sensitivity, figure 3, highlights the completely different nature of the instability mechanisms. For $AR \in [1, 2]$, the instability is triggered downstream the trailing edge: this is similar to what found for the flow past a circular cylinder [7]. For $AR \geq 4.85$, instead, the three-dimensional instability is triggered in a region close to the streamwise edges of the cylinder, where the recirculation occurs.

EXPERIMENTS ON INSTABILITY AND BREAKDOWN OF VISCOUS SUBLAYER IN WALL TURBULENCE OVER RIBLETS

Masahito Asai[*1], Ayumu Inasawa[1], and Shohei Takagi[1]
[1]Department of Aeronautics and Astronautics, Tokyo Metropolitan University, Hino, Tokyo, Japan

Summary Instability and breakdown of the flow very close to streamwise riblets were examined experimentally using a hot-wire rake of 48 sensors with high spanwise resolution to clarify the mechanism of viscous breakdown leading to degradation of the drag reducing effect of riblets in wall turbulence. The result showed that high-frequency (small-scale) fluctuations developed on the ribbed surface distinctly around $s^+ = 16$, the optimal riblet spacing leading to the maximum drag reduction, which strongly suggested that instability of wall shear layer over riblets was intensified for $s^+ \geq 16$, leading to the breakdown of riblet flow.

INTRODUCTION

Surface manipulation with riblets (or longitudinal grooves) is one of the most successful passive means to reduce friction drag in wall turbulence. Several cross-sectional geometries of riblets including triangular, sawtooth, scalloped, blade and trapezoidal, have been proposed and tested, and the optimal riblet spacing (distance between neighboring ridges) was found to lie over 10–20 in wall units, depending on the riblet geometry, as summarized by Bechert [1]. In the viscous regime of $s^+ \leq 10$–15, turbulent vortices have no significant impact on the flow insude grooves, and thus the viscous sublayer over the riblets is laminar-like and the drag reduction due to a viscous effect is linearly proportional to s^+. Beyond this value of s^+, the viscous regime breaks down and drag reducing effect of riblets is saturated at $s^+ = 15$–20. In this concern, Garcia-Mayoral and Jimenez [2, 3] pointed out on the basis of direct numerical simulations and stability analysis of a model flow (having a inflectional profile) over riblets that the flow close to riblets became unstable when the riblet spacing exceeded a threshold value. Their stability result is consistent with studies on the stability of laminar flow over riblets/grooves [4, 5, 6]. However, no experiment detected such an instability event over riblets in wall turbulence thus far. In the present paper, we try to visualize the disturbance field in the viscous sublayer very close to riblets with $s^+ = 13$–24 using a hot-wire rake with high spatial resolution to identify the instability phenomenon in the riblet flow.

EXPERIMENTAL SETUP

The whole experiment was conducted in a rectangular channel of 10 m long with the cross section of 900×100 mm^2. The flow was tripped at the channel entrance by isolated roughness elements and fully developed to turbulent flow for the center velocity $U_c \geq 2.5$ m/s. Riblets had triangular ridges with ridge angle of 45° and trapezoidal valleys, and the height (h) and spacing (s) of the riblets were respectively 1 and 2 mm and therefore the height-to-spacing ratio (h/s) was 0.5, as illustrated in Fig. 1. In order to capture instantaneous velocity field very close to the ribbbed surface, a hot-wire rake consisting of 48 sensors aligned at an equal interval of 1 mm in the spanwise direction was used. Each sensor was a 1-mm-long tungsten wire with diameter of 5 μm. Hot-wire anemometers were operated in a constant current mode for the 48-sensor rake. The hot-wire rake was inserted into the flow from the downstream end of the channel.

RESULTS

We first confirmed that the maximum drag reduction was obtaind for $s^+ \approx 16$ for the present riblets. Figure 2 compares instantaneous streamwise velocity fields in the viscous sublayer (y^+=6), measured by a hot-wire rake, over the smooth surface and ribblets with $s^+ = 19$ (just above the optimal size). We see only a streaky structure consisting of low- and high-speed streaks on the smooth surface. On the other hand, high-frequency (small-scale) fluctuations appeared other than the streaky structure on the ribbed surface, which no doubt resulted from due to instabiliy nature of the riblet flow. We carefully examined the riblet flow for various values of s^+ and confirmed that development of such high-frequency fluctuations could be observed frequently only for $s^+ \geq 16$. Figures 3 (a)–(c) display y-distributions of rms values of low-frequency ($f^+ \leq 0.02$) and high-frequency ($f^+ \geq 0.04$) components of streamwise velocity fluctuations, $u_L^{'+}$ and $u_H^{'+}$ on the riblets with s^+= 13, 16 and 19, respectively, by comparing to the smooth-surface data. The maximum values of the low-frequency component ($u_L^{'+}$) were not different over the smooth and ribbed surfaces for $s^+ \leq 16$, while the high-frequency component ($u_H^{'+}$) for $y^+ < 20$ increased considerably over the riblets compared to the smooth surface data. Interestingly, the increase in $u_H^{'+}$ was the largest for the optimal-sized riblets with $s^+ = 16$, which was considered to be due to the instability of riblet flow.

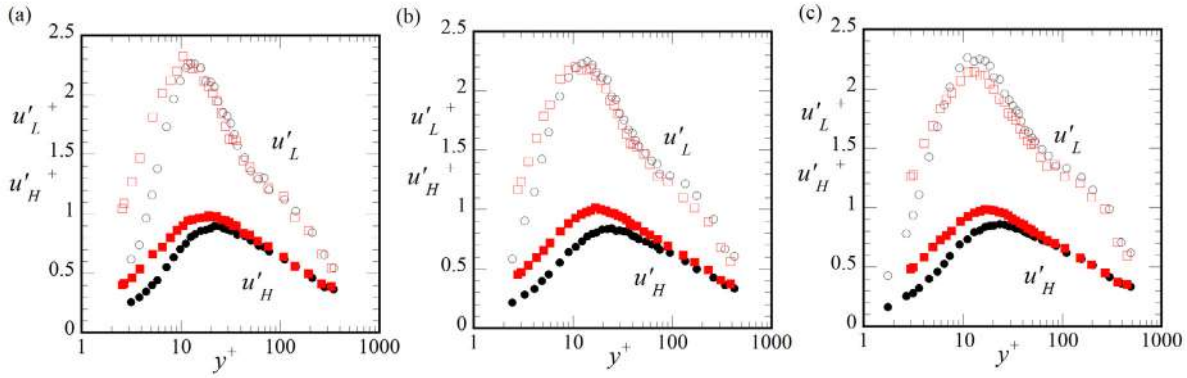

Figure 3: Comparisons of y^+-distributions of $u_L^{'+}$ ($f^+ \leq 0.02$) and $u_H^{'+}$ ($f^+ \geq 0.04$) between smooth and ribbed surfaces. (a) $s^+ = 13$ ($R_\tau = 330$), (b) $s^+ = 16$ ($R_\tau = 400$), (c) $s^+ = 19$ ($R_\tau = 470$) . Black and red symbols denote data for smooth-surface and riblets, respectively.

CONCLUSIONS

We successfully visualized occurrence of high-frequecy (small-scale) fluctuations in the viscous sublayer over the optimal-sized riblets for drag reduction, using a hot-wire rake with high spatial resolution. Increase of such small-scale turbulence strongly suggested that instability of shear layer adjacent to the ribbed surface was responssible for the viscous breakdown of the riblet flow.

IDENTIFYING AND INTERPRETING MULTIPLE EQUILIBRIA OF AN OCEANIC INERTIAL JET

Kunihiro Aoki*[1], Yasumasa Miyazawa[1], Tsutomu Hihara[1], and Toru Miyama[1]
[1]Japan Agency for Marine-Earth Science and Technology, Yokohama, Japan

Summary This study addresses an objective identification of multimodal states in the Kuroshio, which is an oceanic inertial jet being a part of North Pacific western boundary current. The solutions of an ensemble simulations with 80 members conducted in a realistic situation are classified by the Gaussian mixture distribution model, an unsupervised machine learning technique. This model is successful in identifying two distinctive meander current paths, which have been bifurcated from a nearly straight path in the initial state. The spatiotemporal evolutions of a baroclinic energy conversion rate suggests that this bifurcation is induced by baroclinic instability. In addition, two clusters corresponding to each of the bistate in a phase space are located almost along the left singular vector for a tangential linear operator defined at a time just before the bifurcation. Those features suggests that the transition of the Kuroshio state is governed by the dynamical system permitting the pitchfork branch through a symmetry breaking by baroclinic instability.

INTRODUCTION

Multi-equilibria of the current paths in Kuroshio has been recognized in observation since 1960s and is generally thought to have a straight path, middle path, and a large meander path [1] (see also Fig. 1). Previous theoretical studies have explained the transition among the Kuroshio paths as a bimodal regime shift between the straight and large meander paths [e.g., 2, 3, 4, 5]. The transition to the large meander is, recently, thought to be achieved by baroclinic instability triggered by a small disturbance generated to the upstream [e.g., 5]. The remaining middle path has been interpreted as a transient phenomenon from the straight path [e.g., 6]. Given that a single system generally can have multiequilibria in the same scale under the control of nonlinearity, a theory comprehensively describing the trimode in the Kuroshio is expected to be developed. There are no sufficient circumstantial evidences that can lead to elaborating the theory, because the sufficient experiments producing the trimode in the Kuroshio under an uniform condition have not be done so far. The recent advance in computational technology, however, enables us to conduct an ensemble experiment with a larger ensemble size. In this study, therefore, we aim at identifying and interpreting the multiequilibria of the Kuroshio state produced in an ensemble simulation.

METHOD

A regional numerical simulation is developed on the basis of a parallelized version of the Princeton Ocean Model [7]. The model covers the region of 28°–36°N and 128°–142°E with the resolution of 1/36° horizontally and 21 sigma levels vertically. The model topography is derived from 1/120° gridded product. Targeting the large meander event in 2017, ensemble runs with 80 members start from 1 January 2017. For the first one month, the forecasts of the ensemble simulation are converges near optimal values by assimilating the observational data using the technique of the Local Ensemble Transformation Kalman Filter [8]. Free runs are conducted from 1 February 2017 to 14 June 2017. All the ensemble members experience the unique atmospheric forcing and boundary conditions in the entire ensemble simulation.

The ensemble solutions in the free run are classified by the Gaussian mixture distribution model (MDM) [e.g., 9]. The Gaussian MDM method is applicable to find clusters with their means, variances, and occurrence probabilities in a data sample. We apply this method for sea surface height (SSH) at the end-date, which gives the streamfunctions for the geostrophic velocity in the upper ocean. In short, our clustering analysis is a pattern recognition in the geostrophic streamfunction. The optimal number of clusters is determined by the test using information criteria (AIC and BIC). The classification of the SSH fields needs treating a large dimension with the size of the total number of horizontal grids of the numerical model. We classify the SSH fields on a phase space composed of some dominant modes derived from principle component analysis (PCA) performed in the ensemble space for the SSH data. The PCA mode provides a characteristic field in the deviations from the ensemble mean.

RESULTS

All the members have the straight path in the initial state in the free run, reflecting assimilation to the observational data. Some members, however, begin to have the large meander path in a couple of months, while most of the remaining members show the middle path. The Gaussian MDM with 2-class decomposition well-identifies the large meander and non-large meander states occurring with a similar probability (Fig. 1). Those two states is found to be discernible on the first PCA mode axis. Note that the 2-class decomposition is validated by the information criteria. A large part of the non-large meander cluster is composed of the members having the middle path, but some members still have straight

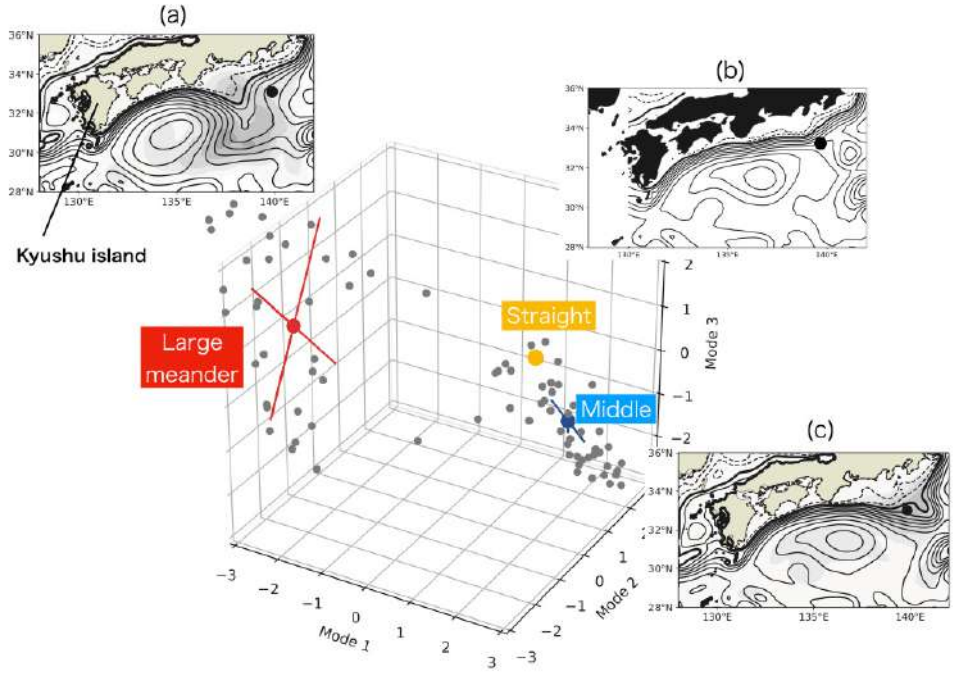

Figure 1: Scatter plot of ensemble solutions for SSH and the means of clusters estimated by Gaussian MDM in the phase space of three PCA modes at the end-date. Lines denote standard deviations. The panels show the SSH field corresponding to the means of the clusters: a) large meander path, b) straight path, and c) middle path.

path. Those two fractions in the non-large meander state is distinguishable on the third PCA mode axis although it is not statistically significant.

Both transitions to the large meander and middle paths is triggered by a small perturbation occurring to the southwest of Kyushu island. A slight difference is that the trigger perturbation for the middle paths appears at somewhat downstream side, compared to the case of the large meander path. The both cases, however, are found to be developed by a systematic baroclinic energy conversion that transfers the potential energy from the background to the anomalous fields. In contrast, some members stably keep the straight path to the end-date in spite of an occurrence of small disturbance. This suggests that the transitions to the large meander and middle paths are allowable for the jet being baroclinically unstable.

DISCUSSIONS

The bifurcation to the bistate suggests that the multiequilibria in the Kuroshio is governed by a system having super-critical instability. Although similar idea has been proposed in previous theoretical studies, they predict the bimodality between the straight and large meander paths [e.g., 4]. Our first PCA mode is obtained statistically, but can be mathematically proven to be equivalent to the left singular vector having the largest groth rate for the tangential linear operator at a time just before the bifurcation. This suggests that the large meander path and middle path can be interpreted as two possibilities that the order parameter characterized by the largest growing mode can take in a fully nonlinear circumstance.

SUBCRITICAL TRANSITION IN WALL-BOUNDED SHEAR FLOWS

Jacob Cohen*[1], Jimmy Philip[2], Franco Auteri[3] and Michael Karp[4]
[1]Faculty of Aerospace Engineering, Technion- Israel Institute of Technology, Haifa, Israel
[2]Department of Mechanical Engineering, The University of Melbourne, Parkville, Australia
[3]Department of Aerospace Science and Technology, Politecnico di Milano, Milano, Italy
[4]Center for Turbulence Research, Stanford University, Stanford, USA

Summary The sub-critical transition in wall bounded simple-geometry shear flows: Couette, Hagen-Poiseuille, and Plane-Poiseuille, is investigated theoretically. The transition process is initiated by a linear transient growth. This stage is well approximated by four decaying normal modes. Because of the minimal number of modes participating in the transition process, it is possible to follow most of the key stages analytically. The theoretical predictions are compared with direct numerical simulations, and very good agreement with respect to the growth of the disturbance energy and associated vortical structures is observed, up to the final stage just before the breakdown to turbulence. This procedure reveals the role of the different boundary conditions associated with these flows in the transition process.

The current study focuses on a sub-critical transition scenario of wall-bounded shear flows, which are stable with respect to infinitesimally small disturbances. We consider Couette flow (CF), Hagen-Poiseuille flow (HPF) and Plane-Poiseuille flow (PPF). The first two of which are predicted by Linear Stability Theory (LST) to be stable at all Reynolds number whereas the last one is predicted to be stable up to Re=5772. In practice, however, these flows transition to turbulence at finite Reynolds numbers, lower than those predicted by LST. Following the analytical procedure outlined for transition in Couette flow[1,2], here we investigate the transition to turbulence of CF, HPF and PPF, where the process is initiated by a Linear Transient Growth (LTG). We compare the evolution of the transition in these three shear flows associated with simple geometries but different boundary conditions.

The first stage of the transition is that of a LTG. It has been shown that the optimal linear disturbance, leading to the maximum transient growth of energy, is associated with a counter rotating vortex pair (CVP) which is independent (or almost independent) of the streamwise coordinate. Taking advantage of this characteristic, we can approximate the LTG process by following the sum of only four normal (decaying) modes. The modes and their three summation coefficients are obtained analytically. Figure 1 shows the LTG for Couette flow (a) and Hagen-Poiseuille flow (b) for Re=3000. Based on previous studies, the respective spanwise wavenumber (β) and azimuthal wavenumber (n) for CF and HPF are chosen to be 1.66 and 1. In both cases the analytical curves associated with the four modes approximate well the optimal LTG obtained numerically by a singular value decomposition. Furthermore, it is clear from the figure that the LTG is much more effective for CF than for HPF with the maximum energy gain ratio larger by a factor of more than 16. Also, the time at which the maximum is achieved is shorter for the HPF (~0.05) compared to that of CF (~0.14). This can be accounted for by defining the Reynolds number based on the shear and viscous diffusion time scales[3], $Re = (U/h)(2h)^2/\nu = 4Re_{CF}$, where U is one of the wall velocities and h the half channel height. Now, since the energy gain ratio and the time to reach maximum energy are respectively proportional to $1/Re^2$ and $1/Re$, the source for the TG difference between the CF and HPF is clear. More importantly, because of the minimal number of modes participating in the transition process, it is possible to follow most of the key subsequent stages analytically. Following the LTG of the four modes, the evolving modified base flow is subjected to an infinitesimally small disturbance. However, it turns out that the combination of the LTG and the four modes may not be enough to generate strong inflection points, necessary for the initiation of a significant secondary inviscid instability. Thus, the nonlinear mutual interactions between the four modes cannot be neglected. Using a series expansion, these nonlinear contributions are accounted for by utilizing Duhamel's principle. The inviscid (Rayleigh's type) instability is known to be sensitive to the base-flow velocity profiles, and indeed the effect of the four modes' mutual interactions on the velocity profiles is significant. This has been established by comparing the linear and nonlinear velocity profiles along the radial coordinate with the ones obtained by DNS results (see figure 2).

In the secondary stability analysis, we take advantage of the fact that the streamwise component of the base flow is O(Re) greater than the velocity components in the cross-section. Furthermore, we use the fact that there is a separation of time scales between the slowly evolving modified base flow, t=O(Re), and the rapidly evolving secondary disturbance, t=O(1). Accordingly, we employ the method of multiple scales to derive the temporal evolution of the disturbance, where at each "frozen time" step, the stability problem is solved by Floquet theory as the modified base flow is periodic along the spanwise/azimuthal directions. Figure 3 demonstrates the effect of Reynolds number on the above described transition scenario in Couette flow. Our analytical model (solid blue) describing the disturbance energy gain is compared with the corresponding DNS results (solid red). As Re is increased from 1000 to 2000 and to 3000, a lower initial disturbance amplitude is required for transition. Moreover, the difference between the two curves, observed for Re=1000, is reduced for Re=2000 and almost disappears for Re=3000. This difference is associated with a high-order nonlinear transient growth effect that has not been accounted for. Nevertheless, this small difference has a negligible effect on the transition. The vortical structures evolving during the transition process are identified using Q

(the second invariant of the velocity gradient tensor)-criterion and are successfully compared with the DNS results. In the presentation, a detailed comparison will be made between the transition scenarios associated with CF, HPF and PPF.

CONCLUSIONS

In all three shear flows (CF, HPF and PPF) the linear transient growth can be approximated by few normal decaying modes. It is demonstrated that the kinetic energy growth of the initial disturbance is not the key parameter in this transition mechanism. Rather, it is the ability of the transient growth process to generate an inflection point in the wall-normal or spanwise/azimuthal directions and consequently to make the flow susceptible to a three-dimensional disturbance leading to transition to turbulence.

ASYMPTOTICS OF THE LOCALIZED PERTURBATION OF A VISCOUS FLUID FLOW DOWN AN INCLINED PLANE

Andrey Kulikovskii[1] and Julia Zayko*[1]
[1]Department of Mechanics, Steklov Mathematical Institute of Russian Academy of Sciences, Moscow, Russia

Summary The study is devoted to the asymptotic behavior of the linear localized perturbation of the laminar slope flow of a viscous fluid. The flow is described by equations in hydraulic approximation, which can be used to model certain natural flows, for example, dense snow avalanches. The localized perturbation is expressed by a double Fourier integral over the streamwise and transverse wave vector components. The asymptotics at large time for this integral is obtained analytically by the steepest descent method. The asymptotic shape of the region of the growing perturbation is found, as well as the wave crests and the lines of constant growth rate of the perturbation.

INTRODUCTION

The stability of thin liquid films has been widely studied since the middle of the 20th century. Most of the results on linear and nonlinear analyses of thin falling films are described in [1–4]. In [5] Benjamin studied the asymptotic behavior of the three-dimensional localized perturbation of a viscous fluid film down an inclined plane. It was shown that the perturbation is concentrated within the elliptical region in the coordinate system moving with dimensionless velocity $U = 3$. The asymptotic behavior of the localized perturbation of the film, described by the integral boundary-layer model [6], was studied numerically using the saddle point approach in [7]; the film was assumed to flow along the vertical wall so that the pressure gradient across the flow was not taken into account.

Equations in hydraulic approximation are widely used to model natural slope flows (see, for instance, [8]). The pressure gradient across the flow plays a significant role in this approach. In this study, we analytically conduct a linear analysis of the asymptotic behavior of a localized perturbation of the slope flow. The flow is described by two-dimensional equations in hydraulic approximation. The steepest descent method and the saddle point approach are used to obtain the asymptotic evolution of the perturbation as $t \to \infty$.

STATEMENT OF THE PROBLEM

Governing equations and dispersion relation

The uniform laminar flow of a viscous fluid down a slope of constant inclination angle is considered. It can be described by equations in hydraulic approximation if the longitudinal wavelength is much larger than the flow depth. For instance, it can be suitable for modeling of dense snow avalanches [9]. The governing equations in dimensionless form are given in [10]; the geometry of the flow is shown in Figure 1(a).

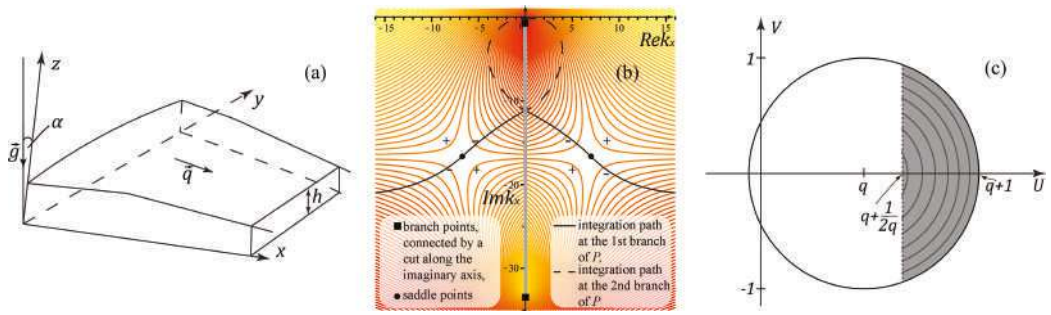

Figure 1: (a) Coordinate system. (b) Topology of the level lines of the function $\mathrm{Im}P = \mathrm{const}$ at the complex plane k_x. The squares define branch points; the gray bold line is the branch cut, lying along the imaginary axis; the circles define saddle points; and the continuous and dashed lines are the deformed integration paths at the 1st and 2nd branches of P, respectively. (c) The gray portion is the region of growing perturbation. The dashed line defines the line where $\mathrm{Im}P = 0$, and the gray circle segments are the wave crests.

We conduct a classical linear stability analysis of the unperturbed flow; the instability condition is $\mathrm{Fr} > 1/2$, where $\mathrm{Fr} = q_0/\sqrt{gh_0\cos\alpha}$ is the Froude number. Here $q = \sqrt{u^2+v^2}$ is the modulus of the velocity vector $\vec{q} = \{u, v\}$, h is the flow depth, α is the constant inclination angle of the slope, g is the gravity acceleration, and subindex 0 denotes the values of the unperturbed flow; h_0 and q_0 are taken as dimensionally independent parameters. The solutions of the dispersion equation are

$$\omega_1 = k_x - iF_0, \quad \omega_{2,3} = k_x - \frac{iF_0}{2} + \sqrt{\frac{k_x^2+k_y^2}{\mathrm{Fr}^2} + 2iF_0k_x - \frac{F_0^2}{4}}. \tag{1}$$

*Corresponding author. E-mail: zayko@imec.msu.ru.

Dimensionless function F_0 represents the friction at the bottom and for the laminar flow of a viscous fluid is $F_0 = 3/Re$, where $Re = q_0 h_0/\nu$ is the Reynolds number and ν is the kinematic viscosity coefficient. All values in (1) and below are dimensionless. In (1) the square root is the double value complex function with two branches; k_x and k_y are the components of the wave vector $\vec{k}$.

Expression for localized perturbation and methods of the study

Denote the localized perturbations of the basic flow depth and velocity components as $w(x, y, t)$. It is expressed by the double Fourier integral

$$w(x, y, t) = \sum_{n=1}^{3} \int_{-\infty}^{\infty} G_n(k_x, k_y) e^{i(k_x x + k_y y - \omega_n t)} dk_x dk_y. \tag{2}$$

For the perturbation of h, u, and v the function w differs by $G_n(k_x, k_y)$. To find the shape of the region of growing perturbation, we must obtain the growth rate of the disturbance for each pair of rays $x = Ut$, $y = Vt$ for all real U, V. Introducing the moving coordinate system $x' = x - Ut$, $y' = y - Vt$, we rewrite the exponent power in (2) as $k_x x' + k_y y' - Pt$, where $P = \omega - k_x U - k_y V$. The imaginary part of the function $P(U, V)$ defines the growth rate of the disturbance for given U, V. The asymptotics of the integral (2) can be obtained by the Laplace method. The function $\mathrm{Im}P$ reaches its maximum in the saddle points, which are obtained from the equations $\partial P/\partial k_x = 0$ and $\partial P/\partial k_y = 0$. For a growing frequency of the dispersion relation (1), the saddle points do not lie at the real axes k_x and k_y so that the steepest descent method is used to transform the integration paths of the integral (2). We apply this procedure subsequently to the integral over k_y and, after it, to the integral over k_x. For the problem considered, we analytically find the saddle points and the topology of the level lines $\mathrm{Im}P = \mathrm{const}$ in the complex planes k_y and k_x. By employing this method, we find the perturbation growth rate for different U and V, the shape of the growing perturbation region, and the wave crests.

RESULTS OF THE STUDY

Note that equations in hydraulic approximation are hyperbolic, so the localized perturbation lies in the circle $(U - q_0)^2 + V^2 \le \mathrm{Fr}^{-2}$. An example of the topology of $\mathrm{Im}P = \mathrm{const}$ level lines in the complex plane k_x and the deformed integration path are shown in Figure 1(b); for this case, $U - q_0 > 0$. It is interesting to note that for the case $U = q_0$ there is an analogy between the function $P(k_x|_{k_y^{saddle}})$ and the complex potential of a flat plate flow, and the critical points of this flow are saddle points for $P(k_x)$.

Introducing the notations $\hat{U} = U\mathrm{Fr}$, $\hat{V} = V\mathrm{Fr}$, $\hat{q} = q_0\mathrm{Fr}$, $\hat{P} = P\mathrm{Fr}$, and $f = F_0\mathrm{Fr}$ and omitting the sign $\hat{}$, we prove that the region of growing perturbation is the portion of the circle given by the following two equations: $(U-q)^2+V^2 \le 1$, $U > q + 1/(2q)$ (the gray region in Figure 1(c)). The growth rate $\mathrm{Im}P$ is independent of V,

$$\mathrm{Im}P = -\frac{f}{2} - fq(q - U), \tag{3}$$

and reaches the maximum in the point $U = q + 1$. The crests of the growing waves are circle segments with the center $U = q$, $V = 0$ (see Figure 1(c)).

CONCLUSIONS

The behavior of the localized perturbation as $t \to \infty$ of a viscous flow down an inclined plane is considered. The asymptotic shape of the growing perturbation region is obtained analytically (the gray region in Figure 1(c)). The result can be useful for natural slope flows and the modeling of thin films.

INSTABILITY PHENOMENA IN SHORT ASYMMETRIC TAYLOR-COUETTE CAVITY

Ewa Tuliszka-Sznitko
Institute of Thermal Engineering, Poznan University of Technology, Poznan, Poland

Summary The paper reports on the numerical investigations of Taylor-Couette flow with rotting inner cylinder and bottom disc, and with stationary outer cylinder and top disc over the range of radius ratio η=0.25-0.6, (Re=100-200). In the investigations the fully 3D DNS code based on the spectral Chebyshev–Fourier approximation is used. Many interesting phenomena are uncovered including the modulated rotating wave, the period doubling cascade and the homoclinic/heteroclinic collision. The period doubling bifurcation is dominated in the flow cases of radius ratio close to η=0.375.

INTRODUCTION

The main purpose of the present numerical research (DNS) is to determine the influence of radius ratio $\eta=R_1/R_2=0.25$-0.6 on the bifurcation phenomena observed by Mullin and Blohm [1] and Lopez et al. [2] in the short Taylor-Couette configurations of η=0.5. The present investigations are thought as complimentary to these results. The DNS computations are performed using code based on the spectral Chebyshev – Fourier approximation (the precision of this method has allowed to gain insight into very complicated flow cases, [3]). To verify the present DNS results the computations obtained for η=0.5 and selected aspect ratios $\Gamma=H/(R_2-R_1)$ have been compared with experimental results of Mullin and Blohm [1]. The comparison has confirmed that for η=0.5 the flow dynamics is governed by a pair of codimension-2 bifurcation points: the double Hopf bifurcation point and the cusp point. The Hopf and Neimark-Sacker bifurcation lines have been reconstructed and the obtained RW_1 and RW_2 flow structures agree with those presented by Lopez et al. [2]. The DNS research has been preceded by the calculations of the saddle-node bifurcation lines along which the transition from the 3-cell structure to the 1-cell structure (and vice versa) takes place (the ENTFIVE code, [4]). These results have shown that the cusp points occur in the wide range of radius ratio η=0.1-0.75 and that the line connecting the cup points creates a parabola in the (Re, Γ) plane with extreme point near η=0.375, [5]. The attention is focused on the modulated rotating wave (MRW) which appears near the cusp point. Following Lopez et al. [2] the investigations of MRW have been based on the one-dimensional parameter path. Lopez et al. [2] have presented (Re=120) the MRW period as a function of Γ. They have found that at lower Γ the increase of T_{MRW} is slow, then it becomes exponential and for the critical value of Γ the MRW period goes to infinity $T_{MRW}\rightarrow\infty$. With increase of Γ (starting from stable state) they have observed consecutively: the stable RW_1 wave, the modulated rotating wave, then, the MRW wave undergoes several saddle-node bifurcations and finally a homoclinic/heteroclinic collision occurs (the MRW wave disappears). Lopez et al. [2] have determined the critical value of Γ at which the MRW wave appears and the value of Γ at which the homoclinic/hereroclinic collision takes place for different Re (see the N_M and C lines in Fig. 25, [2]).

THE RESULTS

The most information on the flow dynamics comes from the velocity components time series (obtained using DNS) - based on the time series the profiles of squared amplitudes $(A)^2$ of the radial velocity component u as a function of Re have been determined for the subsequent values of Γ and η ($(A)^2$ changes linearly with Re in accordance with Hopf bifurcation theory). Then, the unstable areas have been determined for η=0.25-0.6, [5]. Figure1 show time dependent behavior at η=0.475, Γ=3.0404, Re=119.7 (the considered point is very close to the homoclinic collision). Figure1a shows changes of the kinetic energy $k=(u^2+v^2+w^2)/2$ (black line) and the modal energy $\mathbf{u}_0\cdot\mathbf{u}_0^*/2$, $\mathbf{u}_1\cdot\mathbf{u}_1^*/2$ in one period T_{MRW} ($\mathbf{u}_0^*$ and $\mathbf{u}_1^*$ indicate complex conjugate, grey and red lines, respectively). During most of T_{MRW} k and $\mathbf{u}_0\cdot\mathbf{u}_0^*/2$, $\mathbf{u}_1\cdot\mathbf{u}_1^*/2$ have almost constant values. Figure1b shows the variations of u in time obtained in 100 azimuthal sections – it is visible that the flow is 2D during most of T_{MRW} (except for the narrow range of time where $\mathbf{u}_1\cdot\mathbf{u}_1^*/2$ reaches large values). In the investigations of MRW the changes of T_{MRW} with increase of Γ (Re fixed) have been studied. For η=0.475-0.6 the same phenomena have been observed as in Lopez et al. [2], as is evidenced by the similarities of the time series, the phase portraits and the one-parameter path. In the range of η=0.475-0.6 there is no the period doubling bifurcation phenomena and the phase portraits show spiraling orbits. For the flow cases of η=0.375-0.42 the strong period doubling phenomena occur. For η=0.42 a large diversity of phenomena is observed depending on Reynolds number: For small values of Re the one-parameter path shows the occurrence of the period doubling cascade bifurcation, but, for higher Reynolds numbers Re ≥126 the one-parameter paths resemble the solutions observed for η=0.475-0.6. The cascade time series are very complex but in most cases they are regular, see [5]. In such flow cases the strong three-dimensionality is observed – the 3D flow structures coincide with the time ranges in which the modal energy $\mathbf{u}_1\cdot\mathbf{u}_1^*/2$ reaches large values. For the flow cases of η=0.375 the period doubling bifurcation is dominant in the whole MRW area. For η=0.3 the changes of T_{MRW} are milder and all observed unsteady processes are much weaker in comparison to those observed for higher η.

For the flow cases of η=0.375, 0.475, 0.6 the lines of the RMW appearance and the homoclinic collision (above which the flow becomes steady) have been determined for different Re and compared to the corresponding N_M and C lines in Lopez et al. [2]. The comparison shows that scenario proposed by Lopez et al. [2] for η=0.5 is valid for wide range of

radius ratio η (regardless of the differences in the bifurcation phenomena mentioned above, [5]). The investigations have also shown that regardless of the complexity of some time series the elementary flow parameter profiles in the circumferential direction are always smooth, see Figure 1c.

For comparison, the DNS studies have also been performed for the short Taylor-Couette configurations with two rotating end-walls (Re=90-150, Γ=3.7-4.2, η=0.5, 0.45). In these flow cases the rotating discs cause the strong outward motion along the end-walls (two strong Ekman vortices occur) and thus produce a strong symmetric forcing on the flow. The unsteady area results from the interaction of the Hopf bifurcation and the steady-state fold bifurcation. Many interesting phenomena have been uncovered. The results are compared with experimental data published by Mullin [6]. All bifurcation lines presented in [6] (Fig. 2) have been reconstructed.

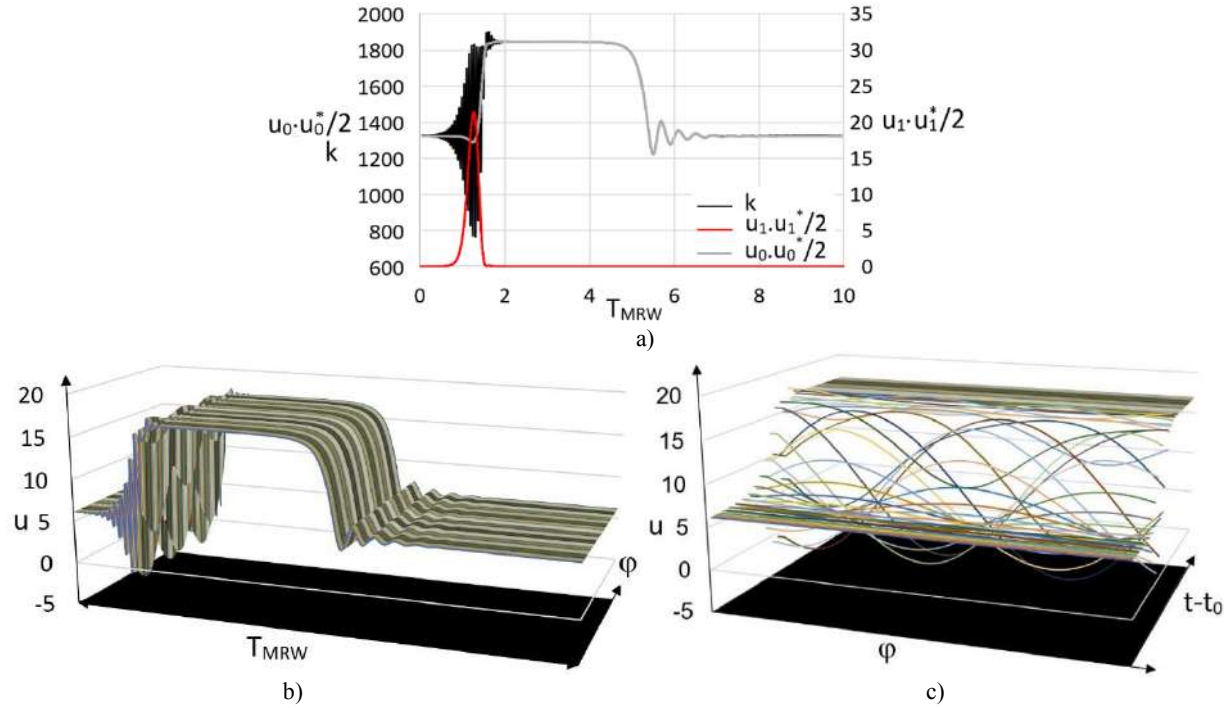

Figure 1. a) The time series (one period) of the kinematic energy k (black line) and the modal energy $\mathbf{u}_0\cdot\mathbf{u}_0^*/2$ (grey line), $\mathbf{u}_1\cdot\mathbf{u}_1^*/2$ (red line), c) the time series of the radial velocity component u obtained for 100 azimuthal sections, c) the azimuthal profiles of the radial velocity u = f(φ) obtained in this part of T_{MRW} where $\mathbf{u}_1\cdot\mathbf{u}_1^*/2$ reaches large values. η=0.475, Re=119.7, Γ=3.0404, [5].

CONCLUSIONS

The presented DNS results clearly show the directions of changes occurring in the short asymmetric Taylor-Couette flow dynamics with changes of radius ratio η. The research has shown that the scenario of bifurcation processes presented by Lopez et al. [2] for radius ratio η=0.5 is valid for a very wide range of η. The most interesting phenomena have been found for η=0.375-0.42 where the period doubling bifurcation is observed.

COMPLEXITY OF PHASE DISTRIBUTION IN TWO-PHASE FLOW USING COMPOSITE MULTISCALE ENTROPY

Gabriela Rafałko*[1], Romuald Mosdorf[1], Grzegorz Litak [2], Grzegorz Górski[1]
[1]Faculty of Mechanical Engineering, Bialystok University of Technology, Bialystok, Poland
[2]Department of Automation, Lublin University of Technology, Lublin, Poland

Summary The paper presents two-phase flow analysis using Composite Multiscale Entropy (CMSE). The two-phase flow of water-glycerol and air phases in a 3 mm, circular minichannel was taken into consideration. The video frames were extracted for particular flows and further computed in order to perform a phase distribution complexity examination in such flow. Finally, CMSE curves and complexity indexes were obtained for the analysed series. It can be concluded that CMSE and CI enable flow pattern analysis and further identification.

INTRODUCTION

During two-phase flow in minichannel changes of gas and liquid phase distribution are observed. The form of gas phase organisation in a minichannel determines certain flow pattern. The analysis of two-phase flow is crucial in understanding different mechanisms of this phenomenon [1, 3]. The flow patterns observed in a minichannel are complex and instable. Numerous studies have shown different approaches to the identification of two-phase flow patterns such as: image analysis methods [2, 7], nonlinear methods [6, 8], or for instance, certain two-phase flow parameters determination [5]. There are numerous two-phase flow analysis methods, however there still is a need of deep investigation of the phenomena observed in a two-phase flow due to the instabilities and changes in phase distribution. Thus, in the paper the concept of composite multiscale entropy (CMSE) is applied in order to analyse the complexity of phase distribution in two-phase flow.

EXPERIMENTAL SETUP AND DATA CHARACTERISTICS

In the experiment two-phase flow patterns in a circular minichannel (3 mm x 3 mm x 60 mm) have been taken under consideration. The flow consisted of two phases, liquid phase: water – glycerol solution (solution's concentration: 45 %) and air phase. The experimental schema is shown in Fig. 1. A pump (4 – Fig. 1) generated compressed air which passed through an air tank (5 – Fig. 1) and a valve (6 – Fig. 1). Next it was directed into the constant pressure air tank (5 – Fig. 1), a flow meter (8 – Fig. 1) and a special micro-bubble generator (1 – Fig. 1). A water tank (7 – Fig. 1) was also a part of the setup. The two-phase flow patterns were recorded using the Phantom v. 1610 high speed camera (2 – Fig. 1). The light (3 – Fig. 1) was directed onto the minichannel.

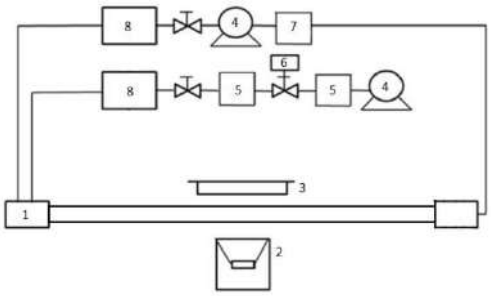

Figure 1. The experimental schema: 1 – a special micro-bubble generator [8], 2 - Phantom v. 1610 high speed camera, 3 –lightning system, 4 – pumps, 5 – a constant pressure air tank, 6 – a valve, 7 – a water tank, 8 – flow meters.

The videos of the flow were recorded using the Phantom v. 1610 high speed camera with a frequency of 5000 fps. The films were divided into the frames which presented grayscale flow pattern images (64 pixels x 1280 pixels) (Fig. 2). The gathered two-phase flow video frames (10 for each observed flow) have been converted into pixel matrices. First, a central part of the frame was extracted (24 pixels x 800 pixels).
Next, each data set presenting observed flow was calculated using CMSE formula for m=2, k=1:49, r=0.2 [9]. Additionally, the complexity index value (CI) [9], which is defined as integral of the CMSE curve was assessed. Figure 3 shows CMSE curves and CI indexes for flows presented in Fig. 2 a-c and Fig. 2 g.

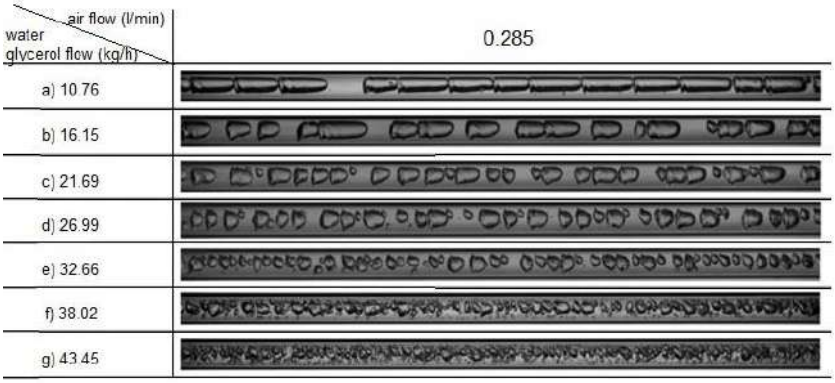

Figure 2. The analysed two-phase flow patterns (water-glycerol and air flow) characterised by constant air flow rate (0.285 l/min) and different water – glycerol flow rates; observed flow patterns: a) long slugs, b) slugs, c) slugs and cap bubbles, d) short slugs and cap bubbles, e) cap bubbles and bubbles, f) bubbles, g) minibubbles.

RESULTS

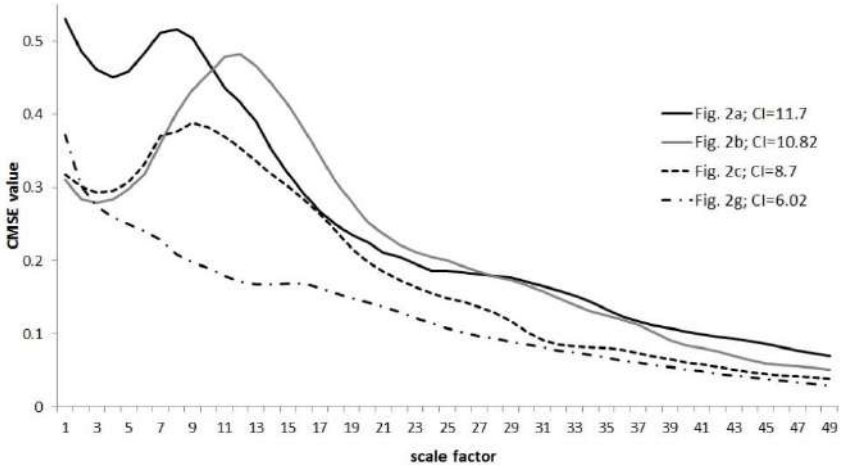

Figure 3. The CMSE curves and CI of four different observed flows.

CONCLUSIONS

Results show that CMSE curves and CI value can unable distinguishing two-phase flow patterns. In the Fig. 3 CMSE for slug flow is similar to a CMSE curve of correlated noise while CMSE for minibubbles presents a curve similar to an uncorrelated noise. The level of CMSE determines the flow pattern order, the lower the CMSE level, the more chaotic/stochastic the observed flow is. As the scale factor increases the level of CMSE decreases – less and less details are observed in the flow.

NAVIER-STOKES SOLUTIONS WITH SYMMETRY RESTRICTIONS AND THEIR RELATION WITH TRANSITIONAL AND TURBULENT PIPE FLOWS

V.G. Priymak*
A.M.Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russia

Summary The problem of Poiseuille flow stability in an infinite circular pipe is a model one for subcritical transition studies since Osborne Reynolds results. The prevailing mathematical model describing all the related physics consists of incompressible unsteady Navier-Stokes equations in cylindrical coordinates (r, φ, x), streamwise periodic velocity, no-slip conditions at the walls, constant mass flux (or constant pressure gradient) driving and naturally 2π-periodic velocity along the azimuthal direction. Navier-Stokes solutions are also assumed to satisfy suitable regularity conditions at $r = 0$. Calculations using this model are very expensive, also the computed dynamics is chaotic and too complex to decode the transition scenario. Therefore, it may be relevant to simplify the mathematical model. In the present study we consider certain simplifications, including popular cases restricting the dynamics to reflectional (about the meridional plane $\varphi = 0$) and rotational (e.g., π-rotational) symmetries. We show that in these two cases certain flow characteristics cannot be properly computed, whereas others are only weakly sensitive to symmetry constraints. Accurate calculations are carried out at two Reynolds numbers Re= 2000 and 4000 corresponding to spatially intermittent flow and essentially uniform turbulence.

PROBLEM FORMULATION

The flow of an incompressible viscous fluid in a pipe $\Omega = \{\mathbf{r} = (r, \varphi, x) : 0 \leqslant r < R, 0 \leqslant \varphi < 2\pi, |x| < \infty\}$ is described here by the Navier-Stokes equations

$$\partial_t \mathbf{v} = -\nabla(p/\rho + \mathbf{v}^2/2) + \nu\nabla^2\mathbf{v} + \mathbf{v}\times\boldsymbol{\omega}, \quad \nabla\cdot\mathbf{v} = 0 \quad \text{in } \Omega, \tag{1}$$

where $\mathbf{v} = (v, w, u)$ is the velocity, $\boldsymbol{\omega} = \nabla\times\mathbf{v}$, and p, ν, ρ are respectively, pressure, kinematic viscosity and constant density. Equations (1) are supplemented with certain initial conditions for velocity. The boundary conditions are periodicity in the axial direction $\mathbf{v}(r, \varphi, x, t) = \mathbf{v}(r, \varphi, x + X, t)$ and no-slip on the wall $\mathbf{v}|_{r=R} = 0$, satisfying the volume flux conservation constraint $U(t) = (1/\pi R^2)\int_0^R r\,dr\int_0^{2\pi} d\varphi u(r, \varphi, x, t) = const$.

Spatial discretization of (1) involves Galerkin trigonometric approximation in x, φ and pseudospectral technique with Chebyshev collocation nodes $r_j = R\cos(\pi j/2Q)$, $j = 0, 1, \ldots, Q$ in radial direction. We represent solution by the truncated Fourier series

$$\mathbf{v} = \sum_{n=-N}^{N}\sum_{m=-M}^{M} \mathbf{v}_{nm}(r, t)\, exp(i\alpha_m x + in\varphi), \alpha_m = 2\pi m/X. \tag{2}$$

For Eqs. (1) written in terms of $\mathbf{v}_{nm}$ there is no physical boundary at $r = 0$, therefore suitable regularity conditions are imposed at the polar axis. These conditions exploit (but do not meet exactly) special behaviour of analytic functions in the vicinity of $r = 0$, established by Theorem 1 of [1]. We require the weaker condition that the Navier-Stokes equations be nonsingular at the origin [1]. Direct numerical simulation using the above mathematical model adequately describes (see [2]) both intermittent and turbulent flow regimes at $1950 \leqslant \mathrm{Re} \leqslant 4000$ without *a priori* requirements of certain rotational or reflectional symmetries.

These long-term and high resolution calculations are very expensive, also the computed dynamics is chaotic and often too complex to decode the transition scenario. Therefore, it may be relevant to simplify the mathematical model. In the present study we consider certain simplifications, including popular cases restricting the dynamics to the reflectional symmetry

$$[v, w, u](r, \varphi, x, t) = [v, -w, u](r, -\varphi, x, t), \tag{3}$$

and π-rotational symmetry

$$[v, w, u](r, \varphi, x, t) = [v, w, u](r, \varphi + \pi, x, t). \tag{4}$$

NUMERICAL EXAMPLES

To understand if the long-life (with an extensive statistically stationary stage) Navier-Stokes solutions with symmetry restrictions do exist and what is their relationship with transitional and turbulent flows in Ω, we carried out special calculations at two Reynolds numbers Re= 2000 and 4000 with $X = 120\pi R$ and $(Q+1)\times(2N+1)\times(2M+1) = 33\times81\times2401$ spectral modes in r, φ, x. Previous work briefly concerns only the cases of reflectional symmetry and turbulent flow regime [1]. We show that the use of symmetry relations (3),(4) turns out to be rather insidious: certain flow characteristics cannot be properly computed, whereas others are only weakly sensitive to symmetry constraints (see Fig. 1, Re= 4000). The same is true in the core region of turbulent puffs at Re= 2000.

*E-mail: vgpriymak@mail.ru.

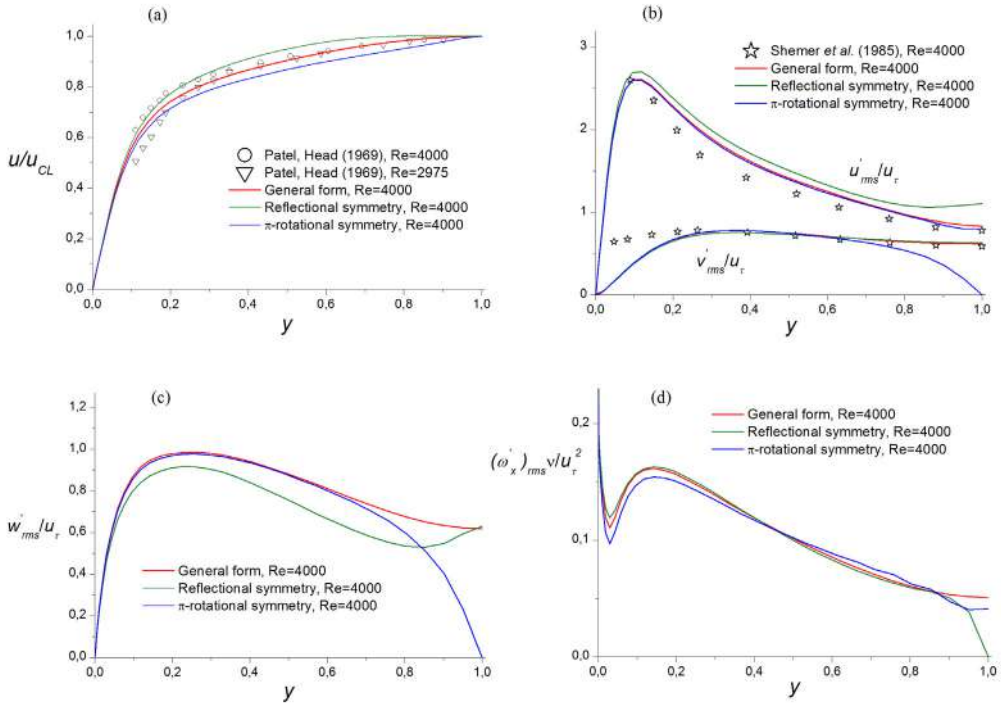

Figure 1: Comparison of flow characteristics corresponding to solutions of the Navier-Stokes equations without symmetry constraints (i.e. of general form), with reflectional symmetry and with π-rotational symmetry. (a) Mean velocity profiles normalized by the centreline velocity. (b) Root-mean-square streamwise and radial velocity fluctuations as functions of distance $y = 1 - r/R$ from the pipe wall. (c) R.m.s. azimuthal velocity fluctuations profiles. (d) R.m.s. streamwise vorticity fluctuations distributions.

CONCLUSIONS

The appeal of using symmetries (3),(4) is due to the fact that the complexity of calculations may be considerably reduced: one half of Fourier modes in (2) is equal to zero both for (3) and (4) conditions.

At the same time we show here that numerical Navier-Stokes solutions with symmetry restrictions cannot accurately describe basic turbulence statistics for actual pipe flow. This fact is sometimes overlooked when constructing simplified mathematical models (see, e.g., [3, 4, 5]): time-periodicity (in a comoving frame) of limiting solutions on the separatrix between laminar and turbulent attraction regions is the result of *a priori* requirements of a π-rotational and reflectional symmetries. Perhaps this is an oversimplification of the mathematical model.

Let us note in conclusion the following technical point. If the initial velocity field satisfies the symmetry conditions, then these conditions are reproduced at arbitrary times even when using universal computer code. Rounding errors cease to play a destabilizing role in this case: the result of multiplying the non-zero value of a variable by a machine zero (when calculating quadratic nonlinear terms) is interpreted by the computer as a machine zero. As a result, we may not even suspect that we are calculating symmetric solutions of the Navier-Stokes equations.

RESPONSE OF A LAMINAR SEPARATION BUBBLE TO CONTROLLED DISTURBANCES WITH MODULATED AMPLITUDE

Pedro B P Panisset[1], Igor B de Paula[1], and Omar H O Pinedo [1]
[1]Department of Mechanical Engineering, Pontifícia Católica do Rio de Janeiro, RJ, Brazil

Summary Laminar separation bubbles are highly influenced by disturbances upstream the separation location. Here, time-resolved velocity fields are measured with PIV in order to resolve variations of bubble topology when subjected to changes in the level of background disturbances. Experiments are carried out in a low turbulence and close return water tunnel. Disturbances are introduced with a vibration ribbon and phase locked acquisitions with respect to excitations enable to use ensemble averaging techniques. Spectra of fluctuations near the inflection point showed amplification of fluctuations in a narrow bandwidth with dominant non dimensional frequencies within a range of 0.08<St<0,1. Proper orthogonal decomposition analysis showed that the most energetic modes reach around 15% of total disturbance energy at the final stages of the separated flow. Spatial distribution of the most energetic modes suggests that the transition was governed by Kelvin Helmholtz instability mechanisms.

INTRODUCTION

Following the technological advances in aerial vehicles and low pressure turbines, improvements of the aerodynamic performance has become essential. Due to the low chord-based Reynold number (from 104 to 106), the flow over an airfoil may separate from the surface and laminar to turbulent transition occur. The laminar separation bubble appears in this context as a result of the transition process result on the separated shear layer. LSB is responsible for changes in the dynamic behavior of the airfoil.

Some works showed that the presence of LSB creates a plato on the coefficient pressure profile [1,2], increasing drag and reducing lift. Reynold number, freestream disturbances (such as acoustic disturbances), freestream turbulence, pressure gradient, surface roughness, geometric discontinuities are the main parameters that promote significant topological changes in the bubble [3]. Depending on the Reynold number and the angle of attack, imposed external disturbances modify the bubble structure [4]. It's a result of the amplification of small-convective perturbations that trigger the laminar-to-turbulent transition process [5]. Optimal effect of the disturbances is linked to the amplitude and frequency which it is generated. However, the selection of the best frequency range is even difficult. Conform the perturbations are introduced, the deformation of the mean flow alter the spectral profile. In this way, more experimental result are needed to confirm this nature of the flow.

The experiment in this work was carried out on a flat plate subjected to an adverse pressure gradient, in a low turbulence and close return water channel. Controlled disturbances were introduced by means of a vibrating ribbon displaced just upstream of the separation point. The vibrating ribbon was induced by a surface-mounted magnetic actuator. Planar, time-resolved PIV technique was used for measurements of quasi-steady state of the bubble. The objective of this study is to examine the free stream turbulence effect on the mean topological feature of the bubble. First, geometrical parameter are compared with the literature. Then, spectral analysis and proper orthogonal decomposition (POD) are performed to give more information about LSB stability characteristics.

EXPERIMENTAL METHODOLOGY

The experiment of this paper was conducted on a low turbulence level and close return water tunnel. With the aid of a frequency inverter ranging 0.1-20Hz, a motor fan generates the flow in the range of 0.05-0.15m/s. The measured turbulence level in the test section is about 0,15%. To this end a hot film and a TSI IFA3000 system were employed. It is important to mention that a great part of turbulent fluctuations lay is within the electronic noise level of the anemometer circuit. A flat plate having 3000mm long was inserted in the test section at 600mm downstream from the test section inlet. The plate is made of transparent polycarbonate. The plate is equipped with a flap for adjustment of the stagnation point on the leading edge. Above the flat plate a false wall was built in order to create a variable pressure gradient on the plate. In the present configuration, the false wall created a convergent, divergent channel over the plate. The angle of divergent wall could be adjusted in order to provide a prescribed constant adverse pressure gradient. The throat height at the vertex of convergent-divergent channel was fixed in 200mm. On the divergent part suction slots were machined on the false wall in order to avoid separation. Centrifugal pumps Sarlo2000 were used for boundary layer suction. The water was pumped to the tunnel corner downstream from the test section.

Controlled disturbances were created using a vibrating ribbon made of steel. The oscillation of the ribbon was provided by an electrical magnet with a controlled current. The magnet was placed in a sealed case that was flush mounted with the flat plate surface.

Time resolved velocity fields were measured using a planar PIV system. High sampling frequency was achieved using a double cavity laser LITRON LDY-300, which provides 30mJ/pulse at 2kHz, and a MotionPro X3Plus, which has a resolution of 1280x1240 and can run at frequencies up to 2000frames per second. Illumination and imaging systems were synchronized by a TSI 610036 synchronizer. For present measurements the sampling frequency was set to

250Hz. A set of spherical and cylindrical lens was used to create the illumination plan for PIV measurements. Polyamide particle tracers with diameters of about 20um and density of 1.03kg/m3 were used for flow seeding. Routines developed in LabView and Matlab platforms allow to control the image acquisition and the PIV processing.

PRELIMINAR RESULTS

According to [6], some topological parameters of LSB are relevant to describe the bubble nature. In this work the Falkner Scan parameter was constant and equals -0.22. The Reynolds number based on the momentum thickness at separation is 332 which do also display a good agreement with the literature. In this study, (γs) was obtained following the methodology proposed by [6]. The empirical correlation proposed in that work predicts an angle of 0.034 rad for a ratio LI /Ld = 0.068. In current experiments an angle γs = 0.038 rad was found which is in agreement with the model proposed for bubbles measured in wind tunnels. Figure 1 show the inflectional velocity profile along the bubble and power spectrum density of the disturbances. As expected, inflection of the profile is more pronounced from near the separation point until the reattachment point. Downstream of the reattachment the velocity profile asymptotically tends to a fully turbulent one.

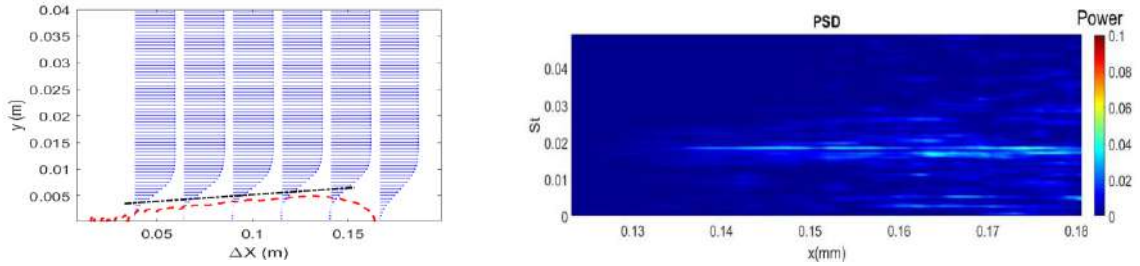

Figure 1. Right: Bubble contour (dashed red), mean velocity vectors (blue vector) and inflection of mean velocity profile (dashed-dot black line). Left: Contour of power density spectrum of the streamwise velocity.

The dominant frequencies on the velocity fluctuations along the separation region can be observed in Figure 1. In this case, no controlled excitations were introduced in the boundary layer. The figure shows a clear energy peak in narrow frequency bandwidth. Near the reattachment point the most prominent perturbations are within the range of nondimensional frequencies of 0.016<St<0.019, where St is the Strouhal number given by St=fδ*/U∞. These spatial structure of flow fluctuations in this frequency range are also characterized. In the full paper, similar results will be presented for the case with controlled excitations.

In order to analyze spatial structure of the fluctuations 2000 instantaneous velocity fields were analyzed using Proper Orthogonal Decomposition (POD) technique. The analysis is done only in the region of reattachment bubble. The first two modes shown in the Fig. 4 represent the same type of structure and show rapid growth of perturbations. These structures resemble those of Kelvin-Helmholtz instability [7]. In the full paper the role of controlled excitation and the transient growth of the bubble will be assessed and the results will be presented accordingly.

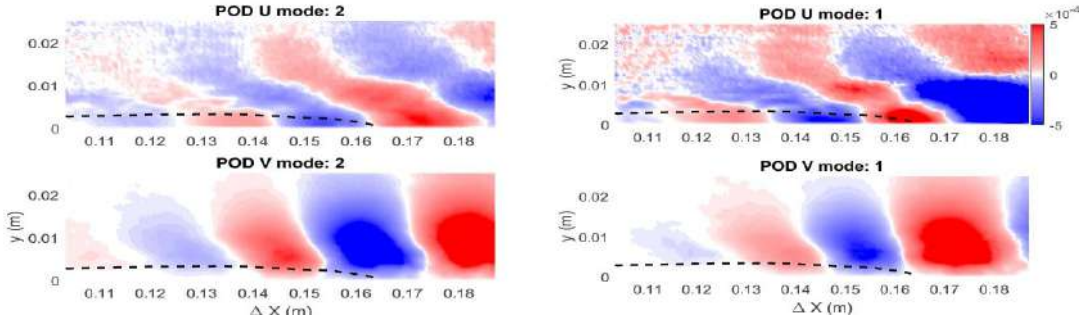

Figure 2. Most energetic POD modes of streamwise and wall normal fluctuations.

INFLUENCE OF NOISE ON THE WAVE NUMBER CHOICE AFTER FIRST INSTABILITY IN THE SPHERICAL COUETTE FLOW

Olga Krivonosova*[1], Maria Gritsevich [2,3,4], Dmitry Zhilenko [1]and Peter Read [5]
[1]Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia [2]Finnish Geospatial Research Institute (FGI), Masala,Finland

Summary In this study we carried out investigations on wave number selection for rotating spherical flow, when its state changes from subcritical to supercritical one in the presence of noise and forcing. Noise is injected to the flow by irregular in time perturbations in the imposed rotational rate and forcing – by rotation with acceleration. The obtained results provide insights into nonlinear interactions and energy exchange between competing modes in model flows and can be extended to flows in astrophysical objects, such as pulsars, and also to the selection of circulation regimes in the atmosphere.

PROBLEM UNDER STUDY

Numerous examples have been reported among experiments and calculations in fluid flows in which multiple stable solutions with different wave numbers can be observed at the same Reynolds numbers [1-3]. In this study experiments [4] and preliminary DNS were carried out to study how the selection of one from two possible wave numbers in the onset of azimuthal waves following the first instability depends on noise amplitude in the presence of the inner sphere acceleration. The acceleration is determined by the initial and final Reynolds numbers and the time of transition between them. The flow of viscous incompressible fluid in the gap between concentric spherical boundaries, induced by their rotation about common axis, is under study. The outer sphere was held stationary, while the inner sphere rotational speed was increased linearly from a subcritical flow (further denoted as 0) to a supercritical one, with azimuthal wave numbers m=3 or m=4 (further denoted as 3 or 4). Noise perturbations were added to the flow by introducing small (not more than 1.5%) irregular in time disturbances into the rotational speed signal. The noise which was used in experiments looks like white noise in accordance with its kind of spectrum. The flow velocity measurements were conducted by using laser Doppler anemometer to investigate the behaviour of competing modes in their stages of damping and growth.

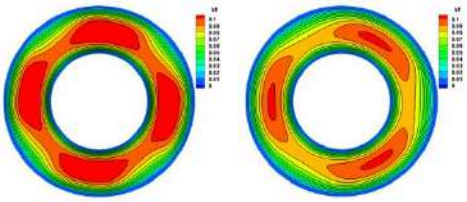

Figure 1. Contour lines of radial velocity component in equatorial plane for azimuthal waves with m = 4 (left) and m = 3 (right)

RESULTS

With an increasing of noise amplitude, a change in the dominant m value was found to occur at the same initial and final Reynolds numbers and acceleration values. It was revealed that several scenarios for wave number transition as a function of noise amplitude can be observed with increasing acceleration rate. At relatively “small” and “large” noise amplitudes, the favoured wave numbers may remain constant - m=3 in the first case and m=4 in the second case independently of the acceleration rate. The values of “small” and “large” noise amplitudes were found to be dependent on initial Re number, corresponding to the beginning of acceleration phase. At intermediate noise level, one change in wave number (from transition $0 \rightarrow 4$ to transition $0 \rightarrow 3$) or two (starting from transition $0 \rightarrow 4$ to transition $0 \rightarrow 3$ and then from $0 \rightarrow 3$ to $0 \rightarrow 4$) were observed with accelerating rate increasing. Effects on wave number transitions with increasing acceleration for constant noise intensity, and with noise intensity increasing at constant acceleration, as obtained in our work, were also observed in experiments [5] on surface water waves, generated under the action of sinusoidal forcing. The imposed noise increases the total time-scale of competing linear mode interactions, ranging from the beginning of ultimate growth of the preferred mode to the time when the damping mode reaches its maximum amplitude. The latter was confirmed by preliminary DNS, as well as change in wave number (from transition $0 \rightarrow 4$ to transition $0 \rightarrow 3$) with accelerating rate increasing.

CONCLUSIONS

It was shown that the action of imposed noise leads to energy transfer from the initially preferred to the corresponding damped mode, increasing both its maximum amplitudes and increments of growth. The noise destroys the results of an acceleration in the boundary conditions and the persistence of the preferred number m=4 is observed.

BOUNDARY LAYER TRANSITION DETECTION USING ADVANCED INFRARED THERMOGRAPHY

A.V. Ivanov*[1], A.V. Boiko[1], D.A. Mischenko[1]
[1]Khristianovich Institute of Theoretical and Applied Mechanics, SB RAS, Novosibirsk, Russia

Summary The problem of accurate experimental detection of boundary layer transition position in wind-tunnel tests is discussed. A new robust and highly resolving technique using IR-thermography is suggested. The developed techniques are successfully applied for boundary layer transition detection in a broad range of base flow parameters and wing model configuration. Thus, a significant and valuable experimental database for verification of boundary layer transition position prediction tools is obtained.

INTRODUCTION

The highest potential for increasing of aircraft efficiency usually attribute to reduction of turbulent friction drag that is the greatest part (about 50%) of total drag of modern commercial aircraft. The most natural way of turbulent drag reduction is flow laminarization, i.e. enlargement of laminar flow run and consequently reduction of turbulent flow regions. The main targets of laminarization are aircraft wings, vertical and horizontal tails. Transition of boundary layer flow from laminar to turbulent state in flight conditions on these wings usually happens due to amplification of boundary layers waves and vortexes triggered by different wing surface imperfectness (like surface roughness, waviness etc) or maybe by different external flow factors like enhanced turbulence level of the free stream or high acoustic level. In order to reach the required laminarization the engineers need new reliable and well verified approaches for calculations of boundary layer flows and prediction of the laminar-turbulent transition position.

In frame of the current experimental study it is supposed to create experimental database for verification of the developed computational transition prediction code. Creation of such verification database suggests exact detection of the beginning and the ending of the laminar-turbulent transition process at significant variation of the base flow parameters (velocity and turbulence level of incident flow) and in a wide range of wing model configuration (attack angle, nondimensional amplitudes of wing surface roughness). In all studied cases the potential flow and boundary layer flow have to be documented accurately together with model geometry and accurate documentation of environmental perturbations (free stream turbulence level, surface roughness etc). Since the present study suggests multiple variations of the model and flow parameters, for detection of transition position we have chosen IR-thermography since this method is non-contact, fast and provides panoramic view of the transition picture.

EXPERIMENTAL SET-UP

The experiments were performed in subsonic low-turbulence wind tunnel T-324 of ITAM SB RAS (Novosibirsk, Russia). The model of 45 degree swept wing (SW45) installed in the test section of T-324 is shown in Fig.1. The model has comprehensive structure including rigid frame (comprising ribs and stringers), outer wing skins made of transparent acrylic sheets (fixed to the frame) and attachable CNC milled leading edge. SW45 model has modified profile NACA 67 1-215 (the same as in studies [1], [2]) and the chord length C=0.8 m in direction normal to the leading edge (LE). The pressure distributions over the model was measured with help of 34 static pressure taps available on the model surface. The integral boundary layer characteristics, potential flow streamlines, streamwise distributions of velocity over the model and freestream turbulence levels were documented with help of hot-wire technique for various angles of attack. The model surface roughness was documented with help of laser displacement sensor. The incident flow turbulence level was varied from low level Tu~0.09% up to enhanced level Tu~0.8%. The incident flow velocity Q_∞ was varied in a wide range from 10 to 50 m/s in order to observe and document transition position shift due to Reynolds number variation.

AN APPROACH FOR INFRARED THERMOGRAPHY FOR LAMINAR-TURBULENT TRANSITION DETECTION

To increase the thermal contrast between laminar and turbulent regions the swept-wing model SW45 was externally preheated before each wind tunnel run with help of array of halogen lamps up to +6°C above ambient air temperature. Then the wind-tunnel starts together with the start of model surface temperature records performed by IR-camera FLIR SC 7300 (with the frame rate about 100 fps). The processing of the recorded IR-movies have shown that in case of low free stream turbulence level, when transition to turbulence caused by amplification of stationary cross-flow vortices only, the IR-images (movie frames) have their maximum temperature contrast in 10-20 seconds after the wind tunnel reach the desired incident flow speed. In this case the averaged transition position can be assessed from a single IR-frame, even if the frame is somehow spoiled by different artefacts caused by initial non-uniformity of the model preheating and significant non-uniformity of the model parts thermal capacity. It was demonstrated here and earlier in [1] that using of time derivative of surface temperature dT_s/dt instead of surface temperature T_s itself provides significant improvement of the transition imaging and helps to get rid of the mentioned artefacts. One should note that when the IR-frames reach their

*Corresponding author. E-mail: andi@itam.nsc.ru .

maximum contrast (10-20 sec after the wind tunnel speed settling) the values of derivatives dT_s/dt usually differ in laminar and turbulent areas not very significantly.

Much harder cases for transition detection by IR-technique are found in the studied regimes with cross-flow dominated transition in cases of enhanced levels of free stream turbulence. In these cases, the transition process becomes unsteady due to significant presence of unsteady, traveling cross flow modes excited due to receptivity to the free-stream turbulence. As a result, the temperature contrast of IR-frames in laminar and turbulent areas become much less pronounced, the number and levels of artefacts growth significantly (see Fig.2 left). The calculation of time derivative dT_s/dt from the recorded IR-movies somehow helps to improve the transition imaging, however the signal to noise ratio still remains low and insufficient for successful transition position detection.

The solution of the experimental problem was found due to detailed temporal analysis of the model surface temperature records. It was found that just after the wind tunnel speed settling, there is a very short time period (1-4 sec only) when the model surface in turbulent areas cools significantly faster than in laminar ones. In fact, during this short period forms the main surface temperature difference between areas with laminar and turbulent flows. The derivatives dT_s/dt calculated in this specified period differ in laminar and turbulent areas with factor of 4(!) that allow detection not averaged transition position only, but also clear detection the beginning and the ending of the laminar-turbulent transition process (see Fig. 2 right)

RESULTS

The present experimental study resulted to development of highly resolving technique for detection of laminar-turbulent transition stages with help of IR-thermography. Application of this technique allowed evaluation of the laminar-turbulent transition position in numerous regimes with various model attack angles and flow speeds including cases of Tollmien-Schlichting waves dominated transition, cross-flow dominated transition (and combination of both), as well at the low and enhanced turbulence levels of the free-stream. The quantitative results of the study will be given in the presentation.

ON THE SIMULATION OF TS WAVES OVER VERY SMALL ISOLATED ROUGHNESS AND ITS RESULTS

Fernando H. T. Himeno*[1], Marlon S. Mathias [1], and Marcello A. F. de Medeiros[1]
[1]Department of Aeronautical Engineering, University of São Paulo, São Carlos, São Paulo, Brazil

Summary Experiments demonstrate that interactions of TS waves of amplitudes about 1% of free-stream velocity with minuscule roughness can trigger transition. Simulating this phenomenon can be difficult as many numerical procedures cannot mesh such small roughness. In acoustic receptivity studies a Taylor-expansion-based non-homogeneous boundary condition on a smooth wall has been successfully used for this purpose. Here we show that such an approach overestimates the roughness effect on the TS wave in a 2D incompressible flow. The study also investigates the effect of roughness on a TS wavepacket in 2D incompressible flows using meshed roughness and will be extended to 3D compressible ones.

INTRODUCTION

The transition to turbulence can be sensitive to very small surface irregularities. [1] investigated experimentally the interaction of a monochromatic TS wave with an isolated cylindrical roughness. They found that for a TS wave of amplitude in the order of 0.5 to 1%, even the smallest roughness still affects the transition. The present study aimed at numerically investigating this phenomenon and extend the analysis to more generic types of TS waves, such as wave packets. Modelling very small excrescences with body fitted grids require high mesh refinement which increases computational cost. Moreover, for many numerical methods including such small roughness can be impossible [4]. Hence, several studies represent small irregularities by a non-homogeneous boundary condition on the wall based on a Taylor expansion of the flow without any roughness. This has been done not only for steady flows [4], but also for unsteady flows in the context of receptivity to acoustic waves [3], both showing that up to roughness heights of $0.1 \times \delta^*$ the results are indistinguishable from body fitted solutions. Here, however, we consider the interaction of a roughness with a TS wave generated upstream of the roughness. We could not find numerical studies of this kind in the literature. To test the approach, simulations were carried out for a small roughness with a body fitted roughness and also with a non-homogeneous boundary condition based on a Taylor expansion for comparison.

METHODS

We used an in-house DNS code in a structured mesh. The time-marching is performed by 4th order Runge-Kutta scheme and the spatial differentiation by a 4th order spectral-like method. A 10th order spatial anti-aliasing filter was applied and buffer-zones were included at the open boundaries to prevent spurious oscillations. The code is parallelized and solves the compressible Navier-Stokes equations as we intend to extend into the compressible regime. Details of the code implementation and validation are found in [2].

PRELIMINARY RESULTS AND CONCLUSIONS

As a preliminary study, we considered a two-dimensional simulation of a flat plate with a rectangular roughness element and verified its influence on the evolution of a TS wave. Parameters were non-dimensionalized by the displacement thickness at the roughness center, δ^*_R, and by the free-stream speed. Based on the experiments from [1], the Reynolds number was $Re_R = 950$. The physical domain was $0 \leq X \leq 800$ and $0 \leq Y \leq 20$ in non-dimensional variables. The disturbance was located at $X_D = 200.51$ and was composed by 10 time-harmonic modes of the fundamental frequency $F = 90 \times 10^{-6}$. The excitation strip had a length $\Delta X_D = 20$. The roughness was centered at $X_R = 320.82$ with length $\Delta X_R = 13.37$ and height $h_R = 0.1 \times \delta^*_R$. The Mach number $M = 0.3$, which can still reasonably represent an incompressible flow, with much reduced simulation time in our code. The velocity derivatives for the Taylor expansion roughness representation were obtained from a numerical simulation of the packet evolution on a corresponding smooth plate. This provided the velocity fields in space and time from which the time varying derivatives were calculated to enforce the non-homogeneous boundary condition not only on the mean flow, but also on the TS waves. Nonlinear effects directly associated with the roughness height cannot be accounted for by this model, but they were not expected to be relevant at such small heights. Figure 1(a) shows the evolution of δ^*. It is seen that the roughness affects the boundary layer thickness and the non-homogeneous boundary condition captured the effect accurately. The approach reproduced the flow precisely, except very close to the roughness, Fig. 1(b). The roughness has only a local effect and the boundary layer returns to the smooth case shortly downstream.

Figure 2(a) shows a comparison of the packet evolution for the roughness models used and for the smooth surface reference case while 2(b) gives the corresponding frequency spectra. The roughness has a small destabilizing effect on the packet evolution which is similar at all unstable frequencies. The Taylor-expansion model substantially overestimated

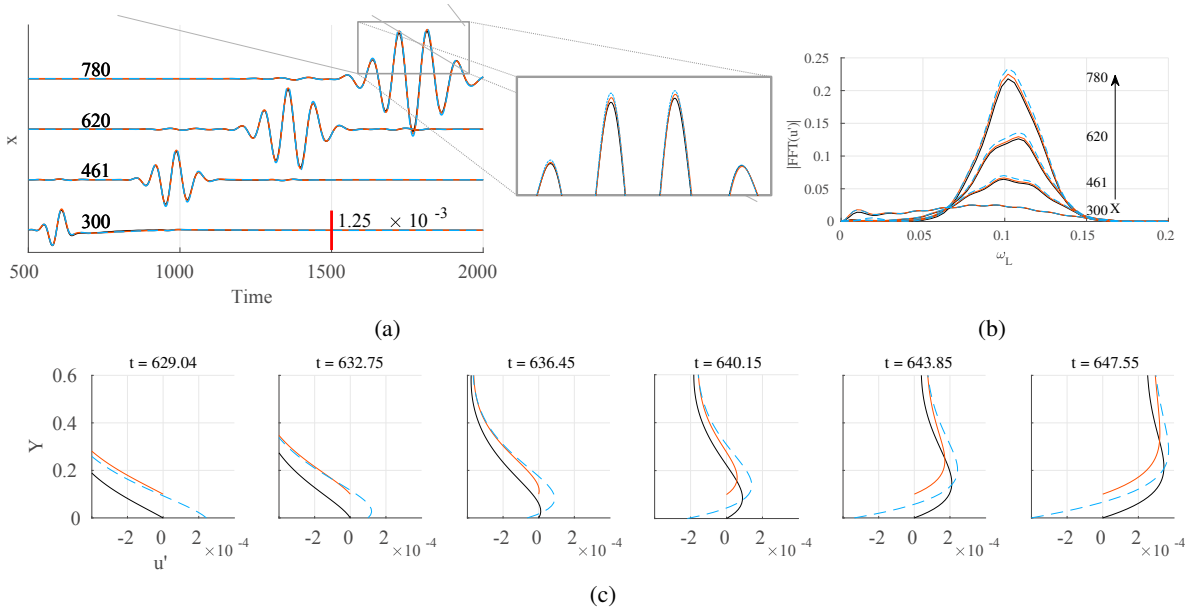
(a) (b)

Figure 1: Mean flow results. a) Displacement thickness evolution. b) Streamlines for the different roughness modelling approaches.



(a) (b)

(c)

Figure 2: Results of TS wave evolution. a) u' acquired at $y = 0.6 \times \delta^*$ and b) its corresponding spectra. c) u' profile showing the phase delay of the Taylor expansion model.

the roughness effect. Figure 2(c) shows profiles of the streamwise velocity fluctuation close to the wall at selected times. It appears that the Taylor model suffers from a phase delay yielding higher oscillations close to the wall. This was not observed on receptivity studies where the flow disturbance did not have a such a complex structure as the TS wave close to the wall. We are currently performing similar tests for smaller roughness where the agreement should improve. We are also trying to reproduce the experiments of [1] with body fitted and Taylor expansion models. The results are not shown due to space limitations, but will be presented at the conference.

TRANSITION IN A LAMINAR BOUNDARY LAYER CONTAINING A SUSPENDED SQUARE ROD

Wei He *[1] and Larry K. B. Li[2]
[1]School of Enginnering, University of Liverpool, Liverpool, UK
[2]Department of Mechanical and Aerospace Engineering, Hong Kong University of Science and Technology, Hong Kong, Hong Kong SAR

Summary Boundary layer transition is an important phenomena in engineering. For example, in aeronautical and automotive engineering, the predicted drag is known to depend strongly on the location of transition. Transition in a flat-plate boundary layer has been extensively studied. In its early stages, transition is governed by Tollmien-Schlichting waves induced by background disturbances and wall roughness. Another possible route to transition is via the formation of a separation bubble in the boundary layer, which can alter the adverse pressure gradient. Previous numerical studies have involved generating a separation bubble by imposing a multi-segment velocity function along the far boundary [1], or by placing an inverted airfoil at the inflow boundary to accelerate the flow downstream [3]. These methods, however, only affect the boundary layer indirectly. The effect of surface roughness on boundary layer transition can be modelled by introducing small surface elements, such as bumps and cavities. The mechanisms behind this, however, are still not fully understood. In this numerical-theoretical study, we investigate transition in a non-inclined flat-plate laminar boundary layer containing a suspended square rod. The inflow is defined as $Re_{\delta^*} = 421.5$, with Re_x at around 2.4 million, as estimated at the outlet of the computational domain. The square rod has sides of length $2\delta^*$ and is placed $213\delta^* \leq x \leq 220\delta^*$ downstream from the leading edge of the plate, with a clearance height of $y = 0.71\delta^*$ (0.1 in dimensionless units) from the plate surface. The square rod is fully immersed in the boundary layer, causing the inner layer flow to be more disturbed than the outer layer flow. When the rod is at $x = 213\delta^*$, the wake immediately downstream of the rod oscillates periodically as a result of the Kelvin-Helmholtz instability. The shed vortices propagate to around $70\delta^*$ before landing on the plate and forming a vortex street along it (see figure $1a$). When the rod is moved to $x = 220\delta^*$, the downstream wake becomes more stable (see figure $1b$). The steady state and mean flows of this boundary layer system will be examined in detail using a linear stability analysis.

AN IDENTYFICATIONOF TWO-PHASE FLOW PATTERNS IN TWO PARALLEL MINICHANNELS

Hubert Grzybowski[1*], Iwona Zaborowska[1], Romuald Mosdorf [1]
[1]Faculty of Mechanical Engineering, Bialystok University of Technology, Białystok Poland

Summary In the paper, the two-phase flow patterns in two parallel circular minichannels with a diameter of 1 mm was identified. The analysis was performed on the pressure drop fluctuations. The data were collected using MPX50DP pressure sensors. In the present experiment the oscillations caused by one type of two-phase flow instability are superimposed to another type, leading to chaotic pressure oscillations. The Principal Component Analysis and Recurrence Quantification Analysis methods were used to the identification two-phase flow patterns in two parallel minichannels in flow boiling. Flow patterns maps were obtained for each of the channels that identified 5 dominant flow patterns.

INTRODUCTION

During non-stationary flow boiling in minichannels there are pressure drop oscillations which are associated with the formation of various chaotically changing flow patterns [1,2]. The continuous transitions between various types of flow patterns make it difficult to set the precise boundaries on flow pattern maps. Additionally flow boiling in parallel channels is associated with flow maldistribution, due to dynamic interaction between channels. Local pressure changes generated by explosive growth of bubbles influences flow in other channel. Many authors use nonlinear analyses to identify flow patterns and assess their complexity [3–5]. From these research methods, most authors use the Recurrence Quantification Analysis (*RQA*). The idea of using the Principal Component Analysis (*PCA*) for *RQA* has been presented in the papers [6-8]. In these papers authors used these methods to create flow pattern maps.

In the paper, *PCA* and *RQA* methods were used to the identification two-phase flow patterns in two parallel minichannels in flow boiling. In the present experiment the short-period density wave oscillations superimposed on long-period pressure drop oscillations were analysed. Flow patterns maps were obtained for each of the channels that identified 5 dominant flow patterns.

EXPERIMENTAL AND DATA CHARACTERISTICS

The scheme of the experimental setup is shown in Figure 1. The distance between minichannels was equal to 5 mm and the inner diameter was equal to 1 mm. During the experiment distilled water was supplied to the heated minichannels from individual surge tanks (Figure 1 - 6, 7). The water flow rate was regulated by a ball valve (Figure 1 - 5). The pressure inside the supply tank (Figure 1 - 3) was kept constant by using the proportional pressure regulator. The heated section consisted of two 150 mm long circular brass pipe with an inner diameter of 1 mm. The two-phase flow patterns at the outlet of the heated section were observed in the glass tube (with an inner diameter of 1 mm) and recorded by a high-speed camera (Figure 1 - 8). The outlet of the glass tube was connected to the overflow tank (Figure 1 - 9). Signals were acquired by the data acquisition system at a rate of 1 kHz. The data recorded for constant heat input equal to 55.8 W and the average mass flux equal to 38.8 kg/m^{2}s was analysed. The observed flow patterns are mainly bubbly, slug, elongated slug or wavy annular flow which also differed in flow velocities. When local pressure exceeds the upstream pressure also flow reversal was observed.

RESULTS

Single cycle of pressure drop oscillations recorded in each channel was analysed using nonlinear data analysis methods. The results the showed that the system is prone to various flow instabilities that usually superimposed on each other. The analysis of the dynamics of chaotic pressure oscillations and recorded videos show that a certain dominant flow patterns can be identified. The *RQA* and *PCA* [6] were used to analyse the pressure drop fluctuations in each minichannel. The *RQA* coefficients were used to obtain the set of independent variables characterising the dynamics of two-phase flow patterns [9]. The analysis allowed to obtain the flow-pattern maps. In Figure 2 the flow pattern maps for both channels are shown. The proposed results allowed to the identification of dominant patterns in the flow in each parallel horizontal channel: I – liquid/wavy annular flow, II – liquid flow, III – bubbly flow, IV – slug/wavy annular flow, V – wavy annular flow. The obtained maps can be used for an analysis of synchronization of appearance of flow patterns in the parallel minichannels.

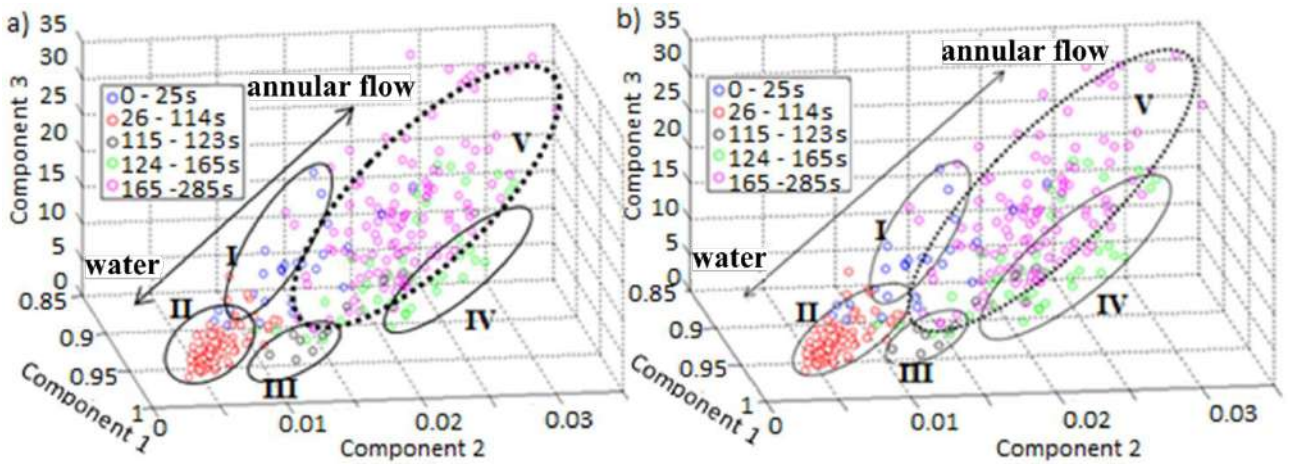

Figure 2. The flow pattern maps for both channels. (a) 1st channel, (b) 2nd channel: I – liquid/wavy annular flow, II – liquid flow, III – bubbly flow, IV – slug/wavy annular flow, V – wavy annular flow.

CONCLUSIONS

To accurately determine the transition of changes in flow patterns within each minichannel, the *RQA* and *PCA* analysis was used. During experiment the flow boiling was affected by several instabilities at once. It was observed that the points representing similar dynamics of the system forms a specific group on the flow pattern maps. Those specifics groups indicate dominant flow pattern which was visible in the minichannels.

ON THE DEVELOPMENT OF METHODS OF LAMINAR-TURBULENT TRANSITION PREDICTION IN AERODYNAMIC FLOWS

Andrey Boiko*[1], Kirill Demyanko[1], Andrey Ivanov[1], Stanislav Kirilovskiy[1], Dmitry Mishenko[1], Yury Nechepurenko[1], and Tatiana Poplavskaya[1]
[1]Khristianovich Institute of Theoretical and Applied Mechanics of SB RAS, Novosibirsk, Russia

Summary Actual fundamental and computational problems of finding the position of laminar-turbulent transition in aerodynamic flows are discussed. Modern popular methods of engineering prediction of transition to turbulence for flows around 2D and 3D aerodynamic configurations for sub- and transonic speeds are reviewed. An original approach based on e^N-method is described and the results of experimental and numerical work aimed at clarifying its calibration for complex flows are highlighted.

INTROFUCTION

Interest in forecasting the position of laminar-turbulent transition on the surface of transport aircraft in cruise regime of flight is actual since the 50s of XX century. Over the past decade, the studies to improve the forecast accuracy has intensified significantly as the traditional means to reduce the drag aiming to save fuel consumption and/or increase the range of flight by profiling and eliminating the flow separation approach their limit. Hence, laminarization of the flow at some elements of aircraft is considered as one of the promising ways in designing modern aircraft was in order to reduce the drag caused by turbulent boundary layer. To this end, engineers and designers need to have appropriate approaches to predict the position of laminar-turbulent transition in aerodynamic applications with a required accuracy.

Currently, engineering gas-dynamic packages as ANSYS Fluent and OpenFOAM are widely used to solve various problems of gas dynamics and heat transfer. These packages do not have built-in tools to analyze the position of laminar-turbulent transition based on the theory of hydrodynamic stability. However, that the position of laminar-turbulent transition mainly depends on the dominant types of the boundary-layer instability as the Tollmien-Schlichting waves and cross-flow vortices. The development of Tollmien-Schlichting waves is typical for the boundary layers occurring at the most elements of the aircraft as fuselage, wings, etc. The appearance of strong cross-flow on a swept wing can lead to the predominance of cross-flow vortices in the laminar-turbulent transition. The wide interest to the engineering e^N-method of laminar-turbulent transition prediction in aerodynamic applications is stipulated by the physically sound linear theory of hydrodynamic stability, which is the foundation for the method, and which correct for both two-dimensional and three-dimensional incompressible and compressible flows, if the level of free-stream turbulence is low enough (low-noise and low-turbulence wind tunnels or cruise flight conditions).

In this presentation, using computations of subsonic and transonic laminar-turbulent flows the operation of software package for the laminar-turbulent transition prediction using the e^N-method in conjunction with the engineering gas-dynamic packages is demonstrated. The complete linearized heat and mass transfer equations for compressible flows, original matrix algorithms for stability analysis, and original pre-processing technologies of data on the flow under study are used. Comparisons are made of the computed transition positions for different flows obtained using the package, the Transition SST empirical model and experimental data. The purpose of these comparisons is both to verify the computed data experimentally and to estimate the limits of the applicability of the Transition SST model and the e^N-method for some aerodynamic applications.

RESULTS

The results are illustrated in Fig. 1 by the computed and experimentally estimated skin-friction coefficients for one of the cases under consideration. For the experimental data [4] the start and the onset of the transition were determined by the behaviour of the intermittency; the skin-friction coefficients were obtained by processing the digitized velocity profiles. The computed data were obtained for the flow past a flat plate under the same external conditions in ANSYS Fluent for the laminar flow, using the empirical Transition SST model, and using the e^N-method in conjunction with the k-ω SST turbulence model. As seen, the data obtained using the e^N-method are consistent with the experimental ones, particularly the difference between them in the streamwise coordinate does not exceed 10%. The difference in the onset of transition between the data obtained using the Transition SST model (associated with the local maximum in the skin friction) and the experimental value (associated with the disturbance maximum) is about 22%. Moreover, the Transition SST model shows significantly narrower transition area than it is obtained in the experiment and in the e^N-method computations.

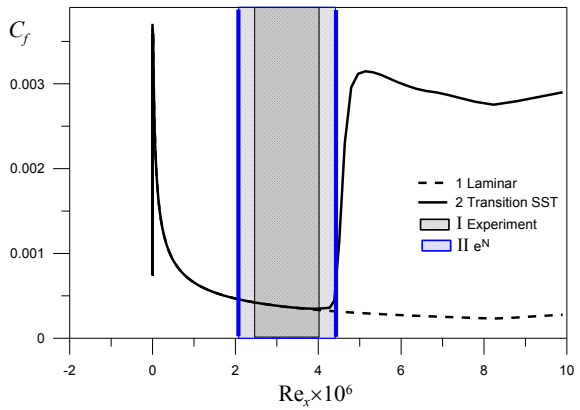

Figure 1. Skin friction coefficients as functions of Reynolds number Re_x at free stream turbulence level Tu=0.03%: computed data for the laminar flow (1); Transition SST model prediction (2); the transition region according to the experiment [4] (I), and the transition region estimated using the transition prediction package under consideration (current study)

One of the main problems in calibrating and verifying the e^N-method is a lack of broad experimental data for different flows and flow conditions. To obtain such data, along with detailed documentation of the parameters of the flow (speed, free-stream turbulence level, etc.) and the parameters of the object (geometry, degree of roughness, angle of attack, etc.), it is necessary statistically accurately to document the position of laminar-turbulent transition on the object surface under study. In experiments with a swept wing model conducted in the low-turbulent wind tunnel T-324 of the Khristianovich Institute of Theoretical and Applied Mechanics of SB RAS, Novosibirsk, Russia, sequences of thermograms of the surface in time were recorded and an advanced algorithm to determine the transition lines was developed [5]. It was observed that using the algorithm the position of transition can be reliably detected in the entire documented area that allows a direct parametric comparison of the experimental data with computations using the e^N-method in conjunction with gas-dynamic packages. The results of this comparison are quite successful. The details will be shown in the presentation during the Congress.

CONCLUSIONS

Thus, the numerical simulation of several two-dimensional and three-dimensional transitional flows at different aerodynamic objects at subsonic and transonic speeds was carried out using the developed software package. The accuracy of the package in determining the transition position was estimated by comparing with experimental data and results of other techniques. To this end an experimental method of conducting parametric measurements in various flow regimes at three-dimensional aerodynamic objects (in general case) with predominance of either Tollmien-Schlichting waves or cross-flow vortices was developed and used successfully in order to statistically accurately document the position of laminar-turbulent transition in a swept-wing boundary layer.

The study was supported by the Russian Science Foundation (grant No. 18-19-00460).

LINEAR STABILITY OF SHEAR-IMPOSED FLOW DOWN A SLIPPERY INCLINED PLANE

Farooq Ahmad Bhat*[1] and Arghya Samanta [1]
[1]Department of Applied Mechanics, Indian Institute of Technology Delhi, New Delhi 110016, India

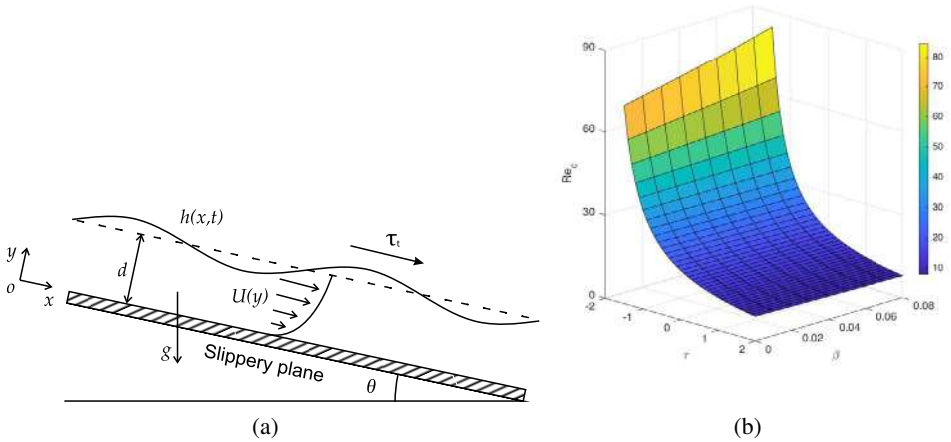
Summary Linear stability of a shear imposed fluid falling down a slippery inclined plane is scrutinized based on the Orr-Sommerfeld equation. An analytical solution is determined by using the long-wave analysis and the technique of Padé approximation and compared with the numerical solution obtained from the Chebyshev spectral collocation method. It is found that the solution of Padé approximation is more accurate than the solution of asymptotic long-wave expansion. Further, the destabilizing effect of wall slip on the primary instability can be reduced by introducing a constant surface shear stress in the counter-flow direction.

INTRODUCTION

The thin film flows are often encountered in natural and technical set-ups, and thus, warrant a special scholarly interest. In particular, the attention in the study of falling film instability has been increased in the last few decades owing to its numerous applications in coating technology, heat exchangers and chemical reactors [1], etc. In this context, a simple shear-imposed free surface flow can be modelled when a falling film flow is bounded by an air-flow, because the free surface is no longer a shear free [2]. Further, in specific practical situations, like flow over super-hydrophobic substrates and porous substrates, the velocity at the solid-fluid interface does not satisfy no-slip boundary condition, and therefore, a semi-empirical Navier-slip boundary condition is necessary at the fluid-solid interface to accurately capture the dynamics of fluid-solid interactions [3]. Here our aim is to decipher the combined effect of slip and imposed shear on the primary instability.

GOVERNING EQUATION AND MATHEMATICAL FORMULATION

Consider a fluid with dynamic viscosity μ, density ρ, and surface tension σ, flowing down a slippery inclined plane with inclination angle θ. Suppose, the free surface is subjected to a constant tangential shear τ_t. Origin of the Cartesian coordinate system is placed on the plane, while x and y axes are levelled along streamwise and cross-stream directions respectively (see fig. 1(a)). Here g is the acceleration due to gravity, $U(y) = \left[\frac{2y-y^2+2\beta}{1+2\beta} + (y+\beta)\tau\right]$ is the base flow velocity, d is the height of the base film, and $h(x,t)$ is the height of the disturbed free surface. Here β is the dimensionless slip length [4] and τ is the dimensionless imposed shear stress [2]. The Orr-Sommerfeld boundary value problem in terms



(a) (b)

Figure 1: (a) Schematic diagram of a shear-imposed film flow over a slippery plane. (b) Variation of critical Reynolds number Re_c with slip length and imposed shear stress when $\theta = 4°$.

of the amplitude of stream function ϕ corresponding to the infinitesimal disturbance can be expressed as

$$(\mathcal{D}^2 - k^2)^2\phi(y) - ikRe[(U-c)(\mathcal{D}^2-k^2) - \mathcal{D}^2U]\phi(y) = 0, \quad (1)$$

$$\phi(0) = 0, \ \ \mathcal{D}\phi(0) - \beta\mathcal{D}^2\phi(0) = 0, \quad (2)$$

$$(\mathcal{D}^2 + k^2)\phi(1) + \eta\mathcal{D}^2U(1) = 0, \quad (3)$$

$$(\mathcal{D}^3 - 3k^2\mathcal{D})\phi(1) - ikRe[\{U(1)-c\}\mathcal{D}\phi(1) - \tau\phi(1)] - k[2i\cot\theta/(1+2\beta) + ik^2/Ca + 2k\tau]\eta = 0, \quad (4)$$

$$\phi(1) + [U(1)-c]\eta = 0, \quad (5)$$

*Corresponding author. E-mail: farooq@am.iitd.ac.in

where k is the wavenumber, c is the wave speed and η is the amplitude of deformed free surface. $Re = \rho U_s d/\mu$ is the Reynolds number and $Ca = \mu U_s/\sigma$ is the Capillary number. The above Orr-Sommerfeld boundary value problem (1)-(5) is solved analytically in the long-wave regime ($k \to 0$) and the critical Reynolds number Re_c is computed

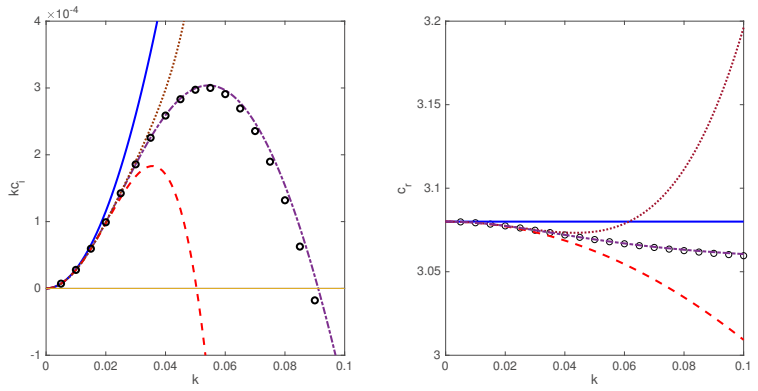
$$Re_c = \frac{(1 + 5\beta + 6\beta^2)5\cot\theta}{(2 + 10\beta + 15\beta^2)[2 + \tau + 2\beta(1 + \tau)]}.$$

Note that the critical Reynolds number Re_c decreases in the presence of wall slip but increases if the imposed shear stress acts in the counter-flow direction (see fig. 1(b)). Following Lange *et al.* [5], the technique of Padé approximation is further employed to improve the result of long-wave approximation. Accordingly, the complex wave speed c can be expressed as a ratio of polynomials in terms of wavenumber k

$$c = \frac{P(k, Re, Ca, \tau, \beta)}{Q(k, Re, Ca, \tau, \beta)} = \frac{\sum_{i=0}^{m} p_i(Re, Ca, \tau, \beta)k^i}{1 + \sum_{j=0}^{n} q_j(Re, Ca, \tau, \beta)k^j}, \tag{6}$$

where $p_i(Re, Ca, \tau, \beta), q_i(Re, Ca, \tau, \beta)$ are the coefficients of polynomials to be determined analytically. Figure 2 demonstrates the temporal growth rate kc_i and phase speed c_r of the infinitesimal disturbance when k varies.

RESULTS



(a) (b)

Figure 2: Variation of (a) temporal growth rate kc_i and (b) phase speed c_r with wavenumber k when $\theta = 4°$, $Re = 11$, $Ca = 2$, $\beta = 0.08$ and $\tau = 1$. Solid, dashed and dotted lines represent 1st, 3rd and 5th order long-wave results respectively. Dash-dotted lines represent the result of Padé approximation, and circular points stand for the numerical result.

In fact, we have compared the analytical results of Padé approximation and different orders long-wave approximation with the numerical results obtained from the Chebyshev spectral collocation method [4]. Obviously, the results acquired from the Padé approximation is more accurate than the different orders long-wave results because it arrests the numerical results very well for a larger range of k, while the long-wave results are valid only in the vicinity of $k \approx 0$. In other words, the Padé approximation enhances the domain of convergence of the long-wave asymptotic expansion.

CONCLUSIONS

A study of linear stability for a shear-imposed flow is accomplished when the bottom wall is slippery. Different orders long-wave solutions and the solution from Padé approximation are computed analytically and verified with the numerical solution procured from the Chebyshev spectral collocation method. It is found that Padé approximation solution is more accurate and matches very closely with the numerical solution over a wider range of wavenumber. In addition, it is noticed that the destabilizing effect of slip length on the most unstable mode will be attenuated as soon as the constant shear stress is applied in the counter-flow direction.

STEADY-STATES FOR STATIONARY AND CONVECTIVELY UNSTABLE FLOWS

Ricardo Dias dos Santos, Mateus Sanglard Schuabb Nunes, Rodrigo Tavares Veloso, and Leonardo Santos de Brito Alves*
Department of Mechanical Engineering (TEM),Universida de Federal Fluminense (UFF),Niterói-RJ,Brazil

Summary Many three-dimensional boundary layers are convectively unstable to stationary modes. Crossflow vortices in swept wings and cones and Görtler vortices in concave surfaces are examples of such modes. This is a challenge to current time integration schemes because these modes will contaminate the steady-state if introduced in a simulation. Due to the physical nature of these modes, any stationary excitation is capable of doing so. As simulated geometries become more complex, it is increasingly more difficult to generate a mesh with a spatial error distribution that is smooth enough to not act as a stationary excitation source. Hence, steady-state contamination often ensues. Recent methodologies have been able to damp oscillatory modes under convectively and absolutely unstable conditions but still need to be evaluated for stationary modes as well. This is the goal of the present study.

INTRODUCTION

Accurate base flows are required for linear stability analysis. For many studies, they should be a disturbance free steady-state of the governing equations. A few methods exist today for the construction of such steady-states. The most traditional one is the class of Newton iteration methods, usually adapted to use continuation techniques as well [1]. However, they are very sensitive to initial conditions, require heavy computational resources for large systems and have severe convergence difficulties for globally unstable problems. Selective frequency damping (SFD) was developed to overcome these difficulties [14]. However, this method has been applied to flows that only have a single dominant self-excited frequency that needs to be filtered and cannot damp stationary modes. Minimal Gain Marching (MGM) Schemes [2] were developed by altering the coefficients of a marching scheme so it becomes linearly numerically stable under linearly physically unstable conditions. Achieving this at the smallest possible time steps prevents nonlinear effects from jeopardizing convergence towards steady-state. Recently, inspired by the use of Krylov-subspaces, a new method has been introduced [3]. Known as BoostConv, it is based on the minimization of the residual norm at each iteration step. The stabilization of dynamical systems is achieved with a small increase in computation time. Furthermore, it can be easily implemented into pre-existing codes with a call to a single black-box subroutine.

A recent comparative study of these different methods applied to the nonlinear and viscous Burger's equation has shown that none of them are able to remove stationary and convectively unstable modes from the steady-state [4]. Such modes are typical of three-dimensional boundary layers with a strong inflectional velocity profile that appear in flows around swept-wings, elliptic cones and circular cones at an angle of attack. They are known as stationary crossflow vortices. Stationary Görtler vortices are another example. They appear on concave surfaces due to an instability of the viscous boundary-layer modified by centrifugal effects induced by the curvature [5]. Crossflow vortices were visualized in experiments [6, 7] and also with direct numerical simulations during the transition process of a swept flat plate boundary layer [8, 9] and of a subsonic realistic swept-wing [10, 11]. Steady-state simulations of a hypersonic flow around the elliptic cone using an implicit Euler scheme could not be grid converged independent of the scheme employed [12] due to these stationary and convectively unstable vortical structures. This was true even when employing a highly dissipative first-order scheme for the spatial discretization. This was likely due to the fact that any changes in grid size and numerical scheme would change the excitation location and amplitude of the stationary crossflow vortices. Later studies were forced to fine tune the grid to excite these stationary crossflow structures at fixed locations independently of the grid employed [13]. These examples illustrate the importance of assessing how these different steady-state generation methods deal with stationary and convectively unstable modes, which is the main motivation of the present study.

PRELIMINARY RESULTS

In order to illustrate these issues, a test case was simulated to evaluate the ability of the discussed methods to reach a steady-state when it is convectively unstable to stationary disturbances. The performances of the implicit Euler (IE), Newton method, MGM, SFD and BoostConv are compared. A modified, one-dimensional transient, dimensionless and viscous Burger's type equation is considered now for this purpose. It is given by

$$\frac{\partial u}{\partial t} = f(u) = \frac{1}{Re}\frac{\partial^2 u}{\partial x^2} - u\frac{\partial u}{\partial x} + R(u - u_s) \tag{1}$$

where R is the source term control parameter, Re is the Reynolds number, x is the dimensionless spatial coordinate, t is dimensionless time, u is the flow velocity field and f is the steady-state residue. The linear and modal stability analysis shows that it becomes convectively unstable at $R = 0$ and transitions to absolutely unstable at $R = Re/4$. Here, $Re = 32$ is used. Both onsets of instability are due to stationary and spatially uniform disturbances.

*Corresponding author. E-mail: lsbalves@id.uff.br.

