realizations, each corresponding to a slender ligament with random surface corrugations, simultaneously ensuring that the random profile is unique to that particular realization. Finally, we provide a statistical description of the droplet size distributions using different ensemble sizes. A detailed exposition of the key aspects of our methodology are discussed ahead.

Numerical Method

We use the open-source toolbox Basilisk [6], which couples finite-volume discretization on octree meshes to solve the two-phase Navier-Stokes equations. The one-fluid formulation with variable density and viscosity is adopted, where the interfacial description and transport is carried out under the Volume-of-Fluid framework coupled with hight function based interface curvature modeling. The solver utilizes a robust and accurate implementation of the surface tension force distribution across the interface, which has been extensively validated in existing literature. More details regarding the numerical schemes involved can be found in Popinet (2009) [5] .

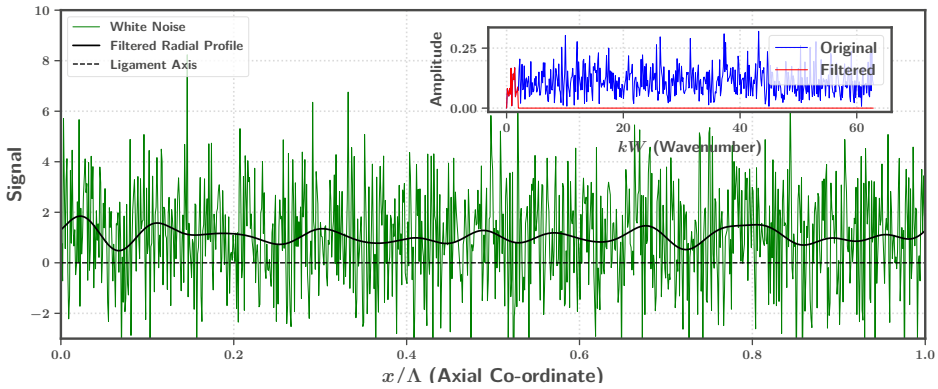

Figure 1: Axial profile of the ligament radius for one spatial period. Inset : Spectral densities of the original and filtered signals.

Surface Corrugation

We consider infinitely long ligaments having zero initial kinetic energy, with spatial periodicity along the axis. A robust random (white) noise generation [4] algorithm is treated by a low-pass filter in order to obtain the shape of the radial profile along the axis of the ligament (fig. 1). The radial profile corresponding to an individual ligament simulation is uniquely determined by the value of the seed used as input for our random noise generator, therefore we are able to ensure that none of the ligaments in our ensembles are identical by simply using unique seeds for each realization. The amplitude of the surface corrugations are controlled by the dispersion of the initial white noise signal. The volume of the corrugated ligament per unit spatial period is controlled by our choice of ligament aspect-ratio.

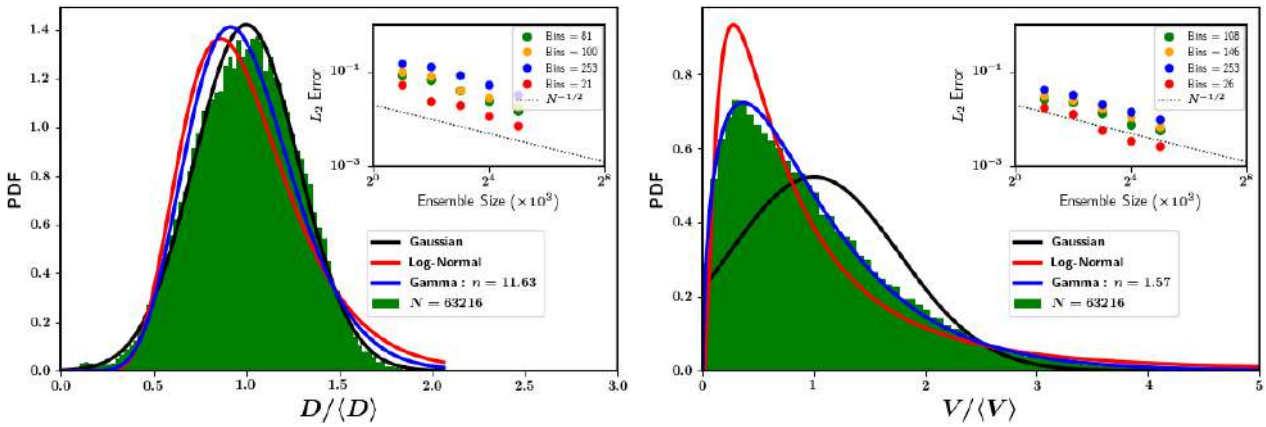
*Corresponding author. E-mail: sagar.pal@dalembert.upmc.fr

Parameter Space

The ensemble is generated by a fixed cut-off wavenumber (normalized by ligament width), a fixed amplitude of the corrugations (normalized by ligament radius), a fixed aspect-ratio of the ligament and the time at which the drops are counted (rescaled by capillary time-scale) denoted by K , ϵ , Λ and T respectively. The aspect-ratio is the length of one spatial period divided by mean width of the initial ligament. In addition, we use Ohnesorge (Oh) number based on the heavier fluid to characterize our ensembles, with $We = 0$ due to the absence of initial kinetic energy. To summarize, the ensemble is completely determined by a point in the parameter space defined as $\Phi \equiv (Oh, K, \epsilon, \Lambda, T)$.

RESULTS & CONCLUSIONS

We present the statistical distributions of droplet sizes and volumes in fig. 2 , which originate from ligament ensembles characterized by $\Phi_0 \equiv \left(Oh = 10^{-2}, K = 2\pi, \epsilon = 0.50, \Lambda = 50, T = 30.0\right)$. The choice of Oh number correlates to millimeter length-scale in air-water systems. The Gaussian and Log-Normal curves are not *fitted* to the histograms, instead, they are determined using the mean and variance of the original data sets. The gamma distributions are defined as proposed in Villermaux et al. [2], are subsequently plotted using values of 'n' corresponding to the best fits to the histograms.



(a) Normalized Diameter

(b) Normalized Volume

Figure 2: Probability Density Functions. Inset: Error convergence with respect to ensemble sizes.

The droplet diameters are most accurately described by a normal distribution, and droplet volumes best described by gamma distributions. Several binning criteria were used to determine the optimal bin-width. Additionally, the numerical experiments were repeated for several different ensemble sizes, with the largest ensemble containing approximately $64,000$ droplets. We observe that the characteristic shapes of the distributions and corresponding fits to the data are independent of both the binning criteria as well as ensemble sizes (not shown). We compute the error of the PDFs for different ensemble sizes, relative to the largest ensemble. A $N^{-1/2}$ scaling is observed (fig. 2 inset), strongly suggesting the absence of any hidden correlations in our numerical experiments. In our ensemble, mean droplet size is rescaled with respect to the initial ligament diameter resulting in $\langle D\rangle/W \approx 3.14$. Considering the fastest growing wavelength of the inviscid Rayleigh-Plateau instability [3], the droplet size corresponds to $\langle D\rangle/W \approx 1.89$, which is significantly different from the value observed in our experiments (where a considerable number of coalescence events give rise to larger drops). Therefore, the evidence suggests that the dynamics of the ligament breakup for our ensemble Φ_0 are not described by dominance of the fastest growing Rayleigh-Plateau modes, instead they involve more complex non-linear interactions amongst the different capillary waves propagating along the ligament, and the subsequent aggregation phenomena post breakup.

In conclusion, we are able to conduct precise and controlled numerical experiments that provide us with reliable and reproducible droplet statistics. The numerical experiment can be repeated to generate ensembles corresponding to different points in our parameter space Φ, therefore resulting in different size distributions. The combination of such distributions characterized by different points in the parameter space could lead to more complicated and asymmetric probability distributions, thereby providing an alternate interpretation to the skewness observed in the drop size distributions typical of more complex fragmentation/atomization processes.

SLIDING DROPLETS: ROLE OF SUBSTRATE SOFTNESS

Mathieu Oléron[1], Matthieu Roché *[1], Julien Dervaux[1], and Laurent Limat[1]
[1] Laboratoire Matière et Systèmes Complexes, Université de Paris - CNRS UMR 7057, Paris, France

Summary Dew collectors rely on the cooling of its surface below atmospheric dew point and allows to harvest water in dry regions. These devices can be optimized in terms of dew nucleation rate and water extraction. The former can be improved by coating the surface of the collector with a polymer layer. However, this coating introduces viscoelastic effects that may be detrimental to water extraction that usually occurs by letting water droplets slide down the surface of the collector. Here, we investigate systematically how droplets slide on a viscoelastic substrate. We show that droplet shape depends on the viscoelasticity of the polymeric layer, and that the presence of the soft coating also alters the transition to an unstable shape of the droplet resulting in the deposition of satellite droplets.

INTRODUCTION

Climate change threatens global water resources, and water scarcity may become a major issue. Scientists and engineers have already proposed candidate solutions to tackle this problem, such as dew collection.

Dew collectors rely on the cooling of a solid surface below the atmospheric dew point. Under this condition, water vapor present in the atmosphere condenses on the surface and can then be collected, by tilting the surface to trigger flow for example. A collector with the highest up-time possible is desirable. To this end, both dew formation and water extraction must be optimized. The first aspect can be improved using polymeric coatings[1]. Optimization of water extraction must circumvent flow instabilities such as pearling[2–4]. The study of this latter problem for droplets on silicon wafers showed that the relevant non-dimensionalized numbers are the capillary number and the Bond number that compare capillary stresses to viscous and gravitational stresses respectively:

$$Ca = \frac{\eta U}{\gamma}, \qquad Bo = \frac{\rho g R^2}{\gamma}, \tag{1}$$

where η is the dynamic viscosity, ρ the density, γ the surface tension, R the radius, U the velocity of the drop and g gravity. When both Ca and Bo are fixed, the shape of the drop is determined. Moreover, droplets reaching capillary numbers $Ca > Ca_c$ experience the pearling instability.

The coating of a surface with a polymer layer increases the nucleation rate[1]. However, these layers are often viscoelastic. When the droplet moves, the substrate dissipates energy, possibly at a larger rate than the liquid that spreads on its surface. As a result, the motion of droplets is slowed down at the surface of elastomers[5]: water extraction is then hindered. These issues may be circumvented by controlling the properties of the coating, such as its formulation or its thickness[6]. However, few studies have investigated droplets sliding on soft substrates[7;8] and a lot of questions remain.

The purpose of this contribution is to report the results of a systematic study of droplets sliding on solid-supported elastomeric layers. We discuss the dependence of the shape of a sliding droplet on the properties of the substrate. We also investigate the modifications to the pearling instability induced by the viscoelastic substrates over a large range of elastic moduli.

EXPERIMENTAL SETUP AND OBSERVATIONS

We deposit a droplet of glycerol on a horizontal piece of glass-supported 5-mm thick silicone elastomer layer. Its shear modulus μ ranges continuously from 1 kPa up to 1 MPa. At time $t = 0$, we tilt the substrate and the liquid starts its downward motion. A camera records a top view of the motion (Fig. 1a), and a LED panel lights the drop from below. As glycerol can absorb atmospheric water, its viscosity η_g may change over time, an issue we account for by measuring η_g with a capillary viscosimeter at the same time the experiment runs. The droplet volume is carefully controlled, in the range $20 \leq V \leq 40$ µL. Inclination angles are set in the range $0 \leq \theta \leq 90$ °. We have good control over Ca and Bo.

Photographs displayed in figure 1b illustrate the shape adopted by the droplet when the shear modulus μ of the sloping plane varies from 1 kPa to 1 MPa, for identical Ca and Bo. We notice a clear difference between the soft and the rigid cases. The softer the substrate is, the more the drop elongates. The drop on the softer substrate also exhibits a rivulet at its back. The comparison of these two experiments indicates that the shape of the droplet running downhill is also controlled by the mechanical properties of the substrate.

We have observed that the pearling instability still occurs above a threshold capillary number. Figure 1c illustrates this phenomenon for a 30 µL drop on a $\mu = 1$ kPa substrate. As the drop slides, it elongates more and more in the flow direction and forms a rear that eventually splits in smaller droplets. The threshold capillary number Ca_c above which we observe the pearling instabilty in our experiments using this soft substrate was $Ca_c \simeq 0.03$. This threshold is larger than that reported for a silicon substrate by Peters *et al.*[3], $Ca_c \simeq 0.007$.

*Corresponding author. E-mail: matthieu.roche@univ-paris-diderot.fr

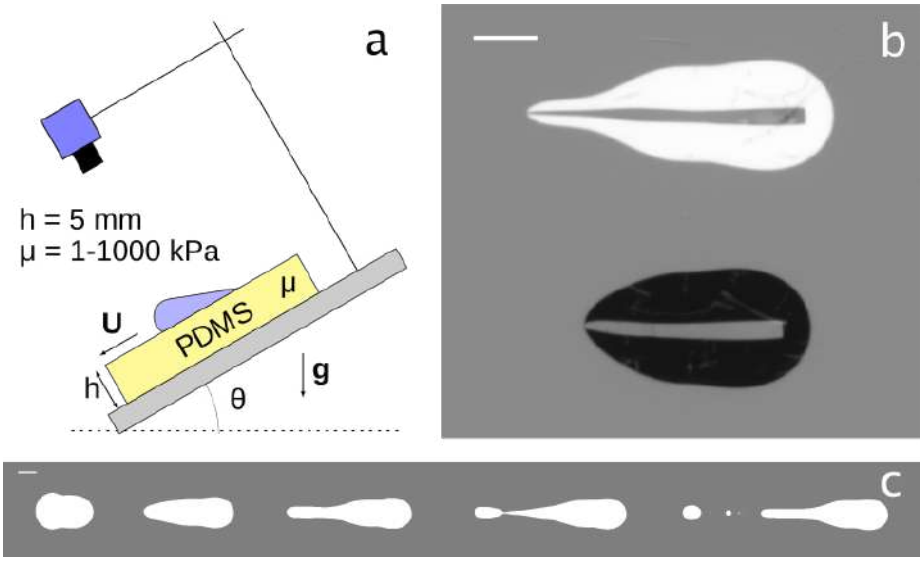

Figure 1: (a) Sketch of our experimental setup. (b) Shape of a glycerol droplets sliding onto two different silicon subtrates. In both pictures, the background has been removed and intensities have been enhanced. The gray stripe inside each drop corresponds to the image of a rectangular filter put upon our light source. Shear modulus μ is equal to 1 kPa (respectively 1 MPa) in the case of the white (respectively black) droplet. $Ca = 0.026$ and $Bo = 0.64$ for both pictures. Scale bar: 2 mm. (c) Pearling instability: binary snapshots of a droplet taken at respectively $t = 0, 2, 7, 10, 10.2$ s, that illustrate the process. $\mu = 1$ kPa, $\theta = 70°$, $V = 30\,\mu$L.

CONCLUSIONS AND PERSPECTIVES

On-going work is carried out at the time of abstract submission to characterize these observations thoroughly. In particular, we study the dependence of droplet shape on the ratio between dissipation in the fluid and in the substrate as well as on the viscoelastic properties of the substrate. We also plan to explore the relationship between the threshold of the pearling instability (*i.e.* Ca_c) and the viscoelasticity of the substrate. We have also identified a dependence of our observations on droplet size. We are looking forward to present and discuss our work during the forthcoming International Congress of Theoretical and Applied Mechanics (ICTAM 2020) in Milan.

DROPLET DYNAMICS ON CHEMICALLY HETEROGENEOUS SUBSTRATES WITH MASS TRANSFER

Danny Groves[1] and Nikos Savva*[2]
[1] School of Mathematics, Cardiff University, Cardiff, United Kingdom
[2] Computation-based Science and Technology Research Center, The Cyprus Institute, Nicosia, Cyprus

Summary We consider the dynamics of thin viscous droplets on chemically heterogeneous surfaces moving under the combined effects of slip, mass transfer and capillarity. The equation governing the long-wave dynamics of the droplet thickness is treated with matched asymptotics to obtain a lower-dimensional system of differential equations for the evolution of the contact line, by assuming that the droplet evolves quasi-statically in the limit of slow mass transfer rates and vanishingly small slip lengths. We also propose a hybrid scheme which couples the results of the asymptotic analysis with the boundary integral method. We demonstrate with a number of representative cases that the reduced system agrees excellently, within its domain of applicability, with simulations performed with the full model, highlighting also a number of interesting features of the underlying dynamics.

MOTIVATION

Moving droplets on surfaces is ubiquitous in the natural world, which also finds application in a broad spectrum of technologies [1]. Yet, their study is inherently complex and many of these applications are based on empirical models derived from experiments. This complexity stems from the multi-scale nature of the phenomenon, from forces that manifest themselves at the macro-scale, such as gravity and capillarity, to the micro-scale effects close to the droplet front. Although impressive progress in contact line phenomena and the broader field of wetting hydrodynamics has been made in recent decades [1, 2], there are several open questions that still remain, including the poorly understood contact line dynamics on surfaces with heterogeneities.

Interesting dynamics also emerge when a droplet is subjected to change in its mass which may occur due to a variety of mechanisms, including, e.g., liquid imbibition through a permeable substrate, pumping liquid into the droplet or evaporation. During mass transfer, two distinct modes or a combination thereof are reported primarily in the context of evaporative dynamics, namely the *constant-radius mode*, during which the contact line appears to be pinned, and the *constant-angle mode*, i.e. when the radius evolves such that the apparent contact angle remains constant [3].

MODEL AND ANALYTICAL METHODOLOGY

In the present study, we consider a thin droplet of variable mass spreading over a horizontal and chemically heterogeneous surface. We assume small slopes everywhere, strong surface tension effects and negligible inertia, which allows us to invoke the long-wave approximation. Hence, the small-slopes expansion of the Stokes equations yields a partial differential equation for the evolution of the droplet thickness $h(\boldsymbol{x},t)$ at position $\boldsymbol{x}$ and time t, namely

$$h_t + \frac{\sigma}{3\mu}\boldsymbol{\nabla}\left[h(h^2+3\lambda^2)\boldsymbol{\nabla}\nabla^2 h\right] = \frac{q}{\rho}. \tag{1a}$$

Here, μ, ρ and σ are the fluid's viscosity, density and surface tension, respectively, λ is the slip length used to alleviate the stress singularity of the moving contact line [2], and $q(\boldsymbol{x},t)$ models the mass flux. This corresponds to a free-boundary problem, where the contact line at $\boldsymbol{x}=\boldsymbol{c}$ must be determined as part of the solution. Equation (1a) is thus complemented with the appropriate boundary conditions at $\boldsymbol{x}=\boldsymbol{c}$, namely

$$h=0, \quad h_\nu = \theta \quad \text{and} \quad \left(\boldsymbol{c}_t - \frac{\sigma\lambda^2}{\mu}\boldsymbol{\nabla}\nabla^2 h\right)\cdot\boldsymbol{\nu} = \frac{q}{\rho\theta}, \tag{1b,c,d}$$

where $\boldsymbol{\nu}$ is the unit outward normal to the contact line and $\theta(\boldsymbol{x})$ prescribes the heterogeneity of the substrate through a spatially varying contact angle. Conditions (1b) and (1c) are the usual conditions applied to contact line problems with sharp interfaces, whereas (1d) is of kinematic type and is directly derivable from a local expansion of (1a) about $\boldsymbol{x}=\boldsymbol{c}$.

Through a systematic asymptotic analysis, which has been previously utilized for three-dimensional droplets of constant mass [4], we derive a new coupled system of evolution equations that governs the Fourier coefficients of the contact line, $c_m(t)$, cast in the form

$$\vartheta^3 - \theta^3 = \frac{9\mu}{\sigma}\sum_m \left(\dot{c}_m(t)\ln\frac{\ell_m(t)}{\lambda} + v_m(t)\right)\mathrm{e}^{\mathrm{i}m\phi}. \tag{2}$$

Here the dot denotes differentiation with respect to t, ϑ is the apparent contact angle, $\ell_m(t)$ is a macroscopic lengthscale and $v_m(t)$ captures the velocity corrections due to changes in the droplet mass. Equation (2) is reminiscent of a Cox–Voinov-type law [1], which is augmented to take into account mass transfer effects. It is obtained by matching asymptotically the bulk dynamics with the flow in the vicinity of the contact line, by assuming vanishingly small values of λ, slow dynamics and nearly circular contact lines.

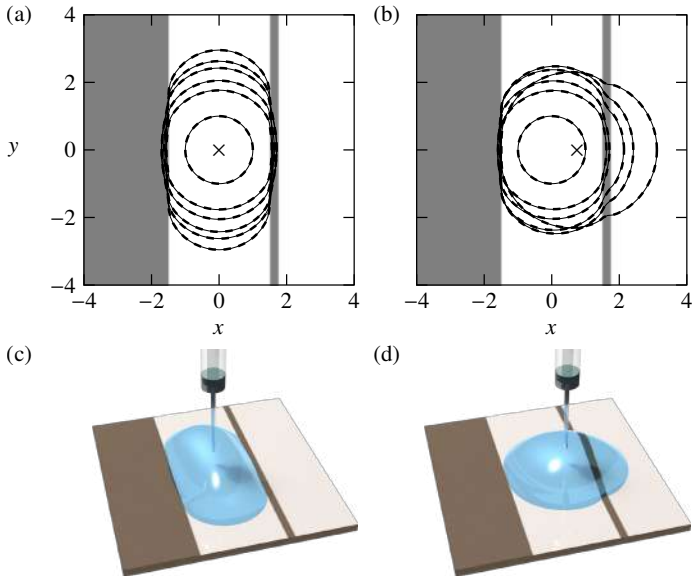

Figure 1: A droplet with liquid injection at two different locations spreading over a chemically heterogeneous substrate (darker shades denote lower wettability regions, i.e. higher contact angles). In (a) and (b) solid curves correspond to contact line profiles at different times as predicted by solutions to (1), whereas dashed curves show the corresponding predictions of (2) with the hybrid approach. The symbols × mark the points of injection. Panels (c) and (d) show renderings of the final droplet shapes in (a) and (b), respectively.

NUMERICAL METHODS AND RESULTS

Numerical experiments are performed to assess how well the predictions of (2) compare with those of full problem, (1). The full problem, which becomes increasingly stiff as λ approaches realistically small values, is solved using a pseudospectral collocation scheme for the spatial discretization and the method of lines for time-stepping. It is seen that the two approaches compare generally favorably and, importantly, simulations with (2) require minimal computational resources compared to those required for the full problem.

Also explored is the development of a hybrid method which improves the agreement with the full model, by leveraging the merits of the lower-order model, (2), but with the inclusion of a small computational overhead. This approach is based on the boundary integral method which allows us to more accurately determine the apparent contact angle ϑ in (2) for a given contact line shape, which then improves the accuracy of the predicted dynamics for $c_m(t)$.

Simulations of a number of representative cases are able to uncover experimentally observed phenomena, such as pinning, stick-slip, and hysteresis-type effects, as well as present convincing numerical evidence that suggests that the reduced and especially the hybrid model can replace the full model within its domain of validity. In this manner, we are able to mitigate considerably the high computing costs required to fully resolve the dynamics across the disparate lengthscales that are present in the system.

Such an example is shown in figure 1, where a localized liquid flux is introduced at two different positions of the free surface of the droplet as it spreads on a substrate decorated with regions of lower wettability. In one case, the droplet becomes elongated and remains trapped between the lower wettability barriers, whereas by shifting slightly the position of the localized flux the droplet is able to move across the rightmost barrier.

CONCLUDING REMARKS

This study shows how the systematic framework presented in [4] can be extended to account for the combined effects of chemical heterogeneities and mass transfer. It is important to highlight that the hybrid theoretical model is able to capture excellently the underlying dynamics, even in cases where the droplet undergoes stronger deformations than those assumed for the analysis to hold (see figure 1), thus offering a compelling alternative approach to full model simulations. Further analysis and extensions to (2) to tackle other complexities will be the subjects of future investigations.

THINNING OF FLUID INTERFACES UNDER DOMINANT SURFACE DISSIPATION

Alejandro Martínez-Calvo *[1] and Alejandro Sevilla †[1]
[1] Grupo de Mecánica de Fluidos, Universidad Carlos III de Madrid, Leganés, Spain

Summary We report theoretical and numerical evidence of universality in the thinning of fluid interfaces at high superficial concentration of surfactants. These saturated interfaces are shown to exhibit an asymptotic balance of surface dissipation with surface tension at small scales, yielding an exponential thinning with an e-fold time that only depends on the surface shear and dilatational viscosities.

INTRODUCTION

The presence of surfactants at fluid interfaces plays an important role in many physical systems of great relevance in biology, medicine and different technological contexts [1, 2, 3]. The rich complexity of bulk and surface interactions hinder both, the precise measurements of the material properties associated with adsorbed surfactant layers, as well as the derivation of appropriate continuum models [2]. These surface material parameters are the surface tension coefficient σ, and the surface shear and dilatational viscosities, μ_s and κ_s respectively, which depend on the temperature and on the superficial concentration of surfactant. An interesting limit to explore is that of high surfactant concentrations, where the interface is said to be saturated, in that the Marangoni stresses are negligible, and the surface viscosities take constant values if the surface rate-of-strain is small enough [4, 5]. This particular limit can be achieved by means of a fluid that acts as a surfactant reservoir able to replenish the interface when the surfactant is depleted by advection. Under these conditions, here we report strong numerical and theoretical evidence suggesting the realizability of a new asymptotic regime where surface dissipation balances surface tension, thereby precluding the appearance of a finite-time singularity associated with capillary drainage. In particular, we consider the thinning of an axisymmetric liquid thread of initial radius R_0 due to capillary drainage. Provided that the local radius satisfies $R(t) \ll \mu_s/\mu$, it can be anticipated that $\sigma/R^2 \sim \mu_s \dot{R}/R^3$, where $\dot{R} = \mathrm{d}R/\mathrm{d}t$ is the radial velocity of the filament, and thus $R(t) \propto \exp(-t/t_c)$, where $t_c = \mu_s/\sigma$ is the *surface-visco-capillary time*, which depends only on material parameters [6].

For a Newtonian interface, the most widely used approximation for the surface stress tensor is the Boussinesq–Scriven (B-S) constitutive equation, which is the surface analogue of the Navier–Poisson law, and that reads

$$\boldsymbol{T}_s = \left[1 + \frac{\Theta - 1}{\Theta + 3}(\boldsymbol{\nabla}_s \cdot \boldsymbol{u}_s)\right] \boldsymbol{I}_s + \frac{1}{\Theta + 3}\left[(\boldsymbol{\nabla}_s \boldsymbol{u}_s) \cdot \boldsymbol{I}_s + \boldsymbol{I}_s \cdot (\boldsymbol{\nabla}_s \boldsymbol{u}_s)^{\mathrm{T}}\right], \tag{1}$$

in dimensionless form, where $\boldsymbol{u}_s$ is the fluid velocity at the interface $\partial\mathcal{V}$, $\boldsymbol{\nabla}_s = \boldsymbol{I}_s \cdot \boldsymbol{\nabla}$ is the surface nabla operator, $\boldsymbol{I}_s = \boldsymbol{I} - \boldsymbol{nn}$ is the surface projection tensor, $\boldsymbol{n}$ being the unit normal vector to the interface (see Fig. 1), and $\Theta = \kappa_s/\mu_s$ is the dilatational-to-shear surface viscosity ratio. Note that (1) has been scaled taking R_0 as the characteristic length scale and the surface visco-capillary velocity $\sigma R_0/(3\mu_s + \kappa_s)$ as characteristic velocity scale.

THINNING OF AXISYMMETRIC THREADS: NUMERICAL SIMULATIONS AND LOCAL ANALYSIS

We numerically integrated the Stokes equations for three different configurations involving the capillary drainage of axisymmetric liquid threads, making use of the B-S constitutive law to implement the surface stress balance. In particular, we studied: (I) a spatially periodic thread in the absence of gravity and immersed in a passive ambient. (II) A liquid bridge of length L/R_0, also immersed in a passive ambient, but vertically oriented with gravity with an associated Bond number $Bo = \rho g R^2/\sigma$. And (III) a spatially periodic thread inside an unbounded liquid bath in the absence of gravity, but with a finite value of outer-to-inner viscosity ratio N_μ. Figure 1 shows several snapshots for the three cases. In panels (a), (e) and (i) the computational domain is indicated with dashed lines, and in panel (d) the inset shows the local structure of the flow around the symmetry plane, displaying an elongated thread connecting the two main drops in case I.

Motivated by the interfacial evolution displayed in figure 1, we developed a simple local theory to explain the numerically observed exponential thinning regime. The local shape of the thread is assumed cylindrical, $r = R(t)$, with an inner velocity field $\boldsymbol{u}(r, z, t) = -2z\dot{R}/R\boldsymbol{e}_z + r\dot{R}/R\boldsymbol{e}_r$, and with a pressure jump $p(t) - \hat{p}(t)$ that depends only on time. Under these conditions, the surface stress tensor (1) simplifies to

$$\mathsf{T}_s^{zz} = 1 - \frac{\dot{R}}{R}, \quad \text{and} \quad \mathsf{T}_s^{\theta\theta} = 1 + \frac{3 - \Theta}{3 + \Theta}\frac{\dot{R}}{R}. \tag{2}$$

In the limit $N_\mu \ll 1$ and for times $t \gg 1$, the surface stress balance $(\hat{\boldsymbol{T}} - \boldsymbol{T}) \cdot \boldsymbol{n} + \boldsymbol{\nabla}_s \cdot \boldsymbol{T}_s = \boldsymbol{0}$ yields

$$\dot{R} = -F(\Theta)\, R, \quad \text{where} \quad F(\Theta) = \frac{3 + \Theta}{3 - \Theta}\left[1 - \lim_{t\to\infty}(p_s - \hat{p}_s)R\right], \tag{3}$$

†e-mail: asevilla@ing.uc3m.es

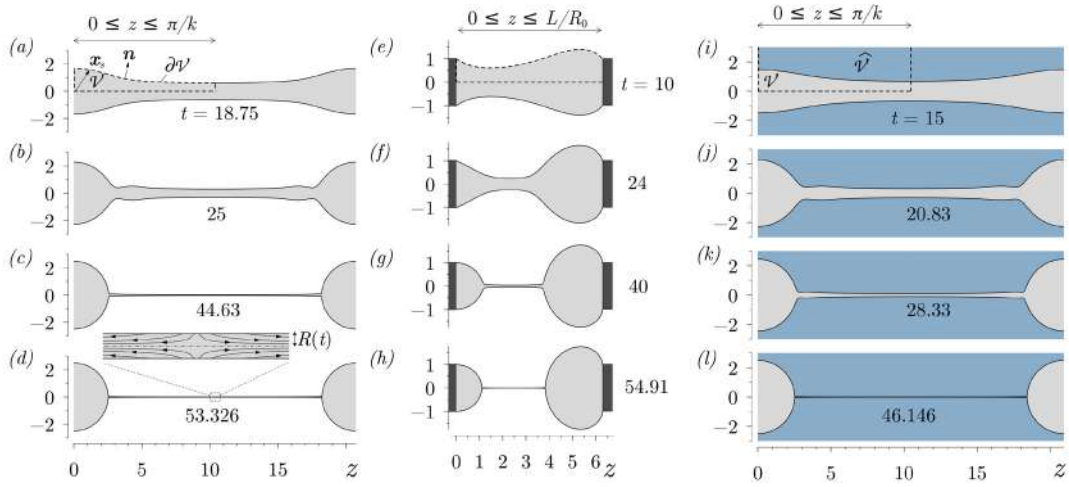

Figure 1: Snapshots of the liquid column obtained from the numerical simulations. (a)–(d) Case I with $Bq = 3.4$, $\Theta = 1$ and $k = 0.303$. (e)–(h) Case II with $Bq = 0.1$, $\Theta = 2$, $L/R_0 = 2\pi$ and $Bo = 0.3$. (i)–(l) Case III with $Bq = 2$, $\Theta = 3$, $N_\mu = 10^{-3}$ and $k = 0.3$.

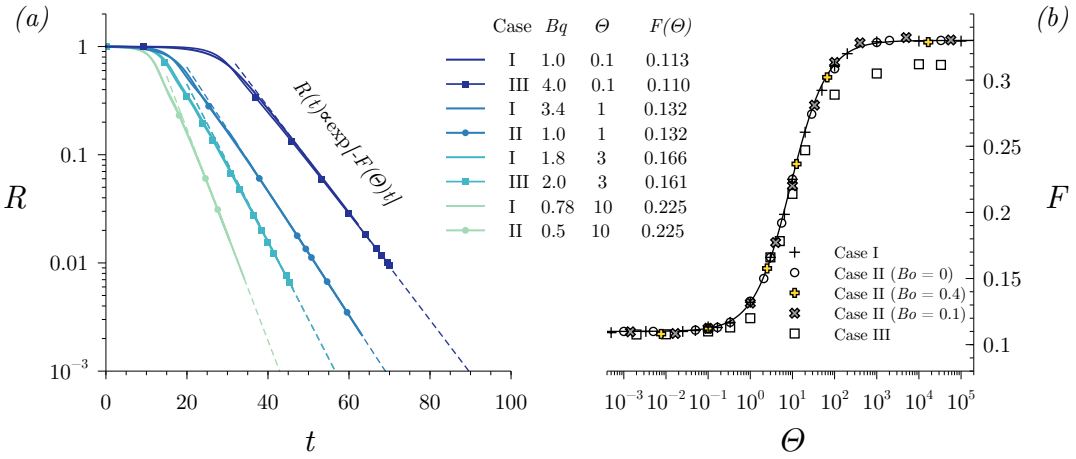

Figure 2: (a) The minimum thread radius $R(t)$ for different conditions specified in the legend. (b) The universal function $F(\Theta)$.

represented for the three cases in Fig. 2(b) together with the approximation

$$F(\Theta) \approx F_{-\infty} + \frac{F_\infty - F_{-\infty}}{2}\left\{1 + \tanh\left[\frac{1}{2}\log\left(\frac{\Theta}{9}\right)\right]\right\}, \tag{4}$$

with $F_{-\infty} = 0.11$ and $F_\infty = 0.33$, which provides a good fit to the numerical results. The solution of (3) is $R(t) \propto \exp\left[-F(\Theta)\, t\right]$, in close agreement with all the numerical results represented in figure 2(a).

DISCUSSION

The present study calls out for a careful experimental campaign to test the new asymptotic regime reported herein. Besides their fundamental hydrodynamic interest, our results pave the way to develop a new non-intrusive measurement technique for the surface viscosity coefficients. Moreover, our findings should be extended to other relevant interfacial thinning configurations involving high concentrations of surfactants, like Plateau borders and films pulled out from a bath, large-amplitude oscillations of surfactant-laden droplets and bubbles, or the retraction of sheets and filaments.

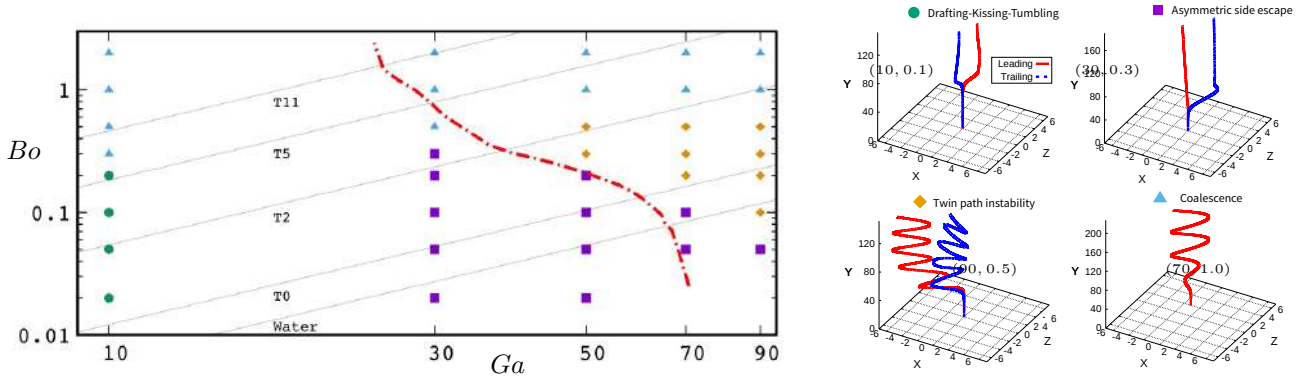
Summary The three-dimensional dynamics of a pair of deformable rising bubbles released in line is investigated by means of direct numerical simulation. A wide parameter range is explored, covering situations corresponding to moderate-to-large Reynolds number and low-to-moderate deformation. Four different interaction scenarios are identified, namely the drafting-kissing-tumbling process already known with rigid particles, a sideways shift of the trailing bubble leaving the leading bubble path almost unaffected, a twin path instability of the bubble pair, and a gradual approach process ending with coalescence. The mechanisms at the root of the escape of the trailing bubble from the wake of the leading one are analyzed, highlighting the specificities of bubbles as compared to rigid particles.

Buoyancy-driven bubbly flows are ubiquitous in geophysics and engineering and offer remarkable dynamics and mixing properties. The chief difficulty in the modeling of such flows stands in the subtle couplings existing between the light deformable dispersed bodies and the surrounding liquid. A fundamental building block in the prediction of the mesoscale structure of these flows lies in the understanding of pair interactions between two neighboring bubbles. Even this canonical situation involves complex and rich dynamics, as many parameters are involved. In particular, the angle between the line joining the centroids of the two bubbles and the vertical plays a crucial role, making the in-line and side-by-side configurations behave very differently. In the in-line geometry, early approaches grounded on potential flow theory [1] predict that two spherical bubbles always repel each other. In contrast, the solution of the full Navier-Stokes equations [2], or the potential flow approach supplemented by a wake model [3], predict an equilibrium distance, owing to the sheltering effect induced on the trailing bubble by the wake of the leading one. In contrast, experimental observations in water [4] reveal that no equilibrium separation distance is reached with sub-millimeter size bubbles, presumably contaminated by surfactants, which always collide and coalesce. Recent experiments [5] uncover much more complex scenarios, including four types of interaction: separation, approach, coalescence and overtaking.

In the present work, we employ three-dimensional direct numerical simulation to examine the fate of two deformable rising bubbles initially released in line in the regime of moderate-to-large Reynolds numbers. We make use of the open source code *Basilisk* [6], taking advantage of the potentialities offered by the adaptive mesh refinement technique to explore subtle mechanisms that find their root at or nearby the fluid-bubble interface, among which those related to vorticity generation and small-scale deformation. When two bubbles are very close to colliding or coalescing, the grid resolution allows us to capture the fluid flow within the film standing between them down to a minimum thickness e_m less than 1% of the bubble radius, which gives an idea of the range of scales resolved in the present approach.
Considering that the two bubbles have the same initial radius a and that the density ρ and viscosity μ of the surrounding liquid are much larger than those of the gas filling the bubbles, the problem under consideration depends on three characteristic parameters, namely the initial dimensionless separation S between the bubble centers, the so-called Galilei number $Ga = V_g a/\nu$ which is a Reynolds number based on the gravitational velocity scale $V_g = (ga)^{1/2}$, and the Bond number $Bo = \rho g a^2/\gamma$, where γ is the surface tension. We explore the range $0.02 \leq Bo \leq 2$, $10 \leq Ga \lesssim 10^2$, which yields Reynolds numbers based on the actual rise velocity from 15 to 10^3, approximately. Having frozen the initial separation to some units ($S = 8$ in what follows), four typical evolutions are observed, depending on Ga and Bo (Figure 1).

When Ga is of $\mathcal{O}(10)$ and the Bond number is lower than a critical value $Bo_c(Ga)$ (with Bo_c typically ≈ 0.3 for $Ga < 50$, then decreasing gradually to less than 0.1 for $Ga = 10^2$), the system follows the drafting-kissing-tumbling (DKT) scenario (Figure 2) already known for rigid spheres [7]. In the final configuration, the two bubbles rise side-by-side along two quasi-vertical lines, the positions of which are almost symmetric with respect to the initial vertical path. For larger Ga, and Bo still less than $Bo_c(Ga)$, a sharp lateral escape of the trailing bubble is observed, while the path of the leading bubble is left virtually unaltered, which defines an asymmetric side escape regime. In these first two regimes, the paths remain planar throughout the rise of the two bubbles. For larger Bond numbers, the two bubbles first rise in straight line, or, for large enough Ga, follow zigzagging or spiraling paths. At some point, they get very close to each other and the film of liquid that still separates them is continuously squeezed and becomes eventually thinner than e_m, which corresponds to the early stages of coalescence. However, for $Ga \gtrsim 30$ (i.e. Reynolds numbers larger than ≈ 250), the former scenario is only observed beyond a second critical threshold $Bo_{c2} > Bo_c$, with $Bo_{c2}(Ga) \approx 0.4 - 0.5$. In the intermediate range $Bo_c(Ga) \leq Bo \leq Bo_{c2}(Ga)$, the two bubbles exhibit approximate oblate spheroidal shapes with an aspect ratio $2.1 \leq \chi \leq 2.8$, and their path would be unstable, were they rising alone [8]. This is why a twin path instability sets in, in which the motion of both bubbles soon exhibits large lateral oscillations. The corresponding paths are still planar for moderate Ga, corresponding to pure zigzagging trajectories, but exhibit a significant three-dimensionality, especially regarding the trailing bubble, when Ga is large enough.



(a) (b)

Figure 1: (a): Regime map showing the subdomains within which each specific interaction scenario is observed. Bullets: drafting-kissing-tumbling, squares: asymmetric side escape, diamonds: twin path instability, triangles: coalescence. (b) Path of selected bubble pairs displaying each of the four scenarios; the corresponding (Ga, Bo) is specified in each panel. Dash-dotted line in (a): approximate neutral curve for the path instability of an isolated bubble [8]; thin solid lines: iso-Mo lines (with $Mo = Bo^3/Ga^4 = g\mu^4/\rho\gamma^3$) corresponding to different liquids, from pure water at the bottom to T11 silicone oil ≈ 10 times more viscous than water at the top.

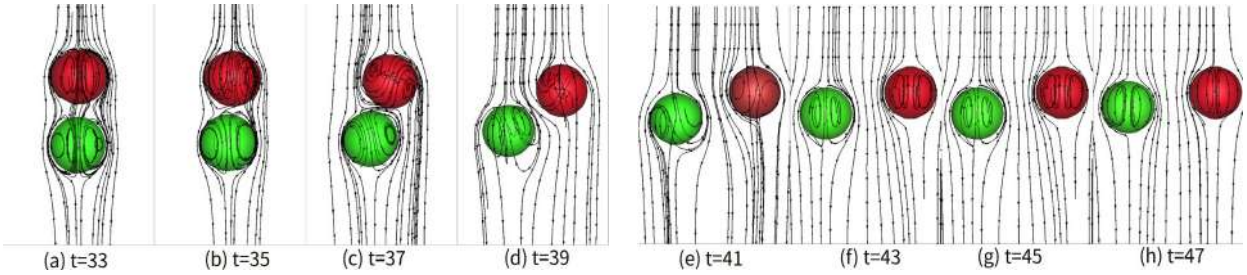


Figure 2: The DKT scenario for a bubble pair with $(Ga = 10, Bo = 0.1)$. Streamlines are plotted in the reference frame of the leading bubble. Time is normalized with the gravitational scale, $(a/g)^{1/2}$.

In all but one (coalescence) of the above scenarios, the mechanism that extracts the trailing bubble from the wake of the leading one plays a key role. It has long be recognized [1] that, as soon as some infinitesimal disturbance shifts the centroid of the trailing bubble from the axis of the leading-bubble wake, the generation of streamwise vorticity past the former results in a sideways force making the in-line configuration unstable. The same mechanism holds for pairs of rigid particles. However, compared to this case, the non-axisymmetric evolutions observed with bubbles take place in a significantly different context. The key difference stands in the weakness of boundary layer effects past clean bubbles, owing to the shear-free condition obeyed by the outer flow at their surface. A direct consequence of this much weaker near-interface vorticity is that, compared to a rigid particle with a similar shape, a much larger lift force is exerted on the trailing bubble for a given lateral deviation from the wake axis, i.e. a given upstream shear. This mechanism is responsible for the vigorous horizontal motions revealed by present simulations.

The vorticity distribution about each bubble is also at the root of the striking difference between the almost symmetric DKT evolution observed for $Ga = \mathcal{O}(10)$ and the asymmetric side escape regime that takes place at higher Ga. Indeed, viscous effects make vorticity significantly diffuse past each bubble for low-to-moderate Ga, and the corresponding vortex dipole results in a fairly long-range repulsive transverse interaction once the bubble pair gets close to the side-by-side configuration. In contrast, the near-bubble vorticity fields are confined to thin boundary layers when Ga is larger, so that they do not interact significantly, leaving the transverse force controlled by the attractive short-range interaction induced by the pressure minimum in between the two bubbles [9]. For short separation distances, the transverse force is strong in the former case, so that it is able to move the formerly leading bubble sideways, which tends to preserve symmetrical lateral offsets of bubble paths after the tumbling stage. Comparatively, the attractive interaction at higher Ga is much weaker, leaving the asymmetry reached at the end of this stage almost unaffected.

THREE-DIMENSIONAL DIFFUSE-INTERFACE IMMERSED-BOUNDARY METHOD FOR FLUID-STRUCTURE INTERACTION WITH DYNAMIC WETTING

Hailong Li[1], Hang Ding *[1], and Hao-Ran Liu[1]
[1] Department of Modern Mechanics, University of Science and Technology of China, Hefei, China

Summary We propose a three-dimensional (3D) diffuse-interface immersed-boundary method to simulate fluid-structure interaction involving multiphase flows and dynamics wetting. In this work, the immersed boundary method is used to accurately enforce the no-slip boundary condition at the solid surface, and a three-component diffuse-interface model is implemented to capture the interfaces. A hybrid capillary force model is proposed to compute the surface tension force that the interface applies to the solid object at the contact line. The stability and accuracy of the method are validated against experimental results for a variety of 3D test cases, including the impact of a droplet on the column surface, the sinking of a superhydrophobic solid sphere from the water surface and the collision between a heavy droplet and a flying mosquito. The numerical results agree well with the experimental data.

INTRODUCTION

Fluid-structure interaction in the presence of a fluid-fluid interface is ubiquitously seen in our lives, and some may stimulate our curiosity. For example, one may be interested in the answer to the questions like why can water striders run on the water surface or will a mosquito survive raindrop collisions. To gain a full understanding of the physics underlying these flow problems, one may have to resort to direct numerical simulation. However, it is quite a challenging job. Firstly, it encounters the difficulty in resolving the stress singularity at moving contact lines (MCLs), due to its incompatibility with the no-slip condition in the continuum mechanics. A recent review of MCL models in numerical simulations can be found in [1]. Secondly, the applications in practice are normally involved with complex substrates, which brings additional difficulties into the simulation of flows with MCLs, especially in 3D simulation. On the other hand, dynamic wetting plays an important role in the interaction between the fluid-fluid and moving objects at a scale smaller than the capillary length. In this work, we propose a 3D diffuse-interface immersed-boundary method to simulate fluid-structure interaction involving dynamics wetting. In this method, a three-component diffuse-interface model is used to model the interface evolution, since it is able to deal with the multi-phase flow with large density ratios [2]. An immersed boundary method is used to model the fluid-structure interaction, because of its flexibility and efficiency in dealing with moving boundary problems. Finally, a characteristic MCL model, which can accurately meet the wetting condition on the complex geometric solid surface, is extended to the 3D flow problems. The stability and accuracy of the method are validated against experimental results for a variety of 3D test cases, including the impact of a droplet on the column surface, the sinking of a superhydrophobic solid sphere from the water surface and the collision between a heavy droplet and a flying mosquito.

NUMERICAL METHODS

We investigate here 3D flows of two incompressible fluids interacting with moving rigid objects. The fluid motion is governed by 3D incompressible Navier-Stokes equations, of which a dimensionless form can be written as

$$\rho(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}) = -\nabla p + \frac{1}{Re}\nabla\cdot[\mu(\nabla\mathbf{u}+\nabla\mathbf{u}^T)] + \frac{\mathbf{f}_s}{We} + \frac{\rho}{Fr}\mathbf{k} + \mathbf{f}_{IB}, \qquad \nabla\cdot\mathbf{u} = 0, \tag{1}$$

where $\mathbf{f}_s$ denotes the surface tension at the interface region that separates the two immiscible fluids, and $\mathbf{f}_{IB}$ represents the force acted by the solid objects on the surrounding fluids.

The three-component is denoted by volume fraction C and the mathematically sharp interface is modeled by a diffuse interface. In this model, the evolution of the gas-liquid interface is described by the volume fraction of the liquid C_L, which is governed by the Cahn-Hillard equation,

$$\frac{\partial C_L}{\partial t} + \nabla\cdot(\mathbf{u}C_L) = \frac{1}{Pe}\nabla^2\psi, \tag{2}$$

where Pe is the Péclet number and ψ is the chemical potential.

The interface of solid objects is represented by the volume fraction of solid C_S, which is updated by a signed distance function according to the centroid location and the rotation angle of the rigid solid object.

To estimate the effect of solid objects on surrounding fluid flow, an immersed boundary method [3] is used here to enforce the no-slip boundary condition at the solid surface. In this method, the solid objects are represented by a set of Lagrangian points and flows are solved on the Cartesian Eulerian points.

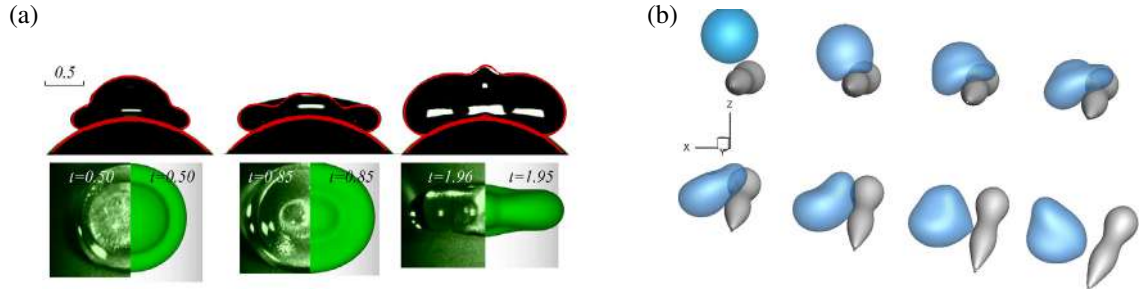

Figure 1: (a). Selected snapshots showing the time evolution of a droplet impact on a concave cylindrical solid surface at different times ($t = 0.54, 0.85, 1.95$), which is in the spreading stage, the largest spreading stage and the retracting stage respectively. The top panel corresponds to the cross-section view parallel to the azimuthal direction, in which the background parts are from the experiment, and the solid red lines are from the numerical result. The bottom panel is the plan view from above the drop, in which the left parts are from the experiment and the left parts are from the numerical result. (b). Time evolution of the collision between the raindrop and flying mosquito at $t = 0,\ 0.54,\ 1.08,\ 1.62,\ 2.16,\ 2.7,\ 3.24,\ 3.78$ from left to right from up to bottom with $Re = 1000$, $We = 10$, $\theta = 140^{\circ}$ and the mass ratio of the mosquito to the droplet is 0.067.

The motion of rigid objects in fluids can be described by its translation velocity and rotation velocity. In this work, the six-degree freedom equations of rigid body motion are solved. The forces exerted on the solid object consists of capillary force, hydrodynamic force and gravity force. Capillary force $\mathbf{f}_{cap}$ is caused by capillary phenomena which occurs at the three-phase contact line. In this model, to deal with complex geometrical solid, the solid surface is divided into lagrangian patches that cover the entire solid surface and a simple projection is used to transfer the integration formula to the solid surface. We prove that it is equivalent to integrate the following equation on the solid surface,

$$\mathbf{f}_{cap} = \frac{3\sqrt{2}}{We\ Cn} \int_{CL} \int_{-\infty}^{+\infty} C_L^2 (1 - C_L)^2 \mathbf{t}\ d\xi_n d\xi_\tau, \tag{3}$$

where Cn is the thickness of diffuse interface, ξ_n and ξ_τ are infinitesimal length along the normal and tangent direction of the contact line, respectively.

RESULTS AND DISCUSSIONS

The dynamics of a water drop impacting onto a cylinder was recently investigated experimentally by Liu et al. [4]. We attempt to numerically reproduce the experimental observations using the present method and make a direct comparison with the experimental data, see Fig. 1 (a). The flow parameters are chosen to be the same as the experimental setup. We also present a model of mosquito body and simulate the dynamic process of the collision between a raindrop and the mosquito, see Fig. 1 (b). The numerical results show that the mosquitoes more likely survive from the collision with raindrops by virtue of their low mass and superhydrophobicity.

CONCLUSIONS

A three-dimensional diffuse-interface immersed boundary method has been proposed to simulate the interaction between fluid-fluid and moving complex geometric solid. The 3D characteristic MCL model is used to satisfy the wetting conditions at the solid surface with arbitrary shape, where the normal directions of the solid and liquid surface are carefully handled and the contact angle hysteresis is also considered. A hybrid capillary model is used to compute capillary force acting on the structure to keep the conservation of momentum. The performance of the approach has been tested by a variety of test cases. The numerical tests show that the approach can produce converged results with mesh refinement and show good agreement with experimental results.

DIRECT MEASUREMENT OF TIME-DEPENDENT EVAPORATIVE FLUX AND DIFFUSED VAPOR CLOUD OF EVAPORATING DROPLETS

Gilgu Lee[1] and Hyoungsoo Kim[1]
[1] Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea

Summary: It is well-known that an evaporative flux of a droplet placed on the substrate is mainly dependent on the location and the contact angle while the vapor of the liquid across the liquid-gas interface continuously is evaporated in time. The evaporation mechanism is driven by diffusion and it is assumed to be steady. In this study, we directly visualize the evaporative flux of an evaporating droplet using a Mach-Zehnder interferometry method to explore the unsteady effect and the density effect of the evaporation. Based on the current measurement technique, we measure the time- and space-dependent evaporative flux by varying the molecular weight of the volatile liquid component and the gravitational effect, which would be important to understand and control a final deposition pattern of the evaporated droplet.

INTRODUCTION

A particle-laden droplet leaves a coffee ring pattern due to the inhomogeneous evaporation rate at the liquid surface. The non-uniformity of the dried pattern is crucial in various areas such as inkjet printing and bio-industry [1, 2]. To understand the particle deposition mechanism, most of these studies mainly tried to observe the flow pattern inside droplets and the movement of the suspended particles, which are directly related to the deposition of the particles. To date, it has been rarely investigated to measure the time-dependent signals including diffused vapor cloud and evaporative flux due to the difficulty of the gas visualization experiments. Alternatively, to see the effect of the diffused liquid components on the evaporation, some studies performed the experiment in a liquid-liquid system, which showed that the induced convection effect alters the evaporation rate [3, 4]. In this study, we question effects of the time-dependent evaporative flux and the diffused vapor cloud on the evaporation. To investigate this, we use the Mach-Zehnder interferometry method to visualize the diffused vapor cloud in time. By using several liquids having different vapor pressures and molecular weights, we systematically and quantitatively compare the evaporation rate in time and space. Furthermore, to see the effect of the gravitational effect, we change the angle of the substrate.

VISUALIZATION OF EVAPORATION OF DROPLET USING INTERFEROMETRIC INSTRUMENT

Laser spatial interference technology was applied to evaporating droplets for the visualization of the diffused vapor. The optical instrument is based on the Mach-Zehnder Interferometer (Figure 1(a)). The first beam splitter is divided into the reference light and measurement light. The measurement light passes through the evaporating droplets, and the reference light passes through the air. The transmitted light is interfered at the last beam splitter, which is recorded by the camera. In the absence of an evaporating droplet, the interfered signal shows a straight (undistorted) fringe pattern (see Figure 1(b)) because two lights are identical. However, if there is an evaporating droplet, the fringe pattern is distorted because refractive indices are different in the reference light and measurement light (see Figure 1(c)). The recorded fringe pattern is transformed into a phase distribution map by the Fourier transform profilometry method [5]. The extracted phase results are converted by the inverse Abel transformation that transforms the projection to the inverse projection for estimating the mole fraction outside the droplet [6]. The local evaporation rate of the droplet is obtained based on the converted mole fraction.

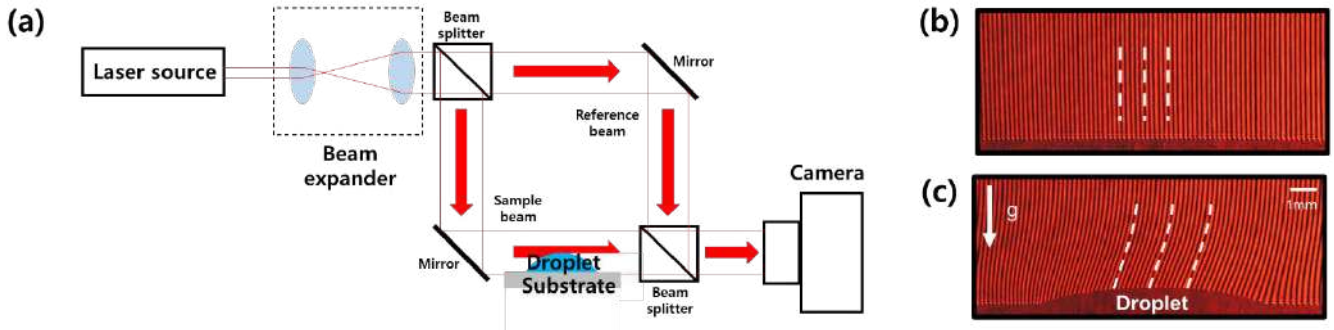

Figure 1. (a) Schematic of the experimental setup of Mach-Zehnder interferometer (b) Undistorted stripe pattern (c) Distorted stripe pattern due to an evaporating droplet.

We measure that a non-uniform evaporation rate along the droplet surface in time. From the measurement result, at the droplet edge, we observe that there is a maximum evaporative flux, which confirms that Deegan's evaporation model is correct [4, 7]. Additionally, we present that the distribution of mole fractions around the droplets is not uniform during evaporation (Figure 2). Figure 2 shows that the distribution of the diffused vapor cloud tends to spread laterally when the droplet is placed on the substrate (Figure 2(a)) while the vertical plume shape of the vapor distribution is measured when the droplet is suspended under the substrate (Figure 2(b)). Based on this observation, we address that the evaporated molecules could change the vapor concentration along the interface of the evaporating droplet, which changes the evaporative flux, as shown the vector arrows in Figure 2. We observe that the evaporative flux is different depending on the orientation of the droplet position. Furthermore, we test the same experiments by varying the molar mass of the liquid. We will compare and discuss the effect of the molar mass on the evaporative flux.

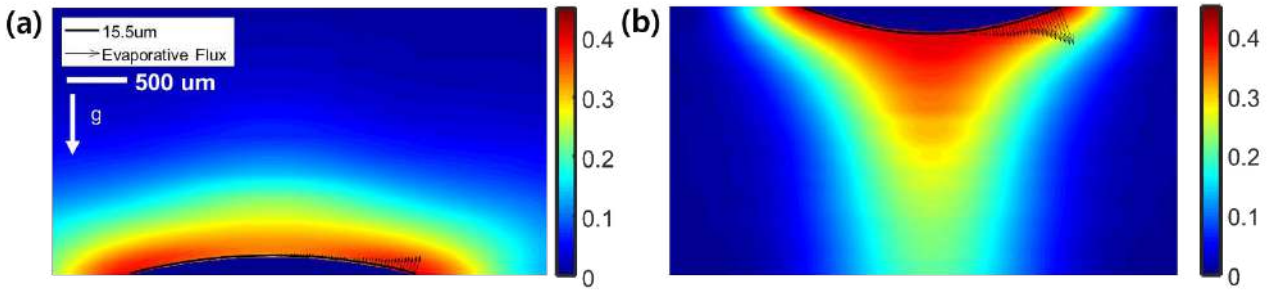

Figure 2. Mole fraction map (color map) and evaporative flux (vectors) of volatile liquid droplet (a) on the substrate and (b) under the substrate.

CONCLUSIONS

We successfully measure the vapor distribution of the evaporating droplet from Mach Zehnder interferometer by varying a molecular weight of liquids and the droplet position. For the first time, we observe that the distribution of the evaporated vapors is not constant in time and space during the evaporation, and also the distribution is significantly different if the droplet is placed on a different position. We expect that this vapor visualization result could provide some insights to understand and control the final dried mark after printing and coating process. Furthermore, the vapor distribution measurement could help to optimize the flow controller and mixer by using vapor-driven solutal Marangoni effect [8-9].

Summary Liquid foams are dispersions of gas bubbles in a soapy liquid matrix. They are also yield-stress fluids, intermediate between solids and liquids, used in various applications for their large specific area, light weight, and insulating properties. In particular, their stability and rheology strongly depend on the type of surfactants used to generate them. To link these macroscopic properties to the microscopic dynamics at the bubble and surfactant scale, we investigate bubble rearrangements, called T1 events, under shear through numerical simulations. We use a two-phase flow level-set method adapted to include surfactant dynamics (Titta et al., Journal of Fluid Mechanics, 2018) and investigate the role of the adsorption depth, a measure of surfactant distribution between the bulk and surface, on surfactant transport and dissipation due to viscous and surface (Marangoni) effects.

INTRODUCTION

Liquid foams are yield stress fluids, as well as ephemeral structures. However, both their rheology and their stability highly depend on the type of surfactants used to generate them [1]. In order to understand the mechanical behavior of foams at the macroscopic scale, we thus investigate the elementary process of foam flow, named bubble rearrangements or T1 events, sketched in figure 1a. These bubble rearrangements are also known to trigger foam collapse [2].

In order to capture the complex coupling between the flow and surfactant dynamics, we use a two-phase flow level-set method that has been adapted to include surfactant dynamics, namely bulk diffusion and bulk/surface exchanges (adsorption/desorption) [3]. The simulation geometry is summarized in figure 1b. It consists in an initial hexagonal arrangement of 2D hemispherical bubbles attached to upper and lower impermeable walls, with a distance of $\frac{2H}{\sqrt{3}}$ between nearest bubble centers. A shear flow is imposed by the velocity $\pm U$ at the walls. Periodic boundary conditions are imposed at the inlet and outlet of the flow. The simulations account for both the flow dynamics through Navier-Stokes equations, as well as the surfactant dynamics, driven by diffusion, adsorption/desorption and advection. Both bulk and surface surfactant concentrations, called F and f, are tracked. The surfactant dynamics feed back onto the flow through Marangoni stresses induced by surfactant inhomogeneities. More details on the physical equations and the numerical implementation can be found in [3].

In this work, we investigate in more detail the role of the so-called adsorption depth $h = f_e/(HF_e)$, i.e. the ratio of the equilibrium surfactant concentration at the interface and in the bulk, here normalized by the domain size. This quantity is a measure of availability for exchange of surfactant in the neighborhood of interfaces. Another key dimensionless quantity is the Péclet number $Pe = UH/D$ which compares advective and (bulk) diffusive mechanisms of surfactant transport.

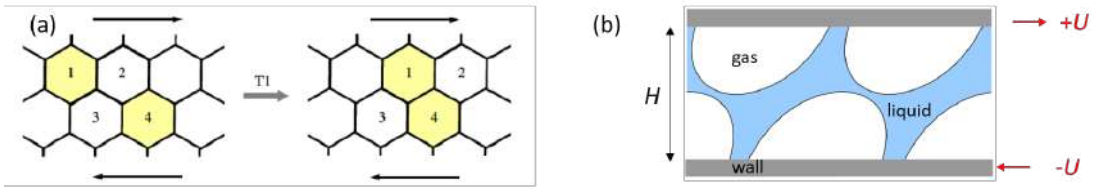

Figure 1: (a) Example of topological rearrangement of type 1 (T1 event). (b) Geometry of sheared bubbles and notations.

SURFACTANT REPARTITION

Before the flow starts, surfactant concentration is homogeneously distributed, both in the liquid and its surface, and at thermodynamic equilibrium ($F/F_e = f/f_e = 1$). After the walls are set into motion, bubbles become stretched in film regions where interfaces slip past each other, and are compressed near Plateau borders where opposite interfaces move either towards or away from each other. This results in zones on the interface that are either depleted or enriched in surfactants (see interfacial surfactant distributions, insets of figure 2), and leads to surfactant adsorption/desorption and bulk surfactant inhomogeneities. Figure 2 shows the surfactant concentrations both in liquid bulk (F) and on the surface (f) during T1 rearrangements at $Pe = 100$. Simultaneous snapshots are shown for two simulations with $h = 1$ (figure 2a) and $h = 0.01$ (figure 2b). Much more heterogeneous concentration distributions (hence stronger Marangoni stresses), both in bulk and on the interface, are observed for $h = 1$ than for $h = 0.01$.

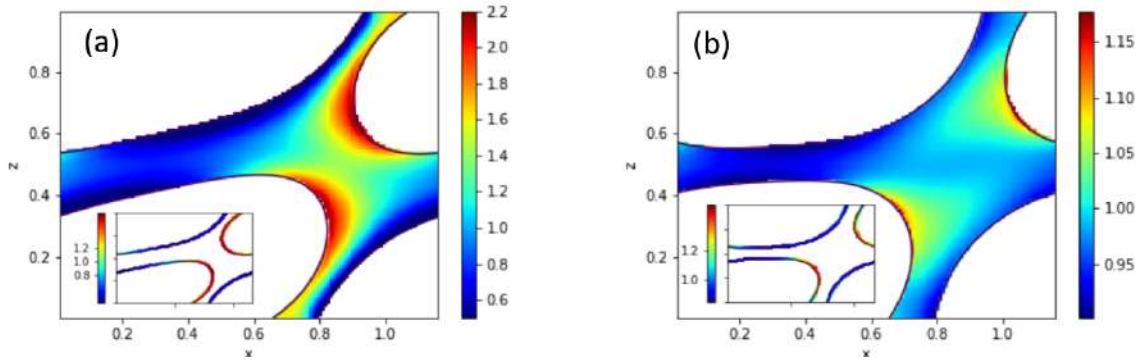

Figure 2: Bulk concentration F (in the liquid) during T1 event for (a) $h = 1$ and (b) $h = 0.01$. Top and bottom bubbles, in white, are moving to the right and left, respectively. Inset: Concentration f along the bubble surface. Bulk and surface concentrations are normalized by their equilibrium values F_e and f_e, respectively.

MECHANICAL RESPONSE

Reaction forces at the walls are computed as the sum of capillary forces at contact lines and the viscous drag forces from the gas and liquid [3]. From this, we calculate the total injected power for steady wall shear P_{inj}, whose temporal evolution is shown in figure 3a. We also compute the total rate of viscous dissipation in the bulk D_v. Figure 3a shows that both P_{inj} and D_v reach a steady state after approximately one bubble rearrangement. Once in steady state, we can therefore extract their time average $\langle P_{inj} \rangle$ and $\langle D_v \rangle$ (dashed lines in figure 3a), reported in figure 3b as a function of the adsorption depth h for two different Péclet numbers. For both $Pe = 1$ and 100, we observe that the total injected power $\langle P_{inj} \rangle$ increases with the adsorption depth. Finally, we also see that the power delivered to the plates is not entirely dissipated by the bulk viscosity : $\langle P_{inj} \rangle > \langle D_v \rangle$. This is because part of the energy supplied by the moving plates must do work at the interfaces, and is associated with an effective surface dissipation due to surfactant diffusion and adsorption/desorption, noted : $\langle D_s \rangle \equiv \langle P_{inj} \rangle - \langle D_v \rangle$ [3]. As h increases, the dissipation increase is mostly due to viscosity at $Pe = 100$ (stronger Marangoni stresses), while it is surface dissipation which increases at $Pe = 1$.

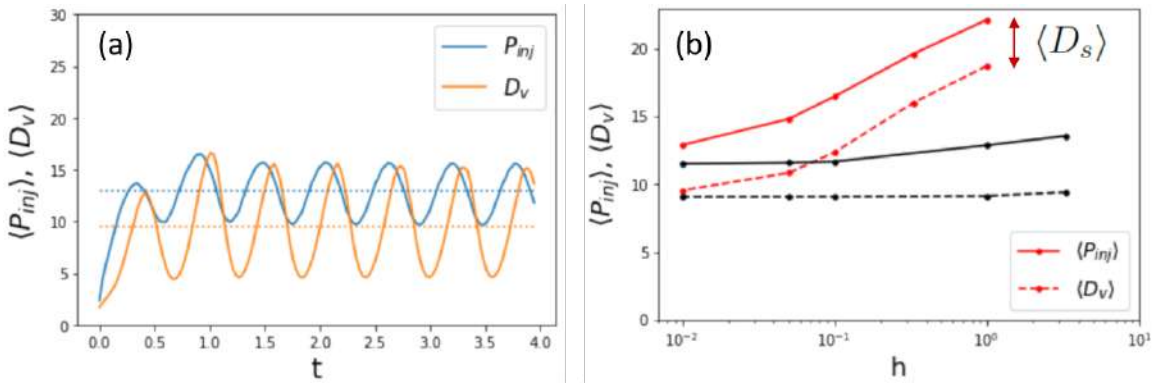

Figure 3: (a) Injected power P_{inj} and viscous dissipation D_v as a function of time t for $Pe = 100$ and $h = 0.01$. (b) Time-averaged injected power $\langle P_{inj} \rangle$ and viscous dissipation $\langle D_v \rangle$ as a function of h for $Pe = 100$ (red) and $Pe = 1$ (black). The difference between the two values correspond to effective surface dissipation $\langle D_s \rangle$.

CONCLUSION

We have shown that variations in adsorption depth result in more heterogeneous surfactant distributions in sheared layers of bubbles. This results in larger forces, which are due to dissipation both in bulk and on the interface. Our results will be compared to a classical model for interfacial dissipation in a simpler geometry [4].

Summary The evaporation dynamics of saline sessile droplets has a strong influence on the corrosion phenomenon under the drop. In order to complete some experimental studies conducted a few years ago, numerical simulations with a two-phase solver, Basilisk are performed. A validation of the model is done considering a pure water droplet following an unpinned of evaporation.

INTRODUCTION

In a marine environment, the sea spray carries small saline droplets coming from the ocean. Those droplets contains chlorides which are an aggressive polluant. The sea spray will deposit droplets on surroundings infrastructures such as buildings or industrial equipment: a drop resting on a surface is called a sessile droplet (Figure 1). In this configuration, the chlorides ions inside the saline sessile droplet are in contact with the material surface. They will etch locally the surface below the droplet and induce atmospheric corrosion phenomenon, such as pitting corrosion (Figure 1). The day/night cycles induce a variation of atmospheric conditions like humidity and temperature creating a repetition of evaporation and condensation phases for the sessile droplets: it increases the corrosion phenomena [2]. After the complete evaporation of the droplet, a salt deposit stays on the surface. The deposit pattern is the consequence of complex flows inside the drop during evaporation and is linked to the location of the corrosion.

(a) (b)

Figure 1: (a) Sessile droplet and (b) example of pitting corrosion.

The aim is to use numerical simulation in order to understand the corrosion induced by saline sessile droplets evaporation. First, pure water droplets are studied to validate the numerical model. Then, saline droplets will be considered.

DYNAMIC OF EVAPORATION

The evaporation of a sessile droplet involves various evaporation modes [1] which may succeed one another (Figure 2). Typical mode is called the constant radius mode or pinned mode: the radius of the drop remains constant whereas the contact angle decreases. This mode appear for particule laden droplets, surfaces with rought surfaces, or droplets wih an initial contact angle below 90 $^\circ$. The pinned mode allows to explain the coffee-ring effect [1]. A second well-known mode called the constant contact angle mode or unpinned mode usually appears, characterized by a constant contact angle whereas the contact line is moving as the radius decreases. The constant radius mode is frequently used to describe evaporation of a pure liquid droplet on a smooth surface: this mode is only academic and we will use it for the first study case of this work. Finally, when the droplet is really small, it becomes quite complicated to determine the exact evaporation behaviour. This last phase is described as a combination of the two first modes : the radius and the contact angle are varying simultaneously, as a stick and slide mode. The stick and slide mode is usually quite short, therefore it is neglected.

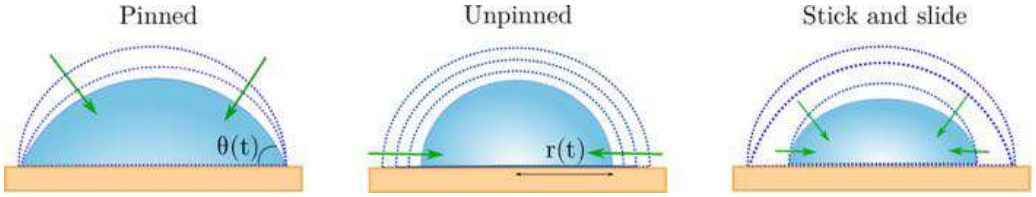

Figure 2: Evaporation modes for a sessile droplet.

We consider a 2D pure diffusive model. The vapor concentration gradient around the sessile droplet drives the evaporation. For sessile droplets with a contact angle θ different than 90 $^\circ$, the evaporation flux across the interface is non-uniform: the flux is stronger near the triple contact line than at the top of the drop (Figure3). Then, a capillary flow inside the droplet compensates this non-uniformity and ensures that the droplet keeps its spherical-cap shape.

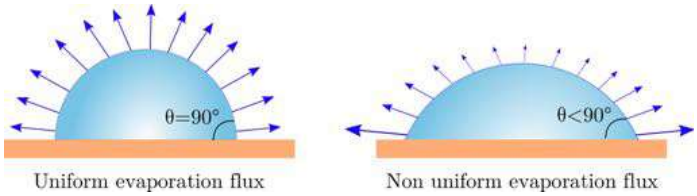

Figure 3: Evaporation flux along the interface for a sessile droplet, depending on the contact angle.

NUMERICAL MODEL

The numerical solver used is Basilisk, a free software, developped at Jean Le Rond DAlembert Institute by Stephane Popinet [3]. It implements numerical methods of finite volume for the Navier-Stokes equations and uses a VOF method to follow the gas-liquid interface with an adaptative mesh. Basilisk is written in C language and allows to simulate a wide range of incompressible flows.

EVAPORATION OF A PURE WATER SESSILE DROPLET

The case we propose is the evaporation of a pure water sessile droplet, evaporating according to an unpinned mode. The simulations have been done with different contact angles. The results (Figure 4) are in good agreement with the experimental results of [4]: when the contact angle decreases, the evaporation rate is higher. Indeed, the radius decreases faster in time for small contact angles. More results about the evaporation flux along the interface of the droplet and about the flows inside the droplet will be presented.

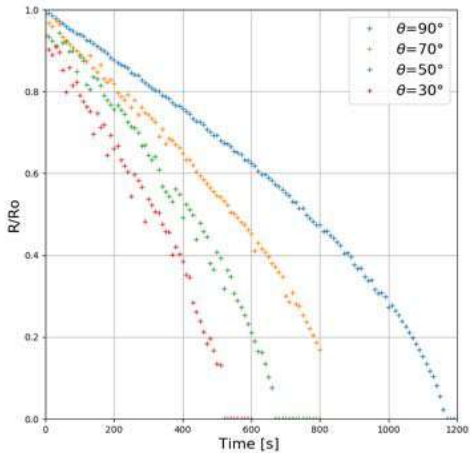

Figure 4: Evolution of the drop radius in time, depending on the contact angle.

CONCLUSIONS AND PERSPECTIVES

The study of a pure water droplet validates our numerical model. A new tracer field for the salt concentration has to be added in order to simulate saline sessile droplet. Coupling Marangoni effects with salt concentration dynamics is an interesting issue we are working on.

ENERGY BUDGETS IN BUBBLE COLLAPSE NEAR A RIGID SURFACE

Minki Kim, Shahaboddin Alahyari Beig, and Eric Johnsen
University of Michigan-Ann Arbor, Department of Mechanical Engineering, Michigan, USA

Summary Damage produced by collapsing cavitation bubbles depends on shock waves produced upon collapse. Additionally, the strength of these shock waves depends on the energy concentration during collapse, which itself is affected by the bubble dynamics. Thus, a better understanding of the underlying physics governing the bubble dynamics is essential to comprehend the damage mechanisms. This study investigates energy transfer pathways and energy concentration during the collapse of a cavitation bubble. Rayleigh−Plesset−type equations and the Boundary Integral Method are used to simulate spherical and non-spherical collapse of a bubble in incompressible and compressible liquids. Each energy partition (e.g., potential, kinetic and acoustic energy) is theoretically defined to compute the component of energy of the bubble and liquid, respectively.

INTRODUCTION

Cavitation occurs due to local pressure reductions in a liquid, leading to the formation of vapor bubbles [1]. When subjected to high pressure regions, the cavitation bubbles undergo a rapid compression that concentrate energy into a small volume, followed by the generation of a pressure wave propagating radially outward, which is capable of damaging its surroundings. In the vicinity of a solid boundary, the collapse becomes asymmetrical, as is evidenced by the formation of a high-speed liquid jet piercing the bubble. The impact of the jet upon the opposite side of the bubble or directly onto the solid boundary generates a shock, which subsequently creates high pressure, temperature, and stress region along the surface as it interacts with the boundary [2]. A better understanding of underlying physics governing bubble dynamics is essential to comprehend structural damage mechanisms, and potentially control/mitigate the erosion.

During the collapse of a cavitation bubble near a solid wall, the initial potential energy of the system is transferred into different modes: kinetic energy of the system, internal energy of the gas and the liquid, and energy radiated away through acoustic radiation. Understanding the energy transfer pathways between different modes helps to determine the origin of the pressure, temperature and shear stresses along the wall. Such quantities are of great importance when investigating cavitation erosion. We carry out numerical simulations of spherical and non-spherical collapse of a single bubble to identify the energy transfer pathways, quantify the energy concentration efficiency, and estimate the pressures and temperatures thereby produced.

METHODS AND PROBLEM SETUP

The efficiency of energy concentration and strength of the emitted pressure waves are expected to depend on the energy transfer between the bubble and the surrounding liquid. Here, the liquid compressibility is hypothesized to play a key role in the energy transfer. To examine the role of compressibility in the context of collapse of a single gas bubble near a rigid wall, we consider two problems: collapse in (a) incompressible, and (b) compressible liquids. Spherical collapse is described using the Rayleigh–Plesset [1] and Keller–Miksis [3, 4] equations. For non-spherical collapse, the mass and momentum equations are solved using the Boundary Integral Method (BIM) [5]. Additionally, we improve the BIM by taking the effects of liquid compressibility into account. This enables us to simulate the inertial collapse of individual bubbles at a higher driving pressure, where liquid compressibility can no longer be ignored. The problem is initialized by considering a bubble at its maximum volume, filled with a non-condensible gas. The collapse is driven by the difference in pressure inside and outside the bubble.

ENERGY PARTITION IN COLLAPSE OF A BUBBLE

Energy in the liquid-bubble system consists of potential (internal), kinetic and acoustic energy. The potential energy of the liquid is the energy stored in the liquid by the pressure at the far field, p_∞ with respect to the state of zero potential energy. It is defined as

$$E_{L,pot} = p_\infty V_B, \tag{1}$$

where V_B is the bubble volume. Another type of the energy in the liquid is the kinetic energy. The kinetic energy of the liquid is the kinetic energy of the fluid particles in the flow, which can be calculated by integrating the local kinetic energy along the boundary of the liquid domain,

$$E_{L,kin} = \frac{1}{2} \oint_{S_B+S_\infty} \phi \frac{\partial \phi}{\partial n} dS, \tag{2}$$

where ϕ is the velocity potential, S_B and S_∞ is the inner and outer boundary of the domain. For the spherical bubble, Eq. 2 reduces to $3/2\left(4\pi\rho_\infty R^3/3\right)\dot{R}^2$, where ρ_∞ is the reference density of the liquid, R is the bubble radius, and $\dot{R}$ is the

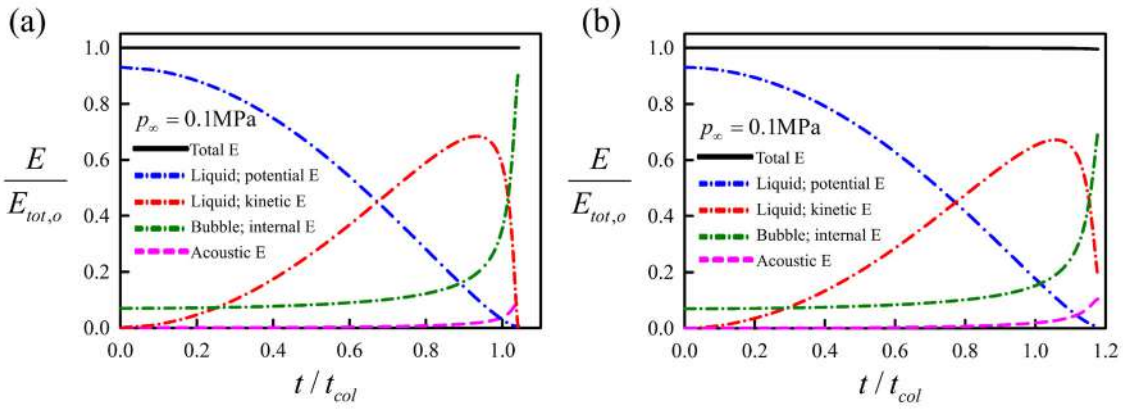

Figure 1: Time evolution of the different modes of energy in (a) spherical and (b) non-spherical collapse of a bubble with p_∞ = 0.1MPa. The total energy (black line), liquid potential (blue line) and kinetic (red line) energy, bubble internal energy (green line) and acoustic energy (pink line) are shown.

bubble wall velocity. The internal energy of the bubble is the sum of the energy of the gas particles in the bubble and can be obtained using the equation of state,

$$E_{B,int} = \frac{p_B V_B}{k-1}, \tag{3}$$

where p_B is the pressure inside a bubble, and k is the specific heat ratio of the gas. Since the bubble is homobaric and follows a polytropic relation, the kinetic energy of the bubble is always zero. The energy of the acoustic waves radiated away from the bubble to the far-field is [5]

$$E_{ac} = \int_0^t -\frac{1}{4\pi}\frac{\rho_\infty}{c_\infty}\dot{V}_B\ddot{V}_B dt, \tag{4}$$

where c_∞ is the reference sound speed in the liquid.

RESULTS AND DISCUSSIONS

Figure 1 shows the time evolution of the different modes of energy in both spherical and non-spherical collapse, both liquid and bubble energy are potential at $t = 0$. During the collapse, this potential energy of the liquid is transferred to internal energy of the bubble and kinetic energy of the surrounding liquid. This latter reaches a maximum value prior to the collapse. Thereafter, the liquid kinetic energy starts to decrease when the bubble reaches the maximum velocity. Differences between the spherical and non-spherical collapse are mainly observed at the final stage of the collapse. When the bubble collapses spherically, the pressure increase inside the bubble decelerates the bubble wall to a full stop at collapse, such that the kinetic energy of the liquid becomes zero. However, in the non-spherical collapse, a re-entrant jet develops and penetrates the bubble. The collapse becomes highly non-spherical when the jet hits the opposite side of the bubble wall. Due to the formation of the liquid jet, a significant portion of the initial potential energy is transferred into the kinetic energy of the surrounding liquid, thus impeding the energy concentration into the bubble potential energy. In both spherical and non-spherical cases, due to liquid compressibility, a substantial portion of the initial potential energy is radiated away from the bubble through acoustic radiation.

CONCLUSIONS

In this study, we investigate the energy transfer pathways into different modes of energy (potential, kinetic, acoustic) during the spherical and non-spherical collapse of a single gas bubble. In the presentation, we will further examine more about non-spherical collapse. For which the initial stand-off distance of the bubble is an important factor determining the efficiency of energy concentration. Thus, energy partition at the final collapse will be compared as the initial stand-off distance varies.

CONTACT LINE DISSIPATION FILTERS DROPLET IMPACT ENERGY

Vanessa R Kern[1] and Paul H Steen *[1]
[1] Department of Chemical and Biomolecular Engineering, Cornell University, Ithaca, New York

Summary The dynamics of 2-15μL water droplets vertically impacting rigid hydrophobic and hydrophilic substrates at $Re = 0 - 800$ and $We < 16$ are recorded at a frame rate of at least 5000 fps and post-processed in MATLAB using sub-pixel edge detection techniques [1]. The partitioning of the droplet's energy between contact line dissipation and vibrational energy is studied in a continuum mechanics framework [3]. It is found that contact line dissipation acts as a filter, filtering out the spreading energy to leave the post contact-line-pinning energy. That is, the post contact-line-pinning energy is shown to be invariant to the impact energy. A method for predicting this partitioning is presented. The partitioned pinning energy depends only on the pinning contact angle (α_P), equilibrium contact angle ($\overline{\alpha}$) and the contact angle hysteresis ($2\Delta\alpha_A$).

EXPERIMENTAL OVERVIEW

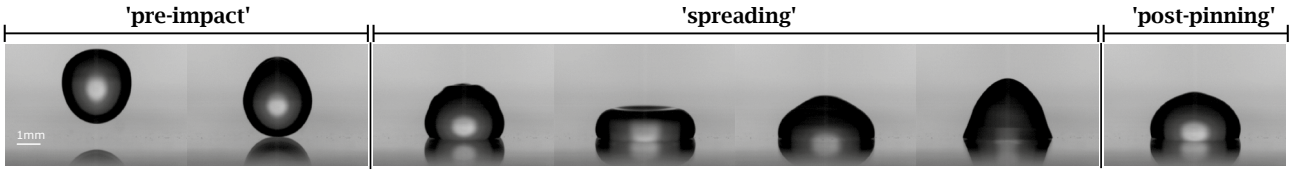

Figure 1: A 13.8 μL water droplet impacting a fluorosilanated glass surface. Time increases left to right. The impacting event can be divided into 3 stages: 'pre-impact', 'spreading', and 'post-pinning'. Each stage has an associated energy contribution.

Water is pumped from a beaker using a Ramé-Hart auto-dispensing system through a syringe tip at a rate of 1.0 μL/s. The droplet is allowed to break from the syringe tip due to gravity and fall onto a homogeneous chemically prepared surface. The impacting event and subsequent dynamics are recorded with a frame rate of at least 5000 fps using a Redlake MotionXtra HG-XL high-speed camera. See Figure 1 for typical experimental images. Multiple syringe tips of gauges 22-30 are used to control the droplet's volume to ±0.1μL. The droplet's 'pre-impact' kinetic energy, K_0, is controlled by varying the fall height. Various surface and liquid combinations are tested to explore a variety of equilibrium contact angles, $69° \leq \overline{\alpha} \leq 105°$, (half) contact angle hysteresis $\Delta\alpha_A = \alpha_A - \overline{\alpha}$, $8° \leq \Delta\alpha_A \leq 22°$, surface tensions, $0.048 \leq \sigma \leq 0.073$ N/m, and viscosities, $1 \leq \mu \leq 20$ cP. Surfaces are characterized using a Ramé-Hart goniometer. Experimental We and Re for each surface/liquid combination are chosen to span a range of K_0, limited to avoid energetic regimes where partial rebound and/or droplet ejection events occur.

DISCUSSION

We will frame our discussion about droplet impact around equation (2.7) from [3], with modified notation:

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(K+\mathcal{A}\right) = -\int_V tr\left(T\cdot D\right)\mathrm{d}V + \int_{\Gamma_{ls}} u\cdot T\cdot n_1 \mathrm{d}s + \sigma\oint_\gamma U\left(\cos\left(\overline{\alpha}+\Delta\alpha\right)-\cos\overline{\alpha}\right)\mathrm{d}l \tag{1}$$

where $\Delta\alpha \equiv \alpha - \bar{\alpha}$ and α is the actual (dynamic) contact angle. The kinetic and surface energies are defined as,

$$K \equiv \frac{1}{2}\int_V \rho u^2 \mathrm{d}V, \quad \mathcal{A} \equiv \sigma_{lg}(A_{lg} - \cos\overline{\alpha}A_{ls}) \tag{2a, b}$$

where subscripts sg, lg and ls denote solid-gas, liquid-gas and liquid-solid interfaces, respectively, and where the surface energy assumes $\sigma_{sg} \approx 0$. The notation is standard.

For normal impact onto a homogeneous surface, we assume that the contact line spreads with radial symmetry, $R(t)$, that is, with a circular shape. We also assume the fluid is inviscid, $\mu << 1$, and incompressible, $\nabla\cdot\boldsymbol{v} = 0$. Together these assumptions allow us to neglect the first two terms on the right hand side of (1), which leaves after integration,

$$\{K+\mathcal{A}\}_0 - \{K+\mathcal{A}\}_p = -\sigma\int_0^{t_s} 2\pi R\dot{R}\left(\cos\left(\overline{\alpha}+\Delta\alpha\right)-\cos\overline{\alpha}\right)\mathrm{d}t. \tag{3}$$

Here, $\{K+\mathcal{A}\}_0$ denotes the droplet's 'pre-impact' energy and $\{K+\mathcal{A}\}_p$ the droplet's 'post-pinning' energy. The right hand side represents the energy dissipated at the contact line (CL) during the 'spreading' stage, where t_s is the duration of the 'spreading' stage, R the radius of the CL, $\dot{R}$ the speed of the CL and $\Delta\alpha$ the deviation of the instantaneous contact

*Corresponding author. E-mail: phs7@cornell.edu.

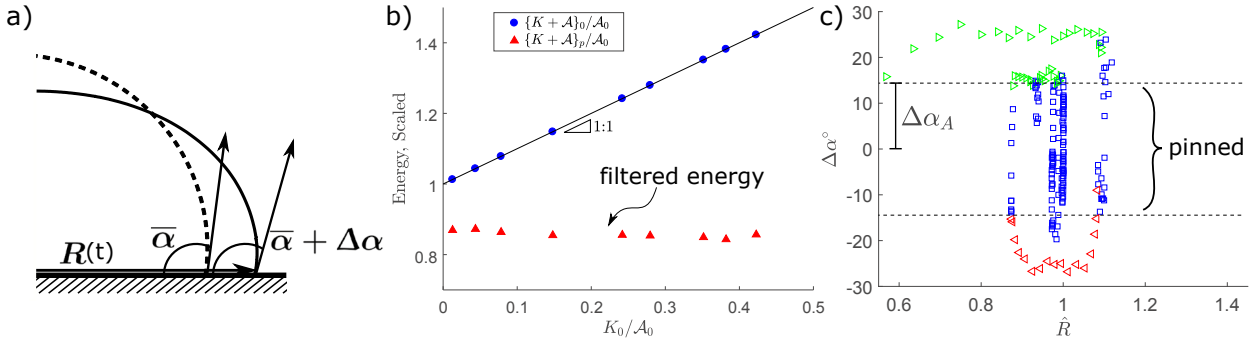

Figure 2: Post droplet impact filtering of impact energy: (*a*) Definition sketch for radial advancing/receding of CL, showing deviation contact angle $\Delta\alpha$, relative to angle $\overline{\alpha}$ measured at rest shape (dashed), at instantaneous spreading radius $R(t)$; (*b*) The 'pre-impact' energy (solid circles) and the 'post-pinning' energy (solid triangles) plotted vs the 'pre-impact' energy for a water droplet impacting a fluorosilanated surface. All energies are scaled by the droplet's 'pre-impact' surface energy; (*c*) $\Delta\alpha$ plotted against $\hat{R}$ for a droplet of water impacting a fluorosilanated surface with an impact kinetic to surface energy ratio, $K_0/\mathcal{A}_0$, of 0.33. Time moves clockwise. ▷ represents an advancing contact line, ◁ a receding contact line and □ a pinned contact line. Advancing/receding occurs when $|\Delta\alpha| > \Delta\alpha_A$. The radius of the droplet's footprint, $\hat{R}$, is scaled by the droplet's equilibrium footprint radius. $\Delta\alpha$ is measured using the goniometer software DropImgAdv and $\hat{R}$ is measured from images in MATLAB using subpixel edge detection techniques [1].

angle from the equilibrium contact angle, $\overline{\alpha}$. Eqn. (3) implies that the only form of dissipation in the system is from the work done by the contact line as it moves along the surface, consistent with [4,5].

In order to quantify $\{K+\mathcal{A}\}_p$, the 'post-pinning' energy, we use sub-pixel edge detection techniques from [1] in MATLAB to track the deflection of the droplet's lg interface. We then decompose the motion of this interface into modal contributions from [2] and calculate the interfacial energy. This calculation is validated by measuring the surface energy directly from the experimental images. The 'pre-impact' kinetic energy, $\{K+\mathcal{A}\}_0$, is calculated by measuring the droplet's fall height, and validated by measuring the impacting velocity from the experimental images. We assume the droplet is spherical prior to impact. Fig. 2 (b) summarizes these findings, showing the invariance of the 'pre-impact' energy to the 'post-pinning' energy.

In order to quantify the 'spreading' energy, the position of the contact line, R, is tracked in time in MATLAB using subpixel edge detection techniques from [1], and the deviation of the contact angle from $\overline{\alpha}$, denoted $\Delta\alpha$, is calculated using the software DropImgAdv. These values are then used to calculate the right hand side of eqn. (3). Typical plots generated during this calculation are shown in Fig. 2 (c). After impact, the droplet's contact line oscillates about its equilibrium value, dissipating energy. If subject to a forced vibration from below, a plot such as Fig. 2 (c) would form a closed loop [4]. In summary, for low $K_0/\mathcal{A}_0$, it is found that eqn. (3) holds.

Lastly, by manipulating equation (3), we arrive at a prediction for the 'post-pinning' energy,

$$\frac{\{K+\mathcal{A}\}_p}{\mathcal{A}_0} = 1 - f(\alpha_P)\left(\cos\overline{\alpha} - \cos\left(\overline{\alpha} + \Delta\alpha_A\right)\right), \tag{4}$$

where $f(\alpha_P)$ represents the geometry of the pinned drop and is explicitly known.

CONCLUSIONS

The dynamics of 2-15μL water droplets vertically impacting chemically modified rigid substrates are studied. It is experimentally determined that droplets vibrate post impact with frequencies and shapes of the pinned $l = 0$ modes detailed in [2]. A discussion of the partitioning of a droplet's energy between 'spreading' and 'post-pinning' is presented and framed using theory from [3]. It is shown experimentally that a droplet's 'post pinning' energy, $\{K+\mathcal{A}\}_p$, is approximately invariant to its 'pre-impact' energy, with the remainder going to contact line dissipation. It is also shown that, for low $K_0/\mathcal{A}_0$, eqn. (3) holds. Lastly, a method for predicting the filtered energy $\{K+\mathcal{A}\}_p/\mathcal{A}_0$ is presented. The filtering depends only on $f(\alpha_P)$, $\overline{\alpha}$ and $\Delta\alpha_A$. The difference between the 'pre-impact' and 'post-pinning' energies represent the energy available for advancing/receding CL motion.

MULTILAYER VOLUME-OF-FLUID FOR COALESCENCE PREVENTION WITH APPLICATION TO A FOAMING WATERFALL

Petr Karnakov[1], Sergey Litvinov[1], and Petros Koumoutsakos*[1]
[1] Computational Science and Engineering Laboratory, ETH Zurich, Switzerland

Summary We present a new algorithm for simulating multiphase flows with bubbles and drops that do not coalesce. The algorithm is more efficient than the standard multi-marker volume-of-fluid method since the number of required fields does not depend on the number of bubbles. Together with a novel particle method for curvature estimation, this allows us to solve problems with large clusters of small bubbles on a uniform mesh. The capabilities of our method and its high performance implementation are demonstrated on simulations of constrained mean curvature flow, drop impact on a liquid-liquid interface and a foaming waterfall. The implementation is open source (`https://github.com/cselab/aphros`).

INTRODUCTION

Many processes in nature and industry involve multiphase flows where bubbles and drops do not coalesce but instead collide or form clusters. Examples include crowns of foam on sea water [1], viscous suspensions, and turbulent bubbly flows in chemical reactors. Coalescence is prevented by surfactants, viscous forces and the Marangoni effect. Numerical simulations of such flows are challenging since they resolve only finite length scales, while the liquid film between bubbles can be arbitrarily thin. Front-capturing methods, such as the volume-of-fluid or level-set methods, cannot describe multiple interfaces in one computational cell, so bubbles always coalesce at shorter distances. To prevent coalescence, the multi-marker volume-of-fluid method [2] introduces a separate volume fraction field for each bubble, which is expensive for systems with many bubbles. The Voronoi implicit interface method [3] uses a single level-set function but has a super-linear complexity and requires a band of cells near the interface which puts limits on the minimal resolution.

NUMERICAL ALGORITHM

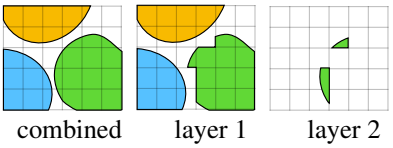

Figure 1: Multiple layers with color functions. Combined field can describe overlapping interfaces, while each layer has at most one bubble per cell.

We propose an algorithm that is equivalent to the multi-marker volume-of-fluid method [2] and uses standard routines of the volume-of-fluid method, but its cost does not depend on the number of bubbles. Our algorithm represents many bubbles with only few fields, referred to as *layers*, and employs *color functions* to distinguish between bubbles. To perform a stencil operation, we combine values from cells of the same color. We apply the algorithm to incompressible multiphase flows with surface tension using a projection-based method for the Navier-Stokes equations and a novel particle method [4] for curvature estimation. The high performance implementation of our solver is based on the Cubism library [5] and shows good scaling of 80% up to 2000 compute nodes of Piz Daint supercomputer. The open source implementation, documentation, examples of simulation setups and visualizations are available at `https://github.com/cselab/aphros` [7].

APPLICATIONS

Constrained mean curvature flow

In the limiting case of no inertia, the equations of fluid flow with surface tension simplify to one expression for the velocity field

$$\boldsymbol{u} = \sum_{l=1}^{L} \kappa_l \nabla \alpha_l - \nabla p,$$

where κ_l and α_l are the mean curvature and the volume fraction field on layer l, the number of layers $L = 4$ and the scalar field $p(\boldsymbol{x}, t)$ is found from the Poisson equation $\nabla^2 p = 0$ to make the velocity field divergence-free. We adopt the initial conditions from [3] which are defined as a Voronoi diagram of a randomly chosen set of 100 points. Zero Neumann boundary conditions are imposed for the volume fraction fields. Initially, the interfaces are straight and form junctions at various angles. The flow minimizes the area (length) of the interfaces such that the angles at triple junctions approach 120°. As seen from Figure 2, our method produces results similar to that of the Voronoi implicit interface method (VIIM) [3]. Both methods operate on a mesh of 256^2 cells. Unlike VIIM, our algorithm has linear complexity to the number of cells and uses standard routines of the volume-of-fluid method.

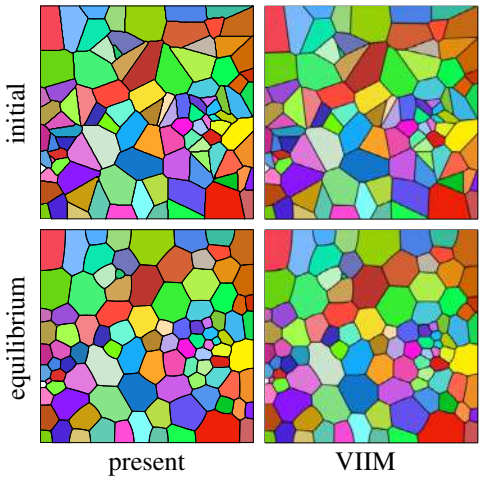

Figure 2: Constrained mean curvature flow. Our method (left) produces results similar to that of the Voronoi implicit interface method [3] (right). Interfaces at triple junctions form 120° angles.

Drop impact on liquid-liquid interface

The second test validates the model on the case of the gravity-driven impact of a liquid drop onto a liquid-liquid interface. The problem is solved in a rectangular domain with a height of 10 cm on a mesh containing $160\times320\times160$ cells with no-slip walls in the vertical direction and periodic conditions in the other directions. Parameters of the problem are taken from numerical study [2] based on experiment [6] (Combination 1): density $\rho_1 = 949$ and $\rho_2 = 1128$ kg/m^3, viscosity $\mu_1 = 0.019$ and $\mu_2 = 0.0063$ Pa $\cdot$ s, gravitational acceleration $g = 9.8$ m/s^2 and surface tension coefficient $\sigma = 0.029$ N/m. They correspond to a water+glycerin drop falling in silicon oil. A spherical drop of a radius 5.1 mm is initially placed at a distance of 67 mm between its center and the interface. The drop rests on the interface without coalescence due to high viscosity of the liquids. Slices of the interfaces are shown in Figure 3 compared to numerical [2] and experimental data [6]. Our algorithm produces the same results as the multi-marker volume-of-fluid method method [2], but it is more efficient for systems with many bubbles or drops.

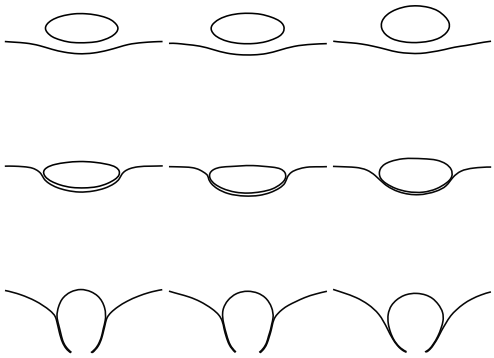

Figure 3: Drop impact on liquid-liquid interface. Our method (left) produces the same results as the multi-marker volume-of-fluid method [6] (center), but it is more computationally efficient for systems with many bubbles or drops. Both methods agree well with experimental data [6] (right).

Foaming waterfall

This application combines various physical processes such as air entrainment, bubble breakup in turbulent flows and generation of foam. The problem is solved in a rectangular domain with a height of 10 cm on a mesh containing $768 \times 384 \times 384$ cells. The initial velocity is zero, and the volume fraction represents the water surface in the middle of the domain. The boundary conditions are periodic in the depth direction and the other boundaries are free-slip walls. Parameters of the problem are density $\rho_1 = 1000$ and $\rho_2 = 10$ kg/m^3, viscosity $\mu_1 = 10^{-3}$ and $\mu_2 = 10^{-5}$ Pa $\cdot$ s, gravitational acceleration $g = 9.8$ m/s^2 and surface tension coefficient $\sigma = 0.072$ N/m. The thickness of the waterfall is 5 mm and the inlet velocity is 1.5 m/s. The sheet of water impacts the surface and causes air entrainment. This generates bubbles that rise and cluster up on the surface. Figure 4 shows a snapshot of the interface and a horizontal cross section through the cluster of bubbles. At this time, the total number of bubbles in the liquid is about 25'000. The cluster of bubbles shows characteristic features of foam: thin membranes separating neighboring bubbles (lamellae) and junctions of multiple membranes (Plateau borders). This case demonstrates that our method of coalescence prevention can describe the formation of clusters with thousands of bubbles.

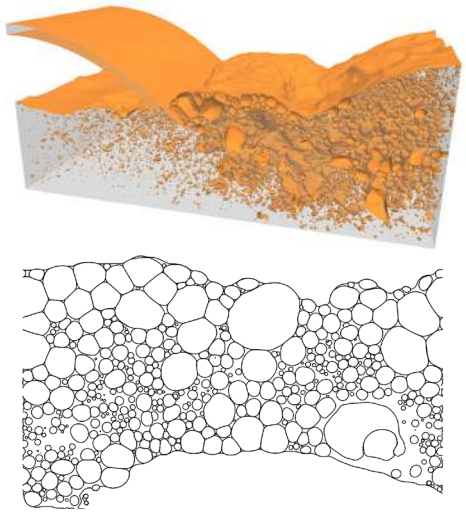

Figure 4: Foaming waterfall. Snapshot of the interface (top) and a horizontal cross section through the cluster of foam (bottom).

CONCLUSIONS

We have presented a new algorithm for simulating multiphase flows with non-coalescing bubbles or drops. Our algorithm produces the same results as the standard multi-marker volume-of-fluid method, but it is more computationally efficient since the number of fields required to represent overlapping interfaces does not depend on the number of bubbles in the simulation. Unlike the Voronoi implicit interface method, it has linear complexity to the number of cells, uses standard routines of the volume-of-fluid method and does not require a band of a few cells between the interfaces. The case of foaming waterfall demonstrates that our method can describe the formation of clusters of foam.

PATTERN FORMATION DURING THE IMPACT OF A PARTIALLY FROZEN DROPLET ON AN UNDERCOOLED SURFACE

Pallav Kant *[1], Henrik Müller-Groeling[2], and Detlef Lohse[1,3]

Summary Impact of a droplet on an undercooled solid surface instigates several physical processes simultaneously. The involved processes are further complicated when the impacting droplet is partially frozen. Here, we experimentally probe the complex interplay between droplet scale motion and phase transition effects during the impact of a binary droplet on an undercooled surface which partially freezes in flight due to the evaporative cooling of the volatile component. We adapt the TIR (Total-Internal-Reflection) optical technique to visualize the nucleation and growth of the solidified phase while the droplet spreads on the surface. Our experiments reveal that when a partially frozen droplet impacts onto an undercooled surface, the presence of crystals near the advancing contact line locally increases the effective viscosity and results in classical viscous fingering.

INTRODUCTION

Freezing or solidification of impacting droplets is omnipresent in nature and technology, be it a rain droplet falling on a supercooled surface, be it in inkjet printing where often molten wax is used, be it in added manufacturing or in metal production processes or in extreme ultraviolet lithography (EUV) for the chip production where molten tin is used to generate the EUV radiation. For many of these industrial applications, a detailed understanding of the solidification process is essential. Whereas a large number of studies have investigated the corresponding interface deformations and the spreading of a droplet after it impinges onto an undercooled surface [1], the *kinetics* of phase transition within the impacting droplet has been addressed only in a few [2]. Moreover, the literature on this topic has been limited to the idealised scenarios where a liquid droplet solidifies post its impact on an undercooled surface, whilst, in nature and in industry complex scenarios arise due to the impact of partially frozen droplets.

In the present work, we adapt the total-internal-reflection (TIR) technique to visualise the phase transition in the vicinity of the liquid-substrate interface after a droplet impacts onto an undercooled transparent surface. This unique technique allows temporally and spatially resolved insight into the nucleation events and crystal growth occurring next to the cold surface on an evanescent length scale ($\sim$ 100 nm), which is otherwise inaccessible through any other optical technique. Through this technique, we are able to reveal the complex interplay between drop-scale fluid motion within droplet and crystal growth that results in morphologies analogous to patterns observed in classical displacement flows.

EXPERIMENTAL METHODS

A schematic diagram of the experimental setup is shown in Fig. 3. In each experiment, a pendant drop of 80:20 binary mixture of hexadecane (99%, Sigma-Aldrich) and diethyl ether (Sigma-Aldrich) was released from the tip of a needle. Both liquids are optically transparent at room temperature and completely miscible. Hexadecane has a high melting point $T_\mathrm{m} = 18°\mathrm{C}$ and is non-volatile at room temperature. Whereas diethyl ether has low boiling point $T_\mathrm{b} = 36°\mathrm{C}$ and is extremely volatile at room temperature. Thus, the evaporation of volatile diethyl ether from a binary droplet hanging from the needle results in the preferential freezing of hexadecane. Thus, in each experiment the pendant droplets while hanging from the needle tip froze from the outside in and the impacting droplet was covered in a frozen shell. The impact event was recorded in side-view as backlit shadow-graphs and in bottom-view *via* the total-internal-reflection technique. The solidified phase appears as a gray-shaded region in the TIR imaging. The impact velocity and shape/size of the droplet at the time of impact were measured from side-view images recorded with a high-speed camera (Photron Mini) at 10000-14000 fps with a macro lens. Bottom view observations (*via* TIR) were recorded using a high-speed camera (Photron Fastcam, NOVA) connected to a long-distance microscope (Navitar 12x Telecentric zoom system) at 80,000 fps.

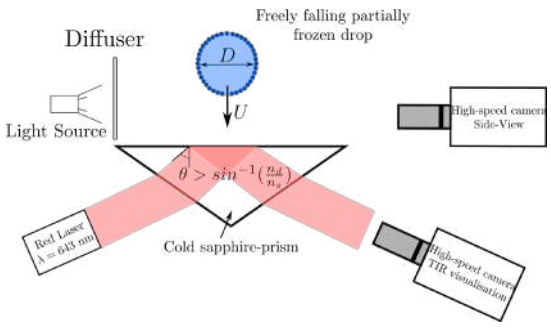

Figure 1: Schematic diagram of the experimental setup employing total-internal-reflection technique to visualise the freezing behaviour of an impacting droplet on undercooled surface.

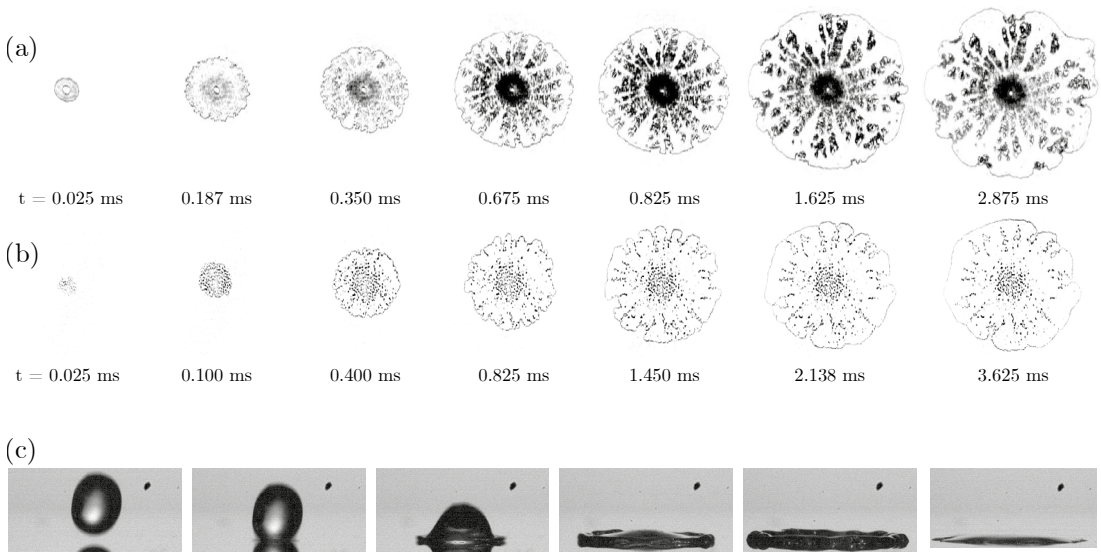

Figure 2: Sequences of experimental snapshots highlighting the outcomes of impact of (a) partially frozen binary droplet on an undercooled surfaces maintained at $\Delta T = T_m - T_s = 9\,\mathrm{K}$ and (b) liquid marble. In both cases the impact velocity of the droplet is $U = 2.8$ m/s. (c) Typical interface deformations associated with the impact of a partially frozen droplet.

RESULTS

Sequence of snapshots in Fig. 2a show the evolution of the footprint of an impacting partially frozen droplet while is spreads on a flat surface at $\Delta T = T_m - T_{substrate} = 9\mathrm{K}$. The Reynolds number $Re = \rho DU/\mu$ associated with the impact is 1150. Typical deformations of the partially frozen droplet, recorded from side-view are shown in the sequence Fig. 2c.

Immediately after the droplet makes contact with the substrate two concentric rings appear in the TIR images; see the first panel of the sequence in Fig. 2a. The outer ring corresponds to the contact line of the droplet that continues to move radially outwards. The inner ring highlights the footprint of the bubble entrapped underneath the droplet interface. In time, we notice that the footprint of the impacting partially frozen droplet evolves in a non-circular fashion, perturbations at the contact line are clearly visible in the images. The solidification first initiates at the center as a cloud of crystallites appears in the middle of the wetted area. Further, the solidified area evolves into growing finger-like patterns as the droplet continues to spread outwards in a non regular fashion. We believe that the growth of solidified phase in this particular fashion is directly related to the presence of crystallites at the droplet interface during spreading. To confirm our hypothesis we performed impact experiments with liquid marbles; see sequence of snapshots in Fig. 2b. In both cases we observe non-regular advancing motion of contact as well as growth of finger-like structure. Furthermore, we noticed that the overall solidification patterns are greatly affected by the impact velocity. The finger-like patterns become increasingly disconnected from the central frozen area with increasing impact velocity; see Fig. 3.

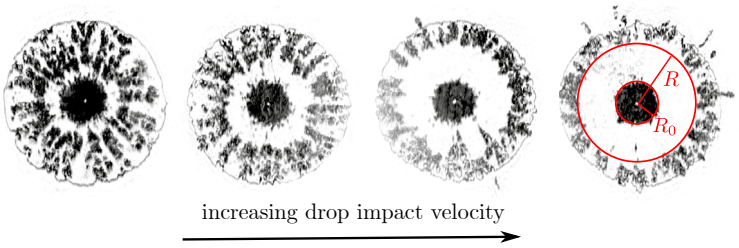

Figure 3: Appearance of the white annular region around the location of impact at high impact velocities.

CONCLUSION

We have shown that the impact of a partially frozen droplet on an undercooled surface results in the formation of growing finger-like patterns. The ongoing investigations explore the parameter space under what exact conditions this instability occurs.

THE EFFECT OF GEOMETRIC PERTURBATIONS ON A STATIC MENISCUS

Eleanor C. Johnstone *[1], Andrew L. Hazel[1], and Oliver E. Jensen[1]
[1] Department of Mathematics, University of Manchester, Manchester, U.K.

Summary We present results for the shape of a static air-liquid meniscus in a rectangular channel with geometric perturbations imposed on the walls. The sensitivity of the meniscus shape to small perturbations is examined in a linearised system. We show that perturbations which change the volume of the system induce long-range responses in the meniscus shape and non-monotonic displacement of the contact line. These experimentally-testable results show that static menisci can be strongly influenced by small occlusions in a channel.

INTRODUCTION

Numerous wetting and coating processes take place within physical domains in which there are small geometric imperfections that can have a profound influence on the dynamics ([1], [2]). Working in a Hele-Shaw geometry, we show here how capillary effects alone allow geometric perturbations to have a long-range impact on static interface shapes.

STATEMENT OF PROBLEM

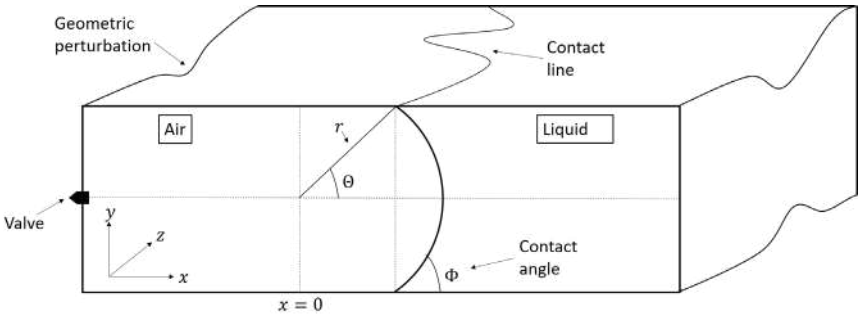

Figure 1: A static meniscus in a rectangular channel with geometric perturbations to the upper and lower walls.

We consider a static air-liquid meniscus in a rectangular channel with non-dimensional size $2L$, 2 and $2W$ in the x, y and z directions respectively; see figure 1. The upper and lower walls of the channel have geometric perturbations, $\epsilon\beta_U(z)$ and $\epsilon\beta_L(z)$ respectively, which are small relative to the height of the channel (so $\epsilon \ll 1$). In practice, these perturbations could be implemented by etching the channel walls with a needle to create a groove, or adding a strip of paint to create a ridge. We assume that the meniscus meets the channel walls with fixed contact angle ϕ. In order to remove translational invariance, we also impose that the volume of fluid in the channel is fixed. Subject to these physical constraints, the problem is then to find the surface of mean curvature for a given channel geometry, given by the Young–Laplace equation.

We assume that the perturbation to the interface shape and contact line displacement are also $O(\epsilon)$. We perturb around the base state in which the meniscus is the arc of a cylinder with radius $R = \sec(\phi)$. Adopting cylindrical polar coordinates (r, θ, z) about an axis lying in the mid-plane of the channel (see figure 1), we can write the interface location as $r = R+\epsilon f(z, \theta)$ and $\theta \in [-(\pi/2) + \phi + \theta_L(z), (\pi/2) - \phi + \theta_U(z)]$. Together with the physical constraints described above, the Young-Laplace equation for the perturbation to the interface shape then becomes the Helmholtz equation

$$\frac{1}{R^2} f + \frac{1}{R^2} f_{\theta\theta} + f_{zz} = -p, \tag{1}$$

with p the pressure difference across the meniscus. The boundary conditions on the upper and lower walls remain that the contact angle is fixed to be ϕ and we also impose the condition that the meniscus meets the side walls normally. The problem is closed with a condition on the volume of fluid in the channel:

$$\int_{-W}^{W} \int_{-\frac{\pi}{2}+\phi}^{\frac{\pi}{2}-\phi} f(z, \theta)\, \mathrm{d}\theta\, \mathrm{d}z \propto \int_{-W}^{W} [\beta_U(z) - \beta_L(z)]\, \mathrm{d}z. \tag{2}$$

The volume constraint allows two specific configurations: a volume-preserving configuration with $\beta_U(z) = \beta_L(z) = B(z)$ (mirror anti-symmetric), and a volume-changing configuration with $\beta_L(z) = -\beta_U(z) = B(z)$ (mirror symmetric). Self-adjointness of the Helmholtz equation (1) shows that the pressure difference at the meniscus has the same dependence

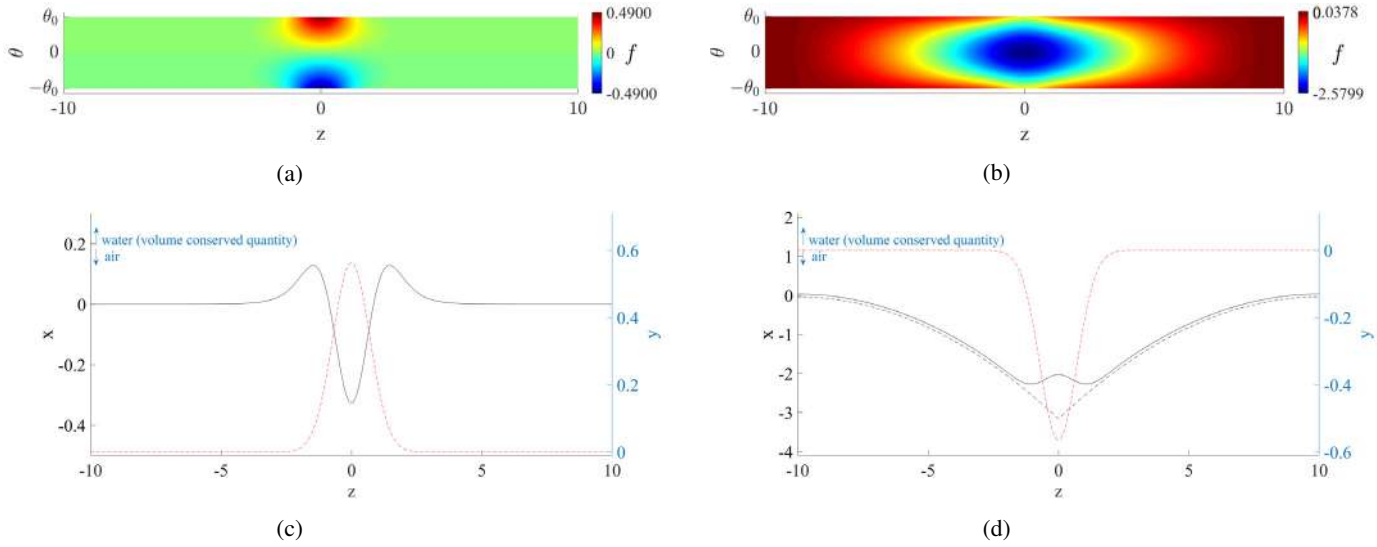

Figure 2: Results for a channel with half-width $W = 10$, half-length $L = 20$ and contact angle $\phi = \pi/16$. (a)-(b): the change in meniscus shape $f(z, \theta)$. (c)-(d): the upper wall contact line displacement $x = f(z, \pi/2 - \phi)\sin(\phi) - f_\theta(z, \pi/2 - \phi)\cos(\phi)$ (black line), and the geometric perturbations $y = \beta_U(z)$ (red dashes). (a), (c): volume-preserving configuration; (b)-(d): volume-changing configuration. The black dashed line in (d) is the far-field approximation (3).

on the boundary data; $p \propto W^{-1}\int_{-W}^{W}[\beta_U(z) - \beta_L(z)]\,\mathrm{d}z$. In particular, for volume-preserving perturbations, no pressure difference at the meniscus is induced and the Helmholtz equation is unforced.

For zero contact angle $\phi = 0$ the problem remains the same, however an expansion to powers of $O(\epsilon^2)$ is needed to obtain the boundary conditions as a degeneracy appears when the meniscus meets the walls tangentially.

RESULTS

We assume that the geometric perturbations to the channel take the form of a Gaussian distribution. The problem (1)-(2) is most easily solved analytically via separation of variables. In the volume-preserving case (figure 2a), the meniscus protrudes into the air at the groove on the upper wall, and recedes at the ridge on the upper wall. Here the response is localised around the perturbation. However in the volume-changing case (figure 2b), the narrow ridges on the upper and lower walls induce a long-range response in the shape of the meniscus, which bulges into the air across the entire width of the channel.

The contact line displacement (2c) is not monotonic for positive z, despite the perturbation being monotonic for $z > 0$. For the volume-preserving configuration there is no contact line displacement for large z; however, for the volume-changing configuration the local perturbation induces a displacement of the contact line which, for a fixed contact angle, depends on the volume of the perturbations.For zero contact angle the functional behaviour in the far-field is given by

$$f(z, \theta) \approx p + \frac{2p}{\pi}\left[(W - |z|)^2\cos(\theta) - \theta\sin(\theta)\right], \tag{3}$$

as shown in figure 2d. Thus since the dependence is quadratic in W, and the induced pressure is $O(W^{-1})$, small perturbations in channels of large width can induce very large contact line displacement.

CONCLUSIONS

We have demonstrated that small narrow occlusions in a rectangular channel can induce significant long-range responses in a static meniscus, including non-monotonic contact line displacement. These results could be observed experimentally. We highlight the sensitivity of this surface-tension dominated system to small disturbances, particularly those which change the volume of the system.

VISCOUS BOUNCING DROPS

Aditya Jha[1,2], Pierre Chantelot[1,2], and David Quéré[1,2]
[1] PMMH, ESPCI Paris, 75005 Paris, France
[2] LadHyX, Ecole polytechnique, 91128 Palaiseau, France

Summary By definition, a water-repellent material is a material on which water drops bounce after an impact, an effect arising from the non-wetting properties of the substrate but also from the low viscosity of water. In this project, we impact increasingly viscous drops to test their bouncing capability. Our findings exhibit the bouncing of highly viscous drops (typically 100 times more viscous than water) with nearly an unchanged contact time but reduced energy post rebound.

INTRODUCTION

In an earlier work done by Richard *et. al.* [1], it was shown that water drops impacting a super-hydrophobic surface can undergo bouncing with an extremely small loss of energy. This was measured in terms of coefficient of restitution ε, the ratio of velocity of the drop post impact to the velocity before impact, which can be as high as 0.9 for water. Furthermore, it was realized that the time τ_0 spent by the drop in contact with the surface is independent of the impact velocity of the drop. It results from a balance between inertia and surface tension, and thus, scales as $\tau_0 \propto \sqrt{\rho R^3/\gamma}$. Here, ρ represents the density of the drop, R is the drop radius while γ is the surface tension. To further venture into the details of the impact phase, Laan *et. al.* [3] studied the effect of viscosity on the spreading which they quantified in terms of an associated impact number. Complementary research by Bartolo *et. al.* [4] looked at the transition of the retraction velocity from an inertial regime to a viscous regime where the Ohnesorge number was found to decide the switch-over velocity. In this experimental study, we investigate the effect of increasing the viscosity of the impacting drop of radius $R = 1$ mm using water-glycerol mixtures.