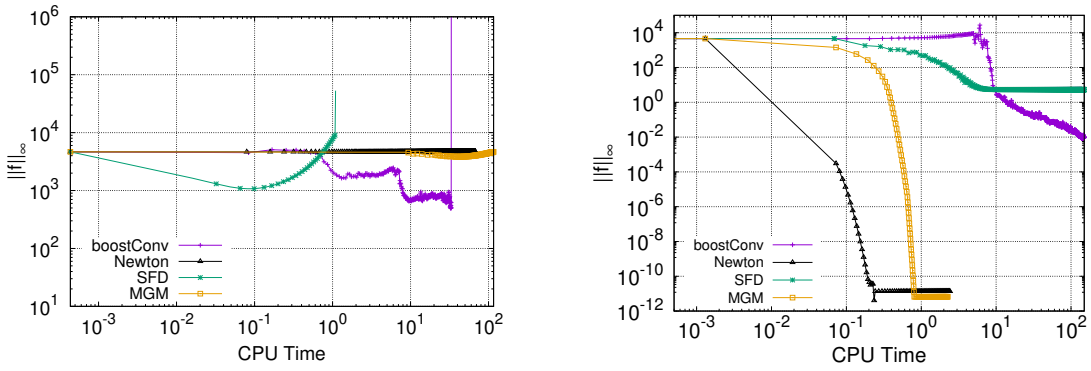

Figure 1: CPU time versus maximum residue norm for each steady-state generation scheme (left) without and (right) with an adaptation designed to allow damping of stationary and convectively unstable modes.

Simulations employed periodic boundary condition and $u(x) = 1$ as initial condition. A sufficiently large domain, $L = 16$ with $N_x = 4001$ grid points, is chosen in order to guarantee enough spacial growth of the disturbance. The time-step was set to $\Delta t = 5 \times 10^{-5}$. The parameter $R = 7.2$ was chosen to ensure that the dominant mode is stationary and convectively unstable. The flow is disturbed by a Gaussian source therm, with a small amplitude, added to the governing equation. Discrete approximations used were a fifth-order WENO scheme [15] for the advective term and fourth-order central scheme for the diffusive term. The explicit Euler scheme was used to march the solution to $t = 4$, where nonlinear saturation occurs and a shock wave is formed. From this point forward, steady-state generation was turned on.

Figure 1 (left) shows that none of the aforementioned schemes is capable of reaching steady-state, since $||f||_\infty$ cannot be reduced to acceptable tolerances. This can only be achieved if the governing equation is modified by a special source term that turns the dominant disturbance into an oscillatory one instead. Figure 1 (right) shows that all schemes achieve a disturbance free steady-state in this case. The implicit Euler scheme with a very large time step (i.e. Newton's method) performs best, followed by MGM. Although they are implicit marching schemes, having a high cost per iteration, they converge with just a few iterations. SFD generates a solution with higher errors and BoostConv converges quite slowly.

CONCLUSIONS AND ADDITIONAL WORK

All existing schemes fail to recover a disturbance free steady-state for a convectively unstable flow dominated by a stationary mode, unless properly modified to turn this mode oscillatory. Two additional test cases involving such modes will be included for the presentation. They use our more advanced in-house codes to evaluate the three-dimensional unsteady boundary-layers susceptible to both Görtler and crossflow instabilities.

ON THE SENSITIVITY OF LEADING EDGE PRESSURE GRADIENT TO FREE-STREAM TURBULENCE INDUCED BOUNDARY-LAYERTRANSITION

André Weingärtner*, Santhosh B. Mamidala, and Jens H.M. Fransson
Department of Engineering mechanics, KTH-Royal Institute of Technology, Stockholm, Sweden

Summary The region of highest boundary layer receptivity to free-stream turbulence is believed to be the nose region of the leading edge, where the boundary layer is thinnest. Thus, the velocity field and the boundary layer shape in this region are expected to be of relevance for the process, even if transition appears further downstream. However, the effect of varying the flow around a given leading edge on transition remains largely unexplored. A unique experimental setup incorporating a multitude of streamwise microphones on a flat plate is employed to elucidate this influence, allowing a large variation of parameters. Results show a twofold effect, depending on free-stream turbulence parameters.

INTRODUCTION

In most experimental studies on the transition to turbulence in zero-pressure gradient boundary layers (BLs), a flat plate in combination with a rounded leading edge (LE) and a trailing flap are utilized. The LE is known to be an important receptivity region for free-stream turbulence (FST) induced BL transition, where streamwise streaky structures (Klebanoff modes) originate (e.g. [1]). Hence, the flow around the LE is expected to be of significance for the transition process, even if the actual transition location is further downstream.

The effect of bluntness of an elliptical LE on transition has been examined by Kendall [1], showing that a decrease in aspect ratio of the ellipse does not affect the Klebanoff mode instabilities, but increases the amplitude of Tollmien-Schlichting waves. Nagarajan et al. [2] performed numerical simulations, revealing different mechanisms taking place, depending on FST conditions. It was concluded that, in general, a blunter LE leads to an earlier onset of transition for given FST conditions.

Elliptical LEs will inevitably generate a suction peak, leading to a region of adverse pressure gradient. This has been shown to destabilize the BL and cause increased disturbance growth rates [3]. In order to eliminate this suction peak, the usage of asymmetrical LEs for BL transition experiments has been proposed (e.g. [4],[5]). The aim with these LEs is to eliminate the suction peak and to minimize the region of non-zero pressure gradient along the LE, in order to quickly reach a Blasius-like BL velocity profile.

Besides the shape of the LE, the second parameter to alter the LE pressure gradient on a BL plate is the angle of the trailing flap. Variation of the flap angle will cause a change in overall circulation of the boundary-layer plate and thus shift the position of the stagnation line. In order to optimize the C_p distribution on the LE and to avoid periodic fluctuations, it is usually desired to position the stagnation line slightly on the measurement side of the LE [5].

It was already reported by Westin et al. [4], although merely as a side note, that the angle of the trailing flap can have a significant effect on the transition location. However, the quantitative effect of flap angle variation – and therefore the shape and severeness of the LE pressure gradient region – on zero-pressure gradient BL transition due to FST remains unclear and is the topic of this paper.

EXPERIMENTAL SETUP

Experiments were conducted in the MTL wind tunnel at the Department of Engineering Mechanics at KTH. The cross-sectional area of the test section is 0.8×1.2 m and its length 7 m. For the present experiments, the reference free-stream speed was held constant at 8 m/s throughout all cases, measured in the zero-pressure gradient region sufficiently far downstream of the LE. Several different turbulence-generating grids were interchanged and installed upstream the LE in order to produce various conditions of FST intensity (Tu) and integral length scale (Λ_x).

The employed flat plate has a total length of 4.5 m (of which 0.26 m is the LE) and fills out the whole width of the tunnel (1.2 m). The mounted LE is from Fransson [5]. The trailing flap has a length of 1.6 m and it was mounted in the diffuser section of the wind tunnel. The unique feature of the BL plate that enabled this type of examination is the method of transition location determination. Embedded inside the plate are a total of 100 electret microphones, ranging in streamwise direction all the way from the LE to the end of the plate. All microphones can be sampled simultaneously, so that the intermittency distribution along the whole plate can be acquired in a single run.

Additionally, a total of 56 pressure taps (of which 16 are located on the LE) are used to determine the static pressure distribution along the plate. Furthermore, hot-wire anemometry was employed in order to measure streamwise velocity profiles of the BL on the LE.

*Corresponding author. E-mail: andrewei@kth.se.

RESULTS

As expected, the C_p distribution along the LE shows a strong dependence on the flap angle ϕ (Fig. 1). The determined optimal flap angle of $\phi = 14.3°$ (black line in Fig. 1) features at first a sharp decrease in C_p and then a gradual approach to $C_p = 0$ without undershoot (i.e. no adverse pressure gradient). A significantly higher flap angle of $\phi = 17°$ causes the stagnation line to move further downstream on the measuring side of the plate, resulting in a strong negative C_p at the nose of the LE and a much slower recovery of the pressure. On the other hand, a low flap angle results in the stagnation line moving further upstream or even to the lower side of the plate. This leads to an even sharper pressure drop, which is proceeded by an undershoot and thus an adverse pressure gradient. The C_p range in this set of experiments is limited by flow separation and turbulent reattachment above $\phi = 17°$ and below $\phi = 12°$.

To quantify the transition location in a non-dimensional manner, the transitional Reynolds number Re_{tr} is introduced. It is defined as $Re_{tr} = U_\infty x_{tr}/\nu$, where U_∞ is the free-stream speed, ν the kinematic viscosity of air and x_{tr} the transition location, i.e. the point where the intermittency of the time signals measured by the microphones was 50%.

The effect of ϕ on Re_{tr} show two separate trends (Fig. 2). For a constant turbulence intensity and integral length scales in the range of 13.6 to 27.5 mm, Re_{tr} appears rather robust against small changes in flap angle around the optimum. Only a significant increase in ϕ causes the transition to appear notably earlier, likely due to destabilizing effects on the boundary layer. The case of $\Lambda_x = 8.4$ mm, however, shows a remarkably different trend. In the range of 12.4 to 14.5°, transition appears noticeably later compared to the higher Λ_x cases. Furthermore, the transitional Reynolds number appears to be sensitive to even slight changes in flap angle around the maximum at about 13.8°. Looking in more detail at the $\Lambda_x = 13.6$ mm case reveals some similarities to the 8.4 mm integral length scale, such as a decrease in Re_{tr} towards very low flap angles or a slight global maximum around $\phi = 14.8°$.

Attempting to reproduce the results of low Λ_x revealed high sensitivity of the measurements to small changes in Λ_x, but where relative changes still can be large. Even dismounting the turbulence-generating grid and positioning it again at seemingly the same upstream distance from the LE resulted in changes in Λ_x of ± 1 mm, that lead to variations in Re_{tr} of around $\pm 1 \times 10^5$. However, the general shape incorporating a global maximum somewhere close to the optimum ϕ remained.

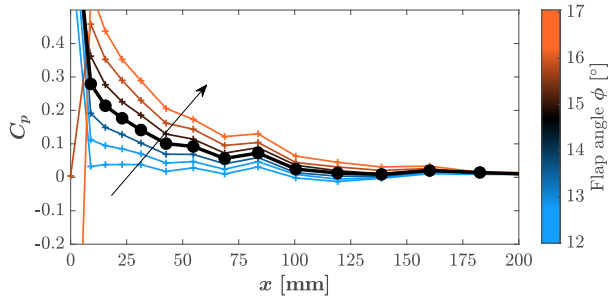

Figure 1: Pressure distribution along the LE for different flap angles ϕ (the arrow indicates increasing ϕ)

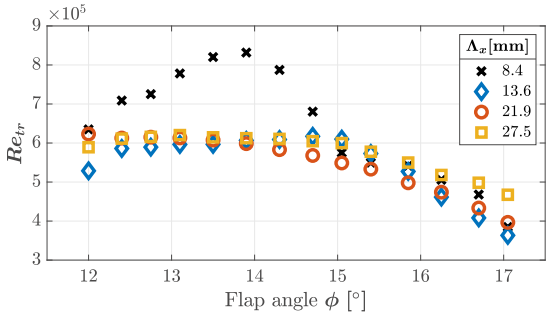

Figure 2: Transitional Reynolds number vs. flap angle for different Λ_x, $Tu = 2\%$ for all cases

CONCLUSIONS AND OUTLOOK

An experimental investigation of the sensitivity of FST-induced BL transition to the LE pressure gradient, altered by changing the trailing edge flap angle, has been performed. At a constant Tu of 2%, the transition location is insensitive for small variations in flap angle for a large range of Λ_x. However, below a certain threshold of integral length scale, Re_{tr} increases significantly and becomes sensitive to small variations in ϕ. Hot-wire measurements of the BL on the LE, which is expected to be a region important for receptivity, will be presented together with a larger database, including variation of Tu.

TRANSITION AND SPATIO-TEMPORAL INTERMITTENCY IN PULSATILE PIPE FLOW

Daniel Morón*[1], Daniel Feldmann[1], and Marc Avila[1]
[1]University of Bremen, Center of Applied Space Technology and Microgravity (ZARM), Am Fallturm 2, 28359 Bremen, Germany

Summary Despite its importance in cardiovascular diseases and engineering applications turbulence in pulsatile pipe flow remains little comprehended. The question remains on how they transition to turbulence and how turbulence behaves once triggered. In this project we explore both. First, using non-modal methods, we look for perturbations that are optimum for triggering turbulence in pulsatile pipe flows. Second we test these perturbations and the turbulence they trigger by performing Direct Numerical Simulations. We consider flows driven by a single harmonic and flows driven by a physiological wave form. We show how the shape of the pulsation dramatically increases the chances for turbulence transition and turbulence survival. Our results suggest that turbulence transition in cardiovascular flows is more likely and widespread than previously thought.

INTRODUCTION

Cardiovascular diseases represent one of the major causes of death worldwide [1]. Their increasing danger has sparked the interest on understanding their causes. One seems to be the presence of turbulence in cardiovascular vessels [2]. This turbulence may exert random shear stresses on the walls that, in the worst scenarios, can lead to the formation of aneurysms in the aorta or other serious injuries.

Ignoring hemodynamic and flexible wall effects, cardiovascular flow may be regarded to as the pulsatile flow of a Newtonian fluid in rigid pipes. This type of flow is not steadily driven rather driven by the heart pulsation, which is composed of a mean and an oscillatory driving force. In this case the bulk velocity is periodically varied as:

$$u_b\left(t\right) = u_s \cdot \left[1 + A\sin\left(2\pi \cdot t/T\right)\right] \tag{1}$$

Transition to turbulence in pulsatile pipe flows depends on three parameters, [3]:

- The (mean) Reynolds number $Re = u_s D/\nu$ which compares inertia and viscous forces on the flow, being u_s the one period averaged bulk velocity, D the pipe diameter and ν the fluid kinematic viscosity.
- The Womersley number $Wo = 0.5 \cdot D \cdot \sqrt{2\pi/\left(\nu \cdot T\right)}$ which represents the relation between pulsation period T and viscous time.
- The amplitude of the pulsation A.

While transition in steady driven pipe flow $A = 0$ is relatively well understood, transition to turbulence for pulsatile pipe flow is not. Linear stability analysis claim the flow is stable for $Re < 10^4$, but experiments and simulations suggest otherwise. In this project we aim to study transition in pulsatile pipe flows and also how turbulence behaves once triggered at physiologically relevant flow regimes.

METHODS

We consider an incompressible viscous Newtonian fluid confined in a straight smooth rigid pipe of circular cross-section and diameter D. The fluid is driven by a time dependent pressure gradient which ensures that the bulk velocity coincides with the desired pulsation at each time step. Two different pulsations have been considered, a simple sinusoidal function as in equation 1 and a physiological like pulsation.

There is an analytical solution to this kind of flows for the idealised case of laminar, axisymmetric, fully developed flow through a smooth pipe and single harmonic driving, the so called Sexl–Womersley flow. The only non zero velocity component is the axial one, which only depends on radial position and time. The SW velocity profile can be added to itself and/or the (parabolic) Hagen–Poiseuille profile to obtain an analytical (laminar) solution for any combination of Wo, A and pulsation waveform

In order to find optimum perturbations that disturb that flow the most, we perform a transient growth analysis as the one used by Xu *et al.* [3]. The method seeks the perturbation that grows the most in terms of energy on top of a laminar flow from the linear point of view. Thus the laminar flow ignores the evolution of perturbations on top of it. For each Re, Wo and A the method points to the most dangerous perturbation out all initial shapes, and initial times.

We then test those optimum perturbations by performing Direct Numerical Simulations where the Navier Stoke's equations are solved.

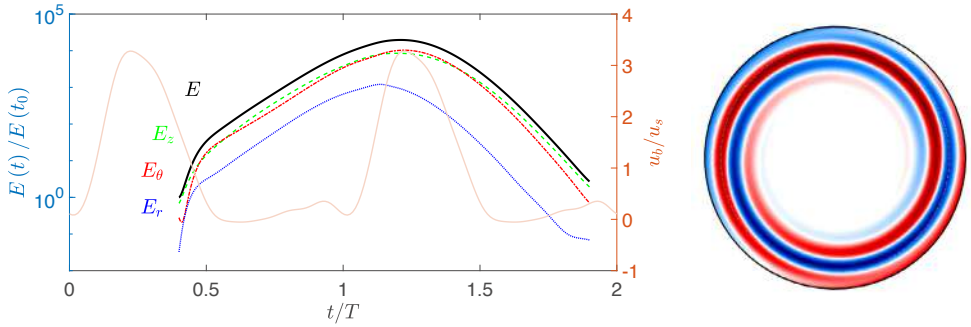

Figure 1: To the left energy of the perturbation that resulted in the biggest transient growth for $Re = 1277$ and $Wo = 12$. See in **black** the total energy, in blue, red, and green, the corresponding radial, azimuth and axial components of that energy. In the background, in orange, the bulk velocity u_b. To the right the axial vorticity of the perturbation at a given pipe (r, θ) cross section. In red, positive values, in blue negative values.

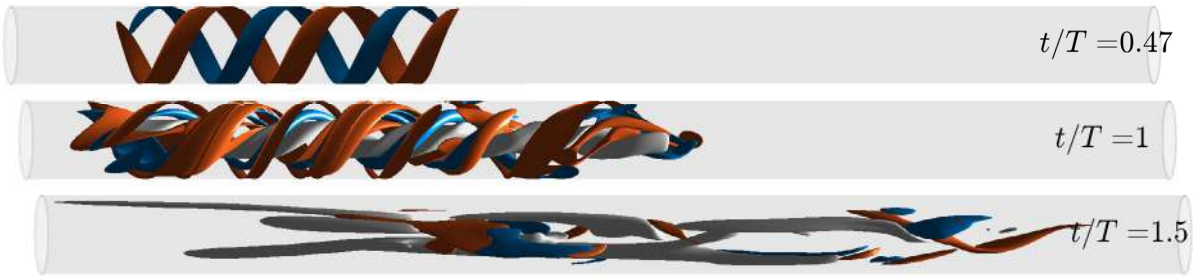

Figure 2: Three different snapshots of the flow in a section of $15 \times D$ axial length for a DNS with a $40 \times D$ long pipe for $Re = 1277$ and $Wo = 12$. The observer is moving with the pulsation speed. The initial perturbation is introduced localized in a $z = 5 \times D$ axially long section. In red $\omega_z \approx 3u_s/D$, in blue $\omega_z \approx -3u_s/D$ in grey low speed velocity streaks with $-0.3 \cdot u_s$.

PERTURBATION ON CARDIOVASCULAR FLOW

In this short abstract we summarise some results for a pulsatile pipe flow driven by a physiologic-like pulsation. See the shape of the pulsation in the background of figure 1. The amplitude is fixed by the pulsation shape itself. In order to model a physiological-like pulsation a particular signal presented in [4] has been selected. In that study they measured the mean velocity of the blood flow at different sections of the aorta of different patients. In our study the signal for the descending aorta section of a young volunteer has been selected. Inspired by the blood flow in the human descending aorta we here focus on $Re = 1277$ and $Wo = 12$.

For this particular case the perturbation that grows the most according to the non-modal analysis, is a helical like perturbation, close to the wall. See the evolution of its energy and its initial shape in figure 1 Then we initialize direct numerical simulations at $t_0/T = 0.4$ with the corresponding laminar SW profile and on top of it the optimum perturbation scaled to $4 \times 10^{-2} \cdot u_s$ in a given axial section.

The perturbation grows in magnitude while it is convected by the flow, see figures 2. At some point it looses its initial helix shape, and results in a set of low velocity streaks. Overall the perturbation is able to survive more than one period as it evolves.

OUTLOOK

We are further analysing results for flows driven by a physiological like pulsation and comparing them with results for a single harmonic pulsation. At the conference we will present how both compare and how on the two cases, perturbations are able to survive longer than a period. We will also show how small geometric imperfections that do not trigger turbulence in steady pipe flow, are able to perturb pulsatile pipe flow enough to intermittently trigger turbulence.

TRANSITIONAL BOUNDARY LAYERS DRIVEN BY FREE-STREAM TURBULENCE

Santhosh B. Mamidala*, André Weingärtner,and Jens H.M. Fransson
Department of Engineering mechanics, KTH-Royal Institute of Technology, Stockholm, Sweden

Summary Challenges in understanding the intricacies of transitional boundary layers (BLs) emanating under free-stream turbulence (FST) over a flat-plate have intiated a renewed interest over the recent years. The present study includes a unique dataset with a big parameter space, providing with incisive experimental renderings on the importance of FST integral length scale (Λ_x) in FST induced transition and not only the turbulence intensity (Tu). We believe that the streamwise unsteady streaks play a vital role in the onset of transiton and their spanwise wavelength strongly depend on the intial FST conditions at the leading-edge (LE). A substantial correlation is observed between the aspect ratio of the streaky structures and a FST Reynolds number. Furthermore, we derive empirical prediction models to forecast the spanwise wavelength and the aspect ratio of the streaks merely based on the FST conditions.

INTRODUCTION

One of the most intrinsic problems in BL reasearch is a flow over a simple geometry like flat-plate with zero-pressure gradient condition. The FST penetrating the BL developing over the flat-plate is a strong disturbance to the laminar BL which will lead to a rapid transtion to turbulence. Since the thirties of the last century, a significant number of studies have been performed on FST induced transition. Despite this, modeling this transition scenario has always been an intricate task. Heretofore, mostly Tu alone was considered in predicting the transitional Reynolds number Re_{tr} ($Tu = u_{\mathrm{rms}}/U_\infty$ & $Re_{\mathrm{tr}} = x_{\mathrm{tr}}U_\infty/\nu$, where u_{rms}, U_∞, x_{tr}, ν are the root-mean square velocity, free-stream velocity, the transition location and the kinematic viscosity, respectively). Not until the studies of [1, 4, 5], where the effect of Λ_x was first examined, it is now believed that Tu is not sufficient enough to model Re_{tr}, the length scale Λ_x should also be treated in future prediction models [2]. It is apparent from recent experiments [2] & direct numerical simulations (DNS) [6], that introducing a Reynolds number based on Λ_x namely $Re_\Lambda = \Lambda_x U_\infty/\nu$ accomodates more flexibility in choosing the parameter space for the investigation. However, for a more explicit interpretation of how FST conditions influence this transition scenario, we need to define a FST Reynolds number as $Re_{\mathrm{fst}} = \Lambda_x u_{\mathrm{rms}}/\nu$ as examined in [2].

Experimental results from [2, 3] ascertain the presence of the elongated streamwise unsteady streaks, which we here believe is of prime importance for the onset of transition. With this stated, it is reasonable that the spanwise scale of streaks λ_z induced by FST is influential for the breakdown to turbulence. Although, the well cited works of [3, 4, 6] indicate that the spanwise scale λ_z fully adapts to the BL thickness which routes to the BL structures with an aspect ratio of one, contrarily it is obscure to interpret that λ_z assymptotes to a same spanwise scale based on BL displacement thickness δ_1 i.e., $\lambda_z/2 \approx 3\delta_1$. Evidently, [2] specificates that the spanwise length scale of the streaks λ_z holds a strong correlation with the LE conditions in the free-stream namely Λ_x & Tu indicating the assymptotic value of λ_z is not crucial for the transition process since for most of the FST conditions, transition takes place far upstream of this value. This symbolizes the vitality of establishing accurate prediction models for spanwise scale λ_z and to explore how the aspect ratio of the streamwise structures behave with FST conditions.

EXPERIMENTAL SETUP

A thorough experimental campaign was performed in the Minimum Turbulence Level (MTL) wind tunnel at KTH-Royal Institute of Technology. The setup consists of a 4.5 m long flat-plate where the base flow was adjusted to zero-pressure gradient conditions by means of the ceiling of the test-section. Several turbulence generating grids were inter-changed and mounted upstream of the leading edge to generate different FST characteristics. The experiments incorporate both single-point and two-point correlation measurements using single sensor hot-wire probes and electret sub-miniature microphones. The initial FST conditions at the leading edge were adjusted using a single hot-wire probe mounted in the free-stream. A new approach using electret microphones mounted inside a cavity under a pinhole orifice was investigated and established to detect transtion location. A total of 100 microphones mounted in the streamwise direction provided a full streamwise intermittency distribution within a simultaeneous sampling time of 60 seconds. The parameter space includes a systematic variation of Λ_x from 4 mm - 36 mm at different levels of Tu (1%-7% in steps of 0.5%). Also, the free-stream speed U_∞ was varied from 6 m/s to 15 m/s unlike other existing FST induced transition experimental studies [1, 2] or DNS [4, 5, 6]. This combination of Re_Λ, Tu and U_∞ provided a total of 83 unique FST conditions at the LE.

RESULTS

The transition onset and the transition location were determined as the position where the intermittency factor (γ) of the microphone signals is 0.05 and 0.5, respectively, where $\gamma = 0$ and 1 indicate a fully laminar and a fully turbulent flow. Two-point correlation measurements along spanwise direction allowed for the estimation of spanwise wavelength

*Corresponding author. E-mail: mamidala@kth.se.

λ_z, where two single-wire probes were placed at the same wall-normal location, one probe being fixed and the other being traversable (minimum resolution between the probes is less than 1 mm). The minimum of the correlation function (of negative sign) corresponds to the averaged half spanwise wavelength of the unsteady streaks [2, 3].

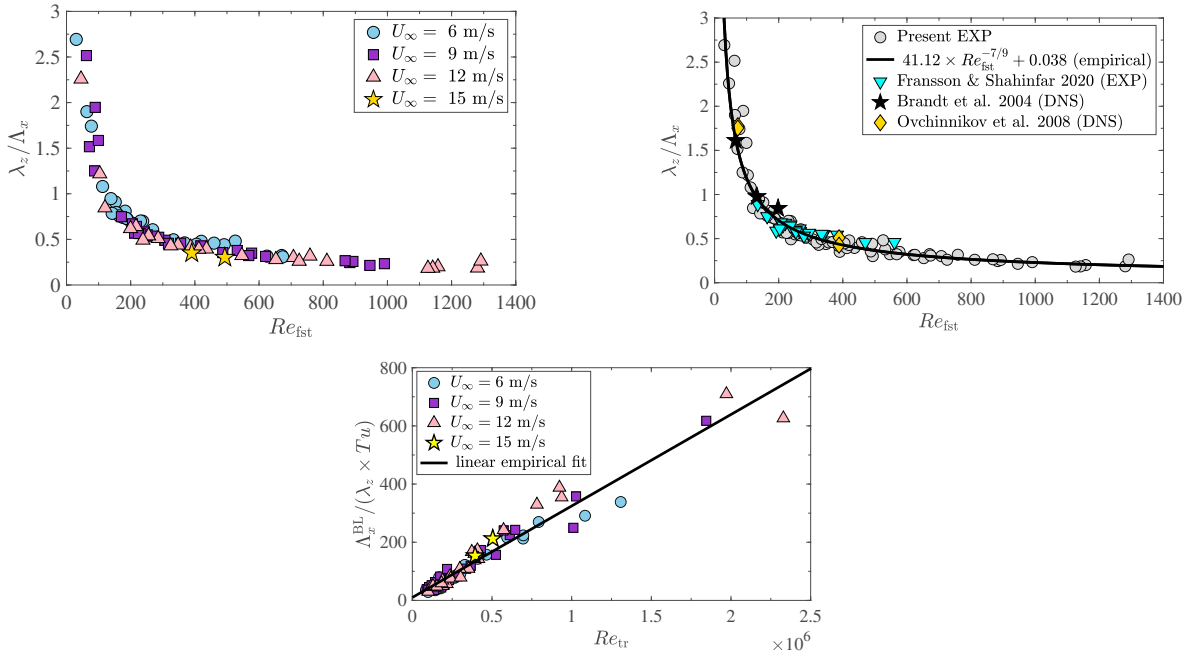

Figure 1: (*a*) Scaled λ_z at the transition onset as a function of FST Reynolds number. (*b*) Present experiments (EXP) compared with previous experiments and DNS. Solid line indicates a curve fit to the data according to eq. (1). (*c*) Aspect ratio of streaks $\lambda_x^{\mathrm{BL}}/\lambda_z$ normalised with Tu versus Re_{tr}. Solid line corresponds to a linear fit to the data as per eq. (2).

In figure 1(*a*), the spanwise wavelength λ_z at $x_{\gamma=0.05}$ is scaled with Λ_x, and is plotted against the FST Reynolds number Re_{fst}. The data obtained at all free-stream speeds agree well with the previous experimental works of [2] and DNS data [4, 6], and collapse onto a single emprical power law (figure 1*b*) defined as:

$$\lambda_z/\Lambda_x = 41.12\, Re_{\mathrm{fst}}^{-7/9} + 0.038\,. \tag{1}$$

The above equation is substantially simpler than eq. (3.7) of [2]. The length scale Λ_x^{BL} measures how large the structures are inside the BL i.e., the maximum streamwise length of the streaks. We can define the aspect ratio of the streaks as $\Lambda_x^{\mathrm{BL}}/\lambda_z$, which corresponds to ratio of maximum length scales inside BL. Figure 1 (*c*), clearly depicts that this ratio when normalised with Tu at the LE, the data closely falls onto a straight line and we see an increased scatter with Re_{tr} according to:

$$\Lambda_x^{\mathrm{BL}}/(\lambda_z \times Tu) = 3.146 \times 10^{-4} Re_{\mathrm{tr}} + 9.981\,. \tag{2}$$

CONCLUSIONS

Current experimental results provide further evidence that the spanwise wavelength of the streaks λ_z as well as the aspect ratio $\Lambda_x^{\mathrm{BL}}/\lambda_z$ strongly correlate with the FST conditions (Λ_x & Tu) at the LE. The empirical model as in eq. (1) aid to predict λ_z solely based on Reynolds number Re_{fst}. The new results promote the emphasis of Λ_x for the transition prediction, indicate that a rooted effort is required in developing future prediction models for Re_{tr}. We believe that, this dataset provides a great potential to prospect further into BL receptivity coefficients which can simply be extracted purely from the parameter space of Re_Λ & Re_{fst}.

THE INTERACTION BETWEEN THE FREE-STREAM TURBULENCE AND A 3D ROUGHNESS ELEMENT IN BOUNDARY LAYERS

Masumeh Gholamisheeri*Kristina Đurović,Santhosh Babu Mamidala,Jens Fransson,Ardeshir Hanifi,and Dan Henningson
Engineering Mechanics, FLOW, KTH Royal Institute of Technology, Stockholm, Sweden

Summary The dynamics of transition-to-turbulence induced by an isolated cylindrical roughness element immersed in the boundary layer subjected to the free-stream turbulence (FST) is investigated through direct numerical simulation (DNS) and hot-wire measurements. The roughness element is located on a flat plate with an asymmetrical leading edge. The flow Reynolds number and aspect ratio of the roughness are chosen such that in the absence of FST it induces a steady wake with high- and low-speed streaks. An impulse response analysis is performed to find the frequencies of the unstable disturbances behind the roughness element. The imposed free-stream turbulence has an intensity of about 2% at the plate leading edge. To find the dynamics behind the roughness element in the presence of FST, the stability and proper orthogonal decomposition (POD) analyses are considered. Numerical results are compared with the hot-wire anemometry (HWA) measurements which are performed at the Minimum Turbulence Level (MTL) wind tunnel at KTH.

INTRODUCTION

Predicting or controlling the laminar-turbulent transition is of great importance. The flow characteristics, surface roughness, and environmental noises can affect the onset of transition. The experimental work by Klebanoff & Tidstrom [1] showed that the natural transition can be promoted with the spanwise-invariant roughness elements. The modified stability properties of the boundary layer flow was known as the cause of the early transition. With the fully three-dimensional roughness elements, however, the transition can be delayed due to the streamwise velocity streaks. Fransson et al. [3] employed an array of the cylindrical roughness elements to delay the transition, however, beyond a threshold the streaks induced by the roughness elements could become unstable. Therefore, their height, shape, aspect ratio, and, the spacing between them have to be chosen carefully. In order to broaden the knowledge of effects of FST on the transition onset, various levels of free-stream turbulence have been experimentally and numerically investigated. A boundary layer subject to FST develops unsteady streaky structures with high and low streamwise velocities [4]. Breakdown to turbulence is caused by a secondary instability that develops on the streaks leading to the formation of turbulent spots. As explained by Schlatter et al. [2], the secondary instabilities appear as growing wave packets situated on the low speed streaks, their magnitude increases as they are dispersing in the streamwise direction. It was noted that although low speed streaks extend high in the boundary layer, where they are susceptible to the disturbances in the FST, other possible breakdown triggering mechanisms such as pressure fluctuations should be considered [2].

The aim of the present study is to assess the interaction between the two above-mentioned mechanisms, *i.e.* FST and isolated roughness element, and also how they influence the transition onset. To this end, high-fidelity direct numerical simulations (DNS) are performed for an isolated cylindrical roughness element, on a flat plate with asymmetric leading edge. At the first stage, the impulse response analysis is performed using the solution in the absence of FST and the frequencies behind the roughness element are identified. The POD analysis is planned for the simulation with the FST in order to find the structures behind the roughness element. Numerical results are compared with the hot-wire anemometry (HWA) measurements which will be performed in the KTH MTL wind tunnel.

NUMERICAL AND EXPERIMENTAL SETUPS AND APPROACHES

The dynamics of a three-dimensional incompressible flow is described by the Navier-Stokes equations which reads as:

$$\mathbf{u}_t + (\mathbf{u}\cdot\nabla)\mathbf{u} = -\nabla p + \frac{1}{Re}\nabla^2\mathbf{u}\,, \tag{1}$$

$$\nabla\cdot\mathbf{u} = 0\,, \tag{2}$$

where, $\mathbf{u}$, p and Re are the velocity vector, pressure and the free-stream Reynolds number, respectively. The roughness element has the diameter $d = 6\,mm$ and height $h = 1.3\,mm$. The computational domain size is equal to $L_x = 200d$, $L_y = 33d$ and $L_z = 13d$ in the streamwise, wall-normal and spanwise directions, respectively.

The plate leading edge is located at approximately $L_{le} = 34d$ downstream of the domain inlet and the roughness element is placed at $75d$ downstream of the plate leading edge and is centered in the spanwise direction. In order to set the simulation conditions, a few experimental measurements were conducted based on which a roughness Reynolds number $Re_{hh} = U_h h/\nu = 250$ is chosen for current studies. Further, based on the size and location of the roughness element, the freestream velocity is set to $6.38\,m/s$. The initial experiments also suggest that with the chosen velocity and roughness aspect ratio, the flow over the roughness element remains in the laminar region.

(a) (b)

Figure 1: High- and low-speed streaks behind the roughness element (a-top), FST-induced streaks before and after the roughness element (a-bottom), and the wind tunnel setup with the grid installed (b).

The DNS are performed using the open-source CFD solver Nek5000 [5]. Spatial discretisation is performed by a spectral element method with the polynomials of order 9 in each spatial direction at each element. The number of spectral elements in the mesh is of the order of 325000 which leads to 325 million degrees of freedom. For time integration, a backward differentiation scheme of order 3 combined with an extrapolation of the same order (together called BDF3/EXT3) is employed.

The experimental measurements will be carried out at the MTL wind tunnel facility at KTH. The test section of the wind tunnel is $1.2\,m$ wide, $0.8\,m$ high, and $7\,m$ long. A trailing flap at the end of the plate allows for positioning the stagnation line at the leading edge, on the upper side of the plate, in order to avoid unsteadiness. To measure the velocity, HWA is used. The traverse system in the wind tunnel allows the probe to be moved along the test section, normal to the plate and in the spanwise direction. The freestream turbulence is generated by turbulence generating grids. The turbulence intensity is proportional to the pressure drop over the grid and the FST length scales are defined by the mesh width, M, and bar diameter d_{bar} of the grid. The desired FST intensity at the leading edge of the plate is achieved by adjusting the distance between the grid and the leading edge. A schematic of an empty test section with a FST grid is shown in Figure 1 (b).

PRELIMINARY RESULTS

Our numerical simulations and the initial experimental results show that with the chosen freestream velocity and roughness aspect ratio, in the absence of FST, the flow remains laminar, although, high- and low-speed streaks are generated behind the roughness element, as is shown in Figure 1 (a-top). The base-flow simulation agrees well with the experiments. Introducing an initial perturbation (wave packet-like disturbance) upstream the roughness element and solving the linearised Navier-Stokes equations reveal that the flow is convectively unstable and in the limit of long times, the disturbances are advected away from the location of origin.

The FST generated streaks are shown in Figure 1, (a-bottom). Fransson and Shahinfar [6] showed that the aspect ratio of the streaky structures correlates with the FST Reynolds number, Re_{FST}, where,

$$Re_{FST} = \frac{u_{rms}\Lambda_x}{\nu} = Tu \cdot Re_\Lambda\,, \quad \text{and} \quad Re_\Lambda = \frac{U_\infty \Lambda_x}{\nu}\,. \tag{3}$$

Here, u_{rms} is the root-mean-square value of the velocity, Tu denotes the FST intensity, Λ_x is the integral length scale, U_∞ represents the free-stream velocity and ν is the kinematic viscosity of the flow. The correlation between the size of the cylindrical roughness element and aspect ratio of the streaky structures will be investigated in the present study.

To further investigate the instabilities behind the roughness element in the presence of FST, stability and POD analysis are to be performed.

EXCITATION OF WATER WAVES BY IMPULSIVELY APPLIED WIND: ORR-SOMMERFELD COMPUTATIONS VS. EXPERIMENTS

Meital Geva and Lev Shemer[1]
School of Mechanical Engineering, Tel-Aviv University, Tel-Aviv, Israel

Summary The stability of flow resulting from impulsively applied turbulent wind over initially quiescent water surface is analysed by coupled viscous Orr-Sommerfeld equations. This linear stability analysis is applied to describe the initial development of wind-waves. The computational results are compared with comprehensive experimental data accumulated in a wind-wave facility at wind velocities ranging from 5.5 m/s to 8.5 m/s. The wind velocity profiles and friction velocities at air-water interface in the simulations are taken from separate measurements performed under steady wind forcing. Instantaneous wave energies were obtained by a reliable ensemble-averaging of multiple independent realizations. The direct comparison of computations with experiments reveals differences indicating that this stability analysis needs to be amended to describe accurately the initial growth of wind-waves.

EXPERIMENTAL AND NUMERICAL RESULTS

Coupled Orr-Sommerfeld equations (OSE) with appropriate boundary conditions at the air-water interface are applied to analyse the interaction of impulsively applied turbulent flow with initially calm water surface in a test section of wind-wave facility. Turbulent log-linear wind profile measured in the facility [1] and an exponential velocity profile in the water were used following the approach applied in [2, 3]. Different numerical schemes were used to solve OSE and assess the initial growth of gravity-capillary wind waves [4, 5].

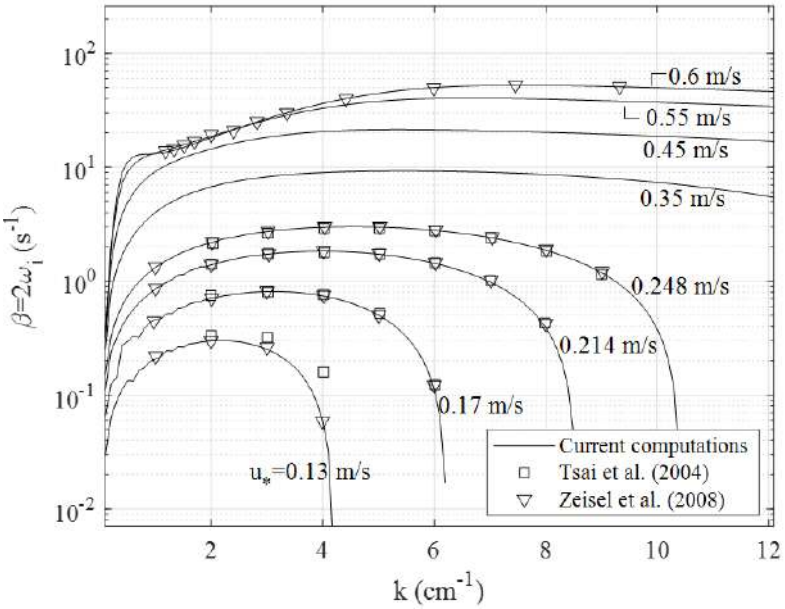

Figure 1. Energy growth rate vs. wavenumber k: validation by comparison with available results.

The Chebyshev polynomials method used in [5] was somewhat modified in this study. The energy growth rates are defined as $\beta_i=2Im(\omega_i)$, where ω_i represents the solution eigenvalues. Fig. 1 demonstrates that the present results are in agreement with earlier studies. It should be stressed that the only existing combined experimental and numerical study on temporal growth of wind-waves by Kawai [3] is limited to very low wind velocities. In the present investigation, the theoretical predictions are compared with the detailed data on the initial growth of wind waves under impulsive wind forcing reported in [6].

The measured wave energy growth at the initial stages of evolution are presented in Fig. 2 for three wind velocities and at three distances from the inlet, x. The representative wave energy at each instant relative to the initiation of the wind, t, was calculated by ensemble-averaging of the instantaneous squared surface elevations $<\eta^2>$ measured in multiple independent experimental realizations. The results clearly demonstrate that during the initial stage following the impulsive application of wind forcing that lasts for few hundred milliseconds, the measured wave energy growth is indeed exponential at all fetches and wind velocities.

[1]Corresponding author. E-mail: shemerl@tauex.tau.ac.il.

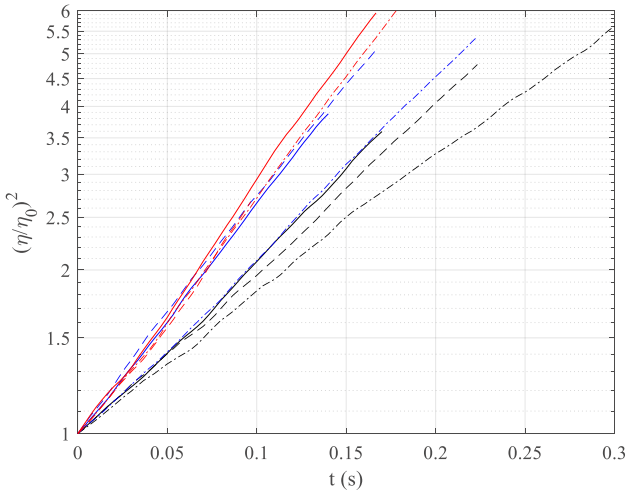

Figure 2. The measured temporal growth of wave energy relative to the initial state. Black: friction velocity u_*=0.35 corresponding to wind velocity U=6.5 m/s, blue u_*=0.45 m/s, U=7.5 m/s, red u_*=0.55 m/s, U=8.5 m/s; solid lines (-): x=120 cm, dashed line (--): x=220 cm, dashed-dot line (-.): x=340 cm [6].

The corresponding growth rates are presented in Table 1. In simulations as well as in experiments, the growth rates β increase with wind velocity. The numerical results are fetch-independent, whereas certain scatter is observed in the measured values of β. It should be stressed that the most unstable mode is usually considered in the OSE analysis, while the experimental results represent the variation in time of $<\eta^2>$. The values representing the growth of the energy of all unstable harmonics are therefore also presented in Table 1. Note that for all wind velocities, growth rates based on the total wave energy and on the most unstable harmonic differ insignificantly.

Table 1. Growth rates β (s^{-1})

		u_*=0.35 m/s	u_*=0.45 m/s	u_*=0.55 m/s
Experiment	x=120 cm	7.63	9.84	10.94
	x=220 cm	7.04	9.77	10.18
	x=340 cm	5.77	7.69	10.19
OSE	most unstable	9.25	21.07	40.34
	sum of harmonics	8.07	19.01	38.09
	sum of harmonics with $-4k^2\nu$	7.14	18.11	36.85

Reasonable agreement between the results of the linear stability based on OSE and experiments for lower wind velocity is demonstrated in Table 1. However, for stronger wind forcing, the theoretically predicted wave energy growth rates are notably higher than those obtained in the experiments. An attempt to account for viscous dissipation by adding the viscous dissipation term $-4k^2\nu$ as done in [5] does not improve the agreement significantly. Alternative dissipation mechanisms are discussed in the full version of the paper.

CONCLUSIONS

The experimental results indicate that the initial ripple grows exponentially in time under application of impulsive forcing. This suggests that linear stability analysis is applicable for the description of the early stage of the temporal wind-wave evolution. The numerical simulations based on OSE take advantage of the availability of carefully accumulated experimental data that describe the actual conditions encountered in the experiments. For relatively weak wind forcing, the agreement of the numerical predictions with measurements is indeed reasonable. However, for stronger wind the present results indicate that accounting for additional dissipation mechanism is essential to obtain not only qualitative but also quantitative agreement with the measurements.

TRANSITION IN BOUNDARY LAYERS INFLUENCED BY FREESTREAM TURBULENCE

Kristina Đurović, Philipp Schlatter, Ardeshir Hanifi and Dan S. Henningson
Department of Engineering Mechanics, FLOW, KTH Royal Institute of Technology, Stockholm, Sweden

Summary We aim at examining and understanding the physics behind the influence of free-stream turbulence (FST) on the boundary-layer transition. A recent experiment by Fransson & Shahinfar (2020) shows significant effects of FST scales. They found that, for the low values of turbulence intensity, an increase in the integral length scale advances the transition, which agrees with literature. However, for high turbulence intensities, the trend is reported to be the opposite. Here we want to understand these results by performing a series of high-fidelity direct numerical simulations. The obtained detailed data will help to understand why the FST integral length scale affects the transition location differently depending on the intensity. This knowledge is crucial for the development of the transition models, which are commonly used in the field of turbomachinery and aeronautics.

INTRODUCTION AND RESULTS

Laminar-turbulent transition induced by the free-stream turbulence is of great relevance due to its occurrence in many practical situations like turbo-machinery flows, flow mixers and also understanding results of the experiments in the conventional wind tunnels. In the two-dimensional boundary-layer flows subjected to FST intensities of 1% or higher, transition usually occurs rapidly bypassing the classical scenario triggered by the Tollmien–Schlichting waves. This type of transition is characterised by the occurrence of the streamwise elongated streaky structures inside the boundary layer. As these streaks travel downstream, they break down into the turbulent spots due to their secondary instability. These spots grow and merge until the flow is fully turbulent.

This type of flow has been extensively studied in the past [2], but always using certain simplifications compared to the real setup (e.g. removing the leading edge, simplified FST generation etc.). With the availability of large-scale computers and corresponding simulation codes, we can now perform computations of the complete physical case, extracting flow details at unprecedented detail, and putting the focus on details potentially neglected previously. Here, we study the effects of the FST characteristic length scales and intensity on the transition in an incompressible flat-plate boundary layer using direct numerical simulation (DNS). The numerical setup corresponds to the experimental investigations by Fransson & Shahinfar (2020) [1].

To accurately simulate a wide range of temporal and spatial scales in the flow, a high-order numerical method is necessary. The code chosen for the proposed project is Nek5000, developed by Fischer et al. [3], and based on the spectral element method (SEM) [4]. The spatial discretization is done using the Galerkin approximation, following the P_N-P_{N-2} formulation. The solution is interpolated within a spectral element employing Lagrange interpolants of orthogonal Legendre polynomials on the Gauss-Lobatto-Legendre (GLL) quadrature points. The non-linear terms are treated explicitly by third-order extrapolation (EXT3), whereas the viscous terms are treated implicitly by a third-order backward differentiation scheme (BDF3). Dealiasing of the non-linear terms is performed using overintegration.

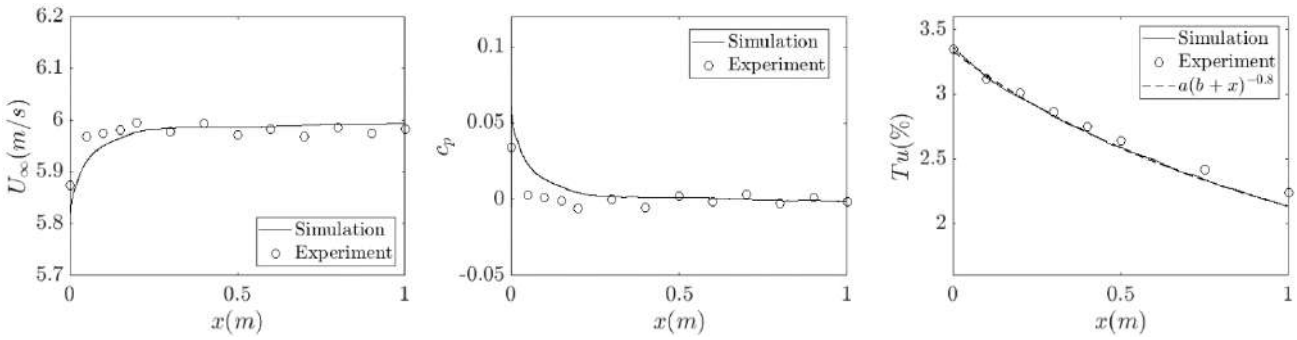

Figure 1. Comparison of the simulation data with the measured data from the experiment: Streamwise distribution of streamwise velocity component (left) and pressure coefficient (middle); decay of the turbulence intensity in the free-stream together with a fit to a power law with exponent -0.8.

FST generation is done in such a way to mimic the isotropic, homogeneous free-stream turbulence generated behind the grid in the wind tunnel. FST is prescribed in the volume section close to the inlet boundaries as a superposition of Fourier modes. The numerical methodology that is used allows us to define the energy spectrum (von Kármán energy spectrum) of the turbulent inflow and thereby to control the integral length scale and turbulence intensity of the FST.

To validate the flow simulation, we first examine behaviour of generated FST. Isotropic grid turbulence is known to follow a decay as a power law. The decay rate is, dependent on the source, between 0.5 and 1 [5]. A least-square fit on the decay of the turbulence intensity was performed (Figure 1, right) yielding a decay rate of 0.8. Thus, the decay of the simulated FST is similar to that of the grid-generated. On figure 1 (left), we show a comparison of velocity distribution in the streamwise direction with data from the experiments. As it can be seen there, we have achieved a good agreement with the experiments, which confirms that we have modelled our simulation with correct boundary conditions. We can also confirm this by looking and pressure coefficient distribution in Figure 1 (middle). A uniform pressure distribution near the leading edge cannot usually be obtained using elliptic or wedge-shaped leading edges, although careful attention to this problem can minimize undesirable effects. From the figure, we see that the pressure decreases smoothly within the first 50 mm, as the flow accelerates from the stagnation point, without producing a suction peak. Based on these data, we can conclude that our model of the experiments, including the plate leading edge and the generation of free-stream turbulence, are in a good agreement with the experiments, thus allowing us to perform the DNS with high fidelity.

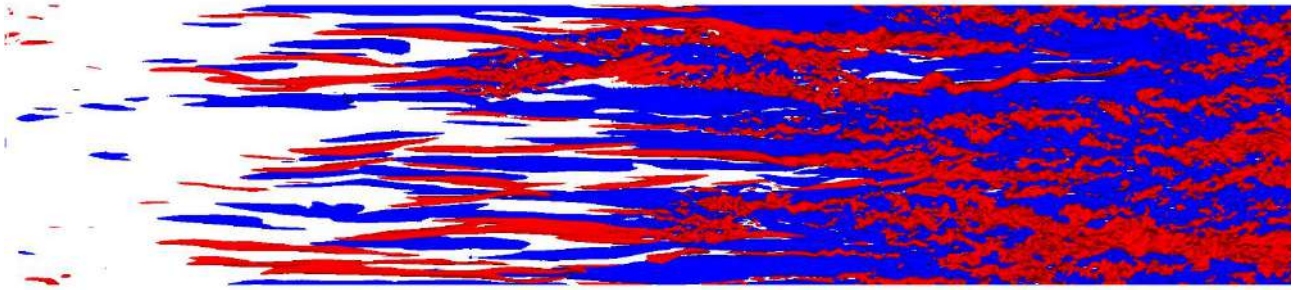

Figure 2. Isocontours of positive (red) and negative (blue) streamwise disturbance velocities.

A snapshot of the flow is shown in Figure 2. The isocontoures of the instantaneous streamwise velocities perturbations are plotted in a plane parallel to the wall close to the surface. From this picture the overall transition mechanism can be deduced. Starting from the inlet position, the perturbations in the boundary layer appear mainly in the streamwise velocity component, in the form of elongated structures. Patches of irregular motion, turbulent spots, are observed further downstream. As these spots travel downstream, they become broader and more extended. Note also that laminar streaks can be observed even downstream of the spots. At the end of the domain, the turbulent region is created by the enlargement and merging of the various spots and therefore the streamwise position at which the flow is turbulent varies with time. Transition location is determined based on an intermittency function similar to that used by Fransson & Shahinfar (2020). Further, we will analyse the streak breakdown by investigating the snapshots of the instantaneous 3D flow configurations and tracing the location of the spot formation. The turbulence spots are identified using the wall-normal derivatives of the spanwise velocity following the process suggested by Kreilos et al [6]. This data can then serve as a basis for a new data-driven version of the nucleation model[6]. By devising such a model, the full dynamics of the transitional boundary layer can be simulated for varying conditions appearing in reality at a greatly reduced computational cost.

Outlook

The final conference contribution will contain a detailed description of the influence of FST scales on laminar to turbulent transition location for four different sets of integral length scales and turbulence intensities. The results will be validated and compared against experiments [1]. These results will be used to improve cellular automaton representation model for a laminar-turbulent transition[6]. Especially the nucleation model, for which the local conditions (turbulence intensity, length scales, etc.) are taken into account, can be improved by employing the new data sets.

Summary The paper presents some of the results obtained during the wind tunnel testing of a morphing wing experimental model representing a full-scale portion of a regional aircraft wing equipped with an aileron. The work is a part from a major morphing wing project realized in an international collaboration Canada-Italy, involving industry (Bombardier Aerospace and Thales from Canada, and Alenia from Italy), research entities (National Research Council Canada and CIRA Italy), but also university partners (Ecole de Technologie Supérieure in Montréal, which was the project coordinator, École Polytechnique de Montréal, and University of Naples Frederico II). The research team developed a system for active control of the morphing wing in order to extend the laminar flow over the upper surface of the wing, and also built an evaluation system which has been used to detect the airflow characteristics using pressure sensors installed on the upper surface of the morphing wing. On the other way, to capture the transition region over the entire wing model surface, infra-red (IR) thermography method was applied.

MORPHING WING PROJECT DESCRIPTION

Called "Multi-Disciplinary Optimization" 505 (MDO 505) the project aimed at the development of morphing architectures and related technologies for wing efficiency improvement to reduce the operating costs for the new generation of aircrafts through a fuel economy in flight, and also to improve aircraft performances, expand its flight envelope, replace conventional control surfaces, reduce drag to improve range and reduce vibrations and flutter.

The developed model of the morphing wing is a portion of an existing regional aircraft wing, its interior consisting of spars, stringers, and ribs, and having a structural rigidity similar to the rigidity of a real aircraft wing. The deformable part is provided by a flexible skin piece mounted on the upper surface of the wing, made of composite materials, and directly actuated in four points by using electrical miniaturized actuators in house manufactured. In order to evaluate the aerodynamic improvement of the morphing configuration, a detection system that gives information about the characteristics of the flow has been built by installing 32 Kulite pressure sensors on the flexible skin. Also, to capture the transition region over the entire wing model surface, infra-red (IR) thermography method was applied ([1], [2]).

As a preliminary step in the project, starting from the reference airfoil of the wing (un-morphed airfoil), a numerical optimization was performed by the aerodynamic team in order to establish some optimized airfoils (morphed airfoils) for various flow cases ([3], [4]). A number of 97 flow cases were considered in the optimization step, and were obtained as combinations of incidence angles (α) (nineteen values, between -3 and +3 degrees), Mach numbers (three values: 0.15, 0.2 and 0.25) and aileron deflection angles (δ) (thirteen values, between –6 and +6 degrees).

The developed experimental model, with a chord and a span both of 1.5 meters in length, was equipped with an adaptive upper surface placed between 20% and 65% of the wing chord. The designed actuation mechanism includes four similar actuators disposed on two lines along two wing ribs, which are at 37% and 75% of the wing's span. Also, along the two actuation lines, the actuators were fixed at 32% and 48% of the local chord (Fig. 1).

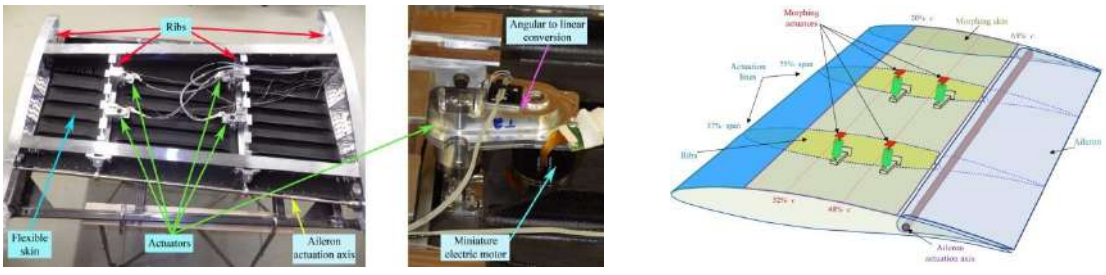

Figure 1. Morphing skin and actuators' positioning on the experimental model.

INSTRUMENTATION AND TESTING OF THE EXPERIMENTAL MODEL

The experimental tests were performed both in the lab conditions, on bench, with no aerodynamic load on the wing, but also, in the NRC wind tunnel facility in Ottawa, for each of the optimized flow cases. The wind tunnel testing aimed at the validation of all stuff integration in the developed model, with aerodynamic loads similar to the real flight conditions, but also at the evaluation of the aerodynamic gain brought by the morphing technology for our project. In these aims, all ninety-seven flow cases have been run in the wind tunnel for both un-morphed and morphed airfoils. For each analysed flow case, the optimization stage provided four linear displacements corresponding to the differences

between the optimized shape and the original shape (un-morphed) of the wing in the actuation points. The development of the control system for the morphing wing supposed the design of a controller able to control each of the four actuators in order to reproduce the required displacements, and in this way a morphed wing shape as close as possible to the optimized one, for each flow case. Several variants of control systems were designed, implemented and experimentally tested for the morphing wing model. The system interfacing the remote computer and the morphing wing experimental model was designed by using a National Instruments Real Time (RT) Target (Fig. 2) ([5]).

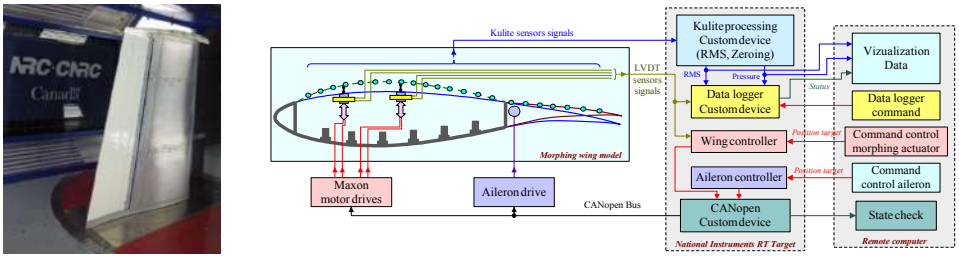

Figure 2. Wind tunnel testing of the experimental model and the interface of the model with the remote computer.

To detect the airflow characteristics and to evaluate the position of the laminar to turbulent transition over the upper surface of the wing the date from the 32 Kulite pressure sensors were used. The Standard deviation and Power spectrum visualization of the pressure data were the main approaches used both in real time, but also in a post-processing phase, to perform this evaluation. The pressure data were recorded at 20 kHz rate, for both un-morphed and morphed airfoils, and were analyzed using the Fast Fourier Transforms (FFT) decomposition to detect the magnitude of the noise in the surface air flow. Both mechanisms allow the estimation of the laminar to turbulent transition point position in the Kulite span-wise station. To capture the transition region over the entire wing model surface the IR thermography method was applied. In the flow case characterized by Mach=0.15, $\alpha=1^\circ$ and $\delta=0^\circ$ the IR thermography technique provided the results presented in Fig. 3. For un-morphed configuration the averaged position of the laminar to turbulent transition over the entire wing surface was estimated to be at 48% of the wing chord, while for the morphed configuration it was estimated to be at 51% of the wing chord. Therefore, for this case, the morphing configuration produced a displacement of the averaged position of the laminar to turbulent transition over the entire wing surface with 3% of the wing chord.

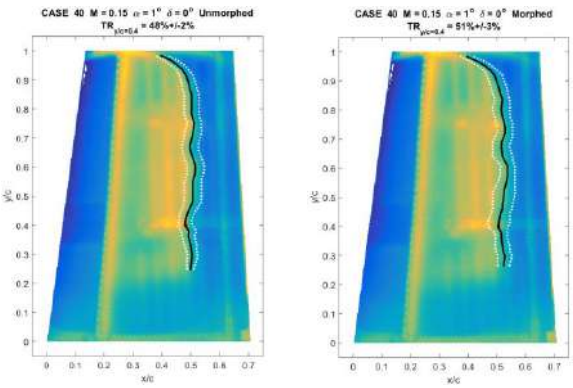

Figure 3. IR thermography results for Mach=0.15, $\alpha=1^\circ$ and $\delta=0^\circ$ flow case.

CONCLUSIONS

Both, the IR analysis and the processing of Kulite data validated the numerical predicted transition location. Therefore, the experiments confirmed the feasibility of the morphing wing technology and created the premises for a future application of this technology on real aircraft, having in mind that our project was based on a real wing segment.

Summary A basic feature of liquid drops is that they can merge upon contact to form a larger drop. In spite of its importance to various applications, drop coalescence on pre-wetted substrates has received much less attention then coalescence on dry substrates or of freely suspended drops. Here, we experimentally and theoretically reveal the dynamics of drop coalescence on a thick layer of liquid [1]. It is shown that these so-called "liquid lenses" merge by the self-similar growth of a bridge connecting the two lenses. Using a slender analysis, we derive similarity solutions corresponding to the viscous and inertial limits. Excellent agreement is found with the experiments without any adjustable parameters, capturing both the spatial and temporal structure of the flow during coalescence. Finally, we consider the crossover between the two regimes and show that all data collapse on a single curve capturing the full range of the coalescence dynamics.

AN ACOUSTO-GRAVITATIONAL BALANCE IN CLIMBING FILMS OF WATER AND OIL

Amihai Horesh, Daniel Khaikin, Mackenzie Karnilaw, Anna Zigelman, and Ofer Manor
Department of Chemical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary We study the contributions of acoustical stresses to wetting. We employ MHz-frequency surface acoustic waves (SAWs), which we generate in an acoustic actuator in the form of a SAW device. When a vertical device is in contact with a liquid reservoir, the SAW supports the climb of silicon oil and water up the device. The fully wetting oil climbs as a nearly flat film. The film supports resonance-enhanced radiation pressure, which satisfies gravitational stresses. Hence, the climbing velocity of oil is mainly determined by an interplay between acoustical and viscous stresses and appears to be independent of gravity. Unlike oil, the partially wetting water meniscus is curved and does not support enhanced radiation pressure. As a result, the water meniscus climbs up the device to a finite height, which is determined from an interplay between acoustical, capillary, and gravitational stresses.

Introduction

In recent years, there is a growing interest in the excitation of films at thicknesses that range from nanometres to micrometres by MHz-frequency vibrations [1]. Recent studies employed surface acoustic wave (SAW) devices, which generate Rayleigh type SAWs, to manipulate liquid films. The excitation of silicon oil by MHz SAWs gives rise to the dynamic wetting of the substrate of the device. Oil films spread along and opposite the path of the SAW [2,3]. Further studies showed that partially wetting water films may undergo similar dynamics should the acoustic stresses in the films exceed the strong capillary stresses at the free surface of water [4,5]. Moreover, SAWs are found to actuate thin films of liquid in different applications. Examples include the SAW induced draining of liquid films and thus the enhancement of the attachment of bubbles to substrates [6], the actuation of dynamic wetting in nanochannels, [7] and the actuation of a nanofiltration process [8]. The contribution of gravity to SAW induced dynamic wetting was ignored to date. Here, we present a study on the balance between acoustical and gravitational stresses in climbing films, which are under the influence of SAWs [9].

Experiment

We present the climb of water menisci and silicon oil films up a vertical SAW device. The experimental system is comprised of a 20 MHz-frequency SAW device, which is mounted on a vertical stage. The edge of the device is submerged in a reservoir of liquid. See Figure 1 for further details. Upon the application of power, a SAW propagates down the device to eventually enter the liquid reservoir. Using a video camera, we monitor the response of the liquid.

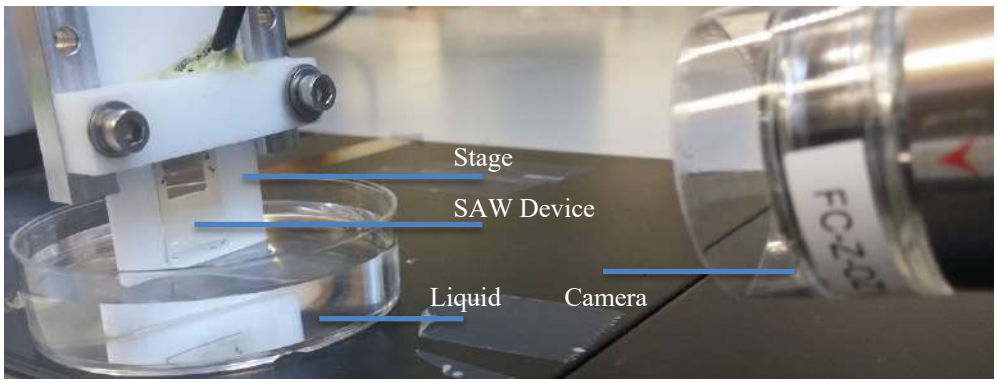

Figure 1. The experimental systems: A SAW device mounted on a vertical stage and touching a reservoir of liquid below.

Findings and Conclusions

Upon the excitation of a propagating 20 MHz-frequency SAW, we observe the climb of liquid atop the solid substrate of the device. Partially wetting water and surfactant solutions satisfy a finite three phase contact angle between the liquid, vapor, and the solid substrate of the device, which gives rise to curved liquid menisci. In the presence of a SAW, the menisci rise up the device to obtain steady state heights above the level of liquid in the reservoir. A theoretical analysis predicts that the steady state heights are determined by a balance between acoustical, capillary, and gravitational stresses. In contrast, silicon oil is a fully wetting liquid. It supports a vanishing contact angle with the SAW device, which gives rise to flat films. In the presence of a SAW, silicon oil films are found to continuously climb up the device (In the absence of the SAW, the oil supports an approximately 1 mm high meniscus with the substrate of the device). Moreover, the climbing velocities of the oil films appear to be steady. They are comparable to the dynamic wetting velocities of oil on a horizontal SAW device. On vertical and horizontal devices, the measured velocities of the oil films are in agreement with a balance between acoustical and viscous stresses. A clue to deciphering the lack of gravitational contributions to the climbing velocity of oil films is that the nearly flat films may support high levels of acoustic radiation pressure. The pressure varies with the film thickness due to acoustic resonance effects. We show that the resonance-enhanced radiation pressure may satisfy the gravitational stresses in the climbing films at any film height. As a result, in the presence of the SAW, the oil films will continuously climb up the device.

COMPETITIVE EVAPORATION OF MULTIPLE THIN DROPLETS

Stephen K. Wilson*[1], Alexander W. Wray[1], Brian R. Duffy[1], Feargus G. H. Schofield[1], and David Pritchard[1]
[1]Department of Mathematics and Statistics, University of Strathclyde, Livingstone Tower, 26 Richmond Street, Glasgow G1 1XH, United Kingdom

Summary A combination of analytical and numerical methods is used to analyse two different but related scenarios in which evaporating sessile droplets influence each other via the concentration of vapour in the atmosphere, namely the evaporation of multiple thin droplets in three dimensions and the evaporation of one or two thin droplets in two dimensions.

INTRODUCTION

The evaporation of one or more sessile droplets is a very exciting and dynamic area of interdisciplinary study in fluid mechanics, with worldwide activity across many different subject disciplines, including physics, chemistry, mathematics, biology and engineering (see, for example, [1]). In particular, in recent years considerable attention has been paid to aspects of evaporation such as the coffee-ring effect [2] and droplet lifetimes [3]. However, while the vast majority of the previous work has concerned a single droplet, in practice most droplets do not occur in isolation, and so interactions between droplets are of great practical and scientific interest. In particular, the critical difference between the evaporation of single and of multiple droplets is the occurrence of the so-called "shielding effect", namely that the presence of other evaporating droplets increases the local vapour concentration in the atmosphere, and so each droplet evaporates more slowly than it would in isolation. In order to better understand this phenomena, in the present contribution we investigate two different but related scenarios, namely the evaporation of multiple thin droplets in three dimensions and the evaporation of one or two thin droplets in two dimensions.

EVAPORATION OF MULTIPLE THIN DROPLETS IN THREE DIMENSIONS

An asymptotic model is derived for the competitive diffusion-limited evaporation of multiple thin sessile droplets in three dimensions under the assumption that the droplets are well separated. Exact solutions of the model are obtained for a pair of and for a polygonal array of identical droplets, and the model is found to perform well even outside its formal range of validity, up to and including the limit of touching droplets. Figure 1 shows the excellent agreement between the exact and asymptotic solutions for the fluxes from a pair of identical droplets. The shielding effect of droplets on each other is demonstrated, and the model is used to investigate the effect of this shielding on droplet evolutions and lifetimes, as well as on the coffee-ring effect. The theoretical predictions of the model are found to be in good agreement with recent experimental results for seven relatively closely-spaced droplets, suggesting that the model could be a useful tool for studying a wide range of other droplet configurations [4].

EVAPORATION OF ONE OR TWO THIN DROPLETS IN TWO DIMENSIONS

We also consider the diffusion-limited evaporation of thin two-dimensional sessile droplets either singly or in a pair. A conformal-mapping technique is used to calculate the vapour concentrations in the surrounding atmosphere, and thus to obtain closed-form solutions for the evolution and the lifetimes of the droplets in various modes of evaporation. Figure 2 shows contours of the vapour concentration for both the one-droplet problem and the two-droplet problem. These solutions demonstrate that, in contrast to in three dimensions, in large domains the lifetimes of the droplets depend logarithmically on the size of the domain, and more weakly on the mode of evaporation and the separation between the droplets. In particular, they allow us to quantify the shielding effect that the droplets have on each other, and how it extends the lifetimes of the droplets [5].

CONCLUSIONS

In the present contribution, we used a combination of analytical and numerical methods to analyse two scenarios in which evaporating sessile droplets influence each other via the concentration of vapour in the atmosphere. There are, of course, many other configurations and other physical mechanisms (such as, for example, via the distribution of temperature in the substrate and/or the atmosphere) via which they can influence each other that are also worthy of investigation.

Summary The deposition and coating of thin films onto curved rigid substrate, involving displacement of air by a liquid, has numerous applications within the technology sectors but faces two major challenges: (i) control of the local film thickness; (ii) ensuring that the coating remains stable. The work reported here investigates the full coverage of two- and three-dimensional curved geometries, of cylindrical, hemispherical and conical shape, by a continuously fed, gravity-driven, thin liquid layer. The modelling approach adopted utilises a first integral formulation of the Navier-Stokes equations leading to a variational formulation in the case of steady flow and an advantageous re-formulation of the dynamic boundary condition at the free surface. Asymptotic analysis, underpinned by the long-wave approximation, enables analytic solutions for the local film thickness and the internal flow to be obtained.

The new results are placed in context by comparing them with recently acquired experiments and flow visualisations specific to film flow on conical surfaces, prior to the onset of and post instability. A perspective is provided in relation to how the findings form the basis for a corresponding stability analyses.

FORMULATION

Problem definition

We consider gravity-driven steady incompressible Newtonian liquid film flow over different two- and three-dimensional shapes, namely a horizontally aligned cylinder, a hemisphere and a cone, see Fig. 1, fed continuously, $\dot{V}$, from above, investigating both the internal flow structure and the free surface shape.

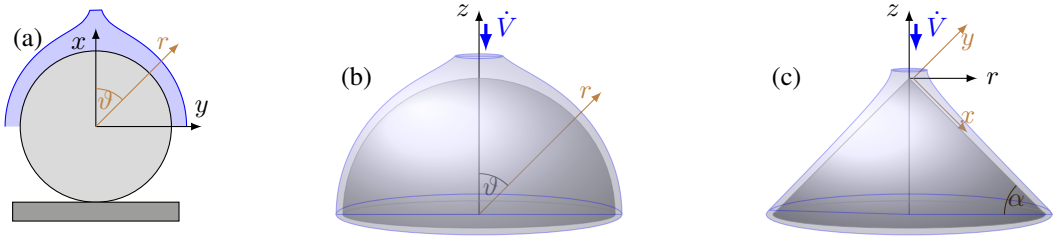

Figure 1: Continuously fed film flow over (a) a horizontally aligned cylinder, (b) a hemisphere and (c) a cone.

First Integral variational approach for steady 3D flow

In [1] a first integral of the Navier-Stokes (NS) equation is derived in an analogous fashion to Maxwell's use of potential fields in developing his classical electro-magnetic theory and governing equations. As is well-known for steady incompressible flow, the streamfunction vector Ψ_k constituting the velocity via $u_i = \varepsilon_{ijk}\partial_j\Psi_k$ with Levi-Civita symbol ε_{ijk} can be introduced to fulfil the continuity equation $\partial_i u_i = 0$ automatically. In a similar manner a traceless symmetric tensor potential $\bar{a}_{ij}$ and a scalar potential Φ are introduced as auxiliary unknowns allowing derivation of the Navier-Stokes equations from the variational principle:

$$\delta \iiint_V \ell\left(\bar{a}_{ij}, \partial_n\Psi_m, \partial_k\bar{a}_{ij}, \partial_i\Phi\right) \mathrm{d}V = 0\,, \qquad \ell = \varrho\bar{a}_{ij}u_iu_j + 2\left[\eta u_j - \partial_j\Phi\right]\partial_i\bar{a}_{ij} + \frac{1}{2}\varepsilon_{ilk}\varepsilon_{jpq}\partial_l\bar{a}_{ij}\partial_p\bar{a}_{kq}\,. \tag{1}$$

By computing the divergence of the tensor equation resulting via variation with respect to $\bar{a}_{ij}$, the Navier-Stokes equations are recovered [1]. Likewise the dynamic boundary condition related to stress equilibrium at a free surface can also be recasted in a first integral form for the tensor potential:

$$\varepsilon_{ikl}\left[\partial_k a_{lm}\mathrm{d}x_m + \left(\sigma_s n_k - \int U\mathrm{d}x_k\right)\mathrm{d}x_l\right] = 0\,, \tag{2}$$

with surface tension σ_s and potential energy density U for an external conservative force. The mathematical formulation is completed by the kinematic boundary condition at a free surface and the no-slip/no-penetration condition at solid walls.

Implementation for axisymmetric flows

Using spherical coordinates $q_1 = r, q_2 = \vartheta, q_3 = \varphi$ for hemispheres and cylindrical coordinates $q_1 = z, q_2 = r, q_3 = \vartheta$ for cones, the independence of the azimuthal angle φ in both cases allows for a reduction of complexity by assuming:

$$\Psi_k = \psi \partial_k q_3 \,, \qquad \bar{a}_{ij} = a_{\mu\nu} \partial_i q_\mu \partial_j q_\nu \,, \qquad \mu, \nu = 1, 2 \,, \tag{3}$$

with a scalar streamfunction ψ and only two[1] additional potentials a_{11}, a_{12}, depending only on the two coordinates q_1, q_2, like also the scalar potential Φ. Making use of the above assumptions, the Lagrangian (1) simplifies to:

$$\ell = \varrho a_{\mu\nu} u_\mu u_\nu + \left[\eta u_\nu - G_{\nu\kappa} \partial_\kappa \Phi\right] \left[2 \left\{G_{\mu\lambda} \partial_\lambda + \Delta q_\mu\right\} a_{\mu\nu} + \partial_\nu G_{\mu\lambda} a_{\mu\lambda}\right] \tag{4}$$

with metric tensor $G_{\mu\nu} = \partial_i q_\mu \partial_i q_\nu$ and the velocity in the μ-direction, expressed via the stream function, $u_\mu = u_i(\partial_\nu \psi)$. The dynamic boundary condition (2) becomes a condition for the scalar potential (with tangential and normal vector t_ν, n_ν):

$$\partial_\nu \Phi + \frac{\sigma}{2} n_\nu - \frac{1}{2} \int U t_\nu \mathrm{d}s = 0 \,. \tag{5}$$

SOLUTION METHOD, RESULTS AND DISCUSSION

The two relevant field equations for ψ and Φ, derived as Euler-Lagrange equations of (4) w.r.t. a_{11}, a_{12}, become integrable by (i) neglecting inertia and (ii) applying an asymptotic analysis, underpinned by the long-wave approximation, as demonstrated in [2] for 2D film flows. Following the same steps as in [2], a single equation for the local film thickness $h = h(\vartheta)$ finally results. Neglecting capillary effects and using r_0 for length scale, this procedure leads to the equation:

$$\left(1 + \frac{3h}{4}\right) h^3 \sin^2\vartheta = \frac{3Q}{2} \left[1 + \frac{h^2}{1+h} \frac{\sin^2\vartheta - 2}{2\sin^2\vartheta}\right] \tag{6}$$

for the flow over a hemisphere with non-dimensional flow rate $Q = 2\eta \dot{V} / \varrho g r_0^4$; the corresponding equation for the thickness $h = h(x)$ for flow over a cone reads:

$$\left(1 - \frac{h'''}{\mathrm{Ca}}\right) \left(\frac{5}{4} \tan\alpha\, h + x\right) h^3 + \left(\frac{h}{\frac{5}{4}\tan\alpha\, h + x}\right)^2 = 1 \tag{7}$$

with the capillary number given as: $\mathrm{Ca} = \sqrt{6\eta\varrho g \dot{V} \tan\alpha}/\sigma$, using $L = \sqrt[4]{12\eta\dot{V}/\varrho g \sin(2\alpha)}$ for length scale and $U = \sqrt{3\varrho g \dot{V} \tan\alpha / 2\eta}$ for velocity scale. Resulting thickness profiles are presented in Fig. 2.

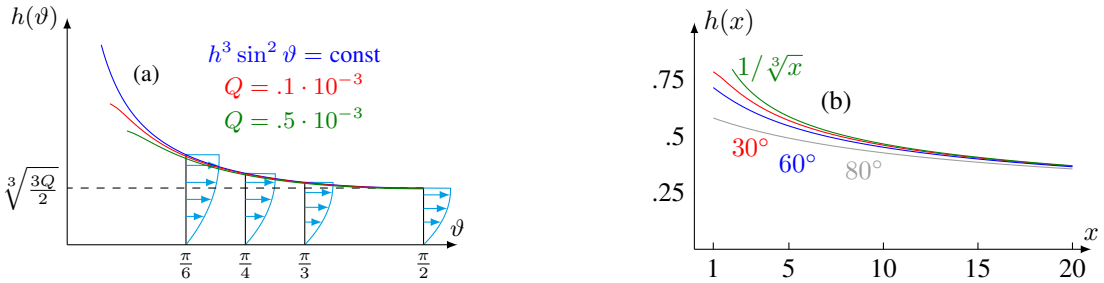

Figure 2: Film thickness predictions for film flow over: (a) a hemisphere and (b) a cone.

Corresponding analytic solutions for unsteady flows with a constant volume instead of a constant flux can also be obtained within the framework of the lubrication approximation by replacing the kinematic boundary condition for steady flow by its unsteady analogue. The above new results are placed in context by comparing them with recently acquired new experiments and flow visualisations specific to film flow on conical surfaces, prior to the onset of and post instability. In conclusion, a perspective is provided in relation to how the findings form the basis for corresponding stability analyses to study the onset of unsteady phenomena such as solitary waves and, in the case of incomplete wetting, rivulet formation.

ROLLING OF NON-WETTING DROPLETS DOWN A GENTLY INCLINED SURFACE

Ory Schnitzer*[1], Anthony M. Davis[2], and Ehud Yariv[3]
[1]Department of Mathematics, Imperial College, London, UK

Summary In their pioneering 1991 paper [1], Mahadevan & Pomeau argued that small non-wetting drops roll, rather than slide, down gently inclined surfaces. Using contact-mechanics arguments, they showed that the rolling speed possesses an anomalous scaling with an inverse dependence upon drop size, in contrast with conventional modes of drop mobility. The Mahadevan-Pomeau scaling was corroborated by the experiments of Quere and coworkers. Here, we go beyond scaling arguments, providing an asymptotic approximation for the speed of rolling droplets. The theory agrees well with experiments and provides a detailed description of the flow field within the drop and close to the moving contact line in particular.

BACKGROUND

Consider a sessile drop on a solid surface, whose size is small relative to the capillary length and whose contact angle is 180 degrees. Under these conditions, the drop adopts a near-spherical shape with a small flat spot in contact with the surface. Mahadevan & Pomeau [1] showed that such small non-wetting droplets roll, rather than slide, down a gently inclined surface. Thus, by balancing the rate of change in potential energy of the drop with an order-of-magnitude estimate for the viscous dissipation in the vicinity of the flat spot, they derived the scaling

$$\mathcal{U} \sim \mathcal{C} \times \frac{\gamma}{\mu} \frac{\alpha}{B^{1/2}}, \tag{1}$$

in which $\mathcal{U}$ is the drop speed, α is the inclination angle, γ is the interfacial tension, μ is the liquid viscosity and $\mathcal{C}$ is an unkown numerical constant; the Bond number is defined as $B = (\kappa a)^2$, wherein a is the drop "radius" defined based on volume and $1/\kappa = \sqrt{\gamma/\rho g}$ is the capillary length, ρ being the liquid density and g the gravitational acceleration. The scaling law of Mahadevan & Pomeau predicts, counterintuitively, that the drop speed is inversely proportional to its size. It was corroborated by the experiments of Quere and coworkers, where the non-wetting conditions assumed in [1] were realised approximately using either superhydrophobic surfaces [2] or liquid marbles [3].

The stress-dissipation singularity usually expected at a moving contact line does not occur for a perfectly non-wetting droplet. Thus, with this assumption, the problem of a rolling drop becomes purely hydrodynamic. To date, the rolling-drop hydrodynamic problem has only been analyzed in two dimensions. In particular, assuming a two-dimensional droplet and the limits $\alpha, B \ll 1$ underlying their three-dimensional scaling analysis, Mahadevan & Pomeau [1] proposed a *local* solution to the flow field close to the contact line. Hodges *et al.* [4], who analyzed a family of related problems, suggested a two-dimensional counterpart of the scaling law (1) and argued that a quantitative analysis of the rolling-drop problem would necessarily be numerical. The two-dimensional problem was later solved numerically in the PhD thesis of Wang [5], who also disputed the validity of the local solution found in [1].

TWO-DIMENSIONAL ROLLING DROPLETS [6]

Recently, Yariv and Schnitzer [6] carried out a detailed asymptotic analysis of the two-dimensional problem. Following [1], their analysis is based on the smallness of the inclination angle α and the Bond number B. First, the problem is linearized for small α, which allows formulating the hydrodynamic problem with respect to the stationary drop shape. Then, both the stationary drop shape and the linearized hydrodynamic problem are analyzed for $B \ll 1$ using the method of matched asymptotic expansions. In particular, the linearized flow field is found by matching a rigid-body rotation in the "outer" drop-scale region, where the drop shape is nearly circular, with the flow field in an "inner" region close to the flat spot of the drop. Besides matching with the outer flow, the flat-spot flow satisfies no-slip and impermeability on the solid flat spot, and kinematic and zero-shear-stress conditions on the fluid interface, which appears flat to leading order (although the local curvature of the interface enters the leading-order problem through the kinematic condition). The flat-spot flow problem was solved analytically using integral transforms. A key feature of the analysis is that the linearized flow problem and the leading-order drop velocity are uniquely determined based on integral force and energy-dissipation relations, which circumvent the need to consider higher orders in the asymptotic scheme. The analysis yields a leading-order approximation for the drop speed:

$$\mathcal{U} \sim \frac{\gamma}{\mu} \frac{\alpha}{2B \ln \frac{1}{B}}. \tag{2}$$

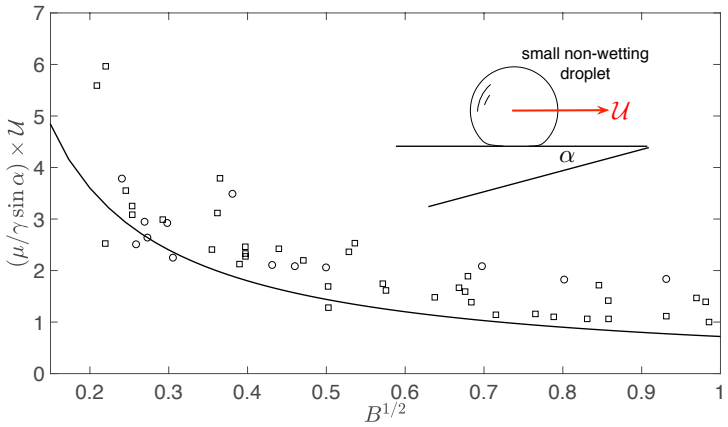

Figure 1: Speed of droplet rolling down an inclined substrate (see text for definitions). Circles: Experiments with glycerol drops on superhydrophobic surfaces [2]. Squares: Experiments with liquid marbles [3]. Line: Eq. (1) with $\mathcal{C}$ given by Eq. (3).

The scaling $1/B \ln B$ differs from that suggested in [4] by the logarithmic factor. The analysis in [6] shows that that logarithmic factor arises because the contribution of the drop-scale region to the total dissipation, which is associated with the deviation of the flow from a rigid-body rotation, is actually not negligible in two dimensions; rather, both the drop-scale and flat-spot regions contribute at the same order, with the leading-order contribution arising from their overlap. It is also shown in [6] that an expansion of the flat-spot flow field close to the contact line agrees with the local solution proposed by Mahadevan & Pomeau [1].

THREE-DIMENSIONAL ROLLING DROPLETS

Here we report on new results of a comparable asymptotic analysis of the hydrodynamic problem governing a three-dimensional rolling droplet. Our approach is similar to than in [6], though the three-dimensional problem is conceptually simpler than the two-dimensional one, as dissipation is dominated by the flat-spot region. Accordingly, calculating a leading-order approximation to the drop speed boils down to formulating and solving the appropriate flat-spot flow problem (and evaluating the associated dissipation). Moreover, the error in this procedure is algebraic in both α and B, in contrast to the logarithmic accuracy of (2). Using a suitable ansatz (see concluding remarks), we obtained a solution to the three-dimensional flat-spot flow field in terms of integral functions of the coordinates. Fortunately, it turns out that the associated dissipation quadrature can still be evaluated in closed form. This gives the prefactor in (1),

$$\mathcal{C} = \frac{3\pi}{16}\sqrt{\frac{3}{2}} \approx 0.72, \tag{3}$$

which gives good agreement with the experiments of Quere and coworkers (see Fig. 1). Furthermore, the behaviour of the flat-spot flow field near the circular contact line can also be obtained in closed form by asymptotic expansion of the integral representations. This shows that near the contact line the flow is mainly in the plane locally normal to the contact line; the flow in that plane is similar to the local flow found in the two-dimensional case up to the multiplicative factor $2\cos\theta$, θ being the azimuthal angle. This analogy breaks down only for $\theta \approx \pm\pi/2$, where the contact line propagates parallel to itself and the local flow is genuinely three-dimensional.

CONCLUDING REMARKS

In both the two- and three-dimensional problems, the flow field in the flat-spot region has the peculiar feature that, in the lab frame, the velocity field happens to satisfy the no-slip and no-shear-stress conditions simultaneously over both the solid flat spot and the mobile fluid interface. This observation allows, in hindsight, enormous simplification in the solution of both flow problems. It also suggests a unique 'peeling' mechanism by which the contact line propagates in the non-wetting case. Remarkably, it also suggests that the asymptotic theory remains unchanged if the no-slip condition on the solid flat spot is replaced by a Navier-slip condition.

AN EXPANSIVE SINGULARITY IN A JUST DETACHED DEVELOPED LIQUID LAYER AND THE TEAPOT EFFECT

Bernhard Scheichl *[1,2], Robert I. Bowles[3], and Georgios Pasias[3]
[1]Institute of Fluid Mechanics and Heat Transfer,Technische Universität Wien,Vienna,Austria
[2]AC2T research GmbH (Austrian Excellence Center for Tribology), Wiener Neustadt, Austria
[3]Department of Mathematics, University College London, London, United Kingdom

Summary We present a rigorous explanation of the celebrated teapot effect via asymptotic analysis of a developed liquid layer passing the trailing edge of a flat plate. Its slenderness, i.e. the reciprocal Reynolds number, represents the primary perturbation parameter. The passage of the flow over the edge is governed by the characteristic "jet-type" viscous–inviscid interaction mechanism, implying a myriad of different phenomena, such as the onset of standing capillary waves, under variation of the appropriately defined Froude and Weber numbers of $O(1)$. Interestingly, for a certain range of these parameters, the fully detached interacting flow hits an expansive singularity whose regularisation on an Euler stage enforces the layer to reattach at the downstream continuation of the plate, guiding the oncoming layer, so as to stay stationary—like poured tea sticking to the underside of a spout.

MOTIVATION AND ESSENCE

Consider the steady, planar flow of a slender Newtonian (liquid) film of uniform properties passing the sharp trailing edge of a horizontal, perfectly smooth and impervious rigid plate in a quiescent (gaseous) environment of constant pressure as gravity acts towards the flow against the vertical direction. We scrutinise the flow in the vicinity of the plate edge, i.e. by taking the vertical height $\tilde{H}$ of the incident unperturbed film at the edge as the reference length scale. This flow configuration, of fundamental concern as ubiquitous in real-world situations, is essentially governed by a complex interplay of inertia with viscosity, gravity, and surface tension and hence controlled by the inverse local Reynolds, Froude and Weber numbers ϵ, g and τ respectively, with ϵ taken as asymptotically small. How a developed, very supercritical free-surface film anticipates the plate edge in terms of viscous–inviscid short-scale interaction was addressed first in [1]. Specifically, there $G := g\epsilon^{-4/7} = O(1)$ and $T := \tau/J_0 = O(1)$, J_0 is the dimensionless undisturbed momentum flux, parametrise the least-degenerate flow description. In the following, we refer to the sketch in figure 1 (a) throughout.

As a start, it is expedient to outline most concisely the basic "jet" interaction law underlying this asymptotic theory and its current extension. To this end, let some viscous flow, initially firmly attached to the plate, undergo an interaction process in order to negotiate locally an upstream influence. Hence, we let all lengths and flow components and the local pressure variation Δp be non-dimensional with its vertical depth, here identified with $\tilde{H}$, the according reference flow speed, and the (locally) uniform fluid density. With interaction at play over some horizontal (streamwise) distance δ_x ($\gg 1$), significant viscous action and plate irregularities remain confined to a sublayer of some vertical depth δ_y ($\ll 1$). Therein, the streamwise flow speed of $O(\delta_y)$ exhibits some perturbation Δu about its base state so that the streamwise component of the Navier–Stokes equations implies the order-of-magnitude balances $\Delta u\,\delta_y/\delta_x \sim \Delta p/\delta_x \sim \epsilon\Delta u/\delta_y^2$. The sought interaction law relating the pressure disturbance Δp, predominantly varying in streamwise direction, to Δu provides a third one finally recovers the well-known dependencies of δ_x and δ_y on ϵ. If we consider a genuine boundary layer, the potential flow induced on its top exerts Δp (triple-deck structure). Otherwise, the pressure vanishes there as for a wall jet or developed free-surface layer (present double-layer structure) so that Δp is typically governed by streamline curvature, i.e. the inviscid lateral momentum transfer, when we first ignore the effect of body/surface forces (hydrostatic pressure and capillarity). Since continuity induces a lateral flow speed in the core layer of $O(\Delta u\,\delta_y/\delta_x)$, the respective momentum balance entails the missing estimate $\Delta u/\delta_x^2 \sim \Delta p$, thus $\delta_y = \delta_x^{-2} = \epsilon^{2/7}$ and the parametrisation of the arising interaction law by G and T, measuring the impact of those forces. In leading order, we describe the flow in the sublayer in terms of horizontal and vertical coordinates X and Z directed respectively from the trailing edge and the lower free streamline, its X-component $U(X,Z)$, the pressure disturbance $P(X)$, and the Z-displacements $H_\pm(X)$ of the lower, detaching $(-)$ and the upper $(+)$ free streamline; all quantities are scaled to $O(1)$ by δ_y, δ_y, δ_y/δ_x^2 and δ_y respectively. In turn, $U \sim Z + A(X)$ as $Z \to \infty$, and for the detached portion of the flow ($X > 0$) and $T \gg \epsilon^{12/7}$

$$\{P, H_-, H_+\} = \left\{ \frac{T}{2T-1}\left[G + \mathrm{sgn}(T-1)A''\right],\ \frac{T-1}{2T-1}\left[A - A(0) - A'(0)X + \mathrm{sgn}(T-1)\frac{GX^2}{2}\right],\ H_- - A \right\}. \quad (1)$$

Here in the first interaction or P/A-law closing the interactive feedback loop capillarity counteracts streamline curvature to cancel it if $T = 1$. We currently investigate this degenerate and the case $T = 1/2$ (capillary waves at vanishing speed).

Compressive interactive branching from the unperturbed wall-bounded flow has proven central in the rational description of the susceptibility of the latter to local corrugations of and separation from the wall: originally established for jet flows [2], it was later applied to gravity-driven free-surface layers [3, 4]; see also the references therein. In contrast, the much less appreciated expansive branching has the numerical marching solution of the interaction problem inevitably

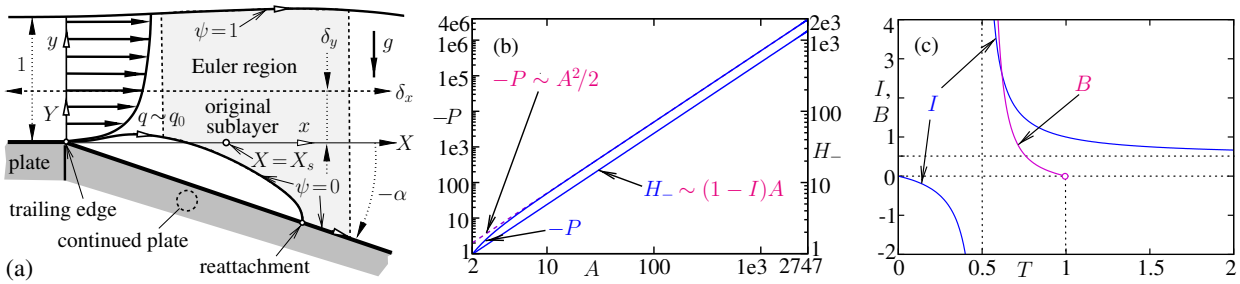

Figure 1: (a) Configuration (not to scale); (b) blow-up past detachment, log-log plot of interpolated numerical data (*solid*, terminate at $A \simeq 2747$, $G = 1$, $T = 0.51$, $I = 25.5$) and asymptote (*dashed*); (c) strengths of interaction I and blow-up B in detached flow.

terminate in a finite-X singularity of generic type [2]. Its physical interpretation was not clarified earlier as in [1] in the context of the attached film anticipating the plate edge. However, we demonstrate that a close counterpart of this blow-up is also met in the detached layer at some $X = X_s(G,T)$ by virtue of the P/A-law for $1/2 < T < T^*(G) < 1$ with X_s increasing towards infinity as T approaches some threshold T^*. Most importantly, this blow-up is regularised over a streamwise extent of relative $O(1)$ by a full Euler stage. Given the smallness of g, this is solely driven by capillarity active on both free surfaces. Moreover, in any physically admissible stationary solution of the elliptic Euler problem initiated by the blow-up, the oncoming flow must turn through some overall angle α ($-\pi \le \alpha \le \pi$) before it recovers as the unperturbed parallel one. However, its vertical linear momentum associated with a non-trivial solution ($\alpha \neq 0$) must be compensated by a pressure net force. In the current setting, this requires the flow to impinge onto a rigid wall. If this represents a continuation of the plate and forms a convex corner (downturn, $\alpha < 0$), we arrive at an unprecedented and exciting rational explanation of the so-called teapot effect, corroborating the original heuristic one [5]: for a sufficiently weak momentum flux J_0, the blow-up prevents the "tea" jet achieving the gravity-driven parabolic downfall, see (1), as it clings to the "spout" due to a local interplay of inertia with capillarity. For a larger one ($T < 1/2$), the interaction mechanism predicts a free jet exhibiting a capillary wave crest; for a smaller one ($T > 1$) and strikingly different capillarity-dominated flow picture, the onset of the waves already above the plate approaches the plate edge as $T \to 1+$.

The existing rigorous *model* of the teapot effect resorts to a capillarity-free ideal-fluid flow [6]. It describes this phenomenon qualitatively correctly, without the need of pre-separation. However, the assumption of a developed incident layer surmounts a deficient and intrinsic parametric non-uniqueness that originates in the artificial neglect of viscosity.

BLOW-UP AND REGULARISING EULER STAGE

Our numerical solutions of the interaction problem confirm excellently the predominantly inviscid nature of the expansive singularity; see figure 1 (b): $-P \sim A^2/2$, $H_- \sim (1-I)A$ as $A \to \infty$ and $I := T/(2T-1)$ measures the strength of the P/A-law, cf. (1). Denote x and y coordinates, non-dimensional with $\tilde{H}$ and aligned with X and Y respectively and originating in $(X,Y) = (X_s, 0)$, and q the streamwise flow component in the core layer, assuming its unperturbed state q_0 above the plate edge, we find $q \sim q_0(y) + Bq_0'(y)/x^2$ where $B := (12/J_0)T^2(1-T)/(2T-1)^2$; see figure 1 (c).

A novel and numerically appealing representation of the free-surface Euler problem regularising the blow-up reads

$$\frac{\partial}{\partial\phi}\Big(\frac{\chi}{q^2}\frac{\partial q}{\partial\phi}\Big) + \frac{\partial}{\partial\psi}\Big(\frac{q}{\chi^2}\frac{\partial\chi}{\partial\psi}\Big) = 0, \quad \chi(\phi,\psi) := q\exp\int_1^\psi \frac{\omega(t)\,\mathrm{d}t}{q^2(\phi,t)}, \quad \begin{cases} \psi = 0\colon\ \theta(-\phi)q^3/(2\tau) + q\partial_\psi q = -\omega(0), \\ \psi = 1\colon\ q^2 = q_0^2 + 2\tau\partial_\psi q. \end{cases} \tag{2}$$

Herein, q is considered as a function of a pseudo-potential ϕ and the streamfunction ψ ($0 \le \psi \le 1$), $\psi = 0$ denotes the lower and $\psi = 1$ the upper free streamline, $\omega(\psi)$ the vorticity impressed by q_0, and θ the Heaviside step function. We discuss the numerical solutions to (2) supplemented with a matching condition reflecting the bifurcation from $q = q_0$ due to the blow-up as $\phi \to -\infty$. It is seen that we force the streamline $\psi = 0$ to reattach in the origin of the (ϕ,ψ)-plane at a flat plate, thus modelling the "spout of the teapot" in a first and most simple manner. Hence, a wedge-flow singularity emerges in the origin, parametrised by the plate angle equal to α. Prescribing α then selects a unique solution for q.

We finally envisage the interesting long-wave limit $\gamma := T - 1 \to 0$, stretching the Euler regime in streamwise direction to $O(\gamma^{-1/2})$. When γ is reduced to $O(\delta_x^{-2})$, i.e. $O(\epsilon^{2/7})$, it collapses with the encompassing interactive stage such that the teapot effect sets in already at the original trailing edge without pre-separation in the accordingly extended theory.

STABILITY OF A PARTICLE-LADEN FILM FALLING DOWN AN INCLINE

Darish Jeswin Dhas S*[1] and Anubhab Roy [1]
[1]Department Applied Mechanics, Indian Institute of Technology Madras, Chennai, India

Summary The stability of particle-laden thin film falling down an incline is investigated using a nonlinear wave theory and a linear stability analysis. In absence of particles, the stability of a gravity-driven thin film has been extensively studied. Yih (1963) [5] in his pioneering study carried out a linear stability analysis and identified a long wavelength instability in a falling film. Subsequently Benney (1966) [1] performed an expansion in wave amplitude and derived a nonlinear wave equation describing the evolution of the film height that reproduced the linear stability findings as a limiting case. The presence of particles alters the rheology of the fluid with the non-uniformity of particle concentration altering the local shear viscosity leading to a coupling with the momentum balance. Using a Benney-like amplitude expansion, a set of coupled nonlinear equations are derived describing the evolution of film height and particle concentration. The modified Benney equation is solved numerically and the threshold of instability is calculated. However, the Benney equation is known to have a finite time blowup beyond the stability threshold. This is countered using a weighted residual approach in conjunction with the lubrication approximation. On linearizing the governing equations, a generalized Orr-Sommerfeld system of equations is derived. The predictions of linear stability analysis are then compared with the results from the nonlinear long wave theories.

INTRODUCTION

Thin liquid films are observed in a wide range of scenarios, of both natural and engineering importance. Tear film formation, glaciers flowing down mountains and coating flows are some of the classical examples of thin liquid films [2]. A lot of work has been done in the case of gravity driven falling films. However, introcuction of particles brings in new physics which is not much understood. In this work, we study the dynamics of a Brownian particle-laden gravity driven falling film. The particles evolve by being both advected by the background flow while also diffusing due to Brownian motion. Both the linear and the non-linear regimes are studied by developing models using the lubrication approximation.

LONG-WAVE THEORY

Consider a particle-laden two-dimensional viscous incompressible thin film falling down an inclined plane under the action of gravity. The particles are colloidal and neutrally buoyant and are assumed to be rigid. The substrate is inclined at an angle α and the height of the film is taken as $h(x,t)$. With the suspensions, the effective viscosity becomes a function of the particle volume fraction (ϕ). Using a Benney-like amplitude expansion about the film aspect ration (ϵ), a set of coupled nonlinear equations are derived describing the evolution of film height and particle concentration.

$$\frac{\partial h}{\partial t}+\frac{\partial}{\partial x}\left(\kappa h^3\right)+\epsilon Re\frac{\partial}{\partial x}\left\{\kappa\left(-\kappa_t\frac{2}{5}h^5+\kappa\kappa_x\frac{8}{35}h^7+\kappa^2\frac{6}{5}h^6\frac{\partial h}{\partial x}-\frac{\cot\alpha}{Re}h^3\frac{\partial h}{\partial x}+\epsilon^2We\frac{h^3}{3}\frac{\partial^3 h}{\partial x^3}\right)\right\}=0 \quad (1)$$

$$\frac{\partial(h\phi)}{\partial t}+\frac{\partial}{\partial x}\left(\phi\kappa h^3\right)+\epsilon Re\frac{\partial}{\partial x}\left\{\phi\kappa\left(-\kappa_t\frac{2}{5}h^5+\kappa\kappa_x\frac{8}{35}h^7+\kappa^2\frac{6}{5}h^6\frac{\partial h}{\partial x}-\frac{\cot\alpha}{Re}h^3\frac{\partial h}{\partial x}+\epsilon^2We\frac{h^3}{3}\frac{\partial^3 h}{\partial x^3}\right)\right\} \quad (2)$$
$$=\frac{1}{Pe_l}\frac{\partial}{\partial x}\left(\chi(\phi)h\frac{\partial\phi}{\partial x}\right)$$

where κ denotes the non-dimensional part of the viscosity such that $\mu=\mu_s\kappa(\phi)^{-1}$, χ denotes the non-dimensional part of the particle diffusivity, Reynolds number defined as $Re=\rho h_0u_0/\mu_s$, Peclet number as $Pe_l=u_0l/D_0$ and the Weber number as $We=\gamma/\rho u_0^2h_0$. This modified Benney equation is solved numerically and the stability threshold is calculated. However, the Benney equation has a major drawback of having a finite time blowup while beyond the stability threshold [3]. Also, the equation remains valid only for a small range of Re. To counter such problems, a depth averaged weighted residual based technique [4] is used to obtain boundary layer equations. Using the Galerkin weighted residual method in this case, the model equations can be written as

$$\frac{\partial h}{\partial t}+\frac{\partial q}{\partial x}=0 \quad (3)$$

$$\epsilon Re\frac{\partial q}{\partial t}=\frac{5}{2}h-\frac{5}{2}\kappa(\phi)\frac{q}{h^2}+\epsilon Re\left(\frac{9}{7}\frac{q^2}{h^2}\frac{\partial h}{\partial x}-\frac{17}{7}\frac{q}{h}\frac{\partial q}{\partial x}-\frac{5}{2}\frac{\cot\alpha}{Re}h\frac{\partial h}{\partial x}+\frac{5}{6}\epsilon^2Weh\frac{\partial^3 h}{\partial x^3}\right) \quad (4)$$

$$\frac{\partial(h\phi)}{\partial t}+\frac{\partial\left(q\phi\right)}{\partial x}=\frac{1}{Pe_l}\frac{\partial}{\partial x}\left(\chi h\frac{\partial\phi}{\partial x}\right) \quad (5)$$

Here, q denotes the flow rate. The above system is solved numerically as done with the modified Benney equations.

LINEAR STABILITY ANALYSIS

For the linear stability analysis, the base state is taken to be that of a Nusselt flow with $h = 1$ and constant particle concentration $\phi = \phi_b$. A normal mode analysis is done by perturbing the variables, say X in the form $X = X_b + X_1 e^{ik(x-ct)}$ with X_b referring to the base flow and X_1 to the infinitesimal amplitude of the wave. This form of linearisation in the momentum equations leads to the Orr–Sommerfeld equation and the same on the concentration equation leads to a similar linear equation, both together forming an eigenvalue problem.

$$\psi''''\kappa_b - 2k^2\psi''\kappa_b + k^4\psi\kappa_b + \kappa_{b1}(\phi U')'' = ikRe\left[(U-c)(\psi'' - k^2\psi) - U''\psi\right] \tag{6}$$

$$\chi_b\phi'' - k^2\chi_b\phi - ikPe_l\,(U-c)\,\phi = 0 \tag{7}$$

Here ψ denotes the stream function and the primes denotes the differentiation with respect to y and $\kappa_{b1}(\phi_b)$ is a consequence of expansion of the viscosity term. The eigenvalue problem can be solved numerically using the Chebyshev spectral collocation method. In the limit of small wavenumbers, the solutions of the full Orr-Sommerfeld system should be equal to the linear solutions of the long-wave theory based models as is shown in figure 2.

CONCLUSIONS

The effect of particles on the stability of a falling liquid film driven by gravity down an inclined plane is studied. Using the lubrication approximation, modified Benney equations and a depth averaged boundary layer equations were obtained and their consistency with the full governing Navier Stokes equations with the particle concentration evolution was check in the linear long-wave limit and shown to be consistent. The finite amplitude disturbances are explored by solving the nonlinear coupled PDEs (equations 1 & 2 and 3, 4 & 5) numerically in a periodic domain.

Summary In this paper, we introduce a new extended version of the shallow water equations with surface tension which is skew-symmetric with respect to the L^2 scalar product and allows for large gradients of fluid height.

INTRODUCTION

Thin film flows are encountered in a large number of industrial applications due to their low resistance to heat or mass transfers. The hydrodynamic regime that is promoted in such applications is a wavy laminar regime for which a significant enhancement of transfers has been observed. Yet, the mechanisms responsible for this enhancement are far from being well understood due to the high numerical cost required to investigate such flows. Indeed, the long-wave nature of the hydrodynamic instability, the weakly turbulent organization of the flow by solitary waves in interaction, the 3D nature of the flow, and the extension of the entrance thermal region (high Peclet numbers) require simulations on extended domains and over extended periods of time, that are still out of reach. A promising approach is offered by the derivation of consistent Saint-Venant-like equations to describe the film flows [1]. Such approaches are based on the long-wave nature of the instability generating surface waves. Elimination of the "rapid variable", here the cross-stream coordinate, leads from the 3D incompressible Navier-Stokes equations with a free-surface to 2D equations where the film thickness h plays a role similar to density and surface tension appears along with third-order terms. These third-order terms are problematic numerically and therefore generally linearized to be dealt with more easily. As a consequence, numerical investigations of these Saint-Venant-like models are limited to regular meshes, which severely impairs their use with complex geometries, for instance when a wall topography is considered. A cure to this problem has been proposed by Vila and coworkers [2, 3] by introducing an additional variable with the dimension of a velocity whose kinetic energy is equal to the surface energy of the film. By writing a transport equation for this additional variable, these authors have been able to recast shallow-water equations with linearized surface tension terms into an "augmented" system of equations with a skew-symmetric structure with respect to the L^2 scalar product which makes the proof of energy estimates. Additionally, the design of compatible numerical scheme is made easier as surface tension terms are then recast as generalized diffusion terms.

However, this strategy is limited to linearized surface tension terms and is therefore not suitable in cases of partial wetting with large contact angles, as can be encountered for instance in the design of plate exchangers for which dewetting phenomena are detrimental to their efficiency. In this paper, we thus propose to extend the formulation proposed in [3] to account for the full surface tension terms.

FORMULATION

We thus consider shallow-water type equations with a full surface tension term:

$$\left\{\begin{array}{ll} \partial_t h + \operatorname{div}(h\mathbf{u}) = 0 & (i) \\ \partial_t(h\mathbf{u}) + \operatorname{div}(h\mathbf{u}\otimes\mathbf{u}) + \nabla P = -\operatorname{div}(\nabla h \otimes \nabla_{\mathbf{p}} E) + \nabla(h\operatorname{div}(\nabla_{\mathbf{p}} E)) & (ii) \end{array}\right. \tag{1}$$

with h the fluid height, $\mathbf{u}$ the fluid velocity vector field. The internal energy E is defined by

$$E(h,\boldsymbol{p}) = \frac{1}{2} g_z h^2 + \frac{\sigma}{\rho}(\sqrt{1+q^2} - 1) \tag{2}$$

where g_z is the gravitational acceleration normal to the plate, σ is the surface tension, ρ the density, $\boldsymbol{p} = \nabla h$ and $q = \|\boldsymbol{p}\| = \sqrt{\boldsymbol{p}^t\boldsymbol{p}}$. Finally, the pressure P is given by

$$P(h,\boldsymbol{p}) = h\partial_h E(h,\boldsymbol{p}) - E(h,\boldsymbol{p}) = \frac{1}{2} q_z h^2 - \frac{\sigma}{\rho}(\sqrt{1+q^2} - 1) \tag{3}$$

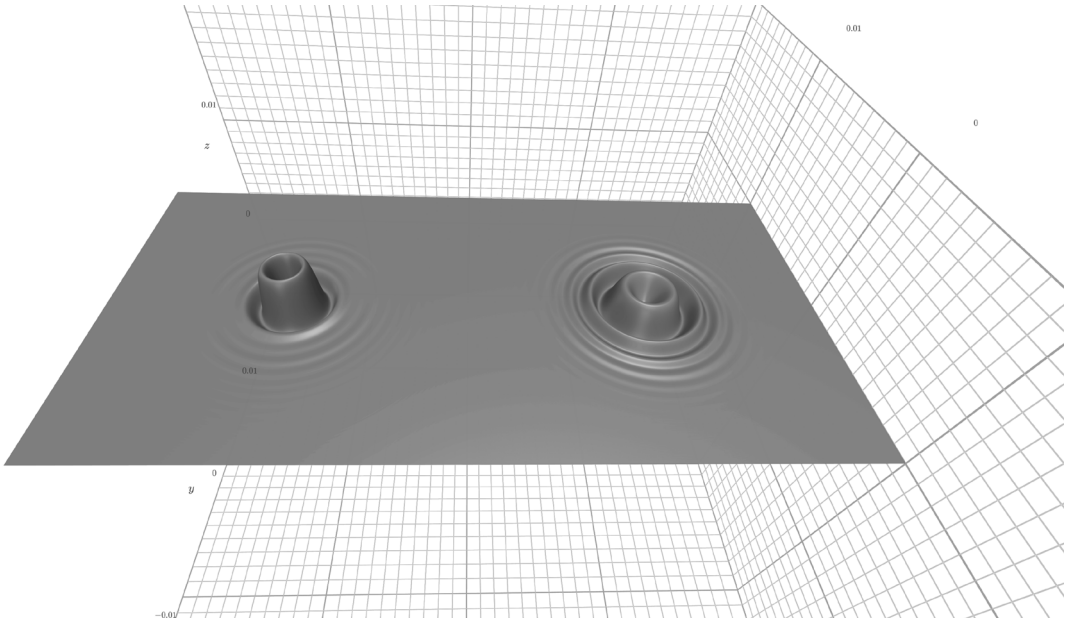

Figure 1: Numerical simulations of capillary-gravity waves considering a two-dimensional Gaussian-shaped deformation of a layer of water; (left) with the full non-linear capillary contribution, (right) with the linearized capillary contribution.