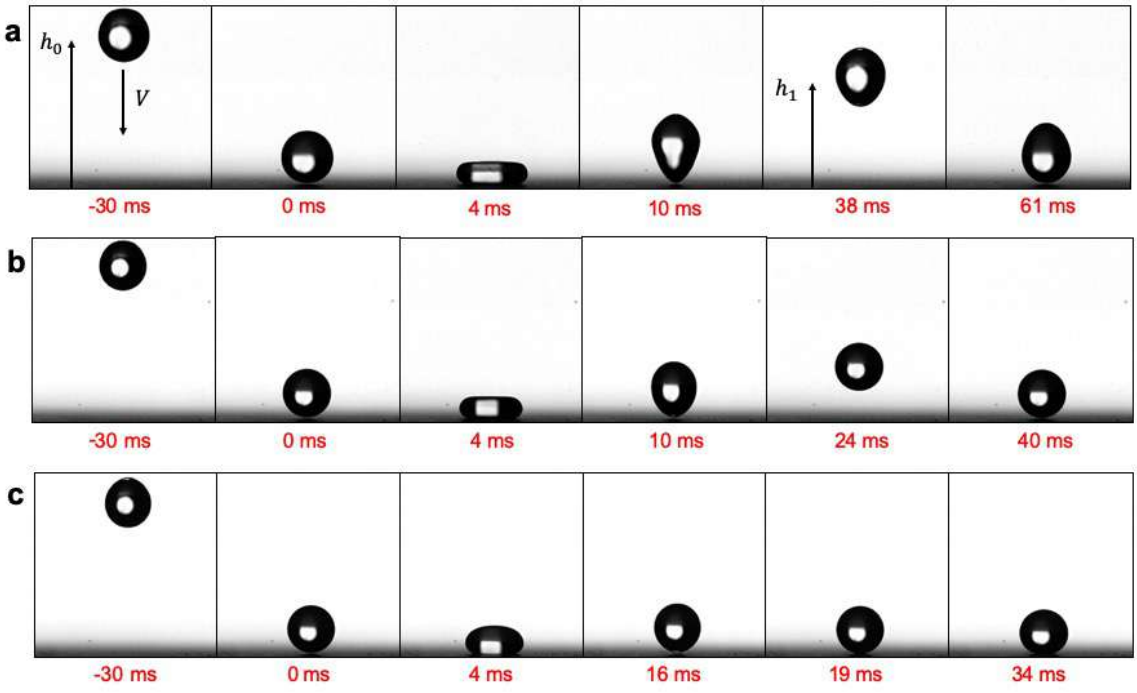

Figure 1: Impact on a super-hydrophobic surface of (a) A water drop (η = 1 mPa.s), (b) A water-glycerol drop (η = 80 mPa.s) and (c)A more viscous water-glycerol drop (η = 200 mPa.s). The radius and velocity remain the same (R =1 mm and V = 0.3 m/s)

Figure 1a shows the behavior of a millimetric water drop impacting and bouncing on a super-hydrophobic surface. Remarkably we see that at 80 times the viscosity of water, bouncing still persists henceforth, extending the phenomenon of bouncing drops to higher viscosity. On a closer inspection, it can be seen that the contact time τ_0 remains nearly the same for both the cases at 10 ms while there is a significant reduction in the take-off energy of the viscous drop exhibited by its reduced maximum height h_1 achieved after impact. Further increasing the viscosity to 200 mPa.s eventually suppresses the rebound thus, defining the limiting bouncing viscosity of this family of drops.

CONCLUSION

In previous studies, the phenomenon of bouncing of a drop has been modeled using a spring-mass system where the stiffness of the spring scales as the surface tension of the drop γ. To take into account the effect of bulk viscosity, we add a damper to the same system whose damping coefficient scales as ηR. Upon simplifying this scaling model, we obtain the limiting bouncing viscosity as function of the Ohnesorge number $Oh = \eta/\sqrt{\rho R \gamma}$. A linearised version of the same equations helps us to understand the slow variation in contact time with increasing viscosity and the variation of coefficient of restitution as well.

STATE- AND RATE-DEPENDENT CONTACT LINE DYNAMICS OVER AN AGING SOFT SURFACE

Dongshi Guan*[1], Elisabeth Charlaix[3], and Penger Tong[2]
[1] State Key Laboratory of Nonlinear Mechanics, Institute of Mechanics, Chinese Academy of Sciences, Beijing 100190, China
[2] Department of Physics, Hong Kong University of Science and Technology, Kowloon, Hong Kong, China
[3] Laboratoire Interdisciplinaire de Physique, CNRS,Universite Grenoble Alpes, Grenoble F-38000, France

Summary The pinning-depinning of an interface is a common phenomenon in nature. Earthquakes on faults and friction between two solid surfaces in contact are two outstanding examples of such pinning-depinning events, which often exhibit a state-dependent increase of pinning strength owing to the contact aging. Here we report systematic measurements of pinning-depinning dynamics at a moving contact line (CL) between a liquid-air interface and a soft solid surface. It is the first time that the state- and rate-dependent pinning-depinning dynamics are observed for a moving CL on an aging soft surface. This work represents a breakthrough in understanding the microscopic origin of the state- and rate-dependent CL dynamics. It should be of broad interest to researchers in the interdisciplinary field of fluid dynamics, soft matter physics, mechanics and solid friction.

INTRODUCTION

While liquid interfaces between two (immiscible) fluids are common in nature and industry, our understanding of their motion over a solid surface is often challenged by the pinning and depinning of the three-phase contact line (CL) between the liquid interface and solid surface due to the physical roughness and/or chemical inhomogeneity on the solid surface. The CL pinning causes the contact angle θ between the liquid and solid surfaces to display some hysteresis. Although considerable progress has been made recently in controlling the wettability of various textured solid surfaces, one still has a poor understanding of contact angle hysteresis on many ambient solid surfaces of practical interest.

The situation becomes more complicated when the solid substrate is made of soft materials, such as elastomers and polymer gels, which deform under the pulling of the capillary force and develop a "wetting ridge" below the CL. The ridge height h is determined by the balance between the normal component of the capillary force $\gamma\sin\theta$ and elastic deformation force Eh, i.e., $h \approx l_s\sin(\theta)$, where $l_s = \gamma/E$ is an elasto-capillary length with γ being the liquid surface tension and E the Young's modulus of the substrate. For a water droplet ($\gamma \approx 72$ mN/m) on a glass substrate ($E \approx 70$ GPa), we have $h \approx 10^{-12}$ m, which is negligibly small. If the glass substrate is replaced by a soft polymer with $E \approx 100$ kPa, we have $h \approx 1$ μm, which will have a great impact on many micro-fluidic and nanotechnology applications. While considerable progress has been made recently in studying the asymptotic shape and development of the wetting ridge, our current understanding of the contact angle hysteresis and CL pinning-depinning dynamics over a deformable surface is still limited, as the (moving) CL, in this case, encounters a slow time-varying (aging) defect landscape.

Here, we report direct atomic-force-microscope measurements of capillary force hysteresis (CFH) of a circular contact line (CL) formed on a long glass fiber [1-4], which is coated with a thin layer of soft polymer film and intersects a water-air interface, as shown in Fig. 1. The measured CFH shows a distinct overshoot for the depinning of a static CL, and the overshoot amplitude grows logarithmically with both the hold time τ and fiber speed V. A unified model based on the slow growth of a wetting ridge and force-assisted barrier crossing is developed to explain the observed time- (or state-) and speed- (or rate-) dependent CL depinning dynamics over an aging soft surface.

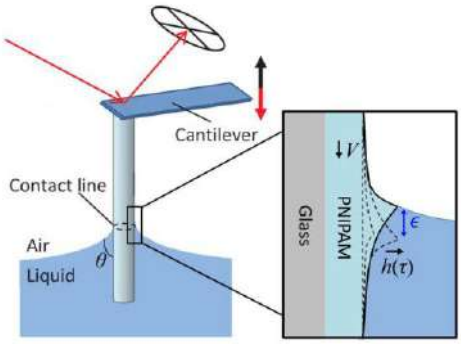

Figure 1. Sketch of the AFM-based capillary force apparatus at a liquid-air interface. "The long needle" AFM involves a vertical glass fiber of diameter d in the range 1-3 μm and length 150-300 μm, which is glued onto the front end of a rectangular cantilever beam. The surface of the glass fiber is coated with a thin layer of soft polymer film (PNIPAM). Inset indicates a slow growing wetting ridge (dashed lines) of height h(t) formed beneath the three-phase CL. The solid line indicates the tangential displacement ε of the wetting ridge resulting from the CL pulling when the fiber moves downward.

*Corresponding author. E-mail: dsguan@imech.ac.cn.

RESULTS and DISCUSSIONS

In the experiment, we use a recently developed "long-needle" atomic force microscope (AFM) to directly measure the capillary force acting on a CL [1-4]. As shown in Fig. 1, the long needle is made of a thin glass fiber coated by a layer of PNIPAM of thickness ~60 nm and is immersed through a liquid-air interface, at which a circular CL is formed on the fiber surface. The long-needle AFM can accurately measure the capillary force, $f_i(s)= -\pi d\gamma\cos\theta_i(s)$, as a function of fiber traveling distance s in the advancing (fiber moves downward, i=a) and receding (fiber moves upward, i=r) directions.

Figure 2 shows the typical CFH loops obtained when the PNIPAM-coated fiber is first pushed downward (advancing, →) and then is pulled upward (receding, ←) through a water-air interface at a constant speed V. Before the fiber starts to move downward, it was partially immersed in the water and was held stationary for a hold time τ. When the fiber advances, the pinned interface is stretched, causing a sharp linear increase in f with the distance travelled s, as shown by a straight line on the left side of the loop. When the restoring force becomes larger than a critical value, $(f_a)_c$, the CL depins with an abrupt decrease in f and then begins a steady stick-and-slip motion with the measured f fluctuating around a mean value f_a in the force curve. It is seen that the overshoot value, $(f_a)_c$- f_a, increases logarithmically with the hold time τ. Similar logarithmic time dependence was also observed for the static fiction between two solid surfaces made of rocks, polymers and other materials. This aging effect was attributed to the slow creeping and/or interfacial strengthening of the asperities in the contact area under the normal stress applied to the solid surfaces. In our case, the overshoot of the depinning force for a static CL, as shown in Fig. 2, is caused by the wetting ridge formed under the pulling of the normal component of the capillary force. This wetting ridge, on which the CL is anchored, acts as a physical barrier that hinders the CL motion.

By taking both the aging effect of the wetting ridge and thermal activation effect of the force-assisted barrier crossing into account, we develop a theoretical model to quantitatively describe the CL depinning force per unit length,

$$\Delta F(\tau,V)= \Delta F_0+ A\ln(1+\tau/\tau_0)+B\ln(1+V/V_0), \quad (1)$$

where ΔF_0 is the residual CFH, which is independent of τ and V. The second and third terms on the right hand side are, respectively, the state- and rate-dependent parts of the CFH. The model describes the experimental data very well, and details will be presented in our recent work [4].

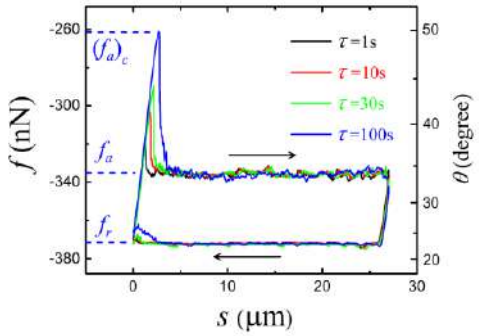

Figure 2. Variations of the measured capillary force f and corresponding contact angle θ when the glass fiber is first pushed downward (advancing, →) and then is pulled upward (receding, ←) through a water-air interface. The measurements are made at a fixed fiber speed V=10 μm/s at room temperature for different hold times: τ =1 s (black), 10 s (red), 30 s (green) and 100 s (blue).

CONCLUSIONS

The above results thus demonstrate that the aging effect of the wetting ridge causes the depinning force to exhibit a logarithmic time dependence for a static CL and speed-weakening for a moving CL. Our experimental findings thus demonstrate a unique microscopic mechanism underpinning the state- and rate-dependent pinning-depinning dynamics, which has many important applications in micro-fluidics and nano-technology. Furthermore, it has important implications to a common class of problems involving depinning dynamics in a defect/roughness landscape, such as friction of solid interfaces.

NUMERICAL INVESTIGATION OF VORTICITY GENERATION MECHANISMS IN MULTIPHASE FLOWS

Daniel Fuster *[1] and Maurice Rossi y[1]
[1] Sorbonne Université, Centre National de la Recherche Scientifique, UMR 7190, Institut Jean Le Rond D'Alembert, F-75005 Paris, France

Summary This work investigates the influence of density ratio and surface tension on vorticity production at relatively high Reynolds numbers. For Weber numbers below 10, the interface response is essentially controlled by surface tension. In that instance, no rollup occurs and the dynamics is only slightly influenced by the Reynolds number. For very large Weber numbers, density ratio plays a critical role on the generation of small structures coming from the destabilization of the vorticity layers generated by the interface. These structures are much Reynolds number dependent. Between these two scenarii, an intermediate regime exists where the interface is significantly affected by the vorticity layer generated but the Reynolds number plays only a minor role. The range of Weber numbers for which this intermediate regime is observed strongly depends on the density ratio.

INTRODUCTION

The presence of an interface between two immiscible fluids is known to act as a source of vorticity that generates thin vorticity layers significantly impacting the interface dynamical response. The generation of vorticity due to the presence of an interface has been theoretically discussed by [1, 2, 3]. In two-dimensional flows the evolution of the circulation Γ of a closed curve $\mathbf{C}$ which crosses an interface S_{int} separating two phases is given by

$$\frac{d}{dt}\Gamma = -\oint_{\mathbf{C}} [\nu\, \boldsymbol{\nabla} \times \boldsymbol{\omega}] \cdot \boldsymbol{t}\, \mathrm{d}\ell + \int_{I_f} S_\omega ds, \tag{1}$$

where the curve I_f is located on the interface S_{int} and connects the two intersections of curve $\mathbf{C}$ with the interface. The first integral is a classical diffusion term and the second integral corresponds to the vorticity sources located at the interface S_{int}. If the surface tension coefficient is denoted as σ and both fluids have the same dynamical viscosity μ, quantity S_ω then becomes

$$S_\omega = -\frac{1}{\rho_m}\frac{\partial(\sigma\kappa)}{\partial s} + [[\frac{1}{\rho}]]\frac{\partial p_m}{\partial s} \tag{2}$$

where $[\![Q]\!] \equiv Q_1 - Q_2$ represents the jump of quantity Q between phases 1 and 2, $\frac{2}{\rho_m} \equiv \frac{1}{\rho_1} + \frac{1}{\rho_2}$, $p_m \equiv \frac{p_1+p_2}{2}$ This equation displays the importance of density differences and surface tension forces on the production of vorticity across the interface. How the vorticity generated impacts the evolution of the interface in non-linear regimes is the topic of this presentation.

NUMERICAL RESULTS

In this work we use the Gerris Flow Solver [4] to investigate the consequences of vorticity generation in the dynamics of the interface throughout simplified problem examples. This software is well suited for the simulation of multiphase flows due to its accurate and robust methods for surface tension and the AMR capabilities, that allow us to well resolve the boundary layers around it.

We start investigating the interaction of a planar interface with a Lamb-Oseen vortex with circulation Γ_0 that is initially placed in the light fluid at distance d_0 from the interface. If the vortex core size is small compared to d_0, the solution of this problem essentially depends on the three dimensionless quantities

$$r_\rho \equiv \frac{\rho_2}{\rho_1}, \quad Re \equiv \frac{\frac{\rho_1+\rho_2}{2}\Gamma_0}{2\pi\mu}, \quad \text{and} \quad We \equiv \frac{\frac{\rho_1+\rho_2}{2}\Gamma_0^2}{(2\pi)^2 d_0 \sigma}. \tag{3}$$

When $r_\rho = 1$ and no surface tension is present the interface acts like a passive tracer that rolls-up creating a spiral where the curvature at the tip increases as $\kappa \sim t^3$. When $r_\rho = 1$ but in the presence of surface tension forces, the vorticity production is approximately symmetric but of opposite sign at both sides of the tip where no vorticity production occurs. Like in the classical Taylor-Culick problem the tip retracts and a rim appears (Figure 1a), the importance of this effect increasing as the Weber number is decreased. For $We < 10 \approx We_c^I$ it is no longer possible to define a rim and surface tension forces just prevent any interface roll up. In Figure 1a we can appreciate the emission of a vorticity sheet that is emitted from the rim when $We > We_c^I$ where, as we can see, the Reynolds number does not alter significantly the interface shape.

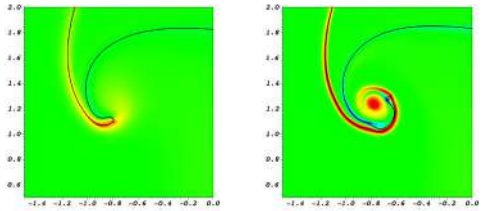
(a) Influence of Reynolds for $r_\rho = 1$ and $We = 10^3$. Zoomed view of the vorticity field and interface at time $t = 15$. $Re = 10^3$ (left) and 10^4 (right).



(b) Influence of Reynolds for $r_\rho = 5$ and $We = 10^3$. Zoomed view of the vorticity field and interface at time $t = 4$. $Re = 10^3$ (left) and 10^4 (right).

The baroclinic vorticity production and its influence on the dynamic response of the interface is significantly different than in the case of surface tension. Unlike the previous case, it can be shown that at short times the vorticity production is possitive and does not change sign at the ligament tip. The vorticity generated at the interface detaches from the tip rolling in the light fluid and, if the Weber number is sufficiently large, the vortex generated stretches the interface creating very small structures (Figure 1b), this phenomenon being extremely sensitive to the Reynolds number.

Numerical experiments reveal that when $r_\rho > 1$ and surface tension is present it is possible to define a critical Weber number, We_c^{II}, below which surface tension effects become dominant over density differences. In this regime the interface rolls up but the structures formed at the ligament tip are stabilized by surface tension forces, the Reynolds number not playing a significant role on the interface structures observed. This transition is shown to essentially depend on the density ratio, which ultimately controls the baroclinic vorticity production: the smaller the density ratio, the larger the value of We_c^{II} is.

During the presentation of this work, a detailed study of this particular problem is displayed. We will also show that these two critical Weber numbers also appear in a variety of other problems involving the non-linear response of interfaces.

DYNAMICS OF VAPOR-GAS BUBBLES NEAR RIGID SURFACES IMMERSED IN A LIQUID UNDER ULTRASONIC TREATMENT

Tatyana Lyubimova[1,2], Oskar Fattalov *[1], Konstantin Rybkin [1]

Summary. In this work, the dynamics of vapor-gas bubbles near rigid surfaces of different hydrophobicity immersed in a liquid under the action of ultrasound (US) is investigated. The experiments have shown a significant effect of surface properties on bubble dynamics. In the case of hydrophilic surface, inertial bubbles formed in a liquid under the action of ultrasound are subjected to the drift near and on the rigid surface and most of them rise when the ultrasound is switched off. For hydrophobic surface, stable attachment of the vapor-gas bubbles to the rigid surface is observed, the bubbles form linear chains (clusters) of bubbles which grow with time and remain attached to the rigid surface when the ultrasound is switched off.

INTRODUCTION

The dynamics of the cavitation bubbles arising in a liquid under the action of ultrasound depends on various factors, either the collapse of the bubbles or their coalescence and the long-term existence of relatively large bubbles both in the volume of the liquid and near rigid surfaces can be observed [1, 2]. The interaction of cavitation bubbles with rigid surfaces is also a subject of discussions [3]. The collapse of the bubbles creates the local extreme pressures and temperatures, as well as shock waves in a liquid, which have significant effect on the surface. This effect can be used as a tool for the formation of new surfaces and nanostructured materials with a very high potential for application, but so far many aspects of this issue have not been fully disclosed.

Ultrasound can also increase the probability of the collision of bubble and particle due to the average forces arising under the action of acoustic field, in particular, the Bjerknes primary force [4] and average vibrational force [5]. In [6], the dynamics of two bubbles is discussed, when the action of the secondary Bjerknes force promotes the movement of the bubbles towards each other. As a result of rapprochement, under certain parameters, their coalescence occurs. The solution of the Rayleigh-Plesset equation involves changing the diameter of the bubble in the liquid under the action of ultrasound with time, as a result, low pressure areas are formed around the oscillating bubble, which helps to keep the bubble near a rigid surface, in this case the secondary Bjerknes force acts on the bubble. As a result, the discharged region around the pulsating bubble involves other bubbles, which contributes to their coalescence. To achieve the resonant frequency of bubble pulsations, it is necessary that the coalescence effect of the bubbles allows them to grow to resonance sizes, which was observed in the experiments. All of the above effects can contribute to the attachment and retention of bubbles near rigid surface.

EXPERIMENTAL METHOD

The source of ultrasound was a metal disk placed at the bottom of the cavity such that the center of the emitter coincided with the center of the bottom of the cavity. It was connected to an ultrasonic source with a frequency f = 40 kHz.

Using the photographs taken in the experiments, we analyzed the temporal evolution of the area of rigid surface covered with the bubbles under the action of ultrasound and after its turning off. The dynamics of individual bubbles near rigid surfaces with different properties was also studied. Deionized and degassed water was used in experiments. Rigid plates were made of amorphous quartz (contact angle 1^0), organic glass (contact angle 51^0) and teflon (contact angle 118^0). New plate was taken for each new experiment, then the surface was cleaned with alcohol, and its washing with distilled water was performed. This was needed because the ultrasound is potentially capable of changing the degree of hydrophobicity of the surfaces of rigid plates immersed in a liquid. After immersion of the rigid plates in the liquid, the ultrasonic emitter was switched on and camera shooting began. Experiments continued for some time after the ultrasound was turned off to study the effect of detachment of bubbles from the surface.

RESULTS

In all series of the experiment, the hydrophobicity of the surface facilitated the attachment of the bubbles to it. The diameter of the attached bubbles continuously increased during the entire time of ultrasonic irradiation due to coalescence with bubbles arising due to acoustic cavitation. At the moment of switching off the ultrasound, the bubbles remained attached to the hydrophobic surface and did not rise, since the surface forces exceeded the force of Archimedes. After turning off the ultrasound, the bubbles oscillating near the surface were rising (Figure 1).

*Correponding author. E-mail: fattalov@mail.ru

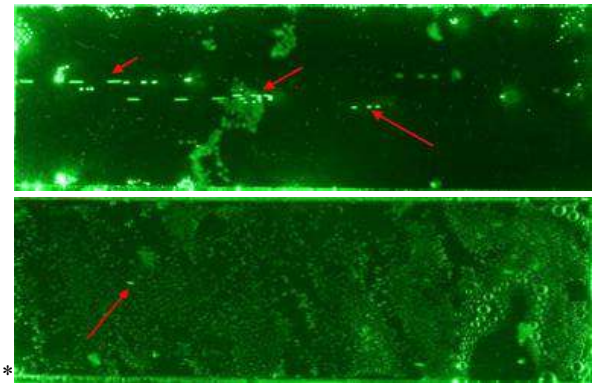

Figure 1. Above – the tracks of bubbles rising near the quartz plate. Almost all the bubbles leave the quartz plate at the time of ultrasound switching off. Below - the teflon surface at the time of switching off the ultrasound. Tracks of single rising bubbles are observed. Gravity is directed to the right.

The dynamics of vapor-gas bubbles on the hydrophilic surface of quartz differ qualitatively from the dynamics of bubbles on the hydrophobic surface of teflon (Figure 2). In this case, single bubbles, formed in the antinode regions of the acoustic wave, oscillate until the ultrasound is switched off. Obviously, in this case, the strength of Archimedes did not exceed the sum of the primary and secondary forces of Bjerknes [5], which allows the bubble to stay near the surface for a long time. It should be noted that the bubbles are aligned in the direction of ultrasound propagation.

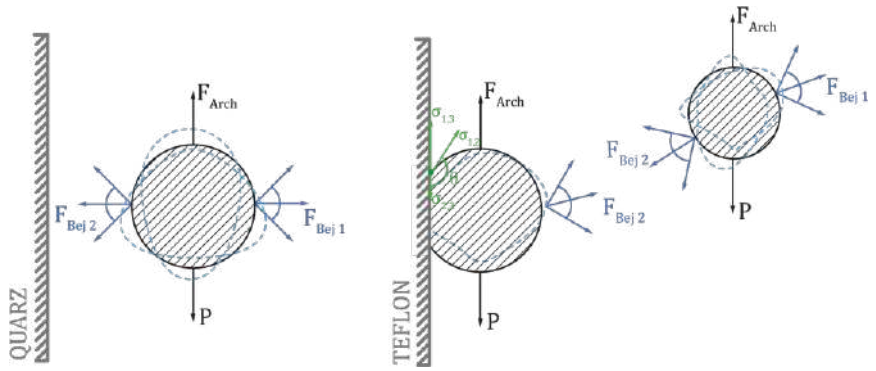

Figure 2. In the case of quartz, the bubble oscillates near the surface. A typical diagram is presented on the right, when a gas-vapor bubble is attached to the surface of teflon and is held on it due to the predominance of surface forces. The second bubble, due to the secondary Bjerknes force, drifts towards the attached bubble.

CONCLUSIONS

Thus, as follows from the experimental observations, in a distilled water under the action of ultrasonic waves near the hydrophilic surface of quartz, inertial oscillating bubbles are formed, most of which rise when the ultrasound is switched off. On the hydrophobic surface, the vapor-gas bubbles form linear chains (clusters) of bubbles that grow with time under the action of ultrasound, the chains are oriented orthogonally to the direction of ultrasound propagation and remain attached to the rigid surface when ultrasound is switched of.

DRAINAGE SPEEDUP OF A DROP ON A SMOOTH SURFACE

Laurent Duchemin *[1] and Christophe Josserand[2]
[1] PMMH, CNRS, ESPCI Paris, Université PSL, Sorbonne Université, Université de Paris, F-75005, Paris, France

Summary The present study aims at understanding the drainage dynamics of the thin air film squeezed between a millimetric droplet and a solid or liquid surface. Solving coupled lubrication equations and analyzing the dominant terms in the solid and liquid-film cases, we explain why the drainage is much faster in the liquid-film case, leading to a shorter coalescence time, as observed in recent experiments.

The thin film drainage until rupture is a widely studied fluid dynamics issue [1], relevant to numerous applications, like the ageing of foams [2], dimple formation and bubble entrapment [3, 4], drop coalescence [1, 5], the surprising non-coalescence of a droplet with a bath [6, 7, 8]. Among the open questions is the time it takes for a free thin film to rupture [9] and the relevant mechanisms at play : usual suspects are thermal fluctuations, Marangoni currents... In the case of gas film drainage, a potential mechanism for the dynamics of drainage is the presence of body forces, like gravity, driving the surrounding liquid [10, 11].

Recently, an experimental investigation of the coalescence of a millimetric drop gently deposited on a thin viscous film [12] has revealed unexpected drainage dynamics. The present study aims at understanding the drainage dynamics of the thin air film squeezed between a millimetric drop and a solid or liquid surface. We solve numerically the coupled lubrication equations for the three layers shown in figure 1 : the bottom part of the liquid droplet, that we suppose inviscid (3), the thin air film (2) and the liquid film underneath (1). The three dimensionless numbers, assuming negligeable inertia, are the Bond number and the Stokes numbers related to regions (1) and (2) :

$$\mathrm{Bo} = \frac{\rho_3 g R^2}{\gamma}, \quad \mathrm{St}_1 = \frac{\eta_1}{\rho_3 R\sqrt{gR}}, \quad \mathrm{St}_2 = \frac{\eta_2}{\rho_3 R\sqrt{gR}}, \tag{1}$$

where R is the radial distance where the slope of the sessile top drop is equal to one, η_1 and η_2 are the dynamic viscosities of the liquid and gas films respectively, γ is surface tension, and g is gravity.

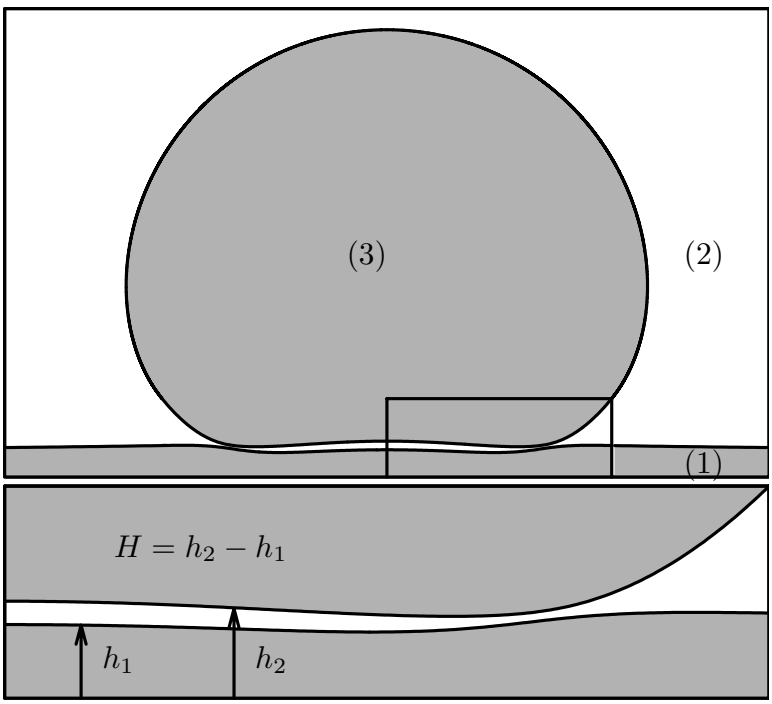

Figure 1: Sketch of a droplet lying on a thin liquid film.

In this study, we focus our attention on the influence of St_1 on the drainage of the air film. Solving the lubrication equations in the liquid-film case ($\mathrm{St}_1 \simeq 0.6$, which corresponds approximately to the experiments described in [12]) and solid-film case ($\mathrm{St}_1 \to \infty$), we obtain two very different drainage dynamics, as seen in figure 2. After the dimple is

*Corresponding author. E-mail: laurent.duchemin@espci.fr

formed, at short time, it is going to drain much faster in the case of a liquid film underneath. This fact is closely related to the continuity of tangential velocity across interface $1/2$: in the solid case, this velocity is zero, whereas it is finite in the case of a liquid film. Then, viscous dissipation in the gas film at the tip of the dimple (where the air gap $H = h_2 - h_1$ is minimal) slows down the dimple drainage, in comparison with the liquid film case.

In the solid-film case, analyzing the lubrication equations in terms of dominant balance of the different terms, we obtain the following long-time behaviour, already obtained for instance by [10] :

$$H_0 \sim t^{-1/4}, \quad H_{\min} \sim t^{-1/2}, \quad \ell \sim t^{-1/4}, \tag{2}$$

where H_0 is the dimple height on the axis of symmetry, H_{min} is the minimum air gap thickness and ℓ the radial size of the region where H is minimal. These scalings are confirmed by the numerical solution, as seen in figure 2, where the solid curves correspond to the solid-film case ($\mathrm{St}_1 \to \infty$).

In the liquid-film case, the dimple deflation obeys a very different dynamics, because viscous dissipation is highly reduced. We theoretically obtain the following different scalings for H_0, H_{min} and ℓ :

$$H_0 \sim t^{-2/3}, \quad H_{\min} \sim t^{-2/3}, \quad \ell \sim t^{-1/3}. \tag{3}$$

These scalings are alos confirmed by numerical simulations, as seen in figure 2. The agreement, although very good, is not perfect because the dominant balance is only an approximation in this case.

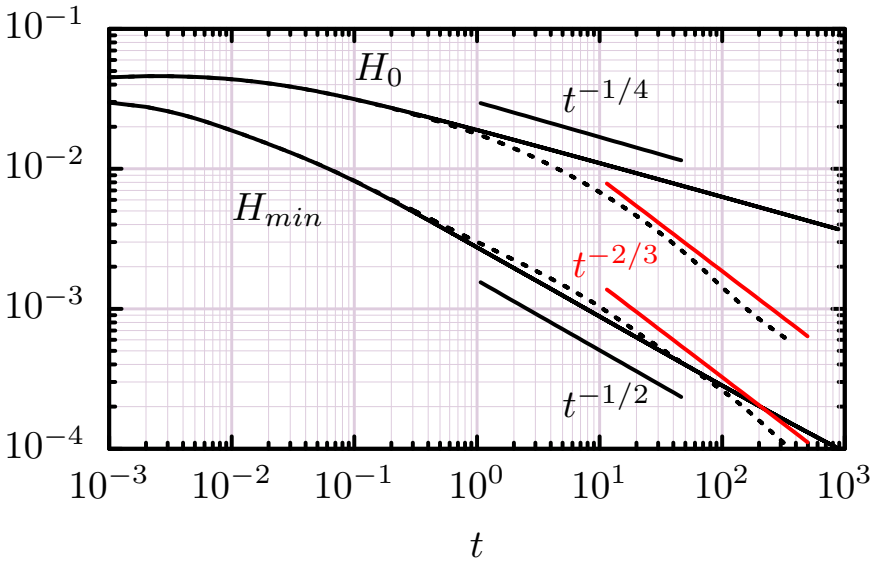

Figure 2: Height of the dimple H_0 and minimum height $H_{\min}$ as a function of time in the case of a liquid film ($\mathrm{St}_1 = 0.6$, solid curves) and a solid film ($\mathrm{St}_1 \to \infty$, dashed curves).

COMPETING MARANGONI AND RAYLEIGH CONVECTION IN EVAPORATING BINARY DROPLETS

Summary For a small sessile or pending droplet it is generally assumed that gravity does not play any role once the Bond number is small. This argument has also been used for evaporating binary droplets, where preferential evaporation can induce composition gradients and hence Marangoni flow and natural convection can emerge. Recent studies have revealed that gravity can indeed be the dominant driving mechanism for the flow inside small evaporating binary droplets [1, 2]. Here, we derive and validate a quasi-stationary model for the flow inside evaporating binary sessile and pendant droplets, which successfully allows to predict the prevalence and the intriguing interaction of Rayleigh and/or Marangoni convection on the basis of a phase diagram for the flow field expressed in terms of the Rayleigh and Marangoni numbers.

MOTIVATION

In applications based on droplet evaporation, e.g. inkjet printing, it is crucial to overcome the coffee-stain effect, i.e. the preferential deposition of solute particles near the rim of the droplet due to a persistent capillary outward flow towards the pinned contact line. By using binary droplets, one can utilize the preferential evaporation of the more volatile component to induce compositional gradients inside the droplet. These gradients can in turn drive recirculating flow, namely Marangoni flow, driven by the composition-dependent surface tension, and natural convection due to density differences of the components. In recent studies it has been shown that natural convection can even dominate in sub-millimeter-sized droplets [1, 2], although de Bond number is small. This observation demands a detailed analysis of the possible flow patterns and the interplay of Rayleigh and Marangoni convection in evaporating binary droplets.

QUASI-STATIONARY MODEL

Based on the observations from full simulations and experiments, the recirculating flow inside the droplet due to Marangoni/Rayleigh convection is usually much faster than the movement of the liquid-gas interface due to evaporation. When the flow is regular, i.e. not chaotic, this observation allows for a quasi-stationary treatment of the flow and composition distribution in the evaporating droplet at each instant during the drying process. By expanding the composition-dependent surface tension and density via a first order Taylor expansion around the instantaneous average composition of the droplet, the problem can be nondimensionalized and three control parameters can be extracted, namely the Marangoni number Ma, the Rayleigh number Ra and the contact angle θ.

PHASE DIAGRAM OF THE FLOW IN BINARY DROPLETS

By doing a numerical parameter study with respect of these three dimensionless parameters, the phase space of the flow and composition distribution in binary droplets can be investigated. We reveal in total five different regimes, which are depicted in Fig. 1. Here, the blue fluid is more volatile, has the higher surface tension but a lower density than the red fluid (e.g. blue: water, red: glycerol). When Ma is large and $|\mathrm{Ra}|$ is small, the Marangoni effect (black stream lines) dictates the flow direction in the droplet (regime *Ma dom.*). Vice versa, in absence of a considerable surface tension difference, natural convection can determine the flow direction (white stream lines, regime *Ra dom.*). If both effects are present, but support opposite flow directions, one gets natural convection in the bulk and a counter-rotating Marangoni vortex in the vicinity of the interface (*Ma vs. Ra*). By reversing the direction of gravity, Ra can become negative. Then, both effects support flow in the same direction (*Ma & Ra same dir.*). If the driving of both mechanisms are sufficiently strong, however, the quick natural convection in the bulk deforms the internal composition field so that it results in altered replenishing diffusive fluxes of the blue liquid close to the apex and the contact line. This eventually leads to a reversal of the interfacial composition gradient and in turn to an emergence of a counter-rotating Marangoni-vortex close to the interface (*Ra reverses Ma*). For negative Marangoni numbers, chaotic flow can be expected due to the Marangoni instability. The entire phase diagram is also a function of the contact angle θ and approximately flips upside down when moving from $\theta < 90°$ to $\theta > 90°$.

*Corresponding author. E-mail: c.diddens@utwente.nl.

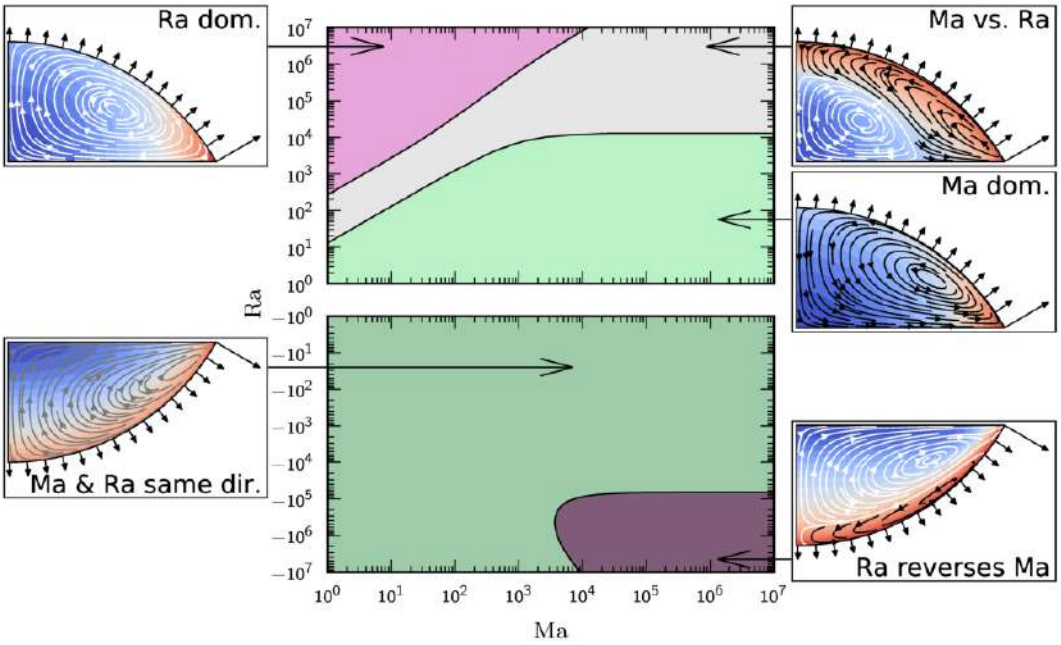

Figure 1: Phase diagram of the different flow scenarios in an evaporating binary droplet with a contact angle of $\theta = 60°$ depending on the Rayleigh and Marangoni numbers.

VALIDATION OF THE QUASI-STATIONARY MODEL

We have compared the result of a full simulation of an evaporating glycerol-water droplet with the prediction of the quasi-stationary model at different instants. By extracting the volume, the contact angle and the average droplet composition from the full simulation at a particular instant, one can directly calculate the corresponding Rayleigh and Marangoni number and use the phase diagram of the quasi-stationary model to predict the flow inside the droplet. The validity of this prediction can be seen in Fig. 2, where the result of the full temporal simulation is compared with the redimensionalized result of the quasi-stationary model, revealing very good agreement in terms of the composition distribution and the velocity field. It is noteworthy that the composition difference entering the Rayleigh and Marangoni numbers is not required to be extracted from the full simulation. Instead, it is calculated by considering the volatilites of both components only. This feature allows to use the phase diagram also for the prediction of experiments on binary droplets, where composition differences inside the droplet are hard to quantify directly. We therefore also validated the quasi-stationary theory with experiments on different binary droplets with different volumes and contact angles, again confirming the predictive power of the quasi-stationary model.

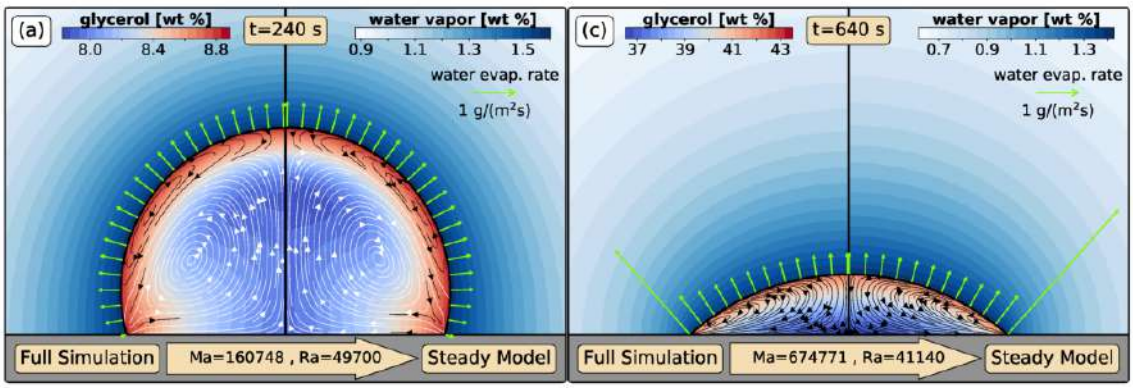

Figure 2: Comparison of a full simulation of a binary glycerol-water droplet (left half) with the redimensionalized prediction by the quasi-stationary model (right half) at different instants. Obviously, the entire flow and composition field is well predicted by the quasi-stationary model, which just requires the contact angle and the Rayleigh and Marangoni numbers as parameters.

SPHERICAL OSCILLATIONS OF ENCAPSULATED MICROBUBBLES: A GENERAL MODEL

Georges Chabouh[1], Benjamin Dollet[1], Catherine Quillet[1], and Gwennou Coupier *[1]
[1] Université Grenoble Alpes, CNRS, LIPhy, F-38000 Grenoble, France

Summary We introduce a model that describes spherical oscillations of encapsulated microbubbles in an unbounded surrounding fluid. A Rayleigh-Plesset-like equation is derived by coupling the Navier-Stokes equation that describes fluid dynamics with the Navier equation that describes solid dynamics via the internal/external boundary conditions. While previous models were restricted to incompressible isotropic shells, the solid shell is modeled here as a compressible viscoelastic isotropic material, then generalised to an anisotropic material. The exact value of the resonance frequency is calculated analytically and the damping constant is computed in the approximation of weak damping. A correction of the widely used Church model for incompressible shells is evidenced, and the effects of shell compressibility and anisotropy are discussed.

INTRODUCTION

Ultrasound contrast agents (UCAs) consist of a gas core surrounded by a stabilizing shell made of various materials, including polymers, lipids, and proteins. After the famous Rayleigh-Plesset equation [1] describing the oscillations of a bubble, several models were developed to describe spherical oscillations of UCAs by adding ad-hoc viscoelastic constants to account for the presence of the encapsulating shell [2], or by modeling the shell as a 3D homogeneous, incompressible, isotropic material, that is described by the Kelvin-Voigt model [3, 4]. Previous works on UCAs focused on incompressible shells [3, 4, 5, 6]. Our model generalises the existing descriptions by accounting for the effect of compressibility and anisotropy of the encapsulating solid shell.

BASIC EQUATIONS

We consider an encapsulated gas bubble immersed in an incompressible fluid with a density ρ_f and a shear viscosity μ_f. The bubble shell is modeled as a visco-elastic solid of initial internal and external radius R_{10} and R_{20} respectively. From the conservation of radial momentum, the internal and external boundary conditions write:

$$-P_G(t) = \sigma^{el}_{rr,1} + \sigma^{visc}_{rr,1} - \frac{2\gamma_1}{R_1}, \qquad \sigma^{el}_{rr,2} + \sigma^{visc}_{rr,2} = -P_{f,2} + S^f_{rr,2} - \frac{2\gamma_2}{R_2}, \tag{1}$$

where γ_1 and γ_2 are the surface tensions and $P_G(t)$ is the pressure of the gas inside the bubble. We assume the gas obeys a polytropic law, such that $P_G(t) = P_{G_0}(\frac{R_{10}}{R_1})^{3\kappa}$, where P_{G_0} is the equilibrium gas pressure and κ is the polytropic exponent of the gas. In the external fluid, P_f denotes for the pressure and S^f for the viscous stress. In the shell, $\sigma^{el}_{rr,i}$ and $\sigma^{visc}_{rr,i}$ account for the elastic and viscous stresses respectively.

The elasticity of the material is characterized by the 3D shear modulus G' and the 3D compression modulus K', while the viscosity of the material is characterized by the shear viscosity μ_G and the compression viscosity μ_K.

We consider the fluid mechanics as being described by the Navier-Stokes equation while the viscoelastic behavior of the shell is described by the Kelvin-Voigt model. We assume that in the shell elastic waves propagate at infinite velocity due to the huge ratio between the expected wavelength and the typical shell thickness. This allows to easily calculate the stresses inside the shell. We obtain a Rayleigh-Plesset-like equation:

$$\begin{aligned}\rho_f\left(R_2\ddot{R}_2 + \tfrac{3}{2}\dot{R}_2^{\,2}\right) = &-P_0 - P_{ac}(t) - 2\tfrac{\gamma_2}{R_2} - 4\mu_f\tfrac{\dot{R}_2}{R_2} + \left(P_G - 2\tfrac{\gamma_1}{R_1}\right)\left[1 - \left(\tfrac{4G'}{3K'+4G'}\right)\left(\tfrac{R_2^3-R_1^3}{R_2^3}\right)\right] \\ &-4G'\left(\tfrac{3K'}{3K'+4G'}\right)\left(\tfrac{R_2^3-R_1^3}{R_2^3}\right)\left(\tfrac{R_1-R_{1e}}{R_1}\right) + 4\tfrac{\dot{R}_2}{R_2}\left[\mu_G\left(1 - \tfrac{4G'}{3K'+4G'}\right) - \tfrac{3}{4}\mu_K\left(\tfrac{4G'}{3K'+4G'}\right)\right] \\ &-4\tfrac{\dot{R}_1}{R_1}\left[\mu_G\left(1 - \tfrac{4G'}{3K'+4G'}\right) - \tfrac{3}{4}\mu_K\left(\tfrac{4G'}{3K'+4G'}\right)\tfrac{R_1^3}{R_2^3}\right]\end{aligned} \tag{2}$$

RESULTS

Assuming a small perturbation around the equilibrium radii, the undamped resonance frequency is found:

$$\begin{aligned}\omega_0^2 = &\left\{\left(3\kappa P_{G0} - \tfrac{2\gamma_1}{R_{10}}\right)\left(1 - \tfrac{4G'}{3K'+4G'}\tfrac{R_{20}^3-R_{10}^3}{R_{20}^3}\right) + 4G'\left(\tfrac{3K'(R_{20}^3-R_{10}^3)}{(3K'+4G')R_{20}^3}\right)\right\} \\ &\times\left\{\rho_f R_{20}^2\tfrac{\left(3\kappa P_{G0} - \frac{2\gamma_1}{R_{10}}\right)(R_{20}^3-R_{10}^3)+4G'R_{20}^3+3K'R_{10}^3}{(4G'+3K')R_{20}^3}\right\}^{-1} - \tfrac{2\gamma_2}{\rho_f R_{20}^3}\end{aligned} \tag{3}$$

*Corresponding author. E-mail: gwennou.coupier@univ-grenoble-alpes.fr

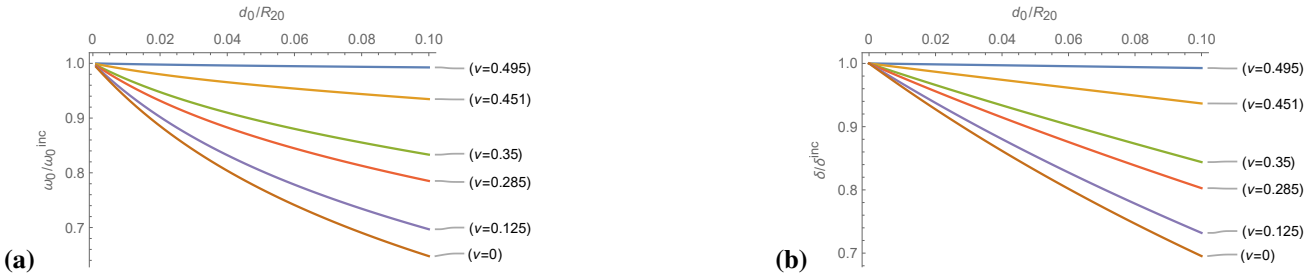

Figure 1: **(a)** Ratio of the undamped resonance frequencies ω_0/ω_0^{inc} and **(b)** Ratio of the damping constants δ/δ^{inc}, where $\omega_0^{inc} = \omega_0(K' = \infty)$ and $\delta^{inc} = \delta(K' = \infty)$ as a function of equilibrium external bubble radius. $G' = 88.8$ MPa is fixed and the pressure at rest in the shell is the atmospheric pressure. We varied K' as $100G', 10G', 3G', 2G', G'$ and $\frac{2}{3}G'$ and the corresponding Poisson ratio $\nu = (3K' - 2G')/(6K' + 2G')$ is shown on each curve.

Figure 2: **(a)** Ratio of the damping constants δ/δ^{inc}, with $\delta^{inc} = \delta(K' = \infty)$, for $\mu_K = 0.7\mu_G$ and **(b)** undamped resonance frequency ω_0^T/ω_0 for different ratio between the orthoradial and radial Young moduli. Poisson coefficients are set to 0.3.

The last term in the above expression is the classical contribution of the surface tension of the outer surface, which acts against an effective mass of fluid whose scale is given by the shell size. All elastic contributions are divided by a mass term, the first term by the external mass term $\rho_f R_{20}^2$ and the second one by the internal mass term which is corrected due to the shell deformation. The Rayleigh-Plesset expression for a free bubble [1] is recovered here with in the above equation taken in the limit of vanishing shell volume ($R_{10} \to R_{20}$), which is not the case for the work done in [3] for incompressible shell.

We discuss how the frequency is modified when the material is compressible. First, when considering as a basis the reference configuration, denoted $\mathcal{R}$, which is considered in [3]: $d_0 = 15$ nm, $P_{G_0} = 101.3$ kPa, $\rho_f = 1000$ kg/m^3, $\rho_S = 1100$ kg/m^3, $\mu_f = 0.001$ Pa.s, $G' = 88.8$ MPa, $\gamma_1 = 0.04$ N/m, $\gamma_2 = 0.005$ N/m and $\kappa = 7/5$. For such a shell whose external radius lies in the range $1 - 10\,\mu$m, we find that $0.99 < \omega_0^{inc}/\omega_0^{Ch} < 1$, which indicates that while our model has led us to neglect the inertia of the shell, this assumption will modify the final result by a negligible amount. Note that in this example, since $\gamma_i/R_{i0} \ll G'$, the inaccuracy that we exhibited in the [3] model has no quantitative consequence.

Compressibility introduces a dependency of the frequency on the shell radius that is more complex than in the incompressible case, where $\omega_0 \propto 1/R_{20}$ in the thin shell limit. It reduces the resonance frequency, all the more that the relative thickness d_0/R_{20} increases, the Poisson ratio decreases, and the shear modulus increases as seen in Fig. 1, the ratio ω_0/ω_0^{inc} is calculated for different values of G' and K', that are set relatively to $\tilde{P} = P_{G_0} - \frac{2\gamma_1}{3\kappa R_{10}}$ by setting $\gamma_2 = 0$ since its contribution is purely additive. In particular, when the bubble radius decreases at fixed thickness, this effect of compressibility will become relatively more important.

Interestingly, the effect of compressibility on the damping is independent from the choice of the model for the viscous Poisson ratio as seen in Figs. (1**(b)** where $\nu_{el} = \nu_{vis}$ and 2**(a)** where $\mu_K = 0.7\mu_G$). Finally, anisotropy can lead to large variations of the resonance frequency (Fig. 2 **(b)**). Our study provides a necessary tool in the interpretation of UCAs' behavior, crucial to extract shell parameters and to compare quantitatively with effective values.

Summary In many cases heterogeneous nucleation is the effective mechanism for phase transition. Solid walls and impurities act as a catalyst for the formation of a new phase by reducing the activation energy needed for phase change. Formation of vapor bubbles close to solid, ideally flat walls is addressed here by exploiting a mesoscale description that couples a diffuse interface modeling of the two-phase liquid-vapor system with Fluctuating Hydrodynamics, extending previous work by the authors on homogeneous nucleation. This methodology provides access to the complete bubble dynamics, from inception to the long-time macroscopic expansion, on time and spatial scales unaffordable by standard techniques for nucleation, such as Molecular Dynamics. Individual bubbles are analyzed demonstrating substantial bubble–bubble interactions.

INTRODUCTION

Fluctuations are crucial for nucleation, the incipit of phase transitions in metastable systems like, e.g., in cavitation, boiling, freezing rain and crystal formation. These activated processes require an energy to overcome the free energy barriers that may be quite high, e.g. tensile strength on the order of $1\,\mathrm{kbar}$ is observed in water. Nevertheless bubble formation is a common experience whenever impurities, dissolved gas and solid walls are present with nucleation enhancement depending on the wetting properties of the system.

Purpose of the talk is illustrating a new model the authors have been developing in recent years which is meant to allow describing the process from nucleation onset to the fully non-linear, inertia dominated stage of bubble dynamics where the model recovers the traditional Navier-Stokes equations. The framework is the diffuse interface model which has been traditionally used to describe immiscible fluids [4]. The authors extended the approach to a fully thermodynamic consistent model for liquid-vapor systems shown able to account for the fully non-linear dynamics that occurs, e.g., in the collapse of a vapor cavity in free space [5] and at solid walls [6].

PHYSICAL MODELING

Thermal fluctuations have been included in the continuum (mesoscale) model demonstrating its ability to describe vapor cavity nucleation in a way which is consistent with statistical mechanics and thermodynamics [7]. Successively [8] the dynamics of a single bubble, from fluctuation induced nucleation to non-linear bubble oscillations *à la* Raileigh-Plesset was addressed in detail [8]. Fluctuation are treated by extending to capillary systems Landau and Lifshitz's pioneering intuition [1] that led to what is presently known as *Fluctuating Hydrodynamics*, see [3] for a beautiful paper on the subject. In a nutshell, the idea is to include a stochastic term in the Capillary-(Van der Waals)-Navier-Stokes equation, where a distributed capillary force accounts for surface tension and a suitable equation of state describes the thermodynamics of the two phase flow [7]. The procedure turns the relevant PDEs into a stochastic system of partial differential equations (SPDEs) where a Weiner process (white noise) of suitable intensity induces thermal fluctuations. The noise intensity is determined through a *Fluctuation-Dissipation Balance* (FDB) that ensures the system reproduces the equilibrium correlations of the fluctuating field, as determined by the field probability distribution functional expressed in terms of entropy fluctuations, Einstein 1910 [2].

The novel advancement over the state of the art in the field to be discussed here concerns the extension of our recent theoretical model and related numerical solution techniques to heterogeneous nucleation at solid boundaries of different wettability (heterogeneous nucleation). The SPDEs, discussed at length in a, as yet, unpublished paper [9],

$$\begin{aligned}
\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) &= 0\,, \\
\frac{\partial \rho \mathbf{v}}{\partial t} + \nabla \cdot (\rho \mathbf{v} \otimes \mathbf{v}) &= \nabla \cdot \boldsymbol{\Sigma} + \mathbf{f}_{\boldsymbol{\Sigma}}\,, \\
\frac{\partial E}{\partial t} + \nabla \cdot (\mathbf{v} E) &= \nabla \cdot (\mathbf{v} \cdot \boldsymbol{\Sigma} - \mathbf{q}) + \mathbf{v} \cdot \mathbf{f}_{\boldsymbol{\Sigma}} + f_q\,,
\end{aligned}$$

describe mass (ρ), momentum ($\rho\mathbf{v}$) and (total) energy E density dynamics, with $\mathbf{f}_{\boldsymbol{\Sigma}}$ and f_q the vector and scalar noise processes respectively associated with momentum and energy fluctuations. Both are in divergence form, as directly follows from the FDB and is physically intuitive since momentum and energy are conserved (at the same rate, mass density is not allowed to fluctuate). The new aspects to be discussed concern the inclusion in the system free energy functional of the surface term f_w that accounts for the (hydrophobic/hydrophilic) interaction with the solid wall

$$F\left[\rho, \theta\right] = \int_V f\left(\rho, \nabla\rho, \theta\right)\, dV + \oint_{\partial V} f_w\left(\rho, \theta\right)\, dS\,.$$

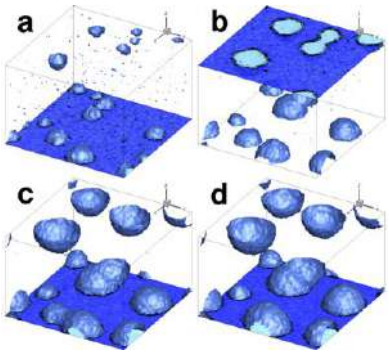

Figure 1: Nucleation on two planar parallel surfaces. For purpose of comparison with literature, the selected fluid is made of Lennard-Jones particles (see [10] for the equation of state derived from molecular dynamics simulations). Dimensionless units are used throughout, based on the following parameters: $\sigma = 3.4 \times 10^{-10}$ m, $\epsilon = 1.65 \times 10^{-21}$ J, $m = 6.63 \times 10^{-26}$ Kg. The liquid density is $\rho_L = 0.48$ (800 Kg/m^3) and the contact angle on both surfaces is $\phi = \pi/2$. The different frames refer to time $t = 90000$, $t = 165000$, $t = 235000$, $t = 258000$ (dimensionless time t = 100000 corresponds to 2.15 μs). Figure adapted form [9].

RESULTS AND CONCLUSIONS

A few snapshots of the system configurations along the nucleation process on two planar, parallel solid walls are illustrated in Fig. 1, [9]. The simulations are run for a Lennard-Jones fluid, i.e. a fluid consisting of Lennard-Jones particles at atomistic level [10], see the caption of the figure for a few more details. The bubbles form right at the wall for this specific case where the equilibrium contact angle is 90°. The dynamics is quite rich, with the bubble undergoing coalescence while they grow one close to the other, see the time history of bubble volumes in the leftmost panel of Figure 2 which also reports on temperature (it should be stressed that the system *is not* isothermal, as appropriate here) and pressure inside the bubbles (middle and rightmost panel). Based in these results, the talk will illustrate the theory behind the model and discuss with several examples the effect of wall wettability on nucleation rate and ensuing bubble dynamics.

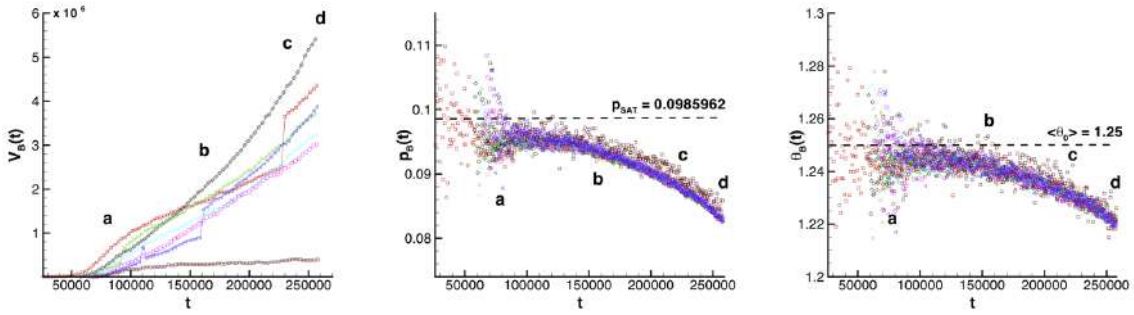

Figure 2: Left panel: Bubble volume evolution.Volume jumps correspond to coalescence events. Middle and right panels: Bubble temperature and, respectively, pressure scatter plot along nucleation (the average field temperature is $\langle\theta_0\rangle = 1.25$ (149 K), the saturation pressure is $p_{SAT} = 0.098$ (4, 1 MPa). In all frames a, b, c, d refer to the configurations shown in Fig. 1. Figure adapted form [9].

CLOSURE OF PHASE-AVERAGED BUBBLY, CAVITATING FLOW MODELS

Spencer H. Bryngelson*[1] and Tim Colonius[1]
[1] Division of Engineering and Applied Science, California Institute of Technology, Pasadena, California

Summary Phase-averaged bubbly flow models are closed by high-order statistical moments of the disperse bubble dynamics. Evaluating these moments in a simulation environment is computationally expensive because the integrands are highly oscillatory. The cost of this closure is demonstrated for an ensemble-averaged bubbly flow model. A machine-learning-based method for accelerating the moment evaluation is formulated.

INTRODUCTION

Bubble cloud dynamics play a central role in phenomena ranging from blast trauma injury[1] to kidney stone pulverization.[2] When the size distributions of bubble nuclei are broad, the average response of the bubbles to pressure fluctuations damps and disperses.[3] Bubbly flow models must account for such size distributions if they are to represent the dynamics of realistic bubbly flows.

PHASE-AVERAGING

Phase-averaged computational methods can represent the interaction between polydisperse bubble clouds and the flow that stimulates them. Current methods utilize either ensemble- or volume-averaging. Volume-averaging,[4] shown in figure 1 (left), represents bubbles as Lagrangian features that advect and evolve according to an assumed bubble dynamics model (e.g. Rayleigh–Plesset). The bubble population, sampled from an equilibrium bubble radius distribution, couples to the suspending liquid via a volumetric smoothing operator. Figure 1 (right) shows ensemble averaging.[5] It represents the bubble population as an evolving probability distribution, again according to a bubble dynamics model, in the equilibrium bubble size space on the Eulerian grid. The bubble population moments couple to the mixture-averaged flow equations and advect via a transport equation.

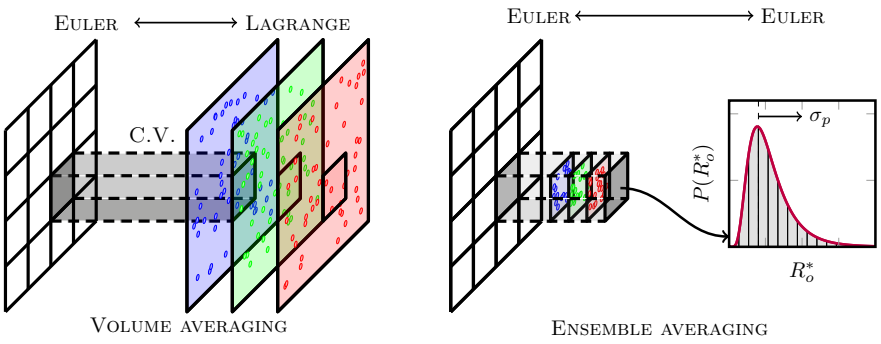

Figure 1: Schematic illustration of phase averaged methods.

Ensemble averaging is computationally cheaper than volume averaging when the bubble population is not significantly polydisperse.[6] However, ensemble averaging methods often approximate the required moments via classes methods. These methods bin and evolve the underlying probability density function. While simple, this approach is computational expensive for broad bubble size distributions. Our goal is to accelerate ensemble-averaged methods for polydisperse cases via a moment-based method.

CLOSURE VIA MOMENT METHODS

Statistical moments often more efficiently represent distributions than bins. Evolution of such moments follow from a population balance equation. This technique has been used to model polydisperse bubbly flows, though has not been applied to cavitating bubble populations, which undergo large volume changes. The moment evolution equations are not a function of only lower order moments when the bubble dynamics are nonlinear. Quadrature-based moment methods[7] can address this issue, though computing high-order moments with them is expensive. Instead, we use a Gaussian closure method. For this, a specific moments $\{l, m\}$ is

$$\mu_{lm} = \int R^l \dot{R}^m P(\vec{\mathbf{x}}, \vec{\boldsymbol{\theta}}) \, \mathrm{d}\vec{\mathbf{x}} \tag{1}$$

*Corresponding author. E-mail: spencer@caltech.edu.

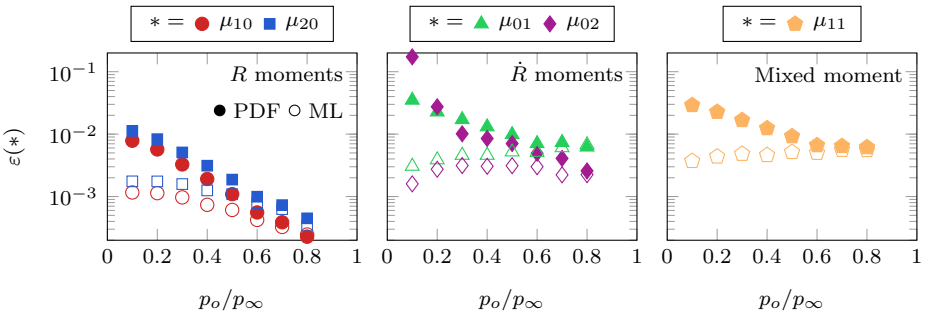

Figure 2: First- and second-order moment model errors. PDF and ML correspond to the Gaussian closure and neural network augmented methods, respectively.

where $\vec{\mathbf{x}} \equiv \{R, \dot{R}\}$ are the internal coordinates and $\vec{\boldsymbol{\theta}}$ are the shape parameters of the probability density function P (e.g. the means and variances). The moment system evolves as

$$\frac{\partial \mu_{lm}}{\partial t} = l\mu_{l-1,m+1} + m \int \ddot{R}(\vec{\mathbf{x}}) R^l \dot{R}^{m-1} P(\vec{\mathbf{x}}, \vec{\boldsymbol{\theta}}) \, \mathrm{d}\vec{\mathbf{x}}. \tag{2}$$

The integral term of (2) is closed by assuming P is a bivariate Gaussian density function and that the Rayleigh–Plesset equation represents the bubble dynamics $\ddot{R}$ with driving pressure ratio p_o/p_∞. The moment system (2) is five dimensional because P has only two shape parameters. This is significantly smaller than the hundreds of bins that significantly polydisperse populations require.[6]

Figure 2 shows that the model error ε is small for all moments when the driving pressure ratio approaches unity. This is because the dynamics are linear in this limit and the Gaussian closure is exact. However, for lower pressure ratios the bubble dynamics are more violent and model errors are significant (figure 2 PDF, filled symbols). This model deficiency results from high-order moment development, which Gaussian closure does not represent. To treat this issue, we train a long short-term memory (LSTM) recurrent neural network (RNN) to augment the low-order moment evolution equation (2). Figure 2 (ML) shows that this significantly decreases the model error for validation cases at low pressure ratios.

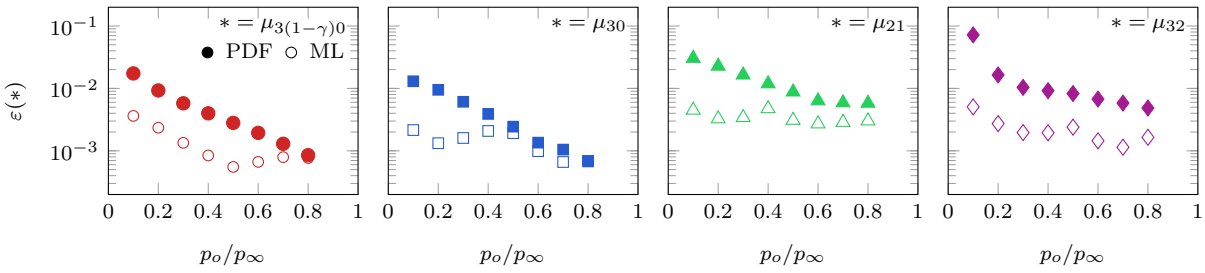

Figure 3: Model errors for the phase-averaged-model required moments.

Ensemble-averaged models require four high-order moments of the evolving population. Assuming Gaussian closure for P is sufficient to evaluate these, though figure 3 (PDF) shows that this again results in significant errors for low pressure ratios, even if the low-order moments are accurate. This is because the statistics are non-Gaussian in this regime. To treat this, we train another LSTM RNN to correct these moments. Figure 3 shows that this again significantly reduces the model errors, particularly for low pressure ratios.

SLUG FLOW DYNAMICS WITHIN CAPILLARY TUBES IN THE PRESENCE OF SURFACTANTS

Assen Batchvarov *[1], Mirco Magnini[2], Lyes Kahouadji[1], Ricardo Constante-Amores[1], and Omar K. Matar[1]
[1] Department of Chemical Engineering, Imperial College London, London, UK
[2] Department of Mechanical Engineering, Nottingham University, Nottingham, UK

Summary The effect of surfactants on the tail dynamics of bubbles propagating through capillary tubes is accessed through an extensive three-dimensional numerical study using a hybrid front-tracking/level-set method originally developed by Shin *et al.* [1]. High Reynolds number flows are shown to result in complex undulation structures at the tails [2] of capillary bubbles. The particular effect of a wide range of surfactant properties including diffusivity, elasticity, and solubility, is investigated, focussing in particular on the interfacial shape of the bubble tail.

INTRODUCTION

The dynamics of bubbles propagating through capillary tubes are of great industrial importance due to their occurrence in applications such as electronic cooling systems, enhanced oil recovery, and coating processes. The scientific foundation of the problem was laid out through the initial experimental work of Taylor [3], who showed that the wall film thickness, h_0/R, reaches an asymptotic value of approximately $1/3$ when $Ca \to 2$. Using lubrication theory, Bretherton [5] showed that this thickness in the limits of $Re \ll 1$ and $Ca \ll 1$ scales as $h_0/R \sim Ca^{2/3}$. In both cases the effect of surface active agents (e.g. surfactants) was not considered. The effect of surfactants was later studied by Ratulowski and Chang [4] and more recently by Olgac and Moradoglu [6]. Both works considered bubble dynamics in the limits of $Re \ll 1$ and $Ca \ll 1$ and found that the presence of surfactants has a liquid film thickening effect. When inertia is present in these flows, the dynamics of the rear bubble menisci exhibit undulations. Recent work by Magnini *et al.* [2] used both lubrication theory and computational fluid dynamics approaches to systematically study the effect of Re on tail dynamics and showed that increasing inertia decreases monotonically the wavelengths of the tail undulations and increases their amplitude. The present work aims to perform a comprehensive computational study of the effect of surfactants on dynamics of gas bubbles in the presence of inertia ($Re \gg 1$).

FORMULATION AND PROBLEM STATEMENT

To study the effect of surfactants on the dynamics of bubbles propagating through capillary tubes we employ a Level Contour Reconstruction Method (LCRM) CFD technique. Using this hybrid front-tracking level-set code developed by Shin *et al.* [1], we solve the two-phase incompressible mass and momentum equations for two Newtonian fluids, with surface tension, neglecting gravity. The two fluids are chosen as air and water, where the density and viscosity ratios represented by ρ_l/ρ_b and μ_l/μ_b, respectively, where ρ_l and ρ_b are the density of the liquid and gas, and μ_l and μ_b denote the viscosity of the liquid and gas, respectively. In addition to the continuity and momentum equations, we solve convective-diffusion transport equations for the interfacial and bulk surfactant species. The following non-dimensional groups can be obtained by using the channel diameter D and average liquid velocity U_l as length and velocity scales, respectively:

$$Re_l = \frac{\rho_l U_l D}{\mu_l},\ Ca_l = \frac{\mu_l U_l}{\sigma_s},\ Pe_c = \frac{U_l D}{D_c},\ Pe_s = \frac{U_l D}{D_s}, \beta_s = \frac{RT\Gamma_\infty}{\sigma_s},\ Bi = \frac{k_d D}{U_l},\ Da = \frac{\Gamma_\infty}{DC_\infty},\ k = \frac{k_a C_\infty}{k_d}, \quad (1)$$

where D_c and D_s are the diffusion coefficients in the bulk and at the interface, σ_s denotes the surface tension of 'clean' interface, R is the ideal gas constant, T is temperature, and $\beta_s = RT\Gamma_\infty/\sigma_s$ is defined as the the elasticity number. k_a and k_d are the adsorption and desorption coefficients, respectively, C_∞ is the concentration of surfactant in the bulk, and Γ_∞ is the saturated interfacial surfactant concentration. Here, Re_l and Ca_l are the liquid Capillary and Reynolds numbers, respectively. The competition between convection and diffusion for the surfactant species is represented by bulk and interfacial Peclet numbers, Pe_c and Pe_s, respectively. Other surfactant-related parameters are elasticity, β_s, Biot number, Bi, Damkohler number, Da, and the adsoprtion depth, k. In addition to the governing surfactant parameters, the present work analyzes the effect of Marangoni stresses on the flow dynamics, $\tau_m = d\sigma/ds$, which have been non-dimensionalised with the viscous stress, $\tau_{vis} = \mu_l U_l/D$, resulting in the definition of the Marangoni number, $Ma = \tau_m/\tau_{vis}$. The local surface tension is defined by a Langmuir adsorption equation of state, $\sigma = \sigma_s \left[1 + \beta_s ln\left(1 - \frac{\Gamma}{\Gamma_\infty}\right)\right]$, where Γ is the local interfacial surfactant concentration.

The three-dimensional computational domain consists of a cylindrical channel of diameter D. The bubble is initially located at the beginning of the channel and its shape is initialised using a cylindrical body and two spherical caps at the front and back. The length of the bubble for the baseline case is $L_b = 5D$, although this will be varied when studying the impact of the bubble length on the flow dynamics. The flow is initiated by imposing a fully-developed parabolic velocity profile at the inlet. A no-slip boundary condition is imposed on the channel wall. The channel length is set to be sufficiently long to allow the bubble to achieve a steady-state motion (e.g. $L_x = 27.8D$).

Figure 1: Effect of varying surfactant solubility through Bi, where other surfactant parameters are kept constant: $Re_l = 443$, $Ca_l = 0.0089$ $Pe_c = Pe_s = 100$, $Da = 1$, $k = 1$, $\beta_s = 0.5$. (a) Spatial variation of the interfacial shape of 'clean' and 'surfactant' bubbles and Ma distribution along the bubble arc length; 3D bubble shapes and interfacial surfactant distribution shown inside the panel; (b) Streamwise tangential velocity at the bubble interface in a reference frame moving with the speed of the bubble tip, plotted as a function of the bubble arc length.

RESULTS

We perform an extensive parametric study of the key non-dimensional groups identified in the previous section. A sample result set is given by Fig. 1, where we show the effect of varying surfactant solubility on the bubble dynamics; the addition of surfactants alters the local surface tension. As the bubble propagates through the channel, surfactants accumulate at the back of the bubble, where they generate surface tension gradients and hence Marangoni stresses, which as seen in Fig. 1, are effective in stabilising the bubble dynamics and suppressing the bubble tail undulations otherwise observed in the surfactant-free case. The highly soluble surfactant, $Bi = 5$, produces the highest concentration gradient at the bubble tail, which results in the highest Marangoni stress. As surfactant solubility is decreased, the effective magnitude of the Marangoni stresses is reduced, however, the overall affected area increases as surfactants are unable to evacuate the interface as quickly and diffusion promotes their movement towards the bubble front. As a result, at moderate solubility, $Bi = 1$, the Marangoni stresses generated at the bubble tail pushes the liquid film inwards. This effect becomes more pronounced for $Bi = 0.1$, where a sudden increase of the film thickness near the bubble tail is apparent in Fig. 1a; this is due to the bubble interface behaving as a rigid wall and imposing a no-slip condition to the flow, as suggested by the u_t decreasing locally to zero, see Fig. 1b. In the the lowest solubility case, $Bi = 0.01$, surfactants are unable to evacuate the interface. The resultant uniform Marangoni stress acts to generate a thicker film region at the back end of the bubble. The film becomes completely rigid in the thicker film region as seen in Fig. 1b, whereas at the front of the bubble surfactants are largely absent and the interface exhibits similar behaviour to that observed for the surfactant-free case.

CONCLUSIONS

This work focuses on investigating the effect of surfactant species on capillary bubble tail dynamics, by employing high-accuracy numerical simulations. In the sample result set presented, we see that by lowering the surfactant solubility, surfactant species are convected towards the bubble tail, where they result in local surface tension gradients. The resultant Marangoni stresses act to rigidify the bubble tail and suppress bubble undulations. In the lowest solubility case, a uniform Marangoni force is generated at the bubble rear end. This induces a no-slip condition on the bubble interface, which is triggers a sharp thicknening of the liquid film in the proximity of the bubble tail.

DYNAMICS OF H2 BUBBLES GROWING AT MICROELECTRODES

Aleksandr Bashkatov*[1], Syed Sahil Hossain[1], Xuegeng Yang[1], Gerd Mutschke[1], and Kerstin Eckert[1,2]
[1] Institute of Fluid Dynamics, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany
[2] Institute of Process Engineering and Environmental Technology, Technische Universität Dresden, Dresden, Germany

Summary Recently a new phenomenon of long-lasting position oscillations of hydrogen gas bubbles produced via electrolysis at horizontally installed microelectrodes has been found. The bubbles grow until their detachment when buoyancy exceeds the retarding forces. The phenomenon itself consists in multiple bubble returns to the electrode. It was found that the mother bubble sits on and is fed by a carpet of small bubbles. The dynamics of the growing bubble was systematically studied and found to be strongly dependent on the cathodic potential and electrolyte concentration. A new insight into the multifaceted and complex process has been established. Regions of different bubble dynamics regimes are summarized in a diagram.

The growth of hydrogen bubbles in water electrolysis is a particularly interesting problem of high practical relevance due to the prominent role of hydrogen in energy storage via power-to-gas processes. However, alkaline water electrolysis is suffering from inadequate efficiency. Major reasons are the blockage of the active electrode area and the increase the ohmic resistance of the electrolyte by the gas bubbles produced. A deeper understanding of the mechanism of hydrogen bubble evolution therefore may provide additional opportunities to control and enhance the process. Microelectrodes are the method of choice [1] to study localized phenomena at H_2 bubbles in detail since they provide a low number of nucleation sites and the possibility to grow relatively large bubbles.

The dynamics of single hydrogen bubbles produced via electrolysis at microelectrode was systematically studied at different cathodic potentials and electrolyte concentration. The hydrogen gas bubbles were generated at a $\varnothing 100$ μm Pt microelectrode installed horizontally in electrolytic cell filled with sulfuric acid of 0.1...1 mol/L concentration, using a three-electrode setup. A mercury/mercurous sulfate electrode (MSE, 0.65 V vs SHE) and a Pt wire ($\varnothing 1$ mm) served as the reference electrode and anode, respectively [1]. High-speed microscopic shadowgraphy at 1000 frames per second and a spatial resolution of up to 820 pix/mm coupled to measurements of the electric current in potentiostatic mode (-2...-10 V) led to observation of three different bubble evolution regimes, including novel dynamic phenomenon covering the transition from monotonic to oscillatory growth reported in [2].

In Figure 1(a) a scheme of a slightly deformed spherical bubble, sitting on the Pt electrode, and the carpet of microbubbles beneath, with their relevant geometric parameters is shown, where H — bubble height, W — bubble width, ε — bubble elongation reflecting its deformation, δ — thickness of the carpet and **j** — current lines directed from anode to cathode. Significant differences have been found in the bubble evolution behavior depending on the potential and electrolyte concentration.

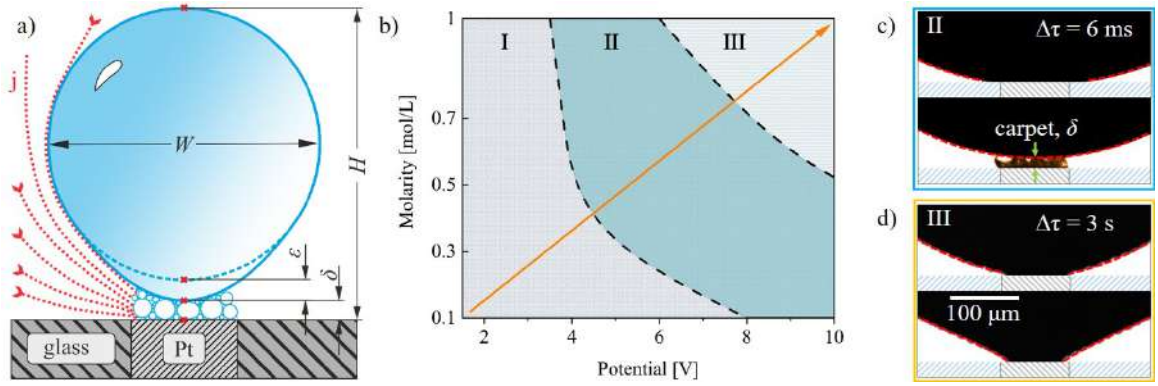

Figure 1: (a) Scheme of slightly deformed spherical bubble sitting on the Pt electrode and the carpet of microbubbles beneath (reprinted from [2]). (b) Diagram representing three distinct regions of the bubble evolution. (c) Bubble at its lowest and highest position in an oscillation phase, at -5 V and 0.5 mol/L, $\triangle\tau$ = 6 ms. (d) Representation of the bubble shape deformation at two distinct moments of time, at -10 V and 1 mol/L, $\triangle\tau$ = 3 s.

Fig. 1(b) visualizes three different bubble growth regimes I, II, III depending on potential and electrolyte concentration which are described in detail in following. The orange colored arrow shows the direction from lower to higher concentration/potential. This increment along the arrow leads to higher retarding forces acting downward, like Marangoni force F_M [3, 4, 5], electric force F_e [2] and a dynamic force F_d due to faster gas generation and hence bubble-carpet interaction. This step-by-step leads to a reduction of carpet thickness, to the appearance of instabilities like bubble position oscillations, and to shape deformations. The transition between the different regimes is smooth. Depending on the

*Corresponding author. E-mail: a.bashkatov@hzdr.de

magnitude of the retarding forces that hold the bubble at the electrode and hence their contribution to the force balance, the bubbles grow in different ways and detach at different diameter and lifetime [1].

In the first 'I' region of Fig. 1(b) the bubble follows smooth and conventional evolution characterized by the growth law, $R \propto t^{1/3}$, as reported in [1]. Furthermore, a permanent existence of a carpet of microbubbles below the main bubble is detected as shown on Fig. 1(a). The evolution in that case proceeds mainly by coalescence with the carpet permanently feeding the main bubble. Depending on the potential/concentration the visible carpet might already exist shortly after formation of a single bubble at the electrode or might appear later as the bubble moves slowly away from the electrode. As the bubble increases in volume, it tends to move upward to detach. However, the distance dependent electric force revealed in [2] increases, and the bubble continues to levitate above the electrode, thereby adsorbing small bubbles from the carpet. At some point, the bubble detaches, as the derivative of F_e becomes negative, while the buoyancy F_b rises. However, at such potential/concentration the increment in the electric force is not sufficient to bring the bubble back to the electrode and hence trigger the oscillations characteristic of the second 'II' region.

The second 'II' region represents the bubble evolution regime during which in time the transition from monotonic to oscillatory growth is observed. The oscillatory phenomenon consists in periodic upward and downward movements of the bubble. Here, the bubble grows and slowly moves upward, while the carpet thickness δ increases. It reshapes the geometry of the current lines **j** directed from anode to cathode affecting the electric force that brings the bubble back to the electrode. In [2] it was shown numerically that the electric force increases together with the carpet thickness until its critical value of around δ_{crit} = 20...30 μm at which the bubble detaches. The oscillation amplitude (and carpet thickness) rises during the oscillations until this critical value δ_{crit}. With concentration decrease, the oscillations regime shown in Fig. 1(b) is shifted towards higher potentials, meaning that the reduction in magnitude of the retarding forces with concentration decrease might be compensated by the potential increment. The images in Figure 1(c) represent bubble positions at two distinct moments of time within one upward-downward phase with $\triangle\tau$ = 6 ms. The first image is the lowest position of the bubble, while the second is the highest, where the carpet can be clearly seen.

The third 'III' region represents the evolution under relatively high potential, providing 'naturally' high retarding forces. By holding the bubble at the electrode, any oscillations and any visible carpet along the whole evolution are suppressed. The bubble sits at the electrode and grows monotonously, mainly by diffusion, whereby progressive shape deformations become visible. Although the F_e is already high at these conditions, the shape deformation additionally contributes to a longer lifetime. The images in Figure 1(d) represent bubble shapes at two distinct moments of time with $\triangle\tau$ = 3 s, while the second image is recorded shortly before detachment.

In summary, depending on voltage and electrolyte concentration, three different bubble evolution scenarios were identified. The magnitude of retarding forces (incl. F_e) governed by the potential/concentration is responsible for the carpet existence and its thickness, positions oscillations and shape deformations of the bubble. The transition from the conventional evolution path to oscillations and to shape deformations is smooth and additionally dependent on the electrode preparation. The impact of the carpet-bubble interaction needs to be taken into account and to be analyzed in a future research, as suggested in [6].

BUOYANCY-DRIVEN BUBBLE MOTION IN A CONSTRICTED TUBE

Zhicheng Zhu[1], Haoran Liu*[1], and Hang Ding[1]
[1] Department of Modern Mechanics, University of Science and Technology of China, Hefei, China

Summary We numerically investigate the dynamics of bubble rising in a constricted tube. The bubble is released from the bottom of a tube, and rises up due to buoyancy. However, a throat in the constricted tube may hinder the bubble motion, possibly leading to the bubble entrapment. To investigate at what conditions that the bubble would pass through or be entrapped at the throat, a diffuse-interface immersed-boundary method is used to simulate this dynamic process. We found that the fate of the bubble is determined by the bubble deformation, buoyancy force, surface tension and the tube geometry. A scaling law is proposed to predict the boundary that separates the two regimes. The theoretical prediction is in good agreement with our numerical results.

INTRODUCTION

Bubble motion in a tube with complex geometries is relevant to a wide range of industrial processes in food, petroleum and energy. Previous studies focused on the deformation and vibration of bubbles in a tube. Hemmat & Borhan (1996) experimentally observed the periodic deformation of drops and bubbles in a constricted tube. Later, Legendre et al. (2005) proposed a mass-spring system model to describe the periodic bubble deformation. Zenit (2009) found that the viscous effect is effectively equivalent to a damper with a fixed coefficient, and then extended the mass-spring model by including the viscous effect. In our work, we consider the axisymmetric flow of a buoyancy-driven bubble in a vertical constricted tube as shown in Figure 1(a), in which the curved solid wall in the middle assumes an arc shape. The bubble with a density ratio of 0.001 to the surrounded liquid is released from the bottom of the tube at the very beginning. Due to the buoyance force, the bubble ascends with time until reaching the throat of the constricted tube, which may hinder the bubble motion, possibly leading to the bubble entrapment. To investigate at what conditions that the bubble would pass through or be entrapped at the throat, a diffuse-interface immersed-boundary method is used to simulate this dynamic process.

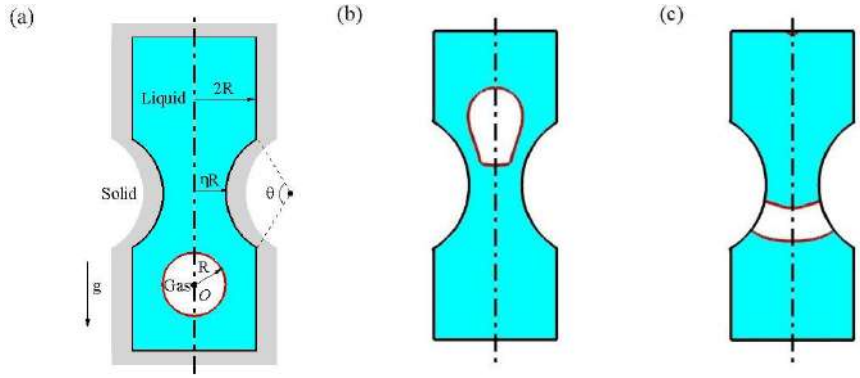

Figure 1. A sketch of a bubble floating in constricted tube. (a) Setup of numerical simulations. Initial bubble radius is denoted by R and the tube throat radius is ηR. (b) Passing model and (c) entrapment model.

NUMERICAL AND THEORETICAL METHODS

The bubble motion in the constricted tube is simulated by using an axisymmetric diffuse-interface immersed-boundary method (Liu & Ding, 2015). It allows us to simulate incompressible multiphase flows involving moving contact lines on the rigid objects of irregular shape with large density and viscosity ratios. The liquid-gas interface is represented by the volume fraction of the liquid, C_L, the evolution of which is governed by the Cahn-Hilliard equation

$$\frac{\partial C_L}{\partial t} + \nabla\cdot(\mathbf{u}C_L) = \frac{1}{Pe}\nabla^2\psi$$

where $\mathbf{u}$ stands for the flow velocity, and the chemical potential ψ is defined as

$$\psi = C_L^3 - 1.5C_L^2 + 0.5C_L - C_L C_S(1 - C_L - C_S) - Cn^2\nabla^2 C_L,$$

and Cn is the thickness of diffuse interface. The motion of fluids is governed by the Navier-Stokes equations,

$$\rho\frac{\partial \mathbf{u}}{\partial x} + \mathbf{u}\cdot\nabla\mathbf{u} = -\nabla p + \frac{1}{Re}\nabla[\mu(\nabla\mathbf{u} + \nabla\mathbf{u}^T)] + \frac{\mathbf{f_s}}{We} - \frac{\rho}{Fr}\mathbf{j} + \mathbf{f}_{IB}$$
$$\nabla\cdot\mathbf{u} = 0,$$

where $\mathbf{f}_s$ donates the surface tension force and $\mathbf{j}$ is the vertical direction. $\mathbf{f}_{IB}$ represents the additional force arising from the immersed boundary method.

The fluid properties of bubble and fluid are used to define the dimensionless group: Reynolds number $Re = \rho UR/\mu$, Weber number $We = \rho U^2 R/\sigma$, Froude number $Fr = U^2/gR$, and Bond number $Bo = \rho g R^2/\sigma$. Here, ρ, μ and σ denote the density, viscosity and surface tension of the fluid respectively.

RESULTS AND DISCUSSIONS

The numerical results confirm that the bubble either passes through or is trapped at the tube throat. We find that when the bubble is smaller than the size of throat, it is just slightly elongated and passes through the throat with ease, namely passing mode (see Figure 1b). On the other hand, a bigger bubble could be captured by the throat, and subsequently contact lines are generated and pinned at the side wall, namely entrapment mode (see Figure 1c). In this case, the buoyancy force is not so strong enough as to break up the bubble, mainly because of the limited size of the throat. As a result, the bubble rests at the throat and the flow vanishes gradually due to viscosity. Figure 2 shows the phase diagram of bubble released from or captured at the constricted tube with respect to η versus Bond number. We can see that the boundaries separating two flow regimes have different trends for small and large bubbles. We use a mass-spring model (Legendre et al., 2005) to analyse the bubble vibration, and also take account of the bubble dynamics near the tube throat. We find that the difference in trends is mainly due to the competition between buoyancy and surface tension forces. A scaling law is proposed to predict the boundary that separates the two regimes. The theoretical prediction is in good agreement with our numerical results. as shown in Figure 2.

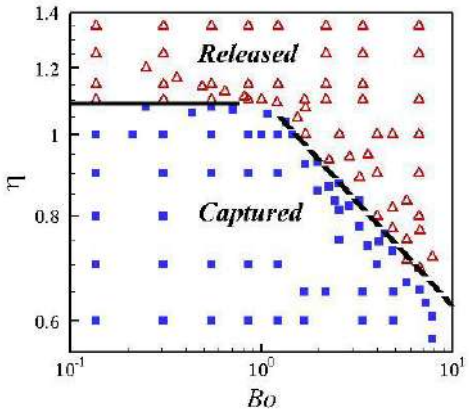

Figure 2. Phase diagram of a bubble floating in constricted tube with respect to η and Bo, including the regimes of released (△) and captured (■). the lines are theoretical predictions for the transition of regimes.

CONCLUSIONS

We numerically simulated the motion of a buoyancy-driven bubble in a constricted tube by using a diffused-interface immersed-boundary method. The effects of bubble-to-orifice ratio η and the Bond number on the dynamics and mode of the bubble have been investigated. Scaling laws are proposed to predict the boundary between passing and entrapment modes. Good agreements between our theoretical predictions and numerical results are achieved.

MICROFLUIDIC DEVICE FOR TESTING STRING-METHOD PREDICTIONS OF GAS BUBBLE NUCLEATION

Summary Gas bubble nucleation is a fundamental phenomenon both throughout the natural sciences and in the production of foams for lightweight, functional materials. Experimental challenges of measuring the kinetics of this rapid, multiscale process pose a roadblock for theoretical modelling of bubbles and foams. Using microfluidic hydrodynamic focusing developed for measurement of protein and chemical kinetics, we built a microfluidic cell to probe gas bubble nucleation of CO_2 in polyol at controlled pressure with millisecond resolution over acquisition times sufficient for optical, IR, and X-ray measurements. Our preliminary validation of a string-method model demonstrates the utility of this device to explore untested predictions of low-barrier nucleation.

CHALLENGES OF MEASURING BUBBLE NUCLEATION KINETICS

The nucleation of gas bubbles is a phenomenon significant as much for its role in the production of foamed materials as for its ubiquity throughout the natural sciences. Substantial progress has been made in the modelling and measuring of bubble nucleation along surfaces[1]; however, nucleation in the liquid bulk, by which most of a foam's cells are born, has proven to be more difficult to study.

Gas bubble nucleation occurs when a reduction in pressure (and/or an increase in temperature) instigates the supersaturation of gas in the liquid—the popping of a cork from a champagne bottle, for example. On the order of milliseconds, nucleated bubbles grow several orders of magnitude—nanometers to micrometers—so locating and capturing a bubble nucleation event is challenging. Gentle rubbing of a surface can reproducibly localize nucleation to allow for high-resolution imaging. Unlike nucleation on surfaces, nucleation events in the bulk are random in space as well as in time, precluding reliable localization of nuclei in experiments. Consequently, theoretical understanding of bulk bubble nucleation has outpaced experimental validation, leaving exciting predictions like the nucleation of a CO_2-rich liquid in PMMA and PS unexplored[2]. Moreover, this problem hinders our understanding of foaming, as Di Maio and Kiran recently found that the "current lack of [nucleation]'s full understanding presents the main actual limitation to modelling the foaming process."[3]

A Solution: Microfluidic Hydrodynamic Focusing

The development of microfluidic hydrodynamic focusing has overcome the challenge of probing fast, random kinetic phenomena, from protein folding[4] to chemical kinetics[5]. In this technique, an outer sheath stream flows around a thin inner stream, shielding the inner stream from the effects of the walls. The inner stream is thin enough that, although the microscopic dimensions ensure laminar flow, the two solutions quickly mix through diffusion and initiate a configurational or chemical change. Subsequent points along the flow thus correspond to chronological moments in the kinetic process, effectively mapping the kinetic timeline along the length of the flow. As a result, long acquisitions required for techniques like X-ray scattering are possible while still achieving millisecond resolution of the kinetics.[4]

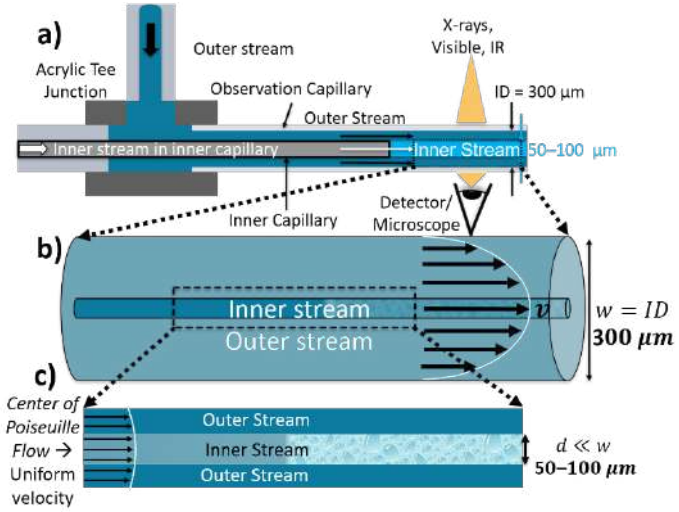

Figure 1. a) Tee-junction flow-focusing device design. The inner stream flows through a thin inner capillary into the observation capillary while the outer stream surrounds the inner capillary to produce sheath flow. The observation capillary can be probed with IR, light, and X-rays. b) Zoomed-in view of the Poiseuille flow field of sheath flow. Bubbles nucleate partway down the channel. c) Zoomed-in view of the laminar, uniform velocity field of the inner stream.

We adapted microfluidic hydrodynamic-focusing devices[4,6] to probe bulk gas bubble nucleation under large, controlled pressure drops (see Fig. 1). We built the device to withstand over 100 bar (10 MPa), which is relevant for industrial foaming and supercritical CO_2 and allows us to explore the unique qualitative behaviour of supercritical foaming[3]. Previous high-pressure microfluidic devices have studied reaction kinetics[5], but we believe that our device is the first to be used to study bubble nucleation. Because the sheath-dominated flow will obey Poiseuille flow, the pressure will drop linearly along the length of the channel, allowing for controlled studies of supersaturation effects. With a thin enough inner stream, the velocity will also be uniform, ensuring a precise correspondence among time, pressure, and distance. By keeping the pressure well above the saturation pressure until the flow enters the observation capillary, we also prevent the effects of the walls leading up to the capillary. We have so far measured nucleation with high-speed optical microscopy, but the design can probed with X-ray scattering, thermography, and FTIR.

RESULTS

To guide our measurements of bubble nucleation, we developed a theoretical model of the nucleation barrier using the string method applied to density functional theory (DFT) with a perturbed-chain statistical associating fluid theory (PC-SAFT) equation of state for the system, as in Xu *et al*.[2] Model parameters were fit and validated with data collected using Di Maio's gravimetry-axisymmetric drop-shape analysis[7]. The model indicates several interesting parameter spaces that yield drastic reductions in the nucleation barrier for us to explore with our microfluidic device.

Experimentally, we have used our device to observe bubble formation and growth with high-speed microscopy as pressure decreases along the channel. Example high-speed micrographs along the length of the capillary are shown in Fig. 2. In these micrographs, we see an onset of bubble nucleation between 48 and 78 mm (roughly 50 and 20 bar) Additionally, we see that the number of bubbles dramatically increases after this onset corresponding with decreasing pressure, a quantity we measure with custom image-processing software. We present a comparison of bubble population with theoretical predictions of the bubble nucleation barrier and explore the possibility of low-barrier CO_2-rich liquid nucleation[2]. We will also present a comparison between measurements of bubble growth and predictions based on a modified Epstein-Plesset model, as well as a discussion of coalescence, as shown in Fig. 2.

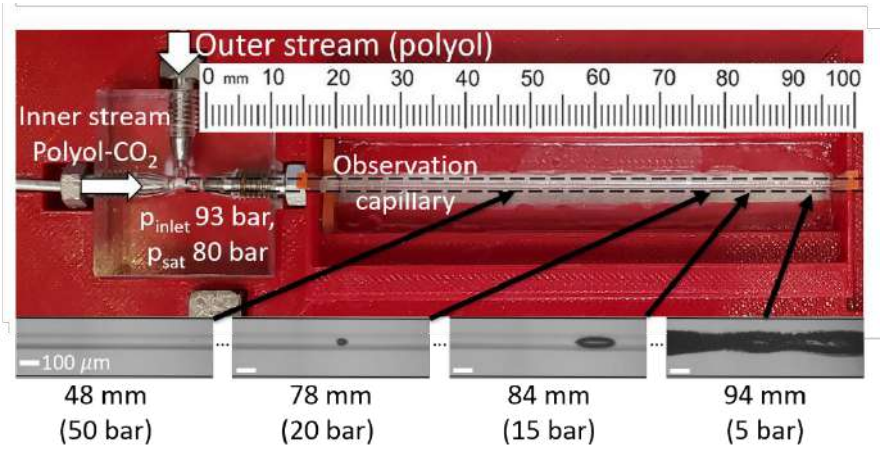

Figure 2. Top: microfluidic flow-focusing device in a 3D-printed mount with polyol-CO_2 saturated at 80 bar (8.0 MPa) entering the observation capillary (quartz) at 93 bar (9.3 MPa), ensheathed in pure polyol. The ruler above indicates the distance along the observation capillary (mm). Bottom: High-speed micrographs along the observation capillary show the inner walls of the capillary outlined in black with the inner stream in the centre. The outer stream of pure polyol separates the inner stream from the capillary walls. Bubbles nucleate, grow, and coalesce into a foam as the pressure in the capillary decreases.

We presented a novel microfluidic flow-focusing device constructed for probing bulk gas bubble nucleation of CO_2 in polyol to explore untested theoretical predictions and enhance understanding of polymer foaming. The device was based on microfluidic principles that effectively map the chronology of fast kinetic processes like bubble nucleation along the length of the channel in a stream of fluid insulated from the inner walls of the device. We adapted these principles for supercritical pressures (100 bar, 10 MPa) and suitability for optical microscopy, X-ray scattering, thermography, and FTIR. Preliminary high-speed micrographs are consistent with our theoretical predictions, holding promise for the exploration of untested theoretical predictions, such as CO_2-rich liquid nucleation predicted in the literature[2].

DYNAMIC TRANSITION APPROACHING JETTING SINGULARITY DURING THE COLLAPSE OF DROP-IMPACT CRATERS

Zi Qiang Yang *[1], Yuan Si Tian [1], and S. T. Thoroddsen [1]
[1] Division of Physical Science and Engineering, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia

Summary Understanding the dynamical transition from capillary-driven to pure inertial focusing is important to revealing the mechanism underlying the most singular micro-jetting produced from drop-impact craters. Herein we study dimple dynamics from the collapse of these craters when the drop is of a different immiscible liquid than the pool. The parameter space is considerably more complex than for identical liquids, revealing intricate compound-dimple shapes. In contrast to the universal capillary-inertial drop pinch-off regime, where the neck radius scales as $R \sim t^{2/3}$, a purely inertial collapse of the air-dimple portrays $R \sim t^{1/2}$ and is sensitive to initial and boundary conditions. Capillary waves can therefore mold the dimple into different collapse shapes. We observe a clear cross-over in the nature of the dynamics from capillary-inertial to purely inertial immediately before the pinch-off. Notably, for singular jetting the cross-over time occurs much earlier, irrespective of the Weber number.

INTRODUCTION

Singularities occur in various branches of physics and mechanics, from the gravitational collapse of black holes to the necking pinch-off of a pendent drop dripping from a faucet. What makes singularities a particularly attractive "laboratories" is the rapid time-scale and small length-scales which expose the key force balance which governs the dynamics. In fluid mechanics the pinch-off of a fluid cylinder is the most iconic example of a singularity, which has been extensively studied over the last three decades. There is a remarkable difference between the pinch-off of a drop from a nozzle vs that of a bubble. For the drop the necking evolves in a self-similar manner, forming conical shape with capillary-inertial scaling of the necking radius, i.e. $R \sim t^{2/3}$ [1]. On the other hand, the pinch-off of a bubble follows a purely inertial dynamics, where $R \sim t^{1/2}$ [2, 3, 4]. Despite a rather modest difference in the two exponent values, the fact that the inertia is inside the neck for the drop, while it is outside of the air-cylinder for the bubble, changes profoundly the dynamical nature of the pinch-off. For the purely inertia collapse the surface tension becomes irrelevant and the dynamics show strong dependence on the initial or boundary conditions. This memory of the boundaries has been best demonstrated for a bubble pinching off from a nozzle with an elliptic cross-section [5, 6].

Herein, we focus on the jetting from the rebounding of a drop-impact-produced crater. The finest and most *singular jets* emerge when a dimple forms at the bottom of the crater and collapses without pinching of a bottom bubble. The final stage of collapse follows pure inertial scaling [7].

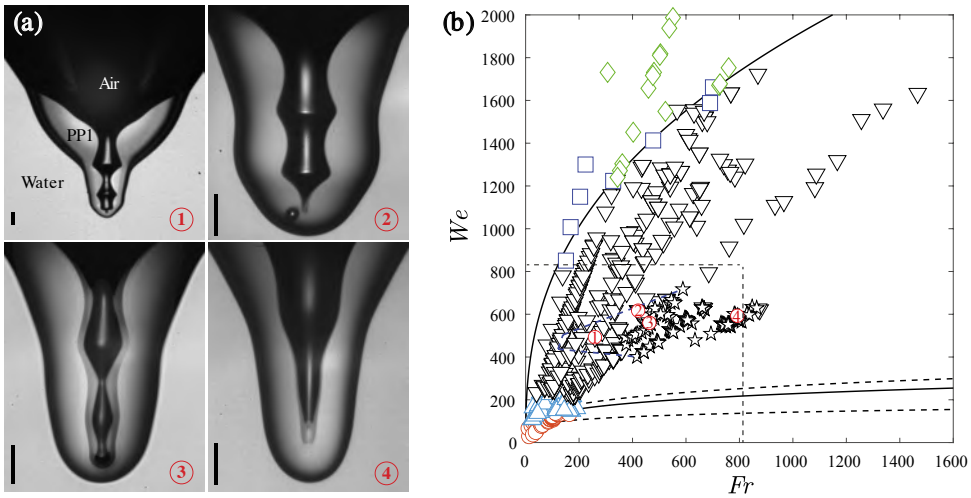

Figure 1: (a) Typical dimple shapes for different impact conditions in the multi-dimple regime corresponding to the circled red numbers in (b). Multi-pinch-offs dimple: ① D = 1.16 mm, U = 1.7 m/s, Fr = 259, We = 493; ② D = 1.02 mm, U = 2.1 m/s, Fr = 421, We = 617; ③ D = 0.93 mm, U = 2.05 m/s, Fr = 463, We = 560 and singular telescopic dimple: ④ D = 0.73 mm, U = 2.38 m/s, Fr = 792, We = 593. The scale bars are 100 μm long. (b) Characterization of the dimples and jets in *Fr-We* space for drop impacts of immiscible liquids. The two dash curves are the bounds of the regular bubble entrapment measured by [8, 9], for identical liquids. The two solid curves mark the bubble entrapment region based on our study. The symbols correspond to different dimple shapes: (○) no pinch-off shallow dimple; (△) dimple pinch-off with bubble going out with jet; (▽) tiny bubble pinched off near secondary critical pinch-off; (☆) singular telescopic dimple; (▽) pinched-off bubble entrapped in PP1 drop; (□) liquid column break-up without dimple pinch-off; (◇) water entrapped in PP1 drop without pinch-off. The dashed cyan lines mark the region of multi-dimples.

EXPERIMENTAL SETUP: We use different immiscible liquids: The pool is purified water, while the drop consists of PP1 (Perfluorohexane, C_6F_{14}). PP1 is 1.71 times heavier than water and has very low surface tension σ_d = 11.9 mN/m. The interfacial tension between the two liquids is 48 mN/m. The range of drop sizes is D = 0.6 - 2.0 mm. By changing drop release-height we get impact velocities U from 0.1 to 3.9 m/s. The corresponding range of Reynolds, Weber and Froude numbers, based on drop properties are: $Re = \rho_d DU/\mu_d = 374 - 10,200$; $We = \rho_d DU^2/\sigma_d = 10 - 2,000$; $Fr = U^2/(gD) = 10 - 1,500$; where g is gravity acceleration, ρ_d and μ_d are drop density and dynamic viscosity.

RESULTS AND DISCUSSIONS

The impact produces a hemispheric crater into the free surface of the pool, with the PP1 drop liquid forming a thin continuous layer coating it. The subsequent rebound can form a bottom dimple whose collapse produces singular jets [7, 8]. The free surface of this dimple therefore remains between air and the PP1 drop liquid. Figure 1 highlights the regime where a dimple forms during its collapse. This occurs at much larger values of We (based on drop properties), than for the classical regime (dashed lines) where the dimple entraps a bubble for identical liquids in both drop and pool [9]. Figure 1(a) shows a prominent new feature of the dimples, i.e. capillary waves travelling down towards their tips, which can lead to multiple pinch-offs. The thinnest and fastest jets emerge when no bubble in pinched off [7].

What is the role of capillary waves in setting up the dimple for the inertial focusing? For the singular jets from bursting bubbles or super-critical surface waves, the dimple dynamics have until recently been formulated in the self-similar capillary-inertial formalism [10, 11], while the final cylindrical collapse has been shown to follow pure inertial focusing [7, 12]. One can therefore expect a dynamical transition in the vicinity of the final jet formation. In Figure 2 we track the radius of pinch-off neck for a typical dimple, shown in the inset. There is a clear cross-over in the nature of the dynamics from capillary-inertial $R \sim t^{2/3}$ to purely inertial with $R \sim t^{0.55}$ [3, 7] at $t_c \simeq 65$ μs before pinch-off, as marked by the arrow. Figure 2(b) shows that the cross-over time scales with the impact time $t_c \simeq 0.235 R_d/U$ for the pinch-off cases. On the other hand, for singular jetting the cross-over time occurs much earlier, irrespective of We.

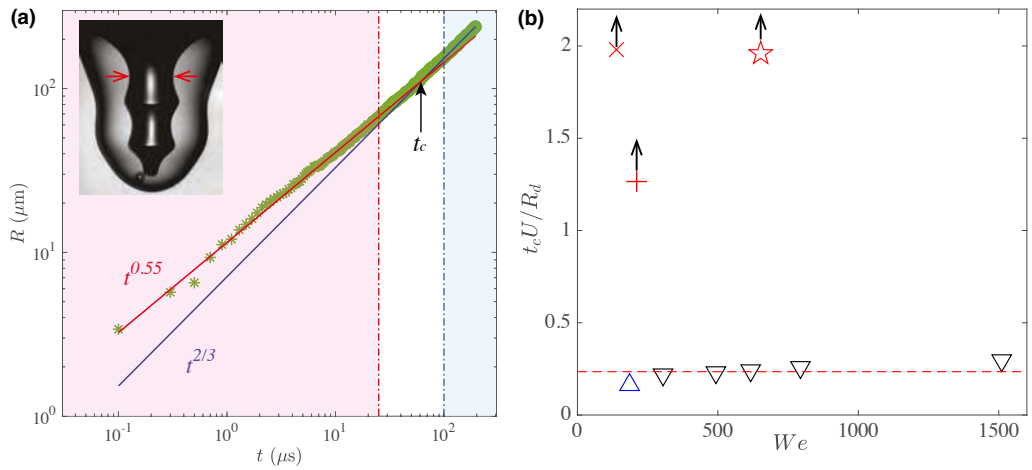

Figure 2: (a) Logarithmic scaling of the dimple radius vs time before pinch-off. There is a transition of power-law exponents from 2/3 to 0.55 closest to the pinch-off. The background shading marks the validity of each, with the arrow indicating the approximate cross-over time t_c. The data is taken from two video clips spanning time-scales from 100 ns to 200 μs before pinch-off. (b) It shows how t_c normalized by the impact time D/U changes with We, for dimple pinch-off (△ & ▽) and singular jets (×, + & ☆). The vertical arrows indicate these are lower bounds, as for these cases the dynamics remain inertial for the entire video clip.

PRESSURE AMPLIFICATION INDUCED BY MULTIPLE CAVITIES COLLAPSE ALONG HIGH-SPEED DROPLET IMPACT INSIDE A TUBE

Wangxia Wu[1], Qingquan Liu *[1], and Bing Wang y[2]
[1] School of Aerospace Engineering, Beijing Institute of Technology, Beijing, China
[2] School of Aerospace Engineering, Tsinghua University, Beijing, China

Summary This paper performs a numerical study of the droplet impact inside a solid tube with the initial speed of 300 m/s. The comparison of impingement is conducted between the dense droplet and the droplet embedded with different arrangement of cavity lines. The results show that the focus shock wave is generated once the droplet impacts on the bottom of the tube which may focus inside the droplet. For the cases of the droplet initial embedded with the cavities, the focus shock wave might induce the cavities collapse, and the transient highest pressure value is observably amplified. It indicates that through the properly arrangement of the cavities the transient highest pressure value can be further amplified.

INTRODUCTION

The high-speed droplet impingement problem especially the extremely high pressure during this procedure has aroused widely attentions nowadays. Once a high-speed droplet impacts on the solid structure, the confined water-hammer shock wave may generate inside the droplet [1]. Also, the shock waves may induce the evolution of cavities inside the droplet, which may induce transient local high pressure [2, 3].

During the high-speed impingement procedure, the local maximum pressure is an important parameter which is closely concerned in engineering applications, for example the generation of high pressure in a particular region can be applied to increase the success of generating inertial confinement fusion [1]. Some researchers pointed out that stronger shock wave may generate when the shape of the target surface conforms with the droplets interface [4]. Besides, previous investigations of the planar shock wave inducing cavities collapse in an open liquid area found that through a reasonable distribution of some cavities can further amplification the maximum pressure value during the cavity collapse [5].

In the present work, a high-speed droplet impact in the tube shape solid which conforms well with the droplets interface is considered. The evolution properties of the water-hammer shock wave is numerical studied by the case of the dense droplet impingement. Moreover, several cases of the droplets embedded with different distributions of cavities are numerically simulated in detail to understand the pressure amplified mechanism during cavity collapse.

PHYSICAL CONFIGURATION & NUMERICAL METHOD

In this work, the droplet with the initial speed of V_0 (= 300 m/s) and the initial diameter of D_0 (= 5 mm) is considered. And the impacted subject is a solid tube with the bottom shape that conforms well with the droplets interface, as shown in figure 1. For the cases that some air cavities are initially embedded, the diameter of all the cavities are 0.04 D_0. The cavities arrange in line and the distance between the center of each of two cavities are all 0.1 D_0. Several configurations are considered in the present work, including the case (I) for dense droplet, and the case (II), (III) and (IV) being corresponded to the droplet embedded with one, two and three cavity lines, as shown in figure 1. In this study, the simulations for all cases begins with the instant that the droplet just interacts with the tube.

The multi-components Eulerian compressible two-phase fluid model is applied to simulated the present problem. The numerical fluxes are obtained by employing a Godunov-Type HLLC approximate Riemann solver coupled with the 5^{th} order WENO scheme. The immersed boundary method is utilized for the solid tube surface, and the top boundary condition is non-reflected boundary condition. The detailed introduce of the numerical setup can be referred to our previous works [2, 3].

RESULTS & DISCUSSIONS

Firstly, in order to understand the properties of the confined water-hammer shock wave during the impinging procedure, the dense droplet impingement problem is investigated, the corresponding numerical result is given in figure 2(a-1) $\sim$ figure 2(f-1). As shown in figure 2(b-1), once the droplet impacts on the bottom of the tube which just conforms well to the droplet itself, a concave shape shock wave is generated, which shows a trend of focus propagation. Therefore, this focus propagation water-hammer shock wave is called as focus shock wave in this work. Since the initial curvature of the shock front is the same as the droplets interface, the shock wave focus at the instant when it propagates to the center point of the droplet, and the highest pressure value is generated, as show in figure 2(e-1).

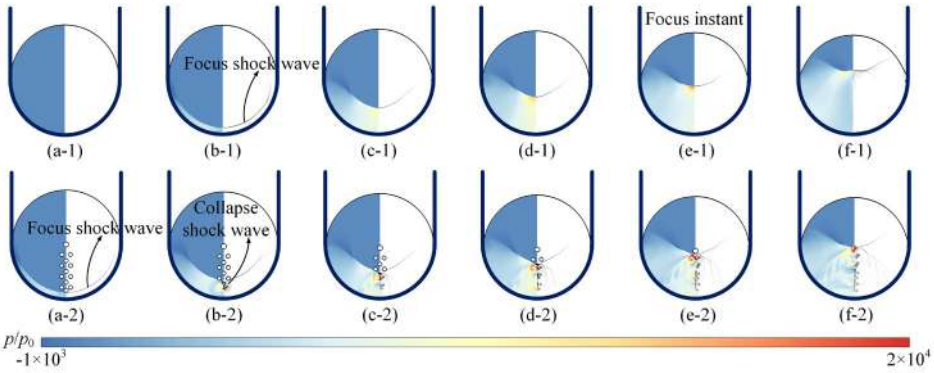

Figure 2: Evolution procedures of different configurations of droplet impingement inside a tube.

As shown in figure 2(a-2) $\sim$ figure 2(f-2), for the cases of the droplet initial embedded with some cavities inside, the focus shock wave might induce the cavities collapse. The collapse shock waves are generated during the cavities collapse process, which induce local high pressure. And the transient highest pressure value is observably larger than the highest pressure value in the dense case.

Figure 3 shows the maximum pressure distributions of different cases during the high-speed impingement. It shows that the maximum pressure values are amplified by multiple cavities collapse. The figure 2(b-2) to figure 2(f-2) are corresponded to several pick pressure value instants in figure 3, respectively. These pick pressure values are all induced by the collapse shock waves interaction, which are generated from the collapse of the cavities of left and right line. Therefore, through the properly arrangement of the cavities, the transient highest pressure value can be further amplified. In the present case, the highest transient pressure value can reach about 11 GPa.

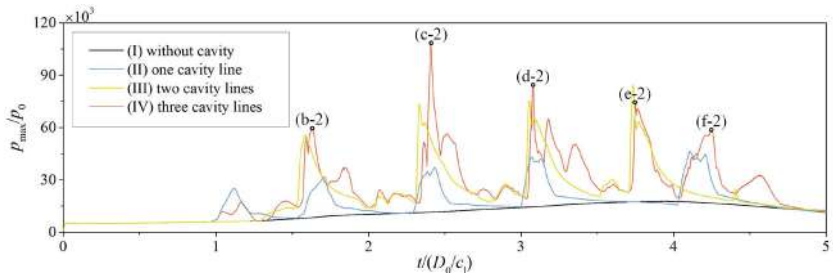

Figure 3: The maximum pressure distributions of different cases during the high-speed impingement.

CONCLUSIONS

The high-speed droplet impact inside a solid tube is then numerically investigated. Once the impaction happens, the focus propagation shock wave is generated since the bottom of the tube conforms well with the droplets interface. When the case initial embedded with the cavities, the highest pressure value induced from cavity collapse is observably amplified. Moreover, the properly arrangement of the cavities can further amplify the transient highest pressure value during the cavities collapse.

NUMERICAL STUDY ON THE INTERFACE-DYNAMICS OF AN ANNULAR BUOYANT JET: EFFECT OF INJECTION VELOCITY

Kuntal Patel *[1]
[1] Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, India

Summary Two-dimensional axisymmetric numerical experiments have been carried out to investigate the dynamics of an annular buoyant jet, made-up of 70% paraffin oil and 30% heptane, rising in stagnant water. A ghost-fluid method based sharp-interface level-set method [1] is used in present numerical simulations to accurately capture the lower-dimensional fluid-fluid interface. Three distinct states of the oil-water system are observed: (1) translation of planar oil-water interface in the axial direction (2) oscillating water-column assisted flotation of a water droplet and (3) formation and breakup of compound droplets; corresponding to the average injection velocity of 0.05, 0.15 and 0.25 m/s, respectively.

INTRODUCTION

Fluid flows involving a single jet or multiple jets exhibit very rich interface dynamics and have practical relevance to many real-time applications. There are several types of fluid flow configurations that involve jet. For example, injection of lighter fluid into a heavier fluid against the gravity [2], simultaneous injection of two different immiscible liquids in a co-flowing fluid [3, 4], etc. In the present work, the configuration corresponding to an annular buoyant jet is considered and the influence of the injection velocity V_i on the interface dynamics is studied numerically.

PROBLEM SET-UP AND CODE VERIFICATION

Computational domain for the present problem along with the boundary conditions is shown in Figure 1(a). In order to simulate this problem, the ghost-fluid method based sharp-interface level set method (SI-LSM) is employed. Details on the implementation of present SI-LSM based multi-phase flow solver can be found in [1]. Grid sensitivity study is done for the case of the annular jet with V_i=0.05 m/s. Based on the results of the grid sensitivity test a grid size of 50 x 800 is adopted for the present simulations. Validation of present numerical methodology is carried out using the problem of jet break-up from Lakdawala et al. [2]. The temporal variation of a jet length obtained from the present simulation is then compared with that reported in [2]. A good agreement is obtained for the same (shown in Figure 1(b)).

RESULTS AND DISCUSSION

Results obtained from the computer simulations reveal that the present two-fluid system exhibit three different types of behavior upon injecting an annular jet. The behavior of the system depends on the average injection velocity (V_i) of an annular jet. Different types of system behavior includes (1) translation of planar oil-water interface in the axial direction (for V_i=0.05 m/s, see Figure 2(a)) (2) oscillating water-column assisted flotation of a water droplet (for V_i=0.15 m/s, see Figure 2(b)) and (3) formation and breakup of compound droplets (for V_i=0.25 m/s, see Figure 2(c)). For the injection velocity of 0.05 m/s, annular jet merges at the center and later oil-water interface becomes planar. Which then translates in the positive axial direction. Eventually, water gets replaced by the oil in the entire domain except at the bottom of the domain. On increasing the value of V_i, interface dynamics shifts from more ordered (for V_i=0.05 m/s) to the chaotic (for V_i=0.15 m/s) one. Chaotic behavior for V_i=0.25 m/s involves the frequent generation and collapse of the compound droplets of varying sizes. The case with the intermediate injection velocity of V_i=0.15 m/s shows transitional behavior — connecting ordered and chaotic state. In this case too, later on, the oil-water interface becomes planar. However, there exists an entrained water droplet at the center and a water film near the bottom of the domain (Figure 2(b)). The water droplet at the center and the film accumulated at the bottom try to settle down. However, the inflow of the oil resists water film from doing so by pushing it in the positive axial direction and this leads to the oscillations of water film (see Figure 3). Moreover, these oscillations of the water film push the water droplet in the positive axial direction and keep it floating. Sequences of the oscillation of the water film and the floating droplet along with the axial velocity distribution are depicted in Figure 3. Further investigation on the influence of the fluid-properties and wall roughness on the interface dynamics is currently under progress.

ACKNOWLEDGEMENT

The author would like to thank Dr. Absar Lakdawala for introducing him to the topic of jet dynamics. Numerical solver used in the present work is the outcome of CFD code development by Prof. Atul Sharma and co-members at CFD Lab (F29) - IIT Bombay. Computational facility provided by CFD Lab (F29) is gratefully acknowledged.

SURFACE TENSION-DRIVEN FORMATION OF MINERAL CAPSULE USING WATER-IN-OIL EMULSION

Kwangseok Park[1] and Hyoungsoo Kim*[1]
[1] Department of Mechanical Engineering, KAIST, Daejeon, South Korea

Summary We demonstrated a facile fabrication of a mineral capsule made through solvent diffusion from a salt-saturated water-in-oil emulsion. If the initial emulsion is smaller than a capillary length, the surface tension is predominant. In this case, we observe that two-dimensional crystallites of the monoclinic salt enclose the emulsion interface, and a spherical shell is made. We investigate the capsule using scanning electron microscopy to see the shape and to measure the size. We suggest a theoretical model to estimate the shell thickness based on an assumption of a thin-walled spherical vessel where the capillarity is dominant. In this talk, from the comparison between the elasto-capillary length and the crystal size, we explain how the self-assembled spherical shell spontaneously forms.

To control the release of the core material or to set apart from the external material, microencapsulation is needed. These days, not only microscale but also nanoscale capsules can be formed through microencapsulation. Polymers have been usually selected as a capsule material due to their biocompatibility and biodegradability.[1] However, the existing microencapsulation methods using polymeric shell (e.g. nanoprecipitation, polymer coating, emulsion coacervation, and layer-by-layer method) have inevitable complexity in the process since they include multiple steps in the fabrication.[2] The process may require either mechanical or ultrasonic agitation to decrease the capsule size.[3] In this sense, for the main process, polymerization must need adjustment of systematic properties such as temperature, pressure, and pH.[4]

To avoid the abovementioned complexity, here, we introduce a novel method that the capsules are fabricated by minerals encapsulating a hydrophilic core through solvent diffusion of a water-in-oil (W/O) emulsion. Here, we use calcium propionate (CaPr) and silicone oil for the capsule material and the oil phase of the emulsion, respectively. The selected mineral CaPr has a monoclinic crystal structure exhibiting plate-like crystallites, and the crystal will grow at the liquid-liquid interface where it will reach to the critical condition for the crystallization due to the diffusion. To test this idea for the experiments, we prepare a CaPr-saturated aqueous solution in the oil, and the emulsion is kept at room temperature and atmosphere. The encapsulation process is sketched in Fig. 1(a) and the obtained capsule shape is taken by SEM as shown in Fig. 1(b).

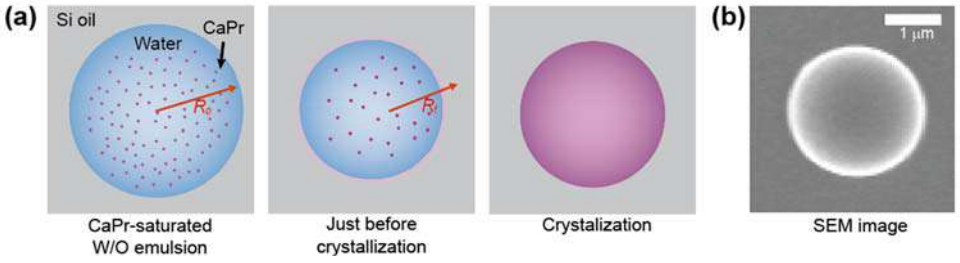

Figure 1. Illustration of fabrication of the process of the CaPr spherical shells via solvent diffusion. (a) Schematics of a W/O emulsion for initial state and after crystallization. (b) SEM image of the CaPr capsule.

We observe that the crystal grew in a different way depending on the initial emulsion size. When the initial size is sufficiently small, capillarity driven by Laplace pressure could help the crystallized CaPr bent and the crystal covers the liquid-liquid interface. If the emulsion size is too large, the crystal will grow out of the emulsion interface. In case of the dominant capillary effect, the bent crystallites can enclose the whole emulsion interface, thereby forming the spherical mineral shell of CaPr (see Fig. 1(b)).

We observe that the crystallized CaPr capsules using scanning electron microscopy. The capsules have a relatively smooth surface and the measured size of the capsules is in the range of O(100 nm) to O(1-10 μm). We expose an electron beam with an acceleration voltage up to 10 kV for a few minutes (1-3 minutes) to check whether the capsule is a rigid sphere or a spherical shell. When the capsules are enough irradiated by the electron beam, the plastic deformation occurs as shown in Fig.2. Presumably, such remarkable deformation may not occur with a rigid sphere, and it can be inferred that the spherical CaPr capsules produced by the current method are shells.

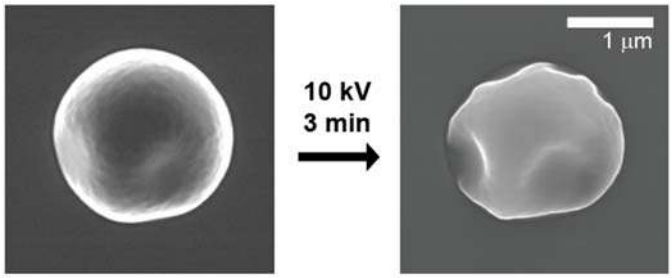

Figure 2. Exposure of 10 kV, 10 μA electron beam to the CaPr capsule with the diameter of 2.55 μm.

To understand the mechanism how the salt capsule made, we develop a theoretical model considering the mineral shell as a thin-walled vessel where the Laplace pressure acts as the internal pressure, and then based on the model, we estimate the shell thickness. In the model, we assume that the Laplace pressure is balanced with the shell stress. With the stress-strain relation and the size change of the emulsion, we calculate the shell thickness and elasto-capillary length. For the case where the W/O emulsion size decreased from the initial 10 μm to 1 μm, the shell thickness and elasto-capillary length are estimated 52 nm and 927 nm, respectively. Since the characteristic length of the emulsion is larger than the elasto-capillary length, the crystal near the emulsion interface can grow larger than the elasto-capillary length, which means the gained energy at the surface is larger than the stored bending energy. Therefore, it can be expected that the bending of the CaPr crystallites is highly spontaneous, and the size of bending element, which can be a single crystallite or several crystallites, is approximately $O(100\ \text{nm})$.

THE THERMOCAPILLARY EFFECT AT GAS BUBBLES GROWING DURING ELECTROLYSIS

S. Sahil Hossain[1], Gerd Mutschke *[1], Aleksandr Bashkatov[1], and Kerstin Eckert[1,2]
[1] Institute of Fluid Dynamics, Helmholtz-Zentrum Dresden-Rossendorf, Bautzner Landstrasse 400, Dresden, 01328 Germany
[2] Institute of Process Engineering and Environmental Technology, Technische Universit at Dresden, Dresden, 01062 Germany

Summary Capillary flow at electrogenerated gas bubbles growing on microelectrodes was unveiled only recently [1]. The primary origin was later attributed to thermocapillarity caused by the inhomogeneous distribution of the electric current density near the bubble foot which results in temperature gradients along the bubble interface [2]. The present paper carries out a systematic numerical investigation of the thermocapillary effect at various operating conditions of the electrolysis, thereby especially considering electrodes of different sizes. A detailed understanding of the thermocapillary flow pattern at microelectrodes is provided. Two vortices are generated, the size and location of which changes when the size of the electrode is increased from small to large with respect to the bubble size. The resulting force on the bubble simultaneously changes from retarding towards supporting the bubble departure. Estimations of the contribution of the Marangoni force to the static force balance at different operating conditions including industrially relevant current densities are given.

Green hydrogen produced by electrolysis powered by regenerative energy sources appears attractive for energy storage and for producing green fuels. A deeper understanding of the dynamics of the growing gas bubbles may allow for improving the efficiency of industrial electrolysis processes.

The existence of thermocapillary flow at the interface of gas bubbles generated by water electrolysis was proven only recently [1, 2]. The resulting force on the bubble is known to affect the bubble dynamics and to retard the departure of the gas bubbles. More recent research in our group includes the effect of an electrostatic force on the static force balance of the bubble and is able to explain oscillatory bubble phenomena [3].

In this study we perform a detailed quantitative characterization of the thermofluidic behaviour of the aqueous electrolyte in the vicinity of the gas bubble. Besides investigating different operating conditions, we systematically extend the analysis of the thermocapillary effect on the bubble from microelectrodes to larger and eventually planar macroelectrodes [4]. In the simulations performed, a coupled system of equations for electric potential, fluid flow and heat transfer is solved using the finite element software COMSOL Multiphysics. The surface tension of the bubble interface is taken to be linearly dependent on temperature.

As sketched in Fig. 1, varying the size of the electrode from small to large with respect to the bubble size leads to a dislocation of the temperature hotspot which is caused by inhomogeneous Ohmic heating. This results in a modification of the size and the position of the two vortices driven by the thermocapillary stress at the bubble interface. Simultaneously, the direction of the Marangoni force on the bubble is found to change from downward to upward. More details will be presented in the talk. Furthermore, the influence of the current density on the thermocapillary effect will be elucidated, and quantitative estimations of the Marangoni force on the bubble with respect to buoyancy will be given [4].

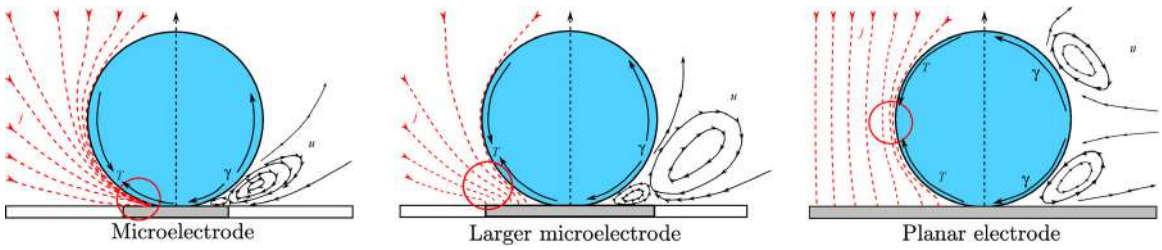

Figure 1: Sketch comparing the current distribution, the position of the temperature maxima and the thermocapillary flow as the electrode size is varied.

BUBBLE DIAMETER DISTRIBUTION IN VERTICAL LIQUID CROSS FLOWS

L.A.O. Guerra[1], J.B.R. Loureiro *[1], and A.P. Silva Freire[1]
[1] Interdisciplinary Center for Fluid Dynamics (NIDF), Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Summary The flow dynamics of gas injected into a liquid cross flow in a vertical pipe is discussed for three distinct injection angles (-45^o, 0^o, 45^o), two orifice diameters (2 and 5 mm), with air and water flow rates varying respectively in the intervals 7.8 to 25.8 lmin^{-1} and 2 to 5 m^{3}h^{-1}. Global and local measurements provide data on the bubble diameter distribution, shapes of bubble, air jet deflection angle, liquid mean velocity profiles and pressure distributions.

INTRODUCTION

To make sure that producing oil wells are capable of mounting enough energy to sustain the desired production during the prospect of their entire economic life, gas and water are normally injected into depleting reservoirs for pressure increase. Additionally, complementary techniques are used to ensure that further necessary energy is transferred downhole. Gas-lift systems resort to the injection of high-pressure gas into the flow column to decrease the hydrostatic weight, hence providing adequate pressure loads for the desired flow rates.

In view of their simplicity, reliability and flexibility, gas-lift systems are extensively used in industry. Their design selection, however, is not straightforward. Several considerations including economical, technological, geographical and environmental aspects must be considered for the best possible choice. Despite the great advantages of these systems – handling of large volumes of solid particles; wide operational range; easy servicing – one severe problem is the small tubing diameters and pumping systems that they are allowed to use, and, consequently, the resulting small flow rates that they deliver.

Optimization of the gas injector is thus a crucial aspect of any successful air-lift system. Optimum designs depend on both (i) the geometric design of the injector (radial, axial, dual, swirl, distributed) and (ii) the injection method (continuous, periodic, pulsatile) (Ahmed W. H. et al. (2016)).

The purpose of the present work is to study the effects of the injection angle on the effectiveness of gas-lift systems. Two different injectors with internal diameters of 2 and 5 mm are tested for three injection angles (-45^o, 0^o, 45^o) and air and water flow rates between respectively 7.8 to 25.8 lmin^{-1} and 2 to 5 m^{3}h^{-1}. Particle Image Velocimetry and Shadow Sizing are used to provide data on flow patterns, including bubble equivalent diameter and velocity distributions and water velocity profiles. Data on pressure losses (hydrostatic, friction, turbulent agitation, acceleration) are also presented.

The work concludes that orthogonal injection (0^o) provides the most beneficial effects.

EXPERIMENT

The test loop consists of a plexiglas vertical pipe (44 mm in diameter and 10 m in length) with air and water charge and discharge systems. Four pneumatic, quick closing, hold up valves are used to determine the hydrostatic pressures. The local measurements resorted to Shadow Sizing (SS) and Particle Image Velocimetry (PIV). A transparent box filled with water was used to eliminate optical distortions. The experimental flow conditions are shown in Table 1.

Orifice Diameter (mm)	Injection Angles (^{o})	Q_g (lmin^{-1})	Q_l (m^{3}h^{-1})
2	-45, 0, 45	7.8, 9.5, 17.4, 26.8, 35.8	2, 3, 4, 5
5	-45, 0, 45	9.5, 35.8	3, 4, 5

Table 1: Experimental flow conditions.

The general flow patterns for the three injection angles are shown in Figs. 1 and 2. The figures suggest (and the measurements confirm) that for *low* gas flow rates the co-current injection angles results in the *highest* frequency of small diameter bubbles. For *high* gas flow rates, the situation is the opposite, the orthogonal and counter-current injection results is distributions with a *higher* number of smaller bubbles. In particular, the orthogonal configuration resulted in distributions with the *highest* number of small bubbles.

Typical bubble diameter distributions are shown in Fig. 3. Mean velocity profiles are shown in Fig. 4. Data on the shape distribution of bubbles, the deflection angle of the gas jet, and pressure distributions were also obtained.

The pressure gradient in a vertical pipe as a result of gas injection in a liquid flow can be split into four contributions due to gravity, wall friction, turbulent agitation and fluid acceleration (Guet and Ooms (2006)). The holdup valves allowed the contribution of the gravity term to the pressure drop be separated from the other three terms. This distinction is important because, although all terms are affected by the direction of gas injection, the gravitational term is always

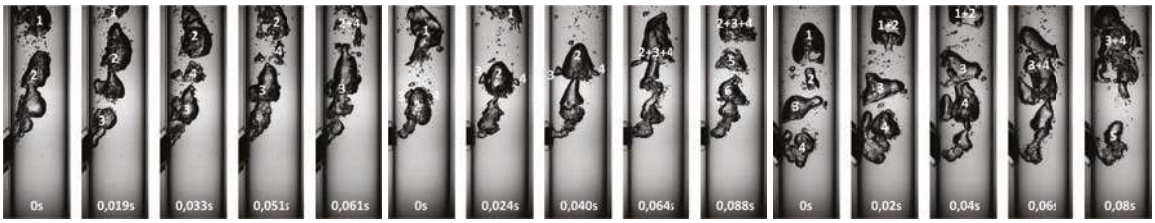

Figure 1: Flow pattern for co-current flow (frames 1-5), orthogonal flow (frames 6-10) and counter-current flow (frames 11-15). Q_l = 2 m^3h^{-1}, Q_g = 9.5 $lmin^{-1}$; d = 2 mm.

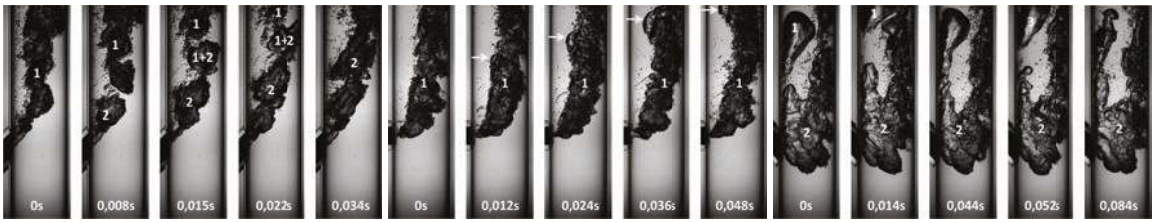

Figure 2: Flow pattern for co-current flow (frames 1-5), orthogonal flow (frames 6-10) and counter-current flow (frames 11-15). Q_l = 5 m^3h^{-1}, Q_g = 35.8 $lmin^{-1}$; d = 2 mm.

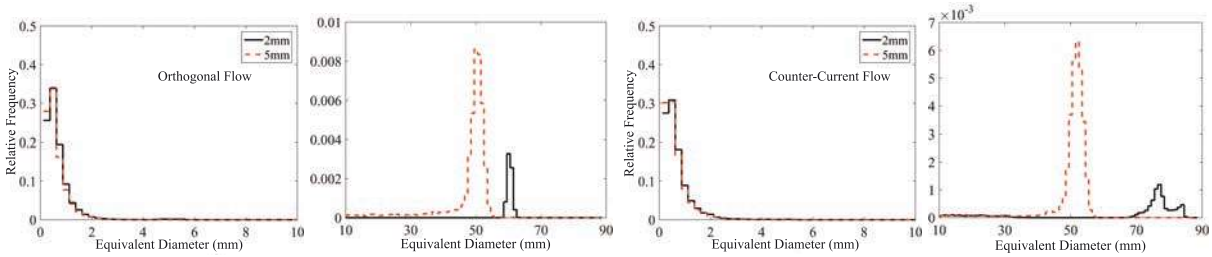

Figure 3: Typical bubble diameter distributions. Orthogonal (two figures on the left) and counter-current (two figures on the right) flows with d = 2, 5 mm and Q_l = 5 m^3h^{-1}, Q_g = 35.8 $lmin^{-1}$.

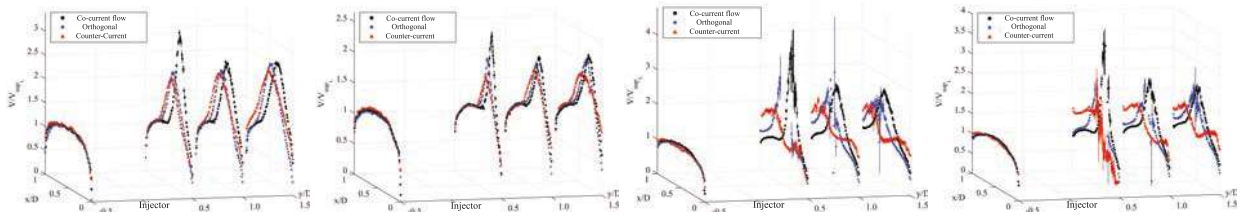

Figure 4: Water mean velocity profiles. (a) Q_l = 2 m^3h^{-1}, Q_g = 7.8 $lmin^{-1}$; (b) Q_l = 3 m^3h^{-1}, Q_g = 7.8 $lmin^{-1}$; (c) Q_l = 4 m^3h^{-1}, Q_g = 26.8 $lmin^{-1}$; (d) Q_l = 5 m^3h^{-1}, Q_g = 26.8 $lmin^{-1}$.

reduced with the increase in gas injection. On the other hand, all other three terms increase with the increase in gas flow rate. This could raise doubts as whether particular gas injection rates would result in combined losses provoked by the last three terms that may *locally* balance the beneficial effect obtained with a reduction of the gravitational term. One observed evident result is that as Q_g increases for a given Q_l the value of ΔP_g decreases (gravitational pressure). One second observed evident result is that as α increases from the negative angle (-45^o) to the positive angle (45^o), the pressure difference increases. This trend is particularly notable for the high injection rates, over 2 m^3h^{-1}. For the low injection rates (below 1.3 m^3h^{-1}), a reduction in ΔP_g is also noticed but much less pronounced. The combined effects of all pressure drop terms was also assessed. The data shows that the beneficial (gravity) and detrimental effects (friction, turbulent agitation and acceleration) tend to cancel each other out yielding equivalent results. In fact, for the highest gas injection rate, it is clear that the upstream injection furnishes the highest pressure losses. However, the differences are small. Over the whole range of tested conditions, the injection in all three directions furnished almost the same total pressure drop.

HIGHLY VISCOUS LIQUID MICROJET FOR ON-DEMAND AUTOMOBILE PAINTING

Kyota Kamamoto[1], Hajime Onuki[1], and Yoshiyuki Tagawa*[1]
[1] Department of Mechanical systems Engineering, Tokyo University of Agriculture and Technology, Tokyo, Japan

Summary The highly viscous liquid jet generator has been developed since the ejection of highly viscous liquid is required. This study introduces a novel device for practical use and the jet velocity of the novel device is investigated. The result shows that the experimental data agrees with the pressure-impulse model when the length ratio is small while it deviates from the model when the length ratio is large. In this research, a new jet-velocity model considering pressure-impulse and mass conservation is proposed. This new model agrees with all experimental data. Furthermore, the data of increment ratio of jet velocity β shows a good agreement with the previous research.

INTRODCUTION

Spray coating is an important process in automobile painting among others. However, it is inefficient and harmful because the spray method needs the use of organic solvent to reduce the paint viscosity [1][2]. One of the solutions to these problems is to eject highly viscous liquid as a microjet. Onuki *et al.,* developed a viscous microjet generator induced by impulsive force [3]. The jet velocity of this device can be computed with pressure-impulse model. It is expected that the painting process will become automated and work environment will be improved.

However, this highly viscous liquid jet generator [3] has problems such as the contact of jet with the inner wall of the injection pipe since there is a nontrivial distance between the meniscus and the nozzle exit (Figure 1 (a)). In this study, a novel device is proposed for practical use (Figure 1 (b)). There is no contact between the jet and the inner wall because the injection pipe of the novel device is short. The jet velocity of the novel device is investigated. The purpose of this study is to clarify the jet behavior of the novel device experimentally. Experiments are conducted with the novel device and the relationship between the length ratio and the velocity ratio is investigated. Finally, the validity of the model is reported.

EXPERIMENTAL SETUP

The experimental setup is shown in Figure 1 (b). The glass syringe filled with silicone oil (viscosity ν = 1, 10, 100 mm^2/s) is dropped freely and collides with a metal plate to generate a jet. The jet velocity V_{jet} and the falling velocity of the syringe U_0 is calculated from the displacement of the jet tip and syringe tip, respectively. A high-speed camera (FASTCAM SA-X) and a light source (LLUB White Led Backlight) are used for shooting. The frame rate is 30,000 fps. The experiments are conducted in the range of 0.23 m/s $<U_0<$1.27 m/s and $3 < l_{top} / l_{bottom}<145$, where l_{top} is the height of the liquid in the barrel, and l_{bottom} is the height of liquid in the nozzle.

RESULTS AND MODEL

The jet velocity is computed by using pressure-impulse approach [3][4]. The velocity ratio V_{jet} / U_0 was previously expressed as

$$\frac{V_{jet}}{U_0} = \beta \frac{l_{top}}{l_{bottom}} \tag{1}$$

where β is the increment ratio of jet velocity, l_{top} / l_{bottom} is the length ratio, and U_0 is the initial velocity. Figure 2 shows the relationship between the length ratio and the velocity ratio. The vertical axis shows the velocity ratio V_{jet} / U_0, and the horizontal axis shows the length ratio l_{top} / l_{bottom}.The experimental data agrees well with equation (1) when the length ratio is small ($l_{top} / l_{bottom} <10$) while it deviates from the model when the length ratio is large ($10 < l_{top} / l_{bottom}$). To consider the reason for the deviation, numerical simulation of the novel device is conducted. The boundary conditions applied are velocity U = 1.0 m/s at the base of the barrel (Figure 3 (a), green line) and the pressure p = 0 at the gas-liquid interface and the top of the barrel (Figure 3 (a), yellow line). The flow field is calculated in no inflow and outflow by using the potential flow. Figure 3(a) shows the potential flow field of the novel device immediately after the impact. According to Figure 3 (a), the position of the stagnation point is higher than the position calculated with equation (1). The influence of stagnation point shift l_s becomes large when l_{bottom} is small (Equation (3)). This is the reason why the result deviated from the previous pressure-impulse model (equation (1)).

To take the stagnation point shift into the consideration, a new model using the law of mass conservation is proposed. The law of mass conservation of the novel device is expressed as

$$\pi r^2 U' = 2\pi r l_s U_0 \tag{2}$$

where the flow velocity in the nozzle is U', stagnation point shift is l_s, the nozzle radius is r, and the magnitude of the fluid inflow U_{in} is estimated as the initial velocity U_0 (Figure 3 (b)). Also, the jet velocity considering l_s is expressed by equation (3) using pressure-impulse approach (Figure 1 (b)).

$$V_{jet} = \beta \left(\frac{l_{top} - l_s}{l_{bottom} - l_s} \right) U_0 \tag{3}$$

*Corresponding author. E-mail: tagawayo@cc.tuat.ac.jp

By using equations (2) and (3), a new model of the velocity ratio of the novel device can be derived. The new model equation is shown below.

$$\frac{V_{jet}}{U_0} = \beta \frac{-(2l_{bottom}+r)+\sqrt{(2l_{bottom}+r)^2+8rl_{top}}}{2r} \quad (4)$$

The velocity ratio of the new model is affected greatly by the absolute value of l_{top}, l_{bottom} and r, instead of the length ratio l_{top} / l_{bottom} which greatly affects the previous model.

The new model is applicable even when the length ratio is large, which cannot be described with the previous model. Previous research [3] shows that the results under different conditions can be unified by using Reynolds number $Re = U'r / \nu$ and the increment ratio of jet velocity β. In order to verify the validity of the new model, the experimental data using the new model are compared with the data from previous research (Figure 4). The horizontal axis shows Reynolds number Re, while the vertical axis shows increment ratio of jet velocity β. Figure 4 confirms that the results of the previous research and this result are in good agreement. The results show that the jet velocity in the novel device can be accurately described by using the new model (Equation (4)).

CONCLUSIONS

In this paper, the jet velocity of the novel device was investigated for the development of the highly viscous liquid jet generator. From the experimental results, it was found that the model using only the pressure-impulse cannot accurately describe the jet velocity of the novel device. Therefore, a new model that considered shift of the stagnation point was proposed. Remarkably, the new model describes the case where the distance ratio was large, which cannot be described by the previous pressure-impulse model. By applying this new model, the results obtained agreed well with previous research. This had proven the validity of the new model.

NUMERICAL ANALYSIS OF HIGH WEBER-NUMBER INTERFACE DEFORMATION

Jakob W. J. Kaiser *[1], Josef M. Winter[1], Stefan Adami[1], and Nikolaus A. Adams[1]
[1] Department of Mechanical Engineering, Technical University of Munich, Garching, Germany

Summary We investigate the interface deformation of a water column in an ambient flow field at high Weber number by high-resolution numerical simulation. We discretize the compressible Navier-Stokes equations with a finite volume approach, and apply a level-set based sharp-interface method with conservative interface-exchange terms to model the interaction of the two fluids. Our simulation results reproduce the flattening of the cylinder and the sheet-stripping at the droplet equator, which are characteristic for this breakup mode. Unsteady vortex shedding results in the local formation of recirculation zones, which contribute to the ongoing sheet-stripping. Resolving interface waves at the very early stages is paramount to reproduce a hat-like structure on the upstream side of the cylinder which is found in experimental investigations of this breakup mode.

MOTIVATION

The breakup of a spherical liquid drop into smaller fragments is of fundamental importance for many technological applications, ranging from internal liquid-fuel combustion engines to manufacturing of medical drugs and splatter of rain drops on supersonic aircrafts. The initial deformation of the drop is driven by a relative velocity to the ambient flow field, which may further lead to the breakup of the drop. The characteristics of the breakup process and, consequently, the final droplet size are determined by the relation of inertial forces, viscous forces, and capillary forces acting on the drop. Thus, accurate process control requires comprehensive understanding of the underlying physical breakup mechanisms.

The breakup process is classified by two dimensionless numbers: the Weber and the Ohnesorge number, which describe the ratio of inertial to capillary forces and the ratio of viscous to capillary forces, respectively. For high Weber numbers, the Shear-Induced Entrainment (SIE) is the dominating instability mode, which exhibits a stripping of liquid material from the "edge" of the drop [7]. Systematic experimental and numerical investigations have been performed to improve the understanding of the breakup process [1, 7]. Many numerical studies focus on two-dimensional setups for efficiency reasons, since from experimental investigations it has been found that the breakup modes of two-dimensional water columns and three-dimensional spherical drops in crossflow are phenomenologically equivalent [1].

In this work, we perform high-resolution numerical simulations of liquid-column breakup in the SIE regime. Based on the setup of Igra and Takayama [3], the focus of our investigation is on the interplay of the interface deformation and the surrounding flow field. We apply a finite-volume approach with flux reconstruction based on low-dissipative WENO schemes to accurately represent small-scale flow structures. and a level-set based sharp interface method to represent the liquid-gas phase interface with conservative interface-exchange terms. High computational efficiency is enabled by a block-structured wavelet-based multiresolution scheme with adaptive local timestepping [4].

METHODOLOGY

The problem is governed by the compressible Navier-Stokes equations including surface tension

$$\frac{\partial}{\partial t}\begin{pmatrix}\rho\\ \rho\mathbf{u}\\ E\end{pmatrix}+\nabla^T\cdot\begin{pmatrix}\mathbf{u}\rho\\ \rho\mathbf{u}\otimes\mathbf{u}+p\mathbf{I}\\ \mathbf{u}(E+p)\end{pmatrix}+\nabla^T\cdot\begin{pmatrix}0\\ \mathbf{T}\\ \mathbf{T}\cdot\mathbf{u}\end{pmatrix}=\begin{pmatrix}0\\ \kappa\sigma\mathbf{n}_\Gamma\\ \kappa\sigma\mathbf{n}_\Gamma\cdot\mathbf{u}\end{pmatrix} \tag{1}$$

where ρ denotes the density, t the time, $\mathbf{u}$ the velocity vector, p the pressure, $\mathbf{I}$ the identity matrix, $\mathbf{T}$ the Cauchy stress tensor, κ the surface curvature, $\mathbf{n}_\Gamma$ the surface normal unit vector, and E the total energy, composed of the internal energy (ρe) and the kinetic energy ($1/2\rho\mathbf{u}\cdot\mathbf{u}$). The system of equations is closed by the stiffened equation-of-state

$$p=(\gamma-1)\rho e-\gamma p_\infty\,, \tag{2}$$

with the ratio of specific heats γ and the background pressure p_∞. Note that we use this equation of state for both fluids, air ($\gamma=1.4$, $p_\infty=0$) and water ($\gamma=6.12$, $p_\infty=3.43\times10^8$ Pa) .

The governing equations (1) are discretized by a finite-volume approach on Cartesian square cells in the domain Ω, which is divided into two subdomains Ω_l (liquid phase) and Ω_g (gaseous phase) by a time-evolving interface Γ. Convective fluxes at cell faces are approximated by the fifth-order WENO (Weighted Essentially Non-Oscillatory) scheme applied on characteristic fluxes, split by the global Lax-Friedrich (GLF) scheme. Viscous fluxes are discretized with a fourth-order central scheme. For temporal discretization, we use a strongly stable third-order Runge-Kutta scheme. The maximum admissible timestep size is determined from a Courant-Friedrichs-Lewy (CFL) stability criterion considering the maximum wave speed, viscous diffusion, and propagation of capillary waves at the interface. In all simulations, we use CFL$=0.5$

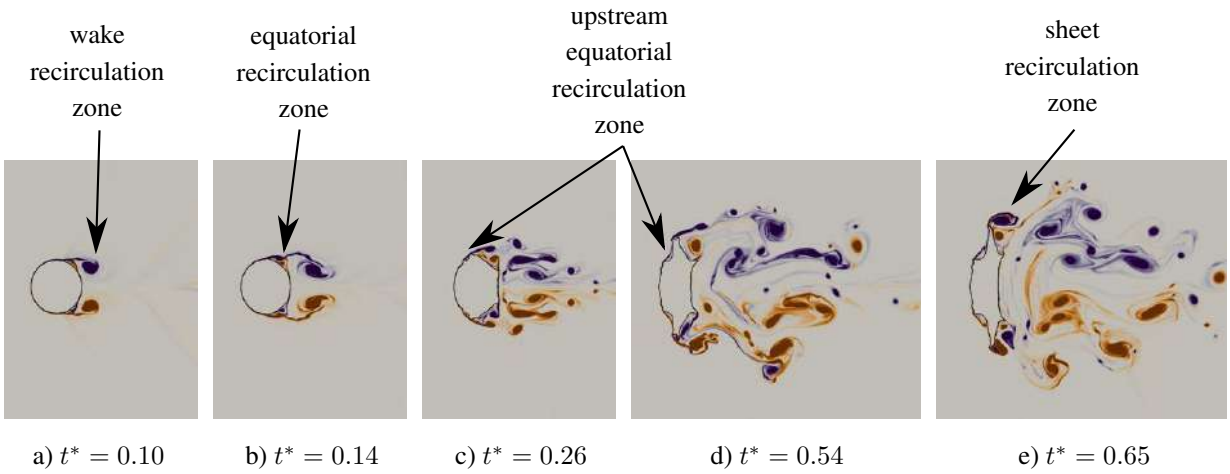

Figure 1: Positive (orange) and negative (purple) z-vorticity streams that interact and form multiple recirculation zones at various instants.

The level-set function ϕ represents the phase interface as the zero-crossing of a multi-dimensional continuous function. The absolute value of ϕ describes the normal signed distance of the cell center $\mathbf{x}$ to the interface Γ. The level set is evolved in time with the advection equation

$$\frac{\partial \phi}{\partial t} + u_\Gamma \mathbf{n}_\Gamma \cdot \nabla \phi = 0\,. \tag{3}$$

The interaction of the two fluids is solved based on the conservative interface-interaction model of Hu et al. [2] with the extension for viscous and capillary forces of Luo et al. [5]. First, the interface velocity u_Γ and the interface pressures $p_{\Gamma,l}$ and $p_{\Gamma,g}$ are obtained from a linearized two-material Riemann solver. Second, momentum and energy exchange across the interface are modeled for each phase by explicit exchange terms, see Luo et al. [5].

PRELIMINARY RESULTS

We simulate the interaction of a shock-wave ($Ma_S = 1.47$) with a water cylinder ($D_0 = 4.8\,\mathrm{mm}$) at $t = 0$. The effective resolution is 200 cells per initial cylinder diameter. Pre-shock air and water are at rest at standard conditions ($\rho_g = 1.20\,\mathrm{kg/m^3}$, $\rho_l = 1000.0\,\mathrm{kg/m^3}$, $p_g = p_l = 1.0\,\mathrm{atm}$).

Fig. 1 shows the $z-$vorticity in the vicinity of the water-column at different instants after shock passage. Note that we normalize the ouptut time following $t^* = t \cdot \sqrt{(\rho_g u_g^2) \,/\, (\rho_l D_0^2)}$. Unsteady vortex shedding after the shock passage results in the formation of a recirculation zone in the wake of the cylinder ($t^* = 0.10$). This vortex stream that is shed at the cylinder equator is diverted at the downstream stagnation point of the cylinder. It interacts with the vorticity stream near the cylinder equator, which leads to the formation of a recirculation zone at the cylinder equator ($t^* = 0.14$). These results agree well with Meng and Colonius [6], who found that the equatorial recirculation zone plays an important role in the sheet-stripping process. Furthermore, our high-resolution simulations show that additional recirculation zones form along the interface, which can be related to local unsteady vortex shedding at the deforming interface. Interface disturbances upstream of the cylinder equator are linked to the formation of a recirculation zone on the upstream side of the cylinder near the equator ($t^* = 0.26$). This recirculation zone is located at later time instants at the transition of a hat-like structure that forms on the upstream side of the cylinder to the water filament ($t^* = 0.54$). Another recirculation zone forms at the tip of the water sheet due to the interaction of multiple vortices in this area, and contributes to the flapping of the sheet in the wake of the cylinder ($t^* = 0.65$).

Our preliminary results underline the close relation of local flow disturbances and sheet-stripping for the breakup in the SIE regime. More detailed analyses of the flow field and interface-deformation dynamics, the hat formation, as well as comparison to experimental data will be presented at the conference.

AEROBREAKUP OF LIQUID METAL DROPLETS WITH OXIDE SKINS

Thomas Hopfes*[1], Zhaoguang Wang[1], Julia Petersen[1], Marcus Giglmaier[1] and Nikolaus A. Adams[1]
[1] Chair of Aerodynamics and Fluid Mechanics, Technical University of Munich, Munich, Germany

Summary This short paper presents experimental results of liquid metal droplet breakup using Galinstan in a shock-induced gas flow. A representative image sequence shows a breakup similar to the multimode regime classified for regular liquids, despite the formation of an oxide skin at the metal surface. Further work will investigate the influence of this oxide skin on the breakup under different flow conditions.

INTRODUCTION

The characterization of atomization processes of liquid metals is a relevant field of research for many industrial applications such as metal powder production, thermal spray deposition and liquid metal cooling systems, as well as in model validation and basic research [1]. As part of the atomization process, secondary atomization describes a drop that is exposed to a disrupting liquid or gas flow and undergoes deformation and fragmentation. Most experiments on this topic are carried out with ordinary Newtonian liquids such as water (see [2] for a detailed review), while others focus on more complex liquids like non-Newtonian polymer solutions (e.g. [3]). In comparison to those fluids, liquid metals provide significantly different properties such as higher ranges of density and surface tension [1], and very different features like the creation of an oxide layer [4] or partial solidification and crust building during the cooldown [5]. These effects are expected to lead to differences in the resulting deformation and breakup behavior.

Reference work on the breakup of liquid metal droplets is often carried out in liquid-liquid systems. For example, Patel and Theofanous [6] investigate the fragmentation of mercury, gallium and acetylene tetrabromide drops in water accelerated by a shock wave in a hydrodynamic shock tube. Ciccarelli and Frost [7] also study molten metal droplets in an ambient flow of water. They differentiate between cold drops that break up due to stripping by the relative flow, and hot drops where the growth and collapse of vapor bubbles dominate the fragmentation. Validating against both these works, Thakre and Ma [5] present numerical investigations and highlight various deformation patterns that lead to a significant increase in surface area. Due to their interest in iron sedimentation, Wacheul et al. [8] study the fragmentation dynamics of liquid gallium. They identify a variety of stable shapes for liquid metal drops and complex dynamics within a cloud of fragments.

Liquid metal breakup in gas has been studied recently in experiments and corresponding simulations. Chen et al. [1] study the aerobreakup of a Galinstan liquid metal column in an air flow induced by a shock wave for moderate Weber numbers. They note a strong similarity to the breakup morphologies in water, but also highlight key differences. Notably, the onset of breakup occurs earlier in non-dimensional time for Galinstan, while also appearing more violently. Further, local bag formation and breakup occurs in a different form. Complementing work by Arienti et al. [9] further details that surface oxides resist deformation and thus lead to irregular shapes of fragments.

However, detailed studies of aerobreakup of liquid metals in gas are rare, and we want to provide further insight by examining this topic and presenting results of the breakup of a single Galinstan droplet in a shock-induced flow.

EXPERIMENTAL FACILITY

A schematic of the shock tube, used for the experiments, is shown in Figure 1. The tube has an overall length of 24 m, an inner diameter of 290 mm and consists of three main parts: the driver, the driven and the test section. Driver and driven sections are initially separated by a diaphragm and the initial pressure values in each section define the flow conditions for the experiments. After the diaphragm ruptures, a shock wave propagates into the driven section and induces a gas flow towards the test section.

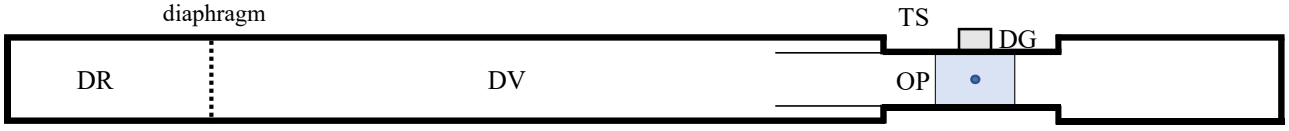

Figure 1. Sketch of the shock tube with driver section (DR), driven section (DV), test section (TS), droplet generator (DG), and optical system at the window with Z-type schlieren and camera (OP).

As part of the test section, a droplet generator produces millimeter-sized Galinstan droplets. Galinstan is a commercially-available liquid metal alloy of gallium, indium, and tin with a very low melting point well below 0°C and nontoxic characteristics [10]. Shortly after the droplet is produced, the shock wave passes the test section and the droplet is exposed to the flow. The resulting deformation and breakup are recorded with a Shimadzu HyperVision HPV-X ultra-high-speed camera with a resolution of 400x250 pixels at up to 5 million frames per second. Simultaneously, PCB Piezotronics ICP® fast-response pressure sensors monitor and record the pressure at a frequency of 1 MHz per channel.

*Corresponding author. E-mail: thomas.hopfes@tum.de

RESULTS

First experiments were conducted using Galinstan as the working fluid and air as surrounding medium. A corresponding image sequence is presented in Figure 2, with the time normalized by the characteristic transport time after Ranger and Nicholls [11]. First images show a string-like appendix on the droplet that results when the drop detaches from the needle of the droplet generator and immediately oxidizes at the surface. This elastic oxide skin prevents a spherical shape, and can also influence the breakup behavior [1]. After the impact of the incident shock, the appendix at the top of the droplet is bent and stretched along the flow direction and breaks into discrete fragments under the effect of Rayleigh-Pletaue instabilities. The main body experiences a pronounced flattening at the windward surface, with a thin sheet developping around the periphery (T = 0.4-0.6). Bags form along the sheet, inflate, and rupture quickly with a splash-like outwards movement that ejects secondary particles (compare the bottom of the drop for T = 0.6-0.8). This process is very similar to what Chen et al. [1] observe in their work. Fragmentation persists continuously and is driven by the repeated inflation and breakup of local bags, as well as by the stripping of fragments from the periphery. This behavior as well as the Weber number of We = 80 match well with the multimode breakup regime defined in the literature [2].

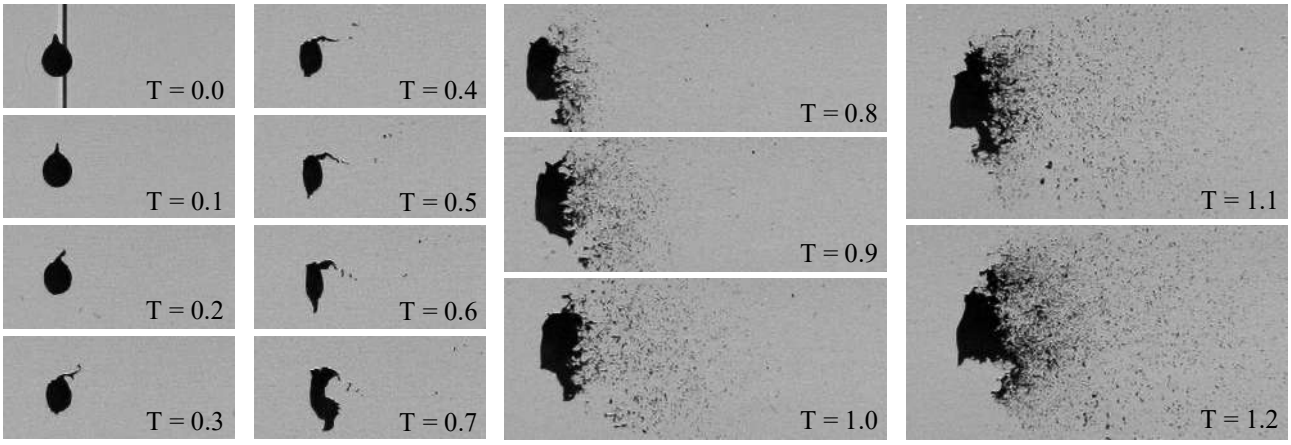

Figure 2. Breakup of Galinstan droplet of initial equivalent diameter d_0 = 3.21 mm for We = 80; The frames show time moments that range from T = 0 (top left) to T = 1.2 (bottom right). The air flow goes from left to right.

CONCLUSION AND OUTLOOK

This short paper presents results of liquid metal droplet breakup in an air flow. High speed photography shows that the oxide skin generated when the liquid is exposed to air influences the initial shape, but also that the breakup in general can be classified in accordance to previous work on regular liquids. To study this classification in more detail, we will conduct experiments at various Weber numbers. In addition, experiments will be carried out with pure nitrogen as the gas in the driven section of the shock tube. This prevents the formation of the oxide skin and allows a direct analysis of the role of the oxide skin and its influence on the breakup. Additional images, videos and a detailed analysis will be presented at the conference.

NUMERICAL STUDY OF PLANAR SHOCK INTERACTING WITH CYLINDRICAL WATER COLUMN CONSIDERING CAVITATION EFFECTS

Zhan Gao[1] and Bing Wang *[1]
[1] School of Aerospace Engineering, Tsinghua University, Beijing, China

Summary The droplet-shock interaction process contributes to the atomization in scramjets. The understanding of cavitation occurring in the shock interacted droplet has been limited yet. This study numerically simulates such interaction process. Compared with previous experiments, the detailed analysis of the wave evolution in the water column reveals that the reflected expansion waves focus near the downstream interface, create the local negative pressures, and trigger the cavitation thereafter. The theoretical derivation shows that the cavitation location depends exclusively on the critical incidence angle of the shock, at which a free precursor shock arises in the refraction pattern. The predicted cavitation location agrees with the numerical results. Planar shocks with different Mach numbers are simulated, and the corresponding cavity collapse pressure are compared.

INTRODUCTION, METHODOLOGY AND VALIDATION

The interaction of a planar shock with a droplet experiences a complex physical process, which can be found in the liquid jet atomization in scramjets. Recent experiments on the planar shock interacting with the cylindrical water column have suggested that cavitation is triggered due to the negative pressures created by focusing of the reflected expansion waves (REW)[1]. However, the physical mechanism of the focusing of the REW is still unclear, and the exact location of cavitation remains unclear. Therefore, the objective of this study is to shed light on the aforementioned problems by numerical simulation and theoretical analysis.

The governing equations consist of Euler equations and scalar transportation equations for the volume of fraction. The thermodynamic state of the fluid is described by the stiffened gas equation of state (SG-EOS). The finite volume method is used to discretize the governing equations. The weighted essentially non-oscillatory (WENO) scheme is applied for the spatial reconstructions to the primitive variables. A Godunov-type Harten-Lax-van Leer Contact (HLLC) approximate Riemann solver is employed to solve the numerical flux at the edges of the cells. A third-order total variation diminishing (TVD) Runge-Kutta scheme is utilized for time marching. The phase transition is implemented referring to Wu *et al.*[3]. Previous experiments suggest that for tap water, the cavitation threshold is around -1 bar. In the shock/droplet interaction, the tap water is compressed by the transmitted shock, and its cavitation threshold is changed[2]. Thus the exact cavitation threshold in experiments[1] is hard to determine, and this study adopts -1 bar as cavitation threshold for convenience.

Figure 1 shows the simulation results compared with the experiments by Sembian *et al.*[1]. In simulation, the Mach number of the incident shock is $Ms = 2.4$ and the water column radius is $r_0 = 4$ mm. The wave structures in the simulation are consistent with those in experiments. The REW passed through cavitation zones in simulation are weaker than that in experiments, because with the -1 bar cavitation threshold cavitation is triggered more easily and absorbs more energies of the waves. The collapse of cavitation bubble generates strong shock waves, which can also contribute to the droplet breakup.

RESULTS AND DISCUSSION

The ray analysis[3] is utilized to analyse the propagation of the transmitted shock wave in the water column, and the detailed analysis will be presented in the full paper, due to limited space here. The incident shock moves and interacts with the air-water interface, and it is reflected back to the air and refracted into the droplet. The refraction wave moves faster than the incident shock because of the difference of fluid impedance. Due to the curvature of the droplet surface, the incident, the reflected and the refracted shock waves connect at the interacting point on the droplet surface in the early stage of interacting. This point is also called as triple-wave point. However, once the triple-wave point reaches a critical one, for instance at critical point C in Figure 1(b), the refraction pattern will change and the refracted shock wave will propagate freely in the droplet, which is called as the free precursor shock (FPS). The reflection of the FPS at the interface will occur, and the REW will generate a local minimum pressure region denoted by F in Figure 1(a). The ray analysis shows that, as the FPS propagates forward, F goes along the envelope line of the firstly reflected rays of that emitted from the critical point C, illustrated as the thick blue line in Figure 2(b). The envelope line intersects with the axial line at $\mathrm{F_e}$, and the two F on both sides of the axial line will finally focus at $\mathrm{F_e}$, causing much lower pressures and cavitation thereafter. The location of the focusing point $\overline{\mathrm{AF_e}} = \min(R\sin(\alpha)/\sin(3\alpha - \beta_c))|\alpha \in [\beta_c/2, (\pi - \beta_c)/4]$, where R is the droplet radius, α is the intersection angle between OC and emitted rays, β_c is the intersection angle between the incident shock and the air-water interface when the FPS arises. β_c is around $37°$ when the incident shock Mach number is 2.4, estimated from simulation[4]. Thus the conclusion is that $\overline{\mathrm{AF_e}} = 1.6R$ when $Ms = 2.4$, which agrees well with the present numerical simulation. The effects of the intensity of incident shock on the cavitation occurrence will also be discussed in detail in the full paper.

Also shown on the right side of (a-d) are the results from Sembian *et al.*[1]. The pressures are normalized by the initial ambient pressure $p_i = 1$ bar. The length of the scale bar is 4 mm.

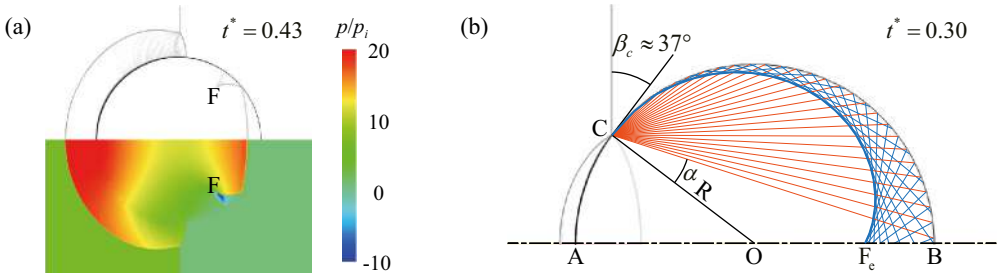

Figure 2: Analysis of focusing of REW. (a) Numerical schlieren contours (top) and pressure contours (bottom) at non-dimensional time $t^* = 0.43$ for $Ms = 2.4$. F denotes the local minimum pressure region generated by REW. (b) Numerical schlieren contours at $t^* = 0.30$ for $Ms = 2.4$ and the illustration of rays (orange) emitted from the critical point C. The blue lines are the firstly reflected rays, and their envelope line (thick blue lines) indicate the locus of F.

CONCLUSIONS

This study numerically simulated the planar shock/water column interaction, in which the agreement between the simulation results and experimental visualization was presented. A detailed analysis is conducted for the evolution of the wave structures inside the water column, especially the focusing of the REW of the FPS. The focusing position, where the cavitation occurs, is derived theoretically, and compared to the present numerical results. The cavitation position in the shocked droplet is dependent on the critical incident angle, at which the refraction pattern of the incident shock changes and the FPS arises. The critical angle is determined by the incident shock intensity and impedance of the fluids, if the droplet is interacted with the planar shock wave. The collapsing pressures of cavitation are compared with different incident shock Mach numbers, showing that it increases drastically with shock Mach number.

A DROP IN A NONLINEAR EXTENSIONAL FLOW

Moshe Favelukis *
Department of Chemical Engineering, Shenkar College, Ramat-Gan, Israel

Summary The deformation and breakup of a drop in a nonlinear extensional creeping flow is the subject of this theoretical report. The problem is governed by the capillary number (Ca), the viscosity ratio (λ), and the nonlinear intensity of the flow (E). The flow outside the drop is different than the linear case ($E = 0$), suggesting closed circulations ($E > 0$) and separating surfaces ($E < 0$). The flow inside the drop predicts that when $E < -3/7$, the number of internal circulations is doubled. When the extensional flow is linear, we have prolate spheroidal drops for uniaxial flow ($Ca > 0$) and oblate spheroidal drops for biaxial flow ($Ca < 0$). For the same Ca, drops with $E > 0$ are more elongated than $E = 0$, and drops with $E < 0$ are less elongated than $E = 0$. Compared to the linear case, $E > 0$ tends to facilitate drop breakup, while $E < 0$ makes the breakup of the drop more difficult.

INTRODUCTION

Many industrial products appear as foams or emulsions in which gas bubbles or liquid droplets are embedded in a liquid. These two-phase systems are often processed in mixing devices generating shear, extensional, or other complicated flows. While the majority of the studies simulate these processes with linear flows, very little is dedicated to nonlinear flows which can describe better (than the linear flow) the flow produced in industrial rotating equipment.

When a drop of one fluid is embedded in another fluid undergoing a linear flow such as simple shear or simple extensional flow, it will deform, and if the strength of the flow exceeds some critical value, it may even break. For incompressible Newtonian fluids under creeping flow conditions, the problem, is governed by the capillary number (Ca) and the viscosity ratio (λ). The deformation of the drop spans a wide domain, from a slightly perturbed sphere up to a slender body. This report is dedicated to the small deformation regime only, obtain at $|Ca| << 1$. A summary of this fundamental topic having many industrial applications can be found in the reviews of Rallison [1] and Stone [2].

Sherwood [3] suggested an axisymmetric nonlinear extensional creeping flow in his slender drop studies. A pointed drop in a two-dimensional nonlinear extensional creeping flow was considered by Antanovskii [4], which argued that the flow field produced in Taylor's four-roller apparatus is better described by a nonlinear flow rather than the linear one. Recently, the nonlinear theory was expanded by Favelukis [5]-[6], in order to cover the small deformation regime as well, where new and exiting deformation and breakup patterns, when compared to the linear case, were found. Thus, it is the purpose of this theoretical report to review the recent findings in [5]-[6] as well as to present new results on the subject of deformation and breakup of a drop in a nonlinear extensional creeping flow at small capillary numbers.

THE GOVERNING EQUATIONS

Figure 1 shows a spherical drop (radius a) positioned at the origin of a cylindrical coordinate system. Far away from the drop, the fluid is subjected to an axisymmetric nonlinear extensional flow, suggested by Sherwood [3] and given by: $v_\rho = -(A\rho + 3B\rho z^2)/2$ and $v_z = Az + Bz^3$. Here A and B can obtain positive or negative values. When $B = 0$, the linear extensional flow is recovered, and we distinguish between uniaxial ($A > 0$) and biaxial ($A < 0$) extensional flows.

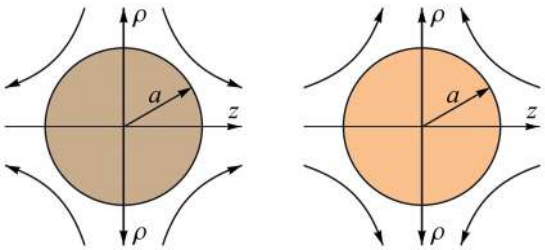

Figure 1. A drop in an extensional flow. Left: uniaxial; right: biaxial.

Let the two fluids be incompressible, Newtonian and under creeping flow conditions. The problem, which is described by the Stokes equations, is governed by three dimensionless parameters: the capillary number $Ca = \mu Aa/\sigma$, the viscosity ratio $\lambda = \mu_{in}/\mu$, and the nonlinear intensity of the flow $E = Ba^2/A$. Here μ_{in} and μ are the internal and external viscosities respectively, and σ is the surface tension.

A general analytical solution to the Stokes equations for any type of axisymmetric flow in spherical coordinates can be found in Leal [7]. The usual boundary conditions suggests: (1) Far from the drop, the undisturbed motion must be recovered; (2) zero normal velocities of the two phases at the interface; (3) equal tangential velocities of the two phases at the interface; (4) equal tangential stresses of the two phases at the interface; and (5) finite velocities and stresses at the origin. The above conditions are sufficient to obtain the $O(Ca^0)$ (spherical) solution, same for uniaxial and biaxial flows, which is then substituted into the normal stress balance in order to obtain the $O(Ca^1)$ deformed shape.

*Corresponding author. E-mail: favelukis@gmail.com

RESULTS AND DISCUSSION

Figure 2 describes streamlines of the $O(Ca^0)$ disturbed motion, for a drop with $\lambda = 1$, as a function of the nonlinear intensity of the flow (E). The first quarter describes the linear case ($E = 0$). When $E > 0$ and as E increases, the flow rate also increases, and above some critical value of E, an external closed circulation is developed near the spherical polar angle $\theta = \pi/2$. This critical E is a function of λ, and as λ increases the critical E decreases. For a bubble or an inviscid drop ($\lambda = 0$) no circulation is possible, for a drop with $\lambda = 1$, $E = 7.03$, and for a solid particle ($\lambda = \infty$), $E = 5/4 = 1.25$. When $E < 0$, a separating surface is created, and as $|E|$ increases, or the flow becomes more nonlinear, the surface moves from $z = \pm\infty$ towards $z = 0$. If $E < -3/7 = -0.429$ (independent of λ), the number of internal circulations is doubled.

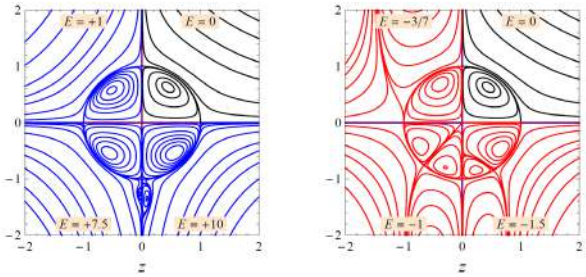

Figure 2. Disturbed streamlines for a drop with $\lambda = 1$. Left: $E \geq 0$; right: $E \leq 0$.

The deformation of a drop with $\lambda = 1$ at $Ca = \pm 0.2$, as a function of the nonlinear intensity of the flow (E), is presented in Figure 3. When the extensional flow is linear ($E = 0$), the literature suggests prolate spheroidal drops for uniaxial flow ($Ca > 0$) and oblate spheroidal drops for the biaxial flow ($Ca < 0$). For the same $|Ca|$, and compared to the linear case, higher deformed drops are obtain if $E > 0$, and lower deformed drops when $E < 0$.

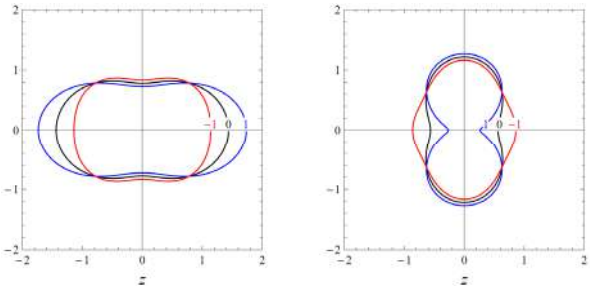

Figure 3. Deformation of a drop with $\lambda = 1$ and $Ca = \pm 0.2$, for different values of E. Left: uniaxial ($Ca > 0$); right: biaxial ($Ca < 0$).

For most cases, the breakup mechanism is by centre pinching ($\theta = \pi/2$ for uniaxial, and $\theta = 0$ and $\theta = \pi$ for biaxial). According to Favelukis [5], $E > 0$ tends to facilitate drop breakup while $E < 0$ makes the breakup more difficult. When $E < -3/7$, the separating surface touches the surface of the drop, which experiences both uniaxial and biaxial flows simultaneously. This weird situation, described in Figure 4, for a drop with $\lambda = 1$ and $E = -2$, for different capillary numbers (Ca), suggests a pinching mechanism progressing from two directions as well as other peculiar shapes.

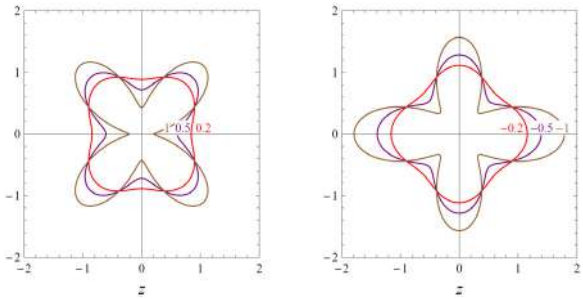

Figure 4. Deformation of a drop with $\lambda = 1$ and $E = -2$, for different values of Ca. Left: uniaxial ($Ca > 0$); right: biaxial ($Ca < 0$).

DYNAMICS OF A BUBBLE RISING IN A VISCOELASTIC LIQUID COLUMN

Pınar Eribol * [1], Arda İnanç [2], M. Naci İnci[2], and A. Kerem Uğuz[1]
[1] Department of Chemical Engineering, Boğaziçi University, Istanbul, Turkey
[2] Physics Department, Boğaziçi University, Istanbul, Turkey

Summary The motion of gas bubbles in non-Newtonian liquids is important for many industrial processes including bubble columns, fermentation, and plastic foam processing. When a gas bubble rises in a viscoelastic liquid, a negative-wake is formed at the tailing end of the bubble and results into important changes at some critical bubble volume. The aim of this study is to find the changes in the velocity, the volume and the shape of the bubble; and the stress around it while establishing a correlation between these elements. For this purpose, the stress will be quantified through a non-invasive optical method called birefringence. The light around a bubble rising in a viscoelastic birefringent liquid will be photographed and employing the stress-optics law, the stress field around the bubble will be determined for various parameters.

Keywords: Stress, viscoleasticity, rising bubble, birefringence

INTRODUCTION

The motion of a bubble rising in a viscoelastic fluid is an important field of study for the purpose of industrial uses. This study becomes interesting due to some factors i.e. the presence of a negative wake at the trailing tip of the bubble, the change in the bubble shape and the jump in the velocity [1-3].

EXPERIMENTAL SETUP & METHODS

A schematic diagram of the experimental setup used in this study is shown in Fig.1. The experimental setup consists of a liquid column, a laser, a polarizer, an analyzer and 3 cameras (camera 1 is for birefringence; and camera 2 and 3 are for volume and velocity measurements, respectively). A glass liquid column with dimensions of 12 cm x 12 cm x 50 cm; and it was made certain that the wall effect on the rising bubble is eliminated with the dimensions preferred. In the experiments, the light emitted by the laser is polarized through the polarizer and then the analyzer repolarizes the light after it passes through the sample medium. When there is a bubble rising through the column, this creates a stress field in the polymeric liquid around the bubble. The birefringent property of the liquid arises when a stress field occurs; and it is captured on the camera as bright fields whereas there is no stress at dark fields.Polyacrylamide (PAAm SH) solutions were prepared with different weight percentages. A fixed weight percentage (1 wt%) of hydroxypropylcellulose (HPC) which is liquid crystalline liquid that is highly birefringent; is added in every PAAm SH solution as PAAm SH does not show enough birefringent property alone (Fig.1b). The solutions are characterized as highly viscoelastic by rheological analysis. The birefringence is calculated through stress optical law (Eq. 1-2). I_o, $I(\theta)$, θ, δ, Δn, χ, h and λ are the intensity of the laser beam, transmitted intensity, the angle between polarizer and analyzer, retardance, birefringence, stretching angle of the polymer, the thickness of the sample medium and wavelength of the laser beam, respectively. The edge detection was performed using Otsu Method on Matlab Image Processesing Toolbox for birefringence, volume and velocity measurements.The bubble volume is calculated through the equivalent diameter, D.

$$I(\theta) + I(\theta + 45) = I_o \sin^2\left(\frac{\delta}{2}\right) = I_o \sin^2\left(\frac{\frac{2\pi h}{\lambda}\Delta n}{2}\right) \tag{1}$$

$$\frac{I(\theta)}{I(\theta + 45)} = \tan^2(2\chi) \tag{2}$$

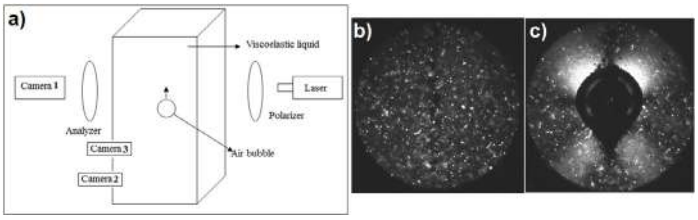

Figure 1: The sketch of the experimental setup (a),the captured image of the birefringence experiment in the absence (b) and presence (c) of a stress field.

*Corresponding author. E-mail: pinareribol@gmail.com.

RESULTS AND DISCUSSION

The results show that there are critical bubble volumes at which the sudden increase in the rise velocity occurs (from Fig. 2a to 2b and from Fig. 2c to 2d). As the bubble rises throughout the column, the viscous and the viscoelastic stresses start having an effect on the bubble; and the bubble shape can change from prolate to cusp-like shape. There is no significant change in the shape of the bubble at the critical point.

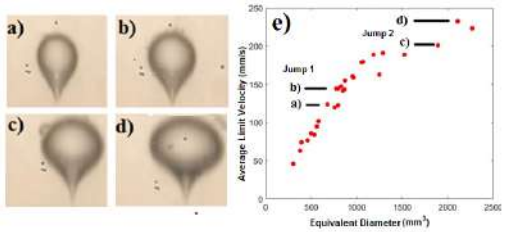

Figure 2: Jumps ocurred from a to b and c to d.

The stress that arises around the bubble is visualized using the birefringence method. The analyzed images displays that the stress around the bubbles increases with the increasing bubble size; and there is a critical bubble volume where no birefringence is observed below it (Fig. 3). The visualized stress is quantified using the stress-optical law (Eqs. 1-2) in terms of retardance, δ and birefringence, Δn. The change in the PAAm concentration alters the viscoelasticity of the solution causing into a change in the formed negative wake. The results indicate that this negative wake is not observed below a critical polymer concentration value. Even when there exists a stress at the tail due to the negative wake, it is relatively much smaller for the lower polymer concentration (Fig. 4a) compared to the higher one (Fig. 4b).

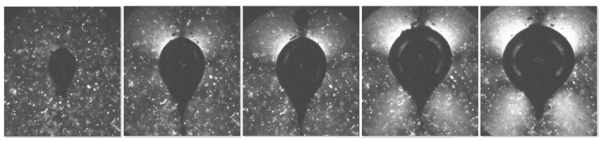

Figure 3: Birefringence observed for increasing volume of bubbles.

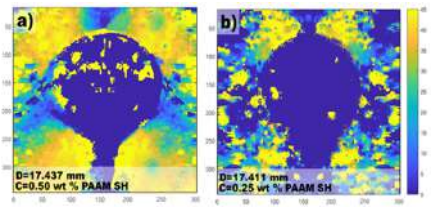

Figure 4: Stretching angle, χ of a bubble (D$\simeq$17.4 mm) at different PAAM SH concentrations a) 0.5 and b) 0.25 wt % .

CONCLUSION

In this study, the light around a bubble rising in a viscoelastic birefringent liquid will be photographed and employing the stress-optics law, the stress field around the bubble will bedetermined for various parameter. The ultimate aim is to find the correlation between velocity, volume and shape of the bubble; and the stress around it.

5 MICRON NARROW BAND ULTRASONIC MIST MAKER

Maryam Ebrahimiazar, Parsia Mohammadshahi, and Nasser Ashgriz
Department of Mechanical and Industrial Engineering, University of Toronto, Toronto, Canada

Summary In the present experiments the ultrasonic atomization of a 2 mm dripping droplet at 2.5 MHz and 40 V was studied. The results show that the size of the generated droplets strongly depends on the size of the liquid on the surface of the piezoceramic. Larger parent drops (~2 mm) generate both large and small droplets. To generate 4-7 micron droplets only, the size of the parent drop should be few hundred microns. Moreover, a new model based on acoustic radiation pressure has been suggested for predicting the size of the generated droplets.

INTRODUCTION

Ultrasonic atomization has numerous applications such as in drug delivery systems, surface coating, ink-jet printing, and mass spectrometry. Ultrasonic nebulizers are advantageous over pneumatic nebulizers in that they can generate droplets in the order of 3-5 microns in diameter. Although there is no general agreement in literature regarding the physical mechanism responsible for the ultrasonic atomization, capillary waves formation has been considered to be the main mechanism. Capillary waves are believed to grow on the liquid surface and eject small droplets from the wave crests. Lang used the Kelvin equation for the critical capillary wavelength and found that the median diameter, D_p, of the generated aerosol can be predicted by

$$D_p = C\lambda_{cr} = C\left(\frac{8\pi\sigma}{\rho f^2}\right)^{1/3} \qquad \text{Eq. 1}$$

where λ_{cr} is the critical wavelength, σ is the surface tension coefficient, ρ is the liquid density, and f is the sound forcing frequency. For sub-MHz ranges, C has been empirically determined to be 0.34.
All the previous ultrasonic nebulizers generate droplets between 2 to 20 microns. The objective of the present study is to design an ultrasonic nebulizer to generate 5-7 micron droplets only.

EXPERIMENTAL SETUP

A commercially available mist-maker piezoceramic with resonance frequency of 2.5 MHz, diameter of 16 mm, and thickness of 1 mm was excited at 2.5 MHz and 40 V. A capillary needle with inner diameter of 0.15 mm was positioned vertically atop of the piezoceramic and was used to generate a 2 mm dripping droplet. Both high-speed and conventional cameras were used for visualization.

RESULTS AND DISCUSSION

Description of Temporal Evolution of the Dripping Droplet

The general sequence of the single ethyl-alcohol droplet impacting on the surface of a piezoceramic operating at 2.5 MHz are shown in Fig. 1. The snapshots presented in these figures are from the conventional camera and selected from different sets of experiments with their time intervals being randomly selected. Fig. 1-a shows the initial impact of a droplet on the surface of the piezoceramic. The image is similar to the droplet impact on a non-vibrating surface, indicating that the acoustic field has not yet affected the droplet dynamics. The interaction between the ultrasonic waves and the droplet causes the initial impacting droplet to deform into a fountain, on the surface of which capillary waves are observed (see Fig. 1-b, and 1-c). The deformed parent droplet into the shape of fountain soon becomes unstable and collapses into large child droplets, forming a thick liquid layer on the surface of the piezoceramic (see figure 1-d), which starts to be atomized and generates both large (100 microns) and fine (4-7 microns) drops. Large droplets of about 100 microns in diameter are formed when intermittent jets breakup directly from the surface of the thick liquid layer on the piezoceramic. The jets elongate, thin out, and eventually break due to capillary pinch off, as shown in Fig. 1-d, and 1-e. Fig. 1-f, 1-g and 1-h show the breakup of few hundred-micron leftover droplets which leads to the formation of fine drops, with diameter in the range of 4-7 microns. No large drop formation is observed in this stage of atomization. The main conclusion from this observation is that ultrasonic atomization and the size of the generated droplets are strongly dependent on the size of the liquid on the surface. Thus, in order to have a continuous formation of fine (4-7 microns) mist, it is essential to continuously introduce a few hundred-micron (200-500 micron) droplet on the surface of the piezoceramic, which is the leading idea for designing and developing a narrow band fine ultrasonic mist generator.

Design and Develop a Narrow Band 5 Micron Ultrasonic Mist Generator

As the results show, continuous introduction of a 200-500 micron droplet on the surface can generate a stream of 4-7 micron mist. To do so, a capillary needle with diameter of 0.15 mm is used for continuous liquid introduction (see Fig. 2-a). As soon as the few hundred-micron droplet is introduced on the surface, atomization starts, and fine mist is generated. The picture presented in Fig. 2-b shows the continuous formation of 4-7 micron mist from the tip of the needle. The newly

designed ultrasonic mist generator is advantageous over the existing ultrasonic nebulizers in that it generates narrow band 4-7 micron mist, and that no liquid is accumulated on the surface of the piezoceramic.

Field of view is 3.5 mm×2.5 mm

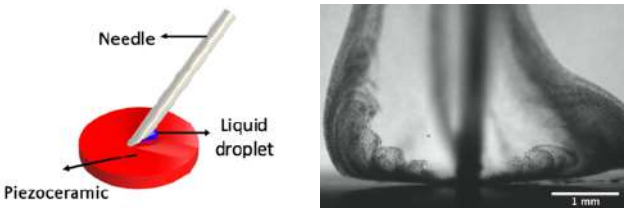

Figure 2- Continuous ultrasonic mist generation

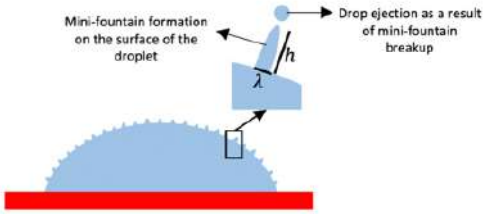

Figure 3- Mini-fountain formation on the liquid's surface and droplet ejection from the surface

Size Distribution Prediction Based on Acoustic Radiation Pressure

When ultrasonic wave reaches the surface of the droplet, due to the mismatch in the acoustic impedance of the liquid and the air, the sound wave reflects back to the droplet. Repeated impact and reflection of the wave on the liquid-air interface results in a steady stress on the droplet, leading to droplet deformation and atomization. Acoustic radiation pressure inside the droplet can be calculated from

$$p_r = p_0 \left(\frac{1}{1 + \frac{\partial \zeta}{\partial z}} \right)^{\gamma} \qquad \text{Eq. 2}$$

in which p_0 is the pressure inside the droplet at rest, ζ is the particle displacement inside the droplet, and γ is the nonlinearity coefficient for the liquid. It is assumed that in ultrasonic atomization, mini-fountains with base diameter of λ_{cr} are formed on the surface of the parent droplet (see Fig. 3), which their height, h can be calculated from pressure balance:

$$p_{in} = p_{ref} - \rho g z + p_r \qquad \text{Eq. 3}$$

where p_{ref} is the reference pressure, and p_{in} is the pressure inside the droplet that can be calculated from Laplace equation. The breakup of each of these mini-fountains will generate a droplet, the size of which can be calculated using mass balance: $\pi \lambda^2 h/4 = \pi D_p^3/6$. Using Eq. 3, the size of the generated droplet is predicted to be 4 micron which is comparable with the results from Malvern laser diffractometer.

CONCLUSIONS

The experimental results show that although all the commercially available ultrasonic nebulizers generate both large and small droplets, it is possible to develop an ultrasonic nebulizer generating 4-7 micron droplets only. This can be done by keeping the size of the parent drop on the surface of the piezoceramic around 200 microns. Additionally, due to acoustic radiation pressure, mini-fountains are formed on the surface of the droplet. Assuming that mini-fountains have a base diameter of λ_{cr}, their height can be calculated by doing a pressure balance at the tip of the fountains. Then, using mass balance, the size of the generated droplets is predicted to be 4 microns.

MHT-X: EFFICIENT MULTIPLE HYPOTHESIS TRACKING FOR MULTIPHASE FLOW ANALYSIS

Peteris Zvejnieks[1], Mihails Birjukovs*[1], Martins Klevs[1], and Andris Jakovics[1]
[1] Institute of Numerical Modelling, University of Latvia, UL, Jelgavas iela 3, LV-1004, Riga, Latvia

Summary An efficient and versatile implementation of offline multiple hypothesis tracking using Algorithm X for optimization has been developed using Pyhthon. The code is intended for scientific applications that do not require online processing. Directed graph framework is used and multiple scans with progressively increasing time window width are used for construction of maximum likelihood trajectories. The current version was developed for applications in multiphase hydrodynamics, e.g. bubble and particle tracking, and is capable of resolving object motion, merges and splits. Feasible object associations and trajectory graph edge likelihoods are determined using weak mass and momentum conservation laws translated to statistical functions for object properties. The code can handle n-dimensional motion with arbitrarily many tracked object properties and is easily extendable beyond the present application. The code is open-source and is in active development.

INTRODUCTION

Multiple Hypotheses Tracking (MHT) is classically considered to be the most reliable method for finding the optimal solution for data association problems [1, 2]. However, is often avoided for real-time (online) applications due to its computational complexity. In this paper, the MHT association search problem is formulated as an exact cover problem within a directed graph framework, which is then solved using *Algorithm-X* (Knuth's algorithm) [3], dramatically reducing complexity of covering the entire search-space of viable solutions. This solution was developed for the analysis of multiphase hydrodynamic systems. In our case, there are several problems of interest: dynamic optical, X-ray and neutron imaging of argon bubble flow in liquid gallium or galinstan; neutron imaging of gadolinium oxide particle flow in liquid gallium; bubble flow simulations using the volume of fluid method [4]. The objective is to trace objects (bubbles/particles segmented beforehand) in time, reconstructing trajectories, resolving interactions (i.e. bubble coalescence and particle adhesion) and performing velocimetry. The output can then be used, for instance, for an in-depth analysis of bubble/particle collective dynamics, comparison of simulation and experiment data, etc. The code was also designed to be able to account for significant shape oscillations for objects that are typical in the above applications. The offline implementation is dictated by scientific use, where real time data interpretation is not required, but rather reliable solutions are expected for potentially very large scale problems within acceptable time intervals. The main framework of our code is universal and can be readily adapted to any type of offline tracking problem beyond the tracing examples showcased herein.

METHODOLOGY AND FIRST RESULTS

For offline tracking, a complete set of measurements for object detection events is required as input. We propose to construct a directed graph with objects as nodes storing object properties, and store association likelihoods between objects on graph edges (edge direction aligned with the arrow of time). This input representation was chosen because of its intuitive interpretation, making it conceptually easier to implement and customize for any application. This MHT implementation, herein referred to as MHT-X, consists of several core parts used to solve for the likeliest set of edges (equivalently, trajectories). This modularity further facilitates adaptability to various problems. In addition to object nodes, two auxiliary *Entry* and *Exit* nodes (*special nodes*) are introduced to handle trajectory endpoints. With the *a priori* knowledge that objects detected in the first and last frames are, respectively, start- and endpoints of trajectories, a starting graph configuration (edges and likelihoods) is initialized. Then the tracing problem is solved in the following steps. First, edges with likelihood below threshold are deleted from the initial graph. Then the main component of the algorithm, graph sweep, is started: a time window is defined that is $Deltat$ time steps wide which is translated trough the graph in time. At every time step (t) associations are attempted within the window: the algorithm searches for trajectories without continuation within $[t; t + \Delta t)$ and for trajectories without origins within $(t; t + \Delta t]$. It is then attempted to associate these trajectories using the *pairwise association conditions* and *combination constraints*. Each of the feasible associations are then evaluated using *statistical functions* (in this case based on trajectory compliance with mass and momentum conservation), yielding their likelihoods. Finally, the association configuration with the highest global likelihood is found. Classically this is a $\mathcal{O}(n) = 2^n$ complexity problem where n is the number of considered associations. To sidestep this, we propose to formulate association optimization as an exact cover problem and solving it using Algorithm X, reducing complexity to $\mathcal{O}(n) = n \log n$ (best case). Complexity is reduced further by clustering associations into disjoint sets before formulating and solving the exact cover problem. After obtaining a solution for each window step, only

*mihails.birjukovs@lu.lv

the associations impossible to form in the next time step are added to the graph. Once the first graph sweep is complete and every node has an inbound and outbound edge(-s), a time window with increased Δt is reinitialized and the graph sweep is started over. This is repeated for increasing Δt to resolve associations over longer ranges, which provides robustness against failed/false object detections. The process stops at a final solution once maximum Δt is reached. The application of MHT-X to simulation and experiment data is illustrated in Figures 1 and 2.

SEA SPRAY AT HIGH WINDS: MECHANISMS OF PRODUCTION AND ROLE IN HEAT TRANSFER AND SURFACE DRAG

Summary The record strengths of recent hurricanes have highlighted needs for improving forecasts of tropical cyclone intensities most sensitive to models of the air-sea interaction. Especially challenging is the nature of sea-spray supposed to strongly affecting the momentum- and energy- air-sea fluxes at strong winds. Even the spray-generation mechanisms in extreme winds remained undetermined. Basing on high-speed video here we identify it as the bag-breakup mode of fragmentation of liquid in gaseous flows known in a different context. From the general principles of statistical physics we develop statistics of the "bag-breakup" events, estimated the production rate of spray and showed, that at extreme winds "bag-breakup" is the dominant mechanism of sea spray production. This findings form a new basis for modeling the sea-spray and air-sea exchange at hurricane wind.

INTRODUCTION

Air-sea interaction at extreme winds is of special interest now in connection with the problem of the sea surface drag reduction at the wind speed exceeding 30-35 m/s. This phenomenon predicted in [1] and confirmed by a number of field [2] and laboratory [3] experiments still waits its physical explanation. Several papers attributed the drag reduction to spume droplets - spray tearing off the crests of breaking waves (e.g., [4,5]). The fluxes associated with the spray are determined by the rate of droplet production at the surface quantified by the sea spray generation function (SGF), defined as the number of spray particles of radius r produced from the unit area of water surface in unit time. However, the mechanism of spume droplets' formation is unknown and empirical estimates of SGF varied over six orders of magnitude [6]; therefore, the production rate of large sea spray droplets is not adequately described and there are significant uncertainties in estimations of exchange processes in hurricanes. Herewith, it is unknown what is air-sea interface and how water is fragmented to spray at hurricane wind.

Using high-speed video, we observed mechanisms of production of spume droplets at strong winds by high-speed video filming, investigated statistics and compared their efficiency [7,8]. Experiments showed, that the generation of the spume droplets near the wave crest is caused by the following events: bursting of submerged bubbles, generation and breakup of "projections" and "bag breakup". Statistical analysis of results of these experiments showed that at hurricane winds the main mechanism of spray production is attributed to "bag-breakup" (Figure 1). On the base of general principles of statistical physics (model of a canonical ensemble) we developed statistics of the "bag-breakup" events: their number and statistical distribution of geometrical parameters depending on wind speed. The size distribution function of bags is lognormal and prescribed by the wind velocity.

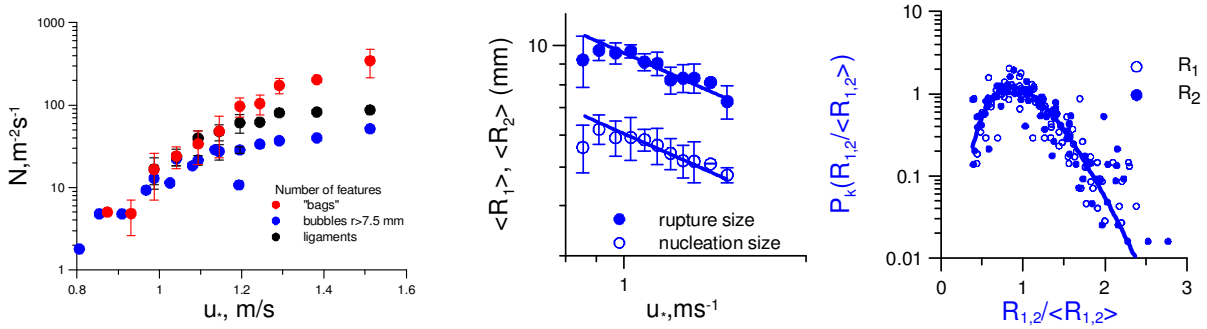

Figure 1. The specific number of events (per unit time per unit area) responsible for generation of spume droplets versus friction velocity (left), average sizes, velocities and lifetimes of "bags" via wind friction velocity (middle) , size distribution of "bags"**(right)**

SPRAY GENERATION FUNCTION

However due to a lack of experimental data, the SGF was constructed with the use of a number of assumptions. In particular, available data on the fragmentation of similar objects were used to estimate the parameters of droplets generated by the "bag-breakup" fragmentation events, namely droplets in gaseous flow or bursting bubbles. To study the peculiarities of the "bag-breakup" fragmentation process at air-water interface, the special experiment was conducted, in which the generation of droplet from a single isolated bag-breakup event was investigated and differences from the fragmentation of droplets and bursting bubbles were identified.

As it was found earlier in [7,8], the "bags" generate spray in two ways:1. Rupturing the film of inflated bag (film spray); 2. Fragmentation of the rim stayed after the bag's rupture (rim spray).

The canopy droplets were generated due to the same mechanism as the fragmentation of the bursting bubbles enclosed in [9] (Figure 1). The spray are generated by the fragmentation of the thin rim around the hole in the canopy due to the Rayleigh-Taylor (R-T) instability due to centrifugal acceleration, but there are differences:

1. The film thickness of a canopy is not constant, but it is the random value with lognormal distribution
2. In contrast to the film of the busting bubble, the thickness of the canopy does not depend on its radius. It is the random value with the average is prescribed by the wind speed ~U^{-2}. This difference can be explained by difference in the mechanisms of the film rupture in these two cases. The mechanism of the bubble rupture is thinning due to

convection in the film. In the case of the bag-breakup the film ruptures presumably due to the Kelvin-Helmholtz instability under the action of the wind. The dependence on the wind speed points this out.

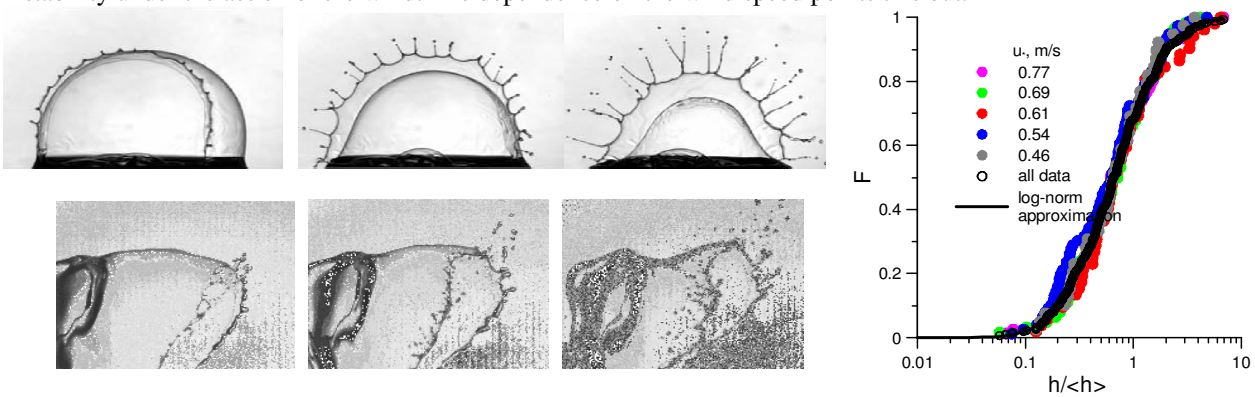

Figure 2. Fragmentation of the bursting bubble from [9] (top) and fragmentation of the canopy of the bag (bottom). Cumulative distribution of the film thiclness.

The size spectrum of the spray from bursting of one canopy of the bag as the convolution of the distribution of the film thicknesses and distribution of the droplets from the film of a certain thickness.

The formation of drops from the rim occurs through two mechanisms. Before the rupture of the canopy, the R-T instability develops at the rear edge of the bag, which results in the formation of a small number of large droplets (type 1). Then, after breaking the canopy, the remaining rim is fragmented to form smaller droplets (type 2) (Figure.2). Given the presence of two mechanisms of formation of droplets, we consider the above groups of droplets separately and examine their statistical patterns and constructed the size spectrum of the rim droplets from one bag as the composition of two lognormal distributions with parameters prescribed by the Weber number of the "bag". Based on this experiment, the distribution function of droplets from one "bag-breakup" event was built.

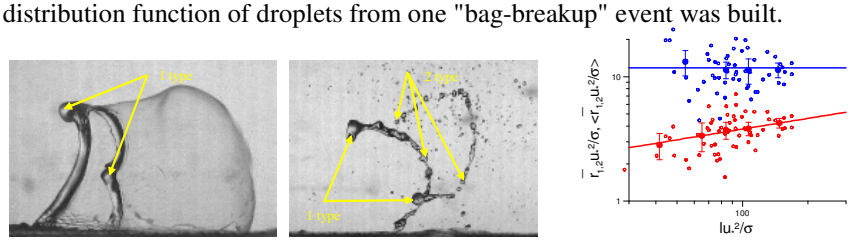

Figure 3. Droplet formation during fragmentation of the rim. Sizes of droplets of the 1-st type (blue) and 2-ng type (red).

The bag-breakup spray generation function is the convolution of the size spectra of bags with the size spectra of droplets produced by a sole bag. An important question is transferring this lab results to field conditions. The main difference between field and laboratory conditions is fetch. To adapt the results of the laboratory measurements of the statistics of the spray generating phenomena to field conditions, we used the so-called "Whitecap Method". It uses the laboratory data on spray generating phenomena normalized by the area of whitecaps and the field data on statistics of whitecaps. Using the proposed SGF, estimates are given for the air-sea fluxes of momentum, sensible and latent heat, and enthalpy.

CONCLUSIONS

We studied the peculiarities of the sea spray production at the stormy winds. The dominant mechanism of generation of spume droplets is shown to be the “bag-breakup” fragmentation. Basing on laboratory experiments with the high-speed video-filming, the SGF for the “bag-breakup” is suggested. The suggested SGF is used for estimates of the spray-mediated momentum and enthalpy fluxes. The estimates showed, that the microphysical processes are essential for intensification of the storms.

DROPLET DIAMETERS AND FLOW RATES IN SPRAYS AND AEROSOLS WITH SUBMICRON DROPLETS

Maksim Mezhericher*[1] and Howard A. Stone[1]
[1] Department of Mechanical and Aerospace Engineering, Princeton University, Princeton, USA

Summary In our recent work we demonstrated a novel liquid atomization process generating micro-sprays and aerosols of submicron-diameter droplets for pure solvents, suspensions and solutions. The process is based on disintegration by gas jets of thin liquid films formed as bubbles on a liquid surface. Here we show that the diameters and flow rates of the produced droplets are governed by the interplay of process timescales including capillary Rayleigh breakup, liquid viscosity and gas jet pressure. Those timescale ratios can be converted into the ratios of specific energies and into the ratios of specific energy rates, provided by the gas jets and dissipated by the atomized liquid. We introduce atomization diagrams as new graphic tool for theoretical determination of the diameters and flow rates of generated droplets, and demonstrate good agreement of our calculations with experiments.

INTRODUCTION

In our previous articles [1,2] we demonstrated a novel liquid atomization process generating micro-sprays and aerosols of submicron-diameter droplets for pure solvents, suspensions and solutions with wide ranges of viscosity and surface tension. The process is based on gas jetting on thin liquid films formed as bubbles on a liquid surface (see Fig. 1a). The research question addressed in this study is development of theoretical description for prediction of droplet diameters and flow rates produced by the new process for various liquids.

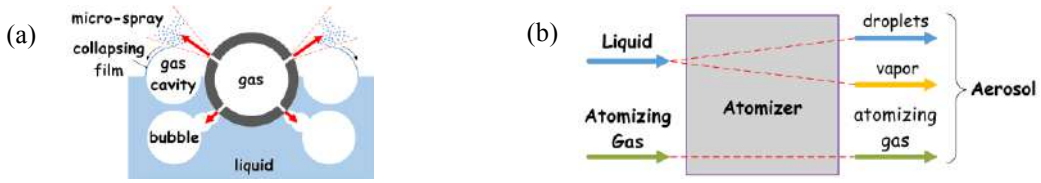

Figure 1. (a) Schematic of liquid atomization process, (b) Control volume for thermodynamic analysis.

MATERIAL AND METHODS

The developed liquid atomization process is analyzed by applying the law of mass conservation and the First Law of Thermodynamics for the control volume shown in Fig. 1b. Assuming steady-state flow for continuous adiabatic process at room temperature, neglecting the changes in potential energy of both fluids, evaporation and the change in liquid kinetic energy, assuming complete ideal expansion of the gas jet, and disregarding drag, we get:

$$e_{\Delta p} = e_c + e_v \,, \tag{1}$$

where $e_{\Delta p}$, e_c and e_v are respectively specific energies supplied by the gas pressure and dissipated by the surface tension and viscosity of atomized liquid. In our previous work [2], using the theory of dimensional analysis, we established that two dimensionless groups $\mathrm{La}_d = \rho_l \gamma_l d / \mu_l^2$ and $\mathrm{N}_d = \Delta p_{gj} d / \gamma_l$ are playing the central role for droplet diameters. Here ρ_l, γ_l, μ_l are density, surface tension and dynamic viscosity of the liquid, $\Delta p_{gj} = p_g - p_\infty$ is pressure drop over the nozzle producing gas jet, and d is droplet diameter. Using the characteristic time scales of the physical phenomena into the liquid atomization, including supplied energy of the gas jet $\tau_{\Delta p}$ $\left(\rho_l l_c^2 / \Delta p_{gj}\right)^{1/2}$, and capillary Rayleigh breakup τ_c $\left(\rho_l l_c^3 / \gamma_l\right)^{1/2}$ and viscous dissipation τ_v $\rho_l l_c^2 / \mu_l$ in the liquid, with approximation $l_c = d$ for all the phenomena, the respective dimensionless groups can be expressed as the ratios of the timescales, La_d τ_v^2 / τ_c^2 and N_d $\tau_c^2 / \tau_{\Delta p}^2$. On the other hand, the energy scales and times scales are connected, $e_{\Delta p}$ $l_c^2 / \tau_{\Delta p}^2$, e_c l_c^2 / τ_c^2 and e_v l_c^2 / τ_v^2, and we again assume $l_c = d$. Therefore, La_d e_c / e_v and N_d $e_{\Delta p} / e_c$, or $\mathrm{La}_d = k_1 e_c / e_v$ and $\mathrm{N}_d = k_2 e_{\Delta p} / e_c$, where k_1 and k_2 are proportionality coefficients. Substituting the two latter expressions into Eq. (1), we get:

$$\mathrm{N}_d = k_1 + k_1 k_2 \, \mathrm{La}_d^{-1} \,. \tag{2}$$

The obtained equation connects between the specific energies provided by the gas jets and dissipated by the atomized liquid in nondimensional form and determines the diameters of the produced droplets.

The balance of specific energy rates in the atomization can be obtained by taking the time derivative of Eq. (1):

*Corresponding author. E-mail: maksymm@princeton.edu.

$$\varepsilon_{\Delta p} = \varepsilon_c + \varepsilon_v \,. \tag{3}$$

Employing the dimensionless analysis and algebraic manipulations similar to those performed above for droplet diameters, two dimensionless numbers $\mathrm{N}_{l,cv} = \rho_l^2 \gamma_l d^3 n_d / \mu_l^3$ and $\mathrm{N}_{l,pc} = \Delta p_{gj}^{3/2} / \left(\gamma_l \rho_l^{1/2} n_d \right)$ playing the central role for droplet flow rates are established, where n_d is droplet production rate. Correspondingly, $\mathrm{N}_{l,cv}$ $\varepsilon_c / \varepsilon_v = k_3 \varepsilon_c / \varepsilon_v$ and $\mathrm{N}_{l,pc}$ $\varepsilon_{\Delta p} / \varepsilon_c = k_4 \, \varepsilon_{\Delta p} / \varepsilon_c$, where k_3 and k_4 are proportionality coefficients. Substituting into Eq. (3), we get:

$$\mathrm{N}_{l,pc} = k_3 + k_3 k_4 \, \mathrm{N}_{l,cv}^{-1} \,. \tag{4}$$

The obtained equation connects between the rates of specific energies provided by the gas jets and dissipated by the atomized liquid in nondimensional form and determines the flow rates of the produced droplets.

RESULTS AND DISCUSSION

The atomization diagrams for diameters and flow rates of water droplets are given in Fig. 2. The droplet diameter and gas jet pressure were varied in Fig. 2a, and the droplet production rate and droplet diameter were varied at $\Delta p_{gj} = 2.5$ bar in Fig. 2b. The central lines of atomization region on the diagrams were obtained from Eqs. (2) and (4), assuming the proportionality coefficients to be order of unity. The lower and upper boundaries of the atomization region are calculated by assuming tenfold difference of the dimensionless numbers N_d (Fig. 2a) and $\mathrm{N}_{l,pc}$ (Fig. 2b) with respect to those of the corresponding central lines $\mathrm{N}_d^* = 1 + \mathrm{La}_d^{-1}$ and $\mathrm{N}_{l,pc}^* = 1 + \mathrm{N}_{l,cv}^{-1}$. From Fig. 2a for $\Delta p_{gj} = 2.5$ bar, we can calculate that the atomization process is expected to generate droplets with diameters in the range 40 nm – 3 μm, and mean droplet diameter ~300 nm. In our experimental studies [1], the arithmetic mean diameter was ~250 nm and the upper boundary of the obtained number based droplet size distribution was ~3 μm, whereas the lowest measured droplet diameter was set by the measuring range 100 nm – 900 μm of the utilized laser scattering device. For the calculated mean diameter of 300 nm, Fig. 2b reads 10^8 drop/s, while the experiment [1] measured 10^7 drop/s. This difference can be attributed to a theoretical assumption of a continuous atomization process, while in fact there is a periodic disintegration by a gas jet of bubbles rising to the liquid surface (Fig. 1). The calculations for other liquids (not shown here), including gasoline, diesel and solutions of sodium alginate, also demonstrated a good agreement between the theory and experiment. Finally, it is worth noting that for the region of $\mathrm{La}_d \geq 1$ in Fig. 2a, the distribution of droplet diameters in the atomization region follows a log-normal law, which is widely observed in technical and natural liquid atomization processes [3].

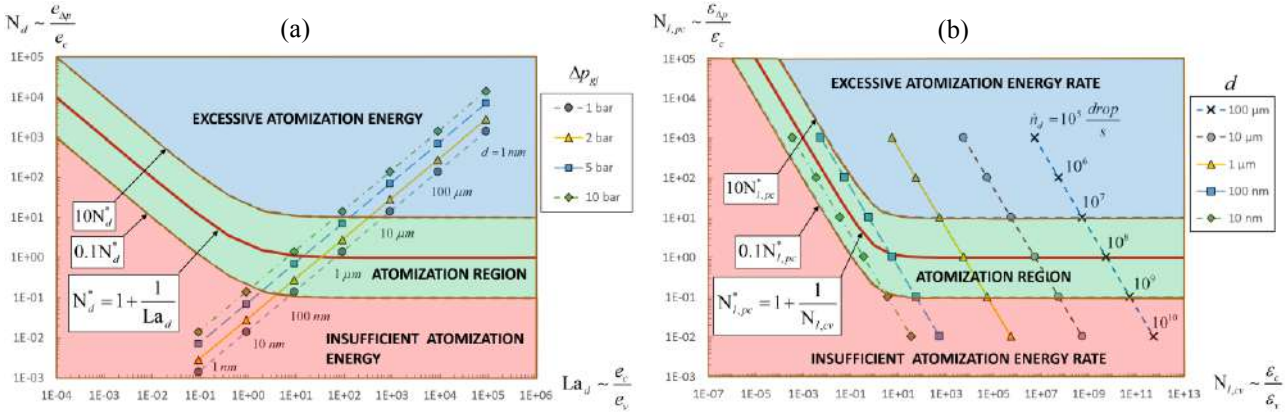

Figure 2. Atomization diagrams for diameters (a) and flow rates (b) of water droplets.

CONCLUSIONS

In this work we demonstrated new theoretical approach to determine droplet diameters and flow rates in sprays and aerosols using atomization diagrams. The approach is based on the first principles of conservation of mass, energy, and energy rates. The comparison between theoretically predicted and measured droplet diameters and droplet flow rates demonstrated a good agreement for new liquid atomization process generating micro-sprays and aerosols of submicron-diameter droplets.

SPONTANEOUS DYNAMICS OF LEIDENFROST DROPS

Rodolfo Brandão * [1] and Ory Schnitzer[1]
[1] Department of Mathematics, Imperial College London, SW7 2AZ London, UK

Summary Recent experiments have revealed that Leidenfrost drops (levitated by their vapor above a hot surface) undergo "symmetry breaking", leading to spontaneous rolling motion in the absence of external gradients/asymmetries. We present a simplified two-dimensional dynamical model of a Leidenfrost drop that predicts an instability of the symmetric Leidenfrost drop, symmetry breaking and spontaneous motion, in compelling qualitative agreement with the experiments. The key enabling mechanism is shown to be the nonlinear coupling between the internal flow of the liquid and the lubricating flow in the vapor thin-film.

INTRODUCTION

A liquid deposited above a sufficiently hot substrate can generate a thin layer of insulating vapour — a phenomenon known as the Leidenfrost effect. This vapour layer prevents direct contact between the liquid and the substrate, thus considerably slowing down the evaporation process.

Particular attention has been devoted to Leidenfrost drops, namely slowly-evaporating drops in the Leidenfrost state. These drops levitate above their own vapor and experience very low friction, attributes that hold promise in various microfluidic applications. Due to the combination of hydrodynamic, thermal and capillary effects, Leidenfrost drops exhibit very rich dynamics, including oscillations, bouncing and directed propulsion using textured surfaces [1].

Recent experiments have revealed that Leidenfrost drops above a flat surface can also generate their own dynamics from a symmetry-breaking mechanism [2]. In detail, a rotational flow can be spontaneously established within an immobilized drop; the rotation induces an asymmetry at the drop base and, when the drop is released, it begins to move at an acceleration approximately equal to the "characteristic slope" of the asymmetry times the gravitational acceleration g, akin to a drop rolling down a virtual inclined plane. The symmetry breaking only occurs for drops smaller than the capillary length $l_c = \sqrt{\gamma/\bar{\rho}g}$, wherein $\bar{\rho}$ is the drop density and γ is the surface tension, but not arbitrarily small, and the range of unstable drop radii depends on the substrate temperature. These discoveries received significant attention, as they may help to explain the exceptional mobility of Leidenfrost drops and open new avenues of practical exploitation.

We theoretically investigate the mechanics enabling symmetry-breaking spontaneous dynamics of Leidenfrost drops based on a simplified two-dimensional model [3]. Our model consists of the equations of motion of the drop with the torques and forces calculated from an instantaneous lubrication model of the vapor thin film.

MODEL

We consider a liquid drop (area πR^2, density $\bar{\rho}$, viscosity $\bar{\mu}$) levitated by its vapor (thermal conductivity k, density ρ, viscosity μ) above a superheated flat surface of temperature ΔT relative to the drop. We shall focus exclusively on the limit $B \ll 1$, where $B = (R/l_c)^2$ is the Bond number. In that case, the drop interface is approximately a circle except close to a small $O(BR)$ "flat spot" at the bottom of the drop. Furthermore, the internal flow in the drop is a superposition of a rigid-body translation, at velocity $\mathcal{U}(t)\hat{\mathbf{e}}_x$, and and rigid-body rotation, at angular velocity $\Omega(t)\hat{\mathbf{e}}_y$ (see Figure 1) [3].

Vapor thin-film

The vapor thickness profile $h(x,t)$ and the vapor pressure $p(x,t)$ are governed by the thin-film equations,

$$\frac{\partial}{\partial x}\left(\frac{h^3}{12\mu}\frac{\partial p}{\partial x}\right) + \frac{\mathcal{U}+\Omega R}{2}\frac{\partial h}{\partial x} = -\frac{\lambda}{h}, \quad p = \frac{\gamma}{R} - \gamma\frac{\partial^2 h}{\partial x^2}, \tag{1}$$

where $\lambda = k\Delta T/\rho l$, l being the latent heat of evaporation. At large distances, $p \to 0$ and the profile h matches that of a non-wetting drop on a horizontal plane,

$$h \sim \frac{1}{2R}\left(x \mp \frac{\pi BR}{2}\right)^2 + h_\pm + o(1) \quad \text{as} \quad x \to \pm\infty. \tag{2}$$

Equations of motion

The drop flows like a rigid body. The linear and angular momentum equations are, respectively,

$$m\frac{d\mathcal{U}}{dt} = \mathcal{P} - \mathcal{F}, \quad I\frac{d\Omega}{dt} = \mathcal{T} - R\mathcal{P} + R\mathcal{F}, \tag{3}$$

where $m = \pi\bar{\rho}R^2$ and $I = mR^2/2$ are respectively the mass and moment of inertia of the drop. The forces and torques appearing in (3) are calculated from the lubrication model for the vapor film and given by

$$\mathcal{P} = \frac{1}{2}\alpha mg, \quad \mathcal{T} = \alpha mgR, \quad \mathcal{F} = \mu(\mathcal{U}-\Omega R)\int_{-\infty}^{\infty}\frac{dx}{h}, \tag{4}$$

where $\alpha = (h^- - h^+)/\pi BR$ is the characteristic slope of the drop base.

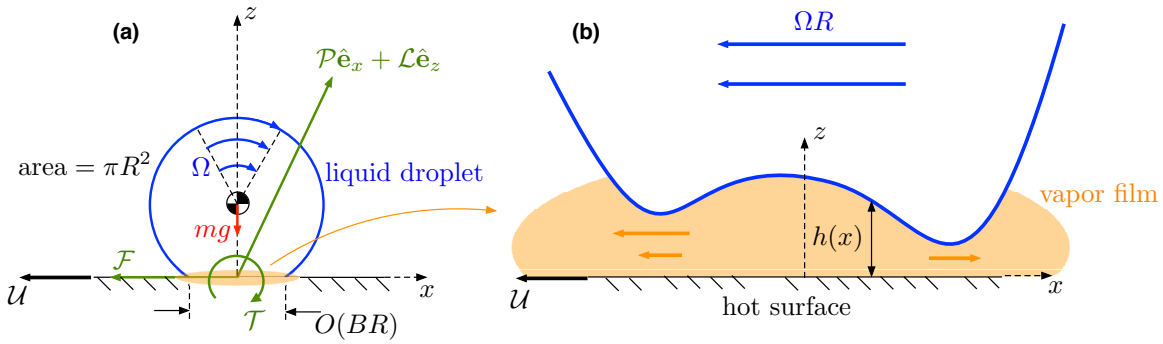

Figure 1: Sketch of a two-dimensional near-circular Leidenfrost drop in a comoving frame. (a) Drop-scale dynamics. (b) Lubrication region.

RESULTS

Free drops

Let us first consider a Leidenfrost drop which is free to move until it reaches a steady state. Fixed points of the dynamical system (3) satisfy the "force-free" condition $\mathcal{P} = \mathcal{T} = \mathcal{F} = 0$. Equivalently, fixed points satisfy the conditions $\alpha = 0$ and $\mathcal{U} = \Omega R$ ("pure-rolling").

Due to the symmetry of the dynamical system, there is always the trivial fixed point $(\mathcal{U}, \Omega) = (0, 0)$ which corresponds to the usual stationary-symmetric state of a Leidenfrost drop [1]. The symmetric state, however, is stable only for $R < R_1 \approx 3.2(\mu\lambda\gamma^5/\bar{\rho}^6 g^6)^{1/13}$. For $R > R_1$, α exhibits two non-trivial zeros corresponding to stable left- and right-going pure-rolling steady states, which bifurcate at $R = R_1$ from the trivial zero.

Initially immobilized drops

The constant-acceleration motion observed in the experiments [2] suggests that the system is not in a steady "pure-rolling" state. Moreover, the experimental data also suggests an inertial time scale much larger than the observation time, which indicates that the experiments are restricted to early stages of the dynamics. To model the initial dynamics of the drop, we note that each experiment in [2] consists of two stages. In the first stage, the drop is immobilized, by a needle, and a steady rotational flow builds within the drop. In the second stage, the drop is released and is free to move for a short duration of time relative to the inertial time scale.

When the drop is immobilized, its dynamics is governed solely by the angular momentum equation in (3) with the forces calculated from (4) with $\mathcal{U} = 0$. Fixed points of this reduced system satisfy $\mathcal{P} - \mathcal{F} = \mathcal{T}/R$, representing the zero-net-torque condition for an immobilized drop. Analogously to the free-drop case, the symmetric state $\Omega = 0$ is stable only for $R < R_2 \approx 6.3(\mu\lambda\gamma^5/\bar{\rho}^6 g^6)^{1/13}$. For $R > R_2$, there are stable steady states of angular velocity $\Omega = \Omega^*$.

Now assume that an immobilized drop rotating at the stationary angular velocity $\Omega = \Omega^*$ is released at $t = 0$. From (3) and (4), the drop starts to move with acceleration

$$\frac{d\mathcal{U}}{dt} = \alpha g. \tag{5}$$

This expression agrees with that observed in the three-dimensional experiments [2].

Further agreement between theory and experiment can be verified by analyzing the dependency of the drop acceleration with the physical parameters. Our model predicts that the acceleration has a maximum as R is varied with all other parameters held fixed. Furthermore, as the temperature difference ΔT is increased, the position of the maximum shifts to a larger radius and the magnitude of the maximal acceleration increases. These trends are in good qualitative agreement with the experiments [2].

X-RAY IMAGING OF BUBBLE FLOW IN LIQUID METAL: SHAPE DYNAMICS UNDER CONFINEMENT

Mihails Birjukovs*[1], Tobias Lappan †[2], Natalia Shevchenko[2], Olga Keplinger[2], Sven Eckert[2], and Andris Jakovics[1]
[1] Institute of Numerical Modelling, University of Latvia, UL, Jelgavas iela 3, LV-1004, Riga, Latvia
[2] Helmholtz-Zentrum Dresden-Rossendorf, HZDR, Bautzner Landstrasse 400, 01328 Dresden, Germany

Summary Argon bubbles injected into thin vessels filled with galinstan are imaged using X-ray radiography. Confinement results in significant bubble deformations and shape variations, agglomeration, as well as intensified merging and breakup. We have developed a shape analysis algorithm suitable for arbitrary bubble shapes. Here it is used to quantify the effects of flow confinement and varying gas flow rate, and to study the physics of breakup and merging in detail. We demonstrate a clear influence of flow rate and container thickness on various bubble characteristics derived from the shape analysis and explain the physical origins thereof, providing insights into collective bubble dynamics and further validating X-ray radiography as a reliable method for analysis of optically opaque gas/liquid systems. The results of this study are relevant to theoretical and applied magnetohydrodynamics.

INTRODUCTION

Bubble flow in liquid metal has several applications, e.g. in metallurgical processes, such as metal stirring, purification and homogenization, and in liquid metal-based chemical reactors [1]. However, bubble flow exhibits complex collective dynamics, therefore appropriate experimental methods are necessary to study the underlying physics in hopes of optimizing industrial processes. One usually experiments with downscaled (via similarity criteria) systems of interest and using low melting point model liquids and inert gases [1]. One of the prospective contactless methods for bubble flow analysis is the high frame rate dynamic X-ray transmission radiography (XTR), which has been successfully validated both experimentally [2] and *in silico* [3]. XTR allows direct observations of gas/liquid phase boundaries, enabling in-detail analysis of bubble shape dynamics and collective behaviour. Bubble breakup [4], coalescence [5] and agglomeration are of special interest, but thus far XTR studies have been limited to qualitative analysis due to challenges related to image processing [4, 5]. Here we present our image processing approach and bubble shape analysis method. Applicable to most types of bubble shapes, these tools are employed to study the effects of flow confinement on bubble collective dynamics.

METHODOLOGY AND PRELIMINARY RESULTS

Previously bubble coalescence and breakup were studied in systems with 12 mm liquid metal thickness using XTR [4, 5]. Here, we turn to much more confined systems with 3- and 6 mm thickness, imaged with gas flow rates 50 - 250 and 50 - 685 cm^3/min, respectively. Injecting large gas volume into flat containers promotes stronger bubble flattening and deformations and intensifies bubble collisions, agglomeration, breakup and coalescence (Figure 1) due to partial container obstruction by ascending bubbles. Using an XTR setup similar to the one in [5], we observe a wide range of different bubble shapes. Their detection and description requires a special approach. Additionally, due to agglomeration, one must accurately resolve thin metal films between bubbles (Figure 1).

To do this, we use uncompressed high resolution images and the following processing steps. Local adaptive binarization followed by a self-snakes filter and single threshold Otsu binarization, after which morphological closing and Canny edge detection are applied. Logical filters remove image artefacts and bubble contours are extracted (Figure 2), allowing to resolve collisions, breakup and collective ascension. Our shape analysis algorithm then finds bubble centroids and computes bubble center lines (BCL) as maximum length curves from the minimum spanning tree of the Voronoi mesh nodes computed from bubble boundary mesh nodes and using the derived boundary curvature distribution (Figure 3). This, in turn, enables one to compute bubble thickness profile over BCL arc length, BCL curvature, length, etc., accounting for bubble shape irregularity and yielding insight into how bubbles split or merge (Figures 3d, 3e). One may also construct a chord connecting the BCL endpoints – the ratio of the chord length to that of the BCL is a measure of bubble ellipticity; the distance profiles between chord and BCL nearest points and integrals thereof over the BCL characterize the degree of bubble bending and irregularity (Figures 3a, 3b, 3c). Chord orientation, for small instantaneous bubble deformations, informs one of rotational motion. In addition, one may derive thickness profiles for metal films separating agglomerated bubbles to study their interactions. All of this (and more) quantifies the effects of

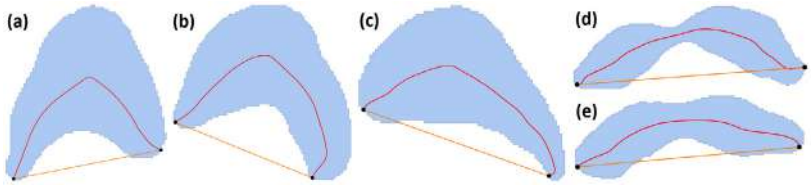

Figure 3: Bubble center lines (red) and principal chord lines (orange) derived using our shape analysis tool. Bubble shapes are represented by light blue areas.

varying flow rate or the degree of bubble confinement. In addition, high XTR frame rate (150 frames per second) allows us to obtain bubble velocity via simple linear velocimetry. Combined with derived shape parameters, analysis of bubble trajectories and envelopes thereof (computed using the statistics-sensitive non-linear iterative peak-clipping (SNIP) algorithm) we are able to construct various correlation curves which should help interpret bubble flow physics.

The approach presented herein is of high interest for subsequent studies of how applying different configurations of magnetic field (not necessarily static) affects bubble/bubble and bubble/flow interactions in liquid metal under geometric confinement because many aspects of these phenomena are currently unclear. Further work will allow us to establish relevant correlations of bubble/flow characteristics and infer physical mechanisms that govern bubble dynamics. Our shape analysis method is also easily applicable to neutron transmission radiography of gas/liquid metal systems [6, 7], but also beyond.

INTERNAL STRUCTURE OF FLOWS CONVEYING COARSE PARTICLES IN OPEN CHANNEL AND PRESSURIZED PIPE

Václav Matoušek[1,2]
[1] Department of Civil Engineering, Czech Technical University in Prague, Prague, Czech Republic
[2] Institute of Hydrodynamics, Czech Academy of Sciences, Prague, Czech Republic

Summary In many industrial applications (e.g. mining, dredging) or geomorphological applications (e.g. river control, stream restoration), transport of coarse solid grains in flow of water must be considered and evaluated. In order to assess the transport successfully, granular support mechanisms must be analyzed and their effect on the flow of the solid-liquid mixture quantified. Particle-laden flows carrying particles at high volume concentrations establish a layered internal structure and occur in the form of sliding-bed flows in pressurized pipes and in the form of sheet flows in open channels with mobile beds. Results and developments are discussed of our work on physical and mathematical modelling of such flows and their internal structures. The results include experimental observations from pipe- and flume set-ups in two laboratories in Prague. Furthermore, present and future activities are outlined of our research work in this field.

INTRODUCTION

In industrial slurry launders or in steep morphological streams with mobile beds, particles are transported at high concentration in flow of carrying liquid. If the transport is intense due to high shear stress applied at the top of the mobile bed, then the flow carrying particles over a plane surface of the eroded bed tends to develop a layered structure across the flow depth. It is typical for such a flow that particles are non-uniformly distributed across the flow depth and a transport layer develops through which the particles are transported above the bed. The distribution of particles is mutually related with the distribution of particle velocity and both are important for an identification of an internal structure of the flow. The particle distribution affects flow resistance and hence a relationship between the flow rate and the flow depth in the open channel flow.

Settling slurry flows in pressurized pipes exhibit very similar behaviour and a comparable internal structure of the flow as sediment-laden open-channel flows. It is of interest to study the two types of particle-laden flow in parallel and to analyse their similarities and differences.

EXPERIMENTS ON INTERNAL STRUCTURE OF PARTICLE-LADEN FLOWS

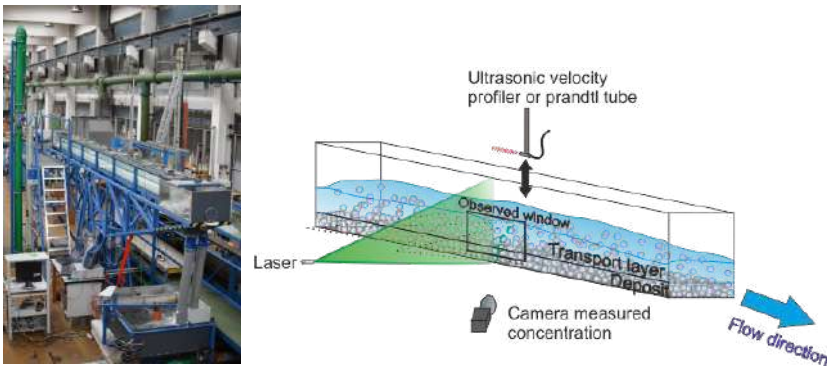

Figure 1. Sediment-transport tilting flume at Czech Technical University in Prague.

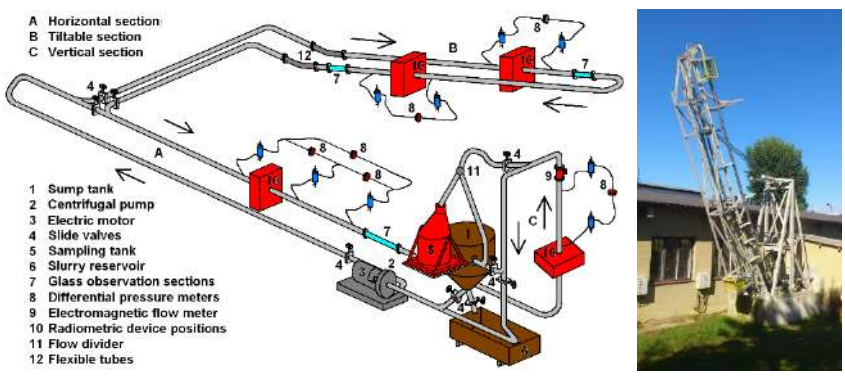

Figure 2 Slurry pipe loop at Institute of Hydrodynamics in Prague.

Our experimental works are carried out on two laboratory set-ups of very different geometries. Experiments in a recirculating tilting flume at the Water Engineering Laboratory of Czech Technical University in Prague produce distributions of flow velocity and sediment concentration along the flow depth (Figure 1) [1]. Our recent investigations focused on collisional transport and our present activities include testing of transport of combined load composed either of one fraction of sediment or of bimodal sediment. The other set-up is a slurry pipe loop (an internal diameter of the pipe is 100 mm) with an inclinable inverted U-tube at the Institute of Hydrodynamics in Prague. It allows to measure distribution of particles across the pipe cross section at various locations along the loop, including the inclinable sections (Figure 2). Our recent tests investigated an effect of a pipe inclination on the distribution of particles in flow of settling (sand-water) slurry. The experimental program continues with testing the effect of particle size distribution on settling slurry flow behavior.

OPEN-CHANNEL SEDIMENT-LADEN FLOW

Experimental information on an internal structure of sediment-laden flow from the tilting flume assists to validate simplified vertical distributions of granular velocity and concentration across the transport layer considered in our recent transport model for collisional load in sediment-laden open-channel flow [2]. The model employs constitutive relations based on the classical kinetic theory of granular flows. For given slope and depth of the flow, the model predicts the total discharge and the discharge of sediment, and the thicknesses of the water layer and of the transport layer with is frictional and collisional sub-layers. An extension of the transport model is work currently in progress and it aims on transport of combined load (combination of contact load and turbulent suspension load). The work includes an analysis of an ability of turbulent eddies to support locally grains at different locations within the transport layer [3].

PRESSURIZED-PIPE SLURRY FLOW

Recent experiments in the slurry pipe loop revealed an anomalous variation in distribution of particles in a settling slurry pipe if it was inclined to positive and negative angles (ascending and descending flows). It was shown that the anomalous behaviour affected the pressure drop in the inclined flow. Model tests revealed that this effect could be captured by our layered model for inclined settling slurry flows [4].

Our present project investigates a suitable granulometric composition of bimodal slurries with an aim to minimize energy costs of the slurry transport. The research is based on an identification and description of mechanisms governing interaction of two fractions in the bimodal slurry flow. A special attention is paid to the proportion of grain sizes and volume concentrations of individual fractions as well as to an effect of flow conditions on an optimization of design and operation of pipelines transporting heterogeneous slurries.

Furthermore, our present modelling efforts include works on a detailed description of pipe flow of fully suspended slurry, including its internal structure, using two-fluid modelling technique and its validation by experimentally determined distributions of particles in the suspension flow at different flow conditions (flow velocities and particles concentrations) [5].

CONCLUSIONS

Works are under way on mathematical and physical modelling of particle-laden flows transporting various fractions of particles in different flow geometries. Our recent results for open-channel sediment-laden flows include an analysis of a transport layer in which collisional support of the particles dominates. At present, a transport layer composed of combined load is studied and prevailing particle support mechanisms identified at local level within in the internal structure of the transport layer. In pipe slurry flows, recent investigations revealed variations in the internal structure of the settling slurry flow caused by changes in an inclination of the pipe. The present and near-future activities focus on sensitivity of the flow structure and flow behaviour on changes in a granulometric (narrow-graded versus broadly graded) composition of the transported fraction of particles.

FRONTIERS IN IMPACT EROSION MODELLING AND TESTING

Stefano Malavasi* , Gianandrea Vittorio Messa, Yongbo Wang, and Marco Negri
Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary The removal of material from solid surfaces due to the impingements of solid particles transported by a fluid, referred to as impact erosion, has been the subject of scientific research for long time due to the serious economic implications of this phenomenon. Owing to the fact that experiments are very costly and difficult-to-perform, since the last two decades there has been an increasingly use of numerical modelling based on Computational Fluid Dynamics (CFD) as an approach for impact erosion prediction. In this keynote, an overview of the state-of-the-art in impact erosion modelling and testing of impact erosion will be presented, with particular emphasis on the efforts made within our research group as well as on the open issues and challenges for future researchers.

Erosion is a general term denoting the removal of material from solid surfaces, which can occur in either a natural or a manmade environment and might be produced by different causes. Focus of the present keynote is a very specific type of erosion, called impact erosion, which is produced by the impingements of solid particles dragged by a carrier fluid. Researchers are intrigued by impact erosion, not only because its occurrence is a threat to the optimal design and management of engineering systems, with important economic implications, but also because of the complex multidisciplinary nature of this phenomenon, at the frontier between fluid and solid mechanics. From the solid mechanics perspective, the challenge is how to estimate the damage that a particle impinging against a surface is potentially capable to provide, which, broadly speaking, consists in establishing a functional relationship for the severity of erosion damage. Since pioneering studies [1-3], it has been agreed that erosion damage is the result of cutting wear, mainly occurring at low particle impact angles, and deformation wear, enhanced at high particle impact angles. Furthermore, it has been experimentally assessed [4,5] that the erosion damage is dependent upon the particle impact velocity, in the form of a power law with exponent generally higher than 2, and upon the particle impact angle, which plays a different role according to the mechanical behavior of the target material (brittle or ductile). Throughout the years, the functional relationship was extended by accounting for many other parameters, including material hardness, particle size and particle shape, and finally turned into empirical formulas called single-particle erosion models [6-8]. Such erosion models provide the basis for erosion prediction via Computational Fluid Dynamics (CFD), following a three-step procedure [8]. Firstly, the particle-fluid flow is calculated using an Eulerian-Lagrangian two-phase model, in which the fluid flow field is solved in an Eulerian, cell-based framework, whereas the motion of the solid phase is represented by tracking the trajectories of a certain number of computational particles. Secondly, the locations and velocities of the particles at their stage of impingement against the solid walls are stored. Thirdly, erosion models are applied to each particle-wall collision and the erosion damage is estimated. The reliability of erosion predictions does not depend only upon the accuracy of the erosion model, but also on that of the calculated particle-fluid flow field, especially close to the solid walls. This is the main challenge of impact erosion modelling from the fluid-dynamic perspective.

A number of research groups throughout the world have been and still are active in the study of impact erosion of hydraulic equipment, with different reference applications. For instance, the research carried out at the Erosion/Corrosion Research Center at the University of Tulsa, as well as in several other institutions in China and northern Europe, is focused on the erosion occurring in oil and gas production processes [8-10]. India and Switzerland have long tradition in the study of erosion in hydraulic turbines, which is a significant issue in the hydropower plants located in those areas owing to the presence of suspended sediment concentration and hard mineral particles in mountainous rivers [11,12]. Finally, it is noted that, in some applications, the removal of material brought about by the erosive action might not be an adverse effect but the key benefit. This is the case, for instance, of the abrasive slurry jet machining [13] for manufacturing processes or the sandblasting technique for cleaning operations [14].

Even our research group (FluidLab at Polimi) has put effort in providing a contribution to the field by trying to increase the reliability and accuracy of CFD-based erosion prediction, with particular interest on the impact erosion produced by liquid-solid slurry flows in industrial systems. Numerical modelling and experimental testing have been combined, the experimental data collected in two setups in the Hydraulic Laboratory of Politecnico di Milano being used to further understand the erosion process as well as to validate the CFD simulations. A preliminary achievement was the assessment of the how the various sub-models and parameters of a CFD-based erosion prediction model affect the erosion estimates, as discussed in the paper [15] referring to the benchmark case of slurry direct impact test. In addition, a significant part of our research has been aimed at developing methods to predict the impact erosion produced by flows with massive amounts of particles, which is not practically possible using the standard methodology due to the high computational cost of Eulerian-Lagrangian models. A mixed Eulerian-Eulerian / Eulerian-Lagrangian approach was first developed [16], in which the tracking of the particle trajectories was limited to the vicinity of wall boundaries, whereas the bulk flow field was solved using an Eulerian-Eulerian model. Later, the mixed Eulerian-Eulerian / Eulerian-Lagrangian was further improved by accounting for the nonlinear time evolution arising from the eroding surface changes [17]. This allowed improving the reliability of the wear estimates by overcoming another serious drawback of the existing methodology, that is, the assumption of steady-state erosion. As a distinctive character of our group, each modelling achievements have been

* Corresponding author. E-mail: stefano.malavasi@polimi.it.

immediately applied to the simulation of complex hydraulic equipment for real applications, such as flow control valves [16, 18, 19], injectors of Pelton turbines [20] and pumps used as turbines [21].

Despite the significant advancements achieved so far, there still exist many unresolved issues in the modelling of the impact erosion processes. For instance, the use of empirically derived single-particle erosion models taken from the literature is a considerable source of uncertainty, even more so when these models are applied outside their calibration conditions. Although some valuable work was done to overcome this issue by developing protocols for case-specific calibration of empirical erosion models [22], the use of physically derived erosion models, based on the laws of solid and damage mechanics, as recently explored at EPFL Lausanne [23], would provide a breakthrough in erosion modelling. Other challenges exist in the modelling of the particle-laden flow. These include, for instance, the modelling of quick particle-particle collisions and enduring inter-granular contacts, which are well known to play a significant role on the development of the wear process [24], and the modelling of the movement of the finite-size particles in the near-wall regions of the flow domain [25]. Finally, it is important to note that any activity of model development requires experimental data for validation. Big challenge is the accurate laboratory testing of impact erosion, especially in complex devices. In this regard, critical issues are the control and the accurate monitoring of the solid concentration in the system [26], and the need to avoid spurious effects related with the change in particle properties (e.g. size and shape) during the execution of the tests [27-29].

A UNIFIED THEORY OF PARTICLE DYNAMICS, THERMODYNAMICS, AND RHEOLOGY OF SOFT PARTICLE GLASSES

Roger T. Bonnecaze[1], Michel Cloitre [2], and Fardin Khabaz [3]
[1] McKetta Department of Chemical Engineering, University of Texas at Austin, Austin, TX, USA
[2] Molecular, Macromolecular Chemistry, and Materials, ESPCI Paris, CNRS, PSL University, 10 Rue Vauquelin, 75005 Paris, France
[3] Departments of Chemical and Polymer Engineering, University of Akron, Akron, OH, USA

Soft particle glasses (SPGs) are concentrated suspensions of deformable particles above the jamming transition. The particles can be microgels, emulsions, core-shell micelles and polymer-coated hard spheres. SPGs exhibit both solid- and liquid-like behaviour. An important challenge is the design of SPGs as additives to impart yield stress and shear-thinning rheology for a range of applications. Here we present a unified theory to do so that connects the particle dynamics, a newly discovered thermodynamics, and the rheology of SPGs. Remarkably, it is also found how to determine multiple dynamical properties from a single dynamical measurement. For example, microrheological measurements of shear diffusivity can predict the shear stress and first and second normal stress differences.

INTRODUCTION

Soft particle glasses (SPGs) are amorphous materials composed of deformable particles jammed at volume fractions beyond close-packing where they are in contact and interact through elastic forces. They include many systems of practical interest such as concentrated emulsions, microgel pastes, micelles, or star polymer solutions. In SPGs each particle is constrained in a cage by elastic forces and cannot move over long distances unless an external stress larger than the yield stress is applied. The flow curve that relates the shear stress to the shear rate is well described by the generic Herschel-Bulkley equation [1]; the first and second normal stress differences follow similar relations. An open and important question concerns the physical origin of these empirical equations and their connection with the particle scale dynamics of SPGs.

Another important challenge is to minimize the number of experiments used to characterize SPGs. There are several important rheological properties for SPGs, such as the flow curves relating shear stress and first and second normal stress differences to shear rate. The measurement of normal stresses is particularly challenging. It is also advantageous to develop microrheological measurements of SPGs, requiring smaller samples, which can be done in parallel on many different formulations at high throughput. For example, it would be useful to determine the first and second normal stress differences from measurements of the shear stress flow curve or to determine all the shear and normal stress flow curves from measurements of the shear-induced diffusion. Interestingly, a thermodynamic theory for SPGs under shear exists. Like all thermodynamic theories, it provides a means to connect one measureable parameter to another, such as shear stress to second normal stress differences or diffusivity to shear stress.