We introduce an additional unknown, denoted $\boldsymbol{v}$, which is co-linear to ∇h and satisfies

$$\frac{1}{2}h\left\|\boldsymbol{v}\right\|^2 = \frac{\sigma}{\rho}(\sqrt{1+\left\|\nabla h\right\|^2}-1) \tag{4}$$

To do so, we define $\mathbf{v}$ as $\boldsymbol{v} = \alpha(q^2)\boldsymbol{p}\sqrt{\frac{\sigma}{\rho}\frac{1}{h}}$ where $\alpha(q^2) = \dfrac{\sqrt{2(\sqrt{1+q^2}-1)}}{q}$.

Note that, in this context, $\boldsymbol{v}$ has the dimension of velocity and transform the capillary energy into some kinetic energy. We show that the augmented system

$$\partial_t U + \operatorname{div}\left(F\left(U\right)\right) = \mathcal{M}. \tag{5}$$

where

$$U = \begin{pmatrix} h \\ h\boldsymbol{u} \\ h\boldsymbol{v} \end{pmatrix}, \qquad F\left(U\right) = \begin{pmatrix} h\boldsymbol{u} \\ h\boldsymbol{u}\otimes\boldsymbol{u} + g_z\frac{h^2}{2}I_d \\ h\boldsymbol{v}\otimes\boldsymbol{u} \end{pmatrix} \qquad \mathcal{M} = \begin{pmatrix} 0 \\ \operatorname{div}\left(h\nabla(f(h,\boldsymbol{v})\boldsymbol{v})^t\right) - \nabla(g(h,\boldsymbol{v})^t\boldsymbol{v}) \\ -f(h,\boldsymbol{v})\operatorname{div}\left(h\nabla\boldsymbol{u}^t\right) \quad -g(h,\boldsymbol{v})\operatorname{div}\boldsymbol{u} \end{pmatrix}. \tag{6}$$

where $f(h,\boldsymbol{v})$ is a symmetric tensor and $g\left(h,\boldsymbol{v}\right)$ a vector field given by

$$f(h,\boldsymbol{v}) = \left(\frac{\sqrt{h}}{\sqrt{1+\frac{\rho h}{4\sigma}\left\|\boldsymbol{v}\right\|^2}}\right)\left(\mathbf{I} - \left(1+\frac{\rho h}{2\sigma}\left\|\boldsymbol{v}\right\|^2\right)^{-1}\frac{\rho h}{4\sigma}\boldsymbol{v}\otimes\boldsymbol{v}\right), \quad g(h,\boldsymbol{v}) = \frac{h\boldsymbol{v}}{2}\left(1+\frac{\rho h}{2\sigma}\left\|\boldsymbol{v}\right\|^2\right)^{-1}$$

verifies: If $(h,\boldsymbol{u})$ is regular enough and the initial velocity $\boldsymbol{v}_0$ satisfies $\boldsymbol{v}_0 = \alpha(\left\|\nabla h_0\right\|^2)\sqrt{\frac{\sigma}{\rho}\frac{1}{h_0}}\nabla h_0$, then $\boldsymbol{v}$ satisfies also (4) and $(h,\boldsymbol{u})$ solves (1)–(3). The proof of this convergence derives from the existence of an energy balance that shows that the total energy of the system is conserved (see [4] for details). Numerical investigations using appropriate schemes have shown that (5) does capture correctly capillary waves (see fig. 1). We now intend to introduce a disjoining pressure to account for dewetting phenomena as proposed by [5].

PHASE SEPARATION OF A CONFINED IONIC-LIQUID – WATER MIXTURE IN A TEMPERATURE GRADIENT

Marc Pascual[1], Arthur Poquet [1], Alexandre Vilquin [1], and Marie-Caroline Jullien *[1,2]
[1]Gulliver CNRS UMR 7083, PSL Research University, ESPCI Paris, 10 rue Vauquelin, 75005 Paris, France [2]Université Rennes1,CNRS,IPR,UMR6251,F-35000 Rennes,France

Summary The phase separation of a confined binary mixture induced by a temperature gradient shows surprizing patterns depending on the composition of the mixture. For all three characteristic patterns identified we notice an accumulation of the most wetting phase in the warmer region. This behavior is explained by the presence of a micrometer-thick wetting layer submitted to thermal interfacial gradient.

PHASE SEPARATION IN THERMOCAPILLARY FORCE FIELD

Introduction

Thermoresponsive ionic liquid (IL) - water (W) mixtures (figure 1(a)) have been proposed for various applications such as selective synthesis and extraction of chemical products [1] or desalination [2]. These applications rely on the reversible separation-recombination of the mixture with temperature loops, but do not propose explicitly any means to isolate selectively one phase or the other (aside from gravity effects [3]). Since it has been shown that wetting effects with the walls and initial volume fraction of each components play a significative role in the phase separation kinetics [4], microfluidic-scale systems are relevant as capillary effects are highlighted. In this presentation we investigate the interplay between phase separation and wetting when a temperature gradient is applied to the system.

Experiment on dynamics of separation

We use a thin cylindrical microfluidic cavity (figure 1(b)) of 1 cm diameter and with a height varying from 20 to 500 μm, placed above a micropatterned heating resistor (Joule effect). When the resistor is switched on, the temperature profile increases radially in the cavity and triggers phase separation which propagates from the center towards the edges. The interfaces formed during this separation are submitted to thermal interfacial tension gradients which induce transport along the gradient [5]. Depending on the IL mass fraction of the solution we identify three phase separation regimes (figure 2(a)-(c)). For both three, the wetting phase is accumulated above the heating resistor while the non-wetting phase is driven towards the colder region. Hence, tuning the wall-fluid affinity allows selecting the component to be concentrated. This behaviour is recovered with lutidine-water mixture and is expected to be universal to all binary system.

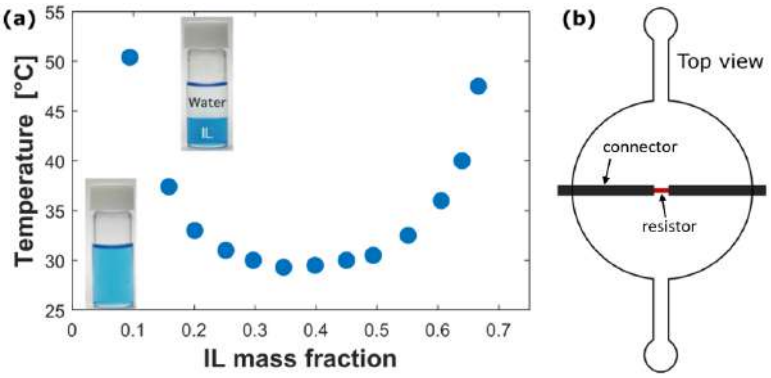

Figure 1: (a) Phase diagram of the LCST (Lower Critical Solution Temperature) IL-water system. The solution is colored with a blue dye. Critical point is at 35 wt% in IL, and 29.2°C. (b) Top view of the microfluidic chip. Diameter is 1 cm. Gold tracks are connecting the chromium microresistor at the center.

The first regime (15 to 35 wt% in IL) depicted in figure 2(a) has been quantitatively studied in more detail. We show that the outer frontier is due to the isotherm propagation, the second frontier is linked to a thermocapillary migration of small droplets and finally the inner frontier corresponds to the accumulation of the phase enriched in IL. Moreover, the complete spreading of the IL-rich wetting phase gives birth to a micrometer-thick film, whom thermal actuation induces a 3D flow which is not obvious in light of figure 2(a). The velocity of droplets dragged by this film are compared to the temperature gradient and film thickness profile. A quantitative description on the model of this 3D flow structure will be discussed during the presentation.
In the second regime (40 to 55 wt% in IL), depicted in figure 2(b), an instability develops at the external frontier. Despite the vertical confinement which drives the viscous dissipation, the instability develops radially. An analogy with the Bénard-Marangoni instability is proposed leading to recirculating cells at the outer frontier.

*Corresponding author. E-mail: marie-caroline.jullien@univ-rennes1.fr.

In the third regime (more than 60 wt% in IL), represented on figure 2(c), water droplets are thermocapillary driven towards the outside, eventually undergo coalescence events but does not lead to an efficient phase separation.
As a whole, we will present experiments, supported by a theoretical model for regime 1, in which phase separation is thermally assisted in a microfluidic cavity and show the richness of physical phenomena involved in the system.

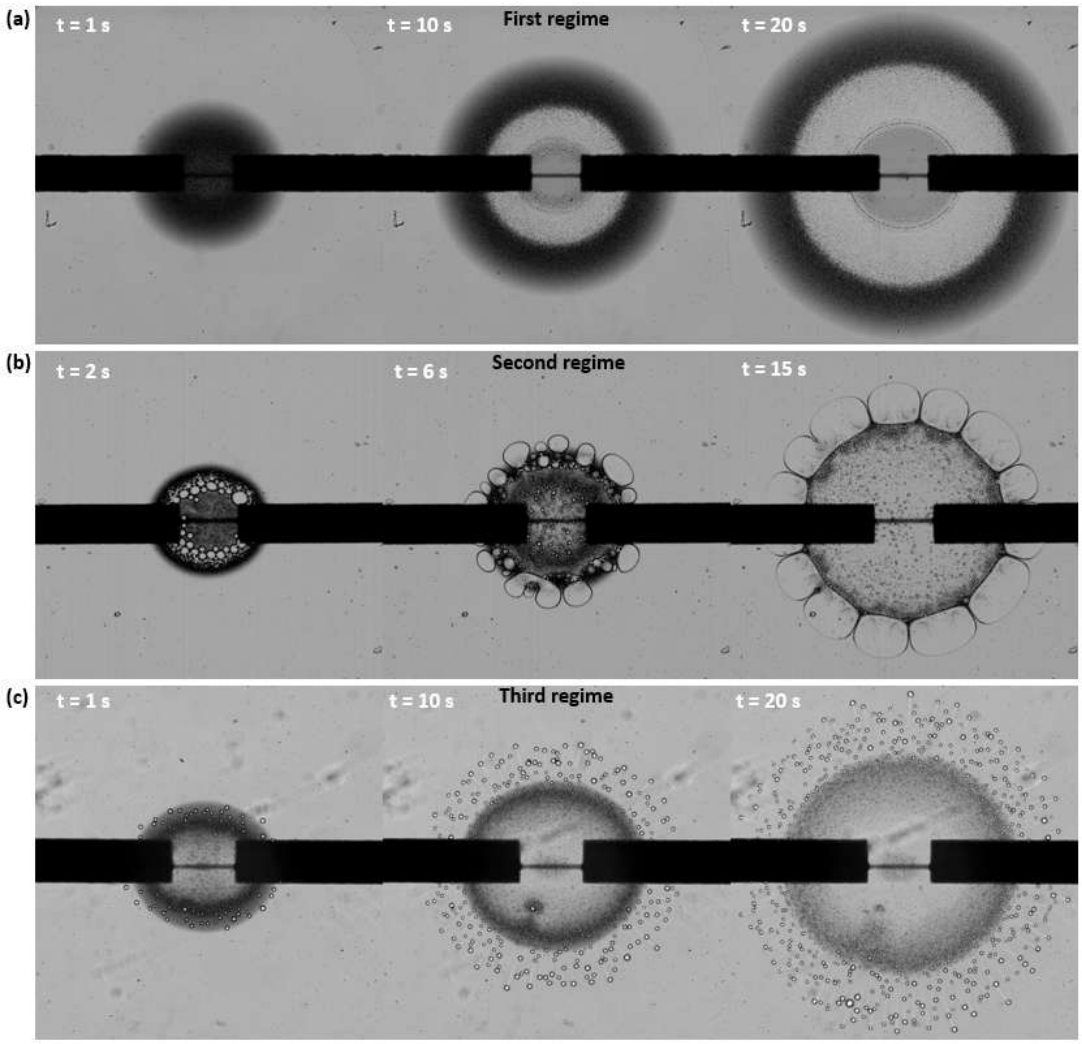

Figure 2: Temporal evolution of the phase separation patterns observed with transmitted light microscopy after resistor switch-on (80 mW). Solutions compositions are respectively: (a) 25 wt% in IL, (b) 45 wt% in IL, (c) 60 wt% in IL. The resistor length is 500 μm for scale.

CONCLUSIONS

Wetting effects coupled to a temperature gradient produce non-trivial patterns during phase separation. Their dynamic is controlled by the interfacial transport which result of thermal Marangoni actuation. It leads systematically to the focusing of the wetting phase at the center of the cavity. This behavior should be universal to all binary systems. This technique can prove relevant for the applications using thermoresponsive binary mixtures.

THE STOKES AND EULER REGIMES OF THIN FILM RUPTURE

Daniel Moreno-Boza*[1], Alejandro Martínez-Calvo [1], and Alejandro Sevilla[1]
[1]Grupo de Mecánica de Fluidos, Universidad Carlos III de Madrid, Spain

Summary Theory and numerical simulations are used to unravel the nonlinear dynamics of non-wetting ultrathin liquid films deposited on solid substrates in the spinodal dewetting regime. The distinguished limits of Stokesian and ideal flow are investigated in detail.

INTRODUCTION

Thin liquid films are ubiquitous in nature and everyday life, and they play important roles in many engineering, medical, and physiological contexts [1]. Here, we shed light on the unstable dynamics of non-wetting ultrathin films of Newtonian liquid of density ρ and viscosity μ deposited on solid surfaces (see Fig. 1a). The liquid film, of initial thickness h_o and constant surface tension coefficient σ at the interface with the surrounding air, is known to become linearly unstable due to the long-range van der Waals (vdW) forces when $h_o \lesssim 100$ nm [2]. The dynamics leading to film rupture has typically been described with lubrication theory, which assumes that the longitudinal length scale is much larger than the film thickness, leading to models with simpler mathematical structure than the Navier-Stokes equations.

Two distinguished limits are addressed in detail, namely that of negligible inertia where the flow is described by the Stokes equations, and the opposite limit of inertial rupture, which admits a potential flow description outside thin viscous boundary layers. The corresponding Stokes and Euler self-similar regimes arising close to rupture are unraveled here for the first time, showing marked differences with respect to previous results obtained with lubrication theory. Regarding the dewetting of very viscous films, the well-known scaling $h_{\text{min}} \propto \tau^{1/5}$, where h_{min} is the minimum film thickness and $\tau = t_{\text{R}} - t$ is the time until rupture [3], cannot be used to describe the local flow close to rupture due to the breakdown of the slenderness assumption close to the singularity. Instead, a non-slender regime with $h_{\text{min}} \propto \tau^{1/3}$ is found upon examination of the complete Stokes equations of motion [4]. The effect of liquid inertia must be retained for metallic film dewetting [5, 6], for which we develop a new self-consistent theory that correctly describes the inertial dynamics close to rupture with the power law $h_{\text{min}} \propto \tau^{2/5}$ stemming from a balance between liquid inertia and vdW forces, the capillary force being asymptotically subdominant. The latter result is in marked contrast with the prevailing descriptions of the inertial limit, which predict $h_{\text{min}} \propto \tau^{2/7}$ from a balance of liquid inertia with capillary and vdW forces [3, 5].

In the general case, the film dynamics is described using the continuity and momentum conservation equations,

$$\nabla \cdot \boldsymbol{v} = 0, \quad \rho\left(\partial_t \boldsymbol{v} + \boldsymbol{v} \cdot \nabla \boldsymbol{v}\right) = -\nabla\left(p + \phi\right) + \mu \nabla^2 \boldsymbol{v}, \tag{1}$$

where $\boldsymbol{v} = (u, v)$ is the liquid velocity field, assumed to be two-dimensional, p is the liquid pressure, $\phi = A/(6\pi h^3)$ is the disjoining pressure, which models the overall effects of the long-range vdW forces, where A is the Hamaker constant. The supplementing boundary conditions include the stress balance and the kinematic condition at the free surface and no-slip at the wall. The appropriate near-rupture scalings for the Stokes and Euler limits are briefly discussed next.

FILM RUPTURE AT SMALL REYNOLDS NUMBERS: SELF-SIMILAR STOKES FLOW

In the limit of negligible inertia, Eqs. (1) and the corresponding boundary conditions were conveniently nondimensionalised by taking $a = [A/(6\pi\sigma)]^{1/2}$, σ/μ, $\mu a/\sigma$, and $A/(6\pi a^3)$ as the relevant scales for length, velocity, time, and pressure, respectively. This choice of scales renders the dimensionless initial film thickness, h_o/a, as the only governing parameter. To unravel the Stokesian dynamics, Eqs. (1) were integrated in time in the inertialess limit, $\rho = 0$, until times very close to rupture, revealing a near-singularity evolution consistent with the power-law $h_{\text{min}} \propto \tau^{1/3}$ as $\tau \to 0$, markedly different from the classical result $h_{\text{min}} \propto \tau^{1/5}$ [3]. Moreover, this difference appears already during the early stages after the onset of the vdW instability, and increases over time. In particular, the 1/5 power law predicted by lubrication theory is only accomplished transiently during a very short intermediate time interval prior to the crossover to the 1/3 power law described in [4] for the first time, to which the reader is referred for more details. To describe the newly discovered self-similar regime, the similarity ansatz $x = \tau^{1/3}\xi$, $y = \tau^{1/3}\eta$, $h = \tau^{1/3} f(\xi)$, $u = \tau^{-2/3} U(\xi, \eta)$, $v = \tau^{-2/3} V(\xi, \eta)$, $p = \tau^{-1} P(\xi, \eta)$, suggested upon consistently balancing the viscous and vdW forces, was introduced into Eqs.(1), allowing us to elucidate the structure of the leading-order flow for $\tau \to 0$. The parameter-free self-similar Stokes equations read

$$U_\xi + V_\eta = 0, \quad U_{\xi\xi} + U_{\eta\eta} = P_\xi - 3 f^{-4} f_\xi, \quad V_{\xi\xi} + V_{\eta\eta} = P_\eta, \quad \text{in} \quad 0 < \xi < \infty, 0 < \eta < f(\xi), \tag{2}$$

in which capillary forces are subdominant. The corresponding self-similar form of the boundary conditions are not included here for brevity [4]. The integration of the latter elliptic system provided the shape $f = f(\xi)$ of the film, with an associated wedge-shaped far-field behavior $f \sim \xi \tan\theta_o$ with an opening angle $\theta_o = 37°$ off the solid. Figure 1(b) shows the self-similar flow along with a transient computation close to rupture, showing excellent agreement.

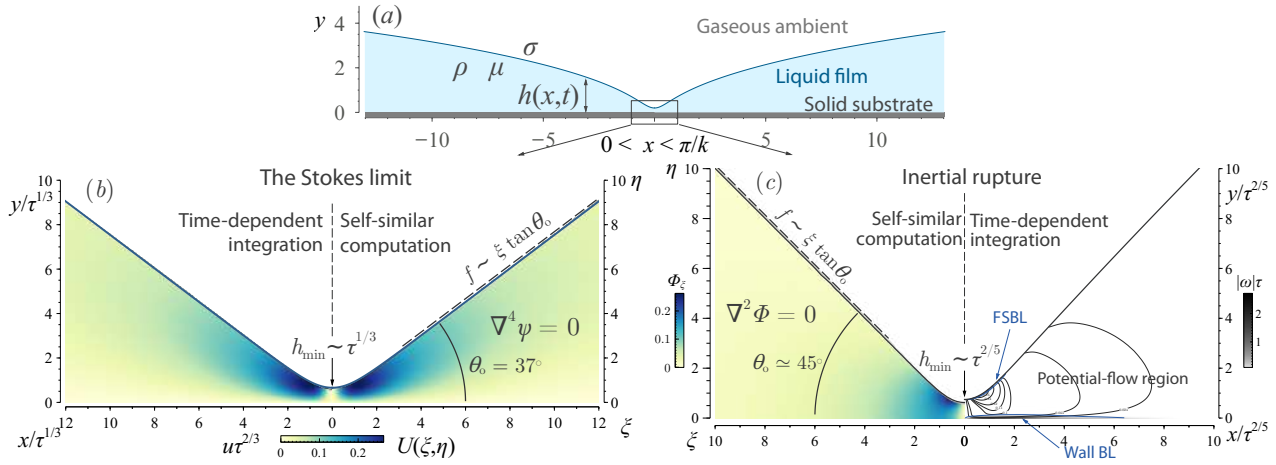

Figure 1: (a) Schematics of a planar thin film approaching the rupture singularity. (b) Stokes self-similar regime: isocontours of U obtained by solving the self-similar system (2), and by using the rescaled velocity $u\,\tau^{2/3}$ for $\log_{10}\tau = -4.62$, and $h_o/a = 4.34$, extracted from the simulation of (1). (c) Euler self-similar regime: filled isocontours of the self-similar potential velocity Φ_ξ and isocontours of the rescaled velocity $u\,\tau^{3/5} \in (0.024, \ldots, 0.16)$ and vorticity $|\omega|\tau$ obtained from the integration of (1) for $h_o/a = 4.34$ and $Oh = 0.188$, for $\log_{10}\tau = -4.62$.

FILM RUPTURE AT HIGH REYNOLDS NUMBERS: SELF-SIMILAR POTENTIAL FLOW

On introducing a, $[A/(6\pi\rho a^3)]^{1/2}$, $(6\pi\rho a^5/A)^{1/2}$, and $A/(6\pi a^3)$ as the relevant scales of length, velocity, time and pressure in Eqs.(1), the relative importance of viscous forces compared with liquid inertia is measured by the Ohnesorge number $Oh = \mu/\sqrt{\rho a\sigma}$ which, together with the dimensionless initial thickness h_o/a, completes the nondimensional description. Numerical integrations of the full Navier-Stokes equations up to very small minimum film thicknesses revealed a well-defined three-region structure (see Fig. 1c). Indeed, the flow displayed a core potential region of vanishing vorticity, surrounded by a pair of viscous boundary layers, one at the solid wall, and another one at the free surface. The minimum film thickness displayed the power law behaviour $h_{\min} \propto \tau^{2/5}$, as deduced from a local dominant balance between inertia and vdW forces described here for the first time. Along the lines of the Stokes analysis, the self-similar ansatz $x = \tau^{2/5}\xi$, $y = \tau^{2/5}\eta$, $h = \tau^{2/5}f(\xi)$, $u = \tau^{-3/5}U(\xi,\eta)$, $v = \tau^{-3/5}V(\xi,\eta)$, $p = \tau^{-6/5}P(\xi,\eta)$ is introduced in Eqs.(1). The leading-order is irrotational, indicating the validity of a potential description in the limit $\tau \to 0$ in terms of self-similar variables. In particular, introducing Φ such that $\Phi_\xi = U$ and $\Phi_\eta = V$, reduces the outer inviscid problem to $\Phi_{\xi\xi} + \Phi_{\eta\eta} = 0$, in $0 < \xi < \infty$, $0 < \eta < f(\xi)$, to be integrated with the boundary conditions

$$\frac{1}{f^3} + \frac{1}{5}\Phi + \frac{2}{5}\left(\xi\Phi_\xi + \eta\Phi_\eta\right) + \frac{1}{2}\left(\Phi_\xi^2 + \Phi_\eta^2\right) = 0, \quad \frac{2}{5}f + \Phi_\eta - f_\xi\left(\frac{2}{5}\xi + \Phi_\xi\right) = 0, \tag{3}$$

accounting for the normal-stress balance and the kinematic condition, respectively, along the unknown free surface $\eta = f$, together with the no-penetration condition $\boldsymbol{n}\cdot\nabla\Phi = 0$ everywhere else. The latter self-similar problem has a similar structure as that derived in [7] to describe the ejection of singular liquid jets from Faraday waves. The integration of this system provided the shape $f = f(\xi)$ of the free surface, with an associated wedge-shaped far-field behavior $f \sim \xi\tan\theta_o$, and an opening angle $\theta_o \simeq 45°$ off the solid. Fig. 1(c) shows the self-similar film shape along with a transient computation close to rupture, showing good agreement. The thicknesses of the wall and free-surface boundary layers were seen to decrease as $\delta_\mu \sim Oh^{1/2}\tau^{1/2}$ and $\delta_\sigma \sim \tau^{6/5}$ as $\tau \to 0$, as deduced by balancing the advective liquid inertia with the viscous forces and with the capillary forces, respectively.

HOW MANY WAYS A CELL CAN MOVE: THE MODES OF SELF-PROPULSION OF AN ACTIVE DROP

Aurore Loisy*[1,2], Jens Eggers[1], and Tanniemola B. Liverpool *[1]
[1]School of Mathematics, University of Bristol, Bristol, UK
[2]IRPHE (Aix-Marseille Université,CNRS,Ecole Centrale Marseille),Marseille,France

Summary Numerous physical models have been proposed to explain how cell motility emerges from internal activity, mostly focused on boundary-driven crawling motion. Here we take a more fundamental view and offer a classification of self-propulsion mechanisms based on general physical principles. We consider a thin drop of active liquid moving on a planar substrate and obtain, using both numerical simulation and asymptotic analysis, travelling-wave solutions to the lubrication equations. This allows us to fully characterize the three possible modes of autonomous motion of this active drop, thereby showing that crawling is not the only way to move. In particular, we find a new mode of self-propulsion which is driven in the bulk rather than at the boundaries, and which signature is the zero traction exerted everywhere on the substrate except near the contact line.

MOTIVATION

Eukaryotic cells have the ability to move autonomously in a variety of environments, and they do so by adapting their mode of migration to the geometrical and physical properties of their surroundings. A minimal system to study motility is provided by a deformable drop of material with anisotropic components that consume energy (active matter [1]) on a flat rigid surface [2, 3, 4]. Several studies have shown self-propulsion of active drops on a surface with a number of related models, e.g. [5, 6, 3, 4]. However the complexity of the underlying dynamics means that identifying similarities and differences between them is difficult. Besides, these studies are mostly focused on crawling, a mode of motion driven by active processes at the boundaries. In view of the complexity and diversity of cell motility, one may want to ask first: what are the physical requirements for autonomous motion, and what are the possible ways to move?

METHODS

Our model (Fig. 1a) is a 2D drop of active nematic liquid on a rigid substrate and confined by surface tension. The fluid motion inside the drop is governed by the incompressible Stokes flow equations. The stress tensor $\boldsymbol{\sigma} = -p\boldsymbol{I} + \eta[\boldsymbol{\nabla u} + (\boldsymbol{\nabla u})^T] + \boldsymbol{\sigma}^a$ (with η the viscosity) includes an active contribution $\boldsymbol{\sigma}^a = -\alpha \boldsymbol{nn}$ where α is the activity coefficient and where $\boldsymbol{n}$ is the director field (a headless unit vector which describes the coarse-grained orientation of the active units). The mechanical interaction with the substrate is modeled by a partial slip boundary condition (with ℓ_u the slip length) and a free surface boundary condition is applied at the interface (with γ the surface tension coefficient and κ the curvature).

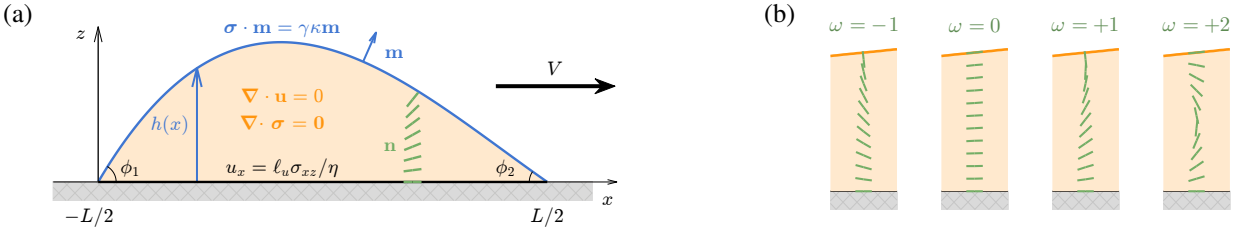

Figure 1: (a) our model is a 2D drop of active fluid moving on a rigid surface, (b) the winding number ω describes the topology of $\boldsymbol{n}$.

We further assume a drop geometry with a small height-to-width ratio and work in the framework of lubrication theory. Restricting to travelling-wave solutions, we can show that the problem reduces to a nonlinear third-order ordinary differential equation for the drop shape $h(x)$:

$$\frac{\gamma}{\eta}\left(\frac{h}{3}+\ell_u\right)hh''' + \frac{\alpha}{2\pi\omega\eta}h = V \qquad \text{if } \omega \neq 0, \tag{1a}$$

$$\frac{\gamma}{\eta}\left(\frac{h}{3}+\ell_u\right)hh''' - \frac{\alpha}{\eta}\left(\frac{h}{3}+\ell_u\right)h' + w_o\frac{\ell_w}{h}\left[1-\exp\left(-h/\ell_w\right)\right] = V \qquad \text{if } \omega = 0, \tag{1b}$$

which involves the drop velocity V as an unknown constant. Here ω is a winding number which counts the number of quarter turns of the director across the drop height (Fig. 1b). The additional term $\propto w_0$ in Eq. (1b) arises from the

*Corresponding author. E-mail: aurore.loisy@bristol.ac.uk
†Corresponding author. E-mail: t.liverpool@bristol.ac.uk

self-advection of active units at a characteristic speed w_0 in a layer close to the substrate of characteristic small thickness ℓ_w (see e.g. [3] for details), and models the effect of cytoskeletal filaments undergoing polymerization and treadmilling. This ODE is supplemented by four boundary conditions: $h(\pm L/2) = 0$, $h'(-L/2) = \phi_1$, $h'(+L/2) = -\phi_2$ where $\phi_{1,2}$ are the contact angles on each side of the drop, and the drop width L is determined from a volume constraint.

RESULTS

Three possible driving sources are embedded in Eq. (1): active stresses ($\propto \alpha$), active self-advection ($\propto w_0$), and a capillary force due to different contact angles [$F_{\text{capillary}} = \gamma(\cos\phi_2 - \cos\phi_1)$] as would result from e.g. an external or self-generated gradient of surface energy. Those give rise to three distinct modes of motion which are illustrated in Fig. 2.

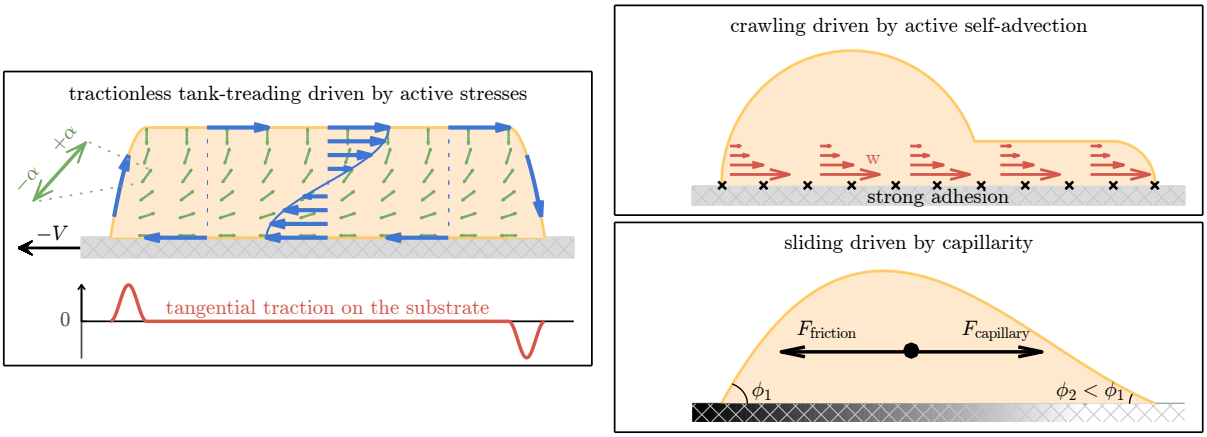

Figure 2: The modes of self-propulsion of a drop of active liquid on a substrate.

We determined travelling-wave solutions to the lubrication equations as a function of a dimensionless activity parameter for each mode of motion. Numerical simulations are used to characterize the drop motion over a wide range of activity magnitudes, and explicit analytical solutions in excellent agreement with the simulations are derived in the weak-activity regime. The main features of each mode of self-propulsion can be summarized as follows.

In self-propulsion driven by active stresses, motion arises from the internal net flow (blue arrows, here drawn in the drop frame of reference) generated by active stresses. The motion direction and speed are controlled by the winding number ω. This mechanism does not require a shape asymmetry and is efficient even in the presence of slip. Remarkably, motion can be achieved without exerting any traction anywhere on the substrate except near the contact line, giving rise to "tractionless tank treading" (see our recent communication [7]). This new mode of motion, driven in the bulk rather than at the boundaries, is particularly suited for moving rapidly through tiny pores, and therefore provides a robust physical mechanism for efficient cell migration in tissues.

In contrast, motion driven by the self-advection of polarized active units at the substrate, known as crawling, is characterized by a strong shape anisotropy and is most efficient in the absence of slip. Therefore this mode of self-propulsion is particularly suited for moving on 2D surfaces which provides strong anchoring points. A prominent example of crawling is mesenchymal migration, a mode of cell motility characterized by strong cell-substrate adhesions, with self-advection provided by actin polymerization in a leading edge protrusion.

In sliding driven by capillarity, the drop is pulled by a capillary force due to gradients. This third mode motion is, unlike the other two, not driven by active processes. Yet it can be coupled to internal activity to create droplets faster than their passive counterparts, thereby giving a new twist to this well-known mechanism.

MARANGONI SPREADING OF NON-NEWTONIAN FLUID ON BATH LEADING TO FINGER INSTABILITY

Xue Ma[1], Menglin Zhong[1], Zhanwei Liu, and Zhenzhen Li[*1]
[1]School of Aerospace Engineering, Beijing Institute of Technology, Beijing, China

Summary Marangoni spreading is involved in fields such as coating and drug delivery. We report finger instability occurs during Marangoni spreading of shear thinning and viscoelastic polymer solution on a deep bath. Temporal dependence of spreading diameter shows elastic dominated and viscous dominated regime. Finger formation is accompanied by thickness perturbation of liquid surface of the order of 5 μm, measured by Transmission Lattice method. We delineate a range of Capillary number and viscoelastic relaxation time, which leads to large and flat fingers. The finger number is a function of polymer concentration, and of molecular weight. This study suggests that thin film instability may occur on bath surface with presence of Non-Newtonian fluids. It indicates conditions for homogenous coating, and shows transient behavior during delivery of Non-Newtonian drugs.

EXPERIMENTAL DESCRIPTION AND OBSERVATION

A drop of PEO solution at 5MDa molecular weight with Non-ionic surfactant is deposited on a bath of polymer solution without surfactant, the bath solution is 8 mm deep, in a square container made of Plexiglas with length and width 20 mm. The drop falls from 4 mm above the bath surface, injected by a syringe pump. Reflection and transmission optical methods are used for observation on the free liquid surface, which is illuminated by a Xenon light. Capillary waves propagates outwards firstly, followed by the Marangoni ridge presented by the dark large band, drop contact line falls behind the Marangoni ridge, with fingering instability developed (Figure 1). The fingers are slightly higher than the bath in its vicinity. For comparison, Marangoni spreading of Newtonian fluid does not show finger instability.

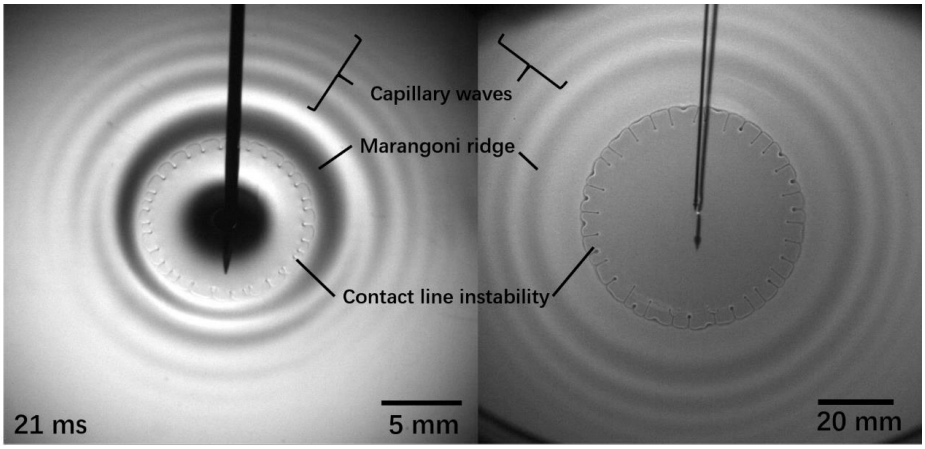

Figure 1: Fingering instability observed with light transmission (left) and reflection (right).

The height perturbation at the position of fingers is determined by Transmission Lattice method [1]. A transparent sheet with black grids is placed under the transparent container, and the LED light for illuminating is under the sheet. Grids frequency on the sheet is 10 lines per mm. Observing the grids above the deformed liquid surface, The grid pattern is distorted by the modulation of the liquid surface topography. Horizontal displacement of the grids pattern caused by liquid surface perturbation is analyzed by sampling Moiré method combined with the phase-shift technique. The propagation of Marangoni ridge [2] is captured during time, with height perturbation at the position of finger tips, which is measured at the order of 5 μm (Figure 2). This indicates that the finger instability is associated with elevation of free liquid surface, which may be caused by viscoelastic property of Non-Newtonian fluid under strong shear [3].

The spreading diameter increases with time. Considering the shear thinning effect of the polymer solution, the shear rate $\dot{\gamma}$ of the free surface flow can be calculated from the equation: $\dot{\gamma}(t)^2 \cdot \left(\eta_\infty + \frac{\eta_0 - \eta_\infty}{1+(k\dot{\gamma}(t))^p}\right) = \frac{\rho \cdot v(t)^2}{t}$, so that to deduce the temporal variation of viscosity. A balance between Marangoni stress and viscous stress gives prediction of spreading diameter $D(t) \sim t^{3/4}$. Figure 3a shows collapsed curves of $D(t) \cdot \eta^{1/4}$, proving the viscosity dominated regime after the time of 10 ms. The spreading is dominated by elasticity before 10 ms. The temporal evolution of finger number is a function of polymer concentration at a fixed molecular weight, and also a function of molecular weight. Figure 3b shows finger number, which is higher for low concentration at a fixed time. This may be due to high spreading velocity for low concentration solution, which has lower viscosity. The average finger width do not change remarkably with solution concentration.

Circles on each curve represent x position of finger tips. **Right,** Bath thickness variation $h - h_\infty$ along finger tips on the contact line, for different time steps. Finger height δh above the surrounding bath is the order of 5 μm for the first 37 ms of spreading.

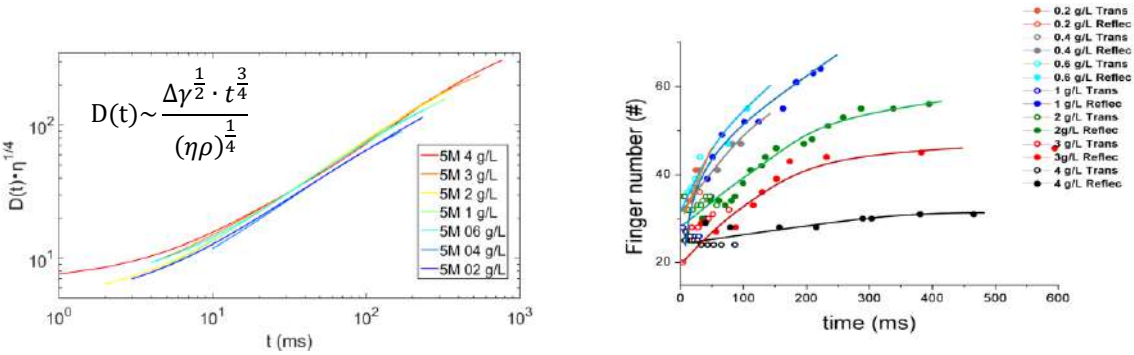

Figure 3: Temporal evolution of spreading diameter (left) and finger number (right).

DISCUSSION

Finger instability is observed under strong shear, caused by Marangoni flow of Non-Newtonian fluid on a free liquid surface of a bath. The elevation of free surface height at the position of finger tips may be caused by normal stress difference at high shear rate. This is consistent with the fact that the height elevation is more pronounced for high concentration of polymer, and for large molecular weight. We think that the elevation of surface height is associated with finger number development, noting that previous studies on thin film instability showed that thicker films produce larger fingers, so that smaller finger number [4]. We also note that the structure of the fingers is reminiscent of crease formation of elastic materials such as hydrogels. An elastic material under compression, which causes accumulation of elastic energy, creases are formed to relieve the elastic energy [5]. In our work, the in-plane strong shear may cause tangential compression in the spreading drop, the first 10 ms second is dominated by elastic response, and energy may be relieved by crease-like finger development.

CONCLUSIONS

Marangoni spreading of viscoelastic and shear thinning polymer solution on a free surface of a bath is studied experimentally. The spreading procedure is elastic dominated at the beginning and viscous dominated later on. The development of fingers is related with the polymer property, which exhibits non-linear effect under strong shear. The origin of the finger development may be thin film finger instability, and/or crease formation to relieve elastic energy. More study on the mechanism of finger formation is needed in the future. This work may provide support on coating technology and lung drug delivery, where Marangoni flow of Non-Newtonian fluid on free surface is important.

INSTABILITY OF A THIN FILM FLOWING UNDER AN INCLINED PLANE

Pier Giuseppe Ledda*[1], Gaétan Lerisson[1], Gioele Balestra[1], and François Gallaire[1]
[1]Laboratory of Fluid Mechanics and Instabilities, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Summary We study the pattern formation of a thin film of viscous fluid flowing under an inclined plane, in the context of the Rayleigh-Taylor instability. We compare the experimental measurements with numerical simulations and theoretical findings. A steady pattern characterized by structures aligned with the flow arises, so-called rivulets, which saturate after some distance from the inlet. The profile is described using a one-dimensional model that well agrees with a two-dimensional pendant drop shape. The impulse response shows a selection of rivulets even in absence of boundary effects, rationalized using a weakly non-linear approach. The stability of the saturated rivulet profile to streamwise perturbations reveals the presence of an unstable mode characterized by lenses which travel on rivulets.

INTRODUCTION

When a heavier fluid is placed above a lighter fluid, a horizontal flat interface is linearly unstable even in absence of inertial effects and the Rayleigh-Taylor instability occurs[1, 2]. The presence of surface tension stabilizes small wavelengths, while large wavelengths remain unstable. When an upper wall confines the overhanging fluid, the problem can be tackled using the lubrication approximation [3], i.e. the wavelength of the perturbations is much larger than the thickness of the liquid. As a result of the instability, regular patterns of growing lenses are observed [4]. When the substrate is inclined, a complete description of the steps that lead from a flat substrate to dripping drops remains to be analyzed.

Experimental apparatus

A very viscous Newtonian fluid is injected under an inclined glass plate (see fig.1a), with a constant flow rate. The angle with respect to the vertical θ can be varied thanks to an orientable structure. Variations of the flow rate are obtained by the height difference between a closed reservoir connected to the injector slit and an open reservoir continuously overflowing. We can impose a steady spanwise modulated boundary conditions at the inlet using sinusoidal-shaped and comb-like blades. The film thickness is measured using a confocal chromatic sensor located on the upper part of the plate.

STEADY PATTERNS

The rivulet profile

When steady boundary conditions are considered, structures aligned with the streamwise direction (rivulets) dominate the flow. Moreover, for a certain range of flow rate and inclination angle, experiments show that rivulets saturate in the streamwise direction after some distance from the inlet (see fig1b). The experimental measurements of the film thickness are compared with non-linear numerical simulations of the two-dimensional lubrication equation accounting for the experimental boundary conditions, with an overall good agreement. At each cross section, the thickness profile is periodic in the spanwise direction. We develop a one-dimensional model, with periodic boundary conditions, in which

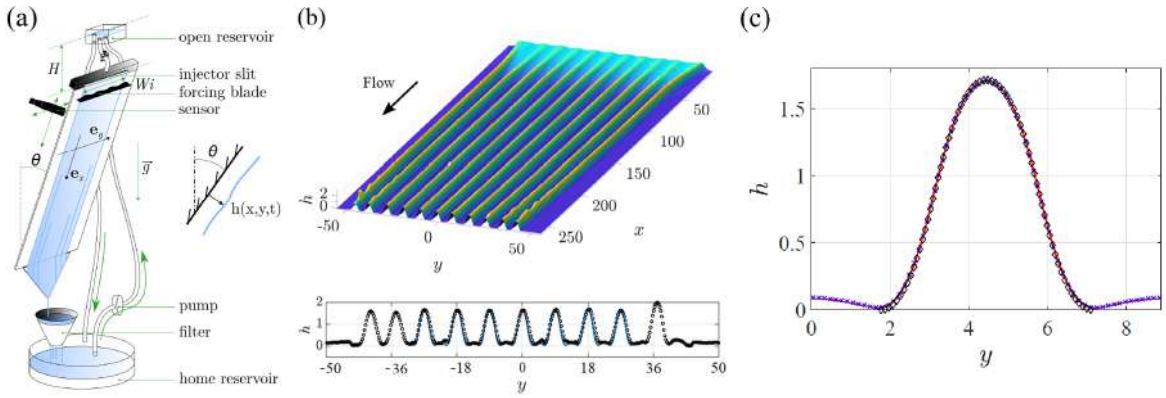

Figure 1: (a) Sketch of the configuration and the experimental apparatus. (b) On the top: typical experimentally measured thickness. On the bottom: comparison between the numerical simulations (blue line) and the experimental measurements (dots) for the saturated rivulets. (c) Comparison of the rivulet profile obtained from the one-dimensional model (red line), the pendant drop shape (black diamonds) and the two-dimensional Stokes simulations with free interface (blue crosses).

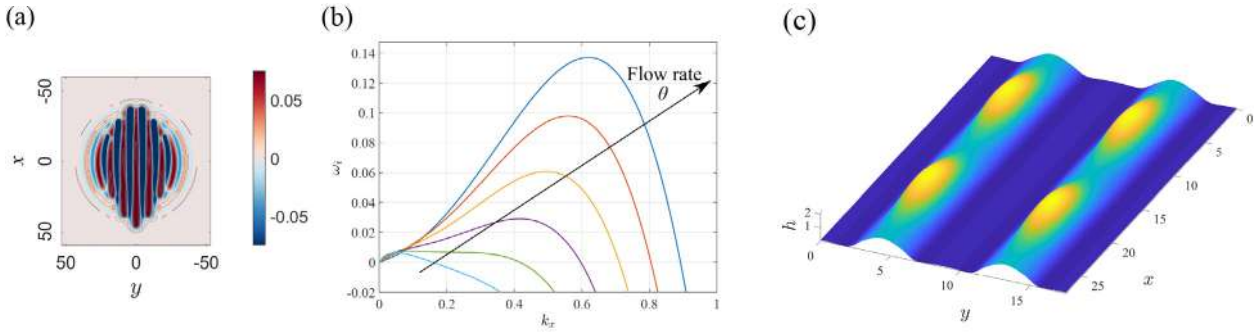

Figure 2: (a) Thickness perturbation iso-contours of the impulse response at long times from the weakly non linear model. (b) Dispersion relations from the rivulet stability analysis. (c) Linear combination of the rivulet profile and its unstable mode from the stability analysis.

the correct flow rate in the direction normal to the rivulet profile is ensured using a Lagrange multiplier. Results show the presence of a region of high thickness (central lobe) which slowly saturates to a constant shape, while the side lobes slowly drain with a power law $h \propto t^{-1/2}$. We thus study the shape of the central lobe imposing the pure static equilibrium between surface tension and hydrostatic pressure, i.e. we consider a two-dimensional static pendant drop. Total wetting conditions are considered, i.e. zero contact angle at the wall where the curvature is set to ensure the correct flow rate in the direction normal to the cross section. The results well agree with the one-dimensional lubrication model and a Stokes simulation with free surface (see fig.1c).

PATTERN SELECTION

Flat film impulse response

Afterwards, we focus on the temporal evolution which leads to a rivulet pattern. We consider the response of the flat film to a perturbation localized in space and time, in absence of boundary effects. While the linearized dynamics of the perturbation η exhibits an isotropic growth of the perturbation, a weakly non-linear model analogous to the Nepomnyashchy equation [3] features the selection of streamwise structures (see fig.2a). The two stages of the temporal evolution, i.e. the linearized isotropic linear growth and the weakly non-linear dynamics, are observed also in the fully non-linear simulations. The flow experiences a natural selection of streamwise structures resulting from the weakly non-linear dynamics, also in absence of boundary effects.

Saturated rivulets stability analysis

We study the survival of the saturated rivulet structures in the context of linear stability analysis. Starting from the rivulet profile $H(y)$ obtained from the one-dimensional model, we consider its stability to perturbations when the profile is perturbed in the streamwise direction with a perturbation of the form $\eta(x, y, t) = \hat{\eta}(y) \exp(k_x x - \omega t)$. In fig.2b we report the growth rate ω_i as a function of the streamwise wavenumber k_x. When lower values of the flow rate and θ are considered, short wavelengths are progressively stabilized until only very large wavelengths are weakly unstable. The unstable mode is characterized by lenses that form on the rivulets and travel on them (fig.2c), in agreement with the experimental observations.

CONCLUSIONS

We built a novel experiment for the flow of a thin film under an inclined plane, analyzing the arising patterns. We compared the experimental measurements with theoretical and numerical results. In the route to dripping, the flat film first destabilizes into a pattern characterized by saturated rivulets. This selection is intrinsic and related to a weakly non-linear mechanism. Subsequently, a secondary instability occurs on rivulets. As the flow rate and θ are decreased the rivulets are progressively stabilized and only very large wavelengths remain weakly unstable. As a result of the instability, rivulets that carry lenses are observed. In a last step, these lenses may eventually drip from the inclined ceiling.

Summary A new model is presented for soft blade coating of Newtonian fluids in the case of a finite reservoir of liquid. In comparison with previous studies, we show here that a new variable, the wetting length (which quantifies the amount of liquid remaining under the blade), is essential to explain the dynamics of the spreading of Newtonian fluids. Its impact on the thickness of the fluid layer is demonstrated through experiments, simulations and a scaling law model.

INTRODUCTION

The spreading of fluids is a crucial industrial process, for example in the cosmetic field, food industry and construction industry. While most of the spread liquids are non-Newtonian, the parameters that govern the deposit in usual configurations are not well understood, even in the case of simple Newtonian fluids. A better understanding of the spreading dynamics is needed to tackle common issues such as formation of inhomogeneous film or defects.

This subject is of great interest for the cosmetic field which uses complex fluids (i.e. polymers, emulsions, suspensions) for moisturizers or gels. It is a challenge to mimic by a mechanical system the gesture followed by the consumers. A promising technique is blade coating with a soft and deformable blade that compares better to real applications (Figure 1). A pioneering study was first conducted by Seiwert *et al.* [1], who studied the spreading of Newtonian fluids experimentally and theoretically, with an infinite reservoir of liquid. In their model they use an analogy with the dip-coating process by introducing a key parameter, the dynamic length, which corresponds to the length of the blade deformed by the fluid. More recent studies, carried out in our group on complex fluids [2], reveal that another parameter should be considered, which is the *wetting length* l_w, defined as the length of contact between the soft blade and the fluid measured along the spreading movement x, as shown in Figure 1. Our work shows that the wetting length is essential to explain the dynamics of the spreading of Newtonian fluids, and its impact on the thickness of the fluid layer is demonstrated.

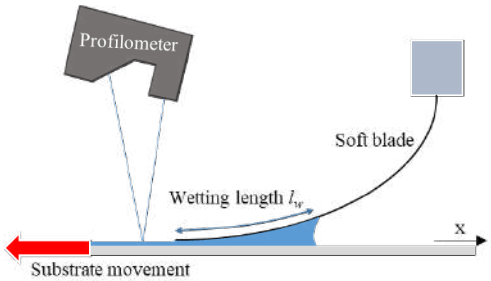

Figure 1. Schematic representation of the soft blade coating experiment.

MATERIALS AND METHODS

The liquids considered here are silicone oils, with viscosity η ranging between 500 and 1000 cSt. They are spread on a PMMA plate using a soft blade made from flexible mylar, with a thickness u =125 µm or 250 µm, cut to a length L of typically 6 cm, with a constant width b = 4cm. The blade is held at a specific height so that its end is just tangent to the surface [1]. A known mass of liquid is deposited under the blade and then spread with a one-way movement, by moving the substrate at a constant speed V (2.5 to 10 mm/s). The changes in the wetting length during spreading are followed from the side and from the top using two optical cameras (at typically 10 frames per second). Finally, the thickness of the liquid layer is measured, using an optical profilometer, at a distance of 2 mm from the end of the blade. Such experimental conditions aimed at correlating the thickness of the film e to the wetting length of the blade l_w. Accordingly, e and l_w are simultaneously recorded during the spreading as a function of the time and treated quasistatically.

RESULTS

Figure 2a shows a typical profile of a liquid film *e(t)* (here silicone oil with viscosity 480 mPa.s), measured parallel to the spreading direction. Two plots are presented: the raw data directly extracted from the profilometer, which exhibits noise due to additionnal reflections, and a filtered curve that was used in the measurements. The film profile exhibits a transitory state in the first 7.5 s, where the thickness increases from 0 to 230 µm, followed by a slow and continuous reduction (from 230 to 15 µm in the last 12.5 s of the spreading experiment). On Figure 2b the corresponding wetting length l_w is presented. It decreases from 22.5 mm to nearly 0 mm while the fluid reservoir is emptied.

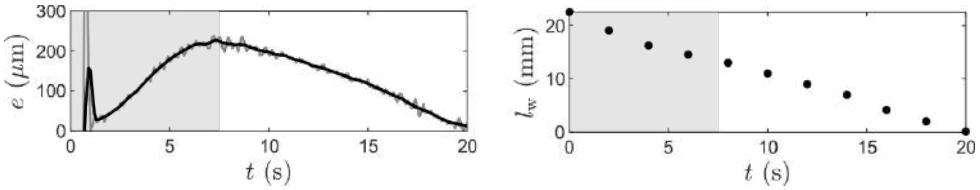

Figure 2. (*a*) Profile of fluid thickness *e* as a function of time *t* for a Newtonian fluid (silicone oil 480 mPa.s, V = 5 mm/s, L = 5.6 cm, u = 125 µm) raw (grey line) and filtered data (black line). (*b*) Evolution of l_w with time for the same experiment

These experiments thus show a clear dependency between the film thickness and the wetting length after a transitory region (in gray) corresponding to the setting in motion of the liquid. This is showed in Figure 3 for two different viscosities. The relation between *e* and l_w is quadratic. To understand how the reservoir size influences the spreading dynamics a full numerical integration of the blade and liquid dynamics was performed by finite difference. The results, obtained with no adjustable parameters, are in good agreement with the experiment (dashed lines).

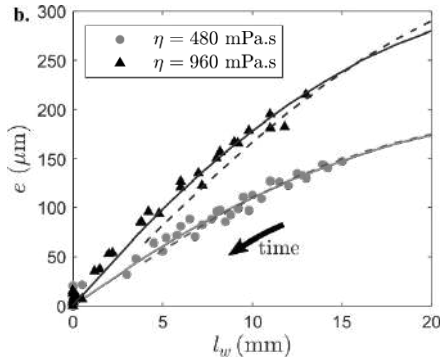

Figure 3. Evolution of the fluid thickness with the wetting length for two different oils with viscosity 480 mPa.s and 960 mPa.s, experiment (markers), simulation (dashed line) and model (line). V = 5 mm/s, u = 125 µm and L = 5.7cm.

The lines represents our model with prefactors 0.15 (for η = 480 mPas) and 0.17 (for η = 960 mPas) corresponding to the best fits (equation 1). To obtain this law, we consider at equilibrium the balance between the torque induced by the lubricating pressure within the film, and the resisting torque coming from blade elasticity (Euler-Bernoulli beam theory) which gives:

$$e \sim l_w \sqrt{\frac{\eta V L^2 b}{EI}} \left(1 - \frac{l_w}{L}\right) \quad (1)$$

where V is the spreading velocity, L the blade length, b the blade width, E the young modulus including the Poisson coefficient correction, and I a geometric factor. By varying also L, V and I we showed a good agreement between the thickness given by the model and the experiments over a wide range of data.

CONCLUSIONS

The present work shows that spreading with a blade cannot be directly compared with the "meniscus" spreading performed in Landau-Levich situations [1]. In particular, the analogy cannot be made when there is a finite reservoir of fluid, for which the distinction between static and dynamic regions is no longer relevant. A new parameter, the wetting length l_w, fully describes the system. Our effort is now focused on expanding the model to shear thinning and yield stress fluids such as carbopol based systems.

SOAP FILM DEFORMATIONS: TOWARD A LOCAL RHEOLOGICAL MODEL FOR FOAMS

Adrien Bussonnière[1] and Isabelle Cantat*[1]
[1]Univ Rennes, CNRS, IPR (Institut de Physique de Rennes) - UMR 6251, F- 35000 Rennes.

Summary The highly confined flow of the liquid phase, trapped between the gas bubbles, is at the origin of the large effective viscosity of the liquid foams. Despite the industrial relevance of this complex fluid, the foam viscosity remains difficult to predict, because of the lack of flow characterization at the bubble scale. Using an original deformable frame, we provide an exhaustive characterization of the dynamical behavior of connected soap films, by measuring the film thickness map, the velocity map and the film tensions during and after the imposed deformation. Two important results are obtained: (i) we show that, for our foaming solution based on SDS and dodecanol, the film tension depends on its extension only and, surprisingly, not on its extension rate. (ii) we provide the first experimental evidence of the interface transfer between a compressed film (resp. a stretched film) and its first neighbor, across their common meniscus, and show that the energy dissipated during the whole deformation is dominated by the viscous dissipation induced by this transfer. We finally discuss the way we could built, on the basis of these two results, a model of foam visco-elasticity consistent with surfactant transport and hydrodynamics laws.

EXPERIMENTAL SET-UP

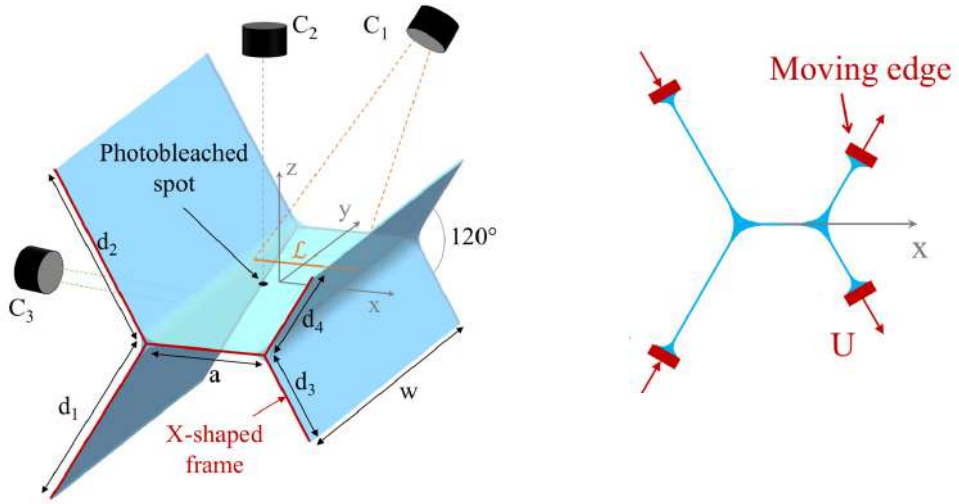

Figure 1: Sketch of the deformable frame on which five soap films, connected along two free menisci, are suspended, and of the position of the different cameras. As shown in the (x, z) plane view on the right, the left films are compressed and the right films are stretched due to the motion of the four moving edges (represented by the red arrows). This leads to a translation of the central film to towards the right meniscus.

The set-up is a deformable frame shown in Fig. 1, on which five flat, rectangular, soap films are produced. The film widths (in y direction) are all $w = 41.5$mm, whereas the length is $a = 6$mm for the central film and a variable length d_i, controlled by four independant piezo-motors, for the lateral films [1]. The foaming solution is made of SDS (2.5 cmc), dodecanol (0.05 g/L), glycerol (15 % in volume) and fluorescein (0.8 g/L). The studied deformation is a compression, during a time τ and at velocity U, for the two films on the left, synchronized with the symmetrical extension on the right. The film thicknesses are measured by an interferometric technique, using a spectral camera recording the reflected light spectrum along the line $\mathcal{L}$ in the (x, z) plane; the velocity field in the same plane is obtained from the motion of a photobleached spot [2] ; and the tension difference between adjacent films is deduced from the meniscus motion [3, 4, 5].

RESULTS

A first observation is that the film extension on the right side is followed by the extraction from the right meniscus of some new film, hereafter called the Frankel's film. This Frankel's film is much thicker than the film initially present (hereafter the initial film) and a sharp frontier between both parts of the film is stable during several seconds, so that the extension of both parts can be easily measured. In the compressed side, we observe a film volume decrease, which indicates that some film has been absorbed by the left meniscus. This absorption / extraction is coupled to an surfactant exchange between the lateral film and the meniscus, and ultimately, between the lateral films and the central film. This transfer induces, in the central film, the extraction of a Frankel's film on the left side and the absorption of the initial film by the meniscus on the right side. The whole central film translate at the velocity U_c. This clearly appears on the film thickness profiles in Fig. 2.

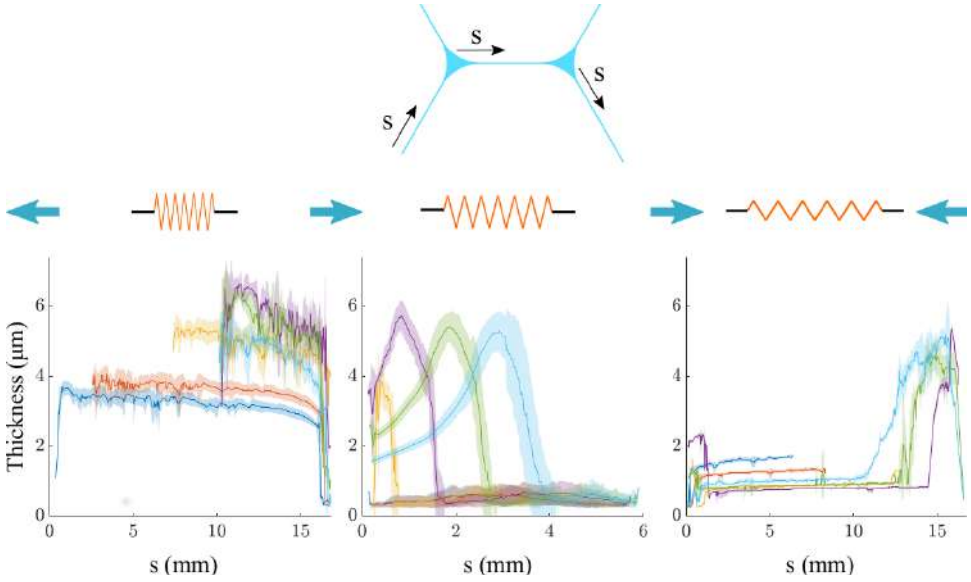

Figure 2: From left to right, film thickness profiles in the bottom left film, central film and bottom right film, at times 0 (blue), 0.04 (red), 0.275 (yellow), 0.475 (purple), 0.776 (green) and 1.25 s (cyan), as a function of the curvilinear abscissa defined above. The films have the mechanical role of elastic springs (represented in red), which tension can relax by transferring some interface to the next film, across their common meniscus (symbolized by the blue arrows). The transfer velocity U_c is ruled by the tension differences by the two films involved, and the meniscus therefore plays the mechanical role of a viscous dashpot.

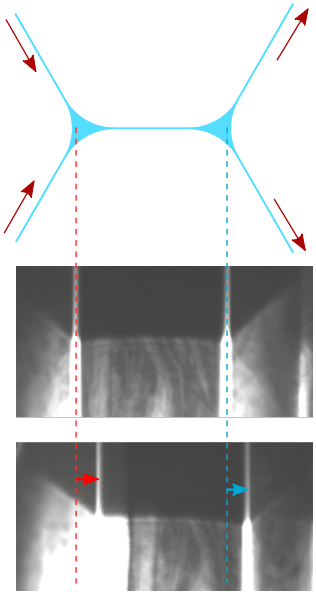

Figure 3: Top view of the experiment showing the small displacement of the free menisci, due to a variation of film tension.

The film tension are uniform on each films [3] and their values σ^-, σ_c and σ^+, respectively in the left, central and right films, can be deduced from the menisci motion shown in Fig. 3. Similarly, the extension ε and extension rate $\dot{\varepsilon}$ are uniform in each film. Importantly, note that, because of the exchanges with the menisci, these quantities are not related to the actual film sizes imposed by the motor motion. They can instead be deduced from the thickness map: if a piece of film is stretched, its thickness decreases, due to the liquid phase incompressibility. A key result we obtained is a master curve representing the film tension σ as a function of its extension ε, with a nice superposition of the all data, whatever the extension rate, in the range $\dot{\varepsilon} \in [1 - 10]\ \mathrm{s}^{-1}$. This shows that, in our parameter range, the intrinsic viscosity of the films is negligible in the apparent viscosity of the whole structure [6]. In contrast, the surface tension difference between the central and lateral films depends on the transfer velocity U_c from one film to its neighbor, which thus appears as a viscous process.

CONCLUSION

Our experiments allowed us to conclude that the thin film are elastic elements in the structure, and that the viscosity arises from the interface transfer from one film to its first neighbour, across the menisci. We propose a model for this viscous contribution, showing that the dissipation is dominated by the shear of a small part of the thin films, located close to the meniscus, as first qualitatively proposed in [7].

Summary A solid, withdrawn from a liquid bath, entrains a thin liquid film. This simple process, first discussed by Landau, Levich and Derjaguin (LLD), is observed in everyday's life and is widely used in industry. However, the liquid flux entrained can be altered by various properties of the withdrawn solid. Here, we develop a model that accounts for the additional presence of a soft solid layer atop the rigid plate. For simplicity, a Winkler's foundation is assumed as an elastic response. A new power-law regime is found for the thickness of liquid entrained $h_\infty \sim \sqrt{\ell_{ec}\ell_{cap}}\,\mathrm{Ca}^{1/2}$ (where Ca denotes the capillary number, ℓ_{cap} the capillary length and ℓ_{ec} an elastocapillary length) at small Ca. At large Ca, the classical LLD scaling law $h_\infty \sim \ell_{cap}\,\mathrm{Ca}^{2/3}$ is recovered. The crossover between the two regimes occurs when the substrate's deformation is comparable to the thickness of the entrained film.

INTRODUCTION

The motion of a liquid meniscus on a wet solid occurs in a wide variety of situations, such as the motion of a confined bubble flowing within a microfluidic channel, or the spreading of a droplet on a substrate [1]. The dip-coating experiment is the canonical example of such phenomena and has important applications in industry [2]. In nature, some animals like humming birds, bees or ants dip their tongue inside liquids to drink, which is argued to be more efficient for viscous liquids (such as nectars [3]) than other drinking processes.

In the last decade, a lot of attention has been devoted to the mechanics of very soft gels (shear modulus $\sim$ kPa), which unveil *e.g.* rich wetting properties as capillary forces can deform such materials over observable microscopic length scales [4, 5]. Nevertheless, the influence of the softness of the wall on a dynamic meniscus is still unknown [2]. Here, we address this question and study theoretically the effect of the softness in the thickness of liquid entrained through a dip-coating process.

MODELING

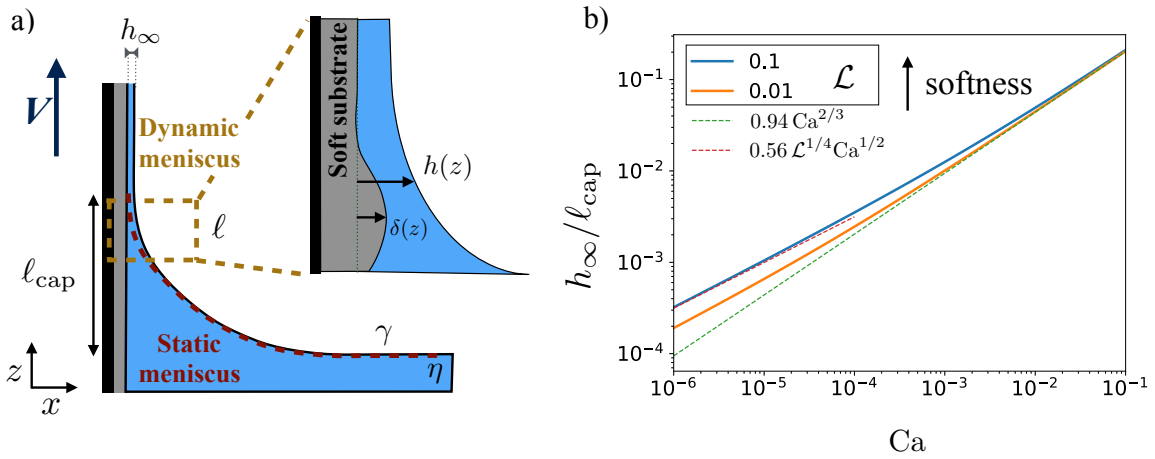

Figure 1: a) Schematic of the dip-coating situation. The inset exhibits a zoom in the dynamic meniscus zone where the flow is localized. The interface curvature imposes a negative Laplace pressure that deforms the soft substrate. b) Normalized entrained liquid thickness versus the capillary number for different values of the dimensionless softness parameter $\mathcal{L} = \rho g s_0/E$. The green dashed line represents the LLD scaling law $h_\infty = 0.94\,\ell_{cap}\,\mathrm{Ca}^{2/3}$, valid at large Ca. The red dashed line is an apparent scaling law $h_\infty \approx 0.56\,\sqrt{\ell_{cap}\ell_{ec}}\,\mathrm{Ca}^{1/2}$.

We consider a two-dimensional plate (see Fig. 1a), withdrawn with a velocity V from a liquid bath of viscosity η, density ρ and surface tension (with air) γ. We assume that the Weber ($\mathrm{We} = \rho V^2 \ell_{cap}/\gamma$, with $\ell_{cap} = \sqrt{\gamma/\rho g}$ the

*Corresponding author. E-mail: vincent.bertin@u-bordeaux.fr

capillary length) and capillary (Ca $= \eta V/\gamma$) numbers are small with respect to 1, so that we can neglect inertia and perform a LLD-like asymptotic matching [6]. Therefore, we describe the flow in the dynamic meniscus zone (see Fig. 1a) using the lubrication approximation. Gravitational drainage is neglected in this regime, and the governing equation for the interfacial profile $h(z)$ is given by the following thin-film equation:

$$\frac{\gamma\Big(h(z)-\delta(z)\Big)^3}{3\eta}h'''(z)+V\Big(h(z)-\delta(z)\Big)=Vh_\infty\,, \tag{1}$$

where the prime denotes the spatial derivative with respect to z, h_∞ is the thickness of the entrained liquid film, and $\delta(z)$ is the displacement field that denotes the normal deformation of the soft substrate induced by the Laplace pressure in the film.

As a minimal description, we use a Winkler's foundation which means that the substrate behaves as a mattress of independent springs – a situation relavant to thin compressible elastic materials. Thus, the displacement field is proportional to the local Laplace pressure, which amounts to $\delta(z) = \frac{s_0\gamma}{E}h''(z)$, where s_0 is a typical length (*e.g.* the length at rest of a spring) and E is an elastic modulus. The natural length scale $\sqrt{s_0\gamma/E} = \ell_{\text{ec}}$ appearing here is called the elastocapillary length. Therefore, a dimensionless softness parameter emerges from this model, as the ratio between elastocapillary and capillary lengths squared: $\mathcal{L} = (\ell_{\text{ec}}/\ell_{\text{cap}})^2 = \rho g s_0/E$.

Injecting the previous elastic law in Eq. 1, we find an ordinary differential equation that is solved here using a 4^{th}-order Runge-Kutta numerical scheme. The entrained liquid thickness h_∞ is found using a shooting algorithm that ensures the curvature matching condition $\lim_{z\to-\infty} h''(z) = \sqrt{2}/\ell_{\text{cap}}$ [6]. We plot in Fig. 1 the resulting entrained liquid thickness versus the capillary number, for two different softness parameters. Two scaling distinct regimes are observed: at large Ca, we recover the LLD scaling law $h_\infty = 0.94\,\ell_{\text{cap}}\,\text{Ca}^{2/3}$, and at small Ca, more fluid is entrained and we find a novel empirical scaling regime $h_\infty = 0.56\sqrt{\ell_{\text{cap}}\ell_{\text{ec}}}\,\text{Ca}^{1/2}$. From the observation of the typical liquid-thickness and displacement fields (not shown here), we observe that the crossover between the two scaling regimes happens when the typical deformation of the substrate is larger than the thickness of the entrained liquid film. Therefore, at small velocity, the wall softness enhances the dip-coating efficiency with respect to the classical LLD scenario.

In future work, the details and potential self-similar properties of this so-called soft-LLD regime will be investigated, as well as other elastic models for the substrate's response.

THE DEPENDENCE OF THE SURFACE TENSION AND CONTACT ANGLE ON THE TEMPERATURE, AS DESCRIBED BY THE DIFFUSE-INTERFACE MODEL

Eugene Benilov*[1]
[1]Department of Mathematics and Statistics, University of Limerick, Limerick, Ireland

Summary Two sets of results are reported in this paper. *First*, asymptotic estimates are used to check two conjectures included in the diffuse-interface model for contact lines: that the boundary condition for a fluid bounded by a solid wall should prescribe the fluid's density (which is indeed true) and that liquid–vapor interfaces are nearly isothermal (which is not true for, say, water, but can be true for a more viscous fluid). The non-isothermaility occurs at a microscopic scale, but can still affect the dynamics of contact lines. *Second*, the diffuse-interface model is coupled to a realistic equation of state for water and used to calculate the surface tension and contact angle of a static liquid–vapor interface, as functions of the temperature. The former result agrees quantitatively with the experimental data, but no data are available to verify the latter, so only theoretical predictions are reported. It is shown that, with increasing temperature, the contact angle becomes either 180° (perfect hydrophobicity) or 0° (perfect hydrophilicity); the former occurs when the boundary-presribed density ρ_0 matches that of saturated vapor and the latter, when ρ_0 matches the liquid density. Such behavior presumably occurs in all fluids, not just water, and for any sufficiently strong variation of parameters, not just that of the temperature. This conclusion is supported by existing observations of drops under variable electric field.

DESCRIPTION OF THE PROBLEM

The diffuse-interface model (e.g., [1]) is based on an assumption that the van der Waals force in fluids can be described by a pair-wise potential exerted by the molecules on each other. If the potential's spatial scale is much shorter than that of the flow, the force term in the governing equations can be simplified, yielding the so-called Korteweg stress. The resulting model provides a tool for studying flows involving contact lines, i.e., curves where the gas, liquid, and solid are in simultaneous contact. To this end, one also needs a boundary condition for fluid–solid interfaces, of which several versions exist in the literature. Firstly, Ref. [2] suggested a condition prescribing the density gradient in the direction normal to the solid boundary; secondly, Ref. [1] put forward a condition prescribing a linear combination of the density gradient and the density itself. It was also conjectured in Ref. [1] that, if the solid–fluid interaction is short-ranged by comparison with the fluid–fluid one, the general boundary condition can be simplified, so that just the density is prescribed. This simplest boundary condition is usually employed in applications.

Curiously, the diffuse-interface model (DIM) has never been coupled with a realistic equation of state (EoS): the one typically used is inconsistent with the ideal-gas limit and does not involve temperature (the latter amounts to spatial isothermality). This EoS, however, allows one to find analytically the profile of the liquid–vapor interface, which comes handy when calculating the flow's macroscopic characteristics (the surface tension and contact angle). Still, the use of a non-realistic EoS renders the DIM somewhat phenomenological rather than physics-based.

A model close to, but still not fully, realistic was examined in Ref. [3], where the DIM was coupled with the van der Waals EoS. Interestingly, simulations carried out in this work showed that interfacial flows can be significantly non-isothermal.

THE RESULTS

The shortcomings of, and discrepancies associated with, the non-realistic equations of state incorporated in the existing versions of the DIM are resolved in the present work. The following results have been obtained:

1. It has been shown that the boundary condition prescribing the density value ρ_0 that the fluid should assume at a solid wall can be derived without assuming that the solid–fluid interaction is short-ranged by comparison with the fluid–fluid one (as conjectured in Ref. [1]). In other words, this boundary condition is based on the same physics as the DIM itself.

2. A parameter region has been identified, where interfacial flows without external heating are almost isothermal. It does *not* include water, where the heat production due to viscosity and compressibility of vapor near the interface is too strong.

   Non-isothermality is not observed in fluids whose van der Waals parameters are not too different from those of water, but the viscosity is considerably higher. The latter slows the flow down and, thus, reduces the heat production.

3. The DIM was coupled to a realistic EoS of water and used to compute the surface tension σ of a liquid/vapor interface as a function of the temperature T – see Fig. 1. The theoretical results agree well with the empiric dependence $\sigma(T)$ [4].

*Corresponding author. E-mail: Eugene.Benilov@ul.ie.

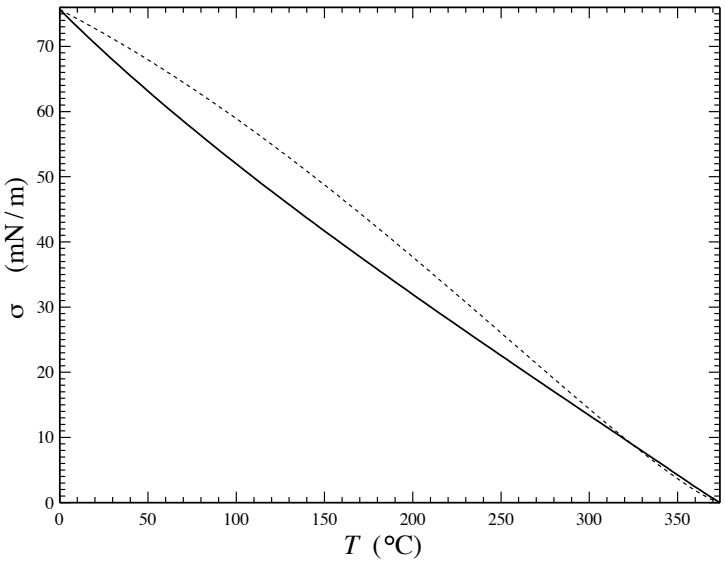

Figure 1: The surface tension σ of the interface between liquid water and its vapor vs. the temperature T. The temperature varies from water's triple-point value to its critical value. The solid curve shows the results computed through the DIM, the dotted curve shows the corresponding empiric results [4].

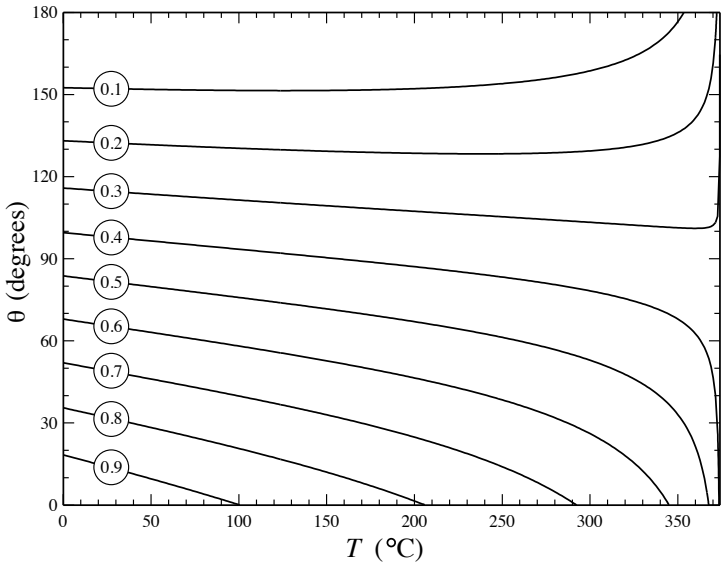

Figure 2: The static contact angle θ vs. the temperature T, for water. The curves are labelled with the corresponding values of ρ_0/ρ_{tp} where ρ_{tp} is the triple-point density of liquid water. The separatrix (dashed line) corresponds to ρ_0 coinciding with the critical density of water.

4. We have also computed the static contact angle θ of a liquid–vapor interface as a function of T for water – see Fig. 2. The results obtained predict that, with increasing T, any substrate would become either perfectly hydrophobic ($\theta = 180°$) or perfectly hydrophilic ($\theta = 0°$): the former occurs at a temperature for which the saturated-vapor density equals ρ_0, and the latter occurs when the liquid density does. It can be argued that states with $\theta = 180°$ or $\theta = 0°$ can be created through *any* parameter variation, not only that of the temperature. To do so, this variation should change either ρ_0 or the densities of the phases – until the former coincides with one of the latter. This argument could explain the observed behavior of droplets under variable electric field [5].

RIVULET STRUCTURE IN A HEATED LIQUID FILM DUE TO THERMOCAPILLARITY

Sergey Aktershev[1], Sergey Alekseenko[1]
[1]Kutateladze Institute of Thermophysics, Novosibirsk, Russia

Summary The formation of a 3D rivulet structure in a heated falling liquid film is investigated theoretically. Within the framework of the spatial approach, a linear analysis of the stability of the heated film flow relative to spanwise perturbations is performed for the first time, and the dispersion dependences are obtained. A numerical method is used to study the nonlinear development of instability. It is shown that a small spanwise perturbation evolves into the time-independent developed 3D rivulet structure.

THEORETICAL MODEL AND RESULTS OF CALCULATIONS

Non-isothermal liquid films are the basis of many technological processes. Theoretical researches of the waves in a heated film are based, usually, on the long-wave approximation, but two different approaches are used. In the first one, based on the lubricant approximation, one equation is derived for film thickness evolution, such as the Benney equation [1], but taking into account the tangential stress on the film surface due to the thermocapillarity. Models using this approach are applicable only for small Reynolds numbers. According to another approach, the Reynolds number is not assumed to be small, and the evolution of the heated liquid film is described by a system of equations for the film thickness, flow rate and temperature. Theoretical models [2-4], based on second approach, have a significantly wider range of applicability on Reynolds number since they are directly deduced from the Navier-Stokes equations with the help of some suppositions concerning the velocity and temperature profiles. Using the second approach, we investigate the occurrence of 3D rivulets in a locally heated liquid film. The results of calculations for small and moderate Reynolds numbers are compared with experimental data. We consider 3D liquid film flow on a locally heated vertical wall. The liquid film is in contact with a fixed gas, and the heat exchange on the interface is described by means of a given heat transfer coefficient α. All properties of a liquid are considered to be constant, with the exception of surface tension, which is linearly dependent on temperature: $\sigma = \sigma_0 - \gamma(T - T_0)$. It is assumed that the perturbations in the film are long-wave (i.e. film thickness h is much smaller than the characteristic size of the rivulet structure L). The system of equations derived in [5] for the film thickness $h(x,z,t)$, flow rates $q(x,z,t)$ and $m(x,z,t)$ takes the following form in dimensionless variables:

$$\frac{\partial q}{\partial t} + \frac{\partial J_1}{\partial x} + \frac{\partial J_{1,2}}{\partial z} = \frac{3}{\mathrm{Re}}\left(h - \frac{\mathrm{Ma}}{2}\frac{\partial T_s}{\partial x} - \frac{q}{h^2}\right) + \mathrm{We}h\frac{\partial \Delta h}{\partial x},$$

$$\frac{\partial m}{\partial t} + \frac{\partial J_2}{\partial z} + \frac{\partial J_{1,2}}{\partial x} = -\frac{3}{\mathrm{Re}}\left(\frac{\mathrm{Ma}}{2}\frac{\partial T_s}{\partial z} + \frac{m}{h^2}\right) + \mathrm{We}h\frac{\partial \Delta h}{\partial z},$$

$$\frac{\partial h}{\partial t} + \frac{\partial q}{\partial x} + \frac{\partial m}{\partial z} = 0.$$

Here $J_1 = \frac{6q^2}{5h} - \mathrm{Ma}\frac{qh}{20}\frac{\partial T_s}{\partial x} + \frac{h^3}{120}\left(\mathrm{Ma}\frac{\partial T_s}{\partial x}\right)^2$, $J_2 = \frac{6m^2}{5h} - \mathrm{Ma}\frac{mh}{20}\frac{\partial T_s}{\partial z} + \frac{h^3}{120}\left(\mathrm{Ma}\frac{\partial T_s}{\partial z}\right)^2$,

$J_{1,2} = \frac{6mq}{5h} - \frac{\mathrm{Ma}}{40}h\left(q\frac{\partial T_s}{\partial z} + m\frac{\partial T_s}{\partial x}\right) + \frac{h^3\mathrm{Ma}^2}{120}\frac{\partial T_s}{\partial x}\frac{\partial T_s}{\partial z}$, $\Delta h = \frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial z^2}$, $T_s(x,z) = \frac{T_W}{1+\mathrm{Bi}h}$, $\mathrm{We} = \left(3Fi/\mathrm{Re}^5\right)^{1/3}$ is Weber number, $Fi = \sigma^3/\rho^3 g\nu^4$ is Kapitsa number, $\mathrm{Ma} = \gamma T_m/\mu\iota_m$ is Marangoni number, $\mathrm{Bi} = \alpha h_m/\lambda$ is Biot number, $\mathrm{Re} = gh_m^3/3\nu^2$ is Reynolds number.

Linear analysis of stability relative to the spanwise perturbation. We study the stability of the unperturbed flow using the spatial approach. Let $h = 1 + \tilde{h}$, $q = 1 + \tilde{q}$, $m = m_0 + \tilde{m}$, $T_s = T_{s,0} + \tilde{T}_s$, where $\tilde{h}, \tilde{q}, \tilde{m}, \tilde{T}_s$ are small perturbations of the thickness, flow rate, and temperature of the film surface. Temperature perturbation can be expressed through perturbation of film thickness in the form $\tilde{T}_s = -E\tilde{h}$, where $E = \mathrm{Bi}/(1+\mathrm{Bi})^2$. Perturbations of the film flow are written in the form $\tilde{h}(x,z) = H_a\cos(kz)\exp(\alpha x)$, $\tilde{q}(x,z) = Q_a\cos(kz)\exp(\alpha x)$, $\tilde{m}(x,z) = M_a\sin(kz)\exp(\alpha x)$. Here $k = 2\pi h_m/L_z$ is the real wave number, L_z is the dimensional spatial period, α is the spatial growth rate of the perturbation. Having substituted these expressions in the linearized equations, we have gained analytical expression for spatial growth rate depending on a wave number k. Dependences of a spatial period of rivulet structure L_z for maximum growth perturbations depending on Re are shown in fig. 1 in comparison with experimental data for various fluids. One can see from the figure that in a wide range of Re, the experimental values of L_z are in good agreement with the parameters of the maximum growth perturbations calculated by an analysis of stability.

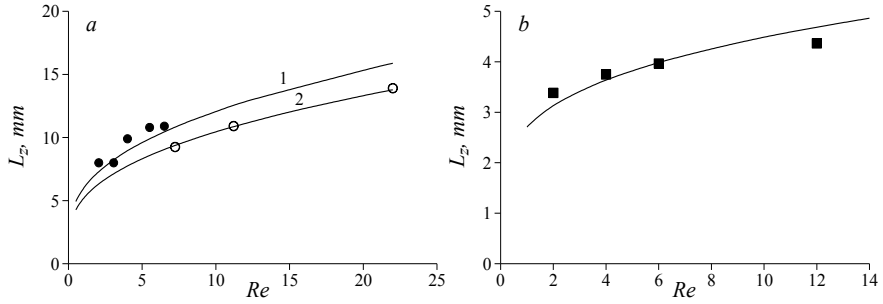

Figure 1. Distance between rivulets L_z, depending on Re for water (*a*) and for liquid MD-3F (*b*). Experimental data of [6]: solid circles for $Ma^* = 150$ and open circles for $Ma^* = 200$. The solid lines mean prediction of the most amplified perturbations (*a*). Squares are experimental data of [7]. The solid line is prediction for $Ma^* = 150$ (*b*).

Nonlinear development of perturbation in a 3D statement. The formation of 3D rivulets in a heated film was modeled by a spanwise perturbation applied to an unperturbed flow. At the inlet (i.e. at $x = 0$) a small z-periodic perturbation of thickness with predetermined wavelength L_z was set: $h = 1 + H_a \cos(kz)$, where H_a is the specified small amplitude of the initial perturbation. The calculations were performed for a film section with a width of one period, i.e. the computational domain represented a rectangle $0 \le x \le X_{end}$, $0 \le z \le L_z$. On the side boundaries of the computing domain (with $z = 0$ and $z = L_z$) the periodicity conditions were set. The calculations have shown that the initial disturbance evolves downstream into the rivulet structure. The calculated developed rivulet structure is shown in fig. 2.

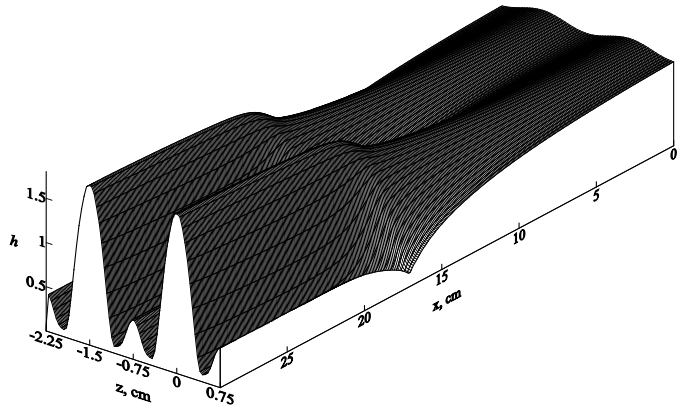

Figure 2. Developed 3D rivulet structure with wavelength $L_z = 1.5$ cm at Re = 5, $Ma^* = 100$, $Bi^* = 0.2$

CONCLUSIONS

The formation of 3D thermocapillary rivulet structure in a heated liquid film was investigated numerically. Using a spatial approach, a linear analysis of the stability was performed with respect to spanwise perturbations, and a spatial growth rate was calculated. Analysis of the experimental data for various liquids and different Reynolds numbers showed that the distance between rivulets agree well with the wavelength of the most amplified perturbation, calculated in accordance to the theory of stability. The stationary rivulet structures were simulated by spanwise perturbations imposed on a pre-calculated stationary 2D flow. Calculation results show that developed rivulet structure has a quasistationary character and very slightly changes downstream. The influence of dimensionless parameters on the developing rivulet structure has been revealed.

Here, we consider the evaporation of a thin liquid film which consists of a binary mixture of volatile liquids. Both the components in the mixture can be volatile. The mixture is in contact with a solid substrate below which is heated and is exposed to a gas phase. Using lubrication approximation and accounting for thermo/soluto-capillarity, we derive evolution equations for the interfacial height and concentration. We then perform a linear stability analysis, with a frozen base-state approximation. Our linear theory demonstrates the existence of principally two modes and the growth rates predicted are used to validate our numerical simulations. Our numerical simulations also allow us to examine the dynamics in the nonlinear regime and analyse how these instabilities evolve with time.

INTRODUCTION

Thin liquid films subject to temperature and concentration gradients are ubiquitous in nature and in technological applications such as coating, wetting, and cooling. The efficiency of these applications largely depends on the dynamics and stability of such liquid films. This is particularly true for coolants which are typically liquids comprising mixtures. While work has been done on stability of evaporating liquid films, focus has mainly been on those laden with surfactants (Hatziavramidis,1992; Danov et. al. 1998; Lin et al. 2000). Machrafi et al. (2010) performed linear stability analysis on a horizontal binary film using water/ethanol mixtures but with the evaporation of water being neglected. In this work, we consider competitive evaporation of components owing to the difference in volatilities. This is important as in most applications, like coating or cooling, the liquid comprises of several organic volatile components. Understanding their stability is key to help improve the efficiency of the application being considered.

PROBLEM FORMULATION

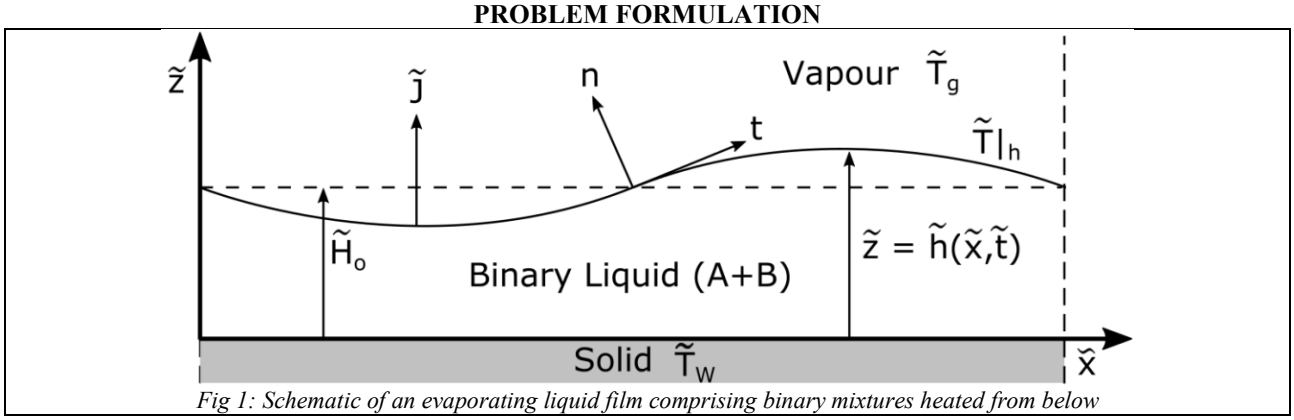

Fig 1: Schematic of an evaporating liquid film comprising binary mixtures heated from below

As shown in Fig 1, a thin liquid film comprising a mixture of volatile liquids A and B is heated from below. The volatilities of the components are dependent on their respective vapour pressures, with the component with highest vapour pressure exhibiting the highest volatility. The mixture is assumed to be ideal while the liquid layer is considered to be Newtonian, with density $\tilde{\rho}$, specific heat capacity $\tilde{c_p}$, thermal conductivity $\tilde{\lambda}$ and viscosity $\tilde{\mu}$, which depend on the local concentration of the two volatile components with the tildes standing for dimensional quantities. The surface tension $\tilde{\sigma}$, also depends on the local concentration as well as the local temperature $\tilde{T}$ given by Eq. (13). The liquid layer is on the top of a horizontal, uniformly heated solid substrate and is in contact with the gas phase with average bulk temperature $\tilde{T_g}$; the gas consists of the vapour of the binary mixture. Initially, the liquid layer has thickness $\tilde{H_o}$ and width $\tilde{L_o}$. Here, we consider a very thin liquid film, giving $\tilde{L_o} \gg \tilde{H_o}$ so that the ratio, $\epsilon = \frac{\tilde{H_o}}{\tilde{L_o}} \ll 1$. This assumption permits the use of lubrication theory. We use $\tilde{H_o}$, $\tilde{U_o} = \frac{\tilde{\nu_A}}{\tilde{H_o}}$ and $\Delta\tilde{T} = \tilde{T_w} - \tilde{T_g}$ as length, velocity and temperature scales. Next, with an assumption of density matched components, the following dimensionless governing equations are obtained.

$$u_x + w_z = 0 \tag{1}$$
$$u_t + uu_x + wu_z = -p_x + (\mu u_x)_x + (\mu u_z)_z \tag{2}$$
$$w_t + uw_x + ww_z = -p_z + (\mu w_x)_x + (\mu w_z)_z \tag{3}$$
$$Pr[(c_pT)_t + u(c_pT)_x + w(c_pT)_z] = (\lambda T_x)_x + (\lambda T_z)_z \tag{4}$$
$$c_t + uc_x + wc_z = Pe^{-1}(c_{xx} + c_{zz}) \tag{5}$$

Considering evaporation of both the components, the following boundary conditions are obtained:
At $z = h(x,t)$;

$$EJ = (-h_x(u-u_s)+w-w_s)(h_x^2+1)^{-\frac{1}{2}} \tag{6}$$

$$-\frac{E^2}{D}J^2 + p - \mathbf{n}\cdot\underline{\underline{\tau}}\cdot\mathbf{n} = p_v + \frac{\mathcal{A}}{h^3} - \left(\frac{\delta}{Ca} + \frac{M_c c}{Pr} - \frac{M_T}{Pr}(\gamma_r + (1-\gamma_r)c)T\right)\frac{h_{xx}}{(h_x^2+1)^{\frac{3}{2}}} \tag{7}$$

$$\mathbf{n}\cdot\underline{\underline{\tau}}\cdot\mathbf{t} = Ca^{-1}(h_x^2+1)^{\frac{1}{2}}(\sigma_x + h_x\sigma_z) \tag{8}$$

$$J_A + \Lambda J_B + \frac{E^2}{2\mathcal{L}D^2}J^3 + \lambda(-h_x T_x + T_z)(h_x+1)^{-\frac{1}{2}} = 0 \tag{9}$$

$$\frac{1}{Pe}\left[\frac{-h_x c_x + c_z}{(h_x^2+1)^{\frac{1}{2}}}\right]_{z=h} = E(cJ - J_A) \tag{10}$$

$$EJ = (w - h_t - uh_x)(h_x^2+1)^{-\frac{1}{2}} \tag{11}$$

$$KJ_A = cT;\quad KJ_B = (1-c)\alpha\beta^{\frac{3}{2}}\Lambda T \tag{12}$$

$$\sigma = c + (1-c)\delta - \Gamma(c + (1-c)\gamma_r)T|_h \tag{13}$$

$$\text{At } z = 0;\ u = w = 0 \text{ and } T = 1 \tag{14}$$

SOLUTION METHODOLOGY

Using long-wave approximations, Eqs (1)-(14) are reduced to evolution equations in interfacial height $H(t)$ and interfacial concentrations $C(t)$. This is then subject to a frozen base state approximation to perform a quasi-steady linear stability analysis. We then undertake transient simulations to understand the non-linear behaviour.

RESULTS

Considering standard ethanol-water solutions and a very thin liquid film (1 micron), we study evolution of the interface height and concentration. With an assumption of slow phase-change, we can consider that the rate of growth of the ensuing soluto-capillary instabilities is faster than the rate of evaporation. Our stability analysis shows that the evaporating film can demonstrate two unique modes of instability: monotonic mode when the most volatile component also has the highest surface tension or an oscillatory mode when the most volatile component has the lowest surface tension. Figure 2 demonstrates the parameter regime (ratio of solutal to thermal Marangoni numbers against relative volatility) where such modes can occur. Further investigation using transient simulations show the late-time behaviour of the film – revealing the nature of pattern formation as these components evaporate.

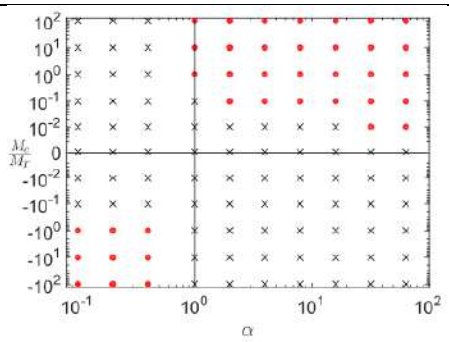

Figure 2: Map showing regions of monotonic instability mode (crosses) and oscillatory instability mode (squares) at $E = 10^{-4}$

CONCLUSIONS

The stability of the evaporation of an horizontal thin liquid layer which consist of a binary mixture of volatile liquids heated from below has been investigated by means of linear stability analysis and transient simulations. Two distinct modes of instabilities, identified from quasi-steady linear stability analysis, are further investigated via transient simulations to understand late-time and non-linear behaviour.

BEDROCK RECONSTRUCTION FROM FREE SURFACE DATA FOR UNIDIRECTIONAL GLACIER FLOW WITH BASAL SLIP

Elizabeth K. McGeorge[1], Mathieu Sellier[*2], Miguel Moyers-Gonzalez[1], and Phillip L. Wilson[1]
[1]School of Mathematics and Statistics, University of Canterbury, Christchurch, New Zealand

Summary In order estimate the volume of ice in a glacier, it is necessary to have a reliable map of its ice thickness distribution. A range of numerical techniques have been developed recently to infer the bedrock location from free surface observations and therefore deduce the glacier thickness. These techniques usually have to make assumptions about the nature of the slip at the base of the glacier. In this contribution, we show that, within the limits of the Shallow Ice Approximation, it is theoretically possible to simultaneously infer the glacier thickness and the basal slip coefficient from the knowledge of the glacier surface altitude and its free surface velocity. Results suggest that the problem of identifying the slip coefficient and the glacier thickness is not an equifinal inverse problem.

INTRODUCTION

The evolution of glaciers and ice bodies have long been known to be a good indicator of climate change. Consequently, much work has been dedicated to predicting their dynamics through mathematical modelling and numerical simulations. Such models require boundary conditions such as bedrock location (DEM) or ice flux at the domain boundaries which are usually unknown a priori. In parallel, the increasing availability of airborne data (satellite, aircraft, or UAVs) providing information about the ice surface altitude or free surface velocity have opened up the prospect of indirectly inferring difficult to measure fields such as the ice thickness from observed free surface observations. A range of numerical methods have been developed in the recent past to solve such inverse problems, see [1,2] and references therein for example, enabling for example the unveiling of the portrait of the contours of the land beneath Antarctica's ice sheet [3]. Such methods often make assumptions about the nature of basal conditions. We show in this contribution, that, within the limits of the Shallow Ice Approximation, it is theoretically possible to simultaneously infer the glacier thickness and the basal slip coefficient from the knowledge of the glacier surface altitude and its free surface velocity.

MATHEMATICAL MODEL

We assume here that the glacier dynamics is well described by the Shallow Ice Approximation [4] and that the flow is unidirectional with x the horizontal direction. Conservation of mass and momentum applied to the glacier requires that

$$\frac{\partial H}{\partial t} = a + \frac{2}{5}(\rho g)^3 \frac{\partial}{\partial x}\left(D \frac{\partial S}{\partial x}\right) \tag{1}$$

where H is the ice thickness, a represents the surface mass balance which is assumed to be known, S is the free surface altitude, ρ the ice density, and g the acceleration of gravity. The diffusion coefficient D is given by

$$S = \left|\frac{\partial S}{\partial x}\right|^2 H^4 \left[AH + \frac{5}{2}\beta A_s\right] \tag{2}$$

In this expression A is Glen law parameter (4.16×10^{-17} $Pa^{-3}yr^{-1}$), A_s the sliding coefficient (5×10^{-14} $m^8N^{-3}yr^{-1}$), and $\beta(x)$ acts as a dimmer switch for the amount of basal slip at the glacier base. Along the length of the glacier $\beta(x) \in [0,1]$. Physically, $\beta(x) = 0$ represents a sticky base and $\beta(x) = 1$ a friction-less base. It is not required for $\beta(x)$ to be constant along the glacier length. This dimmer switch is referred to as the basal slip distribution. Within the assumption of the Shallow Ice Approximation, we find that

$$u_s = -(\rho g)^3 \left(\frac{\partial S}{\partial x}\right)^3 H^3 \left[\frac{1}{2}AH + \beta A_s\right] \tag{3}$$

The free surface altitude S and ice thickness H are related through $S = z_b + H$ where z_b is the bedrock altitude. The governing equations are solved using a simple 1st order explicit, second order accurate in space finite difference scheme.

INVERSE METHODOLOGY

Given two observable variables, u_s and S, it is possible to recover two exact algebraic expressions which allow the direct reconstruction of the unknown variables, $H(x)$ and $\beta(x)$. The first one is obtained by integrating in space eq. (1) assuming a steady-state. This results in

$$0 = \int_0^x a dx - \frac{1}{10}(\rho g)^3 MAH^5 - u_s H + C_0 \tag{4}$$

*Corresponding author. E-mail: mathieu.sellier@canterbury.ac.nz.

where $M = \left(\frac{\partial s}{\partial x}\right)^3$ is known for a given ice surface altitude and C_0 a constant of integration. Eq. (4) combined with a rearranged eq. (3) provide the required two equations which allow the reconstruction of $H(x)$ and $\beta(x)$. A simple Newton's method was implemented to solve the non-linear system of equations.
In order to test the methodology a twin experiment was performed whereby an artificial data set was created by running the model to a steady state for a given distribution of β and z_b. The resulting distribution of ice surface altitude and free surface velocity was then use as the observable data for the inverse problem. An example of the results obtained is illustrated in Figure 1.

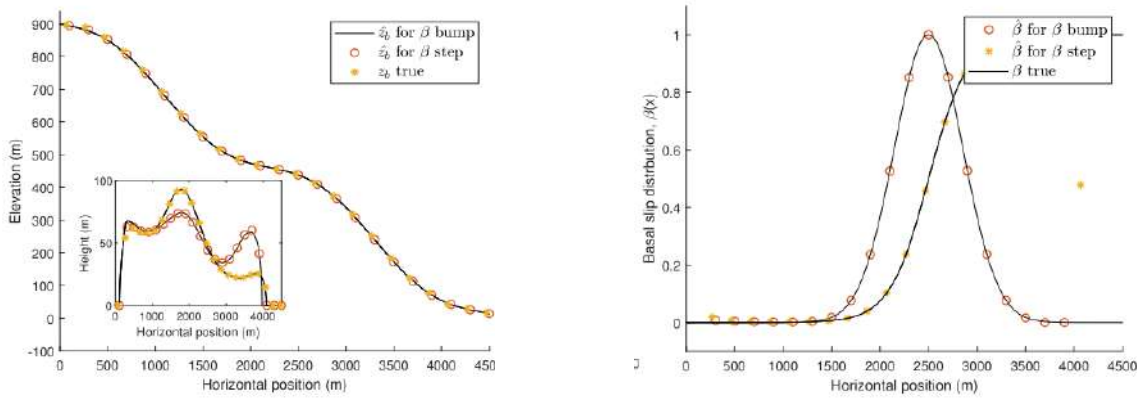

Figure 1: Reconstructed bedrock location (left-hand figure) and reconstructed basal slip distribution. The black lines indicate the true distributions and the symbols the reconstructed ones. Two types of basal slip distribution were tested: a "bump" and a step.

Results confirm the validity of the reconstruction algorithm as the reconstructed fields are indistinguishable from the real ones. Tests with noisy input data confirm that the reconstruction algorithm is also robust to the addition of noise.

CONCLUSIONS

This contribution shows that it is possible to simultaneously reconstruct the bedrock location and basal slip coefficient from observed free surface altitude and velocity. This result suggests that the identification problem is well-posed, i.e. a unique combination of basal slip coefficient and bedrock profiles leads to a unique free surface signature. While the current contribution is limited to uni-directional flow, we believe that it can be extended to three-dimensional flow following a method analogous to [5].

A SIMULATION OF THIN LIQUID FILM FORMING WITH SURFACTANTS BY FULLY EXPLICIT GAS-LIQUID TWO-PHSE FLOW SOLVER WITH INTERFACE-ADAPTED AMR METHOD

Shintaro Matsushita[1] and Takayuki Aoki [2]
[1]Department of Mechanical Engineering, Tokyo Institute of Technology, Meguro, Japan
[2]Global Scientific Information and Computing Center, Tokyo Institute of Technology, Meguro, Japan

Summary A weakly compressible scheme for solving low-Mach number gas-liquid two-phase flows with interface-adapted AMR (Adaptive Mesh Refinement) method is proposed to achieve high-resolution simulation by avoiding solving pressure Poisson equation. A fully explicit time integration is developed by solving independent hyperbolic pressure evolution equation. We have developed a GPU code of the tree-based AMR method, which can greatly reduce the computational cost to assign high-resolution mesh to the region of moving interfaces. The accuracy of our solver is examined by solving a lot of benchmark problems. To reproduce the stable liquid film on liquid surface in gravity, the Marangoni-effect is introduced by considering the transportation equations of bulk/surface surfactant concentrations with adsorption/desorption effects.

INTRODUCTION

In the numerical studies on gas-liquid two-phase flows, high-resolution meshes are required to describe the gas-liquid interfaces in diffuse interface models. In most cases, mesh convergence has not been achieved yet, however, the simulated results of two-phase flows strongly depend on mesh resolution especially for violent flows. Our target is incompressible flows, which have been widely solved by semi-implicit time integrators to keep a large time step without restricted by the speed of sound. The Poisson equation has to be solved by sparse matrix solver to maintain the divergence-free condition. The iteration convergence becomes poor as the matrix size increases, especially for gas-liquid two-phase flows even if we use preconditioned BiGCSTAB method[1]. Therefore, solving the Poisson equation for a large-scale two-phase flow simulation is a challenging problem. We have developed a fully explicit scheme for solving low Mach number two-phase flows with diffuse-interface model to avoid solving Poisson equation based on characteristic theory[2]. To increase the accuracy of the interface behaviour by applying density-weighted advection evaluation[3], we have changed the numerical methods to solve Compressible Navier-Stokes equations to the independent hyperbolic pressure evolution equation derived from isothermal equation of state. The time step is restricted by the sound speed and we reduce it within the range where the weak compressibility is negligibly small and is acceptable for describing incompressible flows.