The aim of this paper is to provide a unified theory that connects the particle dynamics and thermodynamics of SPGs to their dynamical and rheological properties. In doing so, the interconnection among these properties is illuminated. Finally, while the theory is presented for SPGs, we discuss how it can be used for other colloidal systems.

METHODOLOGY

The details of the model and the simulation method have been presented in previous studies [1]. Briefly, the important features are the following. Soft particle glasses are modeled as suspensions of N non-Brownian elastic particles in a solvent with a viscosity, which are jammed in a cubic simulation box at volume fractions larger than the random close-packing of hard spheres (Fig. 1). $N = 1000$ in most of the simulations reported in this work and we checked that the results are not affected by finite size effects. Suspensions with an average radius of unity, polydispersity index of 0.2, and volume fractions of 0.7, 0.8 and 0.9 are studied. The value of the polydispersity agrees with that currently found in experiments, and it prevents crystallization at high shear rates [2]. Because the particles are compressed, they have a polyhedral shape with flat facets at contact instead of their initial spherical shape. We have shown that these elastic contacts are central to the rheological properties of SPGs [1,2]. The excess entropy is computed using the two-body approximation [3].

RESULTS

The steady-state dimensionless shear stress σ/σ_y and first and second normal stress differences N_1/σ_y and $-N_2/\sigma_y$ is plotted against the dimensionless shear rate $\dot{\gamma}\eta_s/G_0$ in Fig. 1. Suspensions show a yield behavior at very low shear rates, and then by increasing the shear rate they start flowing. Note that σ_y is the shear yield stress and G_0 is the low frequency shear modulus. The particle dynamics can also be measured for similar situations. Fig. 2 presents the shear diffusivity as a function of the shear rate and the excess entropy of the system. In fact a thermodynamic relationship is shown to exist between the shear and normal stresses and the excess entropy. Thus, we show these dynamical properties fall onto a

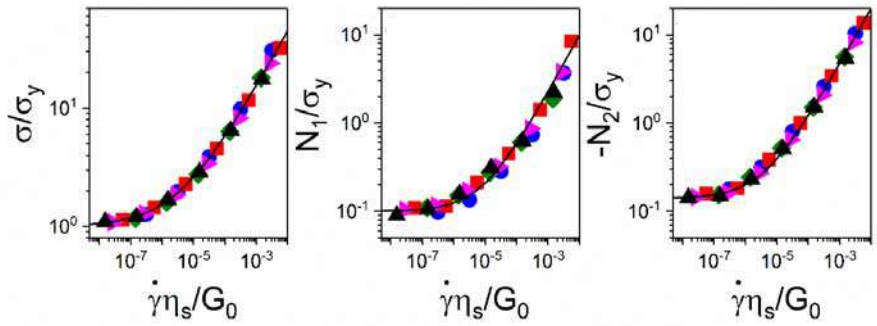

Fig. 1. Shear stress and first and second normal stress differences versus shear rate.

master curve of the shear stress normalized by the yield stress. In Fig. 3a the diffusion coefficient is plotted as a function of the shear stress. The diffusion coefficients of SPGs increase with the applied shear stress and show a universal behavior. Furthermore, the first and second normal stress coefficients, $\Psi_1(G_0/\eta_s)^2$ and $-\Psi_2(G_0/\eta_s)^2$, plotted against the shear stress in Fig. 3b and Fig. 3c also show the collapse onto a master curve. Note that $\psi_1 = N_1/\dot{\gamma}^2$ and $\psi_2 = N_2/\dot{\gamma}^2$, respectively. Thus, from the measurement of the shear stress flow curve, the shear diffusivity and the two normal stresses can be determined. Remarkably, the measurement of any one of the four dynamical properties (i.e., diffusivity, shear stress or viscosity, and first and second normal stress coefficients) allows one to determine the other three.

CONCLUSIONS

We show that the particle dynamics, in the form of shear-induced diffusion, is related to the excess entropy of SPGs. In addition rheological properties of the SPGs are also related to the excess entropy and other thermodynamic descriptors. From this, one interrelate shear-induced diffusion, shear stress and first and second normal stress differences.

YIELDING AND FLOW INHOMOGENEITIES IN SOFT SOLIDS

Emanuela Del Gado * [1]
[1] Department of Physics and Institute for Soft Matter Synthesis and Metrology, Georgetown University, Washington DC, USA.

Summary Soft condensed matter (proteins, colloids or polymers) easily form gels or other amorphous soft solids, where rigidity emerges in diverse structures with a variety of mechanical features. Examples include glass, cement, compacted sand, and even yogurt or chocolate mousse. Through the interplay between their microstructure with an imposed deformation, these materials can be stretched, flow, squeezed or fractured. Controlling and being able to design such processes is of paramount importance in a number of technologies, such soft inks for 3D printing technologies or self-healing materials for soft robotics. I will give an overview of our work on yielding of soft materials, in particular focusing on particle gels and jammed emulsions, where a major challenge is the emergence of persistent flow inhomogeneities.

INTRODUCTION

Soft solids such as densely packed emulsions or dilute particle gels yield and eventually flow under an imposed shear deformation, a feature important for materials from wet cement to food, paint or pharmaceutical products. Controlling the flow properties upon yielding is tough, since the evolution towards the steady-state is often accompanied by strong spatial inhomogeneities, where only part of the material flows while the rest stays jammed. Such phenomenon is called shear banding and has been known for many decades to geologists and engineers, but the question of what favors the stress accumulation and the persistence of flow inhomogeneities upon yielding is fundamentally unanswered.

A consistent theoretical description of the fundamental physical mechanisms that control yielding in such materials is challenging and is a topic of intense debate. Flow induced structuring or ordering transitions may underlie the development of bands flowing at different rates in various complex fluids, and may be affected by effective interactions between molecules, particles or droplets. For soft glassy solids, the flow inhomogeneities delaying the fluidization are thought to emerge from the relaxation of stress heterogeneities elastically stored in the material during the stress overshoot.

MODELS, NUMERICAL SIMULATIONS AND RESULTS

We have designed 3D numerical simulations of soft spheres models, with size polidispersity and in athermal conditions, and of soft dilute particle gels, which are more sensitive to thermal fluctuations. In the simulations, we consider different types of drag coefficients and compare the results obtained using Lees-Edwards periodic boundary conditions with the case in which the same model solid is confined between two walls. We find that the presence of a stress-overshoot and of transient shear banding for large enough samples are a robust feature for overdamped systems. We have characterized the linear response of the material initially subjected to oscillatory rheology and then investigated the yielding behavior of samples of different sizes and aged in different ways. We have also performed an investigation of the microscopic structure, the local packing, the local velocity profile as well as stress and strain localization. We combine these studies with quantitative analysis of the evolution of the shear banding into the steady state flow of the material.

CONCLUSIONS

Understanding the emergence and persistence of flow inhomogeneities in soft amorphous solids requires investigating the stress heterogeneities frozen-in during the material solidification and depending on the material history. Stress localization that preceeds the onset of flow inhmogeneities can be traced back to microstructural features that can be different for different materials, but common underpinnings can be identified in the local and global microscopic mechanical constraints developed in the microstructure at rest and under flow.

CONTRIBUTIONS OF TURBOPHORETIC AND DIFFUSIVE FLUXES TO PARTICLE TRANSPORT IN A TURBULENT SMOOTHWALL PIPE

Tony Zahtila * , Leon Chan, Andrew Ooi, and Jimmy Philip
Department of Mechanical Engineering, The University of Melbourne, Victoria, Australia

Summary In order to understand the wall-ward motion of particles in a turbulent pipe flow, we carry out direct numerical simulations of particles with different Stokes number and model the evolution of particle concentration via a 1D advection-diffusion equation. Employing the DNS data, wall-directed particle number flux that is inhomogeneous in the wall-normal direction is decomposed into a convective turbophoretic flux and a flux due to turbulent diffusivity. Diffusivities for both turbophoretic and diffusive components that are functions of radial distances are employed in an advection-diffusion equation to estimate the particle migration with time, the solution of which is then compared with the DNS particle concertation evolution, and we obtain reasonable agreements. Our findings provide further support to the modelling of particle migration based on the Reynolds averaged equations [1].

INTRODUCTION

The accumulation of particles at solid walls in turbulent pipe flows, where the particle distribution was uniform at the beginning, is a well-known phenomena, arising as a result of the interaction between particle inertia and fluid turbulence. A considerable amount of experimental data [2] in vertical tubes and channels exist which measure particle deposition to surfaces. For $St^+ < 1$, particles only slowly deposit and persist in an even distribution from wall to centreline, however, this quite small deposition increases by orders of magnitude when the dimensionless particle relaxation time increases from $St^+ = 1$ to $St^+ = 10$. Here, $St^+ = \tau/(\nu/u_\tau^2)$, where τ is the Stokes particle relaxation time and superscript $+$ indicates viscous normalization with ν and u_τ, the kinematic viscosity and friction velocity in turbulent wall flows. Beyond $St^+ = 30$, there is a moderate decrease observed in deposition, as these particles' inertia is now sufficient to pass through eddies. More recently, direct numerical simulation of particles in channels [3] showed near-wall concentration peaks over a thousand times the centreline concentration for populations of $St^+ = 10, 50$ and 100.

Prediction of concentration profiles for particles suspended in gas is sought after for efficient delivery of aerosol medications, development of particle based solar receivers and is widely relevant in chemical processing, where quality of the final product often requires particle removal. Recently, particle wall-normal velocity variance determined from DNS carried out in a turbulent channel flow was found to be sufficient to predict steady-state concentration profiles [4]. They show that the dominant effect for heavy particles was turbophoresis, and for lighter particles an additional biased sampling term is required. The present analysis, however, seeks to determine whether it is possible to predict the instantaneous wall-directed flux profile, which evolves as concentration gradients form due to local depletion and accumulation of particles. Knowledge of this instantaneous flux profile would allow for the fast computation of particle concentration profiles as they evolve in time.

NUMERICAL SIMULATIONS AND MODEL DEVELOPMENT

In this study, the Euler-Lagrangian method is used to conduct particle laden point-particle direct numerical simulations (PP-DNS). The fluid is represented by the incompressible Navier-Stokes equations which were solved using the finite volume method. Particles in the simulation were individually represented as points, with particle acceleration computed from the particle relaxation time, as well as, the slip velocity between the particle velocity and the sampled fluid velocity, is represented using the Stokes' drag. Simulations were conducted of a turbulent friction Reynolds number, $Re_\tau = (u_\tau R)/\nu = 180$ pipe flow, with R the pipe radius, laden with four sets of inertial particles with relaxation times, $St^+ = 0.1, 1, 10$ and 100. Each particle set was represented by two million one-way couples particles which collide fully elastically with walls.

Towards the development of a 1D model for the particle concentration ($C*$, where $*$ represents normalisation by the bulk concentration), we calculate particle fluxes as particles cross imaginary surfaces with wall normal spacing of $\Delta y^+ = 4.5$ (as depicted in Figure 1). They are counted across eight hundred snapshots in time and at each snapshot, the local particle concentration and gradient is known. Profiles for turbophoretic and diffusive flux are thus determined from the DNS data. Features of the turbophoretic profile are a monotonic increase from wall to approximately $y^+ = 30$, and then, a monotonic decrease thereafter to the centreline. Broadly, this profile can be interpreted as the mean radial velocity of the particle. The diffusive profile, increasing sharply until approximately $y^+ = 60$ and thereafter moderately decreases, is thought to correspond to the particle radial turbulent fluctuations. These profiles, in part, validate a previously suggested Eulerian description [1] that explained the different deposition regimes across particle sizes, obtained through Reynolds averaging of the particle mass and momentum equations.

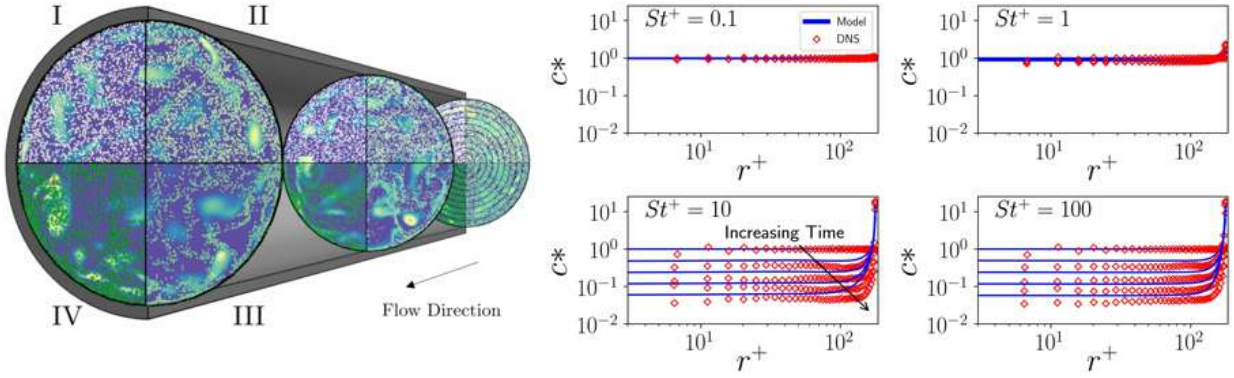

Figure 1: (Left) Visualization of streamwise vorticity and four particle populations ($St^+ = 0.1, 1, 10, 100$), corresponding to quadrants I - IV respectively, at three subsequent snapshots in time, $t^+ = 0, t^+ = 180$ and $t^+ = 360$. Particles are injected uniformly into a fully developed turbulent pipe and the dark rings in the right-most slice represent the imaginary surfaces across which particle fluxes are counted. (Right) Comparison of predicted particle concentration profiles ($C*$) with the DNS obtained results for 5 instances in time, $t^+ = 0$, $t^+ = 900, t = 1800, t^+ = 2700$ and $t^+ = 3600$.

RESULTS

With empirically determined turbophoretic and diffusive profiles, an unsteady one-dimensional advection-diffusion equation is formulated. The equation is solved in finite volume form, in order to impose realistic boundary conditions of no-flux at the wall so that particle number is conserved exactly. The solution is calculated for the same length of time as the DNS, and with the same initially uniform concentration profile as in DNS. The evolution of the particle concentration profiles show fair agreement with those obtained from DNS, and are shown in Figure 2 (with near wall peak concentration within 10% error). As concentration profiles change with time, the separate and evolving contributions of turbulent diffusivity and turbophoresis reveal that increasingly sharp near-wall gradients increasingly oppose the wall-directed convective tendency.

Mechanistically, we observe that low relaxation time particles ($St^+ = 0.1$) sample stream-wise turbulent events in the viscous region ($y^+ < 5$) without bias, however, organisation into streaks is apparent for the remaining cases. Further, sampling of stream-wise vorticity reveals that distinct regimes occur in the segregation of particles (cf. Figure 1). Low relaxation time particles ($St^+ = 0.1$) evenly sample regions of high/low stream-wise vorticity, however there is increasing curvature-fleeing observed across ($St^+ = 1, 10$); and finally, the highest relaxation time particles exhibit segregation but not necessarily with the instantaneously sampled vorticity, suggesting their inertia is significant enough to filter fluid motions. Particle-turbulence interaction has previously been studied in terms of the coherent motions of turbulence, particles able to trace the flow have wall-ward motion that is strongly correlated with the coherent sweeps and ejections of turbulence [5], an effect that becomes complicated with increasing particle inertia. We observe, for instance, $St^+ = 0.1$ particles at $y^+ = 30$ sampling a strong Q2 ejection fluid event yield 99% probability that particle velocity is directed away from the wall, however, this statistic decreases to 70% probability of wall-fleeing for $St^+ = 100$ particles, revealing a decrease in efficiency of the turbulent fluid mechanism to transport particles away from walls.

SUMMARY

In summary, we directly evaluate the turbophoretic and diffusive flux from the DNS of a turbulent pipe flow, and employ these fluxes in a 1D advection-diffusion equation for particle concentration. This model shows reasonable agreement with DNS data. This also gives credence to the Reynolds averaging procedure used in the literature, which can predict the experimentally and numerically observed results for the wall-normal transport of particles. Current work is further aimed at pinpointing the 3D mechanisms in wall turbulence that contribute to the tendency for particles to migrate towards, in particular, quantifying particle-eddy interaction and momentum transport mechanisms as particles increase in inertia.

INERTIAL FOCUSING OF SPHERICAL PARTICLES SUSPENDED IN SQUARE CHANNEL FLOWS

Masako Sugihara-Seki[1, 2], and Hiroshi Yamashita [1]
[1] Department of Pure and Applied Physics, Kansai University, Osaka, Jana
[2] Graduate School of Engineering Science, Osaka University, Osaka, Japan

Summary The inertial migration of spherical particles suspended in square channel flows was investigated experimentally and numerically to obtain the particle focusing positions in the downstream cross-section of the channel. The particle focusing patterns were found to be classified into four types for the ratio of the particle diameter to channel width ~ 0.1; in the regime of the lowest Reynolds numbers, particles were focused on the centre of channel faces (channel face equilibrium position (EP)); in the second and third regimes, additional focusing points were located on intermediate positions symmetric relative to the diagonal (intermediate EP) and on the diagonal near the corners (channel corner EP); in the last regime, they were focused on the channel face EPs and the channel corner EPs. The transitions between neighbouring regimes were described in terms of the bifurcation of EPs.

INTRODUCTION

It has been long known that spherical particles suspended in circular tube flows cross streamlines towards an annulus of 0.6 times the tube radius at low Reynolds numbers (Re) [1]. This focusing phenomenon, referred to as the Segre-Silberberg effect, originates from the inertial effect and has recently gained considerable attention in the field of microfluidics due to the broad range of applications, such as in the separation and filtration of particles and biological cells [2, 3]. In microfluidics, channels of rectangular cross-sections, rather than circular cross-sections, are commonly used. Particles suspended in rectangular channel flows were focused on several discrete points in downstream cross-sections. In particular, spherical particles in square channel flows were observed to approach four points at the centre of channel faces at low Re (<100) [3]. The focusing points and their number in the cross-section vary depending on Re and the ratio of the particle diameter to channel width (size ratio) [4]. In the present study, we investigated experimentally and numerically the variation of the focusing points of neutrally buoyant spherical particles suspended in the square channel flow in the wider range of Re for various size ratios.

METHODS

Experimental methods

Details of the experimental method were described elsewhere [5, 6]. Briefly, polystyrene spherical particles with several ten μm in diameter and 1.05×10^3 kg/m^3 in density were suspended in a glycerol-water solution at a volume fraction of ~10^{-2} %. This suspension was made to flow through a horizontally placed borosilicate square tube of several hundred μm in width by use of a syringe pump. The tube cross-section about 2–3mm upstream of the outlet was observed from the downstream side using a high-speed camera equipped with a long working distance objective. The obtained images were analysed with the public domain software ImageJ to yield the positions of the particle centre in the tube cross-section.

Numerical methods

In the numerical simulation, we considered the motion of a single rigid spherical particle suspended in a pressure-driven flow of a Newtonian fluid through a square channel. The particle was assumed to be neutrally buoyant. The computational method was presented previously [7, 8]. Briefly, we adopted the immersed boundary method for multiphase flows proposed by Kajishima et al. [9]. Using a periodic boundary condition in the main flow direction, we obtained the flow field by a fractional step method, and evaluated the lateral velocity of the particle or the lateral force exerted on the particle.

RESULTS AND DISCUSSION

Figure 2 shows representative examples of the experimental results for the particle distribution over the channel cross-section at various Re for $d/D = 0.125$ and $L/D = 750$, where d, D and L represent the particle diameter, channel width and channel length, respectively. The positions of at least 350 particles were detected in the cross-section and their centre positions are represented by dots in each figure. Figures 2(a) – (d) show four types of the particle focusing pattern. Their Re regimes are called regime A, B, C and D, respectively. Figure 2 indicates the presence of three types of equilibrium positions (EPs): channel face EPs located at the centre of channel faces, channel corner EPs located on the diagonal near the channel corners, and intermediate EPs located at intermediate positions symmetric with respect to the diagonal. In regime A, the particle focusing positions are channel face EPs (figure 2(a)); in regime B, intermediate EPs are added as the focusing position (figure 2(b)); in regime C, channel corner EPs are added (figure 2(c)); in regime D, particles are focused on the channel face EPs and the channel corner EPs (figure 2(d)).

The present numerical computation confirmed these particle focusing patterns. Figure 3 represents the azimuthal angle of EPs, θ_e, in the first quadrant of the cross-section obtained numerically. The horizontal lines at $\theta_e = 0$ and $\pi/2$ represent

the channel face EPs, the horizontal line at $\theta_e = \pi/4$ represents the channel corner EPs, and the other lines represent the intermediate EPs. Solid lines indicate stable EPs, and dotted lines indicate saddle EPs. Note that the centre of the cross-section is an EP, but it is always unstable.

Figure 3 shows that there are three critical Re, i.e., Re_{c1}, Re_{c2}, and Re_{c3}, between regimes A and B, B and C, and C and D, respectively. At $Re = Re_{c1}$, a pair of saddle and stable intermediate EPs (IME_1, IME_2) emerge, corresponding to a saddle-node bifurcation. At $Re = Re_{c2}$, the channel corner EP is changed to be stable accompanying the emergence of saddle intermediate EPs (IME_3), corresponding to a pitchfork bifurcation. At $Re = Re_{c3}$, IME_2 and IME_3 merge and disappear, corresponding to a saddle-node bifurcation. The positions of EPs obtained experimentally and numerically nearly agreed with each other. The critical Re values were comparable, but the values obtained numerically were slightly lower than those obtained experimentally in the case of $d/D = 0.125$.

For larger size ratios, another type of the focusing pattern was observed such that the particles were focused on the channel corner EPs at low Re. For even larger size ratios, we found a direct transition between regime A and regime D, i.e., disappearance of regimes B and C. These variations of the particle focusing pattern can be summarized in the wide range of Re for various ratios of the particle diameter to channel width.

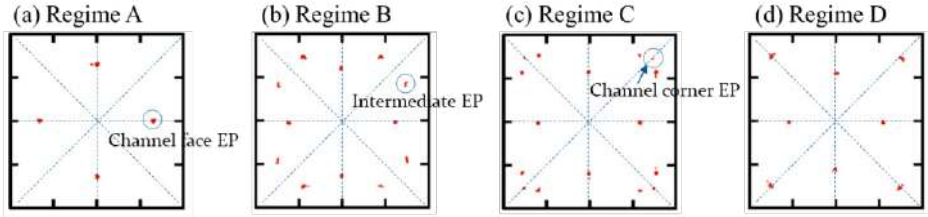

Figure 2. Typical particle focusing pattern in each regime obtained in experiments at Re = (a) 100, (b) 300, (c) 350, and (d) 450, for $d/D = 0.125$ and $L/D = 750$.

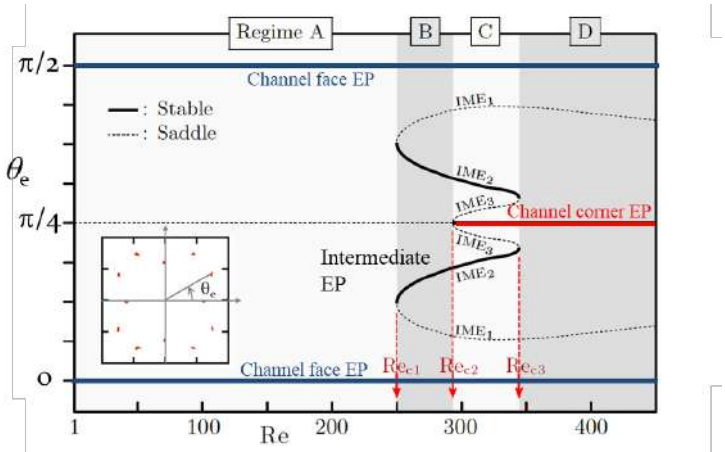

Figure 3. Azimuthal angle of equilibrium positions for spherical particles in square channel flows obtained numerically ($d/D = 0.125$).

CONCLUSIONS

The inertial migration of spherical particles suspended in square channel flows was investigated experimentally and numerically. The particle focusing patterns in the channel cross-section were described as a function of Re and size ratio.

SPREADING OF GRANULAR SUSPENSIONS: SCALE-DEPENDENT DISSIPATION

Menghua Zhao[1], Alice Pelosse[1], Matthieu Oléron[1], Laurent Limat[1], Elisabeth Guazzelli[1], and Matthieu Roché[1]
[1] *Laboratoire Matière et Systèmes Complexes, Université de Paris, CNRS UMR 7057, Paris, France*

Summary We report the results of an investigation of the spreading of granular suspensions on the surface of a solid. We find that the apparent viscosity of these Newtonian bulk suspensions extracted from the characterization of the motion of the line of contact between the suspension, the solid and the atmosphere depends on the size of the particle. This observation is in contrast to the particle-size independence of the apparent bulk viscosity. We show that particles are repelled from the immediate vicinity of the contact line. We discuss the insights that models of spreading flows of suspensions relying on a purely geometric exclusion of the particles close to the contact line provide.

INTRODUCTION

Granular suspensions are obtained by dispersing solid particles with diameters $d_p >> 1$ µm in a suspending liquid. Examples of these complex fluids include concrete and mortar, mud, blood and landslides. The study of the mechanics of these materials is still a very active field, and scientists have now a good understanding of the relation between the flow of these liquids and their formulation. For example, rigid particles dispersed at high volume fractions in Newtonian suspending liquids and experiencing hard-core repulsion only form suspensions that are Newtonian in the bulk [1].

Most models of these materials assume that they behave as an effective medium. This assumption breaks down when the characteristic size $\mathscr{L}$ of the flow becomes comparable to d_p. In this case, much less is known. The viscosity of even dilute suspensions increases as the confinement ratio $\beta = \mathscr{L}/d_p$ decreases [2], and oscillates when $\beta \sim 1$ [3].

Corner flows such as that occuring during the spreading of a droplet on a solid surface in a surrounding atmosphere are examples of flows where $\beta \to 0$. In these flows, the liquid/fluid interface makes an angle θ_{app} with the solid/liquid interface at the contact between the three phases (Fig. 1). For a liquid of viscsotiy η and surface tension γ, the value of θ_{app} is related to the ratio of the capillary stress and the viscous stress, *i.e.* the capillary number $Ca = \eta U_{CL}/\gamma$, by the Cox-Voinov equation [4]:

$$\frac{\theta_{app}^3}{9} = \frac{\theta_m^3}{9} + Ca \ln\left(\frac{x}{\ell}\right) \tag{1}$$

where θ_m is a microscopic contact angle, x is the distance from the contact line at which θ_{app} is measured and ℓ is a microscopic length scale introduced to circumvent stress divergence at the contact line. Here, we show that the apparent viscosity of model neutrally-buoyant suspensions extracted from spreading experiments depends on particle size d_p, in contrast to their bulk apparent viscosity. We bring evidence that this observation results from the existence of a particle-depleted region in the vicinity of the triple-phase contact zone. We discuss the validity of a geometric origin for the observations and indicate perspectives.

MATERIALS AND METHODS

We use polyethylene glycol-ran-propylene glycol monobutyl ether (PEG-ran-PPG ME, Sigma Aldrich, density $\rho_0 = 1056\,\mathrm{kg\,m^{-3}}$, surface tension $\gamma_0 = 35\,\mathrm{mN\,m^{-1}}$) as the suspending fluid. We account for the temperature dependence of its viscosity in the analysis of the data. We use polystyrene beads (Microbeads Dynoseeds TS, average particle diameter $10 \leq d_p \leq 550$ µm, density $\rho_p = 1050\,\mathrm{kg\,m^{-3}}$), carefully dispersed in PEG-ran-PPG ME in a beaker to obtain homogeneous neutrally-buoyant suspensions having volume fractions varying in the range $20 \leq \phi \leq 40\%$. The surface tension of these mixtures is equal to that of PEG-ran-PPG ME [5] and their rheology is well documented [5–8].

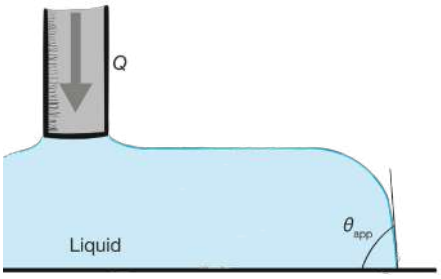

Figure 1: Sketch of the experimental set-up.

We release droplets of suspensions on the surface of a silicon wafer using a steel needle (Vita Needles, inner diameter $d_i = 4.58$ mm) connected to a syringe pump (Harvard Apparatus PHD ULTRA) (Fig. 1). The surface of the wafer is cleaned with acetone, ethanol, and water prior to each experiment using a clean-room cloth. We track the axisymmetry of spreading drops and make sure thant contact angles are measured in this regime. Movies of the side-view spreading of the drop are captured with a digital camera. Contact angles are measured using FiJi. We also record top-view movies to characterize the suspension behavior close to the contact line.

OBSERVATIONS

The apparent shear viscosity η_s of the suspensions we use is proportional to that of the suspending liquid η_0:

$$\eta_s = f(\phi, \phi_c)\eta_0 \tag{2}$$

with $f(\phi, \phi_c) = \left(1 + \frac{5\phi}{4(1-\phi/\phi_c)}\right)^2$ an empirical prefactor, following Eilers' definition [1].Thus, we propose to compare measurements of the apparent contact angle θ_{app} for suspensions with those for the suspending liquid. Following Eq. 2, and plotting data against the capillary number defined on the properties of PEG-ran-PPG ME, we expect to observe parallel $(Ca, \theta_{app}^3/9)$ curves, distinguished by a shift that should account for Eilers' prefactor. Figure 2a and b shows that experiments do not confirm this expectation. We obtain cirves that are indeed parallel to that of the suspending liquid, but their shift depends on particle size.

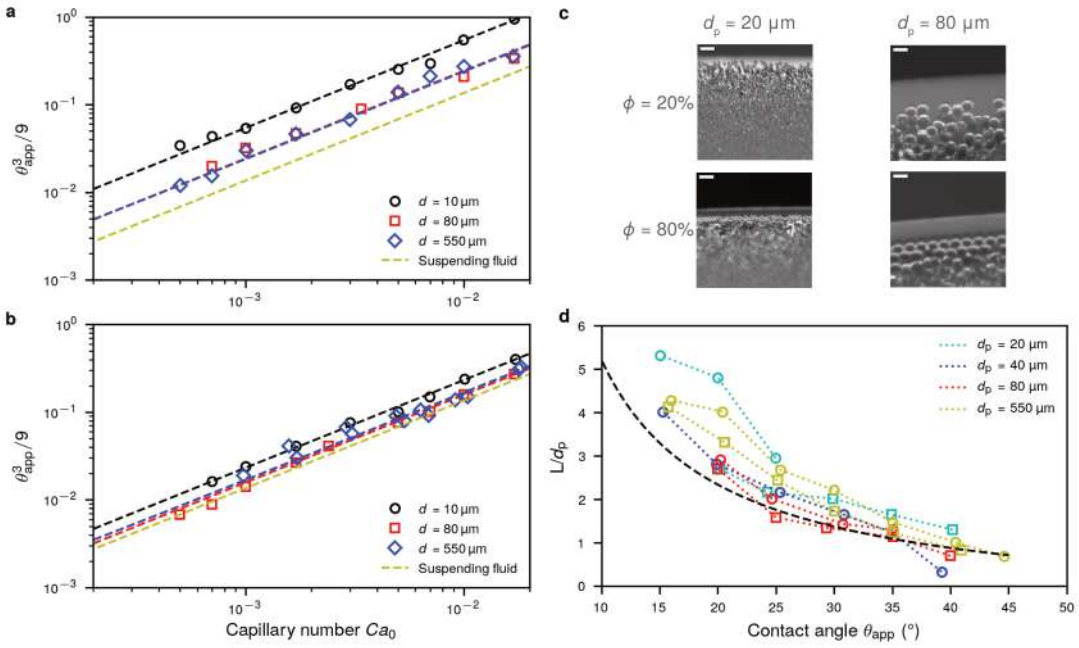

Figure 2: Dependence of the apparent dynamic contact angle θ_{app} on the capillary number Ca_0 of the experiment defined with the properties of the suspending liquid for (a) $\phi = 40\%$ and (b) $\phi = 20\,\%$. (c) Close-up top views of the region around the moving contact line showing the particles and the depeleted region. (d) Size of the depleted region L scaled by particle diameter as a function of the apparent contact angle. Dashed line: geometric predicition.

A look at the moving contact line from the top shows that the region in the immediate vicinity of the triple-contact region is depleted in particles (Fig. 2c). The extent L of this depleted region is a function of d_p (Fig. 2c). However, it seems that geometry may not be enough to explain the apparent viscsosity that we measure.

We are currently working on modelling this problem and discussing the extent to which a simple geometric approach is successful.

CONCLUSIONS

The study of the spreading of Newtonian granular suspensions has received little attention until now. However, simple experiments show that these liquids spread in an unconventional fashion, with a viscosity that is dependent on the size of the particles. These results lead to interesting questions related to the importance of confinement in the flow of suspensions, how bidisperse systems behave, how the shape of the interface evolves spatially, and finally how spreading occurs.

THERMOKINETIC MODEL FOR COMPRESSIBLE MULTIPHASE FLOWS

Ehsan Reyhanian, Benedikt Dorschner, and Ilya Karlin*
Department of Mechanical and Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

Summary We propose a novel kinetic theory to simulate compressible multiphase flows. The model is thermodynamically consistent and thus inherently able to capture the real gas effects. In combination with complete Galilean invariance through adaptively created particles, our model removes the typical restrictions of conventional kinetic methods, such as the lattice Boltzmann method. Owing to full energy conservation, simulations of compressible-multiphase flows are presented for the first time within this framework. Different benchmarks associated with real-gas thermodynamics illustrate the large range of compressible-multiphase problems this model can handle.

INTRODUCTION

The lattice Boltzmann method (LBM) is a kinetic-based approach for the simulation of hydrodynamic phenomena with applications ranging from turbulence to micro and multiphase flows. The fully discretized kinetic equations evolve particle distribution functions (populations) $f_i(\boldsymbol{x}, t)$, associated with a set of discrete velocities $\boldsymbol{c}_i$ according to a simple stream-and-collide algorithm and recovers the Navier-Stokes equation in the hydrodynamic limit. Efficiency of LBM and its ability of dealing with various types of flow and complex geometries have drawn considerable attention.

While various LBM formulations have been proposed for real gases, it is most common to include non-ideal gas as well as capillary effects by an additional force term in the Boltzmann equation. However, validity of conventional LBM is restricted to low Mach numbers or isothermal incompressible flows. Thus, developing an energy-conserving scheme to model high-speed real-gas flows has remained an unresolved issue within the LBM framework.

Recently, the so-called "Particles on Demand for Kinetic Theory" or "PonD" [1] has been introduced, which removes these limitations by defining adaptive sets of microscopic velocities. In PonD, the conventional discrete velocities $\boldsymbol{c}_i$ are regarded as relative velocities with respect to local reference of frame $\boldsymbol{u}, \theta$, where $\boldsymbol{u}$ is the local velocity of the fluid and θ is the temperature, reduced by the lattice temperature, a quantity known for any lattice. The most important consequence of this definition is that the local equilibrium eliminates the Galilean invariance errors and takes a simple yet exact form $f_i^{eq} = \rho W_i$, where weights W_i are constants defined for every set of discrete speeds. This is in contrast to LBM, where a truncated polynomial of the equilibrium distribution function around zero velocity and the lattice temperature is used.

Similarly, we propose to define the velocity sets such that the real gas effects are taken into account. The thermodynamic consistency of the proposed scheme allows us to span a wide range of real-gas phenomena such as super-critical flows, throttling, phase segregation and shock-interface interaction. The relative simplicity of the model and its ability to model the interfacial and phase thermodynamics such as phase-separation and surface tension, make it a promising method compared to its counterparts in the field of fluid dynamics. We start by defining the following particle velocities:

$$\boldsymbol{v}_i = \sqrt{\frac{p}{\rho T_L}}\boldsymbol{c_i} + \boldsymbol{u}, \tag{1}$$

where p is the thermodynamic pressure equation of state (EoS), ρ is density and T_L is the the lattice temperature. Equation (1) thus constructs particles, which are moving relative to the reference frame $\lambda = \{\boldsymbol{u}, \theta\}$ where $\theta = \dfrac{p}{\rho T_L}$. The immediate outcome of this definition is that the ideal gas pressure in the stress tensor is now replaced by the real gas pressure.

The evolution of the flow field is governed by the kinetic equations for the two sets of populations, f_i and g_i. The former maintains the density and momentum, while the latter is adopted to conserve energy. Local conservation of density, momentum and total energy can be evaluated as $\{\rho, \rho\boldsymbol{u}, 2\rho E\} = \sum_{i=1}^{Q}\{f_i, f_i\boldsymbol{v}_i, g_i\} = \sum_{i=1}^{Q}\{f_i^{eq}, f_i^{eq}\boldsymbol{v}_i, g_i^{eq}\}$ where Q is the number of discrete velocities. The populations are evolved in time and space in two steps: First, the semi-Lagrangian advection is performed, where the populations at off-lattice points are streamed along the characteristic $\boldsymbol{x} - \boldsymbol{v}_i\delta t$ to the point $(\boldsymbol{x}, t)$, where δt is the time step [1]. Second step is the collision and we use the classical BGK approximation. While the method applies to a generic EoS, we have adopted the van der Waals EoS in the results presented below.

RESULTS AND DISCUSSION

In this contribution, we shall demonstrate a wide range of thermodynamics that can be addressed with such a generic approach. Exemplarily, we show two benchmarks below.

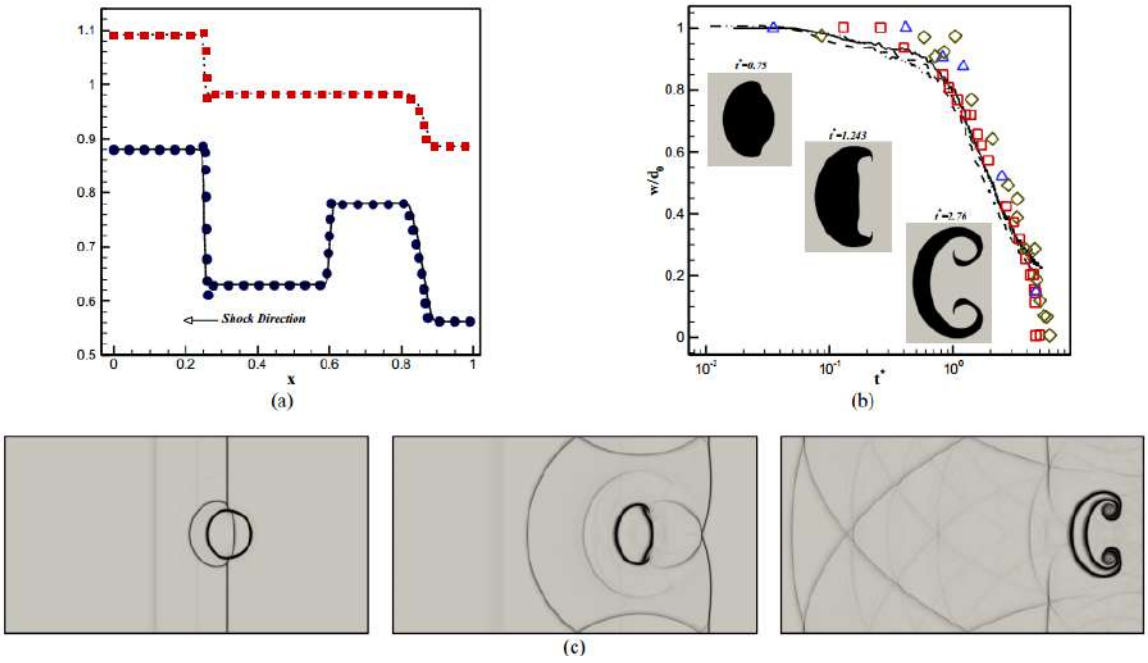

Figure 1: (a) Simulation of an anomalous shock in the van der Waals fluid, $\delta = 1/C_v = 0.0125$. Initial conditions: $(p_{\mathrm{L}}, \rho_{\mathrm{L}}) = (1.09, 0.879)$, $(p_{\mathrm{R}}, \rho_{\mathrm{R}}) = (0.885, 0.562)$ were applied to the left and right part of the tube. The snapshot is taken at time $t^* = (t/L)\sqrt{p_{\mathrm{cr}}/\rho_{\mathrm{cr}}} = 0.45$, where L is the length of the domain. Line: Density [2], dashed: Pressure [2], symbols: Present. (b) 2D droplet center-line width evolution during reduced time $t^* = t(u_g/d_0)\sqrt{\rho_{\mathrm{g}}/\rho_{\mathrm{l}}}(\varsigma_l/\varsigma_g)$; $\varsigma_{l,g}$ is the speed of sound in the liquid and the post-shock gas, $\rho_{l,g}$ are corresponding densities, d_0 is the initial diameter of the liquid column and u_g is the flow speed upstream. Lines: Present scheme, solid line: $M_s = 1.18$, long dashed: $M_s = 1.33$, dashed: $M_s = 1.47$. Symbol: Experiment [3], square: $M_s = 1.18$, delta: $M_s = 1.30$, diamond: $M_s = 1.47$. (c) Schlieren images of the interaction of a shock wave at $\mathrm{Ma} = 1.47$ and a droplet at different times using the present scheme. From left to right: $t^* = 0.298$, $t^* = 0.879$, $t^* = 2.413$.

Anomalous shock: Only compression shocks and rarefaction waves are observed during the simulation of the shock-tube test in an ideal-gas. On the other hand, in the real-gas framework, it has been noted that there exist a region near the vapor saturation line where an anomalous behaviour may be observed in terms of the existence of a rarefaction shock [2]. The fluids that can show such a behaviour are known as BZT (Bethe, Zel'dovich and Thompson) fluids [4]. This anomalous behaviour which is classified as "Nonclassical Gas Dynamics" is characterized by the fundamental derivative defined as $\Gamma = v^3/2c^2(\partial^2 p/\partial v^2)_s$ where c is the speed of sound. For fluids with complex molecules, nonclassic behaviour occurs when $\Gamma < 0$ or when the $\Gamma = 0$ boundary is passed during the evolution of the flow [2]. Note that rarefaction shocks are not admissible in ideal-gases since the fundamental derivative is always positive, i.e., $\Gamma = \frac{1+\gamma}{2} > 0$ where $\gamma = C_p/C_v$ is the adiabatic exponent. The rarefaction shock is clearly visible in Figure 1.a, traveling to the high-pressure side of the tube.

Shock water-column interaction: The interaction of a water column with a planar shock wave and the subsequent deformation of the water column are investigated using the proposed scheme. To this end, a planar shock wave was generated, which separates the post-shock part and the saturated vapor. The droplet resides in the downstream of the shock, where it is initially in equilibrium with its own vapor at the temperature $T/T_{cr} = 0.9$. Simulations were conducted at three different Mach numbers, namely $M_s = 1.18$, $M_s = 1.33$ and $M_s = 1.47$. The time when the shock front reaches to the upstream interface of the droplet was assigned as $t = 0$. The width of the water-column during time has been measured and compared to experimental results in Figure1.b, which shows an excellent agreement. In addition, Schlieren images of water-column at three different times are presented in figure 1.c.

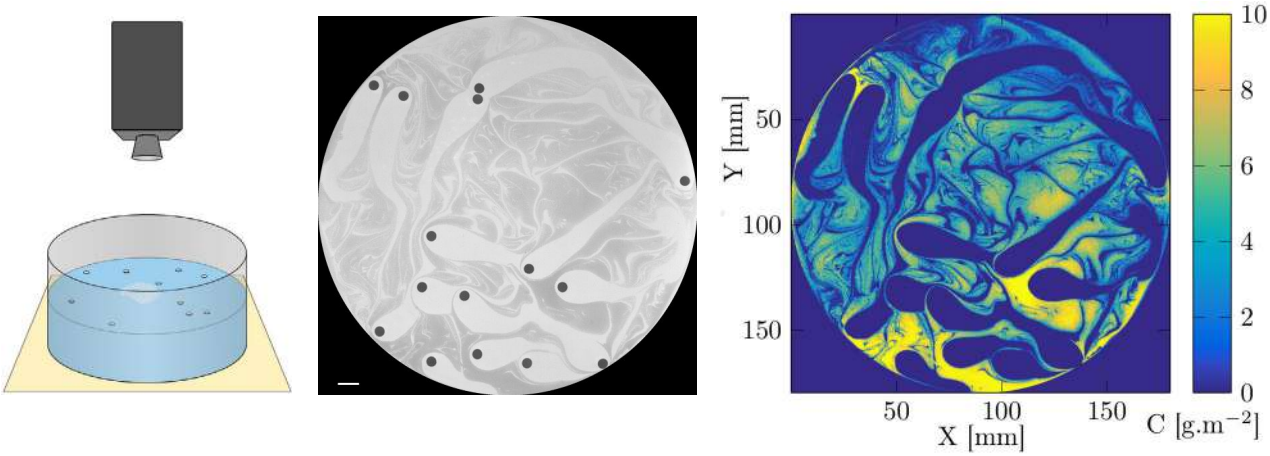
Summary In this experimental study, we report on the mixing properties of floaters by chemical and hydrodynamical currents generated by self-propelled camphor disks swimming at the air-water interface. While mixing is very rapid at short times, the system remains partially unmixed. This intermediate state results from a competition between (i) the mixing induced by the motion of the camphor swimmers and (ii) the unmixing promoted by the chemical cloud attached to each individual self-propelled disk.

INTRODUCTION

In a recent work, we considered a simple and historical system of active self-propelled particles made of camphor disks lying at the air-water interface [1, 2]. Remarkably, the collective dynamics of such swimmers was shown to exhibit multi-scale dynamics mimicking the canonical Kolmogorov K41 fluid turbulence [3]. Here we study mixing of inert floaters initially introduced at the center of such a system, for different numbers of swimmers, and different swimmers diameters. Remarkably, a stationary state is rapidly reached, that does not correspond to a fully mixed state. We show that the origin of this stationary heterogeneous state is associated to the competition between two antagonist mechanisms of mixing and unmixing, and explain the origin of the unmixed region.

EXPERIMENTAL APPARATUS

The experimental apparatus is described in figure 1: A small quantity of inert floating particles is poured at center of a container stirred with camphor swimmers. The concentration field is recorded as a function of time.



(a) (b) (c)

Figure 1: (a) Exprimental apparatus: in a glass container, we set N camphor swimmers, together wih a small quantity of micro-particles of glass at the center; (b) Typical image obtained after 10 minutes for $N = 15$ swimmers of radius 2.5 mm; (c) After calibration, corresponding concentration field.

MIXING PROPERTIES

Mixing is investigated using the standard deviation of the concentration $C_{std}(t) = \sqrt{\langle C^2 \rangle - \langle C \rangle^2}$. When the patch is poured, it gets rapidly stretched and folded by the velocity field induced by the camphor swimmers, as shown in figure 2, so that C_{std} converges rapidly towards a non zero value C^{∞}_{std}; decay is exponential at short times, which is typical of turbulent or chaotic mixing. The reason for this incomplete mixing is obviously the importance of the depletion area around each swimmer. Concentration spectra (not shown here) are also used for the characterization.

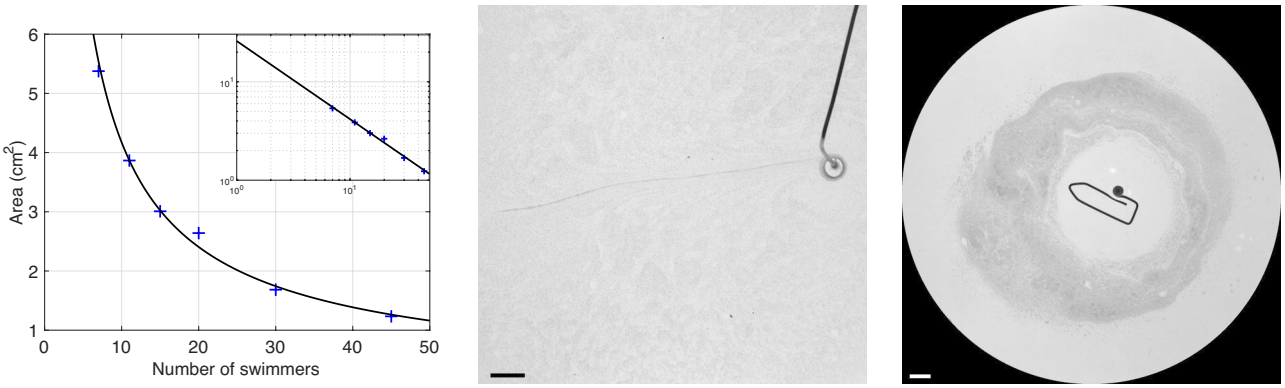
WAKE OF A SWIMMER

The typical area produded by a swimmer is estimated in figure 3a for various numbers N of swimmers. The typical Reynolds number of a camphor swimmer is 50. In order to understand if the wake around the swimmer is of mechanical or chemical origin, we perform two experiments: in the first one we pull a disk without camphor at the same velocity as a swimming camphor disk : no such wake is observed. In the second experiment, a single camphor disk is forced to remain at the same location. The surface of depletion area observed, here 26 cm^2, is in very good agreement with what is observed in figure 3a for $N = 1$.



(a) (b) (c)

Figure 3: (a) Depletion area of a given wake as a function of the number of swimmers N, for camphor disks of radius 2.5 mm; (b) wake produced by a particle not filled with camphor, forced to move at the velocity of a camphor particle; (c) depletion area produced by a camphor disk forced to remain at the same location.

CONCLUSIONS

We studied an original surfacic mixing system, where the velocity field is induced by camphor swimmers actively moving at the surface of the water. Whilst the system rapidly mixes at short times, it reaches a stationary state of imperfect mixing. We proved that the wake around the swimmers, at the origin of this partial mixing, is of chemical origin.

COLLISION EFFICIENCY OF PARTICLES IN A SIMPLE SHEAR FLOW - THE ROLE OF NON-CONTINUUM HYDRODYNAMIC INTERACTIONS

Pijush Patra* , Abhisek Kundu, and Anubhab Roy
Department of Applied Mechanics, Indian Institute of Technology Madras, Chennai, Tamil nadu 600036, India

Summary We calculate the collision efficiency of non-Brownian spherical particle pairs in a non-continuum gas subject to a linear shear flow. When the fluid medium is assumed to be continuum, two types of trajectories exist in a simple shear flow - open and closed. Continuum lubrication forces prevent particles from touching and collisions occur only with the inclusion of colloidal forces. In a rarefied medium, the lubrication forces are weaker than their continuum counterpart and thus allows for particle contact in finite time. The non-continuum modifications to the axisymmetric mobility functions are then obtained based on the theory of Sundararajakumar & Koch (1996) ([7]). Pair trajectories in a weakly rarefied medium are then calculated and compared with known continuum trajectories (given in Batchelor & Green 1972b ([1])). We find that near-field non-continuum interactions are responsible for the occurrence of colliding trajectories in a simple shear flow, even in the absence of colloidal forces.

INTRODUCTION

Pairwise hydrodynamic interactions in a linear flow is of direct interest in studying the rheological properties of a semi-dilute suspension, collision and coagulation of small particles dispersed in a fluid and understanding particle interactions with surfaces. When the suspending medium is treated as a continuum, lubrication forces prevent particle collisions in the pure hydrodynamic scenario. In steady straining motion, all the pair trajectories are open whereas in simple shear flow, there exists open and closed trajectories. Previous studies have obtained particle collisions due to the inclusion of inter-particle forces ([9]), interfacial mobility ([8]), deformation ([5]) and compressibility ([3]). With non-continuum lubrication, we find three types of trajectories - (1) open trajectories that arrive from infinity and depart to infinity without reaching the collision sphere, (2) collision trajectories, are the trajectories arriving from infinity and hitting on the surface of the contact sphere, or emerging from the surface of the contact sphere and going to infinity, and (3) semi-closed trajectories that starts from the surface of the contact sphere and hits back on it. The upstream interception area, which defines the area within which two widely separated particles will eventually collide is determined by a trajectory analysis which includes non-continuum hydrodynamic interactions, attractive van der Waals force and a combination of both.

THEORY

We consider a particle pair in a simple shear field of a non-continuum gas flow given by, $\mathbf{u}^{\infty}(\mathbf{x}) = (\dot{\gamma}x_2, 0, 0)$, which can also be written as $\mathbf{u}^{\infty}(\mathbf{x}) = \mathbf{E}.\mathbf{x} + \mathbf{\Omega}.\mathbf{x}$, where $\mathbf{E}$ and $\mathbf{\Omega}$ are the rate-of-strain and rate-of-rotation. Fluid motion is assumed to be sufficiently slow that satisfy the Stokes equations for creeping flow and particle inertia is neglected due to their small size. We choose a spherical coordinate system (r, θ, ϕ), with origin at the centre of sphere 1 and $\theta = 0$ being the vorticity axis (x_3). The relative velocity between the particles can be written as ([8]):

$$\begin{aligned}\mathbf{V}_{21}(\mathbf{r}) &= \mathbf{\Omega} \times \mathbf{r} + \mathbf{E}.\mathbf{r} - \left[A(s)\frac{\mathbf{rr}}{r^2} + B(s)(\mathbf{I} - \frac{\mathbf{rr}}{r^2})\right].(\mathbf{E}.\mathbf{r}) \\ &\quad - \frac{D_{21}^{(0)}}{k_B T}\left[G(s)\frac{\mathbf{rr}}{r^2} + H(s)(\mathbf{I} - \frac{\mathbf{rr}}{r^2})\right].\nabla(\Phi_{21}) \end{aligned} \tag{1}$$

The mobility functions for two hydrodynamically interacting spherical particles in a linear flow field are denoted by $A(s)$ and $B(s)$ and the Mobility functions for two spherical particles interacting hydrodynamically and moving because of a central potential between them are denoted by $G(s)$ and $H(s)$. $A(s)$ and $G(s)$ are the axisymmetric mobilities (i.e. mobility functions due to the relative motion along the line-of-centres) and $B(s)$ and $H(s)$ are asymmetric mobilities (i.e. mobility functions due to relative motion normal to the line-of-centres). All these mobilities depends on radii-ratio, $\kappa = a_2/a_1$, and non-dimensional centre-to-centre distance, $s = 2r/(a_1 + a_2)$, between the spherical particles. We used uniformly valid axisymmetric mobilities $A(s)$ and $G(s)$ recently developed by Dhanasekaran et al. ([2]). The relative diffusivity due to Brownian motion for two widely separated spherical particles is given by :

$$D_{21}^{(0)} = \frac{k_B T((1 + \kappa^{-1})}{6\pi\mu a_1} \tag{2}$$

The interparticle force potential is usually the sum of an attractive van der Waals force and a repulsive eletrical double layer force. For now, we will consider only the unretarded van der Waals force, $\Phi_{21} = \Phi_{vdW}$. If we assume pairwise additivity of the intermolecular attractions ([4, 6]) we have

$$\Phi_{vdW} = -\frac{A_H}{6}\left[\frac{8\kappa}{(s^2-4)(1+\kappa)^2} + \frac{8\kappa}{s^2(1+\kappa)^2 - 4(1-\kappa)^2} + \log\left\{\frac{(s^2-4)(1+\kappa)^2}{s^2(1+\kappa)^2 - 4(1-\kappa)^2}\right\}\right], \tag{3}$$

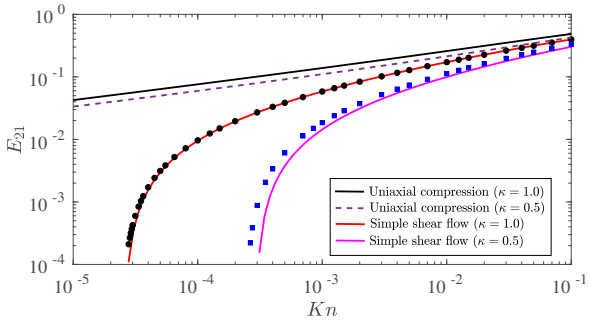
*Corresponding author. E-mail: pijush.bankura2011@gmail.com

where A_H is the composite Hamaker constant for the materials composing the two spheres and the surrounding fluid medium, $k_B = 1.381 \times 10^{-23} JK^{-1}$ is the Boltzmann constant and T is the absolute temperature. We define a dimensionless quantity, N_F, which measures the relative importance of ambient flow to the van der Waals attraction:

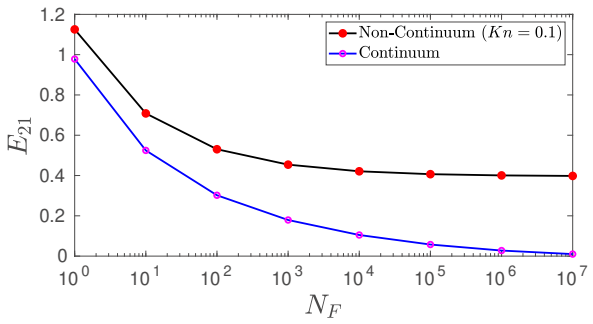
$$N_F = \frac{\frac{1}{4}a_1^2 (1+\kappa)^2 \dot{\gamma}}{A_H D_{12}^{(0)}/K_B T} = \frac{6\pi\mu a_1^3 \kappa (1+\kappa)\dot{\gamma}}{4A_H} \tag{4}$$

RESULTS AND DISCUSSION

Three velocity components obtained from equation (1) form an autonomous system of ODEs which are solved numerically using fourth-order Runge-Kutta method to find pair trajectories. The collision efficiency E_{21} is defined as the ratio of the collision rate in the presence of interactions to that in their absence. We found that the variation of collision efficiency with Knudsen number Kn (see figure 1(a)) in uniaxial compressional flow is different from that of simple shear flow. It is important to note that in case of simple shear flow depending on the radii ratio κ there exist a particular value of Kn below which there is no collision trajectories and those trajectories fundamentally behaves like continuum trajectories.



(a) Only non-continuum interactions



(b) Non-continuum interactions with van der Waals force

Figure 1: Collision efficiency as a function of Kn is plotted in figure (a). The black line in (a) shows the variation of collision efficiency E_{21} in uniaxial compressional flow for $\kappa = 1.0$ and the dashed violet line shows the same for $\kappa = 0.5$. The red curve in (a) indicates the variation of E_{21} with Kn in simple shear flow for $\kappa = 1.0$ when collision efficiencies are calculated analytically and the solid black dots on that line are produced from numerical calculation. The magenta color curve and solid square dots indicate the same for $\kappa = 0.5$. Collision efficiency for two equal sized spherical particles considering continuum hydrodynamic interactions and non-continuum hydrodynamic interactions at $Kn = 0.1$ are plotted in figure (b) as a function of N_F.

CONCLUSION

The present study provides a map of pair trajectories for non-continuum lubrication interactions. The non-continuum interactions results in collision trajectories and no closed trajectories unlike its continuum counterpart. These trajectory calculations will be useful in obtaining pair probability and consequently in calculating the effective viscosity of a non-continuum suspension. This study also provides the calculation of collision efficiency of small solid/liquid particles in gaseous medium in the absence of attractive colloidal forces. This will be particularly important to study droplet growth in clouds.

TURBULENCE IN A NETWORK OF RIGID FIBERS

Stefano Olivieri * [1], Marco E. Rosti[2], Luca Brandt[3], and Andrea Mazzino[1]
[1] DICCA, University of Genova, and INFN, Genova Section, I-16145 Genova, Italy
[2] Complex Fluids and Flows Unit, OIST, Onna-son, Okinawa 904-0495, Japan
[3] Linné Flow Centre and SeRC, KTH Mechanics, S-100 44 Stockholm, Sweden

Summary We study the effect of a network of fixed fibers on various kinds of turbulent flows, in order to provide useful insights for the analysis of particle-laden and porous media flows. To this aim, we perform direct numerical simulations using an immersed boundary method. We first consider the so-called ABC cellular flow finding that, for a sufficiently large concentration where the resulting configuration mimicks the stable solution, the effect of the network can be effectively modelled by means of a Darcy's friction term. We propose a phenomenological expression that is corroborated in the case of the Kolmogorov parallel flow and homogeneous isotropic turbulence. Moreover, we examine the overall energy distribution across the scales of motion, highlighting the presence of small-scale activity with a secondary peak in the energy spectra at a wavenumber characteristic of the network.

INTRODUCTION

The interaction between turbulent flows and fiber-like objects is an intriguing topic concerned by a large number of natural and engineering processes, such as, e.g., aerosol deposition or papermaking. Nevertheless, the understanding of how turbulence is generally modified by the presence of dispersed particles, on a fundamental basis, is still not fully clear [1]. In this work, we tackle the problem by focusing, in particular, on the case where fibers are fixed. On one hand, this can be intended as a preliminary step before considering suspensions of moving fibers. However, it also supplies an essential representation of flow within a canopy, with several features of interest in boundary-layer meteorology, such as the influence of the canopy on the transport and mixing properties [2].

PHYSICAL MODEL AND NUMERICAL METHOD

We consider a cubic domain with side $L = 2\pi$ and periodic boundary conditions. We perform direct numerical simulations (DNS) of the incompressible Navier-Stokes equations, using a finite-difference based code, for a variety of three-dimensional flows, such as homogeneous isotropic turbulence (Fig. 1a). Within this representative volume, we place an ensemble of N one-dimensional fibers (Fig. 1b). Each fiber composing the network has length c. The fiber centroids are evenly spaced placing an integer number of rods along each direction (although one case of randomly spaced fibers is also considered), while the orientation is randomly distributed. To take into account the effect by the fibers on the flow, we employ an immersed boundary (IB) method, which adds an additional localized forcing in order to enforce the no-slip condition. Specifically, we employ the numerical procedure already used for moving and flexible fibers both in laminar and turbulent flow conditions, see e.g. [3, 4].

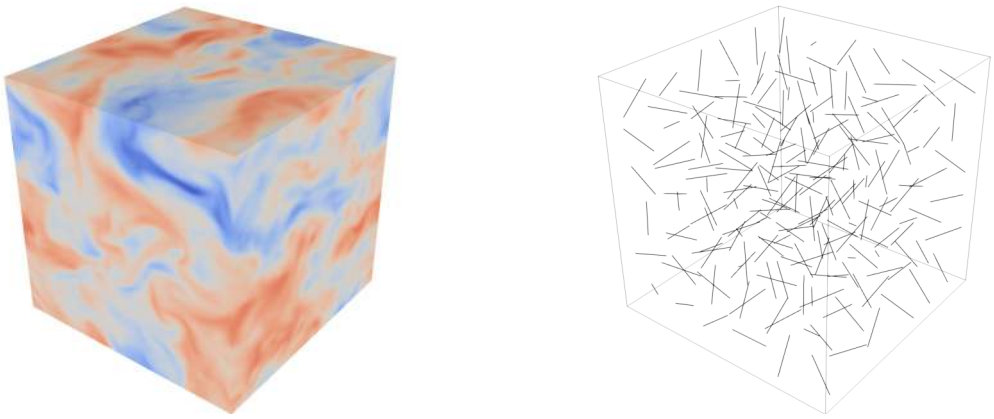

Figure 1: Left: homogeneous isotropic turbulent flow (the colormap showing one velocity component); right: network of $N = 6^3$ fibers with $c/L = (2\pi)^{-1}$ placed in the same triperiodic fluid domain.

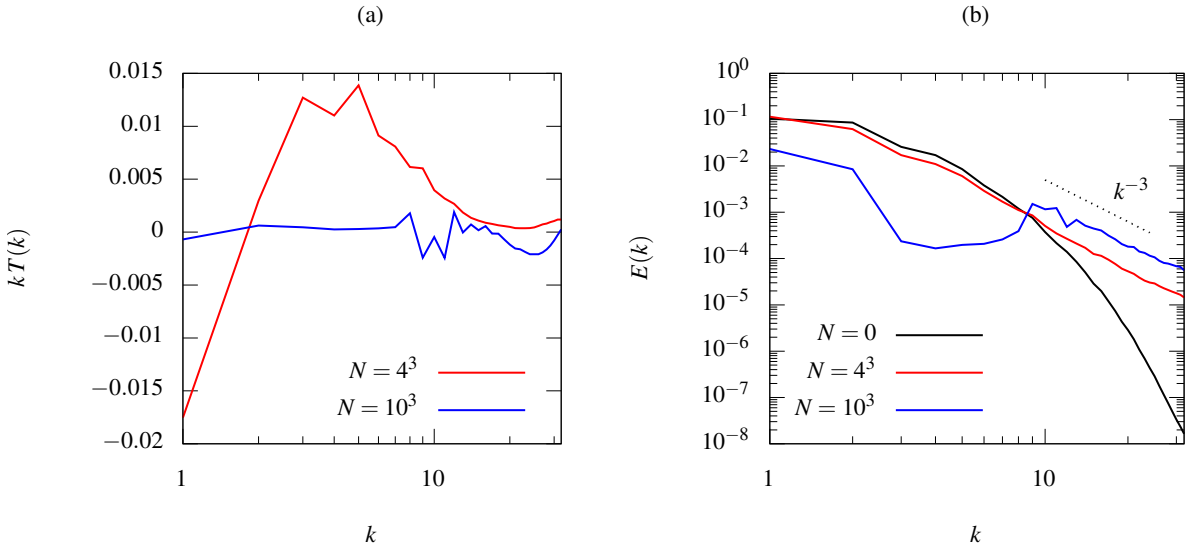

Figure 2: (a) Nonlinear terms appearing into the spectral power balance (multipled by k to improve readibility) and (b) energy spectra, from DNS of homogeneous isotropic turbulence at $Re_\lambda \approx 40$ for different fiber concentrations (black: $N = 0$, red: $N = 4^3$, blue: $N = 10^3$) with fiber length $c/L = (4\pi)^{-1}$.

RESULTS AND DISCUSSION

We first consider a steady large-scale external forcing, for which, if the Reynolds number is below a critical value, the stable Arnold-Beltrami-Childress (ABC) solution is obtained, and investigate the stabilizing effect of fixed fibers on this kind of cellular flow. For the latter, stability analyses have been carried out by several authors, and can be used as a reference to study the effect of a network of fibers. We choose an unstable and chaotic flow condition at a given $Re > Re_{\rm cr}$ and perform a parametric study by varying the number of fibers N and the fiber length c. Results show that, for sufficiently large concentrations, we recover a completely steady behavior. Two main features can be clearly observed: (i) the qualitative resemblance of the large-scale flow structure with that of the (stable) ABC flow; (ii) the presence of small-scale activity at the characteristic wavenumber $k_{\rm c} = 2\pi/(L/\sqrt[3]{N})$, corresponding to the spacing between the network fiber elements. Based on this numerical evidence, we focus on a scale-by-scale analysis and, in particular, we propose an effective large-scale description by means of a simple Darcy's friction term, i.e. $-D\mathbf{u}$, where the friction coefficient is expressed by the following phenomenological expression:

$$D = \alpha\, \nu\, n L \left(\frac{c}{L}\right)^{\frac{2}{3}}, \tag{1}$$

where ν is the kinematic fluid viscosity, $n = N/L^3$ and $\alpha \approx 7$ is a numerical factor.

Hence, we move to corroborate our prediction in the framework of different flow configurations, such as the parallel Kolmogorov flow $\mathbf{u} = (\cos y, 0, 0)$, as well as homogeneous isotropic turbulence. Moreover, we also carry out the corresponding effective simulations, replacing the IB forcing with the Darcy's term computed using Eq. (1).

Focusing on results for HIT (Fig. 2), good agreement is found between the fully-resolved cases and the corresponding effective ones, provided that the fiber concentration and/or the fluid viscosity is sufficiently high. In this condition, the nonlinear terms are substantially negligible (Fig. 2a) and our approach is fully justified. Looking at the energy spectra (Fig. 2b), one can note that the large-scale/low-wavenumber components decrease for increasing fiber concentration, while the opposite occurs for the small-scales/high-wavenumbers, for which we recover the $\sim k^{-3}$ scaling characteristic of viscosity-dominated regimes. For the case with the highest concentration, we can clearly observe the gap for intermediate wavenumbers and the secondary peak at $k = k_{\rm c}$, representing the signature of the same mechanism of energy distribution that was already identified when considering the ABC cellular flow.

Overall, our effective description appears to work well both on a qualitative and quantitative basis when applied to a variety of different flow conditions. Moreover, we underline that our findings could be relevant also for particle-laden flows where the inertia of particles plays a dominating role [5]. Finally, on-going activity is planned indeed to extend the analysis to suspensions of moving fibers.

SUSPENSION SHEAR THICKENING: CONTACT FORCE NETWORKS

Omer Sedes[1], Jeffrey F. Morris * [1], Hernan Makse[1], and Bulbul Chakraborty[2]
[1] Levich Institute, CUNY City College of New York; New York, NY USA
[2] Department of Physics, Brandeis University, Waltham MA, USA

Summary The rheology of suspensions of spheres is simulated. Interparticle forces due to hydrodynamic lubrication, short-range repulsion and contact with friction are included. Strong continuous shear thickening is found at solid fractions $\phi > 0.5$ and discontinuous shear thickening for $\phi > 0.55$. Contact force networks are analyzed here, with a focus on the sub-networks of particles each mutually connected by k or more contacts to other members of this sub-network: this is a k-core. Sampling of the connected structures is performed as a function of ϕ and shear rate within the ensemble of non-equilibrium steady states. The network at small stress is formed of disconnected quasi-linear structures ($k = 1$), which grow and merge to form loops ($k = 2$) and percolating structures at sufficient stress, with the sudden appearance of a system spanning $k = 3$ component at large stress.

INTRODUCTION

Concentrated or 'dense' suspensions display strong shear thickening, a behavior that has been related to shear-induced jamming [1]. In the last several years, the influence of contact forces on shear thickening in suspensions has been studied intensively. At large solid fraction ϕ, strong continuous shear thickening (CST) or discontinuous shear thickening (DST) are observed. Both simulations [2] and theory [3] show that a relatively simple scenario in which lubricated contacts give way to frictionally contacting particles, with the rate of this transition controlled by a repulsive force such as that due to surface charge, is able to capture qualitative features seen in experiment, while experiments specifically probing the development of stress due to contact have been reported [4]. Thus the network of contact forces arises as an important microstructural variable. Here, networks determined from simulations by an established approach [2] are studied. Among several approaches [5, 6] to analyze the networks, we are motivated by prior considerations of granular systems by k-core analysis [6] to consider groups of mutually contacting particles each with k or more contacts to others in this group, forming a 'k-core.' We consider the steady states of the suspension as a function of ϕ and imposed shear rate $\dot{\gamma}$, sampling the network structure as the suspension is sheared through a large number of configurations. This provides network statistics from which we gain insight to how the network develops and is related to the shear thickening transition.

SIMULATION METHOD & RHEOLOGY

The suspension is simulated by the lubricated flow-discrete element method [2]. We study bidisperse suspensions in which the spherical particles have radii a and $1.4a$, with 50% of the particle volume contributed by particles of each size. Hydrodynamic interactions are limited to short-range lubrication forces of the form $\mathbf{F}_{ij}^{\text{lub}} = -\mathbf{R}_2 \cdot (\mathbf{u}_i - \mathbf{u}_j)$, with $\mathbf{u}$ a particle velocity. The resistance tensor $\mathbf{R}_2$ scales as $1/(\delta+h)$ for normal motion and $\log(\delta+h)$ for tangential motion, where h is the pair surface separation, and $\delta = 10^{-3}a$ cuts off the lubrication force singularity which would otherwise occur at contact, $h = 0$. Short-range pair repulsive forces, of form $F_R e^{-\kappa h}$ modeling electrostatic repulsion with Debye length $1/\kappa$, as well as a stiff elastic interaction at contact, are included. At contact, Coulomb friction is modeled, with $F_{\text{C,t}} \leq \mu F_{\text{C,n}}$ relating tangential ($F_{\text{C,t}}$) and normal ($F_{\text{C,n}}$) force components; here $\mu = 1$.

The importance of the contacts to the stress response is illustrated in a simple way by the number of frictional contacts per particle Z growing with shear rate in the upper part of figure 1, just as the relative viscosity increases strongly with shear rate, here in a dimensionless form scaled by $\dot{\gamma}_0 = F_R/(6\pi\eta_0 a^2)$. This plot shows CST for $\phi = 0.54$ and DST at $\phi > 0.55$; while not readily apparent here, it is possible to show that there an S-shape to the $\eta(\dot{\gamma})$ curves for $\phi > 0.55$ accessible under shear stress control. At $\phi = 0.55$, the suspension behavior is, to a close approximation, at the transition from CST to DST.

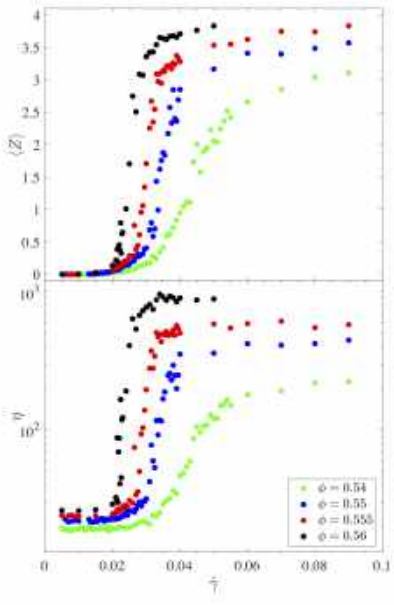

Figure 1: Bottom: relative viscosity η; top: ensemble average contacts per particle, $\langle Z \rangle$, plotted as a function of dimensionless shear rate.

FORCE NETWORK ANALYSIS

The contact number shown in figure 1 is a limited description of the contact state, so we consider the frictional contact network. Typical networks at rates just below and above strong shear thickening are illustrated in figure 2, for $\phi = 0.55$. These show links between frictionally-interacting particles.

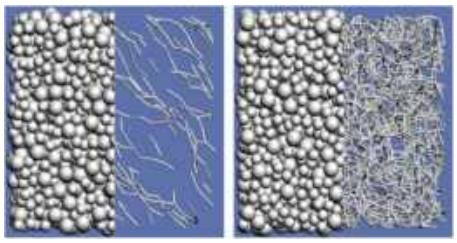

Figure 2: Particle configurations and contact force networks for $\phi = 0.55$, in the low- (left) and high-viscosity (right) states, $\dot{\gamma} \approx 0.025$ and 0.04 in figure 1.

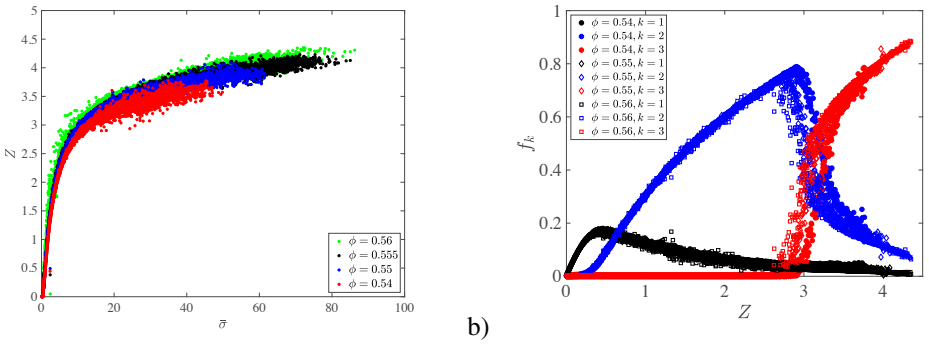
The direction of the frictional force is not indicated. At the lower shear rate (lower viscosity), the network of contact forces is composed of quasi-linear structures along the compressive axis, while in the thickened state the networks become dense and relatively more isotropic. The frictional networks percolate in all directions, but the states are not jammed. Flow is necessary to achieve the stress to drive certain of these close interactions into contact, and thus the contact state is intrinsically linked to the flow.

At very low shear rate, the repulsive force is able to maintain surface separation between all particles. As the rate is increased, some particles are forced into contact, forming first dimers and then the quasi-linear structures of figure 2 (left side); these are $k = 1$ structures, or 1-cores; note that while most have two contacts, progressive pruning of the singly connected structures leaves again singly connected structures and this is a 1-core [6]. These 1-core structures become progressively longer and more dense in the suspension with increase of the shear rate (and consequently the stress), until in the beginning of the rapid upturn of the stress, whether in CST or DST, they begin to merge into 2-cores which percolate across the domain. With increase of the shear rate, the 2-core rapidly grows, with the mean number of contacts per particle Z rising rapidly, until a 3-core that spans the system emerges. Small non-spanning 3-cores are also found just before the system spanning structure, but these do not grow and merge; rather these appear and disappear rapidly. Z is a one-to-one function of the stress, as shown by figure 3a, and the fraction of particles within each core type is shown in figure 3b, as a function of Z.



a) b)

Figure 3: a) Instantaneous average contact numbers, Z, as a function of the dimensionless shear stress, scaled by $F_R/(6\pi a^2)$; b) the fraction of total particles in each size of core as a function of Z over all shear rates simulated for $\phi = 0.54, 0.55$ and 0.56.

An analysis of the stress contributed by each core type finds that in CST, the stress is similar in all core types, with mildly stronger stress contributed by the more highly-connected structures, whereas in the DST regime, there is a very sharp increase in the stress contributed by 3-cores relative to 2-cores. This relationship between the connectivity of the structures and the stress response is indicative of the underlying basis for the mechanical behavior. It is found that when 4-cores arise, at $\phi > 0.58$, the system generally jams, but this point demands further study.

CONCLUSIONS

Shear thickening in dense suspensions is described here by a lubricated-to-frictional rheology, with the transition to the large-viscosity state at a critical level of stress related to a microscopic repulsion force. This leads to development of a frictional contact network, found from simulation to evolve with increasing stress from disconnected quasi-linear structures to loop structures and percolation, and then to a fully dense network. In the language of k-cores, this is roughly a transition from 1- to 2- to 3-cores. The stress response is directly related to the contact state, as stress increases with mean contact number Z. A signature of DST is that there is a sharp increase in stress in the 3-core structures when DST is observed whereas this increase is absent at slightly lower ϕ where CST occurs.

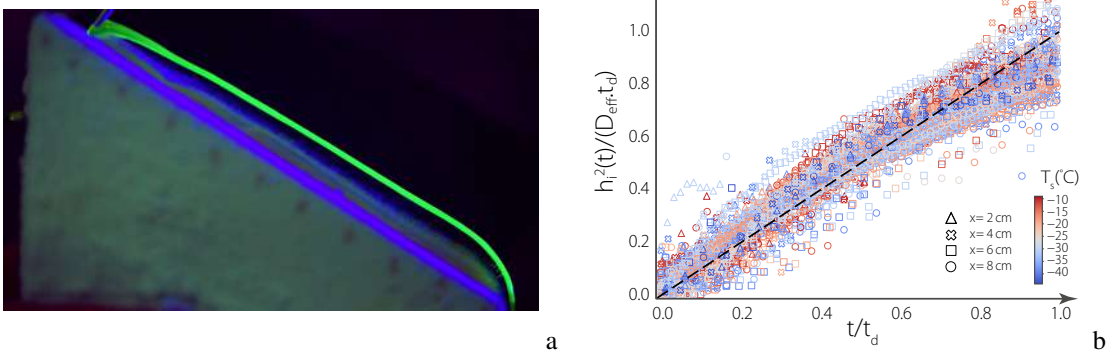
Summary We investigate experimentally the formation of the particular ice structure obtained when a capillary trickle of water flows on a cold substrate. We show that after a few minutes the water ends up flowing on a tiny ice wall whose shape is permanent. We characterize and understand quantitatively the formation dynamics and the final thickness of this ice structure. In particular, we identify two growth regimes. First, a 1D solidification diffusive regime, where ice is building independently of the flowing water. Second, once the ice is thick enough, the heat flux in the water comes into play, breaking the 1D symmetry of the problem, and the ice ends up thickening linearly downward. The system reaches ultimately a stationary state where water continues to flow on ice without solidifying anymore. This linear pattern is explained by considering the competition between the water cooling and its convection.

INTRODUCTION

Solidification in flowing systems is a question encountered in numerous area such as geophysics, metallurgy and aeronautics. From a geophysical point of view, understanding of solidification of lava flows could help preventing the impact of volcanic eruptions on human populations [1]. The metallurgic industry is also interested in understanding the fine coupling between hydrodynamics and solidification to control the aparition of cracks during the formation of metal sheets [2]. Finally, freezing of velocity sensors during commercial flights is thought to be responsible for plane crashes. As a result, understanding the freezing process of small quantities of liquid flowing over a cold surface could help for all those topics. In this study, we will investigate experimentally and theoretically the freezing of a rivulet, obtained by flowing water on a cold solid substrate.

EXPERIMENTAL METHOD

In order to study the effect of different parameters on the shape and the dynamics of the ice structure formed while freezing a rivulet, we built a simple model experiment. We flowed water dyed with fluorescein (water layer thickness h_w) on a aluminium inclined substrate which is cooled to a given temperature, T_s, with liquid nitrogen. We recorded the evolution of the ice thickness h_i, taking advantage of the de-activation of fluorescein upon freezing (see Figure 1a). We vary experimentally the thermal parameters: the substrate and the liquid temperatures (T_s and T_in, respectively).



a b

Figure 1: (a) Side view of the ice structure (brown/black) with water flowing on top (green) (b) Rescaled ice thickness $h_\mathrm{i}^2(t)/(D_\mathrm{eff}t)$, $t \in [0, t_\mathrm{d}]$ as a function of the non-dimensional time t/t_d. D_eff is computed from [5] and t_d, the time where the spatially homogeneous growth ends, is experimentally determined.

INITIAL DIFFUSIVE GROWTH

When growing initially, the ice layer thickness is found to vary with the square-root of time. To understand this short time behavior of the ice layer growth, we model it by using the Stefan condition, where the latent heat produced by the ice formation results from the difference between the heat fluxes through the ice and the water. It reads here:

$$\rho_\mathrm{i}\mathcal{L}\partial_t h_\mathrm{i} = \lambda_\mathrm{i}\partial_y T\left(x, h_\mathrm{i}^-, t\right) - \lambda_\mathrm{w}\partial_y T\left(x, h_\mathrm{i}^+, t\right), \quad (1)$$

*Corresponding author. E-mail: ictam2020@aimgroup.eu.

where ρ_i is the ice density, $\lambda_{i,w}$ are the heat conductivities of the ice and water respectively, and $\mathcal{L}$ the latent heat of solidification. Initially, when $h_i \ll h_w$, the flux through the ice, which scales as $\lambda_i(T_m - T_s)/h_i$, T_m being the water melting temperature, is dominant compared to the flux through the water. This dynamics at short time corresponds to the classical one dimensional problem of the growth of an ice layer when a liquid is suddenly put in contact with a substrate at a uniform subfreezing temperature, usually known as the *classical Stefan problem* [3, 4]. In this situation, the front follows a diffusive dynamics: $h_i(t) = \sqrt{D_{eff}\, t}$, where the coefficient D_{eff} is solution of a transcendental equation that involves T_s, $\mathcal{L}$ and the ice and aluminum thermal coefficients.

In Fig. 1b, we plot the rescaled ice thickness $h_i^2(t)/(D_{eff} t_d)$, where D_{eff} is calculated using a refined model of the classical Stefan problem [5], versus the non-dimensional time t/t_d, $t \in [0, t_d]$. The graph presents the results of 31 experiments and 4 different positions along the plane, where T_s varies from -9 to -44°C and T_{in} from 8 to 35°C. All the data collapse on a line of slope 1, confirming that at short time the ice growth is only determined by the heat transfer toward the substrate without influence of the water flow.

PERMANENT REGIME

After few minutes, the ice thickness reaches a permanent regime where the water continues to flow on the ice wall previously formed. The height of the ice layer grows linearly along the plane, forming an angle β with the metallic plane.

The presence of such a permanent regime can be understood qualitatively by considering the thermal fluxes at the ice-water interface. Because the ice acts as a thermal diffusive layer between the plate and the liquid, the cooling flux - through the ice layer - diminishes as the ice layer thickens and the temperature gradient decreases. On the other hand, since the flowing water is dispensed at constant temperature on the forming ice layer, the heat flux brought to the system is constant. Consequently, an equilibrium is reached when the ice layer thickness is such that both fluxes balance.

To rationalize the peculiar structure formed by the ice, we derive and solve the temperature field in the ice layer and in the water. Coupling this to the flux continuity at the interface, we show that the ice thickness should follow the linear trend:

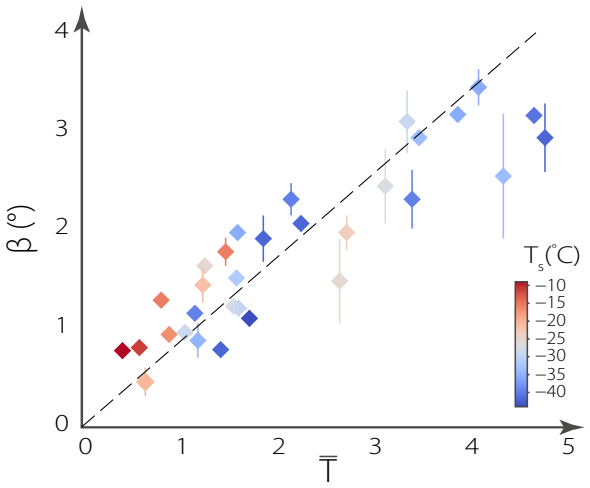


Figure 2: Slope of the ice layer β as a function of the rescaled temperature $\bar{T} = \frac{T_m - T_s}{T_{in} - T_m}$.

$$h_i(x) \sim h_w \frac{\lambda_i}{\lambda_w} \frac{T_m - T_s}{T_{in} - T_m}(1 + a\, x)\ . \tag{2}$$

This calculation predicts, in particular, that the slope of the ice structure β should vary linearly with the reduced temperature $\bar{T} = (T_m - T_s)/(T_{in} - T_m)$. Figure 2 shows precisely the experimental values of β, measured for all of our experiments with different water and substrate temperatures, as a function of $\bar{T}$. The color-code corresponds to experiments performed with different T_s. The dashed line is a linear fit of the data, showing a very good agreement with the prediction of Eq. (2).

CONCLUSIONS

Performing simple experiments and exploring both the ice shape and dynamics, we were able to probe the effect of hydrodynamics on the solidification process. After an initial diffusive growth, we observe a steady regime. It could be explained by a subtle balance between the advection of heat imposed by the water flow and the diffusion through the ice layer.

SEDIMENT TRANSPORT AND SEDIMENT DYNAMICS IN A TURBULENT OSCILLATORY BOUNDARY LAYER: RESULTS OF INTERFACE-RESOLVED SIMULATIONS

Marco Mazzuoli *[1], Paolo Blondeaux[1], and Giovanna Vittori[1]
[1] Department of Chemical, Civil and Environmental Engineering, University of Genoa, Genoa, Italy

Summary The dynamics of sediments under the action of an oscillatory flow in the intermittently turbulent regime is investigated by means of interface-resolved direct numerical simulations. The sediments are mono-sized spherical particles characterised by a diameter and a density typical of silica medium-sand grains. Moreover, the values of the other parameters are chosen to describe sediments under monochromatic sea waves propagating over a flat bed offshore from the breaker line. The simulations required formidable resources and time and reveal the mechanisms which control the interaction of the sediment particles with the turbulent vortices and the pressure gradient oscillations they induce. Limits and capability of the actual sediment transport predictors (proposed for steady flows) to estimate the bed load and the suspended load under oscillatory flows are also discussed.

BRIEF INTRODUCTION AND NUMERICAL APPROACH

The sediment transport induced by non-breaking sea waves can assume significant values because the bottom shear stress and the pressure gradient which are generated by propagating sea waves close to the bottom can mobilize large amounts of sediments. Hence, it turns out that fluid dynamics within the oscillatory boundary layer (OBL) generated close to the bottom is closely coupled with the dynamics of the sediments. The models currently used in coastal engineering applications to predict the sediment transport rate are mainly empirical and the effects associated with the rich dynamics of the OBL are often neglected or misrepresented. In an OBL characterized by the presence moving sediments, the velocity oscillations are characterised by the amplitude U_0^* and the angular frequency ω^* and the properties of the OBL are mainly controlled by two parameters, namely the Reynolds number $R_\delta = U_0^* \delta^* / \nu^*$, based on the thickness of the Stokes boundary layer $\delta^* = \sqrt{2\nu^*/\omega^*}$, and the dimensionless size of sediments d^*/δ^*, ν^* denoting the kinematic viscosity of the fluid and d^* a representative size of cohesionless sediments. The asterisk indicates dimensional quantities. For a wide range of values of R_δ and for values of d^*/δ^* typical of medium-sand, the flow is not always turbulent, but it re-laminarises in the phases of the wave-cycle around the flow reversal and at the beginning of the accelerating phases. Such behaviour characterises the so-called intermittently turbulent regime. Five direct numerical simulations (DNS) of an intermittently turbulent OBL developing over movable sediments were performed. In the DNS, sediments consist of mono-sized spheres characterised by values of the diameter d^* and the density ϱ_s^* typical of silica medium-sand grains. The Reynolds number R_δ is equal to 775, 1000 and 1500 while the dimensionless diameter d^*/δ^* is equal to 0.168, 0.335 and 0.670. Navier-Stokes and continuity equations are solved numerically by means of a finite difference approach which uses a second-order central-difference scheme to discretise the spatial derivatives and a fractional-step method to advance in time. The boundary condition at the moving fluid-solid interface is forced by using the immersed boundary method developed for particulate flows by [1]. Particle collisions are modelled with a Discrete Element Method (DEM) which comprises a linearised spring-dashpot system for normal and tangential stresses between spherical sediment grains. This approach underwent long validation and was adopted by [2, 3]. Figure 1a shows the flow and particle configuration of one of the simulations when the particles are picked-up from the bottom and suspended by turbulent vortices. [3] have recently described some of the present simulations and found that as long as particles roll, slide and saltate without going into suspension, the sediment flow rate can be fairly estimated assuming that the oscillatory flow is just a sequence of steady states, i.e. neglecting the effects of flow acceleration. This results can be justified by the fact that, for the sediment presently considered, the particle relaxation time is much smaller than the oscillation period. In the following, the approach of [4] is followed to develop a relatively simple model of bedload sediment transport which takes into account the dynamics of sediment particles during the wave cycle.

RESULTS AND ONGOING RESEARCH

The numerical simulations show that some of the empirical formulae used to quantify the bed load sediment transport can be tuned to provide a more accurate evaluation of the sediment transport rate. Let us consider the configuration of the present simulations, where sediment particles are spherical and mono-sized. The mean sediment flow rate q_s^* is equal to $\mathcal{V}^{*(p)} v_p^* n^{*(p)}$, $\mathcal{V}^{(p)}$ denoting the volume of a single particle, v_p^* being the particle velocity averaged over the computational domain above the resting bed and $n^{*(p)}$ being the number of particles per unit area that are moving. The dimensionless form of the sediment transport rate turns out to be:

$$\Phi_s = (\pi/6)\, \Psi^{1/2}\, v_p\, p \ , \tag{1}$$

Φ_s and v_p being equal to $q_s^*/(v_s^* d^*)$ and v_p^*/U_0^*, respectively, where v_s^* is equal to $\sqrt{(s-1)g^* d^*}$. Moreover $p = n^* d^{*2}$ is the probability to detect a moving particle over an area of the bed surface of extension d^{*2}. Lastly, the parameter Ψ

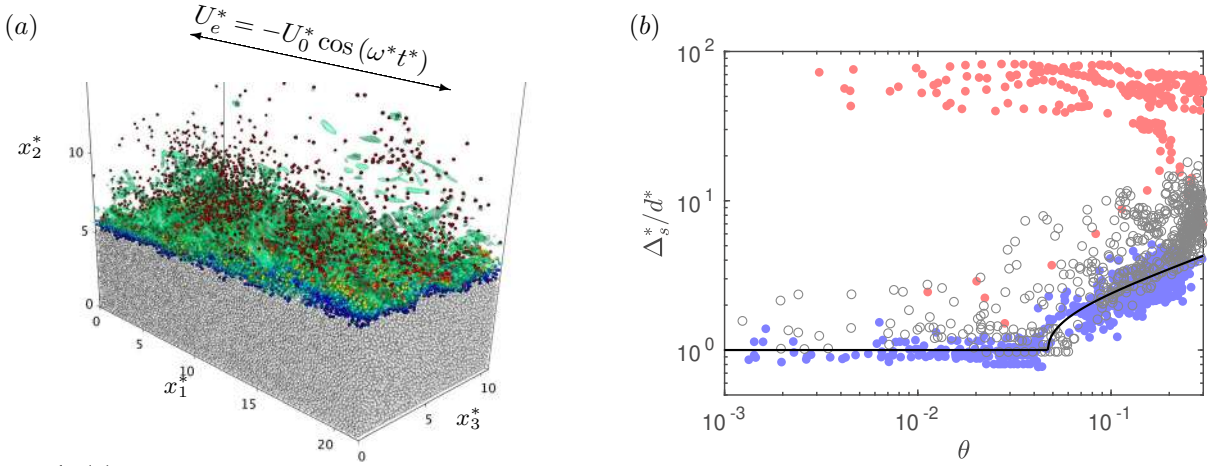

Figure 1: (a) Visualisation of the particle/flow configuration at an instant during the deceleration phases of the run at $R_\delta = 1000$ and $d^*/\delta^* = 0.168$ ($\omega^* t^* = 2.1\pi$). Gray particles are resting while moving particles are shaded by warmer colours according to their velocity. A significant amount of sediment particles is floating under the action of turbulent vortices, which are highlighted by green isosurfaces of λ_2. U_e^* denotes the fluid velocity far from the bed.(b) Values of the dimensionless thickness of the saltation layer plotted versus the Shields parameter for $R_\delta = 1000$ and $d^*/\delta^* = 0.167$ (light red), 0.335 (grey circles) and 0.670 (light blue). Solid thick line is obtained with the expression (5).

is the mobility number which is equal to U_0^{*2}/v_s^{*2}. The particle velocity is estimated on the basis of particle dynamics. The force acting on moving sediment particles results from the balance between the drag force, which is proportional to the square of the fluid velocity flowing around the particles, and the resisting force that is written as a friction force proportional to the resulting bed-normal force (gravitational and lift components) and to a friction coefficient (μ_s or μ_d for static or dynamic conditions, respectively). Assuming that the mean fluid velocity can be approximated by the product between a coefficient, α (~ 10), and the friction velocity u_τ^*, after some manipulations, the dimensionless mean particle velocity is found to be

$$v_p = \alpha \Psi^{-1/2} (\theta^{1/2} - c_1 \theta_{cr}^{1/2}) \ , \quad \text{with} \quad c_1 = \sqrt{\mu_d (c_D + \mu_s c_L)/[\mu_s (c_D + \mu_d c_L)]} \ , \tag{2}$$

where c_D and c_L denote the drag and lift coefficients, respectively, θ the Shields parameter defined as the ratio of the bottom shear stress to $\varrho^* v_s^{*2}$ and θ_{cr} the critical value of θ for the incipient motion of sediments. The values of the c_D and c_L depend on the fluid velocity and can be estimated with the empirical formulae that can be found in the literature (e.g. Schiller-Neumann formula of [5]). The value of p can be estimated by assuming that the momentum transferred from the flow to the bed is distributed in part to the resting bed, leading to inter-granular contact forces, and in part to the moving particles. The threshold of such distribution is θ_{cr}. This concept is expressed mathematically by the equation

$$p = (6/\pi)\, c_2 (\theta - \theta_{cr}) \ , \quad \text{with} \quad c_2 = (c_D + \mu_d c_L)/(\mu_d c_D) \ . \tag{3}$$

Hence, from (1), (2) and (3), estimates of the dimensionless sediment flow rate can be computed

$$\Phi_s = \alpha\, c_2 (\theta^{1/2} - c_1 \theta_{cr}^{1/2})\, (\theta - \theta_{cr}) \ , \tag{4}$$

which meets reasonably well the results obtained by means of the DNS as long as sediment particles do not go into suspension. The reliability of the model described above is strongly related to the maximum distance from the bed surface reached by particles during the wave cycle. Let us refer to this distance as *saltation layer thickness* and denote it with Δ_s^*. Figure 1b shows the values of Δ_s^* normalised by the sediment diameter for $R_\delta = 1000$. The values of Δ_s^*/d^* obtained for $d^*/\delta^* = 0.335$ and 0.670 are fairly approximated by the curve described by the equation

$$\Delta_s^*/d^* = 1 + A_b\, (\theta/\theta_{cr} - 1)^m \ , \tag{5}$$

with $A_b = 1.3$ and $m = 0.55$, which was proposed in several studies on sediment transport in steady flow conditions. However, equation (5) fails in representing the maximum height of particle trajectories for the case at $d^*/\delta^* = 0.168$ because particles are set into suspension rather than saltating. Indeed, in this run, the distance from the bed surface reached by particles is approximately one order of magnitude larger than that of saltating particles.
The interested reader can find a detailed description of further results which were obtained from the present runs in [6].

EULERIAN-EULERIAN TWO-PHASE FLOW LARGE EDDY SIMULATION OF DILUTE SUSPENDED SOLID PARTICLES IN WATER

Antoine Mathieu* [1], Julien Chauchat[1], Cyrille Bonamy[1], Guillaume Balarac[1], and Tian-Jian Hsu[2]
[1] University of Grenoble Alpes, LEGI, G-INP, CNRS, Grenoble, France
[2] Civil and Environmental Engineering, Center for Applied Coastal Research, University of Delaware, Newark, USA

Summary Two-phase flow Large Eddy Simulation methodology is used to investigate dilute suspended load in starved-bed conditions. The objective is to better understand and model the interactions between the fluid turbulence and the particle dynamics, the so-called turbulence-particle interactions. Experimental results involving quasi neutrally buoyant sediments and natural sediments are reproduced numerically using a two-phase flow model: sedFoam implemented in the toolbox OpenFOAM. The numerical results obtained for particle-laden flows showed that the vertical profile of particle concentration for neutrally buoyant sediments is in good agreement with the experimental data while for natural sediments, concentration profile is under-estimated. The major difference between the two configurations is the particle response time while the flow turbulence is the same suggesting that the observed discrepancy is related to the Stokes number which becomes larger than unity for natural sediments.

The suspension mechanism of solid particles in a horizontal boundary layer is a fundamental but poorly understood phenomenon given the complex interactions occurring between the fluid turbulence and the particles. A wide spectrum of temporal and spatial scales are involved in the solid particles suspension making it difficult to be modeled. Up to now, the prediction of the average profile of suspended sediment concentration lacks of physical representation as it relies on empirical formulations. However, a lot of effort has been devoted to develop numerical models to improve its prediction over a broad range of flow and particles parameters. Various modeling techniques such as Eulerian-Lagrangian or Eulerian-Eulerian methodologies are available having different degrees of representation of the physical processes involved and different computational costs.

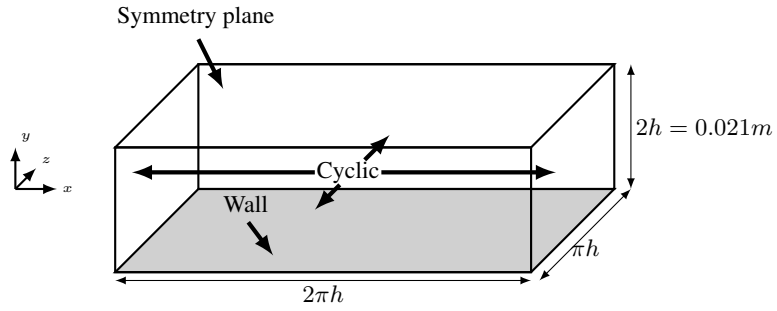

Figure 1: Sketch of the geometry and boundary conditions of the numerical domain for the configuration from Muste et al. (2005) [2].

In the Eulerian-Eulerian framework, both phases are seen as continua. Continuity and momentum equations are solved for both phases and particle-particle and fluid-particle interactions are modeled. The performances of the Eulerian-Eulerian methodology using Large Eddy Simulation (LES) formalism is yet to be demonstrated for turbulent suspension of inertial particles. In this study, the filtered Eulerian-Eulerian two-phase flow model for LES is applied to the experimental configurations from Muste et al. (2005) [2] involving non-inertial almost Neutrally Buoyant Sediments (NBS) and inertial Natural Sediment (NS). Both type of particles are finite sized ($d/\eta > 1$ with d the particle diameter and η the smallest turbulent scales or Kolmogorov scales). Both configurations are in starved bed condition. The mean volumetric concentration of sediment is equal to $\phi_{mean} = 4.6 \times 10^{-4}$.

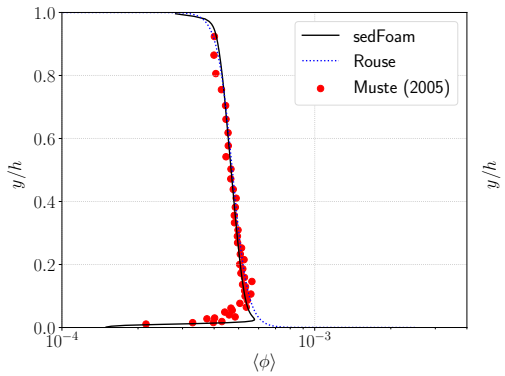

Figure 2: Concentration profiles from NBS configuration using sedFoam compared with analytical Rouse profile and experimental data from Muste et al. (2005) [2].

For both configurations, the hydrodynamic configuration is the same. The targeted friction velocity is $u_\tau = 0.042m.s^{-1}$ giving a Reynolds number based on the wall friction velocity $Re_\tau = 882$. The computational domain is a rectangular box with bi-periodic boundary conditions (figure 1). The flow is driven by a pressure gradient along the x axis in order to match the same discharge as in the experiments.

The mesh is composed of 7 920 000 cells with constant streamwise and spanwise grid resolution $\Delta x^+ = 12.6$ and $\Delta z^+ = 7.0$ in wall units ($+$ symbol with $\psi^+ = \psi u_\tau / \nu^f$). The mesh resolution is stretched along the y axis with the first grid point located at $\Delta y^+ \approx 1$ and $\Delta y^+ \approx 3$ at the top.

*Corresponding author. E-mail: antoine.mathieu@univ-grenoble-alpes.fr.

Particles having a density ratio $\rho^s/\rho^f = 1.025$ and diameter $d = 230\mu m$ are used for the NBS configuration giving a size ratio $d/\eta = 9.5$. The Stokes number for this configuration defined as the ratio between the timescale associated with the particle and the timescale associated with the Kolmogorov scale is $St = t^s/t^\eta = 0.12$ smaller than unity meaning that the particle will follow every fluid velocity fluctuations and should behave as a passive tracer.

The vertical sediment concentration profiles from the experiment and simulation are represented in figure 2 in semi-logarithmic scale. They are compared with the analytical Rouse profile with free surface correction given by expression (1) with ϕ_0 the reference concentration at the reference position y_0 and R_o the Rouse number given by $R_o = v^s_{fall}/\kappa u_\tau$ with v^s_{fall} the particles fall velocity and $\kappa = 0.41$ the von Karman constant.

$$\phi = \phi_0 \left(\frac{y_0(1 - y/h)}{y(1 - y_0/h)} \right)^{-R_o}. \tag{1}$$

Analytical and experimental concentration profiles correspond almost perfectly to the numerical data. Numerical concentration profile follows exactly the Rouse profile on the upper part of the channel. Close to the wall, the two-phase flow model quantitatively reproduces the reduction of concentration observed experimentally. The two-phase flow model is shown to accurately reproduce turbulent suspension of particles having low inertia.

Compared with the NBS configuration, only the particle to fluid density ratio changes in the NS configuration. The particle size is the same with $d/\eta = 9.5$ but the new density ratio is $\rho^s/\rho^f = 2.65$. The same hydrodynamic configuration is kept in order to isolate the influence of the particles inertia. Indeed, by increasing the density ratio, the Stokes number is increased to up to $St = 10.5$. According to Balachandar (2009) [1], the particle dynamics is primarily influenced by eddies in the inertial range of turbulence having the same timescale as the particles.

The concentration profile from simulations of the NS configuration are compared to the measurements and the analytical profile in figure 3. The standard Rouse analytical profile does not reproduce the experimental data. To fit the experiments, the Rouse number needs to be multiplied by S_c the turbulent Schmidt number characterizing the increased efficiency of inertial particles turbulent dispersion. Van Rijn (1984) [4] proposed the following empirical expression for the inverse of the Schmidt number:

$$\frac{1}{S_c} = 1 + 2 \left[\frac{v^s_{fall}}{u_\tau} \right]^2 \tag{2}$$

The concentration profile from the simulations is largely underestimated compared with both experimental data and analytical profile with or without the correction. The two-phase flow model does not seem to accurately reproduce the suspension of inertial particles. Subgrid interaction models from Ozel et al. (2013) [3] using dynamic procedures to take into account unresolved fluid-particle interactions have been tested and the turbulent dispersion of particles is still underestimated.

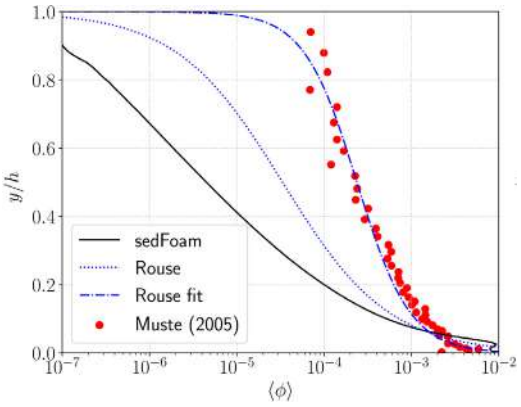

Figure 3: Concentration profiles from NS configuration using sedFoam compared with analytical Rouse profile with correction for inertial particles with $Sc = 0.48$ (Rouse fit) and without correction (Rouse) and experimental data from Muste et al. (2005) [2].

From the results presented in this paper, the Eulerian-Eulerian two-phase flow model can quantitatively reproduce velocity and concentration profiles for unidirectional channel flow laden with finite-size particles with low inertia ($St < 1$). However, when particles become inertial ($St > 1$), the two-phase flow model underestimates the turbulent diffusion and particles settle toward the bottom boundary.

It seems that some of the physics behind the turbulent suspension of inertial particles is not reproduced by the Eulerian-Eulerian two-phase flow equations. This physics is probably associated with small scale processes not resolved by the Eulerian-Eulerian approach and needs to be parameterized in order to get quantitative results. During the conference, the latest numerical results will be presented. The most recent simulations suggest that a correction for the finite size effect of the particles needs to be included in the model to recover the experimental and analytical concentration profiles.

Summary Erosion caused by particle-laden flows is an important phenomenon in many industrial applications, but existing models are restricted to simple geometries. The present work compares erosion predicted by wear models described in the literature with experimental results to assess the applicability of such models for CFD simulations of complex geometries. Numerical simulations for three different Reynolds numbers are used to compare wear patterns occurring in the flows resulting from an impinging jet and a square T-junction. The work reports differences on the extent and magnitude of the damages for both configurations that can be as high as 50%.

INTRODUCTION

Particle-laden flows are a major concern to industries in many sectors. The solid particles that are transported with the flow often cause damage on key components and equipment, reducing their lifespan and reliability. Erosion prediction in those environments are, thus, critical to ensure both high operational safety levels and proper forecast of maintenance interventions and expenditures.

The main issue of erosion prediction on industrial components is that erosion is a highly-complex phenomenon and classical modelling attempts at describing the provoked damages are derived and calibrated mainly through the impinging jet configuration. The absence of a general predictive model hinders the application of most models to other geometries and conditions [1].

This work aims at assessing the applicability of erosion wear models developed for jet impingement to other types of configurations, particularly to a square T-junction (a T-junction made with square cross section pipes). The work discusses how variations in Reynolds number and the change in geometry affect the extent (and the shape profile) of the damage caused by solid particle erosion.

The square geometry for the *Tee* was chosen so as to facilitate the use of removable metal coupons for erosion testing and to reduce the warping of flow visualization techniques. There are few studies in the literature on square Tee's and, for that reason, the numerical results presented of the following sections are compared with experimental data collected at a slurry flow experiment carried out at NIDF/UFRJ.

SET-UP AND CONDITIONS

The investigation conducted in the present work was based upon numerical simulations on the open-source CFD package OpenFOAM. The meshing for both the jet and the square *Tee* geometry were generated trough the `blockMesh` tool, with proper wall refinement to achieve (y^+) values compatible to the selected turbulence model. The hydraulic diameter for both the jet and the square T-junction is D_h = 25 mm. The nozzle distance to wall is also 25 mm and, for the *Tee*, each leg measured 25 D_h.

Water was the continuous phase, with kinematic viscosity of $\nu = 1.0\times10^{-6}\mathrm{m^2s^{-1}}$. Due to numerical requirements of the Lagrangian model, the cell sizes had to be kept larger than the particle sizes in order to avoid instabilities, which led to selecting the κ-ϵ model. The fluid flow was solved using the SIMPLE algorithm and the `simpleFoam` application. The Reynolds numbers are 6.25×10^4, 1.25×10^5 and 2.50×10^5.

The discrete phase was evaluated subsequently to the continuous field. A cloud of particles was released into the domain through the `icoUncoupledKinematicParcelFoam` module with an one-way coupling condition. The solid particles are Mesh 150 carbon silicate (SiC) abrasive particles, with size distribution presented in Figure 1a, density of $\rho_p = 3200\mathrm{kgm^{-3}}$ and sphericity of $\varphi = 0.8$ for the non-spherical drag model of Haider and Levenspiel [2]. In addiction to the default tools, additional libraries were developed to include partially inelastic particle-wall collision as a function of the angle of impact (Grant and Tabakoff [3]) and to compute the erosive damage using wear models available on the literature. The wall material was modelled as AISI 304 stainless steel flat plates, with density of 7896 $\mathrm{kgm^{-3}}$, elastic modulus of 193 MP_a and Brinell Hardness of 123.

Figure 1: Particle size distribution and erosion damage results

RESULTS

The numerical results are presented in Figure 1b, where the erosion profiles for all cases are plotted according to the wear model developed by Oka and Yoshida [4].

It is observed that the damage profile for both geometries are qualitatively similar; they have a W-shaped profile that is expected for slurry flows. Their resemblance is due to the similarity of velocity fields on the centreline of the jet and on the square T-junction, which produce similar dynamic conditions for the transport of the abrasive particles and subsequent wear.

It is also observed that changes on Reynolds number and geometry have effect not only on the magnitude of the damage, but also on the extent of the wear. Reynolds number clearly have an effect on the magnitude of the damage since it is intimately associated to the particles kinetic energy on impact. However, it is the change in geometry that produces interesting results.

The width of the erosion profile is larger at the *Tee* geometry than at the impinging jet configuration. Energy dissipates with the square of distance to the centreline on the jet, whereas the dominant 2D nature of the *Tee* reduces dissipation to the viscous effect of the flow.

The peak value of damage computed for the *Tee* is approximately 50% of that found for the jet at the same Reynolds number. The recirculating regions located on the opposite walls of the stagnation region help divert the trajectories of the particles compared to the jet case, as seen on Figure 1c.

CONCLUSIONS

The present work discusses the influence of Reynolds number and geometry changes on erosion pattern for particle-laden flows. Impact velocities and angles on the square T-junction are well within the values found and calibrated on the impingement jet configuration. This allows a measure of confidence when using the wear models available in the literature. Validation of the numerical results with experiments are also discussed.

The ultimate goal is to apply and validate jet-calibrated erosion models to very complex geometries where direct experimental validation of results becomes increasingly more difficult.

ACKNOWLEDGEMENTS

The authors are thankful to ANP and Petrobras for sponsoring this research effort.

Summary Motivated by the flow of glacial ice sheets over unconsolidated subglacial sediment and the formation of subglacial bedforms, we perform a theoretical and experimental study of the transport properties of particle-laden beds sheared by an overlying thin film of viscous fluid spreading under its own weight in two dynamical regimes. In the first regime, we examine motion at the particle scale as a superposition of a number of contributors to motion, including translational and rotational motion of a single particle, as well as shear flow and parabolic flow of a thin film of viscous fluid past an obstacle. In the second regime, we examine large-scale deformational motion of deep granular beds in terms of a model of bulk erosion and deposition of particles. We also conduct a series of fluid-mechanical laboratory experiments highlighting the mechanisms of particle transport in both regimes.

INTRODUCTION

Particle-laden flows and the transport of granular material at the bed of thin films of viscous fluids spreading under gravity, or viscous gravity currents, are ubiquitous in nature and result in the formation of various geophysical features including subglacial bedforms, moraines, and grounding zone wedges, or accumulations of subglacial sediment in the grounding zones of marine ice sheets, separating freely floating ice shelves from grounded ice sheets that are in contact with the bedrock and subglacial sediment.

We consider particle transport properties in two regimes, involving (a) the viscous transport of individual particles on the small scale and (b) the erosion and deposition of deep granular beds using a bulk transport model. These are detailed in the sections, below.

VISCOUS TRANSPORT AT THE PARTICLE SCALE

The first part of the study is concerned with viscous transport of granular material at the particle scale. In particular, we consider the transport of dense particles sheared by the flow of a thin film of viscous fluid spreading under the action of gravity as depicted in the schematic of Fig. 1a. We assume that the horizontal length scale associated with the flow of the thin film of viscous fluid is much larger than its depth and use lubrication theory to model the flow.

On the particle scale, we consider the motion of a spherical particle translating and rotating in a viscous fluid of nonuniform velocity along a rough horizontal substrate. We assume that the scale of roughness, δ, is small and build upon the methodologies of [9, 7, 3] to determine the motion of the particle in terms of a superposition of four contributions following from the linearity of the Stokes equations. These contributions involve (i) the translational motion of the particle in a fluid at rest far from the substrate, (ii) the rotational motion of the particle in a fluid at rest far from the substrate, (iii) a linear shear flow past a fixed particle, and (iv) a parabolic flow past a fixed particle. The last of these contributions follows from the hydrostatic pressure distribution within the gravitationally spreading film of viscous fluid. Each of these induce a hydrodynamic force and torque on the particle, which depends additionally on the proximity of the particle to the horizontal substrate. These have been determined by [5, 6] and used to determine particle motion by [9, 7, 3] for flows of the type (i)–(iii). We build upon this approach to determine particle motion in the additional presence of a parabolic component of velocity of the type (iv), associated with the flow of viscous fluids under gravity, by using expressions for the hydrodynamic force and torque determined by [10]. We also conduct a series of analogue fluid mechanical laboratory experiments highlighting the mechanisms of particle transport and conditions for particle accumulation. The experiments spanned a range of values for the fluid viscosity, density, source flux, as well as particle size and density.

BULK EROSION AND DEPOSITION OF DEEP GRANULAR BEDS

The second part of the study is concerned with bulk erosion and deposition of a deep particulate material or granular bed. In particular, we consider the flow of a thin film of viscous fluid spreading under gravity over a deep, saturated granular medium as depicted in the schematic of Fig. 1b. Its depth varies owing to the transport of particles sheared by the flow of the viscous fluid, resulting in net particle erosion and deposition. As depicted by the schematic of Fig. 1b, the granular bed consists of an upper layer of mobile particles, sheared by the overlying flow field, and a lower layer

*Corresponding author. E-mail: k.kowal@damtp.cam.ac.uk

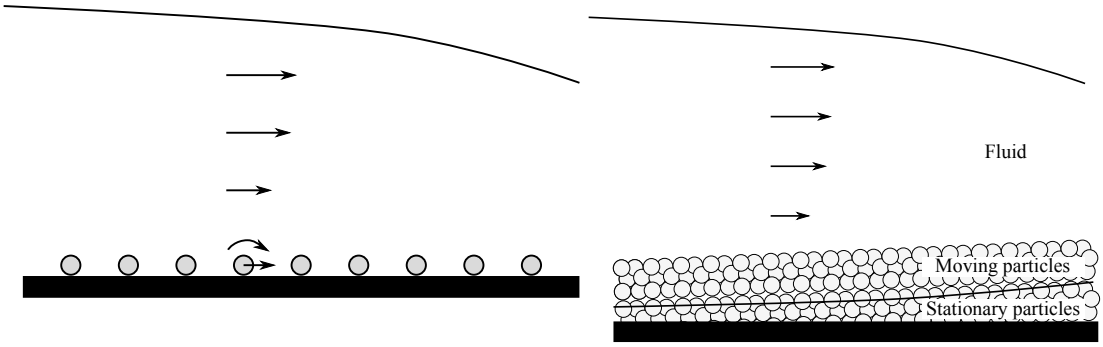

Figure 1: Schematic of the transport of particle-laden substrates at the particle scale (left) and bulk particle erosion and deposition of deep granular beds (right).

of stationary particles, unaffected by the flow. This approach contrasts with that of [8], in which subglacial material is modeled using a purely viscous rheology.

We model the flow of the viscous fluid using lubrication theory, assuming that the horizontal length scale is much larger than the film thickness. We assume that the dominant resistance to the flow of the thin film of viscous fluid is provided mainly by vertical shear stresses and that the Darcy velocity scale for the flow within the granular medium is much smaller than the velocity of the overlying viscous fluid, so that percolation through the pores is negligible. We model the erosion and deposition of particles by applying the principles developed by [4] and modified by [1, 2].

In particular, a particle is set into motion when the bottom shear stress exceeds a fraction of the apparent weight of the particle. Equivalently, this can be thought about in terms of the Shields number θ, involving the ratio of the basal shear stress to the apparent weight of the particle, which needs to exceed a threshold value in order for motion to occur. Following the theoretical development of [11, 4] and [1], we assume that the particle erosion rate is proportional to the excess shear rate above a threshold value, and that the deposition rate is proportial to the particle density per unit area, and inversely proportional to the settling time, or typical saltation time of moving particles during saltation flights. The number density of moving particles additionally depends upon the divergence of the flux of the number of moving particles, which we let to be proportional to the number density of moving particles and the mean particle velocity.

We additionally conduct a series of analogue fluid-mechanical laboratory experiments of the flow of viscous fluids over deep beds of granular material, depicting the main mechanisms of bed deformation.

CONCLUSIONS

We have performed a theoretical and experimental study of the transport of dense granular material sheared by the flow of an overlying film of viscous fluid in two dynamical regimes. We find large accumulations of granular material in regions of high basal shear stress, such as at the contact line of viscous gravity currents, which may serve as an explanation of the formation of glacial moraines and other subglacial bedforms.

We thank Mark Hallworth and the technicians of the G.K. Batchelor Laboratory for assistance in the setup of our experimental apparatus. We acknowledge financial support of the EPSRC-UROP Scheme and the L'Oréal-UNESCO UK and Ireland Fellowship For Women In Science.

PARTICLE-DROPLET INTERACTION IN TURBULENT CHANNEL FLOW

Arash Hajisharifi[1], Cristian Marchioli *[1], and Alfredo Soldati[1,2]
[1] Department of Engineering and Architecture, University of Udine, Italy
[2] Institute of Fluid Mechanics and Heat Transfer, TU Wien, Austria

Summary We examine the interaction between a swarm of small (sub-Kolmogorov) inertial particles and large deformable droplets in turbulent channel flow. To simulate such solid-liquid-liquid flow, we exploit an Eulerian-Lagrangian methodology based on direct numerical simulation of turbulence, coupled with a Phase Field Model to capture the interface dynamics and Lagrangian tracking to compute particle trajectories. We quantify particle-interface interaction in a situation where the droplets have the same density and viscosity of the carrier liquid (mimicking a water-oil emulsion), and particles are one-way coupled with the carrier phase. Our results show that particles can get trapped at the interface and accumulate in the regions of highest positive curvature. Accumulation is modulated by particle inertia: low-inertia particles exhibit a stronger tendency to stay on the interface, whereas high-inertia particles can escape more easily and after shorter trapping.

INTRODUCTION

A large variety of systems involves the adsorption of solid particles to the fluid interface between droplets/bubbles and a carrier liquid. Surface tension drives particle adhesion, thus forming a layer that may change the mechanical and mass transport properties of the interface. Important industrial applications where such phenomenon occurs include scrubbing processes, in which large liquid droplets are exploited to collect dust particles; froth flotation processes, in which particle adsorption to bubbles is essential for separating minerals from the slurry. Most of three-phase computational models available in the literature have been used to study the dynamics of a single particle trapped at a planar fluid interface [1], or the surface stress tensor modification for a pendant drop covered by a monolayer of particles in the low-Reynolds-number limit [2]. Only recently, a multiscale DEM-VOF method was developed to reproduce droplet formation and interface perturbations from a single particle [3]. In this paper, we perform a DNS (Direct Numerical Simulation)-based study of a three-phase turbulent flow in which a solid phase (particles) and a liquid phase (deformable droplets) are transported by a carrier phase (fluid). Specifically, we investigate the interaction between the particles and the droplets in a channel flow configuration. We consider particles with different size to investigate such interaction at varying particle inertia.

Methodology

The computational approach is based on DNS of the Continuity, Navier-Stokes and Cahn-Hilliard equations and on the solution of a Lagrangian equation of particle motion stemming from the balance of the forces acting on the particles (drag force and surface tension force, in the present study). The flow solver is based on a pseudo-spectral method that transforms the field variables into wave space to discretize the governing equations. In the homogeneous directions, all the quantities are expressed by Fourier expansions. In the wall-normal non-homogeneous direction, they are represented by Chebychev polynomials. The time integration algorithm follows an implicit/explicit scheme. All calculations relative to Continuity, Navier-Stokes and Cahn-Hilliard equations are carried out in wave space except for the non-linear terms, which are computed in the physical space and then transformed back to wave space. Particle tracking is performed in the physical space. The particle-interface interaction is modeled by considering a capillary force related to the liquid-liquid surface tension. This capillary force is exerted on the particles when they are in close proximity to the interface, and acts to push the particles towards the interface and capture them there. In other words, the force provides a potential well that drives particle accumulation at the interface, which thus acts as particle adsorber. Such accumulation may be favored or hindered depending on the combined action of turbulence, which tends to deform continuously the interface, and particle inertia, which tends to make particles deviate from fluid streamlines. One expects the surface tension force to be dominant over the other hydrodynamic forces (in particular, drag) at low particle inertia (namely, low Stokes number), thus favouring trapping. Conversely, as particle inertia increases with respect to the surface tension force, one should expect the drag force to become more important, possibly providing a means for particles to escape from the interface.

RESULTS

In this paper we show results relative to friction Reynolds number $Re = 150$ based on the channel half height h (the channel dimensions being $4\pi h \times 2\pi h \times 2h$ in the streamwise, spanwise and wall-normal directions, respectively), Weber number $We = 0.75$ (ratio between inertial forces and surface tension), Cahn number $Ch = 0.02$ (dimensionless interface thickness), Péclet number $Pe = 50$ (ratio between diffusive timescale and convective timescale) and particle friction Stokes numbers $St = 0.1$, 0.2, 0.4 and 0.8. For sake of brevity, we will show results for the $St = 0.8$ particles only. In our framework, particle accumulation is higher (resp. lower) for the lower-inertia (resp. higher-inertia) particles. The capillary force acting on the particles depends on the surface tension and on the local curvature of the droplet interface.

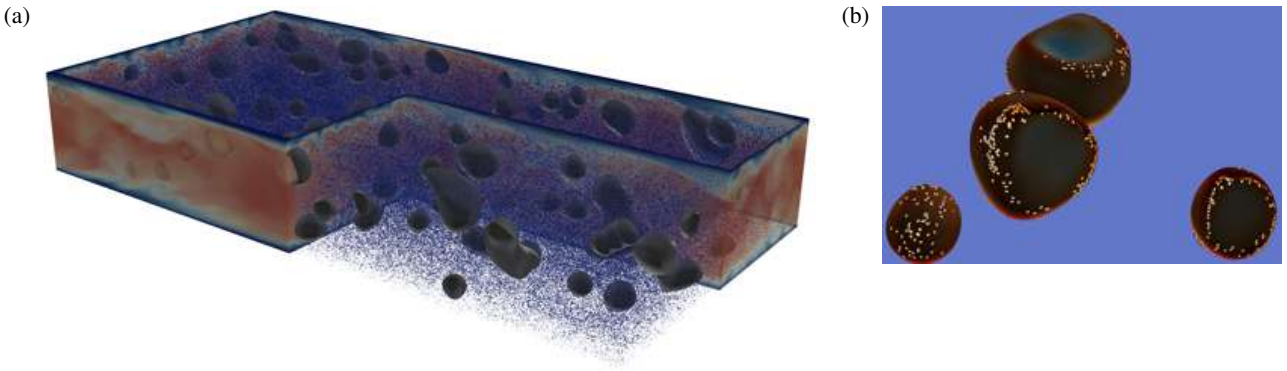

Figure 1: (a) Schematic of three-phase turbulence channel flow. (b) Droplets are rendered by colouring the interface with the local magnitude of curvature: Red areas correspond to higher-than-mean positive curvature (convex interfacial regions), blue areas correspond to the highest negative curvature (concave interfacial regions). Particles (yellow dots) appear to accumulate in regions of highest positive curvature.

The former changes with modification of surface composition and temperature, yet remains constant when these do not vary (as we assume in our simulations). Hence, the only parameter that can change the magnitude of the capillary force in our problem is the local curvature: The capillary force is stronger in regions where the curvature is higher (see Fig. 1b).

While trapped within the interface, particles tend to move towards the regions of highest positive curvature. This sampling is observed for all particle sets, and appears modulated by particle inertia. To quantify this effect, in Fig. 2 we show the Probability Density Function (PDF) of the interface curvature measured at particle position. To compute this PDF, we considered only the position that the particles occupy at the time instant in which they are leaving the interface after being trapped there. The PDF becomes negatively skewed as St increases, indicating higher probability of finding low-inertia particles in regions of strong interface convexity. Particles with higher inertia are believed to possess enough inertia to escape from the interface before reaching these region. Current work is devoted to the understanding of the physical mechanism that actually drive particle detachment from strongly-convex areas of the interface.

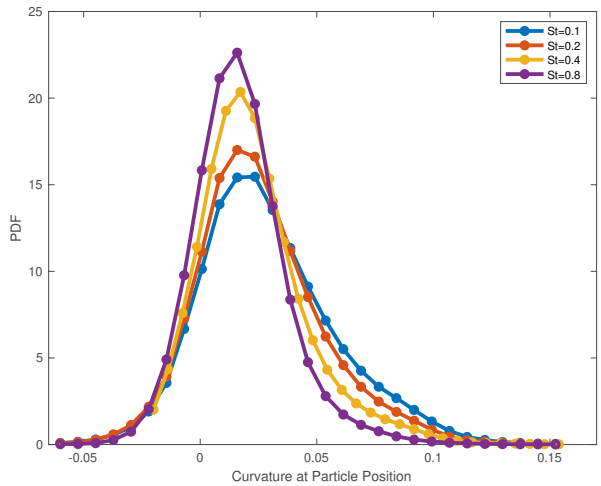

Figure 2: PDF of interface curvature at the position of the particles that are leaving the interface after trapping.

CONCLUSIONS

Our results show that inertia provides particles with a way to escape from the interface and reduce the time window over which particles interact with the interface. Low-inertia particles are found to accumulate at higher rates and are able to stay longer in close proximity of the droplet interface: Once trapped there, these particles exhibit the strongest tendency to collect in regions characterized by highly-positive values of the curvature.

MECHANISM OF TURBULENCE COLLAPSE IN PARTICLE-LADEN TURBULENT CHANNEL FLOW

Partha. S. Gowami *[1], Pradeep Muramulla[1], and Viswanath Kumaran[2]
[1] Department of Chemical Engineering, Indian Institute of Technology, Bombay, India
[2] Department of Chemical Engineering, Indian Institute of Science, Bangalore, India

Summary Direct Numerical Simulation of vertical particle-laden channel flows has been investigated to study the turbulence attenuation mechanism. A discontinuous decrease in the turbulence intensity at a critical volume fraction is observed. At the critical volume fraction turbulent energy production rate decreases by an order of magnitude but the energy dissipation due to particle drag increases by a smaller extent. Consequently, there is a decrease in the total energy dissipation. In the present study, the role of cross stream particle migration on the discontinuous transition, and the disruption of spatio-temporal evolution of the stream wise coherent structures at different particle loading have been explored.

INTOUDUCTION

Particle laden turbulent flows find applications in many industrial and environmental processes. In such flows, the presence of dispersed particle phase, largely influence the dynamic properties of carrier phase. Investigation of wall bounded particle laden flows is very important as presence of wall introduces additional complexity by making the flow inhomogeneous. One of the most complex issue in the dynamics of turbulent particle-gas suspensions is to predict the effect of the particles on the gas phase turbulence, i.e whether the particles will enhance or reduce the fluid turbulence. The broad consensus is that, in the presence of large particle intensity of turbulence increases due to wake formation behind the particles and small particles reduces turbulence due to particle induced drag. In our recent article ([1]), we have extensively studied the turbulence attenuation mechanism, for wide range of volume fractions, particle Stokes number and at two different Reynolds number. For the first time it has been observed in our work that the turbulence attenuation mechanism is not continuous with increase in particle volume fraction. At a critical volume loading, a discontinuous decrease in the fluid turbulence happens with a small change in volume fraction which is of the order of 10^{-4}. We concluded that, the reason for discontinuous decay is the reduction in turbulence production, but not due to increase in particle induced dissipation. In the current work, we have investigated the effect of particle migration on reduction in turbulence production, and disruption of turbulence structures in the presence of particles.The main focus is to quantify the extent of particle migration required in the wall normal direction for disruption of turbulence production. The effect of particle volume loading on the coherent structures have also been investigated.

NUMERICAL METHODOLOGY

The pressure-driven flow of a fluid with kinematic viscosity ν in a vertical channel of width h with average velocity $\bar{u}$ is simulated using two way coupled Direct Numerical Simulations (DNS). An Eulerian-Lagrangian method has been used with point-particle approximation for the particle phase. The dimensions of the channel are $4\pi h \times h \times (2\pi h/3)$ in the flow (x), wall-normal (y) and the span-wise (z) directions. Zero velocity boundary conditions are applied at the walls , while periodic boundary conditions are applied in the flow and the span-wise directions. The pseudo spectral method is used to solve the Navier Stokes equation for fluid phase. For Re $= 3300$, $128 \times 65 \times 64$ and for Re $= 5600$, $192 \times 129 \times 160$ nodes are used in x, y, and z direction respectively. The particle velocity is solved using the Newton'laws, the force on the particles is the sum of the drag force, force due to particle-particle, particle-wall collisions and the gravity. The particles are modelled as hard spheres and perfectly elastic. In the present work while modelling the particle drag force, corrections due to 'undisturbed' velocity at the particle center the wall effect on the particle drag and lift force are considered to capture the physics accurately. The particle phase is coupled with fluid phase by adding a feedback force, which is the neagtive of the particle drag force, to the fluid grid points using projection to the nearest neighbours. The particles are randomly distributed into the unladen turbulent flow, with velocity equal to fluid velocity interpolated at particle position. When the particle-gas suspension reaches steady state, the fluid and particle statistics are averaged in the homogeneous streamwise and spanwise direction over a period of 300 $(h/\bar{u})$ integral time scale.

RESULTS

Simulations are performed to study the effect of particle volume fraction $(0 - 2 \times 10^{-3})$ on turbulence attenuation for different Stokes number $(4.7 - 380)$ for two different Reynolds number ($Re_b = 3300\&5600$). It is observed that the turbulent intensity and Reynolds stress reduces by an order of magnitude at critical volume fraction for all the stokes number investigated here. From figure 1, it can be observed that the turbulence production rate decreases drastically at this critical volume fraction, and there is an increase in rate of energy dissipation due particle drag. But this rate of increase in the energy dissipation due to particle drag does not compensate and also much smaller than the rate of decrease in

*Corresponding author. E-mail: psg@iitb.ac.in.

turbulence production. Such an observation suggests that there is a discontinuous collapse in turbulence intensity due to disruption in turbulence production mechanism but not due to continuous increase in energy dissipation due to particle drag.

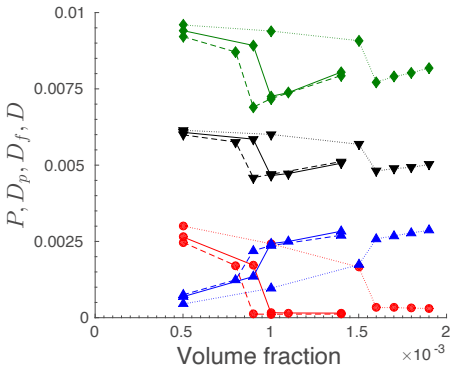

Figure 1: The scaled total rate of dissipation of energy per unit mass $D = -P + D_f + D_p$ ($\diamond$), the rate of transfer of energy per unit mass from the mean flow to the fluctuations $-P = \frac{h}{\bar{u}^3}\langle \overline{u'_x u'_y} \frac{d\bar{u}_x}{dy}$ ($\circ$), the rate of dissipation of energy due to the drag force exerted on the particles $D_p = \frac{h}{\rho \bar{u}^3 V} \sum_I \overline{\mathbf{u} \cdot \mathbf{F}_I}$($\triangle$), and the rate of dissipation of energy due to the mean shear in the fluid $D_f = \frac{\mu}{(\rho \bar{u}^3/h)} \langle \left(\frac{d\bar{u}_x}{dy} \right)^2 \rangle_s$ (∇) as a function of volume fraction for particle Stokes number 7.66 (dotted lines), 38.3 (solid lines), 114.9 (dashed lines)

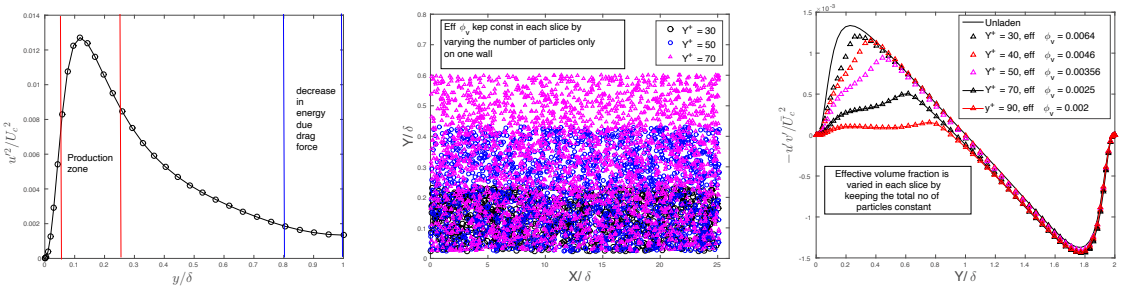
We have also investigated the effect of particle migration in the wall-normal direction. To investigate this effect we have considered two zones in the channel; Zone-1 (case a), where turbulence production and fluid intensity is maximum and Zone-2 (case b), where energy dissipation due to particle drag force is maximum (figure 2a). If the same number of particles are added in the Zone-1 and Zone-2 the percentage attenuation is maximum in case (a) compared to case (b). Another thought experiment is performed by adding the particles only in one half of the channel such that the particles are allowed to migrate from one wall to a certain distance in the wall normal direction for different case studies as shown in figure 2b. The other half of the channel is not disturbed so that there is no modification in turbulence intensity or Reynolds stress. From figure 2c, it can be observed that if the particles migrate less than a critical $y+$, decay in Reynold stress does not happen.



(a) Prodction and dissipation zones (b) Migration along differnet y (c) Decay in Reynolds stress

Figure 2: Effect of particle migration in wall-normal direction on turbulence intensity

CONCLUSIONS

The present findings suggest that there is a critical volume fraction for a particular stokes number where turbulence collapses discontinuously and particle migration in wall normal direction plays important role in behind the phenomena of turbulence collapse.

[3] Department of Industrial Engineering, University of Padova, Via Venezia [1], 35131 Padova, Italy

Summary We use interface-resolved direct numerical simulations to study gravity-free turbulent channel flow laden with small inertial particles with a diameter of three viscous wall-units and 100 times denser than the suspending fluid. The bulk Reynolds number is fixed so that it corresponds in the single-phase limit to a friction Reynolds number $Re_\tau \approx 180$, and three solid volume fractions are considered: 0.003%, 0.03% and 0.3%. The aim of these simulations is to study this flow in the point-particle limit, but without relying on the point-particle approximation to describe the particle dynamics. The resulting dataset is used to study the turbulence modulation by the dispersed phase, and can be used as benchmark to access the validity of one- and two-way coupling point-particle models.

INTRODUCTION

For many years, direct numerical simulations of particle-laden turbulent flows have been carried out using the point-particle approximation. This approximation assumes that the momentum exchange between the phases is well modeled by localised forces that mimic the presence of particles. Moreover, if the particle Stokes number is high enough, the equations governing the particle dynamics are often simplified to a balance between inertial and drag forces. At present, thanks to the continuous increase in computing time together with the development of efficient numerical methods, it has become possible to simulate these flows without relying on the point-particle assumption. Instead, it is now possible to directly enforce no-slip/no-penetration boundary condition on the surface of hundreds of thousands, or even millions of small spherical particles.

The present work revisits interface-resolved DNS of turbulent channel flows in the point-particle limit, without relying on modelling assumptions. We simulated three turbulent channel flow configurations with varying mass fraction. The goal is to mimic the so-called 1-way, 2-way coupling regimes [1]. The number of particles was varied from 500 to $50,000$ particles, simulated on a mesh with $12D/\Delta\ell$ grid points over the particle diameter, corresponding to 13.5 billion Eulerian grid points. The objective of the study is to develop a database for validation of point-particle models, to better quantify the borderline between coupling regimes, and to better understand the underlying mechanisms responsible for turbulence modulation in this complex flow.

NUMERICAL METHOD AND COMPUTATIONAL SETUP

The Navier-Stokes equations are solved with a second-order finite-difference method on a three-dimensional, staggered Cartesian grid, using a fast-Fourier-transform-based pressure-projection method. The solver was extended with a direct forcing immersed-boundary method (IBM) for particle-laden flows developed in [2] and the collision model for particle–particle and particle–wall interactions in [3]. Pressure-driven turbulent channel flow is simulated in a domain periodic in the streamwise and spanwise directions, with no-slip/no-penetration boundary conditions imposed at the walls. The physical and computational governing parameters are reported in table 1. We should note that the first two cases in table 1, *VD* and *D*, have been presented in [4].

RESULTS

Figure 1 (left) shows a visualization of the turbulent channel flow laden with the interface-resolved particles for the dilute case *D* (see table 1). In addition to the flow coherent structures, resmbling those of turbulent channel flow at this relatively low Reynolds number, the figure clearly shows the localized effect of each resolved particle on the flow with high-vorticity regions caused by their wakes. The overall drag, expressed in terms of a friction Reynolds number, is shown in Table 1. As discussed in [4], case *D*, with 3% bulk mass fraction of particles, shows a considerably large increase in drag, while case *VD* has negligible two-way coupling effects. This large increase for case *D* is attributed to a dense and localized layer of particles near the wall, flowing with high velocity. Interestingly, the semi-dilute case *SD*, with a mass fraction ten times larger than *D*, shows a milder increase in drag.

To better understand this milder increase in drag from case *D* to *SD*, we present the profiles of mean velocity and Reynolds stresses in the right-hand-side of figure 1. The mean velocity profile (top label of the figure) shows a significant

Case	Φ (N_p)	Ψ	Notes	Re_τ
VD	0.003% (500)	0.337%	very dilute (VD) case	180 ± 1
D	0.034% $(5\,000)$	3.367%	dilute (D) case	188 ± 1
SD	0.334% $(50\,000)$	33.67%	semi-dilute (SD) case	193 ± 1

Table 1: Computational parameters. Φ/Ψ denotes the bulk solid volume/mass fraction, and N_p the total number of particles. For all cases, the bulk Reynolds number $Re_b = 5\,600$ (i.e. unladen friction Reynolds number $Re_\tau^{sph} \approx 180$); particle size ratio $D/(2h) = 1/120$; particle-to-fluid mass density ratio $\Pi_\rho = 100$, corresponding to a particle diameter (in viscous units) $D^+ = 3$ and a Stokes number $St = 50$. The fluid domain is discretized on a regular Cartesian grid with $(L_x/N_x) \times (L_y/N_y) \times (L_z/N_z) = (6h/4320) \times (2h/1440) \times (3h/2160)$, while the particles are resolved with $D/\Delta x = 12$ grid points over the particle diameter (420 Lagrangian grid points in total). The last column reports the friction Reynolds number Re_τ extracted from the simulations.

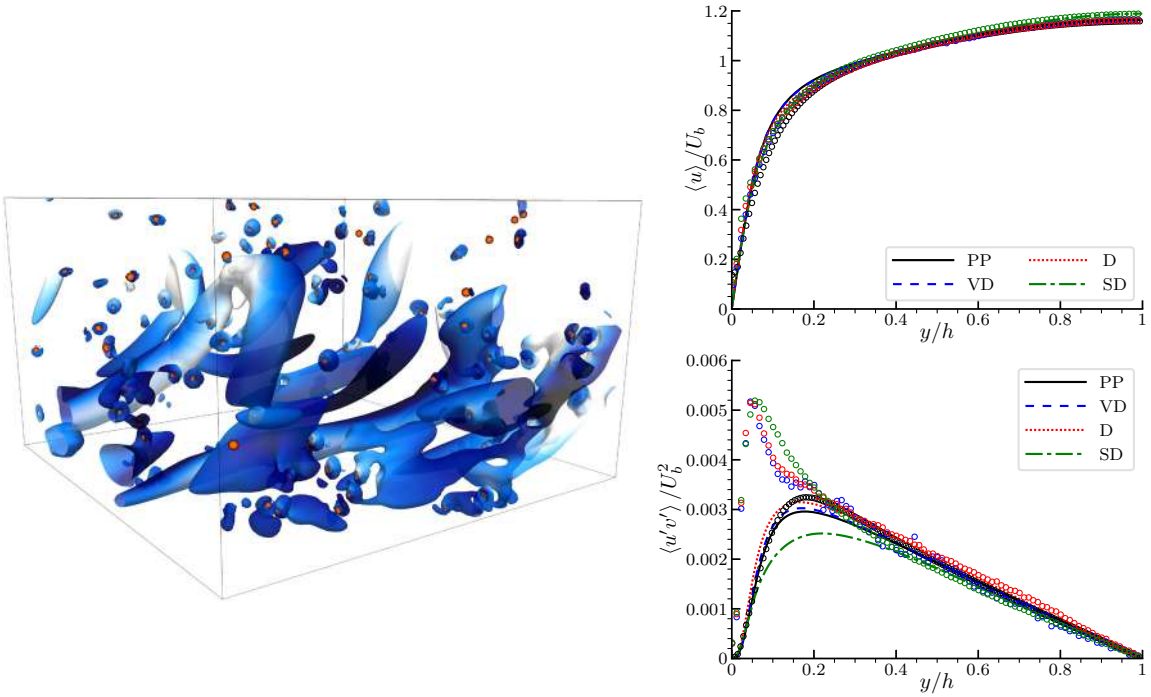

Figure 1: Left: Visualization of case *D* near the wall. Isocontours of the Q-criterion $Q = 20(U_b/h)^2$ coloured by the local wall-normal velocity (blue – low and white – high), with the particles shown in orange. Right: Profiles of mean streamwise velocity (top) and Reynolds-stresses (bottom). The profiles are normalized by the bulk velocity U_b and half channel height h. The symbols (color-matched) pertain to the solid phase velocity statistics. Case *PP*, corresponds to a one-way-coupled point-particle simulation with dynamics driven by a balance between inertial and (Schiller-Naumann) drag forces [4].

increase in centreline velocity for case *D*. This trend is opposite to what is observed in single-phase turbulent channel flow with increased friction Reynolds number, where the centreline velocity normalized by the bulk velocity decreases. This can be a first indication that, despite the increase in friction Reynolds number, some competing mechanism responsible for turbulence attenuation is mitigating the drag increase. Indeed, despite the increase in drag for case *SD*, the profile of fluid Reynolds stresses is greatly reduced (see the bottom panel on the right-hand-side of the figure 1). This suggests that, while for case *D* the flow statistics resemble those of a turbulent channel flow with increase wall friction due to the slip velocity that near-wall particles enforce on the flow, the statistics in case *SD* cannot be qualitatively explained by an effective increase in wall shear. Instead, two-way coupling effects in the bulk of the channel appear to be become non-negligible.

SURFACTANT-LADEN BURSTING BUBBLES

Summary The physical mechanisms which govern the ejection of droplet in bursting bubbles have received a significant interest due to their occurrence in a multitude of natural and industrial applications. The effect of the surfactant, and associated Marangoni stresses on their dynamics have not been reported. For that reason, we perform fully three-dimensional direct numerical simulations in the presence of soluble surfactant to elucidate its effect on the bubble dynamics. The characteristics of the ejected droplets (e.g. number, sizes, velocity) are analysed and the importance of Marangoni stresses are studied.

BACKGROUND

When bubbles are resting close to a liquid-gas interface, the formation of a central jet and subsequently small droplets is observed after they burst. Those droplets play a key role in the exchange between the air and the liquid phase since they have a similar chemical composition as the liquid. The dynamics of surfactant-free bursting bubbles for the ejection of droplets have been widely documented [2-5]. However, the effect of surfactant on the dynamics of the interface is not well understood. The presence of surfactants give rise to the formation of gradients in surface tension, and hence Marangoni stresses in the plane of the interface. We present fully three-dimensional direct numerical simulations where surfactant is either soluble or insoluble.

PROBLEM FORMULATION

The numerical simulation was performed by solving the 3D, two-phase, incompressible Navier-Stokes equations with surface tension. The physical parameters of the system are the initial bubble radius R_o, the liquid density ρ, the liquid viscosity μ, the surface tension σ_s and the gravity g. The viscosity and density ratios correspond to water in air with, $\rho_a/\rho = 1.2 \times 10^{-3}$ and $\mu_a/\mu = 0.018$, where the subscript designates the air phase. The governing equations for the flow have been made dimensionless by using R_o and $t = \sqrt{\rho R_o^3/\sigma}$ as length and time scales, respectively. Therefore, the system is fully described by two dimensionaless parameters: the Ohnesorge number Oh (ratio of capillary forces to viscous forces) and the Bond number Bo (ratio of gravity to capillary forces). Here, we will use Laplace number, La and Bo to parametrise our flow:

$$La = \frac{1}{\sqrt{Oh}}, \quad La = \frac{\rho\sigma R_o}{\mu^2}, \quad Bo = \frac{\rho g R_o^2}{\sigma_s} \tag{1}$$

In our simulations, surfactant is present either on the interface and/or in the bulk, with concentration Γ and C, respectively, allowing mass transfer between the bulk and the interface. The nondimenionalisation of the surfactant transport equations (using the maximum packing concentration, Γ_∞) leads to the following dimensional parameters

$$Pe = \frac{uR_o}{D}, \quad \beta = \frac{R_o T \Gamma_\infty}{\sigma_s}, \quad x = \frac{\Gamma_{eq}}{\Gamma_\infty} = \frac{k}{1+k}, \quad k = \frac{k_a C_\infty}{k_d}, \quad Bi = \frac{k_d R_o}{u} \tag{2}$$

where Pe is the Peclet number (ratio of convective to diffusive time scales at the interface and in the bulk), β is the elasticity number (a measure of the effect of surfactant on the surface tension), x is the surface coverage, Bi is the Biot number (ratio of desorption to convective time scales) and k (ratio of adsorption to desorption time scales) is the adsorption parameter. In the previous equations, u stands for the velocity, D stands for the surfactant interfacial and bulk diffusivities, k_a and k_d stand for the kinetic constants for adsorption and desorption, respectively and C_∞ denotes the surfactant concentration in the bulk.

We use the Level Contour Reconstruction Method proposed by Shin *et al.* (2018) [6] to perform our high-fidelity numerical simulations. The interface-tracking nature of the numerical method facilitates tracking the spatio-temporal evolution of the interfacial concentration field. The numerical simulations have been validated against the work of Lai *et al.* (2018) [4] and Eggers (1997) [1] in terms of scaling arguments with respect to the length of the jet and the breakup of a liquid thread, respectively. The initial bubble shape is determined by solving the Young-Laplace equations.

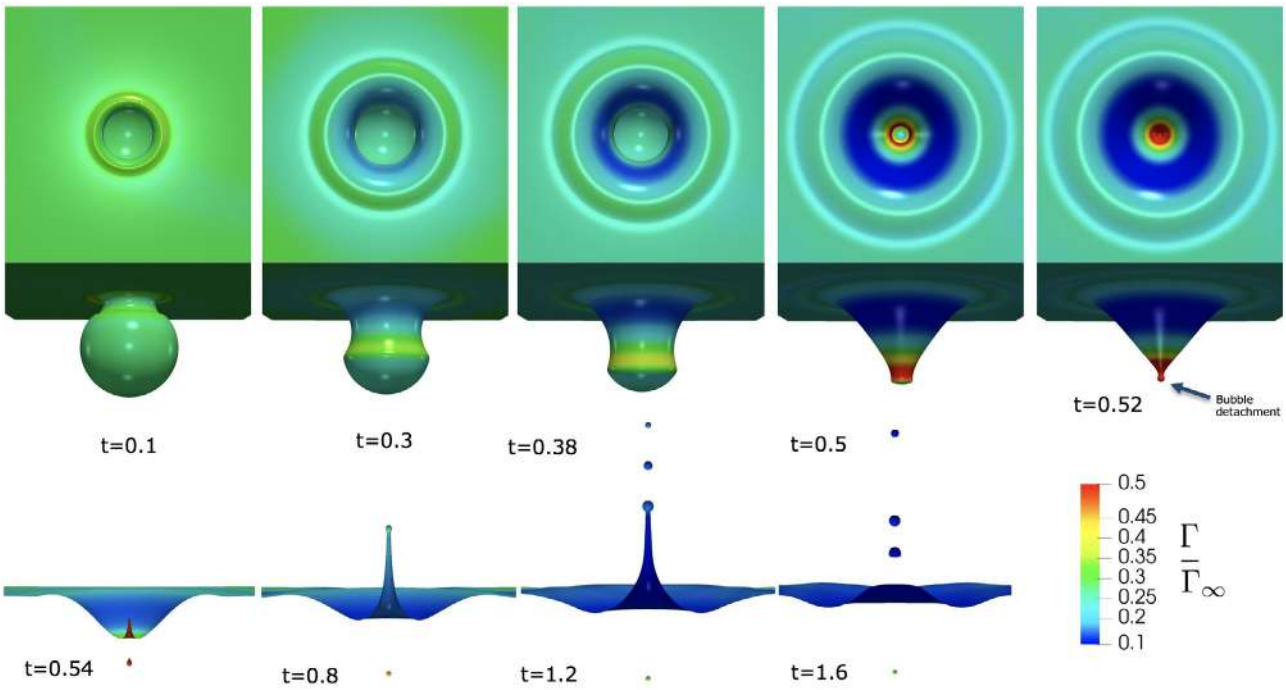

Figure 1: Spatio-temporal dynamics of bursting bubbles in the presence of soluble surfactant with $La = 2000$, $Bo = 10^{-3}$, $Pe_s = 10$, $\beta_s = 0.3$, $Bi = 2$, $x = 0.5$, and $\Gamma_o = x\Gamma_\infty/2$.

RESULTS

To simplify the initialisation of the interface we have removed the spherical cap ($r \sim 0.01R_o$) as in previous studies [3,4]. Fig. 1 shows the spatio/temporal evolution of the interface coloured by the surfactant concentration. As time increases, a higher deformation of the interface is observed, and the bubble tries to penetrate the interface. Surfactant is swept at the back of the bubble where it is accumulated, achieving its maximum surfactant concentration at the moment of the bubble detachment ($t \sim 0.52$). Fig. 1 shows the flow time scales which is in order of microsecond.

In the presence of surfactant, and due to the Marangoni-induced retardation of the dynamics as a result of flow flowing from high-concentration to low-concentration regions, the jet is shorter in length and a reduction of the number of resultant droplets is observed (as the resulting Marangoni stresses induce fluid down from the tip of the jet to the bulk). We have also observed a stronger production of vorticity close to the interface due to the presence of Marangoni stresses (not shown here).

CONCLUSIONS

The effects of surfactant, and associated Marangoni stresses on the dynamics of bursting bubbles are studied. In the sample result presented here we see the spatio-temporal evolution of the interfacial concentration where surfactant species are convected to the back of the bubble. The resultant Marangoni stress acts to retard the dynamics and a stronger production of vorticity is observed.

BREAKUP OF A LIQUID COLUMN JET IN A SURROUNDING GAS FLOWING THROUGH A COAXIAL CYLINDRICAL SHEATH

Takao Yoshinaga*
Research Center for Highly-Functional Nanoparticles, Doshisha University, Kyotanabe, Kyoto, Japan

Summary In this article, breakup phenomena of a viscous liquid column jet in an inviscid stationary surrounding gas are analytically investigated, when the jet flows through a coaxial cylindrical sheath. Under a long wave approximation, axisymmetric nonlinear evolution equations of the jet and surrounding gas are derived and numerically solved under a spatially periodic boundary condition. In the nonlinear analysis, there exist three types of breakup modes: Rayleigh, first and second wind-induced modes, and their existing regions are shown in the parameter space of Weber number and sheath radius. In particular, it is found that the second wind-induced mode always appears even in a small Weber number if the coaxial cylindrical sheath is more closely placed to the jet.

INTRODUCTION

Liquid jets are of great importance in engineering and industrial applications in producing micro-drops and thin fibers, where destabilization in the former and stabilization in the latter play an important role. Such instabilities have been investigated experimentally and theoretically since Lord Rayleigh examined linear instabilities of periodic disturbances on a liquid column. It is known that, when Weber number (=inertial/surface tension) increases, some breakup mode transitions appear from Rayleigh mode to atomization mode through the first and second wind-induced modes [1]. In the Rayleigh mode the surface tension dominates and large liquid drops are produced by pinching, while in the first wind-induced mode produced drops diminish due to the reduction of the surface tension. In the second wind-induced mode, fine liquid drops are produced at the jet surface as well as at the top of the jet, while in the atomization mode fine droplets are produced near the nozzle. In these last two modes the aerodynamic instabilities are dominated. Although the Rayleigh and first wind-induced modes have been examined analytically and experimentally, the second wind-induced and atomization modes are mainly examined in experiments except for linear instabilities and numerical analyses. In this article, analytically examined is breakup of a liquid jet in a surrounding gas flowing through a coaxial cylindrical sheath. The end of this study is to analytically clarify the influence of the sheath wall on the breakup modes from the Rayleigh to the second wind-induced ones in the nonlinear regime.

FORMULATION AND LONG WAVE APPROXIMATIONS

As is shown in Fig. 1, we consider a problem of a viscous liquid jet in a surrounding gas in the (r, θ, z) cylindrical coordinate system. The jet of radius $r = h(\theta, z, t)$ flows through a coaxial cylindrical sheath of constant radius $r = H$ $(h < H)$. Denoting the jet and the surrounding gas as $j = 1$ and 2, respectively, the velocity vector $\boldsymbol{v}_j = (u_j, v_j, w_j)$, the pressures p_j are functions of r, θ, z and time t. The surface tension is denoted as σ, the densities as ρ_j and the viscosities as μ_j, where the gas viscosity is neglected $(\mu_2 = 0)$, for simplicity. The basic equations consist of the continuity and momentum equations, while the boundary conditions consist of the kinematical and dynamical conditions on the interface and vanishing normal velocity is imposed on the sheath wall.

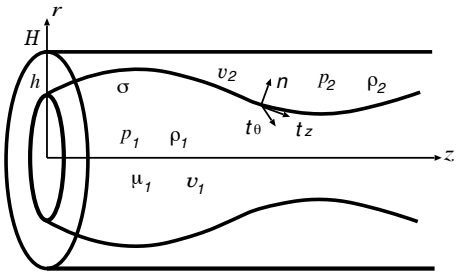

Figure 1: Schematic of a liquid jet in a surrounding gas flowing through a coaxial cylindrical sheath.

In the nonlinear analysis, we consider axisymmetric deformations of the jet, though full-three dimensional linear instabilities are examined in order to see the validity of a long wave approximation. As the long wave approximation, the following series expansions are adopted to the core jet $(0 \le r < h)$ [2]: $w_1 = w_1^{(0)} + r^2 w_1^{(2)} + \cdots$, $p_1 = p_1^{(0)} + r^2 p_1^{(2)} + \cdots$, while to the surrounding gas phase $(h < r < H)$ [3, 4]: $u_2 = u_2^{(0)} + (r-R)u_2^{(1)} + (r-R)^2 u_2^{(2)} + \cdots$, $w_2 = w_2^{(0)} + (r-R)w_2^{(1)} + (r-R)^2 w_2^{(2)} + \cdots$, $p_2 = p_2^{(0)} + (r-R)p_2^{(1)} + (r-R)^2 p_2^{(2)} + \cdots$. In the above and hereafter the radius at the mid-plane of the surrounding gas phase $R \equiv (H+h)/2$ and the thickness $b \equiv H - h$ are introduced for convenience. Then, substituting these expansions into the continuity, momentum equations and the boundary conditions and neglecting the terms of $O(h^2)$ and $O(b^2)$, we finally obtain the following time evolution equations: $\dfrac{\partial h}{\partial t} = -w_1 \dfrac{\partial h}{\partial z} - \dfrac{h}{2}\dfrac{\partial w_1}{\partial z}$, $\dfrac{\partial w_1}{\partial t} =$

*Corresponding author. Email: tyoshina@mail.doshisha.ac.jp

$$-w_1\frac{\partial w_1}{\partial z}-\frac{\partial p_1}{\partial z}+\frac{1}{\mathrm{Re}}\Big(2\frac{\partial^2 w_1}{\partial z^2}+\frac{6}{h}\frac{\partial h}{\partial z}\frac{\partial w_1}{\partial z}\Big),\quad \frac{\partial u_2}{\partial t}=-w_2\frac{\partial u_2}{\partial z}-\frac{1}{\gamma}p_2^{(1)},\quad \frac{\partial w_2}{\partial t}=-w_2\frac{\partial w_2}{\partial z}-\frac{1}{\gamma}\Big(\frac{\partial p_2^{(0)}}{\partial z}-p_2^{(1)}\frac{\partial R}{\partial z}\Big),$$

and the following simultaneous pressure equations: $\Big(A_1\frac{\partial^2}{\partial z^2}+A_2\frac{\partial}{\partial z}\Big)p_2^{(0)}+\Big(A_3\frac{\partial^2}{\partial z^2}+A_4\frac{\partial}{\partial z}+A_5\Big)p_2^{(1)}+A_6=0$, $\Big(B_1\frac{\partial^2}{\partial z^2}+B_2\frac{\partial}{\partial z}\Big)p_2^{(0)}+\Big(B_3\frac{\partial^2}{\partial z^2}+B_4\frac{\partial}{\partial z}+B_5\Big)p_2^{(1)}+B_6=0$. In the above, the coefficients of A_1 to A_6 and B_1 to B_6 are rather complicated functions of h, w_1, w_2 and u_2 and the following pressure relation is to be used: $p_1=p_2^{(0)}+p_2^{(1)}(h-R)+\frac{\kappa}{\mathrm{Wb}}-\frac{1}{\mathrm{Re}}\frac{\partial w_1}{\partial z}$. Nondimensional parameters such as Weber number $\mathrm{Wb}=\rho_1 W^2 a/\sigma$, Reynolds number $\mathrm{Re}=\rho_1 W a/\mu_1$, density ratio $\gamma=\rho_2/\rho_1$ and sheath radius H are introduced in the use of characteristic axial velocity W and jet radius a.

NUMERICAL RESULTS AND CONCLUDING REMARKS

Figure 2 shows typical breakup profiles when the above evolution and pressure equations are numerically solved for sinusoidal disturbances with initial wave number $k=k_m$ corresponding to the linear maximum growth rate. It is found in the figure that the Rayleigh modes appears in (a) by producing large drops and satellites, while the second wind-induced mode in (b) by cusp formation and fine droplets are to be produced from tip of the cusp. On the other hand, the first wind-induced mode appears in (c) by producing smaller blobs connected by threads without pinching. Figure 3 shows existing regions of these typical breakup modes in the parameter space of Wb and H. It is found for $\mathrm{Re}=\infty$ (solid lines) that the second wind-induced mode prevails always for smaller H whose boundary gradually increases with the increase of Wb. On the other hand, when H increases above the boundary, the Rayleigh mode prevails for smaller Wb, while the first wind-induced mode for larger Wb. In addition to this, the Rayleigh mode appears between the first and second wind-induced modes for $200\lesssim\mathrm{Wb}\lesssim 500$. In these existing regions, the second wind-induced mode survives for larger H as $\mathrm{Re}=100$ (broken lines), while as γ increases we can show that the first wind-induced mode appears for much smaller Wb though the second wind-induced mode is always existing in smaller H.

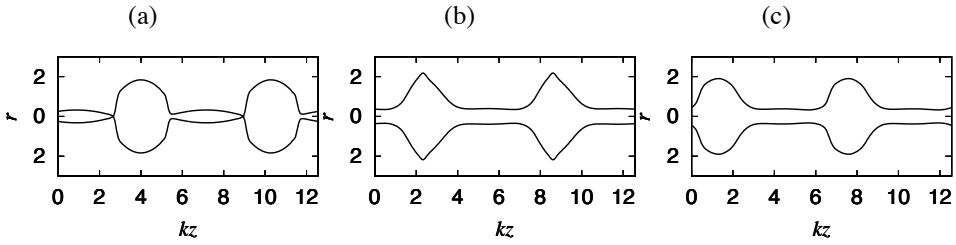

Figure 2: Breakup profiles when $\gamma=0.001$ and $\mathrm{Re}=\infty$, where $H=2$ ($k_m=0.738$) and $\mathrm{Wb}=100$ in (a), $H=2.2$ ($k_m=1.042$) and $\mathrm{Wb}=1000$ in (b) and $H=2.3$ ($k_m=1.042$) and $\mathrm{Wb}=1000$ in (c) .

It is shown in the experiments for the unbounded surrounding gas [1] that the first-wind induced mode appears when $600\lesssim\mathrm{Wb}\lesssim 6500$, while the second-wind induced mode appears when $6500\lesssim\mathrm{Wb}\lesssim 20000$. However, the present results show that the first wind-induced modes can appear for larger Wb than $200\sim500$ depending on H, while the second wind induced mode always appears when $H\lesssim 2$ even for a small Wb which is the most influence of the sheath wall. Consequently, by placing it closely to the jet, the sheath wall could be available to produce the cusp breakup from which fine droplets to be produced.

This work has been partially supported by JSPS KAKENHI Grant Number JP16K06082.

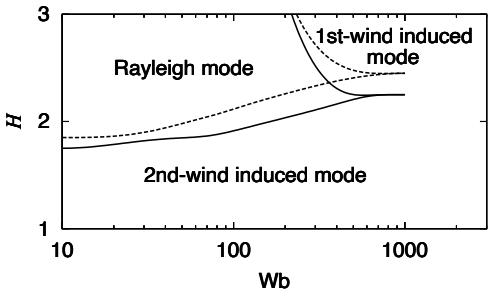

Figure 3: Regions of the Rayleigh and Taylor (1st- and 2nd-wind induced) modes in the parameter space of Wb and H, where $\gamma=0.001$ for $\mathrm{Re}=\infty$ (solid lines) and 100 (broken lines).

A COMPUTATIONAL TECHNIQUE FOR STUDYING SHOCK-INDUCED BUBBLE CAVITATION NEAR COMPLIANT SURFACES

Mohamad Aslani[1], Kourosh Shoele *[1]
[1] Department of Mechanical Engineering, Florida State University, Tallahassee, Florida, USA

Summary A cavitating bubble hitting a solid surface generates a convoluted interaction between the resultant flow field from the bubble dynamic and the sold surface. We present details of a computational technique for a compressible flow solver capable of simulating such a stiff multi-material interaction. The developed scheme uses an interface capturing technique in a control volume setting and tracks the computationally smoothed interfaces using an advection equation for the volume of the phases. In this way, fluid and solid flows are all integrated into a fully Eulerian framework which significantly improves the computational efficiency of the overall algorithm. Preliminary results show that the method is capable of simulating shock-bubble interaction with interfacial forces.

INTRODUCTION

This research is motivated by the importance of understanding the cavitating bubble-compliant surface interaction and the merging technology of cleaning biofilms based on this technique. Biological fouling activities can cause losses in heat transfer efficiency of cooling systems, mechanical blockage in fluid transport systems, and an increase in drag of marine surfaces. Multiple chemical, material, and physical approaches are proposed and utilized to fight against biofouling, but these methods come with several shortcomings. An alternative novel technique in this area is bubble cavitation (commonly known to be a devastating phenomenon). This method is an emerging technology for cleaning biofilms in different industrial and medical applications [1]. It has been used to clean up biofilm on the surface of membrane filtration in the wastewater treatment where ultrasound can significantly decrease the concentration of biofilm near membrane filters through disturbing biofilm extracellular substances without the use of any chemical cleaning reagent. It has also been leveraged in ultrasound histotripsy allowing the noninvasive break down of the tissue using the transient cavitation action of microbubbles. Given the complex procedure of bubble cavitation using compression waves, and convoluted interaction between resultant flow field from bubble dynamic and the characteristics of the biofilm, it is almost impossible to come to the conclusion of the effectiveness of this technology for the removal of marine biofilm solely from experiments. Numerical simulations of such phenomena require compressible multiphase flow simulations with special treatment for solid-fluid interfacial interactions.

Developing high-fidelity numerical techniques capable of simulating gas, liquid, and solid phases are ongoing research. The interfaces in such flows could potentially undergo rapid evolution with deformation in a three-dimensional configuration that requires efficient numerical modeling. In this study, we focus on a numerical technique to simulate compressible gases, liquids, and elastic solids using an interface capturing method [2]. The method takes into account viscous and interfacial forces to accurately model the interaction of a cavitating bubble with a deforming solid interface. The aspects of the developed techniques are briefly discussed in the next two sections.

GOVERNING EQUATIONS

Mass, momentum, and energy conservation laws in the Eulerian framework dictate the governing equations. To describe the continuous medium in the Eulerian framework, we use the backward characteristic model already discussed in [3]. This equation is used to track and evolve the gradient of the deformation in the current framework needed in the Cauchy stress tensor. Finally, an advection equation is required to track the location of interfaces. The overall scheme is written in a quasi-conservative form in order to prevent possible pressure oscillations in the interfaces (for more details see [4-5]). There are extra forces due to the capillary effects which are introduced through the continuous surface force (CSF) model. One important feature of this study is the inclusion of viscous and interfacial forces in the model.

To close the system of equations, we use a constitutive law to model gas, liquid, and solid phases. In this model, the internal energy is defined as

$$e = \underbrace{\underbrace{\frac{\kappa(s)}{\gamma-1}\left(\frac{1}{\rho}-b\right)^{1-\gamma}}_{I} - a\rho + \frac{p_\infty}{\rho}}_{II} + \overbrace{\frac{\xi}{\rho_0}(Tr(\bar{B})-3)}^{III}$$

where (I) is the van der Waals law for the gas phase, (II) is the stiffened gas equation for the liquid phase and (III) part is the neohookean elastic solid model.

NUMERICAL SCHEME

The overall numerical scheme is based on solving the approximate Riemann problem using a modified Harten–Lax–van Leer Contact (HLLC) technique and integrating the equations using a third-order TVD Runge-Kutta method. The HLLC

*Corresponding author. E-mail: kshoele@fsu.edu.

solver is modified to account for elastic solid and the pressure jump in the interface of a liquid due to the capillary effects. It should also be noted that due to the numerical diffusion introduced into the solution from the HLLC method (upwinding) the density and the volume fraction are stiffened systematically and consistently using a compressible version of the Tangent of Hyperbola for Interface Capturing (THINC) method.

PRELIMINARY RESULTS

In this section, we present the preliminary results obtained for the simulation of a bubble interacting with a shockwave. The shockwave is initiated in water (simulated as a stiffened gas) and undergoes a complex geometry change when the shockwave passes through it. This complex geometry is the result of multiple waves interacting with the bubble medium that reflects back and forth and change in the impedance of the mediums. The method is able to accurately capture all of these features as it can be seen in these simulations.

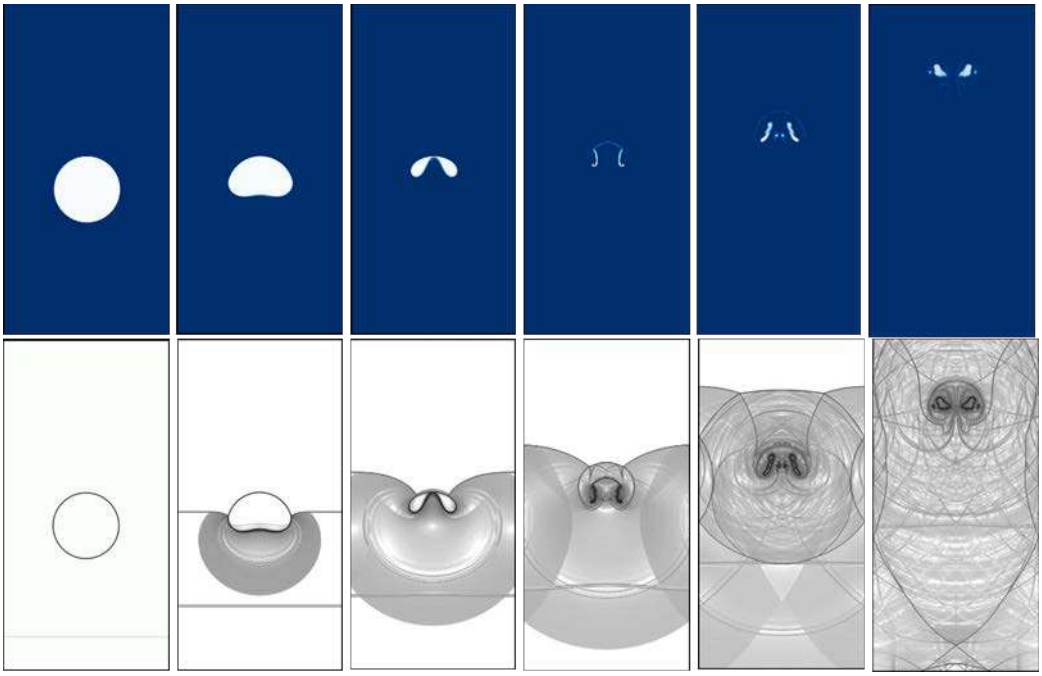

Figure 1. Preliminary results for the shock-induced cavitating bubble. The top is the phasic volume and below are the magnitude f density gradients.

CONCLUSIONS

In this abstract, we briefly discussed the development of a compressible flow solver capable of simulating gas, fluid, and solid phases consistently and accurately. The compressible Navier-Stokes equations were discretized using a finite-volume scheme and the upwind fluxes were found using a modified HLLC scheme. A constitutive law was used to account for the state variables in gas, liquid, and elastic materials. This model will be used to further study the biofilm removal techniques based on cavitating bubbles.

NUMERICAL INVESTIGATION OF THE EFFECT OF PRESSURE ON THE FLOW FIELD AND SPRAY STRUCTURE AND EVAPORATION

Ala sadooghi*[1], Maryam Shahrasebi [2], Hassan Khaleghi[1]
[1] Department of Mechanical Engineering, Tarbiat Modares University, Tehran, Iran
[2] Department of Mechanical Engineering, K.N.Toosi University of techonology, Tehran, Iran

Summary: In this paper, the effect of ambient pressure on the evaporation of the fuel Spray of droplets is numerically investigated in Eulerian-Lagrangian two-phase modeling. In the spray modeling, size distributions for the initial diameter of droplets, Break-Up of droplets, Collision phenomena, and evaporation of droplets are considered. Besides, turbulence dispersion and modulation are investigated simultaneously. Moreover, the coupling between the continuous phase and the discrete phase is 2-ways coupling. Although the evaporation of droplets in both, high and low temperatures has a direct relation with the ambient pressure, it should be noted that the higher impact is regarding high-pressure conditions. Also, the effect of the ambient pressure on the spray structure and spray tip-penetration is shown that the results show the Spray structure is thinner in high ambient pressure which comes with low penetration in the continuous phase. With respect to the continuous phase, the temperature of the gas-phase goes down during the time that the droplets evaporate and get heat from the gas phase, especially in the core of the spray that the number of droplets is more than other parts of the spray. Also, the impact of droplet's momentum on the gas-phase is shown, especially on the Z-direction which is near the attitude of injection direction and the velocity of the continuous phase is changed and increased.

Liquid and gas phase equations

In this section, first, the equations that are governed the gas-phase are introduced, and then the equations that are governed the liquid-phase, which is Lagrangian-phase, are introduced.

On the gas-phase which is the continuous phase, Navier-Stokes equations are governed. Also, the $k-\varepsilon$ turbulent model is used in this study. The general transport equation that includes ϕ and Γ can be replaced by the parameters of Table-1 for having mass, momentum, energy, turbulent kinetic energy, turbulent dissipation energy, and fuel vapor mass fraction.

$$\frac{\partial(\rho\phi\theta)}{\partial t}+\frac{\partial}{\partial r}(\rho\phi u\theta)+\frac{v}{r}\frac{\partial}{\partial \gamma}(r\rho\phi v\theta)+\frac{\partial}{\partial z}(\rho\phi w\theta)=\frac{1}{r}\frac{\partial}{\partial r}\left(\theta\Gamma_{r3}\frac{\partial\phi}{\partial r}\right)+\frac{1}{r}\frac{\partial}{\partial \gamma}\left(\theta\Gamma_{\gamma}\frac{\partial\phi}{\partial \gamma}\right)+\frac{\partial}{\partial z}\left(\theta\Gamma_{z}\frac{\partial\phi}{\partial z}\right)+S_{\phi}+S_{\phi.d}\text{3s3} \quad (1)$$

With respect to two-way coupling, there are some other source terms due to existing droplets in the domain, so they are listed below for mass, momentum and heat transfer equations:

$$S_{m.d}=-\frac{\pi}{6}\frac{\rho_d}{\delta t}\sum_k N_{dk}\{(D_{dk}^{n+1})^3-(D_{dk}^{n})^3\}3 \quad (2)$$

$$S_{u_{i_{dk}}}=-\frac{\pi}{6}\frac{\rho_d}{\delta t}\sum_k N_{dk}\{(D_{dk}^{n+1})^3u_{i_{dk}}^{n+1}-(D_{dk}^{n})^3u_{i_{dk}}^{n}\}3 \quad (3)$$

$$S_{hd}=-\frac{\pi}{6}\frac{\rho_d}{\delta t}\sum_k N_{dk}\left\{(D_{dk}^{n+1})^3\left(C_pT_{dk}\right)^{n+1}-(D_{dk}^{n})^3\left(C_pT_{dk}\right)^{n}\right\}33 \quad (4)$$

It is clear that the total mass evaporation of the spray increases with pressure even in low temperatures. One of the important parameters in the spray is spray tip penetration, which is really affected by pressure and decreases by pressure.

CONCLUSIONS

In this paper, the effect of pressure and temperature on the evaporation spray have been discussed. The effect of the liquid droplets phase is also considered to the gas-phase. The results show the effect of pressure is really important in the evaporation of spray. Also, pressure plays an important role in the diffusion of the droplets in the environments. In addition, the heat that the droplets give from the gas-phase causes a significant drop in the temperature of the gas-phase.

GPU-BASED MODELLING OF A TWO-PHASE FLOW IN CAPILLARY NETWORKS

Sergei Prokopev*[1], Tatyana Lyubimova[1], Anatoliy Vorobev[2], Timofey Zagvozkin[1]
[1] Institute of Continuous Media Mechanics Ural Branch RAS, Perm, Russia
[2] University of Southampton, Southampton, UK,

We model the liquid/liquid displacement flow through capillary tubes using the phase-field approach[1,2]. We assume that a capillary is initially saturated with one liquid that is displaced (or washed out) by the injection of another liquid. An accurate description of such a problem requires a theoretical model that takes into account the interfacial diffusion. For solution of the latter task, one needs to trace the evolution of the shape of a liquid/liquid interface. In addition, miscible interfaces are endowed with dynamic interfacial stresses (e.g. a honey droplet immersed in tea possesses a spherical shape that can be explained by the action of surface tension effects) that also needs to be considered. We develop a new approach for modelling the behaviour of miscible liquids taking into account the effects of interfacial diffusion and dynamic surface tension. Our approach is based on the phase-field method that is applied as a physics-based model for description of heterogeneous binary mixtures. The Boussinesq approximation of the Cahn-Hilliard-Navier-Stokes equations are solved for the configuration of capillary tubes. The governing equations are numerically solved in the pressure-velocity notation, using the fractional-step (or projection) method implemented on the basis of the finite difference approach. We found that the model elaborated is capable to reproduce the classical analytical relation such as Washburn equation for the velocity on the meniscus edge or the formula for the jump of capillary pressure through the interface.

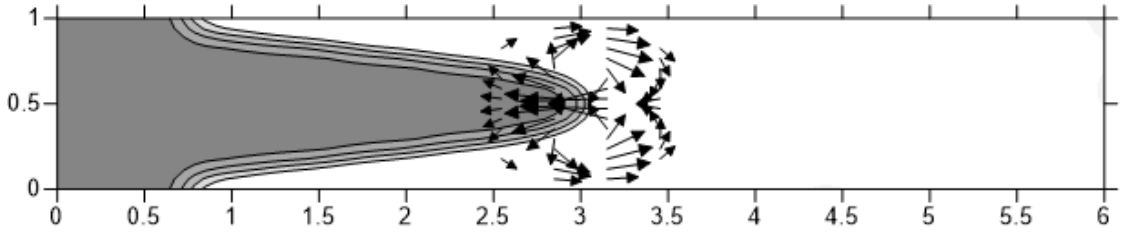

Figure 1. The fields of concentration (isolines) and deviation of the velocity from the parabolic Poiseuille profile (vectors).

Based on the theoretical and numerical model developed for a single capillary we also developed a very detailed description for the immiscible liquid/liquid displacement through a uniform network of capillaries that we use as a rough representation of a micro-volume of a porous medium. We found that, qualitatively, for all considered geometries, the liquid/liquid displacement always undergoes the same set of particular stages: (i) right after the moment of turning on the pressure difference between the ends of the matrix, the liquid/liquid menisci experience a number of capillary oscillations; the magnitude of the oscillations is controlled by the surface tension coefficient and by the Peclet number; (ii) later, the meniscus' shape is set and the piston-like propagation of the displacement front through the matrix can be observed; (iii) when the menisci reach the outlet end of the matrix (the break-through time), some volumes of the displacing liquid still remain on the walls of the matrix; so further pumping of the displacing fluid results in scratching of these remainders from the walls; (iv) finally, the steady stage is reached when the displaced fluid however still remains within some elements of the matrix, although the further pumping of the displacing liquid does not lead to any differences in distribution of the liquids within the matrix. We also showed the Peclet number defines the speed of sliding of the contact line along the walls. We demonstrate that all integral parameters (including the capillary pressure) that characterise the liquid/liquid displacement within the matrices of different sizes converge to some limiting curves, indicating that the matrix with the size less than 10x10 elements is fully sufficient to give the accurate prediction of the capillary pressure in a homogeneous porous medium.

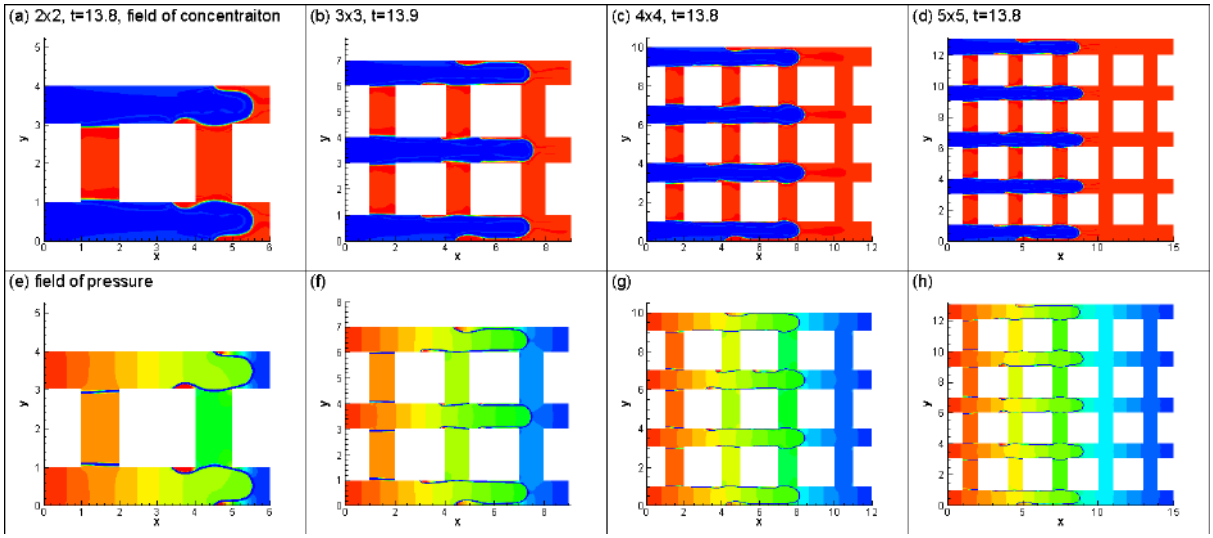

Figure 2. The piece of the matrix of capillary tube network. The example of flow, a,b,c,d are the fields of concentration, e,f,g,h are the fields of pressure

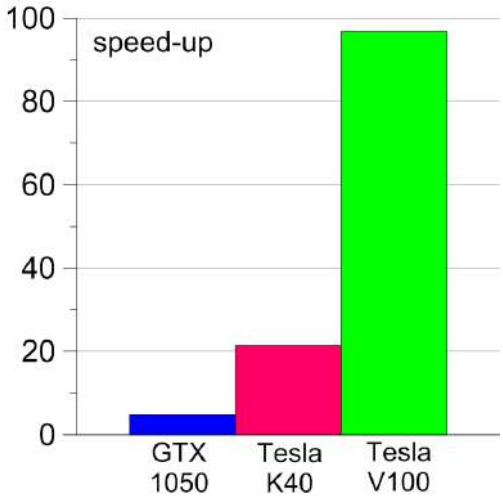
The phase-field theory demands a relatively high numerical resolution. Taking into account the extended geometry that consists of numerous capillaries we deal with significant computational challenge. To cope with all the difficulties we choose a modern effective programming approach of using graphical process units (GPUs) and CUDA toolkit. We use an explicit finite-difference scheme that is easily parallelized among GPU cores. We have written an effective rapid algorithm using CUDA C language. The performance tests demonstrated following speed-up results for some Nvidia GPU devices: GeForce GTX 1050 ~ 5 times, Tesla k40 ~ 20 times, Tesla v100 ~ 100 times. The reference computation was made with the sequential version of the same algorithms on intel i7-4770k.



The speed-up of computations on GPU in comparison with intel i7-4770k.

RANS MODELING OF FLOW STRUCTURE, TURBULENCE AND HEAT TRANSFER IN A SEPARATED DROPLET-LADEN MIST FLOW

Maksim Pakhomov*[1]
[1]Laboratory of Thermal and Gas Dynamics, Kutateladze Institute of Thermophysics, Novosibirsk, Russia

Summary The results of a numerical investigation of the effect of droplets' thermophysical properties on the flow structure, turbulence, and heat transfer in a two-phase mist flow in a backward-facing step are presented. Predictions are carried out for droplets of water, ethanol, and acetone for initial droplet diameters varying in the range d_1 = 1–100 μm. The RANS approach is used to simulate a gaseous phase, and the motion and heat transfer of a dispersed phase are computed using the two-fluid Eulerian model. Gas phase turbulence is predicted using the model of Reynolds stress transport modified for the case of particle presence. It is shown that the addition of droplets leads to a significant increase in heat transfer (up to 50% at M_{L1} = 0.05) in comparison with a single-phase separated flow. The maximal heat transfer enhancement with the use of ethanol droplets is slightly higher than the corresponding value for water droplets (by approximately 10–20%). The length of the region of intensified heat transfer is maximal for water droplets, while it is minimal for acetone droplets. The effect of heat transfer intensification and suppression of carrier gas phase turbulence is minimal for the acetone droplets.

INTRODUCTION

Two-phase droplet-laden separated flows are observed in many engineering and natural processes, such as cyclonic separation, flame stabilization in internal combustors, pneumatic transport, and many others. The effect of the thermophysical properties of three liquids (water, ethanol, and acetone) on flow structure, turbulence, and heat transfer in a droplet-laden mist flow in a sudden pipe expansion is simulated numerically using the Eulerian approach. The aim of the present paper is to numerically examine the effect of the droplets on flow and heat transfer in the mist backward-facing step flow for liquids with various values of latent heat of evaporation (water, ethanol, and acetone).

MATHEMATICAL MODEL

In the present paper, the dilute gas-droplet turbulent flow behind a backward-facing step is numerically examined. The set of steady-state Reynolds Averaged Navier-Stokes (RANS) equations for the gas phase with negligible mass forces is employed in the study. The mean flow is described by the continuity, the two-momentum equations, the energy equation and the equation of vapor diffusion into the binary gas–vapor mixture [1]. Gas phase turbulence is modeled with the use of elliptic blending second moment closure (SMC) [2] with the effect of particles on the carrier phase turbulence. Two-way coupling is achieved between dispersed and carrier phases in the mean and fluctuating transport [3]. The back effect of particles on the carrier phase turbulence (two-way coupling) is considered [1].

NUMERICAL RESULTS AND DISCUSSION

The increase in the Stokes number causes an increase in the mass concentration of droplets in the flow core region (see Fig. 1). The large droplets practically do not penetrate into the recirculation zone and the fraction value increases markedly in the central part of the duct. Initially, an increase in the Stokes number of the dispersed phase leads to an increase in the dispersed phase concentration in the separation zone. The mass fraction of droplets decreases significantly due to their absence in the region of separated flow with further rises of the Stokes number. In the near-wall region, the mass fraction of droplets is significantly less than that in the region of the flow core due to their fast evaporation (at small Stokes numbers) and their absence in this region (at large Stokes numbers).

The addition of droplets leads to a significant increase in heat transfer (up to 50% at M_{L1} = 0.05) in comparison with a single-phase separated flow. The intensification of heat transfer with the use of ethanol droplets is higher (by approximately 10–20%) than the corresponding value for water droplets (see Fig. 2). The region of two-phase flow decreases significantly and the level of turbulence suppression in the carrier phase is decreased (by up to 10–15%) due to the presence of evaporating dispersed particles. The effect of evaporation of acetone particles on the heat transfer and turbulence of the carrier gas phase is minimal.

Fig. 3 shows the turbulence kinetic energy (TKE) profiles of the gas and dispersed phases measured [4] and predicted by authors at the few stations. Distributions of turbulence energy for a single-phase flow (*1*), gas (*2*) and dispersed (*3*) phases have a qualitatively similar form. The level of turbulence in a single-phase flow (*1*) is close to the TCE level in the gas phase of a two-phase flow (*2*). The turbulent energy of droplets (*3*) is less than the corresponding value for gas (*2*). The transverse profiles of the turbulent energy of gas and droplets have a pronounced maximum located in the region of the shear layer, which is typical for experiments [4] and for our numerical data. The largest values of the TKE level for both phases are at the distance x/H = 4–5. This allows concluding that the particles penetrate to this region and interact well with the gas carrier phase. In the region of the reattachment point ($x_R/H \approx 6.2$), the value

*Corresponding author. E-mail: pakhomov@ngs.ru.

of gas turbulence decreases significantly and the kinetic energy of turbulence approaches the value for the carrier medium.

CONCLUSION

The effect of the thermophysical properties of three liquids (water, ethanol, and acetone) on dispersed phase scattering, turbulence, wall friction, and heat transfer in a droplet-laden mist flow in a backward-facing step was simulated numerically using the Eulerian approach.

The fine droplets (Stk < 1) are observed in the whole duct cross-section (flow core, shear layer and recirculation region). The largest droplets studied Stokes number (Stk > 1) do not almost penetrate into the recirculation zone and they dispersed only in the shear and recirculation zones. Gas phase turbulence in the two-phase flow attenuates by fine droplets additions (up to 15%) and an increase of these inlet parameters leads to higher reduction of the gas phase turbulent kinetic energy.

SINGULARITY IN PARTICLE-LADEN FLOW

Seulgi Lee[1], Changhoon Lee *[1,2]
[1] Department of Mechanical Engineering, Yonsei University, Seoul, Republic of Korea
[2] Department of Computational Science and Engineering, Yonsei University, Republic of Korea

Summary Collision of particles suspended in turbulent flows is investigated using a new concept. Under the assumption that motion of particles with small Stokes number is smooth function of space, the velocity is uniquely determined by the position. Therefore, flow of particles exists and is examined to find the condition of collision by noticing that singularity of velocity gradient of particles occurs when collision happens. The motion of particle is derived in Eulerian approach. Using this concept, the singularity of velocity gradient for various Stokes number and gravity is investigated in a Taylor-Green vortex flow and two-dimensional turbulence.

INTROUDUCTION

Particle-laden flows are frequently observed in various environments such as indoor system, industrial problems and natures. For example, the formation of clouds and precipitation is caused by interactions between small droplets contained in atmosphere, and dust from urban pollution can lead many serious health problems. Especially, small sized particles has emerged as an important problem for people's health. Other examples of particle-laden flows for industrial areas are injection of fuel droplets in diesel engines and spray applications in many manufacturing.

However, current mathematical descriptions and comprehension of the underlying mechanisms for particle-laden flow have not been fulfilled yet. It is because that the underlying mechanism for turbulent flows causing the movement of spherical particle is not fully understood by strong nonlinearity and multi-scale nature. Furthermore, the motion of particles having another kind of nonlinearity makes additional complexity.

In order to understand the behaviour of particles suspended in turbulent flow, the interaction between particles and coherent structures needs to be investigated. However, it is quite difficult to describe the solution mathematically. Thus, we consider another approach to understand interaction between particles and background turbulence. The particle velocity can be uniquely determined by position by assuming that particle velocity is a smooth function of space. Then detailed mechanism of collision can be studied by investigating the behaviour of evolution of the particle velocity field.

METHODOLOGY

Taylor-Green vortex flow is used to performing a numerical analysis of collision of particles suspended in the background flow. The reasons of adopting Taylor-Green vortex flow are simple having an exact solution and easy to intuitively understand behaviour of suspended particles. The solutions of Taylor-Green vortex flow in two dimensional domain $[2\pi, 2\pi]$ are given by $u_1 = f(t)\cos x \sin y$ and $u_2 = -f(t)\sin x \cos y$ where $f(t) = e^{-2\nu t}$, ν is the kinematic viscosity of fluid. The exact fluid velocities are used with time.

Eulerian approach for motion of particle

The motion of particles assuming smooth function , the so-called 'flow particle' [1,2] can be derived as below

$$\frac{\partial v_i}{\partial t} + \mathrm{v_j}\frac{\partial v_i}{\partial x_j} = \frac{u_i - v_i + w_i}{\tau_p} \quad (1)$$

where v_i and u_i are particle velocity and fluid velocity and $w_\mathrm{i} = -\tau_\mathrm{p}\ \mathrm{g}$ which is terminal velocity. Here, τ_p is the particle response time. The particle dynamics are determined by the ratio of particle response time τ_p to flow time scale τ_f, namely the Stokes number $St = \tau_\mathrm{p}/\tau_\eta$.

Discretization in space is applied using a spectral method in two-dimensional periodic domain, and a third-order explicit Runge-Kutta algorithm for discretization in time is adopted. The initial particle velocities are generated as the same as a background flow.

RESULTS AND CONCLUSIONS

The motion of particles are investigated with varying Stokes numbers and gravity. Equation (1) can be used to examine the order of magnitude analysis of singularity solution [3-5]. Taking the gradient of Eq. (1) yields a solution that might blow up in finite time in the order-of-magnitude sense as below

$$\sigma(t) \sim \frac{1}{t - t_c}$$

*Corresponding author. E-mail: clee@yonsei.ac.kr.

where $\sigma = \nabla \boldsymbol{v}$ is gradient of particle velocity. This blow-up of the velocity gradient of a particle implies collision between two particles. Our numerical study of Eq. (1) clearly indicates that finite-time singularity is observed for large Stokes number, but strong gravity suppresses or delay the blow up.

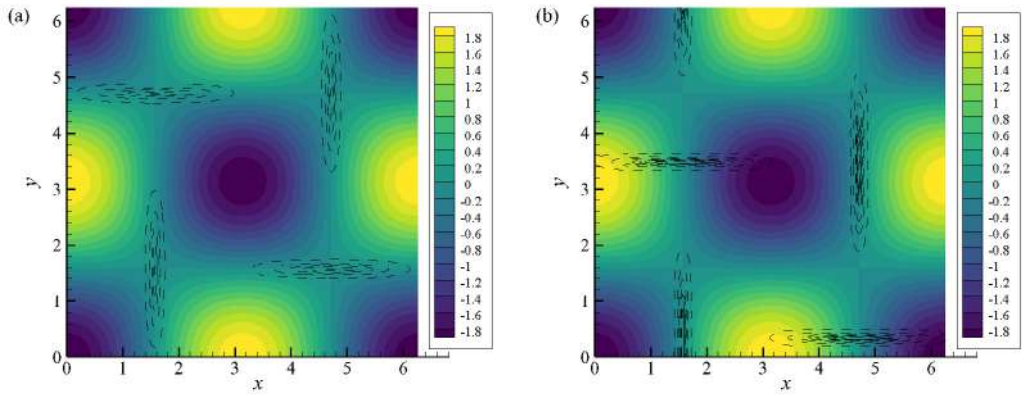

Figure 1. Plots of representing collision of particle. Coloured contour represents vorticity level of the background flow and dashed lines for divergence level of particle are denoted. (a): $\tau_p = 0.5,\ w_2 = 0$ and (b): $\tau_p = 5,\ w_2 = -5$.

Collision of particles are visually shown in Fig. 1, where contour levels represent vorticity for the background flow and dashed line means negative divergence level of particle velocity field. This kind of singularity would provide a more accurate description of the collision process through modelling by finite-time blow-up. Finally, finite-time t_c can be estimated accurately in this simulation. More detailed results will be discussed in the presentation.

NUMERICAL INVESTIGATION OF FILM BOILING HEAT TRANSFER ON THE HORIZONTAL SURFACE UNDER VERTICAL OSCILLATION

Young Seock An[1] and Byoung Jae Kim *[1]
[1] School of Mechanical Engineering, Chungnam Naional University, Daejeon, South Korea

Summary Film boiling is critical to nuclear safety because it directly influences the integrity of the nuclear fuel cladding in the case of accidents involving loss of coolants. The departure frequency of vapor bubbles on a fixed heating wall is in the order of a few hertz. Interestingly, this is close to that for the natural frequency of a typical pressurized water reactor building (about 4–5 Hz). Therefore, if an earthquake with low frequencies occurs, it would cause the nuclear reactor to oscillate considerably. In this scenario, the fluid in the system would undergo an oscillating body force. This study presents numerical simulations of saturated film boiling on a horizontal surface under vertical oscillation.

NUMERICAL METHOD

Figure 1 shows the simulation domain under vertical oscillation with $\ddot{\mathbf{R}} = \ddot{R}\mathbf{j} = A(2\pi f)^2 \sin(2\pi ft)\mathbf{j}$. Simulations were performed at a near critical pressure.

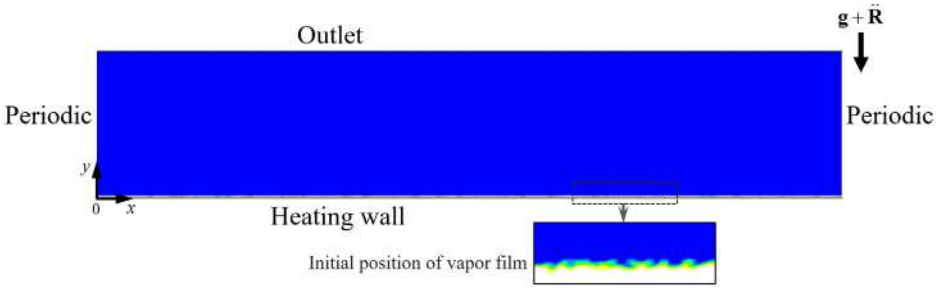

Figure 1. Simulation domain for multimode film boiling in a pool.

The CLSVOF method was used to perform simulations of incompressible two-phase flow with phase change. The mass, momentum, and energy equations are given by

$$\frac{\partial \alpha}{\partial t} + \nabla \cdot (\alpha \mathbf{u}) = \frac{\dot{m}}{\rho_v}, \tag{1}$$

$$\frac{\partial}{\partial t}(\rho \mathbf{u}) + \nabla \cdot (\rho \mathbf{u}\mathbf{u}) = -\nabla p + \nabla \cdot [\mu(\nabla \mathbf{u} + \nabla \mathbf{u}^T)] + \mathbf{F}_{st} + \rho(\mathbf{g} - \ddot{\mathbf{R}}), \tag{2}$$

$$\frac{\partial}{\partial t}(\rho h) + \nabla \cdot (\rho h \mathbf{u}) = \nabla \cdot (k \nabla T) - \dot{m} L, \tag{3}$$

where $\dot{m}$ is the vapor generation rate computed by Sun`s model [2]

$$\dot{m} = \frac{2k_v(\nabla \alpha \cdot \nabla T)}{L}. \tag{4}$$

RESULTS AND DISCUSSION

Figure 2(a) shows the effect of the oscillation frequency on the heat transfer. The oscillation amplitude is fixed at $A = 4$ mm. For low frequencies under 6 Hz, the heat transfer decreases with increasing oscillation frequency. This is caused by the interaction between the vapor bubble rise and the system oscillation. Figure 3 shows the successive snapshots of rising bubbles and the variation of the space-averaged Nusselt number with time. It is interesting to note that all vapor bubbles detach at nearly the same time (t=4.86 s). Different bubbles are separated from the vapor film at the instance when the effective gravity reaches the maximum value. A decrease in the heat transfer can be explained by Fig. 3. Compared to the stationary case, the decrease in low peaks are greater than the increase in high peaks. Moreover, the time period during which the heat transfer is maintained at low values is prolonged. Thus, the average heat transfer becomes lower than that for the stationary case. However, in the region with high frequencies (f>6.25 Hz), the average heat transfer increases with increasing frequency. This is attributed to the agitated liquid flow cased by the oscillation. The agitated liquid flow facilitates the detachment of vapor bubbles from the wall, which prevents the vapor layer from being thick.

Figure 2(b) shows the dominant frequency of the bubble detachment according to the oscillation intensity. The bubble departure frequency is not affected by the oscillation when the oscillation intensity is weak. However, the bubble departure frequency becomes nearly the same as the oscillation frequency when the oscillation intensity is strong.

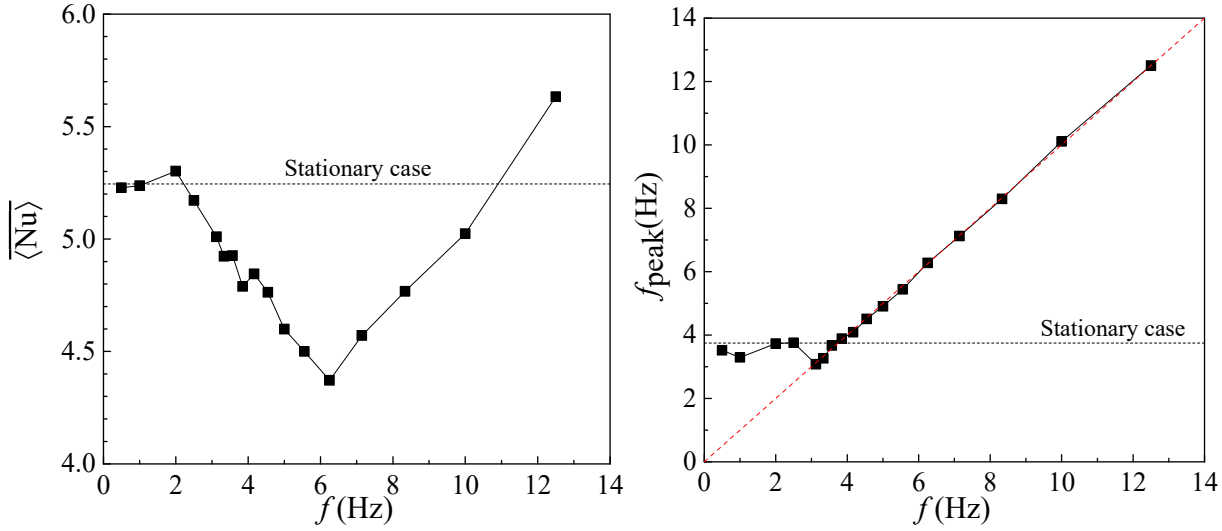

Figure 2. (a) Change in the average heat transfer according to the oscillation; (b) Dominant frequencies of heat transfer for oscillation frequencies.

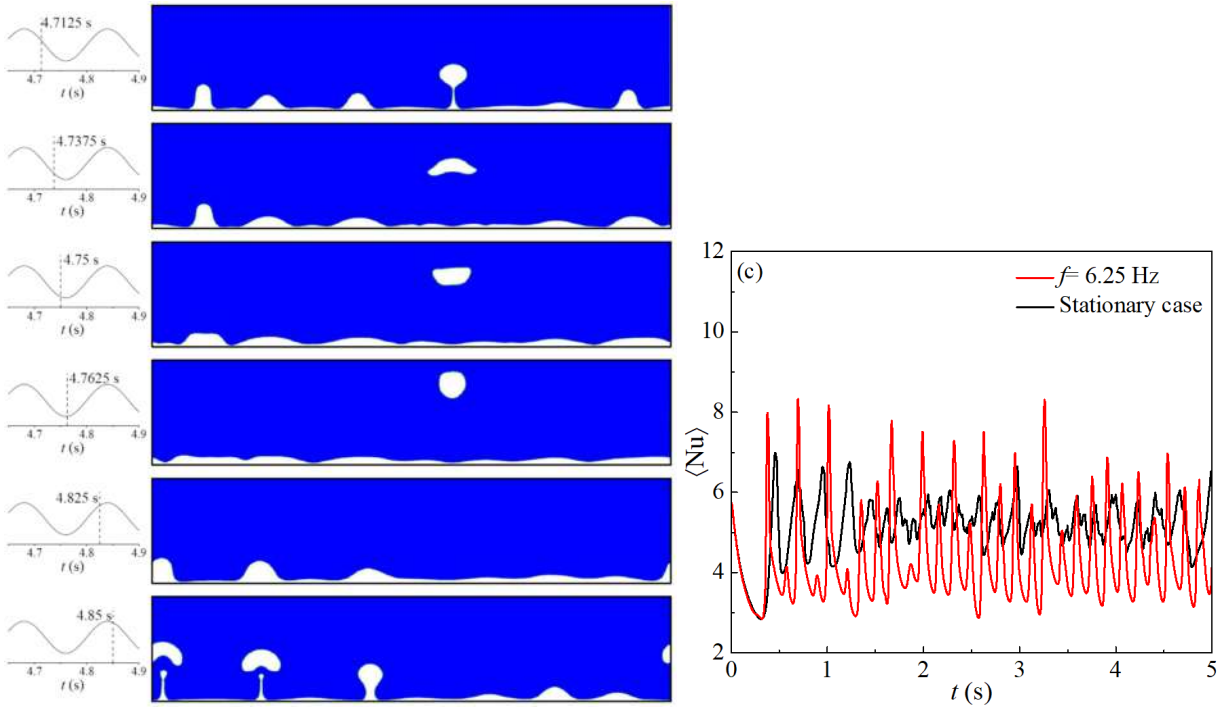

Figure 3. Result for the oscillation frequency of f=12.5 Hz: (a) Successive snapshots of rising bubbles at different time instances; (b) Variation of the space-averaged Nusselt number with time

CONCLUSIONS

The present multimode simulation showed that the system oscillation did not always increase heat transfer and that the oscillation did not alter the bubble departure frequency. From the results so far, there are the three regimes. In the first regime, as the oscillation frequency increases, the heat transfer decreases while the bubble departure frequency remains nearly the same. In the second regime, as the oscillation frequency increases, the heat transfer decreases and the bubble departure frequency becomes the same as the oscillation frequency. In the third regime, as the oscillation frequency increases, the heat transfer increases and the bubble departure frequency synchronizes with the oscillation frequency. This regime classification may not be general. Therefore, in the future, simulations and experiments at a low pressure will be conducted to confirm the heat transfer characteristics.

NUMERICAL STUDY ON THE DYNAMICS OF PERMANENT MAGNETIC PARTICLES SUSPENDED IN A CONFINED SHEAR FLOW

Tae Gon Kang *[1], Im Doo Jung[2], and Seong Jin Park [3]
[1] School of Aerospace and Mechanical Engineering, Korea Aerospace University, Goyang, Republic of Korea
[2] Korea Institute of Materials Science, Changwon, Republic of Korea
[2] Department of Mechanical Engineering, Pohang University of Science and Technology, Pohang, Republic of Korea

Summary A direct simulation method is developed to solve a particulate flow with permanent magnetic particles in an applied magnetic field. The method is based on the finite element method and a fictitious domain method, considering the magnetic and the hydrodynamic interactions among the particles. The circular (or spherical in three-dimension) particles are assumed to be magnetic particles with a constant magnetic moment and negligible susceptibility. The developed method is validated by comparting the particle motions in a shear flow with that from a particle dynamics method based on the Jeffrey model and extended forms of the Oseen-Burgers tensor. In a shear flow, the particle motion and the structure of the particles are highly influence by the ratio between the magnetic torque and the viscous torque and the ratio between the permanent magnetic moment and the strength of the applied field.

INTRODUCTION

Suspensions with permanent magnetic particles are used in a variety of applications. In magnetic powder injection molding to mass-produce small and precise magnetic components, for example, the prediction of the orientation of permanent magnetic particles during cavity filling stage is of great importance since the particle orientations govern the magnetic properties of final products [1]. In this process, particle orientation is determined by the combined effect of the viscous torque due to continuous shearing and the magnetic torque caused by the magnetic moment of the particles and the applied magnetic field. In this regard, we attempt to develop a direct simulation to solve particulate flows with permanent magnetic particles in the presence of an externally applied magnetic field. The developed method is applied to a confined shear flow to investigate the particle orientation and the formation of columnar structures, focusing on the influence of a dimensionless number, called the Mason number, on the particle motions and structure formation.

MODELING AND NUMERICAL METHODS

Since we are concerned with tiny permanent magnetic particles suspended in a highly viscous fluid, the effect of inertia can be neglected, thus the Stokes equation is solved. As for particle motions, a fictitious domain method is employed, enabling us to solve the same governing equation as that of fluid flow, which has been used to solve particulate flows with suspended paramagnetic particles [2]. The governing equations for the particulate flow are given by

$$\nabla \cdot \mathbf{u} = 0 \tag{1}$$

$$\nabla \cdot (\boldsymbol{\sigma} + \mathbf{T}_m) = \mathbf{0} \tag{2}$$

$$\boldsymbol{\sigma} = -p\mathbf{I} + 2\eta\mathbf{D} \tag{3}$$

$$\mathbf{T}_m = \mu(\mathbf{HH} - 1/2\, H^2\mathbf{I}) \tag{4}$$

where $\mathbf{u}$ is the velocity, $\boldsymbol{\sigma}$ the Cauchy stress, η the viscosity, $\mathbf{D}$ the rate-of-deformation tensor, $\mathbf{T}_m$ the Maxwell stress, μ the magnetic permeability, and $\mathbf{H}$ the magnetic field intensity. On the particle surfaces, no-slip condition is imposed as a constraint. The magnetic field in the entire domain is obtained by solving the Maxwell equations. In this study, the Maxwell equations are transformed into a governing equation for the magnetic potential ϕ, given by

$$\nabla \cdot (-\mu\nabla\phi + \mu_0\mathbf{M}) = 0 \tag{5}$$

where μ_0 is the permeability in vacuum and $\mathbf{M}$ the permanent magnetic moment in a particle domain.

The governing equations for the flow and magnetic problems are solved using the finite element method. The weak form for the flow problem is the same as that used to solve flows with suspended paramagnetic particles (See [2,3]). The weak form for the magnetic problem with magnetic particles with a permanent magnetic moment is represented by

$$\int_\Omega \mu\nabla\phi\cdot\nabla\psi\, d\Omega = \int_\Gamma \mu(\nabla\phi\cdot\mathbf{n})\, d\Gamma + \int_\Omega \mu_0\mathbf{M}\cdot\nabla\psi\, d\Omega\,, \tag{6}$$

*Corresponding author. E-mail: tgkang@kau.ac.kr

where ψ is the weighting function for the potential ϕ. The weak form (Eq. (6)), which is applied to magnetic particulate flows, is a new contribution of our study.

RESULTS

To validate the developed numerical method, we solved a single particle problem (See Fig. 1a). The rigid body motion of the particle is compared to that obtained from a particle dynamics method [4]. From Fig. 1b, one can find that both results agree with each other, but with a slight deviation. The difference is thought to be caused by the particle-wall interaction that is not taken into account in the particle dynamics method. Figure 2 shows particle motions in a confined shear flow, affected by the Mason number defined by $Mn = \eta\gamma/\mu_0 MH_0$ and $\lambda = M/H_0$. If Mn is large, the viscous effect is dominant over the magnetic effect. In addition, if λ is large, the magnetic interaction due to the magnetic moment is dominant rather than that due to the external field.

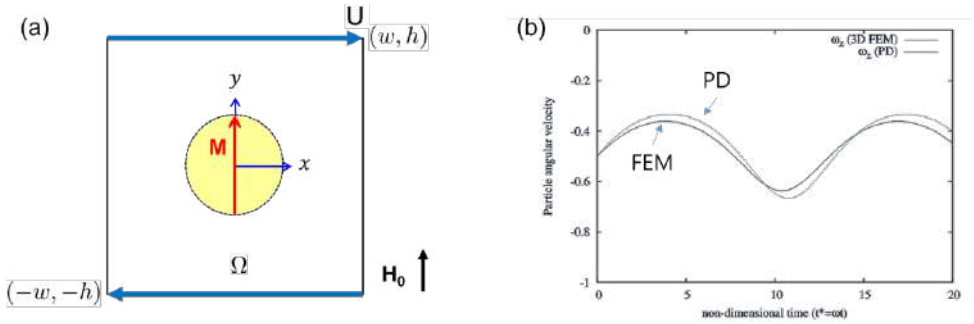

Figure 1. A single particle suspended in a shear flow in the presence of an externally applied field $\mathbf{H}_0$.

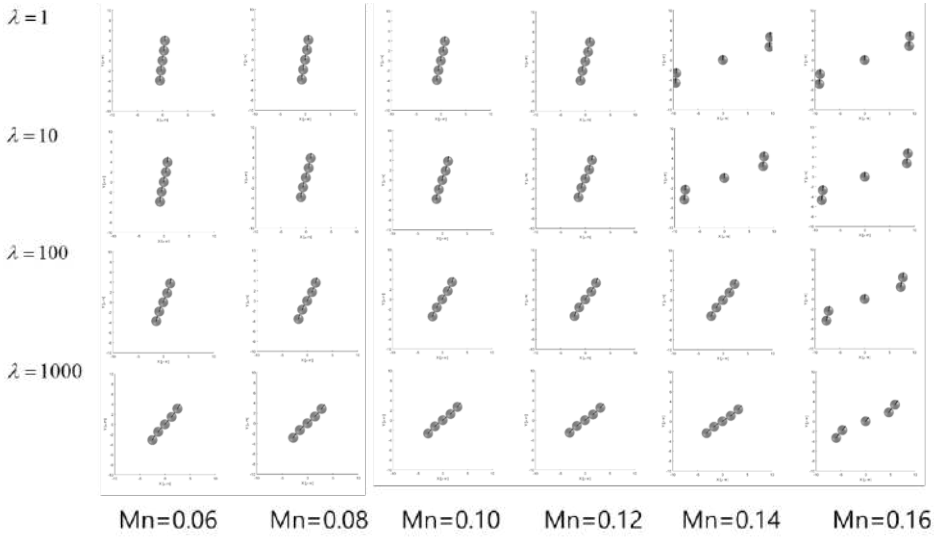

Figure 2. Particle dynamics in a shear flow affected by the Mason number (Mn) and λ.

CONCLUSIONS

We developed a direct numerical method to solve particulate flows with hard magnetic particles (with permanent magnetic moment) in the Stokes flow regime. The developed method is validated by comparing particle motions obtained from the method with those from a particle dynamics method. Particle motions in a confined shear flow are highly influenced by the Mason number and the value of λ.

PREDICTING RARE EVENTS IN STOCHASTIC RESONANCE

L. T. Giorgini * [1], S.H. Lim[1], W. Moon[1,2], and J.S. Wettlaufer[1,3]

Summary In stochastic resonance, a periodically forced Brownian particle in a double-well potential jumps between minima at rare increments, the prediction of which poses a major theoretical challenge. We used a path-integral method to find a precursor to these transitions by determining the most probable space-time path of a particle. We demonstrated the method numerically, which allows us to determine whether a state is following a stable periodic path or will experience an incipient jump. The vast range of systems that exhibit stochastic resonance behavior insures broad relevance of our framework, which allows one to extract precursor fluctuations from data.

Rare events, which frequently accompany fluctuations or phase transitions, arise in a wide range of natural and social systems, such as infectious disease outbreaks, earthquakes, stock market crashes, and many others e.g. [1]. Of particular interest are dynamical systems that have bifurcations, at which sudden transitions to distinct dynamical regimes occur [2]. Even before reaching a bifurcation, noise-induced transitions can occur with low probability [3]. In consequence, a system experiences a large-magnitude change resulting in significant positive and/or deleterious consequences. Hence, it is important to understand the mechanism leading to the occurrence of such events, and to quantify, predict and potentially control them.

The desire to predict these rare events in advance has fueled studies, to simulate [4], classify [5], analyze [6] and predict [7] their properties. Although the existence of early-warning signals for rare events has been suggested, there are few results determining reliable and robust indicators for noise-induced transitions [8]. Because most systems are inherently noisy, understanding the role of noise in inducing these transitions is critical for their quantitative prediction well in advance. We described a theory quantifying the role of noise in rare events, which underlies reliable forecast models.

We studied noise-induced transitions using a class of periodically forced low dimensional stochastic dynamical systems and we identified a novel early-warning indicator for the jumps from one stable state of the system to another. Periodically forced stochastic systems are ubiquitous in nature. For example, periodic forcing and background noise are the main ingredients of stochastic resonance [9] (see [10] for reviews), wherein the response to a weak signal is magnified by noise induced fluctuations that drive hopping from one stable state to the other in a double-well potential with two minima. Settings of relevance range from the human cardiovascular system [11] to the seasonal variability of the Earth's climate [12].

We have developed a theory to predict and study noise-induced rare events within the general framework of stochastic resonance. We have studied a periodically and noise forced system in a double-well potential that jumps between minima, but the time-scale separation of these forcings insures that the system oscillates for a long time about one of the local minima of the potential and only very rarely jumps to the other minima. The ubiquity of such transitions underlies the importance of trying to predict when they will occur.

We have used a path-integral method to determine the particular manner in which the fluctuations around the unperturbed deterministic flow must organize prior to the system jump (see Fig. 1). We characterized the optimal path using a direct comparison principle between the Langevin and Hamiltonian dynamical descriptions, allowing us to express the jump condition in terms of the accumulation of noise around the stable periodic path. In consequence, as a system approaches a rare event these fluctuations approach one of the deterministic minimizers, thereby providing a precursor for predicting a stochastic transition. We have harnessed the signature of this fluctuation behavior as an advanced indicator of a jump and have computed the probability of such rare events. The method provides a framework to examine data in a manner that facilitates predictions across a broad spectrum of stochastic systems.

For more details see [13].

MULTIFRACTAL ANALYSIS OF GAS BUBBLE TRAJECTORIES

Jakub Augustyniak[1], Dariusz M. Perkowski[1], and Romuald Mosdorf [1]
[1] Department of Mechanics and Applied Computer Science, Faculty of Mechanical Engineering, Bialystok University of Technology, Bialystok, Poland

Summary The trajectories of gas bubbles movement generated from nozzles with an inner diameter of 1 mm, 0.38 mm, 0.34 mm and 0.32 mm respectively, and for two liquid column heights: 450 mm and 800 mm were studied. The tests were carried out for an air volume flow rate, whose value ranged from 0.00492 l / min to 0.0645 l / min. This range depended on the diameter of the nozzle and the height of the liquid column (from the periodic detachment of bubbles until the phenomenon of coalescence was observed). The results were recorded using a high speed camera, PHANTOM v1610. An image processing and analysis algorithm was developed, which using tools such as blur filters, edge filters, thresholding, identification, tracking, etc., allowed three-dimensional reconstruction of the movement trajectory of individual bubbles moving inside the bubble column. The work analyzed three-dimensional trajectories of gas bubble motion generated in a liquid filled tank with the help of multifractal analysis algorithm trying to determine the impact of changing the diameter of nozzles generating bubbles and the air delivered to the nozzle on the flow of gas bubbles in the bubble column.

INTRODUCTION

In many industrial processes such as aeration, fermentation, homogenization etc. used in the pharmaceutical, chemical, petrochemical and metallurgical industries, the knowledge of the dynamics of movement of gas bubbles in a liquid is of key importance. The efficiency of such processes depends to a large extent on many factors such as the size of the bubble (closely related to the size of the nozzle) [1-2], the frequency of subsequent departing bubbles (the effect of airflow), bubble residence time in liquid, and others: example of liquid or gas properties. In order to analyze the flow of gas bubbles in a liquid and considering all aspects affecting the nature of the process, a multifractal analysis method was developed. It is able to capture all aspects of a heterogeneous system as subsets of basic elements [3].

EXPERIMENTAL SETUP

The analysis of the trajectory of gas bubbles in liquid was carried out in two glass tanks of 300x300x1500 mm and 300x150x500 mm, respectively, filled with distilled water with a temperature equal to $T = 21 \pm 1$ ° C. Experimental tests were carried out for two liquid column heights: 450 mm and 800 mm (the construction scheme of the experimental setup is shown in Fig. 1). At the bottom of the tank, in the center of the base, a brass nozzle (No. 6, see Fig. 1) with a height of 50 mm was placed. The tests were carried out for four nozzles whose internal diameters had respectively: 1 ± 0.001 mm, 0.38 ± 0.001 mm, 0.34 ± 0.001 mm, 0.32 ± 0.001 mm. Internal diameter measurements were made on a Phenom XL scanning electron microscope.

NON-LINEAR ANALYSIS OF GAS BUBBLE TRAJECTORIES

The nature of the gas bubble path generated in the liquid, and thus its shape, depends on many factors (nozzle size, air flow, medium in which the bubble is generated, etc.). Therefore, a multifractal analysis algorithm (WTMM-Wavelet Transform Modulus Maxima method) that would be able to capture all aspects of the heterogeneous system as subsets of basic elements was introduced [4]. Authors believed that it would allow to determine and compare the degree of complexity of the system based on the range (band) of characteristic exponents in the statistical distribution. The extent of exponent changes is a measure of the complexity of the process being investigated [5]. The results of multifractal analysis are presented as a multifractal spectrum that describes the dimension of a fractal subset of function points. Figure 2 shows a typical multifractal spectrum calculated for a single time series. Analyzed time series were incremental measurements therefore they are without a trend. Such signals are easier to analyze due to the lack of accumulation of error.

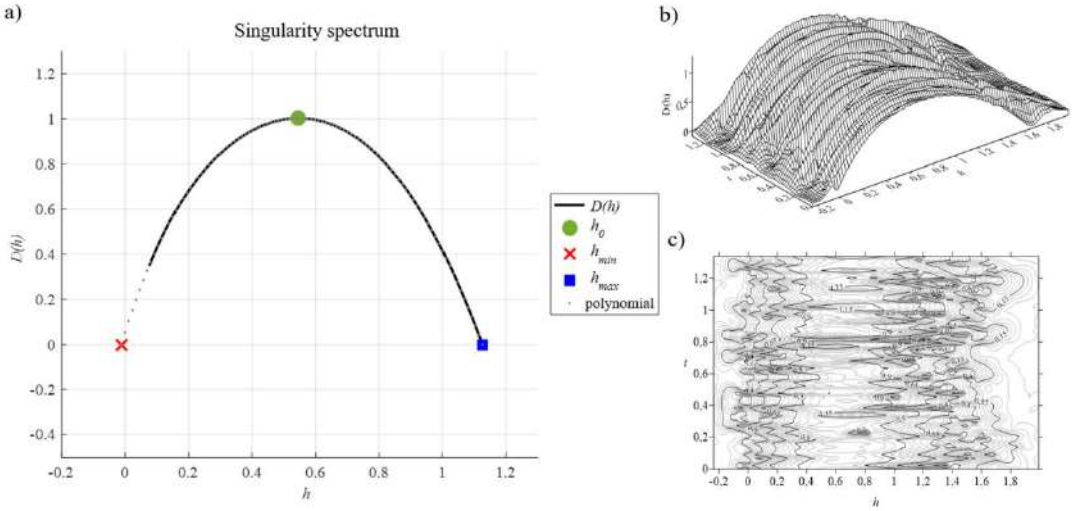

Figure 2. Multifractal spectrum: a) for a single time series for air volume flow rate q = 0.0228 l / min, nozzle inner diameter 0,38 mm and liquid column height 800 mm, b) surface created on the basis of curves characterizing multifractal spectra, c) corresponding contour view (t is a parameterless variable).

Points marked with a x characterize the process of small scale oscillations - h_{min}, where squares define large scale fluctuations of lateral bubble displacement - h_{max}. The highest point of the spectrum (marked with a circle) determines the sum of the small and large fluctuations of the bubble – h_0 (it identifies the entire process). The value of this point (local Hölder exponent) may be associated with the Hurst exponent.

CONCLUSIONS

The authors conducted a series of experiments on three-dimensional reconstruction of gas bubble trajectories with the help of a proprietary computer program. The experiments were carried out for different tank sizes, nozzle inner diameters, liquid height and air volume flow rates. The proposed method allowed to determine and compare the degree of complexity of the system on the basis of the range of occurrence of characteristic exponents in the statistical distribution, where the extent of exponent changes is a measure of the complexity of the examined process. As part of the analysis of recorded data it was established: that the dynamics of motion of gas bubbles moving in a vertical column are significantly influenced by three characteristic values: small-scale high-frequency oscillations (bubble surface deformations), large-scale low-frequency oscillations (deflection of the bubble column from the vertical axis) and Hurst exponent testifying to the behavior of self-similar bubbles; the degree of complexity of the nature of multifractal two-phase flow directly affects the predictability of individual bubble paths [6].

FLUID PLACEMENT IN A CLOSED END PIPE WITH APPLICATIONS IN PLUG AND ABANDONMENT OF OIL AND GAS WELLS

Soheil Akbari and Seyed Mohammad Taghavi
Department of Chemical Engineering, Université Laval, Québec, QC Canada G1V 0A6

Summary The plug and abandonment (P&A) of oil and gas wells is an operation to prevent the migration of the reservoir fluids and the contamination of fresh water resources. The dumping method in the P&A operations is conducted using the placement of a heavy cement plug to replace a light in-situ fluid. In this study, we consider this method and investigate experimentally the placement of a heavy fluid to displace a light fluid, in a closed-end pipe. Both fluids are Newtonian and they have the same viscosity. The heavy fluid is imposed continuously. The experiments present five flow stages: initial jet, mixing region, slumping flow, reaching the pipe end, and turning back of the flow toward the mixing region. Considering the placement flows at different density differences, we find that by increasing the density difference, the penetration front velocity in the slumping flow stage increases.

INTRODUCTION

All oil and gas wells at some point in time must go through the plug and abandonment (P&A) processes. These processes are performed to avoid the contamination of the environment outside the well (atmosphere and water aquifers), which may happen through the leakage of reservoir fluids out the well. The wells are plugged using the cement plugs in the wellbore at specific intervals using several techniques such as the dump bailing method [1]. In this method, the cement slurry is lowered down in a well by a bailer, and the slurry is then placed on a mechanical bridge plug, as illustrated in **??**.a. During this process, the cement slurry displaces the in-situ drilling fluid in the well, ideally with minimum mixing.

The dominant fluid dynamic phenomenon in the P&A operations is the placement (or displacement) flow of two miscible fluids in the wells. In these operations, an extensive range of fluids is used, in which high density differences (up to 600 kg/m^3), and shear-thinning and yield stress rheological behavior are usually found. In order to increase the quality of the cement plug placement, it is necessary to study the key parameters of the displacement of the cement slurry and the drilling fluid. Several parameters can influence the displacement flow behavior, including the type of fluids (Newtonian or non-Newtonian fluids), the physical properties of the fluids (density and viscosity), the type of the flow geometry (pipe, annulus or channel), and the operational conditions (flow velocity and geometry inclination). Based on the aforementioned parameters involved, various kinds of displacement and mixing flows can occur, including stable and unstable flows in exchange or imposed flow configurations. Furthermore, the competition between the governing forces, such as inertia, buoyancy and viscosity, leads to the formation of different flow regimes (e.g. inertial, viscous, etc.).

The density difference produces a buoyancy force. Based on the previous experimental findings [2,3], it is expected that, when the flows are buoyant, the density difference acts to segregate the heavy and light fluids, towards the lower and upper pipe walls. The density difference is represented by the Atwood number ($At = \frac{\hat{\rho}_H - \hat{\rho}_L}{\hat{\rho}_H + \hat{\rho}_L}$) as a dimensionless number, where $\hat{\rho}_H$ and $\hat{\rho}_L$ are the densities of the heavy and light fluids, respectively. The density difference affects the buoyancy force significantly through the densimetric Froude number ($Fr = \frac{\hat{V}_0}{\sqrt{At\hat{g}\hat{D}}}$); here, $\hat{V}_0$, $\hat{g}$, and $\hat{D}$ are the mean imposed velocity, the gravitational acceleration and the hydraulic diameter, respectively. Also, another important parameter is the Reynolds number, $Re = \frac{\hat{V}_0\hat{D}}{\hat{v}}$, where $\hat{v}$ is the kinematic viscosity, defined using the mean density ($\bar{\hat{\rho}} = \frac{\hat{\rho}_H + \hat{\rho}_L}{2}$) and the common viscosity ($\hat{\mu}$) of the two fluids.

In this study, we experimentally consider the placement of a fluid injected into a closed-end pipe (through an inlet), which is representative of the flow domain in the dump bailing method; see **??**b; from a fluid mechanics point of view, this configuration has not been studied in the literature. The two fluids are Newtonian and miscible, and they have the same viscosity. We describe the placement behavior of a heavy fluid used to displace and remove a light fluid from the flow domain. We also investigate the impacts of the geometry inclination and buoyancy in this flow system.

DESCRIPTION OF THE EXPERIMENT

The experiments were conducted in a physical model made of two transparent pipes, representing the dump bailing method. The displacing (heavy) fluid was a solution of water and salt, and the displaced (light) fluid was pure water; both were Newtonian and miscible. For visualization purposes, a specific amount of ink (Fountain Pen India black ink) was added to the heavy fluid. In each experimental test, the outer pipe was initially filled with the lighter fluid. Then, the heavier fluid was injected into the pipe through the inner pipe to displace the lighter fluid. The displacing fluid was fed into the pipe by gravity from an elevated tank, to avoid some unwanted effects, such as flow disturbances. The domain of the study in the experiments, shown in **??**.b, was captured during the experiments using a camera (Basler acA2040, with 4096 grey scale levels). The recorded images were processed by ImageJ and MATLAB to analyze quantitatively the flow parameters, such as the penetration front velocity ($\hat{V}_f$) of the heavy fluid into the light fluid.

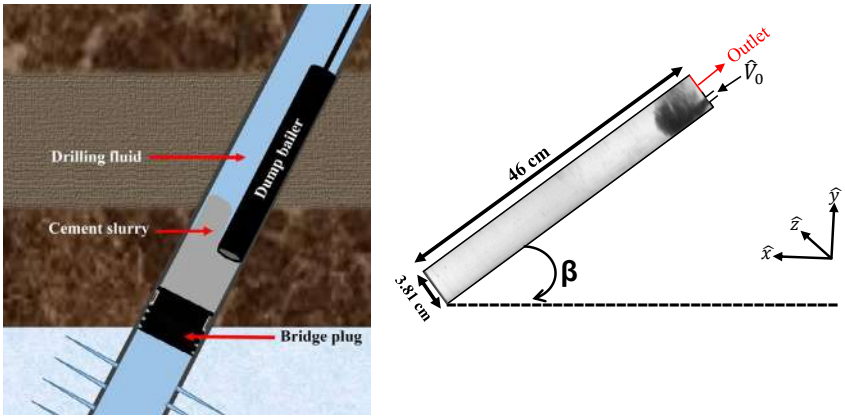

Figure 1: (a) Schematic of the dump bailing method in the P&A process. The bailer contains the cement slurry and it releases the slurry on a bridge plug, which marks the flow domain end. Then, the cement slurry displaces the in-situ drilling fluid in the well. The shape of the fluids interface is illustrative; (b) Schematic view of the domain and parameters in this study.

RESULTS AND DISCUSSIONS

We have observed in our experiments five distinct flow stages. First, the heavy fluid enters the flow domain as a jet, and then a mixing region is developed. After that, the fluid slumps under the light fluid, on the lower wall of the pipe, and moves toward the end of the pipe. The fourth stage is when the fluid front reaches the end of the pipe, and the last stage is turning back of the flow front toward the mixing region. **??**a shows the experimental snapshots of each flow stage. We have attempted to distinguish between these stages and also describe the flow behavior of each stage using dimensionless parameters. As an example, **??**b illustrates the penetration front velocity of the displacing fluid along the length of the pipe (x). This figure shows the front velocity from the beginning of the flow until reaching the pipe end. For $0 < x < 2$, the jet and mixing regions develop, and then the front velocity roughly approaches a constant value for $x > 2$, although this constant limit slightly increases for the higher inclination (β=45°). The figure also depicts that, by increasing Re/Fr (or decreasing the inclination from horizontal), the front velocity in the slumping region increases as well.

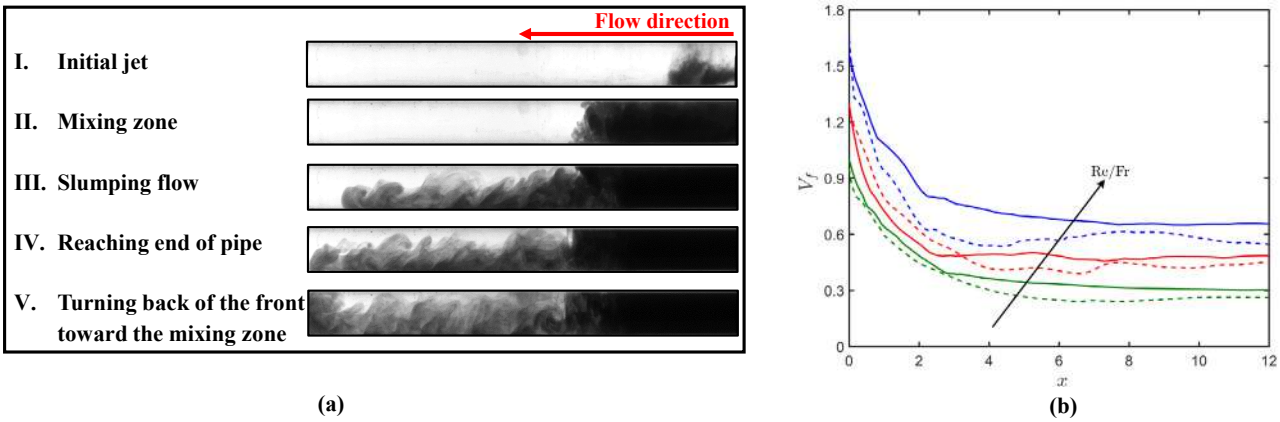

Figure 2: (a) Experimental snapshots of different flow stages observed in our experiments, (b) Dimensionless front velocity ($\hat{V}_f/\hat{V}_0$) of the heavy fluid along the length of the pipe (x= $\hat{x}$ / $\hat{D}$) from beginning of the flow till reaching the pipe end. Different line colors represent Re/Fr=736 (green), Re/Fr=1652 (red) and Re/Fr=2348 (blue). The solid lines are for β=15° and the dashed lines are for β=45°. $Re \approx 8400$ for all experiments. The solid arrow shows the increasing of Re/Fr as an eye guide.

These findings can help us to propose strategies for enhancing the placement efficiency and reducing the fluids mixing in the P&A processes. In the future, we will consider more deeply each stage of the flow and will quantify the impacts of the other hydrodynamic parameters, such as non-Newtonian fluid behavior, on this type of fluid placement.

Summary This paper presents experimental velocity fields obtained through Spatial Filter Velocimetry during single and two-phase flows across tube bundles. Experiments were performed in a test section made of acrylic with 20 rows of 4 tubes of 20mm O.D. mounted in a normal triangular configuration and transverse pitch per diameter ratio of 1.25. Results were obtained for liquid Reynolds numbers of 3909 and 10000, and gas Reynolds number of 77.7. The results indicate that the SFV technique provides accurate velocity data and is suitable to be applied in tube bundles, especially for two-phase flows. Moreover, the gas injection considerably increased the local mean velocities, which indicates significant differences between the flow structure of single and two-phase flows across tube bundles. Finally, the effects of the gas injection were more pronounced for the flow with reduced flow rate.

INTRODUCTION

The flow field characterization of external flows across tube bundles has significant importance for heat exchangers design. However, there are fewer studies concerning the flow field characterization of external flows across tube bundles [1], especially during two-phase flows [2]. The geometry of tube bundles precludes the use of probes close to the region of interest. Moreover, the passage of bubbles during two-phase flows and the high seeding particle concentration of PIV deteriorates the flow visibility, which hinders the application of optical velocimetry techniques. Therefore, the use of optical velocimetry techniques that provide high flow visibility, such as SFV [3, 4, 5], became a promising alternative for the flow field characterization of tube bundles.

Rocha et al. [4, 5] employed the SFV technique for the analysis of the flow field of external flows across tube bundles and obtained sufficient spatial and temporal resolution to characterize the flow turbulence and to extract pressure information from the velocity field. The results of Rocha et al. [4, 5] indicate that the SFV is a suitable technique to be applied in tube bundles.

In this context, the present study concern the flow field characterization of upward external flows across tube bundles. The experiments were conducted during single ($Re_l = 3900$; $Re_l = 10000$) and two-phase flows ($Re_l = 3900$ and $Re_g = 77.7$; $Re_l = 10000$ and $Re_g = 77.7$) to analyze the effects of the gas injection in the velocity profile. Moreover, the turbulent behavior of single and two-phase flows was analyzed.

EXPERIMENTAL PROCEDURE AND DATA ANALYSIS

The experimental apparatus designed and built at EESC-USP (São Carlos School of Engineering at the University of São Paulo) is schematically depicted in Figure 1.

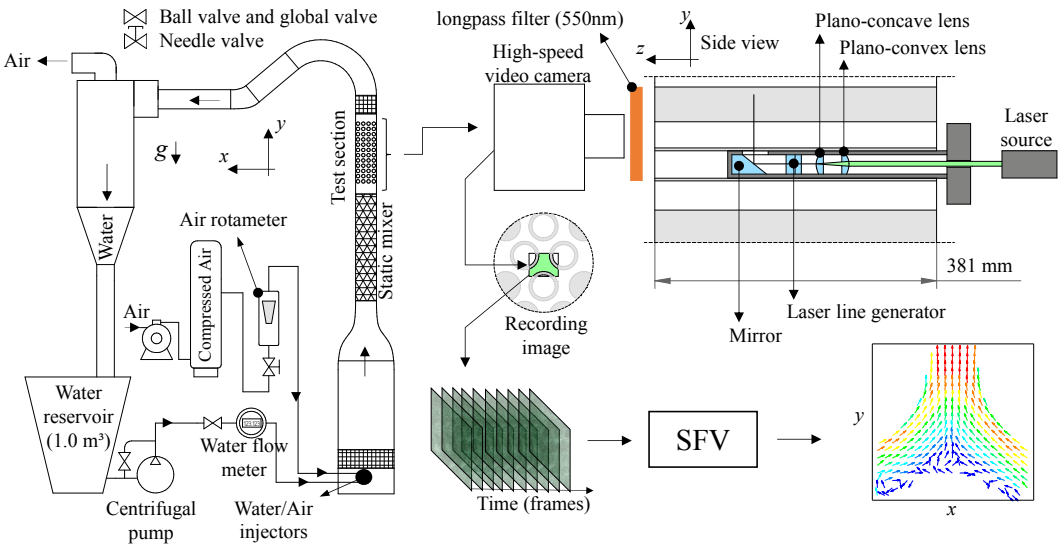

Figure 1: Experimental apparatus and data analysis for the SFV technique application.

During the experiments, water was propelled by a centrifugal pump from the reservoir; then it was directed to the volumetric flow meter. The phases were injected in the bottom of the test section setup and upstream of a static mixer to promote uniform flow and distribution of the phases in the test section inlet. The test section was composed of 20 rows of 4 tubes 381 mm long, each with 20 mm O.D. mounted with a transverse pitch of 25 mm, corresponding to a pitch to diameter ratio of 1.25, in a triangular configuration. Half rods of acrylic were fixed in the lateral of even rows to avoid bypass flow through the laterals. The test section was made of acrylic providing full visual access to the flow within the tube bundle. As illustrated in Figure 1, the optical system used for the SFV application comprised a high-speed video camera (Phantom V2012), a laser source (1W, 520nm), and a setup of mirror and lenses to create a laser sheet perpendicular to the tube axis. In the case of two-phase flow experiments, fluorescent particles, and a longpass filter (cut-off wavelength: 550nm) were used to remove the light reflected on the phases interfaces from the captured images.

RESULTS AND DISCUSSION

Figure 2 shows the averaged velocity profiles obtained for single and two-phase flows with Re_l equal to 3900 and 10000. The gas injection considerably increased the averaged liquid velocities for Re_l equal to 3900. The highest velocity of the velocity field during two-phase flow is approximately 67% higher than the highest velocity of the velocity profile obtained during single-phase flow for the same liquid flow rate. For Re_l equal to 10000, the gas injection increased 35.1 % the highest local velocity obtained during single-phase flow. Therefore, the effects of the gas injection are less pronounced for the highest liquid Reynolds number because of the prevalence of inertial forces of the liquid phase. Moreover, as shown in Figure 2, the gas injection also changed the flow structure by suppressing recirculation regions. The buoyancy effects of the gas phase provided energy to the flow, which balanced the energy dissipation near the tube surface and suppressed the flow separation. Only the bubbly flow pattern was covered during the two-phase flows experiments.

Further investigation concerning the flow turbulence characterization and the velocity behavior along the time was accessed since SFV provides also the velocity variation along the time. The results indicate that the flow separation affected the turbulence strength and the turbulent shear stress. The maximum turbulent shear stress for single-phase flows occurred near the recirculation regions and reached values two times higher than the viscous shear stresses. The maximum turbulence strength in the flow direction occurred near the recirculation regions. The maximum turbulence strength transversal to the flow direction presented the same magnitude than the values observed for the main flow direction, which indicates a high flow mixing [1]. The gas injection increased the turbulence strength in the entire flow field for the two-phase flows experiments, but more effectively for the lowest liquid flow rate.

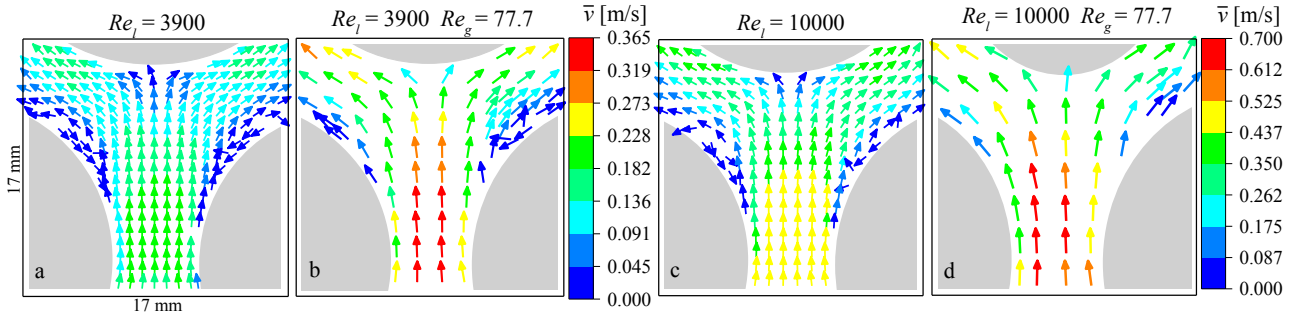

Figure 2: Experimental velocity field along the liquid phase for single (a and c) and two-phase flows (b and d).

CONCLUSIONS

The SFV technique proved to be efficient and reliable for experiments with difficult visual access, such as two-phase flows across tube bundles. The gas injection considerably increased the flow velocity, which indicates significant differences between the flow structure of single and two-phase flows across tube bundles. The passage of bubbles hindered the starting of the flow separation and increased the turbulence strength. Moreover, the effects of the gas injection were more pronounced for the flow with reduced liquid Reynolds number. The flow with the highest liquid Reynolds number possesses a higher inertial force, which mitigates the perturbation caused by the bubbles passage.

REDUCING UNCERTAINTY IN VELOCITY FIELD RESULTS FROM POSITRON EMISSION PARTICLE TRACKING (PEPT) MEASUREMENTS

Avshalom Offner and Jacques Vanneste *
School of Mathematics, The University of Edinburgh, Edinburgh, United Kingdom

Summary Positron Emission Particle Trackiing (PEPT) is an experimental method for visualisation of opaque fluid flow. PEPT produces time-dependent data of particle position, from which the Lagrangian velocity field is easily calculated. Here, we capitalise on the flow incompressibility to infer a divergence-free velocity field that automatically satisfies the system boundary conditions. The results demonstrate how inconsistencies in the original field are corrected, resulting in a smoother, more reliable velocity field.

INTRODUCTION

An abundance of natural and man-made phenomena involve multiphase fluid flows. Key examples include dispersion of pollutants in our atmosphere and mixing of colloids in pharmaceutical manufacturing lines, respectively. The interaction between the phases and the flow tendency to swiftly become turbulent are inherent features that overly complicate the modelling of these flows, and limit our understanding of the underlying physics that drives them. Consequently, studying such flows heavily relies on experimental research, where standard visualisation methods (e.g. PIV or PTV) are typically used to recover the velocity field of the suspended matter. However, in case either the fluid or the environment through which it flows are opaque, optical equipment cannot be used to visualise the flow. We use an alternative technique – Positron Emission Particle Trackiing (PEPT) [1, 2] – that allows for visualisation of opaque fluids or flows inside opaque equipment. In this method, particles are coated with radioactive material, resulting in back-to back photon emissions from positron-electron annihilation events. When flowing in the vicinity of a CT-scanner-like machine, photons annihilated by these particles are detected by array sensors, from which the particle time-dependent position can be recovered.

UNCERTAINTY QUANTIFICATION

As any visualisation method, the particle position recorded using PEPT bares uncertainties. However, as opposed to PIV or PTV where the sampling rate is constant and known a priori, annihilation events are inherently random, making the error in velocity calculations through finite differences difficult to estimate. Moreover, the parameters directly affecting the measurement accuracy are much harder to control, when compared with optical methods (see table 1 for a comparative summary). Inferring a reliable velocity field from data obtained using PEPT is therefore challenging; we wish to make use of the flow incompressibility to calculate a divergence-free velocity field that is the closest possible to the observed data.

Let $\underline{v} = \{v_r, v_\theta, v_z\}$ be the observed velocity field, for which

$$\underline{\nabla} \cdot \underline{v} \equiv \frac{1}{r}\frac{\partial}{\partial r}(r v_r) + \frac{1}{r}\frac{\partial v_\theta}{\partial \theta} + \frac{\partial v_z}{\partial z} \neq 0. \tag{1}$$

Averaging over θ, we define

$$\widehat{\underline{v}}\,(r,z) := \frac{1}{2\pi}\int \underline{v}\,\mathrm{d}\theta \tag{2}$$

and seek a divergence-free velocity field of the form

$$\widehat{\underline{V}} = \widehat{\underline{v}} + \underline{\nabla}\phi, \tag{3}$$

which satisfies

$$\widehat{\underline{V}} = \underset{\underline{u}:\,\underline{\nabla}\cdot\underline{u}=0}{\operatorname{argmin}} \left\|\widehat{\underline{v}} - \underline{u}\right\|^2. \tag{4}$$

	PIV/PTV	PEPT
Sampling rate	constant; controlable	non-constant; uncontrolable
Temporal resolution	adjust high-speed camera FPS	Modify particle activity (coating homogeneity and depth)
Spatial resolution	Camera pixels (known)	Sensor density in array (known; low upper barrier)

Table 1: Comparison between the criteria that set the measurement uncertainty in optical methods (PIV or PTV) and PEPT. The uncertainty in PEPT is much more difficult to quantify and the parameters with which to improve the accuracy are extremely difficult to modify (if at all).

(a) System schematics (b) Radial velocity (c) Axial velocity

Figure 1: System schematics and results.

Taking a curl from (3) we obtain

$$\frac{\partial^2\psi}{\partial z^2}+\frac{\partial^2\psi}{\partial r^2}-\frac{1}{r}\frac{\partial\psi}{\partial r}=r\left(\frac{\partial\widehat{v}_r}{\partial z}-\frac{\partial\widehat{v}_z}{\partial r}\right), \tag{5}$$

where

$$\widehat{V}_r=\frac{1}{r}\frac{\partial\psi}{\partial z}\ ,\ \widehat{V}_z=-\frac{1}{r}\frac{\partial\psi}{\partial r}. \tag{6}$$

defines the stream function of the divergence-free velocity field. Equation (5) can easily be solved numerically using finite differences with no slip and no penetration boundary conditions.

We applied these calculations to a set of data from experiments conducted in a cylindrical mixing tank (see figure 1a). An impeller rotated at 490 RPM mixed 20 wt% of particles immersed in a salt solution. The velocity field inferred directly from the observed data is shown on the left of figures 1b and 1c, where a standard heat map colour scheme is applied (red – positive, blue – negative). The $r-z$ plane was discretised and the velocities were averaged over all particle passes through each element. Elements through which the number of passes was insufficient to deduce a representative average were discarded. To the right of each respective image is the corrected, divergence-free velocity that was calculated using the method described above.

At first glance, the divergence-free velocity field appears as a smoothed version of the raw data. However, the constraints imposed on the velocity field, namely satisfying the boundary conditions and (especially) conserving mass at each element, are responsible for the smoothing effect, clearing local inconsistencies and verifying that velocities decay to zero towards the tank walls.

To conclude, inferring reliable results for the velocity field – a set of data used for nearly all subsequent data-driven calculations (e.g., diffusion or mixing) – is an essential step forward in using the PEPT results to enhance our understanding of multiphase flows that can otherwise not be visualised.

OPTIMAL NONLINEAR RECEPTIVITY ANALYSIS OF A FLAT-PLATE BOUNDARY LAYER

Denis Sipp[1], Georgios Rigas *[2], and Tim Colonius [3]

Summary In a linear input-output analysis framework, the most amplified instabilities are typically described by considering singular vectors of the resolvent operator of the linearized Navier-Stokes equations. In this study, we extend the methodology to take into account nonlinear triadic interactions by considering a finite number of harmonics in the frequency domain using the Harmonic Balance Method. Optimal nonlinear forcing mechanisms that lead to transition and maximize the skin-friction coefficient are identified using direct-adjoint looping. We demonstrate the framework on a zero-pressure flat-plate boundary layer by considering three-dimensional perturbations triggered by a few optimal forcing modes of finite amplitude. Depending on the frequency, spanwise wavenumber, amplitude and symmetries of the perturbation, we recover all the transition stages associated with K-type and H-type transition mechanisms, oblique waves, streaks, and their breakdown. The proposed frequency-domain framework identifies the worst-case frequency disturbances for wall-bounded laminar-turbulent transition.

APPROACH

We introduce a new framework to analyse nonlinear transition scenarios in frequency space. We consider the incompressible Navier-Stokes equations

$$\partial_t u + u\cdot\nabla u = -\nabla p + \nu\Delta u + f(x,y,z,t), \qquad \nabla\cdot u = 0,$$

where $f(x,y,z,t)$ is a momentum forcing and (u,p) is the velocity-pressure field. The configuration is sketched in fig. 1: a flat-plate boundary layer develops in the streamwise x −direction, the wall-normal direction is y, and the spanwise z −direction is homogeneous. These equations are discretized in the (x,y) directions:

$$\partial_t w + Lw + \frac{1}{2}N(w,w) = Pf,$$

where $w(z,t)$ and $f(z,t)$ are now vectors representing the velocity-pressure and forcing quantities and P is a matrix that allows to select forcing components. L represents the Stokes operator and N the nonlinear convection term.

Harmonic Balance Method

The time and spanwise directions being homogeneous, we look for periodic solutions in these two directions. We therefore make the following ansatz:

$$f(z,t) = \sum_{(m,n)\neq(0,0)} e^{im\beta z + in\omega t}\hat{f}_{mn}, \qquad w(z,t) = \sum_{\substack{|m|\leq M,\\ |n|\leq N}} e^{im\beta z + in\omega t}\hat{w}_{mn},$$

where β and ω are the fundamental wavenumber and frequency, that may be chosen arbitrarily. The semi-discretized equations then yield the following coupled nonlinear equations:

$$[in\omega I + L_m + \gamma_{mn}N_0^m(\hat{w}_{00},\cdot)]\hat{w}_{mn} + \sum_{\substack{m=m_1+m_2\\ n=n_1+n_2\\ (m_1,n_1)\neq(0,0)\\ (m_2,n_2)\neq(0,0)}} N_{m_1}^{m_2}(\hat{w}_{m_1n_1},\hat{w}_{m_2n_2}) = P\hat{f}_{mn},$$

which may be recast in the following compact form:

$$R(\hat{w}) = P\hat{f}.$$

Note that P may also be used to select specific forcing components (m,n).