The tree-based AMR method can greatly reduce the number of computational costs by assigning high-resolution mesh to the region around the moving interface. To realize the two-phase flow simulations using higher-resolution mesh, the GPU-code have been developed in CUDA language and successfully combined with the weakly compressible scheme. The surfactants transportation equations with adsorption/desorption effects are introduced to consider Marangoni-effect. Our solver has succeeded to simulate the process of forming thin liquid film onto the liquid surface using real physical parameters while having robustness that allows for arbitrary deformation of interfaces.

NUMERICAL METHODS

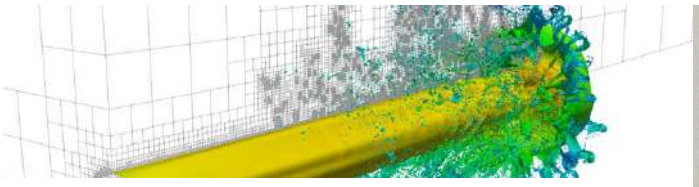
Compressible Navier-Stokes equations under the isothermal equation of state and low-Mach number conditions are solved on staggered grid system. The density-weighted advection evaluation[3] is applied to advection scheme and 3rd order TVD-Runge-Kutta scheme is used for time integration. We solve conservative Allen-Cahn equation by using finite volume method to maintain mass conservation since the density and viscosity are computed by phase-field variables.

The tree-based AMR method is employed for easy handling of frequent refinement and coarsening since adaptations of mesh is applied to the moving interfaces. The extra reserved memory pool data structure are used to reduce the frequency of allocation/deallocation of the global memory on GPU[4].

RESULTS AND DISCUSSIONS

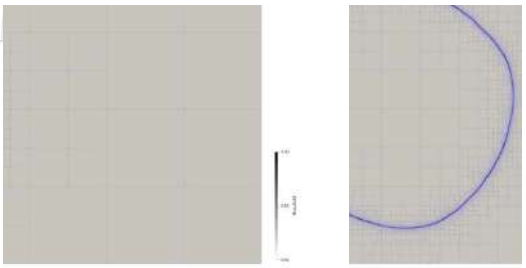
The accuracy of our solver has been examined by carrying out a lot of benchmark problems of two-phase flows. The applicability of violent two-phase flows is examined by simulating the liquid jet break up problem shown Fig.1. It takes about 11 hours by our solver on single Tesla V100 GPU, while it takes about 350 hours (estimated) using 5760 cores of CPU by incompressible solver on uniform mesh in reference[5]. Fig.2 shows the simulation results of soap bubble forming process using 20% glycerine solution and air properties and the equivalent diameter of soap bubble surrounded by very thin liquid film expands to 7.8 times larger at $t = 5.0\,\mathrm{s}$ compared to initial. The stable thin liquid film onto the liquid

surface, which we can often see in daily life, is reproduced in 2D computational domain by introducing the transportation equations of surfactants and the Marangoni-effect using Triton-X100 solution and air properties (Fig.3).



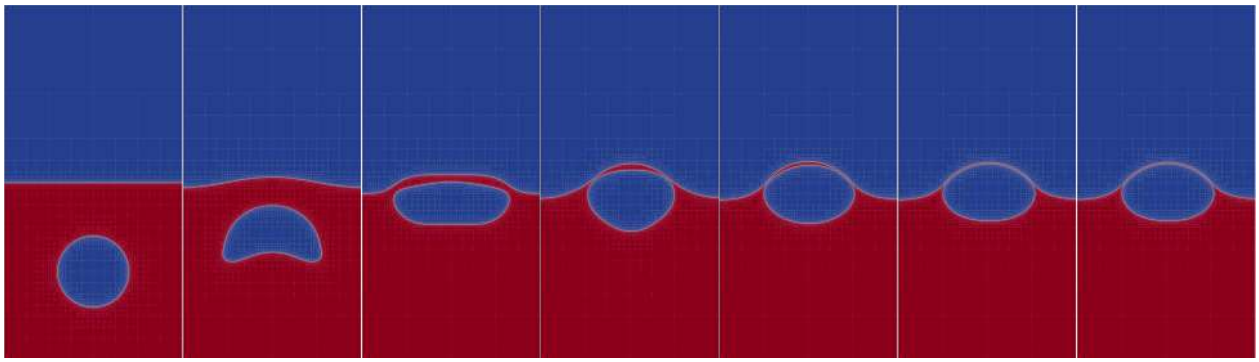
$t^* = 13.6$

Figure 1. The gas-liquid interface of liquid jet breakup problem with 7-level AMR method. The finest width of mesh equals to $\Delta x = D/256$ and the dimensionless time $t^* = Ut/D$, where $U = 100\ \mathrm{m/s}$ is the inlet velocity.



$t = 0.0\ \mathrm{s}$ $t = 5.0\ \mathrm{s}$

Figure 2. The phase-field profile with blue leaf lines for the simulation of forming soap bubble problem. Each leaf has 4^2 meshes and the finest mesh equals to $\Delta x = D/819$, where D is the initial diameter of bubble.



$t = 0.0\ \mathrm{s}$ $t = 0.03\ \mathrm{s}$ $t = 0.06\ \mathrm{s}$ $t = 0.12\ \mathrm{s}$ $t = 0.20\ \mathrm{s}$ $t = 1.0\ \mathrm{s}$ $t = 2.0\ \mathrm{s}$

Figure 3. The phase-field profile with while leaf lines for the simulation of stable thin liquid film onto the liquid surface with surfactant effect. Each leaf has 42 meshes and the finest mesh equals to $\Delta x = D/341$, where D is the initial diameter of bubble.

CONCLUSIONS

We have successfully developed a weakly compressible fully explicit solver for low Mach number gas-liquid two-phase flows combined with tree-based AMR method. Our solver has enough to solve incompressible two-phase flows since the results of benchmarks are in good agreements even if AMR method is applied. Thanks to the efficient GPU-implementation of AMR method and fully explicit scheme, the simulation of liquid jet breakup problem is performed in much shorter time than that of reference's incompressible solver on uniform mesh. In the 2D simulation of forming thin liquid film of soap bubble under the non-gravity, 7.8 times expanding is reproduced by our techniques. The stable liquid film forming onto the liquid surface under the gravity is also achieved by introducing surfactants and Marangoni-effect. By this study, the efficient high-resolution two-phase flow simulation can be achieved and the numerical simulation of forming of thin liquid film can be possible to consider the surfactant effect while keeping numerical stability for violent flows and robustness that allows for arbitrary deformation of interfaces.

THIN FILM FLOWS WITH WAVY WALL SHAPE: AN ASYMPTOTIC ANALYSIS

Corinne Rouby*[1], Kim Pham[1], Rogers Cordova[1], and Agnès Maurel[2]
[1]IMSIA, ENSTA Paris, Institut Polytechnique de Paris, 828, boulevard des Maréchaux-91120-Palaiseau
[2]Institut Langevin, CNRS, ESPCI Paris Tech, 1 rue Jussieu, 75005 Paris, France

Summary We extend the lubrication approximation to a fluid flowing in channels with arbitrary shape functions and moderate aspect ratio. The higher-order model is obtained following an asymptotic analysis resulting in closed forms of velocity and pressure involving the derivatives of the shape functions of the walls up to the second-order. Comparisons with full-scale simulations are given and show good agreement as well as improvements from the classical standard lubrication approximation. Extension of this model to more complex channels involving strong curvature such with high angle elbows will be proposed.

The *Classical Lubrication Approximation* (CLA) accounts for the behavior of viscous flows in thin channels under assumptions of small Reynolds numbers and slowly varying walls. Under these hypotheses, the flow is characterized by (i) a constant pressure across the transverse, say vertical, section and with variations along the channel axis governed by the Reynolds equation [1], (ii) a vanishing vertical velocity and a horizontal one of the Poiseuille's type. The CLA, as it avoids to resolve a full-scale fluid calculation, is used in many fields such as film lubricant, hydraulic fracture mechanics or flows in biological systems such as blood cell transport in narrow capillaries. However, its validity as that of the associated Reynolds equation have to be questioned when the curvature of the channel is not negligible anymore. This is the case for wavy walls or high angle elbows in even more compelling situations. A systematic way to derive such approximation is to use asymptotic techniques which are well-adapted due to the small thickness of the channel compared its length. Starting in the 80s, such *Extended Lubrication Approximation* (ELA) has been applied to channels with a single wavy wall [2] and with two symmetric wavy walls [3]. Recently, Tavakol and co-workers have revisited the problem of a single wavy wall using a slightly different approach in which the asymptotic analysis is applied to the Stokes equations [4]. Experimental and numerical results support their analytical result and exemplify the interest of the improved model to capture accurately the velocity profiles and the pressure drop. Our study follows from this work and extends the lubrication approximation to two non-symmetric wavy walls [5].

EXTENDED LUBRIFICATION APPROXIMATION

We consider an incompressible, steady, two-dimensional pressure-driven flow in a channel of length L. The geometry is defined through the introduction of the upper shape function $y = h_+(x)$ and the lower shape function $y = h_-(x)$ for $x \in (0, L)$ with $h_+ > h_-$ (see Fig. 1). These functions are assumed to be at least C^2 continuous. We introduce the mean line level $y_m(x) = \frac{h_+(x)+h_-(x)}{2}$, the local half-thickness $h(x) = \frac{h_+(x)-h_-(x)}{2}$ of the channel as well as the rescaled vertical coordinate defined by $\mathrm{y} = \frac{y-y_m(x)}{h(x)}$. x .

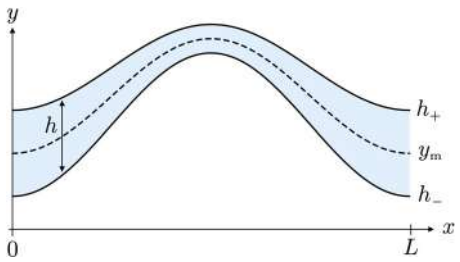

Figure 1: Schematic view of a channel of length L with arbitrary upper and lower shape profiles $h_+(x)$ and $h_-(x)$. The functions $h(x)$ and $y_m(x)$ denote the half-distance between the walls and the average level respectively.

The Reynolds number is assumed to be small so that the flow is governed by the Stokes equations $\nabla \cdot \mathbf{u} = 0$ and $\mu \nabla^2 \mathbf{u} = \nabla p$, where $\mathbf{u} = u\mathbf{e}_x + v\mathbf{e}_y$ and p are the velocity and the pressure fields respectively, and μ is the viscosity of the fluid. Additionally to a no-slip condition on the walls $\mathbf{u}(x, h_+(x)) = \mathbf{u}(x, h_-(x)) = \mathbf{0}$, the boundary conditions are defined as prescribed a Poiseuille inlet velocity profile $\mathbf{u}(0, y) = \frac{3\Phi}{4h(0)} \left(1 - \mathrm{y}^2\right) \mathbf{e}_x$ (Φ being the fluid flux) and a vanishing outlet pressure $p(L, y) = 0$. The lubrification model is obtained by conducting an asymptotic analysis based on

*Corresponding author. E-mail: corinne.rouby@ensta-paris.fr

the introduction of the small parameter $\varepsilon = \frac{h(0)}{L} \ll 1$, which accounts for the slenderness ratio of the channel. The main result of our study is the following approximation of the exact solution up to the second order in the small parameter ε :

$$u(x,y) \simeq \frac{3\Phi}{4h}\left(1-\mathrm{y}^2\right)\left(1+\frac{4h'^2-hh''}{10}\left(1-5\mathrm{y}^2\right)+\frac{2hy_{\mathrm{m}}''-12h'y_{\mathrm{m}}'}{3}\,\mathrm{y}\right), \tag{1}$$

$$v(x,y) \simeq \frac{3\Phi}{4h}\left(1-\mathrm{y}^2\right)\left(h'\mathrm{y}+y_{\mathrm{m}}'\right), \tag{2}$$

$$p(x,y) \simeq \mu\Phi\int_x^L \frac{3}{2h^3}\left(1+\frac{2}{5}\left(h'^2+hh''+5y_{\mathrm{m}}'^2\right)\right)\mathrm{d}x' + \frac{3\mu\Phi}{4h^2}\left(h'(1-3\mathrm{y}^2)-2y_{\mathrm{m}}'\mathrm{y}\right), \tag{3}$$

see [5]. The classical lubrication approximation is obtained from Eqs. (1)-(3) by simply putting the derivative of y_{m} and h to zero. Hence, in the standard case, the velocities and the pressure depend only on the (half) relative distance h between the walls. Note that the prescribed parabolic inlet velocity profile is matched only on *average* by the second-order approximation.

VALIDATION OF THE MODEL TOWARDS DIRECT NUMERICAL SIMULATIONS

To inspect the accuracy of the ELA model specified by Eqs. (1)-(3), we consider a channel profile where both y_{m} and h vary, see Figure 1. The direct problem is solved with COMSOL MultiPhysics. We report in Figure 2 the fields of the velocity components (u, v) and of the pressure p computed numerically from the direct problem and the corresponding fields predicted by the CLA and ELA (note for the CLA, the vertical velocity is negligible).

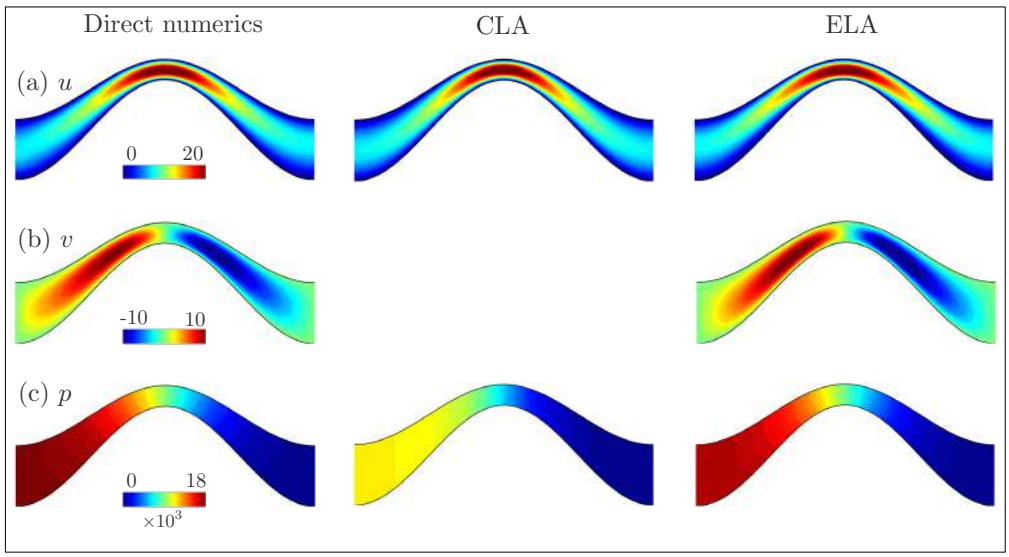

Figure 2: Results for the profile (P1). Fields of the velocity components (u, v) and of the pressure p in full scale simulations, CLA and ELA (note in the CLA theory, the vertical velocity is negligible and thus is not plotted).

It is noticeable that CLA and ELA have the same good accuracy to capture the right variations on the horizontal velocity u since the correction of ELA appears at the second order. On the other hand, the effect on the vertical velocity v is much more significative and again this is expected since the correction appears at the first order. As for the pressure, which is of particular interest since the pressure drop due to expansions/constrictions are important in many practical situations, the gain in the ELA is significant with an error between the prediction and the direct numerics of about 5% for ELA and of about 40% for CLA. Expectedly, ELA offers the most significant improvement with respect to CLA when the channels contain constrictions with large variations of the centerline. This results in high vertical velocities and pressure drops widely underestimated by CLA and accurately reproduced by ELA. The current work aims to be generalized by investigating more complex situations including walls with high angle elbows as well as flows with moderate (yet non-negligible) Reynolds number.

INFLUENCE OF CORRUGATION ON SURFACE WETTABILITY

Dariusz Asendrych[1]
Institute of Thermal Machinery, Częstochowa University of Technology, Częstochowa, Poland

Summary The paper presents the results of numerical simulation of the liquid flow at the inclined surfaces. The aim of the research was to analyse the influence of surface texture and Reynolds number on the wetting efficiency. The simulations allowed to recover the morphological flow structure being dependent on the inertial and the surface tension forces. Surface corrugation turned out to modify the flow pattern and in turn to influence wetting efficiency. As the result the increased interfacial area enhances the mass, heat and momentum transfer processes in 2-phase flow systems commonly encountered in various industrial applications.

INTRODUCTION

Two-phase gas-liquid flows are commonly encountered in industry. The processes they are involved in are mostly operated in packed bed columns providing large contact area between phases and thus ensuring enhanced mass, momentum and heat transfers. Various designs of structured packings have been offered in recent years (see e.g. [1,3]) allowing to improve hydrodynamic characteristics to better control pressure drop or liquid holdup. However, deeper understanding of gas-liquid-solid interactions is still required to further optimise packing designs. This goal can be achieved with the help of Computational Fluid Dynamics (CFD) allowing to perform parametric studies and to test various parameters. Due to geometrical complexity of packings available commercially most of works deal with simplified cases considering flat [5] or corrugated surfaces [2,3]. Such an approach allows to separate various influences and to formulate optimisation guidelines. One of the key feature of the packing is to ensure high surface wettability and to increase the residence time of liquid within it. This can be improved by surface texture. As shown in [2] the portion of wetted surface can be enlarged by several per cent when compared to the flat one. In contradiction Isoz [3] showed the reduction of wetting efficiency at textured surfaces. Such a lack of consistency seems to convince that further research efforts are needed.

NUMERICAL MODEL

The paper presents the numerical analysis of a flow structure and a surface wettability on flat and corrugated surfaces. The flow was modelled using a classical system of equations including mass and momentum conservation laws. A 3D Eulerian unsteady model combined with Volume of Fluid (VOF) method was developed allowing for reconstruction of a gas-liquid interface [4]. Surface tension was included in the momentum equation as a source term. Water and air at ambient conditions were used as working fluids.

The simulations were conducted for flat and corrugated surfaces inclined to the horizontal direction by the angle of 60°. Plate size (length - 60mm, width - 50mm) were chosen for consistency with literature (e.g. [1,5]). Computational domain took a form of a cuboid with height equal to 10mm. Surface texture had a shape of triangular waviness with a scale 2.8mm and a height varied in the range 0.3-0.9mm. The inflow was simulated with the velocity inlet boundary condition. Liquid entered a domain as a liquid film with prescribed thickness and parabolic velocity profile. At plate the non-slip boundary condition was applied with contact angle 70° characterising a water-steel system. Side boundaries were treated as walls with the slip boundary condition. Pressure outlet was applied at the bottom boundary. Numerical grid, consisting of 1.13 million cells, was selected as a result of relevant tests with various meshes. Time step of 25μs was used for all the cases under consideration.

RESULTS AND DISCUSSION

A series of CFD simulations was conducted for inclined flat and corrugated surfaces for varying Reynolds number and corrugation heights. At first the simulations were performed for flat surface allowing for model verification with literature CFD and experimental data [1,5]. Flow evolution upon Reynolds number (from droplet-like flow through the system of rivulets, up to film flow [4]) was found to be fully consistent with reference results and thus proving model relevance. The simulations for corrugated surfaces showed a qualitative and quantitative modifications of the flow structure. A sample results obtained for Reynolds number 50 are shown in Fig. 1. As can be seen for the flat surface (Fig. 1, left) liquid entering a plate forms a number of small rivulets which are broken into droplets. Surface texture increases resistance to the flow and the rivulets keep higher integrity what prevents them from break up process (see Fig. 1, right). As a result portion of wetted surface slightly increases improving surface wettability. Moreover, detailed analysis of the velocity field showed that for textured plate liquid phase "needs" more time to reach the bottom edge, thus increasing residence time in control volume.

[1] Corresponding author. E-mail: darek@imc.pcz.czest.pl.

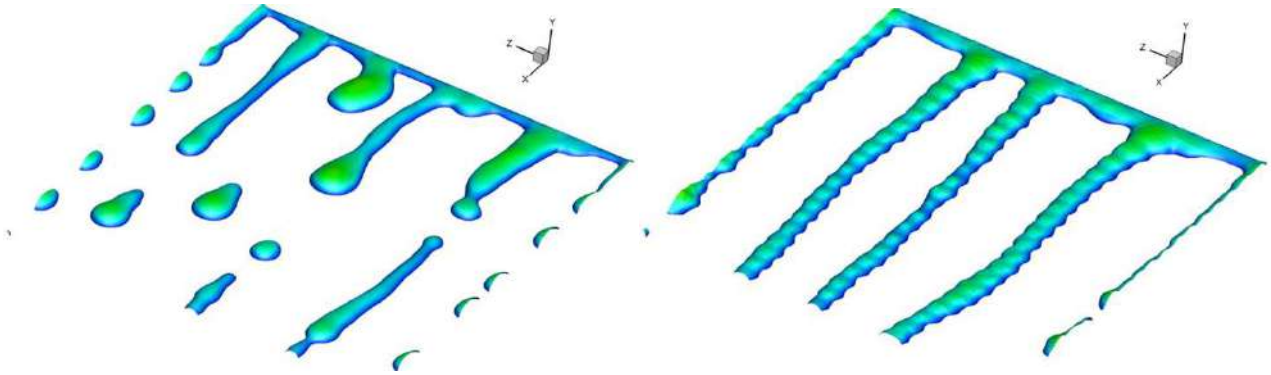

Figure 1. The flow structure on flat (left) and corrugated (right) surface for Re = 50. Surface corrugation - 0.3mm.

Parametric simulations allowed to test the influence the corrugation height can have on a flow structure and surface wettability. As can be seen from data collected in Fig. 2 wetting efficiency increases with Reynolds number reaching 100% at appr. Re=200 for flat surface. Modified flow structure for textured surfaces leads to increase of wetted area, which is hardly visible for corrugation height h=0.3mm while noticeable for h=0.6mm. It shows that corrugation promotes wetting efficiency by additional drag acting against gravity and leading to local liquid accumulations.

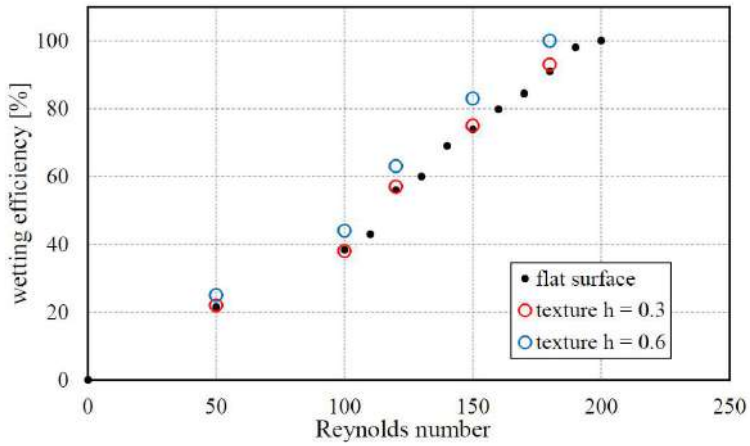

Figure 2. Influence of Reynolds number on wetting efficiency for varying surface texture height.

CONCLUSIONS

The CFD simulations presented in the paper seem to convince that surface corrugation can improve hydrodynamic characteristics of packed beds. However, corrugation shape (wavelength, height, symmetrical/asymmetrical) can still be optimized to further increase wetting ability as well as liquid holdup and its residence time. These parameters are of special importance in separation, distillation or absorption processes taking place in packed bed columns.

ABSORPTION, FILM FORMING AND RUNOFF DUE TO WIND-DRIVEN RAIN

Aytaç Kubilay*[1], Dominique Derome[2], and Jan Carmeliet [3]
[1]Laboratory of Multiscale Studies in Building Physics, Empa, Switzerland
[2]Department of Civil and Building Engineering, Université de Sherbrooke, Canada
[3]Chair of Building Physics, Department of Mechanical and Process Engineering, ETH Zurich,Switzerland

Summary There is a need for experimental data, specially for model development and validation, of wind-driven rain (WDR) absorption in porous building materials and rainwater runoff. The present study reports field measurements of WDR that are conducted with high spatial and temporal resolution in a test setup consisting of two parallel building models. Porous building materials with varying pore size distributions, water absorption characteristics and thickness are installed and monitored during rain events with different characteristics.

INTRODUCTION

Wind-driven rain (WDR), referring to the droplets carried by the wind and impinged on the building facades, influences the hygrothermal performance and the durability of building facades significantly. Therefore, WDR intensity is used as a main boundary condition in studies for moisture transport in building envelopes. With more extreme rain events expected due to climate change, building damage risks could increase in the coming decades, reinforcing the need for accurate information on the spatial and temporal distribution of WDR.

Distribution of WDR reaching urban surfaces can be quantified by numerically solving for the wind flow around buildings and the trajectories of rain droplets [1]. Once rain droplets impinge on the surface, WDR leads to complex phenomena that involve spreading, splashing, rolling or bouncing, coalescence of droplets, hemiwicking on the surface, absorption in a porous medium, evaporation, film forming and runoff under gravity. While absorption and moisture distribution of WDR have been investigated in the past, few studies have considered film forming and runoff, especially on building materials [2]. Limited quantitative rain runoff data from experiments or numerical modeling are currently available [3]. Development and validation of such numerical models require complete measurement datasets to provide representative validation data for numerical simulations.

This study aims to quantify the moisture content absorbed by the porous building materials and the occurrence of runoff by field measurements. Measurements are performed at a test site at Empa, Dübendorf, Switzerland and compared with one-dimensional numerical results.

METHODOLOGY

Field measurements

The field measurements are performed between April-November 2019 on a setup consisting of two parallel building models as shown in Fig. 1. The building models are formed using cubic structures, each with dimensions of H×H×H = 2×2×2 m^3. The authors presented two earlier measurement campaigns to estimate the spatial and temporal distribution of WDR intensity, one of which featured the same geometry [4]. Here, in addition to the WDR gauges, porous building materials with varying pore size distributions, water absorption characteristics and thickness are installed.

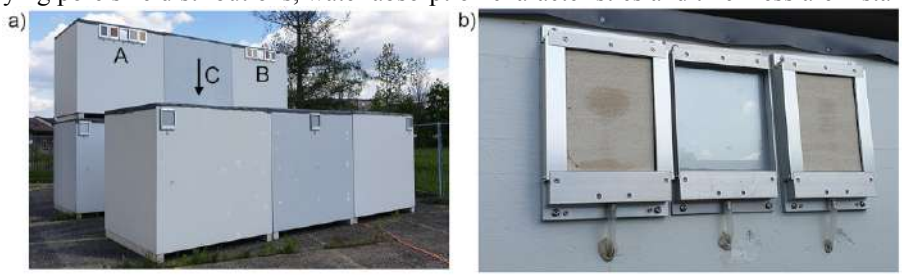

Figure 1. a) Measurement geometry and sensor positions. b) Two Savonnières limestones and the WDR gauge at location C.

The porous materials are placed at locations A, B and C as indicated in Fig. 1a, all on the downstream building. Locations A and B have symmetrical positioning of 4 different porous materials (Pietra Serena sandstone, Meule sandstone, Savonnières limestone and clay brick, from left to right at location A). The materials at location A are 8 mm thick, while the ones at location B are 20 mm. At location C, which is at a lower height behind the upstream building, two Savonnières limestones are installed as shown in Fig. 1b. One of them is 8 mm thick, while the other one is 20 mm. Each of the 10 collectors are equipped with a load cell to measure the absorbed rainwater. A tipping bucket mechanism is used to measure the rainwater that runs off from the surface. The collectors are connected via tubing to the tipping bucket mechanism placed inside the cubes. At each location, an additional WDR gauge is installed at the center to measure the local WDR intensity as reference. Additional WDR gauges are installed on the upstream building.

In order to measure the approach-flow wind direction and wind speed, a meteorological mast is positioned west (upstream) of the measurement site. The meteorological mast is equipped with a 3D ultrasonic anemometer and two cup anemometers to measure the approach wind flow profile. The horizontal rainfall intensity is measured 0.4 m above the

[1]*Corresponding author. E-mail: aytac.kubilay@empa.ch

ground by a rain gauge positioned near the weather mast. Additionally, measurements of relative humidity, air temperature and solar radiation are performed. Different types of rain events have been fully documented.

Numerical modelling

In the current study, the porous materials (20×15 cm^2) are modeled using one-dimensional domains. The coupled heat and moisture transport equations commonly used in building physics applications are given below [5]:

$$\left(c_0\rho_0+c_l w\right)\frac{\partial T}{\partial t}=-\nabla\left(q_c+q_a\right) \quad (1)$$

$$\frac{\partial w}{\partial p_c}\frac{\partial p_c}{\partial t}=-\nabla\left(g_l+g_v\right) \quad (2)$$

where c_0 denotes the specific heat of dry material, ρ_0 the density of dry material, c_l the specific heat of liquid water, w the moisture content, T absolute temperature and p_c capillary pressure. The derivative $\partial w/\partial p_c$ represents the moisture capacity of the porous material. q_c and q_a denote the conductive and advective heat fluxes, while g_l and g_v the liquid and vapor moisture fluxes. The moisture content in the material upper bound is the capillary moisture content. The rain droplets are absorbed via capillary action until saturation occurs. In cases where the surface reaches capillary saturation and the rain flux is larger than the possible absorption by the material, the excess water flows over the surface as runoff.

RESULTS

Fig. 2 shows a rain event with several rain spells that was measured between June 9-16, 2019. The measured absorption and runoff for the two Savonnieres samples, as well as the total WDR amount measured by the WDR gauge, are presented for location C. The measurements show that the 8-mm sample reaches saturation during all three rain spells, while the 20-mm sample is not fully saturated during the initial two rain spells. As a result, a smaller amount of runoff is measured on the thicker sample.

For the numerical simulations, the total WDR amount is used as a flux boundary condition. The comparison of simulations with experiments show that the numerical model underestimates the runoff amount for both samples. For the 8-mm sample in Fig. 2a, numerical model accurately predicts the absorbed rainwater, as well as the rate of evaporation. On the other hand, for the 20-mm sample in Fig. 2b, the absorbed amount of water during the initial two rain spells is overestimated. Furthermore, even though the numerical model reaches near saturation during the first rain spell, the runoff amount is much lower than the measured value. This indicates that the commonly-used flux boundary condition for wetting of building facades due to WDR is unable to capture the fate of discrete raindrops. Further, the droplet physics after impingement on the material can be quite different for dry and wet surfaces. The numerical simulations should take into account droplet spreading and surface film formation in order to accurately estimate the moisture transport during a rain event.

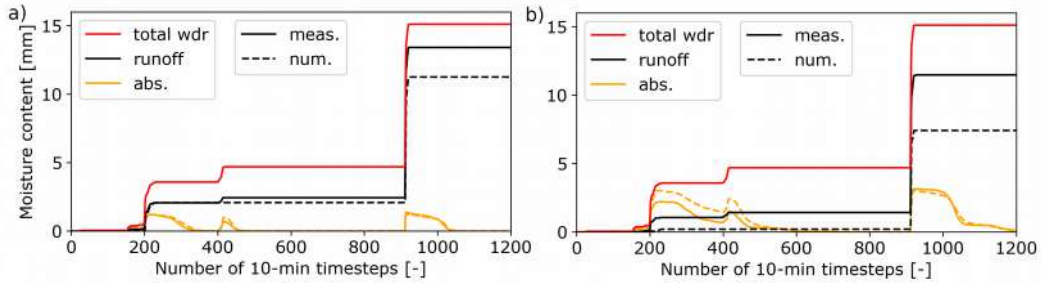

Figure 2. Comparison of the experimental absorption and runoff amounts with the numerical results on the a) 8-mm and b) 20-mm Savonnières stone samples.

CONCLUSIONS

A new measurement campaign for WDR is presented on two parallel buildings, featuring rainwater absorption and runoff measurements. Work is currently on-going both experimentally and numerically. The complete experimental dataset can provide valuable insight in raindrop absorption and runoff mechanisms for porous building materials and can act as a basis for numerical model development.

NUMERICAL SIMULATION OF THE FILM OBLIQUE STRETCHING PROCESS

Mengnan Zhang*[1,2], Jun Zeng [1,2], Erjie Yang [1,2], Fucheng Tian [1,2], andLiangbin Li [1,2,3]
[1]National Synchrotron Radiation Lab, University of Science and Technology of China, Hefei 230029, China
[2]Anhui Provincial Engineering Laboratory of Advanced Functional Polymer Film, University of Science and Technology of China, Hefei 230029,China
[3]CAS Key Laboratory of Soft Matter Chemistry, University of Science and Technology of China, Hefei 230029, China

Summary Finite element methods (FEM) used in the optical film processing field can accelerate the development of film research. The FEM is carried out to simulate the processing of oblique stretching for the first time, the membrane hypothesis is developed and a complete numerical case is given. The stabilization techniques *discrete elastic viscous stress splitting* (DEVSS) is introduced into the simulation and the energy equation, as well as temperature effect, are also considered. The (Phan-Thien and Tanner) PTT viscoelastic constitutive model has been adopted for the simulation, which is regarded as one of the most realistic fluid models. Material parameters of polycarbonate (PC) and proper boundary conditions are given to the simulation. Finally, the contours of the temperature and thickness are present, based on which the effect of the heat transfer coefficient is discussed briefly.

The oblique stretching

The optical film is an essential film in many industrial fields, where oblique stretching is a vital method for the fabrication of optical films such as polarization film. Nonetheless, there is a lack of research and no complete analysis of this method currently, so we aim to analyze the oblique stretching processing in this work. As can be seen in Fig.1, the process of oblique stretching is present. Two rows of closely arranged clamp groups, with variable spacing, grip left and right side edges of the film respectively. Moving those clamps gives the tensile force to the film as well as drives the film forward. That the distance between the clamps is from small to large, leads to the stretching of the film. In addition, the gradual increase of the clamps spacing means the continuous increase of the clamp's velocity, and that is the key to setting the boundary conditions. Additionally, when a delay is imposed on one side (the point at which the stretching starts is *FS* on the right but *LS* on the left in Fig.1), the oblique stretching condition comes into being as a result. Under the membrane hypothesis proposed by Agssant et al [1], the 3D computing domain can be reduced to an in-plane field, all conservation equations are averaged throughout the thickness direction.

The stabilization techniques DEVSS algorithm, presented by Guenette and Fortin [2], which has been proved to improve numerical stability, is applied in this work. The PTT viscoelastic constitutive model [3,4] has been adopted for the simulation, which is regarded as one of the most realistic fluid models. And, the energy equation is also considered, the effects of temperature on rheological properties are taken into consideration. For sake of more realistic input parameters, the polycarbonate (PC) material is taken as the reference. Rheological measurement is performed on PC and the parameters are present as the result. Finally, under the proper boundary conditions of kinematic, thickness, and temperature are set into the model.

To solve those governing equations numerically, spatial discretization is essential. In this work, the computational domain is discretized by quadrilateral elements and the unknown variables are approximated by means of interpolation. The Galerkin weighted residual method is employed and the Newton-Raphson iteration is used for solving sharp nonlinear character governing equation.

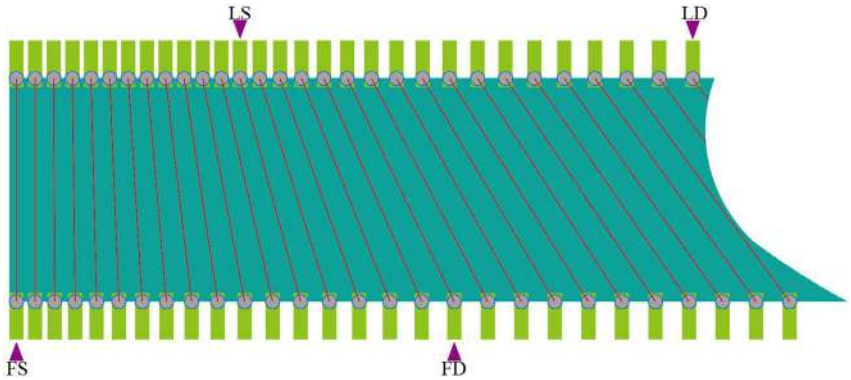

Figure 1. Diagrammatic of oblique stretching

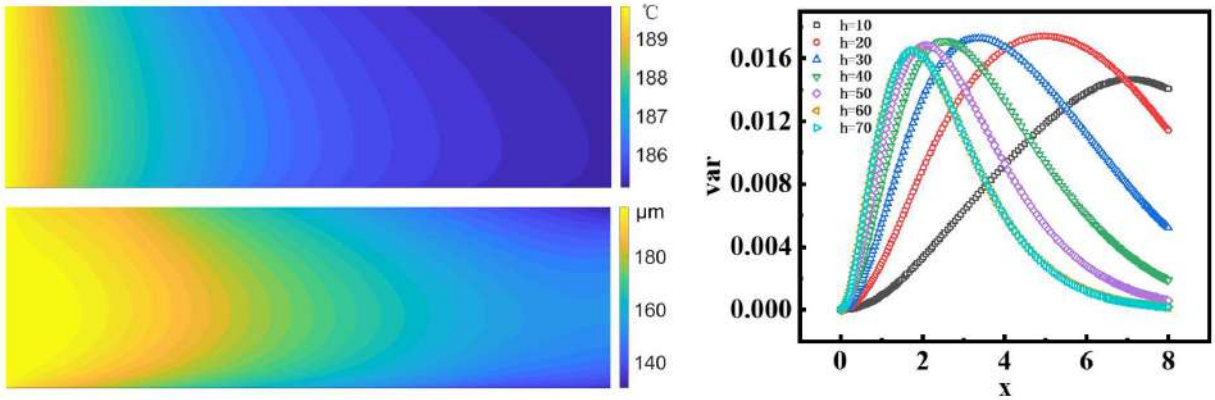
*Corresponding author. E-mail: mnzh@mail.ustc.edu.cn

Result

Taking the parameters and proper boundary conditions above-mentioned, the final result obtained after iterations. Fig.2(a) illustrates the distribution of the temperature and thickness. The temperature drops from the initial 190 ℃ to the ambient temperature 185 ℃ gradually. The thickness uniformity is particularly important for the optical film, from the contour, the thickness distribution appears the “bowing” phenomenon as the result of processing methods (stretching site is located on both sides). Further analysis shows that there is always a couping effect of the physical field (kinematic field, temperature field) in the oblique stretching process.

The variance of the temperature along the width-direction is plotted, as can be seen in Fig.2(b) with the change of heat transfer coefficient (HTC). Every point of the curve in Fig.2(b) represents the variance of the temperature distribution along the width direction. There always be a period in the curve showing an upward trend, on account that the initial temperature is not the same as the ambient temperature. After reaching the peak value, the variance will decline, the location of the peak value and the degree of the decline depend on the HTC as the result. The larger HTC is, the location of the peak value happens early and the reduction gets greater, which means that the variance of temperature becomes small at the end of oblique stretching. But there is no obvious distinction among the variety of HTC. The thickness variance keeps the same trend, it goes up and steadily and then goes up again. The unevenness of the thickness is always rising because the stretching is kept going during the whole process.



(a) (b)

Figure 2. (a) Contours of temperature and thickness (b) The variance of thickness as heat transfer coefficient changes

The theoretical analysis and numerical implementation are present in this work and the result based on that is discussed briefly at the end. The stretching in the direction of width meanwhile will be considered and more accurate and efficient algorithms will be developed in future work.

Summary We experimentally and theoretically investigate the drying process on flat thin films spread from aqueous solutions of surfactants. The stability of these films is observed to be strongly dependant of the evaporation rate, the film thickness and the surfactant adsorption kinetics. A consistent mechanism based on an evaporation-induced Marangoni instability is suggested and the results are rationalised with a theoretical model and numerical simulations using the Navier-Stokes solver Basilisk.

INTRODUCTION

Wet film deposition is a key process in metallurgy, plastic or glazing industry as it is a quick and efficient way to functionalise large surfaces. Regarding environmental and economical stakes, achieving thin and homogeneous waterborne coatings on glazing is a major challenge. Although attractive, the development of such coatings is still limited by the apparition of defects in the liquid film during the drying step. Yet, in extended flat films Marangoni flows, induced by surface tension gradients, can result in defects in the thin film [1] or film dewetting [2]. In this talk, we tackle how the coupling of solvent evaporation and surfactant adsorption at the surface can induce Marangoni flows and hydrodynamic instabilities in drying flat films. The influence of the coating conditions (evaporation rate, initial thickness, viscosity) and the surfactant adsorption dynamics over the film stability are questioned.

MATERIALS AND METHODS

An automatic blade coater is used to deposit a liquid film of an aqueous solution of surfactant on a horizontal glass plate ($30\ cm3x330\ cm$) laid on a backlight. The initial coating thickness is controlled by adjusting the blade height within the range $[20\ \mu m,\ 150\ \mu m]$. The setup is placed within a hermetic box for controlling relative humidity between 20 % and 90 %.
The drying behaviour of the film is monitored with a camera positioned above the film. To measure and map the film thickness over time, we use the light adsorption method [3]. Nigrosin dye is added to the solution at a concentration of $1\ g.L^{-1}$. This inert dye matches with the Beer-Lambert law of adsorption for a wide range of adsorption. Thus, thickness is calculated from the light adsorption through the film height. As a regular pattern seems to develop on the film, the thickness map is numerically studied to extract the emergent wavelength and the amplitude of the thickness variations.
Most experiments are conducted with sodium dodecyl sulfate (SDS) at a concentration of 82 mM. Critical micelle concentration (CMC) and surfactant adsorption dynamics are studied with a tensiometer, using the pendant droplet method.

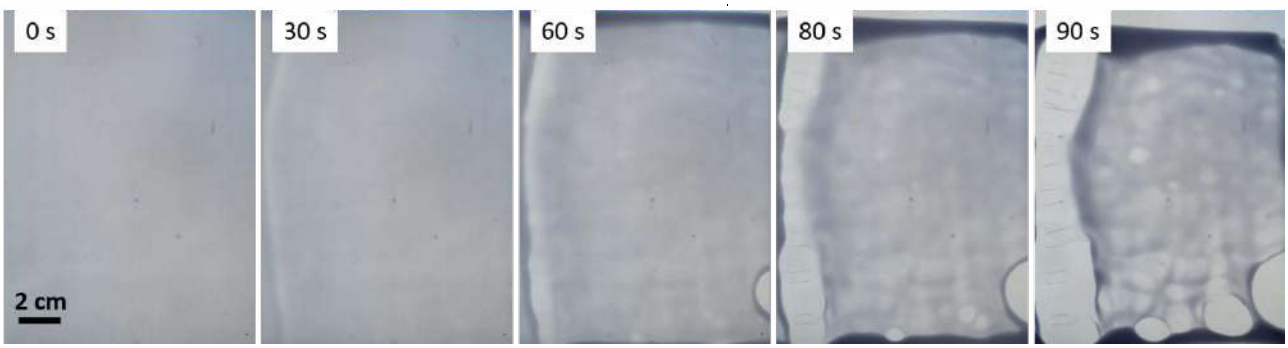

Figure 1. Snapshots of a liquid film of an aqueous solution of SDS (82 mM) that is drying under a relative humidity of 30%. A die is added for observation. An instability develops in the film with an emergent wavelength of the order of the centimetre.

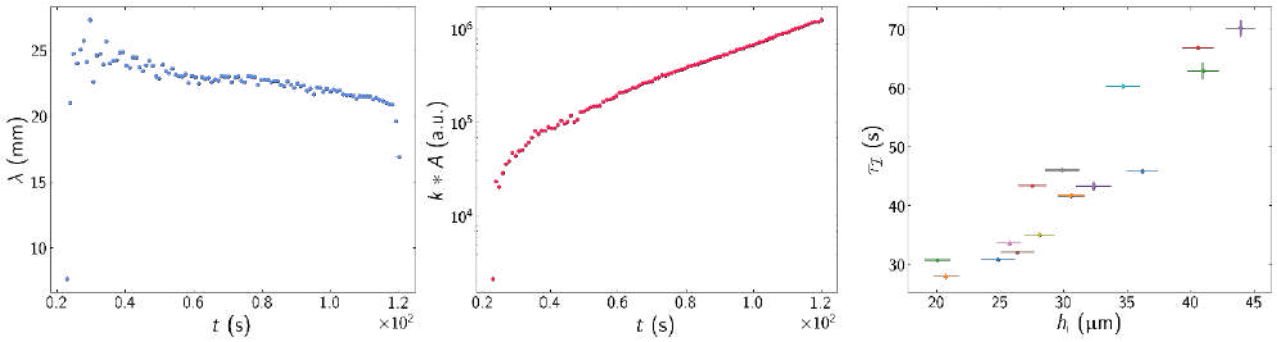
RESULTS & DISCUSSIONS

*Clément Robert. E-mail: clement.robert@m4x.org

As shown in Figure 1, under strong evaporation rate (30% relative humidity), a thin film of an aqueous solution of SDS is unstable. We can observe two phenomena: the development of instability patterns at the surface of the film, leading to hole nucleation, and the receding of the frontline. In the following, we consider the central part of the film (away from the receding frontline).
By a numerical analysis, these patterns may be associated to a characteristic wavelength and an amplitude over time. The characteristic wavelength of the thickness fluctuation in the film remains quite constant over time (Fig 2a.) while the amplitude increases exponentially (Fig 2b.). The exponential growth at constant wavelength is characteristic of the linear regime of an instability. This is studied for different experimental conditions (evaporation rate, initial thickness, viscosity or surfactant concentration) and for surfactants with different adsorption dynamics.
This instability is triggered by solvent evaporation and surface tension gradients. Indeed, liquid films in a humid atmosphere (90% relative humidity), i.e. with a very low evaporation rate, are completely stable and neither instability nor front receding are observed. Likewise, aqueous film without surfactants are quite stable on glass.



(a) (b) (c)

Figure 2. (a) Wavelength and (b) amplitude along time of the perturbations a drying liquid film of an aqueous solution of SDS. (c) Characteristic time of the instability depending on the initial thickness of the wet film of SDS.

To explore the influence of the thickness on the instability, we spread liquid films at different initial thickness. For each experiment, a characteristic time τ_i can be determined from the amplitude exponential growth. In figure 2c., the characteristic time of the instability is plotted against the initial thickness of the wet film in the corresponding experiment. A growing trend is observed: the thinner the initial film, the quicker the instability develops.
The role of the surface adsorption dynamics of the surfactant in the stability was also studied by deposit solutions containing different surfactants. Solutions of anionic surfactants with a very low adsorption barrier (i.e. with a quasi-immediate adsorption), such as SDS, are unstable. However, surfactants with slow adsorption dynamics, due to energy barriers (cinematically-limited adsorption), appears to be stable when deposit under evaporation. The adsorption dynamics seems then to be crucial in this instability.

CONCLUSIONS

An experimental study of drying aqueous thin films of surfactants brings out an instability responsible of the film destabilisation by amplification of natural perturbations. Our experiments highlights that the coupling of evaporation and surface tension gradients is the driving force of this instability. Besides, a larger thickness of the film or a slow adsorption dynamics are stabilizing parameters in those film.
These observations lead us to propose a mechanism relaying on an evaporation-induced Marangoni instability. Solvent evaporation in a thin film leads to an increasing solute concentration. When the film is perturbed, surfactant concentration increases stronger in the thinner areas of the film than in the thicker areas. If surfactants adsorb quick enough, these bulk concentration gradients result in surface concentrations gradients and thus in surface tension gradients. These induces Marangoni flows and trigger the liquid from thinner areas to thicker areas, hence amplifying the perturbations until hole nucleation.
For a broader comprehension, this phenomenon is rationalised through a theoretical model and with numerical simulations using the Navier-Stokes solver Basilisk [4-5] and a multilayer description [6].

VERY-LARGE-SCALE MOTIONS AND DUST CONCENTRATION STRUCTURES IN ATMOSPHERIC BOUNDAR YLAYER

Xiaojing Zheng*[1,2] and Wei Zhu[2]
[1]Research Center for Applied Mechanics, Xidian University, Xi'An, 710071, China
[2]College of Civil Engineering and Mechanics, Lanzhou University, Lanzhou, 730000, China

Summary In this paper, concentrations of PM10 particles with size less than 10 μm and three-component wind velocities are measured synchrounously at various heights by the Qingtu Lake Observation Array (QLOA). Two-point correlation analysis reveal the existence of very-large-scale motions (VLSMs) in the flow fields of the sand-laden flows, and for the first time point out that the PM10 concentration fields also have similar organized structures as the turbulent structures in the flow fields. Through comparing the VLSMs in the flow fields of clean-air and sand-laden flows as well as the structures of PM10 concentration fields from the perspective of streamwise length scales, inclination angles, turbulent kinetic energy and their distributions, the relations and differences of the three types of structures are discussed.

INTRODUCTION

Previous studies on the high-Reynolds-number turbulent flows in the ASL have revealed the existence of the very large scale motions (VLSMs) whose streamwise scales are larger than 3 times the thickness of the boundary layer (δ) [1,2]. Till now, it has been widely accepted that VLSMs contribute more than 50% of the turbulent kinetic energy and Reynolds stress, and have a significant modulation effect on small-scale structures [3,4], which consequently play dominating roles in dust transport [5,6]. In addition, it is found that the structure is at an oblique angle to the free stream [7], and the inclination angles of VLSMs decrease linearly with the increase of the friction wind velocity [8]. However, there have been rare reports up to date concerning the morphological characteristics and energy contribution of VLSMs in sand-laden flows in the ASL, and it has been not clear whether there exist organized structures of particle concentration in sand-laden flows or not. Answer to this question may provide an insight to the mechanism of dust transport with respect to the effect of VLSMs in the ASL.

EXPERIMENTAL SETUP AND DATA PROCESSING

The field measurements were conducted at the Qingtu Lake Observation Array (QLOA) site. The experimental facility and QLOA site were introduced in details in Ref [2]. For wind-velocity measurements, 11 sonic anemometers were installed on the main tower (from 0.9 m to 30 m), with a sampling frequency of 50 Hz. For PM10 concentration measurements, 11 aerosol monitors were installed on the main tower at the same heights as the sonic anemometers and recorded with a frequency of 1 Hz. The sonic anemometers and aerosol monitors were linked by acquisition instruments, which were synchronized in time by the Global Positioning System (GPS). The selection and pretreatment on the raw velocity data are consistent with that in Ref [2], including stratification stability judgement, wind direction adjustment, de-trending manipulation and steady wind selection.

RESULTS AND DISCUSSIONS

Figure 1 illustrates the two-point correlation contours of streamwise fluctuations and PM10 concentrations in the sand-laden flow fields. The black solid line in Figure 1a is the isoline with a correlation coefficient of 0.05. From the positive correlation regions in Figures 1a and 1b, we can clearly identify coherent structures with streamwise scale larger than 3δ in both sand-laden flow fields and PM10 concentration fields, and the two types of structures both present obvious inclination angles to the streamwise direction.

Further, we conducted statistical analysis on the morphological characteristics of VLSMs in sand-laden flow fields and dust concentration structures, including their streamwise scales and inclination angles. Figure 2a shows the variations of the average streamwise scales of the VLSMs respectively in clean-air and sand-laden flow fields and those of dust concentration structures with height. Here the Taylor's frozen hypothesis is used and assuming that the dust particles have the same velocities as the convectional velocities of the local surrounding flow fields. It can be seen that both the streamwise scales of the VLSMs in clean-air and particle-laden flow fields increase with height, while the scales of the PM10 concentration structures are larger than 3δ in our measured region, which are larger than the scales of VLSMs below 14m and basically do not vary with the height; For the region above 14m, the streamwise scales of the three types of structures are statistically equal and all increase with height. Such difference and similarity may come from a combinational effect of surface shear and particles' intertia. The former reduces the energy of low-frequency

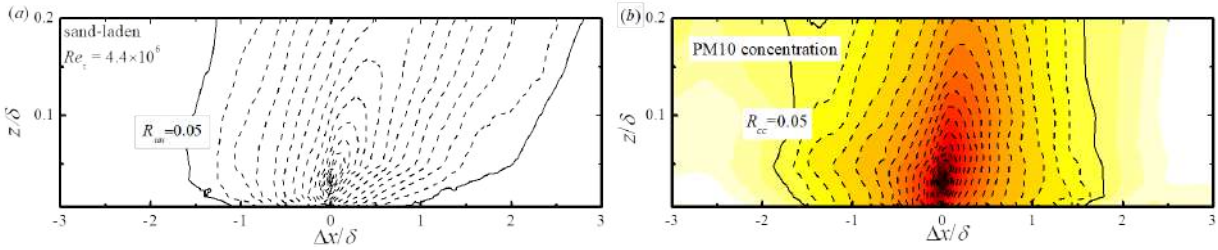

Figure 1: Two-point correlation contours of (a) the steamwise velocity and (b) PM10 concentration fluctuations at z_{ref}=5m and Re_τ=4.4 × 10^6.

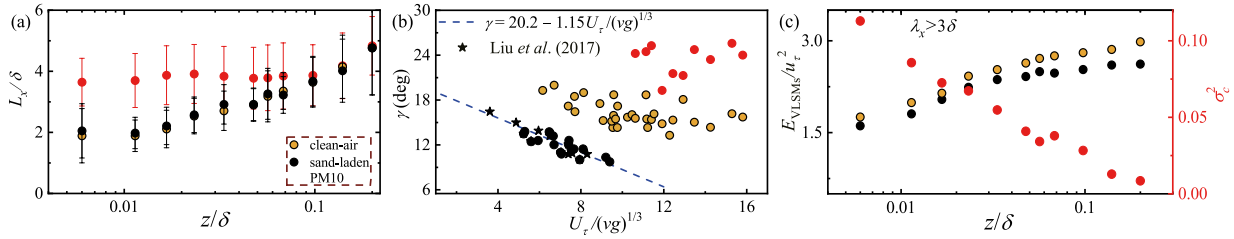

Figure 2: Variations of (a) the streamwise scales (a) the inclination angles and (c) the fluctuation energy of VLSMs and PM10 concentration structures with z/δ and u_τ.

fluctuations (large-scale structures in flow fields) while the latter attenuates the response of PM10 structures to the high-frequency fluctuations of flow fields near surface. In addition, Figure 2b shows that the inclination angles of VLSMs in the sand-laden flows increase with the sand flux and are larger than those in the clean-air flows, which both decrease with the frictional wind velocity u_τ. This is because the angles of VLSMs and PM10 structures are dominated by different factors, the former by the streamwise wind velocity gradient, while the latter by the coherence of the wall-normal wind fluctuations. Besides, Figure 2c shows the comprisons of the energy of the VLSMs in the clean-air and sand-laden flow fields and that of PM10 concentration structures varying with height. It can be found that in both clean-air and sand-laden flow fields, the energy of VLSMs increase with the height, while the energy of PM10 concentration fluctuations presents a decreasing trend with height. For the increase of the energy of VLSMs, it can be explained by the input of the external energy in ASL, in other words, the 'top-down' mechanism. However, the PM10 particles are released from the land surface and the strength of the concentration fluctuations decrease with the height, which make the energy of PM10 concentration structures decrease with height.

CONCLUSIONS

Based on the field measurements of high-Reynolds-number turbulent flows in ASL with dust entrainment, we found the existence of the super-large-scale (>3δ) structures of PM10 concentration fields. The inclination angles of the PM10 structures are larger than that of the VLSMs in flow fields, and the streamwise scales of PM10 structures do not vary with the height and are larger than that of the VLSMs at the lower height. The fluctuation energy of PM10 structures decrease with height, which is qualitatively different from the varying trend of the engergy of VLSMs in the flow fields.

ON THE GROWTH OF BARCHAN DUNES

Carlos A. Alvarez[1] and Erick M. Franklin*[1]
[1]School of Mechanical Engineering, UNICAMP - University of Campinas, Campinas, Brazil

Summary Barchans are crescent-shaped dunes, with horns pointing downstream, that are found in different environments. We investigate experimentally the formation of subaqueous barchans. Controlled grains were poured in a channel filled with water, forming a conical pile. Afterward, a turbulent water flow was imposed, entraining the grains and forming a single barchan while a high-speed camera recorded the bedform evolution. We show that most of the grains migrating to horns come from upstream regions on the periphery of the dune. These results diverge from the generally accepted description that the barchan horns are formed from the advance of the lateral flanks of the bedform. Our results reveal a new mechanism for barchan formation, valid, at least, for the subaqueous case. A great part of what is presented here can be found in Phys. Rev. Lett. 121, 164503 and Phys. Rev. E 100, 042904

INTRODUCTION

The growth and migration of sand dunes result from the interaction between a fluid flow and a granular bed, when, under moderate shear stresses, grains are entrained by the fluid as a moving layer. This mode of transport is called bedload. Under one-directional flow conditions, crescent-shaped dunes with horns pointing downstream, known as barchan dunes, usually appear. Barchan dunes can be found in environments as different as rivers, Earth's deserts and on the surface of Mars, for example. However, despite being similar in shape, their scales vary from the centimeter and minute under water [1, 2, 3, 4], to the kilometer and millennium on Mars [5]. Because of their smaller length and time scales, subaqueous barchans are the ideal object to study the growth and migration of barchan dunes.

Although frequently found in nature, some aspects of the morphodynamics of barchans are still not fully understood. One of them concerns the trajectories of individual grains over the bedform, and how they affect its shape, inducing the growth and maintenance of barchans. This study investigates experimentally the formation and evolution of subaqueous barchans.

EXPERIMENTAL SETUP

The experimental device consisted of a water reservoir, two centrifugal pumps, a 5-m-long closed-conduit channel, a settling tank, and a return line. The channel was made of transparent material (acrylic) and had a rectangular cross section 160 mm wide by 50 mm high (2δ = 50 mm). The test section started at 3 m (40 hydraulic diameters) downstream the channel entrance, assuring that the water flow was fully developed in the test section. A high-speed camera of complementary metal-oxide-semiconductor type (CMOS) with a spatial resolution of 1280 px $\times$ 1024 px at frequencies up to 1000 Hz was placed above the channel to record the bed evolution. Figure 1(a) shows a photograph of the test section arrangement.

Prior to each test, controlled grains were poured in the test section (previously filled with water), forming a single conical pile at the bottom wall. We used round glass beads (density of grains ρ_s = 2500 kg/m^3 and bulk density of 1500 kg/m^3) with diameters of 0.15 mm $\leq d \leq$ 0.25 mm and 0.40 mm $\leq d \leq$ 0.60 mm, where 2% of them had a different color (but same density and diameter) and were used as tracers. Afterward, a turbulent water flow was imposed, entraining the grains and forming a single barchan while a high-speed camera recorded the bedform evolution. The cross-sectional mean velocities of water U were 0.243, 0.294 and 0.364 m/s, corresponding to Reynolds numbers based on the channel height $Re = \rho U 2\delta/\mu$ of 1.21×10^4, 1.47×10^4 and 1.82×10^4, respectively, where ρ is the fluid density and μ its dynamic viscosity. With this procedure, each experiment concerned one single barchan that loosed grains by its horns, decreasing slowly in size while migrating. By using an image processing code written in the course of this work, the centroids of the tracers and of the barchans were identified, and the trajectories of tracers were computed using particle tracking velocimetry (PTV). Figure 1(b) shows some pathlines of tracers over a developed barchan made of 0.40 mm $\leq d \leq$ 0.60 mm glass beads superposed with a photograph of the barchan dune.

MAIN RESULTS

Figure 1(c) shows the trajectories of some tracers that migrated to horns during the growth of a barchan dune (some movies are available on Ref. [6]), where pathlines are blue at the pile initial position and red at the barchan final position. We observe that a large part of grains migrating to horns was originally in upstream regions on the periphery of the dune, and that their path is described approximately by an arc of circumference with, therefore, significant transverse displacements. Numerical computations using CFD-DEM (computational fluid dynamics - discrete element method) reproduced well these experimental findings [7]. Our results show that most of grains migrating to horns of subaqueous barchans do not come from the lateral flanks of the initial heap or dune, as usually assumed in the aeolian case, providing then a new picture for the growth of subaqueous barchans.

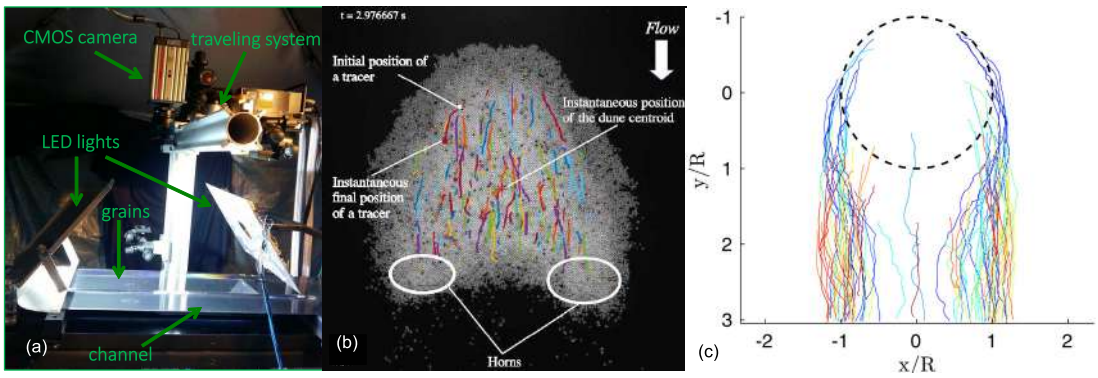

Figure 1: (a) Photograph of the test section; (b) pathlines of tracers over a developed barchan; (c) Trajectories of some tracers that migrated to horns during the growth of a barchan dune, where R is the radius of the initial pile. Adapted from Refs. [1, 2].

CONCLUSIONS

We have shown that most of the grains migrating to horns came from upstream regions on the periphery of the dune, with significant transverse displacements. These results diverge from the generally accepted description that the barchan horns are formed from the advance of the lateral flanks of the bedform. Our results reveal a new mechanism for barchan formation, valid, at least, for the subaqueous case.

IMPULSIVE FORCES FROM SHEARING: NON-EQUILIBRIUM MECHANICS OF DILATANCY IN GRANULAR SNOW AVALANCHES

Othmar Buser and Perry Bartelt*
WSL Institute for Snow and Avalanche Research, SLF, Davos, Switzerland

Summary Snow avalanches represent an important class of granular flows that find a true mechanical equilibrium only under exceptional conditions. For the most part avalanches flow outside the equilibrium state. In the following we find the slope-perpendicular, impulsive forces associated with terrain steepness and roughness that change the flow density of the avalanche. These forces are responsible for the attainment of equilibrium and therefore, in the end, avalanche speed, flow height and runout. Because we consider the acceleration of the center-of-mass of a flowing ensemble of snow particles in the slope-perpendicular direction, the approach can be classified as a computationally reduced, mixed Eulerian-Lagrangian calculation method. Moreover, we adopt a macroscopic approach that can be implemented within the framework of existing shallow-water-type avalanche dynamics models.

INTRODUCTION

The very word *avalanche* invokes a physical system which is mechanically out-of-balance. This impression is nowhere more apparent than when watching snow avalanches descend steep mountain slopes (Fig. 1). The front of the avalanche appears to explode upwards. Plumes of snow particles and ice-dust are pulsed into the air. The particles and dust reach heights of 50m in fractions of a second, indicating large slope-perpendicular accelerations [1]. The heights reached by the powder clouds is all the more perplexing because the upward moving mixture of snow particles and ice-dust must be accelerated *against* gravity and overcome the forces of air-drag.

The mechanical source of the upward movement was identified by Reynolds [2] as early as 1885. Reynolds maintained that a sheared granular ensemble must dilate (expand). In snow avalanches, these dilations are extreme. The high-rate of shearing, caused by the flow of snow particles over rough, steep terrain, leads not only to large slope-perpendicular accelerations, but also to *overshoots*; that is, the amount of energy introduced by shearing in the slope-perpendicular direction is more than needed to maintain the static equilibrium of the ensemble. This idea requires mathematical clarification.

SLOPE-PERPENDICULAR ACCELERATIONS AND GRANULAR DILATANCY

We consider a column of snow particles in the avalanche (Fig. 1). The height of the column h is given by the z-position of the granule located farthest from the running surface (the highest particle in the column). The total mass of the column of particles is M. It is possible to find the z-location of the center-of-mass of the column, which we denote k. The distance k is to be considered a Lagrangian variable that will be transported with the avalanche velocity in the slope parallel direction. Let E represent the potential energy of a granular column which is related to the sum of the force of gravity Mg_z and the inertial force $M\ddot{k}$,

$$E = Fk = M(g_z + \ddot{k})k. \tag{1}$$

The gravity g_z acts in the slope-perpendicular z-direction. The reaction to this force N acts on the ground. The reaction therefore consists of the hydrostatic component Mg_z and the dynamic part $M\ddot{k}$ associated with the acceleration of the center-of-mass $\ddot{k}$. The rate of change of the potential energy is then

$$\dot{E} = \dot{F}k + F\dot{k} = M\dddot{k}k + M\left(g_z + \ddot{k}\right)\dot{k}. \tag{2}$$

Here we adopt the ideas of Reynolds and say that the γ fraction of the shear work $\dot{W}$ is used to change the potential energy of the column, $\dot{E} = \gamma\dot{W}$. Therefore,

$$M\left[\dddot{k}k + \left(g_z + \ddot{k}\right)\dot{k}\right] = \gamma\dot{W}. \tag{3}$$

The third-order equation implies the column ensemble will experience overshoots and, if undamped, will obtain an dynamic, oscillating equilibrium. More importantly, however, is the fact that the state of the column is strongly dependent on the "input" function, $\dot{W}$. Because of the changing terrain and roughness, the work function $\dot{W}$ will continually place the snow avalanche outside equilibrium. A static equilibrium will only be obtained after a certain time when the dynamic oscillations are damped, and the $\dot{W}$ input function disappears, for example on smooth, flat slopes. This energy must be some part of the random kinetic energy (granular temperature) which has movements in the slope-perpendicular z-direction. This approach is explained in detail in [3].

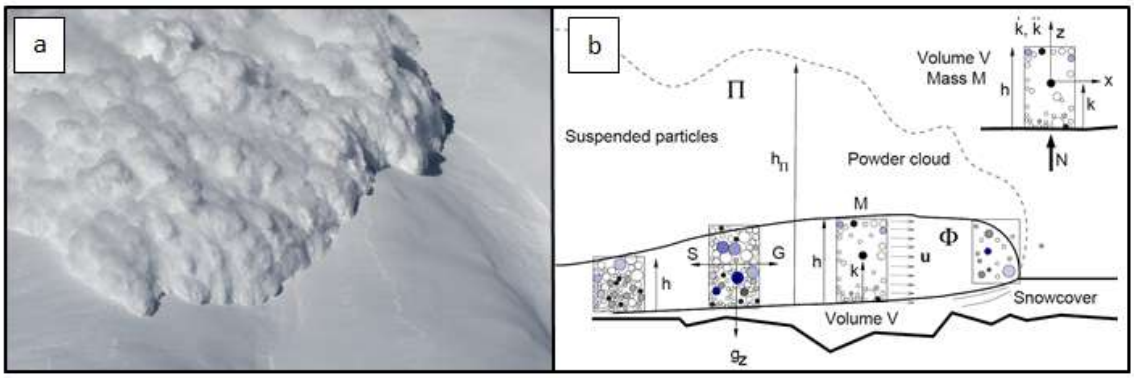

Figure 1: a: The front of a mixed flowing/powder snow avalanche. Behind the cloud Π of ice dust, there is a granular core Φ. The height of the cloud is between 20m and 30m. b: Column model. The avalanche core Φ is divided into columns with mass M and volume V. The height of the column is h, the center-of-mass is located at k. The center-of-mass moves with velocity $\dot{k}$ and $\ddot{k}$.

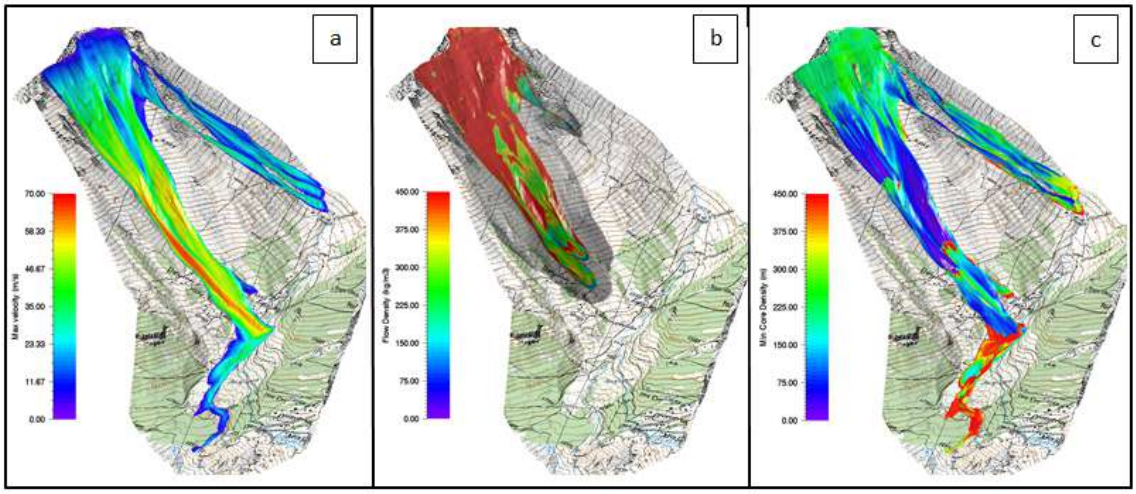

Figure 2: Calculation of the 25.2.1999 Vallée de la Sionne avalanche. a) Calculated flow velocity. d) Flow density of the avalanche core. The front is fluidized, the tail of the avalanche is dense. The location of the cloud is depicted in transparent grey. c) Minimum calculated flow density of the avalanche core.

NUMERICAL RESULTS

We introduced Eq. 3 into a depth-averaged avalanche dynamics program [4]. This was accomplished by breaking the third-order equation down into a system of three-first order equations for k, $\dot{k}$ and $\ddot{k}$. We used the model to simulate a large mixed flowing/powder avalanche measured recorded at the Swiss Vallée de la Sionne test site (Figure 2). The calculated avalanche velocities are in good agreement with measurements. However, the most important improvement of over existing calculations is the prediction of the avalanche flow densities and the formation of the avalanche cloud. The avalanche front is highly fluidized (front density of 100kg/m^3, tail density of 400kg/m^3.) At the end of the event the avalanche transformed into a completely dense flow (lubricated by meltwater). The observed and calculated runout distances are in good agreement.

CONCLUSIONS

Slope-perpendicular accelerations are produced by shear work in the avalanche core. These accelerations dilate the avalanche flow body (fluidization) producing low density flows with extreme runout distances.

PHASE TRANSITION OF ENERGY TRANSFER IN NEAR-INERTIAL WAVE–VORTEX INTERACTING TURBULENCE

Jin-Han Xie*[1]
[1]Department of Mechanics and Engineering Science at College of Engineering, State key laboratory for turbulence and complex systems and Beijing Innovation Center for Engineering Science and Advanced Technology, Peking University, Beijing, 100871, PR China

Summary The energy budget of the oceanic mesoscale eddies remains an unsolved problem where the known energy injection is much larger than the discovered energy dissipation. By studying a near-inertial wave–mesoscale eddy coupled model, this work proposes a new mechanism that in the turbulent states wave-vortex interaction induces a downscale energy transfer and finally a small-scale dissipation at the ocean interior. The existence of this new energy path is understood as the emergence of phase transition of changing energy transfer direction in the spectral space. This phase transition is justified and studied in details using forced-dissipative numerical simulations.

INTRODUCTION

The mesoscale eddy, which has horizontal scale from one to hundreds of kilometers, contains a significant part of the ocean energy, however, its energy budget remains not well understood: wind forcing and large-scale circulations injection energy into the mesoscale eddies, and the mesoscale eddies dissipate at the boundaries and be converted to other types of motions, but the known amount of energy injection is much larger than that of the energy dissipation [1, 2]. Several candidates are thought to be responsible for the mesoscale eddy energy closure, such as loss of balance [3] and stimulated wave generation [4].

Another energy reservoir in the ocean is the near-inertial waves (NIWs) which contain around 50% of the wave energy. There are a variety of mechanisms potentially explaining that NIWs can extract energy from balanced flow, and they have been studied in various setups and parameter regimes. Gertz and Straub [5] run numerical simulations in a periodic box with O(1) Rossby number and find that the energy transfer between 2D and 3D motions is crucial. Also with O(1) Rossby number, [6] considers a channel flow with forcing on both low and high frequencies, they find that the Reynolds stresses of NIW act as a kinetic energy sink for mesoscale motions. In [7], numerical simulations in a channel flow with external forcing find the direct extraction dominates while the mechanism of stimulated NIW generation is of subdominant. NIW is also found to absorb mean flow energy in the frontogenesis [8]. In this paper, using the two-dimensional NIW–mesoscale eddy coupled model [4] we study the turbulent wave-vortex interaction and find a new mechanism that the NIW induces downscale energy transfer, and finally the energy dissipates at the interior.

The bidirectional energy transfer has been observed in numerical simulations of the rotating stratified turbulence, which is a key feature of the atmospheric and oceanic flows, e.g. [9]. However, the mechanism for bidirectional energy transfer is less understood. This work on the reduced model of NIW-eddy turbulent interaction uses a simple setup to provide a phase-transition explanation to the wave-induced bidirectional energy transfer.

MODEL

We consider forced dissipative system of the NIW-eddy interaction with single-vertical-mode waves [4]

$$M_t + \mathcal{J}(\psi, M) - \frac{\mathrm{i}N^2}{2m^2 f}\nabla^2 M + \frac{\mathrm{i}}{2}M\nabla^2\psi = F_M + D_M, \tag{1a}$$

$$q_t + \mathcal{J}(\psi, q) = F_q + D_q, \tag{1b}$$

$$\text{with} \quad q = \nabla^2\psi + \frac{\mathrm{i}f}{2}\mathcal{J}(M^*, M) + \frac{f}{4}\nabla^2|M|^2, \tag{1c}$$

where M is the complex wave amplitude such that $u + \mathrm{i}v = -\mathrm{i}fM\mathrm{e}^{-\mathrm{i}ft+\mathrm{i}mz}$ with u and v the two horizontal velocities, $\mathcal{J}$ denotes the Jacobian, N is the Brunt-Väisälä (buoyancy) frequency, m is the vertical wavenumber of the NIW, f is the Coriolis frequency, ψ is the stream function of the quasigeostrophic mean flow corresponding to the eddies. F_M and F_q are random forces acting on the wave and mean fields, respectively, and we define a parameter R such that the energy injection ratio between the wave and mean fields is R^2. D_M and D_q are dissipations of the wave and mean fields, respectively, where both large- and small-scale dissipations are included.

*Corresponding author. E-mail: jinhanxie@pku.edu.cn

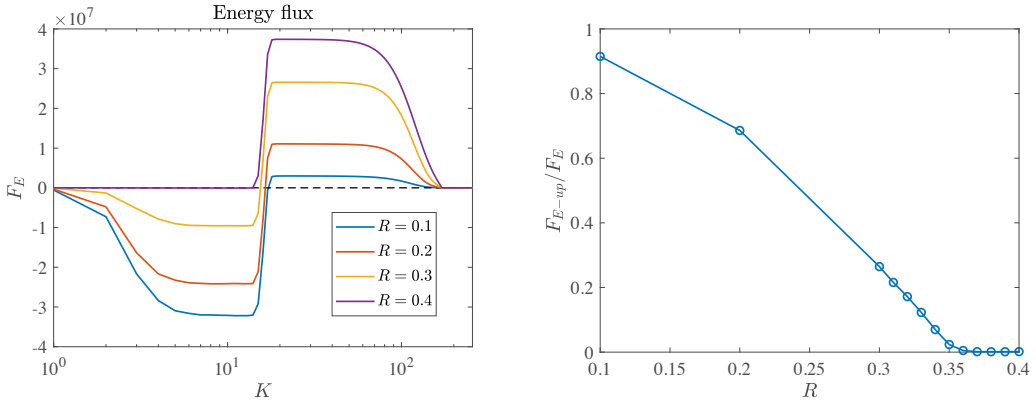

Figure 1: The left panel shows the dependence of total energy flux on parameter R. Negative and positive values of F_E represent upscale and downscale energy transfers, respectively. The black dashed line is 0 for reference. The right panel shows the dependence of the upscale flux ratio on the parameter R.

NUMERICAL RESULTS

We run numerical simulations of the coupled system (1) with different energy injection ratio R^2 and examine the energy transfer scenario of the coupled model. The numerical simulations use a Fourier pseudospectral method with 2/3 dealiasing in space, a resolution 512×512 in a domain of size $2\pi \times 2\pi$ and a fourth-order explicit Runge–Kutta scheme in time, in which the nonlinear terms are treated explicitly, and linear terms implicitly use an integrating factor method. We take the forcing wavenumber to be $k_f = 32$ for both wave and eddy forcings. The large- and small-scale dissipation wavenumbers are designed to be $k_{large} \approx 0.4$ and $k_{small} \approx 100$, respectively.

In figure 1, the left panel shows the dependence of total energy flux in the spectral space on parameter R. As R increases, energy first transfers upscale, then bidirectionally and finally downscale. The right panel of figure 1 shows the dependence of upscale energy flux ratio F_{E-up}/F_E on R, where F_{E-up} and F_E are the magnitudes of the upscale and total energy transfer, respectively. As R increases from zero, the upscale energy flux ratio decreases and reaches zero at a critical value $R \approx 0.36$, implying a second-order phase transition for the direction of energy transfer.

SUMMARY AND DISCUSSION

We run numerical simulations of the NIW-eddy coupled model to study the dependence of energy transfer on the ratio of the energy injection into the wave and vortex components. We find a phase transition of the direction of energy transfer: when the injection of the wave energy is weak, the energy transfers upscale, while when the injection of wave energy is strong, the energy transfers downscale; with intermediate wave energy injection the energy transfers bidirectionally. The transition from the bidirectional energy transfer and the downscale energy transfer shows a second-order phase transition.

The existence of turbulent states with bidirectionally energy transfer is a candidate for explaining the mesoscale energy puzzle: when the effect of (near-inertial) waves is not negligible, energy can transfer to downscales and finally dissipate at the ocean interior. Moreover, we propose that the strength of downscale energy transfer depend on the portion of the wave energy injection. Compared with the previous mechanism of wave absorption of the mean-flow energy (e.g. [3, 4]), this work focuses on the more realistic energy transfer in turbulent states. Three-dimensional numerical simulations are demanded in the future to justify the existence of the new mechanism in the real ocean.

THE BOUNDARY ZONAL FLOW (BZF) AND ITS IMPORTANCE FOR THE HEAT TRANSPORT IN ROTATING THERMAL CONVECTION

Summary For rapidly rotating turbulent Rayleigh–Bénard convection in a slender cylindrical cell, experiments and direct numerical simulations reveal a boundary zonal flow (BZF) that replaces the classical large-scale circulation for the non-rotating case. The BZF is located near the vertical side wall and enables enhanced heat transport there. Although the azimuthal velocity of the BZF is cyclonic (in the rotating frame), the temperature is an anticyclonic traveling wave of mode one whose signature is a bimodal temperature distribution near the radial boundary. The BZF width is found to scale closely as $\delta_{BZF} \propto Ra^{1/4}Ek^{2/3}$ where the Ekman number Ek decreases with increasing rotation rate.

Turbulent convection, where a fluid is driven by a thermal gradient is one of the most important mechanisms for the transport of heat in astro- and geophysical systems, but also plays a crucial role in many industrial applications. In particular in natural systems such as the Earths atmosphere or the convection zone in stars, the flow is not only highly turbulent but also strongly influenced by the rotation of their celestial body due to Coriolis forces. In the laboratory and in numerical simulations, thermal convection is usually studied in the Rayleigh-Bénard setup, where a horizontal fluid layer is confined by a warm plate at the bottom and a cold plate at the top and confined laterally by adiabatic sidewalls [1]. Under Oberbeck-Boussinesq-conditions, i.e., homogeneous fluid properties, this system is governed by only two dimensionless control parameters: the Rayleigh number ($Ra = \alpha g \Delta H^3/(\kappa\nu)$) and the Prandtl number ($Pr = \nu/\kappa$). Here α, ν, and κ denote the thermal expansion coefficient, the kinematic viscosity, and the thermal diffusivity, respectively. Furthermore, g is the gravity and Δ the temperature difference between the bottom and the top. The main integral response parameters that is considered is the Nusselt number $Nu \equiv \langle \mathcal{F}_z \rangle_{t,V}$, where $\langle\cdot\rangle_{t,V}$ denotes the time- and volume-averaging and $\mathcal{F}_z \equiv (u_z(T - T_0) - \kappa\partial_z T)/(\kappa\Delta/H)$ is the normalized vertical heat flux with u_z being the vertical component of the velocity and T_0 the average of the top and bottom temperatures. Under rotation, the rotation rate Ω is incorporated in another dimensionless control parameter, the Rossby number $Ro = \sqrt{\alpha g \Delta H}\ /\ (2\Omega H)$ or, alternatively, the Ekman number $Ek = \nu/(2\Omega H^2)$.

Most studies are conducted in cylindrical systems with aspect ratios between the diameter D and the height H, $\Gamma = D/H$ close to one. When no rotation is present, the flow self-organises in such cylinders into a large-scale convection role (LSC) that spans over the entire cell height [1], and transports warm fluid from the bottom to the top along one side and cold fluid from top to bottom on the opposite side of the cylinder.

In rotating convection, the LSC breaks down and is replaced by vortical structures that are aligned in vertical direction, i.e., along the rotaion axis. The intrinsic linear scale of separation of these vortices is reduced with increasing rotation rate, suggesting that one might reduce the geometric aspect ratio, i.e., $\Gamma < 1$ while maintaining a large ratio of lateral cell size to linear scale; such convection cells are being implemented in numerous new experiments [5].

We present numerical and experimental measurements for rotating RBC in a $\Gamma = 1/2$ cylindrical cell for $Pr = 0.8$, $10^8 \leq Ra \leq 5 \times 10^{14}$, and $1/Ro < 20$. We find that under sufficiently fast rotation, an annular flow, denoted a boundary zonal flow (BZF), occurs that has profound effects on the overall flow structure and on the spatial distribution of the vertical heat flux. In particular, within the BZF the mean azimuthal velocity is positive, i.e., the flow is in cyclonic direction, while the radial core has on average negative azimuthal velocities, i.e., anticyclonic flow. Within the BZF, warm fluid rises along one side, while cold fluid sinks on the opposite sides, creating an azimuthal temperature distribution (see fig. 1a and b), which on the first glance is similar to the LSC. However, in contrast to the LSC, these temperature bands are located only in a region close to the lateral sidewall (at distance $\delta_{BZF} < 0.3R$ away from it). As shown in the space-time plots in fig. 1(a and b), while the velocity is cyclonic, the entire structure drifts in anticyclonic direction. In the experiment one can detect the BZF as two distinct maxima in the temperature probability density function (PDF) when measured sufficiently close to the sidewall at sufficiently large rotation rates ($1/Ro$), as shown in fig. 2a. This bimodality is absent in the PDF of the temperature measured in the radial bulk of the cell (fig. 2b). The heat flux inside the BZF is significantly larger than in the radial bulk, as is shown in fig. 1c.

The size of the BZF (δ_{BZF}) decreases with increasing rotation rates but increases with Ra, following $\delta_{BZF} \propto Ra^{1/4}Ek^{2/3}$. We note, that this scaling is in contrast to the expected scaling of Stewartson layers [2] and thus we believe that the mechanisms responsible for the BZF are not understood [6]. Furthermore, the robustness of the BZF state

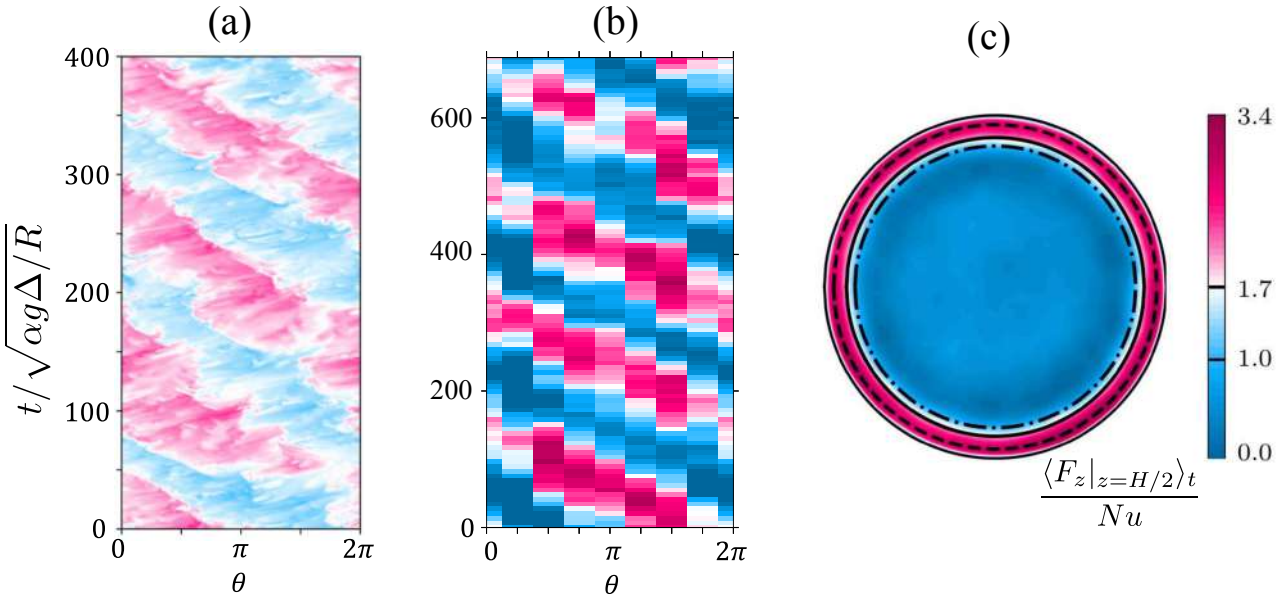

Figure 1: Temperature at the sidewall and vertical distance z=H/2 from the bottom plate as a function of azimuthal position (x-axis) and time (y-axis) in simulation (a, $Ra = 10^9$) and experiment (b, at $Ra = 5 \times 10^{13}$). Warm areas are marked in red. Cold regions are marked in blue. (c): Average heat flux at midheight ($z = H/2$) normalised with the Nusselt number. The heat flux in the BZF is significantly enhanced compared to the heat flux inside the bulk.

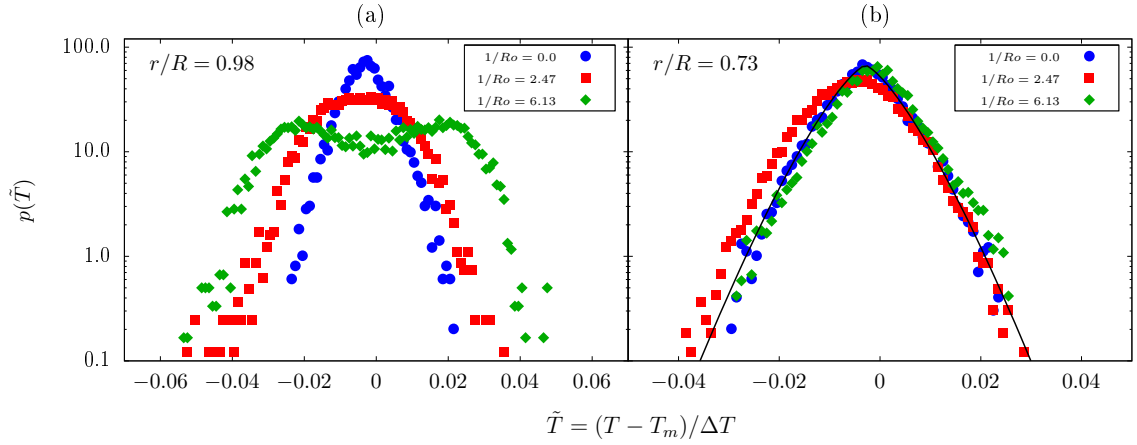

Figure 2: Probability density distribution of the reduced temperature $T - T_m/\Delta T$ at height z/L=0.49 and $Ra = 4.9 \times 10^{13}$ for radial distances from the center line $r/R = 0.98$ (a) and $r/R = 0.73$ (b) and for three different $1/Ro$.

as evidenced by its existence over 7 orders of magnitude in *Ra* in DNS and experiment and over a range $1/2 \leq \Gamma \leq 2$ and $0.1 \leq Pr \leq 4.4$ suggests that this flow structure might play a crucial role for the heat transport in rotating RBC and thus needs to be understood for generalising observations in DNS and experiments.

INITIAL STAGE OF THE LOBE-CLEFT FORMATION AT A GRAVITY CURRENT FRONT

Lin-Sen Zhang and Jian-Jun Tao *
SKLTCS, CAPT, Department of Mechanics Engineering Science, College of Engineering, Peking University, Beijing, 100871, P. R. China

Summary Different from the traditional lock-exchange setup, a rotatable apparatus is designed to study the initial stage of the three dimensional instability that leads to the formation of lobe and cleft structures at the gravity current fronts. It is shown that the measured initial dominating spanwise wavenumbers have a 1/3 scaling law with the Grashof number at moderate Grashof numbers, agreeing with the prediction of a Rayleigh-Taylor Instability (RTI) model. Furthermore, after a Schmidt number modification suggested by the RTI model, the previous results for a small Schmidt number (Härtel *et al*., J. Fluid Mech. 2000) turn to be consistent with the present experimental data with a high Schmidt number, confirming that the initial dominating spanwise wavenumber of lobe and cleft structures depends on the Schmidt number substantially.

INTRODUCTION

Gravity currents are the the flows driven by horizontal density differences, and are common phenomena occurring in nature and industrial applications, e.g. sand storm and avalanche [1]. A key feature of the current front is the lobe and cleft structures, which dominate the local transportation process. Simpson carried out pioneering experiments [2] by using saltwater and freshwater within a lock-exchange tank, and found that the thin light fluid layer beneath the front nose was necessary for the formation of lobes and clefts. Based on the stability analyses of the two-dimensional density and velocity fields obtained numerically in advance [3], the locations and the spanwise wavenumbers of the most unstable modes for different Grashof numbers (Gr) were obtained for unit Schmidt number (Sc), and it was stated that the dependence of the growth rate on Sc was weak unless Sc was very small. Recently, three dimensional numerical simulations and stability analyses revealed that the original formation mechanism of lobes and clefts is the Rayleigh-Taylor instability (RTI), and the initial dominating spanwise wavenumber can be estimated with a RTI model for given Gr and Sc without any details of the density and velocity fields [4],

$$k_{max} = \left(\frac{Gr}{2}\right)^{\frac{1}{3}} \left(\left[2(1+\frac{1}{Sc}) + \sqrt{4(1+\frac{1}{Sc})^2 - 3} \right]^2 - 1 \right)^{-\frac{1}{3}} = \left(\frac{Gr}{2}\right)^{\frac{1}{3}} \mathcal{F}(Sc). \quad (1)$$

However, it has been difficult to examine experimentally the initial linear stage of the mode evolution, because opening the lock gate or suddenly stoping the moving floor plate [2, 5] bring strong disturbances to the front interface and stimulate nonlinear evolutions, which may cause underestimate of the dominating wavenumbers [4]. Therefore, the systematic experiments on the linear stage of the three dimensional instability at the current front have been lacked so far, and this is the main motivation of the present paper.

METHODS AND RESULTS

In order to avoid the strong local disturbances caused by lifting the lock gate, rotatable tanks around their horizontal axles are constructed. The experimental procedure is as follows. The tank is placed vertically at first, then the thin plate separating the bottom denser fluid (solution of $CaCl_2$) and the upper lighter fluid (distilled water) is withdrawn. After the disturbed interface recovers to its equilibrium state, the tank is rotated to its horizontal position and the gravity current will be formed. In the experiments, we used three tanks, which have the same length (500mm) and width (150mm) but different heights h, i.e. 43.4mm, 74.2mm and 117.8mm. The Grashof number is defined as $Gr = 2gAh^3/(\nu^2)$, where g, A, and ν are the gravitational acceleration, the Atwood number, and the kinematic viscosity, respectively. The denser fluid is dyed in order to show the interface clearly, and the influence of the dye addition on the density is considered. The Schmidt number $Sc = \nu/D$ at the laboratory temperature is 833, where D is the concentration diffusivity.

The top views of the front evolution are recorded by a CCD camera mounted above the tank, and the edges of the fronts are extracted and tracked by image processing. As shown in Fig. 1 (a), the current front moves downstream (x direction) with time, and its leading edge changes from a straight line to a curve varied periodically in the spanwise (z) direction, indicating the formation of lobes and clefts. The three-dimensional instability leads to streamwise vortices, which correspond to the dark bands arranged regularly in the spanwise direction. Therefore, the rotatable tank is validated to study the linear stability of the current front at least for moderate Grashof numbers. The time series of the front leading edge are recorded as shown in Fig. 1(b) and the initial dominating spanwise wavenumber k_{max} can be determined.

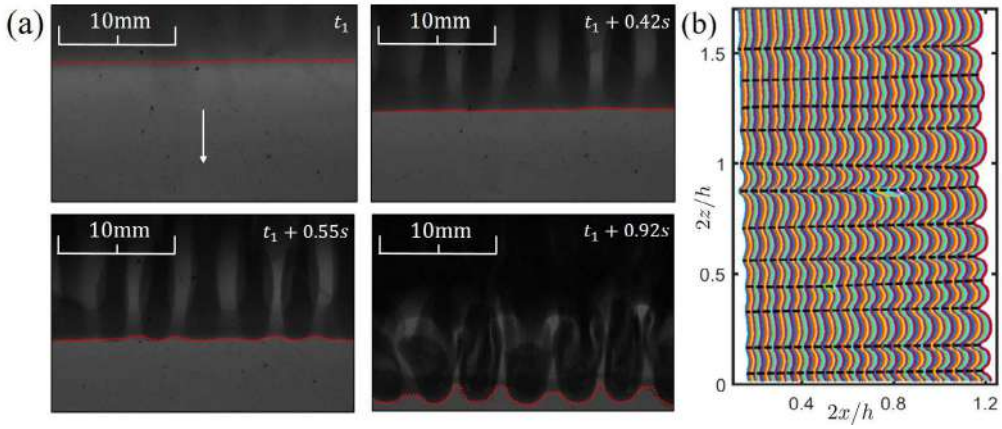

Figure 1: (a) Top view of the current front at different time for $Gr = 5 \times 10^6$. The white arrow indicates the moving direction of the front and the front leading edge is shown by the red line. (b) The front leading edges with a time interval of 0.01s as $Gr = 1 \times 10^6$. The dashed lines represent the tracks of the clefts.

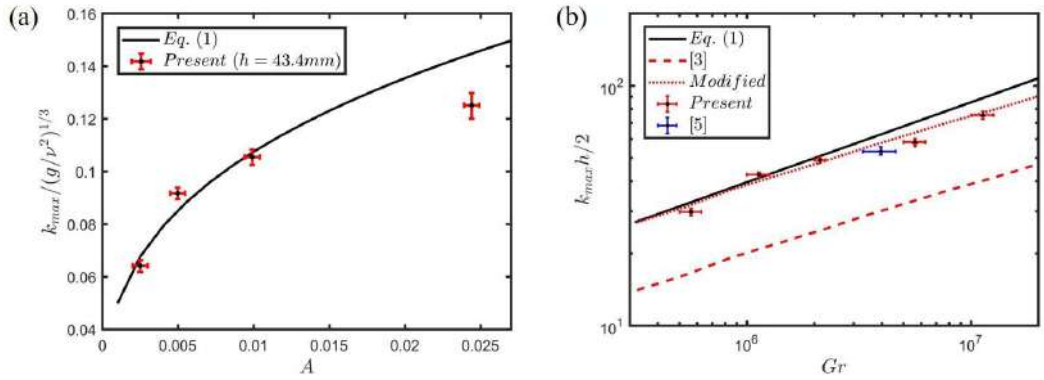

Figure 2: The measured initial dominating spanwise wavenumber as a function of (a) Atwood number and (b) Grashof number in comparison with the theoretical curve of the RTI model. The previous linear result for $Sc = 1$ [3] is shown as the dashed line.

It is shown in Fig. 2(a) that the measured k_{max} varies with A just as predicted by the RTI model (Eq. 1) when A is small, indicating the the original formation mechanism of the lobes and clefts is the Rayleigh-Taylor instability [4]. It is noted that in the present experiments the slight variation of Sc for different solution densities is ignored. According to the RTI model (Eq. 1), k_{max} at the linear stage has a scaling law of 1/3 with Gr, which is confirmed by the present experimental data as shown in Fig.2 (b), especially at moderate Grashof numbers. The previous linear result [3] for $Sc = 1$ is shown as a dashed line in Fig. 2(b), and has large discrepancies with the present measurements and other previous experimental data [5] because of the Schmidt number difference. In fact, based on Eq. (1), we may modify the previous result [3] by simply multiplying $\frac{\mathcal{F}(Sc=833)}{\mathcal{F}(Sc=1)} = 1.92$, and then the dashed line changes to the dotted line as shown in Fig. 2(b), which is consistent with the present experimental data very well, confirming that the Schmidt number has an important effect on the initial spanwise length scale of lobes and clefts.

CONCLUSIONS

In order to experimentally study the linear instability of the gravity-current front, rotatable tanks are designed and used to avoid the strong local disturbances caused by the traditional lock-exchange setup. It is shown that the measured spanwise dominating wavenumber has a 1/3 scaling law with the Grashof number and a dependence on the Schmidt number as predicted by the RTI model, suggesting that the original formation mechanism of lobes and clefts is the Rayleigh-Taylor instability.

KATABATIC PRANDTL SLOPE FLOWS IN THE VERY-STABLE REGIME

Inanc Senocak*[1] and Cheng-Nian Xiao[1]
[1]Department of Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, USA

Summary We investigate the nature of patchy turbulence in stably stratified Prandtl slope flows with and without ambient wind forcing using direct numerical simulations. The slope angle, Prandtl number and two newly established dimensionless numbers, namely the stratification perturbation and the wind forcing numbers, form the dimensionless parameter space to realize a turbulent patch that persists over the slope plane. We use conditional statistics to characterize the flow in turbulent and non-turbulent patches in katabatic slope flows to and contrast it against the flow states in the weakly stable regime. Additionally, we demonstrate the ineffectiveness of the gradient Richardson number as a stability parameter and investigate the plausibility of the new dimensionless numbers to serve as an improved criterion of stability.

INTRODUCTION

Turbulence in strongly stratified fluids is one of the least understood subjects in fluid mechanics. Comprehension of the subject matter plays a central role in developing computer models of stable atmospheric boundary layer (SABL), nocturnal winds in mountainous terrain, and winds over large ice sheets in polar regions and glaciers. Stable conditions in atmospheric boundary layer starts to develop around evening hours due to radiative cooling of the surface to clear skies. Conditions within SABL can range from fully developed turbulent to intermittently turbulent and even near calm state, which make it difficult to predict computationally [1].

Ludwig Prandtl was the first to derive an exact solution to idealized slope flows within a stratified medium [2]. The Prandtl solution has been shown to describe qualitatively the vertical profiles of wind speed and temperature of katabatic winds in mountainous terrain or over large ice sheets in polar regions. In the Prandtl model, winds aloft are quiescent. Lykosov and Gutman [3] incorporated the effect of a uniform ambient wind field into Prandtl's original formulation, which we refer to as the *extended* Prandtl model. The vertical profiles of buoyancy and velocity are exponentially damped sinusoidal solutions in the original Prandtl model. The velocity profile in the extended Prandtl model appears as a mere shifting of the velocity profile produced by the original Prandtl model.

In a series of publications [4, 5, 6], we have studied the fluid instabilities in idealized slope flows. We have shown through linear stability analysis and direct numerical simulations that Prandtl slope flows are prone to two types of instabilities: stationary vortical rolls aligned in the along-slope direction and travelling waves propagating in the along-slope direction. The analyses have shown that dynamical stability of slope flows is governed by the slope angle, Prandtl number and the stratification perturbation number, which is a measure of the disturbance to the background stratification due to cooling at the surface. When an ambient wind field aloft exists, wind forcing number emerges as an additional dimensionless number highlighting the uniqueness of the stratification perturbation parameter as a dimensionless number. These new developments have enabled us to argue the ineffectiveness of the current practice of using a single Richardson number to describe the stability of stratified slope flows. In Xiao and Senocak [5], the stratification perturbation number was proposed as a potential quantitative metric to demarcate stably stratified flows into super, very stable and weakly stable regimes.

In the present work, we use the newly established dimensionless parameter space to study a patch of turbulence over an infinitely wide slope with a constant inclination angle and negative heat flux imposed at the surface. The advantage of the present approach is that a unique flow state can be identified such that a patchy turbulence persists at all times over the slope plane. This idealized configuration enable us to study the slope flow in the very-stable regime with the help of conditional statistics and contrast it against fully developed turbulent conditions in the weakly stable regime.

TECHNICAL BACKGROUND

The governing equations for conservation of momentum and energy under the Boussinesq approximation for an incompressible slope flow with a constant ambient wind aloft can be written as follows [3]:

$$\frac{\partial u_i}{\partial t} + \frac{\partial u_i u_j}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\nu \frac{\partial u_i}{\partial x_j}\right) + b g_i, \tag{1}$$

$$\frac{\partial b}{\partial t} + \frac{\partial b u_j}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\beta \frac{\partial b}{\partial x_j}\right) - N^2 g_j (u_j - U_j), \tag{2}$$

where ν is the kinematic viscosity, β is the thermal diffusivity. N is the constant Brunt-Väisälä frequency. Buoyancy b is related to the potential temperature Θ as $b = g(\Theta - \Theta_e)/\Theta_r$, where Θ_r is a reference potential temperature and Θ_e is the environmental potential temperature. Non-dimensional gravity vector is defined as $g_i = [g_1, g_2, g_3] = [\sin\alpha, 0, \cos\alpha]$,

*Corresponding author. E-mail: senocak@pitt.edu

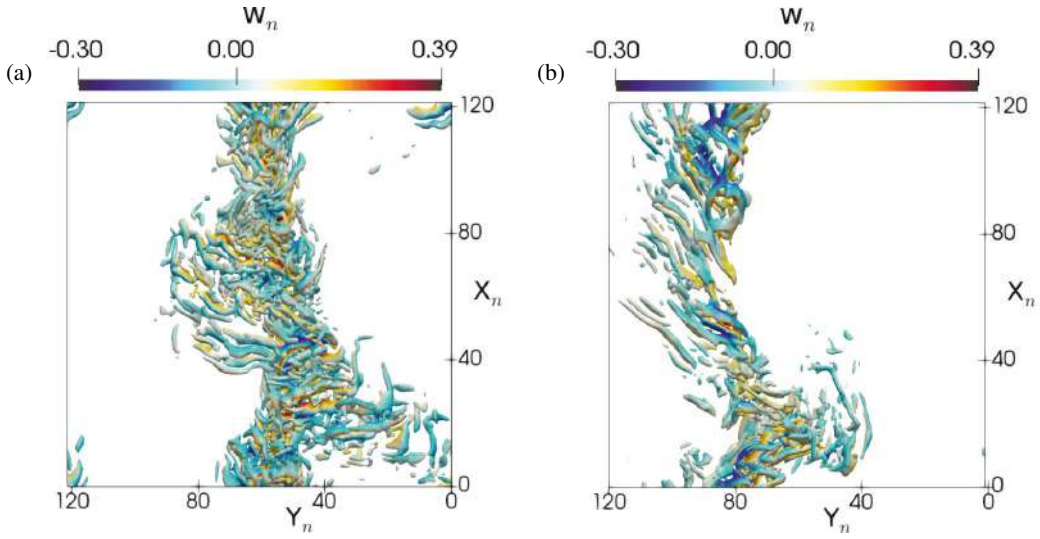

Figure 1: Q-contour visualisations of a patch of turbulent region in slope flows with and without ambient wind forcing. Colour represents for the slope normal velocity. $\alpha = 5^\circ$ (a) $\Pi_s = 25$, $\Pi_w = 0$; (b) $\Pi_s = 19.8$, $\Pi_w = 320$. $Ri_g = 1.14 \times 10^{-3}$ for both cases. Main slope flow direction is from top to bottom.

where α is the slope angle. The ambient wind vector is assumed to be of the form $(U_j) = (U_\infty, 0, 0), U_\infty < 0$. The governing equations are completed by the divergence free velocity field condition for incompressible flows.

The dimensionless numbers involved in the Prandtl slope flow with an ambient wind field can be determined with the help of the Buckingham-π theorem.

$$\alpha, \quad Pr \equiv \frac{\nu}{\beta}, \quad \Pi_s \equiv \frac{|B_s|}{\beta N^2}, \quad \Pi_w \equiv \frac{U_\infty^2}{\nu N}, \tag{3}$$

where B_S is the constant negative heat flux imposed at the surface. Because there is no external length scaled imposed on the Prandtl slope flow familiar dimensionless numbers such as the Reynolds, Richardson, or Froude number do not appear in the above list. Π_s was introduced in [4] as the stratification perturbation number, and Π_w in [6] as the wind forcing number. [6] used the analytical solution of the extended Prandtl model [3] to further show that the gradient number is a function of the four dimensionless numbers given in equation 3 as follows:

$$Ri_g = \frac{N^2}{\left(\frac{\partial u}{\partial z}\right)^2_{\max}} = \frac{\mathrm{Pr}}{\left(\sqrt{2\Pi_w}\mathrm{Pr}^{3/4}\sin^{1/2}\alpha + \Pi_s\right)^2}, \tag{4}$$

The above relationship is significant because it shows that a single gradient Richardson number is insufficient to define the dynamic stability of stratified slope flows.

RESULTS

Figure 1 illustrates the nature of patchy turbulence that can persist in the very-stable slope flow regime. Prandtl number of 0.71 and a slope angle of 5° is used for both cases shown in Figure 1. We use equation 4 to identify flow states with the same Ri_g number but with different Π_w, Π_s. Figure 1a represents a case with no ambient wind aloft, whereas Figure 1b has a wind forcing number of $\Pi_w = 320$ and a smaller $\Pi_s = 19.8$. An instantaneous visualization of the vorticity field via the Q-criterion reveals the differences in the flow states. The flow field corresponding to the larger stratification perturbation $\Pi_s = 25$ is more turbulent like with numerous smaller eddies than its counterpart at the same Ri_g number with a nonzero wind forcing number $\Pi_w = 320$. This illustration serves as a visual evidence of the ineffectiveness of gradient Richardson number to describe the dynamic stability of slope flows. It appears that for a fixed Ri_g, surface buoyancy flux has a stronger destabilization effect than the ambient wind higher aloft. Statistical results from these fields will be compared against the weakly stable regime and presented in the final abstract.

BINARY INTERACTIONS BETWEEN BARCHAN DUNES

Willian Righi Assis*[1] and Erick de Moraes Franklin[1]
[1]School of Mechanical Engineering, University of Campinas, Rua Mendeleyev, 200, Campinas, SP, Brazil.

Summary Barchan is a crescentic-shape dune, often organized in dune fields. When in a dune field, dune-dune interactions play a significant role in regulating the dynamics and sizes of barchans. The present work experimentally investigates the different types of interactions between two barchans and which physical aspects govern the behavior of those interactions. The experiments were conducted in a closed-conduit channel of transparent material, where pairs of granular piles were poured in and a high-definition camera used to acquire images of the bedforms. As a result, five different patterns were identified for both aligned and off-centered configurations, and we propose interaction maps that depend basically on the ratio between the number of grains of each dune, Shields number (θ) and alignment of barchans. This paper is based on Ref.[3] and reproduces many of its parts.

INTRODUCTION

Barchans are crescent-shaped dunes that form in areas of unidirectional fluid flow with horns pointing downstream [1]. In nature, they are found in deserts and rivers, for example, and in industry they can be found inside oil pipelines and dredging lines. Although the study of isolated dunes helps to understand their dynamics, barchans generally do not appear isolated, but belong to dune fields, where they can be influenced by their neighbors whose speeds and sizes are different [2].

The contact (or quasi-contact sometimes) of dunes, termed collision [2], that happens in dune fields plays a significant role in regulating the size of barchans, by redistributing sand and also creating small barchans from large ones. In a previous study [3], the short-range interactions occurring between two subaqueous barchans were experimentally investigated and five different patterns were identified and interaction maps that depend basically on the ratio between the number of grains of each dune, Shields number, and alignment of barchans were proposed.

EXPERIMENTAL SETUP

The experimental setup consisted of a water reservoir, two centrifugal pumps, a flow straightener, a 5m long closed-conduit channel with rectangular cross-section (width $\alpha = 160$mm and height $\beta = 50$mm), a settling tank and a return line. The test section is 1m long and starts 40 hydraulic diameters downstream of the channel inlet. A total number of 123 tests were performed, for which we used different populations of grains (not mixed): round glass beads ($\rho_s = 2.500$ kg/m^3) with 0.15mm $\leq$ d $\leq$ 0.25mm and 0.40mm $\leq$ d $\leq$ 0.60mm, angular glass beads with 0.21mm $\leq$ d $\leq$ 0.30mm, and zirconium beads ($\rho_s = 4.100$ kg/m^3) with 0.40 mm $\leq$ d $\leq$ 0.60, where ρ_s and d are, respectively, the density and diameter of grains. Reynolds number based on the channel height, $Re = \rho\overline{U}\beta/\mu$, varied from 1.13×10^4 to 1.82×10^4, where μ is the dynamic viscosity, ρ the density of the fluid and $\overline{U}$ the cross-sectional mean velocity of water. The Shields number $\theta = (\rho u_*^2)/((\rho_s - \rho)gd)$, which is the ratio between drag on grains and their relative weight, varied from 0.019 to 0.106, where u_* is the shear velocity and g is the magnitude of gravity. The total number of grains on each pile was computed as the mass of the initial pile divided by that of one single grain. We identified the different patterns by recording the bedforms with a digital camera and afterwards processing the images.

RESULTS AND DISCUSSION

Five different patterns were observed as resulting from the binary interaction (for both aligned and off-centered configuration): 1) chasing (Figures 1a and 2a), when the upstream dune does not reach the downstream one; 2) merging (Figures 1b and 2b), when the upstream dune collides with downstream one and there is no loss of grains; 3) exchange (Figures 1c and 2c), when, after the collision, a small barchan is ejected and, being the smaller one, outruns the other and migrates downstream; 4) fragmentation-chasing (Figures 1d and 2d), when the downstream dune splits into two or more barchans; and 5) fragmentation-exchange (Figures 1e and 2e), when the fragmentation initiates as in 4), but, the upstream barchan being still faster than the splitting dune, they collide. Once they touch, an off-center exchange occurs, and a small barchan is ejected. Figures 3 (a),(b) and (c),(d) depict points from each test in terms of the Shields number (θ) versus the ratio between the number of grains of each dune $\xi_N = \Delta_N/\Sigma_N$, and boundaries between different patterns for the aligned and off-centered barchans, respectively. The alignment of barchans is represented by the offset parameter σ (dimensionless),

*Corresponding author. E-mail: righiassis@gmail.com

computed as the transverse distance between the centroid of approaching barchans, η, divided by their average width: $\sigma = 2\eta/(W_u + W_d)$, where W_u and W_d are the widths of the upstream and downstream bedforms, respectively. These maps provide a comprehensive and simple classification for the short-range interactions of subaqueous barchans and they may be useful for predicting the collisions of barchans in different environments.

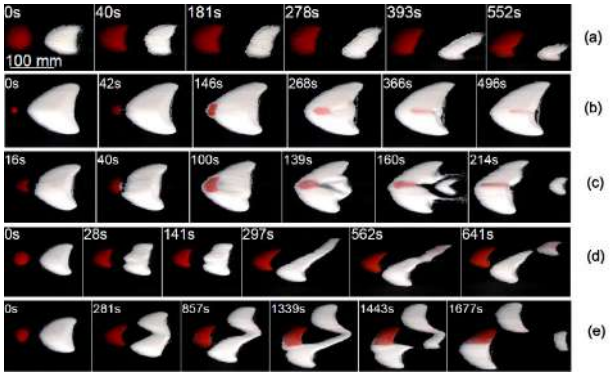

Figure 1: Snapshots of barchan interactions for aligned dunes. In the snapshots, the water flow is from left to right, the upstream pile consisting of red glass beads and the downstream pile of white glass beads. Figure extracted from [3].

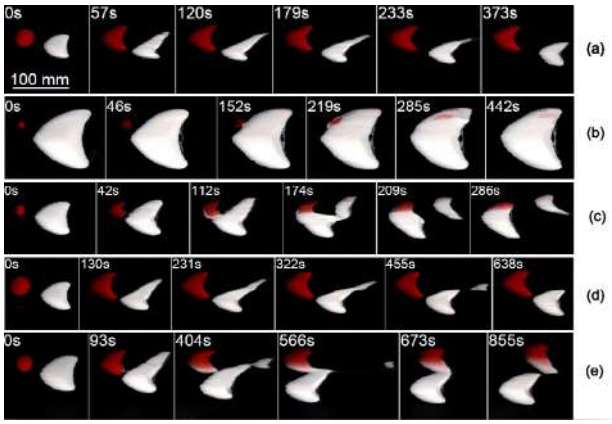

Figure 2: Snapshots of barchan interactions for off-centered dunes. In the snapshots, the water flow is from left to right, the upstream pile consisting of red glass beads and the downstream pile of white glass beads. Figure extracted from [3].

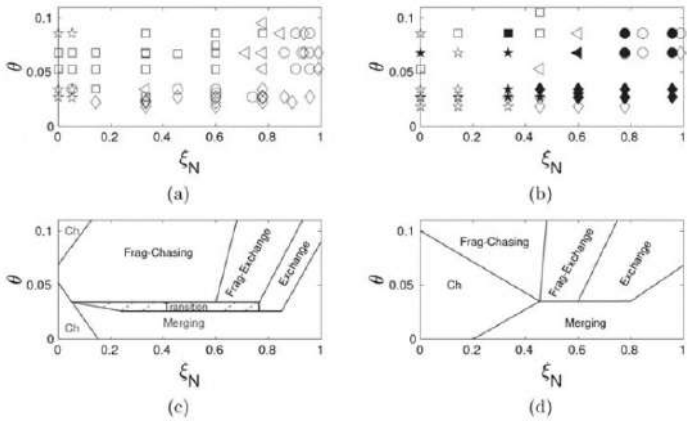

Figure 3: (a and b) Patterns of barchan-barchan interactions as functions of ξ_N and θ for (a) aligned and (b) off-centered barchans. Stars, diamonds, circles, squares, and triangles correspond to chasing, merging, exchange, fragmentation-chasing, and fragmentation-exchange, respectively. In (b), open symbols correspond to $\sigma < 0.5$ and solid symbols to $\sigma \geq 0.5$. (c and d) Boundaries between different patterns for the aligned and off-centered barchans, respectively, where Ch stands for chasing and Frag to fragmentation. Figure modified from [3].

SCENARIOS OF LANDSLIDE TSUNAMI IN THE SOUTH CHINA SEA

Hua Liu*[1], Zhiyuan Ren [2]
[1]Key Laboratory of Hydrodynamics (Ministry of Education), Shanghai Jiao Tong University, Shanghai, China
[2]National Marine Environmental Forecasting Center, Beijing 100081, China

Summary We adopt the Herschel-Bulkley rheological theory to describe the viscoplastic debris landslide flow and the shallow water equations to compute the propagation of tsunamis induced by the time-dependent deformation of the seafloors. The one-way coupled method of the landslide induced tsunami is implemented through satisfying the kinematic bottom boundary condition. With respect of the Baiyun slide, the effects of remolding rate, initial and residual yield strength on landslide and tsunami are studied numerically. To predict the potential landslide tsunami hazard in the South China Sea, the scenarios of the landslides with the different volumes in the Baiyun slide and the Brunei Slide are presented. Comparison with the non-deformation model in the near-field illustrates the crucial role of rheological property in the landslide tsunami modelling. Furthermore, the characteristics of the propagation of landslide tsunami in the South China Sea and coastal hazards are analyzed.

INTRODUCTION

In the past decade, many studies have focused on the potential earthquake tsunami from Manila Trench of the South China Sea[1]. Nevertheless, the landslide tsunami should be included in tsunami hazard analysis based on the historical records and potential submarine landslide in the South China Sea. The mechanism of the tsunami which struck the southwest coast of Taiwan in the eighteenth century was considered as a submarine mass failure[2]. In 1992, earthquake swarms of magnitude 3.4-3.7 occurred near Hainan Island. Two gauges at Yulin port and Sanya port recorded tsunami wave around 0.78 m and 0.5-0.8 m respectively. However, it is still an open question how can such a small earthquake generates a significant tsunami near Sanya.

The past and potential tsunami sources in the South China Sea have been reviewed. The Baiyun slide along the northern margin of the South China Sea and the Brunei slide near the southern margin may generate giant submarine landslide which could be triggered by a seismic activity or hydrate disassociation[3]. It is interesting to understand the potential landslide tsunami to coasts of the South China Sea. Although some preliminary results of the landslide tsunami from the Baiyun slide or the Brunei slide have been studied by using the solid submarine landslide model, it is still necessary to provide a comprehensive analysis of landslide tsunami included deformation and regression process of landslide.

In this study, we mainly focus on numerical study on rheological landslide and potential landslide tsunamis in the South China Sea. The mathematical formulation of the coupling submarine landslide and water wave generation will be discussed.

NUMERICAL MODEL

Based on the Herschel-Bulkley rheological theory, the depth averaged governing equations of the viscoplastic debris flow can be formulated in the horizontal two-dimensional form[4,5],

$$\frac{\partial h}{\partial t}+\nabla\cdot\left(\left(h_p+\alpha_1 h_s\right)\mathbf{u}_\mathbf{p}\right)=0\,, \tag{1}$$

$$\begin{aligned}&\frac{\partial\left(\mathbf{u}_\mathbf{p}\left(h_p+\alpha_1 h_s\right)\right)}{\partial t}+\left(\left(h_p+\alpha_2 h_s\right)\mathbf{u}_\mathbf{p}\cdot\nabla\right)\mathbf{u}_\mathbf{p}+\mathbf{u}_\mathbf{p}\nabla\cdot\left(\left(h_p+\alpha_2 h_s\right)\mathbf{u}_\mathbf{p}\right)\\&+\left(1-\frac{\rho_w}{\rho_d}\right)gh\nabla\left(h+b\right)=-\frac{\tau_y\,\mathrm{sgn}\left(\mathbf{u}_\mathbf{p}\right)}{\rho_d}-\frac{\alpha_3\tau_y}{\rho_d}\mathbf{f}_\mathbf{s}\,,\end{aligned} \tag{2}$$

$$\frac{\partial\mathbf{u}_\mathbf{p}}{\partial t}+\mathbf{u}_\mathbf{p}\cdot\nabla\mathbf{u}_\mathbf{p}+\left(1-\frac{\rho_w}{\rho_d}\right)g\nabla\left(h+b\right)=-\frac{\tau_y\,\mathrm{sgn}\left(\mathbf{u}_\mathbf{p}\right)}{\rho_d h_p}\,, \tag{3}$$

in which, t is the time, ρ_w and ρ_d denote the density of water and debris fluid, b is the still water depth, g is the gravitational acceleration. ∇ is the horizontal gradient operator. τ_y is the yield stress. The parameters α_1, α_2, and α_3 are determined by the Herschel-Bulkley rheological flow model for the case of small slope assumption. $\mathbf{u}_\mathbf{p}$ is the plug layer velocity of the debris flow. Including the remolding progress, the yield strength is written as,

$$\tau_y\left(\gamma\right)=\tau_{y,\infty}+\left(\tau_{y,0}-\tau_{y,\infty}\right)e^{-\Gamma\gamma}\,. \tag{4}$$

in which, the initial yield strength and residual yield strength is noted by $\tau_{y,0}$ and $\tau_{y,\infty}$. γ is the total shear deformation, and Γ is the remolding rate.

The tsunami propagation is simulated by the nonlinear shallow water equations. The numerical model GeoClaw based on the nonlinear shallow water equations is used to simulate the propagation of landslide tsunami. The model has

*Corresponding author. E-mail: hliu@sjtu.edu.cn

been validated in many recent tsunami events.

The slide process of debris flow could last a relatively long duration (10 min to 2 h), while the duration of most earthquake motion only lasts around 5 – 200 s. Compared with tsunami propagation time, the landslide duration can not be ignored. When a submarine landslide occurs, the landslide slide model is firstly used to calculate the evolution of the debris landslide flow. Then the process of the landslide in terms of landslide thickness is coupled with the nonlinear shallow water equation model based on the kinematic boundary condition[3].

The rheological landslide modeling needs to take into account several parameters. The slide thickness depends on the geological measurement. The selection of rheological parameters is based on the numerical experiments and previous studies since it is hard to measure them. The density of 1860 km/m^3 is adopted herein.

RESULTS AND DISCUSSION

The landslide tsunami from the Baiyun slide is studied by the numerical model, concerning the effect of initial and residual yield strength, and remolding rate. The grid solution for landslide tsunami is 15 arc-sec. In tsunami simulation, the grid size is one arc-min in tsunami simulation, and is refined to 15 arc-sec grids near coastal measured locations. Regarding the potential submarine landslide tsunami of the Baiyun slide, the tsunami propagation for the cases of typical volumes of 10 km^3, 50 km^3, 100 km^3, and 200 km^3 is plotted in Fig. 1. The generation and propagation of tsunami are following the slide process. The tsunami wave amplitude and wavelength depend on the volume and maximum thickness of the slide. The slide with a volume of 200 km^3 could generate the most hazardous tsunami.

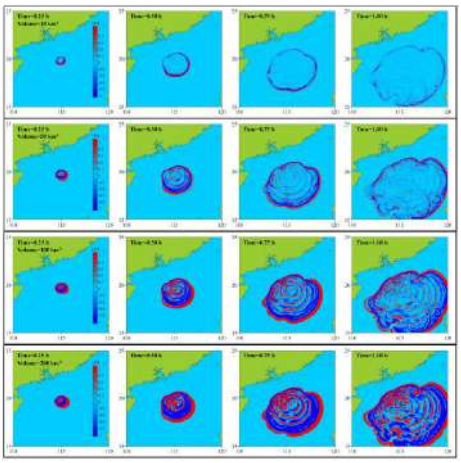

Figure. 1. Evolution of tsunami wave in the near-field for different landslide volumes. The time interval is 0.25 h.

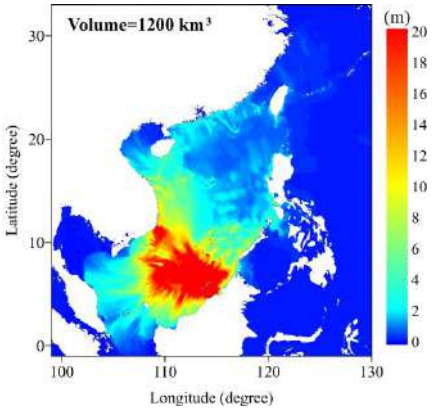

Figure. 2. Distribution of the maximum landslide amplitude induced by Brunei slide of 1200 km^3.

The distribution of the maximum landslide amplitude induced by Brunei slide of 1200 km^3 is shown in Fig. 2. It is noted that the giant landslide could generate a huge tsunami in the South China Sea, especially for the northern part. The tsunami could attack the coast of Brunei, Malaysia, Indonesia, Vietnam, Philippines, and South China. The tsunami in the near-field could exceed 10 m, and still be over 2 m in the far-field. The wave periods for Yongxing island, Zhongsha island, Huangyan Island are 30 min, 20 min, 17 min, respectively.

CONCLUSIONS

A numerical model to deal with tsunami induced by debris flow landslide is developed. The landslide model is described by the Herschel-Bulkley rheological theory including the remolding process, while the tsunami wave propagation is computed by the nonlinear shallow water equations. This paper presents scenarios of the submarine landslide tsunamis in the South China Sea computed by the coupling numerical model of the landslide model and the wave generation model. The details of the validation of the numerical model and the effects of the initial yield strength and the residual yield strength will be discussed in the presentation.

MULTI SCALE QUANTITATIVE SIMULATION OF TEMPORAL AND SPATIAL EVOLUTION OF SNOW DISTRIBUTION IN ALPINE REGION

Ning Huang*[1], Guang Li[1], and Jie Zhang[1]
[1]Key Laboratory of Mechanics on Disaster and Environment in Western China, Lanzhou University, Lanzhou, China

Summary The snow distribution in cold mountain area has a profound impact on the earth's climate and ecosystem. Due to the complex underlying surface and the nonuniform wind, the snow distribution in the mountains presents highly inhomogeneity. Based on the simulation of wind field through LES method, we obtain the snow distribution over a complex terrain that considering the effects of snowfall, snowdrift and snowmelt. The Particle Number Concentration Statistical method is introduced into LES to describe the snowfall and obtain the initial snow distribution; the parameterized snowdrift and snowmelt models are applied to characterize the movement and ablation of snow. The simulation results show that the initial snow distribution of complex terrain is obviously inhomogeneous, especially under large wind. The snowdrift and snowmelt processes exacerbate the nonuniform of snow.

INTRODUCTION

Snow is widely distributed in the global with significant interannual and seasonal variations. Snow always shows a nonuniform distribution under the action of the wind, especially in mountainous terrain. So far, these snow products are mainly obtained from remote sensing retrieval, such as multispectral imaging AVHRR and moderate resolution spectral imagingMODIS. The temporal and spatial resolution of remote sensing retrieval is low while the change of snow cover is relatively fast, and the accuracy is usually poor duo to the interference of many nature factors. Additional, as one of the most important fresh water resources, snow distribution have a profound impact on the allocation of freshwater resources. Thus, the real-time snow products (such as snow distribution, snow depth and diameter distribution of snow particles) with high resolution are essential to prevent snow disasters and predict global climate changes in the future.

Recently, numerical simulations were developed (Nemoto & Nishimura, 2004) as computer technology became more and more advanced. However, most of above works are implemented over flat surface. Furthermore, early snow models treat the precipitation simply as an input, which usually comes from one or several meteorological stations. They didn't consider the preferential deposition of precipitation (Lehning et al., 2008; Mott et al., 2014), which refers to the spatially variable deposition of snowfall due to the complex near-surface flow field in mountainous terrain.

In this paper, the Lagrangian dynamic subgrid-scale (SGS) model is introduced into the ARPS in order to match the nonuniform drag force due to the saltating snow particles. Then a Lagrangian particle tracking model was introduced into ARPS and the drifting snow and falling snow deposition over complex terrain with mixed sizes of snow grains were The sublimation of mid-air snow particles is modeled by the sublimation rate formula of ice crystals9, and its feedback effects on the air temperature and moisture is considered through introducing temperature and moisture source terms into the corresponding diffusion equations. simulated. Finally, a drifting snow parameterization scheme considering slope effect is developed so that a snow distribution forecast model in mountain area based on snowfall and snow drifting Simulations is established.

MODEL

The Advanced Regional Prediction System (ARPS5.3.3) is a three-dimensional, non-hydrostatic, compressible Large-eddy simulation (LES) model which is developed by University of Oklahoma. Here is used for a snow drift simulation (Huang and Wang, 2016). The Lagrangian Particle Tracking Method combined with fourth order Ronge-Kutta method is used to track the snow grains (Huang and Wang, 2016). And the effect of sublimation of ice crystal was taken into consideration (Huang and Shi, 2017).

Here we proposed a new formula of snow transport rate over flat surface ($\theta = 0^0$) based on the LES simulations of Huang & Wang 2016), which agrees well with both the wind tunnel experiments and field observations:

$$Q(0) = \frac{\rho u_*^3}{g}\left(1 - \frac{u_{*t0}^2}{u_*^2}\right)\left(3.7 + 4.7\frac{u_{*t0}}{u_*} - 4\frac{u_{*t0}^2}{u_*^2}\right) \quad (1)$$

And then we can get the formula of snow transport rate over slope surface as:

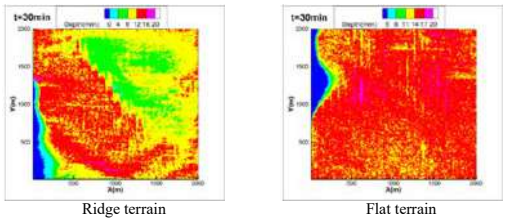
*Corresponding author. E-mail: huangn@lzu.edu.cn.

Thematic Session FM

$$Q(\theta_s) = \frac{\rho u_*^3}{gM}\left(1 - \frac{u_{*t0}^2}{u_*^2}M\right)\left(3.7 + 4.7\frac{u_{*t0}}{u_*}\sqrt{M} - 4\frac{u_{*t0}^2}{u_*^2}M\right) \quad (2)$$

RESULT AND DISCUSSION

For the flat terrain of Fig. 1, the snow depth is fairly uniform, especially in the middle of y=0.8~1km. Although there are some partial recirculation zones and vorticities in the sides, the difference of snow depth is very small. Compared with the ridge terrain, we can draw the conclusion that the blocking effect of large terrain is the main factor which leads to an uneven distribution of snowfall. And the nonuniform wind field due to undulating topography may aggravate the uneven distribution of snowfall.



Ridge terrain Flat terrain

Fig. 1 Snow depth distribution of different terrains

Fig.2 shows the time evolution of snowbed for the two cases. Considering the effect of local topography, we found that the erosion events usually happen at the windward side, and deposition at the leeward side, no matter what wind speed is. And it is different from the preferential deposition of snowfall, which has various patterns when wind speed increases (Wang & Huang, 2017). However, the change of snow depth due to drifting snow is sensitive to wind speed, for 2 orders of magnitude is found between 2 cases. It indicates that the distribution of snow deposition caused by drifting snow is dominantly controlled by terrain, but the quantity is governed by wind speed.

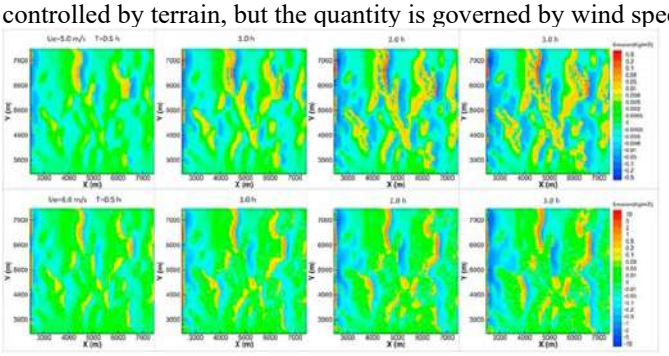


Fig. 2 Erosion and deposition of snow due to drifting snow under different wind speeds.

CONCLUSIONS

In this paper, we proposed a new formula of snow transport rate over flat surface based on the LES simulations of Huang and Wang (2016) and corrected it by take account of slope effect, temperature, and time effect. Then combining it to the snowfall model of Wang and Huang (2017), which introduces a Lagrangian particle tracking model into ARPS to simulate the falling snow deposition over complex terrain, we established a snow distribution model for alpine terrain considering both snowfall and snow drifting processes. The validation wind tunnel experiments and field observations show high accuracy of our model in snow depth evaluation.

OPTIMAL CLOSED-LOOP WIND FARM WAKE STEERING CONTROL UNDER TRANSIENT ATMOSPHERIC CONDITIONS

Michael F. Howland*[1], Aditya S. Ghate[2], Sanjiva K. Lele[2], and John O.Dabiri[3]
[1]Department of Mechanical Engineering, Stanford University, Stanford, CA 94305
[2]Department of Astronautics and Aeronautics, Stanford University, Stanford, CA 94305

Summary Wake interactions between wind turbines reduce the annual energy production of the collective wind farm as a result of greedy, individual turbine control. The potential for wake steering control, the intentional yaw misalignment of a wind turbine with respect to the incoming wind direction, to increase wind farm power production within large eddy simulations of realistic atmospheric boundary layers (ABL) was investigated. As a result of the atmospheric diurnal cycle, the dynamics of the atmosphere are transient, and therefore, a dynamic, closed-loop wake steering control strategy was selected. While wake steering control is able to increase a six wind turbine wind farm power production approximately 5% in conventionally neutral and transient stable atmospheric conditions, the increase in power production is sensitive to the control architecture, wind farm layout, and surface cooling rate.

MOTIVATION AND LARGE EDDY SIMULATION SETUP

Horizontal axis wind turbines generate turbulent wakes which persist 10-15 wind turbine rotor diameters downstream [1]. With modern utility-scale wind turbine wakes reducing power production for generators kilometers downwind, recent efforts have focused on wind farm control schemes which sacrifice individual wind turbine power production for the benefit of the collective wind farm as a replacement for the contemporary standard greedy turbine operation. While greedy wind turbine operation entails the yaw alignment of the nacelle and the incoming wind direction, wake steering control intentionally misaligns certain turbines with respect to the incoming wind direction in order to laterally deflect the wake region away from downwind generators [2]. The potential for wake steering to increase the power production of a six wind turbine array was recently shown in a full-scale field experiment where increases with respect to baseline greedy operation between 7-13% were found for moderate wind speeds [3]. However, typical studies of wake steering have focused on stationary atmospheric simulations [2] or static wind farm control based on lookup tables [3, 4]. The turbulent ABL, however, is rarely stationary with the quasi-stationary conventionally neutral state infrequently observed in field experiments [5]. As such, the goal of the present study is to assess various wake steering control architectures under transient atmospheric stability conditions associated with the diurnal cycle in large eddy simulations.

Large eddy simulations are performed using the in-house code *PadéOps*[1]. The psuedo-spectral code has been utilized in a number of geophysical applications previously and is described thoroughly in the associated references [6, 7]. Simulations are performed initially in a quasi-stationary conventionally neutral ABL. Six wind turbines are embedded in the ABL with the array designed to approximately represent the layout studied in [3]. The finite wind farm is represented using the concurrent precursor framework where fringe regions [8] are used (Figure 1(a)). Once the wind farm reaches the quasi-stationary state associated with the conventionally neutral ABL, a suite of simulations are performed to analyze the sensitivity of the effect of wake steering on wind farm power production as a function of the control architecture, wind farm layout, and stable ABL surface cooling rate. All power production results are compared to a simulation of the same setup with greedy wind farm control. The closed-loop wake steering controller architecture is shown in Figure 1(b). The optimal controller is the gradient-based wake steering methodology developed by Howland *et al.* [3]. The state estimation utilizes the ensemble kalman filter method developed by [9]. Open-loop control, where the yaw misalignment and power production state are not fed back to the controller, and closed-loop control cases are tested.

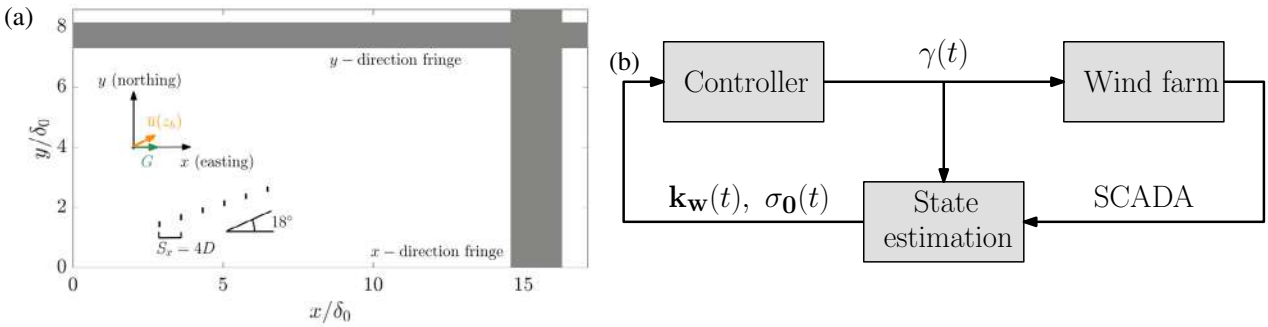

Figure 1: (a) Large eddy simulation computational setup primary simulation. Fringe regions [8] are used in the x and y directions to force the primary simulation to match the concurrent precursor simulation. Six actuator disk model wind turbines are incorporated into the primary domain. The geostrophic wind direction G is shown in green and the mean velocity at wind turbine hub height $\overline{u}(z_h)$ is shown in orange. (b) Closed-loop wake steering controller architecture.

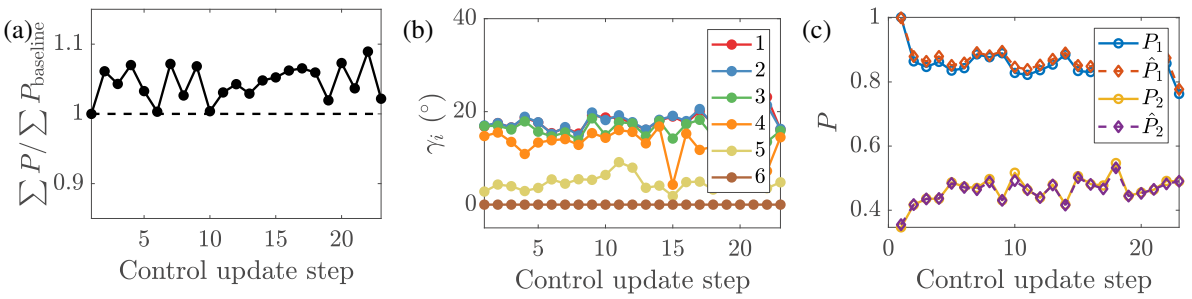

Figure 2: (a) Time averaged wind farm power production as a function of the control update steps for the conventionally neutral ABL case. The wind farm power is normalized by the power of the aligned wind farm case. (b) Yaw misalignment angles and (c) simulation P and state estimated model $\hat{P}$ power production for the first and second upwind turbines in the array as a function of the control update steps. The yaw misalignment is updated with a period of 50 minutes.

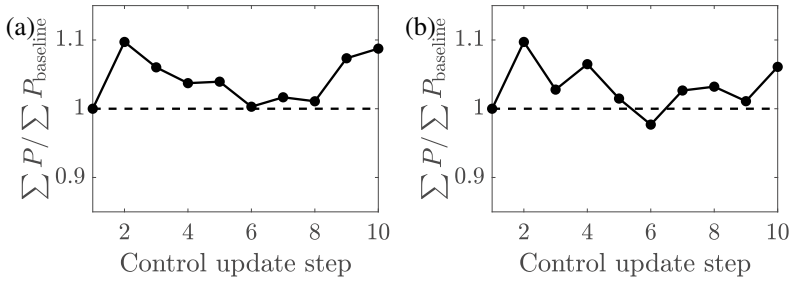

Figure 3: (a) Time averaged wind farm power production as a function of the control update steps for the stable ABL case with (a) closed-loop control and (b) open-loop control. The wind farm power is normalized by the power production of the greedy wind farm case. The yaw misalignment is updated with a period of 30 minutes.

SIMULATION RESULTS

The suite of large eddy simulations reveal sensitivity in the wind farm power production to the choice of control architecture, wind farm layout, and surface cooling rate. In the conventionally neutral ABL, both open-loop and closed-loop control (Figure 2) produce power increases over the greedy operation, with the mean power production increase of approximately 5%. However, when the wind farm alignment is $14°$ instead of the $18°$ shown in Figure 1(a), the wind farm power production increase with wake steering decreases to approximately 1% due to the reduction of partial waking with the mean wind speed at wind turbine hub height of approximately $15°$. In the stable ABL, the wake steering control benefits are larger for the closed-loop (Figure 3(a)) than for open-loop (Figure 3(b)) control, with power production increases over the greedy baseline of 4.7% and 3.5%, respectively. This reveals that closed-loop control is able to dynamically adapt to the changing stability and boundary layer state in transient stable ABL flows. With increased surface cooling, the power production increases over greedy operation are reduced due to a rapid stability transition. Overall, the results suggest that the specific wind farm layout and ABL state will dictate the optimal wake steering strategy and closed-loop, dynamic wake steering increases wind farm power production in transient flows compared to open-loop approaches.

EXPERIMENTAL STUDY O FZONAL JETS IN PLANETAR YATMOSPHERES: MULTI-STABILITY AND LONG-TERMDYNAMICS

Daphné Lemasquerier *[1], Benjamin Favier[1], and Michael Le Bars[1]
[1]Aix Marseille Univ, CNRS, Centrale Marseille, IRPHE UMR 7342, Marseille, France

Summary The stability and dynamics of gas giants' zonal jets are still poorly understood. Here, we use an experimental approach to address the question of zonal jets formation and long-term evolution. A strong topographic β-effect is obtained inside a rotating water tank thanks to the paraboloidal shape of the upper free surface. A turbulent forcing is performed using small-scale jets at the base of the tank. We identify a subcritical transition and associated hysteresis cycle between two distinct regimes. In the first regime, jets are weak in amplitude, steady and remain spatially locked to the forcing. In the second one, we observe dynamical and dominant jets, independent of the forcing scale. Kinetic energy spectra are in that case consistent with theoretical predictions of so-called zonostrophic turbulence, relevant to planetary applications.

INTRODUCTION

Turbulent flows in planetary atmospheres are constrained by many dynamical effects such as rapid rotation or density stratification which contribute to the rich dynamics observed on many planets. One of the striking features of rapidly-rotating atmospheres is their ability to sustain azimuthal flows whose direction alternates with latitude. The best example is probably Jupiter, for which zonal jets are clearly visible in the weather layer as witnessed by Voyager, Cassini and more recently Juno [1]. The origin, robustness and potential long-term dynamics of these jet-like structures are however still not fully understood. In particular, to which extent they penetrate in the deep interior of Jupiter is still unclear, although recent indirect measurements suggest that they are deeper than initially thought [2].

In this work, improving upon the results of Cabanes *et al.*[3], we explore experimentally the long-term dynamics of zonal jets driven by a topographical effect in a rapidly-rotating water tank. The extreme parameter regime reached by our experiment allows us to vary the intensity of the forcing while remaining in the rotationnally-constrained regime, relevant for these large-scale atmospheric features.

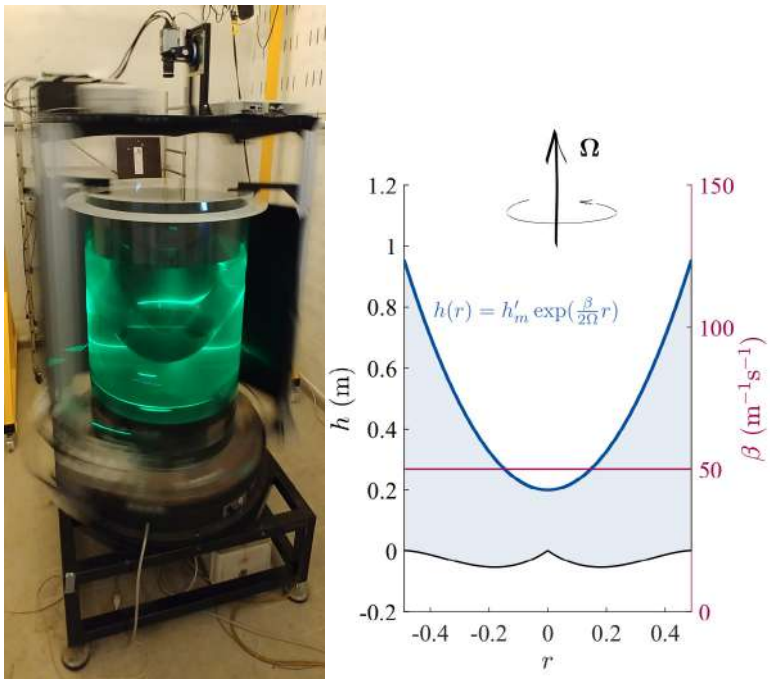

Figure 1: Details of the experimental setup. Left: Picture of the experiment after the spin-up is completed. The tank is 1.6 m high, 1 m in diameter and rotates at 75 rpm. Right: height and β as a function of the cylindrical radius.

EXPERIMENTAL SETUP

A cylindrical transparent container of radius $R = 0.5$ m is filled with 440 litres of water and is rapidly-rotating around its vertical axis. At rest, the water depth is $h = 58$ cm and once the platform is rotating at $\Omega = 75$ rpm, the water height varies parabolically from $h = 20$ cm on the axis of rotation up to $h = 95$ cm at the edge of the domain (see Figure 1). The bottom of the tank is not flat but slightly curved so that the total water column height $h(r)$ varies exponentially with cylindrical radius r. The topographic β-effect, given by $\beta = (2\Omega/h)\mathrm{d}h/\mathrm{d}r$, is thus constant across the experiment, $\beta = 50$ m^{-1}.s^{-1}. An experiment with a flat bottom surface (as in [3]) would lead to a non-uniform β-effect, which is a further complication we want to avoid. Small-scale fluctuations are generated by an array of 64 injection and 64 suction points, with a typical inlet radius of 2 mm, regularly distributed in a non-axisymetric pattern and connected to 6 independent pumps.

Measurements are performed on a fully-immersed horizontal plane using Particle-Image Velocimetry (PIV). The fluid is seeded with 40 μm fluorescent particles which are illuminated with a 2 W 532 nm green laser. Their peak emission is approximately at 607 nm and thus appears orange when excited by the laser. This allows to filter out inevitable reflections from various parts of the experiment and dramatically improves the quality of the PIV measurements.

*Corresponding author. E-mail: lemasquerier@irphe.univ-mrs.fr.

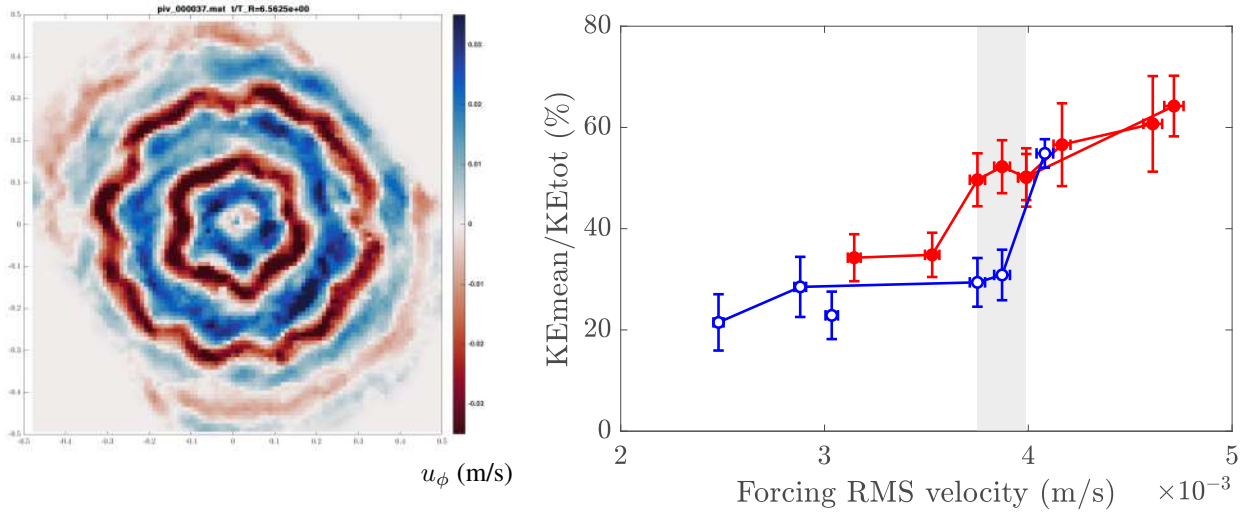

Figure 2: Left: instantaneous azimuthal velocity field as measured by PIV in a horizontal plane across the experiment for the second regime. Red is prograde while blue is retrograde. Right: ratio between the kinetic energy in the azimuthally-averaged flow and in the total flow as a function of the forcing amplitude. Blue corresponds to experiments where the forcing is gradually increased while red corresponds to experiments where the forcing is decreased. Bi-stability is observed inside the grey area.

BI-STABILITY AND LONG TERM DYNAMICS

The rotation rate is fixed to $\Omega = 75$ rpm for all experiments. This corresponds to an Ekman number of $E = \nu/(\Omega R^2) \approx 5 \times 10^{-7}$ where ν is the kinematic viscosity of water. Our control parameter is the intensity of the forcing which we measure as the root-mean-square fluctuating velocity at the beginning of the experiment, when the mean flow has not developed yet. In all cases, the typical velocity is of the order of $u \approx 4 \times 10^{-3}$ m/s, so that the typical Rossby number is approximately $Ro = u/(\Omega R) \approx 10^{-3}$.

For each experiment, once the platform is rotating, we first wait for the fluid to spin-up and reach a solid-body rotation state. The pumps are then activated and we record the spatio-temporal evolution of the velocity field in the PIV plane. This allows to separate the contributions of the azimuthally-averaged zonal flow from those of the small-scale fluctuations. For all cases, we observe the formation of zonal flows which correspond to the azimuthally-averaged part of the flow (see Figure 2). Note that contrary to most previous experiments, we reach the so-called zonostrophic regime characterised by a dominant instantaneous zonal flow (see [3] for more details).

In addition, the detailed PIV measurments allow to distinguish between two dynamical regimes. For low forcing amplitudes, coherent steady zonal flows are obtained, whose typical size matches that of the forcing. As the forcing amplitude increases, the system switches to a much more dynamical regime characterized by stronger and wider zonal flows and merging events. We can even construct the full transition diagram between the two states, and we observe a hysteretic behaviour as shown in Figure 2. Finally, we have performed several realisations of the same experiment and observed that the system is actually multi-stable in the zonostrophic regime: we have found at least three different quasi-steady states with different jet positions and structures, but similar jet sizes and amplitudes.

CONCLUSIONS

Using a large-scale experiment, we have identified a new transition in β-plane turbulence between two different regimes. One is characterised by relatively weak zonal flows locked at the forcing scale while the second regime, more relevant for planetary applications, is characterized by intense large-scale jets. We observed a hysteretic behaviour at the transition between the two regimes, which remains to be explained. The long-term dynamics of the zonal flows in the second regime are now being studied in more details. In particular, these results have been reproduced using a quasi-geostrophic two-dimensional code which confirms the robustness of the transition observed experimentally.

ONE-DIMENSIONAL MODELS FOR EXCHANGE FLOWS AND THEIR APPLICATION TO THREE-DIMENSIONAL TURBULENT NUMERICAL SIMULATIONS

Steven J. Kaptein[1], Vincenzo Armenio[2], Herman J.H. Clercx[1], and Matias Duran-Matute*[1]

Summary We use two recently developed parametrizations of the horizontal density gradient leading to one-dimensional models to reproduce strongly stratified gravity-driven exchange flows at high and low Schmidt number values. These models were extensively tested against results from laminar two-dimensional simulations and are shown to outperform the models with the classical constant parametrization for the horizontal density gradient. Finally, we use these models as drivers in three-dimensional direct numerical simulations of continuously forced turbulent exchange flows with periodic boundary conditions, and we present the results of the evolution and characteristics of these flows.

INTRODUCTION AND DESCRIPTION OF THE PROBLEM

Modeling and understanding of turbulent strongly stratified flows remains an ongoing problem within environmental fluid mechanics. Exchange flows driven by horizontal density differences occur in many natural environmental situations and are ideal to further our insight into turbulence in strongly stratified flows, but modeling all the relevant scales of such flows poses several challenges. Idealized three-dimensional models with periodic horizontal forcing can be used for such an endeavor. However, the horizontal density differences are often parametrized using an imposed, constant horizontal density gradient that results in the stratification to grow out of bounds: a phenomenon usually called 'runaway-stratification'. In this work, we present a way to overcome this limitation.

The problem set-up (shown in Figure 1) is inspired by different experimental configurations (e.g. [3]) and consists of two reservoirs connected by a channel of height h and length L, with $L \gg h$ (implicitly assuming that end effects at $x = \pm L/2$ can be ignored). Each reservoir contains water with a different initial salt concentration, denoted by the salinity values s_1 and s_2 in the left and right reservoirs, respectively. Initially, the salinity $s(x, z)$ in the channel is uniform in the vertical, and the salinity gradient in the along-channel direction is constant: $\partial s/\partial x = (s_2 - s_1)/L$. In the channel, both the top and bottom boundary are solid boundaries. The aim of our study is to reproduce the flow in the center of the channel (around $x = 0$), first for the laminar case and second for the turbulent case. For the latter, we are resolving all scales using direct numerical simulations (DNS). The flow is governed by three non-dimensional parameters: the gravitational Reynolds number $Re_g = U_g h/\nu$, the Schmidt number $Sc = \nu/\kappa$, and the aspect ration of the channel $\Gamma = h/L$ where $U_g = \sqrt{(\Delta\rho g h)/(\rho_0)}$, with $\Delta\rho$ the density difference between the the water in the two containers, g the acceleration due to gravity, ρ_0 the density at $x = 0$ and $t = 0$, ν the kinematic viscosity, and κ the molecular diffusivity.

ONE-DIMENSIONAL MODELS

To achieve our goal, the key aspect is to decompose the density of the fluid ρ as

$$\rho(x, y, z, t) = \rho_r(x, y, z, t) + xG(z, t), \tag{1}$$

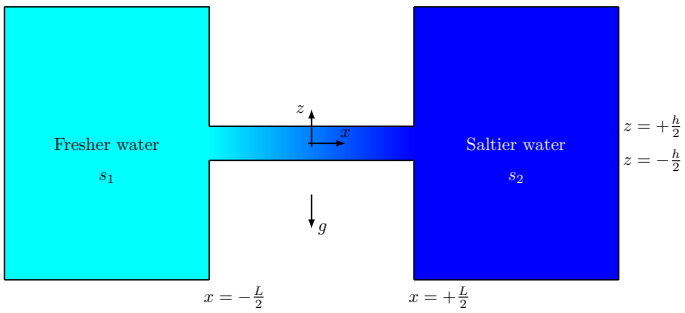

Figure 1: Side-view of the domain, with the initial distribution of salinity. This sketch is not to scale as $L \gg h$, and we assume very large (infinite) salt reservoirs. The salt concentration in the left reservoir is denoted by the salinity s_1 and in the right reservoir it is denoted $s_2 > s_1$. The acceleration due to the gravity g is in the negative z-direction.

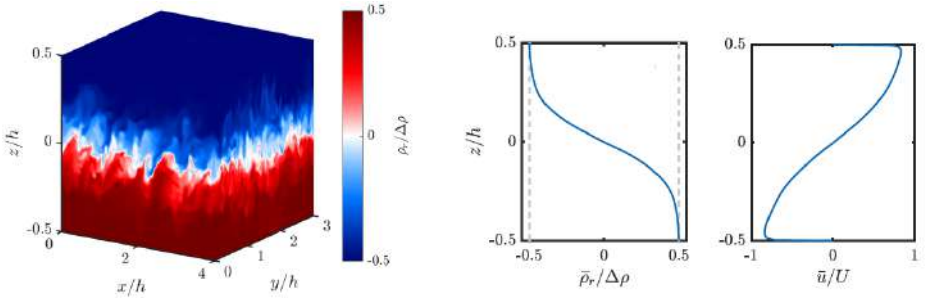

Figure 2: Results of a 3D DNS with horizontally periodic boundary conditions for the turbulent flow around the center ($x = 0$) of the channel with $Re_g = 5 \times 10^6$. Left: snapshot of the three-dimensional distribution of the normalized density. Right: horizontally averaged vertical profiles of the density and of the horizontal velocity.

where ρ_r is the part of the density that has to be solved for and $G(z,t)$ is an imposed horizontal density gradient. For the horizontal density gradient $G(z,t)$, we propose a parameterization of the form

$$G(z,t) = a_0 + a_1 \left|\tilde{\rho}\right| + a_2 \left|\frac{\partial \tilde{\rho}}{\partial z}\right|, \tag{2}$$

where $\tilde{\rho}$ is the horizontal average of ρ_r, and a_0, a_1 and a_2 are constants to be determined. Note that with this parametrization the horizontal density gradient is constant over the vertical in the absence of stratification; it decreases at the boundaries with the onset of stratification; and it increases in the center of the channel once the flow converges to a two-layer system. When $a_1 = 0$ and $a_2 = 0$, the classical constant horizontal density gradient parametrization is recovered, and we refer to this as the 1D0 model. In the case $a_2 = 0$ but $a_1 \neq 0$, the parametrization resembles the one proposed in [1], and we refer to this parametrization as 1D1. Finally, the case where all three parameters are different than zero is referred to as 1D2 [2].

To satisfy the initial condition $a_0 = \Delta\rho/L$, and to satisfy the top and bottom no-slip boundary conditions as $t \to \infty$, $a_1 = -2/L$. Finally, we assume that the shear at $z = 0$ is always such that $a_2 = \Gamma/3$.

Four different flow regimes are found by exploring the parameter space defined by Re_g, Sc, and Γ. The classical 1D0 model, which considers a constant horizontal density gradient, only performs well in the diffusion dominated regime, where the stratification is weak. The new 1D models outperform the classical model in all other regimes, but they perform differently depending on the Schmidt number. For low Sc values the 1D1 model performs best while for high Sc values, the 1D2 model performs best. Most importantly, runaway stratification is prevented with both the 1D1 and the 1D2 models.

IMPLEMENTATION OF 1D MODELS FOR 3D SIMULATIONS OF TURBULENT FLOW

The 1D models are used to force 3D direct numerical simulations with horizontal periodic boundary conditions. These simulations focus on a small enough domain close to the center of the channel to have enough resolution to solve all the relevant scales. The simulations start with the fluid at rest. For small values of Re_g, a steady laminar flow is attained after a short transient time. As the value of Re_g increases, Holmboe waves appear at the interface. Finally, for large enough Re_g values, the flow becomes turbulent and turbulent mixing between the two fluids occurs at the interface. Figure 2 shows results of one 3D DNS for the turbulent flow around the center of the channel. The fact that vertical profiles of neither the density nor the velocity are imposed allows them to vary in time revealing their interplay and the interplay with the turbulence characteristics at the interface.

CONCLUSIONS

In this work, we show how recently developed 1D models of exchange flow can be applied to forced 3D direct numerical simulation set-ups with horizontally periodic domains. This opens a whole new range of possibilities to reproduce, using high-resolution simulations, the dynamics of different environmental situations where other actors such as tides or wind can interact with the exchange flow.

CASCADE OF RESONANCES TO ACHIEVE INTERNAL WAVE TURBULENCE

Géraldine Davis[1],Timothée Jamin[1],Julie Deleuze[1],Sylvain Joubaud[1,2],and Thierry Dauxois*[1]
[1]Univ Lyon, ENS de Lyon, Univ Claude Bernard, CNRS, Laboratoire de Physique, Lyon, France [2]Institut Universitaire de France (IUF)

Summary We study experimentally the interaction of weakly nonlinear internal waves in a stratified fluid confined in a trapezoidal tank. The set-up that leads to internal wave attractors has been devised to present ingredients conducive to internal wave turbulence. It eventually achieves a nonlinear cascade in frequencies and wavevectors via triadic resonant interactions, which results at large forcing amplitudes in a k^{-3} spatial energy spectrum.

INTRODUCTION

Fluids stratified in density develop waves beneath the surface, in their bulk. Nowadays these so-called internal gravity waves, whose origin comes from the simple Archimedes' principle, are the center of many theoretical and numerical studies, but also of major scientific cruises across the oceans. In the weakly nonlinear regime, these fluid systems may develop wave turbulence that corresponds to a large number of dispersive and weakly nonlinear interacting waves [1]. Internal waves are distinguishable among waves with a still unclear understanding, in particular due to their very unusual dispersion relation. We present here an experimental set-up that allows us to get efficient nonlinear energy transfers through frequencies and wavelengths and finally internal wave turbulence signatures.

The experimental set-up, sketched in Fig. 1, is a confined trapezoidal domain filled with a linear stratified fluid of density $\rho(z)$, function of the vertical coordinate z. The energy is injected at a very large scale by means of a vertical moving boundary oscillating around its mid horizontal axis, with a half cosine shape $a(t)\cos(\pi z/H)$.

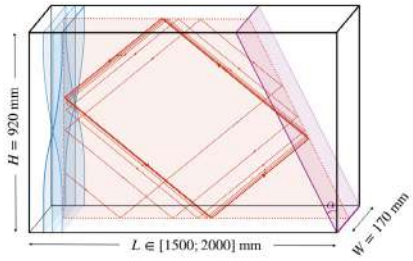

Figure 1: Experimental set-up with the generator (resp. slope inclined with an angle α) on the left (resp. right) of the tank. An example of ray tracing from a single point located on the left hand wall and corresponding to an oscillation at a given frequency $\omega = \pm N \sin\theta$ is shown in the case of a linearly stratified fluid with constant N-value.

INTERNAL WAVE ATTRACTORS

In a confined domain with an inclined slope, internal waves generated at a given frequency will concentrate on a closed loop [2] because of the peculiar reflection mechanism for internal waves. Indeed, even if Fig. 1 presents an example of ray tracing for a single emitting point, any initial point leads to the same loop, provided the frequency is kept constant. Similar to an internal wave billiard, different angles of propagation (*i.e.* different frequencies) lead to different attractors with simple or more complicated shapes.

In laboratory experiments in which viscosity cannot be overlooked, internal wave attractors are preserved but instead of a vanishingly small width, the balance between focalization and dissipation leads to a finite width. The energy, large just after the focusing reflection, is progressively dissipated along the perimeter of the attractor before being focused again by the slope.

It is important to stress that energy focalization and transfer to small scales both have here a pure linear origin since only the linear dispersion relation has been used so far. In the experimental domain presented in Fig. 1, this physical mechanism provides an energy transfer between wavelengths: this is a first important ingredient in the context of wave turbulence as it increases the number of waves with different wavevectors in interaction.

Owing to energy focusing, after each reflection on the slope, the reflected beam has a larger amplitude and is therefore more prone to reach the threshold for triadic resonant instability (TRI) [3]: a beam with primary frequency ω and wavevector $\mathbf{k}$ will generate two subharmonic waves with frequencies $\omega_\pm$ and wavevectors $\mathbf{k}_\pm$, satisfying the temporal and spatial resonance conditions $\omega = \omega_+ + \omega_-$ and $\mathbf{k} = \mathbf{k}_+ + \mathbf{k}_-$. Then, any wave in the domain may again become unstable through TRI and/or interact with any other wave to generate a third one, the latter process being without any amplitude threshold. One thus obtains a necessary ingredient for wave turbulence: a physical mechanism providing multiple nonlinear resonant interactions between waves of various wavelengths and frequencies.

*Corresponding author. E-mail: Thierry.Dauxois@ens-lyon.fr.

FROM THE LINEAR TO THE NONLINEAR REGIME

Let us focus first on the transition to the nonlinear dynamics with a monochromatic forcing. The amplitude of the generator a is gradually and slowly increased. One distinguishes several different regimes: the *linear regime* (a) with a monochromatic response leading to a nice IWA. Then, (b) corresponds to a TRI-perturbed IWA. The third and turbulent-like regime (c) is characterized by a broadband temporal spectrum and a spatial pattern in which one hardly recognizes any IWA. When the amplitude is further increased the temporal spectrum becomes richer. If some peaks are still visible at large forcing (especially at the forcing frequency), a rather continuous temporal spectrum is established (not shown here).

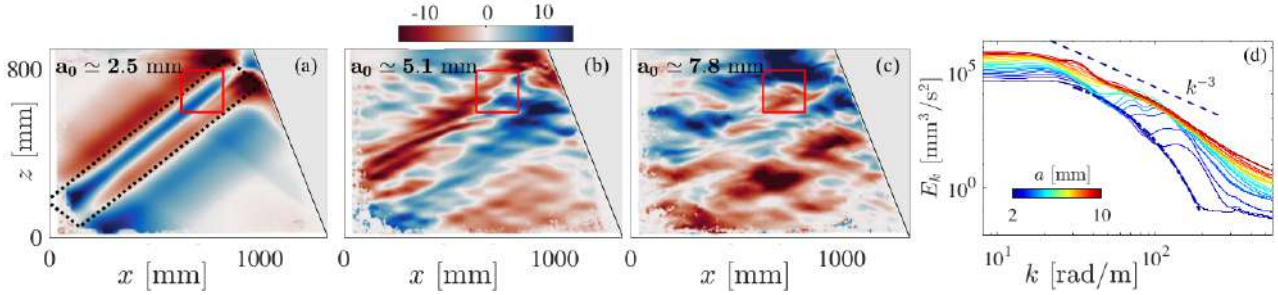

Figure 2: (a-c) Three snapshots of the horizontal velocity fields (in mm/s) measured when $a = 2.5$, 5.1 and 7.8 mm. (d) Energy density $E_k = k\langle\hat{u}(k,\theta,t)^2 + \hat{w}^2(k,\theta,t)^2\rangle_{\theta,t}$ as a function of the wavenumber k for the experiment shown in panels (a) to (c). The different curves correspond to increasing values of the amplitude a from 2 to 10 mm.

SPATIAL SPECTRA

Figure 2(d) presents the evolution of the spatial energy spectrum $E_k(k)$ as a function of the wavenumber $k = |\mathbf{k}|$ as the forcing amplitude is gradually increased. The analysis has been performed only on the low frequency band (*i.e.* $\omega < N$). The velocity field is then essentially composed of propagative waves [4].

In the linear regime, IWA have been shown to have an exponential spatial power spectrum $I_0 \exp(-\beta k)$, when dissipation due to the lateral walls dominates that of the bulk [5]. This behaviour is indeed observed at small amplitude ($a = 2$ mm), as shown by the dashed blue line.

When a is slightly increased, the attractor is destabilized by TRI and a small bump is visible around $k = 150$ rad/m (corresponding to a 4 cm wavelength). It corresponds to subharmonic waves which have a wavelength smaller than the typical width of the attractor [3]. Further increasing a, the bump not only moves towards smaller values of k but also widens.

At large forcing, these different ingredients lead to a richer spectrum that is compatible with a power law decay $E_k \sim k^{-3}$. Notice that the same power law is obtained for the vertical wavenumber k_z (not shown here). To reinforce our point, we checked the exponent for various IWA, using different forcings (monochromatic or modulated in frequency) and different geometrical parameters.

CONCLUSIONS

The trapezoidal and stably stratified domain has been shown to be an excellent experimental set-up to study weakly nonlinear interacting internal waves. Different forcings, monochromatic or stochastic, lead to a well defined power law behavior of the energy spatial spectrum. These are the first experimental signatures of internal wave turbulence.

MEASUREMENT AND MODELING OF INDEX OF REFRACTION STRUCTURE PARAMETER IN NEAR-MARITIME ENVIRONMENT

Chris Jellen[1], John Burkhardt[1], Charles Nelson[2], Miles Oakley [2], and Cody Brownell[*1]
[1]Mechanical Engineering Department, U.S. Naval Academy, Annapolis, Maryland, USA
[2]Electrical Engineering Department, U.S. Naval Academy, Annapolis, Maryland, USA

Summary To better understand optical propagation through the atmospheric surface layer, measurements of optical and environmental variables have been obtained continuously for more than a year at a site near the Chesapeake Bay in Maryland, USA. With this data, machine learning tools are applied to facilitate the creation of reduced-order models for the index of refraction structure coefficient, C_n^2, used in most optical turbulence estimates.

INTRODUCTION

As an electromagnetic beam propagates through a complex medium such as the atmosphere, fluctuations in the refractive index result in scintillation – increased variance in irradiance at the receiver or target, and excessive beam spreading [1, 2]. These effects are referred to as optical turbulence. Optical turbulence in the atmosphere is caused by the turbulent mixing of natural temperature variations. As a beam passes through regions of varying temperature (and therefore varying refractive index), its wave front becomes perturbed, causing additional beam spread, increased variance, and a reduction in irradiance on target (see Fig. 1).

Optical turbulence is most commonly quantified by C_n^2, the coefficient in the second order structure function for refractive index. The structure function defined in terms of temperature is $D(r) = [T(x) - T(x+r)]^2$, and for isotropic turbulence this is expected to take the form of $\mathrm{D(r)} = {C_T}^2 * \mathrm{r}^{\left(\frac{2}{3}\right)}$ where r is the spatial separation between temperature observations, ${C_T}^2$ is the structure coefficient for temperature, and square brackets denote averaging. Because of the proportionality between temperature and index of refraction, C_n^2 may be calculated directly from temperature measurements via ${C_T}^2$.

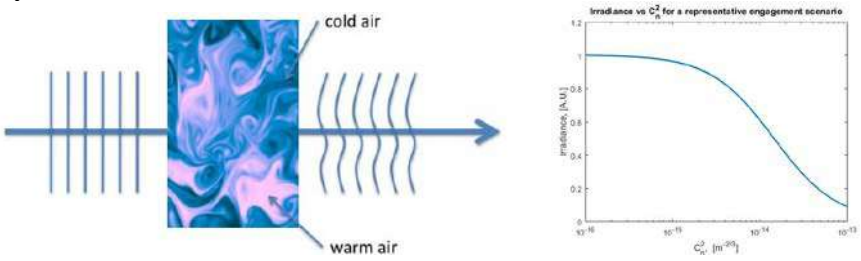

Figure 1. Schematic of light propagation through a complex medium (left) and influence of C_n^2 on irradiance at receiver (right).

Current models for laser beam propagation require path-integrated values of C_n^2, and rely on reduced order estimates of C_n^2 derived from limited physical observations – typically wind speed, time of day, and air-surface temperature difference. These models are effective in high-altitude environments where optical turbulence is low, but predictions become inaccurate close to the ground [3]. In low-altitude maritime environments, a large number of environmental factors affect optical turbulence. Current models assume that factors such as atmospheric temperature and humidity are constant over a beam's path. Due to the assumptions and simplifications inherent in existing physical models, predictions for C_n^2 break down close to sea level. This can significantly reduce the operational effectiveness of naval laser systems. A Naval Postgraduate School study suggested that other environmental factors such as the properties of the ocean below the propagation path made current models inaccurate for maritime environments [1]. An improved model for predicting the refractive index structure parameter using environmental data will enhance the accuracy of current models for laser propagation in maritime environments.

In this work, an extensive measurement campaign has been conducted to obtain C_n^2 values along with corresponding meteorological data in a maritime environment. Using this data, machine learning tools are then applied to understand the most relevent physical parameters and for the fabrication of new models for the prediciton of C_n^2.

MEASUREMENTS

A scintillometer is used to collect field measurements along a fixed propagation path of approx. 1-km over the Chesapeake Bay at the mouth of the Severn River in Annapolis, MD. The scintillometer consists of a transmitter and receiver, can be used to measure C_n^2 between observation stations (see Fig. 2). At each end of the propagation path, a weather station and oceanographic snode were used to measure a variety of environmental parameters, including air and

* Corresponding Author. E-mail: brownell@usna.edu.

water temperature, wind speed and direction, pressure, humidity, rainfall, and wave height. In addition to these weather stations and current profilers, other local atmospheric, oceanographic, and environmental parameters were collected. Atmospheric readings from a NOAA weather station in Annapolis Harbor were compiled to validate those measurements taken by the weather stations at each end of the path. Additional oceanographic parameters were taken from a NDBC data buoy located in Chesapeake Bay, less than two miles from the propagation path. In order to capture diurnal effects, sunrise and sunset times each day were used to determine the time after sunrise (temporal hour weight) for each reading. Sample C_n^2 data is shown in Fig. 3, indicating a wide range of atmospheric conditions over the observation period.

Figure 2. Measurement locations over Severn River.

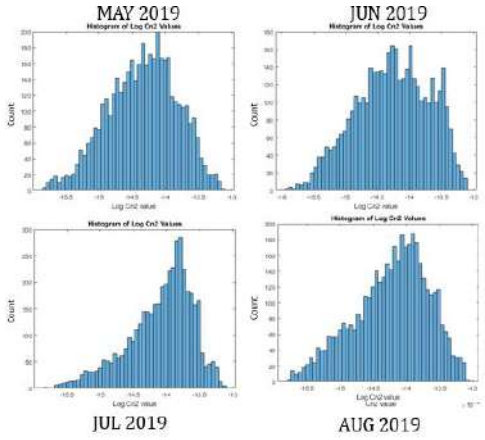

Figure 3. Histograms of (log) C_n^2 data collected over four months.

RESULTS

After training and testing individual regression trees, a random forest model was trained and tested using data from May 2019 to October 2019. This involved generating 500 distinct regression trees, each which used different environmental parameters at different times to make splits. The predicted value of C_n^2 from each final regression tree was averaged to generate an overall prediction for the value of C_n^2 given the environmental measurements in the training set. These predictions were compared to the field measurements of C_n^2 using five-fold cross validation. A plot of predicted C_n^2 vs. measured C_n^2 for the test indices, along with a red line to indicate perfect prediction accuracy, is given in Figure 4. The random forest model performed markedly better than any individual regression tree or multivariate linear model. When predicting the Log of C_n^2, the random forest model had a mean square error of 0.058, a percent error in Log prediction of 1.1%, and a model R^2 of 0.795, indicating that the predictions fell on or near the line of measured C_n^2 values. While the model performed well overall, the performance differed based on how close each test point was to training data in time. This was further investigated by re-training the model on one the subset of May 2019 data, with one day removed, and then testing the model on the removed day observations and observations taken three weeks later, in June of 2019.

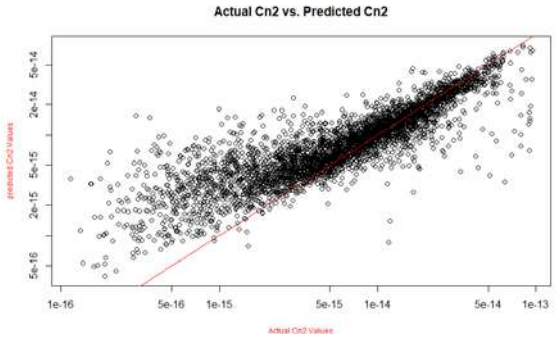

Figure 4. Random forest model, 500 trees, all predictors.

CONCLUSIONS

Linear models showed limited predictive capacity, even when compared to current bulk-atmospheric models. A non-linear regression tree model showed markedly improved predictive performance when compared to three multivariate linear models. This result encouraged investigation into other non-linear and ensemble non-linear machine learning models. The random forest model developed from the training data had the lowest absolute and percent error of any class of model. While the predictive power of the random forest model was better than a single regression tree or linear model, as quantified by the mean square error, the random forest model struggled to generate accurate prediction for data far removed from the training set.

WIND-TUNNEL STUDIES ON MECHANISMS OF GRAINS EMISSION IN TURBULENT BOUNDARY LAYER

Jie Zhang[1,2], Guang Li [1,2], Bo Yang [1,2]and Ning Huang [*1,2],
[1]Key Laboratory of Mechanics on Disaster and Environment in Western China, Ministry of Education of China, Lanzhou University, Lanzhou, China

Summary Grains emission is an important process of Aeolian transport which is common phenomena on many planets in the solar system and has great impact on landform formations as well as climate and ecosystems. To well understand the mechanisms of grains emission, wind-tunnel, a sophisticated device which is good at reproducing the wind condition of turbulent boundary layer and simulating the Aeolian transport, is generally employed. Here we firstly introduce the wind-tunnel laboratory in Lanzhou University and subsequently illustrate two elaborate wind-tunnel studies on grains emission to reveal the mechanisms of aerodynamic entrainment in turbulent boundary layer and the effect of surface renew in emission process.

WIND-TUNNEL LABORATORY IN LANZHOU UNIVERSITY (LZU)

The multifunctional environmental wind tunnel of Lanzhou University is designed to study scientific issues related to the wind-blown sand process in nature. Therefore, it is required to have the following basic functions: simulate the wind profile similar to the atmospheric boundary layer, and have an enough space for the development of turbulence boundary layer and wind-blown sand stream.

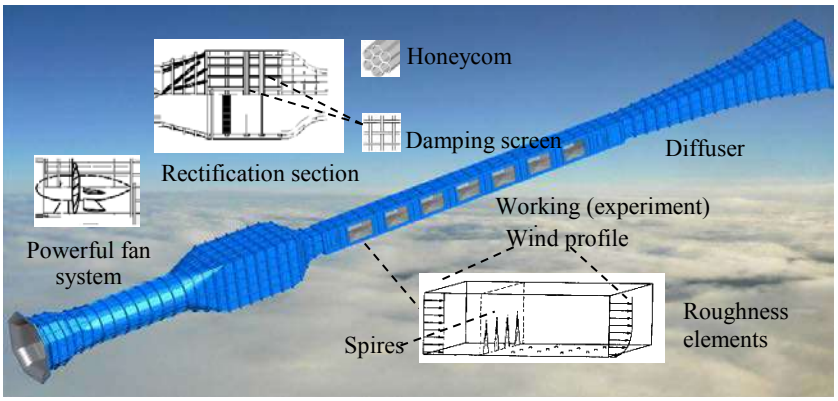

Figure 1: Sketch map of the wind tunnel of LZU.

As shown in Fig. 1, it is a blow-down wind tunnel, which is in total 55 m long, including a powerful fan system, a rectification section, a working section and a diffuser. High-speed and turbulent wind can be generated by a fan of 75 Kw in the first part. Then, the turbulent air flows into the rectification section. Here, the flow speed is slowed down because of a bigger cross-section. Turbulent eddies in the original flow generated by the fan are destructed by a combination of honeycomb and damping screens (rectangular grids) deployed in this part. After passing the rectification section, the air flow becomes uniform. The rectified air flow is accelerated in the working section which has a smaller but uniform cross-section of 1.3 m (width) × 0.45 m (height). The length of the working section is about 22 m, which is enough for the development of turbulence and wind-blown sand stream. Some spires or roughness elements (or both) are set up in the front of this section to generate a turbulent boundary layer. Finally, the air flows out from the diffuser with an increasing cross-section. The wind tunnel is controlled by a computer and the wind speed can be adjusted between 3 and 40 m/s which is normal wind speed range in natural.

WIND-TINNEL EXPERIMENT ON AERODYNAMIC ENTRINMENT

A series of wind tunnel experiments were executed to deepen our understanding of aerodynamic entrainment in turbulence. The experimental data show that the prevalent model cannot even qualitatively predict the aerodynamic entrainment rate. The conventional linear relationship between entrainment rate and mean surface shear stress is only confirmed for continuous flux for sufficiently large surface shear stresses. Additionally, intermittent entrainment, which is sensitively affected by wind turbulence, exists and follows an exponential law (Fig. 2a). We revealed the physical behavior of surface particles exposed in turbulent boundary layer, the regimes of aerodynamic entrainment and three different thresholds. We showed that fluctuations in surface shear caused by turbulence and the variation of the entrainment threshold caused by the spatially varying surface condition can both be represented by distribution functions that should be introduced into the theoretical modeling to fully describe aerodynamic grain entrainment.

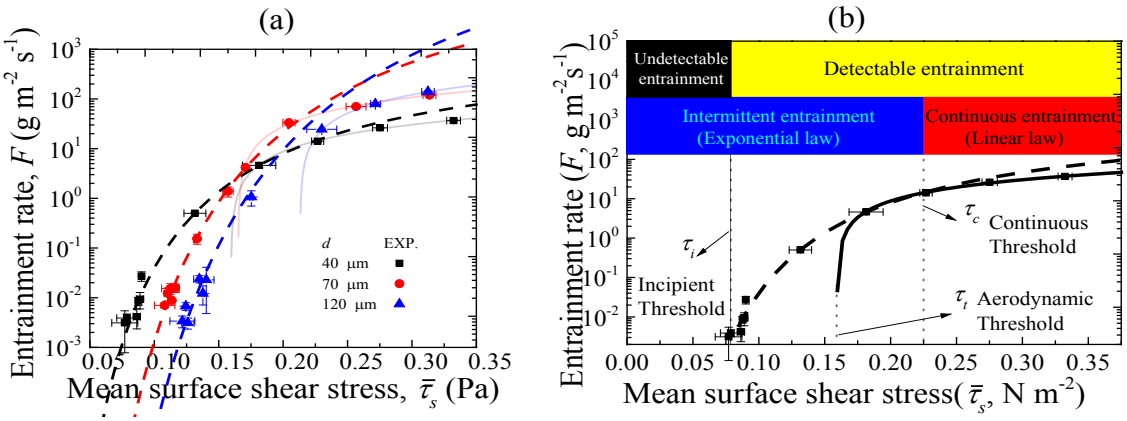

Figure 2: (a) Measured entrainment rate F vs. mean surface shear stress $\bar{\tau}_s$; (b) Regimes of aerodynamic entrainment. Three different thresholds are defined. The incipient threshold is defined as the minimal mean surface shear stress below which grain entrainment could not be detected. The continuous threshold corresponds to the minimal mean surface shear stress above which grain entrainment continuously occurs to activate the linear law. The aerodynamic threshold is the minimal average shear stress required to give rise to the motion of surface particles. The value aerodynamic threshold could be obtained by fitting the data of continuous entrainment to the linear law.

INVERSTIGATION OF DUST EMISSION OVER VARIOUS SOIL SURFACES

Wind-tunnel experiments are carried out on dust emissions from different soil surfaces to better understand dust emission mechanisms. The effects of surface renewal on aerodynamic entrainment and the saltation bombardment are analyzed in detail, and the measurements are used to test published dust models. It is found that flow conditions, surface particle motions (saltation and creep), soil dust content and ground obstacles all significantly affect dust emission, causing dust emission to change in orders of magnitude. Aerodynamic entrainment is highly effective, if dust supply is unlimited, as in the first 2-3 minutes of our wind-tunnel runs (Fig. 3a). While aerodynamic entrainment is suppressed by dust supply limit, surface renewal through the motion of surface particles is found to be an effective pathway to remove the supply limit ((Fig. 3b)). Surface renewal is also found to be important to the efficiency of saltation bombardment. We have thus demonstrated that surface renewal is a significant mechanism affecting dust emission and we recommend that this mechanism be included in future dust model.

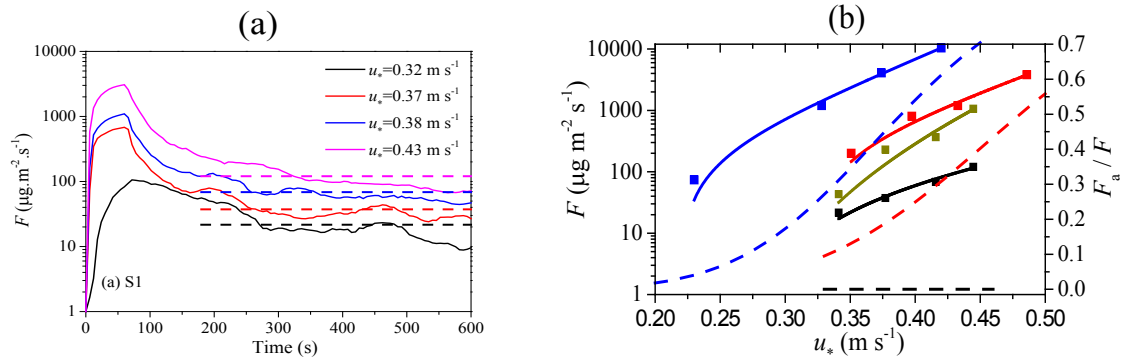

Figure 3: (a) Dust emission flux series over natural soil surfaces; (b) Measured (dots) and predicted (solid lines) dust emission flux vs. friction velocity over different surface. The ratios of aerodynamic emission flux to total flux are shown as the dashed lines and corresponding to the right vertical axis. The contribution of aerodynamic emission increases, because of surface renew.

CONCLUSIONS

The multi-function environmental wind-tunnel with a long working section built in Lanzhou University is a sophisticated device which has been validated to effectively study the mechanisms of Aeolian Process by many successful experiments.

STATISTICAL ANALYSIS OF TURBULENT FLOW OVER WAVY SURFACE

Enwei Zhang, Xiaoliang Wang, Wangxia Wu, and Qingquan Liu *
School of Aerospace Engineering, Beijing Institute of Technology, Beijing, China

Summary The turbulent flow over the wavy surface is numerically studied based on LES approach with the dynamic one-equation subgrid-scale stress model. A series of flow variables are extracted and analysed in detail, including the time-averaged flow velocity, turbulent kinetic energy, Reynolds shear stress and the wall pressure. Besides, the properties of flow fields and the statistical characteristics of turbulence are investigated and compared, in the consideration of different ratios between amplitude and wavelength of the wavy surfaces. The results show that, due to the pressure-induced form drag, the streamwise time-averaged velocity decreases with the ratio between amplitude and wavelength of wavy surface in both the viscous and logarithmic regions. The maximum values of turbulent kinetic energy and Reynolds shear stress appear at the region close to the trough of wavy surface.

INTRODUCTION

The turbulent flow over wavy surface exists in a large number of engineering and environmental problems. Both large-scale flow such as atmospheric flow over complex terrain and small-scale flow such as experimental channel flow are examples of this kind of flows. So, understanding the turbulent characteristics of the flow over complex wall geometry is of significance for studying the mechanism of flow, which is valuable for utilization of environmental resources, providing references for the engineering applications.

The last several decades has seen a lot of achievements in this problem, including turbulent boundary layer flow [1,2], heat and mass transfer [3,4], and so on. Experiments by Hamed A.M. et al.[1] provided velocity profile, turbulent kinetic energy and Reynolds shear stress over two dimensional and three dimensional large-scale wavy walls. Takenobu [4] used large eddy simulation to study the flow and gas dispersion over wavy walls with three ratios of wave amplitude to wavelength. However, the mechanism of turbulent flow over wavy walls and the relationship between velocity profile and wall pressure distribution are still not well understood. Therefore, turbulent flow over wavy walls with different ratios of wave amplitude to wavelength are systematically studied by large eddy simulation model (LES).

NUMERICAL METHOD

The problem considered here is a three dimensional fully developed turbulent flow over wavy surface. We define the x, y, z as streamwise, spanwise and vertical direction respectively. The filtered incompressible Navier-Stokes equations and the continuity equation for describing resolvable turbulent flow field are as follow:

$$\frac{\partial u_i}{\partial x_i} = 0, \tag{1}$$

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho_0}\frac{\partial p}{\partial x_i} + \nu \nabla^2 u_i - \frac{\partial \tau_{ij}}{\partial x_j} \tag{2}$$

where, u_i are the filtered velocity components, τ_{ij} are the subgrid-scale stress modelled by dynamic one-equation model. Periodic boundary conditions are applied in streamwise and spanwise directions, top and bottom boundaries are applied as no-slip walls. In the vertical direction, the first layer of the grids is clustered near the wall with Δz^+= 0.5. The Reynolds number is defined as $Re = U_b h/\nu$(= 4000), where the h is half-height of the channel, U_b is bulk velocity, ν is kinematic viscosity. OpenFOAM is utilized for numerical simulation with the SIMPLE algorithm for pressure-velocity coupling. The time averaging starts after reaching a fully developed turbulence (corresponding to 15 flow cycles) and continues for another additional 30 flow cycles. The LES model is validated by several simulations in agreement with experiment results for turbulent flow over wavy structures. Then the LES model is used to study turbulent characteristics of flow over wavy surface of different ratios of wave amplitude to wavelength.

RESULTS AND DISCUSSIONS

Figure.1 shows turbulent characteristic information of flow over wavy surface of ratio 0.05. The separation zones behind the wave crest expand with increase of the wavy surface ratio (a/λ_x). The region of separation zones locate at $x/\lambda_x \in$[0.3, 0.55] for a/λ_x= 0.025, $x/\lambda_x \in$[0.2, 0.7] for a/λ_x= 0.05, $x/\lambda_x \in$[0.15, 0.75] for a/λ_x= 0.075, $x/\lambda_x \in$[0.1, 0.8] for a/λ_x= 0.1. The direction of vertical time-averaged velocity profile for cases $a/\lambda_x > 0.05$ is in contrast from cases $a/\lambda_x < 0.05$ at the position of x/λ_x= 0.7. In the near wall region, the distribution of streamwise time-averaged velocity along the wavy wall appears to be out-of-phase with wall geometry as shown in Figure 1(a). In Figure 1(b), the high upward velocity occurs at the stoss side of the wall near wave crest while the high downward velocity region locates

*Corresponding author. E-mail: liuqq@bit.edu.cn

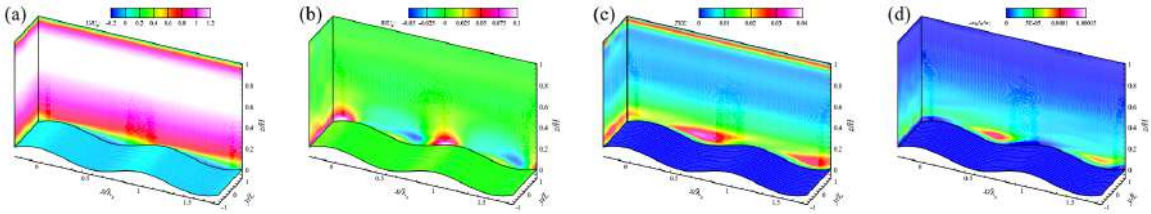

Figure 1: (a) Streamwise time-averaged velocity (b) vertical time-averaged velocity (c) turbulent kinetic energy and (d) Reynolds shear stress contour with a/λ_x= 0.05.

at the lee side expanding to the next stoss side of the wall. As shown in Figure 2, the streamlines exhibit a quasi-elliptical pattern in the separation zone, which locate under the elevation of wave crest. Above the wave crest, the streamlines are horizontal. But at the reattachment region, streamlines are a little bit concave which are consistent with other study [4].

Turbulent kinetic energy and Reynolds shear stress increases with ratio of a/λ_x. For the small ratio case, the region of high turbulent kinetic energy is also small. But for the other cases, the regions of high turbulent kinetic energy locate approximately between $x/\lambda_x \in$[0.3, 0.7] and $z/H \in$[0, 0.1] for a/λ_x= 0.05, $x/\lambda_x \in$[0.2, 0.9] and $z/H \in$[0, 0.15] for a/λ_x= 0.075, $x/\lambda_x \in$[0.1, 1.1] and $z/H \in$[0, 0.2] for a/λ_x= 0.1. And the regions of high Reynolds shear stress occur between $x/\lambda_x \in$[0.3, 0.7] and $z/H \in$[0, 0.1] for a/λ_x= 0.075, $x/\lambda_x \in$[0.2, 0.8] and $z/H \in$[0, 0.15] for a/λ_x= 0.1. In addition , the maximum turbulent kinetic energy and Reynolds shear stress occur at $x/\lambda_x \approx 0.5$ as shown in Figure 1(c) and Figure 1(d), which are approximately distributed symmetrically in one wavelength range.

The dimensionless streamwise time-averaged velocity decreases in both viscous region and logarithmic region with increase of ratio of a/λ_x as a result of the impediment of the wavy wall. The flow over wavy surface is different from the flat wall turbulent flow in viscous region, and the dimensionless velocity U^+ of the former is smaller than the latter [5].

The pressure distribution for different ratios of a/λ_x is diversified. As shown in Figure 3, there is negative pressure zone starting from wave crest and expanding to the stoss side, and a small positive pressure zone occurs at the stoss side of the wall near wave crest. In Figure 4, the form-drag induced by pressure distribution increases with increase of ratio of a/λ_x, while the viscous drag decreases.

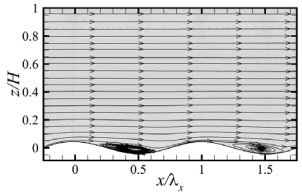

Figure 2: Time-averaged field streamline.

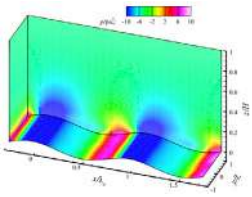

Figure 3: Pressure distribution contour with a/λ_x= 0.05.

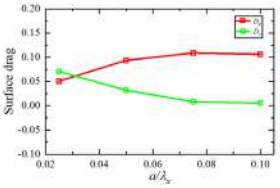

Figure 4: Form drag and viscous drag with different ratio of a/λ_x.

CONCLUSIONS

A large eddy simulation (LES) model for turbulent flow over wavy surface is constructed and validated. Then, it is used to study the turbulent characteristics of flow over various wavy surfaces. Main conclusions can be drawn as follows:

Separation zones behind the wave crest expand with increase of ratio of wave amplitude to wavelength.

The region of high turbulent kinetic energy and Reynolds shear stress expand with increase of ratio of wave amplitude to wavelength. $x/\lambda_x \approx 0.5$ is the position where the maximum turbulent kinetic energy and Reynolds shear stress occur.

The dimensionless time-averaged velocity decreases with increase of ratio of wave amplitude to wavelength. In viscous region and logarithmic region, the dimensionless velocity U^+ are lower compared with flat wall turbulence.

The form-drag occurs owing to the pressure distribution near wall and increases with the wavy surface ratio, while the viscous drag decreases.

PHASE-DEPENDENT SEDIMENT CONCENTRATION CARRIED BY NONLINEAR WAVES

Yiqin Xie[1,2], Yanrong Kuai[2], Jifu Zhou *[1,2], and Xu Wang[2]
[1]School of Engineering Sciences, University of Chinese Academy of Sciences, Beijing, China
2Key laboratory for Mechanics in Fluid Solid Coupling Systems, Institute of Mechanics, Chinese Academy of Sciences, Beijing, China.

Summary A sediment transport model coupled with numerical wave flume is built to simulate the hydrodynamic characteristics of nonlinear waves by using the Reynolds-averaged Navier-Stokes equations and the *k-ε* turbulence model. The model is validated by experimental data. It is shown that the model can well reproduce the spatial and temporal distribution of sediment concentration carried by nonlinear waves. Then, the variation of sediment concentration is studied. The results show that sediment carrying capacity increases almost linearly with wave height, whereas it increases more slowly with wave period. The averaged sediment concentration in different phase stages behaves similarly, and the averaged sediment concentration of the wave crest stages is higher than that of the wave tough stages.

INTRODUCTION

Sediment movement is one of the fundamental problems in coastal engineering research, which has a significant impact on ecological environment and human activities. In the process of wave propagation in the coastal region, the wave surface steepens with increasing wave height, and may eventually break. Then the nonlinearity becomes very strong, which plays an important role in the distribution of sediment concentration and further influences sediment carrying capacity carried by waves. Therefore, it is of significant implication to analyse the distribution law of sediment concentration carried by nonlinear waves.

A great progress has been made in the investigation of sediment carrying capacity with many empirical formulas obtained. For example, Dou Guoren [1] derived a formula of sediment carrying capacity under waves and currents by means of energy superposition. Liu Jiaju [2] analysed the data of sediment concentration profile near coastal areas and acquired a formula via dimensional analysis. Li Ruijie [3] obtained a formula based on sediment concentration profile obtained from the solution of two-dimensional sediment transport model. However, these formulas are limited to either linear waves or currents. Few attention is paid to the effect of nonlinearity of waves.

In the present paper, a sediment transport model coupled with numerical wave flume is built to simulate the hydrodynamic characteristics of nonlinear waves by using the Reynolds-averaged Navier-Stokes equations and the k-ε turbulence model. Then, sediment transport process induced by nonlinear waves is investigated. The variation of sediment concentration with wave parameters is analysed. The averaged concentration in different phase stages is discussed.

SEDIMENT TRANSPORT MODEL

The numerical wave flume for unsteady incompressible fluid is governed by the two-phase RANS equations:

$$\frac{\partial u_i}{\partial x_i} = 0 , \tag{1}$$

$$\frac{\partial \rho u_i}{\partial t} + \frac{\partial \rho u_i u_j}{\partial x_j} - \frac{\partial}{\partial x_j}\left(\mu_{eff}\frac{\partial u_i}{\partial x_j}\right) - \frac{\partial u_i}{\partial x_j}\frac{\partial \mu_{eff}}{\partial x_j} = -\frac{\partial p_d}{\partial x_i} - \left(g_j \cdot x_j\right)\frac{\partial \rho}{\partial x_i} , \tag{2}$$

where u_i is velocity in the ith direction, ρ is the fluid density, g_j is the jth component of the gravitational acceleration, p_d is the fluid dynamic pressure, and $\mu_{eff} = \mu + \rho\nu_t$ is the dynamic viscous coefficient, composed by the molecular dynamic viscosity and the turbulent viscosity, ν_t is obtained by solving the *k-* ε turbulence model. The VOF method is used to track the free surface location.

The suspended sediment concentration is acquired from the advection-diffusion-settling equation:

$$\frac{\partial c}{\partial t} + \frac{\partial\left(u_i - w_s\delta_{i3}\right)c}{\partial x_i} = \frac{\partial}{\partial x_i}\left(\varepsilon_s\frac{\partial c}{\partial x_i}\right) , \tag{3}$$

where w_s is the sediment settling velocity and can be determined by Van Rijn's method [4], ε_s is the sediment diffusivity.

The boundary conditions are specified as follows for wave motion and sediment transport, respectively. Nonlinear waves are generated using the stream function theory at the inlet of the wave flume. A sponge layer is employed to eliminate wave reflection at the outlet of the flume. No-slip condition is adopted for the velocity field at the bottom. No-flux of sediment is applied at the free surface. At the flume bottom, an empirical pickup function is adopted, which specifies the sediment flux as a function of bed shear stress.

RESULTS AND DISCUSSION

* Jifu Zhou. Email：zhoujf@imech.ac.cn

The numerical model is verified by experimental data from Amoudry, et.al[5], as shown in Table 1. In Figure 1, it is shown that the simulation results agree well with experimental data.

Table 1. The parameters of the cases to verify numerical model

Case	h/m	H/m	T/s	d/mm	λ_r /m	η_r /m	w_s /(m/s)
A	4.5	0.85	5	0.329	0.37	0.04	0.017
B	4.5	1.11	5	0.329	0.43	0.05	0.017

To analyse the influence of wave height and period on the sediment carrying capacity, several cases are specified based on case A and case B respectively with the wave height changing from 0.5 m to 2 m and the wave period from 4 s to 8 s. By double integrating sediment concentration over one wave period and the whole water depth, one can easily obtain the sediment carrying capacity of a wave. Figure 1 and Figure 3 show the variation of sediment carrying capacity with wave height and wave period, respectively. It is found that sediment carrying capacity increases with wave height and wave period as well.

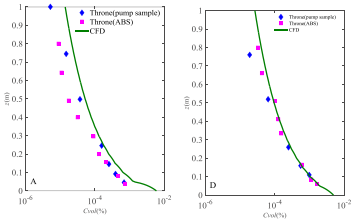

Figure 2. The vertical distribution of period-averaged concentration.

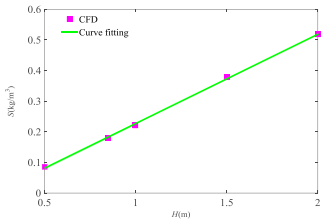

Figure 3. Sediment carrying capacity varying with wave height.

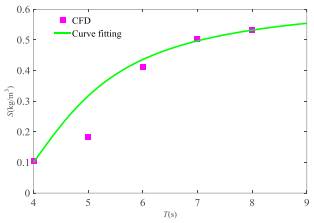

Figure 4. Sediment carrying capacity varying with wave period.

Further analysis goes for the variation of averaged sediment concentration with wave height and period in different phase stages. One wave period is divided into four stages as shown in Figure 4. Figure 5 and Figure 6 present the numerical results. It is obvious that the averaged concentration in different stages varies similarly to the sediment carrying capacity. Nonetheless, the averaged sediment concentration in wave crest stages (stage 1 and stage 4) is higher than that in tough stages (stage 2 and stage 3). This result is probably of implication for parameterizing sediment carrying capacity of nonlinear waves.

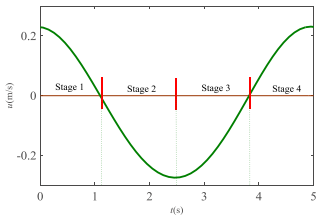

Figure 6. Schematic diagram of stage division in one wave period.

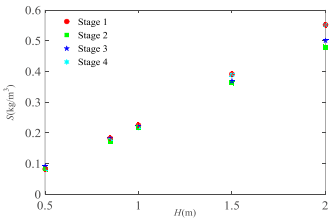

Figure 7. Averaged concentration varying with wave height.

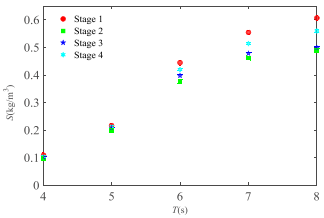

Figure 8. Averaged concentration varying with wave period.

CONCLUSIONS

A sediment transport model coupled with numerical wave flume is built and validated by experimental data. Based on this model, sediment carrying capacity of nonlinear waves is analysed. The numerical results demonstrate that the sediment carrying capacity of nonlinear waves increases almost linearly with wave height, whereas it increases more slowly with wave period. The averaged concentration in different phase stages behaves similarly. The averaged concentration in wave crest stages is higher than that in wave tough stages. This is probably of implication for parameterizing sediment carrying capacity of nonlinear waves.

EFFECT OF UPDRAFT ON NON-SUPERCELL TORNADO GENESIS

Koji Sassa[1], and Haruna Nagano [1]
[1]Faculty of Science and Technology, Kochi University, Kochi, Japan

Summary The present experimental study aims to clarify the effect of updraft on tornado genesis. We tested three updraft fans with different diameter at three bottom heights and at three driving voltages settled on a cold outflow intruding into environmental flow. The results showed that tornado-like vortices changed their rotation direction and size depending on the characteristics of updraft. The vortices were sometimes unstable and a pair of counter rotating vortex also was appeared. These facts shows that the characteristics of updraft affect tornado genesis. The updraft slightly smaller than the width of cold outflow is found to be suitable for tornado genesis.

INTRODUCTION

Tornadoes frequently occur in Japan and cause damages. Most of them are non-supercell ones which are classified as Type III by Agee and Jones (2009). Although such type tornadoes are relatively weak, they brake houses and plants. Different form supercell tornadoes, the parent clouds of non-supercell tornadoes do not have meso cyclones. Moreover such tornadoes sometimes occur at the same time of the development of parent clouds. Therefore, it is difficult to catch the tornado genesis by weather radars. We need to understand the flow condition of tornado genesis in order to predict the occurrence of tornadoes.

We have made the laboratory experiments to reproduce the environment of tornado genesis (Sassa and Watanabe 2016, Sassa and Komatsubara 2017). We showed the flow condition suitable for tornado genesis, in which the velocity of cold outflow is slightly higher than that of the environmental flow. In this case, the local front between the cold outflow and the environmental flow is fixed and the tornado-like vortex is formed at the end of the local front. The updraft velocity was also confirmed to affect the tornado genesis. However, we have still not examined how the other characteristics of the updraft, e.g., its diameter and height, affect the tornado genesis.

The present experimental study aims to investigate the effect of the updraft characteristics to the tornado genesis.

EXPERIMENT

The experimental set up is composed of our original outflow simulator reproducing cold outflow from cumulonimbus, the environmental flow simulator and a fan generating updraft as shown in Fig. 1. Our experimental system is quite different from traditional tornado simulators (e.g., Church et al. 1977). We do not need any chamber to keep tornado-like vortex. The outflow simulator is a kind of blow down type wind tunnel having cooling system. The height and width of its outlet are h = 40 mm and b = 100 mm, respectively. The cooling system is composed of thin aluminum heat sink, Peltier elements and water tank. We can easily control the velocity and temperature of cold outflow. The environmental flow simulator is also a kind of blow down type wind tunnel. Its outlet is 120 mm in height and 500 mm in width. The outlet of the outflow simulator faced the outlet of the environmental flow simulator. The gap between both simulators is 1050 mm. Then, it is simulated that the cold outflow intrudes in environmental flow. The origin of the coordinate system is set at the centre bottom of the outlet of outflow simulator and the coordinates are x: downstream, z: upward and y: perpendicular to x and z. Three updraft fans were examined. Their diameters, d, of fan A, B, C are 50, 90 and 150 mm, respectively. They were set at x = 150 mm and y = 80 mm. Their bottom height was set at z = 50, 100, 150 mm. Applied voltage driving fan was set to 12, 14, 16 V. Totally, we made 27 cases of experiment at various updraft conditions. In the present study, we set the outflow velocity, Uo = 0.3 m/s and the environmental flow velocity, Ug = 0.2 m/s. One Peltier element was driven at 5 V in the present experiment. Horizontal plane at z/h=0.125 was illuminated by laser sheet light and filmed by hi-speed cameras at 1000 fps in frame rate. The mist from ultrasonic humidifier was used as tracer for visualization. Horizontal velocity components, u, v, were measured by using dynamic PIV method. We also filmed the flow fields by ordinal video camera at 30 fps in order to examine flow situation.

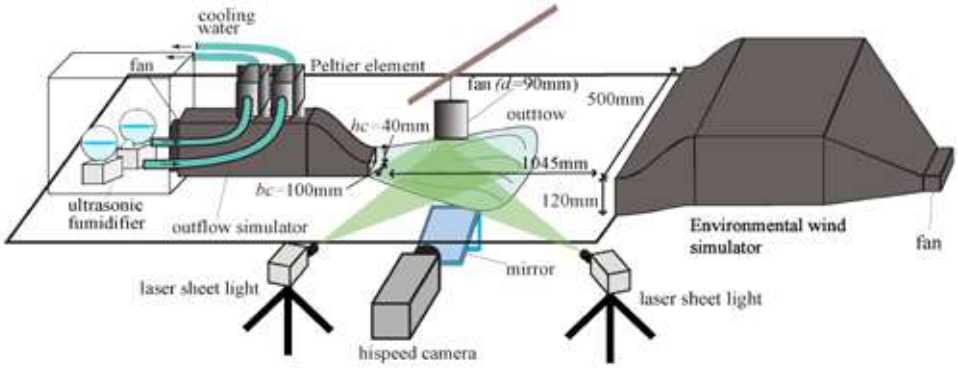

Figure 1. Experimental setup. Base plate is made of

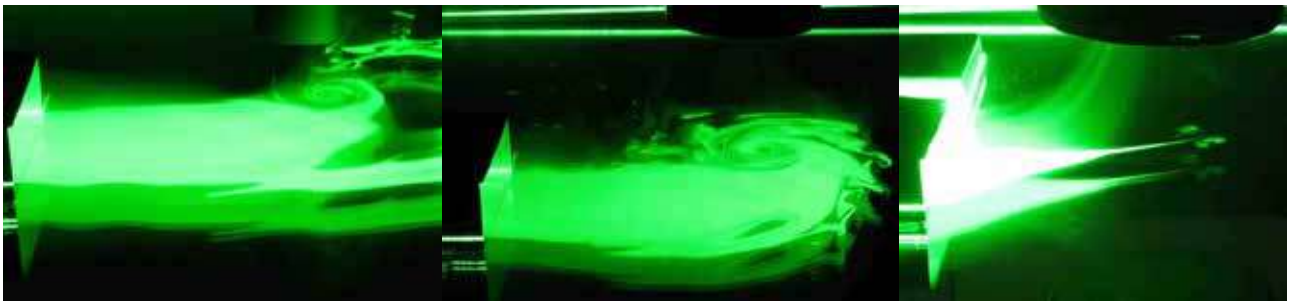
RESULT AND DISCUSSION

The smallest updraft by fan A cannot stretch the cyclonic vorticity of horizontal shear at the local front in most of cases. The small tornado-like vortex is generated only in the lowest height, z = 50 mm as shown in Fig.2a. In this case, the updraft is quite localized, then cold outflow flows downstream and the local front is not formed. The tornado-like vortex was formed in the mixing layer between the cold outflow and the environmental flow.

In the case of fan B, the diameter of updraft region is slightly smaller than the width of the cold outflow. Such situation is similar to that relation between the actual updraft of cumulonimbus and the cold outflow. As shown in Fig.2b, the local front is clearly formed and the tornado-like vortex appears at the left hand side edge of the local front. The tornado-like vortex is the most stable in all cases and its intensity is also highest. Such situation was observed in relatively larger heights. The updraft of fan B is too strong to generate the tornado-like vortex at z = 50 mm. In this case, the rotation direction of the tornado-like vortex frequently changed cyclonic to anticyclonic and vice-versa as the direction of horizontal shear changes.

Fan C simulates the situation that the updraft region is larger than the width of cold outflow like the mesocyclone in a supercell. Most of cold outflow is sucked up due to strong updraft and the local front becomes not to be clear as shown in Fig. 2c. In this case, the rest of the cold outflow forms counter rotating vortex pair. It is similar to the pair of cyclonic and anticyclonic tornadoes observed in a supercell (Bluestein et al. 2007). But the tornado-like vortex becomes to be relatively stable at z =150 mm. These facts show that the effective region of updraft is changed by the height of fan and the characteristics of tornado-like vortex is also altered depending on the width of updraft.



(a) fanA:d=50 mm at z=50 mm (b) fan B:d=90 mm at z=100 mm (c) fan C:d=150 mm at z=100 mm

Figure 2. Typical example of tornado-like vortex

CONCLUSIONS

The width and height of updraft were found to affect the structure of tornado-like vortex. Despite the location of the updraft fan was fixed at the left hand side edge of the cold outflow, cyclonic and anti-cyclonic vortices appeared depending on the updraft situation. Even the counter rotating vortex pair was observed. These facts shows that the present experiment can simulate not only non-supercell tornado but also supercell tornado. The most suitable condition for tornado genesis was found that the updraft region is slightly smaller than the cold outflow as observed in actual cumulonimbi.

FLOW THROUGH A POROUS MEDIUM AND GROUND HEAT EXCHANGERS

Iosifina Iosif Stylianou[1], Paul Christodoulides[2a)], Lazaros Aresti[2], Savvas Tassou[1]& Georgios A. Florides[2]
[1]Institute of Energy Futures, Brunel University London, Uxbridge, Middlesex UB8 3PH, UK
[2]Faculty of Engineering and Technology, Cyprus University of Technology, Limassol, Cyprus

Summary The thermal response of vertical Ground Heat Exchangers (GHEs) is examined when the ground sublayer involves underground water flow. A numerical model constructed to allow for the presence of porous media regions and a consequent validated computational finite elements model in FlexPDE software lead to an analysis of several factors effecting the efficiency of the GHE, such as summer and winter mode of operation, underground temperature variation in small depths, borehole radius, borehole grout properties, U-tube diameter, U-tube leg and borehole centers distance, groundwater flow velocity.

INTRODUCTION

Geothermal energy, the thermal energy generated and stored in the Earth, is a fast-growing Renewable Energy Source. It has been used since Paleolithic times for bathing, through the use of water from hot springs, as well as since ancient Roman times for space heating. It is nowadays used for electricity generation as well, in addition to district heating, space heating, spas, industrial processes, desalination and agricultural applications. Depending on the depth geothermal energy systems (GES) can be classified as deep or shallow. One of the most common approaches for lower and mid-depth applications for shallow GES is the borehole vertical Ground Heat Exchanger (GHE), where using a Ground Source Heat Pump (GSHP) fluid circulates through pipes (U-tubes) and an indirect thermal contact is achieved between the fluid and the subsurface. GHE technology is of higher efficiency for air-conditioning compared to conventional systems as the underground environment provides lower temperature for cooling and higher temperature for heating, with the underground temperature being approximately equal to the mean annual atmospheric temperature of the year [1–2].

A GHE system is controlled by the effective area, the thermal conductivity of the subsurface, the velocity of the circulating fluid, the equipment involved, (type and size of pipes, the grouting material, etc.), the presence of underground water in the form of an aquifer, and so on. A parametric analysis of the aforementioned factors using simulations and validation tools can lead to the optimization of the GHE system. For more on the design aspects of GHEs the reader is referred to [3]. An aquifer is the saturated permeable geologic unit that can transmit significant quantities of water under ordinary hydraulic gradients [4]. In order to describe the flow through a porous medium, Darcy's law needs to be applied. The theory, allowing the estimation of the velocity or flow rate within an aquifer was firstly established by Darcy [5] based on experimental results. Model results with various seepage velocities (i.e. Darcy's velocity over porosity) indicate that groundwater flow influences the average GHE temperature, and in the water-baring layer the average temperature is lower than in the dry regions [6]. It is also noteworthy that the temperature of the affected ground layer reaches a steady-state much sooner than in other regions.

The effect of an aquifer on a GHE is examined in this paper through numerical modeling in the FlexPDE software based on the convection-diffusion equation and Darcy's law. FlexPDE is a general-purpose software that builds a mesh, constructs a system finite-elements model (FEM), solves it, and presents an easy to use graphical output for steady-state, time-dependent and free boundary problems.

MATHEMATICAL MODEL OF GHEs IN POROUS MEDIA

The basic three-dimensional equation governing the convective and conductive heat transfer is given as

$$\rho c_p \frac{\partial T}{\partial t} + \rho_f c_{pf} u_{in} \cdot \nabla T + \rho_w c_{pw} u_p \cdot \nabla T + \nabla \cdot (-\lambda \nabla T) = Q, \quad (1)$$

where ρ denotes the density [kg m^{-3}], u the velocity [m s^{-1}], T the temperature [K], c_p the specific heat capacity [J kg^{-1} K^{-1}], λ the thermal conductivity (W m^{-1} K^{-1}), Q the power density of the heat source [W m^{-3}]. Subscript f denotes fluid, w denotes water, in denotes inside tube and p denotes porous media. At the boundary between the fluid and the tubes (Darcy's regime) the convective heat flux is $h\Delta T$, where h is the convective heat transfer coefficient of the process [W m^{-2} K^{-1}] and ΔT is the temperature difference at the boundary. The convection heat transfer coefficient h can be estimated to be $h = \lambda \mathrm{Nu}/\mathrm{D_H}$, where $\mathrm{D_H}$ is the hydraulic diameter (in this case the tube-inside diameter) and Nu is the Nusselt number. The Nusselt number in this case can be expressed through the Dittus–Boelter correlation as $\mathrm{Nu} = 0.023\mathrm{Re}^{0.8}\mathrm{Pr}^{n}$, where $\mathrm{Pr} = \mu c_p/\lambda$ is the Prandtl number, $\mathrm{Re} = \rho c_p d_{in}/\mu$ is the Reynolds number, μ is the dynamic viscosity [kg m^{-1} s^{-1}, and porosity $n = 0.4$ for heating and 0.33 for cooling. For more on the fluid properties necessary for the application of the equations above and the various boundary layers of the GHE the reader is referred to [7–8].

COMPUTATIONAL MODEL AND RESULTS

The desired model based on the numerical model above was created in the FlexPDE environment with the following meshed ground layers (zones) from top to bottom: 80 m of dry well area; 25 m of high water-velocity area (0.00005 m s^{-1}); 55 m of low water-velocity area (0.0000000116 m s^{-1}); 5 m of base area shown in purple. The configuration above is a model for an existing borehole GHE in Lakatameia area, Cyprus, and has been validated through Thermal Response Testing (TRT) [7]. The underground temperature in the Lakatameia BH, for depths over 7 m is 22°C, with 1°C increase per 100 m. The best-fit equations for the temperature gradient were imposed on the numerical model to match the ground

temperatures used in simulations to the actual temperatures of the ground during the experiments (Figure 1 for deep zone). The results for the computational model show a good agreement with TRT measured values (Figure 2).

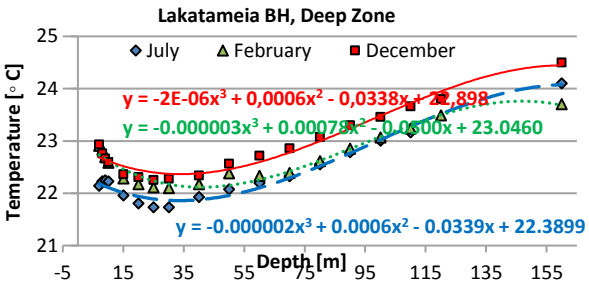

Figure 1. Recorded underground temperature at the Lakatameia borehole (BH) deep zone (7–160m), shown is the best-fit equation.

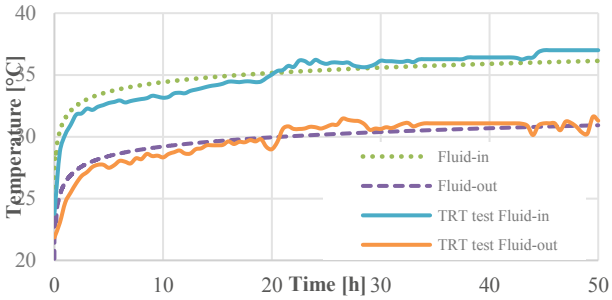

Figure 2. TRT recorded temperatures (December) at the Lakatameia BH (TRT Fluid-in/out) in comparison with the FlexPDE script calculated values (Fluid-in/out).

The thermal response of the GHE can then be examined with confidence for both cooling and heating regimes (see [7] for details). For cooling, one can conclude that the greater the difference between the input water temperature and the ground temperature, the greater the rejected heat to the ground, while the higher the exiting water temperature, the greater the rejected heat to the ground. Similarly, for heating, the greater the difference between the input water temperature and the ground temperature, the greater the absorbed heat from the ground, while the lower the exiting water temperature, the greater the absorbed heat from the ground.

The effect of the groundwater velocity is examined through a parametric analysis for various BH radiuses. Results show that a smaller BH radius keeps a lower temperature of the fluid of the GHE (cooling mode) due to the thermal properties of the grout used in the specific geological formation. It turns out that the relation of the absorbed power per m (= $mc_w\Delta T$) of BH length to the BH radius (Figure 3), reveals that although the total power absorbed by the ground is kept the same (5710 W) in all cases, the dry layer and the low underground water-velocity layer respond rather uniformly in absorbing power, as opposed to the high underground water-velocity layer that decreases exponentially with radius.

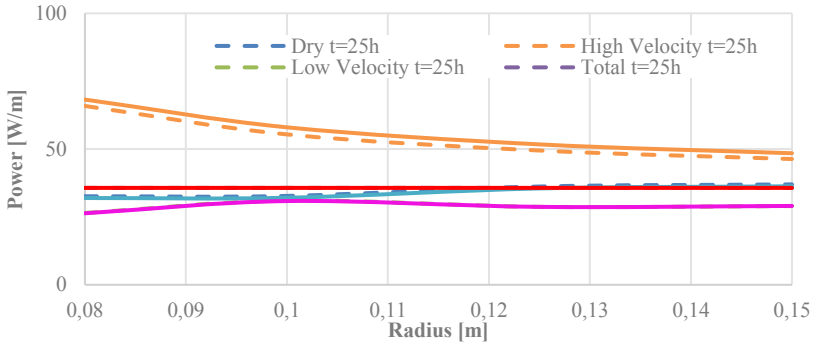

Figure 3. Absorbed power per m against the BH radius for the three layers of the BH for 25h of GHE operation.

CONCLUSION AND DISCUSSION

A more complete parametric analysis, for the cooling mode of the GHE, can involve the analysis of (i) the grout thermal conductivity, (ii) the U-tube size, (iii) the distance between BH and tube leg centers, (iv) underground water velocities [7]. The study presented in here is an important step toward investigating the importance of the presence of an aquifer in the construction of a BH GHE and can be further extended for factors such as the summer and winter mode of operation, the underground temperature variation due to seasonal changes, the BH thermal resistance and multiple BHs [6].

DUNE-DUNE INTERACTIONS IN A QUASI-TWO-DIMENSIONAL CORRIDOR

Karol A. Bacik[1], Colmcille P. Caulfield[2,1], and Nathalie M. Vriend [2]
[1]Department of Applied Mathematics and Theoretical Physics, University of Cambridge, Cambridge, UK
[2]BP Institute, University of Cambridge, Cambridge, UK

Summary: Sand dunes rarely occur in isolation, but usually form vast collectives known as dune fields or dune corridors. The large scale organisation of the dune fields cannot be explained by the properties of individual dunes, but it is controlled by the mesoscale dune-dune interactions. The physics of these interactions is poorly understood, not least due to the shortage of prolonged geophysical observations. To circumvent the limitations of field observations, we investigate the dynamics of a quasi-two-dimensional dune corridor. We discuss wake-induced interactions and show how they control the structural stability of a dune corridor.

INTRODUCTION

Sand dunes spanning several orders of magnitude can be found in deserts, on river beds, as well as on other planets [1]. Dunes often form larger collectives known as dune fields. Notwithstanding significant progress in our understanding of single dune dynamics, the morphologies of dune fields are still poorly understood. Most importantly, it is not clear if the configurations we observe in the field are steady or transient [2]. At the same time making accurate predictions on dune field evolution is of chief societal importance. Migrating dunes not only enhance desertification, but they also regularly bury roads, rail tracks or even buildings.

Here, in order to uncover fundamental physical principles governing dune field dynamics, we investigate a train of quasi-two-dimensional moving over an unerodible substrate.

EXPERIMENTAL SET-UP

The experimental set-up consists of a 2 m diameter annular flume fixed to a turntable and a paddle assembly (see Fig. 1). Counter-rotation of the two components induces a turbulent water flow in the 9 cm wide channel. Sufficiently vigorous flows can mobilise glass beads (d = 1mm), which rest at the bottom arranged in discrete dunes. By using circular geometry, we avoid practical problems of fluid and sediment resupply at the boundaries. Moreover, rotating systems facilitate data collection with a stationary cameras, which can be used to record the topography evolution and image the flow field through particle tracking.