Nonlinear Optimization

The optimization of the forcing $\hat{f}$ is based on a gradient-based method. The objective functional is the mean-shear stress integrated over the flat-plate:

$$J(\hat{w}) = (\hat{w}_{00}-w_b)^*C^*C(\hat{w}_{00}-w_b), \qquad Cw = \int_{\text{flat plate}} \partial_y u dx.$$

This cost-functional may directly be related to the drag coefficient increase $\Delta C_D = \frac{2\nu J^{0.5}}{L}$, and accurately quantifies the transition to turbulence. Here w_b is the base-flow (the solution of the governing equations without forcing) and L is the length of the flat-plate. The gradient of the cost-functional with respect to the forcing may be obtained through a Lagrangian formulation:

$$\mathcal{L}(\hat{w},[\tilde{w},\lambda],\hat{f}) = J(\hat{w}) - \tilde{w}^*\big(R(\hat{w}) - P\hat{f}\big) - \lambda\big(\hat{f}^*Q\hat{f} - A^2\big).$$

The first term on the rhs is the objective functional, the second term represents penalization of the governing equation and the last term restricts the amplitude of the forcing to a given amplitude A (based on the scalar-product Q)

RESULTS

The considered (m,n) components for the forcing and response are shown in figure 1 (right). This setting, also called fundamental forcing, allows triggering of 2D Tollmien-Schlichting waves $(0,\pm1\omega)$, 3D streaky structures $(\pm1\beta,0)$ and oblique waves $(\pm1\beta,\pm1\omega)$. Nonlinear interactions may then generate higher-order structures, such as $(\pm2\beta,0)$ streaks or $(\pm3\beta,\pm1\omega)$ oblique waves. The result of the optimization process for $\beta = 33.3\times10^{-5}$, $\omega = 11.7\times10^{-5}$ and $A = 14.1\times10^{-5}$ (considering U_∞ and ν to nondimensionalize all quantities and the flat-plate length $L = 360000$). The result is shown in figure 2. Is is seen that the optimal forcing consists in oblique waves and the response in streaky structures that undergo sinuous instabilities. Links with linear resolvent analysis [4], oblique wave transition scenario [3], minimal seed to turbulence in the time-domain [1] or various other types of transition scenarios [2] will be discussed.

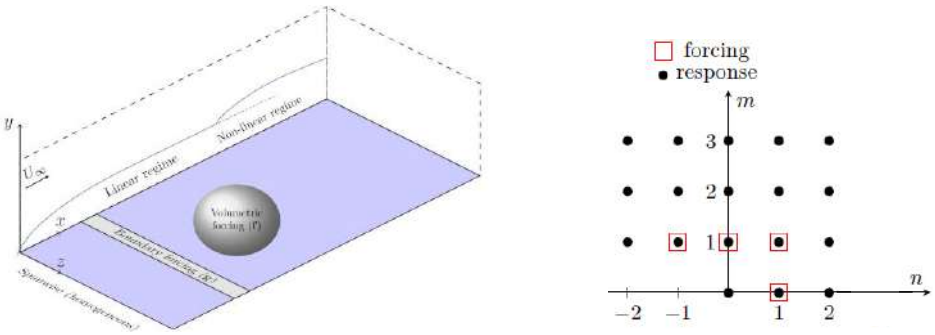

Figure 1. Left: Schematic of the zero-pressure gradient flat-plate set-up. Transition of the laminar boundary layer is triggered here only by volumetric momentum forcing (no suction/blowing). Right: components considered for forcing and response.

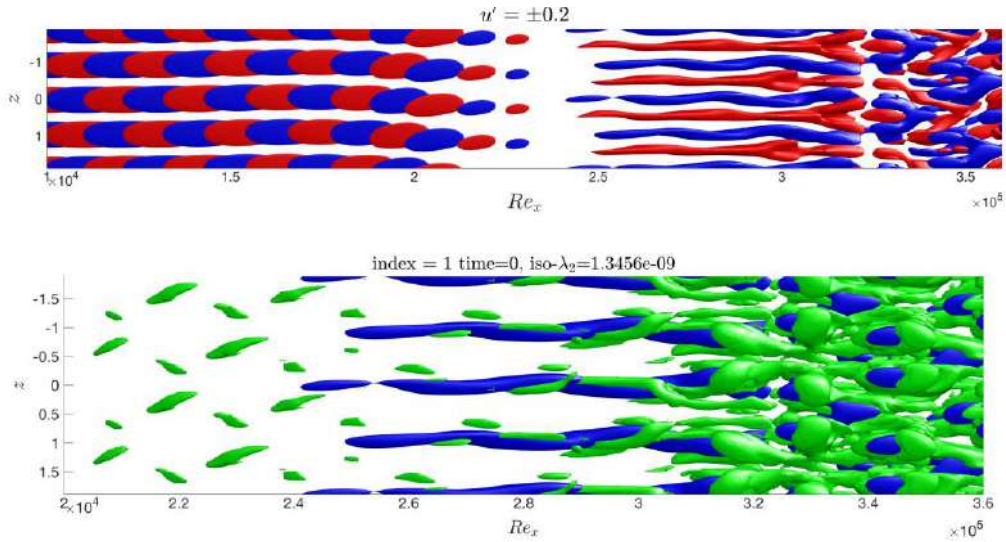

Figure 2. Optimal oblique forcing at $\beta = 33.3\times10^{-5}$ and $\omega = 11.7\times10^{-5}$ for $A = 14.1\times10^{-5}$. FREE-STREAM TURBULENCE INDUCED BOUNDARY-LAYER TRANSITION IN LOW-PRESSURE TURBINES

Kristina Đurović [1], Luca De Vincentiis[1], Daniele Simoni[2], Davide Lengani[2], Jan Pralits[3], Dan S. Henningson[1], and Ardeshir Hanifi[1]

Summary The aerodynamic efficiency of turbomachinery blades is highly affected by the occurrence of laminar-turbulent transition in the boundary layer over them, as it significantly affects flow characteristics. Depending on the free-stream turbulence level, different path towards a turbulent state can be identified. The present study uses direct numerical simulation to investigate the flow behaviour of a low-pressure turbine blade. Isotropic homogeneous free-stream turbulence is prescribed at the inlet. Two levels of the free-stream turbulence intensity were investigated. We observed that, in the low-turbulence case on the suction side, the Kelvin-Helmholz instability dominated the transition process and full-span vortices were shed from the separation bubble. In the high-turbulence case transition proceeded more rapidly, where the generated streaks broke down into turbulent spots and caused bypass transition. On the pressure side, we have identified the appearance of longitudinal vortical structures. These structures are not produced by Görtler instability.

INTRODUCTION

Numerical simulations of the fluid flow have become an imperative part of the turbomachinery design process. Prediction of the onset and the extension of transitional flow regim is of great interest, since they significantly affect the drag and the lift forces. Especially, in low-pressure turbine applications, understanding of transition behaviour is of significant practical interest since the behaviour of boundary layer largely determines the overall efficiency of the low-pressure turbine. Investigation of transitional flows in a low-pressure turbine have been performed earlier, both in experimental and numerical works. Studies have shown that in the case of laminar separation of the boundary layer, velocity fluctuations are amplified along the inflection point of the velocity profile which in turn induce the formation of roll up vortices [1, 2, 3, 4]. There are recent high-fidelity computations that focus on data analysis of loss quantification. These recent works [5, 6, 7] highlighted some typical characteristics of the boundary-layer structures. However, since the flow physics is highly complex further efforts are needed to better understand it.

Here, we investigate the role of free-stream turbulence (FST) on the dominant transition mechanisms in the flow over a low-pressure turbine blade. This paper discusses the numerical setup and presents the preliminary results obtained from these direct numerical simulations.

METHODS AND RESULTS

In the present study, we use direct numerical simulation as the main tool to investigate the flow behaviour. The numerical tool used for the simulations is Nek5000 [8]. The incompressible Navier-Stokes equation together with the continuity equation subject to constant fluid properties are directly solved in the non-dimensional form. The free-stream turbulence is prescribed as a superposition of Fourier modes with a random phase shift. The amplitude of the free-stream modes is scaled using the von Kármán spectrum. Three-dimensional simulations have been performed with two levels of FST of the incoming flow ($Tu = 0.19$, and 5.2%).The simulation was designed to follow the experiments by Lengani & Simoni [9].

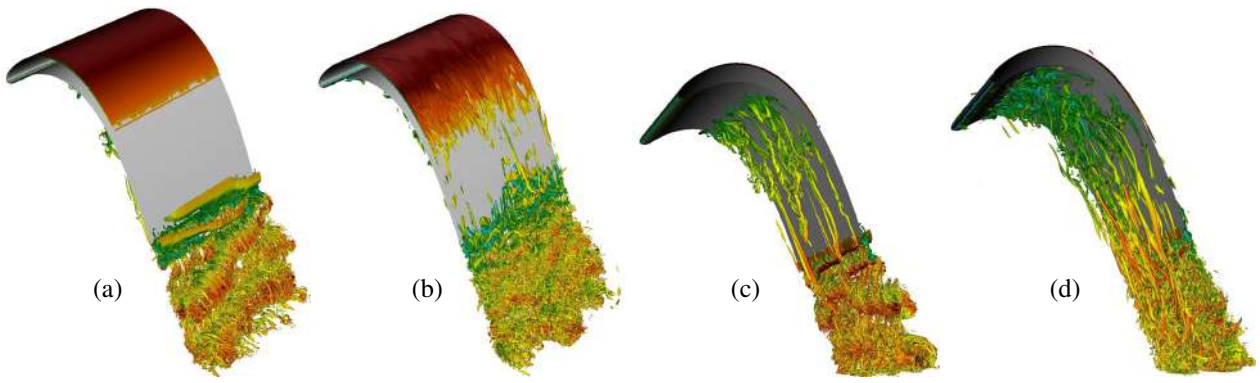

Figure 1: Visualization of instantaneous λ_2 structures on the suction side (a) for low FST case, where we see Kelvin-Helmholtz rolls; (b) for high FST case, showing developed streaks and turbulent spots; and on the pressure side (c) for low FST case; (d) for high FST case, showing longitudinal structures observed in both cases (coloured with streamwise velocity)

*Corresponding author. E-mail: kdj@mech.kth.se

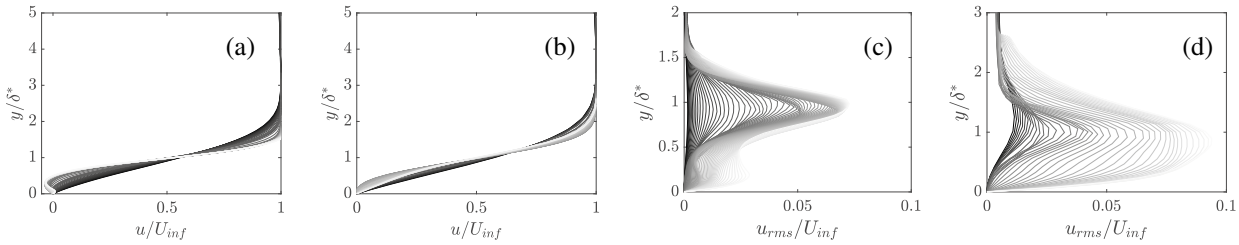

Figure 2: Distributions of normalized u_{rms} and mean velocity u by the the free stream velocity U_{inf} versus normalized wall-normal coordinate y by the displacement thickness δ^* at different streamwise locations. (a) mean velocity distribution for the low FST case; (b) mean velocity distribution for the high FST case; (c) u_{rms} distribution for the low FST case; (d) u_{rms} distribution for the high FST case. Lighter line corresponds to location further away from leading edge.

The response of the boundary layer on the suction side is visualized in Fig. 1(a) and (b). For low FST case (a), we can see structures that resemble the Kelvin-Helmholtz rolls. These rolls are observed to appear around 80 % of the chord and they are convected downstream. We can also notice the appearance of a laminar separation bubble. In the high FST case (b), the laminar part of boundary layer is dominated by distinct streamwise streaky structures. These streaks reach an amplitude of roughly 10% of freestream velocity for the high FST case before their breakdown to turbulence. Turbulent spots appear at around 90 % of the chord and the turbulent boundary layer that is formed close to the trailing edge is attached to the blade surface. Figure 1 also shows the response of the boundary layer on the pressure side to the external perturbations: in (c) for low FST case and (d) for high FST case. It is interesting to note the appearance of longitudinal vortical structures. These structures do not arise due to Görtler instability, despite that they emerge on a concave surface. In our simulations, we found that the local values of Görtler number are always below the critical one, which is in agreement with previus findings [1, 10].

The time- and span-averaged velocity profiles at different streamwise locations on the suction side of the blade are plotted in Fig. 2 (a) and (b). The profiles of mean velocity for the low FST case illustrate flow reversal in the separated region. This separation bubble does not reattach. In the high FST case, we can see that velocity profiles transition from laminar to turbulent ones and flow stays attached over the whole suction side. In Fig. 2(c) and (d), profiles of the root-mean-square (r.m.s.) values of streamwise velocity at different streamwise locations are shown. In the low FST case (c), r.m.s. fluctuations of streamwise velocity indicates that in the first half of the separation bubble the growth rate of velocity perturbation is relatively slow and profiles exhibit a second peak close to the wall. The outer peak in the shear layer grows rapidly in the second half of the bubble, because of amplification of disturbances due to Kelvin-Helmholz instability, leading to formation of large scale eddies and breakdown. Interestingly, all the profiles exhibit their maximum at the inflection point, further supporting the dominant role of the inviscid instability in the transition process in the low FST case. In the high FST case (d), peak values of u_{rms} increases in the streamwise direction, while the location of the maximum value moves slightly towards the wall.

CONCLUSIONS

We have performed direct numerical simulations of the FST-induced boundary-layer transition on a low pressure turbine blade. We observed that in the case of low FST, the Kelvin-Helmholz instability dominated the transition process on the suction side and full-span vortices were shed from the appearing separation bubble. Transition on the suction side proceeded more rapidly in the high FST case, where the generated streaks broke down into turbulent spots and caused the boundary layer transition. On the pressure side we have identified the appearance of the longitudinal vortical structures which are not produced by Görtler instability as the Görtler number in the current case is smaller than the critical value.

TOWARDS A THEORETICAL UNDERSTANDING OF SPATIOTEMPORAL INTERMITTENCY IN WALL-BOUNDED SHEAR FLOWS

Dwight Barkley

Summary The route to turbulence in wall-bounded shear flows is reviewed with emphasis on what is known from experiments and numerical simulations. Some key open theoretical questions concerning the intermittent region are then addressed. These include the following: turbulent-laminar fronts in planar shear flows; the connection between puff splitting and the onset of weak slugs; the onset of oblique turbulent bands as a problem in pattern formation.

INTRODUCTION

Explaining the route to turbulence has been a long and tortuous journey. After years of missteps, controversies, and uncertainties, we are at last converging on a unified and fascinating picture of transition in wall-bounded shear flows such as pipes, channels, and ducts. Classically, subcritical transition (such as in a pipe), was thought to imply a discontinuous route to turbulence. We now know that this is not the case – subcritical shear flows may, and often do, exhibit continuous (second-order) transition. From this we understand how to define precise critical points for systems without linear instabilities and how to characterize the onset of turbulence in terms of non-trivial, but universal power laws, e.g. Lemoult et al. (2016); Sano & Tamai (2016); Chantry et al. (2017).

For a range of Reynolds numbers above the critical point wall-bounded shear flows are spatiotemporally intermittent with coexisting turbulent and laminar domains. See Tuckerman et al. (2020) and references therein. Eventually at higher Reynolds numbers the turbulent-laminar intermittency gives rise to fully turbulent flow, often referred to as featureless turbulence or as uniformly turbulent flow. From experiments and from direct numerical simulations of the Navier-Stokes equations we now know a great deal about the dynamics of the turbulent and laminar domains within the intermittent regime, e.g. Coles (1962); Wygnanski & Champagne (1973); Darbyshire & Mullin (1995); Prigent et al. (2002); Nishi et al. (2008); Duguet et al. (2010) However, our theoretical understanding of the structure and dynamics of turbulence within the intermittent regime remains limited.

In this talk I will briefly summarize for the non-experts some of the outstanding theoretical challenges to understanding the intermittent route to turbulence in wall-bounded shear flows. I will then discuss recent ideas on how to address some of these challenges.

TURBULENT-LAMINAR FRONTS

Understanding turbulent-laminar intermittency is largely a question of understanding fronts between turbulent and laminar flow (Coles, 1962; Pomeau, 1986; Barkley et al., 2015) and how the large-scale mean flow is dictated by turbulent structures (Barkley & Tuckerman, 2007; Duguet & Schlatter, 2013). In the case of pipe flow, geometry restricts the allowed turbulent structures to relatively simple localized patches known as puffs. In the case of planar shear flows turbulent patches take the form of oblique bands that split, fragment and change orientations resulting in a much more complex spatiotemporal situation (Chantry et al., 2017; Shimizu & Manneville, 2019). The large-scale mean flow is especially significant in this case and it especially challenging. By working in tilted computational domains (minimal band units) one can captures some, but not all of the features of turbulent-laminar intermittency in planar flows (Barkley & Tuckerman, 2005; Tuckerman et al., 2020). I will present some ideas on how to address turbulent-laminar fronts for planar flows in this setting.

PUFF SPLITTING

The onset of sustained turbulence in pipe flow is dictated by the interplay between puff decay and puff splitting (Avila et al., 2011). Neither process is fully understood, although puff decay does not present any difficulties for computations and experiments, other than resolving long time scales. There have been studies of puff splitting e.g. Shimizu et al. (2014), but on the whole the process lacks theoretical understanding. Moreover, at the upper end of the transition region in pipes, turbulence begins to expand in the form of slugs – first weak slugs and eventually strong slugs (Barkley et al., 2015). I will address possible connections between puff splitting and expansion in the form of weak slugs.

PATTERN FORMATION

It has long been recognized that the formation of oblique turbulent bands from uniform turbulence, as Reynolds number is decreased, has all the hallmarks of a pattern formation problem. See Tuckerman et al. (2020) and references therein. One can view the problem in terms of spatial dynamics in which space is map to a temporal variable and this provides a compact and appealing description of the transition. However, past (unpublished) evidence indicates that this transition does not fall into the classical Eckhaus picture. I will review and discuss this issue.

EFFECTS OF LAYER INTERACTIONS ON THE INSTANTANEOUS STABILITY OF FINITE STOKES FLOWS

Chen Zhao[1], Zhenli Chen *[1], and Dong Li[1]
[1]School of Aeronautics, Northwestern Polytechnical University, Xi'an, China

Summary Stability analysis of Stokes flow is of practical importance, such as in flow control. In the present work, stability of finite Stokes flow, formed by two synchronizing oscillating parallel plates, is analyzed via instantaneous linear stability theory when the interactions between two Stokes layers over flat plates are considered. Effects of the distance between two plates on the stability are studied. The effects are strong when the ratio of Stokes layer thickness to the half distance between two plates is larger than 0.12. In view of the maximum instantaneous growth rate, with the decreasing of wall distance, the interactions between two Stokes layers destabilize the flow first, and then stabilize the flow. The most instantaneous unstable mode is of higher wavenumber. The flow is stable over a period when the two plates are very close. It is observed that the phase of maximum instantaneous growth rate appears earlier when two plates move closer. However, the mode which have the maximum instantaneous growth rate may not be the most unstable mode in view of the net growth over a period.

INTRODUCTION

The Stokes flow is usually viewed as a prototype to analyze the stability of unsteady flows because of its analytical velocity profiles. Linear stability of the Stokes flow can be analyzed via the Floquet method or an instantaneous linear stability theory(LST).[1] Floquet method is used to predict the net growth of a perturbation over an entire period of an oscillating base flow, whereas in the instantaneous LST, the base flow is treated as quasi-steady.[3] In instantaneous LST, Orr-Sommerfeld equation is solved at every frozen state. Even if a base flow is Floquet-stable, it can still support substantial perturbation growth during finite time of a period.[4] Thus, the instantaneous LST has advantages in analyzing the transient growth of the perturbations. The instantaneous stability of the finite Stokes flow was analyzed by Luo and Wu.[4] However, in their analysis, the two walls are so far from each other that the interactions between Stokes layers can be neglected. Thus, in the present work, the instantaneous LST is used to study the effects of wall distance on the stability of Stokes flows.

PHYSICAL MODEL AND NUMERICAL METHOD

We consider a two-dimensional viscous incompressible parallel flow bounded by two infinite parallel plates separated by a distance of $2h^*$. The finite Stokes flow is produced by the synchronizing oscillations of two plates with a velocity $U_0^*\mathrm{Cos}(\Omega t^*)$. The oscillation has a period of $T = 2\pi/\Omega$. The phase of oscillation is $\varphi = t^*/T$. The streamwise and normal directions are indicated by x and y. The Stokes layer thickness is defined as δ^* and nondimensionlized as $\delta = \delta^*/h^*$. The corresponding Reynolds number is $Re_\delta = U_0^*\delta^*/\nu$. In present research, $Re_\delta = 1560$. The infinitesimal perturbations are governed by Orr-Sommerfeld equation. The instantaneous linear stability theory is used to solve the governing equation with the given real spatial wavenumbers α to analyze the temporal stability of the flow. The temporal growth rate of perturbations is signified as ω_i. The most unstable transient mode is determined over all phases of a period.

RESULTS

To analyze the effects of Stokes layer interactions on the stability of the flow, maximum velocity and frequency of the oscillation are kept invariant. The distance between two plates is changed to formulate two Stokes layers. It is observed that the second-order derivatives of the base flow velocity to y, signified as D^2U, at the central parts between two plates

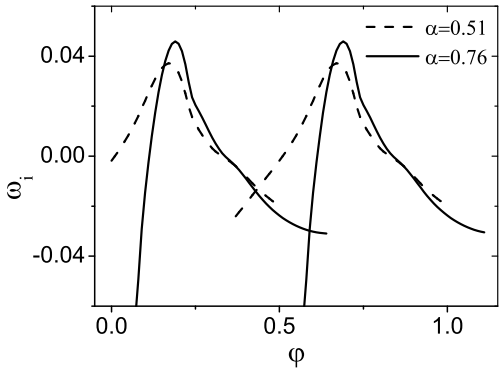

Figure 5: Instantaneous growth rates of two different modes varying with phase at $\delta = 0.4$.

depart from zero for a finite value when $\delta > 0.12$, shown in Fig.1. Thus, it is reasonable to deduce that the effects of layer interactions should be considered when $\delta > 0.12$, which is also proved in Fig.2. Maximum instantaneous growth rate at different δ and the corresponding spatial wavenumber are depicted in Fig.2. With the decrease of h^*, the interactions between the Stokes layers destabilize the flow first, and then stabilize the flow. When the two plates move to be very close, the maximum growth rate can be negative, which signifies that the flow is stable over a period. And the spatial frequency of the most instantaneous unstable mode increases with the shorter distance between two plates.

The instantaneous growth rates of the most unstable mode over a period are compared for the cases at $\delta = 0.0625$ and 0.12, shown in Fig.3(a). The results of two cases are identical, which is consistent with Fig.2. The eigenvectors of two cases at different phases are compared in Fig.3(b). It is found that the eigenvectors of two cases near the central parts between two plates are slightly different at the later time of a period. Fig.4 presents the instantaneous growth rates of the most unstable mode for the cases at $\delta = 0.2, 0.4, 0.6$ and 0.8. It shows that the phase of maximum growth rate appears earlier when the two plates move closer. The instantaneous growth rates of two different modes at $\delta = 0.4$ are depicted in Fig.5. Mode $\alpha = 0.76$ has the maximum instantaneous growth rate. However, mode $\alpha = 0.51$ grows for a longer time interval than mode $\alpha = 0.76$, which means that the mode which has the maximum instantaneous growth rate may not be the most unstable mode in view of the net growth over a period.

NONLINEAR EVOLUTION AND ACOUSTIC RADIATION OF HELICAL-MODE WAVEPACKET IN THE NEAR-NOZZLE REGION OF A SUBSONIC CIRCULAR JET

Zhongyu Zhang[1] and XuesongWu *[1,2]
[1]Department of Mechanics, Tianjin University, Tianjin 300072, P.R. China
[2]Department of Mathematics, Imperial College London, London SW7 2AZ, U.K.

Summary In the near-nozzle region of a circular jet, helical modes with different azimuthal wavenumbers coexist and interact with each other. In this work, the nonlinear evolution of a wavepacket consisting of an arbitrary number of interacting helical and axisymmetric modes are investigated theoretically using high-Reynolds-number asymptotic approach. Furthermore, the acoustic radiation of such a form of disturbance is analysed on the basis of the first principles. Unlike acoustic analogy, which predesignates the sound sources in a heuristic manner, our current asymptotic approach to aeroacoustics determines the physical sound sources unambiguously by analysing the large-distance asymptote of the near-field hydrodynamic fluctuations. It is shown that interactions of subsonic modes generate a slowly modulated mean-flow distortion and emit low-frequency sound waves on the scale of the wavepacket envelope. [1]

NONLINEAR EVOLUTION: A WEAKLY NONLINEAR CRITICAL-LAYER THEORY

In the near-nozzle region, a thin shear layer develops along the lip line and its thickness δ^* is much smaller than the nozzle diameter D^*. A helical mode with azimuthal wavenumber m is weakly three-dimensional because $m/r_c \ll 1$ plays the role of the spanwise wavenumber, where $r_c = O(D^*/\delta^*)$ denotes the centre of the shear layer, normalized by δ^*. It follows that all helical modes, together with their 'side-band' components share the same critical layer since the phase speeds of these components are all close to that of the neutral mode (Long & Petersen, 1992; Strange & Crighton, 1983). In particular, when $r_c^{-1} = O(\epsilon^{1/5})$, the nonlinear inter-modal interactions and azimuthal modulation become important simultaneously when the linear growth rates reduce to $O(\epsilon^{2/5})$, where ϵ is a measure of the helical mode magnitudes (Wu, 1993). In the cylindric coordinate system (x, r, θ), the disturbance can be expressed as $A(\tau, \bar{x}, \theta)\phi(r)\mathrm{e}^{\mathrm{i}(\alpha x - \omega t)}$, where α and ω denote the axial wavenumber and frequency of the common carrier wave. Different helical modes (with the axisymmetric mode being a special case) and their side-band components are accommodated by the dependence of the amplitude function A on the azimuthal coordinate θ and the slow time variable $\tau = \epsilon^{2/5}t$. The spatial evolution is described by the slow axial variable $\bar{x} = \epsilon^{2/5}x$.

In the majority of the jet flow, the wavepacket is linear and inviscid, but nonlinear interactions take place in the critical layer, where viscosity and non-equilibrium both appear at leading order in the governing equations. Unlike an axisymmetric mode or a two-dimensional mode in a planar mixing layer, either of which has a strongly nonlinear critical layer (Zhang & Wu, 2020), a wavepacket of helical modes is governed by weakly nonlinear critical-layer dynamics; see a recent review by Wu (2019). For a laminar base flow, the non-parallelism associated with the axial spreading of the jet enters at a higher order than does the non-equilibrium with respect to τ and $\bar{x}$. This leads to the translating-critical-layer effect (Cowley, 1985; Wu & Zhuang, 2016) and influences the modulation significantly. The present theory is a composite theory including both effects of non-equilibrium and non-parallelism. By matching the solutions in the critical layer and the bulk of the jet, the amplitude evolution-modulation equation is derived, which turns out to be an integro-partial-differential type with respect to the slowly temporal and spatial variables, τ and $\bar{x}$ (Zhang & Wu, 2019). A significant feature of this equation is that the nonlinear terms are history-dependent and involve derivatives with respect to θ.

ACOUSTIC RADIATION: A FIRST-PRINCIPLE DESCRIPTION FOR ACOUSTICS

Unstable wavepackets are considered to be an important sound source, especially in the case of circular jets. The analysis of the disturbance in the main jet and critical layer allows one to investigate how such a wavepacket radiates sound on the basis of first principles, and the key and natural idea is to identify the radiating part of the disturbance by examining the large-distance asymptote of the near-field disturbance (Wu & Zhang, 2019).

The eigenfunction of a subsonic unstable wavepacket attenuates exponentially in the radial direction, and hence the wavepacket itself radiates only exponentially small sound waves. However, the nonlinear interaction of the wavepacket generates a slowly-breathing mean-flow distortion, which emits sound waves with low frequencies of $O(\epsilon^{2/5})$. Such a radiation mechanism is broadly similar to that described by Wu & Huerre (2009) for a single pair of subsonic helical modes in the developed regime of a circular jet. For the present multiple helical modes in the near-nozzle region, the main difference is that the physical emitter is no longer the leading-order mean-flow distortion, and instead it is the secondary-order mean-flow distortion that radiates the primary sound waves.

An equivalent sound source in the context of Lighthill's analogy is derived by matching with the near-field solution, and it contains the contributions from the critical layer and the bulk of the jet. The radiated acoustic field consists of azimuthal components with $m = 0, \pm 1, \ldots$, and the respective intensity is of $O[\epsilon^{(11+|m|)/5}]$. It follows that the axisymmetric sound is at leading order and the sound waves with azimuthal wavenumbers $m = \pm 1$ are the next.

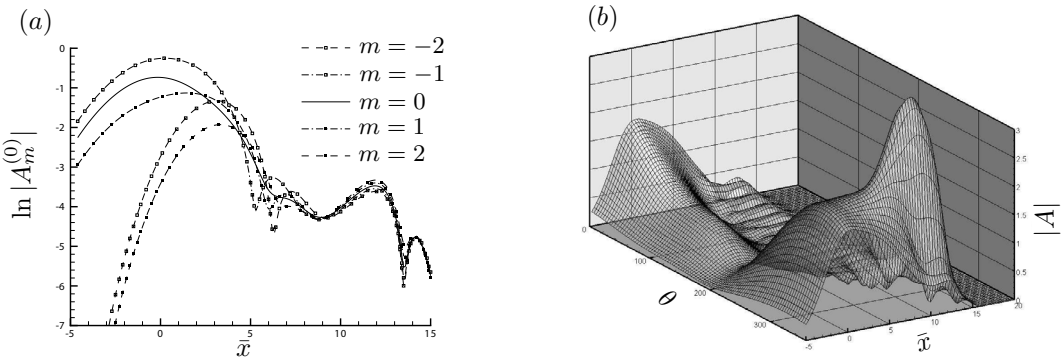

Figure 1: (a) Evolution of $A_m^{(0)}$, the amplitude of the central-frequency components of axisymmetric ($m=0$) and helical ($m=\pm1$, ±2) modes; (b) evolution of the total amplitude $|A|$ shown as a perspective plot against the streamwise and azimuthal variables, $\bar{x}$ and θ.

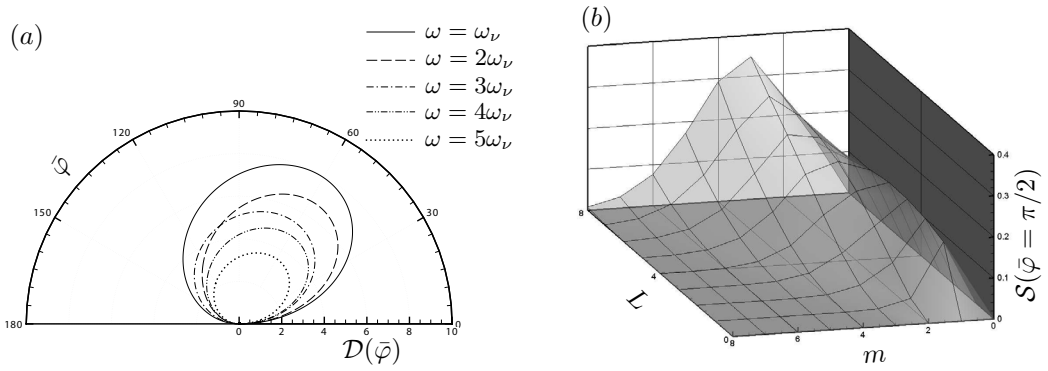

Figure 2: (a) Directivity of sound waves with azimuthal wavenumbers $|m|=1$ and frequencies $n\omega_\nu$, $n\in\mathbb{Z}^+$, where $\omega_\nu=\epsilon^{2/5}\Delta$ is the difference frequency; (b) spectrum of the sound in the direction making $\pi/2$ angle to the downstream axial direction.

MAIN RESULTS AND CONCLUSIONS

Of interest is a wavepacket consisting of helical and axisymmetric modes, each having side-band components with frequencies $\omega+n\epsilon^{1/5}\Delta$ $(n=0,\pm1,\ldots)$. In this case, the solution for the amplitude function A can be decomposed as $A(\tau,\bar{x},\theta)=\sum_{m,n}A_m^{(n)}(\bar{x})\exp\left[\mathrm{i}(m\theta-n\Delta\tau)\right]$. The nonlinear evolution depends on the modes seeded upstream. Figure $1(a)$ displays the development of $A_m^{(0)}$ when nine helical modes $(m,n),m,n=0,\pm1$ with frequencies $\omega+n\epsilon^{2/5}\Delta$, in which $\epsilon=0.09$, $\omega=1.37$ and $\Delta=0.20$ are seeded. The mutual interactions of the seeded modes excite modes $m=1,2$ (and their sideband components). All modes eventually attain nearly the same amplitudes, and attenuate under the influence of nonlinearity, Figure $1(b)$ shows a perspective plot of $|A|$ as a function of $\bar{x}$ and θ.

The helical modes and their side-band components in the wavepacket generate low-frequency components. These components attenuate only algebraically in the radial direction and evolve to acquire the character of sound waves. Figure $2(a)$ shows the directivity of the acoustic components $m=\pm1$ with frequencies $n\omega_\nu=\epsilon^{2/5}n\Delta$. Panel (b) displays the spectrum at $\pi/2$ angle to the downstream axial direction.

Further results on the nonlinear evolution and acoustic radiation will be presented at the Congress.

HYPERSONIC ATTACHMENT-LINE INSTABILITIES WITH LARGE SWEEP MACH NUMBERS

Youcheng Xi*[1] and Song Fu †[1]
[1]School of Aerospace Engineering, Tsinghua University, Beijing, 100084, China

Summary Highly swept flows over a cold cylinder that give rise to large sweep Mach numbers are studied. Using local and global stability theory, an attachment-line mode is found to be is found to be dominant for the laminar-turbulent transition along the leading edge, which agrees well with experimental observations. It is obviously demonstrated that the global modes display the features of both attachment-line modes, as in sweep Hiemenz flow, and cross-flow-like modes further downstream along the surface. In contrast to incompressible flows, results from high sweep Mach number show that the leading-edge curvature has a destabilizing effect on the attachment-line mode for large span-wise wave number but a stabilizing effect for small span-wise wave number.

INTRODUCTION

The leading edge of a wing plays a very important role in boundary layer transition, especially in hypersonic region. However, the Mach number effect of compressible attachment-line instability is still not clearly understood, most prominently in the hypersonic region. Two significant problems address our interests. First, as highlighted in the series of experiments from Gaillard[1], instability mechanisms are not well understood in the high sweep Mach number region. Also, in high-speed regions, the relation between attachment-line modes and cross-flow modes is far from clear. In some cases [2], the attachment-line instabilities in the leading-edge region connected with cross-flow modes further away from the leading edge. Contrarily, these connections may disappear in some other cases as pointed by Paredes[3].

METHODOLOGY

The hypersonic flow around a swept cylinder is studied here based on relevant experimental conditions [1]. A cylinder of radius $R = 33mm$ is assumed to be of infinite length in the spanwise direction. The incoming flow impinges onto the the surface of the cylinder with a sweep angle Λ. A high fidelity base flow is obtained by solving the full Navier-Stokes equations with a high-order shock-fitting method. Both local and global stability theory are used for identification of the instabilities. And non-negligible variations of base ow with respect to x direction together with the curvature effect around the attachment line and the features of downstream region can be taken into account properly by the global stability analysis, simultaneously.

STABILITY ANALYSIS

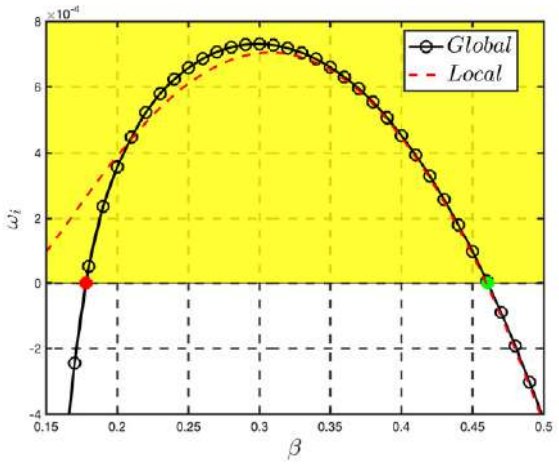

Figure 1: Dependences of ω_i on β of C3376 cases. The black line with black circles represents the results from global calculations and the red dashed line represents the results from local calculation. The red and green points represent the critical value points.

*E-mail: xiyc14@mails.tsinghua.edu.cn

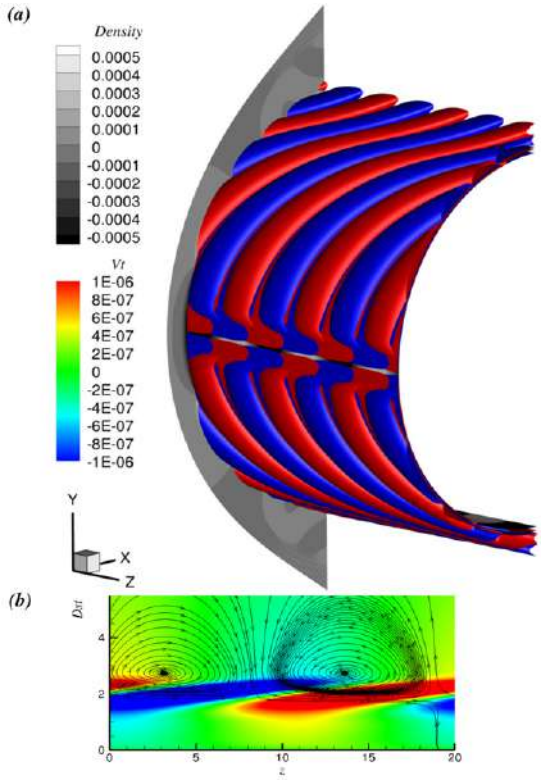

Figure 2: (a) The leading global modes of the eigenvalues $\omega = (0.25097, 0.00073146)$ is visualized by iso-surface (positive values in red, negative values in blue) of the surface tangential velocity perturbations for case C3376a, contours of the relative density perturbation are also shown at the background. (b) represents contour of the $x - z$ plane cross-cut at $y = 0.001$ for surface tangential velocity perturbation $V_t(x, y, z)$ together with the streamline over this plane.

CONCLUDING REMARKS

The analysis is performed using high fidelity realistic base flow, calculated by high-order shock fitting methods, together with the local/global stability model, which fully resolves the base flow and all the geometry information. The theoretical results match well with the experimental results. According to the global stability analysis, the leading attachment-line global mode is also found to be connected with cross-flow like modes further away from the attachment-line. As first presented by Mack[2] over an adiabatic wall surface with relative low sweep Mach number, this connection also exists over cold wall surface with corresponding high sweep Mach number.

Based on the local and global analysis, we also found that the attachment-line mode, unlike the incompressible cases, at the simulation conditions is not entirely suppressed by the leading curvature. For the cases at sweep Mach number 5.8, the growth rate of leading global mode is found a little bit larger than local calculation when the span-wise wave number β is above 0.2084 and the global growth rates are lesser than local calculations when the span-wise wave number is lower than 0.2084. This finding indicates that the leading edge curvature has double effect on the attachment-line modes which slightly destabilizes the mode for large span-wise wave numbers and stabilizes the mode for low span-wise wave numbers.

2D SELF-SUSTAINING PROCESSES IN PLANE POISEUILLE-COUETTE FLOW INVOLVING CRITICAL LAYER / BOUNDARY LAYER INTERACTION

Andrew Walton [*1] and Rishi Kumar[1]
[1]Department of Mathematics, Imperial College London, South Kensington Campus, London SW7 2AZ, UK

Summary Plane Poiseuille-Couette flow is well-known to exhibit a linear Tollmien-Schlichting-type instability provided the wall sliding speed does not exceed a critical value. Here we investigate how this instability is modified by the inclusion of finite-amplitude effects. A large Reynolds number self-sustaining structure is found which involves the interaction of two nonlinear critical layers with near-wall Stokes regions. A global property of the flow-field, involving the vorticity of the mean-flow distortion, is used to determine the amplitude of the modes which are found to exist beyond the linear cut-off. In the situation where the phasespeed is almost equal to the sliding speed, a new nonlinear structure arises involving critical layer/shear layer interaction. The numerical results from this latter interaction are found to compare well with full solutions of the Navier-Stokes equations.

INTRODUCTION

A dynamical systems approach to transition, in which equilibrium solutions of the Navier-Stokes equations play a key role in transitional and turbulent dynamics, has become increasingly popular in recent years. The relevant equilibrium solutions are those in which there is a mutual interaction between a roll flow in the cross-stream plane, a streamwise streak and a wave propagating in the streamwise direction. This interaction is fundamentally three-dimensional in nature and has no obvious two-dimensional analogue. If we wish to consider Tollmien-Schlichting (TS) instabilities, which are inherently two-dimensional, then the roll/streak/wave theories are not directly applicable, even at high Reynolds number, unless a very specific spanwise variation is imposed. In this talk we discuss self-sustaining processes that can operate in two dimensions, involving the interaction of internal critical layer dynamics with structures that arise near the boundaries. As a specific example we consider plane Poiseuille-Couette flow (PCF) which is well-known to support a TS form of instability provided the sliding speed $V < V_c \simeq 0.34$ [1]. The basic PCF can be written in the non-dimensional form

$$U_0 = 1 - y^2 + Vy, \tag{1}$$

where the channel walls are positioned at the scaled locations $y = \pm 1$ and V is the scaled wall speed. The Reynolds number R here is based on the channel half-width and the maximum velocity of the Poiseuille component of the flow.

A new investigation of the linear stability of this flow through the use of the Orr-Sommerfeld equation has revealed surprisingly intricate stability properties as the sliding speed is increased, with multiple neutral curves co-existing for $V < V_c$. In figure 1(a) we show the results of some recent computations. For $V = 0.017$, we note the existence of a stable intrusion inside the familiar neutral curve that one would expect for plane Poiseuille flow. As V is increased, this finger of stability extends to smaller R before slicing off a portion of the original neutral curve (figure 1(b)), thereby generating a second curve. Eventually however, as $V \to V_c-$, all regions of instability disappear. In this talk we will see that, by comparing Navier-Stokes solutions with a nonlinear asymptotic SSP model, such a model can accurately describe the nonlinear solutions that bifurcate from the upper neutral curve in figure 1(b).

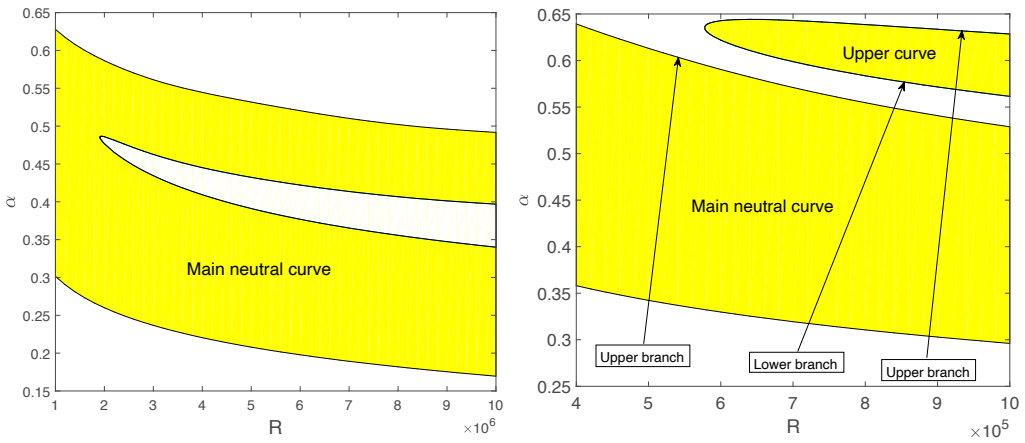

Figure 1: Linear neutral curves for PCF. (a) $V = 0.017$; (b) $V = 0.019$. Wavenumber α versus Reynolds number R. The shaded regions are unstable.

*Corresponding author. E-mail: a.walton@imperial.ac.uk

PROPERTIES OF THE SSP

Consider the quantity

$$\tau_M(y) = \frac{1}{2\pi}\frac{d}{dy}\int_0^{2\pi} (u - U_0)\, d\xi \tag{2}$$

as a measure of the vorticity associated with the mean-flow distortion brought about by nonlinear wave interaction. Here $\xi = \alpha(x - ct)$ is a travelling wave coordinate, while $u(\xi, y)$ represents the streamwise velocity of a disturbance with wavenumber α and phasespeed c. Integration of the Navier-Stokes equations reveals that τ_M assumes the same value at both walls. It follows from this that any jump in vorticity occurring across internal critical layers must be exactly balanced by an equal and opposite jump across the boundary layers that adjoin each wall. Away from these regions the flow is essentially inviscid in nature with the travelling waves satisfying a form of Rayleigh's equation. The critical layers in our theory are of strongly nonlinear type, ensuring that the regularising effects of viscosity are only encountered at high order with the singularity occurring in the Rayleigh equation effectively smoothed out by nonlinear effects via a jump condition.

FORMULATION OF THE SSP

We will consider two different interaction structures. The first consists of two internal critical layers embedded within an inviscid region, with Stokes layers adjoining each wall. The solution procedure consists of solving a Rayleigh eigenvalue problem subject to nonlinear jump conditions at the singular points: this determines c as a function of wavenumber and sliding speed. The amplitude of the modes is found by calculating the vorticity jumps across the two critical layers and two Stokes layers and setting the total jump to zero. Although the Rayleigh part of the problem is a numerical one, the jumps can all be determined analytically, leading to an explicit expression for the amplitude in terms of the wavenumber and sliding speed. Calculations show that solutions exist for sliding speeds considerably in excess of the linear cut-off. This structure is relevant to solutions which bifurcate from the upper branch of the main neutral curve in figure 1(b).

As the mode amplitude is increased, calculations show that $c \to V$ and hence the upper critical layer moves ever closer to the Stokes region. A new distinguished scaling describes how the two layers merge, forming a near-wall shear layer. In this novel structure, although a Rayleigh equation still governs the bulk of the flow, the vorticity jump across the lower Stokes layer is now a higher-order effect, leaving the amplitude dependence determined by balancing the jumps across the single critical layer and the shear layer. Again, these jumps can be computed analytically and an explicit formula for the amplitude obtained. More detail concerning these structures will be given in the talk: see also [2], [3].

COMPARISON OF ASYMPTOTIC THEORY WITH NAVIER-STOKES SOLUTIONS

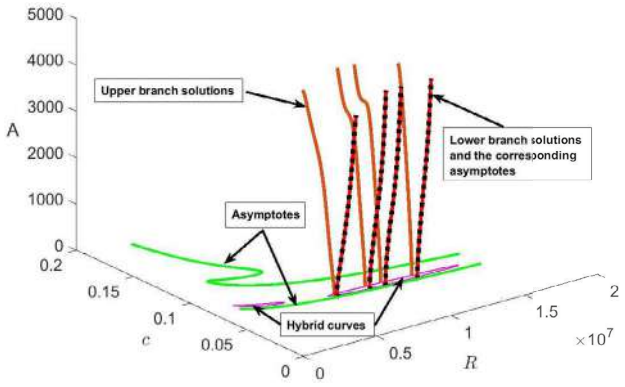

Figure 2: Solid lines: Navier-Stokes solutions at fixed R that bifurcate from the upper linear neutral curve (denoted 'hybrid curve' here). Dots: asymptotic predictions arising from the SSP theory. The sliding speed $V = 0.025$.

To test the accuracy of the asymptotic SSP at finite Reynolds number we have computed nonlinear travelling wave solutions of the full Navier-Stokes equations by a homotopy process starting from the upper curve on figure 1(b). The results, together with asymptotic predictions, are shown in figure 2. The solutions which bifurcate from the lower branch of this curve can be seen to be in excellent agreement with those arising from the asymptotic theory.

Summary The first non-modal linear stability analysis of an unsteady ablation waves in the context of inertial confinement fusion is carried out. Optimal initial perturbations are computed using a direct-adjoint method obtained by applying the Lagrange multiplier technique. The non-normality of the perturbation evolution operator under the assumption of a frozen mean flow is also studied. Ablation wave perturbations are found to be prone to transient amplification at both short and intermediate final times whether for small or large perturbation wavelengths. Two distinct mechanisms of optimal growth are presently identified. These results contrast with previous results based on normal mode analysis, simulations and dedicated experiments of selected perturbation configurations, for which only large wavelengths are subject to a possible amplification whereas small wavelengths are damped.

INTRODUCTION

Inertial confinement fusion (ICF) aims at achieving controlled thermonuclear fusion by imploding spherical hollow pellets filled with light fusible nuclei [1]. These implosions occur under the action of an external irradiation flux which is tailored to induce a deflagration, or *ablation*, heat wave that thrusts inwardly the pellet outer shell, the *ablator*, chosen to be opaque to the incident irradiation. The resulting flow consists of a subsonic heat front, or *ablation front*, coinciding with the leading edge of the expansion wave of the heated material, that penetrates into the ablator, preceded by a forerunning shock wave (Fig. 1 top). Inherently unsteady, such ablation flows are compressible and highly nonuniform with a steep heat front, owing to the strong nonlinearity of the heat transport and the intense incident heating. The success of ICF depends on reaching, and maintaining for a sufficiently long time, the high temperatures and densities in the fusible payload that are necessary to ignite thermonuclear reactions.

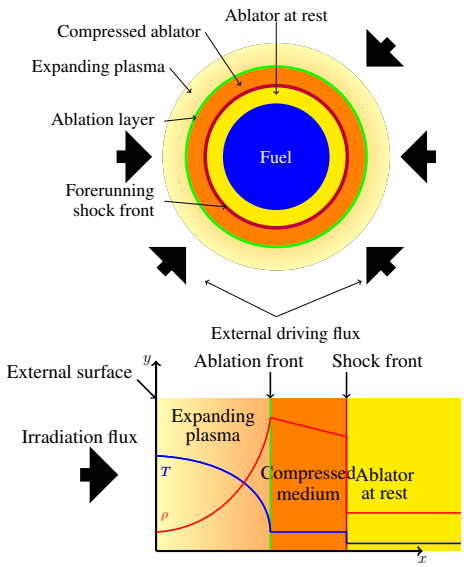

Figure 1: (top) Configuration of the early stage, so-called *shock transit phase*, of an ICF pellet implosion. Pellet sizes are of the order of one millimeter and implosion durations are in the 10–20 nanosecond range. (bottom) Structure of a planar ablation wave representative of the shock transit phase.

Hydrodynamic instabilities that develop during a pellet implosion, because they could induce burn-through of the ablator, excessive losses of symmetry, too large amounts of mixing between the heated and colder parts of the fusible, are detrimental to such a goal [1]. The understanding of hydrodynamic perturbation dynamics during such implosions is therefore of primary importance to ICF. In particular, the hydrodynamic stability of ablation fronts remains one of the most critical issues to the success of ICF [2].

NON-MODAL LINEAR STABILITY ANALYSIS

The hydrodynamic stability of ablation flows has been theoretically investigated using simplifying mean-flow assumptions that are not necessarily met in actual cases: e.g. mean-flow steadiness, low Mach-number approximation, unbounded domains, discontinuous ablation front, flow region uniformity of some sort [3]. In addition, these works have exclusively relied on the method of normal modes, focusing on the least stable eigensolutions that only yield asymptotic stability results and thus omitting possible transient growth phenomena proper to non-normal operators. Moreover, ablation flow unsteadiness induces finite durations of perturbation evolution regimes, thus logically raising the question of short-term perturbation dynamics [4]. More realistic configurations are classically investigated by means of multidimensional numerical simulations with ICF hydrodynamics codes which incorporate the most relevant physical phenomena. These "full-physics" simulations which overcome the above shortcomings, consist in computing perturbation amplifications from selected perturbed initial or boundary conditions that are considered to be the "most dangerous" for a given mean-flow configuration. Besides the computational cost of such simulations, this way of proceeding faces a major difficulty in having to deal, in actual ICF implosions, with multiple perturbation sources whose contributions remain, for some of them, unsufficiently known and controlled.

*Corresponding author. E-mail: gregoire.varillon@polytechnique.edu.

Given this context, methods of non-modal stability theory [5], being capable of identifying the most dangerous perturbations in time-dependent flows of finite durations, are not only most appropriate but also appear to be a necessity. Since the current cost of full-physics simulations forbids the implementation of such methods with existing ICF hydrocodes, we presently have recourse to a simplified modeling of unsteady ablation waves. This modeling is provided by self-similar solutions to the Euler equations with nonlinear heat conduction in slab symmetry. Some of these solutions are representative of the first stage of a pellet implosion, or *shock transit phase*, during which the fore-running shock wave is still traveling inside the ablator [6]. In particular these self-similar flows present the complete structure of an ablation wave: a leading shock front, a compressed region, an ablation layer and an expanding flow region (Fig. 1 bottom).

Optimal initial perturbations and global modes

In the present work we report on results obtained from the first non-modal stability analysis ever performed on an ablation flow relevant to ICF. Dealing with an unsteady mean flow, optimal initial perturbations (OIPs) are searched by means of direct-adjoint iterations.

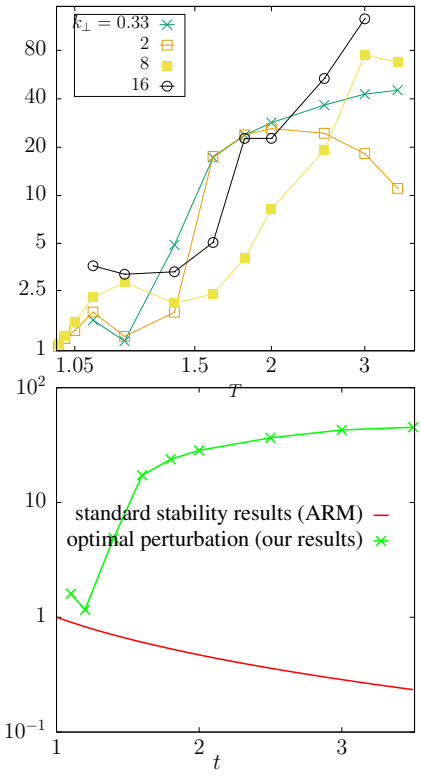

Figure 2: (top) Gain curves of perturbations norm for various transverse wavenumbers. (bottom) Amplification of perturbations norm in the case of the classical ablative Richtmyer–Meshkov instability (ARM) in red, and the amplification of the optimal initial perturbation in green.

The adjoint problem is derived from the Lagrange multipliers technique [7]. In the process, we obtain for the first time, to our knowledge, a proper formulation of a Lagrange functional in the case of an incompletely parabolic system of evolution equations with perturbed dynamical boundaries. This analysis is supplemented by a study of the non-normality of the ablation flow by means of the numerical range and global modes of the perturbation evolution operator under the assumption of a frozen mean flow. Optimal initial perturbations and global modes are characterized in terms of linear propagating waves (acoustics, entropy, vorticity).

Amplification of initial perturbations previously held to be stable

The optimization of initial perturbations exhibits short-term perturbation amplification for all transverse wavenumbers spanning the perturbation spectrum classically considered for ICF pellets and all terminal times within the duration of the shock transit phase of a pellet implosion (Fig. 2 top). These results contrast with previous results based on normal mode analysis, simulations and dedicated experiments of selected perturbation configurations, for which only large wavelengths are subject to a possible amplification whereas small wavelengths are damped. This finding points out the necessity of a non-modal analysis for ablation flows in the context of ICF. Optimal growth mechanisms are analyzed to consist in *acoustic–vorticity wave interactions* at short terminal times and *ablation layer–shock front couplings* at long terminal times. A physical analysis of OIPs shows that these strongly differ from the perturbation configuration of the ablative Richtmyer–Meshkov instability (ARM) [8] usually held as one of the most dangerous in ICF. In particular, OIPs may lead to stronger amplifications than the ARM configuration of identical wavenumber (Fig. 2 bottom).

CONCLUSIONS AND PERSPECTIVES

In the present work we have conducted the first non-modal analysis of ablation flows relevant to inertial confinement fusion. Our results show that ablation flows are prone to amplifying a wide range of perturbations and particularly that perturbation wavelengths up to now believed to be stable may actually lead to strong transient amplifications. This work illustrates the necessity of non-modal analysis in the context of ICF and paves the way to a receptivity analysis and, on the longer term, to *optimal design* of ICF pellets.

VISCOUS EFFECT ON THE CYLINDRICAL RAYLEIGH-TAYLOR INSTABILITY

Renhao Zeng, Jianjun Tao *, and Yuanbo Sun
Department of Mechanics and Engineering Science, Peking University, Beijing, China

Summary The three-dimensional Rayleigh-Taylor instability (RTI) at the cylindrical interface between two viscous fluids is analysed without the irrotational assumption. It is revealed that the most unstable mode is three dimensional, and the corresponding azimuthal wavenumber increases step by step with the increase of the interface radius R. Depending on the scale of the amplitude of the wavenumber vector relative to 1/R, the cylindrical RTI may be close to different asymptotic cases, e.g. the semi-infinite planar viscous limit, the semi-infinite planar inviscid limit, the finite-thickness but inviscid limit, or the finite-thickness creeping-flow limit, and the growth-rate curves show different scaling laws accordingly.

INTRODUCTION

The Rayleigh-Taylor instability (RTI) may occur at the interface when the lighter fluid is accelerated into the heavier one. Chandrasekhar considered the RTI of an radially accelerated spherical interface between incompressible viscous fluids [1]. For the cylindrical interface, the effects of compressibility, geometry, and nonlinearity have been studied for inviscid fluids [2, 3]. With the irrotational assumption, where the tangential stress at the interface and the unstable vorticity field are ignored, the viscous effect was considered to study the Rayleigh-Plateau instability rather than the RTI as claimed in the paper's title [4]. Therefore, the full three-dimensional stability analysis of RTI at the cylindrical interface between viscous fluids, to the best of our knowledge, has not been carried out so far, and is the main objective of the present paper.

PHYSICAL MODEL AND RESULTS

We consider a cylindrical interface separating two incompressible, immiscible, and viscous fluids, i.e. the inner fluid 1 and the outer fluid 2. The fluids are subjected to a steady inward deceleration $\vec{g} = g\vec{e}_r$, where $g > 0$ and $\vec{e}_r$ is the unit radial direction. The outer fluid is denser than the inner, i.e. $\rho_2 > \rho_1$, and the kinematic viscosity ratio is named as $S = \gamma_2/\gamma_1$. The characteristic length, time, and pressure scales are selected as $(\nu_1^2/g)^{1/3}$, $(\nu_1/g^2)^{1/3}$, and $\rho_1(\nu_1 g)^{2/3}$, respectively, and the dimensionless linearized governing equations for the disturbing velocity $\widetilde{u}$ and pressure $\widetilde{p}$ can be obtained. The Atwood number is defined as $A_t = \frac{\rho_2-\rho_1}{\rho_2+\rho_1}$. Following the method proposed in our previous paper [5], the disturbing velocity is decomposed into an irrotational part $\widetilde{\vec{u}}_j^1$ and a viscous part $\widetilde{\vec{u}}_j^2$, and the normal mode is introduced in the form of $f(\widetilde{r},\theta,\widetilde{z}) = F(\widetilde{r})e^{i(n\theta+\widetilde{kz})+\widetilde{\sigma t}} + c.c.$, where n, $\widetilde{k}$, and $\widetilde{\sigma}$ are the azimuthal wave number, the axial wave number, and the growth rate, respectively. The initial interface lies at $R = r_0/(\nu_1^2/g)^{1/3}$, and the total wavenumber $\widetilde{k}_t$, the amplitude of the wavenumber vector, is defined as $\widetilde{k}_t = \sqrt{\widetilde{k}^2 + \frac{n^2}{R^2}}$.

It is assumed that at far field $\widetilde{\vec{u}}_2$ dies away and the boundary conditions at the axis are the same as used in [6]. After applying the continuity conditions at the interface for the velocities and the stresses, we can obtain the dispersion relation $\widetilde{\sigma} = f(n, \widetilde{k}, A_t, R, S)$. For details of the solving method we refer to the previous paper [5]. When the character wavelength is much smaller than the interface radius, or $\widetilde{k}_t \gg 1/R$, the system degenerates to the infinite plane case, and the viscous dispersion relation reduces to the same as that of Bellman *et al.* [7]. For inviscid fluids, the dispersion relations of the three-dimensional and two-dimensional cases [2, 3] can be recovered from the present relation as well.

Different from the inviscid cases studied previously, the most unstable mode of the cylindrical viscous RTI has finite azimuthal and axial wavenumbers. For interfaces of small radii R at $A_t = 0.5$ and $S = 1$, e.g. $R = 0.1$ and 1 as shown in Fig. 1, the most unstable mode is anti-symmetric in the cross section, i.e. $n = 1$. With the increase of the interface radius R, the azimuthal wavenumber of the most unstable mode increases step by step, and the corresponding axial wavenumber

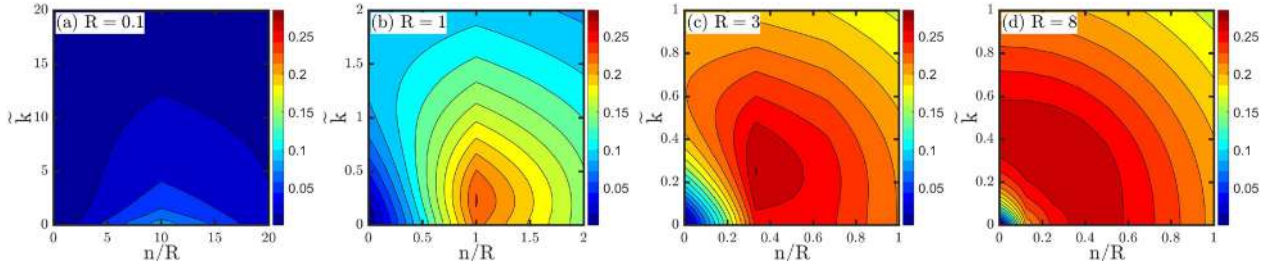

Figure 1: The isocontours of the growth rate $\widetilde{\sigma}$ in the wavenumber n-$\widetilde{k}$ space. $A_t = 0.5$ and $S = 1$.

*Corresponding author. E-mail: jjtao@pku.edu.cn

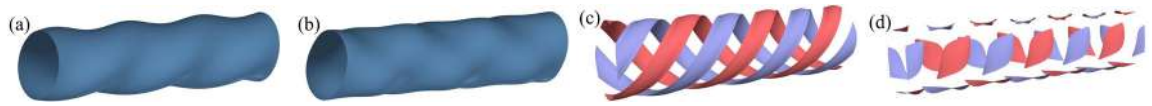

Figure 2: The interfaces and the isosurfaces of vorticity for the most unstable mode of $(R, A_t, S) = (8, 0.5, 1)$ are shown in (a)(b) and (c)(d), respectively. (a) and (c) are the results for the single mode, and (b) and (d) are the superposition of the modes with the positive and negative axial wavenumbers. Red and green isosurfaces in (c) and (d) represent the positive and negative axial component of vorticity, respectively.

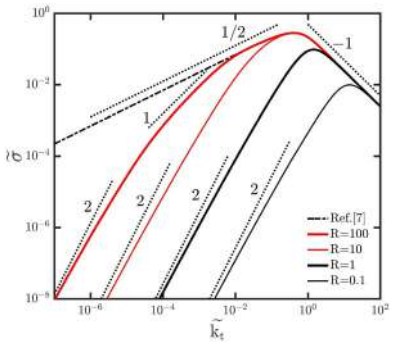

Figure 3: The growth rate $\widetilde{\sigma}$ as a function of $\widetilde{k_t}$ at different R. $A_t = 0.5, S = 1$, and $n = 0$. The result of semi-infinite planar viscous RTI is shown as the dot dash line.

increases as well at each step of the azimuthal wavenumber. When R is large enough, the growth rate is nearly isotropic and the RTI is close to the case of plane interface between semi-infinite fluids. Some examples of the unstable interface and the isosurfaces of vorticity are shown in Fig. 2. It is noted that the interface distortion is amplified in order to show the mode pattern clearly.

It is shown in Fig.3 that the growth rates for different R have different scaling laws at different wavenumber ranges. When the wavelength is much smaller than the cylindrical interface radius, or the total wavenumber is much larger than $1/R$, the curvature effect becomes weak and the cylindrical RTI is close to the plane case. For plane interface between semi-infinite viscous fluids, the approximate but analytical solution of Bellman and Pennington [7] can be expanded for large k as

$$\sigma = \nu_c k^2 + \frac{1}{2}\nu_c^{-1} k^{-2} g k A_t - \nu_c k^2 + O[(gkA_t)^2] \approx \frac{gA_t}{2}\nu_c^{-1} k^{-1}, \tag{1}$$

where the combined viscosity $\nu_c = (\mu_1 + \mu_2)/(\rho_1 + \rho_2)$. Therefore, $\widetilde{\sigma}$ scales as $\widetilde{k_t}^{-1}$ for different R at high $\widetilde{k_t}$ regime as shown in Fig. 3. In the presentation, other slopes of the growth rate shown in Fig. 3, i.e. 2, 1, 1/2, will be explained in terms of the finite-thickness and creeping flow limit, the finite-thickness but inviscid limit, and the planar and inviscid limit, respectively. In addition, the effects of the Atwood number and the viscosity ratio will be discussed as well.

CONCLUSIONS

In the previous studies on the cylindrical RTI, the viscous effect was ignored and higher wavenumber lead to higher growth rate of the unstable mode. When the viscous effect is considered, it is revealed that the most unstable mode is three-dimensional and has finite azimuthal and axial wavenumbers, which increase generally with the increase of the interface radius. When the total wavelength is much longer than the interface radius, the finite-thickness effect brought by the cylindrical geometry substantially lower the growth rate in comparison with the semi-infinite planar case as shown in Fig. 3, and causes different scaling laws at different wavenumber regimes.

MECHANISM OF CROSSFLOW INDUCED BREAKDOWN IN A HYPERSONIC THREE- DIMENSIONAL BOUNDARY LAYER

Caihong Su*[1], and Yufeng Han[1]
[1]Lab for high-speed aerodynamics, School of Mechanical Engineering, Tianjin University, Tianjin, China

Summary The mechanism of transition induced by crossflow is investigated for a hypersonic swept flat plate boundary layer using direct numerical simulation (DNS). Results show that the nonlinear evolutions of the stationary vortex can lead to a slight increase of the wall friction coefficient. However, laminar breakdown occurs only when secondary instability modes set in. Stability characteristics of the distorted mean flow are analyzed using linear stability theory. It shows that the process of laminar breakdown can be divided into two stages. During the first stage, the infection point of the mean flow appear, and the modes with high frequency modes are unstable and amplify. Then followed by the second stage, low-frequency modes are significantly amplified so that the flow profiles are greatly modified and breaks down to turbulence.

INTRODUCTION

For a sustained hypersonic flying vehicle, an accurate prediction of boundary-layer transition is of great importance for evaluating the aerodynamic force and designing the thermal protection system. For a complex three-dimensional body, crossflow instability may arise and dominate transition. Conceptually, transition induced by crossflow instability involves the following stages [1-2]: 1) primary instability, which could manifest as either stationary or travelling vortex; 2) secondary instability following the saturation of the crossflow vortex; 3) breakdown to turbulence. Most research work focus on primary and secondary instabilities, and only a few studies are concerned with the laminar breakdown to turbulence, but mainly in low-speed regime. In the current paper, we are concerned with the mechanism of crossflow induced breakdown of a hypersonic blunt plate boundary layer. We are aiming to show that during breakdown, how the stability characteristics of the mean flow are changed, finally leading to turbulence.

METHODOLOGY AND MEAN FLOW

The flow over a swept flat plate with a circular nose is investigated, as shown in Fig. 1. The Mach number is 6, and the nose radius is 3.5cm. The temperature of the oncoming flow is 226.5K. The swept angle is 45°. The governing equations are three-dimensional Navier-Stokes equations. The reference length is taken as the nose radius. The physical quantities of oncoming flow are used to non-dimensionalize the equations except $\rho_\infty u_\infty^2$ for pressure. The Reynolds number so defined is 79100. The computations involve two steps. 1) Steady computations. First, the base flow containing the bow shock ahead of the body is computed. Then a domain behind the shock, downstream of the nose, as shown in Fig.1, is taken out to compute the evolution of the stationary vortex. 2）Unsteady computations. Secondary instability modes are introduced on the flow distorted by the stationary vortex to trigger transition. High-order difference schemes are used to discretize the governing equations. The wall is non-slip and assumed to be adiabatic.

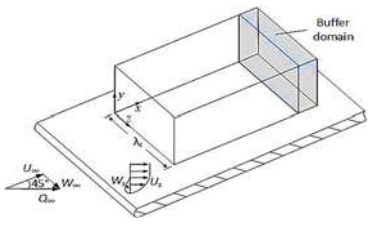

Figure 1 Computational model.

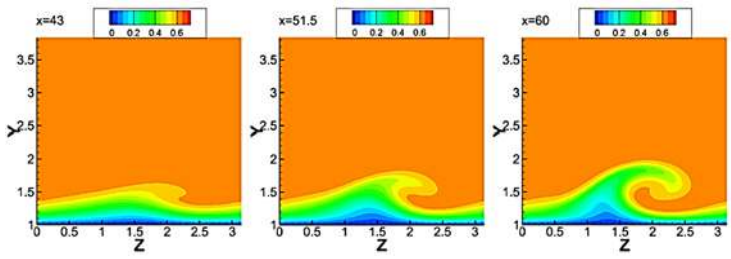

Figure 2 Contour of streamwise velocity fluctuations at different x for β=2.

RESULTS

Evolution of stationary vortex

The computation of the evolution of the stationary vortex starts at x=6 (with the origin at the center of the circular nose). Its spanwise wavenumber is taken to be β=2, and the computational domain in the spanwise direction is taken as one wavelength of the stationary vortex. As shown in Figure 2, the stationary vortex grows and saturates. It was found that the evolutions of stationary vortex with different spanwise wavenumbers are similar (not shown here).

Breakdown to turbulence

As the stationary vortex grows, the mean flow is distorted, so that it is susceptible to secondary instability. Bi-global analysis is performed for the modified mean flow at x=36 to obtain the secondary modes. Two secondary instability

*Corresponding author. E-mail: su_ch@tju.edu.cn.

modes of type z with frequencies of ω=4 and 5 are introduced simultaneously at x=36 to trigger transition. The initial amplitudes of two modes are 0.01. Figure 3 shows the iso-surface of streamwise velocity with u=0.55. Figure 4 shows the wall friction coefficient, in which the case without introducing secondary modes is also plotted for comparison. It can be seen that the stationary vortex causes a slight increase of C_f as it saturates, but the stationary vortex alone cannot trigger transition. As the introduced secondary modes amplify, breakdown occurs. It can be divided into two stages. In stage I, starting from x=46.25 to x=52.5, C_f deviates that of the laminar flow but agrees with that of the stationary vortex. Then stage II follows, where C_f continue to grow and the flow finally transitions to turbulence.

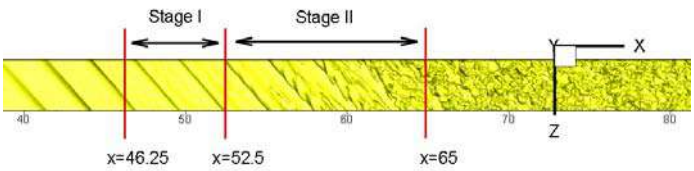

Figure 3 Iso-surface of streamwise velocity (u=0.55).

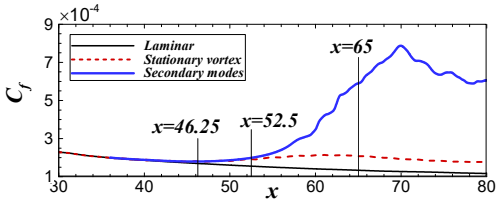

Figure 4 Wall friction coefficient.

Mechanism of breakdown

Distorted mean flow of stage I and stage II is shown in Figure 5a and 5b, respectively. In stage I, infection points appear in the upper part of the mean flow profile, which indicates a type of instability. While in stage II, the infection point weakens and meanwhile the lower part of the mean flow is modified significantly and finally evolves into a turbulent profile. Figure 6 shows the unstable region of the mean flow obtained by linear stability analysis, in which the case without introducing secondary modes is also plotted for comparison. As expected, in stage I (figure 6a-6d), for both cases, the unstable region of the mean flow enlarges, indicating more unstable modes are to amplify and in turn modify the mean flow. While in stage II, for the case of secondary modes, the modes with high frequencies gradually decay (see figure 6e) and meanwhile those with low frequencies amplify (see figure 6f). At x=62.5, multiple groups of modes appear. Finally at x=65, there is no unstable mode and the flow becomes turbulent. In contrast, for the case of stationary vortex, unstable region does not change much.The modes with low frequencies (near ω=0) are marginally unstable, and the laminar breakdown does not occur.

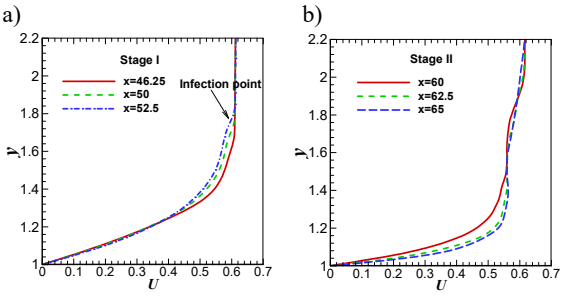

Figure 5 Distorted mean flow of a) stage I and b) stage II.

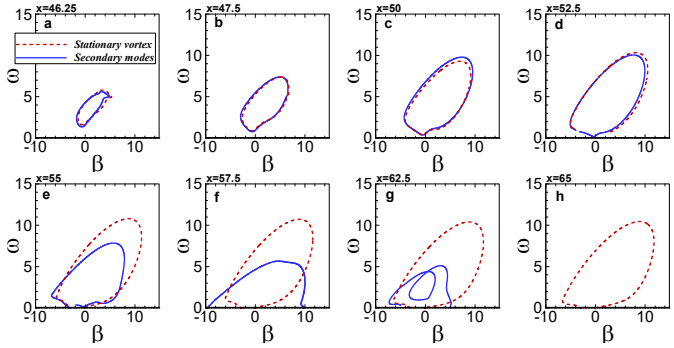

Figure 6 Unstable region of distorted mean flow.

CONCLUSIONS

The mechanism of transition induced by crossflow is investigated for a hypersonic swept flat plate boundary layer. The whole process of transition including the evolutions of stationary vortex, secondary modes and the laminar breakdown is simulated using DNS. Results show that breakdown occurs only when secondary instability modes set in and amplify. The process of breakdown involves two stages. In stage I, C_f deviates from the value of laminar flow, but agrees with that of the stationary vortex. And in stage II, C_f continues to grow and the flow breakdowns to turbulence. Stability characteristics of the mean flow show that, during stage II, the high-frequency modes decay and meanwhile the low-frequency modes become significantly unstable, and the mean flow is modified rapidly to a turbulent profile.

THE INFLUENCE OF THREE-DIMENSIONALITY ON ROSSITER MODES IN A COMPRESSIBLE OPEN CAVITY

Marlon Sproesser Mathias*[1] and Marcello A F Medeiros[1]
[1]São Carlos School of Engineering, University of São Paulo, São Carlos, São Paulo, Brazil

Summary We study the stability of a compressible flow in an open cavity. First, bi-global instability analysis was performed in a region of the parameter space where Rossiter and centrifugal modes are unstable, with the Rossiter modes substantially more unstable. Next, DNS was carried out investigating the interaction of these modes. Without the centrifugal modes the non-linear regime of the Rossiter modes has sharp spectral peaks that diverge substantially from Linear Stability Theory (LST) predictions and approach empirical predictions of Rossiter modes. In the presence of centrifugal modes, the Rossiter modes are much more broad band in spectra, but frequency and other aspects are substantially closer to LST predictions.

INTRODUCTION

Open cavities represent a canonical flow that has been extensively studied. However, the parameter space is vast and there remains several areas that require investigation. Two well-known modes of open cavity flows are the Rossiter modes and the centrifugal modes. The Rossiter mode is predominantly 2D [1], while the centrifugal mode is essentially 3D [2, 3]. These modes can co-exist, but their mutual interaction has not been studied in great detail. Here we investigate a scenario where the Rossiter modes are much more unstable and have much higher frequencies than centrifugal ones. This is a typical scenario, in particular at higher Mach [4, 5]. We carried out LST of the bi-global type to investigate the modes and performed nonlinear DNS to study their interaction. Despite the frequency and amplitude difference the centrifugal mode had a remarkable effect on the Rossiter mode dynamics.

METHODS

The study used two different tools, both developed in our research group. A DNS was used for the flow simulation, which integrates the compressible Navier-Stokes equations using a stretched Cartesian grid; a spectral-like finite differences scheme; a 4th order Runge Kutta method for time marching; and buffer-zones at the open boundaries. The LST was performed by a Jacobian-free time-stepping algorithm. More details of both methods can be found in [6].

RESULTS

The flow parameters in this study are: cavity aspect ratio $L/D = 2$, Reynolds number $Re_D = 1000$, Mach number $Ma = 0.5$, incoming boundary layer thickness $D/\theta_C = 100$. L and D are the cavity length and depth and θ_C is the boundary layer momentum thickness at the cavity leading edge.

Figure 1 exhibits the results from the linear stability analysis. The left-hand side plots show the leading (most unstable) flow modes as a function of the span-wise wave-number β, the top graph shows the real part of the eigenvalue, which corresponds to the temporal growth; and the bottom graph shows the imaginary part, which gives to the mode frequency.

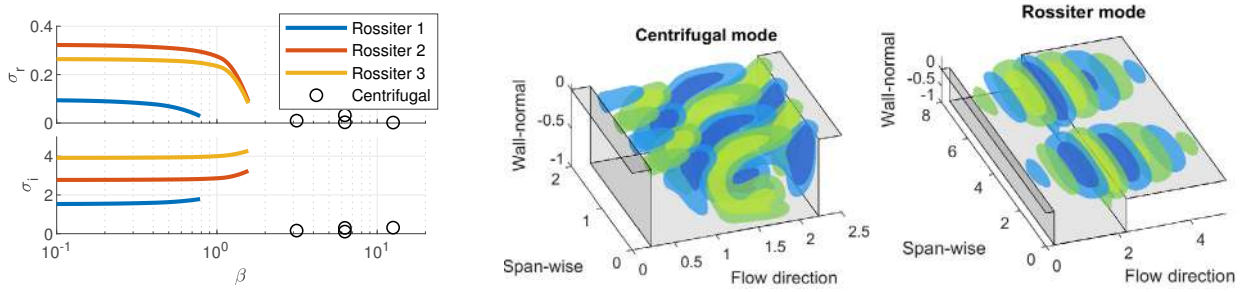

Figure 1: Linear stability results. (left) Eigenmodes as a function of β. (centre) iso-surfaces of stream-wise velocity for a centrifugal mode. (right) iso-surfaces of stream-wise velocity for a Rossiter mode

Rossiter modes are most unstable when $\beta = 0$, that is, 2D, but may also be unstable for long span-wise wavelengths, i.e. low β. Centrifugal modes are essentially 3D. In our set of parameters, they are much less unstable than the Rossiter modes, and are unstable only at values of β that are higher than the highest β for an unstable Rossiter mode. The right-hand side plots of Fig. 1 show iso-surfaces of stream-wise velocity for a centrifugal and a 3D-modulated Rossiter modes.

*Corresponding author. E-mail: marlon.mathias@usp.br.

Figure 2 (top) shows the time series of pressure at the cavity trailing edge obtained from DNS for different span-wise domains and grid refinements. Figure 2 (bottom) shows their spectra as a function of time, which was obtained by using a moving time window. In the figure, the resulting frequencies are compared with those predicted by the LST and by a Rossiter mode empirical equation [4]. LST and empirical frequency predictions are close, but distinguishable. From Fig. 1, LST predicts modes R1 to R3 to be unstable, with mode R2 as the most unstable. Accordingly, the 2D simulation shows that initially mode R2 is the dominant and exhibits the frequency predicted by LST. In the colour logarithmic scale used, when mode R2 is discernible, harmonics are also seen. Soon after, mode R2 frequency approaches the Rossiter mode empirical predictions, which are slightly lower than LST predictions. In the third and final stage, mode R1 becomes the dominant with a frequency very close the empirical prediction.

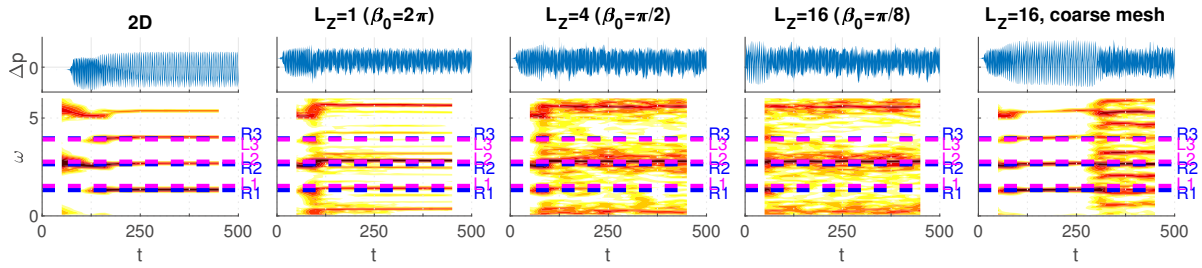

Figure 2: (top) Time series of pressure at the cavity trailing edge for various span-wise domain lengths. (bottom) Spectra as a function of time, logarithmic colour scale.

The next simulation is 3D, with a span-wise domain ($L_Z = 1$) that is large enough for one centrifugal mode, but not enough for unstable 3D Rossiter modes. In the early stages, the 3D simulation somewhat resembles the 2D one. However, they differ severely in later stages, where mode R2 remains the dominant at a frequency close to LST predictions. The 3D simulation produces a flow in which the Rossiter modes are closer to the linear theory predictions. Also consistent with LST, a centrifugal mode is observed in the spectrum, at low frequency and small amplitude.

The two largest span-wise domains tested admit many centrifugal modes and also unstable 3D Rossiter modes. Their results are essentially statistically independent on the span-wise domain. Mode R2 is dominant, the centrifugal modes are also observed, while modes R1 and R3 are not observed. The spectral peaks become much broader, but the frequency of the R2 mode is closer to the LST predictions than to the empirical ones. Once more, the 3D simulation results are fairly consistent with LST, including the frequency of the Rossiter mode and the fact that the observed mode is the most unstable according to LST. It is also observed that the spectra are much broader than in 2D or short 3D simulation.

For the last simulation the span-wise refinement was reduced such that it could not capture the centrifugal mode. The flow dynamics remain very similar to 2D simulations for a long initial period. This suggests that it is the centrifugal mode that leads to the dominance of the R2 mode. At the later stages of this simulation the results are more irregular, but we believe this is an artifact of the poor resolution.

FINAL REMARKS

Rossiter modes are essentially 2D, but 3D effects must not be disregarded. Despite being much less unstable than the Rossiter modes in our paremeter set, the centrifugal modes have a very substantial impact on the dynamics of the Rossiter modes. The final stage of the 3D non-linear simulation with sufficiently long span-wise domains are consistent with LST predictions in that the most unstable mode as predicted by LST (R2 mode) is the dominant and its frequency is closer to the LST predictions than to empirical ones. However this result is crucially dependent on the presence of centrifugal modes. In essence, it seems that LST provides good prediction, but not for the reasons expected. Tests we made for $D/\theta = 35$, other conditions remaining the same, showed a similar pattern. However, it is yet unclear whether this is a general result or a coincidence restricted to this parameter range. The final paper and presentation will include extended results and more in depth analysis.

SOUND GENERATION IN A HOLE-TONE CONFIGURATION

Javier Sierra Ausin*[1,2], David Fabre[1], Vincenzo Citro[2], and Flavio Giannetti[2]

Summary The purpose of this work is to investigate the flow dynamics in a "hole-tone" configuration, namely the flow through two successive apertures (Fig. 1), a configuration which is known to lead to powerful tonal noise at moderately low Reynolds numbers. Thresholds of instability are determined using fully compressible linear global stability analysis. The resulting nonlinear saturated state is then characterized through a weakly nonlinear asymptotic method starting from compressible equations. Results of these global approaches are then compared to direct numerical simulations using an augmented incompressible model, which consists of considering the flow as locally incompressible (under the hypothesis of acoustic compactness), and introducing compressibility into the boundary conditions to model the impedance of a resonant cavity and of a monopolar radiation in the downstream domain. The augmented model confirms the existence of a bistable range of Re leading to two possible fundamental frequency, in accordance with observations from a previous an experimental campaign.

INTRODUCTION

The problem of a flow passing through two circular holes in a plate (known as the hole-tone configuration) is encountered in many practical applications, including human whistling, wind instruments, whistling of a tea kettle [1] or birdcalls (devices used by hunters to imitate bird singing) [2, 3].

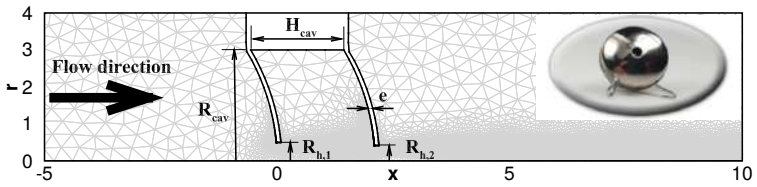

Figure 1: Sketch of the hole-tone configuration, frame of reference and definition of geometrical parameters. An example of computational mesh is also reported in light gray. An actual birdcall is depicted in the upper right corner. e denotes the thickness of the cavity wall, radius of holes $R_{h,i}, i = 1, 2$, radius and length of the cavity are denoted by R_{cav} and H_{cav} respectively. Values of geometrical parameters can be found in Longordardi et al. [3].

The physical mechanism responsible for whistling made the object of debates among acousticians the second half of the 19th century. [4, 5, 6]. Early attempts approached the problem mainly from a purely acoustic point of view, the influence of the mean flow was neglected. Another possibility are the so called lumped models, where the hydrodynamical component of the system is modeled by a system of a limited number of degrees of freedom. Recently, the problem of sound generation has been tackled with linearized Navier Stokes equations. The instability mechanism at the threshold has been analyzed on the one-hole [7, 8] and the two-hole configuration [2] using incompressible Navier Stokes equations where the compacity of acoustic sources is assumed and with compressible [3] LNSE. These efforts allowed to identify the difficulties associated to boundary conditions which has been addressed in [9, 10]. An experimental campaign on the hole-tone configuration carried out by [11] has shown the appearance of complex dynamics such as quasi-periodic or chaotic behaviours for low to moderate Reynolds numbers. Theoretical and numerical determinations should provide some answers to the reason behind dynamics and the underlying physical mechanism.

PRELIMINARY RESULTS

Most of sound generating devices are in essence self-sustained oscillators composed of two parts: An *acoustic system* which acts as a resonator and a *hydrodynamic system* which can be a shear flow. The purpose of this work consists in the analysis of dynamics of the double hole tone configuration with an special emphasis on the hydrodynamic part. Four approaches are carried out. The first is a stability analysis based on *linearised compressible Navier Stokes equations* (LNSE) [3] which allow the determination of the Threshold Reynolds numbers. The second is *weakly nonlinear asymptotic* method based on multiple-scale approach[12, 13] allowing to characterize the saturated state for values of Re slightly above the threshold. The third is a direct numerical simulation (DNS) of the full compressible equations. This strategy leads to strong constraints on the time step and domain dimensions in the range $M \ll 0.05$, making a parametric study costly. To overcome this limitation, a fourth approach is proposed, namely a DNS based on an *augmented incompressible*

Dashed lines corresponds to the frequency determined via compressible linearised Navier Stokes equations, solid lines to compressible weakly nonlinear stability, crosses (×) to unstable frequencies and circles (○) to stable frequencies determined by augmented model

model [2, 3] assuming the flow as locally incompressible and incorporating the effect of compressibility as impedance-like boundary conditions at the inlet, outlet, and bottom of the cavity. Underlying assumptions of the methodology are compactness and monopolar radiation, and these assumptions have been verified in experiments [11]. The inlet and the cavity are modelled as a Helmhotz resonator whereas at the outlet a radiation boundary condition is imposed.

$$\int_{\Gamma_i} \Big[\frac{\partial p'}{\partial t} + \frac{S_i}{V_i M^2}\mathbf{u}' \cdot \mathbf{n}\Big] dS = 0, \quad (i = \text{inlet or cavity}); \qquad \int_{\Gamma_{out}} \Big[\frac{\partial^2 \mathbf{u}' \cdot \mathbf{n}}{\partial t^2} + \frac{8}{M S_{out}} p'\Big] dS = 0 \tag{1}$$

This fourth approach has previously been validated in the linear regime [3]. In the present work, validation will be done by comparison with fully compressible results (linear, weakly nonlinear and fully nonlinear). Once validated, the augmented incompressible model will be used for parametric exploration of the parametric space. Particular attention will be paid to ranges of parameters where experiments show rich nonlinear dynamics, including bistable behavior (with hysteretic transition between two modes with different frequencies), quasi-periodic, and chaotic regimes. Preliminary results have already confirmed the existence of a range of Reynolds number Re of bistability, characterized by the existence of two stable limit cycles with different frequencies. The properties of these states are in good accordance with linear and weakly nonlinear approaches close to the thresholds, but deviations are observed for larger values of Re.

Furthermore, compressible linear and weakly non linear stability allow to characterize the instability mechanism using structural sensitivity tools. The results indicate a purely hydrodynamic feedback mechanism originating from a "wavemaker" region localized along the shear layer in the region between the two holes, see Fig. 2.

ONSET OF SUSTAINED TURBULENCE IN CHANNEL FLOW AND PLANE COUETTE FLOW

Masaki Shimizu*[1] and Paul Manneville[2]
[1]Graduate School of Engineering Science, Osaka University, Toyonaka, Japan
[2]Hydrodynamics Laboratory, CNRS-UMR 7646, Ecole Polytechnique, Palaiseau, France

Summary We investigate the onset of turbulence in channel flow (CF) and in plane Couette flow (PCF). The spatiotemporally fluctuating turbulent patterns in both systems experience a continuous transition. The critical values for sustained turbulence are $\mathrm{Re_g} \simeq 712$ in CF and $\mathrm{Re_g} \simeq 337$ in PCF. In the vicinity of $\mathrm{Re_g}$, the two systems obey directed-percolation (DP) universality however with different spatial dimensionality, 1D for CF and 2D for PCF. This comes from the symmetry difference in the minimal turbulent elements of the two systems. In CF they correspond to downstream active heads, which move obliquely at a constant speed along a chosen direction, yielding an asymmetrical, effectively 1D, turbulent pattern. On the other hand, the minimal elements in PCF, the spots, have the potential to extend in either span-wise direction and form a symmetrical, effectively 2D, pattern.

INTRODUCTION

In several kinds of wall-bounded flows, the transition to turbulence has recently been shown to be continuous and obey directed-percolation (DP) universality in the sense of critical phenomena [1–5]. In channel flow (CF) and Waleffe flow (WF), which are flows between two-parallel planes, the transition to turbulence was reported to belong to the spatially two-dimensional DP (2D-DP) universality class [1, 3]. In the case of CF, several studies have however experimentally and/or numerically proven the existence of sustained turbulence significantly below the DP critical point [6–9]. We scrutinized this inconsistency in [5], gave evidence of a symmetry-breaking bifurcation of the turbulence pattern, and showed that the transition does not follow 2D-DP below the bifurcation point. On the other hand, a discontinuous transition around $\mathrm{Re_g} \sim 325$ was observed in plane Couette flow (PCF) [11, 12]. On the basis of their study of WF, Chantry *et al.* [3] attributed this discontinuous character to size effects and advocated a 2D-DP continuous transition at $\mathrm{Re_g}$ in PCF, but in a very narrow range of Reynolds number and in a (very) long time limit, $t \sim O(10^5)$. In the following we summarize our numerical findings on the characteristics of the transition to turbulence around $\mathrm{Re_g}$ in CF and PCF.

CHANNEL FLOW

In transitional CF various turbulent patterns are observed depending on the Reynolds number. Figure 1 displays two kinds of pattern below and above $\mathrm{Re_2} \simeq 1010$. For $\mathrm{Re} < \mathrm{Re_2}$ all localized turbulent bands (LTBs) point to the same direction. On the other hand, for $\mathrm{Re} > \mathrm{Re_2}$ LTBs of both directions exist and the turbulent pattern is statistically symmetrical. This change is associated with a pitchfork bifurcation controlled by the 'transversal splitting' rate [5]. Above $\mathrm{Re_2}$ turbulence expansion becomes intrinsically two-dimensional and obeys 2D-DP (Fig.2 left). On the other hand, turbulence spread below $\mathrm{Re_2}$ follows 1D-DP (Fig.2 right), because the LTB density only fluctuates in the direction perpendicular to their main orientation, under the control of the 'longitudinal splitting' rate.

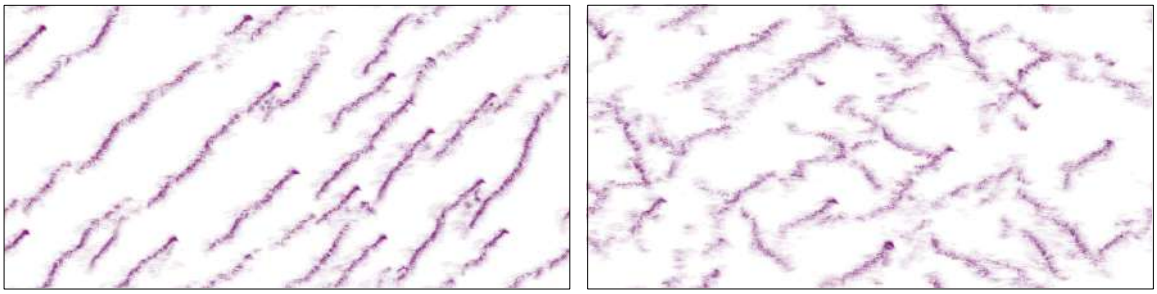

Figure 1: Symmetry-broken pattern at Re=850 (left) and symmetry-restored pattern at Re=1050 (right). The flow direction is from left to right. The domain size is (1000,2,500).

PLANE COUETTE FLOW

In PCF's transitional range, two kind of turbulent patterns are found: the tight-banded pattern [12, 13], Fig. 3 (right), and the spatiotemporally fluctuating pattern, Fig. 3 (left). The band pattern is only obtained upon quasi-static decrease of Re. Both types of pattern seem to coexist around $\mathrm{Re_g}$ at least over our observation time $O(10^5)$. Whereas the band pattern is seen to decay abruptly, the fluctuating pattern goes through a continuous, seemingly 2D-DP, transition at $\mathrm{Re_g} \simeq 337$ though the statistics over sampling durations $O(10^5)$ is not yet good enough (Figure 4).

*Corresponding author. E-mail: shimizu@me.es.osaka-u.ac.jp

Unlike in CF but like in WF, the fluctuating pattern in PCF remains statistically symmetrical in the vicinity of $\mathrm{Re_g}$ (Fig. 3, left). This is because turbulent spots keep a tail-head symmetry that leaves them the potential to stretch into either oblique direction equally [12].

CONCLUSIONS

Our numerical simulations showed that the onset of fluctuating turbulent patterns is continuous in CF and PCF although in PCF the band pattern stably persists for long durations around $\mathrm{Re_g}$. The transition in CF starts with an asymmetrical one-sided flow pattern while following 1D-DP. By contrast, in PCF the fluctuating turbulent pattern is always symmetrical and the transition follows 2D-DP. This difference comes from the characteristics of minimal elements that maintain turbulence. The minimal element in CF corresponds to the downstream active head (DAH) [10], which is necessary to maintain an LTB and shows relative periodic motion while traveling to one side of the span-wise direction. The collective motion of DAHs without frequent transversal splittings results in the one-sided flow pattern illustrated in Fig. 1 (left) [5]. On the other hand, the turbulent spot in PCF shows chaotic motion, keeps the symmetry with respect to stream-wise and span-wise directions, and leads the symmetrical pattern (Figure 3 left). This symmetry difference is at the origin of the observed universality-dimension discrepancy between these two flows.

TOWARDS GLOBAL PERTURBATION ANALYSIS OF LIQUID/GAS FLOWS

Simon Schmidt*[1], Lutz Lesshafft[2], Outi Tammisola[3], and Kilian Oberleithner[1]
[1] Laboratory for Flow Instability and Dynamics, Technische Universität Berlin, 10623 Berlin, Germany
[2] LadHyX, CNRS/Ecole Polytechnique/Institut Polytechnique de Paris, 91128 Palaiseau, France
[3] FLOW, Engineering Mechanics, KTH Royal Institute of Technology, SE-100 44 Stockholm, Sweden

Summary We develop a framework to compute linear global modes for interfacial liquid/gas flows by linearising a state-of-the-art nonlinear flow solver. Eigenpairs of the the underlying linearised Navier-Stokes operator are extracted by time-stepping of the linearised solver. The methodology is applied to compute global modes of a planar two-phase wake. The linear model is able to accurately predict the onset of global instability and the frequencies of the leading eigenvalues compare excellently to the observed frequencies of the nonlinear flow. The flexibility of the framework further allows straightforward extensions to more complex flow scenarios.

INTRODUCTION

Shear flows of two immiscible fluids can exhibit distinctively different and potentially more complex stability characteristics compared with their single-phase equivalents. This can be due to the presence of not only a momentum gradient of the adjacent fluids but also a density and viscosity gradient. Furthermore, the presence of a surface tension force can influence the stability of the flow.

While surface tension usually acts stabilizing in plane flow configurations, a study by [2] found that for certain configurations, surface tension destabilises a plane wake or jet flow which is stable in its absence. These somewhat surprising results are partially confirmed in a subsequent study by [1] who found an unstable global mode for some of the configurations of the former study. However, for other configurations they found no global instability, thereby raising doubts concerning the validity of the surface tension-induced destabilisation found by [2]. Assessment of the stability of such flows is usually done through the framework of linear stability analysis, which seeks solutions of the Navier-Stokes operator, linearised around a steady base flow. In a local analysis, the underlying base flow is assumed to be parallel and therefore only dependent on one spatial coordinate, whereas for a global analysis it might be inhomogeneous in all spatial coordinates.

Although global analysis has become a standard tool for analysing single-phase flows, its application to multi-phase flow has not found widespread attention, yet. The work of [2] is one of the very few reported applications of global stability for liquid/gas flows. In their approach, the linearised operator is constructed explicitly. Here, we explore a different approach, by developing a framework which allows for computation of global modes by means of time-stepping of a linearised DNS solver, capable of computing two-phase flows. For our study, we choose the open-source code BASILISK [3], which offers an adaptive quad/octree spatial discretisation and a geometrical Volume-Of-Fluid (VOF) interface representation, combined with a well-balanced surface tension scheme. We perform nonlinear and linear computations to shed more light on the surface tension induced instability investigated by [2].

LINEARISATION PROCEDURE FOR INTERFACIAL FLOWS

We decompose the flow into a basic state and an infinitesimal perturbation $\epsilon \ll 1$, which gives $\mathbf{u} = \mathbf{U} + \epsilon\mathbf{u}'$ and $p = P + \epsilon p'$ for the velocity and pressure respectively. A continuous level-set function ϕ can be derived from the discontinuous volume fraction c and is perturbed as $\phi = \Phi + \epsilon\phi'$. Therewith associated are a perturbed curvature $\kappa = K + \epsilon\kappa'$ and a normal vector $\mathbf{n} = \mathbf{N} + \epsilon\mathbf{n}'$. Inserting this decomposition into the nonlinear Navier-Stokes equations, and the transport equation of the level-set function, while retaining only leading-order terms in ϵ, we arrive at

$$\begin{aligned}[\tilde{\rho} + H_\epsilon(\Phi)(1-\tilde{\rho})](\partial_t\mathbf{u}' + \mathbf{u}'\cdot\nabla\mathbf{U} + \mathbf{U}\cdot\nabla\mathbf{u}') + 2[\delta_\epsilon(\Phi)\phi'(1-\tilde{\rho})](\mathbf{U}\cdot\nabla\mathbf{U}) \\ = -\nabla p' + \frac{1}{Re}\nabla\cdot\left[(\tilde{\mu} + H_\epsilon(\Phi)(1-\tilde{\mu}))\left(\nabla\mathbf{u}' + \nabla^T\mathbf{u}'\right)\right] + \frac{1}{Re}\nabla\cdot\left[(\delta_\epsilon(\Phi)\phi'(1-\tilde{\mu})\left(\nabla\mathbf{U} + \nabla^T\mathbf{U}\right)\right] \\ + \frac{1}{We}\left[\kappa'\mathbf{N}\delta_\epsilon(\Phi) + K\mathbf{n}'\delta_\epsilon(\Phi) + K\mathbf{N}\phi'\partial_\Phi\delta_\epsilon(\Phi)\right], \quad (1a)\end{aligned}$$

$$\partial_t\phi' + \nabla\cdot(\Phi\mathbf{u}') + \nabla\cdot(\phi'\mathbf{U}) = 0, \quad (1b)$$

where $H_\epsilon(\Phi)$ is the Heaviside function and $\delta_\epsilon(\Phi)$ the Dirac Delta function, derived from the zero contour of Φ.

GLOBAL MODES OF A PLANAR TWO-PHASE WAKE

Nonlinear simulation

In the study of [2] no validation of the studied configurations is performed. Therefore, it remains to be shown whether the computed linear modes really are present in the nonlinear flow, and if so, whether their shapes and frequencies are accurately predicted by linear theory. We therefore present nonlinear results for selected wake-type configurations of their study. All flows are confined in a channel with $h = h_2/h_1 = 1$ where $h_1 = h_2 = 1$ are the heights of the respective fluid streams in the half-channel at the inlet, and subscripts 1,2 refer to the inner and outer fluid stream, respectively. The plug flow velocity ratio of both streams at the inlet is $\Lambda^{-1} = (U_1 + U_2)/(U_1 - U_2) = -1.4$. The density and viscosity ratios are $\rho_2/\rho_1 = 1$ and $\mu_2/\mu_1 = 1$. We fix $Re = \frac{\rho_2 U_2 h_2}{\mu_2} = 316$ and compute results for Weber numbers $We = \frac{\rho_2 U_2^2 h_2}{\sigma}$, ranging from $We = 16.\bar{6}$ to $We = 3.\bar{3}$. Indeed, the nonlinear simulations show an unsteady flow in this regime as is seen in figures 1b, 1c. In particular, the flow at $We = 12.5$ oscillates at a single frequency while for $We = 10$ two frequencies are present which are destabilised solely through surface tension.

Linear Stability Analysis

For the linear stability analysis, a steady base flow is computed for $We = \infty$, as shown in figure 1a. The computation of linear global modes is done by constructing a low-dimensional subspace representation of the linearised Navier-Stokes operator using an Arnoldi procedure. The Krylov vectors spanning the subspace are obtained by time-stepping of the linearised solver. Following the nonlinear analysis, we compute linear global modes for the same range of Weber numbers. The predicted frequencies in all cases are close to those computed for the nonlinear flow and compare well to the results of [2] (figure 1d). The growth rates are consistent with the onset of growth in the nonlinear computations.

CONCLUSIONS

We investigated the global linear stability of a plane two-phase wake and compared the results to nonlinear simulations. The linear analysis is able to accurately capture the bifurcation point of the flow and the global mode frequencies are in excellent agreement with the predicted frequencies of the nonlinear flow. To the authors knowledge, the present study is among the first applications of global linear stability analysis using the full set of linearised Navier-Stokes equations to interfacial flows. The methodology of time-stepping of a linearised DNS-solver further offers the flexibility for application to more complex and potentially three-dimensional flows without much difficulty.

ABSOLUTE AND GLOBAL INSTABILITY INDUCED BY THREE-DIMENSIONALITY IN LAMINAR SEPARATION BUBBLES

Daniel Rodríguez*[1], Elmer M. Gennaro[2], and Leandro F. Souza[3]
[1]ETSIAE-UPM (School of Aeronautics)-Universidad Politénica de Madrid,Spain.
[2]São Paulo State University (UNESP),Campus São João da Boa Vista SP,Brazil.
[3]Institute of Mathematical and Computer Sciences,University of São Paulo,São Carlos-SP, Brazil.

Summary Laminar separation bubbles (LSBs) are dominated by inflectional instability of disturbance waves. Under certain conditions, this instability can become of absolute nature, leading to self-excited flow oscillations and vortex shedding. Analyses of 1D velocity profiles show that a peak reversed flow $> 15\%$ is required for the onset of absolute instability. This threshold is larger than the reversed flow reported for most LSBs, and that the $\sim 7-8\%$ required for self-sustained 3D instability. The absolute/convective instability of separated flows is revisited here. Spanwise distortion of separated shear layers is shown to have a strong destabilizing effect, leading to absolute instability for LSBs with mean reversed flow much lower than 10%. This absolute instability gives rise to a 3D global oscillator, that triggers laminar-turbulent transition without requiring external disturbances.

INTRODUCTION

Laminar flow separation is an usual phenomenon on aerodynamic surfaces that takes place when strong enough adverse-pressure-gradients and moderate Reynolds numbers are present. Flow instability and laminar-turbulent transition dominate the evolution and dynamics of the separated flow and the formation of a laminar separation bubble (LSB). Failure of the detached flow to reattach within a short distance, forming what is known as a long LSB, implies important detrimental modifications of the aerodynamic performance. This process, named bursting, and the search for a criterion for its prediction have been an active topic of research since Gaster [1]. The analysis of the flow instabilities occurring in separated flow has successfully guided many research efforts. LSBs are dominated by convective amplification of instability waves by the inflectional mean velocity profiles [2, 3]. Intriguingly, a similar scenario is recovered in direct numerical simulations in which the convective instability is neglected by prescribing undisturbed inlet conditions (e.g. [4, 5]). Pauley *et al.* [4] postulated that the onset of spontaneous vortex shedding, related to the shift from convective to absolute nature of the inflectional instability, could be used as an indication of bursting. Using the peak reversed flow $u_{rev} = -u_{min}/U_\infty$ to quantify the intensity of the recirculation region, different works (e.g. [6]) attempted to determine a threshold for the onset of absolute instability in velocity profiles representative of separated boundary layers; a general agreement exists that $u_{rev} \geq 15\%$ is required. However, most of the works in the literature report peak reversed flows substantially lower than 10%. The prominent amplifier behavior manifested by LSBs does not fully explain the very rich physics observed in experiments and numerical simulations, suggesting that other instability mechanisms must be at play. Indeed, instability analyses considering global eigenmodes have identified at least two self-excited mechanisms in nominally 2D LSBs: a 3D instability of centrifugal type and an oscillator-type instability arising from regions of local absolute instability. Rodríguez *et al.* [8] showed that the three-dimensional instability becomes active for $u_{rev} \sim 7-8\%$ and thus should play a role in the dynamics of relatively weak separation bubbles: the flowfields would develop a spanwise modulation and become fully three-dimensional, even in the absence of external excitations [7].

This contribution revisits the absolute/convective inflectional instability of separated shear layers. First, a new criterion for the existence of absolute instability in this kind of flows is proposed, that depends on the location of the inflection point relative to the separation streamline. Second, fully three-dimensional, spanwise-modulated LSBs arising from the self-excited centrifugal instability are analyzed using (i) an extension of the classical WKBJ analysis to cross-stream planes (as opposed to 1D velocity profiles) and (ii) direct numerical simulations.

METHODOLOGY

The stability of three-dimensional (spanwise-periodic) LSB flows of the form $\bar{\mathbf{q}}(x, y, z)$ is studied, where x, y and z are the streamwise, wall-normal and spanwise directions. Assuming that the base flow properties evolve along the streamwise direction much slower than on the cross-stream plane, separation of scales allows a local analysis of 2D X-planes, where $X = \gamma x$ is the slow variable and $\gamma \ll 1$. At each X-plane, disturbances behave locally as $\hat{\mathbf{q}}(y, z; X)\exp[\mathrm{i}(\alpha(X)x - \omega t)]$. A partial-derivative-based eigenmode problem is obtained by substitution of the former modal disturbance form in the linearized Navier-Stokes equations. Successive solutions of the eigenvalue problem determine the dispersion relation $D(\alpha, \omega, X) = 0$, with α and ω being complex quantities, that describes the local behavior of disturbance waves.

The absolute/convective analysis proceeds then in the classical manner [9]. The character of the disturbances at each X is determined by the complex frequency ω_0 at the zero-group-velocity condition $0 = c_g = \partial\omega/\partial\alpha$. If the growth rate (imaginary part, $\omega_{0,i}$) is positive, then a disturbance introduce at X will grow in time at the location of introduction, and the base flow is said to be absolutely convective at X. If $\omega_{0,i} < 0$, the flow is either stable or convectively unstable at X. The existence of absolute instability over a sufficiently large spatial region can result in self-excited, synchronized

oscillations over all X planes, i.e. a global oscillator. Such a global oscillator is analyzed by further proceeding with the WKBJ expansion and applying the saddle-point condition $\partial\omega/\partial X = 0$.

Direct numerical simulations based on the non-linear Navier-Stokes equations in disturbance form are also solved in this work to (i) compute the three-dimensional LSB flows subject of analysis, (ii) validate the results of the WKBJ analysis, and (iii) investigate the non-linear regimes and laminar-turbulent transition subsequent to the appearance of absolute instabilities of the 3D flows.

SUMMARY OF RESULTS AND CONCLUSIONS

A geometrical criterion for absolute inflectional instability: As opposed to previous research in which a quantitative threshold for the onset of absolute instability was sought, a geometrical criterion based on the local relative location of the inflection point with respect to the separation streamline is proposed. For analytic 1D velocity profiles, it is found that the inflection point must be within the recirculation region for absolute instability. While this is formally a necessary condition, it is found to approximate reasonably well the critical curve for $\omega_{0,i}$ for a broad range of parameters [10].

Absolute instability resulting from spanwise distortion of LSBs: DNS with selective frequency damping was used to compute the steady, 3D LSB flows resulting from the non-linear saturation of the primary centrifugal instability. The spanwise modulation of the reversed flow region increases locally the peak reversed flow at some locations, attaining values above $u_{rev} = 15\%$. The separation streamsurface is distorted, being displaced from the wall at the same locations, while the inflection point moves towards the wall, satisfying the geometrical criterion stated above (figure 1(a)). These spanwise modifications enable the appearance of absolutely unstable inflectional waves, at conditions under which either the initial 2D LSB or the spanwise average of the 3D distorted LSB are only convectively unstable (figure 1(b)). This finding is also of application to LSBs that become 3D due to mechanisms different from the centrifugal instability, e.g. by streaks or Klebanoff modes introduced by free-stream turbulence [5].

A 3D global oscillator and transition to turbulence: Following from the absolute inflectional instability, a self-excited global oscillator appears whose properties are well predicted by the WKBJ analysis (figure 1(c)) [11]. DNS is used to study the subsequent non-linear evolution, showing the formation of vortex loops akin to those observed by Watmuff [2], and transition to turbulent regime. In this scenario, laminar-turbulent transition in separation bubbles is shown to be possible in the total absence of external disturbances.

EFFECTS OF IMPINGING SOUND WAVES ON LINEAR AND NONLINEAR INSTABILITY OF SUPERSONIC BOUNDARY LAYERS

Fufeng Qin*[1] and Xuesong Wu[1]
[1]Department of Mathematics, Imperial College London, London, UK

Summary This paper investigates linear and nonlinear evolution of radiating modes in supersonic boundary layers under the influence of impinging sound waves. It is found that the ensuing boundary-layer response is extraordinarily large for a subset of the parameters, the sound frequency ω_s and the incident angle θ_s. Moreover, for a particular pair of (ω_s, θ_s), resonant over-reflection, corresponding to the reflection coefficient being infinite, occurs with the reflected wave taking on the character of the neutral radiating mode. The linear and nonlinear evolution of the radiating mode is significantly affected by the incident sound wave.

INTRODUCTION

Laminar-turbulent transition of super- and hyper-sonic boundary layers is crucial for the design of vehicles as the aerodynamic drag and thermal loading differ drastically depending on whether the flow state is laminar or turbulent. Linear stability theory [1] shows that a supersonic boundary layer may support two types of inviscid modes. One is the subsonic mode travelling relative to the mean flow at a phase velocity smaller than the sound speed. This mode is associated with the generalized inflection point of the mean flow, and its energy is trapped in the boundary layer. The other is the supersonic mode, which propagates faster than the sound relative to the mean flow. The corresponding eigenfunction is oscillatory while attenuating, or remaining bounded in the far field when the mode is neutral. This implies that a supersonic mode emits sound to the far field [2,3], and so it is also termed a radiating mode.

Wind tunnel experiments suggest that acoustic waves play a significant role in the onset of transition. These acoustic disturbances are emitted from the turbulent boundary layers on the nozzle and tunnel walls, and/or radiated due to the wall inhomogeneities (e.g. roughness). Transition positions in conventional and quiet tunnel are notably different [4]. There are at least two mechanisms by which an incident acoustic wave influences transition. One is receptivity and the other is the direct effects on the amplification of instability modes. In the present work, we focus on the latter.

THEORETICAL ANALYSIS

We consider a supersonic boundary layer that forms over a semi-infinite plate due to a uniform stream with velocity U_∞. The flow is described by the Cartesian coordinate system (x, y), where x and y are along and normal to the wall respectively, both non-dimensionalized by a characteristic boundary-layer thickness δ^*. We assume that the Mach number $M = O(1)$, and the Reynolds number $R = \rho_\infty U_\infty \delta^*/\mu_\infty \gg 1$. A sound wave impinges on the boundary layer at an angle of incidence, and is reflected by the latter so that the pressure in the far field takes the form

$$p_s \sim \epsilon_s p_I [\mathrm{e}^{\mathrm{i}\gamma_s y} + \mathscr{R}\mathrm{e}^{-\mathrm{i}\gamma_s y}]\mathrm{e}^{\mathrm{i}\alpha_s(x-c_s t)} + \text{c.c.}, \tag{1}$$

where ω_s is the frequency, α_s and γ_s are the streamwise and normal wavenumbers respectively of the incident wave. They satisfy the acoustic dispersion relation $c_s \equiv \omega_s/\alpha_s = 1 - \sqrt{1 + (\gamma_s/\alpha_s)^2}/M$. The intensity of the incident sound wave is denoted by p_I, while $\mathscr{R}$ is the reflection coefficient. We are interested in the slow acoustic wave with wavelength comparable with δ^* so that $\alpha_s = O(1)$.

Reflection and Resonant Over-reflection The boundary-layer response to an incident slow acoustic wave is described by a double-layered structure consisting of a main layer and a critical layer; the latter is a thin region surrounding the critical level y_c at which the base flow velocity $U(y)$ equals the phase speed, that is, $U(y_c) = c$. In the main layer, the pressure of the sound wave satisfies the compressible Rayleigh equation. The boundary-layer response may be measured by $p_s(y_c)$, the pressure at the critical level y_c. Both of $\mathscr{R}$ and $p_s(y_c)$ are determined by integrating the Rayleigh equation supplemented by a jump condition from the analysis of the critical layer. In general, $\mathscr{R}$ is finite. However, for a certain angle of incidence and frequency, $\mathscr{R}$ becomes infinite, which is referred to as resonant over-reflection.

Direct Effects on the Linear and Nonlinear Instability For the incident acoustic wave with α_s and ω_s satisfying the dispersion relation of a neutral radiating mode (with possible detuning), resonance takes place between them. The excitation and evolution of the radiating mode can be described by using the nonlinear critical-layer theory in the non-equilibrium regime [5]. Crucially, due to the resonance the sound wave with an $O(\epsilon_s)$ magnitude excites a radiating mode with a much larger $O(\epsilon_s R^{1/3})$ amplitude. The pressure and streamwise velocity in the main layer can be written as

$$(u, p) = \epsilon_s R^{1/3} A(\tilde{x})(\hat{u}_0, \hat{p}_0)\mathrm{e}^{\mathrm{i}\alpha(x-ct)} + \epsilon_s p_I [\mathrm{e}^{\mathrm{i}\gamma_s y} + \mathscr{R}\mathrm{e}^{-\mathrm{i}\gamma_s y}]\mathrm{e}^{\mathrm{i}\alpha_s(x-c_s t)} + \text{c.c.}, \tag{2}$$

where $\tilde{x} = R^{-1/3}x$ is the slow variable describing the evolution of the mode. The acoustic wavenumber α_s is allowed to differ from that of the neutral radiating mode by $O(R^{-1/3})$, that is, $\alpha_s = \alpha + R^{-1/3}\alpha_d$ with $\alpha_d = O(1)$ representing the

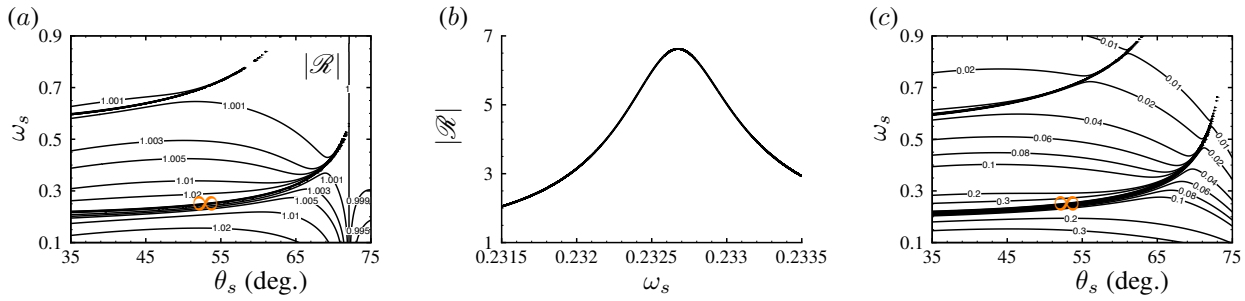

Figure 1: Reflection and absorption of incident sound waves: (a) contours of $|\mathscr{R}|$ in the $\theta_s - \omega_s$ plane with the incident angle θ_s defined by $\cos\theta_s = \alpha_s/\sqrt{\alpha_s^2+\gamma_s^2}$ and the resonant point is indicated with the symbol '∞'; (b) variation of $|\mathscr{R}|$ with ω_s at $\theta_s = 40°$; (c) the pressure $|p_s(y_c)|$ at the critical level.

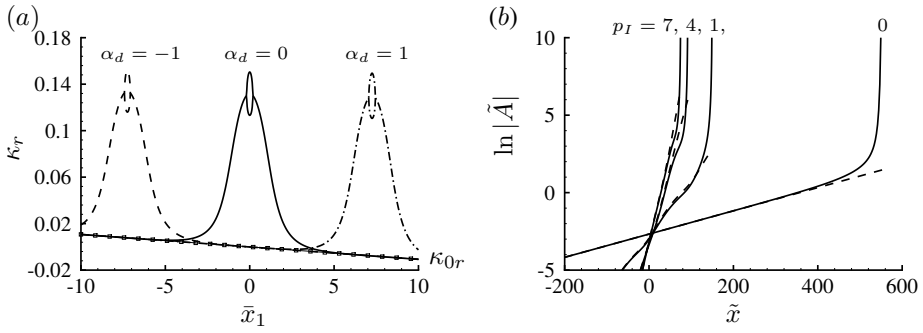

Figure 2: Effects of the incident sound on instability: (a) the modified growth rate in the linear stage when $p_I = 7$, with symbols representing the local growth rate κ_{0r} in the absence of incident sound; (b) nonlinear evolution of the mode in the presence of incident sound waves with different amplitude p_I. The dashed lines represent the corresponding linear solutions.

detuning. The excitation and evolution become nonlinear. After analysing the nonlinear interactions in the critical layer [5], we derive the evolution equation governing the amplitude function $A(\tilde{x})$,

$$A'(\tilde{x}) = \kappa_0 \tilde{A} + \mathscr{N} + \tilde{F} e^{i\alpha_d \tilde{x}}, \tag{3}$$

where κ_0, $\mathscr{N}$ and $\tilde{F}$ represent the unperturbed growth rate, nonlinear term and effective forcing respectively. The amplitude equation admits an equilibrium solution $A_e e^{i\alpha_d \tilde{x}}$, which represents the nonlinear response. The general solution for A can be written as $A_e e^{i\alpha_d \tilde{x}} + \tilde{A}$, with A_e entering the equation for $\tilde{A}$. When $\tilde{A} \ll 1$, $\tilde{A} \sim e^{\kappa \tilde{x}}$. The response A_e modifies κ_r, the growth rate in the linear stage. The nonlinear evolution equation is solved numerically.

RESULTS AND CONCLUSIONS

Results are given for a $M = 6$ boundary layer as a representative. Figure 1(a) depicts contours of $|\mathscr{R}|$ in the $\theta_s - \omega_s$ plane. The reflection coefficient is almost unity for most parameters, but it increases rapidly when the parameters approach the two strips, where very steep gradients are present. Figure 1(b) shows that the reflection coefficient soars to a large but finite value in a small range of the frequency for a fixed incident angle, suggesting the sensitivity of the response. Figure 1(c) shows that the strong critical-layer pressure appears as well in the two strips, indicating that the boundary layer acts as a sound board to magnify the incident acoustic waves. Figure 2(a) shows that the modified growth rate κ_r can be larger than the unperturbed growth rate by one order of magnitude. Figure 2(b) shows that increasing the intensity of sound waves promotes nonlinear amplification and advances the eventual blow-up. Further results will be presented at the Congress.

OPTIMAL OBLIQUE TRANSITION IN COUETTE FLOW

Jan O. Pralits*[1], Alessandro Bottaro[1], and Stefania Cherubini[2]
[1]Department of Civil, Chemical and Environmental Engineering, University of Genoa, Genoa, Italy
[2]Department of Mechanics, Mathematics and Management, Polytechnic University of Bari, Italy

Summary A weakly nonlinear approach is described to identify the couple of oblique waves capable to optimally excite transition to turbulence in plane Couette flow. Optimal oblique wave pairs of finite amplitude are found in a wavenumber range substantially different from their linear counterpart, and lead to rapid breakdown past a threshold value of the disturbance amplitude. Direct numerical simulations of the Navier-Stokes equations corroborate the weakly nonlinear results.

BACKGROUND

The breakdown of laminar shear flows is a central problem in fluid mechanics since the early experiments by Osborne Reynolds [1] in pipe flow. Despite the simplicity of unidirectional shear flows (plane Poiseuille and Hagen-Poiseuille, Couette), the physical processes by which environmental effects trigger transition to turbulence are still largely unexplained; this is partly due to the fact that such flows undergo transition at Reynolds numbers for which the linear hydrodynamic stability equations predict a stable behavior, and to the non-normal nature of the equations themselves. The transition phenomenon in such flows must thus be based on nonlinear mechanisms, possibly exploiting transient disturbance energy amplification. A recent approach to identify initial disturbances of finite amplitude capable to optimally initiate the transition process relies on nonlinear optimization theory [3, 2]. Such a theory is very powerful, the main drawback being that it is virtually impossible to explore the full parameter space, because of the computational cost of carrying out many direct simulations in the adjoint looping procedure until convergence of the chosen cost functional, for each set of parameters.

The need for an alternative optimization strategy is here coupled to the investigation of a physical mechanism believed to be central to turbulence breakdown in parallel shear flows: the growth and interaction of oblique waves. In a recent paper, Pralits et al. [4] have described a weakly nonlinear approach capable to identify disturbances growing optimally on top of a mean flow distorted by the Reynolds stresses produced by the disturbances themselves. The results of that study depart significantly from previous, linear, optimal perturbation analyses and point to very receptive regions of wavespace which can support a self-sustaining cycle, as demonstrated by companion numerical simulations. That analysis was based on the self-interaction of a single oblique wave. The goal which we set in the present paper is to extend that work to identify the couple of obliquely travelling waves capable to optimally trigger transition via mutual interactions.

The role and importance of oblique waves in the breakdown of shear flow is by-now well established. The original work on the issue dates to the early nineties, when Schmid & Henningson [5] described a transition scenario in plane Poiseuille flow which occurred on a much faster time scale than that based on the three-dimensional destabilization of initially two-dimensional streamwise travelling waves. Interestingly, this oblique transition scenario was sped up by an increase in initial amplitude and wave angle; waves with a spanwise wavenumber β larger than the streamwise one (α) experienced more rapid amplification and faster spreading of the spectral energy into modes with high streamwise wavenumbers. Here, the oblique transition scenario is optimized by focussing on the oblique waves and on the ensuing streamwise streak/vortex mode; the initial (algebraic) growth of the oblique waves in subcritical conditions is enhanced by the presence of a strong mean flow distortion, in a process which feeds onto itself.