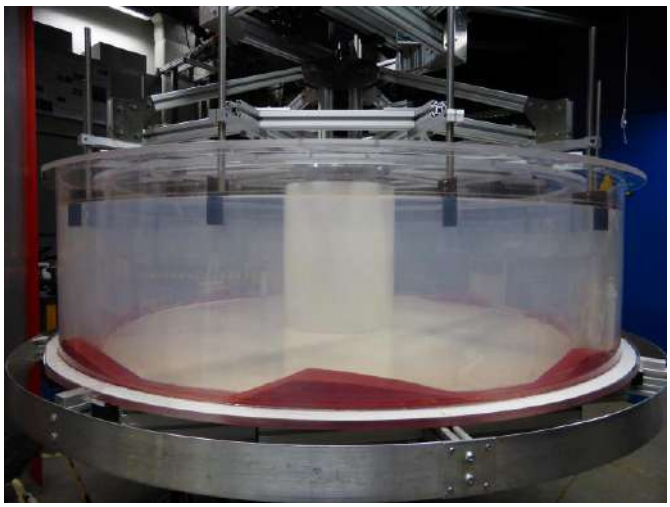

Figure 1. **Experiment.** A spider assembly of 12 paddles counter-rotating with the tank mounted on a turntable. The topography corresponds to a quasi-2D dune corridor with 8 dunes.

WAKE-INDUCED INTERACTIONS

Previous experiments revealed that two dunes, one directly upstream of the other, can interact at large distances even if they are not in direct contact [3]. The feedback is induced by the wake forming behind the upstream dune. Turbulent fluctuations in the wake enhance sediment flux over the downstream dune and thus increase its migration rate. This change in the migration rate can be described as an effective dune-dune repulsion, which prevents dune collisions.

In this study, instead of probing pairwise interactions, we consider sand dunes arranged in a quasi-two-dimensional periodic train. Specifically, we test how the morphology and migration rate of the corridor depends on the distance between neighbouring dunes. For sparse arrangements, the dunes are dynamically independent but as the gap between the dunes narrows, wake-induced effects ensue. We investigate the physical underpinnings of the inter-dune coupling and explore its consequences for the structural stability of the dune corridor.

CONCLUSIONS

Laboratory aqueous experiments show that wake-induced effects can affect the properties of sand dunes embedded in a dense dune field. Velocity field fluctuations in the wake enhance sediment transport and thus affect the shape and the migration rate of individual dunes.

SIMULATION OF EFFECTS OF ELECTRIC FIELD ON THE SNOW PARTICLE TRAJECTORY

Hongxiang Yu[1,2], Guang Li[1,2], and Ning Huang[*1]
[1]School of Civil engineering, Lanzhou University, Gansu, China
[2]School of Architechture, Civi l and Environmental Engineering, Ecole Polytechnique Federal de Lausanne, Lausanne, Switzerland

Summary Snow particles will be charged due to the collisions with each other or with the ground in snow drifting, and form a strong electric field compared to the atmospheric electric field. This field will also have an impact on the trajectory of snow particles. In this work, we set up the charge separation model for calculating the charge caused by the asymmetric collision. We simulate the single particle's trajectory in the flow field, and analysis the factors that affect the saltation trajectory.

INTRODUCTION

Snow drifting is a common phenomenon in high and cold regions, and has an important impact on the local environment and socioeconomic consequences (Bartelt and Lehning, 2002). It affects the mass balance of snow cover, thereby impacting on the radiation balance and hydrological processes (Luce et al., 1999). It changes snow distribution, forming snow patterns like snow ridges, ripples and dunes, as well as cornices (Vogel et al., 2012). The uneven accumulation due to snow drifting also lead to disasters such as avalanches, building collapse, road and rail traffic safety problems, and agricultural production damages (McClung et al., 2006).

Since the snow particles are charged, the additional associated electric field also has impact on their motion trajectories. Schmidt (1999) estimated the electric field force of snow particle with 0.14 mm size at a height of 0.5 cm above the bed and found that it could counterbalance gravity, which exceeds the gravity, and the direction is opposite. However, Schmidt only calculated the first hop of the snow particle in the electric field. Omiya (2012) calculated the influence of electric field force on the jump length and jump height of moving particles under the assumption that all particles are negatively charged, and, but all the particles are negative charged. the resulting electrostatic force creates an acceleration of 0.0004g (g: gravitational acceleration), this small value could be caused by calculate charges using bulk-method during the experiment. And But in most of snow drifting snow models, the electric effects are ignored. Thus, it is necessary to accurately study the trajectories of snow particles of different polarities in drifting snow electric field. In this contribution, we develop a model that describes the influence of charge separation on particle trajectories in drifting snow.

METHOD AND MODEL

In this manuscript, we calculate the single particle's trajectory moving in a neutral atmospheric boundary layer. As is shown in Fig. 1, snow particles jump with an initial velocity, after falling back to the ground and bouncing back to the air, after multiple collisions with ground, the saltation trajectory becomes stable.

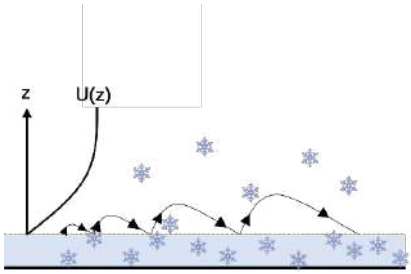

Fig.1 Schematic diagram of calculation.

Charge separation model of collision snow particles

Assuming a mixed-size granular system composed on N particles, and the particle size distribution is Φ(R). During the transportation, the repeat collisions between two particles and the multi-collisions among different types of particles can happen. According to the assumption proposed by Latham and Mason (1961) that it is either H^+ or OH^- that can transfer during the contact, and the mobility of H^+ is higher than OH^-. Here we also assume that the particles are covered totally by H^+ and OH^- ions, as is shown in Fig. 1, and assume that the transferred charge carrier as H+.

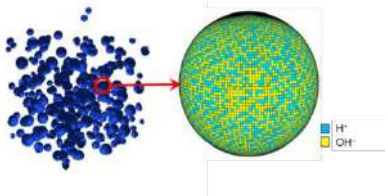

Fig 2. The schematic of H^+ and OH^- distribution on the snow particle surface

Assume the $c_{H+,i}$(n) and $c_{H+,j}$(m_j) are the ion concentration of particle i after nth collision and particle j after m^{th} collision. The net transferred charge from particle j to particle i can be calculated as:

$$\langle Q_i(n)\rangle = \rho_0 A_0 C_{i,j}\{\alpha(m_j)S_j c_{H+,j}(m_j-1)[1-c_{H+,i}(n-1)]3 - \alpha(n)S_i c_{H+,i}(n-1)[1-c_{H+,j}(m_j-1)]\} \quad (1)$$

In which, S_i and S_j are the maximum deformation area of the two particles, respectively, α is the H^+ transfer probability. The detailed derivation is available from (Yu et al., 2017). After Li times of collision, the mean charge on the particle *i* is:

$$\langle Q_i(L_i)\rangle = \rho_0 A_0 \sum_{n=1}^{L_i}\sum_{j=1,j\neq i}^{N} C_{i,j}\{\alpha(m_j)S_j c_{H+,j}(m_j-1)[1-c_{H+,i}(n-1)]3 - \alpha(n)S_i c_{H+,i}(n-1)[1-c_{H+,j}(m_j-1)]\} \quad (2)$$

In which, the initial hydrogen ion concentration $c_{H+,i/j}(0)$ is related to air humidity.

CONCLUSION AND DISCUSSION

The complete saltation trajectory of these three different polarities of particles are shown in Fig 3, when the saltation movement are trend to be stable, the saltation height of positive particle is 54.6% larger than the neutral particle, and that of the negative particle is 54.6% smaller than the neutral particle. The height of suspension particle is the lowest, the suspension height is 88.2% smaller than the neutral particle.

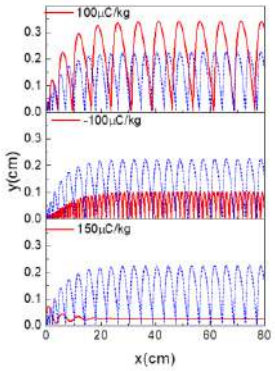

Fig 3. Four kinds of charge to mass ratio of particles' trajectory (the blue dash represents the neutral particle's trajectory).

During the wind blow snow, the charge separation happens during the asymmetric collision between particles and the ground. The polarity of snow particles is positive or negative, which is dependent on the size distribution. The charged snow particles moving in the electric field can change its trajectory with the effect of the electrostatic force.

TSUNAMI WAVE RUNUP ON A NON-UNIFORMLY SLOPING BEACH

Arghya Bandyopadhyay*[1] and Dipannita Maji[1]
[1]Department of Mathematics, Khalisani College, Chandannagar, India

Summary Ocean bottom bathymetry plays an important role in tsunami propagation [1, 2]. In an earlier work [3], the first author analytically studied tsunami waves in a continuously sloping non-uniform bottom profile of the form $y = -qx^r$, $q > 0$, $0 < r < 2$. The complete analysis of the wave integral involving double Hankel integrals leads us to a four-wave structure, one component of which gives rise to forerunner and another component provides a new expression for wave runup. This study also unfolds other characteristics of wave underlining the effect of bottom bathymetry in a tsunami wave motion generated by a periodic bottom disturbance.

PROBLEM AND ITS SOLUTION

For a two-dimensional linear shallow water waves due to a sudden bottom upheaval past a sloping beach $y = h_0(x)$ (Figure 1), the surface displacement $\eta(x,t)$ satisfies the differential equation

$$\eta_{tt} - gh_0(x)\eta_{xx} - gh_0'(x)\eta_x = \eta_{0tt} \tag{1}$$

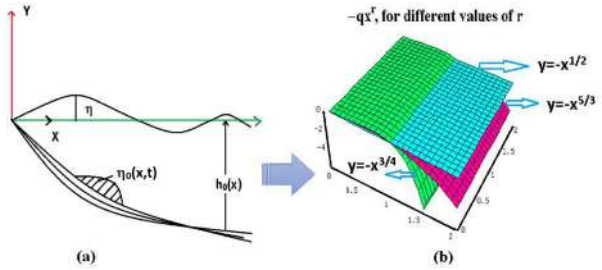

Figure 1: Illustration of bed profile $y = -qx^r$ with choice of axes (a) Cross-sectional view (b) Three dimensional view

The solution of which subject to appropriate initial condition can be obtained with the use of Hankel transform as

$$\eta(x,t) = (\gamma\sqrt{gq})^{-1} \int_0^\infty x^{(1-r)/2} J_\nu(\xi\gamma^{-1}x^\gamma)d\xi \int_0^\infty \alpha^{(1-r)/2} J_\nu(\xi\gamma^{-1}\alpha^\gamma)d\alpha \int_0^t \ddot{\xi}_1(\alpha,s)\sin\sigma(t-s)ds \tag{2}$$

where $\sigma = \xi\,(gq)^{\frac{1}{2}}$, $\gamma = 1 - \frac{r}{2}$, $\nu = \frac{r-1}{2-r}$ and $h_0(x) = qx^r$. An analysis of the expression in (2) over $0 < t < \tau$ for a periodic ground motion shows that η may be regarded as the superposition of four distinct waves $\eta \equiv \eta_1 = \eta_{11} + \eta_{121}^{\pm} + \eta_{122} + \eta_{123}^{\pm}$, where $\pm$ signs indicate that the corresponding expressions are different for $\nu \geq 0$ and $\nu < 0$ respectively while η_{11} and η_{122} remain unchanged. The forms of the above four waves when analysed provide us a full view of the wave structure. The detailed mathematical calculation involved in the whole process is daunting and beyond the scope of this submission, instead we only mention the form of the wave components η_{11} and η_{123} which are the reasons of the forerunner and wave runup respectively. A brief discussion on the significance of these four wave structure and its interaction with the ocean bed is provided subsequently.

The component η_{11} of η identified as forerunner [3] of the wave system

$$\eta_{11} = \frac{\sqrt{\pi}\xi_0^{2\nu+2}}{\Gamma(\nu+1)(2\gamma)^{(2\nu+1)}} \sum_{m=0}^\infty (m+1)^{-1}(\omega t/2)^{m+3/2}\left[J_{m+1/2}(\omega t) + iJ_{m+3/2}(\omega t)\right] \sum_{n=0}^\infty \frac{(-1)^n}{n!}\left(\frac{\xi_0\gamma^{-1}x^\gamma}{2}\right)^{2n} \times$$
$$\times \frac{1}{\Gamma(n+m+\nu+2)} \int_0^\infty {}_2F_1\left(-n,-n-\nu;\nu+1;\left(\frac{\alpha}{x}\right)^2\gamma\right)\zeta_1(\alpha)d\alpha$$

The component $\eta_{123}^{\pm}$ of η

$$\eta_{123}^{\pm} = \gamma\Gamma_k z_0^{2\nu+2} x^{-\nu\gamma}\left[1 + i\omega\int_0^t dt\right]\left[\sum_{n=0}^\infty \frac{(-1)^n}{\Gamma(2n-2\nu+1)}\left\{\sum_{l=0}^{N_k}(-1)^l\binom{N_k}{l}(\omega t)^{N_k-l}\int_0^1 x_1^{-L_k} z_0^l \frac{\partial^l P_1}{\partial z_0^l} e^{j(\omega t x_1 + l\pi/2)}dx_1 + \right.\right.$$
$$\left.\left. + (-1)^{n+k}\cos\omega t \int_0^1 x_1^{-2n-1} z_0^{N_k}\left(\frac{\partial}{\partial z_0}\right)^{N_k} P_1 dx_1\right\}\right]$$

Here k=1, 2 refers to $\nu > 0$, $\nu < 0$, $N_k = 2n, 2n+1$, $L_k = l+1, l$, $P_1 = z_0^{-2\gamma} J_\nu(z_0 x^\gamma x_1)\bar{f}_\nu(z_0 x_1)$, $\Gamma_k = \Gamma(1-2\nu)Re\left[e^{j(\omega t x_1 + l\pi/2)}\right], \Gamma(-2\nu)Im\left[e^{j(\omega t x_1 + l\pi/2)}\right]$.

The analysis of η-integral for t >τ : paired four wave composition of η

For the part of the motion when $t > \tau$, it can be shown that $\eta \equiv \eta_2 = \eta_1(x,t) + \eta_1(x,t-\tau)$. This means to each of the four wave-system consisting of η_1, there correspond two similar wave forms; of these two, one follows the other with a time-lag of τ.

DISCUSSION OF THE RESULTS

To illustrate the above results, we consider one particular periodic bottom disturbance with amplitude $\zeta_1(x) = \sqrt{x}e^{-\sqrt{x}}$. The nature of η_{11} and η_{12} are depicted near the shore for a time period of $t < \tau$, that is at the sub-quake range, it is clear that η_{11} dominates the spectrum for small time. This η_{11} is the forerunner which comes ahead of the forced wave (Figure 2).

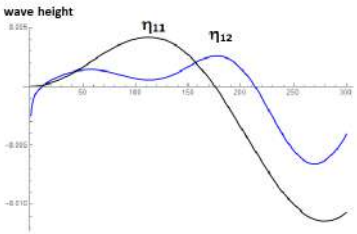

Figure 2: Illustration of the forerunner η_{11} at the shore which clearly shows the dominance of η_{11} over η_{12} for $t < \tau$(= 150 s)

Again, this dominance of η_{11} in the spectrum is even more prominent if the small-time behaviour of the comparable component η_{122} is in same phase with η_{11} or not. This perhaps explain the existence of forerunners or otherwise in many of the tsunami events. The wave component η_{123} is the reason of wave evolution at the shore and it dominates the spectrum after certain time, to be precise after $t > \tau$. To our understanding, the expression of η_{123} may be taken as the analytical measure for runup in case of generation of tsunami waves in a physical setting like the one considered here (Figure 3).

Another thought-provoking fact is realized with the ocean bed profile where we find different wave forms reaching the shore - elevation or depression according as the ocean bed profile is convex downward (i.e. with r = 1.1 or $\nu > 0$) or convex upward (i.e. with r = 0.8 or $\nu < 0$), all other parameters remaining same (Figure 4).

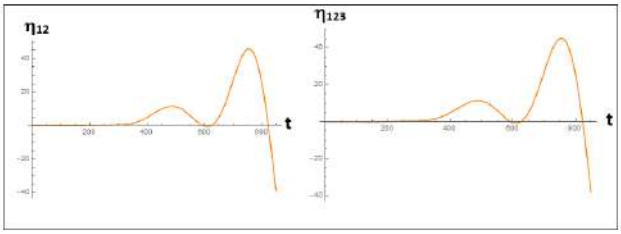

Figure 3: Equivalence of η_{123} and η_{12} for large time depicting dominance of η_{123} at shore.

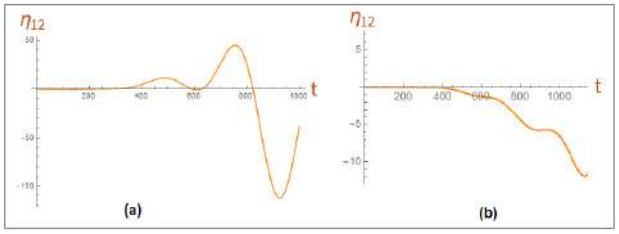

Figure 4: (a) wave elevation when the ocean bed is convex downward (b) wave depression when the ocean bed is convex upward

CONCLUSIONS

The analytical solution found here highlights the following - (i) waves behave in a quartet (ii) from this quartet forerunners can be isolated and (iii) the expression of runup can be determined. Further, (iv) ocean bathymetry effects in wave evolution and acts as one determining factor whether an elevation or a depression wave would reach the shore. In 2011 Tohuku tsunami, forerunners were observed in Japan sea [5], this observational finding matches with our mathematical finding.

PARTICLE MOTION NEARBY ROUGH SURFACES

Christina Kurzthaler[1], Lailai Zhu[1,2], Amir Pahlavan[1], and Howard A. Stone*[1]
[1]Department of Mechanical and Aerospace Engineering, Princeton University, NJ 08544, USA
[2]Linné Flow Centre and Swedishe-Science Research Centre (SeRC),KTH Mechanics,SE-10044,Sweden

Summary Interactions between particles and boundaries are ubiquitous in nature and play a pivotal role in microfluidic applications. For low-Reynolds-number motions we study the hydrodynamic couplings between particles and solid, rough boundaries, which are characterized by periodic and random surface textures. Using the Lorentz reciprocal theorem, we derive analytical expressions for the grand mobility matrix of a spherical particle and find that roughness-induced velocities vary non-monotonically with the characteristic wavelength of the surface. In contrast to motion near a plane wall, we predict particle translation perpendicular to the applied force. Also, we find that particles drift along tilted, grooved surfaces, which makes possible particle separation with respect to size.

INTRODUCTION

Transport processes at low Reynolds number are significantly altered by confining geometries omnipresent in biological environments and microfluidic devices. These topics include transport of red blood cells in microchannels [1], active motion of microorganisms in their natural habitats [2], and diffusion of macromolecules in crowded cells [3]. A well-known consequence of the reversibility of Stokes flows is that a rigid spherical particle that sediments nearby a vertical planar wall does not experience a hydrodynamic force perpendicular to the wall and thus maintains a constant distance from the wall [4, 5]. This behavior has been shown to change dramatically once time-reversal symmetry is broken. In particular, elastohydrodynamic couplings between a spherical particle and a deformable boundary induces a lift force and, thus, motion away from the surface [6, 7]. Furthermore, hydrodynamic couplings between swimming microorganisms and boundaries lead to surface accumulation or repulsion depending on the flow fields produced by the propulsive mechanisms [8].

In contrast to plane, smooth surfaces, biological surfaces display a large variety of surface features, including rough and structured topologies. These corrugated surface textures alter the surrounding flow fields and thereby hydrodynamically impact nearby particle motion, which represents the main topic of this study.

THEORETICAL FRAMEWORK

We consider the translational and rotational motion of a spherical particle with radius a in an incompressible flow of a viscous fluid of viscosity μ nearby a rough surface, S_w (see Fig. 1). In the presence of an external force $\mathbf{F}$ and torque $\mathbf{L}$, the particle translates at a velocity $\mathbf{U}$ and rotates with angular velocity $\mathbf{\Omega}$. For low-Reynolds-number flow, the quasi-steady fluid velocity $\mathbf{u}(\mathbf{r})$ and pressure fields $p(\mathbf{r})$ are described by the continuity and Stokes equations,

$$\nabla \cdot \mathbf{u} = 0 \quad \text{and} \quad \mu \nabla^2 \mathbf{u} = \nabla p, \tag{1}$$

with associated stress field, $\boldsymbol{\sigma} = -p\mathbb{I} + \mu\left(\nabla\mathbf{u} + \nabla\mathbf{u}^T\right)$ and no-slip boundary conditions on the particle surface, S_p, and rough wall, S_w. The translational and rotational velocities of the sphere, $\mathbf{U} = \mathbf{U}(\mathbf{r}_S, h)$ and $\mathbf{\Omega} = \mathbf{\Omega}(\mathbf{r}_S, h)$, depend on its instantaneous position, $\mathbf{r}_S(t) = (x_S(t), y_S(t))$, and distance from the surface, $h(t)$.

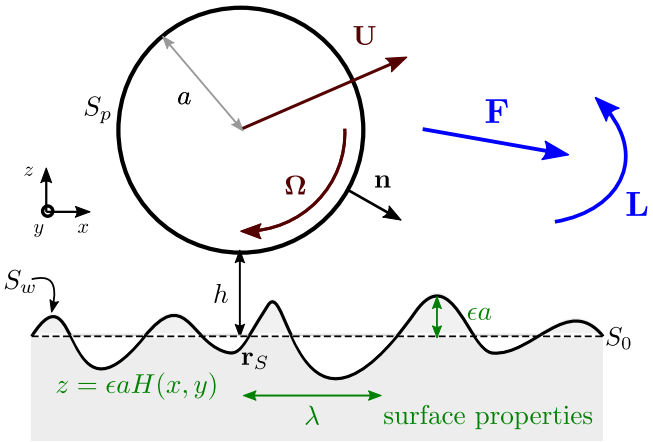

Figure 1: Model set-up for the motion of a sphere near a random rough surface.

We describe the small height fluctuations of the surface by $z = \epsilon a H(x, y)$, where $H(x, y)$ denotes the shape function and ϵa the surface amplitude with small dimensionless parameter $\epsilon \ll 1$, which permits expansion of the velocity field, $\mathbf{u} = \mathbf{u}^0 + \epsilon\mathbf{u}^1 + \mathcal{O}(\epsilon^2)$, and similar expansions for other fields. Due to the linearity of the Stokes equations and the rigid boundaries of the suspended particle and the rough wall, the velocity field generated by the particle motion must be coupled linearly to the applied forces and torques. Consequently, the translational and rotational velocities, $\mathbf{U}$ and $\mathbf{\Omega}$, are related to the forces and torques of the problem, $\mathbf{F}$ and $\mathbf{L}$, via the grand mobility tensor $\mathbf{M}$.

By employing the method of domain perturbations and utilizing the Lorentz reciprocal theorem for viscous flows, we arrive at the general form for the *grand mobility matrix* of the sphere next to a rough wall

$$\mathbf{M} = \mathbf{M}^0 - \epsilon a \int_{S_0} H(x, y)\mathbf{K}\, \mathrm{d}S + \mathcal{O}(\epsilon^2), \tag{2}$$

*Corresponding author. E-mail: hastone@princeton.edu.

which represents the principal finding of this work. Here, $\mathbf{M}^0$ denotes the mobility tensor corresponding to the well-established problem of a sphere translating and rotating near a plane, smooth wall [4, 5, 9, 10]. The coupling tensor $\mathbf{K}$ can be assumed known as it depends on the zeroth-order problem only. As a main consequence, the velocities of the externally driven sphere, up to the second order in the surface roughness, can be obtained for arbitrary surface shapes $H(x, y)$.

RESULTS

Roughness-induced velocities

We apply the theoretical predictions to elucidate the roughness-induced velocities of a sphere near a random rough wall characterized by a wavelength λ and random surface amplitudes (see Ref. [11] for more details). The particle velocities are determined by the local geometry of the underlying, random surface, and, therefore, we are interested in average quantities such as the variance of particle velocities near rough surfaces. The variance is determined by the distance of the particle from the wall h/a and the characteristic wavelength of the surface λ/a. We find that velocity fluctuations decay rapidly with respect to the particle-surface distance. Thus, for increasing distances transport is governed by the average wall contribution rather than details of the surface structure.

Furthermore, the variances of the velocities perpendicular and transverse to the applied force display a maximum at a characteristic wavelength λ that depends on the particle distance from the wall. These findings can be rationalized, since for a particle close to the surface, $h/a \ll 1$, the fluid flow in the lubrication layer between the rough surface and the particle dominates the hydrodynamic couplings. However, the velocities of particles that are located further away $h/a \gtrsim 1$ are affected by hydrodynamic interactions with larger parts of the underlying surface texture. For large and small wavelengths roughness-induced velocities become small and the particle essentially experiences the presence of a smooth wall.

Particle trajectories near a grooved surface

We study the trajectories of spheres with different radii a near a grooved surface with characteristic wavelength λ, see Fig. 2. In particular, the particles follow the shape of the underlying surface and display a drift along the grooves. The drift velocity varies with particle sizes and makes possible separation of particles. Moreover, drift is determined by the strength of the hydrodynamic interaction with the surface, which varies non-monotonically with λ/a and separates, e.g., $a/\lambda = 1/4$ from other (even larger) spheres. Thus, by varying the wavelength of the grooves a particular particle size can be selected from others.

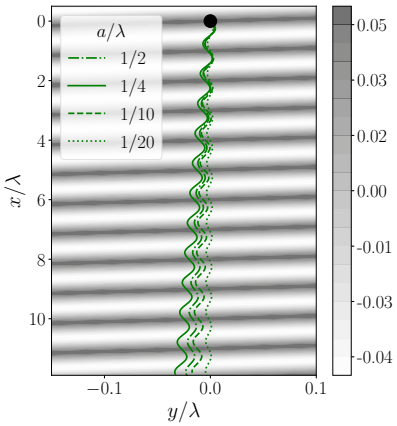

Figure 2: Trajectories, $x_S(t), y_S(t)$, for particles of different radii a near a grooved surface with tilt angle of $\pi/4$ between the force $\mathbf{F} = F\mathbf{e}_x$ and the oriented grooves and distance $\lambda/h(0) = 20$. The colorbar indicates hills (dark) and valleys (white) of the surface and the black dot the initial particle position.

CONCLUSION

We have presented an analytical expression for the mobility of a sphere near a textured surface. In particular, we find that roughness-induced velocities decay rapidly with the particle-surface distance and exhibit a non-monotonic behavior with respect to the characteristic wavelength of the corrugated surface. Our findings indicate that details of the surface roughness impact fluid flow and transport phenomena locally and are therefore expected to be important for surface-accumulation of particulate matter, e.g. biofilm formation. We anticipate that our predictions may allow novel particle separation methods and may allow non-invasively inferring surface properties by monitoring transport of particles near rough surfaces. Our theoretical predictions can be further extended to elucidate the impact of surface roughness on the motion of self-propelled agents.

Summary A concentrated, vertical monolayer of identical spherical squirmers, which may be bottom-heavy, and which are subjected to a horizontal shear flow, is modelled computationally by two different methods: Stokesian Dynamics, and a lubrication-theory-based method. The effective shear viscosity is found in general to be increased by the squirming motions.

BACKGROUND

Suspensions of swimming micro-organisms exhibit fascinating collective behaviour, ranging from steady, regular patterns, as in bioconvection [1], to random coherent structures, sometimes referred to as bacterial turbulence [2], with many variants in between. There have been many models of such behaviour, most of which have been developed to see if the observations can be explained by physical processes alone, without requiring an understanding of biological or chemical signalling or intracellular processes. Continuum models have been very successful for dilute suspensions, in which the cells interact with their environment but not with each other: bioconvection results from either a gravitational instability when the upswimming of dense cells leads to a gravitationally unstable density profile, or a gyrotactic instability in which the cells' non-uniform density or geometric asymmetry causes them to be reoriented in a shear flow [2]. Even when gravity is unimportant the stresses applied by the cells' swimming motions (a swimmer acts as a force dipole or stresslet) lead to instability and random bulk motions [3,4].

In this paper we wish to consider concentrated suspensions, in which the flow is dominated by cell-cell interactions. Continuum models fail because there is no agreed way of incorporating cell-cell interactions into the model equations – in particular the particle stress tensor $\mathbf{\Sigma}^{(\mathbf{p})}$ – even when the interactions are restricted to near-field hydrodynamics together with a repulsive force to prevent overlap of model cells. We seek to understand the rheological properties of an idealised suspension from direct numerical simulations. The cells are modelled as identical steady spherical squirmers [5,6,7]: spheres of radius a which swim by means of a prescribed tangential velocity on the surface, $u_\theta = \frac{3}{2}V_s \sin\theta(1+2\beta\cos\theta)$, where θ is the polar angle from the cell's swimming direction, V_s is the cell swimming speed and β represents the stresslet strength; inertia is negligible. The suspension is taken to be a monolayer, embedded in an infinite fluid, in which the sphere centres and their trajectories are confined to a single plane, which is vertical in cases for which gravity, $\mathbf{g}$, is important. The spheres may be bottom-heavy, so that when the swimming direction of a sphere, $\mathbf{p}$, is not vertical the sphere experiences a gravitational torque $\mathbf{L}$, where $\mathbf{L} = -\rho v h \mathbf{p} \times \mathbf{g}$ and v, h are the cell volume and the displacement of the centre of mass from the geometric centre; ρ is the average cell density, assumed the same as that of the fluid. The monolayer is taken to be driven by a simple shear flow in the same, $x-y$, plane: $\mathbf{U} = (\gamma y, 0, 0)$, with shear-rate γ; we will also take $\mathbf{g} = -g(\sin\alpha, \cos\alpha, 0)$, so the flow is horizontal if $\alpha = 0$.

METHODS

We have previously studied the rheology of semi-dilute (three-dimensional) suspensions of squirmers – volume fraction $c \leq 0.1$ - in which every cell interacted only with its nearest neighbour [8]. General pairwise interactions could be computed exactly using the boundary element method, supplemented by lubrication theory when cells were very close together. Cells were prevented from overlapping computationally by the inclusion of a repulsive interparticle force $\mathbf{F} = \mu a^2 \gamma F_0 \tau e^{-\tau\epsilon}/(1+e^{-\tau\epsilon})\hat{\mathbf{r}}$ where $\hat{\mathbf{r}}$ is the unit vector along the line of centres and ϵ is the minimum permitted dimensionless spacing [9]. In [8] τ was taken equal to 10^3 and F_0 was varied. It was found that the swimming activity made very little difference to the effective shear viscosity when the spheres were non-bottom-heavy, but the suspension showed significant non-Newtonian behaviour, such as anisotropic effective shear viscosity and normal stress differences, when the cells were bottom-heavy.

Here we use two different methods of simulation for very concentrated monolayer suspensions, with areal fraction c up to 0.7. One is a full numerical simulation using Stokesian Dynamics [9,10], while in the other we assume that cells in which every cell interacts with other cells in the domain and mirror domains by assuming additivity of forces. The interaction is described using lubrication theory alone. This model was recently used to investigate the stability of a regular array of bottom-heavy squirmers, swimming upwards in the absence of an imposed shear flow [11]. The point of this is to see if lubrication alone is good enough to account for all the interesting rheological behaviour of a concentrated suspension, or if some effect of more distant particles is necessary, in the case of squirmers. As well as illuminating the physics, this might make related computations significantly cheaper than the full Stokesian Dynamics. For inert and force-free spheres, Leshansky & Brady [12] reported in a footnote that suppressing all far field interactions made less than 5% difference to the quantities they were computing.

RESULTS AND DISCUSSION

In addition to β, α, τ, F_0 and the areal fraction c, the governing dimensionless parameters are: the dimensionless swimming speed, $Sq = \frac{V_s}{a\gamma}$, and $G_{bh} = \frac{\rho v g}{(3\mu a V_s)}$, the 'bottom-heaviness parameter'. The initial objective is to compute the effective shear viscosity, η_{eff}, which in Stokesian Dynamics is obtained from the off-diagonal terms of the particle stress tensor $\mathbf{\Sigma}^{(p)}$, defined as the average over all spheres of the stresslet for a single particle [13]:

$$\mathbf{S} = \int_{A_p} [\frac{1}{2}\{(\sigma \cdot \mathbf{n})\mathbf{x} + \mathbf{x}(\sigma \cdot \mathbf{n})\} - \frac{1}{3}\mathbf{x} \cdot \sigma \cdot \mathbf{n}\mathbf{I} - \eta(\mathbf{un} + \mathbf{nu})]dA, \tag{1}$$

where σ is the stress tensor and $\mathbf{u}$ is the velocity. and A_p is the surface of the particle with outward normal $\mathbf{n}$.Then

$$\eta_{eff} - 1 = 2.5c\frac{< S_{xy} + S_{yx} >}{20\pi/3}. \tag{2}$$

The result of the Stokesian Dynamics simulations for horizontal shear flow ($\alpha = 0$) is that, for non-bottom-heavy spheres ($G_{bh} = 0$) η_{eff} increases with c more rapidly than for non-swimming spheres. Examination of the cell trajectories suggests that this is associated with the interior of the suspension forming horizontal layers when the spheres do not swim, but becoming veryirregular when theydo (presumably increasing the local rate of energy dissipation). The increase in η_{eff} is greater for larger swimming speeds ($Sq = 10$ rather than $Sq = 1$), but is not much affected by the squirming mode β ($-3 \leq \beta \leq 3$) or the magnitude of the inter-particle repulsion, F_0. Bottom-heaviness, in a horizontal flow, reduced η_{eff} in general, but not by much.

In the lubrication theory model η_{eff} is calculated in a different way: a regular array of squirmers is placed between two rigid planes parallel to the x-axis, at $y = \pm H$, and these are translated parallel to each other with speeds $\pm V$; only the cells closest to the planes are set into motion by them, through the stress in the lubricating layer, and these then cause their other neighbours to move too. Once the shear stress on the planes, S_W, has become steady, on average, η_{eff} is calculated as $\eta_{eff} =< S_W > H/V$. Preliminary results indicate that η_{eff} is not greatly affected by the squirming alone, in the absence of bottom-heaviness. However, it is significantly reduced for bottom-heavy squirmers in horizontal shear flows. Preliminary results for the normal stress difference will also be presented.

There have been few experimental studies on the effective viscosity of suspensions of microscopic swimmers. Notable among those few are the measurements of Rafai *et al.* [14] on suspensions of motile algae (*Chlamydomonas reinhardtii*), which are close to spherical, are bottom-heavy, and *pull* themselves through the fluid (equivalent in the squirmer model to $\beta > 0$). The effective viscosity in a horizontal shear flow was found to increase with volume fraction much more dramatically than for a suspension of dead cells, in agreement with the above Stokesian Dynamics prediction. On the other hand, Sokolov Aronson [15] measured the effective viscosity of a suspension of bacteria (pushers: $\beta < 0$), and found a significant decrease in shear viscosity with swimming speed. However, this could be attributed to the rod-like geometry of the bacteria. Apparent agreement with our lubrication theory predictions is coincidental.

UNIFYING DISPARATE EXPERIMENTAL VIEWS ON SHEAR-THICKENING SUSPENSIONS

Philippe Bourrianne *[1], Thibaut Divoux[2] and Gareth H. McKinley,
[1]Hatsopoulos Microfluids Lab, Department of Mechanical Engineering, MIT, Cambridge, MA 02139, USA
[2]Department of 1Department of Civil and Environmental Engineering, MIT, Cambridge, MA 02139, USA

Summary: Shear thickening denotes the rapid and reversible increase in the viscosity of a suspension of rigid particles under shear. This ubiquitous phenomenon has been documented in a broad variety of multiphase particulate systems, but the relative contributions of hydrodynamic interactions and frictional contact between particles to the magnitude of shear thickening is still highly debated. We explore here a discriminating experimental study using a model shear-thickening suspension that allows us to tune independently both the surface chemistry and the surface roughness of the particles. We show here that both properties matter when it comes to continuous shear thickening (CST) and that the presence of hydrogen bonds between the particles (which enhance solid friction) is essential to achieve discontinuous shear thickening (DST). Moreover, a simple argument allows us to predict the onset of CST, which for these highly-textured particles occurs at a critical volume fraction much lower than that previously reported in the literature.

INTRODUCTION

Suspensions composed of rigid particles dispersed in a liquid matrix are ubiquitous in daily life, from cosmetics and consumer products (e.g., toothpaste) to foodstuffs (e.g., coffee) and engineering materials such as fresh cement paste. Their flow properties display a broad variety of rheological behavior depending on the volume fraction φ and the nature of the physico-chemical interactions between particles [1, 2]. In the semi-dilute regime, suspensions show a shear-thinning response, *i.e.* their shear viscosity η decreases for increasing applied shear rate $\dot{\gamma}$. Such behavior, which results from long-range hydrodynamic interactions and possible shear-induced structure formation, is amplified in the presence of attractive interactions between particles. Conversely, so-called "dense suspensions" (i.e., suspensions with high volume fractions of dispersed solids) exhibit shear-thinning under weak shearing conditions, followed by a 'shear-thickening transition' for sufficiently large shear, characterized by a rapid and reversible increase of viscosity with applied shear rate, or shear stress [3]. The magnitude of the shear thickening is enhanced by increasing the volume fraction. At intermediate volume fractions, continuous shear thickening (CST) ranges from a mild increase in viscosity that was initially explained by lubricated hard-sphere interactions [4] to a more pronounced effect when particle interactions involve frictional contacts [5]. Finally, for very large volume fractions, closer to the jamming volume fraction φ_J, the viscosity may jump by orders of magnitude at constant shear rate [6]. The nature of local inter-particle interactions, mediated by the suspending solvent, affects this picture. Indeed, the shear-thickening transition is enhanced when particles show moderate attraction [7], and suppressed in presence of strong short-range interparticle attractions due to the presence of a yield stress

The relative contributions of the solid friction and the chemical interactions at the molecular scale to the magnitude and dynamic of the DST remain to be quantified, but are embodied qualitatively in the magnitude of the friction coefficient between particles. Here we report an experimental study on suspensions of colloidal fumed silica particles suspended in a viscous oligomeric polar solvent. We show that these suspensions, which do not exhibit any ageing, drying, migration or settling (in sharp contrast to cornstarch or other non-Brownian suspensions) can display both CST and DST transitions at much lower volume fractions than values traditionally reported in the literature, and by varying surface chemistry and particle roughness we can systematically investigate the conditions required to achieve shear-thickening.

Experimental Fluid Formulation

To study the shear thickening transition, we utilize two distinct fumed silica systems that enable us to vary both the roughness and the hydrophilicity of the particles, while holding the average particle size constant at $D \simeq 300$ nm. These textured fumed silica particles are composed of a large number ($N_u \approx 150$) of small nodules of size R_u that are fused together permanently during the initial flame synthesis. The sintered aggregates confer nanometric textures and high specific areas to the particles [see Fig. 1(a)]. The particles are hydrophilic due to both the presence of surface hydroxyl groups and to their intrinsic submicronic roughness – as seen in the picture in Fig. 1(b) – which, in line with Wenzel theory, amplifies the wettability characteristics. When dispersed in a polar solvent such as polypropylene glycol, the fumed silica particles display a stabilizing solvation layer that prevents irreversible aggregation. The resulting suspensions are transparent and show excellent stability over time with no thixotropy or ageing. We have prepared suspensions at various volume fractions φ by varying the mass ratio of particles dispersed. In order to directly probe the effect of the particle surface chemistry, we also prepare corrresponding suspensions of hydrophobic fumed silica particles. These particles are coated with a nanometric layer of silanes; they display identical geometrical features (R_u, N_u and D) as the hydrophilic particles [see Fig. 1(d)] but have different surface chemistry.

*Corresponding author. E-mail: gareth@mit.edu.

RESULTS

The steady rheological responses of both of the different classes of suspensions are measured by a slowly increasing and then decreasing ramp of shear stress imposed in a cone and plate geometry connected to a stress-controlled rheometer and the results are shown in Figure 1 below.

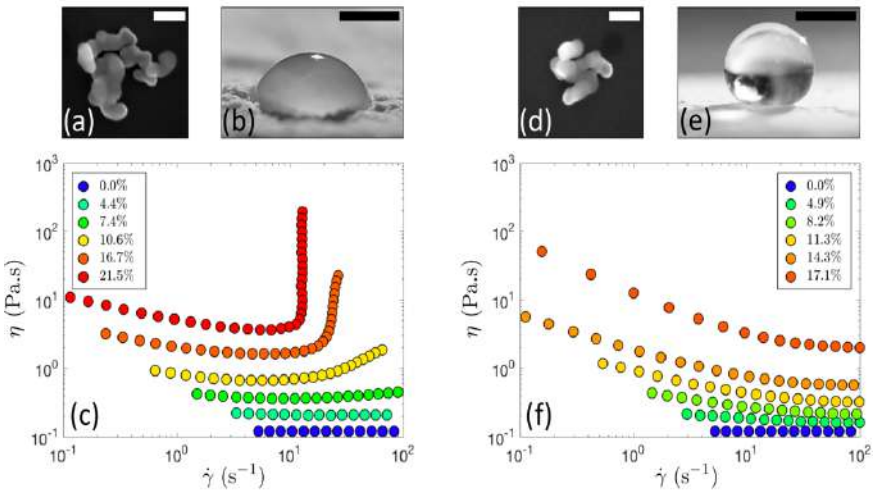

Fig 1(a) SEM image of a hydrophilic fumed silica particle (100nm scale bar). (b) Hydrophilic fumed silica particles coated on a glass slide are wetted by a drop of water. (scale bar 1 mm). (c) Flow curves measured for suspensions of hydrophilic fumed silica particles. (d) SEM picture of a hydrophobic fumed silica particle (100 nm scale bar). (e) A water drop is repelled by a coating made by depositing a layer of hydrophobic fumed silica particles on a glass slide. (1mm scale bar). (f) Viscosity of a suspension of hydrophobic fumed silica as a function of shear rate at various volume fractions φ. The suspensions of hydrophobic particles display a shear-thinning response for all the volume fractions tested.

The rheometric responses of hydrophilic fumed-silica suspensions are reported in Fig. 1(c) for volume fractions ranging between $\varphi = 0\%$ and 21.5%. Increasing the mass fraction of dispersed particles leads to a departure from the Newtonian response of the pure solvent. At low volume fractions, the suspension shows a weakly shear-thinning behavior characterized by a slow decrease of the viscosity for increasing shear rates. At intermediate volume fractions ($\varphi \simeq 7.4\%$), the shear-thinning behavior persists at low shear rates ($\dot{\gamma} \lesssim 20s^{-1}$), whereas the viscosity begins to slowly increase at high shear rates, which is characteristic of continuous shear thickening (CST). This trend is amplified for increasing volume fractions of fumed silica, up to $\varphi = 16.7\%$ for which the viscosity jumps by an order of magnitude over a narrow range of shear rates. Finally, for even larger volume fractions ($\varphi = 21.5\%$), an abrupt shear-thickening transition occurs at an almost constant critical shear rate of about 15 s^{-1}, which corresponds to DST. Strikingly, these volume fractions are significantly lower than that reported in the literature, where shear thickening is usually observed for $\varphi \approx 50\%$ in the vicinity of the jamming point in dense suspensions with more regular shapes. In order to directly probe the effect of the particle surface chemistry, we repeat the same rheological measurements on suspensions of hydrophobic fumed silica particles coated with a nanometric layer of silane. As observed in Fig. 1(f), these hydrophobic suspensions exhibit a strikingly different response from that observed with hydrophilic particles at the same volume fraction. They display a purely shear-thinning response over the entire range of volume fractions explored and the shear-thinning becomes more pronounced for increasing volume fractions, in part due to the gradual appearance of a yield stress at large volume fractions.

CONCLUSIONS & ONGOING WORK

We have formulated a series of suspensions that are transparent, stable with time and can show pronounced shear-thickening (or shear-thinning) at moderate volume fractions of suspended particles The pronounced differences in rheological behavior between two suspensions of particles with similar surface roughness and volume fractions but two different surface chemistries show that the microscopic mechanism for shear thickening is based on a synergy between solid friction and reversible hydrogen bonding; with the latter being crucial for discontinuous shear thickening at moderate volume fractions. To clarify the important contribution of particle surface roughness to the above picture, we have also performed another series of rheological experiments on rougher particles. These particles are composed of a larger number of nodules of smaller size corresponding to a markedly higher specific surface area. However, these "rough" particles possess the same global size as the "smoother" particle suspensions studied here. By combining results for all four systems as well as introducing a quantitative metric for the extent of shear-thickening, we are developing a comprehensive rheological state map for designing bespoke shear-thickening fluid systems with customizable extents of shear-thickening at user-prescribed critical shear stresses.

Summary Understanding the interaction of swimming bacteria with flows is crucial for societal and environmental challenges such as infections, soil contamination and cell sorting. Here we present a combined experimental, numerical and theoretical study on bacterial bulk rheotaxis *i.e.* the non-trivial orientation of bacteria in shear flows at low Reynolds number. Using tracking of a large number of bacteria we obtain high-accuracy spatially dependent velocity and orientation distributions for a wide range of flow rates, in excellent agreement with our kinematic model which includes both hydrodynamic and stochastic effects. Theoretical analysis reveals the relevant scaling laws using a dimensionless chirality parameter and which explains the full reorientation dynamics including a very slow saturation at large shear rates due to the existence of a marginally stable fixed point in orientation phase space.

INTRODUCTION

It has been found more than half a century ago that some microorganisms swimming close to surfaces orient with respect to flow gradients and break the left-right symmetry (rheotaxis). Interestingly, bacterial rheotaxis in bulk has been discovered by Marcos *et al* [1] recently who have shown that surface interactions are not required for bacteria to drift towards the positive vorticity direction ("to the right") but the helical flagella shape leads to chirality-induced lift forces. In combination with the viscous drag on the bacteria head this leads to a rheotactic torque reorienting bacteria in flows which eventually cross streamlines by swimming along their direction of orientation. Brownian noise or bacteria tumbling randomizes the shear induced orientation dynamics but does not destroys the effect.

Despite the fact that quantitative observations of mean rheotactic velocities of bacteria have been reported and reproduced by numerical simulations [1] the details of the underlying physical mechanisms were not fully revealed. Here we combine an experimental, numerical and theoretical analysis to systematically investigate bulk rheotaxis of *E. coli* bacteria. Microfluidic experiments are performed in wide channels and a large number of bacteria tracks are recorded as projections into planes parallel to the bottom wall at different distances from the latter. Careful tracking of active bacteria as well as passive tracers allows then to obtain precise rheotactic velocities and orientation distributions at different positions in Poiseuille flow at various flow rates. Our findings constitute a full characterization of bacteria rheotaxis under shear flow, spanning the complete space of the Poiseuille channel flow and a comprehensive understanding of the physical mechanisms and relevant parameters behind it [2].

RESULTS

A dilute suspension of *E. coli* bacteria was injected at a given flow rate Q into a microchannel (Fig. 1(a)) which imposes a planar Poiseuille flow sufficiently away from the side walls. Using a high magnification objective lens bacteria tracks were recorded as projections into the x-y plane at different distances z from the bottom wall (Fig. 1(b)).

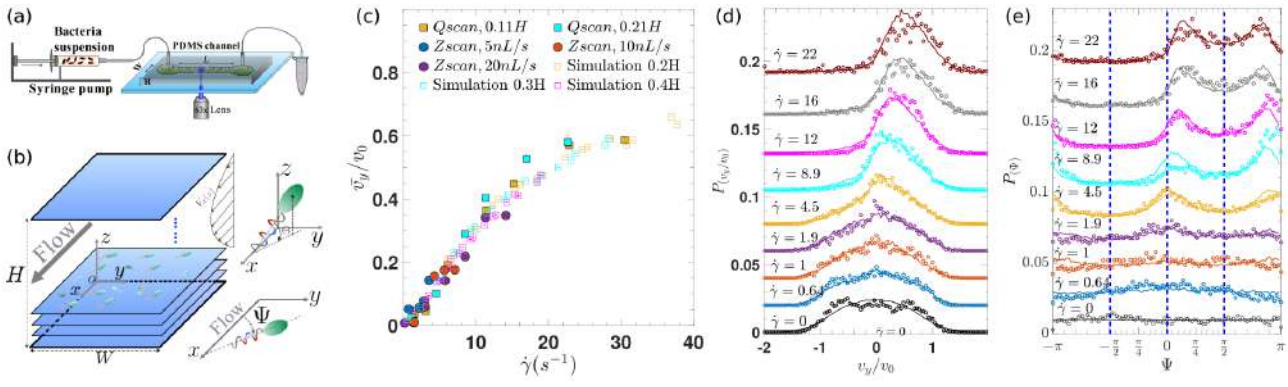

Figure 1: (a) Experimental microfluidic setup; (b) Coordinate system, definition of bacteria orientation (ψ, θ), and sketch of the different z-layers used to track bacteria in Poiseuille flow; (c) Mean scaled rheotactic velocity depending on the local shear rate at different flow rates Q and positions z; (d,e) Bacterial probability distribution of the rheotactic velocity (d) and orientation ψ (e). Open circles are experimental data, and solid lines obtained from Brownian dynamics simulations.

*Corresponding author. E-mail: andreas.zoettl@tuwien.ac.at

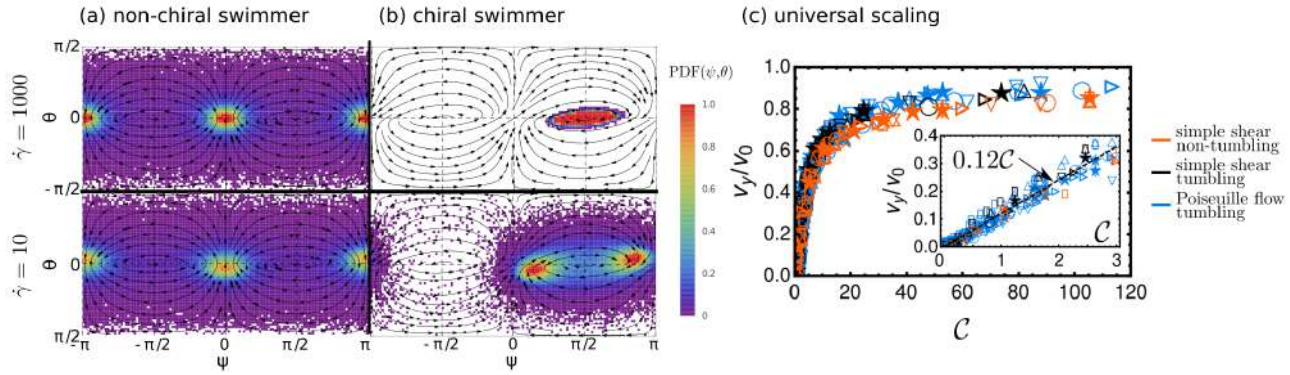

Figure 2: (a,b) Phase space curves and orientatioin probability function for a non-chiral (a) and a chiral (b; $\nu = 0.06$) microswimmer at different shear rates $\dot{\gamma}$; (c) master curve of rheotactic velocities for a wide range of different systems parameters (represented by different symbols) reveals universal scaling using the dimensionless chirality number $\mathcal{C}$.

Different local shear rates $\dot{\gamma}$ can be obtained in two ways, either by varying the imposed flow rate Q or by varying the position z inside the channel. Fig. 1(c) shows mean drift velocities $\bar{v}_y$ as a function of local shear rates from different data sets, scaled by the average intrinsic bacteria velocity $v_0 = 25\mu m s^{-1}$, and which almost collapse to a single curve. The large amount of recorded data allowed us for the first time to determine the velocity distributions $p(v_y)$ and in-plane orientation distributions $p(\psi)$ of bacteria away from surfaces with high accuracy (Fig. 1(d,e)).

In order to understand the detailed physical mechanisms behind bacterial rheotaxis we develop a theoretical framework which captures the dynamics of individual bacteria. We account for the elongated and chiral shape of the flagellated bacteria, their self-propulsion, tumbling, translational and rotational noise, and their advection and rotation in Poiseuille flow. In the absence of noise the coupled equations for the in-plane (ψ) and out-of-plane (θ) orientations read [2, 3]

$$\dot{\psi} = \frac{\dot{\gamma}}{2}(1+G)\sin\psi\tan\theta + \dot{\gamma}\nu\cos\psi\frac{\cos 2\theta}{\cos\theta}, \qquad \dot{\theta} = \frac{\dot{\gamma}}{2}(1-G\cos 2\theta)\cos\psi + \dot{\gamma}\nu\sin\psi\sin\theta. \tag{1}$$

where $0 < G < 1$ depends on the swimmer aspect ratio, and ν is the dimensional chiral strength which only depend on bacterial shape. Fig. 2(a,b) show the orientation phase space curves (black arrowed lines) for a non-chiral ($\nu = 0$) and a chiral ($\nu = 0.06$) microswimmer and the probability distributions at high ($\dot{\gamma} = 1000$) and low ($\dot{\gamma} = 10$) shear rates when Brownian and tumbling noise is included. Non-chiral swimmers exhibit bimodal, left-right symmetric distributions with peaks aligned and anti-aligned with the flow, similar as for passive microscopic elongated particles [4]. In contrast, the solution of Eq. (1) for chiral swimmers reveals an attractive phase space region for orientations to the right ($\psi > 0$) which includes a linearly marginally stable fixed point, which effectively traps low-noise trajectories at relatively high amplitudes and is resonspible for the slow saturation of the rheotactic velocity at high shear rates. At lower shear rates bimodal peaks occur, in agreement with experiments (Fig. 1(e)), as a consequence of the competition between swimmer alignment with flow due to their elongation, and attraction towards the right [2].

A theoretical analysis and linearization both near the flow-aligned peaks and the marginally stable fixed point allows us to extract the relevant scaling laws which determine the strength of the rheotactic velocity depending on the swimmer aspect ratio, the chiral strength, the local shear rate, and Brownian and tumbling noise [2]. Our analysis now suggests to introduce a dimensionless *chirality number*

$$\mathcal{C} = \frac{\dot{\gamma}\nu}{D_r^{\text{eff}}} \tag{2}$$

as the main relevant physical quantity which regulates rheotaxis. Here we use D_r^{eff} as the effective rotational diffusion constant steming from rotational Brownian motion and tumbling. In Fig. 2(c) we show the rheotactic velocity for a wide range of different parameters as a function of the chirality number $\mathcal{C}$ which indeed collapse.

CONCLUSIONS

Here we have demonstrated experimentally, numerically and theoretically the detailed orientation and velocity distribution of swimming *E. coli* bacteria in shear flows at low Reynolds number. Our results contain the first comprehensive analysis of bacterial rheotaxis in bulk, of possible relevance for various biomedical and technological applications.

Summary We present a numerical study of the dynamics of an elastic fiber in shear flow. The simulations are done in the bead-spring framework including hydrodynamic interactions in two theoretical schemes: the Generalized Rotne-Prager-Yamakawa model and a multipole expansion corrected for lubrication. We focus on the evolution of an initially straight fiber oriented in the flow direction. In the simulations fibers have aspect ratio from 20 to 200 and various bending stiffnesses: fiber shape vary from highly bent to straight. We discover variations of the fiber shapes and dynamics that follow powers, e.g. the fiber curvature changes as fiber stiffness to the power -1/4, and show that time scales of fiber rotation (length dependent) and fiber bending (stiffness dependent, length independent) determine the fiber motion. The numerical results are further supported with an analytical elastica model.

INTRODUCTION

The behavior of fibers immersed in the shear flow is a phenomena studied experimentally [1, 2], theoretically and numerically [3, 4, 5] in the context of fundamental understanding and technological applications of fibrous materials [6]. Here we focus on the dynamics of a single, flexible fiber that is initially stretched in the direction of the shear flow. We perform numerical simulations for different lengths and stiffnesses using a bead-spring model of a fiber. The results demonstrate that for a finite aspect ratio the fiber end effects are important to understand the shape of the fiber and its evolution, at least in part because they introduce a separate time scale.

METHODS

In simulations we use the bead-spring model common to studies of the dynamics of suspensions in the regime of small Reynolds numbers [7]. The fiber consists of N beads (with diameter d, position $\mathbf{R}_i$) that are interacting with stretching and bending potentials, and the fiber is placed in a fluid of viscosity η undergoing a shear flow with shear rate $\dot{\gamma}$. Between every two consecutive beads in the chain we impose the FENE stretching potential with equilibrium distance d between the bead centers and maximum stretch $0.1d$, which has a stretching resistance large enough to mimic an inextensible structure. Indeed, the observed changes in the fiber length does not exceed 0.1% of the total fiber length. The bending potential E_{bi} acts between every three consecutive beads $(i-1, i, i+1)$ restricting the shape of the fiber. We used harmonic $E_{bi} = \frac{A'}{2}(\theta_i - \pi)^2$ and cosine $E_{bi} = A'(1+\cos(\theta_i))$ bending potentials, where $\theta_i = \text{arc cos}\left(\frac{(\mathbf{R}_{i-1}-\mathbf{R}_i)\cdot(\mathbf{R}_{i+1}-\mathbf{R}_i)}{|\mathbf{R}_{i-1}-\mathbf{R}_i||\mathbf{R}_{i+1}-\mathbf{R}_i|}\right)$. The dimensionless bending stiffness $A = A'/(\pi\eta\dot{\gamma}d^3)$ and the number of beads N are treated as parameters. We used two different hydrodynamic interactions (HI) models: the Generalized Rotne-Prager-Yamakawa (GRPY) [8] and the Hydromultipole algorithm [4] based on the multipole expansion corrected for lubrication. In case of the GRPY approximation, to prevent sphere overlap, spheres that are more distant than nearest neighbors interact with the repulsive part of the Lennard-Jones potential. We focus here on GRPY with harmonic bending potential.

RESULTS

The quantity that we investigate in detail is the maximum curvature κ over the fiber length at every instant of time. For each consecutive three beads $(i-1, i, i+1)$ the local curvature κ_i is the inverse of a radius of a circle circumscribed on points $\mathbf{R}_{i-1}, \mathbf{R}_i, \mathbf{R}_{i+1}$. For each time we take the maximum of κ_i over all nearest neighbor triplets in the fiber and denote this quantity κ. An example of κ as a function of time is shown in Figure 1A. We will focus on two characteristic features of $\kappa(t)$: a time τ_b that is needed for a fiber to bend (interval from the beginning of the simulation to the rapid increase in κ) and maximum of κ observed over time that we will denote κ_b. In Figure 1B the corresponding shapes of the fiber are shown during the time instances marked in Figure 1A.

The maximum bending curvature κ_b as a function of dimensionless bending stiffness A is presented in Figure 1C. Generically a fiber of a given length will have three distinct behaviors as a function of A. First, in the regime of the smallest A, κ_b is limited primarily by the excluded volume of the beads. Second, in the regime of the intermediate A, κ_b is best described by the local bending. In this regime the shape follows the scaling law $\kappa_b \propto A^{-1/4}$ that can be understood from the interplay between the shear flow and elasticity, as we demonstrate with the elastica model. Third, in the regime of large A the fiber bends globally leaving the scaling law typical for the second regime. The transition between the second and third regimes depend on N and for larger N occurs at larger A.

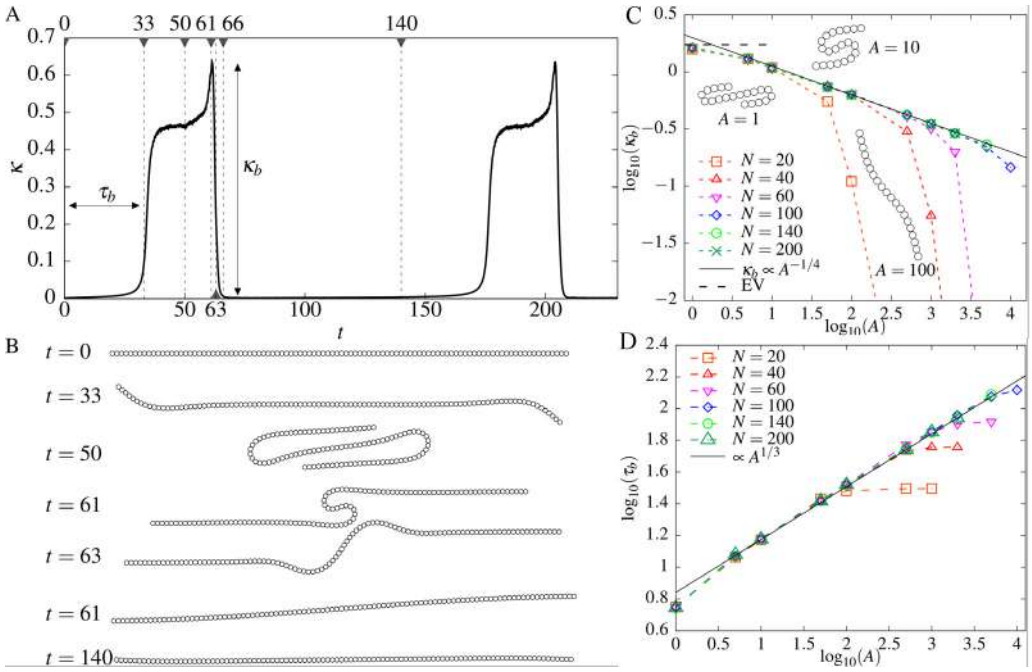

Figure 1: Flexible fiber in the shear flow calculated with the GRPY model. (A) The maximum curvature chosen over the fiber length as a function of time for the fiber of length $N = 100$ and $A = 100$. (B) Fiber shape corresponding to the time instants marked in the panel A and the same simulation. (C) The maximum curvature κ_b that a fiber reaches during simulation as a function of A for different N. The EV denotes the curvature limit from the excluded volume of the spheres. In the insets the characteristic bent shapes of the fiber with $N = 20$ are shown. (D) The bending time τ_b as a function of A and N.

Another aspect of the transition between the second and third regimes of fiber bending arises from the detailed inspection of the bending times τ_b. In Figure 1D we show τ_b as a function of A for different N. Again, for a given fiber length we can distinguish three regimes: regime of small A, regime of intermediate A ($\tau_b \propto A^{1/3}$) and regime of large A (τ_b saturates). To justify the slope in Figure 1D we use the elastica model with an additional assumption: at the fiber end a constant hydrodynamic force is present. It is perpendicular to the fiber direction and oriented as the rotational component of the shear flow. This assumption is justified by the results obtained from the bead-spring approach.

The τ_b does not depend on the fiber length in the low and intermediate regimes of A (owing to the local nature of bending), however the transition between the local and global bending does depend on N. This can be understood from a competition of the two time scales present in the system. The time scale τ_r that a straight and stiff fiber needs to perform a quarter of periodic rotation in the shear flow and the time scale τ_b that the fiber end needs to bend from the stretched, flow aligned configuration. The behavior $\tau_r \propto N$ and its values are visible as saturation times in Figure 1D. Furthermore, using the τ_b the phase space of the shapes of elastic fiber evolving in the plane of shear flow can be explained.

INSTABILITIES AND DYNAMICS OF PHORETIC SUSPENSIONS

Tullio Traverso*[1], Sébastien Michelin [1]
1LadHyX, Ecole Polytechnique, Palaiseau, France

Janus phoretic colloids self-propel as a result of self-generated chemical gradients, and influence each other hydrodynamically and chemically. The shape and surface chemical properties of the particles, which are design parameters, determine the relative importance of such interactions which, in turn, characterize the large-scale collective dynamics of the suspension in a fundamental way. We use a kinetic model to investigate the competition and interaction of self-propulsion with hydrodynamic and chemical couplings. Using linear stability analysis we discuss the role of such design parameters in determining the onset of instabilities. Nonlinear numerical simulations are then used to investigate the subsequent nonlinear collective dynamics in dilute suspensions of chemically-active Janus swimmers.

INTRODUCTION

A fascinating analog to biological signalling is provided by the collective behaviour of synthetic autophoretic Janus particles (JPs). Unlike living cells, their motion is governed by deterministic laws which relate the hydrodynamic forcing to the chemical environment of the particle. We exploit this relationship to derive a self-consistent kinetic model which we use to assess the relative importance of hydrodynamic and chemical interactions in the dilute regime for different particles configurations.

FROM SINGLE-PARTICLE DYNAMICS TO THE KINETIC MODEL OF A SUSPENSION

Self-diffusiophoretic particles, such as JPs, drive an apparent slip velocity on their surface, $\mathbf{u}_s$, in the presence of a local chemical gradient along their surface, ∇C, which can be self-generated (e.g. by asymmetric activity) or due to the presence of other swimmers. The chemical properties and the shape of the particle determine its self-propulsion velocity u_0, the coefficient for the drift and rotation into an external chemical gradient, ξ_t and ξ_r (orange arrows in Fig.1), and the far-field chemical and hydrodynamic signature (background colour field and thin blue arrows in Fig.1 respectively), the latter being characterised by an active stress tensor $\boldsymbol{\sigma}_a$ [1].

We represent the configuration of a suspension of auto-phoretic swimmers by means of a distribution function $\Psi(\mathbf{x},\mathbf{p},t)$ of the particle position $\mathbf{x}$ and director $\mathbf{p}$ [2]. The evolution of the suspension is described by a Smoluchowski equation

$$\frac{\partial \Psi}{\partial t} = -\nabla \cdot (\Psi \dot{\mathbf{x}}) - \nabla_p \cdot (\Psi \dot{\mathbf{p}}) \quad (1)$$

where ∇_p is the gradient operator on the unit sphere and the fluxes are determined by the particles response to the hydrodynamic and chemical fields, $\mathbf{u}(\mathbf{x},t)$ and $C(\mathbf{x},t)$, through the particles velocities $\dot{\mathbf{x}}$ and $\dot{\mathbf{p}}$. They read

$$\dot{\mathbf{x}} = u_0\mathbf{p} + \mathbf{u} + \xi_t \nabla C - D\nabla(\ln\Psi) \quad (2)$$

$$\dot{\mathbf{p}} = \boldsymbol{\Omega} \times \mathbf{p} + \xi_r(\nabla C \times \mathbf{p}) \times \mathbf{p} - d_r \nabla_p(\ln\Psi) \quad (3)$$

where $\boldsymbol{\Omega}$ is half the vorticity vector while D and d_r are the particles translational and rotational diffusion. The chemical concentration evolves according the an advection-diffusion equation with a source term proportional to the particle density $\Phi(\mathbf{x},t) = \int \Psi(\mathbf{x},\mathbf{p},t)\,\mathrm{d}\mathbf{p}$ and a decay term, $-\beta C$. Finally, the hydrodynamic field follows the incompressible Stokes flow equations forced by the active stress, which, at the suspension level, is approximated by $\boldsymbol{\Sigma}(\mathbf{x},t) = \int \boldsymbol{\sigma}_a \Psi \,\mathrm{d}\mathbf{p}$. The connection between the properties of the particle and the model for the suspension is encapsulated in u_0, ξ_t and ξ_r (through which $\boldsymbol{\sigma}_a$ can be determined) all of which are functions of the first two moments of the activity and mobility distribution on the surface of the particles.

LINEAR STABILITY AND THE ROLE OF SELF-PROPULSION

We analyse the linear stability of the uniform and isotropic state and study two destabilising mechanisms associated with attractive chemical interactions (i.e. when either ξ_t or ξ_r are positive) which we refer to as chemotactic limit, due to $\xi_r > 0$ while $\xi_t < 0$, and phoretic limit, due to $\xi_t > 0$ while $\xi_r \approx 0$. The main difference between these mechanisms is that the former induces particles to polarize first and then to swim towards regions of higher particles concentration (Fig.2a), while the latter induces particle aggregation without polarization and occurs also for $u_0 = 0$. Interestingly, we find that self-propulsion stabilise long-wavelength modes in the phoretic limit [5], which could explain why experimentally observed clusters never coalesce [3]. High values of u_0 will eventually stabilize the suspension in both the chemotactic and phoretic limit. Within a realistic range of D, the linear stability is solely determined by an interplay between phoretic interactions and self-propulsion, which also determines the most unstable wavelength.

HYDRODYNAMICALLY INDUCED DISORDER

The long term dynamics are investigated by numerically integrating equation (1) coupled with the Stokes flow equations and the advection-diffusion equation for C, in a square periodic 2D domain. Due to the fact that a nonzero active stresslet, $\boldsymbol{\sigma}_a$, is associated with $\xi_r \neq 0$ we focus on the chemotactic limit, where the interplay between chemical and hydrodynamic interaction characterize long term dynamics, as opposed to the phoretic limit, where $\boldsymbol{\sigma}_a, \xi_r \approx 0$.

In the chemotactic limit polar order must emerge for aggregates to form (Fig.2a), which allows the hydrodynamic perturbations of many particles to positively superimpose, driving a large scale flow that prevents ordered structures to appear (Fig.2b). If the hydrodynamic interactions are not taken into account, the patterns in Fig.2a appear circular and static with the mean director field always pointing radially toward the centre of the aggregates. We consider this behaviour as the precursor to cluster formation, as observed in particle-based simulations even at low area fraction [4].

We define $\mu_{2,2}(t)$ as an intrinsic measure of how scattered the energy density is on the Fourier plane, i.e., of the variety of length scales in the particle distribution. As we can see from Fig.2c, the presence of an induced flow field continuously depletes energy from the chemically unstable modes, which is injected at other wavenumbers, including at higher spatial frequency, which are chemically-stable modes and where particle diffusion dominates [5].

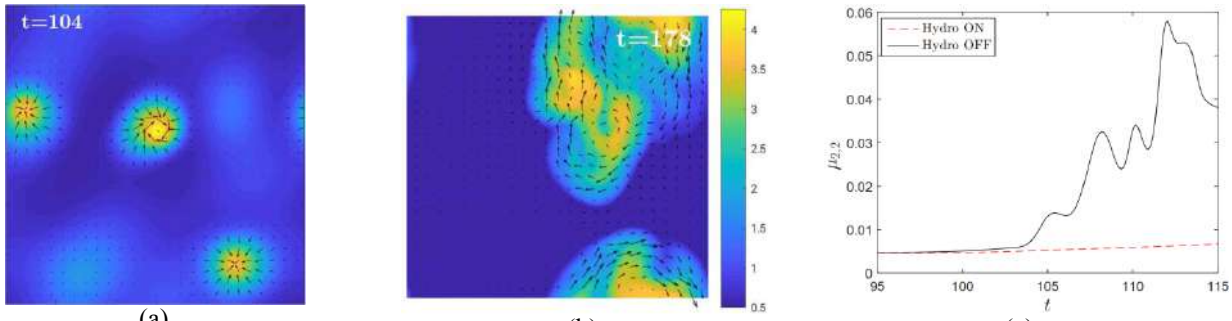

Figure 2. (a-b) Colour: Particle density Φ; arrows: (a) Mean particles orientation; (b) flow velocity u. (c) Amplitude of $\mu_{2,2}(t)$. Black and red line correspond to simulations with and without hydrodynamic interactions, respectively.

CONCLUSIONS

Based on the stability analysis, we clarify the role of self-propulsion at the onset of collective motion: while it is a necessary ingredient for the chemotactic mechanism, it has a purely stabilising effect to those modes promoted by attractive phoretic drift. Our numerical simulations suggest that strong self-generated hydrodynamic field within suspensions of auto-chemotactic JPs ($\xi_r > 0$) smoothen the energy spectrum and ordered long-wavelength structures cannot form [5].

HYDRODYNAMIC INTERACTIONS OF MOTILE CELLS WITH A SOLID SURFACE

Abel-John Buchner[1], Junaid Mehmood[1], Koen Muller[1], and Daniel Tam*[1]
[1]Laboratory for Aero and Hydrodynamics, TU Delft, Delft, Netherlands

Summary Motile micro organisms swim through complex environments and often interact with solid surfaces. Their swimming is influenced by the proximity to solid substrates, through hydrodynamic and steric interactions. The influence of hydrodynamic forces on cell-wall interactions remains unclear and previous studies have often been limited to 2-dimensional flow cells, confining the trajectories of the swimming cells. Here, we investigate the interaction of free-swimming cells with surfaces in an unconstrained 3-dimensional flow chamber. Our tracking experiments focus on C. reinhardtii. Motile cells are recorded simultaneously by four separate cameras and triangulated in 3-dimensions. Kinematic statistics are calculated from approximately 30,000 swimming tracks. Our results provide evidence for long-range hydrodynamic interaction, which induces orbiting behaviour in the near-surface region.

MOTIVATION

On the micron scale, motile cells swim through environments with complex topographies and their motion is affected by interactions with solid surfaces. Elucidating these interactions is key to the understanding of biophysical processes such as fertilization, surface colonisation and biofilm growth. The mechanical interactions between motile cells and solid walls have been the focus of previous experimental [1, 2, 3] and theoretical studies[4]. In particular, investigations of the ciliated cells of Chlamydomonas Reinhardtii in microfluidic Hele-Shaw cells has highlighted the importance of contact interactions between the cilia and the solid wall [2, 3]. In these studies, the depth of the Hele-Shaw cell is of a few body lengths. This geometry constrains the natural motion of the cells to mostly two-dimensional trajectories, which can be tracked with an optical microscope. Here, we use a multi-view microscope, which supports the three-dimensional tracking of unconstrained swimming micro-organisms. Our experimental setup has a sufficiently large depth of field to record freely swimming cells over long time periods. The accurate calibration of the experimental setup [5] supports tracking within one body length accuracy in all directions, which enables us to resolve the near boundary cell dynamics and to distinguish between the cells that come in direct contact with the wall and the cells that do not.

Near the wall, we find two distinct cell-wall interactions, contact and non-contact interactions, leading to different scattering dynamics. From the long time recording, we also characterize an orbiting behaviour within 10-20 body lengths of the wall, whereby cells repeatedly return to the surface.

METHODOLOGY

We track *Chlamydomonas reinhardtii*, a green alga and common model organism for motility studies of size approximately 10μm and swimming at $\sim 100\mu\text{m.s}^{-1}$. We introduce a dilute suspension of cells at a density of 2×10^4 cells.mL^{-1} in a large flow chamber, whose smallest dimension is approximately 2mm in the direction of the optical axis. This cell suspension is illuminated by an LED light source at a wavelength beyond the phototactic range of the cells, and recorded simultaneously by four sCMOS cameras at 50 fps, see figure 1a. Each camera records the motion of the swimming cells off centre through a single large objective lens, such that the viewing axes of the four camera converge on the measurement domain from varying angles, see figure 1b. The depth of field is large and the entire 2mm depth of the flow cell is in focus. We developed an accurate calibration method within the framework of projective geometry using tools from computer vision [5]. This calibration supports the accurate triangulation of the three dimensional position of the cells and allows us to track all the cells in the suspension over the entire depth of field, see figure 1c. Our tracking algorithm is robust, and we track cells over long periods of time. Here, we report data extracted from $\sim$ 30000 individual tracks.

RESULTS

We first consider cell trajectories within a near wall region of 10 body lengths. We find two distinct dynamics at the wall, which can be identified as contact and non-contact interactions and lead to different scattering dynamics. First, cells approaching the wall with a higher angle come in direct contact with the solid surface and leave it at a fixed angle. Such contact interactions are characterized by a decrease in swimming velocity at the point of nearest approach and are associating with a scattering angle in the wall plane. Second, cells approaching the wall with a shallower angle often do not approach the wall within contact region and are scattered at a shallow angle. For non-contact interactions, the velocity remains constant through the wall interaction and the swimming direction in the wall plane remains unchanged. Our results are consistent with cell scattering at lower angle due to hydrodynamic interactions.

We then consider the trajectories of cells tracked over longer time intervals, and identify an orbiting behaviour, whereby cells repeatedly approach the wall, see figure 1d. Such cells are captured within 10-30 body lengths of the wall for long periods of time. We find this orbiting behaviour to be mostly due to an increase in the swimming angle towards the wall for cells within this region. This observation is qualitatively consistent with the hydrodynamic capturing of puller type cells through hydrodynamic interactions.

AZIMUTHAL MOTION OF LARGE NEUTRALLY BUOYANT PARTICLES IN POISEUILLE FLOW

Sudarshan Sridharan*[1] and Christian Poelma [1]
[1]Department of Mechanical, Maritime & Materials Engineering, Delft University of Technology, Delft, The Netherlands

Summary Poiseuille flow in a pipe with neutrally buoyant particles is investigated using Shadowgraphy-PTV. The considered pipe to particle diameter ratios (D/d) are 20 and 5.5. The bulk Reynolds number is varied between Re_b = 200 and Re_b = 800. As expected, the particles are observed to migrate radially to a location corresponding to the Segré-Silberberg annulus. In addition, we observe unexpected behaviour, as the D/d = 5.5 particles in the annulus move in a helical motion with a constant azimuthal velocity. This behaviour persists throughout the pipe. The effect of particle size and the Reynolds number on this azimuthal velocity is investigated.

INTRODUCTION

Wall-bounded particle-laden flows at low Reynolds number are known for particles inertially migrating to the Segré-Silberberg annulus [2]. This is predominantly due to the effect of shear around the particle resulting in a lift force acting radially towards the annulus [2]. Modelling these flows is challenging when the inertial contribution becomes significant, even at very low particle concentration [4]. Experiments at bulk Reynolds numbers $Re_b > 100$ show the dependence of the location of the stable annulus on the Reynolds number and pipe to particle diameter ratios (D/d) [1]. Furthermore, particles take longer to accumulate in the annulus than that predicted in the Stokes limit. An unstable annulus along with the stable annulus is also reported at Re_b = 600-800 [3]. These experimental results are generally based on stochastic analysis of particle radial positions at different streamwise locations from the entrance of the pipe and thus do not provide insight on the Lagrangian track of a particle.

In order to study the nature of particle trajectories, the particles are tracked along the pipe using a Shadowgraphy-PTV setup. The flow is imaged along two perpendicular directions resulting in three-dimensional reconstruction of particle tracks. Based on our observations, particles with D/d = 5.5 exhibit peculiar behaviour spiralling along the azimuthal direction after they have migrated to a radial position at 0.3D from the centre of the pipe.

EXPERIMENTAL SETUP

A flow loop is constructed at the Laboratory for Aero & Hydrodynamics in TU Delft for this study, with a 3.8 m long pipe with 10 mm diameter (D). The flow is driven by a constant head maintained in the overflow tank employed. The suspension enters the pipe through an inlet chamber containing a flow conditioner, followed by a smooth contraction. The suspension is collected in a reservoir from the pipe and pumped back to the overflow tank using a peristaltic pump, forming a closed loop. The considered bulk Reynolds numbers (Re_b) are 300, 400, 500, 600, and 700, based on flow rate measurements. A neutrally buoyant solution is prepared using the calculated amount of water and glycerol to match the density of the Polystyrene particles ($\rho_p = 1035\ kg/m^3$). The suspension has a kinematic viscosity of 1.53 x $10^{-6}\ m^2/s$ at 18.5 ^{o}C. The particle concentration is kept below 0.1% in order to avoid particle-particle interaction.

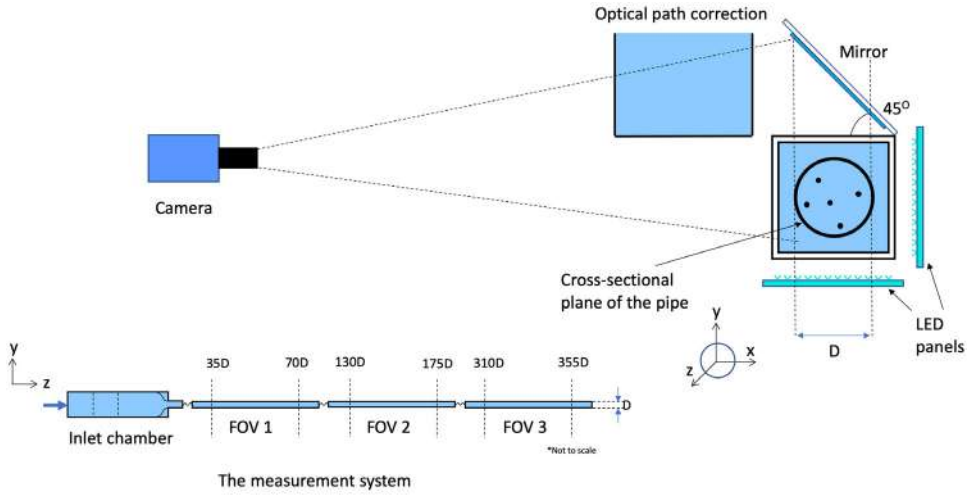

Figure 1: A schematic diagram of optical system used to reconstruct the three dimensional position of a particle in the pipe in the cross-sectional ($x - y$) plane. The particles are tracked in three field of views: FOV 1, FOV 2, and FOV 3 corresponding to 35-70D, 130-175D, and 310-355D from the pipe entrance respectively.

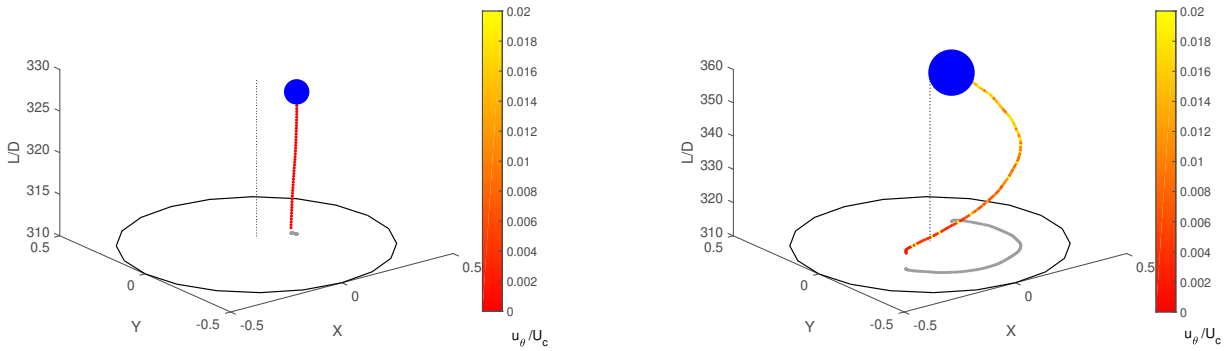
*Corresponding author. E-mail: S.Sridharan@tudelft.nl.

The imaging system employed is designed to image the suspension in two perpendicular planes using a single camera. An Imager sCMOS camera with 50 mm lens is placed perpendicular to the $(y-z)$ plane. A mirror is placed at 45^o with the horizontal (x-axis) over a rectangular PMMA section enclosing the pipe. This system provides two images simultaneously along perpendicular directions in the $(y-z)$ and $(x-z)$ planes with the $z-axis$ as the epipolar line, allowing three dimensional reconstruction of any particle in the field of view. The difference in optical path between the two views is compensated by employing a water filled container (Figure 1). The particles are tracked along 45D of pipe length at three different field of views, 35D-70D, 130D-175D, and 310-355D from the entrance with a spatial resolution of 0.22 mm and a temporal resolution of 0.02 s.

RESULTS

The particle positions reconstructed are used to generate radial probability distribution functions (PDFs) and the trajectories are used to determine the particle velocity. The particles with D/d = 20 and D/d = 5.5 accumulate in a stable annulus at 0.4D and 0.3D from the centre of the pipe respectively. However, the trajectory of particles with D/d = 20 and D/d = 5.5 show a sharp contrast. Particles with D/d = 20 are observed to travel mostly parallel to the pipe centreline in the measured field of view, migrating slowly in the radial direction. However, particles with D/d = 5.5 are observed to also undergo displacement along azimuthal direction (Figure 2). These motions are consistently observed in all the three field of views, from 35D-350D.



(a) D/d = 20. (b) D/d = 5.5.

Figure 2: Particle trajectories reconstructed in three-dimensional space at Re_b = 600. The flow direction is from bottom to top. The colormap denotes the azimuthal velocity (u_θ) of the particle normalized with the centreline velocity (U_c). The circle indicates the flow domain and the gray line represents the projection of tracks in the $(x-y)$ plane.

The particles moving along azimuthal direction rotate over 300 degrees in the measured field of view and have a constant azimuthal velocity after they migrate to the stable annulus. No preferred direction of the azimuthal displacement is observed as the particles move either in clockwise or anti-clockwise direction around the z-axis. As Re_b increases, more particles are observed to spiral in the azimuthal direction. Moreover, the azimuthal velocity of particles in the annulus increases with Re_b proportionally, with $u_\theta/U_c \approx 0.02$. This behaviour is briefly mentioned recently [3] in suspension with particles of D/d = 8. We will investigate this behaviour further with different pipe to particle sizes and supplement the PTV results with fluid velocity field measurements.

CONCLUSION

Large neutrally buoyant particles (D/d = 5.5) in Poiseuille flow migrate radially to a stable annulus as expected. However, they also move along azimuthal direction in contrast to particles of D/d = 20. The azimuthal velocity of the particle accumulated in the annulus is proportional to the bulk Reynolds number. The nature of such motions will be further investigated in suspensions with different pipe to particle diameter ratios.

Summary Hydrodynamic signalling is widely used at the planktonic scale. To understand how millimetric organisms use hydrodynamic signals to perceive their environment, we need to model how both inertial and unsteady effects influence the flow field produced by an active organism swimming in a viscous flow. Here, to address this question, we propose a model based on the method of Matched Asymptotic Expansions. This model allows us to calculate, as an expansion, the flow field produced by an active spherical particle, for an arbitrary time-dependent motion. The present technique unifies previously known results and extend them to the case of an active particle.

CONTEXT

Copepods are widespread millimetric crustaceans living in almost all waters on Earth. Although copepods are blind, they are able to detect preys, predators and mates by using hydrodynamic signalling. However, we do not know how they process and extract relevant information from the turbulent flow background. To address this question, we need a mathematical model of the hydrodynamic signals produced by their targets (Fig. 1b).

Copepods targets have a typical size of the order of $a = 1\,\mathrm{mm}$ and move with typical velocity of the order of $U = 1\,\mathrm{mm\,s^{-1}}$. Their Reynolds number, $\mathrm{Re} = aU/\nu$, is thus of order 1. Moreover, their motion is affected by unsteady effects of typical timescale τ, and the associated Strouhal number, $\mathrm{St} = a/(U\tau)$, is in many cases of order 1. In this context, both inertia and unsteadiness affect the disturbance flow produced by a millimetric swimmer.

STATEMENT OF THE PROBLEM

Let us assume that the swimming organism is moving with velocity $\mathbf{u}$. In the framework moving at velocity $\mathbf{u}$, the disturbance flow field, $\boldsymbol{v}$, is a solution of the following Navier–Stokes equation

$$\mathrm{Re}\,\mathrm{St}\frac{\partial \boldsymbol{v}}{\partial t} - \mathrm{Re}\,(\boldsymbol{u}\cdot\nabla\boldsymbol{v} - \boldsymbol{v}\cdot\nabla\boldsymbol{v}) = -\nabla p + \nabla^2\boldsymbol{v}, \quad \nabla\cdot\boldsymbol{v} = 0, \tag{1}$$

where typical length, velocity and density are taken to be a, U and ρ to make the problem dimensionless. This equation is complemented with the boundary conditions $\boldsymbol{v} = \boldsymbol{u} + \boldsymbol{u}_s$ on the particle surface (where $\boldsymbol{u}_s$ is the active velocity on the particle surface) and $\boldsymbol{v} \to 0$ at infinity.

In the asymptotic limit $\mathrm{Re} \ll 1$ and $\mathrm{St} \lesssim 1$, equation (1) is the Stokes equation. In that case, inertia and unsteadiness can be neglected and classical methods can be used to obtain the force acting on the swimming organism and the flow produced (Fig. 1a) [1, 2]. In contrast, when fluid inertia is taken into account (when $\mathrm{Re} = O(1)$ and $\mathrm{St} \ll 1$) or when unsteadiness is taken into account (when $\mathrm{Re}\,\mathrm{St} = O(1)$ with $\mathrm{Re} \ll 1$), the problem complexity increases drastically.[3, 4]

In the past, some important works have addressed how to solve the Navier–Stokes equation (1) in some particular limits (Table 1). However, when both inertial effects and unsteady effects are taken into account, we do not known how these effects combine for an active particle. This is the main question we want to address in this communication.

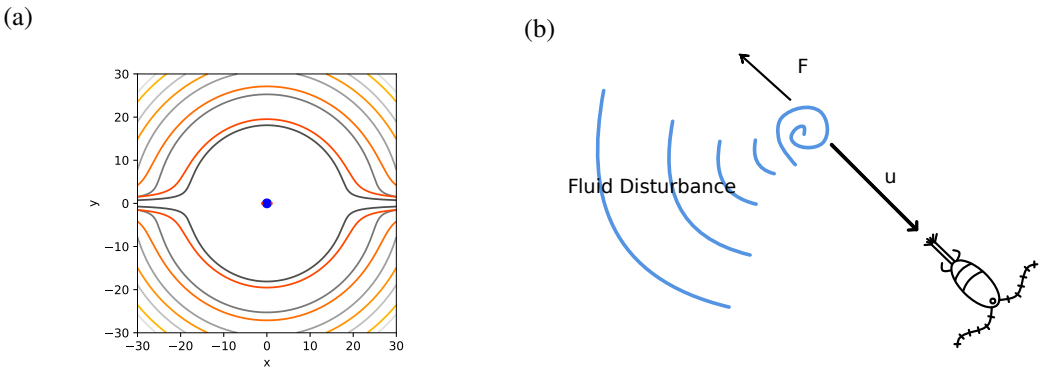

Figure 1: (a) Streamlines of the Stokes solution (grey) and Oseen approximation (red) for a sphere (blue) moving at constant velocity ($a = 1$ and $\mathrm{Re} = 8$). (b) Sketch of a millimetric organism swimming unsteadily. The force $\mathbf{F}(t)$ is force exerted on the fluid by the swimmer and $\mathbf{u}(t)$ is its instantaneous velocity.

The second and the third columns correspond to references addressing passive or active particles. We use symbols to refer to analytical expressions of the flow field ($\star$) or the force acting on the particle ($\circ$).

MATCHED ASYMPTOTIC EXPANSION METHOD

We apply a method that relies on Matched Asymptotic Expansion of the flow field $\boldsymbol{v}$. In the outer region, $\boldsymbol{v}$ is expanded as a series of the small parameter $\epsilon = \sqrt{\mathrm{Re}\,\mathrm{St}}$. We then match the outer solution to an inner solution near the active particle. This method allows us to calculate both the force acting on the particle and the flow field $\boldsymbol{v}$ including corrections due to inertia and unsteadiness.

The proposed solution can be seen as a generalisation to active particle of the force derived by Lovalenti and Brady for passive particles [10]. We can also recover the results of Wang and Ardekani [7] on the force acting on an active unsteady particle. The novelty of the present method, is that it allows us to calculate the flow field produced by an active particle, a result that is not accessible with methods based on the reciprocal theorem.

This method will be used to compute the flow field generated by a millimetric organism that produces a time-periodic active force. It will then be compared to the experimental data of Kiorboe and Jiang [11] on swimming copepods.

RECIPROCAL FRAMEWORK FOR THE SELF-PROPULSION OF CHEMICALLY ACTIVE COLLOIDS

Bhargav Rallabandi*[1], Fan Yang[2], and Howard A. Stone[2]
[1]Department of Mechanical Engineering, University of California, Riverside, USA
[2]Department of Mechanical and Aerospace Engineering, Princeton University, Princeton, USA

Summary Active colloids generate chemical gradients through surface chemical activity, using which they then can self-propel via phoretic mechanisms. Here, we discuss a framework to model the self-propulsion of N non-Brownian active colloids that interact chemically and hydrodynamically. This is achieved by combining multipole expansions for the chemical transport with the Lorentz reciprocal theorem for low-Reynolds-number hydrodynamics. The framework yields explicit analytic predictions for the particle velocities that are shown to be in good agreement with exact results where available. We then apply the model to a binary mixture of particles with different mobilities and find behaviors that include pair-chasing, attraction and aggregate formation. The framework is computationally advantageous in that it circumvents the matrix inversion common in problems involving colloidal suspensions.

BACKGROUND

The self-propelled motion of particles suspended in viscous fluid has widespread applications in biological systems and for microscale assembly. In synthetic microscale systems, chemical gradients are often used to drive the motion of suspended particles with engineered surface properties. A particle whose surface interacts with the solute through a short-range potential will translate when exposed to a gradient of a chemical potential. This type of motion, known as diffusiophoresis, can be generated by several physical mechanisms, including van der Waals forces, steric interactions or an electrostatic potential between a charged particle and ions in solution [1]. Chemically active colloids are typically designed with materials that catalyze chemical reactions, generating chemical species whose gradients drive particle motion through phoretic mechanisms.

PROBLEM SETUP AND APPROACH

Here, we consider the low-Reynolds-number motion of N rigid, self-propelling colloids suspended in a Newtonian fluid. Each particle i translates with velocity $\mathbf{V}_i$ and rotates with angular velocity $\mathbf{\Omega}_i$ as a result of surface chemical flux $\varphi_i(\mathbf{x})$ at the particle surfaces S_i (due to surface chemical reactions). We are interested in determining the motion of the particles given their positions and the surface chemical fluxes. We assume that the flow is sufficiently slow that the transport of chemical $c(\mathbf{x})$ is diffusion dominated. Thus, each particle experiences a gradient of chemical concentration $\nabla c(\mathbf{x})$ that is a function of the positions of all of the particles and chemical in the system. The local chemical concentration gradient causes the development of a thin slip layer around each particle, that ultimately leads to its motion. We use the common modeling framework in which we model the slip layer using an effective slip velocity condition

$$\mathbf{v} = \mathbf{v}_s(\mathbf{x}) = M(\mathbf{x}, c(\mathbf{x}))\nabla \mathbf{c}(\mathbf{x}) \quad \text{for} \quad \mathbf{x} \in S_i. \tag{1}$$

Here, M is a phoretic mobility that can depend explicitly on the position along the particle surface as well as on the local concentration field.

Past studies have solved the coupled chemical-hydrodynamic problem by directly solving the Stokes equations subject to the slip conditions and a balance of forces and torques, for example using multipole expansions [3]. Here, we develop an alternative framework that utilizes the Lorentz reciprocal theorem to circumvent the solution to the detailed fluid velocity and pressure fields and instead directly yield the kinematics of the problem. The result is that the the translation and rotation ($\mathbf{V}$ and $\mathbf{\Omega}$) of the particles can be expressed directly as integrals of the slip velocity over the particle surfaces in N- particle systems. In contrast with other approaches in the literature for N-body hydrodynamics [2], the framework developed here does not involve the inversion of a grand mobility matrix and thus is computationally advantageous.

We apply the framework to the common case of spherical particles in unbounded flow. We further focus on particles with uniform surface chemical fluxes, so any motion of the particles is a direct consequence of either chemical or hydrodynamic interactions between the particles. We apply our framework to two particles in an electrolyte solution (where $M(c) \propto c^{-1}$ for which the particles co-move or counter-move depending on the relative sign of their mobility. We find our theory to be in excellent agreement with exact solutions [4] up to the time when the particles make contact. We then apply the framework to multiple particles, exploring the behavior of the system for a binary mixture of two populations of particles – one with positive mobility (chemical seeking) and the other with negative mobility. In these multi-particle binary systems, we observe the formation of particle pairs and propelling clusters that transiently change geometry as the system evolves in time (Fig. 1). At long times, we generally find that the positive-mobility particles form a single large aggregate, expelling the negative-mobility ones. However, we also encounter situations in which the large aggregate may trap negative-mobility particles as "inclusions". We find the presence of these inclusions to greatly enhances the propulsion speed of these aggregates, which may prove useful as a strategy for microscale assembly.

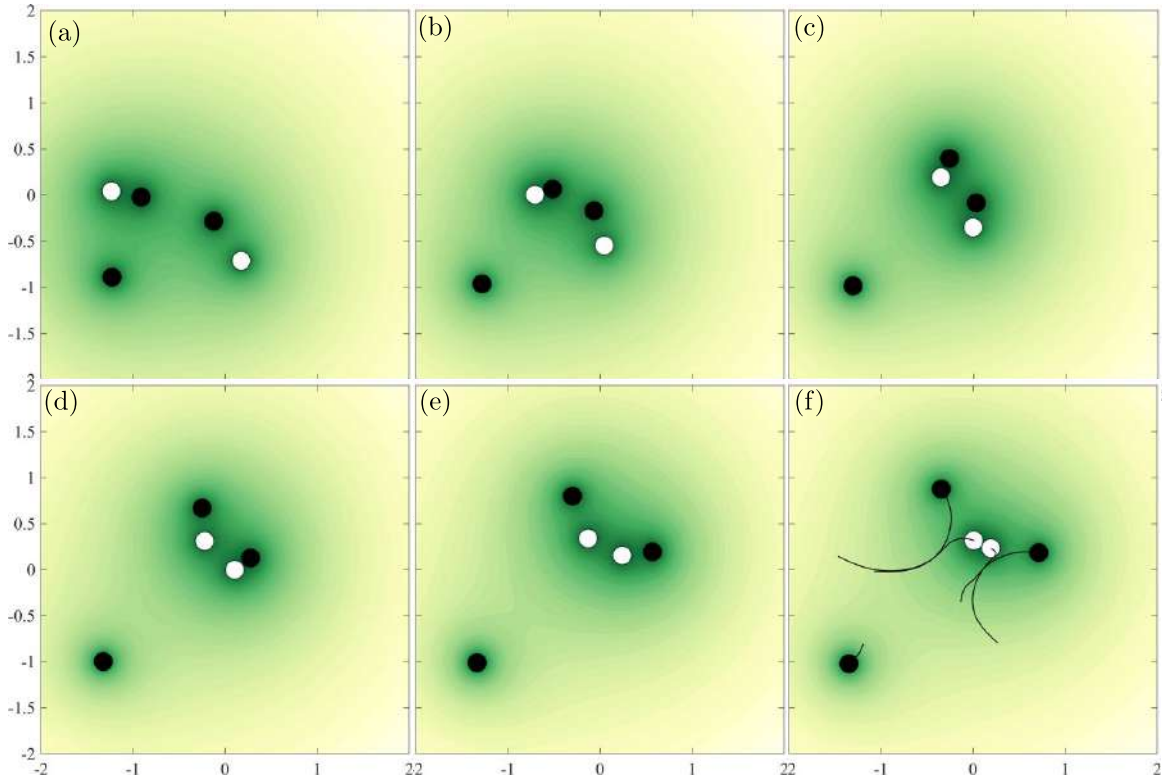

Figure 1: Sample trajectories of 5 particles with uniform surface chemical flux; light particles are attracted to the chemical while dark particles are repelled from it. The shading indicates the concentration field (dark indicates higher concentration) which is generated by the particles and diffuses away. Particle behaviors include transient pairing (b), chasing (c–d) and aggregation (f).

CONCLUSIONS

Our main result is the development of a versatile formalism that accurately and efficiently models the motion of hydrodynamically interacting active particles. We use the Lorentz reciprocal theorem in our work, which circumvents the construction of the detailed velocity fields in the fluid volume, in contrast with earlier approaches. We build on results in the literature to evaluate the motion of widely separated spheres, retaining contributions up to the level of force and torque quadrupoles. We then apply the theory to problems with multiple spheres with uniform surface fluxes, recovering results of earlier work in the literature and demonstrating new effects due to chemical inhomogeneities in the system.

MODELING CONCENTRATION POLARIZATION AND FOULING LAYERS IN CROSSFLOW ULTRAFILTRATION

Gun Woo Park* and Gehard Nägele
Institute of Complex Systems (ICS-3), Forschungszentrum Juelich

Summary We present a boundary layer approximation (BLA) method for calculating the concentration-polarization (CP) layer and dispersion flow in crossflow ultrafiltration with a cylindrical membrane [1]. Results are discussed for various feed dispersions of colloidal particles, namely hard spheres, charge-stabilized particles [2], solvent-permeable non-ionic microgels [3, 4], and deswelling ionic microgels [5]. State-of-the-art methods are used for the gradient diffusion coefficient and viscosity entering the calculation of filtration profiles [3, 5]. We show that the BLA profiles are in quantitative agreement with predictions by a finite-element method [1]. The BLA results are compared with predictions by a similarity solution [4]. The BLA method is extended to conditions where a filter cake is formed at the membrane, with permeate flux results presented for a hard-sphere system [6].

INTRODUCTION

Crossflow ultrafiltration (UF) is a pressure-driven separation and enrichment process for colloidal dispersions where the feed dispersion is continuously pumped through a membrane pipe (Fig. 1, left). The applied transmembrane pressure (TMP) causes the solvent to flow out of the membrane, while the colloidal particles are retained inside the tube. Consequently, a particle-enriched diffuse layer is formed near the membrane, which reduces the filtration efficiency. This concentration-polarization (CP) layer is due to the balance of flow advection of particles towards, and gradient diffusion away from the membrane. The CP layer reduces the permeate flux, which can be attributed to the particles-created osmotic pressure counteracting the TMP. With increasing TMP, the particles near the membrane become immobilized, forming a crystalline so-called cake layer (Fig. 1, right). The cake layer is commonly believed to be at the origin of the limiting flux behavior, i.e., the experimentally observed horizontal flattening of the mean permeate flux at large TMP.

We have developed an efficient boundary layer approximation (BLA) method for accurately calculating the flow and concentration profiles in the UF of colloidal dispersions, on accounting for the concentration dependence of transport properties and osmotic pressure inside the inhomogeneous CP layer [1]. The BLA method is easily applied to feed dispersions including hard spheres (HS), solvent-permeable non-ionic microgels (MG), and ionic microgels (ion-MG) which deswell with increasing concentration [5]. To illustrate the importance of the concentration dependence of gradient diffusion and dispersion viscosity, we also report concentration profiles for constant transport (CT) coefficients. Fig. 2 shows BLA results for the particle volume fraction profile $\phi_w(z)$ at the membrane wall for different dispersions, in comparison with finite-element method (FEM) results (symbols), demonstrating the excellent agreement between both methods. We further compare with CP layer predictions for hard spheres by an earlier boundary layer similarity solution (sBLA) [4], which differs significantly from the FEM/BLA results. Gradient diffusion away from the membrane is the largest (smallest) for hard spheres (ionic microgels). Hence, hard spheres have the most strongly developed CP layer and osmotic pressure for equal operation conditions, and hence the lowest permeation efficiency. For hard spheres, there is only a moderate increase of gradient diffusion with increasing concentration, differently from charge-stabilized particles. Regarding the filtration efficiency, this is over-compensated by an accordingly increasing viscosity, resulting in a $\phi_w(z)$ curve only mildly larger than that for constant transport (CT) coefficients of values taken at the feed concentration.

We have extended the BLA to conditions where a crystalline filter cake is formed (Fig. 1, right). The cake layer contributes to the hydraulic resistance entering the employed Darcy-Starling law relating permeate flux to TMP and osmotic pressure. For hard spheres, Fig. 3 illustrates the effect of the cake layer on the pipe-length averaged permeate flux $\langle v_w \rangle$, as a function of the length-averaged TMP. According to the figure, the cake is responsible indeed for an (apparent) limiting flux behavior at large TMP where a large fraction of the membrane is covered by the cake (inset).

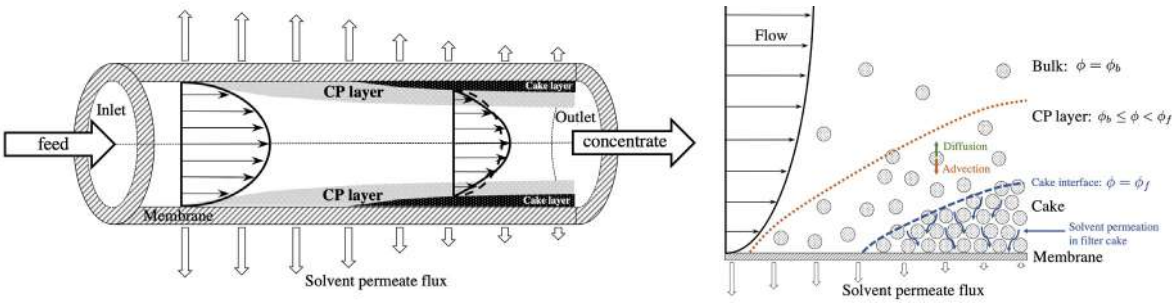

Figure 1: Left: Sketch of inside-out crossflow in a cylindrical membrane pipe. Right: CP and cake layers of particles near a perfectly retentive membrane, with an axially declining solvent permeate flux. In our model, a cake is formed for particle volume fractions ϕ exceeding the freezing transition value ϕ_f, which for hard spheres is equal to 0.494.

THEORY AND MODEL

We consider crossflow of a monodisperse feed dispersion inside a cylindrical membrane (see Fig. 1), for a small feed volume fraction and constant pressure values $p_{in} > p_{out} > p_{perm}$ at the inlet, outlet and inside the permeate, respectively. The particles are small enough that diffusion is dominated by Brownian motion, and sedimentation is negligible (ultrafiltration regime). The suspension-averaged incompressible flow and the particles flux are described macroscopically by coupled effective Stokes and diffusion-advection equations, respectively, incorporating a concentration-dependent gradient diffusion coefficient and effective viscosity, which we calculate with the salient hydrodynamic interactions included. The permeate flux through the fully particle-rejective membrane is described by the Darcy-Starling law, using an accurate input for the osmotic pressure derived microscopically from the particle interactions [1], and using the width-dependent hydraulic resistance due to the cake layer determined by the Carman-Kozeny relation for hard spheres [6]. The FEM results were generated using the COMSOL Multiphysics software for meshing and numerical solution [1].

CONCLUSIONS

The CP layer predictions by the simplifying BLA method based on a leading-order matched asymptotic expansion were shown to be in quantitative agreement with elaborate FEM results, for all considered feed dispersions and operating conditions. This justifies the approximations in the BLA method. The differences in the wall concentration curves of the similarity solution (sBLA) can be attributed to the less accurate pressure profiles obtained by the latter method.

The CP layer influence on ultrafiltration is small for ionic microgels since the gradient diffusion coefficient is distinctly larger than the one for neutral particles (e.g., HS and MG), with the accordingly small viscosity contribution by the charged particles. We have shown that the additional hydraulic resistance due to the cake layer leads to an apparent limiting flux behavior. The qualification apparent is used since the permeate flux is still weakly increasing with increasing at large TMP values where most ($> 80\%$) of the membrane wall is covered by the filter cake. If only the permeate flux reduction due to the osmotic pressure is considered, the permeate flux profile in Fig. 3 with an inflection point is obtained, showing linear growth at large TMP of slope inversely proportional to the hydraulic resistance of the bare membrane.

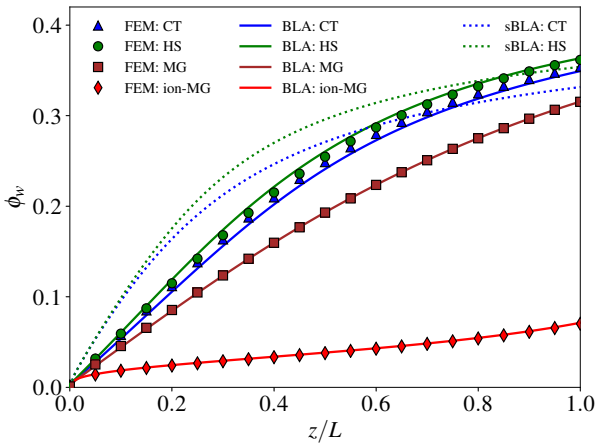

Figure 2: CP layer particle volume fraction $\phi_w(z)$ at membrane wall, as function of distance z to the inlet of the tube of length L. Results are shown by the finite-element method (FEM: symbols), boundary layer method (BLA; solid curves), and similarity solution (sBLA: dashed curves), respectively. The considered aqueous dispersions are hard spheres with concentration-dependent (HS: green color) and constant transport properties (CT; blue color), solvent-permeable non-ionic microgels (MG: brown color), and ionic microgels (ion-MG: red color). See [1].

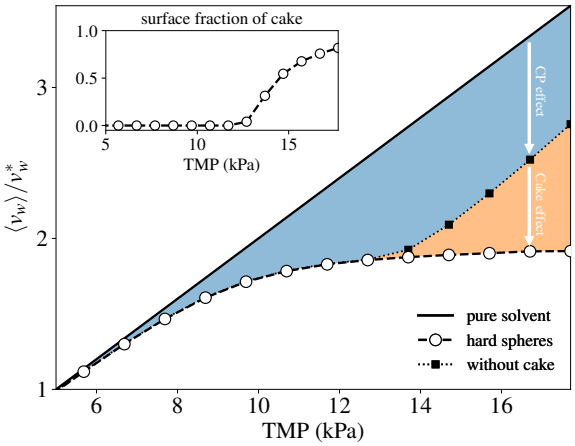

Figure 3: CP and cake layer effects on the tube-length averaged permeate flux $\langle v_w \rangle$ as a function of length-averaged TMP, quantified using the BLA method. The permeate flux is normalized by its value v_w^* at 5 kPa (open circles). The pure solvent line is the permeate flux for vanishing CP and fouling layers. The colored areas hallmark the flux reduction due to the CP (blue) and cake (sepia) layers. Filled squares: permeate flux including CP layer effect (see text). Dashed and dotted lines are guides to the eyes.

PARTICLE CAPTURE IN A MICROCHANNEL: TAKING INERTIAL EFFECTS INTOACCOUNT

Donatien Mottin[1,2], Florence Razan[2], Frédéric Kanoufi[3], and Marie-Caroline Jullien*[1]
[1]Univ Rennes, CNRS, IPR (Institut de Physique de Rennes) – UMR 6251, F-35000 Rennes, France
[2]ENS Rennes, SATIE, UMR-CNRS 8029, Campus de Ker Lann, 35170 Bruz, France
[3]UniversitédeParis, ITODYS, CNRS, UMR7086, Paris, France

Summary **In the growing field of bioassays, there is a crucial need to determine *a priori* the experimental conditions that would lead to an efficient particle capture. In this presentation, we investigate the capture of density matched particles on a surface in a straight microchannel and underline the importance of inertial effects at low Reynolds numbers. A theoretical model for particle capture is proposed, supported by experimental and numerical results. More precisely, we will present a statistical model that allows predicting the distribution of the particle concentration in a cross-section, leading to a predictive model for the particle capture for any Reynolds number below 15.**

INTRODUCTION

The question we address is how many particles are captured on a specific surface in a microchannel when a particle-ladden liquid is continuously injected. This question is of fundamental interest in many domains. Typically, a lot of biological processes involve nano or micro-particles that might link to a reactive surface under flow [1]; predicting the capture rate is crucial in such a context. Oppositely, the adsorption of particles on the wall in a porous media may lead to clogging, profoundly changing the flow conditions [2]. The capture of molecules by a reactive surface has already been extensively studied, especially in the electrochemistry community [3], the question being whether this approach applies for particles. In this experimental, numerical and theoretical work, we propose to fill the gap by establishing a new capture law suitable for particles. We show that the fluid inertia has to be taken into account, even at very low Reynolds number, as it is responsible for a force that repels particles away from the walls.

EXPERIMENTS

Experiments are performed in a microfluidic channel of height H and width W_c, represented on Figure 1. Water is injected in the channel at a flow rate Q, laden with polystyrene particles of radius a that are density matched with the water solution, of diffusion coefficient D, and at a concentration c_0. The particles are coated with a carboxylate layer COOH, exhibiting negative surface charge COO^- in water. A gold surface of length L and width W_s, coated with a positively charged polymer, is located on one wall of the channel. The two charged surfaces (the particle surface and the gold surface) create a short range electrostatic force that makes the particle adhere definitively to the capture surface.

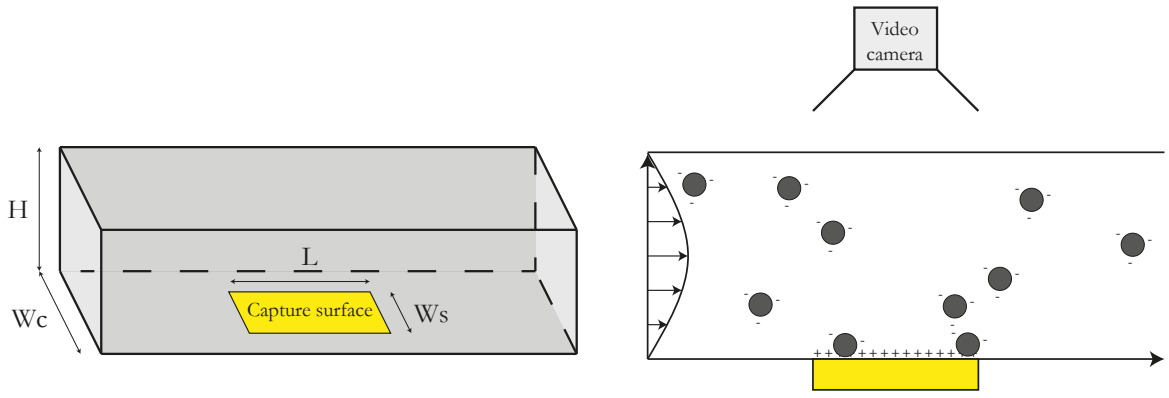

Figure 1: Sketch of the experimental setup. The particle-ladden water is injected at a flow rate Q and the negatively charged particles, of radius a and diffusion coefficient D, are injected at a concentration c_0. In the channel, of width W_c and height H, stands a positively charged capture surface, of width W_s and length L, located on one of the wall of the channel. Observation is done via a video camera through a reflective microscope.

Observation is carried out using a reflection microscope. The gold capture surface reflects light while polystyrene particles do not, making image processing easy. The number of adsorbed particles versus time is obtained and a linear fit allows the extraction of the capture rate J, *i.e.* the number of particles which adsorb on the capture surface per second.

Results of such experiments for molecule capture, subject only to diffusion and convection, have been extensively presented in the literature and have been rationalized by Squires *et al.* [3]. Several regimes exist, discriminated by the

*Corresponding author. E-mail: marie-caroline.jullien@univ-rennes1.fr

channel Péclet number $Pe = \frac{QH}{DLW_c}$ and the Péclet number related to the capture surface length $Pe_S = \frac{QL^2}{DW_cH^2}$. Applying this theory directly to particles, due to a low diffusion coefficient, implies $Pe \gg 1$ and $Pe_S \gg 1$. This corresponds to a regime called Partial Capture limited by Convection (PCC), represented on Figure 2a for molecule capture. In that case, the capture rate has been computed by [5] and is equal to $J_0 = 1.468\, c_0 DW_s Pe_S^{1/3}$.

The results of our experiments are presented on figure 2b. The black line corresponds to the theoretical prediction for molecule capture in the PCC regime, while our experiments for particles are represented by purple dots. These results clearly show that while some of the points are well predicted by the theoretical model for molecule, most of them are well below the curve showing that the actual capture rate is way smaller. An accurate model calls for deriving the particle concentration profile in a cross-section along the channel.

DISCUSSION

In the presentation, we propose a statistical model that takes into account additional forces, first observed by Segré and Silberberg [4] that act on particles flowing in a Poiseuille flow. These forces are linked to fluid inertia. One force tends to push the particle away from the walls and the other away from the center of the channel, as computed in [6]. The balance of the two forces focuses the particles at intermediate position. These effects lead to a depletion of the particles in the vicinity of the wall. Conversely, the particles are also submitted to diffusion that tends to restore a homogeneous concentration profile. By solving this complete problem we will show that we can reproduce the experimental data without any adjustable parameter. In fact, the PCC theory has to be amended by introducing a correction factor ξ, such that $J = \xi J_0$. The ξ factor takes into account the depletion of particle near the capture surface due to a balance between diffusion and lift forces. Figure 2c displays the concentration profiles for the two highlighted experimental data obtained by Lagrangian numerical simulations, and clearly shows that the concentration profile is deformed due to the flow and affects the capture rate.

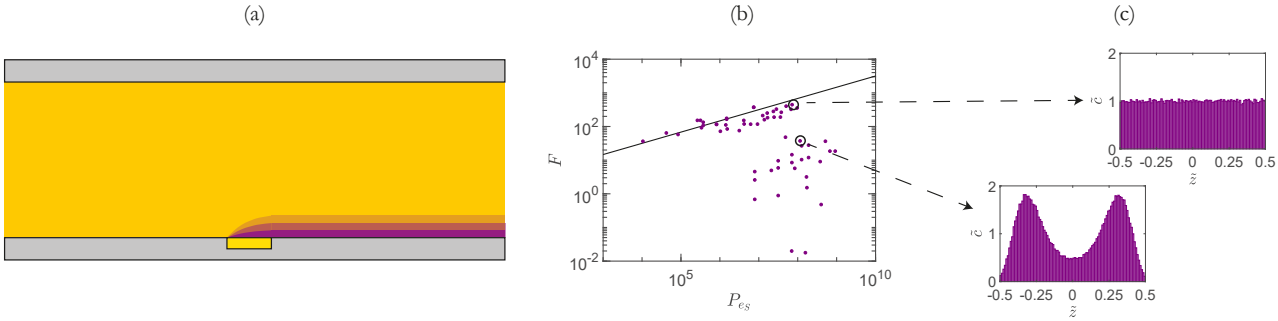

Figure 2: **(a)** Lagrangian simulation of molecule capture in the PCC regime, side view. Flow goes from left to right. In the liquid, yellow corresponds to high molecule concentration and purple to low molecule concentration. The gold rectangle represents the capture surface. **(b)** Dimensionless capture rate $F = J/(DW_s c_0 Pe_S^{1/3})$ versus the surface Péclet number $Pe_S = QL^2/(DH^2W_c)$. (Purple dots) Experiments. (Black line) Theoretical model for molecule capture in the PCC regime. **(c)** Particle normalized concentration $\tilde{c} = c/c_0$ profiles along the height of the channel $\tilde{z} = z/H$, obtained via Lagrangian simulations for the two highlighted experimental parameters.

As a whole, we propose a new law for particle capture at low Reynolds numbers. This work predicts both the particle concentration profile in the channel, but also the capture rate on a specific surface for spherical, rigid, and density matched particles. This work paves the way for ongoing research on more complex particles. This work should also have direct applications, for example in biological processes involving nano or microparticles capture. We will also present a free-of-access user friendly software. Based on the work, it allows an automatic computation of the particle concentration profile and capture rate in a channel. We expect this software to be an important tool for experiment design.

INTERACTIONS AND COLLISIONS OF CHEMICALLY-ACTIVE DROPLETS

Kevin Lippera[1],Matvey Morozov[1],Michael Benzaquen[1],and Sébastien Michelin*[1]
[1]LadHyX, Ecole Polytechnique, Institut Polytechnique de Paris, 91128 Palaiseau, France

Summary Chemically-active droplets swim by exploiting the non-linear transport of chemical solutes they consume or release by the Marangoni flows induced by such solutes. Experimentally, their hydrodynamic and chemical interactions result in complex avoidance dynamics and trajectories, and are a canonical example of active matter. The present work proposes for the first time a complete quantitative modeling and analysis of the head-on collision of two droplets, providing a significant insight in the non-linear rebound dynamics as well as the resulting collective behaviour emerging from variability in the droplets' size.

CHEMICALLY-ACTIVE SWIMMING DROPLETS

Active particles and droplets have recently attracted much attention from the physics and fluid mechanics communities, as canonical examples of synthetic swimmers that can self-propel at the micron scale without relying on any external actuation such as a macroscopic magnetic field or mechanical forcing. Instead, the isotropic emission of large swollen reverse micelles from their surface during their slow solubilization provides them with a chemical activity, which can be turned into self-propulsion when coupled to the transport of such large molecular compounds by the Marangoni flows they create.

For an isolated droplet, when advection is large enough compared to molecular diffusion (i.e. above a critical Péclet number Pe_c), the isotropic steady state becomes unstable and a new self-propelling branch arises through a transcritical bifurcation. The broken directional symmetry results in a net polarity Π of the surface concentration distribution, which is directly proportional to the swimming velocity V in the case of an isolated droplet in a fluid at rest [1, 3].

The Marangoni flows generated by a swimming droplet induce the hydrodynamic drift of other droplets, as for any other suspended body at microscopic scale. Furthermore, the chemical activity of the droplet also modifies the solute content, generating additional chemical gradients on its neighbours. These chemical interactions are repulsive: indeed, these droplets display negative auto-chemotaxis (they swim away from their own chemical wake). As a result, swimming droplets interact both hydrodynamically and chemically, and these two routes are intrinsically coupled through the non-linearity of the system. As a result, an accurate and complete modeling of active droplets' collective dynamics has so far remained elusive and relies mostly on far-field approximations.

COLLISION AND REBOUND OF A SINGLE DROPLET AND A RIGID WALL

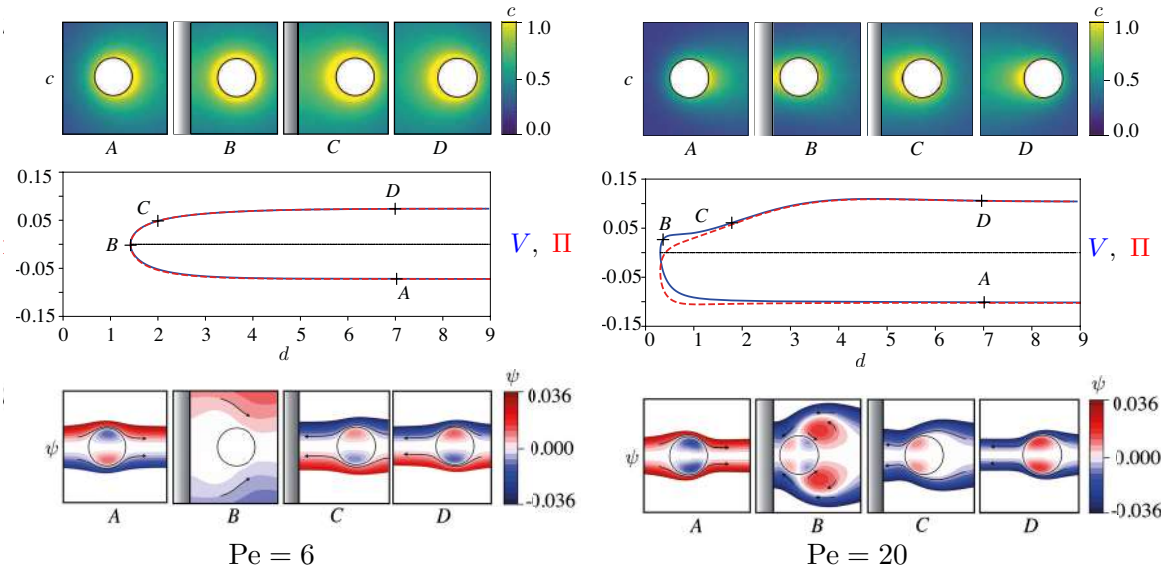

Figure 1: Collision dynamics of a chemically-active droplet and a rigid wall for intermediate (left, $\mathrm{Pe} = 6$) and large advection-to-diffusion ratio (right, $\mathrm{Pe} = 20$). In each case, the evolution of the droplet velocity and chemical polarity is presented, as well as snapshots of the concentration distribution and streamfunction at four successive stages of the collision (A–D).

In this work, we exploit the axisymmetry of a head-on collision of a single droplet onto a rigid wall to analyse the fully-coupled hydro-chemical dynamics for arbitrary wall-to-drop distance. A novel modeling and simulation framework based on a time-dependent body-fitted bi-spherical grid is used to compute the hydrodynamic and chemical fields exactly regardless of the droplet-wall distance [4]. The same approach further allows us to demonstrated that all the conclusions below are directly applicable to the head-on collision of two identical droplets.

The wall-drop collision is characterized on Figure 1 for intermediate and large Péclet number. In both cases, the approaching droplet is slowed down by the solute accumulating between its active surface and the confining wall. Eventually, this repulsion reverses the chemical polarity of the droplet, which rebounds and starts swimming away. The relative importance of advection and diffusion in the solute transport (Pe) plays however a critical role in the detailed collision dynamics. For moderate Pe, the collision is almost symmetric and droplet polarity and velocity match exactly, suggesting that the hydrodynamic influence of the wall is negligible: the entire collision is dominated by chemical interactions.

In contrast, for larger Pe, the front-back asymmetry of the droplet's chemical footprint is more pronounced [3] and, as a result, the rebound distance of the droplet (i.e. its minimum distance to the wall) decreases with Pe. Additionally, the rebound is highly non-symmetric: the reacceleration of the droplet is significantly slowed down by its internal quadrupolar Marangoni flow, which maintains an accumulated solute content away from the wall and holds the droplet back. Eventually, chemical repulsion by the wall overcomes this effect and the droplet completes its rebound. Yet, this nonlinear effect significantly delays the droplet's departure, e.g. in comparison with an elastic shock.

ASYMMETRIC COLLISIONS OF TWO DROPLETS AND LONG-TERM DYNAMICS

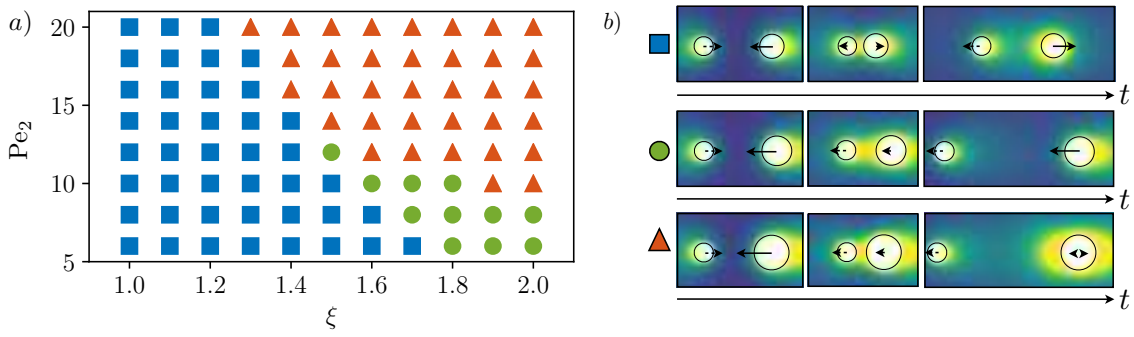

Figure 2: (a) Phase diagram of the collision of two droplets of different radii in terms of the Péclet number and size ratio ξ. (b) Illustration of the three dynamical regimes identified in (a).

We finally extend this study to the asymmetric head-on collision of two droplets with different radii, which are thus characterized by different chemical footprints [5]. Using the same modeling approach, three different dynamical regimes are identified depending on Pe and the size ratio ξ (Figure 2). When both droplets have a similar radius (ξ not too large), both rebound under the effect of the chemical repulsion induced by the other. Their collision is asymmetric, with the smaller droplet rebounding first.

However, for larger size contrast, the larger droplet is still swimming fast enough toward the smaller one, when the latter starts swimming away, leading to the emergence of two new and complex dynamical regimes. In the first one, observed for small enough Pe, the chasing of the smaller droplet by its larger neighbour eventually leads to the formation of a bound state where both droplets swim at the same velocity and in the same direction. In contrast, when Pe is large enough, the collision may provoke a mode switch for the larger droplet which stops swimming and starts pumping fluid symmetrically along its axis. This non-swimming state is however likely unstable and further interactions with other droplets will likely set it again into motion. Its pre-collision directionality will however be lost. This effect is expected to play a critical role in the long-term collective dynamics of such active droplets.

PRE-SHEAR HOLDS THE KEY IN UNDERSTANDING DISCONTINUOUS SHEAR THICKENING

Tabish Khan[1] and Prabhu Nott *[1]
[1]Department of Chemical Engineering, Indian Institute of Science, Bangalore, India

Summary The phenomenon of discontinuous shear thickening (DST) in dense non Brownian suspensions has gained considerable attention in the last few years. The dominant opinion expressed in previous studies is that it is a stress controlled transition from lubricated to frictional state, modulated by short range repulsion between the particles. Typically, most of the experiments are done in such a way that the suspension is first pre-sheared, typically for an hour longer, before rheological measurements are made. However, little is known about what happens during the pre-shear, and why it need to be done for such long times. We provide clear evidence that pre-shear holds the key to understanding the change in response from continuous shear thickening (CST) to DST, and finally 'shear jamming', where the suspension shows Newtonian behaviour at lower shear stresses but shears at constant high shear stress, like dry granular materials. We provide arguments as to why large strains are required, and comment on the implication of our findings on slurry transportation in industries.

INTRODUCTION

Shear thickening is a non-Newtonian behaviour, generally exhibited by suspensions, in which the shear stress increases faster than linearly with shear rate. The rise in viscosity with shear rate could be continuous (CST) or discontinuous (DST), depending on the volume fraction (ϕ) of particles. The phenomenon of shear thickening has fascinated scientists and children alike, stemming from videos where a person is seen running on cornstarch suspension[1]. This behavior has been captured in various types of systems and is now believed to be the generic feature of dense suspensions.

Shear thickening is now believed to be a shear stress dependent transition from lubricated to frictional state, controlled by short range repulsions between the particles. A recent phenomenological theory was proposed by Wyart and Cates [2], where stress dependent jamming volume fraction relates DST with S shaped transition. Although, experiments on non Brownian suspensions [3,4] fits well for lower ϕ rheology, highly concentrated suspensions of spherical particles seems to diverge from the theory [2]. A common protocol in most experiments [4,5] is that the suspension is pre-sheared for an hour or so before rheological measurements are performed. Cwalina and Wagner [5] pre-sheared their suspenions for an hour and Pan et al [4] also points out the need of long shearing for DST. Here, we show that pre-shear holds the key in understanding DST and captured the evolution the microstructure by shear stress/rate sweep experiments. We report the transition of the microstructure from CST to DST to shear jamming, where a suspension behaves like a Newtonian fluid at low stress but creeps at higher stress, like granular matter. By performing series of experiments on non-Brownian suspensions like shear stress/rate sweep, constant shear rate and shear rate reversal, we report that the non Brownian concentrated suspensions of spherical particles show much slower dynamics than two body lubrication theory prediction, which we attribute to collective behaviour shown by N particle system.

Materials and methods

The experiments were conducted on polystyrene particles of 80 μm diameter in a Newtonian solvent of water and glycerol mixture. The composition was chosen such that the fluid is neutrally buoyant with the particles and tested using centrifugation at 2000 rpm for 5 minutes. This was done to prevent sedimentation or creaming during the experiments. Experiments were performed on parallel plate and concentric cylinder with temperature control and solvent trap to prevent evaporation.

Experimental conditions are maintained such that Re = $\frac{\rho\dot{\gamma}a^2}{\mu}$ is small enough ($< 10^{-3}$) to neglect inertia and Pe = $\frac{6\pi\mu a^3\dot{\gamma}}{k_BT}$ is large enough ($> 10^7$) to neglect thermal motion.

RESULTS AND DISCUSSION

Fig 1 shows the response during shear stress sweeps between $\tau = 0.01$ Pa to $\tau = 300Pa$ for ϕ =0.58. Various colours represent consecutive forward stress sweeps and the direction of the arrow represents the increasing number of sweeps. Dense suspensions always undergoes CST in the first few sweeps, followed by S shaped curve, associated with DST. Finally, the suspension behaves like Newtonian fluid at low stress but creeps at higher stress, like granular matter. At this stage, any attempts to increase $\tau > 300Pa$ accelerates the system to high shear rates. Constant shear rate experiments were also performed which exemplified the effect of pre-shear. It was found that dense suspensions underwent jamming at constant shear rate as well, but large strains O(100) were required. Shear reversal experiments on pre-sheared sample support our findings of slow microstructural buildup, dominated by frictional contacts. The viscosity rise was found to be independent of shear rate, although large strains O(10) were required, signifying the slow collective behaviour shown by spherical particles in dense suspensions.

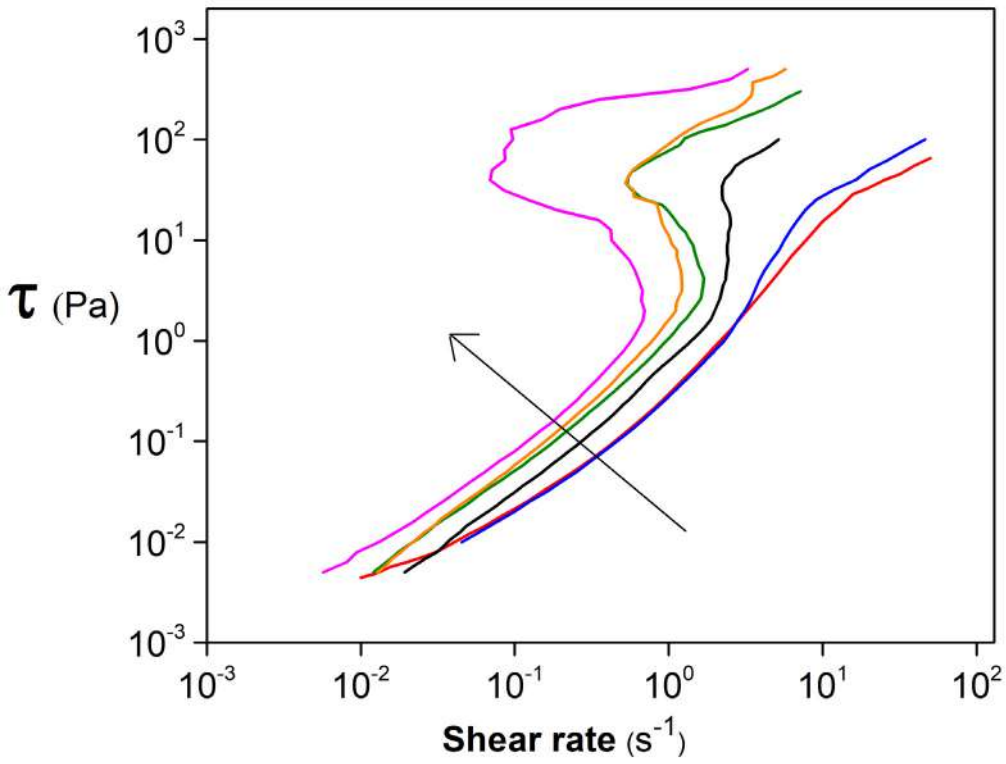

Figure 1: Shear rate sweep

CONCLUSIONS

Pre shear holds the key in obtaining DST and here we have shown the evolution of the microstructure that results in the transition from CST to DST to rate independent plastic shear during shear stress/rate controlled experiments. To exemplify the effect of pre shear, experiments were performed at constant shear rate such that low shear rate require less strain to undergo jamming. Friction forces dominate shear thickened rheology and the microstructure requires larger strain units to jam from lubricated state during shear reversal experiments. These observations imply a slow collective microstructural rearrangement of concentrated non Brownian suspensions.

TRANSITIONS IN A TAYLOR-COUETTE FLOW OF DILUTE NON-COLLOIDAL SUSPENSIONS

Changwoo Kang[1,2] and Parisa Mirbod [*1]

[2]Department of Mechanical Engineering, Jeonbuk National University, Jeonju-si, Republic of Korea

Summary

Flow transitions of neutrally buoyant and non-colloidal particles confined in a Taylor-Couette system have been numerically investigated by numerical simulations using suspension-balance model and rheological constitutive laws. It has been shown that particles destabilize the flow of dilute suspensions (ϕ_b=0.1). Furthermore, the circular Couette flow transitions to wavy vortex flow via non-axisymmetric spiral vortex flow and wavy spiral vortex flow have been observed.

INTRODUCTION

Particle-laden or suspension flows in a Taylor-Couette system, in which flows are contained between two coaxial cylinders, encounters in numerous applications; food processing, bio and chemical reactors, micro-mixers, micro-reactors, and engineering processes. In particular, shear-induced particle migration occurring by the rotating cylinder has been a crucial issue since it can affect the flow field leading to a change of velocity profile of suspensions [1]. Moreover, the Taylor-Couette flow is known to reveal various stable regimes as the rotation rate of the inner and outer cylinders varies. However, very few works have analysed the effect of finite size particles on flow transitions. Ali et al. [2] performed the linear stability analysis for a suspension in circular Couette flow and showed that the particles destabilize the flow of dilute suspensions ($\phi_b \leq 0.005$). They showed that the critical Taylor number decreases as the particle concentrations increases, and increasing the ratio of particle density to fluid density decreases the stability of the flow [2]. Majji et al. [3] performed experiments on the inertial flow transitions of a particle-fluid suspension in the Taylor-Couette flow with rotating inner and stationary outer cylinders. They found that the primary effects of the particles are a reduction of the maximum Reynolds number (Re) for the circular Couette flow. They also reported the onset of non-axisymmetric flow states not seen for a pure fluid where only inner cylinder rotates. In addition, when Re was decreased, for dilute suspension flows ($0.05 \leq \phi_b \leq 0.15$) the sequence of flow transitions followed by wavy Taylor vortex flow (WTV) → Taylor vortex flow (TVF) → spiral vortex flow (SVF) → ribbons (RIB) → circular Couette flow (CCF). However, for higher volume fractions (ϕ_b=0.2 and ϕ_b=0.3), a non-axisymmetric flow structure the so-called wavy spiral vortex flow (WSV) was observed. For ϕ_b=0.2, the flow transitions followed the sequence of WSV → WTV → WSV → TVF → SVF → RIB → CCF with decreasing Re. On the other hand, the sequence simplified for ϕ_b=0.3. It involved only non-axisymmetric flow structures: WSV → SVF → CCF.

We numerically examine flow transitions for a Taylor-Couette flow of dilute suspensions in the present study. The flow of neutrally buoyant and non-colloidal spherical particles between infinite two coaxial cylinders, in which the inner cylinder rotates at a constant angular velocity and the outer one is stationary, is considered (Fig. 1). We revisit the work reported by Majji et al. [3] where the radius ratio of cylinders is $\eta(=r_i/r_o)$=0.877, the particle size $\epsilon(=d/a)$ which is the ratio of annular gap (d) to the radius of particles (a) is 60, and the bulk particle volume fraction (ϕ_b) is fixed with ϕ_b=0.1. The Reynolds number is defined as $Re=\rho r_i \Omega_i d/\mu_o \mu_s(\phi_b)$ where $\mu_s=(1-\phi/\phi_m)^{-1.82}$ with ϕ_m=0.68 and μ_o is the solvent viscosity [3].

MATHEMATICAL FORMULATION

In this study, the suspension balance model (SBM) [4] is introduced for suspensions modelling. The SBM considers the suspension as a continuum consisting of solid and fluid phases. We assume that the particles suspended in an incompressible fluid are non-colloidal and non-Brownian. Using the SBM, the flow of non-colloidal hard-sphere suspensions is governed by incompressible continuity and momentum conservation equations written as

$$\nabla \cdot \langle \mathbf{u} \rangle = 0 \tag{1}$$

$$\frac{D\langle \rho \mathbf{u} \rangle}{Dt} = \langle \mathbf{b} \rangle + \nabla \cdot \langle \mathbf{\Sigma} \rangle \tag{2}$$

$\langle \mathbf{\Sigma} \rangle$ is the average suspension stress. For non-Brownian suspensions, the constitutive law for the suspension stress can be given by $\langle \mathbf{\Sigma} \rangle = -\langle p \rangle_f \mathbf{I} + 2\mu \langle \mathbf{S} \rangle + \langle \mathbf{\Sigma} \rangle_p$. $\langle \mathbf{\Sigma} \rangle_p$ is the particle stress and defined as $\langle \mathbf{\Sigma} \rangle_p = -\mu_o \mu_n(\phi) \dot{\gamma} \mathbf{Q} + 2\mu \mu_p(\phi) \langle \mathbf{S} \rangle$ [5]. Here, μ_n is the normal stress viscosity expressed as $\mu_n(\phi)=K_n(\phi/\phi_m)^2/(1-\phi/\phi_m)^2$ with K_n=0.75 [5] and $\dot{\gamma}=\sqrt{2\mathbf{E}\mathbf{E}}$ is the local shear rate. The tensor parameter ($\mathbf{Q}$) considers the anisotropy of the normal stress [4].

The particle-phase mass balance is given by

*Corresponding author. E-mail: pmirbod@uic.edu

$$\frac{\partial \phi}{\partial t} + \mathbf{u} \cdot \nabla \phi = -\nabla \cdot \mathbf{j} \quad \text{where} \quad \mathbf{j} = \frac{2a^2}{9\mu_o} f(\phi) \nabla \cdot \Sigma^p. \tag{4}$$

The sedimentation hindrance function, $f(\phi)=(1-\phi/\phi_m)(1-\phi)^3$, indicates the mean mobility of the particle phase [4].

The governing equations (Eqs. (1), (2) and (4)) were discretized in the cylindrical coordinate system using a finite volume method. A second-order central difference scheme was used for spatial discretization of derivatives except for the convective term ($\mathbf{u} \cdot \nabla \phi$) of Eq. (4), which utilized the QUICK scheme for the discretization. A hybrid scheme is applied for time advancement with a third-order Runge-Kutta scheme and Crank-Nicolson method. A fractional-step method is employed for time integration and the Poisson equation that resulted from the second stage of the fractional-step method is solved by a fast Fourier transform (FFT).

Computations are carried out on a cylindrical grid system with $96(r)\times512(\varphi)\times64(z)$ grid points and $L_z = 4d$. The grid cells are uniform in the azimuthal (φ) and axial (z) directions, while more grid points are allocated near walls in the radial direction (r). The no-slip condition is imposed on both cylindrical surfaces, and the migration flux of particles is set to be zero at the walls. The flow and particle concentration are assumed to be periodic in the axial direction (z).

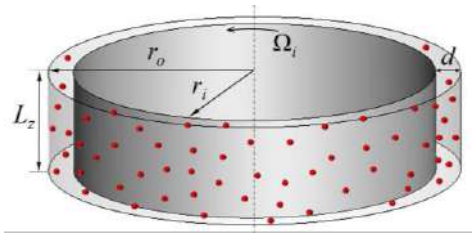

Figure 1. Schematic diagram of suspensions in a Taylor-Couette flow.

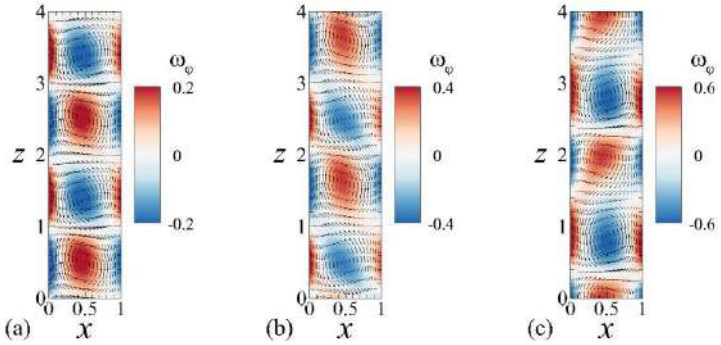

Figure 2. Contours of azimuthal vorticity component (ω_φ) with velocity vectors in a r-z plane for $\epsilon=30$; (a) Re=125, (b) Re=140, (c) Re=165 and $x=(r-r_i)/d$. Velocity vectors were plotted for every four and two points in the radial (r) and axial (z) directions, respectively.

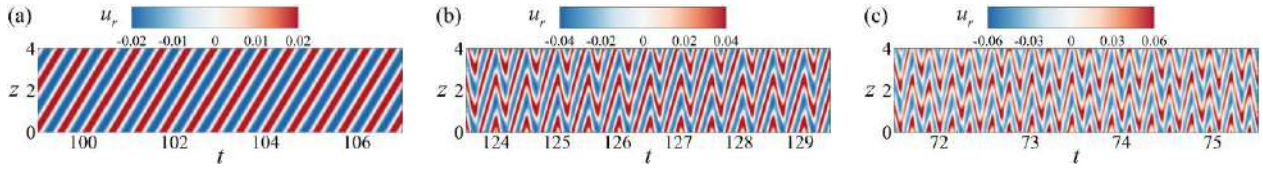

Figure 3. Space-time diagram of radial velocity (u_r) at the midgap (x = 0.5) and a given φ for $\epsilon=30$; (a) Re=125, (b) Re=140, (c) Re=165.

RESULTS

Figure 2 shows instantaneous flow field in a r-z plane for several Re, and space-time diagram of radial velocity (u_r) corresponding to the Re are plotted in Fig. 3. As the Reynolds number increase, the flow becomes unstable and non-axisymmetric counter-rotating vortices are developed in the annulus (Figs. 2(a), 3(a)). These vortices have a spiral mode (SVF) showing the inclination of vortices and the traveling to the axial direction. With increase in the Reynolds number to Re=140, an oscillation occurs in the axial traveling wave (Fig. 3(b)). These oscillations arise from the appearance of wavy pattern propagating to the azimuthal direction in spiral vortices. We refer these non-axisymmetric flow structure as wavy spiral vortex flow (WSVF). A transition to wavy vortex flow (WVF) occurs at higher Re=165 where the space-time diagram clearly shows an oscillation of vortices in time (Fig. 3(c)). The oscillation propagates in both axial and azimuthal directions resulting from the rotating wave of wavy vortices.

BIFURCATION AND STABILITY OF A SUSPENSION OF GYROTACTIC SWIMMER IN A VERTICAL PIPE

Lloyd Fung*[1], Rachel N. Bearon[2], and Yongyun Hwang[1]
[1]Department of Aeronautics, Imperial College London, London, UK
[2]Department of Mathematical Sciences, University of Liverpool, Liverpool, UK

Summary It is well known that a downflowing suspension of bottom-heavy swimming microalgae (e.g. *Chlamydomonas*) forms a beam-like structure, known as a gyrotactic plume, which is prone to a blip instability. In this study, we employ population-level continuum models, such as the Fokker-Planck (FP) and Generalised Taylor-Dispersion (GTD) models, and perform bifurcation and stability analyses for a downflowing suspension through a vertical pipe. It was found that the steady basic-state plume solution robustly exhibits a sophisticated two-parameter bifurcation composed of transcritical and cusp bifurcations. The stability analysis is also performed around the computed solution. It revealed that the GTD model provides more realistic predictions than the FP model when compared with experimental observations. However, the GTD model is only applicable to unidirectional shear flow. To this end, we will present a new model that only perform just as well as the GTD model in vertical shear flows, but also remains applicable in other scenarios.

INTRODUCTION

Bottom-heavy swimming microalgae, such as *Chlamydomonas*, *Dunaliella* and *Volvox*, are commonly found in nature and industrial bioreactors. These microorganisms are 'gyrotactic': their swimming orientation is determined by the balance between the gravitational torque posed by the bottom heaviness and the viscous torque of the background shear. Through a series of pioneering experiments where bottom-heavy microalgae are suspended in a downflowing vertical pipe, Kessler [1] showed that the swimmers move towards the pipe centre and a beam-like structure (known as a plume), demonstrating their gyrotactic nature. Furthermore, under certain condition, the gyrotactic plume was found to spontaneously break down into multiple blips along the streamwise direction [2, 3] due to instability.

The precise continuum description for the behaviours of suspensions of swimming microorganisms has been understood as a long-standing challenge. As such, even the pioneering experiment by Kessler [1] has not been fully analysed with any existing continuum model. Only recently, a similar set up was analysed in a vertical channel flow [4]. The objective of this study is to revisit the original experiment of Kessler in a vertical pipe and perform a comprehensive theoretical analysis using continuum models. A particular emphasis of this study is given to the assessment of the performance of the continuum models. For this purpose, we consider three types of continuum models: the Fokker-Planck (FP) model [5, 6], the Generalised Taylor Dispersion (GTD) theory [7, 8] and a new model recently developed by the authors. The most important difference between the three models is the form of the diffusivity tensor for the cell transport equation: the FP model is a simplified approximation of the covariance-matrix form of the diffusivity expression with a constant correlation time scale [5, 6], whereas the GTD model is obtained by considering the dispersional relationship between the swimmer's translational and orientational motility [7, 8]. Recently, there has been a growing body of evidence that the GTD model shows superior performance over the FP model, especially when the background shear rate is high [9, 10]. In this study, we shall demonstrate that the use of the GTD model is essential to provide a theoretically consistent description for the plume structure and the blip instability observed experimentally.

Meanwhile, we shall also demonstrate the performance of the new model we have developed. Coincidentally, the GTD model and the new model share the same results in this example with vertical shear flows. However, we shall demonstrate that the new model is more applicable and accurate in other flow cases.

RESULTS AND DISCUSSION

As in the experiment of Kessler [1], we consider a downflowing suspension of bottom-heavy swimmers in a vertical pipe. All the results shown here are based on the parameters obtained for *Chlamydomonas nivalis*. They are made dimensionless with the swimming velocity of each swimmer, the averaged cell number density and the pipe radius.

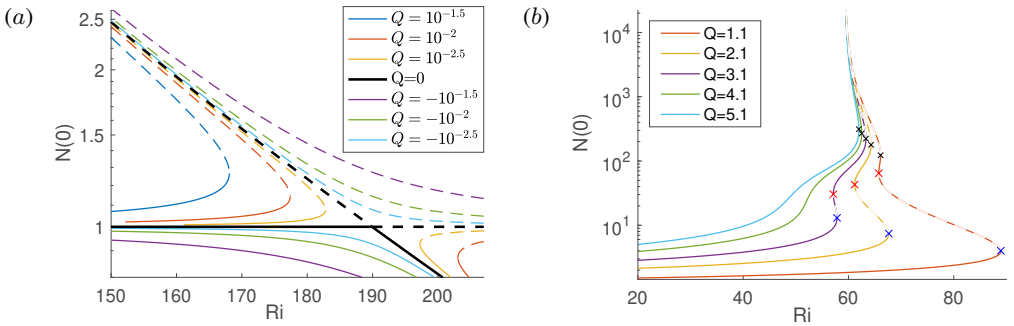

Figure 1: Bifurcation of steady basic-state plume solution for the GTD model at (a) low and (b) high flow rates. Here, the blue, red and black crosses (x) indicate the first, second and third saddle-node points, respectively. In both figures, ———, stable; - - - -, unstable. Also, in (b), $N(0) \to \infty$ when $Ri = Ri_s (\simeq 59)$

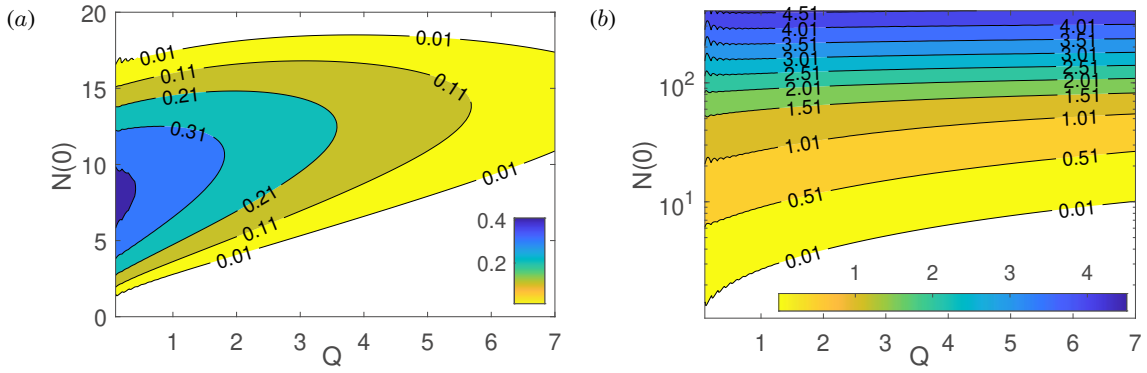

Figure 2: The maximum growth rate of the axisymmetric mode in the $N(0) - Q$ plane from (a) the FP model and (b) the GTD model.

Bifurcation of basic state (steady plume solution)

The steady parallel basic state is computed for the three models. We note that when the flow rate is low, the three models share almost identical result due to their same asymptotic behaviour in the limit of zero background shear. Figure 1 shows its bifurcation diagram represented by the cell number density at the pipe axis ($N(0)$) for several flow rates (Q) with respect to the Richardson number (Ri) which would represent the averaged total cell number density. When the suspension is stationary ($Q = 0$ in figure 1(a)), there exist two solutions, one of which is the stationary uniform suspension ($N(0) = 1$), while the other non-trivial solution ($N(0) \neq 1$) is characterised with a non-uniform cell number density and a non-zero flow velocity. These two solutions meet at $Ri = Ri_c(\approx 190)$ and interchange their stability, forming a transcritical bifurcation. As Q is increased, the transcritical bifurcation point turns into a saddle-node point (i.e. imperfect bifurcation) through an imperfect bifurcation (figure 1(a)). Another cusps bifurcation in the $Q - Ri$ parameter space is shown for at moderately large flow rates ($Q = 1.1$) in figure 1(b) with the GTD model. The bifurcation is an artefact of the GTD model and can be removed when the Smoluchowski equation is resolved directly instead. However, as the solution is continued, it becomes singular (i.e. $N(0) \to \infty$ at $Ri_s \approx 59$). The singularity is a robust behaviour originating from the diminishing diffusivity at increasingly strong shear, as we shall demonstrate analytically. As Q is increased further, the saddle-node points merge for both models, implying a cusp bifurcation occurring in the $Q - Ri$ parameter space.

Stability analysis

Linear stability analysis is performed with the steady plume solutions computed, and the maximum growth rate for the axisymmetric case (relevant to the blip instability) is presented in the $N(0)$-Q space in figure 2. The FP model gives a stabilising result at high $N(0)$. This is not consistent with experimental observation, and is found to be an artefact of the inaccurate diffusivity of the FP model at high shear rate. Meanwhile, the GTD model gives a growth rate that is strongly correlated with $N(0)$. This indicates the instability is likely localised at the high shear region near the centreline of the pipe. Finally, for the stability for non-axisymmetric modes, the FP model exhibits an instability, the growth rate of which is comparable with that for the axisymmetric case. This is in contrast to the GTD model, which exhibits a highly suppressed non-axisymmetric instability, as well as to the experimental observation where such instability has never been reported previously.

CONCLUDING REMARK AND THE NEW MODEL

In this study, we have performed a bifurcation and stability analysis for the experiment of Kessler [1] using both the FP and GTD models. The results evidently indicate the better predictive nature of the GTD model, consistent with the previous observations [9, 10]. However, the GTD model is only applicable in unidirectional shear flows and the linearised stability around a unidirectional flow profile. To extend the use of continuum modelling, we have developed a new model. It shares the same result as the GTD model in this example, meaning it is at least as accurate as the GTD model. However, in a more general flow case where the GTD model is not applicable, the new model remains accurate.

Summary We investigate the shear-induced aggregation phenomenon occurring in a dilute suspension of colloidal particles. A Discrete Element Method (DEM) built in the framework of Stokesian Dynamics (SD) is employed. The method takes into account both hydrodynamic and colloidal forces between particles and it is able to simulate in detail each aggregation event occurring in the suspension. Simulations were run coupling the DEM with a Monte Carlo algorithm in order to study the aggregation kinetics and the morphology of a large population of colloidal aggregates.

INTRODUCTION

In a sheared suspension the aggregation of colloidal particles occurs as a result of the binary encounters induced by the gradient of the flow field [1]. However, the occurrence of aggregation is not easily predictable, in that complex interaction between the approaching aggregates establishes; far field and near field (i.e. lubrication) hydrodynamic interactions may in fact deviate the relative aggregate trajectories to the point of preventing the formation of a contact; on the contrary, colloidal interactions (for instance due to Van der Waals attraction forces) act favouring the aggregation.

A detailed view of the aggregation process can be obtained by running Stokesian Dynamics (SD) simulations. This technique, by using a first order multipole expansion of the flow field around each primary particle, allows one to properly model the whole spectrum of the hydrodynamic interaction between particles; for this reason SD has been extensively used to predict aggregation dynamics [2], aggregate restructuring [3] and aggregate breakup [4].

In this work we make use of Stokesian Dynamics, coupled with proper models for the adhesive interactions, to study the aggregation process occurring in a dilute suspension of colloidal particles. To overcome the typically large computational cost of multi-particle Stokesian Dynamics simulations, a Monte Carlo (MC) approach has been developed. The role of the MC algorithm is to sample a statistically expected sequence of encounter events. Each of these events is then individually simulated by Stokesian Dynamics to ascertain the occurrence of aggregation and to obtain the morphology of the new generated aggregate. The advantage of such a combination is that Stokesian Dynamics is used to track the motion of just two aggregates at a time, allowing one to obtain detailed information about the aggregation dynamics at a reasonable computational cost.

NUMERICAL METHOD

We coupled Stokesian Dynamics simulations with an event-driven, rejection-free Monte Carlo algorithm [2]; the MC algorithm is used to reproduce a particular realization of the process through the sampling of a statistically expected sequence of encounter events. To setup the MC algorithm we use the shear-induced Smoluchowski encounter rate $f_{ij} = \frac{4}{3}\dot{\gamma}\left(R_i + R_j\right)^3 / V$, where $\dot{\gamma}$ represents the shear rate intensity, R_i and R_j are the external radii of the considered aggregates and V is the total volume of the suspension. The outcome of the encounter event is ascertained deterministically by using detailed Stokesian Dynamics simulation, counting for both colloidal and hydrodynamic interactions. The calculation scheme is depicted in Figure 1: At the beginning of the simulation, the solid fraction of the suspension, an

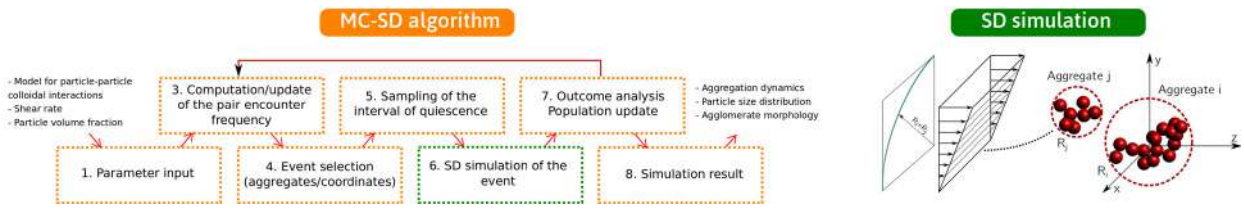

Figure 1: left) Monte Carlo - Stokesian Dynamics algorithm used for the simulation of a shear-induced aggregation process. right) Qualitative representation of a Stokesian Dynamics simulation.

initial distribution for the size and the morphologies of the aggregates and the shear rate conditions are chosen. The simulation is initialized by computing the encounter frequencies relative to all the pairs of suspended particles and, based on these, the details of the encounter are determined, in terms of involved aggregates and initial positions in the flow. At this stage, the Stokesian Dynamics simulation of the event is performed and, based on the outcome, the population is updated and the procedure repeated until the desired number of events is simulated. Between events, an interval of quiescence is imposed. Such an interval represents the time elapsing between two subsequent encounters, during which the population is assumed to remain unaffected.

The circumference represents the radius of the theoretical aggregation section. top right) Aggregation efficiency between two aggregates i and j as a function of their aspect ratio. Both aggregate are made by 12 monomers. bottom right) Aggregation efficiency as a function of the aggregate size ratio.

RESULTS AND DISCUSSION

Simulations were run starting from a monodisperse population of 200 simulated primary particles with radius equal to $0.5\,\mu\mathrm{m}$, dispersed in a suspension with a solid fraction equal to 10^{-4} and subject to a uniform shear rate of intensity $\dot{\gamma} = 10\,\mathrm{s}^{-1}$.

The most direct consequence of aggregation is the reduction of the number concentration of the suspended particles and the generation of new, larger aggregates. The left plot in Figure 2 shows the concentration of monomers and dimers as a function of time. As apparent, the monomer concentration drops rapidly in the first stage of the process and a significant fraction of dimers is promptly produced. However, both the classes are still present in a significant amount for long times. This can be explained by the fact that the shear-aggregation dynamics is governed by the larger aggregates, which, once generated, because of their larger cross section, are the most likely to intercept and aggregate other suspended clusters. This is made apparent also by the self-accelerating behaviour of the population average size (green curve). Thus, from the plot one can conclude that, at the end of the simulation, monomers, dimers and other small clusters coexist along with few large aggregates. It is worth to point out however that over a certain size breakup phenomena set in, dampening the aggregate growth.

To obtain further insights into the aggregation dynamics additional Stokesian Dynamics simulations were run according to a grid-based scheme: the encounter cross section (of radius $R_i + R_j$) is divided by using an equally spaced grid. Each node of the grid is used as a release point of an aggregate j, which moves, with the imposed flow field, towards an aggregate i. After scanning the whole grid space, an aggregation cross section can be constructed (middle plot in Figure 2) and the aggregation efficiency evaluated as the ratio between the flow rate of aggregates through the effective aggregation cross section and the flow rate through the aggregation section one would obtain by neglecting hydrodynamic and colloidal interactions. The results of this analysis for the encounter between two aggregates composed by 12 primary particles and with different aspect ratios are reported in the top right plot of Figure 2. It can be noticed that as the aspect ratio of the aggregates increases the aggregation efficiency reduces. This can be explained in the light of a lower time-averaged cross section of elongated aggregates, which reduces the chances of contact. In the bottom right plot of Figure 2 the case of the encounter between two differently sized aggregates is addressed; in this case the size disproportion appeared to be most detrimental factor on the aggregation efficiency. This can be explained by considering that as the size of the aggregates increases a larger disturb is induced in the surrounding flow field; this disturb makes the approaching cluster to substantially deviate from the the rectilinear streamline, finally preventing aggregation.

In conclusion, Stokesian Dynamics have been shown to represent a valuable tool to study the aggregation phenomena occurring in a colloidal suspension. The technique can be used to get precise information about the aggregation mechanism, the morphology of the aggregates and the kinetics of the process. However, the relatively large computational cost suggests to employ such information to fine tune computationally cheaper population balance models.

Summary In this work we study the trajectories of swimming microorganisms near boundaries. In particular, we explore the effect of shape change due to bending on the trajectories of swimmers near walls. For this analysis we use a simple toy model of a swimmer formed by two spheres linked by a torsional spring. The spheres capture hydrodynamic interactions of a head and tail while the torsional spring allows the swimmer to bend. We see that in the presence of a wall, swimmers can bend leading to substantially altered dynamics and trajectories. We illustrate a number of trajectories varying the initial orientation, geometry and flexibility of the swimmer.

INTRODUCTION

Swimming microorganisms are routinely found near surfaces. Confining surfaces can dramatically alter the trajectories of microswimmers such as bacteria or spermatozoa [1,2] and the interaction between swimmers and a nearby surface may lead to the formation of a biofilm through the attachment of colonist of bacteria to the surface [3]. Far-field hydrodynamics are frequently utilized to explain interactions between a swimmer with nearby boundaries [4,5]. Using this method a number of studies have quantified the dynamics of the swimmers close to walls and have showed that swimmers tend to accumulate walls [6, 7]. Most studies keep the geometry of swimmers fixed despite the fact that many swimmers tend to be quite flexible [8] and flexibility can alter trajectories [9]. In this work we investigate the trajectories of flexible swimmers near boundaries.

MINIMAL MODEL

In order to capture the effects of shape change due to bending, on the trajectories of swimmers, we use a minimal hydrodynamic model. As shown in Figure 1, we use two spheres, one to capture the hydrodynamic drag of a head and another to capture the drag and thrust generated by a tail. Spheres have radii r_B and r_A, for head and tail respectively, and we define the ratio $\lambda = r_A/r_B$. Sphere A propels the swimmer by an imposed fixed thrust $\mathbf{F}_T = F_T\hat{\mathbf{e}}_1$ and is called a pusher for $F_T > 0$ or a puller for $F_T < 0$. The centres of these two spheres are connected by hydrodynamically insignificant thin rods (each length $L/2$) and a linear torsional spring (stiffness k) in the middle. Sphere A is at distance h_A from the wall and we refer to the angle between the unit vector from sphere A to sphere B, $\hat{\mathbf{r}}$, and a unit vector parallel to the wall $\hat{\mathbf{e}}_\parallel$ as the swimming angle θ. The angle between $\hat{\mathbf{r}}$ and the thrust direction $\hat{\mathbf{e}}_1$ is called bending angle δ, which takes positive or negative values corresponding to bending towards the wall or away from the wall, respectively. For simplicity, the sizes of the spheres are assumed to be considerably smaller than the scale of the body ($\beta = r_B/L << 1$). The flow field induced by the motion of each sphere is approximated by a point force Stokeslet, and a source doublet. In order to capture the effect of nearby surface using far-field approximations, the swimmer is assumed to be far away from the wall, $\alpha = L/H_A << 1$, where H_A is the initial distance to the wall. We use image solutions to satisfy the no-slip boundary condition on the wall. Each sphere interacts with the nearby sphere and the nearby wall as if in a background flow field $\mathbf{u}_\infty(\mathbf{x})$ according to Faxén's laws. To leading order the swimmer bends in response to a torque dipole on the swimmer induced by the background flow field.

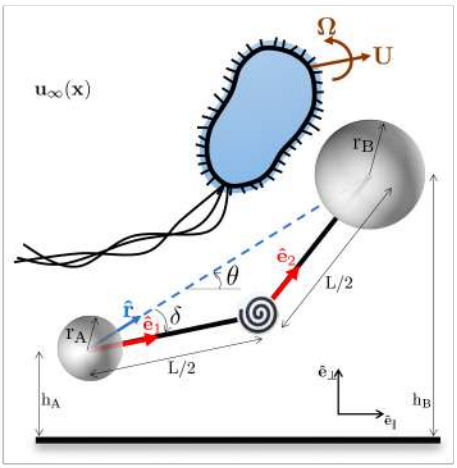

Figure 1: Schematic of the elastic swimmer.

RESULTS

We define the initial orientation of the swimmer as θ_i where the thrust is pushing (pulling) the swimmer towards (away from) the wall for $\theta_i < 0$ and away from (towards) the wall for $\theta_i > 0$. Figure 2(a,b) show the contour plots of normal velocity, rotation direction, and bending angle, as a function of the initial orientation θ_i, and the aspect ratio λ for pullers and pushers. The simple picture is that due to hydrodynamic interaction with the wall, a flexible swimmer will bend, a curved swimmer will then experience an angular velocity to direct the swimmer either toward the wall or away from it, for example, when a pusher bends toward the wall $\delta < 0$, the angular velocity re-orients it downward $\Omega < 0$. The grey area in figure 2(a,b) shows the terminus attraction zone after some time, starting at θ_i (the darker grey area is for a rigid swimmer). A straight rigid swimmer ($\delta = 0$ and $k \to \infty$) can maintain a parallel trajectory over long times. On the other hand, elastic swimmers that are initially swimming parallel to the wall, display repulsion or attraction for pushers and pullers respectively. In general swimmers' trajectories tend to have a sensitive dependence on the initial configuration. Figure 2c) shows that a pusher which is initially pointing slightly towards the wall, swims for a long time near the wall with an initial attraction but eventually escapes. In contrast, pullers tend to move towards the wall.

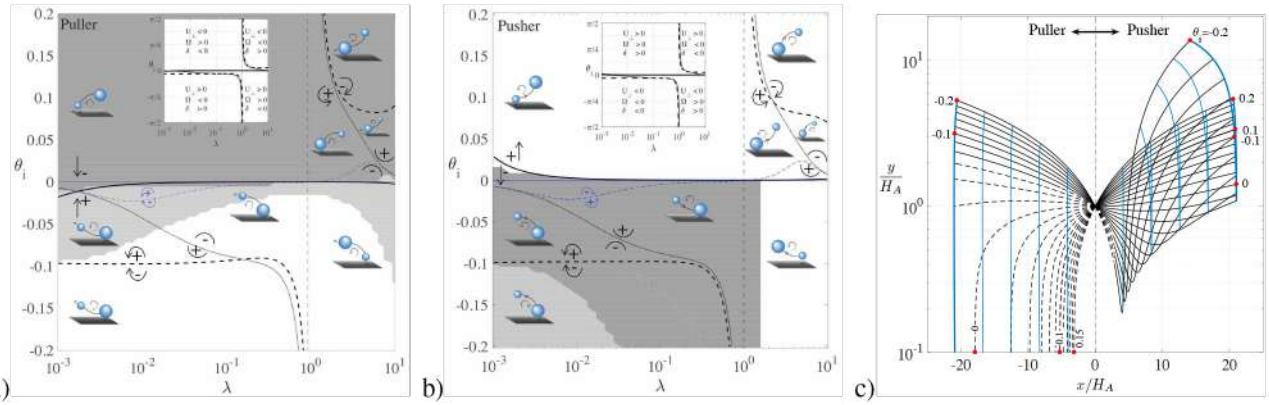

Figure 2: (a,b) Contour plots of normal velocity $\mathbf{U}_\perp = 0$ (solid lines), angular velocity $\mathbf{\Omega} \cdot (\hat{\mathbf{e}}_\parallel \times \hat{\mathbf{e}}_\perp) = 0$ (dashed lines), and bending angle $\delta = 0$ (dotted lines) as a function of aspect ratio λ and initial orientation θ_i. Blue lines are for a rigid swimmer. Grey (white) area is the terminus attraction (escape) zone. (c) Trajectories for initial orientations θ_i. Blue lines correspond to the position of the swimmer after times $t/H_A/U = 1, 2, 3, 4, 5$. Dashed lines in c) correspond to bending towards the wall. Results are obtained for $|F_T|/\mu H_A U = 1, \theta_i = 0, \lambda = 0.1, k/\mu H_A^2 U = 10^{-4}, \alpha = \beta = 0.1$ unless mentioned otherwise.

CONCLUSIONS

Near-wall dynamics of swimmers is a very rich and complex phenomenon. In this paper, we explored the dynamics of an elastic swimmer near a no-slip wall and demonstrated that wall-trapping dynamics of microorganisms can be significantly altered by shape change due to flexibility.

ELASTIC RINGS SEDIMENTING IN A VISCOUS FLUID

Magdalena Gruziel-Słomka[1], Paweł Kondratiuk[2], Piotr Szymczak[2], and Maria L. Ekiel-Jeżewska*[1]
[1]Institute of Fundamental Technological Research, Polish Academy of Sciences, Pawińskiego 5B, 02-106, Warsaw, Poland

Summary Dynamics of elastic rings settling under gravity at low-Reynolds-number are analyzed numerically. The bead model is used with Rotne-Prager-Yamakawa approximation of the hydrodynamic mobility matrix for the beads. Several attracting dynamical modes are found for a wide range of values of the elasto-gravitational number, and for many different initial configurations. The modes are stationary configurations, stationary shapes with the beads moving periodically along the ring, rotating rigid configurations or periodically changing shapes. Very stiff rings are circular and orient vertically. Less stiff ones tend to form almost circular and almost flat structures that are inclined with respect to gravity. Even more flexible rings deform significantly and reach one of several characteristic periodic orbits. Mean sedimentation velocities of different modes in general are different.

INTRODUCTION

Recently, there has been a lot of interest in topology and dynamics of deformable, closed, thin and long elastic chains (here called rings) moving in a viscous fluid. The motivation for developing theoretical models comes from biological systems such as DNA, proteins or ring polymers that spontaneously form similar structures [1, 2, 3]. Moreover, elastic rings can serve as simple models of vesicles, red blood cells [4], or swimming microorganisms, e.g., bacteria or algae [5]. Theoretical models of sedimenting elastic rings help to investigate the influence of gravity on the dynamics of microorganisms, to design new diagnostic tools in medicine and to apply ultracentrifugation to sort proteins or DNA.

SYSTEM AND ITS THEORETICAL MODEL

Here we focus on sedimentation of an elastic unknotted ring. We assume that the Reynolds number is much smaller than unity and that the Brownian motion is negligible. We report our recent results [6] on characteristic attracting dynamical modes and their shapes. Additionally, we evaluate and discuss the corresponding sedimentation speeds. An elastic ring is modeled as a chain of N overlapping identical spherical beads of diameter d. Centers of the consecutive beads are connected by springs of equilibrium length $l_0 = 0.6d$ and a large spring constant $50F_0/d$, where F_0 is a gravitational force, corrected for buoyancy, acting on each of the beads. The harmonic bending potential energy equals to $-\sum_{i=2}^{N-1} A^*\phi_i^2/(2l_0)$, where ϕ_i is the angle between the springs attached to the bead i, and A^* is the bending stiffness. A wide range of values of the stiffness ratio $\tilde{A} = 6 \times 10^4 \times A^*/(F_0 N^3 l_0^2)$ is studied, where $A^*/(F_0 N^3 l_0^2)$ is the inverse elasto-gravitational number. To prevent a chain self-crossing, Lennard-Jones potential energies $\epsilon[(\sigma/r_{ij})^{12} - (\sigma/r_{ij})^6]$ are summed up over non-consecutive beads i, j with center-to-center distances $r_{ij} < 2^{1/6}\sigma$, where $\sigma = d/2$ and $\epsilon = dF_0/4$.

The dynamics is based on the Stokes equations. The motion of center $\boldsymbol{r}_i$ of bead i satisfies $\dot{\boldsymbol{r}}_i = \sum_{i=1}^{N} \boldsymbol{\mu}_{ij} \cdot \boldsymbol{F}_j$, with the force $\boldsymbol{F}_j$ determined from the sum of the spring, bending and Lennard-Jones potential energies presented above, plus the gravitational force (corrected for buoyancy), $\boldsymbol{F}_g = (0, 0, F_0)$. We adopt the Rotne-Prager-Yamakawa approximation for the mobility matrix $\boldsymbol{\mu}_{ij}$ [7] and solve the dynamics numerically.

RESULTS

Initially horizontal circle remains circular and horizontal while sedimenting. Therefore, we start our analysis from evaluating evolution of elastic rings that initially form flat circular rings in elastic equilibria, slightly inclined with respect to the horizontal plane. We observe that an elastic ring tends to one of several attracting orbits, depending on the stiffness ratio $\tilde{A}$. Rings with a large stiffness ratio $\tilde{A}$ after a long time become *vertical* and remain circular. When $\tilde{A}$ decreases, the final stationary shapes become more and more *tilted* from vertical, and deviations from circular and planar shape increase. Then, for even more flexible rings, other attracting modes are observed. In the *swinging* and *flapping* modes, the ring shape changes periodically with time, as illustrated in Fig. 1. One of shapes from each sequence in Fig. 1 is also

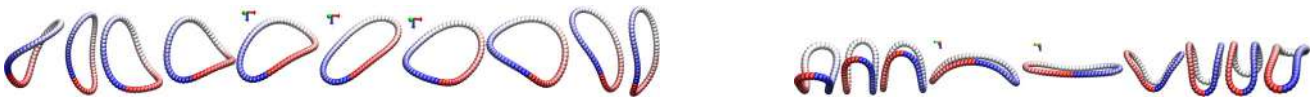

Figure 1: Snapshots from the swinging (left) and flapping (right) modes [6]. Gravity points down.

*Corresponding author. E-mail: mekiel@ippt.pan.pl

shown in Fig. 2a where names of all the modes are associated with certain characteristic shapes. In the *frozen rotating* and *figure eight* modes, the rigid shapes, shown in Fig. 2a, rotate around vertical axis. In the *tank-treading* mode, the beads move periodically along the configuration shown in Fig. 2a. In the *toroidal* modes with *two* or *three coils* ($\mathcal{T}_{2,1}$ or $\mathcal{T}_{3,1}$), the beads swirl in the poloidal direction and rotate in the toroidal direction, i.e., around vertical axis. In Fig. 2a, we also demonstrate that for the chosen class of the initial configurations, the smaller $\tilde{A}$, the more compact is the ring, with the smaller radius $\bar{R}_g$ of gyration (evaluated with respect to the center-of mass), averaged over many periods. Here $R_0 = Nl_0/(2\pi)$ is the radius of the initially circular and inclined ring.

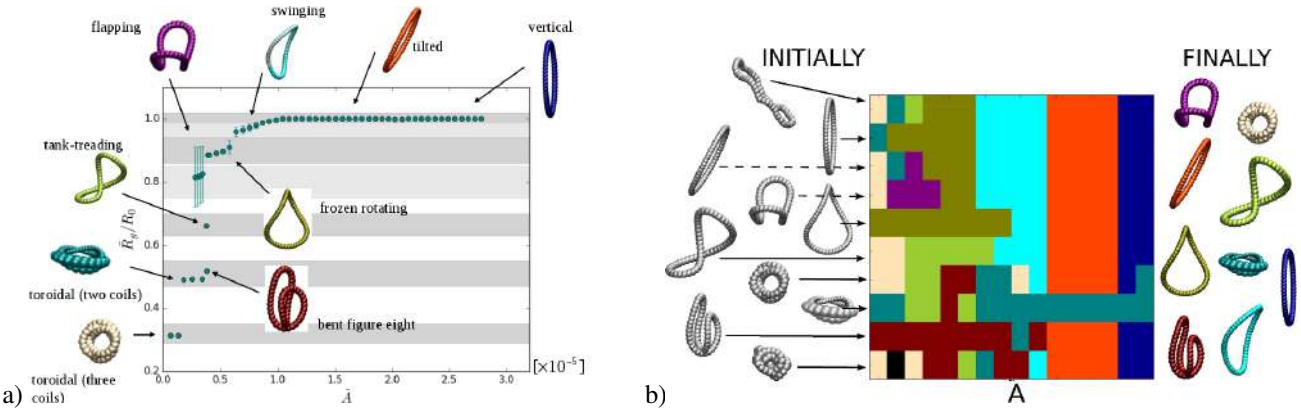

Figure 2: Shapes of sedimenting elastic rings, characteristic for different attracting dynamical modes with $N = 60$ and different values of the stiffness ratio $\tilde{A}$ [6]. Gravity points down except the toroidal, three coils mode for which it points towards the reader. The initial configurations are: a) flat circular ring in elastic equilibrium, inclined by $\beta_0 = 16^\circ$ to the horizontal plane; b) characteristic shapes from the attracting dynamical modes, shown in panel a). In panel b), $\tilde{A} \in [0.23, 2.37]$, with a nonlinear scale shown in Fig. 20 of Ref. [6].

In Fig. 2b, we present simulations performed for another family of initial conditions. Each row in Fig. 2b corresponds to an initial configuration (indicated by arrow), that appeared in a different long-time dynamical mode shown in Fig. 2a. The colors correspond to the final stages of the evolution, shown at the right. The initial configuration in the last row and black color of the final stage correspond to an irregular coil.

The results shown in Fig. 2 illustrate very rich dynamics of sedimenting elastic loops. We have found many different attracting dynamical modes for the stiffness ratio $0.1 \leq \tilde{A} \leq 2.5$. Moreover, for a given value of $\tilde{A}$, different modes can emerge from different initial configurations. To complete the analysis performed in Ref. [6], we have also evaluated and analyzed sedimentation speeds of elastic loops in different modes, and for different values of $\tilde{A}$. Shapes, gyration radii and sedimentation velocities of elastic rings from the same mode only weakly depend on the stiffness ratio $\tilde{A}$, but in general they are significantly different for different dynamical modes observed for the same value of $\tilde{A}$. For example, as shown in Fig. 2b, a very compact shape of the toroidal mode with two coils has been observed in a wide range of the stiffness ratio, coexisting with almost circular vertical and tilted modes for $\tilde{A} \geq 1.22$. A more compact toroidal mode with three coils has been also detected for larger values of $\tilde{A}$. As the result, for a larger value of $\tilde{A}$, gyration radii and sedimentation velocities of different modes can differ even as much as by a factor of 3 and 2, respectively.

We analyzed dynamics of elastic loops made of different numbers of beads N. For $N > 15$, elastic rings behave similarly in similar ranges of the stiffness ratio $\tilde{A}$, i.e., in similar ranges of the elasto-gravitational number. This finding indicates that the attracting dynamical modes described here are generic for dynamics of very elastic sedimenting rings.

SURPRISING HYDRODYNAMICS OF BACTERIA NEAR SURFACES

Debasish Das*and Eric Lauga
Department of Applied Mathematics and Theoretical Physics, Centre for Mathematical Sciences, University of Cambridge, Wilberforce Road, Cambridge CB3 0WA, UK.

Summary Recent experiments [1] have shown that a sulfide-oxidizing bacterium named *T.majus* can transition from swimming in circles to a surface-bound state where it stops swimming while remaining free to move laterally along the surface. In this bound state, the cell rotates perpendicular to the surface with its flagella pointing away from it. Using simulations and theory, we demonstrate the existence of a fluid-structure interaction instability that causes cells with relatively short flagella to become surface bound [2]. In both the bound and dynamic states, we find that bacterium gets attracted to the wall consistent with far-field force dipole assumption [3]. However, on simply changing the shape of the cell body from a sphere *T.majus* to a prolate spheroid, relevant for cells such as *E.coli*, we find that the cell swims in circular trajectories but at a certain height above the surface.

INTRODUCTION

Bacteria are one of the most important life-forms on Earth. Being one of the first organisms to have appeared on the planet, they have evolved to thrive in a variety of environments. Peritrichous (multi-flagellated) bacteria, such as *T. majus* or *E. coli*, self-propel in fluids by using specialized rotary motors to rotate multiple helical filaments, enabling swimming of the whole cell. In the present work, we focus on the surface interactions mechanisms of bacteria such as *T. majus* that have a large spherical cell body compared to their flagellar length, in contrast with *E. coli* that have a relatively smaller but elongated prolate-spheroidal cell body.

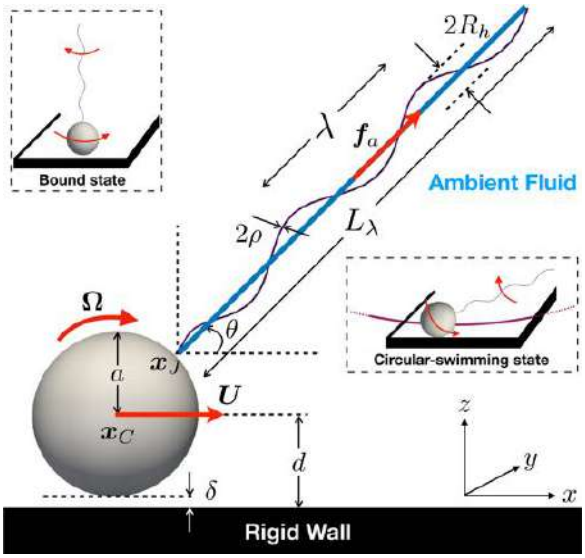

Figure 1: Schematic diagram of a flagellated bacterium swimming near a plane surface. The cell body is modeled as a rigid sphere (case of *T. majus* bacteria) or a prolate spheroid (*E. coli*) and the flagellar filament as a rigid right-handed (*T. majus*) or a right-handed (*E. coli*) helix rotating along its axis for the numerical simulations. The cell body undergoes rigid body translation and rotation at velocities $\boldsymbol{U}$ and $\boldsymbol{\Omega}$, respectively. The flagellum tilt angle is denoted by θ. The two possible final steady states of a bacterium near a surface are shown as insets: surface-bound (top left) and circular swimming (bottom right).

In recent experiments, the swimming behavior of *T. majus* cells was studied near surfaces [1]. Quite surprisingly, it was found that instead of swimming along the surface in circles (as well established for many species), many freely swimming cells became dynamically surface-bound. In this bound state, cells remained free to move laterally along the surface and their bodies continuously rotated around their center in the direction perpendicular to the surface while their flagellar filaments pointed away from the surface, rotating in the opposite direction. The bound state is in stark contrast to the classical situation of bacteria swimming in circular paths near surfaces [4]. The question therefore arises regarding the mechanism at the origin of this transition to a bound state.

Mathematically, we define the cell to be in the surface-bound state when the flagellum axis is perpendicular to the surface, i.e. $\theta = \pi/2$ (Fig. 1), and consequently, the radius of circular trajectory is $R = 0$. In the bound state, a small perturbation in the tilt angle of the flagellum is expected to destabilize the cell and cause it to swim parallel to the surface in circles. What exactly makes this state stable? Using a combination of theory and simulations, we show that the transition from swimming to a bound state can be rationalized as an instability due to fluid-structure interaction. We then focus on the question: how does changing the shape of the cell body from a sphere to a prolate spheroid change these swimming dynamics near surfaces?

BIOMECHANICAL MODELING

The fluid dynamics of bacteria are described by the incompressible Stokes equations solved using a combination of slender body theory [5, 6] and boundary element method [7]. *T. majus* cells rotate in a counterclockwise direction when viewed from the posterior side, which motivates us to model the fraction of flagella on the cell-surface that cause propulsion bundled together as a single right-handed clockwise rotating helix in the numerics, or as a rigid active pushing rod for the theory (details of the theory can be found in Ref. [2]). This assumption holds particularly well for *E. coli* as their flagella are known to be in a bundled configuration when swimming. The cell body of *T. majus* is assumed to be a sphere of radius a, also chosen as the relevant length scale for the problem. For *E. coli* cells, we have an additional dimension for body width, $b = \alpha a$, where α is the cell body aspect ratio. The cell body is centered at $\boldsymbol{x}_C$ while the

*Corresponding author. E-mail: dd496@cam.ac.uk.

flagellum is attached to the cell body surface at the junction point, $\boldsymbol{x}_J$ (Fig. 1). The minimum distance between the cell-body surface and the plane rigid wall is δ and the distance between the center of the cell-body and the wall is $d = a + \delta$. The tilt angle of the flagellum measured with respect to the horizontal direction is denoted by θ, so that $\theta = \pi/2$ and $\theta \neq \pi/2$ correspond to surface-bound and circular-swimming state, respectively.

RESULTS AND CONCLUSIONS

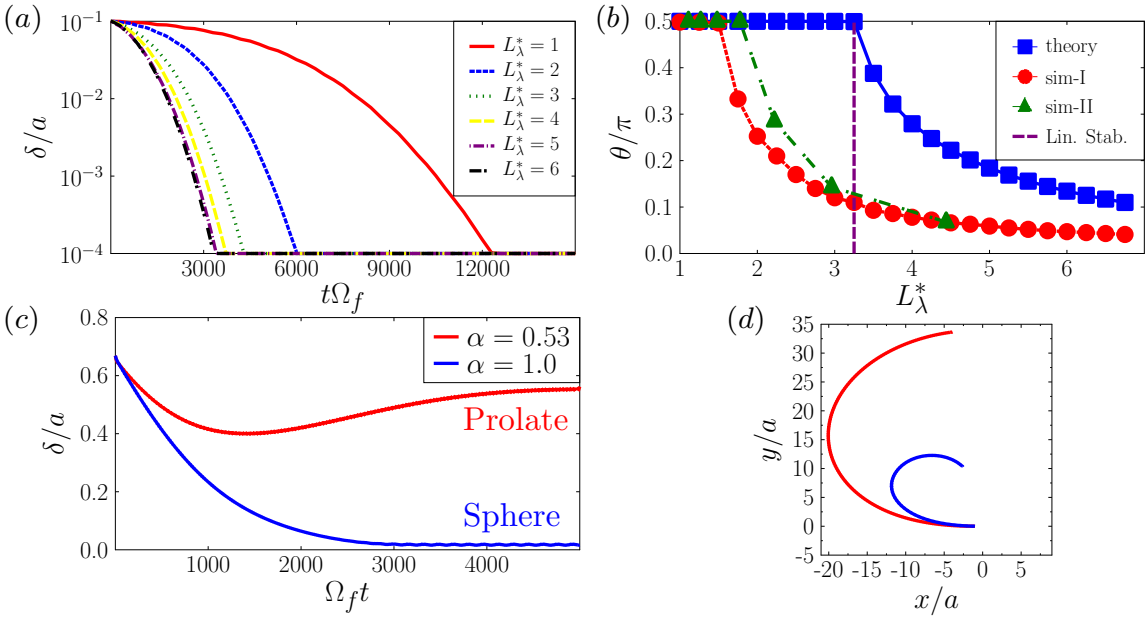

Figure 2: (a) Temporal evolution plot of δ/a for various flagellar lengths L_λ^*; (b) Pitchfork bifurcation of the tilt angle, θ/π, plotted against the flagellum axial length, L_λ^*; (c) temporal evolution of δ/a for a swimming bacterium with spherical and prolate-spheroidal cell body; (d) trajectories in the $x - y$ plane corresponding to (c).

In the numerical simulations, the cell body is placed at a distance $\delta^* = 0.1$ from the wall with its flagellar filament initially parallel to the wall ($\theta = 0$). The geometrical parameters of the flagellar filament are assumed to be similar to that of *E. coli*. In the first set of simulations (sim-I), the axial length of the filament is varied from $L_\lambda = 1.0\,\mu\text{m}$ to $6.75\,\mu\text{m}$ while the cell body radius is fixed at $a = 1\,\mu\text{m}$. In the second set of simulations (sim-II), we fix the number of turns at $N = 2$ and axial length at $L_\lambda = 4.44\,\mu\text{m}$ while the cell body radius is varied from $a = 1\,\mu\text{m}$ to $4\,\mu\text{m}$. We plot in Fig. 1a the dynamics of $\delta(t)$ for six values of the flagellum length, L_λ^*, for sim-I. In each case, the cell gets attracted to the wall regardless of the flagellar filament length. As the cell gets closer to the wall, the coupling between translation and rotation becomes stronger which causes the filament to tilt away from the wall, see Fig. 1b. This tendency to tilt away from the wall due to cell body-wall interaction is resisted by the viscous torque experienced by the translating flagella as well as an attractive torque that tends to align the helix parallel to the wall arising from helix-wall hydrodynamic interactions. As a result, the tilt angle reaches a dynamical steady state whose value depends on L_λ^*. Hence, a large ratio of cell body size to flagellar length can cause a transition from circular swimming along the surface to a bound state.

The results in Fig. 2a & b are obtained using a semi-analytical approach [2], while those in Fig. 2c & d are obtained using a full boundary element method. Here, we show next that on simply changing the shape of the cell body from a sphere (relevant for *T. majus*) to a prolate spheroid (relevant for *E. coli*), the cells swimming parallel to the surface in circular trajectories do so at a finite height above the surface of magnitude similar to the width of the body (Fig. 2(c)). The trajectories viewed from above the surface are shown in Fig. 2(d). This is a rather surprising result as bacteria are force-free organisms and, as force-dipoles swimming in a fluid medium, they should always be attracted towards no-slip surfaces [8]. Similar observations were made in a previous work [9] but only for $\alpha < 0.7$. The development of a simple mathematical model to explain these curious findings is under progress.

THE SEDIMENTATION OF CLOUDS OF SPHERICAL PARTICLES IN VORTICAL FLOWS

Laurence Bergougnoux*[1], Benjamin Marchetti[1], and Elisabeth Guazzelli[2]
[1]Aix Marseille Univ, CNRS, IUSTI, Marseille, France 2MSC, CNRS, University of Paris, Paris, France

Summary We present a jointed experimental and numerical study examining the influence of vortical structures on the settling of clouds of solid spherical particles under the action of gravity at low Stokes numbers. The two-dimensional model experiments use electroconvection to generate a two-dimensional array of controlled vortices which mimics a simplified vortical flow. The motion of the clouds are tracked when settling through this vortical flow. The interplay between the multibody particle interactions and the interaction between the particles and the spatial structures of the flow is examined by comparing the experimental cloud dynamics to the predictions of point-particle numerical simulations.

INTRODUCTION

In many natural phenomena or industrial applications, heavy particles are transported in complex flows. The flow structures may happen to promote the stirring and dispersion of the particles. But the opposite can also take place and the flow configuration may contribute to the focussing and accumulation of particles within specific regions of the flow. A typical example in the natural environment is the observed patchiness of plankton concentration caused by wind-induced Langmuir cells occurring at the surface of lakes and oceans. The objective of this work is to examine the settling of a collection, i.e. a cloud, of solid spherical particles through the local spatial structures of the flow, i.e. large vortices. The key question is whether this cloud maintains a cohesive entity or disintegrates and spreads when settling through this complex flow structure. The present work considers a simple vortical flow, specifically a cellular flow consisting of counter-rotating vortices, which is a model flow capturing key features of vortical effects on the particles. It addresses the interaction of these controlled vortices with the individual particles of the settling cloud as well as the particle interactions between themselves. The focus here is on flow regimes ranging for negligible to small but finite inertia but at low Stokes numbers.

EXPERIMENTS

Following [1], we use electroconvection to generate a two-dimensional array of controlled vortices and track settling clouds using a set of synchronized cameras located below and in front of the cell as depicted in figure 1 (a). The transparent cell is filled with an aqueous mixture of citric acid (UCON® oil can be added to increase the viscosity). The magnetic field is generated by a checkerboard of magnets placed behind the back wall of the cell. The electric current is created by two electrodes placed on the opposite small sides of the cell. The coupling between the magnetic field and the uniform electric current gives rise to an electromagnetic force in the fluid. The flow generated by this force is a periodic flow of counter-rotating vortices that is characterized by particle image velocimetry (PIV). Clouds are prepared by mixing a weighted amount of spherical particles with the same fluid as that filling the cell. Different fluids and particles (polystyrene or polymethyl methacrylate spheres having different radii, $a = 70, 115$, and $175\,\mu$m) are used to explore regimes going from that of Stokes to that of small inertia. The clouds are injected at the top of the cell and their time-evolution can be tracked when settling through the vortices.

NUMERICAL MODELING

We adopt the simplest model containing the minimum physics to describe the problem. At low Reynolds number, the particles of the clouds are represented by identical point forces. The velocity of a given sphere is then its own terminal velocity (such as when the single particle falls in a quiescent fluid) incremented by the local fluid velocity [2] and the sum of the velocity disturbances (only represented by its far-field portion, i.e. the Stokeslet) coming from the other particles [3, 4]. When inertia becomes finite, the crudest approximation is to replace the far-field Stokes interactions between the particles by the steady far-field Oseen interactions (i.e. the Oseenlet), i.e. assuming steady Oseen wake interactions between the particles [5, 6].

RESULTS AND COMPARISON

When settling in a quiescent fluid in the Stokes regime (i.e. regime of negligible inertia), a cloud of spheres remains first roughly spherical with a leakage of particles in a vertical tail and then evolves into a torus. After falling at least 500 times its radius, it can become unstable and break up into secondary droplets which deform into tori themselves and break

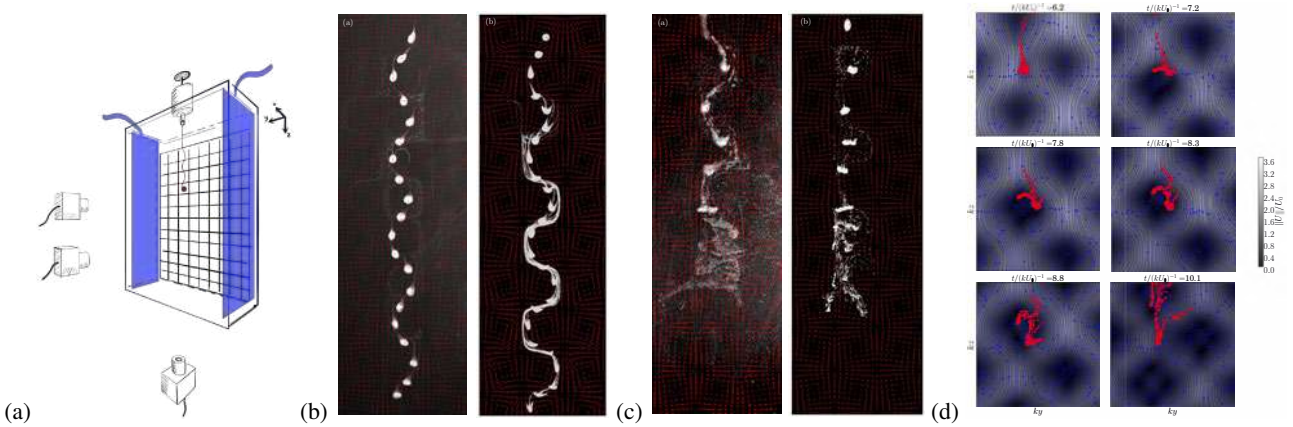

Figure 1: (a) Sketch of the experimental apparatus. (b) Comparison of the experimental (left) and numerical (right) chronophotographies of a cloud in the Stokes regime. (c) Comparison of the experimental (left) and numerical (right) chronophotographies of a cloud in a finite-inertia regime. The time between successive photos is kept constant (2 s in the experiments and a corresponding interval in the simulations) in order to indicate the difference in velocities along the trajectory. (d) Cloud break-up in the inertial regime: flow field computed at successive times in the vertical plane in the cloud reference frame for a typical Oseenlet simulation. High (low) velocity is indicated in white (dark). The quasi periodic structure of counter-rotating vortices has a velocity U_0 and a spatial wavenumber k.

in a repeating cascade. The key feature of this Stokes cloud is the chaotic motion of the particles which leads to escapes from the cloud toroidal circulation and to particle leakage [3, 4]. When inertia is small but finite, the cloud deforms into a flat torus that eventually destabilizes and breaks up into a number of secondary droplets but particle leakage is much weaker. The inertial cloud evolution is strongly determined by the importance of Oseen-wake-mediated interactions [5, 6].

When the cloud settles in the vortical flow in the Stokes regime, it follows the downstream flow of the successive vortices and displays zigzagging motions due to the modulations caused by the periodic cellular flow as illustrated in figure 1 (b). It does not maintain a spherical shape as it is slightly stretched in the elongational region of the flow, in particular close to the stagnation points surrounding the purely rotational regions at the centers of the vortices. A significant leakage of particles at the cloud rear is observed. The small particles released into the vortical flow can become trapped inside the vortices. Break-up does not occur as the travel distance of the cloud is not long enough. Similar qualitative evolution is found by the point-particle simulation using the Stokeslet approximation. When inertia is increased and becomes finite, the flow structure induces a stronger cloud deformation as evidenced in figure 1 (c). The cloud eventually widens in the elongational portions of the flow and breaks into multiple pieces. Point-particle simulations using an Oseenlet (instead of Stokeslet) approximation can capture this phenomenon.

A more quantitative comparison between experiments and simulations can be obtained by examining the time evolution of the vertical and horizontal coordinates of the cloud centre of mass as well as quantities such as the cloud projected surface in the horizontal plane normalized by its initial value. Point-particle simulations, which contain the minimal physics to describe the coupling between particle-particle and particle-flow interactions, capture well the cloud dynamics. A significant leakage of particles is observed at the rear of the clouds. It is greatly amplified by the vortical flows by comparison with clouds settling in quiescent fluids. It is also intensified when inertia is increased and becomes finite.

An important output of the present work is that the vortical structures induce a faster break-up of the clouds into multiple shatters in the finite inertia case. This phenomenon is evidenced by visualizing the flow field surrounding the cloud in the cloud reference frame for a typical Oseenlet simulation, see figure 1 (d). The cloud successively expands and contracts when falling in the consecutive upward and downward, respectively, elongational portions of the flow. When inertia is finite, the oscillation between the expansion and contraction phases is no longer reversible and the cloud expansion becomes stronger. When the cloud reaches an upward elongational region of the flow wherein there is a slow-down of the velocity, break-up then happens as the widened cloud winds around the vortical structure. The remaining pieces of the cloud spread in the flow structures and can undergo the same break-up process.

THE EFFECT OF SURFACE ATTACHMENT OR GRAVITATIONAL TETHERING ON PLANKTONIC FEEDING FLOWS

Anders Andersen[1*] and Thomas Kiørboe[1]
[1]National Institute of Aquatic Resources and Centre for Ocean Life, Technical University of Denmark, DK-2800 Kgs. Lyngby, Denmark

Summary We use a simple low Reynolds number flow model to examine and explain the effect of attachment or gravitational tethering on the flow in interception feeding plankton. We show that under general assumptions it is favourable to be freely swimming instead of tethered to a surface or gravitationally attached since the resulting feeding flow past the cell is more intense, leading to a larger clearance rate.

INTRODUCTION

Marine zooplankton feed in a nutritionally dilute environment. To enhance prey clearance rates many species swim through the water or create a feeding current. Many species are non-motile when feeding, either due to gravitational tethering (many copepods) or by direct attachment to a surface (many unicellular organisms). Several authors have independently suggested that attachment or gravitational tethering leads to a more efficient feeding flow [1-5], whereas two recent computational fluid dynamics (CFD) studies of attached and freely swimming choanoflagellates have suggested the opposite, that freely swimming flagellates have higher clearance rate than those attached to a surface [6, 7]. What causes this difference is not evident. Here, we use an analytical flow model to explore and quantify the effect of attachment on the prey encounter rate of the feeding flow in an interception feeding model flagellate, and we show that free swimming is superior to attachment in terms of clearance rate.

POINT FORCE MODEL

To model and compare feeding flows of tethered and freely swimming planktonic organisms we apply a flow model based on the Oseen solution for the low Reynolds number flow due to a point force next to a solid sphere [8-10]. As model organism, we consider a uniflagellate pulled by a single flagellum (figure 1a). The thrust force $\boldsymbol{T}$ represents the force on the flagellum from the water whereas the force $\boldsymbol{F}$ represents the force from the flagellum on the water. The force $\boldsymbol{F}$ gives rise to a flow past the no-slip sphere that represents the spherical cell body, and the resulting stress on the surface of the cell leads to the force $\boldsymbol{K}$ that is opposite to the thrust force and smaller in magnitude. If the cell is tethered, the stalk provides an external force that holds the cell in place and the flow past the cell is simply the flow due to the force $\boldsymbol{F}$. In the case of a freely swimming cell, the flagellum pulls the cell through the surrounding water with a constant velocity $\boldsymbol{U}$ that is determined such that the resulting Stokes drag $\boldsymbol{D}$ makes the net force on the model flagellate vanish.

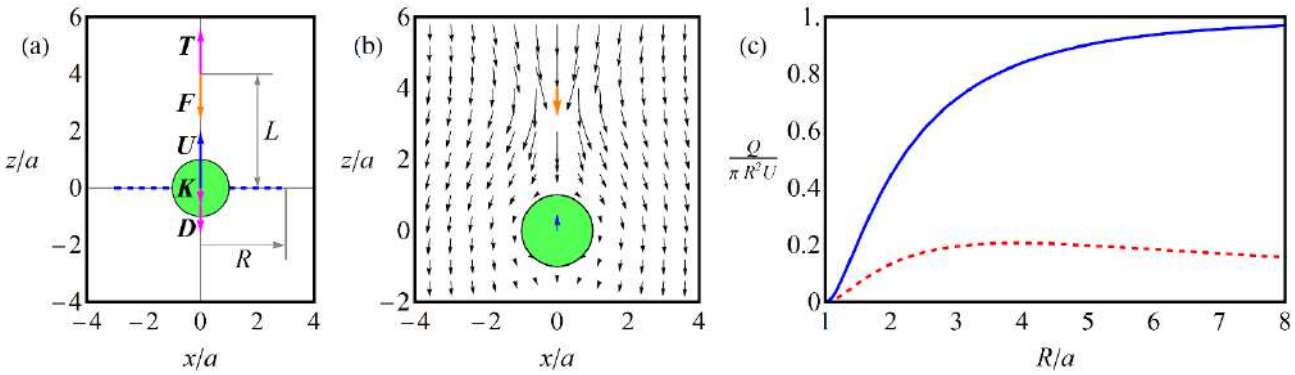

Figure 1. Point force model, flow field, and prey clearance rate. (a) Point force model and prey encounter zone of freely swimming flagellate. The thrust force $\boldsymbol{T}$ represents the flagellum that pulls the spherical cell (green) with velocity $\boldsymbol{U}$. The radius of the cell is denoted a, and the thrust force acts at a distance $L = 4\,a$ from the centre of the cell. The annular prey encounter zone in the equator plane (blue, dashed) represents tentacles extending form the cell and has outer radius R. (b) Velocity field relative to the cell when the model flagellate is freely swimming. (c) Clearance rate as function of the outer radius of the prey encounter zone when the model flagellate is tethered (red, dashed) and freely swimming (blue, solid), respectively.

FEEDING FLOW AND CLEARANCE RATE

The flow relative to the cell body of the freely swimming flagellate is directed backwards, and it is most intense past the front half of the surface of the cell (figure 1b). Depending on the detailed morphology of the flagellate, prey particles may be intercepted by the flagellate either directly on the cell body or on tentacles extending from it. Here we consider an annular encounter zone of outer radius R in the equator plane around the cell (figure 1a), and we assume that the clearance rate is equal to the flow rate Q relative to the cell and through the annular encounter zone. The flow rate Q depends on the outer radius R of the encounter zone, but it is always larger by at least a factor of three when the flagellate is freely swimming in comparison with the tethered situation (figure 1c).

DISCUSSION

In contrast to the commonly accepted view [1-5], our model demonstrates that tethering decreases rather than increases the clearance rate of interception feeding zooplankton, consistent with the recent CFD simulations of tethered and freely swimming choanoflagellates [6, 7]. The clearance rate of a zooplankton organism of course depends on the detailed architecture of the flow generation apparatus and the structures on which prey particles are intercepted. Our simple model relies on the assumption that the flagellum generates the same force whether or not the flagellate is tethered or freely swimming, and we further assume that the prey encounter zone is at rest relative to the cell. Our presumption is that our qualitative conclusion is correct as long as these two key assumptions are satisfied, and that it is therefore valid for a large class of ecologically significant zooplankton.

THE EFFECT OF LOCAL FLUID RHEOLOGY ON PHORETIC MODES

Patrick S. Eastham[1] and Kourosh Shoele*[2]
[1]Department of Mathematics, Florida State University, Tallahassee, FL, USA
[2]Department of Mechanical Engineering, Florida State University, Tallahassee, FL, USA

Summary Many micro-swimmers, either biological or artificial, affect the local environments through which they move. For bacteria, this is done through feeding on surrounding nutrients; for micro-robots, this is done through surface heat dissipation or chemical reaction as a byproduct of swimming actuation. These mechanisms have the theoretical potential to alter the local material properties of the surrounding fluid. This raises the question of whether it is possible for a swimmer to modify local fluid rheology in order to enhance its locomotion. Our work intends to answer this question by providing asymptotic and numerical categorization of the effect of different modes of swimming. Additionally, experimental exploration of the role of a fluid's local rheology on swimming performance is an active area of research, and our analysis should aid in the interpretation of experimental results.

INTRODUCTION

In published work over the past several years, we have investigated the role of nutrient-dependent viscosity on the swimming and feeding performance of microswimmers [2]. To introduce variable viscosity, we assume that the fluid is governed by a variable-viscosity Stokes equation and the nutrient is transported by an advection-diffusion equation. The coupling of these PDEs is through the nutrient-dependent viscosity:

$$\mu\big(c(\mathbf{x})\big) = \mu_0\left[1 + k\,c(\mathbf{x})^{\xi}\right] \tag{1}$$

where μ_0 is the far-field viscosity, k measures the sign and strength of the coupling, and ξ governs the nonlinearity of the relationship. The form of the nutrient-dependent viscosity is chosen in the form of a "power-law" so that it may capture both the strength and sign of the coupling as well as the potentially non-linear relationship between concentration and viscosity. All of these components are well-motivated, as demonstrated in Fig. 1(c), by comparisons to real-world materials.

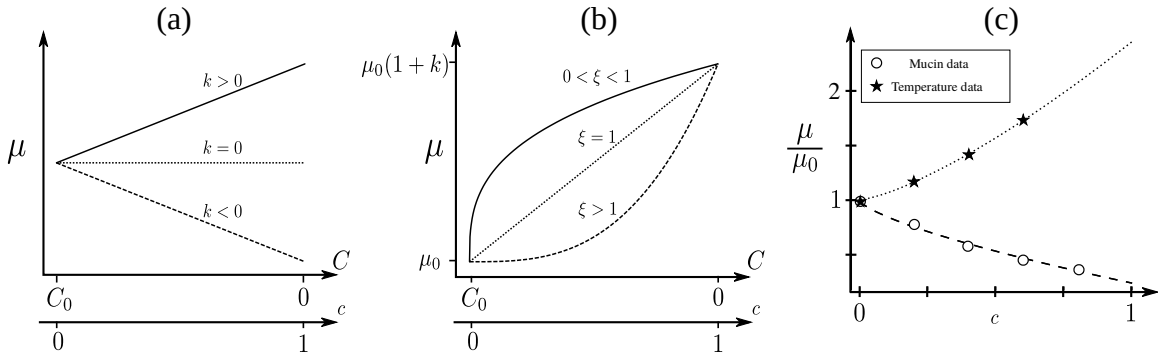

Figure 1: The nutrient-viscosity relationship for (a) various k, fixed $\xi = 1$, and (b) various ξ, fixed $k > 0$, and (c) fit to two real materials, using Eq. 1. Fitting the data for viscosity vs. concentration of Mucin, a protein, gives $k = -0.76$ and $\xi = 0.70$ [3]; fitting the data for viscosity vs. water temperature gives $k = 1.45$ and $\xi = 1.35$ [1]. The power-law coefficient ξ determines the nonlinearity of relationship, while the magnitude and sign of k determines the strength of the relationship and whether the viscosity increases or decreases near the surface of the squirmer ($C = 0$, $c = 1$), respectively. Note that C is the dimensional nutrient variable and c is its dimensionless counterpart

This coupling also eliminates the ability to find an analytic solution. Through both asymptotic and numerical methods, it is possible show that the swimming speed, feeding rates and power expenditure are all affected by nutrient-dependent viscosity. Additionally, the mode of swimming is also found to affect the locomotion performance. In particular, the major force difference between the variable- and constant-viscosity cases was through modification of the fluid pressure gradient, as opposed to the rate-of-strain tensor (see Fig. 2). This modification to the pressure gradient either helps or hurts swimming performance based on whether the modified pressure force was working "for" or "against" the swimming body. This major modification to a "volume force" like pressure, with little modification to "surface force" of the velocity gradient was surprising and is the focus on the work presented here.

Statement of Problem

We present our findings about the competing effects of surface forces (slip velocities, rate-of-strain forces) and volume effects (pressure gradients, variable viscosity) on the locomotion performance of a Janus particle. In particular, it will be discussed whether an organism or artificial micro-robot could actively control the presence of volume effects in order to aid their locomotion.

*Corresponding author. E-mail: kshoele@fsu.edu.

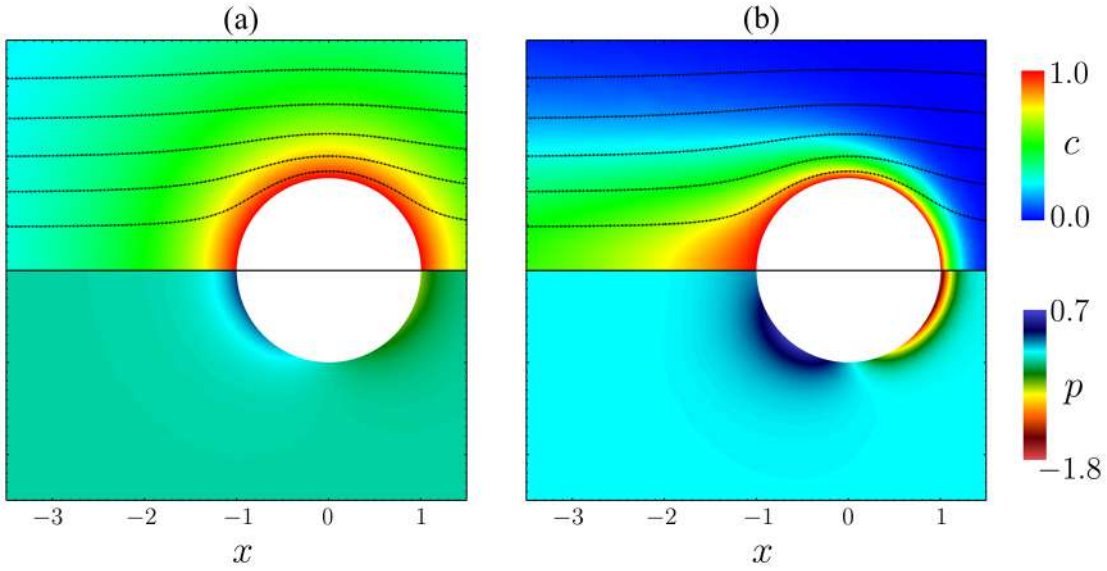

Figure 2: Effect of Pe on a treadmill squirmer with $\xi = 1.0$ and $k = 0.5$; nutrient field with streamlines on top and pressure field on bottom. (a) Pe $= 0.01$, both nutrient and pressure are symmetric due to the diffusion-dominated regime. (b) Pe $= 10$, advection-dominated regime causes an asymmetry in pressure and nutrient fields which results in larger modifications to swimming speed and nutrient flux. This pressure change for large Pe is *not* present in the constant-viscosity case.

CONCLUSIONS

In this abstract, we briefly present the connection between local versus non-local effects on the locomotion efficiency of Janus particles. While the local effect are found to modify the local gradient of the scalar and as a results induces a surface tangential forces which changes the phoretic locomotion efficiency of the particle, the non-local effect primarily modifies the pressure field around the object and induce more asymmetric pressure forces on the body. The combined use of both mode of locomotion can be leveraged to enhance the transport of Janus particles using phoretic locomotion mode.

RHEOLOGY OF NON-BROWNIAN DENSE SUSPENSIONS: AN OPTIMISED IMPLEMENTATION OF THE FICTITIOUS DOMAIN METHOD IN OPENFOAM®

Michel Orsi*[1], Laurent Lobry[1], Stany Gallier[2], and François Peters[1]
[1]Institut de Physique de Nice, CNRS UCA, Parc Valrose, 06108 Nice CEDEX 2, France
[2]ArianeGroup, Le Bouchet Research Center, 91710 Vert le Petit, France

Summary Non-Brownian concentrated suspensions of particles embedded in low-Reynolds-number flows are ubiquitous in industry (e.g. food, transport and civil engineering) as well as in biological or natural flows (blood, mud or lava flows). Fresh concrete or uncured rocket fuel are two examples of concentrated suspensions for which the highest particle volume fraction is desired, while specific rheological and flowing properties are required. These dense suspensions exhibit a complex rheological behaviour that is far from being totally understood. Numerical simulations can help shed light on the intricate physics of suspensions at the particle scale. The aim of the present work is to provide a highly optimised parallel implementation of a fictitious domain method (FDM) in OpenFOAM®, in order to give the opportunity to simulate large systems with a high amount of particles.

INTRODUCTION

The complexity characterising the rheology of dense suspensions mainly stems from the wide variety of fluid-particle or particle-particle interactions (Brownian, hydrodynamic, frictional or collisional) as well as from the physical properties of particles (roughness, shape, size distribution, etc.) [4]. Even idealised cases involve strong non-Newtonian effects such as shear-thinning, shear-thickening, particle migration and anisotropic normal stresses and microstructures [2, 5, 6].

Due to the importance of flow-particle interactions, particle-scale numerical methods are of primary interest. For low-Reynolds-number suspensions, different techniques have been previously developed; some of them are highly specialised and may not tackle any kind of flow or fluid [4, 7]. Therefore, direct numerical simulations (DNS) have emerged as an attractive alternative, allowing to solve particulate flows with arbitrary particle shape, Reynolds number or rheological constitutive equation [4]. The very first class of DNS methods dedicated to particulate flows followed a boundary-fitted approach wherein only the domain occupied by the fluid is meshed. For sheared concentrated suspensions, in which particle separation can be vanishingly small, remeshing becomes extremely involved and makes this approach impractical for more than a few particles. In contrast, non-boundary-fitted methods are much more suited for the simulation of suspensions with a high number of particles: the whole domain is mapped onto an Eulerian fixed grid and particles are embedded in this regular non-moving mesh. These techniques include different methods, such as the immersed boundary method, the lattice Boltzmann method or the fictitious domain method, being the latter considered in the present work.

In the fictitious domain method, particles are modelled via a body-force introduced in the momentum equation to enforce a rigid body motion. For the sake of computational efficiency, the body-force quantities are defined in the present approach at the Eulerian grid points and an advection step is inserted into the method, so that the body-force remains attached to the particles as they move along.

A peculiar feature of concentrated suspensions is that the average separation distance between particles becomes extremely small. The so-called lubrication forces arise between particles in near-contact because of the draining of interstitial fluid in the gap, and it is singular in the limit of touching particles. Consequently, the rheology of suspensions is modified by lubrication forces and important effects occur [3, 4]. Keeping the grid spacing high enough for large scale simulations while accounting for the low-scale lubrication effects requires the modelling of the latter [3]. A last essential ingredient for accurate simulations of non-Brownian suspensions is the modelling of contact interactions between particles, as contacts inevitably occur despite lubrication because of particle roughness [3].

FICTITIOUS DOMAIN METHOD

Let $\mathcal{D}$ be the computational domain including the fluid domain $\mathcal{D}_f$ and the solid particle domain $\mathcal{D}_p$, so that $\mathcal{D} = \mathcal{D}_f \oplus \mathcal{D}_p$; each of the N particles is assumed to be rigid and homogeneous with density ρ_p; the boundary between fluid and particle domains is noted $\partial\mathcal{P}$. The idea of the fictitious domain method is to extend the Navier-Stokes equations in the whole domain $\mathcal{D}$, including particles. They are thus supposed to be filled with the fluid, which is supposed here to be Newtonian and incompressible with density ρ_f and viscosity μ. Continuity and momentum equations for an incompressible flow in the whole domain $\mathcal{D}$ read:

$$\begin{gathered} \nabla \cdot \mathbf{u} = 0 \\ \rho_f \left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = \nabla \cdot \boldsymbol{\Sigma} + \rho_f \boldsymbol{\lambda} \end{gathered} \tag{1}$$

where $\mathbf{u}$ is the velocity field and $\boldsymbol{\Sigma} = -p\mathbf{I} + 2\mu\mathbf{E}$ is the fluid stress tensor for a Newtonian fluid, being p the fluid pressure and $\mathbf{E} = \frac{1}{2}\left(\nabla\mathbf{u} + \nabla\mathbf{u}^T\right)$ the rate-of-strain tensor; the term $\rho_f\boldsymbol{\lambda}$ is a body-force that enforces the rigid body motion inside

*Corresponding author. E-mail: michel.orsi@univ-cotedazur.fr.

the particles which is non-zero in the particle domain $\mathcal{D}_p$ and zero in the fluid domain $\mathcal{D}_f$. So, the velocity field inside particles is given by a rigid body motion $\mathbf{u} = \mathbf{U} + \mathbf{\Omega} \times \mathbf{r}$, where $\mathbf{U}$ and $\mathbf{\Omega}$ are the particle translational and rotational velocities, respectively, and $\mathbf{r}$ denotes the position vector with respect to the particles centre of gravity $\mathbf{r} = \mathbf{x} - \mathbf{x}_G$.

Particles motion is given by Newton's equations and reads:

$$\begin{aligned} M\frac{d\mathbf{U}}{dt} - \left(1 - \frac{\rho_f}{\rho_p}\right) M\mathbf{g} &= \mathbf{F}^{hyd} + \mathbf{F}^{sub}(\mathbf{U}, \mathbf{\Omega}) + \mathbf{F}^{int} \\ \mathbf{J} \cdot \frac{d\mathbf{\Omega}}{dt} + \mathbf{\Omega} \times (\mathbf{J} \cdot \mathbf{\Omega}) &= \mathbf{T}^{hyd} + \mathbf{T}^{sub}(\mathbf{U}, \mathbf{\Omega}) + \mathbf{T}^{int} \end{aligned} \tag{2}$$

where M and $\mathbf{J}$ stand for the particles mass and inertia tensor and $\mathbf{g}$ is the gravity acceleration. $\mathbf{F}^{int}$ and $\mathbf{T}^{int}$ are the force and the torque due to contact interactions between particles: they take into account elastic interactions as well as friction and are implemented as shown by Gallier et al. (2014) [3]. $\mathbf{F}^{hyd}$ and $\mathbf{T}^{hyd}$ are the hydrodynamic force and torque exerted by the fluid on the particles, respectively, and read:

$$\begin{aligned} \mathbf{F}^{hyd} &= \int_{\partial\mathcal{P}} \mathbf{\Sigma} \cdot \mathbf{n}\, dS \\ \mathbf{T}^{hyd} &= \int_{\partial\mathcal{P}} \mathbf{r} \times (\mathbf{\Sigma} \cdot \mathbf{n})\, dS \end{aligned} \tag{3}$$

where $\mathbf{n}$ is the outward-pointing unit normal vector on the boundary $\partial\mathcal{P}$. $\mathbf{F}^{sub}$ and $\mathbf{T}^{sub}$ are the sub-grid hydrodynamic force and torque correction, respectively: they are computed from the linear and angular velocities of the particles using theoretical expressions and account for the unresolved (sub-grid) part of the flow. Denoting the $6N$ vectors $\boldsymbol{\mathcal{F}}^{sub} = (\mathbf{F}^{sub}, \mathbf{T}^{sub})$ and $\boldsymbol{\mathcal{U}} = (\mathbf{U}, \mathbf{\Omega})$, the generalized sub-grid force reads [1, 3]:

$$\boldsymbol{\mathcal{F}}^{sub} = -\boldsymbol{\mathcal{R}}^{sub}_{FU} \cdot \boldsymbol{\mathcal{U}} \tag{4}$$

where the resistance matrix $\boldsymbol{\mathcal{R}}^{sub}_{FU}$ depends on the particles position. Integrating the momentum equation on a particle $\mathcal{P}$ and using the rigidity constraint and the definitions of the hydrodynamic force and torque yields:

$$\begin{aligned} \mathbf{F}^{hyd} &= -\rho_f \int_{\mathcal{P}} \boldsymbol{\lambda} d\mathbf{x} + \frac{\rho_f}{\rho_p} M\frac{d\mathbf{U}}{dt} \\ \mathbf{T}^{hyd} &= -\rho_f \int_{\mathcal{P}} \mathbf{r} \times \boldsymbol{\lambda} d\mathbf{x} + \frac{\rho_f}{\rho_p} \left[\mathbf{J} \cdot \frac{d\mathbf{\Omega}}{dt} + \mathbf{\Omega} \times (\mathbf{J} \cdot \mathbf{\Omega})\right] \end{aligned} \tag{5}$$

Finally, using these expressions in Eqs. 2 provides:

$$\begin{aligned} \rho_f \int_{\mathcal{P}} \boldsymbol{\lambda} d\mathbf{x} &= \frac{(\rho_f - \rho_p)}{\rho_p} M \left[\frac{d\mathbf{U}}{dt} - \mathbf{g}\right] + \mathbf{F}^{int} + \mathbf{F}^{sub}(\mathbf{U}, \mathbf{\Omega}) \\ \rho_f \int_{\mathcal{P}} \mathbf{r} \times \boldsymbol{\lambda} d\mathbf{x} &= \frac{(\rho_f - \rho_p)}{\rho_p} \left[\mathbf{J} \cdot \frac{d\mathbf{\Omega}}{dt} + \mathbf{\Omega} \times (\mathbf{J} \cdot \mathbf{\Omega})\right] + \mathbf{T}^{int} + \mathbf{T}^{sub}(\mathbf{U}, \mathbf{\Omega}) \end{aligned} \tag{6}$$

The system of equations is split into two sub-problems. The fluid sub-problem – Eqs. 1 – is a standard Navier-Stokes problem in $\mathcal{D}$ whereas the particle sub-problem corresponding to Eqs. 4 and 6 together with the rigid body motion mainly consists in enforcing the rigid body motion inside the particles and in coupling the interaction and the sub-grid forces to the flow. These coupled sub-problems are solved using the algorithm described by Gallier et al. (2014) [3].