WEAKLY NONLINEAR MODEL

The decomposition of the whole field starts by considering a pair of oblique waves of wavevector $(\alpha, \pm\beta)$ and amplitude ϵ. First-generation interactions yield two ϵ^2 terms: one represents the mean flow correction, denoted with subscript 00, and the second, which behaves like $e^{2i\beta z}$, represents a streamwise-independent streak/vortex. Other first-generation terms of wavevectors $(2\alpha, 0)$ and $(2\alpha, \pm 2\beta)$ are not included on account of the numerical results by Schmid & Henningson [5] which show that such terms are of smaller amplitude than the others. The decomposition reads:

$$\begin{bmatrix} U(y) \\ 0 \\ 0 \\ P(x) \end{bmatrix} + \epsilon \begin{bmatrix} u_{1\pm1}(y,t) \\ v_{1\pm1}(y,t) \\ w_{1\pm1}(y,t) \\ p_{1\pm1}(y,t) \end{bmatrix} e^{i(\alpha x \pm \beta z)} + \epsilon^2 \begin{bmatrix} u_{00}(y,t) \\ v_{00}(y,t) \\ w_{00}(y,t) \\ p_{00}(y,t) \end{bmatrix} + \epsilon^2 \begin{bmatrix} u_{02}(y,t) \\ v_{02}(y,t) \\ w_{02}(y,t) \\ p_{02}(y,t) \end{bmatrix} e^{2i\beta z} + c.c., \tag{1}$$

where *c.c.* indicates the complex conjugate of a complex vector. Replacing into the Navier-Stokes equations, collecting like-order terms we obtain a hierarchy of equations. In particular at leading order we have the equations for the base flow

*Corresponding author. E-mail: jan.pralits@unige.it

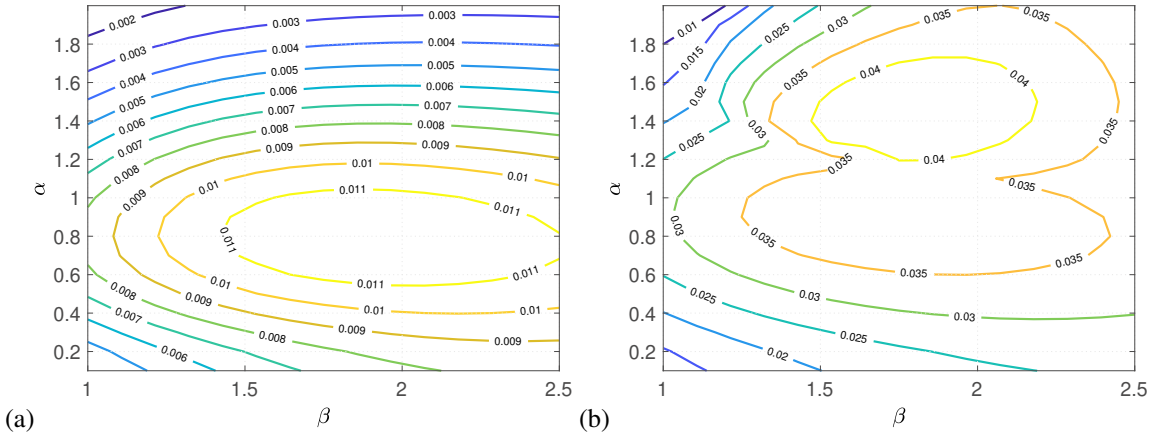

Figure 1: Contours for $e(T)$ at $Re = 400$ and $T = 10$, (a) $\epsilon = 0.01$, (b) $\epsilon = 0.02$.

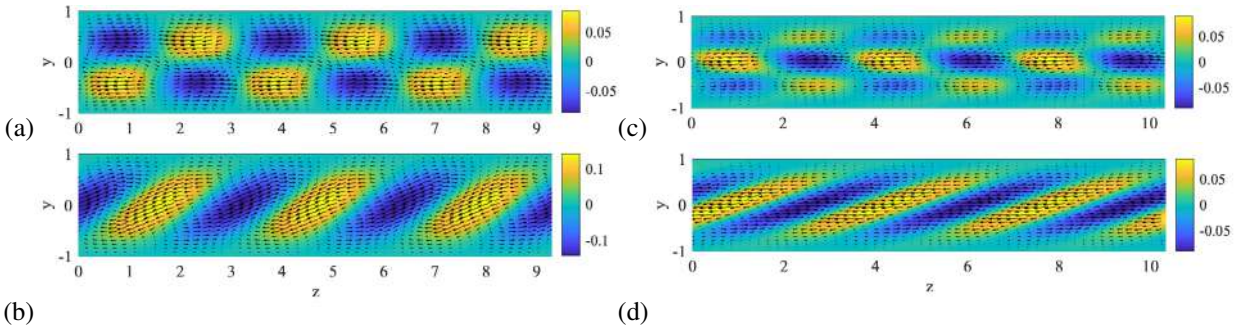

Figure 2: The shaded contours represent the positive and negative streamwise velocity components, whereas the vectors represent wall-normal and spanwise components of the oblique waves. (a) and (b) show solutions at $t = 0$ and $t = T$, respectively, for $\epsilon = 0.01$ and (α, β) from the energy peak in Figure 1(a). (c) and (d) show solutions at $t = 0$ and $t = T$, respectively, for $\epsilon = 0.02$ and (α, β) from the energy peak in Figure 1(b).

correction, forced by the Reynolds stress; at order ϵ we find homogeneous equations for modes $(\alpha, \pm\beta)$, and at order ϵ^2 equations for mode $(0, 2\beta)$ appear. Homogeneous boundary conditions are imposed for all solutions. The system of equations is solved in a direct-adjoint procedure with the objective to optimize the total energy of the unsteady perturbation $e(t) = e_{1,1}(t) + e_{1,-1}(t) + e_{0,2}(t)$ evaluated at a given target time $t = T$. The target time is chosen small on account of the rapidity of the phenomenon being investigated, and not to cover time periods over which further interactions (not accounted for by the weakly nonlinear model) might occur. Such interactions, giving rise to higher modes, are observed in companion direct numerical simulations.

RESULTS

Sample results are shown here for the case in which the Reynolds number (Re) is 400 and $T = 10$. As the amplitude ϵ is increased the maximum response energy $e(T)$ is found for oblique waves which are substantially different from the optimals of the linear case. This can be observed in Figure 1, where we report the response energy $e(T)$ in the (α, β) plane for two values of ϵ. As ϵ increases above a certain threshold, a second energy peak appears at a value of the streamwise wavenumber which is about twice that of the linear case. Optimal oblique waves and their response at the target time are presented in Figure 2, with ϵ, α and β taken from the energy peaks in Figure 1.

These oblique optimal perturbations lead to rapid breakdown past a well defined threshold value of the disturbance amplitude. Direct numerical simulations of the Navier-Stokes equations substantiate the weakly nonlinear results, providing thresholds for transition close to the predictions of the weakly nonlinear model.

STATIONARY AND TRAVELLING CROSSFLOW MODES IN LOW TURBULENCE ENVIRONMENTS

Marco Placidi*[1], Chetan Jagadeesh[2], and Chris J. Atkin[3]
[1]Department of Mechanical Engineering Sciences, University of Surrey, Guildford, UK

INTRODUCTION

Controlling the transition from laminar to turbulent flow represents one of the possible strategies to achieve the IATA 2050 emission targets due to climate change. At least in principle laminar flow can deliver a reduction in the skin friction drag, which minimises fuel burn per mile and pollutant emission. However, many processes affect the laminar/turbulent transition; these are not yet fully understood. Here, we investigate the role that the environmental disturbances (i.e the level of FreeStream Turbulence intensity (FST or Tu) have on the crossflow instability, which is typical of three-dimensional boundary layers.

Summarising the state of the art, Crouch et al. (2015) reported that consensus is that for low-turbulence environments ($Tu << 0.2\%U_\infty$) the transition process is dominated by roughness-induced stationary crossflow, while for high turbulence levels ($Tu > 0.2\%U_\infty$) the same process is dominated by the travelling disturbances. This behaviour is corroborated by a number of studies in the literature (Deyhle and Bippes, 1996; Bippes and Lerche, 1997; White et al., 2001; Dagenhart and Saric, 1999; Hunt, 2011; Eppink, 2014; Schrader et al., 2010; Downs and White, 2013). Is it also well-known that the flight environment is characterised by extremely low levels of turbulence intensity (Saric et al., 2011), however, due facility limitations most of the previous experimental work was not be conducted in such environments. Herewith, we aim to further explore the sensitivity of stationary and travelling modes to FST by exploiting the extremely low FST in our facility ($Tu = 0.01\%U_\infty$) and by enhancing it via the means of two turbulence screens, which produced $Tu = 0.33\%U_\infty$ and $Tu = 0.41\%U_\infty$, respectively.

EXPERIMENTAL FACILITY AND SETUP

Experiments were conducted in the closed-circuit 'Gaster low-turbulence wind tunnel' at City, University of London. The turbulence intensity, measured in the empty tunnel, was less than 0.006% of the free-stream velocity, U_∞, within the frequency range $4Hz - 4kHz$ at $U_\infty = 16\ ms^{-1}$. The tunnel test section measures $3\ ft \times 3\ ft \times 6\ ft$ and is equipped with a 3-axis traverse system.

To create favourable conditions for the development of crossflow instability, a combination of a $45°$ swept flat plate and equally swept displacement bodies were used. The plate measured $1535\ mm$ in chord. Further details on this experimental setup are reported in Placidi et al. (2017) and van Bokhorst (2018). To investigate the effect of FST two different turbulence grids were employed to increase the level of environmental disturbances.

Time-resolved velocity measurements are obtained via a *Dantec* Constant Temperature Anemometry, with a miniature boundary layer hot wire sensor. Mean velocity and root-mean-squared (rms) of the bandpass filtered velocity are denoted by capital letters and a prime, respectively. The freestream velocity was set to $16\ m/s$, with uncertainty determined following Hutchins et al. (2009), below 2%.

PRELIMINARY RESULTS AND DISCUSSION

Preliminarily, the quantity $rms[(U - \overline{U})/Ue]$ is evaluated to represent the stationary mode amplitudes as in Hunt (2011). These are shown in figure $1(a)$ to (d) for different chordwise locations from $x/c = 27\%$ to $x/c = 31\%$. At all chordwise locations, the amplitude of the primary stationary modes is affected by the level of FST. At $x/c = 27\%$ in figure $1(a)$, the amplitude of the stationary disturbance is halved by the presence of the grids, and its growth is much hindered compared to the clean low-turbulent case (see figures $1(a)$ to (d)). Bippes and Lerche (1997) and Downs and White (2013) pointed out that while the initial amplitude of the travelling mode is set by the FST, the initial amplitude of the stationary modes is due to the roughness. In the current case, however, the first measurement location was $x/c = 27\%$ and, therefore, it is not to be considered a true initial amplitude given the location of the neutral stability point. It is however clear from figure $1(d)$, that while in the low-FST case the stationary mode amplitude magnitude has reached $rms[(U - \overline{U})/Ue] \approx 0.25$, this has barely increased in the presence of the screens (i.e. in the enhanced Tu cases). This behaviour preliminary confirms that the environmental disturbance level does have an impact on the amplitude and growth of the standing waves, which are hindered for high Tu levels. We will discuss during the presentation how, by increasing the FST, the travelling crossflow modes begin dominating the transition process.

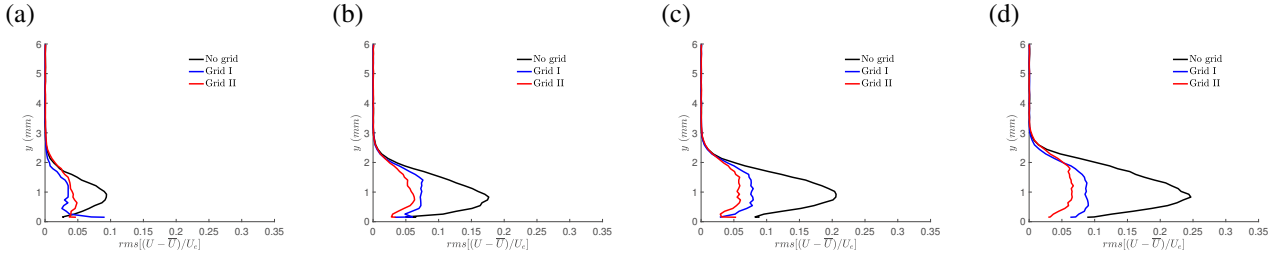

Figure 1: Amplitude of the primary stationary CF mode at (a) $x/c = 27\%$, (b) $x/c = 29\%$, (c) $x/c = 30\%$, and (d) $x/c = 31\%$ for the different Tu levels.

CONCLUSIONS

This study confirms that, at low FST (i.e. $Tu \leq 0.01\%$), the transition process is dominated by the stationary modes; whilst travelling modes are still present, their influence on the transition process is marginal. However, when the level of FST is enhanced ($Tu \geq 0.33\%$), the travelling modes acquire more importance and tend to dominate the laminar/turbulent transition process. This work adds to the sparse literature on low levels of freestream turbulence (i.e. $Tu < 0.01\%$).

STABILITY ANALYSIS OF PERFECTLY EXPANDED AND UNDER-EXPANDED SUPERSONIC JETS

Michael Karp and M. J. Philipp Hack*
Center for Turbulence Research, Stanford University, Stanford, USA

Summary The stability properties of supersonic perfectly and under-expanded jets are investigated by means of global linear stability theory. Weakly nonparallel jets are known to be convectively unstable in the absence of the nozzle. Our focus is on assessment of the effects of the nozzle and shock cells on the instability mechanism. It is found that the explicit representation of the nozzle within the computational domain gives rise to absolute instability owing to a coupling between the downstream-propagating Kelvin-Helmholtz mode and the upstream-traveling acoustic wave, which occurs in the vicinity of the nozzle lip. The presence of shock cells in under-expanded jets has a stabilizing effect on the absolute instability, although the instability mechanism is qualitatively similar to the perfectly expanded case.

INTRODUCTION

Understanding the mechanism of unsteadiness in supersonic jets may aid in developing quieter and more capable jet engines. In this work, the stability properties of perfectly expanded and under-expanded jets are investigated by means of global linear stability theory. In particular, we are interested in analyzing the effect of the nozzle on the instability mechanism and the role of the shock cells.

In global stability analyses, unstable eigensolutions represent absolute instabilities, which may be triggered spontaneously in the flow, while convective instabilities, which require persistent excitation, are associated with stable eigensolutions [1]. Nichols & Lele [2] investigated a perfectly expanded non-parallel jet using global stability analysis, albeit excluding the nozzle from the computational domain. In line with local stability theory, all eigensolutions were found to be stable with the least stable eigenfunction describing an upstream-traveling acoustic mode.

METHODOLOGY

We perform global stability analyses of axisymmetric supersonic jets, with the aim of assessing the role of the nozzle and the shocks on the instability mechanism. To isolate the effect of the nozzle lip and the shock cells, we consider three distinct setups. The first case represents a plain weakly non-parallel jet, serving as a reference case for comparisons with the literature (e.g., Ref. [2]). The second case corresponds to a fully expanded jet and includes the nozzle in the computational domain. The third considered case describes an under-expanded jet and allows assessment of the role of shock cells.

Our aim is to obtain and compare the most unstable eigensolutions for each of the setups. We compute the base flows as axisymmetric, steady, and laminar solutions of the nonlinear compressible Navier-Stokes equations for an ideal gas. Since the laminar base state may be globally unstable, a steady solution to the governing equations is recovered by the application of selective frequency damping [3]. The stability analysis employs the linearized compressible Navier-Stokes equations, with application of numerical sponge layers to ensure the dampening of the perturbations towards the boundaries of the computational domain. A detailed description of the direct numerical solver is given in Ref. [4].

RESULTS

The nozzle exit mach number is set to $M_e = 1$ and the acoustic Reynolds number, based on the nozzle exit radius, is $Re = 10,000$. The laminar base flows are presented in Figure 1, in terms of contours of the Mach number. Only the region in the vicinity of the nozzle exit is shown. The base flow for the case without the nozzle (Figure 1(a)) matches that of the fully expanded jet (Figure 1(b)) in the region downstream of the nozzle. The base flows for the cases with nozzle are calculated by setting the ratio of the nozzle exit pressure and the ambient pressure to 1 for the fully expanded jet (Figure 1(b)) and 2.4 for the under-expanded jet (Figure 1(c)).

The most unstable eigenmodes for each of the base flows are described below. Here, we focus on axisymmetric perturbations since local stability theory predicts that the mechanism extracting energy from the shear layer is most effective for such disturbances. The most unstable eigensolutions are $\omega = 0.395 - 0.004i$, $\omega = 0.399 + 0.136i$, and $\omega = 0.687 + 0.090i$ for the baseflows in Figure 1(a), Figure 1(b), and Figure 1(c), respectively. The reference case without the nozzle is globally stable, indicative of a convective instability, whereas the fully expanded and under-expanded cases are unstable, implying absolute instability. Thus, for the plain jet without explicit representation of the nozzle, we recover the classical result of convective instability in cold jets previously reported by [2]. The representation of the nozzle within the computational domain introduces an absolute instability, even in the absence of shock cells. The under-expansion reduces the growth rate of the instability, although the configuration remains absolutely unstable.

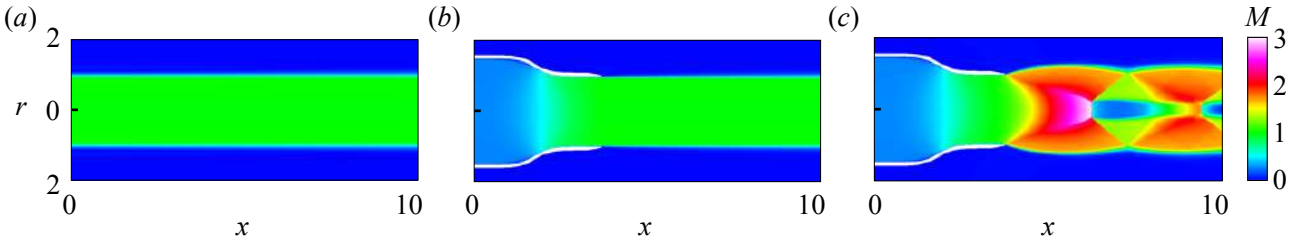

Figure 1: Base flow Mach number contours. Only the region in the vicinity of the nozzle is shown. (a) Without nozzle. (b) Fully expanded nozzle. (c) Under-expanded nozzle.

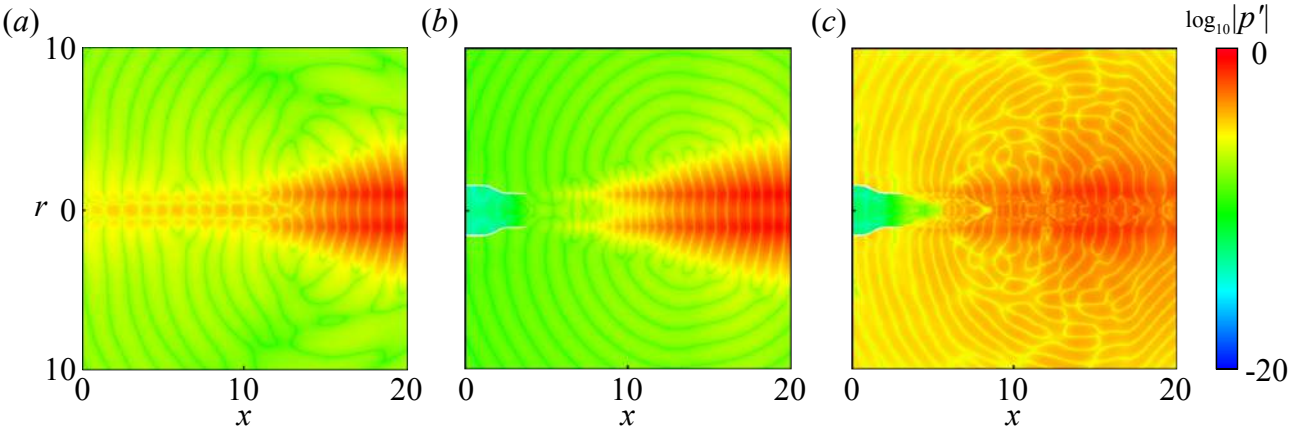

Figure 2: Pressure eigenfunction. The contours correspond to the decimal logarithm of the magnitude of the real part. Only the region in the vicinity of the nozzle is shown. (a) Without nozzle. (b) Fully expanded nozzle. (c) Under-expanded nozzle.

The corresponding eigenfunctions are presented in Figure 2. The pressure is chosen as a representative quantity, and the decimal logarithm of the magnitude of the real part is shown for the three considered cases. For the plain jet (Figure 2(a)), high magnitudes are obtained within the shear layer, where downstream spatial amplification occurs. Outside of the core of the jet, an upstream-traveling acoustic wave is observed, qualitatively similar to the least stable mode reported by Nichols & Lele [2]. Similar features can be seen for the fully expanded nozzle jet (Figure 2(b)). That case exhibits a coupling between the upstream-traveling acoustic wave and the shear layer mode in the vicinity of the nozzle lip, which leads to absolute instability. For the under-expanded nozzle jet (Figure 2(c)) qualitatively similar features are observed; however, the magnitudes in the region outside of the jet core are significantly elevated compared to the other cases, suggesting that the part of the eigenfunction associated with the shear layer is appreciably weaker than that in the other cases.

CONCLUSIONS

Global linear stability analysis of supersonic jets is conducted to determine the role of the nozzle lip and the shock cells in the instability mechanism. Three setups are considered to isolate the effect of the nozzle lip and shock cells. It is found that while the plain non-parallel jet is only convectively unstable, the representation of the nozzle within the computational domain introduces absolute instability. Inspection of the most unstable eigenfunction points to a coupling between the shear layer mode and the upstream-traveling acoustic wave in the vicinity of the nozzle. The effect of the under-expansion is a reduction in the instability growth rate. Nevertheless, the mechanisms of instability are qualitatively similar for both fully expanded and under-expanded jets.

Summary An accurate physics-based boundary layer transition (BLT) prediction method integrated with computational fluid dynamics (CFD) solvers is pursued for a range of aerospace applications. An important aspect of this work involves an approach that employs linear stability computations for a canonical set of configurations to train physics based, data driven models. The performance of a data driven model is evaluated for the planar Mack modes over a blunt, circular cone at zero degrees angle of attack and flow conditions selected to match the HIFiRE-1 flight test with Mach numbers in the range of 3.8 to 5.5. An additional study pertains to the modeling of TS and CF instabilities over the swept wing boundary layer of the CRM-NLF aircraft configuration at the conditions of a recent wind tunnel experiment at the NASA LaRC. The results of this study will be included in the final presentation.

EXTENDED SUMMARY

According to the CFD Vision 2030 [1], the most critical area in CFD simulation capability that will remain a pacing item for the foreseeable future is the ability to adequately predict viscous flows with transition-to-turbulence and flow separation. A majority of CFD computations are carried out under the assumption that the flow is turbulent everywhere, allowing the use of the computationally efficient Reynolds-averaged Navier-Stokes (RANS) based turbulence models throughout the flowfield. However, for several applications ranging from wings with natural laminar flow (NLF) technology, high-lift configurations, rotorcraft flows, unmanned aerial vehicles, and even more importantly in supersonic and hypersonic vehicles, the strong assumption involving a fully turbulent flow can lead to significant errors in the prediction of relevant performance metrics. Furthermore, most of the RANS models are incapable of modeling the process of transition from laminar to turbulent flow because of the complexity involved in the physics of the transition onset process.

Semiempirical correlations based on the linear stability theory (LST) and parabolized stability equations (PSE), such as the e^N method [2, 3], remains one of the most widely used approaches for the transition prediction in aircraft design computations. The LST and PSE track the evolution of small amplitude disturbances. The e^N method does require the specification of a critical N-factor that must be obtained from correlations against experimentally measured transition locations. Both LST and PSE can account for the amplification of the dominant primary instabilities encountered on aircraft wings, i.e., the Tollmien-Schlichting (TS) and crossflow (CF) waves, or in 2D high-speed configurations, i.e., the planar Mack mode waves. However, the application of these approaches toward a coupled computation of laminar and turbulent parts of a flowfield entails an increased computational cost and complexity, suffers from a lack of robustness, and often requires adequate understanding of transition physics and hydrodynamic stability theory that typical users of CFD solvers may not know.

The present research seeks to blend the so-called physics-based approach for transition modeling with the RANS-based approaches, with the eventual goal of developing a reliable and cost efficient, yet robust and user-friendly approach for CFD integrated modeling of BLT. To that end, two separate flow configurations are considered in the present work:

- Axisymmetric boundary layer over a 7° half-angle, circular cone with a nose radius of $r_n = 2.5$ mm at zero degrees angle of attack in a hypersonic free stream that corresponds to the ascent phase of the HIFiRE-1 flight test [4] with freestream Mach numbers in the range of $3.8 - 5.5$ and freestream unit Reynolds numbers in the range of $3.3 \times 10^6 - 21.4 \times 10^6$ m^{-1}. Earlier research [5] had shown that the onset of transition during the HIFiRE-1 flight experiment correlated with an amplification factor of $N \approx 13.5$ for the planar Mack modes.

- Swept wing boundary layer over the common research model with natural laminar flow (CRM-NLF) aircraft at flow conditions selected to match those from a recent wind tunnel experiment in the National Transonic Facility (NTF) at the NASA Langley Research Center [6]. In this configuration, TS instability, and potentially, the CF instability as well, may be expected to play an important role in transition, provided that the attachment line remains laminar.

An important aspect of the physics-based approach for transition modeling involves N-factor correlations based on a data driven surrogate model for linear amplification characteristics of the relevant classes of instability waves. A commonly used approach of this type is based on curve fits or multi-dimensional interpolation of an a priori database of stability characteristics for locally similar profiles. However, the application of this approach to hypersonic boundary layers over blunt spherical nose-tip cones leads to large, unacceptable errors in the predictions of amplification factors, mainly due to its failure in accounting for the effects of the entropy layer on the boundary-layer profiles along the length of

the model. We propose and demonstrate an alternate approach that provides substantially improved transition predictions for hypersonic flow configurations with entropy-layer effects. The performance of this model for the HIFiRE-1 vehicle at the flight ascent time of 21.5 s is illustrated in Figure 1. Specifically, Fig. 1(a) shows the evolution of the heat-transfer coefficient with a prescribed transition location, whereas Fig. 1(b) shows the comparison of the N-factor curves based on the data driven model with the results based on the LST, for selected disturbance frequencies in increments of 10 kHz. The excellent performance of the proposed model has also been confirmed over a broad set of flow conditions as well as for cone configurations with nose radius and half-angle values that do not fall within the database used to develop the model. Finally, the same model is shown to outperform the LST calculations for underresolved basic states [7]. Requiring little expertise on the user's part, such data driven models can make physics-based transition prediction accessible to nonexpert users. Furthermore, on a practical front, the highly efficient transition predictions based on this model can be used for accurate estimates of the temporal variations in the heat load on the vehicle as the latter flies through several candidate trajectories, making it a useful, physics-based tool during trajectory analysis.

An additional component of the ongoing research involves the modeling of transition in swept wing boundary layer flows that are relevant to subsonic, commercial transport aircraft. Transition under these conditions may be attributed to TS and CF instabilities, provided that the attachment line flow remains laminar. Highly useful transition measurements for a canonical flow configuration of this type were obtained during NASA's recent experiments on the CRM-NLF that was tested in the NTF. In such flow configurations, the transition onset location can have a significant impact even on the surface pressure distribution, and hence, an integrated modeling of the laminar and turbulent parts of the flow field becomes essential. Figure 2 indicates the mean flow characteristics on CRM-NLF model, computed with NASA's OVERFLOW 2.2o by using Menter's SST-2003 two-equation turbulence model along with an imposed transition front based on the experimental measurements. The transition front is visualized via surface contours of the turbulence index at the flow conditions of $M_\infty = 0.856$, $Re_{MAC} = 15 \times 10^6$ and $AoA = 1.5°$. The meeting presentation will include the results of transition analysis for the computed boundary layer flow over the CRM-NLF configuration.

This research was sponsored by the NASA Transformational Tools and Technologies (TTT) Project of the Transformative Aeronautics Concepts Program (TACP) under the Aeronautics Research Mission Directorate (ARMD).

INSTABILITY AND TRANSITION OF A BOUNDARY LAYER FLOW ALONG AN ARROW: RELAMINARIZATION IN FREE-FLIGH TESTS

Julio Ortiz*[1], Toshinari Hasegawa [1], Atsushi Serino [1], Takeshi Miyazaki [1]and Hiroki Sugiura [2]
[1]Department of Mechanical Engineering and Intelligent Systems, University of Electro-Communications, Tokyo, Japan
[2]JAXA, Tokyo, Japan

Summary The laminar-turbulent and turbulent-laminar transitions of an archery arrow's boundary layer flow are explored experimentally. Two types of experimental procedures were carried out to measure the arrow's drag coefficient (C_D): wind tunnel tests in the JAXA's 60 cm × 60 cm Magnetic Suspension & Balance System (MSBS) and free-flight tests. During the free-flight tests, an acceleration sensor was fixed inside the arrow's shaft to measure the instantaneous aerodynamic loads exerted on the projectiles. From the acceleration sensor data, the laminar-turbulent transition and the relaminarization of the boundary layer flow were found in the range $1.6\times10^4 < Re < 1.8\times10^4$.

INTRODUCTION

The trajectory of an arrow is highly sensitive to the aerodynamic properties, such as the drag, lift and pitching moment coefficients. More than half of the contribution to the drag comes from the frictional drag exerted on an arrow shaft. The frictional drag increases if the boundary layer flow along the arrow shaft becomes turbulent.

Recently, two support-interference-free measurements were performed, i.e. wind tunnel tests with JAXA's 60 cm × 60 cm Magnetic Suspension & Balance System (MSBS) and free-flight tests [1,2]. The state of the boundary layer was inferred from the value of the angle of attack. A transition region was found in the Reynolds number range $1.2 \times 10^4 < Re < 1.9 \times 10^4$, in which both the laminar and turbulent values of the drag coefficient (C_D) were observed. It was concluded that even a very small angle of attack developed during the arrow's flight could trigger the laminar to turbulent transition. In this paper, the results of free-flight tests using an acceleration sensor are given compared with those from the MSBS wind tunnel tests.

EXPERIMENTAL APPARATUS

Arrow's description

Modern commercial arrows are slender and light bodies composed by three main elements: a shaft, point and vanes. The shaft utilized in the present study is the aluminium alloy-based A/C/E (Easton: Figs. 1a and 1b). Its external radius is 2.62×10^{-3} m. A bulge-type point is attached at the front part of the shaft. At the rear part of the arrows, 3 straight vanes are fletched to give stabilization during the free-flight. The model of the vanes is the Easton Diamond Vanes size 175. The length of the arrow is 0.638 m and its total mass is 14.2×10^{-3} kg.

(a) (b)

Figure 1. (a) Arrow suspended magnetically in the MSBS and (b) acceleration sensor being inserted in the arrow's shaft.

MSBS tests

The MSBS is a wind tunnel in which arrows can be suspended magnetically against gravity [1], as shown in Fig. 1a. A valuable advantage of the MSBS is that it allows to fix the arrows without any mechanical support that would disturb the measurements. The arrow's drag coefficient was obtained from the MSBS tests. The experiments were carried out in a Reynolds number range $0.28\times10^4 < Re < 1.41\times10^4$. The Reynolds number is defined as $Re=2Ur/\nu_{air}$, where U is the wind velocity, r the arrow's radius and ν_{air} is the air's kinematic viscosity at room temperature.

Free-flight experiments

The second type of experiment consists of shooting arrows using a compressed air launching system to measure the aerodynamic loads exerted during free-flight. An acceleration sensor was introduced in the arrow's shaft allowing us to measure the exerted force and angular velocity in the three spatial components.

The indoor free-flight tests were carried out with two different distances of 17.7 m and 55 m between the shooting and the target positions. For both cases, any type of air conditioning system was turned off to avoid the influence of wind

*Corresponding author. E-mail: ortiz.julio@uec.ac.jp.

gusts. The arrow's trajectories were recorded using high-speed video cameras located at the launching and target positions. From the recorded videos were obtained the initial and final arrow's velocity and angle of attack. The free-flight experiments were carried out in a Re number range 1.2×10^4 <Re< 2.1×10^4.

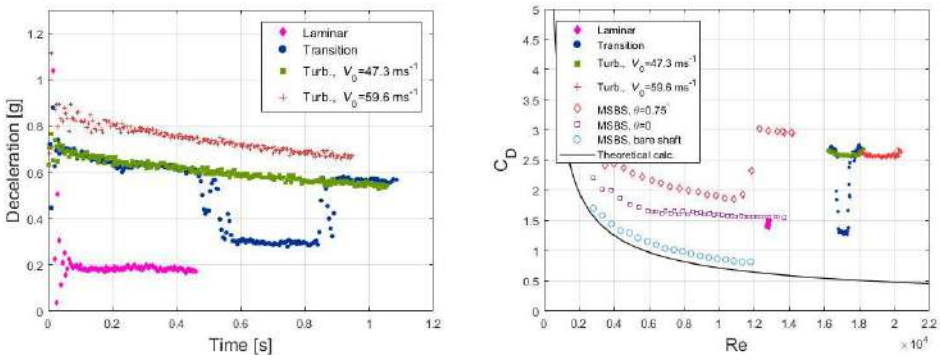
The acceleration sensor was designed by Logical Product (LP-UUEC002) and has a total length of 0.069 m, including the holders located at the two ends of the sensor (Fig.1b). The holders are designed to avoid excessive vibration. The total mass of the sensor (including the holders and battery) is 1.37×10^{-3} kg. The measurement frequency is 200 Hz and it can record deceleration up to16g (g denotes the gravitational acceleration) and a maximum rotation rate of 2250 dps.

RESULTS

Figure 2a shows the instantaneous deceleration values measured with the acceleration sensor, for shots with initial velocities of 47.3 ms^{-1} and 56.9 ms^{-1} with closed squares (■) and the summation symbols (+), respectively. The shots were carried out in the 55 m archery range. The flying times for the faster and slower shots were 0.95 s and 1.05 s, respectively. Interestingly, a relaminarization of the arrow's boundary layer was found to take place during free-flight for a shot with an initial velocity of 52.8 ms^{-1} (●). The transition from turbulent to laminar boundary layer was evidenced by the reduction in the deceleration during the time range 0.45 s < t < 0.85 s. For t > 0.9. A laminar-turbulent transition took place again due to uncontrolled instabilities in the boundary layer induced by unexpected air flow near the target.

Figure 2b shows C_D as a function of Re obtained from the two tests. In open circles (○) are shown the results corresponding to a shaft with no vanes. Such results agree with the theoretical predictions for a laminar boundary layer around a semi-infinite non-rotating cylinder. The small difference between the theoretical predictions and the MSBS measurements arises from the pressure drag. Open squares (□) show the larger C_D values obtained for an arrow aligned with the wind flow (θ =0). The C_D values correspond to a laminar boundary layer. It is possible to appreciate that the 3 straight vanes yield the drag increase of almost 100%. Open diamonds (◇) show the results when an angle of attack of θ =0.75° was fixed during the MSBS tests. An abrupt increase in the value of C_D suggests a laminar-turbulent boundary layer transition at Re = 1.2×10^4.

Closed symbols show the instantaneous C_D computed as $C_D = F_D/\left(\frac{1}{2}\pi\rho_{air}r^2{v_s}^2\right)$, where F_D is the exerted drag force, ρ_{air} is the air's density and v_s is the instantaneous arrow's velocity. Since the initial velocities are determined from the high-speed video camera recordings, it is possible to compute v_s by integrating the deceleration information. The laminar values of around 1.5 were obtained for Re ≈ 1.3×10^4, which is consistent with the MSBS results. Turbulent values around 2.6 are found for the shots of 47.3 ms^{-1} (■) and 56.9 ms^{-1} (+). In contrast, C_D reduced from a turbulent value 2.65 to a laminar value 1.3, when the relaminarization takes place (●).



(a) (b)

Figure 2. (a) Time evolution of the arrow's deceleration and (b) C_D as a function of Re.

CONCLUSIONS

In the present study, the static and instantaneous values of the drag coefficient of archery arrows were measured experimentally. Laminar and turbulent boundary layers were found for shots with different launching conditions. The process of laminar-turbulent and turbulent-laminar transitions was found to take place experimentally from the data provided by an acceleration sensor mounted inside an arrow in free-flight. Further theoretical approaches are required to elucidate the detailed mechanism of the boundary layer transition process.

EFFECT OF GAP WIDTH ON VISCOUS FINGERING INSTABILITY IN HELE-SHAW CELL

Sada Nand* Vandita Sharma,and Manoranjan Mishra†
Department of Mathematics, Indian Institute of Technology Ropar, Punjab, India

Summary The flow through a Hele-Shaw cell with a very fine gap between the glass plates is equivalent to the two dimensional porous media flows. In this work, we focus on experimentally and numerically understanding the effect of the gap in the Hele-Shaw cell on viscous fingering instability observed in various applications like enhanced oil recovery, chromatography separation etc. For the experimental investigation, a radial Hele-Shaw cell with T-section for liquid infusion is used. For a small gap width, rigorous fingering patterns with tip splitting are observed, which disappear on increasing the gap between the glass plates. In order to understand three dimensional effects, numerical simulations are performed using Stokes equation in contrast to commonly used Darcy's law. The numerical results are in qualitative agreement with the experiments.

INTRODUCTION

Displacement of miscible fluids in porous media finds huge applications in many industrial, environmental and engineering areas such as enhanced oil recovery, contaminant transport in geological aquifers etc. Mobility gradient between the displaced fluids in porous media flows results in a hydrodynamic instability called viscous fingering (VF). A less viscous fluid displacing a more viscous one deforms the interface into finger like patterns termed as VF [1]. The understanding of these chaotic patterns is of critical importance in the generation of interfacial instabilities. In the laboratory, VF is visualised and analysed using a Hele-Shaw cell [2], which comprises of two transparent glass plates separated by a gap. For gap width much smaller than the other dimensions of the cell, the flow through Hele-Shaw cell is equivalent to the two dimensional porous media flows [1]. We aim to explore how small the gap width must be in order to neglect the three dimensional effects. In this work, we vary the gap width in the Hele-Shaw cell and analyse its effect on VF patterns. Further, non-linear simulations are performed using COMSOL Multiphysics® [3] to support the experimental findings. As we are interested in the variation in gap to understand the flow dynamics, the gap-averaged Darcy's law may not be able to capture the physical mechanism [4]. As such, we use the Stokes equation for the conservation of momentum. Two different COMSOL Multiphysics® modules are coupled in order to model the hydrodynamic instability.

EXPERIMENTAL SET UP & MODELLING

We use a radial Hele-Shaw cell with glass plates of dimensions 300mm $\times$ 300mm $\times$ 10 mm to experimentally understand various facets of miscible VF on varying the gap width b, between the glass plates. Experiments are performed with the point source. The two fluids are prepared using different concentration by volume of Glycerol in water. The less viscous fluid has less concentration of glycerol in water and also contains dye for visual contrast. It is verified that the dye does not affect the viscosity of the fluid. The experiments are performed by initially filling the cell with high viscous fluid, followed by continuous injection of the less viscous fluid at a constant flow rate Q using a COLE-PARMER-D201253 pump. For an effective infusion of fluids we fabricated a T-section [5], which is attached to the Hele-Shaw cell. There is no need to change the pipes for injection of different fluids when using a T-section. Dynamics are captured with the help of the Sony FDR-AX40 camera fixed above the cell. Viscosity contrast is defined by log-mobility ratio R, defined as the natural logarithm of the ratio of the viscosity of the displaced fluid to that of the displacing fluid (here less viscous).
For the numerical study, we perform a three-dimensional study using COMSOL Multiphysics®. To model the porous media flows, Darcy's law is used in literature [1, 6]. But the Darcy's law encorporates gap-averaged quantities. Consequently, to study the effects of gap width on viscous fingering dynamics, we use Stokes equation coupled with the convection-diffusion equation for solute concentration for the mathematical modelling. The governing equations by considering Newtonian, incomressible and homogenous fluids are:

$$\nabla \cdot (\vec{u}) = 0, \tag{1}$$

$$0 = \nabla.[-p\mathbf{I} + \mu(c)(\nabla\vec{u} + (\nabla\vec{u})^{\mathbf{T}})], \tag{2}$$

$$\epsilon_p \frac{\partial c}{\partial t} + \vec{u} \cdot \nabla c = \epsilon_p D \nabla^2 c \tag{3}$$

where $\vec{u} = (u, v, w)$ is the velocity vector, p is the hydrodynamic pressure, D is the diffusion coefficient and μ is the dynamic viscosity of fluid and ϵ_p is the porosity of the medium. Arrhenius type relation is assumed between viscosity and concentration, defined as $\mu(c) = \mu_1 e^{R\,(c-c_1)/(c_2-c_1)}$, where $R = \ln\left(\frac{\mu_2}{\mu_1}\right)$ is the log-mobility ratio. $\mu_i, c_i, i = 1, 2$ respectively denote the viscosity and concentration of two fluids ($i = 1$ for displacing fluid). If $R > 0$ then $\mu_2 > \mu_1$:

which is favourable for VF. The continuity equation (equation(1)) and Stokes equation (equation(2)) are solved using Creeping flow (spf) module which is coupled with the Transport of Diluted Species (tds) module for the convection-diffusion equation (equation(3) for solute concentration. For the numerical study a cylindrical geometry of 300 mm diameter and gap width, b, in mm scale is used. The meshing of the domain is done using user-controlled mesh. We use a free triangular mesh, with swept distribution for capturing the three dimensional effects.

RESULTS AND DISCUSSION

For the experiments, we fix the flow rate Q and log mobility ratio R and vary the gap width. We first specify a gap width $b = 0.5$ mm, for which rigorous fingering patterns are observed when less viscous (blue) fluid displaces the more viscous (transparent) fluid as evident in figure 1(a). The tip splitting mechanism in which the tip of a single finger splits into multiple fingers is clearly visible for $b = 0.5$ mm. On increasing the gap width further, a suppression in instability is observed. For instance when we double the gap width, $b = 1$ mm, a few bumps at the interface are observed up to $t = 7$ sec. which develop into toe shaped fingers at later time (see figure 1(b). Further we numerically explore the gap width effect by considering a three dimensional study. We show a quarter of the fluid injection plane in figure 1(c,d) which are in good qualitative agreement with the experimental findings. With an increase in gap width, the instability is abated for a larger gap width. Thus, the gap width has a significant effect on the VF dynamics and must be clearly chosen in the Hele-Shaw cell experiments to understand the porous media flows and avoid three dimensional effects.

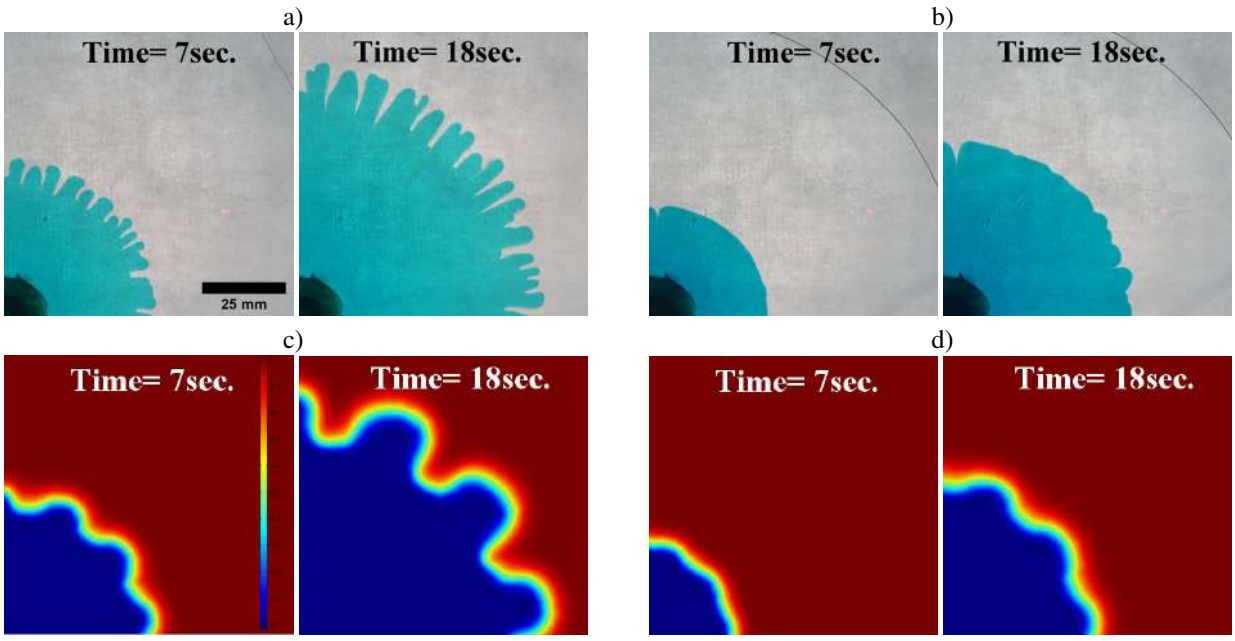

Figure 1: Comparison of the VF patterns observed in experiments (a), b)) with the results of numerical simulations (c), d)). Rigorous fingers are observed for a gap width of 0.5 mm (a,c) in comparison to a gap width of 1 mm (b,d).

CONCLUSIONS

The effect of gap width between the glass plates in the Hele-Shaw cell on the VF dynamics is explored using a deligently designed experimental set up. A range of VF dynamics from rigorous to toe shaped fingers are observed on varying the gap width. An increase in gap width results in an abated instability. The experimental results are in good qualitative agreement with the numerical simulations performed using Stoke's equation.

BOUNDARY LAYER TRANSITION ON BLUFF BODIES DUE TO TRIP AND ITS IMPLICATION IN CRICKET

Gaurav Chopra[1], Aditya Desai[1], and Sanjay Mittal[*1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Kanpur, India

Summary The transition of boundary layer on cylinder and sphere, by a trip, is investigated via computations and experiments. The effect of location and height of the trip on transition is studied. It is found that the formation of the laminar separation bubble (LSB) is bypassed for trips larger than a critical height. The flow on both the trip- and non-trip-side of the body is affected. The swing and reverse-swing of a cricket ball are explained.

INTRODUCTION

"Drag-crisis" in bluff body flows refers to the transition of boundary layer from a laminar to turbulent state and is associated with a steep drop in drag with increase in Reynolds number (Re) beyond a certain critical value. On smooth bodies, the transition is accompanied with the formation of LSB ([1, 2, 3]). An early transition can be engineered via a boundary layer trip or surface roughness. This is utilized in sports projectiles. For example, [4] investigated the role of seam/surface roughness in swing and reverse-swing of a cricket ball. The objective of the present work is to study the effect of the location (θ_T) and height (d_T with respect to diameter) of a trip on the transition of boundary layer on bluff bodies. The study utilizes large eddy simulations (LES) via a stabilized finite element method with a sigma model ([2]) and a very fine grid to resolve the flow, an as well as experiments in the low-speed and low turbulence National Wind Tunnel Facility (NWTF) at Indian Institute of Technology Kanpur. Force, surface pressure measurements, oil flow visualization & PIV are carried out in the experimental study ([3, 4, 5]). The trip on the cylinder is a wire along its span located on one side at an angle θ_T from the stagnation point. On the other hand, it resembles the seam of a cricket ball for the study on a sphere.

RESULTS

It is found that the location and height of the trip affect the transition of flow very significantly. Only a few results are described here: computational for the cylinder, and from experiments for the sphere. Detailed results will be presented at the conference. The variation of time-averaged coefficient of drag ($\overline{C}_D$) with Re for a smooth and cylinder with trip at $\theta_T = 55^o$ and $d_T = 0.25\%$ and 1.0% is shown in figure 1 (a). The drag crisis begins at $Re = 1.0 \times 10^5$ for the smooth cylinder. The transition on the upper and lower surfaces are very similar. In contrast, the drag crisis for the cylinder with $d_T = 1\%$ trip is a two-staged phenomenon. The first stage corresponds to transition on the trip side (TrS) at a relatively lower Re, compared to a smooth cylinder, while the flow on the non-trip/smooth side (SmS) stays laminar. Natural transition of the flow on the non-trip side constitutes the second stage. The Re for this transition is close to that for a smooth cylinder.

Figure 1 (b) shows the variation of time- and span-averaged coefficient of peak suction pressure ($-\overline{C}_{Ppeak}$) with Re. It is observed that the 1% trip affects the suction on not just the trip-side (TrS) but the smooth-side (SmS) as well. Transition on TrS, causes $-\overline{C}_{Ppeak}$ to be larger on TrS and smaller on SmS compared to that during natural transition on a smooth cylinder. On the other hand, transition on SmS causes $-\overline{C}_{Ppeak}$ to be much larger on SmS and lower on TrS compared to that on the smooth cylinder. These two phenomenon, respectively, explain "swing" and "reverse swing" of a cricket ball ([4]). Figure 1 (c) shows the time- and span-averaged streamlines for cylinder with 0.25% and 1% trips at $Re = 3.0 \times 10^5$. An LSB forms between the points of laminar separation (LS) and turbulent reattachment (TR). These along with the point of turbulent separation (TS) are marked in the figure. LSB forms in all cases when there is no trip. However, it does not form on the trip-side for the 1% trip. The large trip leads to a by-pass transition. For the case of 0.25% trip, the LSB on the TrS forms at a lower Re compared to the smooth cylinder.

Figures 2 (a) and (b) show the variation of time-averaged coefficient of drag ($\overline{C}_D$) and side force ($\overline{C}_Z$) with Re, respectively, for smooth sphere and cricket ball at an seam angle (θ_{Tr}) of 20^o. Qualitatively, the phenomenology of drag-crisis is similar to that of the flow past a cylinder. With increase in speed, the cricket ball goes through three regimes (2 (b)). In the regime of no-swing (NS), which occurs for Re less than that for transition, the trip has no effect on the boundary layer and it undergoes Laminar Separation (LS). Therefore, the side-force on the ball is close to zero. In the regime of conventional-swing, the boundary layer on trip-side of the ball undergoes transition while that no the smooth side remains laminar. An LSB forms on the trip-side. This is followed by the regime of reverse-swing (RS), wherein the boundary layer undergoes a natural transition on the smooth-side leading to the formation of an LSB, while the LSB on the seam-side disappears.

Also shown is the data for smooth cylinder. (c) Close up view of time- and span-averaged streamlines of the TrS and SmS for $Re = 3.0 \times 10^5$.

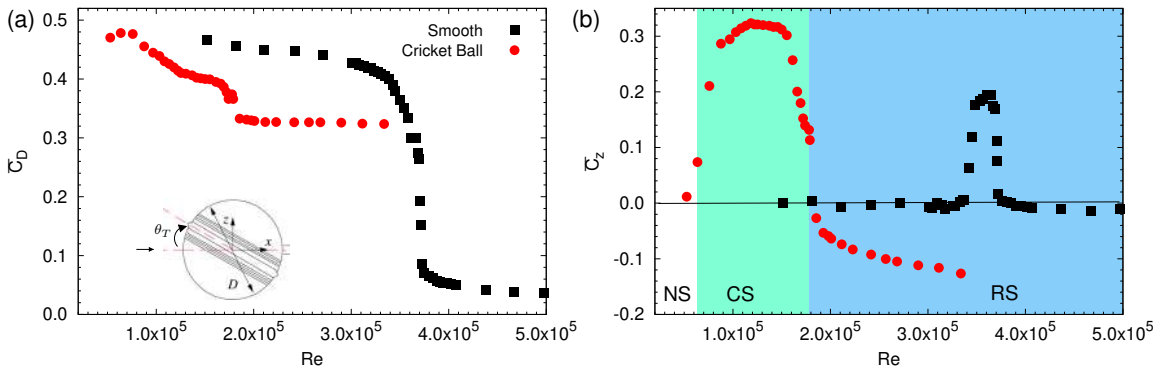

Figure 2: Flow past a smooth sphere and cricket ball (experimental study): (a) variation of time averaged coefficient of drag ($\overline{C}_D$), and (b) coefficient of side force ($\overline{C}_Z$) with Re.

CONCLUSIONS

The effect of a trip on the transition of boundary layer on bluff bodies has been investigated via experiments and computations. The trip prepones the transition. However, the location and height of the trip have a profound effect on the nature of transition. As in natural transition, LSB forms on the trip side if the height of the trip is relatively low. On the other hand, a by-pass transition occurs for a larger trip height. The trip appears to affect the flow not only on the side it is present, but also on the non-trip side of the bluff body. The seam and surface roughness are responsible for the side force on the cricket ball leading to swing and reverse-swing.

EXPERIMENTAL STUDY OF AN EFFECTIVE MECHANISM OF DISTRIBUTED EXCITATION OF UNSTEADY GÖRTLER VORTICES BY LOW-FREQUENCY FREESREAM TURBULENCE

Dmitry Mischenko*[1], Vladimir Borodulin[1], Andrey Ivanov[1], and Yury Kachanov[1]
[1]Khristianovich Institute of Theoretical and Applied Mechanics, SB RAS, Novosibirsk, Russia

Summary The paper is devoted to experimental investigation of a distributed vortex receptivity mechanism that is able to efficiently excite unsteady (in general) Görtler vortices in boundary layers on curved walls. The quantitative study is carried out in a broad range of problem parameters in a Blasius type boundary layer developing on a concave surface. The receptivity coefficients are estimated. The problem of linear unsteady Görtler instability of this particular boundary layer is studied in complementary experiment. All main stability characteristics are obtained and compared with calculations based on linear stability theories.

INTRODUCTION

The Görtler instability is widespread in various shear flows with curved streamlines at sub-, super-, and hypersonic speeds. The instability is caused by centrifugal force, which action is essentially nonuniform in the cross-flow direction due to presence of a strong cross-flow mean-velocity gradient. The paper presents results of a systematic quantitative experimental study of, apparently, one of the most important mechanisms of excitation of unsteady (in general) Görtler vortices [1] in cases of boundary layers developing at conditions of enhanced level of freestream vortex disturbances. This mechanism is associated with distributed scattering of longitudinal low-frequency and stationary freestream vortices on the natural streamwise nonuniformity of the growing boundary layer and is able to excite unsteady Görtler modes and to affect significantly their downstream evolution. Distributed excitation of Görtler modes by freestream vortices was studied quantitatively for the first time in [2]. Similar mechanisms at excitation Cross-Flow and Tollmien-Schlichting instability modes in boundary layers were successfully investigated experimentally in [3-5]. The present work is devoted to a systematic study of distributed excitation of Görtler modes and complements preliminary results obtained in [2].

EXPERIMENTAL SETUP

Two paired series of measurements were performed in the low-turbulence wind tunnel T-324 of ITAM SB RAS (Novosibirsk, Russia) at one and the same base-flow conditions: (1) a main experiment on distributed vortex receptivity and (2) an additional experiment devoted to obtaining experimental linear stability characteristics (increments and phase velocities) of unsteady Görtler modes. The data of the experiment (2) were necessary for obtaining quantitative characteristics of the receptivity mechanism studied in experiment (1) – the coefficients of the distributed vortex receptivity. Detailed hot-wire measurements were carried out in a boundary layer of the Blasius type developing on a concave surface of the high-precision experimental model (with radius of curvature R of 8.37 m) at freestream velocity U_e = 9.18 m/s. The two experiments were carried out using completely controlled unsteady disturbances (of both the boundary layer and of the incident flow), which were generated by special disturbance sources. The results were obtained for Görtler vortices of three frequencies f = 8, 13, and 17 Hz (the corresponding frequency parameter F = 9.29; 15.09 and 19.73) with spanwise wavelengths λ_z = 7 to 24 mm (the corresponding dimensionless spanwise scale Λ = 119 to 758) in a range of Görtler numbers G^* = 8.6 to 21.0. Estimates of the distributed receptivity coefficients at excitation *steady* Görtler modes were also obtained (see below).

MAIN RESULTS

It has been found that the results of experiment (2) are in a good agreement, in general, with the results of calculations based on the locally-parallel and nonlocal non-parallel theories of unsteady Görtler linear instability by A.V. Boiko [1]. (Figure 1*a* shows calculations based on locally-parallel theory only.) The growth of spanwise scale and frequency of unsteady Görtler modes is found to lead to worsening of correlation of experimental and calculated data (which is consistent with [1]). New experimental data complement previous studies [1] (carried out only for three spanwise scales of disturbances) and are suitable for verification of various theories of unsteady Görtler linear instability of boundary layers on concave walls.

It has been found in experiments (1) that the distributed vortex receptivity mechanism is capable of efficient excitation both steady and unsteady Görtler vortices and modifies significantly laws of downstream evolution of unsteady (at least) Görtler modes (Figure 1). As a result, the distributed receptivity can lead to either amplification or suppression of unsteady Görtler modes and, in particular, is able to provide the growth of almost neutrally stable Görtler vortices.

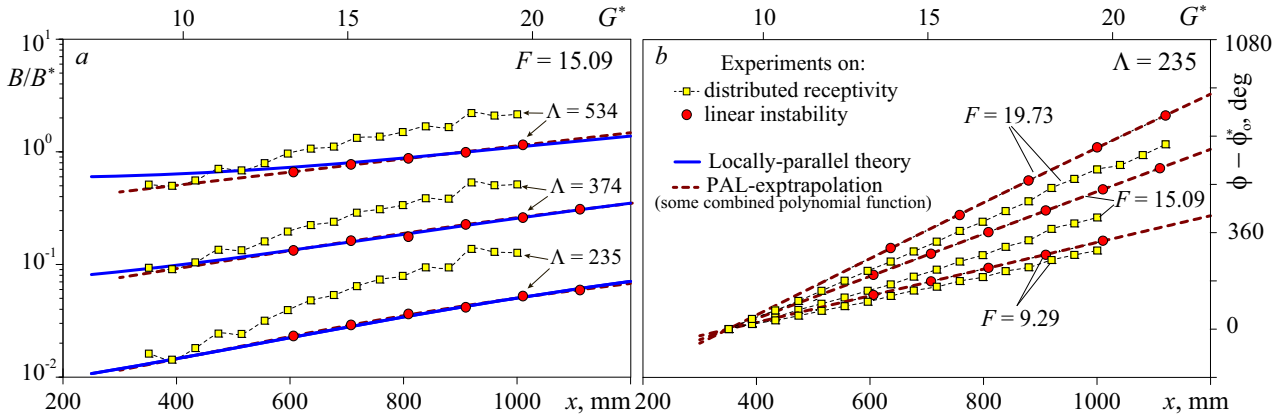

Figure 1. Example of comparison of streamwise distributions of spectral amplitudes (*a*) and phases (*b*) of unsteady Görtler modes developing under action of distributed vortex receptivity mechanism (squares) and of the linear stability mechanism only (circles).

Estimates of quantitative values of the coefficients of distributed vortex receptivity were obtained in present work by solving the corresponding complex, mathematically incorrect problem (similar to [5]). It was found that the amplitudes and phases of these coefficients are independent on streamwise coordinate. In the studied range of parameters, the amplitudes of the coefficients increase (in a linear way) with disturbance frequency, as well as with their spanwise scale (especially in the high-frequency region, see Figure 2). It was found that, due to a number of reasons, it is impossible to obtain directly, in a similar way, the corresponding estimates of the experimental distributed receptivity coefficients at excitation of *steady* Görtler vortices. Nevertheless, they were obtained by means of linear approximation the frequency dependence of the coefficients amplitudes at excitation of *unsteady* Görtler vortices with subsequent extrapolation to the zero frequency. It turned out that the distributed vortex receptivity responsible for excitation of stationary Görtler modes is much weaker compared to the case of nonstationary modes.

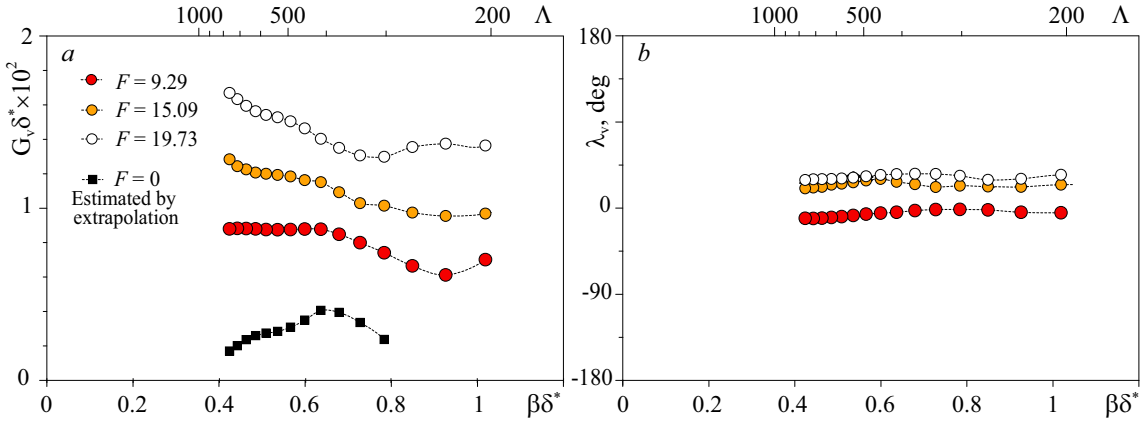

Figure 2. Amplitudes (*a*) and phases (*b*) of distributed vortex receptivity coefficients versus spanwise wavenumber of Görtler modes β. Here $\delta^* = 1.6$ mm is a boundary layer displacement thickness corresponding approximately to the center of region of obtaining of the coefficients.

The results obtained in the present experiments can be used for verification of various theories of distributed excitation of unsteady and steady Görtler modes by freestream vortices and can be applied to estimations of locations of the laminar-turbulent transition in boundary layers on concave walls. The enhancement of power of the studied receptivity mechanism with frequency, along with simultaneous weakening of the linear Görtler instability mechanism [1], is able to lead to a significant expansion of the frequency range, in which freestream vortices can affect the laminar-turbulent transition in various practical applications.

RESOLVENT ANALYSIS OF BOUNDARY-LAYER FLOWS INTERACTING WITH FINITE-EXTENT VISCO-ELASTIC INSERT

Jean-Lou Pfister[1], Nicolo Fabbiane[1], and Olivier Marquet[*1]
[1]ONERA, DAAA, University Paris Saclay, France

Summary Based on linear fluid-solid stability analysis, we investigate the attenuation of Tollmien-Schlichting waves in a boundary-layer flow developing on a wall with a finite-extent visco-elastic insert. A resolvent analysis of the fluid perturbation in the rigid-wall configuration is first performed to determine the optimal amplification and forcing. The harmonic fluid-solid response to the optimal fluid forcing is then computed for the compliant-wall configuration, based on the linearization of the Arbitrary-Lagrangian-Eulerian formulation [3]. The attenuation of Tollmien-Shlichting waves obtained at low frequencies relies on a wave-cancellation mechanism. The amplification of Travelling-Wave Flutter at high frequencies relies on the existence of nearly unstable solid modes excited by the fluid forcing.

The use of compliant walls to delay the laminar/turbulent transition in boundary layers ([1],[2]) was inspired by the skin properties of animals, like dolphins. It is now well established that three types of instabilities occur in laminar boundary-layer flows developing over *infinite-length* compliant walls: Tollmien-Schlingthing (TS) waves, Travelling Waves Flutter (TWF) and Static Divergence instability. The effect of compliant walls has been mainly investigated using local stability analysis, reyling on the assumption of an infinite extent of the elastic wall in the streamwise direction. Based on resolvent analysis and harmonic fluid-solid linear response, we here investigate the effect on the flow perturbation of a finite-extent visco-elastic insert in the wall.

RIGID-WALL CONFIGURATION AND RESOLVENT ANALYSIS

The nominal flow configuration is a two-dimensional boundary-layer flow developing over a rigid wall. The local Reynolds number $Re(x) = U^*_\infty \delta^*(x)/\nu$, based on the freestream velocity U^*_∞ and the local displacement thickness $\delta^*(x)$ at the streamwise position x from the leading edge of the wall, varies in the range $3000 \leq Re(x) \leq 3179$ between the inlet and the outlet of the computational domain. For such Reynolds numbers, the Blasius boundary layer is convectively unstable to Tollmien Schlichting waves at any streamwise position. In the following, all variables are made non-dimensional using U^*_∞ and the displacement thickness at the inlet $\delta^*(x_i)$, as the velocity and length scales, respectively. The flow, modelled with the incompressible Navier-Stokes equations, is decomposed into a steady component $[\mathbf{U}, P]$ and an infinitesimally small perturbation $[\mathbf{u}, p] = [\hat{\mathbf{u}}, \hat{p}]\, e^{i\,\omega t}$, where $[\hat{\mathbf{u}}, \hat{p}]$ is the harmonic flow response at frequency ω to the harmonic momentum forcing $\hat{\mathbf{f}}$. The linear input-ouput relation between the momentum forcing and the harmonic flow velocity $\hat{\mathbf{u}}$ is formally written

$$\hat{\mathbf{u}} = \mathbf{R}(\omega)\,\hat{\mathbf{f}} \quad , \quad \mathbf{R}(\omega) = \mathbf{C}\,\left(\mathrm{i}\omega\,\mathbf{M} + \mathbf{L}(\mathbf{U})\right)^{-1}\mathbf{B}, \tag{1}$$

where $\mathbf{R}(\omega)$ is the hydrodynamic resolvent operator, $\mathbf{L}$ is the linearized Navier-Stokes operator around the base flow velocity $\mathbf{U}$, $\mathbf{M}$ is the mass matrix accounting for the time-independence of the divergence-free condition, while $\mathbf{B}$ and $\mathbf{C}$ are prolongation and extension operators, respectively. The no-slip condition imposed at the rigid wall is embedded in the definition of the resolvent operator. The resolvent analysis then consists in determining the largest singular values of this operator. They can be computed as the largest (positive) eigenvalues λ_k^2 of the following eigenvalue problem

$$\mathbf{R}(\omega)^H \mathbf{R}(\omega)\,\hat{\mathbf{f}}_k = \lambda_k^2\,\hat{\mathbf{f}}_k \tag{2}$$

Ordered by decreasing values, these eigenvalues represent the gain between the kinetic energy of the flow perturbation (output) and a norm of the focing (input), i.e. $\lambda_k^2 = \hat{\mathbf{u}}_k^H \hat{\mathbf{u}}_k / \hat{\mathbf{f}}_k^H \hat{\mathbf{f}}_k$. The harmonic flow response associated to the largest energy gain λ_0^2 is plotted as function of the frequency in Figure 1, with the solid curve. The large energy gains obtained in the frequency range $0.05 \leq \omega \leq 0.15$ are associated to the amplification of low-frequency Tollmien-Schlichting waves, displayed in Fig.2(a) using the pressure field. The shorter-wavelength Tollmien-Schlichting waves obtained at higher frequency are not amplified, as those displayed in Fig.2(b) at $\omega = 0.45$.

HARMONIC FLUID-SOLID RESPONSE IN THE VISCO-ELASTIC-WALL CONFIGURATION

To attenuate the Tollmien-Schlichthing waves that are amplified at low-frequencies, we insert in the rigid wall a solid patch of non-dimensional length 100 and thickness 5 at the distance 25 of the inlet domain. This solid patch is made of an incompressible visco-elastic material, modelled by a generalization of the one-dimensional Kelvin-Voigt constitutive relation. The elastic component of this stress tensor is proportional to the non-dimensional Young modulus E_s, while the viscous component is proportional to the non-dimension damping D_s. These non-dimensional parameters are fixed

*Corresponding author. E-mail: olivier.marquet@onera.fr

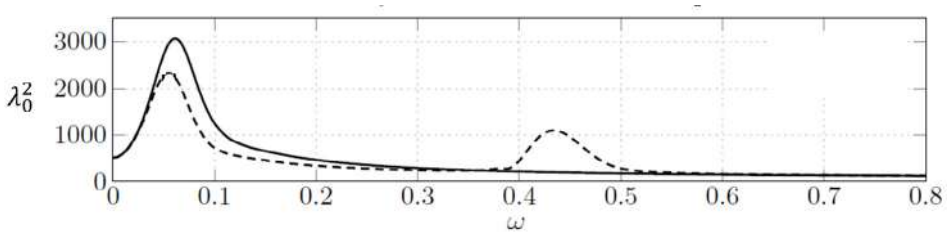

Figure 1: Energy gain as a function of the frequency ω. The solid line depicts the optimal energy amplification of the rigid-wall boundary-layer flow. The dashed line is the linear response to the optimal fluid amplification. The low-frequency and high-frequency peaks corresponds to the amplification of Tollmien-Schlichting (TS) and Travelling-Wave-Flutter (TWF) instabilities.

to $E_s = 1$ and $D_s = 0.2$ in the following (see [4]). The attenuation of the Tollmien Schlichting waves induced by the visco-elastic coating is assesed by computing the linear harmonic response of the fluid-solid perturbation to the optimal flow forcing $\hat{\mathbf{f}}_0$ previously determined. Formally, this is written

$$\left(\mathrm{i}\omega \begin{bmatrix} \mathbf{M}^f & 0 \\ 0 & \mathbf{M}^s \end{bmatrix} + \begin{bmatrix} \mathbf{A}^f(\mathbf{Q}) & \mathbf{C}^{fs} \\ \mathbf{C}^{sf} & \mathbf{A}^s(E_s, D_s) \end{bmatrix} \right) \begin{bmatrix} \hat{\mathbf{q}}^f \\ \hat{\mathbf{q}}^s \end{bmatrix} = \begin{bmatrix} \mathbf{P}\,\hat{\mathbf{f}}_0 \\ 0 \end{bmatrix} \tag{3}$$

In the first line that represents the linear harmonic equation governing the fluid perturbation $\hat{\mathbf{q}}^f$, $\mathbf{A}_f$ is the linearized Navier-Stokes operator written in the Arbitrary-Lagrangian-Eulerian formulation (see [3] for more details) and $\mathbf{C}_{fs}$ represents all the coupling terms with the solid perturbation $\hat{\mathbf{q}}_s$. In the second line that represents the linear harmonic equation governing the solid perturbation, the operator $\mathbf{A}_s$ represents the stress-strain elation of the visco-elastic patch and $\mathbf{C}_{sf}$ accounts for all the couplings with the flud perturbation, as for instance the hydrodynamic loading at the fluid-solid interface. Solving the above linear problem for several frequencies, one can define the energy gain between the input and the output of the fluid-solid configuration, i.e. $\lambda_0^2 = \hat{\mathbf{u}}^{f\,H}\hat{\mathbf{u}}^f / \hat{\mathbf{f}}_0^H \hat{\mathbf{f}}_0$, where $\hat{\mathbf{u}}^f$ is the velocity component of the fluid perturbation $\hat{\mathbf{q}}^f$. This quantity is plotted in Fig. 1 with the dashed curve. It clearly shows the attenuation of low-frequency Tollmien-Schlchting waves and the amplification of higher-frequency waves, kwown as the Travelling-Wave-Flutter waves. They are respectively depicted Fig. 2(c) and (d), with contours of the vertical displacement in the visco-elastic patch. For the low-frequency Tollmien-Schlichting Waves, the vertical displacement of the visco-elastic patch is in-phase with the flow pressure perturbation, and out-of-phase for the Travelling Wave Flutter.

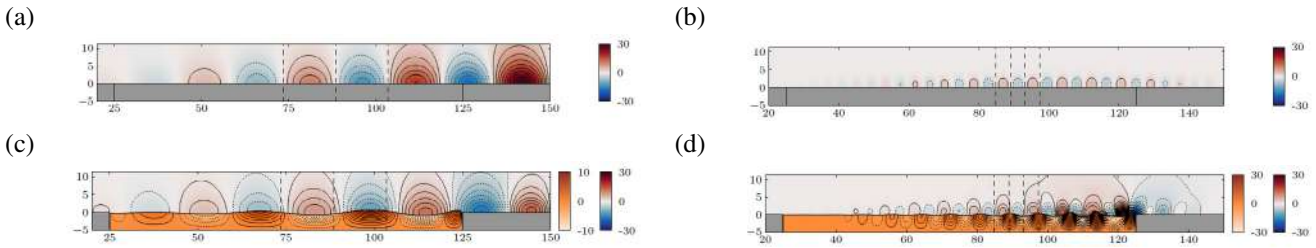

Figure 2: . Attenuation of low-frequency TS instability by the visco-elastic patch. (a) Optimal response of the flow for the rigid-wall configuration. (b) Response of the compliant-wall configuration to the optimal flow forcing. Isolines of the pressure and vertical discplacement are shown in the fluid and solid, respectivley.

A decomposition of the linear fluid-solid harmonic response, not detailed here, allows better understanding the attenuation of low-frequency waves and the amplification at high-frequency waves. In particular, we will show that the attenuation of TS waves relies on a wave-cancellation mechanism, while the amplification of TWF is related to the excitation by the flow of nearly unstable solid eigenmodes. We will further discuss the fluid-solid response to the sub-optimal fluid forcing, thus highlightenig the interest of performing a resolvent analysis of the fluid-solid operator. Results of this fluid-solid resolvent analysis will be compared to the harmonic fluid-solid response to optimal fluid forcing, described above.

TRANSITION TO TURBULENCE IN PLANE COUETTE-POISEUILLE FLOW WITH EXTERNAL NOISE

Tao Liu[1], Lukasz Klotz[2], Benoît Semin[1], Ramiro Godoy-Diana[1], José Eduardo Wesfreid[*1], and Tom Mullin[3]
[1]Physique et Mécanique des Milieux Hétérogènes (PMMH),UMR 7636 CNRS,ESPCI,Sorbonne University,University of Paris, 7 Quai Saint Bernard, Paris, France
[2]Institute of Science and Technology, Am Campus 1, 3400 Klosterneuburg, Austria
[3]Mathematical Institute, University of Oxford, Oxford OX2 6GG, UK

Summary We report the results of an experimental investigation of the effects of noise on the critical Reynolds number required for sustained turbulence in plane Couette-Poiseuille flow. We establish the critical point by decreasing the Reynolds number from a fully turbulent state. At $Re_c = 650$, the characteristic decay time approaches infinity and this is found to be independent of the level of noise. On other hand, the time and space averaged amplitude of the statistical permanent state after the decay is sensitive to the external noise level.

INTRODUCTION

The transition to turbulence in confined shear flow is sub-critical and characterized by the coexistence of laminar and turbulent regions at moderate Reynolds number. In order to study this scenario, we have built a plane Couette-Poiseuille flow (CPF) experimental set-up [1]. The CPF shares similarities with plane Couette flow (PCF), plane Poiseuile flow, flow in shallow lake induced by wind and boundary layer (BL) etc. However, the presence of noise in the set-up has an influence on the transition [3]. The noise effects are studied by varying the noise level in the system. The critical Reynolds number Re_c of CPF is defined using the life time of transient turbulent decay; the time and space averaged amplitude is characterized as a function of Re for different noise levels.

EXPERIMENTAL SET-UP

The sketch of the set-up is illustrated in Fig. 1 (a). It consists of two parallel glass plates with a distance $2h = 11mm$ between a glass plate and a moving belt, a length of $L_x/h = 390$ and a height of $L_z/h = 90$. The belt with a velocity U_{belt} induces a shear flow that results in a pressure gradient driving the counter flow (see Fig. 1 (b)). The flow profile is Couette-Poiseuille in laminar regime. The Reynolds number is defined as $Re = U_{belt}h/\nu$, where ν is kinematic viscosity of water. The coordinates x^*, z^* and the time t^* are made dimensionless by h and U_{belt} respectively.

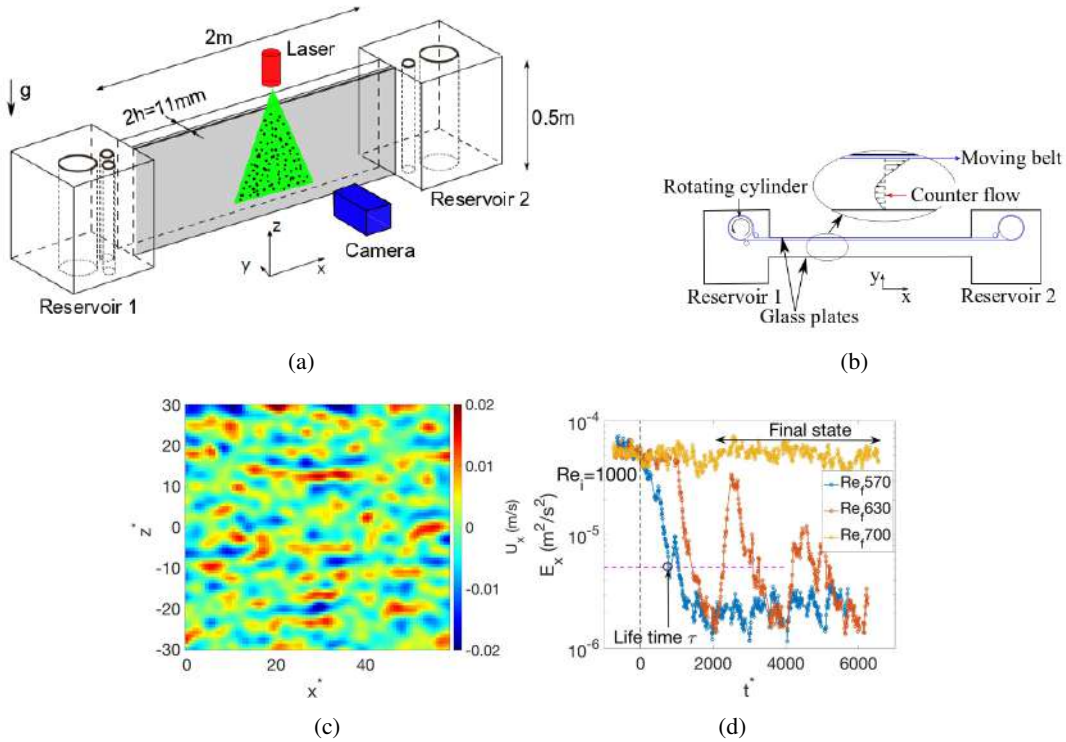

Figure 1: (a) Experimental set-up. (b) Bottom view. (c) 2D velocity field of streamwise small scale flow U_x from PIV measurments at initial Reynolds number $Re_i = 1000$ after spatial filtering with a cutoff wavelength $\lambda^* \leq 14.8h$ which removes large scale flows. The noise is created in the reservoir where the belt turns around and enters the channel from the reservoir 1. We have investigated two levels of noise: 1) with grids at the entrance of channel (low noise) and 2) without grid (high noise). Particle image velocimetry (PIV) is used to measure the velocity field in xz plane at the y^* position where the velocity is zero in CPF profile; the velocity field is filtered spatially to remove large scale flows induced by the position variation of the belt (Fig 1 (c)). The experimental protocol is the following: the flow is initialized at $Re_i = 1000$ (fully turbulent) and then suddenly decreased to lower Re_f, which is referred to as quench experiments.

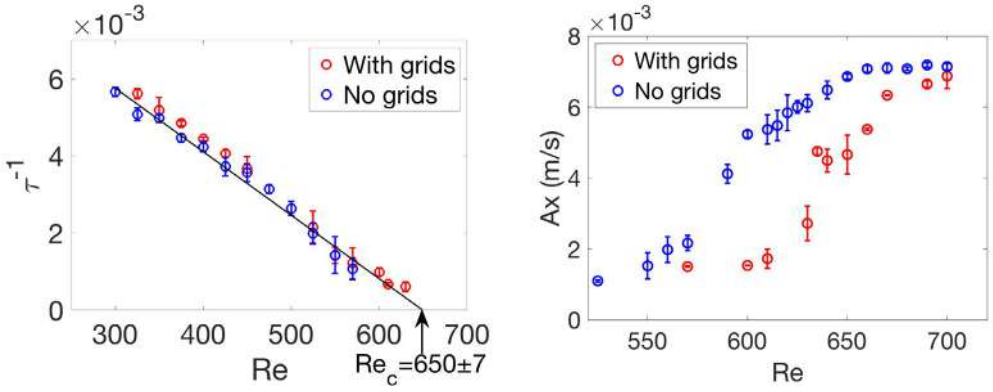
RESULTS



(a) (b)

Figure 2: (a) The inverse of life time τ^{-1} as a function of Re for the measurements with grids in red and without grids in blue, solid line fit $\tau^{-1} \propto (Re_c - Re)$ fit with ($Re_c = 650$), error bar is standard deviation of several realizations. (b) Time and space averaged amplitude of final state $A_x = \sqrt{E_x}$ as a function of Re for measurements without and with grids, error bar is standard deviation of several realizations.

The typical energy evolution $E_x(t^*)$ for different final Reynolds number Re_f is presented in Fig. 1 (d). The life time τ is defined as the first time when $E_x(t^*)$ decreases to a threshold of 10 percent of initial energy level. The final state is the period after the initial transient decay (Fig. 1 (d)). Fig. 2 (a) shows the inverse of life time τ^{-1} is proportional to Re which has been observed in other confined shear flows [4][5]. The intersection point bewteen the fit $\tau^{-1} \propto (Re_c - Re)$ and the Re axis give the critical point at $Re_c = 650$. The Re_c is independent of the external noise. In contrast, the time and space averaged amplitude A_x as a function of Re shows that the apparent threshold is shifted and the final state is modified by different noise levels. We are currently exploring the possibility of modelling the phenomena using a 1D spatio-temporal dynamical systems model with noise [3].

CONCLUSIONS

A critical value of Re for plane Couette-Poiseuille flow is found to be $Re_c = 650$ using quench experiments irrespective of the external noise in the system. By way of contrast, the amplitude has different apparent thresholds and final states for various external noise level. The amplitude diagram is not suitable to define the threshold in a system with pronounced noise. While a definite threshold cannot yet be ascribed to transition in the presence of noise, we are working on a low-dimensional model with multiplicative noise to progress our understanding.

THE EFFECT OF STREAKS ON THE INSTABILITY OF JETS

Chuhan Wang[1], Lutz Lesshafft*[1], Petrônio A.S. Nogueira[2], André V.G. Cavalieri[2], and Peter Jordan[3]
[1]Laboratoire d'Hydrodynamique, CNRS / Ecole Polytechnique / Institut Polytechnique de Paris, Palaiseau, France

Summary The presence of streaks in the shear layer of jets, issuing from a round nozzle, breaks the axisymmetry of their steady-state solution. If the streaks are considered to be part of the base flow, for the purpose of linear instability analysis, the instability eigenmodes are thus affected by their presence. The resulting change of growth rates and spatial shapes of eigenmodes, related to the shear instability in jets, is investigated here for the setting of parallel base flows. The shape of *optimally* growing streak structures inside an initially axisymmetric jet are identified first, and their nonlinear growth to finite amplitude is simulated in time. Linear perturbation eigenmodes of the streaky base flow are then computed in the two-dimensional cross-plane. Consistent with similar studies in plane shear layers, it is found that sinuous streaks have a stabilising effect on the shear instability, whereas varicose streak structures lead to stronger instability growth.

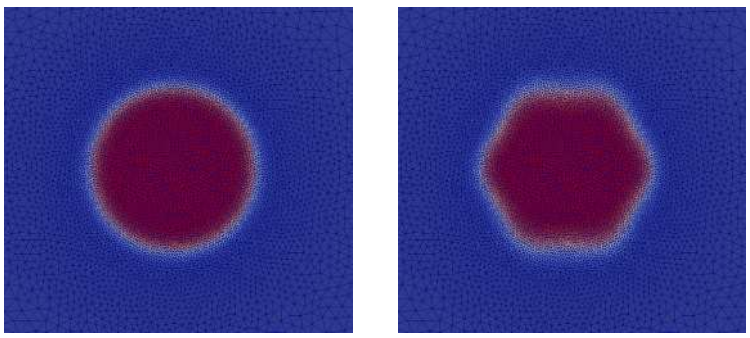
STREAKS IN JETS

Rolls and streaks, and their role for instability dynamics and laminar-turbulent transition, have been extensively studied in the context of wall-bounded shear flows. *Rolls*, as vortices in the cross-plane of the flow, transport high-speed fluid towards the wall and low-speed fluid away from the wall, thereby creating *streaks* in the main flow velocity. These streaks are themselves subject to instabilities, and are even assumed to be responsible for the self-sustained process of wall-bounded turbulence. However, the very presence of rolls and streaks in *free* shear flows such as jets has hardly been recognised until very recently. Nogueira *et al.* [1] documented the appearance of streaky structures in the turbulent velocity field of a high-speed jet, by processing of experimental data, and showed how these could be modelled through transient-growth and resolvent analysis.

Jiménez-González & Brancher [2] computed "optimal" roll shapes for streak creation in jets, in the sense of maximum streak energy growth, but these authors did not investigate the modal instability of the resulting streaky jet flow. Marant & Cossu [3] carried out linear instability calculations for a parallel plane shear layer with streaks; a similar study of jet dynamics has been completed recently [4]. Another recent study, by Pickering *et al.* [5], investigates the formation of streaks in developing jets in response to forcing input, concluding that streaks may be suspected to dominate perturbations in jets at low frequencies.

SCOPE AND METHODOLOGY

The objective of our work is to characterise how, and under what conditions, rolls and streaks may enhance or decrease the shear instability of jets from an axisymmetric nozzle. Our approach follows in several aspects the shear-layer study [3]. In order to reduce the complexity of computations and the number of influence parameters, parallel base flows (invariant in the main flow direction) are considered. Temporal instability eigenmodes in a strictly axisymmetric base flow are characterised by an integer azimuthal wave number m, but this decoupled dynamics of different m is bound to disappear with the introduction of azimuthal base flow modulations, via the appearance of streaks.



(a) without streaks (b) with six streaks

(e) $\omega = 1.040 + 0.416i$ (f) $\omega = 0.881 + 0.437i$ (g) $\omega = 0.773 + 0.344i$ (h) $\omega = 0.705 - 0.013i$

Figure 2: Some eigenmodes (streamwise velocity) of the axisymmetric base flow (top row) and the streaky base flow (bottom row) from figure 1. The imaginary part of ω is the temporal growth rate.

We first identify the roll/streak structures that experience the strongest transient energy growth due to the lift-up effect. Recovering the results of Jiménez-González & Brancher [2], we find that *sinuous* perturbations, which represent wavy deformations of the jet shear layer, grow the fastest. *Varicose* perturbations, which lead to azimuthal variations of the shear layer thickness, also grow, but at a lower rate. Consistent with earlier results for plane shear layers, the linear sensitivity of shear instability growth rates in jets is zero at first order.

We then consider the effect of finite-amplitude rolls and streaks in the base flow. The nonlinear character of this problem leads to several influence parameters, including the roll and streak amplitudes. Roll shapes are imposed, characterised by the number of vortices along the azimuth, by their radial distribution and individual circulation, and the creation of streaks is obtained by nonlinear time-stepping in the jet cross-plane. Frozen instances of this time-dependent streaky parallel jet are taken as base flows for linear instability analysis. An example of such a streaky base flow (with *sinuous* streaks) is shown in figure 1b.

CURRENT RESULTS

When finite-amplitude rolls are introduced into an axisymmetric jet flow, the ensuing streaks appear in the form of symmetric distortions of the shear layer. For the example shown in figure 1, optimal rolls were computed according to the criterion of maximum streak growth [2], and the number of rolls was fixed as six. The Reynolds number was set to 1000.

Temporal eigenmodes of the non-streaky axisymmetric base flow and its streaky counterpart are represented side by side in figure 2, with their eigenvalues given in the caption. Note that the presence of streaks breaks the azimuthal symmetry of mode shapes, except for $m = 6$, which corresponds to the number of streaks. In this example, as for all sinuous streak perturbations, the streaks have a stabilising effect on all eigenmodes. The opposite is true for *varicose* rolls and streaks: when such structures are present in the base flow, the unstable modal growth rates are increased, and an enlarged interval of axial wavenumbers is unstable.

Absolute instability in streaky base flows has also been investigated: it has been found that streaks of any spatial shape lead to a *stabilisation* of the absolute growth rate, over all tested parameter ranges. Streaks therefore do not seem to promote the occurrence of self-excited oscillations in jets.

TAILS OF TURBULENT SPOTS IN SHEAR FLOWS

Pavan KASHYAP*[1], Yohann DUGUET [1], and Matthew CHANTRY[2]
[1]LIMSI-CNRS, Université Paris Saclay, Orsay, France
[2]Department of Physics, Oxford, UK

Summary The far field of localized turbulent patches (spots) and the associated large-scale flow are investigated in various wall-bounded shear flows. A computational study is performed in large periodic domains using the efficient parallel spectral code *Channelflow 2.0*. The large-scale flow generated by the localized spots is observed to be structured according to the symmetries of the laminar base flow. Simulations show that the velocity fluctuations decay algebraically away from the spot, with a decay exponent depending on the structure of the large-scale flow but independent of the Reynolds number.

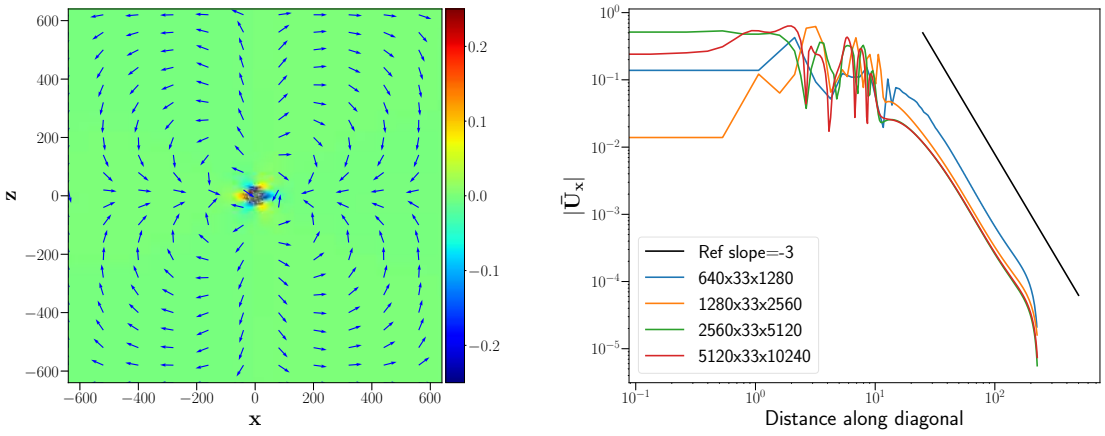
INTRODUCTION

Localized turbulent spots are routinely interpreted as seeds of turbulence in wall bounded shear flows, in a manner analogous to the nucleation of the liquid phase during condensation. They have been studied in numerical simulations [1][2] and experiments for different wall bounded shear flows such as plane Couette flow (pCf) [3][4], plane Poiseuille flow (pPf) [5] and Couette-Poiseuille flow (CPf)[6]. Growth mechanisms have been documented in these studies [7]. Simulations in moderate-sized numerical domains have previously suggested that the tails of localized structures [8, 9] display exponential decay for the velocity field. However proper numerical investigation of the far field of these spots requires even larger domains, necessitating parallel computing. Besides, the impact of the Reynolds number on the behavior for each of these flow cases still remains an open question.

In order to effectively analyse the far field of the spots, numerical simulations have been performed in large domains using the open source parallelized spectral code Channelflow 2.0 (*https://www.channelflow.ch/*). The dimensions of the domain used for the simulations are Lx, Ly, Lz=1280,2,1280 for a spectral resolution of up to Nx, Ny, Nz=5120,65,10240, where x, y and z stand for the streamwise, wall-normal and spanwise coordinates, respectively. A parametric study in the Reynolds number was also performed for pCf, pPf, CPf and for the recently considered Model Waleffe flow (mWf) [10].

RESULTS AND DISCUSSION

The large-scale flow generated by these localized turbulent spots features a quadrupolar structure for pCf and mWf while it exhibits a dipolar structure for the case of pPf and CPf. The tails were found to decay algebraically away from the spot. This algebraic decay is observed over one and a half decade, thereby conclusively characterizing the nature of the tails. The decay exponents have been measured as ≈ -3 for the quadrupolar structure and ≈ -2 for the dipolar structure with negligible error bars. A visualization of the quadrupolar structure for pCf is shown in Figure 1 together with the algebraic decay. The exponents are summarized in Table 1.



(a) (b)

Figure 1: Turbulent spot in plane Couette flow, Re=400 (a) directional vector field for the large-scale flow represented by unit vectors, (b) spatial decay of streamwise velocity along the diagonal $X = Z$ of the domain.

*Corresponding author. E-mail: kashyap@limsi.fr

The quadrupolar flow appears in the cases featuring approximate central symmetry in the plane parallel to the plates, such as pCf and mWf. The dipolar structure, on the other hand, dominates when the bulk pressure gradient driving the flow breaks this central symmetry and the large-scale flow changes its structure accordingly. A parametric study in terms of the Reynolds number (Re) has been carried out for all the shear flow cases (3 different values of Re for each flow case). The exponent is found to be independent of the Reynolds number.

Sl No.	Type of Flow	Structure of Large-scale flow	Decay Exponent
1.	pCf	Quadrupolar	≈ -3
2.	mWf	Quarupolar	≈ -3
3.	pPf	Dipolar	≈ -2
4.	CPf	Dipolar	≈ -2

Table 1: Algebraic decay exponents for in-plane velocities in the far field.

CONCLUSION

The large-scale flow generated by localized turbulent spots in wall bounded shear flows is found to correspond to a quadrupolar structure in pCf and mWf, but to a dipolar structure in pPf and CPf, respectively. Simulations in large domains conclusively show algebraic decay for the velocity tails of these spots in all four wall-bounded shear cases examined herein. The computed exponents are found to be independent of the Reynolds number of the flow.

DYNAMICS OF AN AXISYMMETRICALLY EXCITED JET IN CROSSFLOW

Elijah Harris[1], David D. W. Ren[1], Stephen Schein[1], Robert M'Closkey[1], Luca Cortelezzi[2], and Ann Karagozian[1*]
[1]Department Mechanical and Aerospace Engineering, UCLA, Los Angeles, CA 90095-1597, USA
[2]Department of Aerospace Science and Technology, Politecnio di Milano, Milano, Italy

Summary The present experimental study involves a gaseous jet issuing into a uniform crossflow, where the resulting upstream shear layer (USL) is naturally absolutely unstable. The jet is axisymmetrically excited with sinusoidal, square wave, and multi-pulse square wave temporal waveforms to explore implications of such forcing on structural, mixing, and dynamical characteristics. Analysis of the USL shows evidence of synchronization of the flow to the forcing as the forcing amplitude increases, the critical conditions for which differ amongst the waveforms. These analyses are made via snapshot POD of the velocity field extracted from stereo PIV and time delay embedding of velocity fluctuations along the USL. PLIF imaging is utilized for quantification of excitation effects on molecular mixing, where the synchronized jet is shown to significantly enhance mixing compared with the unforced jet.

BACKGROUND AND CONTEXT OF PRESENT STUDIES

The transverse jet or jet in crossflow (JICF) has been extensively studied in the past due to its numerous engineering applications, especially those pertaining to propulsion systems[1,2]. One main interest of prior studies has been to quantify the rate of mixing between the jet and crossflow for a range of flow conditions[3,4]. In the absence of external excitation, the natural instabilities along the upstream shear layer of the jet transition from a relatively weak convective instability at higher jet-to-crossflow momentum flux ratios (J) to that of a strong pure-tone absolute instability at lower J values[5,6,7]. The critical transition in the USL is seen to occur, for a fixed Reynolds number, as J is reduced below approximately 10 and/or if the jet-to-crossflow density ratio (S) is reduced below around 0.4. The nature of these shear layer instabilities plays a significant role in the overall development of jet vortical systems, structural characteristics, and hence mixing dynamics, particularly influencing the structure of the counter rotating vortex pair (CVP) associated with the jet cross-section[8,9,10]. When the jet is convectively unstable, the weak instabilities result in weaker vorticity rollup along the shear layer, in some cases resulting in cross-sectional asymmetry of the jet and generally poorer mixing, while an absolutely unstable USL, with stronger pure-tone instabilities, typically produces strong vortex rollup along the shear layer, a more symmetric cross-sectional CVP, and improved overall mixing[4].

In controlling the JICF, earlier experimental studies on axisymmetric excitation of the jet indicate that one can significantly augment the spread and penetration, depending on the flow regime[11,12,13]. For a convectively unstable jet at higher J values, the flow readily responds to sine wave or square wave excitation, but for the naturally absolutely unstable jet at lower J values, temporal square wave excitation within a range of prescribed temporal pulsewidths typically has a more significant effect on jet penetration and spread than that of a sine wave[13]. Yet improved jet penetration and spread via square wave excitation is not always associated with improved molecular mixing, as documented via acetone planar laser induced fluorescence (PLIF) imaging[14]. More recently it has also been documented that when axisymmetric sinusoidal excitation is applied, the jet USL can synchronize to the forcing frequency via complex dynamical processes[15], with attendance implications for mixing[16]. For a particular forcing frequency, as the transverse jet's USL becomes absolutely unstable (J is lowered), the forcing amplitude required to synchronize or "lock-in" to the forcing becomes much larger, and in some cases produces states of quasiperiodicity between the forcing and natural instability frequencies.

Building on the above-noted JICF axisymmetric excitation studies, it is of interest to explore the influence of alternative temporal waveforms, including those generating multiple vortex rings which can collide or otherwise interact, to determine the effects on jet dynamics as well as molecular mixing within the flowfield. The dynamics are analyzed through PLIF imaging so that the relationship to changes in structural characteristics and mixing may be made. Proper orthogonal decomposition (POD) of data extracted from particle image velocimetry (PIV) as well as hotwire-based time series analysis also enable investigation of synchronization dynamics under various forcing conditions.

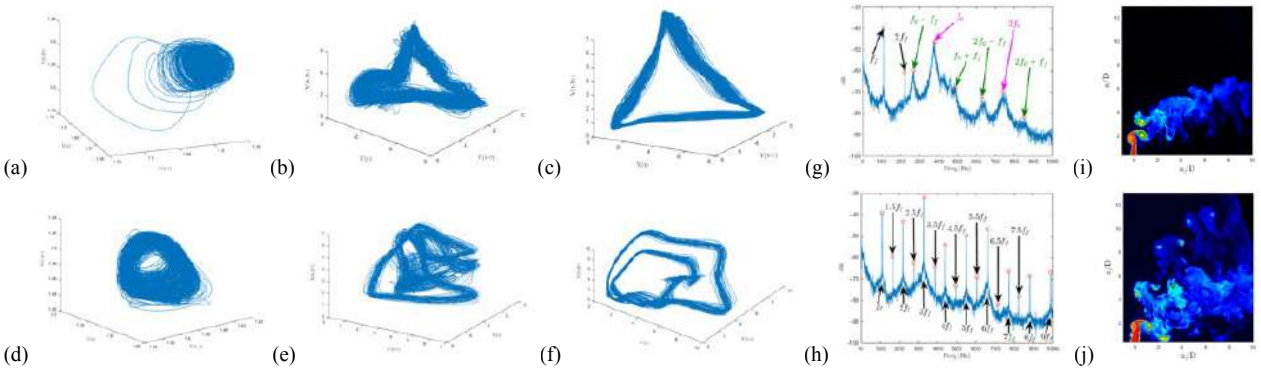
EXPERIMENTAL APPROACH AND SAMPLE RESULTS

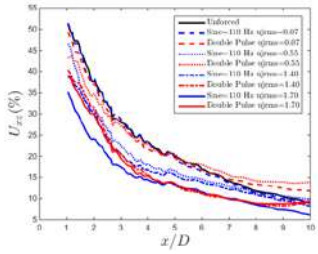
The present experiments are conducted in a low speed air wind tunnel, where the transversely injected, nozzle-generated jet has constituent species consisting of He, N_2, acetone, and DEHS-oil, the latter two of which are tracers for PLIF and PIV imaging, respectively. For the laser diagnostics, a dual cavity Q-switched Nd:YAG laser (Quantel Evergreen 30266) is triggered at rates relative to the excitation frequencies such that phase advancing data are acquired. For the results shown here, the jet Reynolds number is fixed at Re_j=1800, with S = 1 and J=6, corresponding to a naturally absolutely unstable USL. Axisymmetric excitation is applied via a loud speaker mounted in a plenum upstream of the jet nozzle exit. Adaptive feedforward control for the jet excitation system[14] is implemented to enable formation of relatively accurate temporal waveforms, including sine wave, square wave, double or triple pulse square wave (2 or 3 pulses per period with adjustable pulsewidths and amplitudes), and sawtooth waveforms.

Figures 1 (a-f) depict representative phase portraits generated from time delay embedding of the vertical velocity fluctuations measured via hotwire anemometry at 1.5 diameters along the jet USL. Figures 1(a-c) correspond to the sinusoidally excited JICF forced at f_f=110 Hz, while Figures 1(d-f) correspond to an excitation waveform which has two square wave pulses in a single forcing period, where f_f=55 Hz. For each series, the forcing amplitude, quantified by the

* Corresponding author. Email: **ark@seas.ucla.edu**

RMS of the mean subtracted jet velocity ($u_{j,rms}$), increases from $u_{j,rms}$=0.07 m/s to $u_{j,rms}$=1.70 m/s. The sine wave forcing results in a quasiperiodic USL (Fig. 1(a), with a corresponding power spectral density or PSD plot in Fig. 1(g)), and does not lock-in until $u_{j,rms}$=0.55 m/s. In contrast, for double-pulse square wave excitation, even at the lowest forcing amplitude, the jet is already locked-in to the double pulse forcing (Fig. 1(d), with a corresponding PSD plot shown in Fig. 1(h)). As the forcing amplitude increases, the phase portraits for both excitation waveforms become much cleaner, yet more with complex closed loop trajectories and shapes. Interestingly, the double pulse forcing begins to resemble that of a period doubling loop formation (e.g., seen in Figs. 1(e) and 1(f)), though here this could simply result from the two distinct pulses being formed in a single period.





(k)

Figure 1. Resulting effects of axisymmetric jet excitation in a naturally absolutely unstable transverse jet (J=6 at Re_j=1800) with sinusoidal (a-c and g, i) and double pulse (d-f and h, j) temporal perturbations. Phase portraits of vertical velocity fluctuations at 1.5 diameters along the jet USL are shown for $u_{j,rms}$=0.07 m/s (a & d), 0.55 m/s (b & e), and 1.70 m/s (c & f), with a mean jet exit velocity of $U_j \sim 3.4$ m/s. Power spectral density (PSD) plots for forcing at $u_{j,rms}$=0.07 m/s are shown in (d) & (i). Instantaneous centerplane PLIF images for $u_{j,rms}$=1.70 m/s are shown in (i) and (j). Centerplane-based Unmixedness as a function of downstream location x/D for these waveforms with variable excitation amplitudes is shown in (k).

Structural changes in the jet also differ based on different excitation conditions. Instantaneous centerplane PLIF images such as those in Figures 1(i-j) show that sinusoidal excitation produces minimal alteration from the unforced case, even at a larger amplitude, while double pulse forcing substantially bifurcates the jet at the same amplitude. Such images enable quantification of molecular mixing via the Unmixedness parameter[4], where lower Unmixedness corresponds to improved mixing. Downstream Unmixedness evolution shown in Figure 1(k) demonstrates that either of the excitation waveforms can enhance mixing as compared to that for the unforced jet. But at a fixed excitation amplitude, in several cases sinusoidal excitation produces better overall mixing than the double pulse square wave forcing, potentially due to the nature of synchronization of the jet and the sometimes deleterious effects of jet bifurcation on mixing. These and related findings for other waveforms and excitation conditions suggest there may be combinations of excitation parameters, in many cases related to the degree of vortex ring interactions and shear layer synchronization, which may be used to optimize transverse jet dynamics and mixing.

ON THE BOUNDARY-LAYER FLOW OVER A ROTATING CONE: ENERGY EIGENMODE COMPARISONS

Zahir Hussain*[1], Stephen Garrett[2], and Sophie Calabretto[3]
[1]School of Engineering, University of Leicester, Leicester, UK

Summary We investigate boundary-layer flow over a rotating cone by perturbing the mean flow leading to disturbance equations that are solved via a more accurate spectral method involving Chebyshev polynomials. The formulation enables an energy analysis of production and dissipation terms for any eigenmode, which lends further physical insight into the energy signatures within the flow. For both techniques, the results obtained show that reducing the cone half-angle destabilises the flow by decreasing the critical Reynolds number, which lends further support to the authors' earlier hypothesis that an alternative mode is the most dangerous for slender rotating cones. Importantly, favourable comparisons are yielded with existing experiments and theoretical investigations in the literature. Meanwhile, further details will be provided of comparisons with DNS simulations in the pipeline.

INTRODUCTION

There has been considerable research on the flow over rotating geometries, particularly the Von Kármán flow over a rotating disk, which has long been used as a model for flow over a swept-wing, since the early work of [6]. Recently, the stability of rotating boundary layer flows has experienced increased attention in the literature and has been investigated within a wide range of flow setups and variations. In particular, the flow over a rotating cone represents a complex generalisation of rotating disk flow, and involves the introduction of a cone half-angle, which is equal to 90° for a rotating disk. Recently, research on this geometry has accelerated, with theoretical global linear instability [13], numerical simulations [12] and experimental investigation of broad cones [10], which follows on from earlier experimental work on the rotating-disk boundary layer [9]. In this paper, we will build upon the investigation of boundary-layer transition over rotating cones. Specifically, we consider a family of rotating cones in still fluid, with major emphasis on the parameter values represented by the crossflow instability, for which the cone half-angle ψ is large, typically greater than 40° and less than 90°. Conversely, cones with half-angles in the parameter regime less than 40° are referred to as slender cones, where the boundary-layer flow is instead susceptible to a centrifugal instability [8]. In particular, following recent findings, we focus on the changing nature of the dominant instability mechanism, which has been observed to transition from crossflow to a centrifugal instability mechanism as the half-angle is reduced from 90°. The methods used in this study develop a linear stability analysis of the full disturbance equations via a spectral numerical code, which is subsequently used to analyse the energy production and dissipation terms for the crossflow instability modes. The approach follows that of [2] for a compliant rotating disk, and has been verified successfully for related investigations on the rotating disk by [1].

ENERGY ANALYSIS

Continued and long-standing research on the rotating disk, in particular by the late Prof. Carpenter and co-workers has led to the possibility of analysing energy production and dissipation terms for any eigenmode. The energy analysis of [2] for a rotating disk enables the calculation of various energy sources using the Chebyshev–tau technique. It should be noted that the various energy production and dissipation terms identified represent the various energy signatures, namely: (i) the Reynolds stress energy production terms, P_i; (ii) the viscous dissipation energy removal term, D; (iii) the pressure work term, PW_i; (iv) contributions from work done on the wall by viscous stresses, S_i; (v) terms arising from streamline-curvature effects and the three-dimensionality of the mean flow, G_i. The total energy, TE, is then given by the sum of these individual contributions, which are either positive (production) or negative (dissipation). The method facilitates an accurate quantitative analysis of the energy as it passes through the flow, and has been applied successfully to the flow over rough rotating disks by [3, 5], as well as for the BEK family of flows by [1].

In figure 1, we present an analysis of the various significant energy source terms for a range of ψ as it is decreased from 90° to 20°. Positive values indicate energy production, whereas negative values denote energy dissipation, with the sum of each source term giving the total mechanical energy (TE), which is normalised to ensure consistent comparisons of energy production and dissipation. From the results, we observe that there are two major contributors to the energy signature of the flow over a rotating cone in still fluid, most notably the Reynolds stress energy production term P_2 and the viscous dissipation energy removal terms D. The overall total mechanical energy TE is positive. Meanwhile, there is a small contribution to energy reduction attributed to terms arising from streamline-curvature and the three-dimensionality of the meanflow, such as G_1, but in general other contributions are negligible compared with P_2 and D.

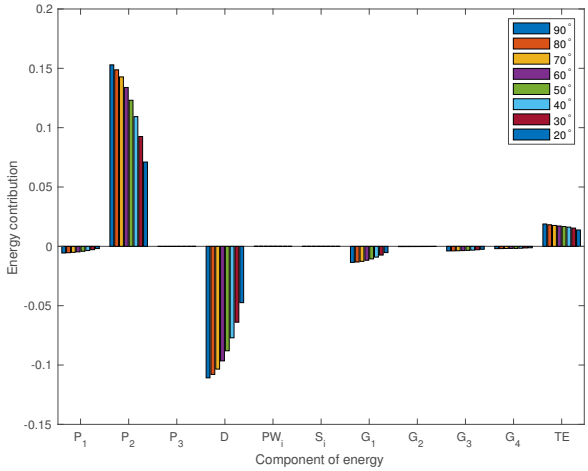

Figure 1: Energy distribution of the Type I mode with maximum total energy at 25 units of Reynolds number from the mode's onset for a range of values of ψ. Energy bars move from left to right for each source of energy as ψ is reduced from $90°$ to $20°$. Contributions from P_3, PW_i, S_i and G_2 are non-zero but negligible.

CONCLUSIONS

We discuss the variation of energy sources as ψ is decreased from $90°$ to $20°$. While the Reynolds stress production term P_2 and viscous dissipation terms D dominate the overall energy distribution, the difference between energy generated and dissipated remains positive $TE > 0$ corresponding to unstable disturbances. Furthermore, TE decreases only marginally with reduced ψ. However, we see very rapidly decaying values of P_2 and D with reduced ψ. Essentially, the dominant energy signatures are leaving the crossflow 'type I' disturbance mode as ψ is decreased, with minimal overall difference. As less energy is produced by P_2, in similar fashion less energy is dissipated by D. We may ask the question, where has this energy moved to? Physically, energy is transferred between the base flow and type I disturbance mode, and it appears that, as ψ is reduced, less energy is produced and dissipated. Therefore, it may be that these energy signatures move into an alternative mode, such as that identified by [7, 8] for slender rotating cones. Hence, we propose the hypothesis that these energy signatures move from interacting between the base flow and type I mode to instead interacting between the base flow and an alternative mode governed by the centrifugal instability mechanism, as described mathematically in [7] and [8]. It can be argued that this finding yields possibly stronger evidence of the emergence of the alternative mode as ψ is decreased than the previous argument based on the reduction in growth rates observed in [4]. Such findings are in agreement with developing DNS simulations in progress, which show the gradual reduction of modal energies as ψ is reduced from $90°$. Furthermore, we observe contrasting behaviour as ψ is decreased below the critical value of $40°$ as the modal energies gradually increase. This interesting finding may indicate the strengthening of the hypothesised alternative centrifugal mode below $40°$ and as such requires further careful investigation.

THE EFFECT OF LARGE PARTICLES ON THE LAMINAR-TURBULENT TRANSITION

Willian Hogendoorn*[1], Bidhan Chandra[1], and Christian Poelma[1]
[1]Multiphase Systems (3ME, P&E), Delft University of Technology, Delft, The Netherlands

Summary In this study the effect of finite size particles on laminar-turbulent transition in pipe flow has been investigated. In particular the influence of particle concentration and diameter on the behaviour of turbulent puffs is studied, which has not been investigated in depth before. Particle Image Velocimetry is applied in addition to pressure drop measurements in order to quantify the flow field around the particles. By using Particle Tracking Velocimetry the velocity of the finite size particles is measured. At the same time, the local particle concentration is measured as well. These unique and synchronous measurements gives us a complete picture of the effect of particles on the change in transition behaviour.

INTRODUCTION

Transition to turbulence in pipe flow has been extensively studied since Reynolds discovery in 1883. Also polymer addition to (pipe) flows and the drag reduction it realises has been studied in depth as well. Less attention, however, has been given to the laminar-turbulent transition of particle-laden flows. Particle-laden flows are very relevant, as these flows are ubiquitous in nature and industry. Recently [1, 2] it has been shown that particles completely alter laminar-turbulent transition behaviour. For higher particle concentrations, a gradual transition is observed, without turbulent puffs in the intermittent region. This is different compared to the classical, single-phase transition. The results we present, involve a more detailed analysis of particle induced transition behaviour. For this study relatively big particles are used to increase the particle-to-pipe diameter ratio, in order to investigate the effect of particle diameter on this change in transition behaviour. In addition, by using relatively big particles, Particle Image Velocimetry (PIV) is feasible to obtain flow field characteristics.

EXPERIMENTAL SETUP

Experiments are performed in a slightly adapted version of the setup which is described in [1]. In short, a 1-cm diameter pipe (D) with a total length of 310D is used. Salt (Na_2SO_4) is added to the water to match the densities of the fluid and the polystyrene particles. The flow is pressure driven by means of an overflow tank. An orifice plate, comparable with Wygnanski et al. [3] is used as a trigger mechanism. After this trigger there is 125D development length, followed by the measurement section. A schematic of this measurement section is shown in Fig. 1. At first a pressure drop measurement over 125D is applied (Δp_1). This Δp_1 is used for average pressure drop measurements. Another pressure drop measurement (Δp_2) is performed directly after Δp_1. As this pressure drop sensor is used to measure local pressure fluctuations, the differential distance is 5D. For low particle concentrations, Particle Image Velocimetry is applied to measure the velocity field around the particles and the corresponding disturbance which is introduced by the particles. In addition to the laser light sheet, LED back-illumination is used. By doing so, the velocity of the finite size particles can be determined by using Particle Tracking Velocimetry (PTV). Moreover, by identifying all the finite size particles in the camera image, the local particle concentration (ϕ) is measured synchronously.

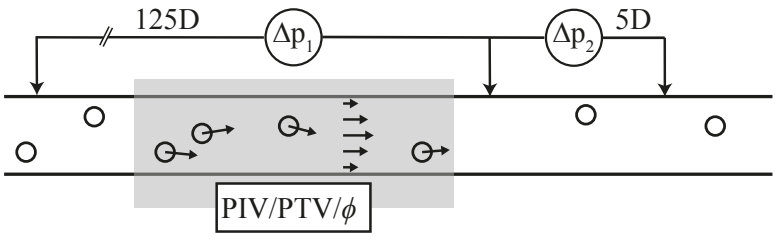

Figure 1: Schematic of the measurement section of the experimental setup. Two different differential pressure sensors are used, which measure the pressure drop over 125D and 5D, respectively. A few diameters before Δp_2, Particle Image Velocimetry, Particle Tracking Velocimetry and a concentration measurement is applied.

RESULTS

A typical result for the streamwise centerline velocity, the corresponding local particle concentration and the pressure drop (Δp_2) as function of τ, for a transition flow is shown in Fig. 2. Here, τ is defined as $t\frac{\overline{u}}{l}$, where t is the time, $\overline{u}$ is the mean flow velocity and l is a typical length scale, for which we used 20D. Note that the pressure drop data is

*Corresponding author. E-mail: W.J.Hogendoorn@tudelft.nl.

recorded after (spacewise) the PIV and concentration data. However, by correcting the pressure drop data with the mean advection velocity of the flow and the spatial lag, all three measurements can be regarded as being measured at the same location. Because the spatial lag is only a few diameters, it is assumed by using Taylors frozen turbulence hypothesis that the structure of the flow remains similar. The maximum particle concentration (center panel) in this time series occurs for $\tau \approx 5$. At the same time, a drop and rise of the centerline velocity (upper panel) can be observed. This drop and rise of the centerline velocity resembles a characteristic sawtooth shape which is typical for a puff (see e.g. [1, 4]). In the timeseries for the pressure drop (bottom panel) also a characteristic fluctuation, which is corresponding with a passing puff, can be seen.

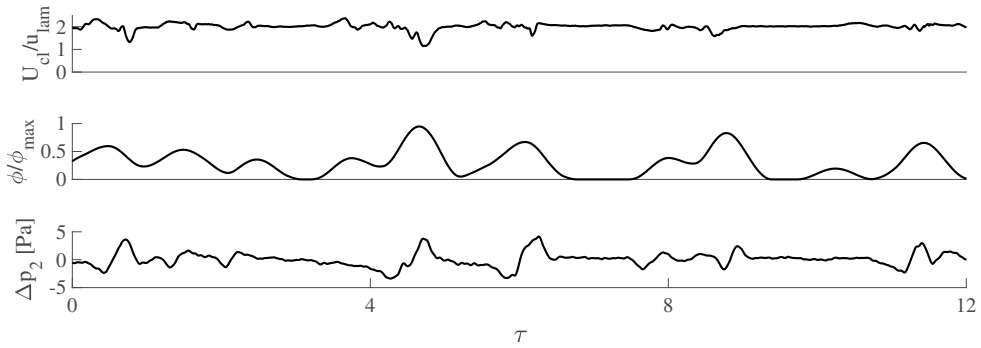

Figure 2: Steamwise centerline velocity, particle concentration and pressure drop signal as function of dimensionless time, τ.

In addition to the synchronous timeseries from Fig. 2, PIV data is recorded. An instantaneous flow field, corresponding with $\tau \approx 5$ in Fig. 2 is shown in Fig. 3. The color of the vectors represents the radial velocity component. This flow field is superimposed on the particle image in which the finite size particles appear in black. From the particle image, the particle position, velocity and concentration can be determined. The results of this data processing will be presented at the Congress.

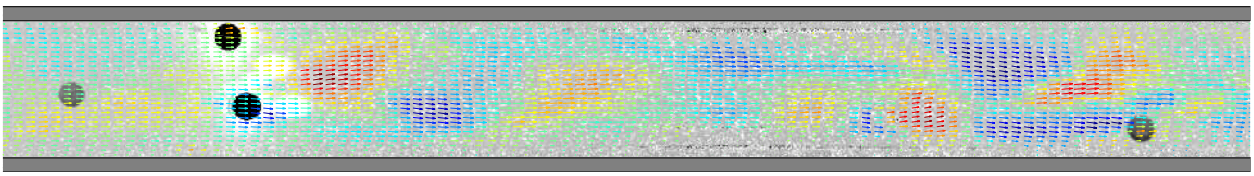

Figure 3: Instantaneous flow field of a typical puff in a dilute suspension, corresponding with $\tau \approx 5$ in Fig 2. This flow field is superimposed on the particle image, in which the finite size particles appear in black. The color of the vectors represents the radial velocity component.

CONCLUSIONS

Experiments are performed in particle-laden, transitional pipe flow. The effect of relatively big particles on the change in laminar-turbulent transition behaviour is investigated by using different, combined measurement techniques. Synchronous velocity, concentration and pressure drop measurements are performed. Particle Image Velocimetry is applied to measure the overall flow field and Particle Tracking Velocimetry is used in addition, to obtain the velocity of the particles. Combining all the data gives us a wealth of information about the effect of particles on the change in transition behaviour.

FRACTAL NEUTRAL STABILITY CURVES IN TAYLOR'S THREE-LAYERED FLOW

Jonathan J Healey*[1]
[1]Department of Mathematics, Keele University, Keele, Staffs. ST5 5BG, UK

Summary In 1931 Taylor published a pioneering study of the linear stability of stratified shear layers, i.e. horizontal flows where gravity is in the vertical direction, and fluid density varies vertically. The resulting buoyancy term is important in many geophysical applications. In one example, Taylor considered a uniform shear with three layers, each of constant density, with densities increasing downwards, and showed that this flow is unstable. We revisit this flow, but with smoothed density profiles, thus including effects of density diffusion neglected by Taylor. This minor change is shown to create infinitely many new instability modes, and their neutral curves have a self-similar fractal structure, even though they are determined by the linear Taylor-Goldstein equation. We indicate how the presence of such a structure may influence laminar-turbulent transition scenarios.

INTRODUCTION AND PROBLEM FORMULATION

Fractal behaviours are usually associated with nonlinear dynamical systems, so it is of interest to observe that they can also be produced by linear stability equations arising in hydrodynamic stability theory. The Taylor-Goldstein equation, see [1], describes the stability properties of linearized inviscid waves in horizontal parallel shear layers of Boussinesq fluid where density varies in the vertical direction, which is a common scenario in geophysical flows. It can be written

$$(U-c)\left[v''-k^2v\right]-U''v-\frac{g\bar{\rho}'\sec^2\phi}{\bar{\rho}(U-c)}v=0, \tag{1}$$

where $U=U(y)$ is the basic velocity in the x direction, $\bar{\rho}=\bar{\rho}(y)$ is the basic density profile, g is acceleration due to gravity, k is the magnitude of the wavevector, ϕ is the waveangle ($\phi=0$ for two-dimensional waves), c is the complex phase velocity, $v=v(y)$ is the vertical component of the disturbance velocity, and primes denote differentiation with respect to the vertical coordinate y. In homogeneous flow, where $\bar{\rho}'=0$ everywhere, (1) reduces to the Rayleigh equation. However, the presence of $\sec^2\phi$ in the buoyancy term shows that buoyancy effects are important for highly oblique waves with $\phi\to\pi/2$, even when $\bar{\rho}'$ is small.

Although (1) has been studied in detail for many years, and for many geophysical flows, the author recently observed a new phenomenon for this equation (and perhaps for linear ordinary differential equations in general), in which the neutral stability curves were found to have an underlying fractal structure, see [2]. Plane Couette flow was considered, and $\bar{\rho}'/\bar{\rho}$ was taken to be a quadratic function of y. In the present paper we investigate whether such unusual behaviour occurs in other flows, especially in flows of practical importance. We also suggest mechanisms whereby the fractal structure of the linear stability problem might produce novel laminar-turbulent transition scenarios.

We consider a flow first introduced by Taylor in his 1931 paper, [1], in which the flow is an infinite uniform shear, with two interfaces where there are step changes in density, as shown in figure 1(a). Taylor used this example to illustrate how even stable stratification ($\bar{\rho}'\leq 0$ everywhere) can destabilize an otherwise stable flow. In fact, this flow turns out to be a useful model for flows encountered in the ocean, where a well-mixed layer of intermediate density lies between a less dense upper layer and a more dense lower layer, see [3], and references therein. The instability resulting from a shear flow with this density structure is sometimes called the Taylor-Caulfield instability.

Suppose that a dynamical process at an earlier time has resulted in the layered structure described by Taylor, but the fluid is now at rest. Allowing diffusion of density across the originally sharp interfaces results in a density profile like that in figure 1(b). When the total density change is small, the buoyancy coefficient, $-\bar{\rho}'/\bar{\rho}$, has a profile like that in figure 1(c), which can be conveniently modelled by

$$Ri(y)=-\frac{g\bar{\rho}'}{\bar{\rho}U'^2}=\left(Ri_0+Jy^2\right)\mathrm{e}^{-y^2+y_0y}, \tag{2}$$

where Ri is the local Richardson number (a dimensionless quantity formed from a ratio of buoyancy frequency and shear) and U' is the constant shear. Subsituting (2) into (1) and imposing homogeneous boundary conditions, $v\to 0$ as $y\to\pm\infty$, gives an eigenvalue problem for c, with instability if $\mathrm{Im}(c)>0$ for $k>0$. When $y_0=0$, Ri is symmetric about $y=0$, and when $y_0\neq 0$ the density jumps across each interface are different, as in the cases shown in figure 1. We consider $J>0$ and $Ri_0\geq 0$, giving stable stratification.

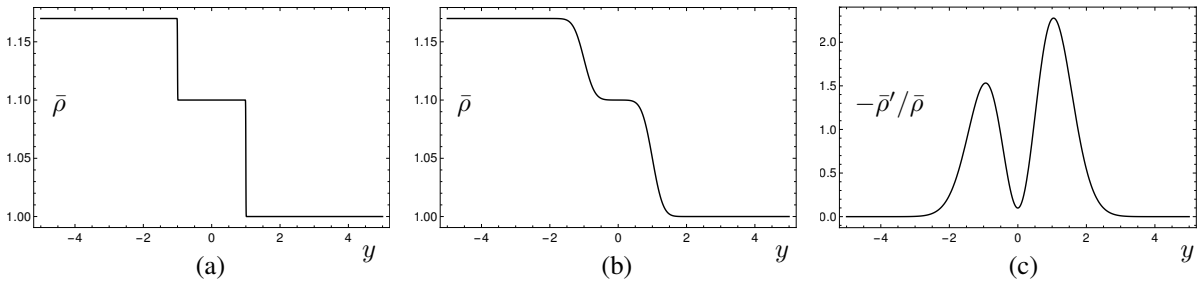

Figure 1: (a) Step density profile for Taylor's flow; (b) density for Taylor's flow with diffusion; (c) qualitative variation of buoyancy term for profile (b).

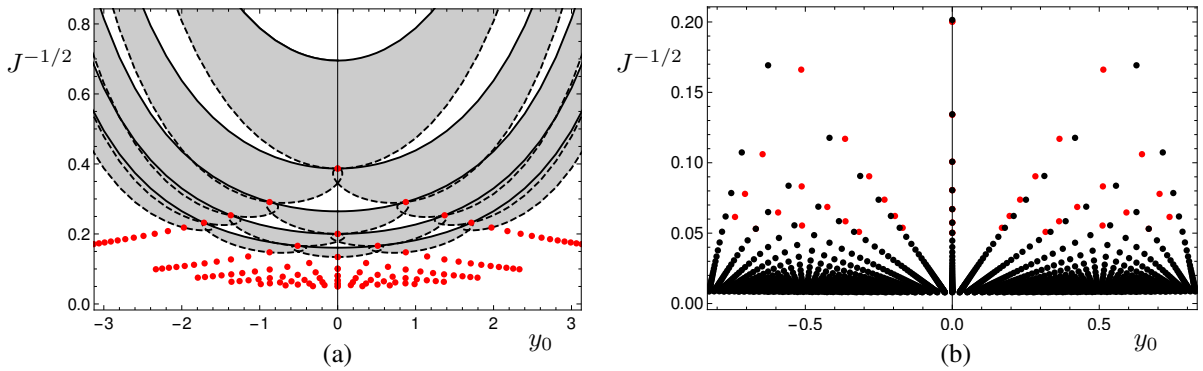

Figure 2: (a) Neutral curves for $k = 1$, $\phi = 0$, $Ri_0 = 0$. Solid lines have $c = 0$; dashed lines have $c \neq 0$; red dots are points where three different neutral curves cross each other. (b) Red dots as in (a); black dots are asymptotic predictions for the red dots where neutral curves cross each other based on WKB theory when $J \gg 1$ and $|y_0| \ll 1$.

RESULTS AND CONCLUSIONS

Note that the step density changes in figure 1(a) allow dispersion relations to be derived analytically, giving a quartic in c, see [1]. But the smooth density profile in figure 1(b) supports arbitrarily many unstable modes when $J \sec^2 \phi$ is large. This case has been solved numerically, and neutral curves are shown in figure 2(a). The following pattern can be observed: Working down from the top of the diagram, there is one large unstable region below the top solid neutral curve, there are two unstable regions below the second solid neutral curve, there are three unstable regions below the third solid neutral curve, etc. There is one red dot along the second solid neutral curve, there are two red dots along the third solid neutral curve, there are three red dots along the fourth solid neutral curve, etc. This pattern has been verified numerically down to the fifth solid neutral curve. A numerical search procedure has been developed for locating the points where three neutral curves cross, marked by red dots, and many more of these points have been obtained than the neutral curves themselves.

A WKB theory has been developed for obtaining asymptotic solutions to (1) with (2) for $J \gg 1$ and $|y_0| \ll 1$, and this theory produces explicit expressions for J and y_0 at the red dots. These predictions are shown in figure 2(b) as black dots. These black dots follow the same fractal pattern found in [2], and predict the positions of red dots more and more accurately as J increases and $|y_0|$ decreases, i.e. towards the origin of figure 2(b).

In the presentation we also show neutral curves in the wavenumber plane for fixed sets of profile parameters with streamwise wavenumbers and spanwise wavenumbers on the axes. There are multiple bands of unstable wavenumbers, with the number of unstable regions increasing from one for $Ri_0 \to 1/4$, to arbitrarily many as $Ri_0 \to 0$. By adjusting profile parameters we can tune resonant wave interactions involving any desired number of resonant waves. This gives the possibility of novel weakly nonlinear amplitude equations that may produce chaotic spatio-temporal dynamics.

In this paper we have shown that the fractal behaviour found for a special flow in [2], also appears in a diffused version of Taylor's three-layered flow, and so can be expected in a variety of flows of practical importance. The associated multiple unstable bands in wavenumber planes can generate many types of weakly nonlinear behaviour which may be important in the laminar-turbulent transition of these flows.

DECAY AND SPLITTING PATHWAYS IN TRANSITIONAL CHANNEL FLOW

Sébastien Gomé*[1], Laurette Tuckerman[1], and Dwight Barkley[2]
[1] Laboratoire de Physique et Mécanique des Milieux Hétérogènes (PMMH), CNRS, ESPCI Paris, PSL Research University, Sorbonne Université, Université Paris Diderot, Paris 75005, France

Summary Transition to turbulence in shear flows is characterized by intermittent laminar-turbulent patterns, which statistically proliferate or decay depending on the Reynolds number. We study the time evolution of turbulent bands in a tilted plane channel flow geometry via direct numerical simulations using pseudospectral code ChannelFlow. Turbulence decay or spreading processes are exponentially distributed, which is the signature of a memoryless process. Statistically estimated time scales for decay or splitting of a band are plotted as a function of the Reynolds number and lead to the estimation of a critical Reynolds number $Re_{\mathrm{cross}} \simeq 950$, with an associated time scale of 10^6 advection times. With such a large time scale, the use of statistical mechanics methods such as the rare event approach is necessary to evaluate the mean decay or splitting time. Spectral analysis of a band during a decay or a splitting event is helpful to determine the stochastic pathway followed by a turbulent band, and to disentangle deterministic and stochastic behaviors during laminarization.

STATISTICAL TEMPORAL EVOLUTION OF A TURBULENT BAND

Transition to turbulence in wall-bounded flows follows a globally subcritical route far below the Reynolds number at which laminar flow linearly destabilizes. For plane channel, plane Couette or pipe flows, turbulence is sustained after finite amplitude perturbations, and takes the form of intermittent turbulent-laminar patterns. In a pipe, these turbulent puffs are shown to be metastable. They can decay or split obeying stochastic mechanisms [1]. In planar shear flows such as plane Poiseuille or Couette flows, the intermittent turbulence takes the form of oblique bands in the streamwise-spanwise plane. Direct numerical simulations of plane Couette flow in a slender but long tilted domain show that transition also follows the 1D Directed Percolation class, and that turbulent bands are memoryless as their lifetimes or splitting times are exponentially distributed [2]. The characteristic time scales for decays (τ^d) or splittings (τ^s) depends on the Reynolds number Re. A critical Reynolds number can be defined at the crossing of the two curves $\tau^d(Re)$ and $\tau^s(Re)$. In pipe and plane Couette flows, these critical Reynolds number are respectively approximately 2000 and 325.

Direct numerical simulations of plane channel flow are carried out in an oblique geometry, via the pseudo-spectral code ChannelFlow. A statistical study of band decay or splitting is performed in a long ($L_z = 100h$) narrow ($L_x = 6.6h$) domain, tilted with an angle $\theta = 24°$ with the streamwise direction (h denotes the half-gap between the two rigid plates) [3]. Snapshots from an a band at $Re = 1050$ are used as initial conditions for simulations at higher or lower Re. Decay or splitting are observed to occur at times that are exponentially distributed:

$$P(\text{decay or splitting at T} \geq \text{t})) = \exp(-(\text{t} - \text{t}_0)/\tau^{\text{d/s}})$$

The slope of the distribution $\tau^{d/s}(Re)$ for decay or splitting cases is estimated via a maximum likelihood estimator, and its dependence on Re is shown on Figure 1. Time scales seem to follow super-exponential trends, and their crossing point is estimated to be $Re_{\mathrm{cross}} \simeq 950$.

The trend $\tau^{d/s}(Re)$ is similar to the one obtained in pipe flow [1], and differs from that of plane Couette flow [2]. This could be due to their inherent different local shear rates, especially near the walls, which could induce more sustained turbulent rolls in channel flow.

Since time scales are very large, computing the statistical evolution of the band is presumably expensive between $Re = 900$ and 1100. Therefore, a rare event approach is desirable to bridge the gap between these Reynolds numbers. This requires adequate score functions to measure the distance between a state A (*e.g* a turbulent band) and another state B (*e.g* the laminar state), in order to select preferentially trajectories between A and B.

TRANSITION PATH DURING SPLITTING AND DECAY EVENTS

A turbulent-laminar pattern in plane channel flow acts as a metastable state, which can either transit to the laminar state (decay), or to another pattern with a different wavelength (splitting). The evolution of the flow field during these transitions is monitored via spectral quantities, which are obtained through Fourier transforms. Large-scale structures are characterized by spectral coefficients $\hat{u}_{0,1}$ and $\hat{u}_{0,2}$ which respectively represent a one and a two-band structure.

Laminarization of a turbulent band is shown to proceed by a sharp disappearance of small-scale structures (streaks and rolls) and by a slow decay of the one-band pattern $\hat{u}_{0,1}$, which becomes prominent after a specific time.

Figure 2a presents the decay process for different initial conditions, with a shifted time t^* so that each final t^* is the same in all the cases. For all the simulations, $\hat{u}_{0,1}$ collapse to the same exponential slope at the end of the decay

*Corresponding author. E-mail: sebastien.gome@espci.fr

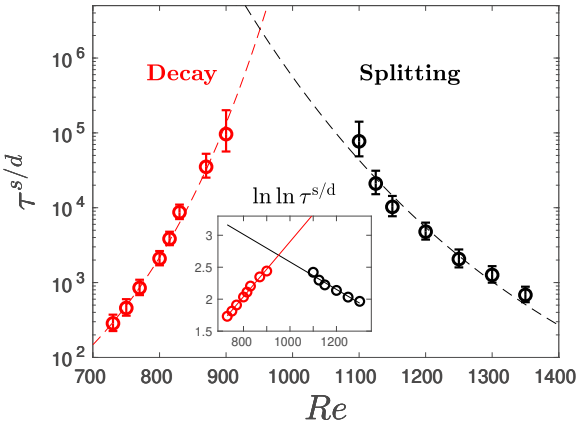

Figure 1: Evolution of mean lifetimes (red) and splitting times (black) with Reynolds number Re. The error bars correspond to 95% confidence intervals for the estimated parameter τ. Insight: $\ln\ln\tau^{s/d}$ versus Re and associated linear interpolations.

process. This is also the case for $\hat{u}_{0,2}$, but with an expected higher slope. Each spectral quantity undergoes a loss of effective randomness after a certain time, that differs for each wave number. From this time on, flow structures follow a deterministic route to the laminar state, governed by linear dissipation.

In the case of a band splitting, the system transits from a one-band ($\hat{u}_{0,1} > \hat{u}_{0,2}$) to a two-band pattern ($\hat{u}_{0,2} > \hat{u}_{0,1}$). All simulations seem to statistically follow the same path, as illustrated in Figure 2b: from the one-band attractor (1), $\hat{u}_{0,2}$ decreases and then grows to finally outpace $\hat{u}_{0,1}$. Meanwhile, the third harmonic $\hat{u}_{0,3}$ reaches a maximum nearly at the half of the trajectories, as a result of $\hat{u}_{0,1}$ and $\hat{u}_{0,2}$ interactions. These trends are currently under investigation by applying a rare events approach to turbulent band splitting.

A COMPREHENSIVE STUDY ON THE INSTABILITIES ARISING IN THE WAKE OF A ROTATING CYLINDER

Javier Sierra Ausin*[1,2], David Fabre[1], Vincenzo Citro[2], and Flavio Giannetti[2]
[1]Institut de Mécanique des fluides de Toulouse (IMFT),Toulouse 31400,France
[2]Dipartimento di Ingegneria Industriale (DIIN),Università degli Studi di Salerno,Fisciano (SA),84084,Italy

Summary A complete description of the bifurcation scenario of a uniform flow past a rotating circular cylinder is aimed. Linear stability theory is used to depict neutral curves and analyze the arising unstable global modes. Special emphasis is paid to the identification of bifurcations with codimension higher than one. Three codimension-two bifurcation points are detected, namely a Takens-Bogdanov, a cusp and generalized Hopf, which are closely related to qualitative changes in orbit dynamics. The occurrence of the cusp and Takens-Bogdanov bifurcations for very close parameters (corresponding to an imperfect co-dimension-3 bifurcation) is shown to be responsible for the emergence of multiple steady states. Direct numerical simulations confirmed the presence of homoclinic and heteroclinic orbits which are classical in the presence of Takens-Bogdanov bifurcations. Finally, a weakly nonlinear analysis is accomplished in the neighborhood of the Generalized Hopf bifurcation to determine the fold of two limit cycles of opposing stability in the vicinity the subcritical Hopf bifurcation curve.

INTRODUCTION

The flow past a circular cylinder is one of the classical flow configurations which has long received attention from the fluid dynamics community. This kind of flow has direct implications for flow control by using wall motion and has recently received particular attention [1, 2, 3, 4] .

Linear stability approaches, see i.e. [5, 6], have precised the picture, showing the existence of two separated regions of instability in the (Re, α) plane, where α is the nondimensional rotation rated and Re the Reynolds number. At large rotation rates $\alpha \geq 4.5$, there is a region in the plane of parameters (Re, α) where multiple steady states coexist [5, 7, 8]. It has been conjectured by [7] the fact that multiple steady states collapse into a *cusp* bifurcation point. In the vicinity of *cusp* bifurcation, three coexisting steady states exist. The counting of steady states supports the hypothesis of a *cusp* bifurcation. However, near a *cusp* bifurcation one should not find an unsteady transition as it is the case of Mode II. The presence of a connection between a Hopf bifurcation and a saddle-node is an indicator of other type of codimension-two bifurcation, a 0^2 or *Takens-Bogdanov* bifurcation. Nevertheless, the generic type of this bifurcation does not explain the existence of three steady states. Actually, in the neighbourhood of the onset at which multiple steady states arise, dynamics are driven by the third-order normal form of the unfolding of the TB bifurcation.

Furthermore, it has been identified a third codimension-two point, namely a Generalized Hopf (GH) bifurcation.

PRELIMINARY RESULTS

Cusp-Takens Bogdanov normal form The Cusp-Takens Bogdanov normal form reads:

$$\frac{dy_1}{dt} = y_2, \qquad \frac{dy_2}{dt} = \beta_1 + \beta_2 y_1 + \beta_3 y_2 + \epsilon y_1^3 + c_1 y_1 y_2 - y_1^2 y_2 \tag{1}$$

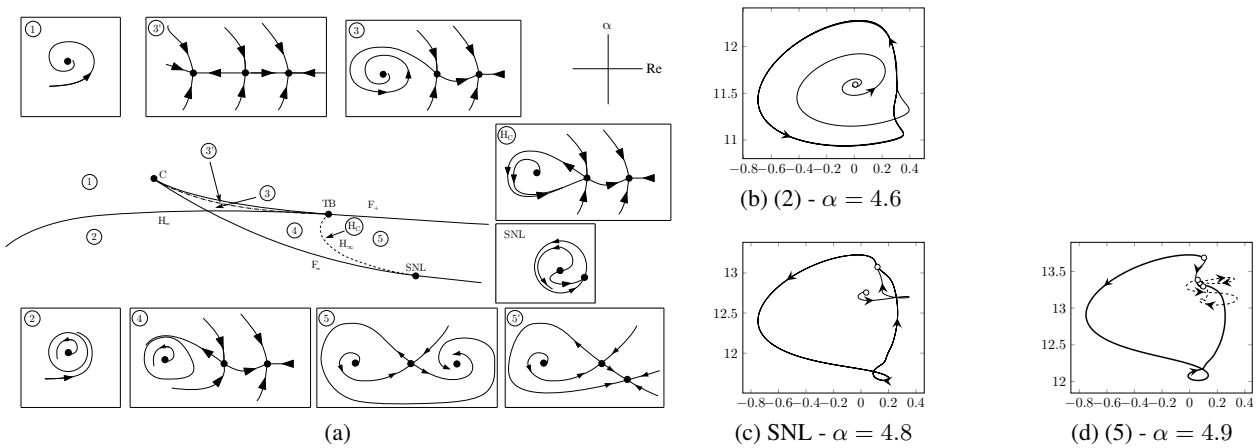

Figure 1: (a) Bifurcation diagram predicted using the normal form 1 in the stable focus case (adapted from [9]), and qualitative phase portrait in regions (1), (2), (3), (3'), (4) , (5), (5') and along curve H_∞. (b-d) Phase portrait (F_x, F_y) of the dynamics of the rotating cylinder at $Re = 170$, where empty dots denote steady state solutions.

Figure 2: (a) Qualitative bifurcation scenario in the vicinity of the GH bifurcation. (b) Comparison of the amplitude of stable (solid line) and unstable (dashed line) limit cycles for three Re_c, where Re_c denotes the Reynolds number at the subcritical Hopf bifurcation. Light grey curve corresponds to $Re_c = 250$, dark grey to $Re_c = 200$ and black to $Re_c = 170$. (c) Strouhal number for each limit cycle is shown.

where β_1, β_2 and β_3 are unfolding parameters (mapped from the physical parameters (Re, α)), c_1 and ϵ (which can be rescaled to ± 1) are fixed coefficients which depend on the nonlinear terms of the underlying system. Note that this normal form Eq. 1 generalizes both the normal form of the standard TB bifurcation (which is recovered for $\beta_1(Re, \alpha) = 0$) and the one of the fold bifurcation (which is recovered for $\beta_3(Re, \alpha) = 0$). The occurrence of both these codimension-2 conditions for very close values of the parameters is characteristic of an imperfect codimension-3 bifurcation and justifies the relevance of the associated normal form.

The dynamics of the normal form has been explored by [9, 10] who classified the possible phase portraits and the associated bifurcation diagrams as a function of the unfolding parameters $(\beta_1, \beta_2, \beta_3)$ along a spherical surface. They showed that all possible bifurcation diagrams fall into three possible categories, called *focus, saddle and node* according to the values of the coefficients c_1 and ϵ. The situation $0 < c_1 < 2\sqrt{2}$ and $\epsilon = -1$ corresponds to the *stable focus case* and is found to lead to a bifurcation diagram Fig. 1. In order to confirm the global stability results, we performed also a parametric study by using time-stepping simulations for several rotation rates at a fixed Re, see Fig. 1 (b-d).

Generalised Hopf bifurcation The governing equation is a Stuart Landau equation, depending on a small parameter $\epsilon^2 = Re_c^{-1} - Re^{-1}$:

$$\frac{dA}{dt} = (i\omega_0 + \epsilon^2\lambda_0 + \epsilon^4\lambda_1)A + (\nu_{1,0} + \epsilon^2\nu_{1,1})|A|^2A + \nu_{2,0}|A|^4A \tag{2}$$

From Eq. 2, a GH bifurcation occurs on the Hopf bifurcation curve and whenever $Re(\nu_{1,0}) = 0$. When $Re(\nu_{1,0}) < 0$ (resp. $Re(\nu_{1,0}) > 0$) the Hopf bifurcation is subcritical (resp. supercritical). The amplitude of the limit cycle $|A|_\pm = \sqrt{-\frac{Re(\nu_1)}{2Re(\nu_2)} \pm \sqrt{\frac{Re(\nu_1)^2}{4Re(\nu_2)^2} - \frac{Re(\lambda)}{Re(\nu_2)}}}$ and its frequency $\omega\pm = \omega_0 + Im(\nu_1)|A|_\pm + Im(\nu_2)|A|_\pm^2$ where $\nu_1 = \nu_{1,0} + \epsilon^2\nu_{1,1}$, $\lambda = \epsilon^2\lambda_0 + \epsilon^4\lambda_1$ are directly computed from Eq. 2 via Weakly NonLinear analysis, see Fig. 2 (b-c). When the Hopf bifurcation is subcritical ($Re(\nu_{1,0}) < 0$) there is a range in ϵ^2 where both solutions are positive real solutions, $|A|_\pm \in \mathbb{R}_+$. The inner unstable (resp. outer stable) limit cycle increases (resp. decreases) its amplitude as the distance from the Hopf bifurcation increases until both periodic orbits collide and disappear, that occurs when $\frac{Re(\nu_1)^2}{4Re(\nu_2)^2} = \frac{Re(\lambda)}{Re(\nu_2)}$.

FROM HYDRODYNAMIC INSTABILITY TO THE ONSET OF LAGRANGIAN CHAOS

S. W. Gepner*[1] and J. M. Floryan[2]
[1]Warsaw University of Technology, Institute of Aeronautics and Applied Mechanics, Warsaw, Poland
[2]Department of Mechanical and Materials Engineering, The University of Western Ontario, London, Canada

Summary It is demonstrated that channel modifications in the form of longitudinal grooves lead to a decrease of hydraulic drag and to the onset of a travelling wave instability at very low Reynolds numbers ($Re < 10^2$). The growth of these waves leads to the formation of saturation states which are both time- and space-periodic and have the form of downstream-travelling vortex pairs combined with periodic, in-plane motions. Secondary flows remain laminar and relatively uncomplicated but result in complex advection patterns leading to chaotic particle trajectories, thus creating the potential for low Reynolds number mixing enhancement. The qualitative and quantitative analyses of particles trajectories demonstrate the onset of Lagrangian chaos and enhanced mixing.

INTODUCTION

The mixing of fluids is a two-stage phenomenon composed of molecular transport processes (such as diffusion and reaction) overlaid on top of mechanical stirring [2]. Molecular transport depends on material properties and is in general slow. The stirring part is due to the kinematics of the flow and its role is to create stretching and folding of material interfaces leading to the increase in concentration gradients and in contact area. This enables the otherwise slow diffusion to act more rapidly and across shorter distances [4]. Consequently, efficient stirring is associated with flow kinematics that results in complicated flow patterns. While flow turbulization is an effective way to achieve such flows [5], its use is infeasible in a number of problems [5], either due to size constraints or the fragile nature of the fluid, e.g., when biological macromolecules are present in the flow. Such flows are typically laminar and their effective stirring remains a challenge.

For laminar flows, effective stirring can be achieved by means of *chaotic advection* [1, 2, 3], a phenomenon in which fully laminar, relatively simple velocity fields (in the Eulerian representation) result in a chaotic response in the Lagrangian view [1, 2]. The high complexity of motion results from the fact that the dynamical system that describes the motion of individual fluid particles might be non-integrable, leading to chaotic trajectories and, consequently, to improved stirring.

The principles of chaotic advection have been applied to various designs and studies (see [3] for an extensive review). Both passive and active methods have been proposed to generate a chaotic response. The former approach relies on the use of obstacles such as bars or blades, wall patterns or various geometry modifications that force turning and redirection of the flow. The latter require external actuation, e.g., some form of stirrers and/or external body forces.

In this work, we propose a new method to induce chaotic advection by means of naturally occurring hydrodynamic instabilities. This method has not been previously proposed to the best of our knowledge [3]. The onset and amplification of the unstable modes eventually leads to a time-dependent saturation state which is still laminar. These instabilities are promoted through the introduction of wall corrugations of different spatial distributions and amplitudes. Geometrical modifications of the conduit geometry place this approach in the passive flow control category. It should be stressed that the mechanism leading to the onset of chaos is due to the flow three-dimensionalization and its non-stationarity rather than due to the flow modifications created directly by the surface grooves.

PROBLEM STATEMENT

Corrugation patterns which are especially suitable for low-Reynolds ($Re < 10^2$) number destabilization leading to three-dimensional, time-periodic nonlinear states that do not cause a large drag penalty are regular grooves oriented in such a manner that lines of constant elevation run parallel to the direction of the flow [6, 7]. The geometry considered here is periodic in the span-wise direction, formed by a sequence of diverging-converging sections as illustrated in Figure 1a. The pattern of surface topography is characterized by the amplitude S and the wave number α, and the mean channel

opening is $2h$. The flow is driven by a specified pressure gradient and, depending on geometrical parameters, can lead to a decrease in hydraulic drag relative to the reference plane Poiseuille flow. Figure 1b illustrates variations of the flow rate Q as a function of the corrugation amplitude for selected corrugation wave numbers.

The growth of an unstable mode activates nonlinear effects which eventually limit the disturbance growth and lead to the formation of a saturation state. The nonlinear saturated state is characterized by a system of three-dimensional vortices with a downstream propagating wave superimposed on them. The resulting three-dimensional flow pattern travels in the downstream direction, resulting in a periodic redirection of the velocity vector. An example of the topology of such a state determined for $(\alpha, S) = (1, 0.4h)$ at a Reynolds number $Re = 110$ is illustrated in Figure 1c. The two vortex pairs travelling downstream are identified by different colours associated with the helicity of the velocity field. These colours identify different directions of vortex rotation. The iso-surfaces of the streamwise velocity component illustrate periodic flow redirection. The formation of the saturated state is accompanied by a slight slowdown of the flow and an overall increase in the hydraulic drag. This process is illustrated in Figure 2a displaying variations of the flow rate as a function of the Reynolds number for a representative geometry $(\alpha, S) = (1, 0.4h)$.

Although the saturated state is rather simple, its three-dimensional and time dependent character more than satisfies the necessary conditions for the onset of chaotic advection [2]. The onset of Lagrangian chaos is verified by tracking trajectories of individual particles advected downstream by the velocity field of the saturated state. Integration of particle paths is performed using the classical RungeKutta (RK4) method, with the numerical error controlled by asserting appropriately small integration time steps. Qualitative insight into the character of the flow is given in Figure 2b, which shows intersections of particle trajectories by planes perpendicular to the streamwise direction taken at selected downstream positions and marked using colours which depend on the initial particle position (at $z = 0$). In this example, the channel geometry is given by $(\alpha, S) = (1, 0.4h)$ and $Re = 110$, with particles initially distributed uniformly within a single periodic section of the channel (top left in Figure 2b). One may observe that the initially straight segment of tracer particles is both stretched and bent, and the particles are eventually uniformly distributed throughout the channel section where they were initially placed, with some of the particles being advected to neighbouring channel sections. Such behaviour indicates that stirring associated with the saturated state results in complex patterns of particle movements and that it is indeed a case of chaotic advection. An attempt to quantify the stirring effectiveness of the saturated state is illustrated in Figure 2c, which shows elongation of the initially straight segment of tracer particles with the downstream distance, with $l(z)$ representing length of the deformed segment reproduced from trajectory intersections at position z and $l(0)$, the initial length.

CONCLUSIONS

The onset of chaotic dynamics is illustrated for the case of a low Reynolds number flow. This onset relies on the formation of a natural flow instability whose growth leads to the formation of a saturated state which is periodic both in time and space. The resulting chaotic advection [1] provides the means for achieving an effective stirring and results in enhancement of transport processes.

EXPERIMENTAL CONFIRMATION OF LINEAR STABILITY ANALYSIS FOR A SUBMERGED JET

Julia Zayko[1], Alexander Reshmin[1], Vladimir Trifonov[1], Linar Gareev[*1], and Vasily Vedeneev[1]
[1]Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary In this study, theoretical and experimental analysis of perturbation growth in submerged air jet is conducted. For the first time for this type of flows the comparison with linear stability theory is done. Both growth rates and wave lengths are measured experimentally. Both branches of growing perturbations are in excellent agreement with theory.

INTRODUCTION

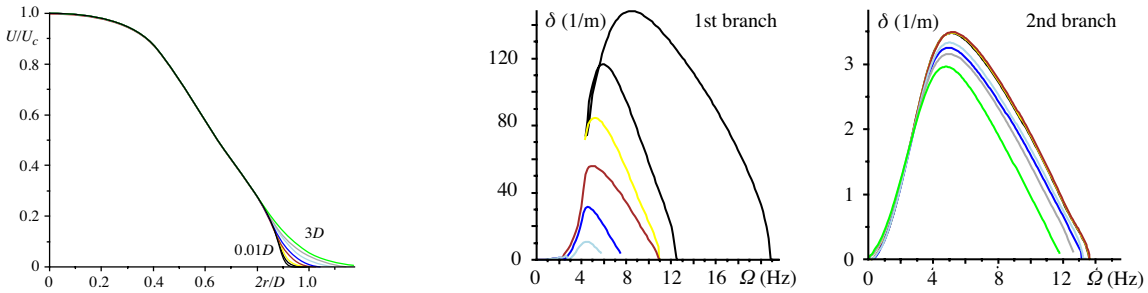
In the linear stability theory of shear flows, only a few classical results have been tested experimentally, e.g. Blasius boundary layer [1, 3], Poiseuille flow in a round pipe [2], the plane Poiseuille flow [4, 5]. Stability of free shear flows, e.g. jets and wakes, and perturbation growth in such flows are much less studied experimentally, because of low critical Reynolds numbers and free jets breakdown near the orifice. Recently, a new method for the formation of laminar jets of $D = 0.12$ m in diameter, which stays laminar at the distance $5.5D$ from the orifice for the Reynolds number $\sim 10\,000$ was proposed [6]. In this study, by comparing experimental results with theoretical stability analysis, we conclude that the perturbation growth follows the prediction of the linear stability theory.

THEORETICAL STABILITY ANALYSIS OF A JET

To theoretically analyse the evolution of artificial axisymmetric perturbations, we performed the spatial stability analysis of the jet.

For each frequency $\omega \in \mathbb{R}$ and azimuthal wave number $n = 0$ the boundary-value problem for the Rayleigh equation defines an eigenvalue problem to find axial wave number $\alpha(\omega, n) \in \mathbb{C}$. Then the perturbation wave length is found as $\lambda = 2\pi/Re(\alpha)$, and $\delta = -Im(\alpha)$ is the perturbation growth rate.

For the considered velocity profiles [6] near the orifice (fig. 1a) two branches of growing perturbations exist (fig. 1b). The first branch is generated by two inflection points farthest from the jet axis, the second one by the infection point closest to the jet axis. The frequency range of growing perturbations is similar for both branches and corresponds to $0 < \Omega < 14$ Hz. The frequencies $\Omega = 4 - 6$ Hz corresponding to the maximum growth are also similar for both branches. However, wavelengths are different (fig. 2a)



(a) (b)

Figure 1: (a) Mean velocity profile for $U_c = 1.5$ m/s ($Re = 5680$) at the distances $x/D = 0.01$, 0.04, 0.1, 0.25, 0.5, 1, 2, 3 from the orifice. (b) Theoretical spatial growth rate δ versus excitation frequency Ω at different distances from the diffuser (color coding corresponds to fig. 1a).

EXPERIMENTAL STUDY OF PERTURBATION GROWTH

Experimental apparatus

In figure 1a jet velocity profiles at different distances x/D from the diffuser are shown; x is the coordinate along the jet axis, U is the velocity component along the jet axis, U_c is the velocity at the jet axis. The jet visualization system consists of laser and video camera. Light-reflecting glycerin particles of ~ 10 μm in diameter are generated at the aerosol generator and introduced to the flow. A segment of the jet is illuminated by the laser light sheet. The image is taken by the camera, whose optical axis is normal to the plane of the laser light sheet (figure 2b). Perturbations are introduced into the jet by a wire ring installing close to the orifice. The ring oscillates with specified amplitude and frequency, which is governed by a controller. Two rings, whose radii are equal to inner and outer inflection point locations, were used.

(a) (b)

Figure 2: (a) Theoretical (color curves) and experimental (points) wavelengths λ versus excitation frequency Ω. (b) Visualization of the jet for different values of the ring oscillation frequency.

Results

We study the perturbation growth in the laminar jet at the Reynolds number $Re = 5680$ (the velocity at the jet axis $U_c = 1.5$ m/s), for which the length of the laminar jet portion in the unperturbed condition is ~ 0.6 m. We aim to show that introduced perturbations with the frequencies from the range $4 - 6$ Hz (corresponding to the theoretical maximum growth rates) grow spatially and yield the maximum shortening of the laminar jet length, whereas, for the frequencies beyond this range the influence of the introduced perturbations on the laminar jet is not as essential.

Visualized flow patterns for various perturbation frequencies are shown in figure 2b. In the absence of oscillations the ring presence in the jet does not affect the laminar region length. The visualization shows that the shortest laminar portion of the jet occurs for the frequencies from the range $4 - 6$ Hz.

Theoretically and experimentally obtained wavelengths are compared in figure 2a for ring radius corresponding to the outer inflection point. Experimental points are close to theoretical curves, thus we may conclude that experimental values are in agreement with modal theory predictions. Experimentally measured growth rates are also in a good agreement with theory.

The analysis of the second mode, excited by a smaller ring is conducted by PIV. Measured wavelenghts are also close to the theoretical prediction.

CONCLUSIONS

An axisymmetric laminar jet stability is theoretically analyzed for the jet profile [6]. For the regime $Re = 5680$, two branches of growing perturbations exist, for both of them growth rates and wavelengths have been studied.

The influence of the perturbations produced by the oscillating ring on the laminar jet is experimentally investigated. It is shown that experimental wavelengths and growth rates of perturbations are in good agreement with linear stability theory predictions.

Summary The modelling and simulation of wave packet and its Mach wave radiation are presented in this paper. It involves a wave packet of instability modes calculated by disturbance equation. And Mach wave radiation field is computed based on a matched-asymptotic-expansion. Reasonable predictions of the acoustic field can be made by present hybrid approach.

INTRODUCTION

The study of jet noise has a long history and received renewed interest in recent years, in particular for the aviation industry. Since the 1970s, the discover of coherent structures opens a way for analysis of the sound-producing mechanisms. Several previous theoretical researches have described that large-scale coherent structures constitute a dominant source of jet noise. Tam & Burton [1] [2] extended linear stability theory into the far field on relates sound to the growth and decay of instability waves in supersonic jet. More Recent work has focused attention on the nonlinear development of instability waves and more complex models, these coherent wave-packets structures were first employed by Avital et al. [3] and reviewed by Jordan & Colonius [4]. Additionally, Wu [5] regarded the nonlinear effects of supersonic instability waves on Mach wave radiation by using a matched asymptotic expansion combined with the multiple scale method, and accounted for the nonlinear spatial evolution of instability waves through nonlinear terms arising from the critical layer. Cheung & Lele [6] analysed a forced two-dimensional shear layer by linear and nonlinear PSE models. The influence of nonlinear mechanisms in sound generation has also been examined by Suponitsky et al. [7].

For predicting the acoustic far field, there are three techniques: directly, an equivalent source base on acoustic analogy, or Kirchhoff surface. But the latter two methods require some prior knowledge about far field sound source. The primary objective of current study is to develop a hybrid approach for analysis and prediction of acoustic radiation process in supersonic jet. In this effort, the nonlinear disturbance equation is employed to simulate the evolution of instability wave packets. Afterwards, we extent the theoretical method that has been previously explored by Wu [5] to compute the associated Mach wave radiation. Results from our current calculations are compared against experiment data and similar DNS calculations for accuracy.

COMPUTATIONAL TECHNIQUE

In this section we provide a brief description of the approach. Conceptually, the domain is divided into two regions: a near-field and a far-field. In near-field, the hydrodynamic motions are dominant, while acoustic propagation has a predominant effect in far-field. An axisymmetric jet is computed from experimental fitting function in [1], for Reynolds number $Re = 70000$, Mach number $Ma = 2.1$, Prandtl number $Pr = 1$. In addition, the steady base flow is artificially excited by particular instability waves, which obtained by linear stability problem defined by Orr-Sommerfeld equation.

$$\phi(x,r,t) = \hat{\phi}(r)e^{i(\alpha x-\omega t)} + c.c \tag{1}$$

The behaviour of the instability waves can be determined through the direct computation of nonlinear, compressible, axisymmetric disturbance equations (2) for the density ρ, velocities u_i, temperature T, and pressure p. The code was developed by our group. Details regarding the simulations are omitted for space reason.

$$\frac{\partial U'}{\partial t}+\frac{\partial E'}{\partial x}+\frac{\partial rG'}{r\partial r}=\frac{\partial E_v'}{\partial x}+\frac{\partial rG_v'}{r\partial r}+k \tag{2}$$

The near-acoustic field is an overlap region, here, the local solution of wave equation matched to the inner hydrodynamic pressure fluctuations, and to the outer, behaviour of propagating acoustic. By theoretical analysing, the radiation process is clear. While a Mach wave front propagates along the characteristics line ζ=constant, its acoustic energy propagates along the other line ξ=constant. For wave packets consist of a train of instability waves, we introduce an extrapolation of integral suggested by Wu [5]. The acoustic pressure in far-field can be determined by the following formula:

$$\hat{p}_0\left(\bar{\xi},\tilde{\omega},\tilde{r}\right)=\frac{e^{-\pi i/4}}{\tilde{r}}\left(\frac{\alpha q^3}{2\pi M_a^2c^2}\right)^{1/2}\ell_\infty\hat{Q}\left(\bar{\xi},\tilde{\omega},\tilde{r}\right)\exp\left\{-\frac{iM_a^2\tilde{\omega}^2\tilde{r}}{2\alpha q^3}\right\}\int_{-\infty}^{\infty}A(\zeta)\exp\left\{\frac{\alpha q^3}{2M_a^2c^2\tilde{r}}\left(\bar{\xi}-\zeta\right)^2\right\}d\zeta \tag{3}$$

RESULTS AND DISCUSSION

The numerical result of pressure contour at a certain frequency was displayed in figure 1. It can be seen obviously that Mach wave radiation (acoustic energy) is highly directivity along a fixed line. One can trace the line back to a location where the "sound emission", which coincides approximately to the saturation of peak frequency. Figure 2 to figure 4 show the results of wave packets with *St=0.3~0.5*, for natural jet and excited jet (excited at *St=0.4*). Comparing with relevant experimental data [8], results are in a good degree of quantitative agreement.

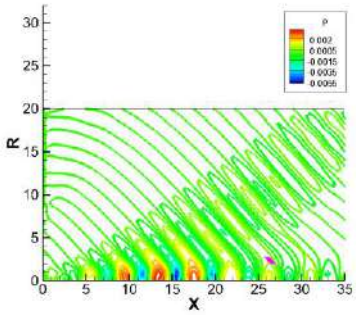

Figure 1. Pressure contour of Mach waves in near-field.

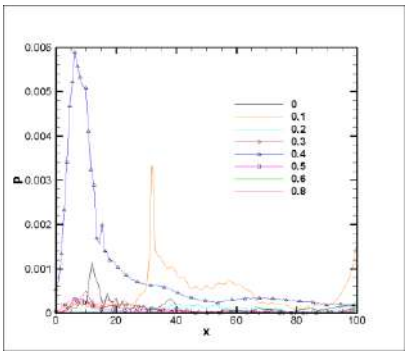

Figure 2. Pressure fluctuations for excited jet.

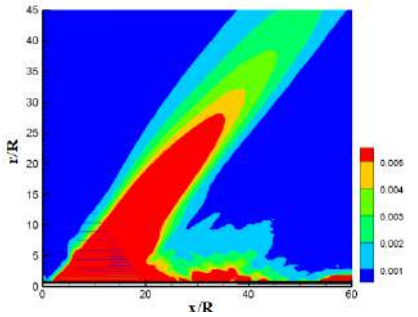

Figure 3. The time-averaged acoustic intensity for excited jet.

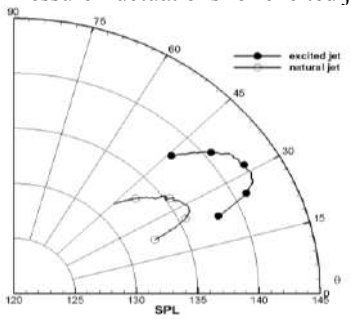

Figure 4. Overall sound-pressure level directivity.

Figure 2 demonstrated that instability with frequencies around *St=0.4* grow initially, then nonlinear effects become apparent. Afterwards the overall fluctuation amplitude attains a saturated situation and spectral content shifts to lower frequencies. This can also be seen in figure 3. Even though spectral are broaden, the downstream lobe pattern is quite directivity. Directivity patterns of noise in downstream region for both excited and natural jet are shown in figure 4. There is a considerable increase in the SPL with excitation for a given frequency, but a very little change in the directivity of radiation between natural and excited jets. This implies that two cases may have same mechanism responsible for noise generation path.

It can be note that present approach can successfully predict the features of Mach wave radiation associated with instability wave packets, quantitatively as well as qualitatively.

A more complete analysis of wave packets and their Mach wave radiations will be presented at the Congress.

OBLIQUE SOLITARY WAVES IN CHANNEL FLOW

Yohann Duguet*[1], Chaitanya Paranjape[2], and Björn Hof[2]
[1]LIMSI, University Paris-Saclay, Orsay, France
[2]IST Austria, Klosterneuburg, Austria

Summary In subcritical fluid flows such as channels and pipes, the way turbulence manifests itself at the lowest possible flow rates has been a long-standing question. It appears possible to sustain turbulent flow in experiments and numerics at much lower values of the Reynolds number Re than previously thought. The flow takes the form of isolated stripes of turbulence oblique with respect to the flow. The angle of these stripes saturates at 45° as Re is decreased towards the critical point of the system. This talk addresses the self-sustaining mechanisms for such complex flows by identifying relative equilibrium and periodic orbit solutions of the full Navier-Stokes equations with analogous properties.

INTRODUCTION

The nature of the simplest non-trivial flow occuring in a channel as the Reynolds number is decreased has remained mysterious for decades. Recently it was established numerically that it consists of isolated stripes of turbulence oblique with respect to the flow, with an angle close to 45° [1, 2]. Equally recently this numerical prediction has been validated in the experimental set-up developed at IST Austria using localised disturbance applied over a finite time (see fig 1).

Figure 1: Experimental realisation of growing turbulent stripe at Re=750 (flow from left to right).

Since the laminar Poiseuille flow is linearly stable, it is desirable to understand which mechanisms cooperate to sustain such non-trivial flow structures. Tollmien-Schlichting waves predicted by linear stability theory at higher flow rates have a radically different spatial structure and are no relevant candidates to explain the growth and nonlinear saturation of oblique turbulent stripes.

NOVEL INVARIANT SOLUTIONS

The appropriate bifurcation scenario rationalising the appearance and sustenance of such oblique turbulent structures has not been clarified yet. We expect it to start from a branch of nonlinear solutions with the following properties : a) spatial localization, b) an oblique orientation with respect to the mean flow, with angles comparable to experimental observations, c) composed of quasi-streamwise vortices and streaks not aligned with the interface. In the present study, we demonstrate numerically the existence of unstable travelling waves satisfying all the above properties at once. These travelling waves form a large family of nonlinear states parametrized by two wavelengths and by their angle with respect to the streamwise direction.

We use a deterministic approach in terms of unstable solutions of the Navier-Stokes equations in a slanted periodic domain, where the angle becomes one of the control parameters [3]. Edge states in the form of localised travelling waves, and their subsequent bifurcations, act as a scaffold for the turbulent dynamics down to very low values of Re consistent with the experimental thresholds. Numerical simulations are based on the freely available code *channelflow.org*. Invariant solutions are identified numerically using edge tracking coupled with a Newton-Krylov method and arc-length continuation. A complete parametric study is performed including their stability, the investigation of their large-scale flow, and the robustness to changes of numerical domain. The solutions display robust spatial localisation as the width of the numerical domain is increased, which demonstrates their relevance to the solitary states identified in experiments. All solutions emerge in saddle-node bifurcations at values of Re lower than the previously found solutions. Relative periodic orbit solutions bifurcating from each branch of travellling waves have also been computed. For each of the solutions found, a large-scale is present parallel to the interface [4]. It coexists with a stripe core dominated by a regular array of quasi-streamwise vortices streaks. Outside the stripe core the streamwise orientation streaks is deviated by the large-scale flow.

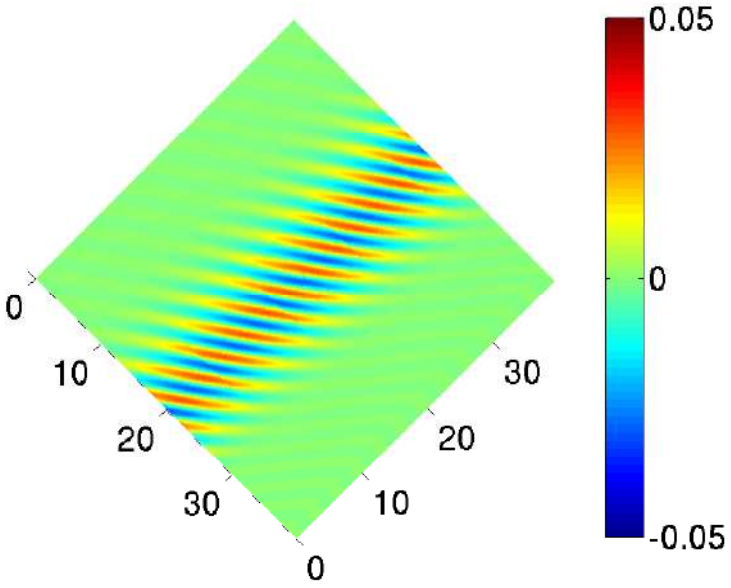

Figure 2: Nonlinear travelling wave solution found with an orientation of 45° for Re=720 (flow from left to right).

CONCLUSIONS

We have presented new families of nonlinear travelling wave solutions of channel flow featuring spatial localization, oblique orientation with respect to the mean flow direction, and streamwise vortices and streaks [5]. All the solutions reported here are linearly unstable although the number of unstable directions is generally very low, ranging from one for edge states up to six for upper branch solutions near their onset. The multitude of possible angles displayed by turbulent stripes falls within the range of angle values where the travelling waves and their bifurcated states exist. A natural question that arises is whether the range of angles of the TWs bears a direct relation to the selection process of stripe angles in turbulent flows.

LOCAL RECEPTIVITY THEORY FOR GENERATION OF INVISCID MODES IN SUPERSONIC/HYPERSONIC BOUNDARY LAYERS

Ming Dong*[1], Yinhui Liu[1], and Xuesong Wu[2]
[1]Department of Mechanics, Tianjin University, Tianjin, China
[2]Department of Mathematics, Imperial College London, UK

Summary This paper studies the receptivity of inviscid first and second modes in a super/hypersonic boundary layer due to the interaction between a freestream acoustic wave and a small isolated surface roughness element. A large-Reynolds-number asymptotic theory is developed, which reveals the key process of the local receptivity. Through parametric study, the dependence of the receptivity efficiency on the relevant parameters is provided. The numerical results are compared with the finite-Reynolds-number calculation and direct numerical simulation, and favourable agreement is achieved for sufficiently large Reynolds numbers. An improved asymptotic theory is further developed to render high-accuracy predictions at moderate Reynolds numbers.

PHYSICAL MODEL AND ASYMPTOTIC SCALING

As is sketched in Fig. 1-(a), we consider a thin flat plate inserting into a supersonic uniform perfect-gas flow, and an isolated roughness element, with a height much lower than the boundary-layer thickness, is located at a distance L downstream of the leading edge. We introduce a sound wave in the freestream, which propagates at an incident angle θ, and simultaneously, a reflection occurs due to the presence of the plate. We define the characteristic length as the boundary-layer thickness at the roughness $\delta = \sqrt{\nu_\infty L/U_\infty}$, where the subscript ∞ denotes the quantities of the oncoming flow, and U and ν represent the velocity and the kinetic viscosity, respectively. The oncoming Mach number M and the Reynolds number R are defined as $M = u_\infty/a_\infty$, and $R = U_\infty\delta/\nu_\infty$, respectively, with a being the sound speed. We are interested in the supersonic regime with $M > 1$, and assume $R \gg 1$.

The roughness height h^* is taken to be of $O(R^{-1/3}\delta)$ or smaller, then the mean-flow distortion is governed by a double-deck structure, consisting of the main layer with $O(\delta)$ width and a much thinner wall layer in an $O(R^{-1/3}\delta)$ vicinity of the wall; see regions I and II of Fig. 1-(b), respectively. A direct consequence is that the mean-flow distortion in the main layer is of $O(hR^{-1/3})$, where $h \equiv h^*/\delta$. Both the freestream acoustic waves and the inviscid Mack modes have phase speeds and frequencies of $O(U_\infty)$ and $O(U_\infty/\delta)$, respectively, and their wavelengths are comparable with the local boundary-layer thickness δ. Therefore, in order to satisfy the 'resonance condition', we take the roughness width to be of $O(\delta)$. Additionally, a thinner Stokes layer driven by the inviscid acoustic wave appears in the $O(R^{-1/2}\delta)$ vicinity of the wall, shown as region III in Fig. 1-(b), which also acts as an active layer in the receptivity process.

Through scaling analysis, the first two orders of receptivity are revealed. (i) The leading-order receptivity is caused by the deformation of the sound-generated Stokes layer by the curved wall. For an acoustic wave with an infinitesimal amplitude $\mathcal{E}_a \ll 1$, the Stokes-layer streamwise velocity near the roughness is amplified to $O(\mathcal{E}_a hR^{1/2})$, in order to satisfy the no-slip condition. The continuity equation indicates that the associated transverse velocity is $O(\mathcal{E}_a h)$, and generates an unsteady outflux of the same size to the main layer. Such a forcing on the main-layer Rayleigh equation leads to the excitation of an inviscid Mack mode with amplitude of $O(\mathcal{E}_a h)$. This process is in principle the same as an canonical receptivity problem induced by an unsteady blowing and suction. (ii) The second-order receptivity is due to the interaction between the acoustic signature and the roughness-induced mean-flow distortion. The roughness induces an $O(R^{-1/3}h)$ steady perturbation in the main layer, where this perturbation interacts with the $O(\mathcal{E}_a)$ acoustic signature, producing a volumetric unsteady forcing of $O(\mathcal{E}_a R^{-1/3}h)$, and simultaneously, an unsteady outflux of the same size is driven from the viscous wall layer.

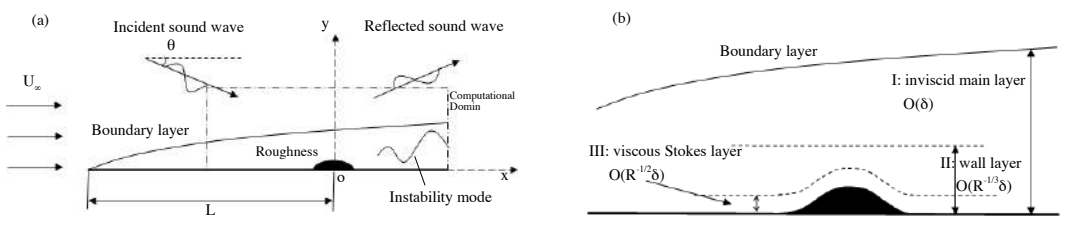

Figure 1: (a): Sketch of the physical model; (b): the asymptotic structure of the receptivity problem.

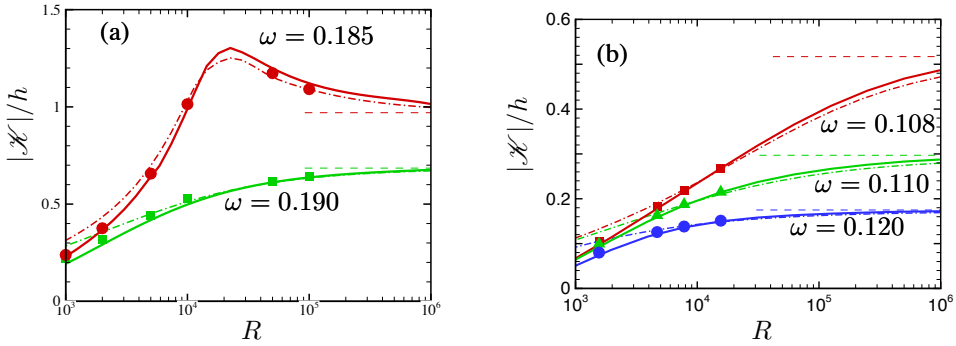

Figure 2: Comparison of the receptivity coefficient to planar fast acoustic waves with wave angle $\theta = 45°$ for $M = 4.5$ (a) and 5.92 (b). Solid lines: finite-R calculations; dashed lines: asymptotic predictions; dot-dashed lines: improved asymptotic predictions; symbols: DNS results.

A LARGE-REYNOLDS-NUMBER THEORY AND ITS IMPROVED VERSION

In the main layer, the flow field ϕ (where ϕ represents any flow quantity) is decomposed as a base flow ϕ_B, a mean-flow distortion $h\bar{\phi}$, an acoustic signature $\mathcal{E}_a\hat{\phi}_a$ and the excited perturbation $h\mathcal{E}_a(\tilde{\phi}_0 + R^{-1/3}\tilde{\phi}_1 + \cdots)$,

$$\phi = \phi_B + h\bar{\phi} + \mathcal{E}_a\hat{\phi}_a + h\mathcal{E}_a(\tilde{\phi}_0 + R^{-1/3}\tilde{\phi}_1 + \cdots). \tag{1}$$

The Fourier transformed perturbations $\hat{\phi}_{0,1}$ are governed by $\mathbf{L}\hat{\phi}_0 = 0$, and $\mathbf{L}\hat{\phi}_1 = \mathbf{F}$, where $\mathbf{L}$ is the Rayleigh operator and $\mathbf{F}$ is the volumetric forcing in the second-order receptivity. Both equations satisfy an attenuation condition at the far field and an unsteady outflux condition at the wall. The Rayleigh operator poles when the frequency and wavenumbers satisfy the dispersion relation of the eigenmodes, and the receptivity coefficient $\mathscr{K}$ is obtained by evaluating the residual contributions from the poles. Such a treatment is the same as that in the finite-R theory[1].

Since the Rayleigh equation is less accurate in a moderate Reynolds number due to the viscous effect, we also develop an improved large-R asymptotic theory, which takes into account the $O(R^{-1/2})$ correction induced by the Stokes layer to the inviscid perturbation in the main layer. In the improved theory, an $O(R^{-1/2})$ term obtained by analysing the transverse velocity of the flat Stokes layer is added in the wall boundary condition of the Rayleigh equation, which predicts a more accurate dispersion relation of the eigenmodes as compared to the Orr-Sommerfeld equation.

NUMERICAL RESULTS

For case studies, we select two typical oncoming Mach numbers, i.e. $M = 4.5$ and 5.92. A systematical parametric study is carried out for the excitation of both the first and second modes by both the freestream fast and slow acoustic waves, and the dependence of the receptivity efficiency on the relevant parameters is provided. Fig. 2 compares the receptivity efficiency to a typical incident acoustic wave obtained by the asymptotic theory (dashed lines), finite-R calculation[1] (solid lines) and direct numerical simulation[2] (symbols). The finite-R calculations agree with the DNS results almost precisely at moderate Reynolds numbers, while in the large-R limit, they approach the large-R asymptotic predictions. Such a phenomenon indicates the consistency of the three approaches. One may criticize the accuracy of the asymptotic theory although it can reveal the intrinsic receptivity mechanism. However, if we improve the asymptotic theory by taking into account the $O(R^{-1/2})$ viscous correction (dot-dashed lines), then the predictions can agree with the finite-R calculations even when R is a few thousands.

CONCLUSIONS

This paper develops a large-R asymptotic theory to predict the receptivity efficiency of supersonic/hypersonic inviscid modes due to roughness-sound interaction. The key receptivity process is clearly demonstrated. Additionally, an improved asymptotic theory that accommodates the $O(R^{-1/2})$ correction from the viscous Stokes layer is developed, which can yield a more accurate prediction on receptivity in comparison with the finite-R theory even when R is a few thousands.

INSTABILITIES AND INTERMITTENCY IN A CUBIC SHEAR-DRIVEN CAVITY

Pierre-Emmanuel des Boscs*[1] and Hendrik C. Kuhlmann [1]
[1]Institute of Fluid Dynamics and Heat Transfer, TU Wien, Vienna, Austria

Summary The incompressible fluid flow confined in a cubic box, driven at the top surface by a constant shear stress is investigated using a spectral-element method. The steady basic flow loses its reflection symmetry through a pitchfork bifurcation at $\mathrm{Re}_P = 53478$, where two steady flows emerge which are antisymmetric to each other. Both asymmetric flows become linearly unstable to oscillatory perturbations at $\mathrm{Re}_H = 55720$, giving rise to limit cycles. At $\mathrm{Re} = 57300$, the limit cycles are destabilized by nonlinear bursts, allowing the system to visit both limit cycles. As in the lid-driven cavity, the transition to turbulence follows a Pomeau–Manneville scenario.

INTRODUCTION

Flows in cavities are of particular interest in fluid mechanics. For instance, the *lid-driven cavity* (LDC) serves as a canonical benchmark for CFD codes, exhibits complex flow patterns, and shows a non-trivial dynamical evolution to turbulence. The transition to chaos in the cubic LDC arises through a slightly subcritical Hopf bifurcation [1] followed by nonlinear bursts [2]. The limit cycles play an important role in the nonlinear dynamics [3] which was further explored considering flow symmetries and finding a Neimark–Sacker bifurcation [4].

The *shear-driven cavity* (SDC) in which a constant stress is prescribed on one boundary, instead of a constant velocity in the LDC, has received much less attention. The SDC serves as an approximation to the flow over an open [5] or liquid-filled cavity [6]. It is also equivalent to a thermocapillary flow in an open differentially-heated cube in the limit of a small Prandtl number, which has some application in open-boat crystal growth. Here we investigate the structure and the dynamics of the flow in the SDC as the shear stress is increased. Of interest are differences and similarities of the scenario with the one in the lid-driven cavity (LDC).

PROBLEM FORMULATION AND NUMERICAL METHODS

We consider the Navier-Stokes equations for an incompressible fluid of density ρ and kinematic viscosity ν confined in a cubic cavity of edge length L. The flow is driven by a constant shear stress τ imposed on one side of the cube and parallel to the edge. The only dimensionless parameter is the Reynolds number $\mathrm{Re} = \tau L^2/\rho\nu^2$ in which the velocity scale $\tau L/\rho\nu$ is derived from τ and the viscous time scale L^2/ν.

The flow is computed using the spectral-element code `Nek5000`. It is based on a $\mathbb{P}_N/\mathbb{P}_{N-2}$ formulation with the polynomial order $N = 6$. The tensor-product mesh is compressed towards all boundaries to be able to resolve the boundary layers on the solid walls and the free surface where the stresses are high. To obtain the basic flow the `BoostConv` algorithm proposed by [7] is used. The implementation of latter algorithm does not require major adaptations of the transient solver as it modifies the flow variables only at some specific time steps. `BoostConv` is typically faster than a selective-frequency-damping approach. To solve the eigenvalue problem which arises in the linear stability analysis the Arnoldi method is employed, using a time-marching technique.

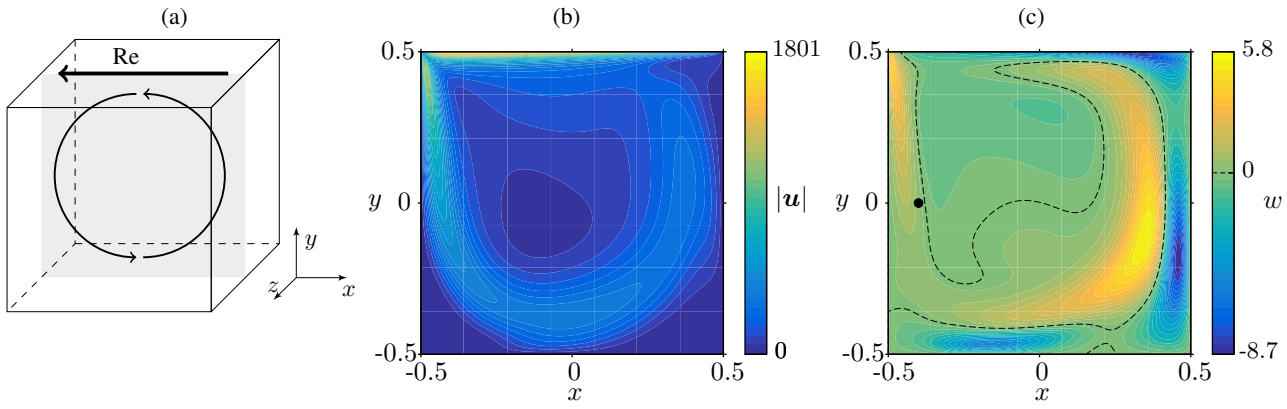

Figure 1: (a) Sketch of the setup. The direction of the shear stress is indicated by the top arrow. The symmetry plane is shown in gray. (b) Velocity magnitude of the basic flow in the symmetry plane $z = 0$ for $\mathrm{Re} = 54000$. (c) Spanwise velocity component w in the symmetry plane $z = 0$ for $\mathrm{Re} = 54000$. RESULTS AND DISCUSSION

Bifurcation scenario

As the Reynolds number is increased a pitchfork bifurcation arises at $\mathrm{Re}_P = 53478$ and the flow loses its reflection symmetry with respect to $z = 0$. Figure 1(c) shows the distribution of the spanwise velocity component of one of the steady asymmetric solution branches in the plane $z = 0$ at a supercritical Reynolds number. As a measure for the symmetry breaking we consider the asymmetry parameter $S = \int_V |\boldsymbol{u} - \mathcal{S}(\boldsymbol{u})|^2 \mathrm{d}V$, where $\mathcal{S} : (u, v, w)(x, y, z) = (u, v, -w)(x, y, -z)$ is the symmetry map. We find $S^2 \sim \mathrm{Re} - \mathrm{Re}_P$ (not shown), which is indicative of a supercritical pitchfork bifurcation. A linear stability analysis of the basic flow confirms the above results of the above numerical simulations. The critical mode is very similar to the deviation of the slightly supercritical finite-amplitude flow from the symmetric flow. The critical mode consists of a single steady Taylor–Görtler vortex, centered on the symmetry plane, whose velocity magnitude takes a maximum close to the downstream bottom corner of the cavity. The two critical modes are distinguished by the sense of rotation of the Taylor–Görtler vortex.

Further increasing the Reynolds number the translation invariance in time is broken. For $\mathrm{Re}_H \geq 55720$ small deviations from any of the steady asymmetric flow states start growing until the amplitude of oscillation saturates, defining two limit cycles. These limit cycles are related to each other *via* the operation $\mathcal{S}$. The peak-to-peak amplitude $P[S(t)]$ of the time-dependent asymmetry parameter $S(t)$ is found to grow with the square root from the second critical point, i.e. $P[S(t)]^2 \sim \mathrm{Re} - \mathrm{Re}_H$, indicating a Hopf bifurcation. The eigenmode consists of series of Taylor-Görtler vortices which are advected downstream while slowly drifting in the spanwise direction. The latter effect is caused by the steady symmetry-broken flow. The two limit cycles towards which the system can evolve are stable at least up to $\mathrm{Re}_I = 56200$. For $\mathrm{Re} > \mathrm{Re}_I$ intermittency can set in.

For $\mathrm{Re} > \mathrm{Re}_I$ bursting events can be observed even though the system sits on a limit cycle for a long time (several viscous time units). This is demonstrated in fig. 2(a). The bursts arising at $t \approx 44$ and $t \approx 48$ enable the system to visit wide regions of the phase space and thus allow the system to switch between the two limit cycles. The bursts are characterized by a lower frequency than the fundamental frequency of the limit cycles (fig. 2), suggesting the existence of one or a couple of additional low-frequency limit cycles.

Conclusions

Similar to the cubic LDC the transition in the SDC follows a Pomeau–Manneville scenario where intermittent bursts progressively destabilize the system. However, the behavior of the system is significantly different: In the LDC the flow undergoes subcritical Hopf and Neimark–Sacker Bifurcations involving the limit cycles of different nature (one is antisymmetric, the other is not). In the SDC the flow is progressively destabilized by a sequence of supercritical pitchfork and Hopf bifurcations which are both antisymmetric to each other.

EXPERIMENTAL CONTROL OF TOLLMIEN-SCHLICHTINGWAVES USING PRESSURE SENSORS AND PLASMA ACTUATION

Pedro P.C.B. Brito*[1], Pierluigi Morra[2], André V.G. Cavalieri[1], Thiago B. Araújo[1], Ardeshir Hanifi[2], and Dan Henningson[2]
[1]Aerodynamics Department, Instituto Tecnológico de Aeronáutica (ITA), São José dos Campos, Brazil
[2]Linné FLOW Centre, KTH Royal Institute of Technology, 10044 Stockholm, Sweden

Summary An IFFC (*Inverse Feedforward Control*) technique was applied to the boundary layer around a NACA 0008 airfoil at zero angle of attack aiming to delay the transition to turbulence by cancelling Tollmien-Schlichting (TS) waves. Experiments were carried out in an open-circuit wind tunnel. Microphones were used as sensors instead of hot-wires, which is an affordable option, especially for 3D disturbances requiring a higher number of sensors, and the actuation was performed with modulated plasma. Different penalizations were applied to the control law to minimize spurious actuation signals caused by zeros of the transfer functions. The results show that closed-loop control leads to attenuation of TS-wave spectra of about one order of magnitude, showing the good performance of IFFC with the present choice of sensors and actuators.

INTRODUCTION

This work focus on the delay of transition to turbulence in boundary layers due to its significant impact in the aerodynamics area. The transition delay means a reduction of the friction coefficient, which is responsible for more than half of the total drag on aircraft in cruise flight (Schrauf, 2005), therefore, the advances in transition delay represent a potential way for improving the fuel consumption on aircraft.

The control technique for transition delay tested here is a first try of the Inverse Feedforward Control (IFFC) proposed by Sasaki et al. (2018), which is used to cancel the Tollmien-Schlichting (TS) waves by taking advantage of its linearity and acting via destructive interference.

The control strategy of the IFFC is based on the obtention of the transfer functions between the inputs d (disturbance) and u (actuation) and two sensors y and z, which leads to the obtention of the control kernels (K), which depends on the open-loop transfer function G_{yz} and the actuation transfer function G_{uz}. The former can be obtained with stochastic excitation of disturbances d, while the latter is taken with white-noise actuation. Such transfer functions do not require calibration of sensors or determination of detailed actuator properties, as their intrinsic properties may be absorbed in the determined amplitudes and phases. The control is performed with a superposition of open-loop operation with the actuation (u) to cancel the output (z). The downstream output can be written in the frequency domain as

$$Z(\omega) = [G_{yz} + K(\omega)G_{uz}(\omega)]Y(\omega) \tag{1}$$

and the actuation signal in the frequency domain is taken as $U(\omega) = K(\omega)Y(\omega)$.

The control law is thus amenable to experimental applications. This is attempted here, with a plasma actuator and a pair of flush-mointed microphones. The latter replace hot wires often used in transition studies, and offer an affordable option for sensing TS waves. However, microphones are also sensitive to other disturbances, such as acoustic waves, and an objective of this study is to determine their applicability to transition control.

EXPERIMENTAL SETUP

Experiments were carried at Instituto Tecnológico de Aeronáutica (ITA) at the Kwei Lien Feng laboratory in an open-circuit wind tunnel. The test section has 4.0m x 1.28m x 1.0m and the level of turbulence is less than 0.1%. The experiments were performed on a NACA 0008 airfoil for a Reynolds number of $5.7{\cdot}10^5$. The wing was made of composite materials and had a plexiglass plate mounted at the center to allow easy assembling of different sensors and actuators. A slit situated at $x/c = 0.1$ was connected, with 37 tubes of equal length, to a 200W loudspeaker outside the wind tunnel, which was used to trigger the TS waves. Figure 1 shows the model placed in the test section.

The primary sensors used in the experiment at the wall of the wing were microphones, instead of hot wires. The microphones had a diameter of 1/4", and the purpose of using them was to prove their capability of behaving well in boundary layer transition control experiments. The advantages of using them rely on the fact that they are less intrusive than typical hot-wires due to the fact of being placed inside and tangent to the wall. Perhaps more importantly, electret microphones have a very low cost, which makes them suitable for flight test campaigns and situations were a large number of sensors need to be placed.

A Minipuls 2.1 system, manufactured by GBS Elektronik®, was used as the high voltage source to generate plasma for actuation. The system generates AC voltage up to 20kV (Vpp) with an operational frequency range of 5-20 kHz. The

*Corresponding author. E-mail: pedropcb@ita.br.

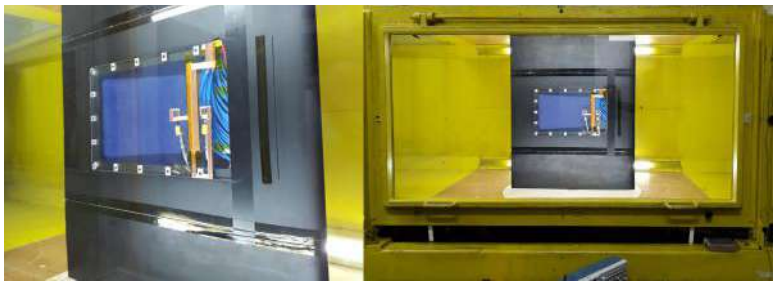

Figure 1: Zoom view of the wing (left) and side view of the test section with the loudspeaker on its top (right).

system provided a potential difference around 10kV at the dielectric (plexiglass plate) throughout two thin strips of copper that worked as electrodes along the span of the wing, so that plasma could be generated.

Acquisition and control were carried out usind a dSpace system, where the control law was implemented in real time. The actuation signal was used as an amplitude modulation for plasma excitation, which is felt in the flow as a fluctuating body force.

RESULTS

The results for the attenuation of the TS waves using closed-loop control are summarized in Figure 2, where the PSD of the signals of the z sensor show attenuation of one order of magnitude when a penalization R = 200 is applied.

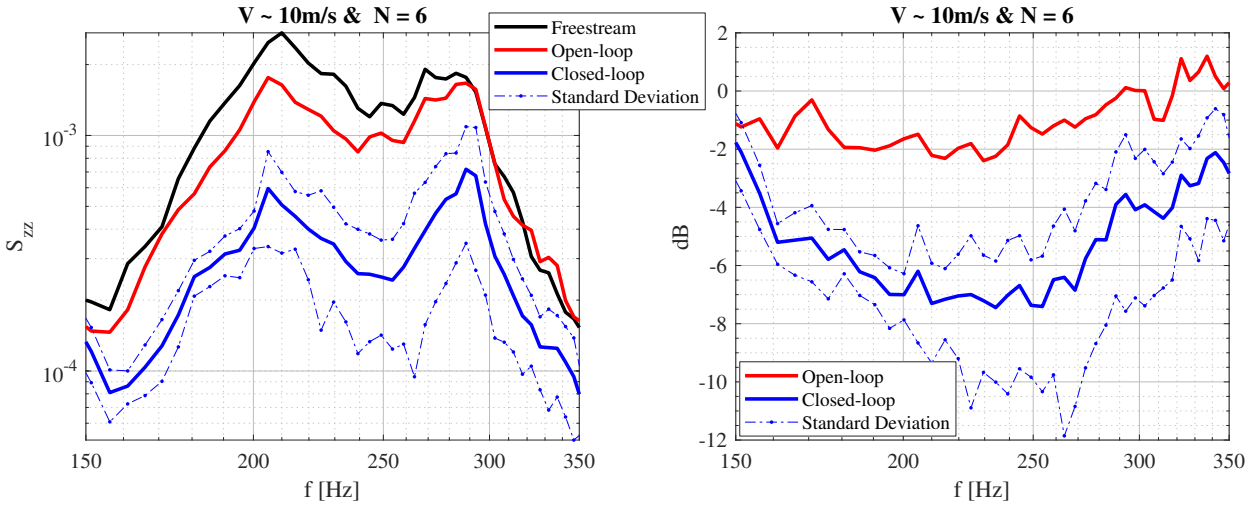

Figure 2: PSD signal for z sensor (left) and attenuation in dB (right)

In Figure 2, six experimental runs were carried out, and the full lines represent the mean value for the whole frequency range. A considerable standard deviation is noticed around the closed-loop data due to the free-stream velocity fluctuations ($\pm 0.5 m/s$) at the open-circuit wind tunnel. Therefore, most of the time, the control law was applied for velocities different from the design value. When the wind tunnel velocity is close to the target velocity of the control law design, attenuations of 10dB are obtained.

CONCLUSIONS

The present results show how closed-loop control can help to delay the transition to turbulence on boundary layers. Inverse feedforward control (IFFC) was shown to be robust, with significant attenuation of TS waves even with fluctuations of free-stream velocity. Finally, the present work shows how microphones can be used as sensors for closed-loop control of transitional boundary layers. Their relative low cost opens new possibilities for the application of multiple sensors in experimental implementations of control, which is relevant for complex 3D disturbances.

RECENT DEVELOPMENTS ON THE ONE-WAY NAVIER-STOKES EQUATIONS

Omar Kamal[1], Georgios Rigas[2], Matthew Lakebrink[3], and Tim Colonius[*1]
[1]Division of Engineering and Applied Science,Caltech,Pasadena,CAUSA [2]Department of Aeronautics, Imperial College London,UK
[3]The Boeing Company, Hazelwood, MO USA

Summary The One-Way Navier-Stokes equations (OWNS), based on a approximate parabolization of the linearized, compressible Navier-Stokes equations in frequency space, are a fast alternative to global methods for stable, weakly non-parallel base flows. The method alleviates ambiguities and inaccuracies associated with streamwise marching in the parabolized stability equations (PSE). In this work, we generalize the method originally developed for weakly compressible free shear flows to flows at all speeds, from incompressible to hypersonic, and for three-dimensional wall-bounded flows in arbitrary, body-fitted generalized coordinates. We demonstrate DNS-like accuracy for the evolution of inlet disturbances in the hypersonic boundary layer on a 7-degree half-angle sharp cone, and we use OWNS to investigate worst-case disturbance growth in hypersonic boundary layers on flat plates.

INTRODUCTION

Current methods to track the spatial evolution of linear disturbances in boundary layers and other weakly non-parallel shear flows are direct numerical simulations (DNS), linear stability theory (LST), and parabolized stability equations (PSE). DNS, although most accurate, is computationally intensive, especially with complex geometries. LST is more computationally efficient but typically employs the parallel-flow assumption which introduces error as seen in [2], which studies the stability characteristics of a Mach 4.5 flat-plate boundary layer. PSE may seem as the optimal method between DNS and LST but there are intrinsic disadvantages. Instead of formally deriving a one-way operator, PSE achieves a stable spatial march by numerically damping all upstream propagating waves, as well as a subset of the downstream propagating ones, by using an implicit axial discretization along with a restriction on the minimum step size, or by explicitly adding damping terms to the equations [7]. In either form, the associated damping prevents the upstream waves from destabilizing the spatial march, but also has the unintended consequence of damping and distorting, to differing degrees, all of the downstream waves. This has, in turn, profound negative consequence for non-modal instabilities that are associated with an interacting group of modes [7].

Thus, we introduce a novel technique, the One-Way Navier-Stokes (OWNS) equations, which represents a path forward to overcoming the deficiencies of PSE. Originally developed for hyperbolic equations (e.g. Euler), OWNS employs a rigorous parabolization technique to generate well-posed, one-way approximations [6]. Efficient (fast) approximations of the resulting operator can then be made using recursive filters that were originally developed for non-reflecting boundary conditions. Aside from the parabolization itself, and unlike PSE, the numerics are convergent and not restricted to a dominant wavelength. The only restriction is the parabolization itself–meaning that OWNS can be applied in flows such as boundary and free shear layers that are dominated by downstream propagation, i.e. flows lacking feedback. Originally developed for free shear flows, the method was extended to wall bounded flows and validated by comparison with PSE and DNS for a variety of flow speeds [3]. We now include temperature-dependent fluid properties and a general non-orthogonal curvilinear coordinate system and apply this methodology to transitional hypersonic boundary layers. In the present work, we compare results from DNS of a sharp cone to validate the newly developed fully-compressible OWNS.

After linearizing the compressible Navier-Stokes equations about some time-independent base flow and discretizing in the curvilinear cross-stream directions (η, ζ), we can transform the equations into the characteristic space and obtain a one-way equation in the frequency domain via the Laplace transform yielding

$$\frac{\mathrm{d}\widehat{\phi'}}{\mathrm{d}\xi} = M\widehat{\phi'} + \widehat{g}, \tag{1}$$

Where ξ is streamwise direction. Note that we employed the thin shear-layer approximation by ignoring streamwise viscous diffusion. Since Eq. 1 is a linear ODE with $\widehat{g}$ being evaluated explicitly, we can instead assume a homogeneous ODE, i.e. $\widehat{g} = 0$, without a loss of generality. Using an eigenvalue decomposition of $M = VDU$, the exact parabolization in terms of characteristics with differential-algebraic equation (DAE) of index 1 is

$$\frac{\mathrm{d}\phi_+}{\mathrm{d}\xi} = M_{++}\phi_+ + M_{+-}\phi_-, \qquad U_{-+}\phi_+ + U_{--}\phi_- = 0. \tag{2}$$

Performing the spatial march with the exact parabolization would be computationally intractable and thus we use an approximate one-way marching using a high-order recursive filter. Derivation of the recursive parameters and the approximate one-way equation can be found in [6, 5] with the final DAE system being

$$\frac{\mathrm{d}\phi_+}{\mathrm{d}\xi} = M_{++}\phi_+ + M_{+-}\phi_-, \quad (M - ib_+^j I)\phi^j = (M - ib_-^j I)\phi^{j+1}, \quad \phi_-^{N_b} = 0. \tag{3}$$

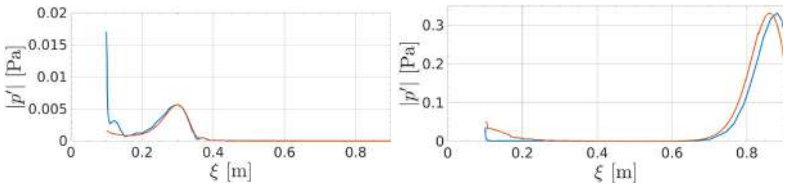
RESULTS

We validate the newly developed hypersonic OWNS framework in curvilinear coordinates by analyzing the boundary layer flow over an axisymmetric 7-degree half-angle sharp cone from [4]. The results for the wall-pressure perturbations are compared to their DNS solutions in Figure 1.



(a) $\mathrm{Re}_\infty = 1.46 \times 10^6\ \mathrm{m}^{-1}$ (b) $\mathrm{Re}_\infty = 4.06 \times 10^6\ \mathrm{m}^{-1}$

Figure 1: Comparing wall-pressure perturbations between OWNS (red) and DNS (blue) from [4] with mode S initialized at the inlet at $f = 400$ kHz. Flow over an axisymmetric 7-degree half-angle sharp cone with wall temperature of 300 K and Mach 7.3, $p_\infty = 789$ Pa, $T_\infty = 267$ K (left), and Mach 7.4, $p_\infty = 2129$ Pa, $T_\infty = 268$ K. (right)

Apart from the initial transient associated with the choice of inlet perturbation, we see excellent agreement between OWNS and DNS. To visualize the disturbance field, we plot the temperature perturbations for $\mathrm{Re}_\infty = 4.06 \times 10^6\ m^{-1}$ and $f = 475$ kHz in Figure 2.

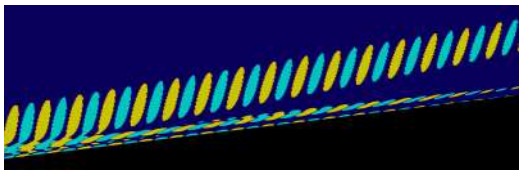


Figure 2: Temperature perturbations from OWNS at $\mathrm{Re}_\infty = 4.06 \times 10^6\ \mathrm{m}^{-1}$ and $f = 475$ kHz. Same flow conditions as Figure 1 (right).

We see the trapped acoustic waves between the wall and relative sonic line along with the subsonic "rope-like" structures in the region where the disturbances travel subsonically with respect to the freestream. However, due to substantial wall-cooling ($T_w/T_e = 0.8635$), there is an additional mode – the supersonic mode. This mode occurs when the phase speed of the disturbances in the freestream is slow enough such that they travel supersonically *upstream* relative to the freestream and creates an acoustic radiation from the boundary layer. This is qualitatively corroborated from [1].

CONCLUSION AND FUTURE WORK

We applied linear OWNS in studying transitional hypersonic boundary layers with full compressibility in general curvilinear coordinates. We demonstrated excellent agreement to DNS of 7-degree half-angle sharp cone from [4]. In the presentation, we will demonstrate how OWNS can be used an an efficient tool to investigate worst-case disturbance growth in hypersonic boundary layers on flat plates.

PARAMETRIC ANALYSIS OF 3D RECEPTIVITY IN LAMINAR SEPARATION BUBBLES VIA A NOVEL MULTI-FREQUENCY ITERATIVE METHOD

Eduardo Martini*[1,2], Daniel Rodríguez[3], André V. G. Cavalieri[1], and Peter Jordan[2]
[1]Instituto Tecnológico de Aeronáutica, São José dos Campos/SP-Brazil

Summary When formed, laminar separation bubbles (LSBs) typically lead to boundary layer transition to turbulence. Two-dimensional receptivity analyses show large gains, indicating that transition may occur via non-normal amplification of external perturbations. However, stability analysis reveals that the flow first becomes unstable via three-dimensional perturbations, and since in experiments such flows typically exhibit three-dimensional structures, a two-dimensional pathway to transition may not describe the appropriate dynamics. The sensitivity analysis of three-dimensional perturbations is addressed using a novel strategy, which provides optimal gains and modes for all frequencies using a single iterative scheme, resulting cost reduction of an order of magnitude lower in comparison with previous methods. These low computational costs allow for a parametric investigation of gains with frequency and LSB strength.

INTRODUCTION

The input-output analysis of flows provides useful insights into the system's dynamics. Optimal force and response modes, and the associated gains, can be used to explain by-pass transition: in flows which exhibit very large receptivity, small-but-finite perturbations are amplified up to the point where non-linear interactions become relevant and initiate the transition of the flow to a turbulent state.

Such mechanism have been explored to explain transition in laminar-separation bubbles (LSBs), which are formed by strong adverse-pressure gradients in laminar boundary layers. The bubbles are highly unstable, and when formed, frequently lead to transition. Different pathways to transition are possible: the flow can become globally unstable, leading to modal perturbation growth, or large receptivity can trigger non-linear dynamics, as mentioned before. Two-dimensional receptivity in LSBs exhibits large gains for the optimal forcing [1]. Rodríguez *et al* [2] showed that laminar separation bubbles are intrinsically unstable to three-dimensional perturbations, even in the absence of continuous external excitation, which is probably connected to the three-dimensionality typically seen for these flows in experiments. Due to computational cost, and the need to perform large parametric analyses to quantify the impact of the LSB mean properties on the development of perturbations, three-dimensional receptivity of LSBs has not yet been explored.

High computational cost makes direct singular-value decomposition (SVD) of system matrices, which can be used to compute optimal force and response modes, applicable only to small systems. To approach more complex systems, model reduction [3] and matrix-free methods have been proposed [4]. The choice of reduction basis is crucial for reduction strategies. For instance, eigenmodes, though they form a complete basis, may be a poor choice, as a large number of modes is frequently necessary to describe the dynamics of non-orthogonal systems. Such poor convergence was observed by Alizard *et al* [1]. Matrix-free methods compute modes and gains directly for the full system for a given frequency, not requiring model reduction. But high computational cost nonetheless hinders large parametric studies.

METHODS

Here we propose a variation of the method proposed by Monokrousos *et al*, using a matrix-free iterative method based on the system's transient response to compute optimal force and response modes for all frequencies simultaneously. The method is based on an iterative integration of the following set of equations

$$\frac{d}{dt}u_n(t) = Au_n(t) + f_{n-1}(-t) \tag{1}$$

$$\frac{d}{dt}f_n(t) = A^\dagger f_n(t) + u_n(-t) \tag{2}$$

with A and $A^\dagger$ representing the linearized Navier-Stokes operator and its adjoint, respectively. In the frequency domain the n-th iteration can be written as $\hat{f}_n(\omega) = (R^\dagger(\omega)R(\omega))^n \hat{f}_0(\omega)$, with $R = (-A - \mathrm{i}\omega)^{-1}$. Thus $\hat{f}_n(\omega)$ and $\hat{u}_n(\omega)$ converge to optimal force and response modes. The first iteration is set as spatial white noise, and as an impulse in time. Temporal filters are used to perform a frequency-dependent normalization, and a variation of the Arnoldi method is proposed as a way to accelerate convergence and compute sub-optimal modes and gains. Computational requirements are an order of magnitude lower than those associated with the method used by Monokrousos *et al* when results for many frequencies are desired.

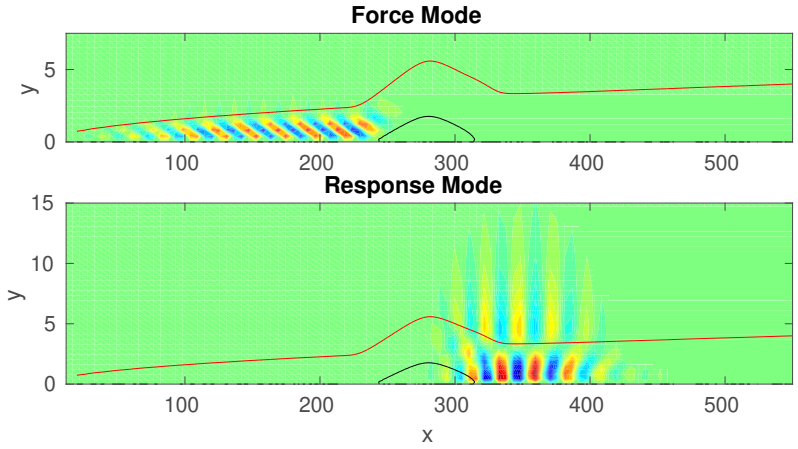

Figure 2: Force and response modes for $f = 0.018$, for a flow with $\delta_{max} = 5.0$ (colour map). Black and red lines indicate iso-contours of the baseflow streamwise velocity for $U = 0.0$ and 0.9.

RESULTS

Optimal force and response modes for laminar-separation bubbles are computed, with a large parametric study involving the bubble strength, frequency and three-dimensionality effects. An inverse formulation of the boundary-layer equations is used for the computation of steady two-dimensional bubbles, as in Rodríguez *et al* [2]. A distribution of the displacement thickness is imposed, reproducing the features of an adverse-pressure gradient separation bubble. The maximum separation thickness in boundary-layer units, δ_{max}, is used to parametrize the flow. Preliminary results for two-dimensional perturbations for different values of δ_{max} are presented in figure 1, with the optimal force and response modes for $\delta_{max} = 5.0$ presented in figure 2. Modes show excitation of TS waves in the downstream part of the bubble.

Using the proposed method, a three-dimensional sensitivity analysis for these flows is possible with moderate computational cost. The transition of the dominant mode from a planar TS wave, for boundary layers with zero pressure gradients, to three-dimensional structures related to TS-KH instability, seen in larger separation bubbles, can then be mapped. Such calculations are ongoing, and results will be presented at the conference.

The input-output framework has also been used in the study of turbulent flows. Working with the Navier-Stokes equations linearized around the mean flow, where the remaining non-linear terms are treated as an unknown external force, Mckeon & Sharma showed that large gain separation between the optimal and suboptimal modes can lead to a flow response which is insensitive to details of these external forces [5]. The approach has been used to construct low-rank flow modes and predicting large scale coherent structures in many flows. The method here presented has thus potential to assist in the study of both transitional and turbulent flows.

GLOBAL STABILITY OF AXISYMETRIC LIQUID-LIQUID FLOW FOCUSING

M. Rubio[1],N. Rebollo-Muñoz[1],M.G. Cabezas[*1],M.A. Herrada[2],and J.M. Montanero[1]

Summary We study both numerically and experimentally the stability of the steady jetting regime of liquid-liquid flow focusing. The base flow is calculated by solving the full Navier-Stokes equations and boundary conditions for arbitrary values of the viscosities and flow rates. The linear stability analysis of the base flow is conducted by calculating its global eigenmodes. The minimum flow rate is determined as that for which the growth factor of the dominant mode becomes positive. We find good agreement between this theoretical prediction and preliminary experimental values. Numerical results will be used to analyze the mechanisms responsible for the instability.

INTRODUCTION

The axisymmetric liquid-liquid flow focusing configuration has been frequently studied because of its very diverse applications, such as fabrication of particles encapsulating different actives [1], or emulsions with high monodispersity [2]. In the most common operation mode, the outer flow stretches an inner liquid droplet or meniscus, which is attached to the feeding capillary, and forces the ejection of a microjet (steady jetting tip streaming, SJTS). This jet eventually breaks up into droplets due to the capillary instability. The SJTS mode keeps running if the expelled volume is properly replaced by injecting liquid into the tapering droplet/meniscus. The diameter of the emitted jet can be reduced by decreasing the injected flow rate. If the rest of parameter conditions are fixed, there is a minimum value of the flow rate below which SJTS becomes unstable.

The stability analysis of the steady tip streaming produced by axisymmetric liquid-liquid flow focusing has received very little attention. Gañán-Calvo and Riesco-Chueca [3] studied the jetting-to-dripping transition when the liquid stream is focused by another liquid current in the presence of a circular orifice, and compared the critical inner-to-outer flow rate ratios in the experiments with those leading to the convective-to-absolute instability transition in the jet. More recently, Mu *et al.* [4] studied the stability of the same configuration both experimentally and theoretically. They successfully explained their experimental observations and direct numerical simulations by distinguishing the instability originated in the emitted jet from that localized in the tapering meniscus.

The calculation of the linear global modes [5] is an adequate tool to predict the instability of SJTS. The idea is to assume that an infinite jet tapers from the liquid meniscus, and to interrogate this basic flow about its response to small-amplitude perturbations [6]. SJTS becomes unstable if the largest growth rate of the eigenfrenquency spectrum is positive. In this case, the system evolution is asymptotically (i.e., for sufficiently large times) dominated by the corresponding mode whose growth leads to either the interruption of the ejection or self-sustained oscillations. The complexity of the global stability analysis probably explains why it has been applied to very few SJTS configurations, including axisymmetric liquid-liquid flow focusing.

Cruz-Mazo *et al.* [7] and Ponce-Torres *et al.* [8] have recently obtained the stability limits of SJTS in gaseous flow focusing and the cone-jet mode of electrospray, respectively. The theoretical predictions agreed remarkably well with the experimental data for all the cases of electrospray analyzed [8]. However, SJTS became unstable for flow rates larger than those predicted by the asymptotic linear stability in gaseous flow focusing with small applied pressure drops [7]. This instability is caused by the short-term superposition of the eigenmodes. A natural question is which of these two possible scenarios the liquid-liquid flow focusing configuration corresponds to.

RESULTS

The pressure and velocity fields are calculated from the axisymmetric and incompressible Navier-Stokes equations, which are integrated taking into account the kinematic compatibility and equilibrium of tangential and normal stresses at the interface. We impose fully developed velocity profiles at the inlet section. The non-slip boundary condition is prescribed at the solid walls. The free surface shape is obtained as part of the solution by considering the anchorage condition of the triple contact line at the edge of the feeding capillary. We impose the standard regularity conditions at the symmetry axis, and the outflow conditions $u_z^{(k)} = w_z^{(k)} = F_z = 0$ at the right-hand end of the computational domain. We verified that the results are not significantly affected by this last condition by comparing the stability limits for different lengths of the discharge cell. The fluid domain is mapped onto a fixed numerical domain through a coordinate transformation. We conducted simulations for different mesh sizes to ensure that the results did not depend on that choice.

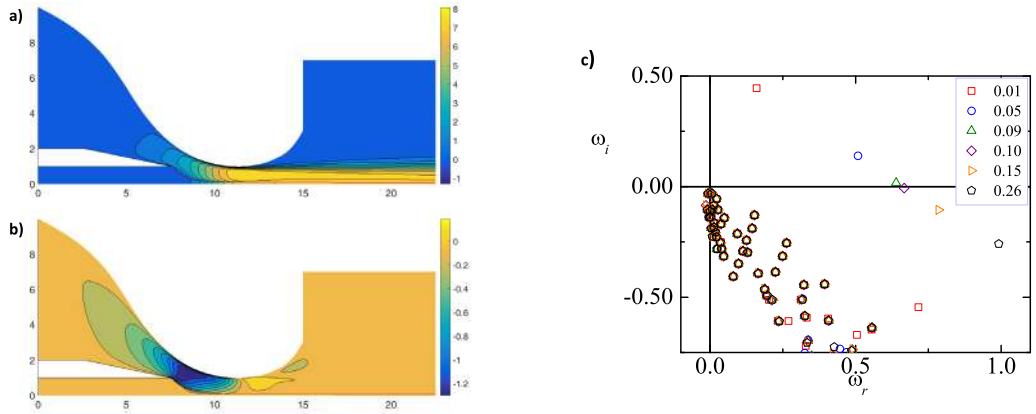

Figure 1: a) Axial and (b) radial adimensional velocity field of the base flow for Q_A=0.15 and Q_B= 20.7. c) Eigenfrequencies for Q_B= 20.7 and different internal flow rates Q_A (symbols).

Q_B	Numerical		Experiments	
	Q_A	R_j	Q_A	R_j
15.78	0.098	0.075	0.1	0.073
20.66	0.097	0.066	0.1	0.064
24.58	0.103	0.063	0.1	0.056
28.21	0.109	0.060	0.1	0.064

Table 1: Minimum inner flow rate and jet radius for different outer flow rates obtained numerically and in experiments. The liquids are 100 cSt silicone oil (inner) and water (outer).

First, the base solution of the problem is calculated, and then, the linear global modes are calculated by assuming the temporal dependence $U(r,z;t) = U_0(r,z) + \varepsilon\delta U(r,z)\, e^{-i\omega t}$ $(\varepsilon \ll 1)$, where $U(r,z;t)$ represents any hydrodynamic quantity, $U_0(r,z)$ and $\delta U(r,z)$ stand for the base (steady) solution and the spatial dependence of the eigenmode, respectively, while $\omega = \omega_r + i\omega_i$ is the eigenfrequency. Both the eigenmodes δU and the corresponding eigenfrequencies ω are obtained as a function of the governing parameters. The dominant eigenmode is that with the largest growth factor ω_i. If that growth factor is positive, the base flow is asymptotically unstable [5].

The experimental setup was similar to that described in [3] but for the flow focusing device. In our experiments, a capillary tube, with inner radius $R_c = 100$ μm, is located coaxially inside a glass converging-diverging nozzle at a distance $H = 380$ μm to its neck of diameter $D = 199$ μm. We focused a 100cSt silicone oil jet using a water stream.

For the sake of illustration, Fig. 1 shows numerical results for the configuration and system of the experiments. The variables are made dimensionless with the capillary radius R_c, the liquid density ρ_i, and the capillary time $t_c = \rho_i R_c^3/\sigma$, where σ is the interfacial tension. The discharge cell radius R and Length L are 7 and 7.5 times the capillary radius respectively. The dimensionless inner and outer flow rates are Q_A and Q_B, respectively. Fig. 1.a) and b) show the axial and radial dimensionless velocity of the base flow and the dimensionless interface shape F_z (red line) for Q_A= 0.15 and Q_B= 20.7, corresponding to SJTS. It can be observed how the outer stream speed in the nozzle orifice considerably exceeds that of the inner current. This makes the jet accelerate in that region, which produces the flow focusing effect. Fig. 1.c) shows the eigenfrequencies for different values of the inner flow rate Q_A and Q_B= 20.7. The sign change in the growth factor of the eigenfrequency responsible for the instability is used to determine the minimum stable flow rate Q_A= 0.97. Table 1 compares minimum flow rates and the corresponding jet radii R_j obtained numerically with those measured in experiments.

TRANSITION TO TURBULENCE OF ELECTRICALLY CONDUCTING LIQUID FLOW DRIVEN BY A ROTATING MAGNETIC DIPOLE IN A RING CHANNEL

Didzis Berenis* and Ilmars Grants
Institute of Physics, University of Latvia, Salaspils, Latvia

Summary Electrically conducting liquid flow driven by a rotating magnetic dipole in a cylindrical ring channel is studied numerically with a focus on the hydrodynamical instability and transition to turbulence. In a narrow ring the flow itself and its instability resembles the related rotating magnetic field driven flow in a cylinder. That changes in a wide ring when an intense radial jet develops on the mid-plane. This jet looses stability either to wave-like three-dimensional deformation or to axially symmetric vertical displacement depending on ring's geometry. In the latter case two stable steady solutions emerge. As the flow intensity increases the jet switches chaotically between two mirror-symmetric patterns.

INTRODUCTION

Suppose that we wish to create possibly strong flow with a rotating permanent magnet in a confined volume. Evidently the best would be to insert the magnet in the middle of the volume since the magnetic field would then close almost entirely through the liquid. We arrive naturally to the ring channel configuration with conducting liquid surrounding a magnet. It has similarities with the traditional RMF configuration where magnetic inductor surrounds the liquid [1]. In both cases the magnetic field lines propagate in the azimuthal direction creating a time-averaged azimuthal body force [2]. The motion of liquid is expectedly similar, however, we find that it is not always the case.

FORMULATION AND METHODS

Incompressible Navier-Stokes equation with axially symmetric azimuthal body force is used to study electrically conducting liquid flow in a ring channel. Half-height of the ring H and momentum diffusion time H^2/ν are used as distance and time-scales, respectively, where ν is the kinematic viscosity. For definiteness, ring inner radius is set equal to H. Thus, only ring outer radius R and magnetic Taylor number Ta are free parameters which serve as the geometrical and dimensionless force parameter respectively.

Flow is driven by a rotating magnetic dipole on the ring axis creating a time-averaged azimuthal body force with an analytical expression [2]. Linear instability problem is addressed numerically with spectral methods by time integration of the axially symmetric base flow and infinitesimal azimuthally periodic perturbation. Weakly turbulent regimes are calculated with direct numerical simulation using spectral methods. Large eddy simulation using finite volume fluid dynamics software is performed for flow calculations in developed turbulence regimes.

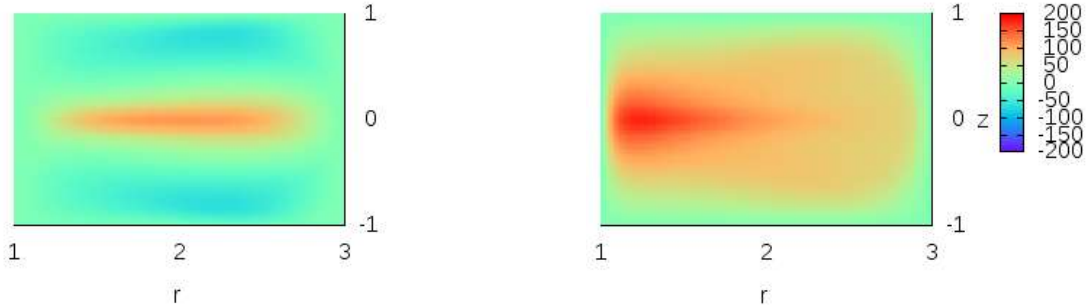

Figure 1: Velocity distribution in the ring cross section before the instability occurs ($R = 3$, $Ta = 1.7 \cdot 10^5$): (a) radial; (b) azimuthal

RESULTS

In the traditional RMF configuration magnetic inductor surrounds the liquid [1], time-averaged azimuthal body force drives the primary swirl and the presence of vertical solid walls creates secondary flow via so-called Ekman pumping [3]. It may be expected in the ring channel too that interplay of the secondary recirculation with the primary swirl eliminates vertical variation of the rotation outside thin Bödewadt boundary layers. However, it is so only for small outer ring radius $R < 2$. In which case the instability also is similar to the RMF counterpart.

*Corresponding author. E-mail: didzis.berenis@lu.lv

For $R > 2$ a radial jet develops on the mid-plane (Fig. 1) with high radial velocity. Magnetic force is overwhelmed by convective and viscous forces in the jet. Strong vertical variation of azimuthal flow persists in the core of the flow. For $R < 3$ jet instability manifests itself as a wave in the azimuthal direction. The critical magnetic Taylor number $Ta_{\rm cr}$ drops sharply at $R \approx 3.2$ with the flow's maximum dimensionless velocity ($Re_{\rm cr}$) falling below 70 (Fig. 2). Two new axially symmetric steady solutions emerge in the result of a monotonic ($\omega_{\rm cr} = 0$) instability. These solutions have vertically displaced radial jet and they are mirror images of each other with respect to the mid-plane.

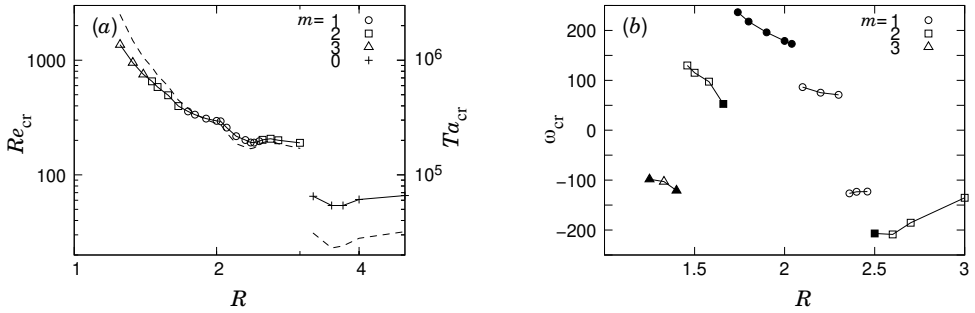

Figure 2: Instability conditions (a) shown in terms of critical Reynolds number (solid line) and magnetic Taylor number (dashed line). Frequency of the least unstable mode at the instability onset (b). Negative frequency values imply co-rotation with the magnetic field. Filled and open dots in (b) mark vertically symmetric and un-symmetric instability, respectively.

Direct numerical simulation shows that the radial jet also dominates weakly turbulent flow causing chaotic switching between two patterns as flow intensity increases (Fig. 3). Large eddy simulation is used to investigate the flow at yet higher velocities. Continuation simulations are in progress with an aim to explore conditions leading to switching events as well as probability density function of the time interval in between.

Estimates show that the flow regime as in Fig. 3 with $Ta = 10^6$ may be reached in an experiment with a transparent electrolyte with characteristic values of material properties: electrical conductivity – $50 S/m$, density – $1.2 \cdot 10^3 kg/m^3$, kinematic viscosity – $1.2 \cdot 10^{-6} m^2/s$. Taking characteristic size $H = 0.05m$ and magnetic field magnitude at the inner radius – $0.2T$ the necessary radial frequency of the magnet is $\approx 300 rad/s$ which can be easily achieved.

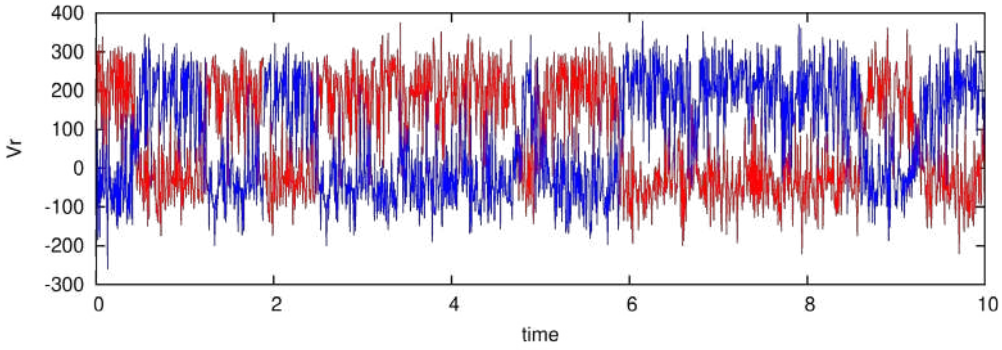

Figure 3: Time series of the radial velocity in two points at $z = \pm 1/3$; $Ta = 10^6$, $R = 4$.

CONCLUSIONS

The rotating magnetic dipole creates azimuthal body force in a conducting liquid ring surrounding it. This force drives primary swirl and secondary recirculation. In a wide enough ring $R > 2$ the flow develops mid-plane radial jet being a detached boundary layer by nature of the force balance. By exchange of stabilities two new mutually symmetric stable steady states arise for $R > 3.2$. These solutions are reflected in the turbulent flow as two symmetric patterns between which the flow wanders randomly. Stirring efficiency of the considered configuration allows to observe the phenomenon experimentally in a transparent electrolyte.

FLOW REGIMES IN ROTATIONAL MOTIONS OF IMMISCIBLE PURE VISCOUS AND VISCOELASTIC FLUIDS

Diana Broboana and Corneliu Balan*
REOROM Laboratory, Department of Hydraulics, University Politehnica of Bucharest, Bucharest, Romania

Summary The goal of the present paper is to investigate the transitory flow regime between two immiscible liquids in rotational flows: water-oils and water-viscoelastic fluid, respectively. The qualitative differences between the two cases are analyzed. For the tested range of spin velocity, three distinctive flow regimes are observed in the case of Newtonian liquids: (i) linear, (ii) transitory and (iii) chaotic. Direct visualization of the interface's evolution is correlated with the torque measurements and the numerical simulations. The onset of the transitory regime is characterized by a sharp decreasing of the torque and the appearance of the Kelvin-Helmholtz instability at the interface between water and the tested liquids. The final aims of the study are: (i) to determine the elasticity influence on the flow dynamics, (ii) to correlate the interface pattern with the fluids rheology.

INTRODUCTION AND GOAL OF THE STUDY

The rotational flow of immiscible liquids in confined symmetric vessel might be considered a benchmark problem for the modelling of fluid interfaces. In the previous published works, the focus was mainly the analysis of the wavy interface between pure viscous fluids, when the bottom wall of the vessel is rotated, [1], [2]. The present paper is a starting study of the transitory rotational flow regime between immiscible viscoelastic fluids, associated to the Kelvin-Helmholtz (KH) instability of the interface. The correlation of the measured torque on the upper disk with the patterns of the wavy interface and the fluid elasticity is the main goal of the work.

EXPERIMENTAL, FLOW VISUALIZATION AND NUMERICAL SIMULATIONS

The immiscible fluid samples of different densities and viscosities, with measured interfacial tensions in the range of 0.025 – 0.045 N/m, are initially at rest in a confined cylindrical transparent vessel with diameter d = 66 mm. The height of water in the vessel is 20 mm, twice the height of the less dense liquid sample. The moving upper disk is connected to the MC 301 Anton Paar rheometer; the input are continuous or discrete ramps of pre-selected rotational speeds (n) and the output is the measured torque (T). The dynamics of the interface is simultaneously visualized with two digital cameras: (i) Nikon J5 (60 fps at 10 Mpixel resolution) and (ii) Photron UX100 (4000 fps at 1.3 Mpixel resolution), respectively. In Fig. 1 and Fig. 3.a are shown the dependences $T(n)$ for the tested samples and the corresponding evolutions of the interface are presented in Fig. 2 and Fig. 3.b, respectively.

In the case of water – Newtonian oil contact, there are observed 3 well defined regimes (Fig. 1). During the linear regime (split in 2 regions) T is increasing with n (almost linear), the oil keeps the contact with the upper rotated disk and the interface has a symmetric shape (I.1-I.3 in Fig. 2). The onset of the transitory regime starts at the sharp decreasing of the measured torque, when water is removing the oil from the rotational disk and the interface becomes wavy, similar in shape with the periodic KH pattern (II.1-II.3 in Fig. 2); this regime is characterized by almost constant T. In the third regime, defined as chaotic (III.1-III.3 in Fig. 2), the shape of KH waves are deformed and progressively, as the spin rotation is increasing, the emulsion is formed in the vessel. In this regime high fluctuations of the torque are recorded.

The numerics performed with the Fluent code (using the VoF method for the interface modelling) give a fair representation of the flow dynamics (both qualitatively and quantitatively) in the linear and transitory regimes, Fig. 1.b.

The first 2 regimes are also observed during the evolution of the water – viscoelastic fluid interface, Fig. 3. Due to the presence of elasticity, the magnitude of the experimental time (t_e) at fixed input velocity step plays an important role in the dynamics of the interface. The perturbation is amplified by elasticity even at constant low spin velocity, so the shape of the interface at n = const. may be changed from patterns I.1 to II.1 (Fig. 3.b) at any of the input steps from Fig. 3.a., if t_e is long enough. The fluctuations of T are high during t_e = 100 s (Fig. 3.a) at all velocities, with the exception of the regime II (100 rot/min $> n >$ 75 rot/min), where the wavy interface is lack of periodic symmetry.

This behavior is qualitatively similar with the Newtonian fluid, since in both cases the onset of a stable KH patterns (i.e. wavy interfaces, II.2 in Fig. 2 and II.1 in Fig. 3.b) is associated with a sharp decreasing of the torque. However, the high fluctuations of T are observed for the Newtonian fluid only in the regime III. But this is not the only difference between the analysed cases. As spin velocity is increasing, the wavy viscoelastic interface becomes more close to the bottom of the vessel, but at the same time only the viscoelastic fluid remains in contact with the moving disk, contrary to the Newtonian case. As consequence, the water is almost completely covered inside the vessel with a viscoelastic membrane, with the exception of the bottom wall.

CONCLUSIONS

The performed experimental investigations proved the direct relation between: (i) the sharp decreasing of the torque and the onset of the KH instability at the interface, (ii) the fluid elasticity and the torque/interface fluctuations at constant spin

velocity. In the case of viscoelastic interface, the time variation of the measured torque, corroborated with the analysis of the parametric plot $T(dT/dt)$, suggests the existence of at least three attractors (no shown in this abstract).

THE EFFECT OF WALL COMPLIANCE UPON THE STABILITY OF ANNULAR POISEUILLE-COUETTE FLOW

Avni Chotai*[1] and Andrew Walton[1]
[1]Department of Mathematics, Imperial College London, South Kensington Campus, London, SW7 2AZ, UK

Summary Driven by a constant axial pressure gradient, the viscous flow through the concentric annular region between a stationary outer cylinder and a sliding inner cylinder is known as annular Poiseuille-Couette flow (APCF). The linear stability of this flow to infinitesimal, axisymmetric disturbances is studied asymptotically at large Reynolds numbers and computationally at finite Reynolds numbers when the inner cylinder possesses a degree of flexibility. A brief description of the asymptotic structure of lower-branch neutral modes will be followed by illustrations of the resulting asymptotic solutions, and it will be seen that the compliant nature of the inner cylinder results in the existence of unstable elastic modes that are not present in the rigid counterpart of the problem.

INTRODUCTION

APCF can be characterised by the constant sliding velocity V of the inner cylinder and the ratio of radii of the inner to outer cylinder δ, where $0 < \delta < 1$. The linear stability of APCF (with a rigid inner cylinder) to axisymmetric disturbances has been studied extensively by Walton [1], who confirmed that multiple neutral curves co-exist for certain choices of the parameters V and δ. This flow is of particular relevance in medicine; thread-injection is a minimally invasive technique for the transportation of medical implants into the body. In view of this application, the inner cylinder is modelled as compliant in this study and the effect of this on the linear stability of APCF is investigated.

Consider steady, incompressible APCF between two infinitely long cylinders. With horizontally orientated cylinders that are concentric, the geometry of this problem naturally lends itself to the use of a cylindrical coordinate system whose axial axis aligns with that of the cylinders; (x, r, θ) represent the non-dimensional axial, radial and azimuthal directions respectively. Assumed to be unaffected by the inner cylinder's compliance, the basic flow has only an axial component given by

$$U_0(r) = 1 - r^2 + \left(V - 1 + \delta^2\right)\ln(r)/\ln(\delta), \quad \delta \leq r \leq 1. \tag{1}$$

The flow is perturbed by axisymmetric disturbances of the travelling-wave form $\epsilon\hat{q}(r)\exp(\mathrm{i}\alpha(x-ct)) + c.c.$ where $\epsilon \ll 1$ and $\hat{q}(r)$ is the disturbance amplitude. The wavenumber α and wavespeed c are assumed to be real and complex respectively. Typical no-slip boundary conditions apply on the wall of the rigid outer cylinder. The inner cylinder, which flexes only radially so as to preserve the axisymmetry of the problem, is described by a spring-backed plate model [2]. Thus the following kinematic and dynamic conditions are to be satisfied on the inner cylinder:

$$\mathrm{i}\alpha(V-c)\hat{u}(\delta) + \hat{v}(\delta){U_0}'(\delta) = 0, \qquad \hat{p}(\delta) = \frac{2}{R}\hat{v}'(\delta) + \left(-\alpha^2 c^2 m + \frac{K}{R^2}\right)\frac{\hat{u}(\delta)}{{U_0}'(\delta)}. \tag{2}$$

Here, m and K represent the mass per unit area and spring stiffness per unit area of the inner cylinder respectively. We have neglected damping, tension and flexural rigidity. $\hat{u}(r), \hat{v}(r)$ and $\hat{p}(r)$ correspond to the axial, radial and pressure perturbations respectively. The Reynolds number R has been defined to be proportional to the axial pressure gradient in light of our 'thread-injection' application. This system results in a generalised eigenvalue problem for α that can be solved numerically via a Chebyshev collocation method. The system can also be analysed asymptotically at large R.

ASYMPTOTIC ANALYSIS AND COMPARISON WITH FINITE REYNOLDS NUMBER RESULTS

As a first step, the inner cylinder is assumed to be stationary to enable us to focus on the effects of compliance. At asymptotically large Reynolds numbers, we anticipate that the bulk of the flow is dominated by inertial forces. Near the cylinder walls, however, viscous forces become significant and there is a balance between the inertial, pressure and viscous terms in the governing linear disturbance equations. The lower-branch mode behaviour is captured by a three-zone structure (see figure 1) consisting of an inviscid core surrounded by viscous wall layers of thickness $O(R^{-2/7})$. Critical layers, where the basic velocity is equal to the wavespeed of the mode, are embedded in the viscous layers. The wavenumber and wavespeed of the lower-branch neutral mode are found to be such that $\alpha \sim R^{-1/7}\alpha_0$ and $c \sim R^{-2/7}c_0$. Seeking a balance of pressure and compliant terms in the dynamic condition, we fix $K \sim R^{12/7}K_0$ and $m \sim R^{4/7}m_0$. With these scalings, the inner cylinder's flexibility has a leading order effect on the lower-branch mode. Near $r = \delta$, we have $U_0 \sim R^{-2/7}\lambda_-^{(0)}y$ for a scaled radial coordinate y and $\lambda_-^{(0)} = 2 + (1-\delta^2)/\ln\delta$. In the lower viscous layer, let the variables u_-, v_- and p_- represent the appropriately scaled leading order terms of the axial velocity, radial velocity and pressure disturbances respectively. Substitution of these variable expansions into the governing linear disturbance equations gives, to leading order,

$$\mathrm{i}\alpha_0 u_- + \frac{\mathrm{d}v_-}{\mathrm{d}y} = 0, \quad \frac{\mathrm{d}^2u_-}{\mathrm{d}y^2} - \mathrm{i}\alpha_0\left(\lambda_-^{(0)}y - c_0\right)u_- - \lambda_-^{(0)}v_- = \mathrm{i}\alpha_0 p_-, \quad \frac{\mathrm{d}p_-}{\mathrm{d}y} = 0, \tag{3}$$

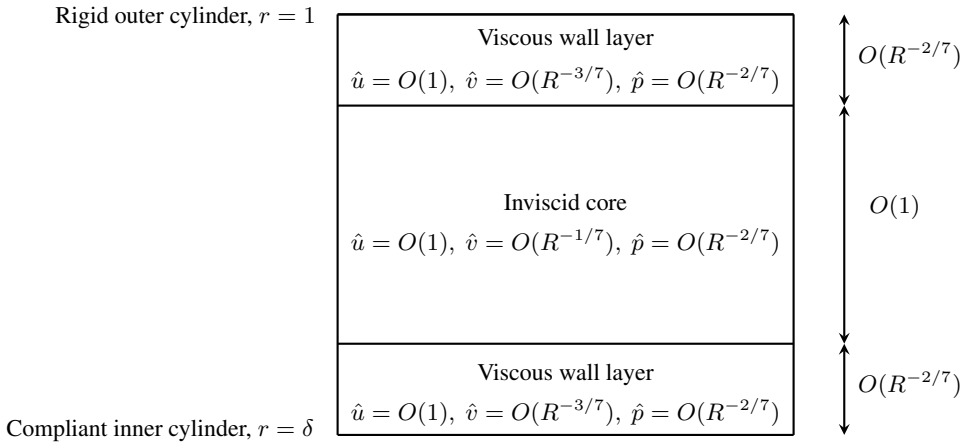

Figure 1: Schematic of the asymptotic structure of the lower-branch mode, where $\alpha = O(R^{-1/7}),\ c = O(R^{-2/7})$.

subject to matching the disturbance behaviour in the core as $y \to \infty$ and

$$\lambda_-^{(0)} v_- - \mathrm{i}\alpha_0 c_0 u_- = 0, \quad \lambda_-^{(0)} p_- = \left(K_0 - {\alpha_0}^2 {c_0}^2 m_0\right) u_- \quad \text{on} \quad y = 0. \tag{4}$$

We note the compliance affects the lower-branch mode through the boundary conditions only. The analysis of the lower-branch structure results in a complex-valued eigenrelation that describes how α_0 and c_0 depend on the problem parameters. This can be solved numerically using a Newton-Raphson method for fixed δ, K_0 and m_0. Figure 2 shows solutions α_0 of the lower-branch eigenrelation for various values of the expression $\tilde{K} = K_0 - {\alpha_0}^2 {c_0}^2 m_0$ and fixed $\delta = 0.5$.

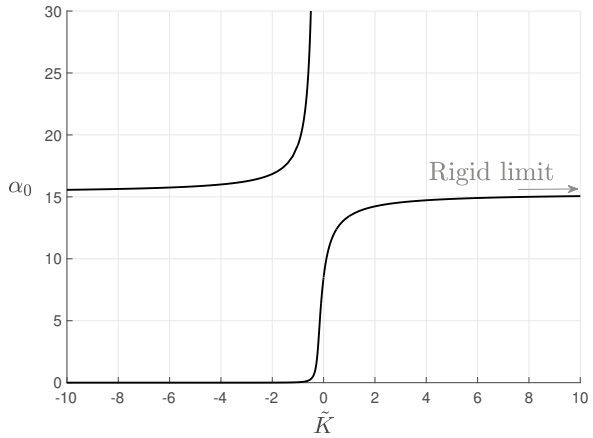

Figure 2: Solutions α_0 of the lower-branch eigenrelation for various $\tilde{K} = K_0 - {\alpha_0}^2 {c_0}^2 m_0$ and fixed $\delta = 0.5, V = 0$.

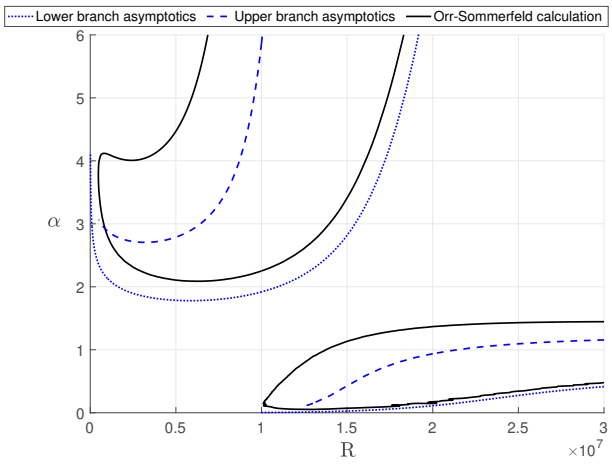

Figure 3: $\delta = 0.5, V = 0, \tilde{K} = -10^{12}$. Comparison of neutral stability curves obtained by asymptotic analysis with those obtained by solving an appropriate Orr-Sommerfeld type equation.

CONCLUSIONS

Illustrating the scaled wavenumbers of the lower-branch neutral modes, figure 2 unveils the existence of two neutral 'elastic' modes that arise from the flexibility of the inner cylinder, specifically when $\tilde{K}$ is negative. There exists only one neutral mode for positive $\tilde{K}$, and the wavenumber in the rigid limit is approached from below as $\tilde{K}$ is increased. Figure 3 shows the neutral stability curves obtained from solving an appropriate Orr-Sommerfeld type equation using a Chebyshev collocation method. These are compared to the neutral curves found from the asymptotic analysis of the lower and upper-branch structures. Agreement between the two methods increases at larger R. The upper-branch asymptotic structure, for which $\alpha = O(R^{-1/11})$ and $c = O(R^{-2/11})$, is obtained by an approach similar to that used for the lower-branch mode.

ON THE INSTABILITY OF THE FLOW AROUND RECTANGULAR CYLINDERS

Alessandro Chiarini*[1], Maurizio Quadrio[1], and Franco Auteri[1]
[1]Department of Aerospace Sciences and Technologies, Politecnico di Milano, via La Masa 34, 20156 Milano,Italy

Summary In this work we perform a Floquet stability analysis of the two-dimensional symmetric periodic flow past rectangular cylinders with aspect ratio (AR) between 1 and 5. We show that the occurrence and/or the nature of the secondary instability strongly depends on the aspect ratio of the cylinder. In particular, three ranges of AR can be identified: (i) for $AR \in [1, 2]$, the well known "mode A" three-dimensional synchronous instability is found at a spanwise length scale $\beta \approx 1.6D$ (for $AR = 1$ a further instability of quasi-periodic nature, usually called "mode B", is found for larger Reynolds number at $\beta = 2.6D$); (ii) for $AR \in [3, 4.75]$, the base flow is found to be stable to three-dimensional perturbations, but a secondary two-dimensional instability of the flow occurs; (iii) for $AR \geq 5$, a three-dimensional instability of (almost) subharmonic nature is found at $\beta \approx 2.1D$.

The investigation of the stability of the steady flow around bluff bodies is of great interest to a number of different applications, especially in the field of vortex-induced oscillations [1]. While the circular cylinder is a natural prototype of bluff body, extensively investigated [2], rectangular cylinders are also very interesting both from the viewpoint of applications and that of basic research, since they display flow features that are different with respect to the circular cylinder case: they have sharp edges where flow separation occurs and, depending on the aspect ratio of the rectangle AR, flow reattachment can be present on its lateral sides. In this work we are particularly interested in the effect of the aspect ratio of the cylinder on the secondary instability of the cylinder wake, usually leading to a three-dimensional flow.

The three-dimensional instability of blunt bluff-body wakes has been first investigated by Robichaux et al. [3]. For a square cylinder ($AR = 1$), they reported a three-dimensional instability classified as a subharmonic instability. Blackburn and Lopez [4] then showed this kind of instability to be precluded by the spatio-temporal symmetry of the base flow, and provided new evidence of the quasi-periodic nature of this instability. The subharmonic character of the instability is however recovered when the symmetry of the base flow is broken by slightly rotating the cylinder [5]. The impact of the aspect-ratio on the 3D secondary instability has been investigated in [6] for $0 < AR < 1$, but a comprehensive overview of the effects of the aspect ratio for $AR > 1$ is still lacking. This work addresses the stability of the flow past rectangular cylinders with aspect ratios $AR \in [1, 5]$, investigating both the first instability that leads to a periodic flow as well as the secondary one, by a Floquet stability analysis.

We found several interesting phenomena for both the first and secondary instabilities. In particular, we found that the quantitative and, more importantly, the qualitative nature of the secondary instability of such flows strongly depends on the aspect ratio of the cylinder. In this respect, three subranges of AR can be identified: (i) $AR \in [1, 2]$, (ii) $AR \in [3, 4.75]$, (iii) $AR \geq 4.85$.

For $AR \in [1, 2]$, the first three-dimensional instability is found to occur at $Re = U_\infty D/\nu \approx 200$ (U_∞ is the free-stream velocity, D is the cross-stream size of the cylinder and ν the kinematic viscosity). This a synchronous instability with spanwise length scale $\beta \approx 1.5D$, as shown in the left panel of figure 1 where the Floquet multipliers (μ) for $AR = 1$, $Re = 200$ and $\beta \approx 1.5D$ are plotted: the unstable Floquet multiplier with $|\mu| > 1$ is real and positive. The unstable mode in this case is usually referred to as "mode A" [5]. For the flow past the cylinder with $AR = 1$, a second three-dimensional

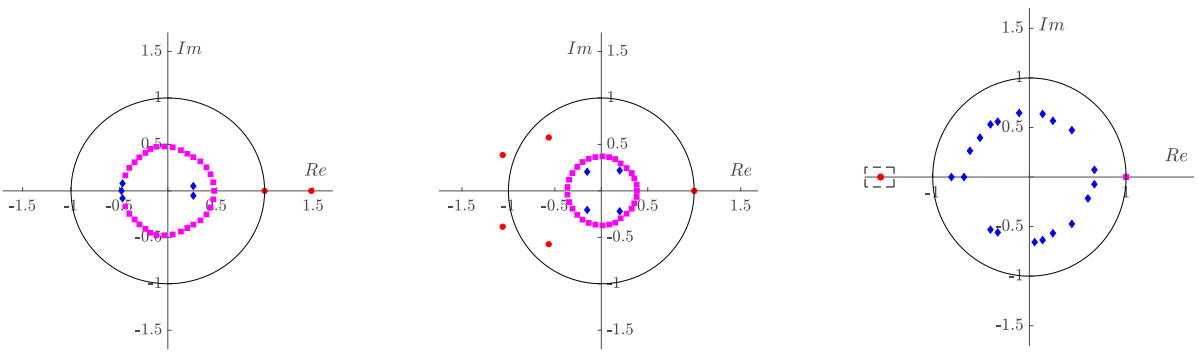

Figure 1: Left: Floquet multipliers for $AR = 1$, $Re = 200$ and $\beta = 1.5D$. Centre: Floquet multipliers for $AR = 1$, $Re = 225$ and $\beta = 2.6D$. Right: Floquet multipliers for $AR = 5$, $Re = 550$ and $\beta = 2.1D$

instability is found at larger Reynolds number ($Re \approx 225$). This instability has a spanwise length scale $\beta \approx 2.6D$ and is of quasi-periodic nature, as shown in the central panel of figure 1: the unstable Floquet multipliers form a complex conjugate pair with negative real part. Interestingly enough, this instability is not found for $AR = 2$.

For $AR \in [3, 4.75]$, no 3D instability is found by Floquet linear stability analysis for $Re < 400$, and DNS shows that no three-dimensionality arises up to $Re = 450$. However, a second two-dimensional instability seems to occur in this range of aspect ratio and Reynolds number, which makes the flow loose the spatio-temporal symmetry of the wake. This is shown in figure 2, where a snapshot of the $2D$ flow for $AR = 4$ at $Re = 450$ is plotted.

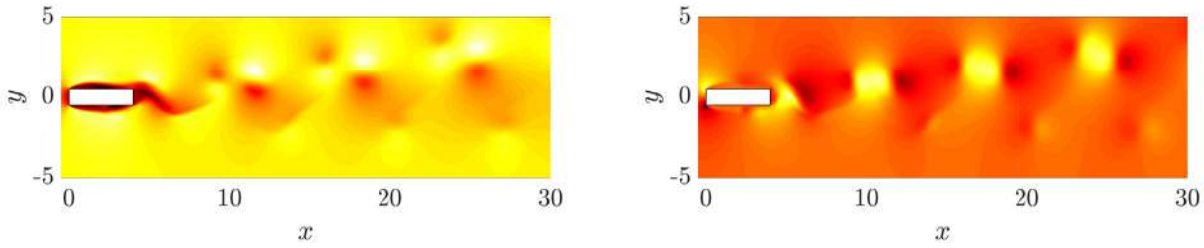

Figure 2: Baseflow for $AR = 4$ at $Re = 450$, without any stabilisation. Left: streamwise of the velocity. Right: cross-stream component of the velocity

For $4.85 \leq AR \leq 5$, a three-dimensional instability is found for $Re \approx 500$. In contrast with what found for $AR \in [1, 2]$, the instability is almost subharmonic and has a spanwise length scale $\beta \approx 2.1D$. This is shown in the right panel of figure 1 where the Floquet multipliers for $AR = 5$, $\beta = 2.1D$ and $Re = 550$ are plotted: the unstable multipliers form a complex conjugate pair with negative real part and imaginary part almost null (in the figure they seem to collapse to the real axis as $\text{Im}(\mu) \approx 10^{-3}$).

Aiming at investigating the nature of such instabilities, we exploit several tools: e.g a detailed investigation of the $2D$ base flows, $3D$ DNSs, linear stability analysis of snapshots of the base flows. An interesting result that further highlights the different nature of the three-dimensional instabilities found for $AR \in [1, 2]$ and $AR \geq 4.85$ is provided by the structural sensitivity [7] that allows one to locate the flow region where the instability is triggered. The structural