RESULTS

In the present study, the fluid sub-problem is solved using the open-source finite volume library OpenFOAM® on an isotropic Cartesian mesh with a constant grid spacing. The idea is to take benefit from the parallelisation facility available in OpenFOAM® to make the simulation of large systems with a high amount of particles possible. The algorithm described by Gallier et al. (2014) [3] is adapted to work under the OpenFOAM® environment, paying particular attention to the optimisation of the code. Different classical particle configurations are studied in order to validate the method.

ON THE BOUNDARY CONDITIONS IN CELL MODELS OF FILTRATION IN MEMBRANES

Daria Khanukaeva*, Leonid Ostrer, Anatoly Filippov
Department of Higher Mathematics, Gubkin Russian State University of oil and gas, Moscow, Russia

Summary The cell model used for the simulation of filtration flows in membranes requires the statement of boundary conditions on solid, porous and hypothetical liquid surfaces. In the present work the mechanical aspects of boundary conditions are discussed. The effect of slip and no-slip is analysed for a micropolar flow across a solid cylinder. Two types of conditions are compared for the porous-liquid cylindrical surface. Various types of conditions at the outer cell surface are compared for a spherical cell. Their impact on the membrane hydrodynamic permeability is demonstrated, the condition of their equivalence is formulated.

INTRODUCTION

Membrane technologies are among the most intensively developing branches of science. They deal with micro level interaction of fluids with porous media. So, understanding the specifics of these processes is of crucial importance for the development, production and exploitation of membranes.

A cell model technique introduced by Happel and Brenner [1] has become an instrument for a simulation of hydrodynamic processes in membranes. It considers a membrane as a set of identical cells. Each cell includes solid or porous or composite core and liquid shell. A filtration problem is replaced by a flow problem for a separate cell. The influence of cells on each other is taken into account by setting corresponding boundary conditions at the outer surface of the cell. The solution of the problem is used further for the evaluation of the membrane hydrodynamic permeability - a macro-characteristics which can be measured in an experiment. Recently the cell model was extended to the filtration of micropolar liquids, that is liquids with microstructure [2]. The obtained solution includes classical results as a limiting case.

All cell models consider boundary value problems (BVPs) with boundary conditions some of which are set phenomenologically. This internal property of the model influences the solution and, in turn, the interpretation of the experiment. Therefore an adequate choice of the boundary conditions in a cell model is responsible for a correct simulation of the membrane operation. The present work is devoted to the mechanical consideration, comparison and discussion of various conditions at the boundaries of the cell.

CONDITIONS ON A SOLID SURFACE

Original Happel and Brenner's cell model included a solid core and liquid envelope. The filtration flows are slow enough for the Stokes approximation to be valid. So, in the absence of the external body forces this flow is governed by the continuity and the Stokes equations:

$$\begin{aligned} &\nabla \cdot \mathbf{v} = 0, \\ &\mu \Delta \mathbf{v} = \nabla P, \end{aligned} \tag{1}$$

where $\mathbf{v}$ is the velocity vector, P is the pressure, μ is the liquid viscosity coefficient. The most widely used condition on the solid surface is the no-slip condition, while various types of slips are more and more actively used in modern models. If one considers a cylindrical cell in a uniform flow perpendicular to its axis both mentioned boundary conditions give unique solutions of the corresponding BVPs. Meanwhile, in the case of a single cylindrical obstacle in an infinite uniform flow one obtains the Stokes paradox for the no-slip boundary condition and some solution depending on the unknown slip parameter if the slip condition is used. This inconsistency is traditionally attributed to the extra simplification of the model by the Stokes approximation. On the other hand, the reason may be in the extra simplification of the liquid representation. A simple swarm of material points used for the description of a fluid in classical hydrodynamics may not represent all the aspects of a flow interaction with a solid surface.

We consider a uniform micropolar liquid flow in the same statement with the following governing equations:

$$\begin{aligned} &\nabla \cdot \mathbf{v} = 0, \\ &-(\mu + \kappa)\nabla \times \nabla \times \mathbf{v} + 2\kappa \nabla \times \boldsymbol{\omega} = \nabla P, \\ &-(\delta + \varsigma)\nabla \times \nabla \times \boldsymbol{\omega} + 2\kappa \nabla \times \mathbf{v} - 4\kappa \boldsymbol{\omega} = 0, \end{aligned} \tag{2}$$

where the viscosity coefficients $\kappa, \delta, \varsigma$ and microrotation velocity vector $\boldsymbol{\omega}$ are introduced. The hyper stick conditions ($\mathbf{v} = \mathbf{0}, \boldsymbol{\omega} = \mathbf{0}$) on the cylinder surface also lead to the Stokes paradox. No-slip only for the linear velocity results in a growth of microrotation velocity on the boundary. Besides, the slip condition for the tangential velocity component along with the impermeability condition is satisfied automatically. There is no need to introduce an artificial slip parameter, because tangential stress is proportional to the tangential component of the velocity. So, we have demonstrated that for a micropolar liquid the slip condition is equivalent to the no-slip for the linear velocity, because the energy of the translational motion transfers into microrotation on the solid-liquid boundary.

CONDITIONS AT THE POROUS-LIQUID INTERFACE

A composite cell with a solid-porous core represents a partially degraded membrane. The coupled flow problem should be considered for the regions occupied by liquid and by porous medium. System (1) in the case of Newtonian liquid flow or system (2) in the case of micropolar liquid flow should be supplemented with an appropriate system for a flow in porous medium. It includes the continuity equation and the Brinkman equation for the Newtonian liquids and the continuity equation, the Brinkman-type equation and the moment of momentum equation for the micropolar liquids [3]. The coupled liquid-porous flow problem in the framework of a cell model for a micropolar liquid and composite solid-porous-liquid cell was set and solved in [2]. In the case of fully degraded membrane the core may become fully porous, so the flow takes place in the whole volume of the membrane and porous-liquid interface plays a principal role in the formation of a flow pattern.

In the present work the problem of a uniform infinite micropolar flow across a single porous cylinder is considered. The most natural conditions on its surface are the continuity of all the velocity components and the continuity of the normal stress. The last condition can be the continuity of the couple stress or the continuity of the tangential stress. They are not equivalent and represent different mechanical properties of the considered interface. The former leads to the tangential stress on the cylinder surface and minimal disturbance of the flow when it passes the obstacle. So, the uniform flow in this case slightly deforms depending on the permeability coefficient of the porous medium. The latter, on the opposite, simulates a gel-like inclusion with zero drag. The streamlines circulate inside the cylinder like in the Hadamard-Rybchinscky problem of flow over a droplet of one liquid in another liquid.

CONDITIONS AT THE HYPOTHETICAL OUTER SURFACE OF THE CELL

Four boundary conditions at the outer surface of the cell are known in the classical cell models. They are Happel's no-stress condition, Kuwabara's vorticity-free condition, Kvashnin's condition of the velocity profile symmetry and Cunningham's condition of the flow uniformity. Analytical solution is known for each of them as well as the expression for the hydrodynamic permeability of the membrane. The question is which of them should be taken for the characterisation of the membrane and for the comparison with the flow experiment results.

In the present work all the mentioned conditions are considered in the problem of flow in a spherical cell both for Newtonian and micropolar liquid flow. All of the obtained solutions possess the following peculiarity: the tangential velocity profiles intersect in one point, that is there exists a surface inside a cell where the value of the tangential velocity is independent of the boundary condition at the outer cell surface. The existence and uniqueness of this surface was proved for a solid-liquid cell in Newtonian liquid flow [4], but it is also observed in a composite solid-porous-liquid cell and for the micropolar liquid flow.

Basing on the found peculiarity, we have formulated a hypothesis that all four mentioned conditions give equivalent estimate for the hydrodynamic permeability. In [2] it was demonstrated that the membrane porosity gives the strongest effect on the hydrodynamic permeability. So, we investigate the dependence of the hydrodynamic permeability on the membrane porosity using known solutions with the aforementioned conditions. For low porosity values (less than 20%) three of the considered conditions were found to give equal estimates of the hydrodynamic permeability in the linear approximation, while Cunningham's condition is not equivalent to them. Besides, it was proved that all conditions give substantially different estimates of the hydrodynamic permeability for high values of the membrane porosity. So, the inner structure of highly porous membranes should be analysed for an adequate choice of the mechanical model for flow modelling in them.

CONCLUSIONS

The effect of boundary conditions in classical macro scale problems is restricted by the area adjacent to the boundary. In the micro scale problems the whole flow domain is the vicinity of boundaries. Thus, the conditions set at the boundaries influence the flow dramatically. We have considered peculiarities of solid-liquid, porous-liquid interaction and specifics of the outer surface boundary conditions in cell models for the filtration processes. The micro mechanism of no-slip on a solid surface is modelled for a micropolar liquid flow. The membrane degradation process and its influence on the flow pattern was formulated using boundary condition at porous-liquid interface. The influence of the boundary conditions at the outer surface of the cell on the hydrodynamic permeability was investigated. Equivalence of three conditions was proved for low porous membranes. Substantial effect of any boundary condition was demonstrated for highly porous membranes.

STRUCTURE AND DYNAMICS OF HYDRODYNAMICALLY INTERACTING BROWNIAN PARTICLES IN A SPHERICAL CAVITY

Xikai Jiang*[1]
[1]Institute of Mechanics, Chinese Academy of Sciences, Beijing, China

Summary The structure and dynamics of confined suspensions of particles with arbitrary shapes are of interest in many disciplines. A numerical study on the diffusion of spherical and cylindrical particles in a spherical cavity is presented here. A general geometry Ewald-like method is used to capture hydrodynamic interactions between particles with arbitrary shapes, satisfy the fluctuation-dissipation theorem, and include appropriate no-slip boundary condition at the confining wall. We explore how hydrodynamic interaction, particle volume fraction and shape, and fraction of cylinders affect the equilibrium structure and diffusion of particles. We found that particles form layered aggregates near the wall that can influence particle dynamics. Hydrodynamic interactions strongly affect the particle diffusion. Our results offer fundamental insights into the dynamics and structure of proteins in cells.

INTRODUCTION

Diffusion under confinement is central to multiple physical, chemical, and biological systems, including colloidal and protein suspensions, devices for particle separation, and transport through membranes. A model system to study the diffusion and structure of highly concentrated particles under confinement could offer insights into the dynamics of crowded macromolecules, such as proteins, inside cells where they typically occupy 20 to 40% of the cytoplasm volume. Previous studies have shown that crowding between macromolecules hinders the diffusion of intra-cellular particles [1]. A previous review discussed several factors that could lead to the hindrance, including the viscosity of cytoplasm, steric effects, hydrodynamic interactions (HI), and other shortrange interactions between particles [1]. Recently, a theoretical study was used to model the behavior of a concentrated colloidal dispersion confined in a spherical cavity [2]. The authors studied the structure and diffusion of hydrodynamically interacting spherical particles confined in a spherical cavity following a Stokesian dynamics (SD) approach [3]. They concluded that confinement, particle concentration, and HI jointly contribute to the short- and long-time equilibrium transport properties of the confined suspensions. Their results included the prediction of the critical particle volume fraction where crowding effects begin to emerge. At high volume fractions, the diffusion coefficient of the particles was found to be affected by particle structure within the cavity. That study was limited to spherical particles. In this work, a numerical approach is used to study structure and dynamics of spherical and cylindrical particles in a spherical cavity.

METHOD

Let's consider N_P finite-size particles in a viscous fluid of viscosity μ, confined in a spherical cavity of radius R. The surface of each suspended particle is discretized into a set of N_S nodes that constitute a mesh. On the surface nodes, we define structural spring potentials that maintain particle shape, volume and surface. Assuming external forces/torques are zero, the force balance in the N_P particles under a zero Reynolds number condition is then translated into the $N_{IB} = N_P \times N_S$ surface nodes as follows,

$$\boldsymbol{f}_\nu^H + \boldsymbol{f}_\nu^B + \boldsymbol{f}_\nu^C + \boldsymbol{f}_\nu^{EV} = \boldsymbol{0}, \tag{1}$$

for every node $\nu = 1, \ldots, N_{IB}$; where $\boldsymbol{f}_\nu^H$ is the $3N$ hydrodynamic force, $\boldsymbol{f}_\nu^B$ is the $3N$ Brownian force, $\boldsymbol{f}_\nu^C$ is the $3N$ constitutive force and $\boldsymbol{f}_\nu^{EV}$ is the $3N$ vector with all the excluded volume interactions: particle-particle and particle-wall. Assuming that the probability density for nodal positions is continuous for the Fokker-Planck equation, an equivalent stochastic differential equation for the motion of nodes is written as follows [4],

$$d\boldsymbol{R} = \left[\boldsymbol{M}\cdot\boldsymbol{F} + \frac{\partial}{\partial \boldsymbol{R}}\cdot\boldsymbol{D}\right]dt + \sqrt{2}\boldsymbol{B}\cdot d\boldsymbol{W}, \tag{2}$$

where $\boldsymbol{R} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N)$ denotes a $3N$ vector containing the spatial coordinates of the nodes, $\boldsymbol{D} = k_B T \boldsymbol{M}$ is the $3N\times3N$ diffusion tensor, k_B is Boltzmann constant, T is the absolute temperature, and $\boldsymbol{M}$ is the $3N\times3N$ mobility tensor. In addition, $\boldsymbol{U} = \boldsymbol{M}\cdot\boldsymbol{F}$ contains the $3N$ fluctuating velocities from the hydrodynamic interactions and $\boldsymbol{F}$ is the $3N$ vector that contains the non-HI and non-Brownian forces on the nodes. The divergence of the diffusion tensor $\frac{\partial}{\partial \boldsymbol{R}}\cdot\boldsymbol{D}$ is the drift resulting from the configuration-dependent mobility of the confined particles and $d\boldsymbol{W}$ is a random vector, the components of which are obtained from a real-valued Gaussian distribution with zero mean and variance dt; $d\boldsymbol{W}$ is coupled to the diffusion tensor through the fluctuation-dissipation theorem: $\boldsymbol{D} = \boldsymbol{B}\cdot\boldsymbol{B}^{\boldsymbol{T}}$. The force distributions at moving solids are discretized as distributions of regularized point-forces. The smoothing function for the delta function scales as the distance between surface nodes that are used to represent moving particles. At each node a purely repulsive Lennard-Jones potential is used for particle-particle and particle-wall excluded volume interactions. Method details are described in Ref. [4].

RESULTS AND DISCUSSIONS

At low concentrations, the particle number density distribution is uniform in the interior of the cavity. As the concentration increases, a layered structure appears for both spherical and cylindrical particles (see left panels in Fig. 1). From right panels in Fig. 1, it was also found that long-range HI leads to a position-dependent diffusion of the particles inside the cavity; the particles diffuse faster near the center of the cavity and slower near the walls. The HI also decrease the global mobility of the suspended particles, when compared with their diffusion in the bulk. The increase in particle concentration also results in a decrease of the particles' diffusion coefficients; this effect is observed for free-draining and HI particles. However, the concentration decrease of the diffusion rate is stronger when HI are considered. Lubrication forces, or short-range HI, influence the dynamics of highly concentrated suspensions; they generate a direction dependent diffusion, where particles diffuse at a lower rate when moving towards the walls than when moving parallel to the walls. The no-slip conditions at the walls, i.e. zero particle mobility, work synergistically with lubrication forces, resulting in an stronger wall dependence of the diffusion coefficients in the radial direction. Importantly, lubrication gives rise to a sub-diffusive regime (crowded mobility) at high particle concentrations. The sub-diffusive regime, characterized by the diffusion-to-crowded transition time and the mobility power law exponent, becomes more prominent as the concentration increases.

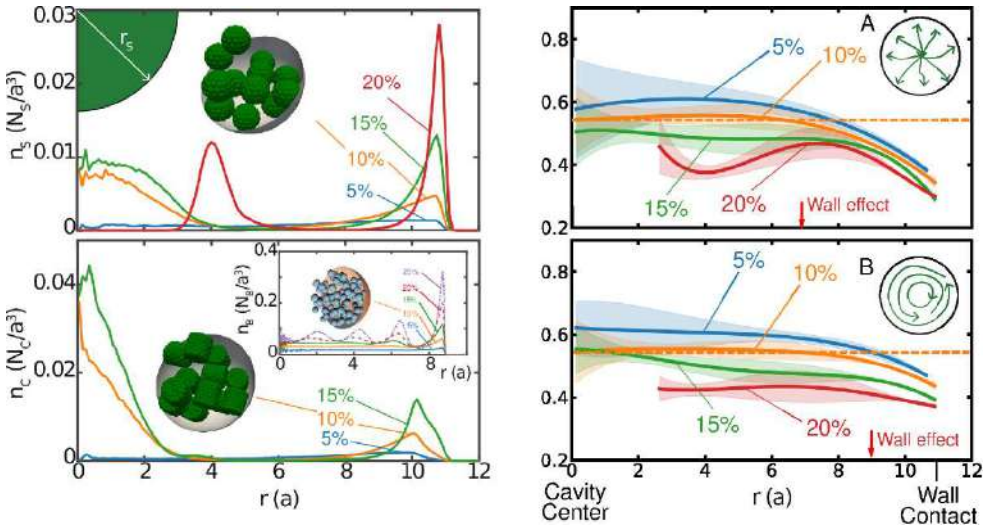

Figure 1. (left) Number density of particles in a spherical cavity of radius R = 15 as a function of particle concentration. (left-top) Spheres with radius r_S = 3; (left-bottom) cylinders with radius r_C = 2.62 and height $h_C = 2r_C$. Snapshots for volume fraction ϕ_{HI} = 10% are shown for both systems, while number density of HI "beads" is included in the inset. (right) Short-time diffusion coefficients for spherical particles (r_S = 3) that are confined in a spherical cavity with R = 15. (right-top) Radial diffusivity and (right-bottom) tangential diffusivity. The coefficients are normalized by the diffusivity of a spherical particle in bulk at infinite dilution, $k_BT/(6\pi\mu r_S)$. The orange dashed line represents averaged "inner" diffusivities for ϕ_{HI} = 10%. The filled shadow area around each curve represents their statistical errors.

CONCLUSIONS

The structure and dynamics of hydrodynamically interacting Brownian particles in a spherical cavity were studied using numerical simulations. Results for spherical and cylindrical particles were obtained and compared. It was found that particle volume fraction, particle shape, and hydrodynamic interactions between particles have important effects on particle density distributions and short- and long-time diffusions.

Summary The energy cost for transporting suspensions in micro-channels may be reduced by using slipping walls. A theoretical model is presented here for the effective viscosity, μ_{eff}, of a dilute suspension of freely suspended identical solid no-slip spherical particles carried by a Poiseuille flow between parallel slip walls. Compared with no-slip walls (Feuillebois et al., *J. Fluid Mech.*, 800:111, 2016), this viscosity strongly depends on the ratio of the wall slip length to particle radius, λ/a, for given ratio of the gap between walls to particle diameter $H/(2a)$: in the very confined case $H/(2a) = 2$ and for a very large slip $\lambda/a = 1$, the suspension intrinsic viscosity $[\mu] = (\mu_{\text{eff}} - \mu_0)/(\mu_0\phi)$, where μ_0 is the fluid viscosity and ϕ is the low suspension volume fraction, is divided by 3 compared with the no-slip case and divided by 5 compared with Einstein's result (5/2) for an unbounded suspension.

The effective viscosity of a confined flowing suspension is the relevant quantity to consider for particle transport (see e.g. [1] [2]). This viscosity depends on the suspension volume fraction and on the ambient flow field. Assuming a dilute suspension (i.e. at small volume fraction $\phi \ll 1$) of either spherical or elongated particles and a high-frequency ambient flow field, in the sense that all particles occupy all possible positions and orientations with equal probability, made it possible to calculate the suspension effective viscosity in Couette [3] and Poiseuille [4] flows between two parallel planar no-slip walls.

The same approach is used here for slip walls and no-slip spherical particles. On each wall the impermeability condition reads $\mathbf{u} \cdot \mathbf{n} = 0$ where $\mathbf{u}$ is the fluid velocity and $\mathbf{n}$ is the unit vector normal to the wall and pointing into the liquid. The usual Naviers's [5] slip boundary condition is applied on each wall:

$$\mathbf{u} = \lambda \frac{\partial \mathbf{u}}{\partial n}\,, \tag{1}$$

where $\lambda \geq 0$ is the wall slip length, assumed to be uniform and identical for both walls and n is the normal coordinate along $\mathbf{n}$. The Poiseuille flow velocity profile $u_0(z)$ with these slip conditions (1) on walls W_1, W_2 is sketched in Fig. 1.

The average pressure drop for driving particles in this flow field is derived by using Lorentz reciprocal theorem. The suspension effective viscosity is obtained from the relationship between this pressure drop and the volume flow rate. The result for the suspension intrinsic viscosity $[\mu]$ (defined in the summary) is:

$$[\mu] = \frac{9}{4\pi\left(1 + 6\dfrac{\widetilde{\lambda}}{\widetilde{H}}\right)\left(\widetilde{H} - 2\right)} \int_1^{\widetilde{H}-1} \left[\left(1 - 2\frac{\widetilde{z}_c}{\widetilde{H}}\right)\widetilde{S}_{xz} - \frac{1}{\widetilde{H}}\widetilde{Q}_{xzz}\right] d\widetilde{z}_c\,, \tag{2}$$

where $\tilde{H}, \tilde{\lambda}, \tilde{z}_c$ are made dimensionless with a sphere radius a. We denote $\widetilde{H}$ the normalized gap between walls and $\widetilde{z}_c$ the normalized position of the centre of a test particle (see Fig. 1). Eq. (2) involves (as is classical for the viscosity of suspensions) the stresslet component S_{xz} on a particle, that is a symmetric first moment of stresses on its surface. It also involves the quadrupole component Q_{xzz}, second moment of stresses. The normalized components of the stresslet $\widetilde{S}_{xz}$ and quadrupole $\widetilde{Q}_{xzz}$ appearing in (2) are defined as $\widetilde{S}_{xz} = S_{xz}/(\mu_0 a^3 k_1)\,, \widetilde{Q}_{xzz} = Q_{xzz}/(\mu_0 a^4 k_1)$, where k_1 is the linear shear rate at wall W_1.

Taking into account the full interactions of a sphere with both slip walls is not presently accessible. Two single-wall models are used here: the "nearest wall" (nw) and "wall superposition" (ws) approximations. The stresslet and quadrupole on a sphere near a single slip wall are calculated from analytical solutions of the Stokes equations in bispherical coordinates [6, 7]. Both nw and ws models are validated by comparing to earlier accurate results [3, 4] in the case of no-slip walls.

The suspension intrinsic viscosity $[\mu]$ is evaluated in the range $2 \leq H/(2a) \leq 100$ and $\widetilde{\lambda} \leq 1$. It depends strongly on $\widetilde{\lambda}$ for small $H/(2a)$, as detailed in the summary and shown in Fig. 2. The main contribution to the dependence on $\widetilde{\lambda}$ comes from the factor $1/(1 + 6\widetilde{\lambda}/\widetilde{H})$ in (2), which is independent of particle-wall interaction. This strong variation of $[\mu]$ on $\widetilde{\lambda}$ may have practical applications for particle transport in microfluidics. A handy fitting formula for $[\mu]$ is provided. Finally, outlooks for experiments are proposed: for instance, a non-optical microcapillary rheometer [8] may allow to measure first the slip length in pure fluid and then the suspension effective viscosity for comparison with the present theory. Details of this paper are available in [10].

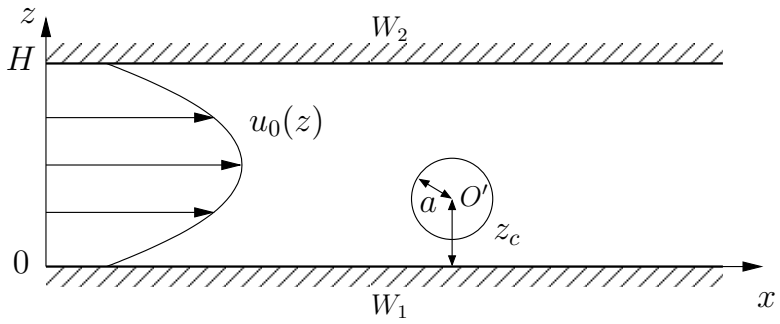

Figure 1: Sketch of a single sphere with centre O' and radius a freely suspended in a Poiseuille flow between two parallel solid slip walls W_1 and W_2.

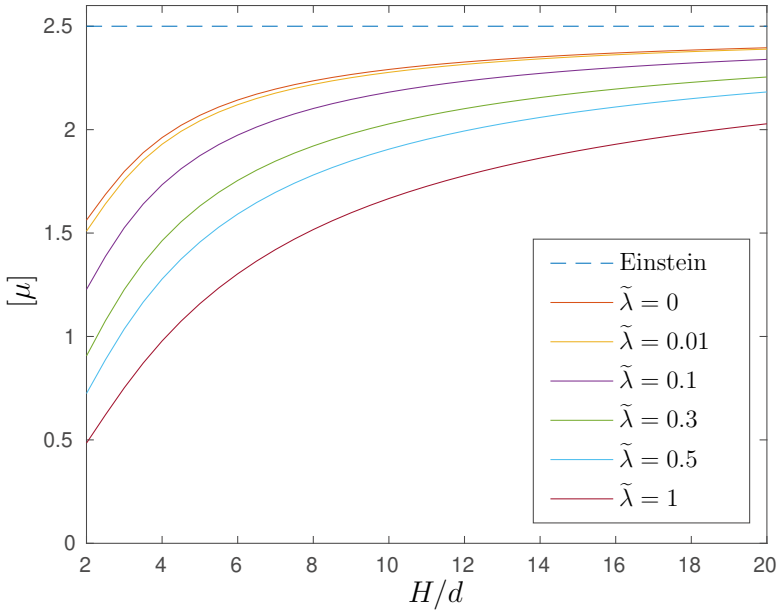

Figure 2: Variations of the suspension intrinsic viscosity $[\mu]$ calculated with the "wall superposition" model versus H/d (with $d = 2a$) for various values of $\widetilde{\lambda}$. From top to bottom: Einstein's [9] result 5/2 for an unbounded suspension and present results for a bounded suspension with $\widetilde{\lambda} = 0, 0.01, 0.1, 0.3, 0.5, 1$.

INCLUSION OF HYDRODYNAMIC WALL EFFECTS IN CONTINUUM MODELS OF MICROORGANISM SUSPENSIONS

Michael Gravatt[1], Alys Clark[2], Vinod Suresh[1,2], and Richard Clarke*[1]
[1]Department of Engineering Science, University of Auckland, Auckland, New Zealand
[2]Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand

Summary The absence of hydrodynamic interactions between swimming microorganisms and solid boundaries is a known issue with existing continuum models for cell suspensions. Using flow singularity representations, together with their image systems, we simulate the extent to which hydrodynamic wall effects influence average cell orientations. We then proceed to show that existing continuum models can give accurate predictions for cell concentrations in confined suspensions when they use these cell orientation fields.

INTRODUCTION

In recent years there has been a great deal of interest and activity in developing continuum-level models capable of describing suspensions of swimming microorganisms. Such models are useful since these kinds of active suspensions pervade almost every facet of daily life, and have implications in areas ranging from healthcare to bioprocessing. While the existing models have enjoyed success in describing a number of phenomena, one recognised shortcoming is the neglect of hydrodynamic interactions between cells and solid surfaces in confined settings, which are known to affect the swimming motion of individual cells. We address this issue here by providing a means by which wall hydrodynamics can be incorporated into existing continuum models.

FORMULATION

Microorganism Flowfield

We adopt the following flow singularity approximation for the flow field $\boldsymbol{V}$ generated by a squirming microorganism of radius $a \ll 1$, located at $\boldsymbol{x}'$ and swimming with constant speed V_c in a direction $\boldsymbol{p}$ in the vicinity of a nearby horizontal solid surface [1]

$$V_i(\boldsymbol{x}) = a^3 B_1 p_j D_{ij} + a^2 B_2 S_{jk} U_{ijk} + V_i^I + O(a^4) \tag{1}$$

where

$$S_{ij} = \frac{4\pi}{3}\left(p_i p_j - \frac{\delta_{ij}}{3}\right), \quad U_{ijk} = \frac{3\hat{x}_i\hat{x}_j\hat{x}_k}{\hat{r}^5}, \quad D_{ij} = -\frac{\delta_{ij}}{3\hat{r}^3} + \frac{\hat{x}_i\hat{x}_j}{\hat{r}^5} \tag{2}$$

($\hat{\boldsymbol{x}} = \boldsymbol{x} - \boldsymbol{x}'$, $r = |\hat{\boldsymbol{x}}|$, δ_{ij} is the Kronecker delta) are, respectively, the squirmer stresslet, the symmetric component of the force-dipole and the potential dipole flow field. The coefficients B_1 and B_2 characterise the cell's swimming action. The image systems for these singularities that make up V_i^I ensure that no-slip and no-penetration conditions are satisfied on the nearby wall, and are given by [2], [3]. By comparison with full numerical simulation of finite-sized cells near a solid boundary, we can show that the above singularity representation provides a reasonable approximation.

Cell Conservation Model

We now consider a semi-dilute suspension of squirming micro-organisms contained between no-slip walls at $z = \pm H_z$. We assume that the suspension is homogeneous in the horizontal directions (x, y), and that vertical variations in cell concentrations, $n(z)$, satisfy the classical steady cell conservation model [4]

$$\frac{dJ}{dz} = 0, \quad J = D\frac{dn}{dz} - \left(V_c \langle p_3(z)\rangle + W\right) n \tag{3}$$

subject to $J(\pm H_z) = 0$, where $\langle p_3(z)\rangle$ is the steady average vertical component of orientation. Cell-wall and cell-cell hydrodynamic interactions lead to an additional advective flow $\boldsymbol{W}$. However, the hydrodynamic effect of the wall is much greater on $\langle p_3(z)\rangle$, and consequently it is on this that we focus in what follows. In the standard cell conservation model $\langle p_3(z)\rangle$ is governed by a Fokker-Planck equation, while observing appropriate kinematics. In the absence of any biases (as is the case here) this approach predicts $\langle p_3(z)\rangle = 0$. We instead use Discrete Particle Simulations (DPS) to determine $\langle p_3(z)\rangle$ in the presence of cell-wall hydrodynamic interactions.

*Corresponding author. E-mail: rj.clarke@auckland.ac.nz

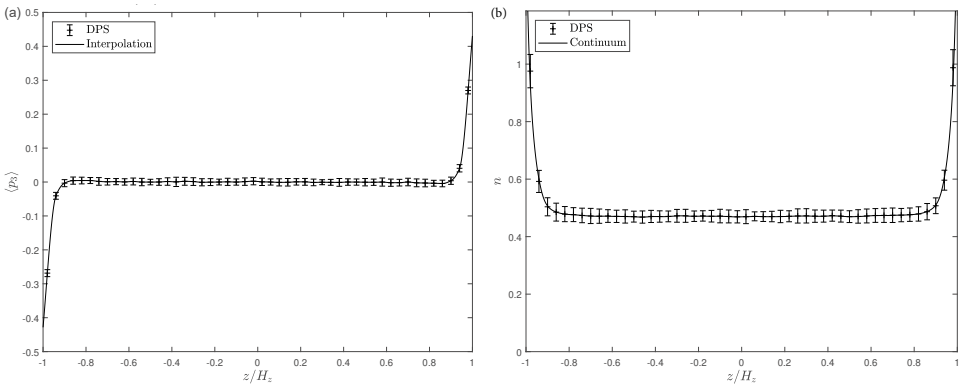

Figure 1: (a) Average vertical component of orientation as a function of vertical position, as computed using Discrete Particle Simulations (walls lie at $z/H_z = \pm 1$) (b) Cell concentration as function of vertical position, as computed explicitly using both Discrete Particle Simulation (markers) and the cell conservation model (3) with cell orientation field informed by DPS (solid line). In both cases the cell is swimming at one body length per second, $D_r = 0.13$, $D = 1.3$ and $B_2/B_1 = -1$. Bars indicate 95% confidence intervals.

Discrete Particle Simulations

The Discrete Particle Simulations explictly track the dynamics of N squirmers, their motions being governed by:

$$\frac{d\boldsymbol{x}_j'}{dt} = V_c \boldsymbol{p}_j + \boldsymbol{\eta}_j + \sum_{k=1}^{N} \boldsymbol{V}_k^I + \sum_{k=1,k\neq j}^{N} \boldsymbol{V}_k, \quad \frac{d\boldsymbol{p}_j}{dt} = \boldsymbol{\xi}_j + \frac{1}{2}\sum_{k=1}^{N} \boldsymbol{\Omega}_k^I \times \boldsymbol{p}_k + \frac{1}{2}\sum_{k=1,k\neq j}^{N} \boldsymbol{\Omega}_k \times \boldsymbol{p}_k \tag{4}$$

($j = 1, \ldots, N$) where $\boldsymbol{V}_k$ and $\boldsymbol{\Omega}_k$ are, respectively, the flow velocity and vorticity fields generated by the kth squirmer, i.e. in addition to their self-motility, cells are advected by the flows due to the other cells, and flow field images in the walls. Diffusion is captured via stochastic terms $\boldsymbol{\xi}_j$ and $\boldsymbol{\eta}_j$, sampled from the conditional probability distributions

$$P_1(\theta, t|\theta_0, t_0) = \frac{A}{\sqrt{D_r(t-t_0)}} \exp\left(-\frac{(\theta-\theta_0)^2}{4D_r(t-t_0)}\right) \sin(\theta - \theta_0), \tag{5}$$

$$P_2(z, t|z', t_0) = \frac{1}{\sqrt{4\pi(D(t-t_0))}} \left[\exp\left(-\frac{(z-z')^2}{4D(t-t_0)}\right) + \exp\left(-\frac{(z+z'+2H_z)^2}{4D(t-t_0)}\right) + \exp\left(-\frac{(z+z'-2H_z)^2}{4D(t-t_0)}\right)\right], \tag{6}$$

respectively. P_2 accounts for non-hydrodynamic cell-wall interactions through a biased random walk in z (randon walks in x and y are unbiased), and D_r is the rotational diffusivity. Long-time averages over multiple realisations are then taken to determine $\langle p_3(z) \rangle$ and $n(z)$.

RESULTS

Figure 1(a) shows the average vertical component of the cell orientation field as a function of depth within the suspension as computed using DPS. Whereas classical continuum models, which do not account for wall hydrodynamics, would predict no orientational bias ($\langle p_3(z) \rangle = 0$), we can see that these hydrodynamics interactions lead to an average turning of the cells towards the walls. The consequences of this effect on the cell concentration can be seen in Figure 1(b), where an elevation in cell levels close to the walls is observed. By contrast, the continuum model (3) with $\langle p_3(z) \rangle = 0$ would predict a constant cell concentration profile through the suspension. However, we see that when the $\langle p_3(z) \rangle$ computed using DPS is used, the non-constant cell concentration predicted by DPS can be recovered.

CONCLUSIONS

These results illustrate the extent to which hydrodynamic interactions with solid surfaces can affect the bulk concentration of cells, and also suggest that these effects can be captured in the standard continuum models when the wall-influenced cell orientations are used. Here we have computed these steady orientations by numerically time evolving (4), however, it may be possible to derive these more directly by setting to zero the left-hand side of (4b) and solving.

TRANSITION FROM CLOGGING TO CONTINUOUS FLOW IN CONSTRICTED PARTICLE SUSPENSIONS

Mathieu Souzy*[1], Iker Zuriguel[2], Alvaro Marin[1]
[1]Physics of Fluids, University of Twente, The Netherlands
[2]Departamento de Física, Facultad de Ciencias, Universidad de Navarra, Spain

Summary When suspended particles are pushed by liquid flow through a constricted channel they might either pass the bottleneck without trouble or encounter a permanent clog that will stop them *forever*. However, they may also flow intermittently with great sensitivity to the neck-to-particle size ratio D/d. In this work, we experimentally explore the limits of the intermittent regime for a dense suspension through a single bottleneck as a function of this parameter. Using high-resolution and high-speed optical video microscopy in a microfluidic constriction, we reveal that there is a sharp transition from a clogged state to a continuous flow, where clog does not develop at all.

MANUSCRIPT PREPARATION

When people, animals, or particles are forced through a constriction, the flow may become intermittent due to the development of clogs that obstruct the constriction. Despite the diverse nature and scale of these systems – including hungry sheep herds [1], pedestrian crowds trying to escape a room in a life-and-death situation[2], discharge of dry granular silos [3], suspended hydrated particles transported through pipelines, electrons passing through nanoconstrictions on a liquid helium surface, sand hourglasses[4], or mice escaping a water pool – a distinctive phenomenology is always observed: particles or bodies flow in erratic bursts separated by short period of arrest (see Fig 1). The analogy is not only qualitative, and in all cases the number of escapees per burst follows an exponential distribution, and the probability distribution of time lapses separating the passage of consecutive bodies seems to exhibit a power-law tail with characteristic exponents that depend on diverse system parameters [1].

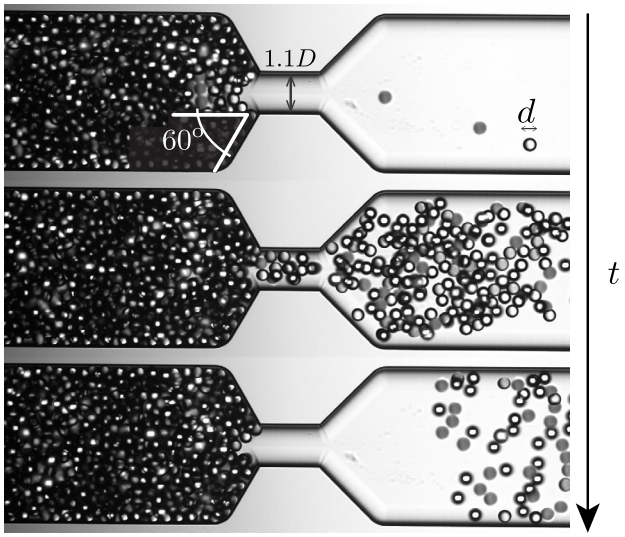

Figure 1: Successive snapshots of a burst in a suspension of particles with a diameter d that intermittently flow through a constriction – having a neck width $1.1D$ and height D – by a volume-driven flow ($D/d = 3.03$). From top to bottom: clog previous to the burst, burst, and clog after the burst.

In our work [5], we experimentally investigate the flow of a suspension getting through a constriction. We explore the critical sensitivity of the intermittent particle flow on the neck-to-particle size ratio D/d by using high-resolution and high-speed optical video microscopy in a microfluidic device. The fluidic system consists of a transparent straight channel of borosilicate glass with a rectangular cross-section which reduces to an almost square cross-section of $100 \times 110\,\mu\text{m}^2$ to form the neck.

As can be seen on Figure 2, the spatio-temporal diagrams at the constriction neck reveal a qualitative difference in the flow behavior: from a blocked situation (top diagram) to uninterrupted particle flows (bottom diagram). For $D/d \leq 2.43$ only few particles (which appear in dark) escape before a clog is formed. As D/d is increased, the intermittent particle flow regime emerges and the flowing intervals become longer and more abundant. This regime persists until the flow becomes continuous, so the bursts intermittency becomes unmeasurable. In our system, the intermittent flow is thus observed for $2.43 < D/d < 5.26$.

*Corresponding author. E-mail: m.p.j.souzy@utwente.nl

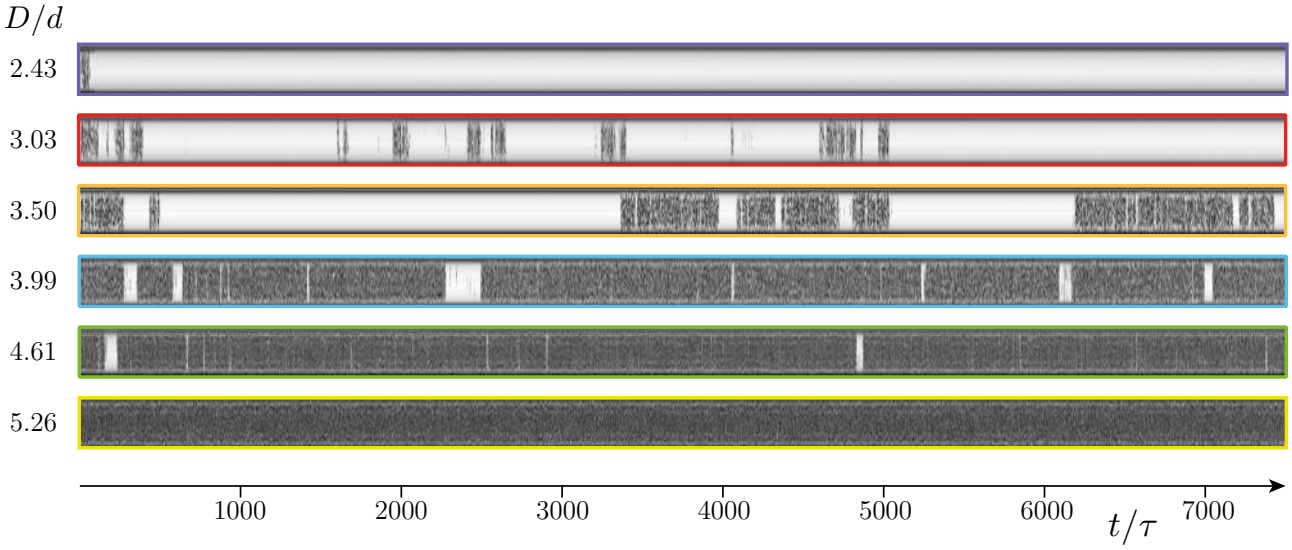

Figure 2: Spatio-temporal diagrams at the constriction neck for various D/d. For $D/d \leq 2.43$ only few particles (which appear in dark) escape before a permanent clog is formed. When increasing D/d, intermittent particle flow is observed, eventually reaching particle continuous flow for $D/d \geq 5.26$. Time is normalized by the Stokes time τ a particle takes to travel its own diameter.

Furthermore, we make use of high time- and space-resolution experiments to obtain the distributions of arrest times (T) between successive bursts, which display power-law tails ($\propto T^{-\alpha}$) with characteristic exponents. These exponents compare well with the ones found for as disparate situations as the evacuation of pedestrians from a room, the entry of a flock of sheep into a shed or the discharge of particles from a silo. Nevertheless, the intrinsic properties of our system (i.e. channel geometry, driving and interaction forces, particle size distribution) seem to introduce a sharp transition from a clogged state ($\alpha \leq 2$) to a continuous flow, where clogs do not develop at all. This contrasts with the results obtained in other systems where intermittent flow, with power-law exponents above two, were obtained.

In addition, we also plan to address the question of the physics behind clogging arches break out by investigating the pressure signal during both clog-construction and clog destruction process. This should help to clarify furthermore the crucial role of the driving force (the suspending fluid dragging the dispersed particles). Indeed, although the phenomenological behavior of a suspended flow is similar to that of dry cases (like the discharge of a silo), the interactions between the particles are strongly affected by the presence of the fluid. By monitoring the pressure signal, we ambition to investigate if there is a signature of the clogging process which could be used to predict clogging, which would make a remarkable diagnostic tool to avoid clogging (by interrupting the flow for instance) for a broad range of applications.

CONCLUSIONS

To conclude, our study [5] show that volume-driven flow of dense non-adhesive particle suspension going through a constriction exhibits intermittent flow behavior with a striking similarity as in dry granular matter [3, 4], human crowds [2], or animal herds [1]. At low Reynolds number and in the absence of particle aggregation or particle/wall adhesion, the geometry of the system (neck-to-particle size ratio and constriction angle) prescribes the flow regime entirely. At low D/d the flow is quickly interrupted by the formation of stable particle arches spanning the constriction, while at large D/d the flow is continuous and no stable arches develop (at least in the experimental timescale). A transitioning intermittent regime is reported for $2.43 < D/d < 5.26$, for which we have investigated the distribution of the time lapse T/τ between the passage of consecutive particles. The distribution displays a characteristic power-law tail $\propto (T/\tau)^{-\alpha}$ with values of α below two in all cases. This is an unexpected result which implies that for our system, even when flow is intermittent, a permanent clog may occur. Therefore, our system exhibit a remarkable sharp transition from a clogged state (when there is a non-zero probability that a permanent clog eventually occurs) to a continuous flow for $D/d \approx 5$.

Summary Elucidating the physics behind the morphological and orientation dynamics of single, elastic polymers in viscous flows is key to the understanding of the complex rheological phenomena found in polymer solutions (shear thinning, normal stress differences, etc) and of a wealth of biophysical processes (cilia and flagellar propulsion, intracellular streaming). In the last decades, the study of elastic filaments in shear flows at low Reynolds number has been mainly limited to simple shear [1, 2] and straining flows [3]. Depending on the mechanical properties of the polymer, various dynamics have been reported. Together with tumbling motion, flexible and semi-flexible polymers usually show morphological transitions, which stems from a balance between flow induced stresses, bending elasticity and thermal fluctuations. Examples include the coil–stretch [4] and stretch–coil [3] transitions in pure straining flows, and elastic shear-induced transitions [1, 2] and irregular tumbling motion in simple shear flows. In this work, we combine fluorescence microscopy experiments and computational modeling to study the dynamics and conformation transitions of elastic Brownian actin filaments in oscillatory flows in a microfluidic channel. The use of a pulsatile flow adds a new time scale associated with the oscillation, and is motivated by the relevance of non-steady flows in biological processes [5] (cardiovascular flows, nutrient and waste transport in animals, growth and motion of cells) and on-chip applications [6] (particle sorting, focusing and mixing, microrheology and clog mitigation).

MATERIALS AND METHODS

We follow standard protocols for the polymerization of fluorescent actin filaments. They are observed in an inverted microscope equipped with an high NA water-immersion objective, at a distance of $\approx$150 µm from the bottom wall of a vertical Hele-Shaw cell, whose width W =150 µm, is much larger than the typical dimension of the deformed filaments (5 to 20 µm). In these conditions, the filaments experience a 2-D flow gradient in the observation plane, with a shear rate that can be approximated as uniform along the centerline. A sinusoidal shear rate $\dot{\gamma}(t) = \dot{\gamma}_M sin\left(\frac{2\pi}{T}t\right)$, with amplitude $\dot{\gamma}_M$ of 0.5-5 s^{-1}, is imposed by applying an oscillatory external pressure using a couple of commercially available pressure controllers. We vary the oscillations period T from 1 to 10 s. The filaments centerline $r(s,t)$, parametrized by arclength s, is extracted from time-lapse images through a custom-made image segmentation algorithm. We compute the gyration tensor as:

$$G_{i,j}(t) = \frac{1}{L}\int_0^L \left[r_i(s,t) - \bar{r}_i(t)\right]\left[r_j(s,t) - \bar{r}_j(t)\right] ds \tag{1}$$

where $\bar{r}(t)$ is the instantaneous center-of-mass position and L the filament contour length. The eigenvectors of the gyration tensor are used to find the mean filament orientation angle χ with the flow direction, while its eigenvalues (λ_1,λ_2) are used to compute a sphericity parameter $\omega = 1 - 4\lambda_1\lambda_2/(\lambda_1 + \lambda_2)^2$, which varies from $\omega = 1$ for a straight shape to $\omega = 0$ for a nearly isotropic configuration.

RESULTS

A constant shear rate can be represented as a linear superposition of a rotational flow and an elongational flow, with equal magnitude. While the pure rotational part is responsible for the tumbling motion of the filament, the elongational part can be further split into a compression region and an extensional region. In a sinusoidal flow, however, every half period the flow reverses its direction, leading the compression and extensional quadrant to be inverted. In Fig.1a are reported two typical image sequences of a 12 µm actin filament during a single oscillation. Here, the imposed maximum viscous stresses ($\dot{\gamma}_M = 3.7\,s^{-1}$) are large enough to overcome bending resistance [2], and hence we observe strong deformations. In both cases, the initial orientation ($\chi_0 = \chi(t=0)$) lies in the compression quadrant ($\pi/2 \leq \chi_0 \leq \pi$). Despite a small difference in χ_0, one can observe a different evolution of the orientation angle. The filament in the upper panel is trapped in the compression and extensional quadrants for $0 < t < T/2$ and $T/2 < t < T$, respectively. As a consequence, a continuous buckling of the polymer is found in the first half cycle, while a continuous stretching occurs in the remaining part of the period. We call this deformation dynamics as a CB-CS pair (Continuous Buckling-Continuous Stretching). A different situation is found in the second example (lower panel). Here, the rotation induced by the shear is large, and the filament crosses the boundary between the compression and extensional quadrant. As a result, at the

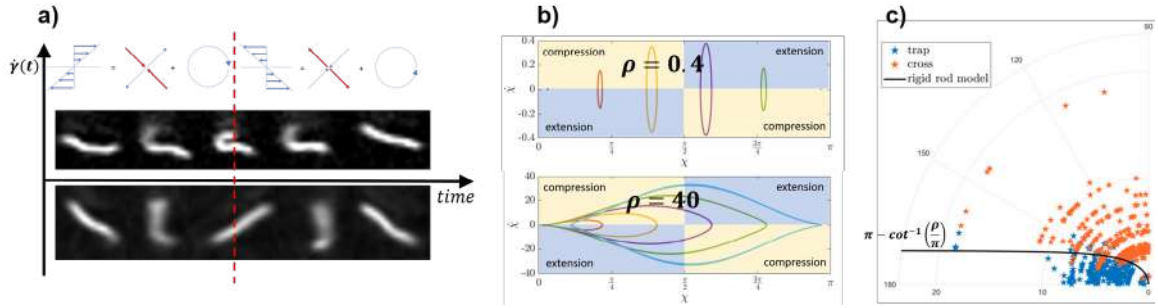

Figure 1: (a) Typical image sequences of a deformed actin filament during a sinusoidal shear rate. (b) Orbits in the (χ,$\dot{\chi}$) phase space of a rigid rod in an oscillatory shear flow, for two different dimensionless periods ρ (see text). (c) Polar plot showing the probability for a filament of being trapped in the compression quadrant, as a function of initial orientation and dimensionless period.

beginning of each half period, it is always initially oriented along the compression axis, and thus can be deformed and stretched twice during one period. We call this event as a Buckling-then-Stretching pair (BTS-BTS). In order to describe the orientation and deformation dynamics of the filaments, we first consider the simplest possible model for a fiber in a simple shear flow: the rigid rod model, which can be derived by the solution of Jeffery's equation in the limit of infinite aspect ratio. The evolution of the rod orientation in 2-D is governed by:

$$\dot{\chi}(t) = \dot{\gamma}(t) sin^2(\chi(t)) \tag{2}$$

The solution to the above ODE:

$$\chi(t) = cot^{-1}\left[cot(\chi_0) + \frac{\rho}{2\pi}\left(1 - cos(\frac{2\pi}{T}t)\right)\right], \tag{3}$$

with $\rho = \dot{\gamma}_M T$, is independent of the filament length L. In the (χ,$\dot{\chi}$) phase space, Eqs. 3 and 2 correspond to closed orbits, whose shape depends on the initial orientation χ_0 and dimensionless period ρ. As illustrated in the upper panel of Fig. 1b, for small ρ, the oscillations are confined to a small range of orientation around the initial configuration. As ρ increases (bottom panel), the phase-portraits extend and eventually span the whole orientation quadrant. Based on such orbits, we compute the probability to change shear quadrant during a semi-period, given any initial filament orientation $\chi_0 \in [\pi/2, \pi]$. For a given ρ, we found two distinct angular intervals, separated by:

$$\chi_0^\star(\rho) = \pi - cot^{-1}\left(\frac{\rho}{\pi}\right) \tag{4}$$

When $\chi_0 \geq \chi_0^\star$, the filament is trapped in the compression quadrant, while if $\chi_0 < \chi_0^\star$, it can sample the whole phase space. Eq. 4 determines a boundary between two regions in a polar plot (ρ,χ_0), which can be tested against our experimental data, obtained for different combination of $\dot{\gamma}_M$ and T, and for various L. As shown in Fig. 1c, the agreement is excellent, suggesting that the orientation dynamics of semi-flexible filaments is not strongly affected by the deformation, as also reported in a recent work [1].

Based on the above observations, we expect the deformation dynamics to dependent on the couple (ρ,χ_0). In particular, we expect the trapping region to be associated with CB-CS events, while the crossing region to BTS-BTS pairs. We have tested these predictions. The scenario is qualitatively in accordance with our expectations, although the transition is blurred from the presence of rotational diffusion. Moreover, a second transition to simple tumbling motion is found for initial angles close to $\pi/2$. In these region, filaments rotate so fast that they rapidly reach the extensional quadrant before any deformation is possible. We also perform numerical simulations matching the experimental conditions, using inextensible Euler–Bernoulli beam theory and nonlocal slender-body hydrodynamics in the presence of thermal fluctuations [2]. We observe a good agreement between experimental results and simulations.

[3]Department of Mechanical Engineering, University of Alberta, Edmonton, Canada

Summary Simultaneous use of a high frequency alternating electric field and a laser induced heat source generates vortex flows inside microfluidic channels which can be used for manipulating particles at the micro- and nano- length scales, including live cells and biomolecules. Here, we present a theoretical model to describe the hydrodynamics of this phenomenon. Semi-analytical solutions for the temperature, pressure and velocity fields have allowed us to systematically analyse the effect of relevant material properties and experimental parameters. Further we have studied the flow patterns under the influence of two heating sources to address their potential interference. Results from this work provide useful insights into the design of efficient rapid electrokinetic patterning techniques using opto-electrothermally induced vortex flows.

INTRODUCTION

Opto-electrothermal tweezers (OETTs) represent an interesting hydrodynamic phenomenon, wherein opto-electrothermally activated and maintained microscale vortices can be used effectively as tweezers for manipulating matter at the micro- and nano- length scales. The typical experimental set-up for generating such flows consists of two Indium tin oxide (ITO) coated glass slides separated by spacers forming a microfluidic channel. The ITO acts as the electrodes to which an external high frequency AC field is applied. The microfluidic channel is filled with an electrolyte solution, typically aqueous KCl. On simultaneous application of a highly focused laser beam (wavelength: 1064nm) on the surface of the electrode, vortices are generated inside the microfluidic channel, with a stagnation zone on the optical axis at the surface of the irradiated electrode (Figure 1a). Particles of micron and sub-micron length scales suspended in the electrolyte are transported via viscous drag and subsequently trapped in the stagnation zone. By modulating the optical landscape, the aggregation of trapped particles can be manipulated non-invasively. This phenomenon, originally devised for manipulating colloidal assemblies, is also known as Rapid Electrokinetic Patterning (REP) [1].

The physical mechanism behind the phenomenon is as follows. The incident laser creates localized heating of the electrode, generating thermal gradients of the order of 10^5 K/m in the electrolyte. This creates local perturbations in the electrical permittivity and conductivity of the fluid, which is manifested in the form of a volumetric force. As a result, toroidal micro-vortices form which are capable of trapping particles. The strength of the micro-vortices, measured in terms of the fluid velocity is a function of the material properties of the electrode and electrolyte such as electrical and thermal conductivities, as well as experimental parameters, such as the frequency of the AC field, and the heating profile of the laser source. Despite experimental efforts and some direct simulations of particular systems, there has not been a systematic investigation on the nature of the governing equations and dependence of the temperature and velocity fields on physical parameters. We fill this gap by developing a rigorous theoretical model, semi-analytical solution and detailed parametric analysis.

MATHEMATICAL MODEL

The OETT problem can be decomposed into two sub boundary value problems (BVPs), which are thermal and hydrodynamic respectively. The thermal problem describes the temperature field in the fluid which is essential for computing the volumetric opto-electrothermal force. Heat transfer in the fluid is conduction dominated as the thermal Peclet number is small, $\sim O(10^{-3})$. The hydrodynamic problem describes the fluid flow in the system due to the volumetric force, which is coupled to the thermal problem by the Stokes equation, as the Reynolds number for the flow is small, $\sim O(10^{-3})$. Non-dimensionalization of the BVPs identifies six governing dimensionless parameters: ϕ (ratio of thermal conductivity of the fluid to that of the electrode), ν (dimensionless absorption coefficient of the electrode towards laser radiation), δ (dimensionless electrode thickness), λ (dimensionless width of the laser beam), κ (a dimensionless Coulombic forcing which depends on the electrical conductivity and permittivity of the fluid, and the AC frequency) and the Biot number Bi accounting for thermal convection between environment and the device. ϕ and ν can be modulated by the selection of materials, δ and λ are mainly controlled by experimental set-up, and κ is influenced by both materials and operating conditions. Noting axisymmetry about the optical axis, the thermal BVP can be solved using the Hankel transformation resulting in a semi-analytical solution in closed-form. The hydrodynamic BVP has been solved using the finite volume method in the cylindrical coordinate system.

RESULTS

Flow pattern predicted from the proposed model agrees well with experimental results; a qualitative comparison can be seen from Figures 1b and 1c. Using the same non-dimensionalization introduced in the modelling we can collapse the

*Corresponding author. E-mail: ttang1@ualberta.ca

experimental data (temperature and velocity obtained with different AC fields and laser powers) onto a single curve which agrees well with the solution from the model (comparison not shown). The model also allows us to systematically study the effects of the six dimensionless parameters identified earlier. The parametric analysis is useful in understanding how the hydrodynamics of opto-electrothermal micro-vortices can be modulated by designing material and experimental parameters. For example, a linear relationship is found between κ and the magnitude of dimensionless velocity (see Figure 1d for the point located on the optical axis midway between the two electrodes). Because κ depends on the frequency of the AC field, this allows for precise control of the velocity using the AC frequency, compared to the commonly used control using voltage.

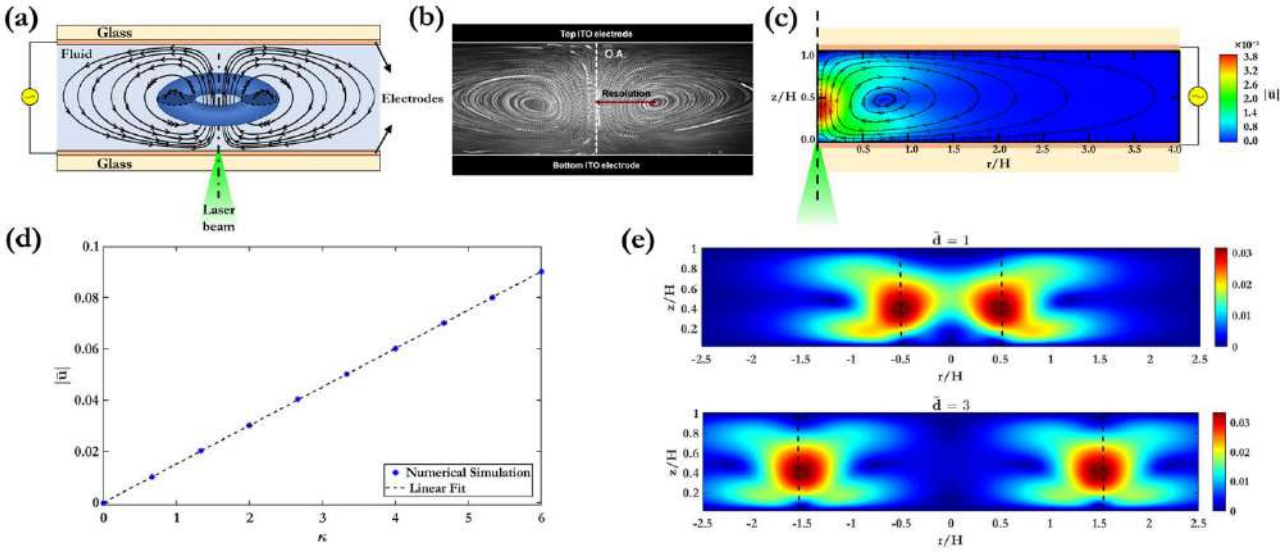

Figure 1. (a) Schematic of the experimental set-up for creating an OETT. (b) A visual representation of the OETT vortex obtained by Kwon et al experimentally [2]. (c) Solution of the governing BVPs showing the velocity field and streamlines which resemble the experimental observation in (b). (d) The influence of non-dimensional parameter κ on the magnitude of the dimensionless fluid velocity, for the point located on the optical axis midway between the two electrodes. (e) The interference between two adjacent opto-electrothermal vortices when the dimensionless separation between the optical sources are 1 and 3 respectively.

The system of governing equations is linear and homogeneous, therefore, by superposition of the solutions, we have studied the effect of multiple optical sources on the hydrodynamics. Figure 1e shows strong interference between two optical sources when their separation is the same as the height of the microfluidic channel, and no interference when their separation is three times the height. This implies that each optical source is associated with a quantifiable resolution beyond which the addition of another optical source will have little influence and the two vortices will essentially be independent of each other. This resolution can be interpreted as the radius of the stagnation zone of the micro-vortex, and therefore, can be correlated to the size of the particle cluster trapped in an OETT device. It is hence possible to control the size of the particle aggregation by modulating the flow patterns resulting from interacting vortices.

CONCLUSIONS

The present study proposes a mathematical model for the hydrodynamics of opto-electrothermal tweezers used to manipulate micro- to nano- particles. Predictions from the model are in good agreement with experimental results. The systematic analysis of material and experimental parameters would offer precise control of the process which would be pertinent in sensitive operations, e.g., those involving live cells. Non-dimensionalization and grouping of the physical parameters into dimensionless forms allow for wide applicability of our results.

DYNAMICS OF PARTICLES SUSPENDED IN VISCOELASTIC LIQUIDS IN CONFINED FLOWS IN MICROFLUIDIC APPLICATIONS

Gaetano D'Avino and Pier Luca Maffettone
Dipartimento di Ingegneria Chimica, dei Materiali e della Produzione Industriale, Università di Napoli Federico II, P.le Tecchio 80, 80125 Naples, Italy

Summary Solid particles suspended in viscoelastic fluids are encountered in a variety of industrial applications. Viscoelasticity of the suspending medium has a strong influence on the particle motion leading to phenomena not observed in Newtonian fluids [1]. In the last years, our group developed efficient numerical methods based on the Arbitrary Lagrangian-Eulerian technique to accurately compute the flow and stress fields around rigid or deformable particles of arbitrary shape immersed in a viscoelastic fluid subjected to a general flow field [2-4].
We here present an overview of the recent results on the dynamics of particle dynamics in microfluidics channels with specific emphasis on their self-assembly in ordered trains.

INTRODUCTION

The focusing of particles at the centerline of a microfluidic channel induced by fluid viscoelasticity has been of great interest over the last years [5]. Particle alignment in a viscoelastic medium can be achieved in a simple straight microchannel avoiding extra components and/or complex designs of the device. In brief, a particle suspended in a viscoelastic medium experiences a motion with a component transversal to the main flow direction. Since the 'transversal velocity' is 2–3 orders of magnitude lower than the main flow velocity, very long channels (compared to the cross- section characteristic dimension) are required to achieve highly efficient alignment. Microfluidics is, then, a very well-suited framework to exploit the migration phenomenon. To date, 3D particle focusing induced by fluid viscoelasticity is a well established, finely controllable technique to manipulate trajectories of particles with spherical shape. Two aspects are of interest in this presentation: what happens when the spherical particles are close enough to hydrodynamically interact, and what happens when the particles are non-spherical.

Spherical Particle Self-Assembly in Ordered Trains

Very recent experiments and simulations have shown that when inertia is negligible viscoelasticity is able to rearrange the microstructure and promote ordering [6]. The formation of a train of particles at approximately equal distances has been observed in a shear-thinning viscoelastic fluid, while no ordering has been reported for constant viscosity fluids. The relevant parameters are: the confinement ratio R/H (see Fig.1), Weissenberg number $Wi=\lambda/t_f$ (the characteristic time λ of the fluid and the characteristic time t_f of the flow), solid volume fraction ϕ.

The sketch of the experimental situation is reported in Fig. 1. Three phenomena are observed: Caging of the particle at the channel axis for the crossflow migration; Ordering of the particles to form a train with a specific interparticle distance; possible pairing of particles to form doublets.

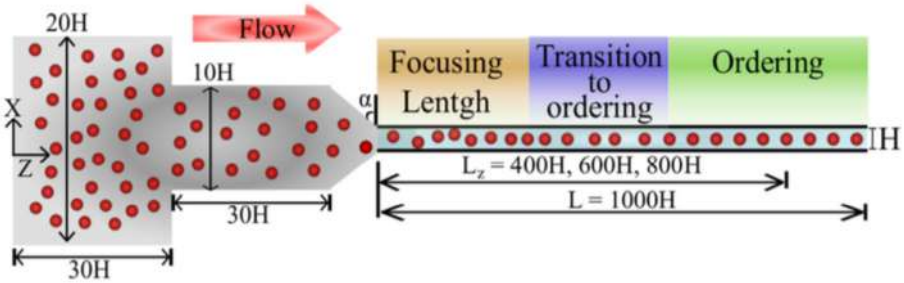

Figure 1. Microfluidic device with relevant dimensions. Particles of radius R converge gently to the glass channel, align after a certain length, and then self-order.

The main experimental outcomes are: i) fluid viscoelasticity drives self-assembly of particle trains in a straight microfluidic channel; ii) Throughput up-to 2400 particle/second; iii) Shear-thinning required to achieve the ordering; iv) Dominant distance between ordered particles does not depend on *Wi*-values; v) larger *Wi*-values enhance the fraction of ordered particles at a given dimensionless distance from inlet; vi) at larger loadings formation of particles doublets.

MODELING

Figure 2 shows the basics of the modelling efforts. We assume that caging is already occurred in the inlet section of the cylindrical tube of Fig. 1. The tube is extremely long (L/D>>1) and the number of particles flowing at the channel axis is very large. Relative velocity between consecutive particles is three orders of magnitude lower than the main flow velocity.

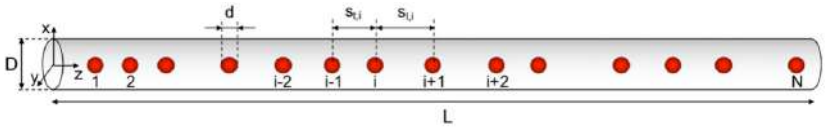

Figure 2. The simplified modelling situation with a train of particles at the channel axis.

We assume that each particle hydrodynamically interacts only with the leading and trailing one. Complete direct numerical finite element simulations of the problem with just three particles on a line are numerically solved to yield particle translational velocity for different interparticle distances.
The results show that the spatial evolution of the microstructure strongly depends on the particle volume fraction and initial distance distribution. In general, at very low volume fractions, weak hydrodynamic interactions prevent significant changes of the initial microstructure. At intermediate values of the particle concentration, ordering is possible. At high volume fractions, strings of nearly-touching particles form. A partially ordered structure in inflow strongly increases the ordering efficiency. On the contrary, the *Wi*-value has a small effect on the ordering phenomenon as in the experiments. A simple stability analysis justifies this scenario.

SPHEROIDAL PARTICLES

Similar analysis has been carried out with couples of spheroidal particles, which are assumed to lay on the channel axis with the largest dimension aligned with it as confirmed by recent numerical simulations [7]. Preliminary results show that, at a moderate confinement ratio, spheroids with small aspect ratio behave very similar to spherical particles. The most relevant quantitative difference concerns the attraction region at small distances: for spheroids, the critical Weissenberg number is slightly lower and, more importantly, the attraction region is narrower than the spherical particle case. A behavior similar to spherical particles is also observed when the confinement ratio is reduced. In this case, the attraction region at large distances is never observed whereas attraction at small distances is always present except for high values of the Weissenberg number. As the aspect ratio of the spheroid is increased, a relevant qualitative difference from the spherical case is observed: the attraction region at small distances is not present, i.e., the relative particle velocity is always positive at small interparticle distances. Hence, regardless of the Weissenberg number, two close spheroids always repel and reach an equilibrium distance or a sufficiently large distance such that hydrodynamic interactions become negligible. Hence, in this case, the formation of doublets is reduced.

A possible explanation for the attraction/repulsion dynamics at small distances can be based on the local stress field in the fluid domain around the particles. In the fluid between two spherical particles at a relatively large distance, the stress field is found to be qualitatively similar to the one expected for an isolated particle. The stress distribution is, of course, quantitatively different from the isolated case because the particles are still relatively close one to each other. On the contrary, as the interparticle distance is reduced, the stress is more uniform in the gap. In this case, indeed, the fluid between the two particles travels at approximately the same velocity of the particles leading to a small velocity gradient that, in turn, produces low viscoelastic stresses. In the former case, the normal stress gradient at the internal particle surfaces counteracts the stress around the external part of the particles, giving rise to a net force that pushes the particles away. On the other hand, the weak stress gradient between the particles in the second case of is not able to contrast the external stresses resulting in particles attraction. The local stress field for spheroidal particles confirms this argument. The shear rate between two close spheroids (that repel) is found to be not uniform. This is likely due to the particle shape and, more specifically, to the large curvature near the tips of the spheroids. Such effect is similar to what observed for the lateral migration of a spheroid where, around the tip, the normal stresses are larger as compared to spherical particles, leading to wall repulsion even when the spheroid is very close to the wall [7].

Ordering of spheroidal particles is under investigation.

REORIENTATION OF PASSIVE AND ACTIVE CHIRAL PARTICLES IN MICROFLOWS

Francesca Tesser[1], Olivia du Roure[1], Justine Laurent[1], Andreas Zöttl[2], Anke Lindner*[1]
[1]PMMH, ESPCI, Paris, France

Summary We investigate the dynamics of passive and active chiral microparticles in viscous shear flows. In such flows, helical particles are known to drift in the vorticity direction, with the sign of the rheotactic drift being function of the handedness. When a sphere is added to the helical particle, the sphere acts like and anchoring point and the rheotactic drift becomes a rheotactic torque now orienting particles into the vorticity direction. Here we use microprinted helices with a spherical "head" with perfect control of the helix shape as well as the handedness. Using this model system, we investigate the effect and the strength of the rheotactic torque. Due to the comparable shapes of E-coli bacteria, formed by a helical flagella bundle and a body, our study can also shed light on bacterial dynamics close to surfaces, being inherently more complex compared to the passive microparticles.

INTRODUCTION

Helical particles in viscous shear flows migrate across streamlines as a result of their shape and the shear flow [1]. Such chirality-induced effects are also at the origin of rheotactic effects in E.coli bacteria, due to the helical structure of their flagellar bundle. In this case, the rheotactic drift in combination with viscous friction on the bacterial head produces what is known as rheotactic torque, acting as a bias on the orientation of the cell [2]. For elongated particles, this torque applies at the same time as the usual Jeffery tumbling and its effect is to modify dramatically the periodic closed orbits of the Jeffery dynamics into spiral orbits. By using a high-resolution micro-printing technique, we fabricate micro-particles with a controlled and tuneable chiral shape, like the one of a simplified but passive bacterium. We use them to perform experiments where the re-orientation dynamics can be observed under shear flow as the particle is transported in a micro-fluidic channel close to a surface. In other words, we print both left-and-right handed helices attached to a spherical body and follow them individually as they move away from their initial Jeffery orbit, eventually flip and are stabilized perpendicularly to the flow direction with the helix on the right or left according to their handedness. We show how this stabilization mechanism depends on the shear rate and the helix geometry and compare the experimental results with a theoretical model including the rheotactic torque and Jeffery dynamics. Finally, we discuss similarities of the observed dynamics of micro-printed helices with a head to the swimming of E-coli bacteria close to surfaces [3].

EXPERERIMENTAL SET-UP AND METHODS

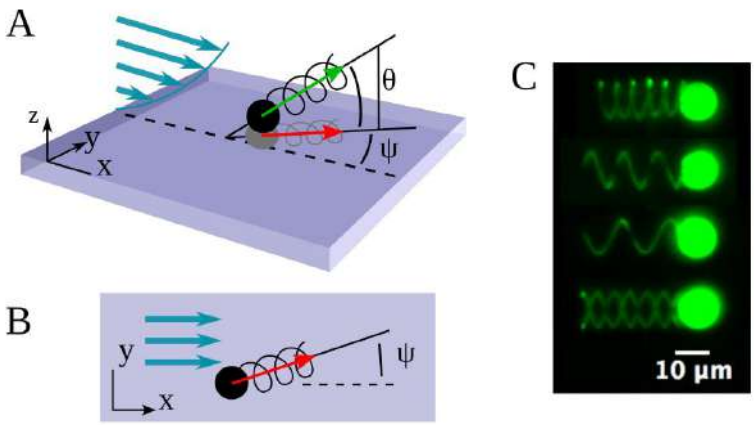

Figure 1. (A) Sketch of the experimental set up. The particle is transported by the flow in the vicinity of the bottom substrate, its orientation is characterised by the in plane angle Ψ and dipping angle Θ describing, respectively, the orientation with the flow direction and the orientation with the horizontal wall. (B) The particle projection as it is seen by the camera. The red arrow represents the particle projected length. (C) Fluorescent particles with different geometries (same radius 5 µm). From top to bottom: pitch values 5,10,15µm and a particle having two helices with opposite handedness with pitch 10 µm. From [4].

Fig. 1 shows the experimental set-up. Particles are flown close to the bottom of a microfluidic chamber far away from bounding side walls and thus experience a viscous shear flow in the z-direction. We follow the particles while they are transported downstream and record their tumbling and reorientation dynamics. Flow is imposed via a syringe pump.

The micro-particles are fabricated using a Nanoscribe 3D printer at the highest resolution possible. Helices are formed by less than 1 µm thick filaments and are of typical radius of 5 µm for a length of 1 µm. The pitch can be varied from 5 to 15 µm. A spherical particle is attached to the helices and has in all cases a radius of 5 µm. The densities of the particles

and the surrounding fluid are closely matched such as to only induce very weak sedimentation bringing the particles towards the channel bottom and maintaining them there.

RESULTS

We first investigate the reorientation dynamics of the helical particles as a function of their shape properties. The tumbling and reorientation dynamics are shown on fig. 2 for one Jeffery orbit on the top row and for the slow reorientation dynamics in subsequent oscillation periods on the bottom row. One observes a clear reorientation towards an orientation perpendicular to the flow direction, in this case with the helix pointing downwards. When the handedness is inversed (not shown) the orientation is also inversed, now with the helix pointing upwards.

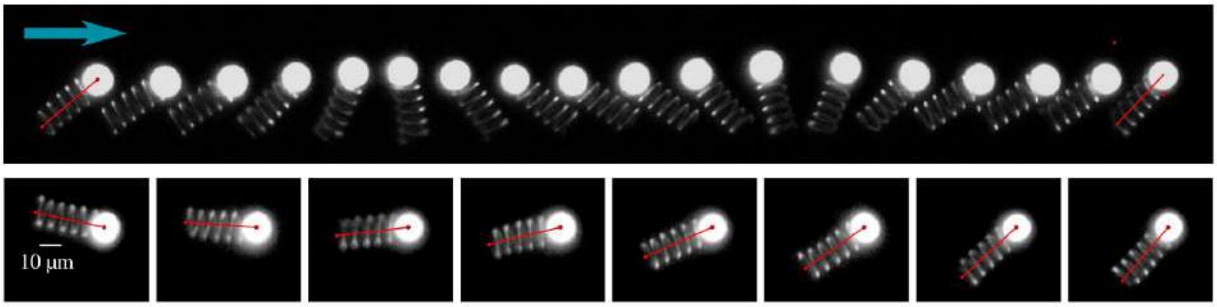

Figure 2. Top: subsequent snapshots of a particle over one period tumbling. The flow direction is from left to right. Bottom: snapshots of the particle orientation at its maximum oscillation amplitude, one image is shown every 5 oscillating periods. This series shows the slow reorientation of the particle to a direction more and more perpendicular to the flow, with the helix pointing down (left handed helix here). From [4].

We investigate the typical timescales for these orientation dynamics as a function of helix shape and show that they are function of the strength of the rheotactic torque. By performing a large number of experiments, we establish that for each handedness there is a stable orientation and that particles are able to switch orientation when initially positioned along an unstable orientation. Finally, we discuss an extra stabilizing effect given by the particle density inhomogeneity that, together with the presence of the wall, prevents the flip from happening from a limited range of initial conditions.

Finally, we compare our findings to recently discovered oscillatory surface rheotaxis of E-coli bacteria and show that those partially have the same origin as the particle reorientation of the passive objects discussed above.

CONCLUSION

Here we have investigated the dynamics of micro-printed left-and-right handed helices attached to a spherical body transported in a shear flow close to a surface. We followed these particles individually as they move away from their initial Jeffery orbit, eventually flip and stabilized perpendicularly to the flow direction with the helix on the right or left according to their handedness.

We showed how this stabilization mechanism depends on the shear rate and the helix geometry and compared the experimental results with a theoretical model including the rheotactic torque and Jeffery dynamics. Very good agreement has been obtained. Finally, we have shown the similarities between the observed dynamics of micro-printed helices with a head and the swimming of E-coli bacteria close to surfaces under flow.

PARTICLE DYNAMICS DURING DIRECTED ASSEMBLY INTO BANDS

Andrew Yee[1] and Minami Yoda[*1]
[1]Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA USA

Summary Evanescent-wave visualizations have shown that suspended colloidal particles assemble into near-wall structures—"bands"—in combined Poiseuille and electroosmotic counterflow through microchannels. A small fraction of tracer particles are used to estimate particle concentrations and velocities during the various stages of band assembly. The number of particles attracted to the wall in the initial accumulation stage appears to grow exponentially, while the particle velocities are significantly less than the superposition of the flow and electrophoretic velocities throughout assembly.

INTRODUCTION

The manipulation and assembly of suspended particles flowing through a microchannel is of current interest in microfluidics and nanotechnology [1; 2]. This work studies a novel type of directed assembly driven by shear flow and dc electric fields (of magnitude $|E|$) where particles of radius $a = O(10^{-7}$ m) in dilute (bulk volume fraction $\varphi_\infty < 5\times10^{-3}$) suspensions are attracted to, then assemble into periodic elongated structures, which we call bands, near the channel wall (Fig. 1). This assembly occurs in Poiseuille and electroosmotic (EO) "counterflow" when these flows are in opposite directions and when $|E|$ exceeds a minimum value, $|E_{min}|$, which depends upon the near-wall shear rate $\dot{\gamma}$ and φ_∞ [3]. A number of banding characteristics, such as the time for bands to form after applying the electric field, appear to depend upon the electric field offset $|E|-|E_{min}|$, or how $|E|$ compares with the minimum value for band assembly [3]. Unlike previous reports of colloidal assembly [5], band assembly occurs in a flowing solution and very far from the electrodes.

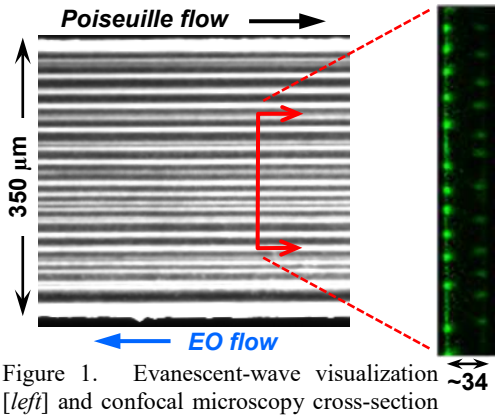

Figure 1. Evanescent-wave visualization [*left*] and confocal microscopy cross-section [*right*] of bands in a channel with a cross section of 34 µm × 350 µm [4].

Based on observations, band assembly is comprised of three stages: 1) (particle) accumulation; 2) band formation; and 3) steady-state (bands). Initial analyses based on spatially averaged grayscales of images of these structures obtained with evanescent-wave visualization suggest that the particle concentration grows exponentially during the initial accumulation stage [6]. Since the particle concentration is too high to allow detection of individual particles, these studies used "two-color" particle visualizations, where ~1% of the particles were tracers labeled with a different fluorophore to investigate particle dynamics over time for a range of flow conditions and determine if the number of near-wall particles also has an exponential growth during the accumulation stage.

EXPERIMENTS

These studies considered Poiseuille and EO flow of a dilute suspension through the central straight section of a S-shaped fused-silica microchannel of length 2.8 cm and cross section 34 µm × 320 µm at $\dot{\gamma} < 1800$ s^{-1} and $|E| < 500$ V/cm; in all cases, the flow Reynolds number was $O(10^{-1})$ (Fig. 2). A mixture of $a = 240\pm5$ nm polystyrene (PS) particles labelled with a red fluorophore with ζ-potential $\zeta_p = -55\pm7$ mV at $\varphi_\infty = 1.7\times10^{-3}$, plus tracer particles labelled with a green fluorophore with $\zeta_p = -60\pm7$ mV at $\varphi_\infty = 1.7\times10^{-5}$, were suspended in 1 mmol/L sodium tetraborate solution. The flow was illuminated by evanescent waves through the bottom channel wall and green particles with centers within 0.5 µm of the wall were imaged at three different distances from the channel inlet, namely $x = 0.61$ cm, 1.4 cm and 2.2 cm. Individual green particles can be discerned in the typical image over a field of view 203 µm square during the steady-state stage (Fig. 3), along with faint images of the bands which are mainly comprised of red particles.

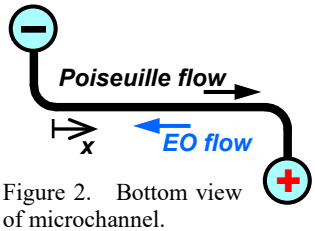

Figure 2. Bottom view of microchannel.

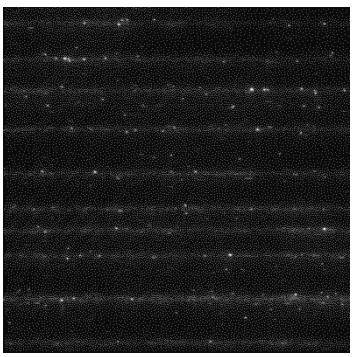

Figure 3. Contrast enhanced image of bright green tracers and faint red particles at $\dot{\gamma} = 1760$ s^{-1}, $|E|-|E_{min}| = 40$ V/cm.

All of the experiments started with "pure" Poiseuille flow, and then a dc electric field was applied at time $t = 0$. Images were acquired with an electron multiplying CCD camera at 10 Hz to estimate the number of tracer particles, and with a CMOS camera at 500 Hz to estimate the velocity of these tracer particles as a function of $t > 0$.

*Corresponding author. E-mail: minami@gatech.edu.

SUMMARY OF RESULTS

In all cases, particles are attracted to, and accumulate near the, microchannel wall before the particles assemble into bands. Tracer particle centers were detected in images where the background was minimized by subtracting off an average image. The average number of tracer particles N_p over the 203 μm square field of view was then determined as a function of time t (after the electric field is applied) over four independent realizations, and appears to grow exponentially during the accumulation stage for different $|E|-|E_{min}|$ at $\dot{\gamma} = 1760\ s^{-1}$ (Fig. 4), suggesting that the total number of particles also increases exponentially (assuming that the tracers are a consistent fraction throughout the flow). The band formation stage appears to start when $N_p \approx 50–80$, decreasing as $|E|-|E_{min}|$ increases.

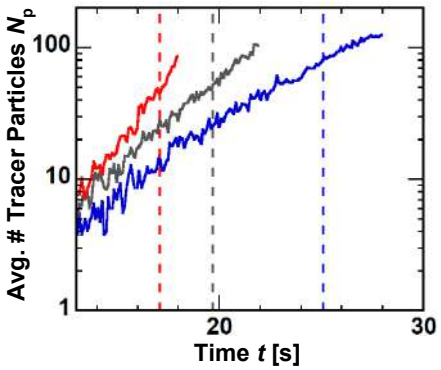

Figure 6. Semilog plot of the average number of particles *vs.* time t at $|E|-|E_{min}|$ = 16 [*blue*], 40 [*gray*], and 63 V/cm [*red*]; the dashed lines denote the end of the accumulation stage for each case.

The average tracer particle velocities U_p, determined using multilayer nano-particle tracking velocimetry at different particle-wall separations h (where a particle at $h = 0$ touches the wall) [7], are consistently lower than those predicted by the exact solution, *i.e.*, the superposition of the flow and particle electrophoretic velocities, during the accumulation stage, although U_p appears to increase slightly over time (Fig. 5). Interestingly, the slopes of the velocity profiles 3 s before the end of the accumulation stage and in steady state are within 10% of $\dot{\gamma}$.

During the steady-state stage, the particle velocities were analysed for particles within, and between, the band structures. The velocities of the tracer particles between the bands are essentially identical to those observed near the end of the accumulation stage, but those for the tracer particles within the bands are much lower, and essentially independent of h (Fig. 6). This suggests that the motion of the particles within the bands is severely hindered by interparticle interactions. Although the estimates of h for the particle velocities within the bands may be flawed because the high density of particles there will convert most of the evanescent-wave illumination to propagating waves, which do not have an exponential decay in their intensity, this result also indicates that the particles within the bands are moving *en masse*, irrespective of their distance from the wall.

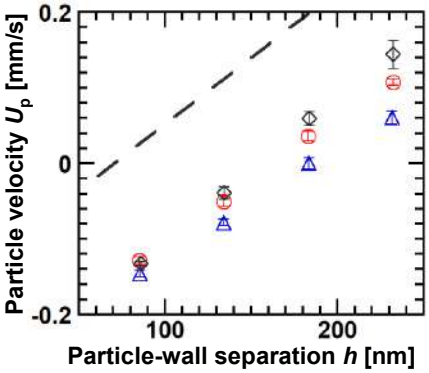

Figure 5. Particle velocity profiles 7 s (△) and 3 s (○) before the end of accumulation, during steady-state (◇), and compared with the expected particle velocity [*dashed line*] at $\dot{\gamma} = 1760\ s^{-1}$, $|E|-|E_{min}| = 16$ V/cm. The error bars denote standard deviations.

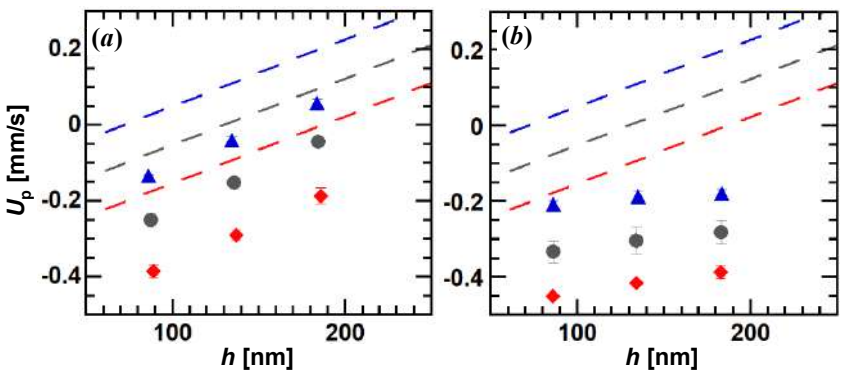

Figure 6 Particle velocity profiles between the bands (***a***) and within the bands (***b***) during the steady-state stage at $\dot{\gamma} = 1760\ s^{-1}$ and $|E|-|E_{min}| = 16$ (▲), 40 (●), and 63 (◆) V/cm and compared with the expected particle velocity [*dashed lines*]. Both graphs have the same vertical axis label; the error bars denote standard deviations.

BREAKUP OF SHEAR ACTIVATED NANO-THERAPEUTICS IN A MICROFLUIDIC DEVICE BY A CFD-STOKESIAN DYNAMICS APPROACH

Lorenzo Vasquez Giuliano[1], Graziano Frungieri *[1], Antonio Buffo[1], and Marco Vanni[1]
[1]Dipartimento di Scienza Applicata e Tecnologia, Politecnico di Torino, Torino, Italy

Summary The treatment of arterial obstructions can be strongly improved by the development of drug carriers with a highly localized action. Our research focuses on the investigation of Shear Activated Nano-Therapeutics, a novel class of drug carriers consisting in aggregates of nanoparticles, which are locally activated by the breakup induced by the viscous stress acting on them as they travel in obstructed blood vessels. We adopted a coupled Computational Fluid Dynamics - Stokesian Dynamics technique able to compute the history of the viscous shear forces experienced by the aggregates and to study the dynamics of breakup. We investigate the behaviour of different potential morphologies of the aggregates, in order to identify the most suitable for such a delivery strategy and to identify the critical structural properties to be taken into account when designing such carriers.

INTRODUCTION

Arterial obstructions represent one of the main causes of disease and death worldwide [1]. When treating this disease, the dose of active agent that can be administered to the patient has to be carefully chosen in order to limit the potential adverse effects due to the free circulation of the drug in the blood stream. For this reason, targeted drug delivery techniques have received considerable attention over the last years. One of the most promising delivery strategy is based on the observation that in obstructed blood vessel abnormally large shear stress are present. This feature of the hemodynamic condition has therefore pushed research towards the development of Shear Activated Nano-Therapeutic (SANT) particles [2]. SANTs are micro-metric agglomerates of polymeric primary nanoparticles on which a clot-lysing drug is deposited. As the nanoparticles are held together mainly through relatively weak Van-der-Waals forces, SANTs can be engineered in such a way that they break up into smaller fragments when they enter a high shear zone; these fragments, because of their smaller size, experience lower hydrodynamic drag forces, thus they are more likely to adhere to the obstruction and to perform their clot-lysing action.

In this work we use a coupled Computational Fluid Dynamics - Stokesian Dynamics approach able to investigate the breakup dynamics of aggregates of primary particles [3, 4]. We tested our method on a microfluidic device designed in such a way as to mimic a pathological vessel obstruction. CFD simulations are performed to compute the flow field in the device and to extract a set of particle trajectories including the history of experienced shear stresses. Stokesian Dynamics simulations are instead carried out to compute the distribution of mechanical stress inside the aggregate structure, from which the occurrence of breakup can be predicted. We investigate different potential SANTs morphologies by comparing them in terms of conditions for the onset of breakup and size distribution of the generated fragments.

METHODS

Computational Fluid Dynamics

We used ANSYS Fluent 19.2 to simulate the flow field of a Newtonian fluid with viscosity $\mu = 1 \times 10^{-3}\,\mathrm{Pa \cdot s}$ flowing in a rectangular microchannel. The presence of the clot is modelled by introducing a 90% lumen obstruction. The domain is divided in 10^5 hexahedrical cells (left panel in Figure 1). The flow rate is adjusted in order to obtain the typical values of shear stress in a blood vessel (10 Pa in the unrestricted vessel and 100 Pa in the obstructed vessel).

The computed flow field is used to extract the trajectories of a set of 1000 aggregates. Being their Stokes and Reynolds numbers much lower than the unity, the aggregates can be treated as tracer particles, i.e. massless particles with negligible inertia; their equation of motion therefore reads as:

$$\dot{\mathbf{x}}_\mathbf{p}(t) = \mathbf{u}(\mathbf{x}_\mathbf{p}(t)) \tag{1}$$

where $\dot{\mathbf{x}}_\mathbf{p}(t)$ is the velocity of the particle and $\mathbf{u}(\mathbf{x}_\mathbf{p}(t))$ is the velocity of the flow at the particle position.

Stokesian Dynamics

In Stokesian Dynamics (SD) simulation, the morphology of the aggregates is taken into full account. This technique, by using a first order approximation of the flow field, allows one to evaluate the hydrodynamic forces acting on each primary particle composing the aggregate and, based on these, to evaluate the normal stress acting at each inter-particle contact [4]. In order to identify the most suitable morphology for our delivery strategy, three classes of clusters characterized by different shape and porosity are studied; we analyze the behaviour of aggregates obtained by a diffusion limited aggregation (DLCA), Random Close Packing aggregates (RCP) and hollow RCP aggregates. In order to get statistically robust results, for every class we studied 100 aggregate realizations. Therefore, a statistical analysis has been conducted in order to count for the variety of aggregate morphologies and aggregate trajectories.

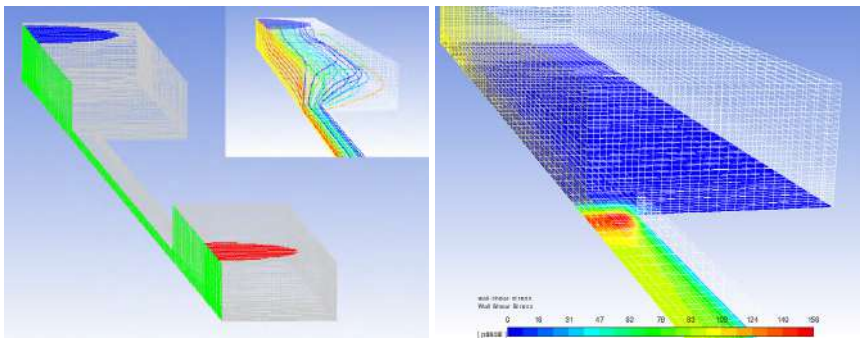

Figure 1: Left) Microchannel with inlet (blue surface), outlet (red surface), symmetry plane (green surface) and walls (grey surfaces). The inset shows the trajectories of a subset of tracer particles. Right) Wall shear stress on the bottom wall of the microchannel.

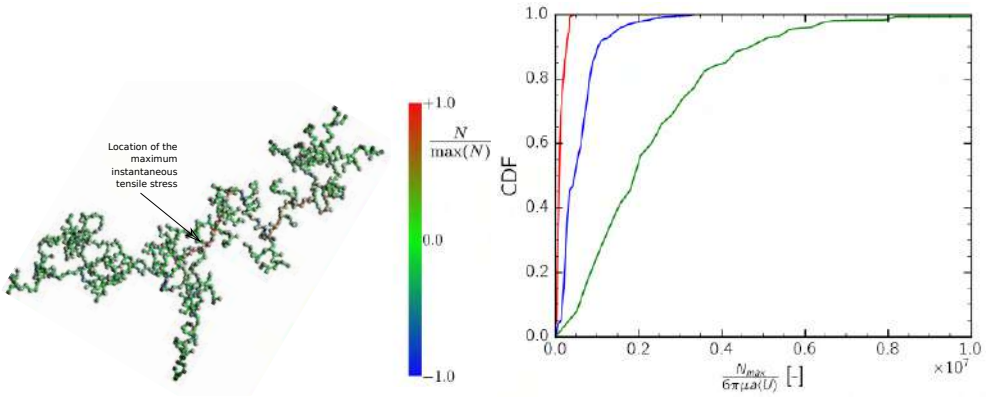

Figure 2: Left) Distribution of normal force in a DLCA cluster. A ball and stick representation has been used to highlight the inter-particle bonds. Right) Cumulative Distribution Function of the maximum tensile force experienced by RCP clusters (red), DLCA (blue) and hollow RCP (green). On the x-axis, a is the radius of the NPs, $\langle U \rangle$ is the average velocity in the constricted section.

RESULTS

The flow field in the microdevice and the trajectories of a set of tracer particles were obtained by running CFD simulations. Figure 1 right) reports the contour plot of the shear stress evaluated at the bottom wall of the microchannel. It can be noticed that the shear stress is relatively mild ($\approx$ 10 Pa) in the unrestricted section, it reaches a peak value ($\approx$ 150 Pa) at the entrance of the constricted section and then goes down to a value of 100 Pa in the narrowed region.

By Stokesian Dynamics we computed the distribution of the normal forces at the inter-particle contacts of the aggregates, as they move along the microchannel. A sample instantaneous distribution for a DLCA cluster is shown on the left side of Figure 2. For this class of aggregates, the highest tensile forces are observed in the internal region, thus suggesting that the expected dominant mechanism of breakup should be the fragmentation in two almost equally sized fragments. On the contrary, in the case of RCP and hollow RCP clusters, the highest tensile forces are observed in the external region, so that a progressive erosion of the cluster should instead be expected [4]. In the right plot of Figure 2 the mechanical responses of three different populations of aggregates are compared through the Cumulative Distribution Functions of the maximum experienced tensile stress. Hollow RCP aggregates emerged as the most fragile structure (i.e. the highest internal tensile force were observed for this class), RCP aggregates as the most resistant, whereas DLCA aggregates had an intermediate behaviour.

Results are encouraging and show the feasibility of such a deliver strategy. The CFD-Stokesian Dynamics approach appears as a promising tool to identify the fundamental properties of the aggregates to take in account when designing shear-activated drug carriers.

ON THE INFLUENCE OF THE SECONDARY FLOW ON THE EFFICIENCY OF A MEMBRANELESS MICROFLUIDIC FUEL CELL

Wiebke Rösing*, Jörg König, and Christian Cierpka
Department of Mechanical Engineering, Technische Universität Ilmenau, Ilmenau, Deutschland

Summary The efficiency of membraneless microfluidic fuel cells is limited by the formation of concentration boundary layers at the electrodes, resulting in low power density and low fuel utilization. This work demonstrates a novel method to enhance the diffusion-limited mass transport by decreasing the size of the concentration boundary layer using a transversal secondary flow. The so-called Dean vortices are induced by a curved microchannel and enhance the mass transport of fresh reactant towards the electrodes. In this study, numerical simulation, electrochemical characterization methods and astigmatic particle tracking velocimetry (APTV) are used to characterize the correlation between the fuel cell efficiency and the transversal secondary flow.

Introduction

Novel microfluidic fuel cells have arouse enormous interest due to their possible application in portable electronic devices, such as mobile phones or clinical diagnostic devices [1,2]. They are a possible alternative to conventional batteries, because of their high energy density, low weight and the ability to be used without charging for a long period of time [1,3]. In microfluidic fuel cells, fuel and oxidant flow in parallel at low Reynolds number without convective mixing. The membraneless architecture eliminates problems such as ohmic losses of the membrane, the complex water management of the membrane and the challenge to miniaturize the membrane. Since the first published work in 2002 [3], numerous studies were published in the field of microfluidic fuel cell technology. However, it is still difficult to commercialize microfluidic fuel cells, because at practical flow rates and useful cell voltages poor fuel utilizations below 10% and low power densities persist problematic [4]. This is mostly caused by the formation of concentration boundary layers at the electrodes as shown in Figure 1. A possibility to reduce the size of the concentration boundary layers is to increase the flow rate. However, this results in a further decrease in fuel utilization due to a shorter residence time of the fuel and oxidant at the respective electrode. A simple alternative method for the suppression of the concentration boundary layer expansion is a passive flow control by using a curved microchannel, which induces a transversal secondary flow as sketched in Figure 2b) [5]. The generated counter rotating vortices, known as Dean vortices, enhance the transport of fresh reactant from the center of the channel to the concentration boundary layers. The strength of the Dean vortices can be characterized by the Dean number *De* [6]

$$De = Re3\sqrt{\frac{D_h}{2R}}3.$$

The Dean number depends on the radius of curvature R (see insert in Figure 4), the Reynolds number Re and the channel geometry expressed in terms of the hydraulic diameter D_h. In microfluidic fuel cells a controlled supply of reactant towards the electrodes is required, which can be easily achieved by adjusting the strength of the transversal flow by the variation of the Reynolds number for a channel with given radius of curvature.

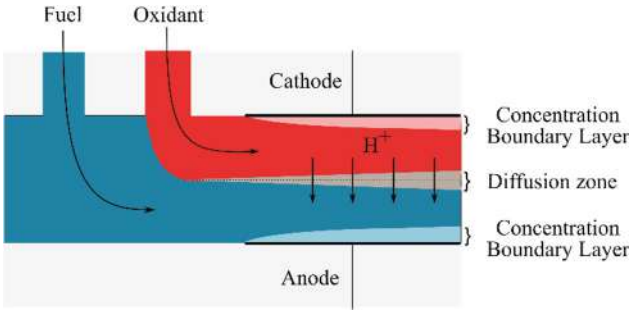

Figure 1. Schematic of the membraneless microfluidic fuel cell.

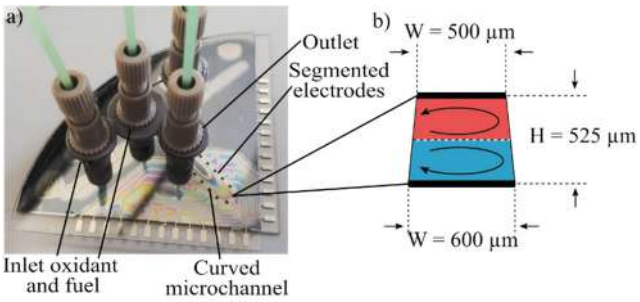

Figure 2. a) Photograph of the microfluidic device with segmented platinum electrodes on the top and the bottom of a curved microchannel. b) Cross-sectional view of the microchannel with sketched Dean-vortices.

In order to characterize the correlation between the performance of a microfluidic fuel cell and the transversal secondary flow, a partly curved microchannel with integrated segmented electrodes on the top and bottom of the microchannel was fabricated (Figure 2). This microfluidic fuel cell was characterized by using electrochemical measurement methods, astigmatic particle tracking velocimetry (APTV) [7] and numerical simulations.

Results

Numerical simulations were used to compare the performance of a straight and a curved microfluidic fuel cell. Hence, a numerical model including fluid dynamics, mass transport, charge conservation and chemical reaction kinetics with appropriate boundary conditions was applied. The numerical simulation demonstrate that by using a curved microfluidic fuel cell instead of a straight microfluidic fuel cell an increase of current density of about 8% at low flow rates (30 ml h^{-1}; De = 6.69) and an increase of 30% at higher flow rates (100 ml h^{-1}; De = 22.32) can be achieved, due to the induced counter rotating vortices [5]. To validate the results of the numerical simulation, astigmatic particle tracking velocimetry measurements were carried out to measure volumetrically all velocity components in the straight and curved channel part in between the segmented electrodes of the microfluidic device. The APTV measurement verifies the formation of two counter rotating vortices in the curved channel part, which are in good agreement with the numerical results. Furthermore, the microfluidic device with segmented electrodes enables a comparison of the electric current density obtained without the influence of Dean vortices in the straight channel part and with the enhanced mass transport induced by the Dean vortices in the curved channel part. Within this device electrochemical measurements were performed at first using a simple redox pair ferrocyanide/ferricyanide. The electrochemical measurements show that the formation of the concentration boundary layer diminishes the electrochemical reaction and thus decrease the current density along the straight part of the microchannel by about 20%. However, the Dean vortices appearing in the curved channel part enhance the mass transport and, therefore increase the current density (Figure 4). The higher the flow rate and thus the Dean number, the higher the current density of the electrodes (6,7,8) at the curved channel part compared to the current density of the electrodes (1,2,3) at the straight channel part.

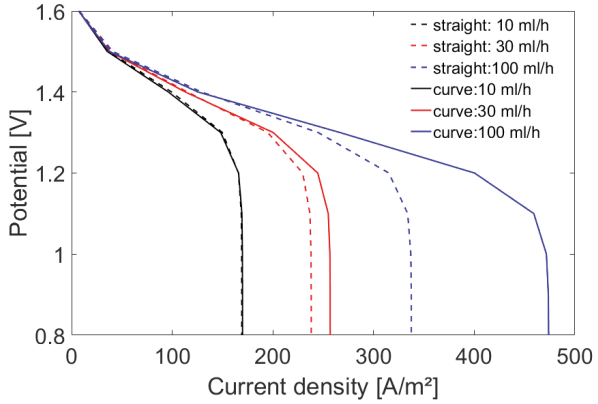

Figure 3. Simulated polarization curves for straight and curved microfluidic fuel cell at the three volumetric flow rates.

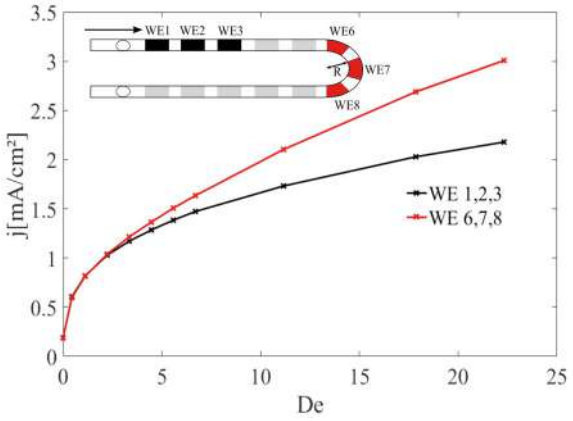

Figure 4. Experimental results for the current density measured simultaneously at working electrode 1 (WE1), WE2 and WE3 and at WE6, WE7 and WE8. Data were obtained by applying a potential of 400 mV in 5 mM potassium ferrocyanide and 5 mM potassium ferricyanide using 1 M KCl as supporting electrolyte with various flow rates resulting in Dean numbers ranging from 0 to 22.

Conclusion and Outlook

This study shows the performance improvement of a microfluidic fuel cell by decreasing the size of the concentration boundary layer at the electrodes using a curved microchannel, which induces counter-rotating vortices. Further experimental results, including polarisation curves and additional APTV measurements will be discussed at the conference to get a better understanding of the correlation between fuel cell efficiency and the flow physics.

DROPLETS IN SHEAR FLOWS

Marco Edoardo Rosti*[1] and Shu Takagi[2]

Summary We study the rheology of a two-fluid emulsion in semi-concentrated conditions; the solute is Newtonian while the solvent an inelastic power law fluid. The problem at hand is tackled by means of direct numerical simulations using the volume of fluid method. The analysis is performed for different volume fraction and viscosity ratio under the assumption of negligible inertia and zero buoyancy force. Several carrier fluids are considered encompassing both the shear-thinning and thickening behaviours. We show that the effective viscosity of the system increases for shear-thickening fluids and decreases for the shear-thickening ones for all the viscosity ratios considered. The changes in the emulsion viscosity are due to modifications of the coalescence in the system obtained by changing the carrier fluid property.

INTRODUCTION

Emulsions are mixtures of two or more liquids that are partially or totally immiscible. They are present in many biological and industrial applications such as waste treatment, oil recovery and pharmaceutical manufacturing and are also relevant in the field of colloidal science where the accuracy and the control of the production process of functional materials rely on the knowledge of the complex microstructure of the suspension [1]. In this work we focus on the rheology of biphasic emulsions by means of direct numerical simulations.

The study of rheology is motivated by the many fluids in nature and industrial applications which exhibit a non-Newtonian behavior, i.e., a nonlinear relation between the shear stress and the shear rate; the relation between these macroscopic behaviors and the microstructure is often studied assuming suspensions of objects in a Newtonian solvent with dynamic viscosity μ. Einstein [2] was the first to provide a closure for the effective viscosity μ_e of a dilute rigid particle suspensions with vanishing inertia, and showed theoretically that μ_e is a linear function of the particle volume fraction Φ. Non-rigid and deformable objects, such as deformable particles, capsules and droplets behave differently because of their deformation and in the latter case also coalescence and breakup. Taylor [3] took into account the deformation and extended Einsten's relation by introducing the viscosity ratio between the two phases λ (defined as the disperse phase over the matrix phase viscosity), and more recently Pal [4] derived expressions to evaluate the effective viscosity of infinitely dilute and concentrated emulsions using the effective medium approach. These relations assume limiting cases to model surface tensions effects (either going to zero or infinite) and thus direct numerical simulations are a valuable tool to overcome these limitations. De Vita et al. studied the effect of coalescence [5] and showed that the effective viscosity is a concave function of Φ, i.e., μ_e has a maximum for an intermediate value of Φ and then decreases with the volume fraction. The volume fraction for which the maximum is reached decreases with the viscosity ratio λ and μ_e is again a convex function of Φ in the case of droplets when the coalescence of the solute phase is suppressed; in this case, their behaviour resembles what found for deformable particles, thus confirming that coalescence is a key mechanism that can dramatically change the rheology of emulsions.

In this works we account for the coalescence and study how it affects the rheology of emulsions adding an additional complexity to the system by considering non-Newtonian solvents. To be best of our knowledge, no systematic study of the rheology of concentrated emulsions are available in the literature and the present work is aimed to fill in this gap.

NON-NEWTONIAN FLUID MODELS

Several models have been developed to capture the different behaviours of various non-Newtonian fluids and in the current study, we focus on the simple inelastic power law models, where the local viscosity of the fluid is a function of the sole local value of shear rate. A relation that can be used to summarize the behaviors previously described for complex fluids is

$$\mu_{pl} = K\dot{\gamma}^{n-1}, \tag{1}$$

where n is the flow index and K the fluid consistency index. A Newtonian behavior is recovered when $n = 1$ and $K = \mu$, while values of the flow index above and below unity, $n > 1$ and $n < 1$, denote shear-thickening and shear-thinning fluids, respectively. In general, the local viscosity of the non-Newtonian fluid increases with $\dot{\gamma}$ for shear-thickening fluids, while it reduces for shear-thinning ones, which means that the fluidity of shear-thickening fluids reduces increasing the shear rate, while the opposite is true for shear-thinning fluids. The viscosity of a power law shear-thinning fluid becomes infinite for null shear-rate; to overcome this numerical issue, the Carreau fluid model is used instead in which the local viscosity is computed as

$$\mu_{ca} = \mu_\infty + (\mu_0 - \mu_\infty)\left[1 + (k\dot{\gamma})^2\right]^{(n-1)/2}. \tag{2}$$

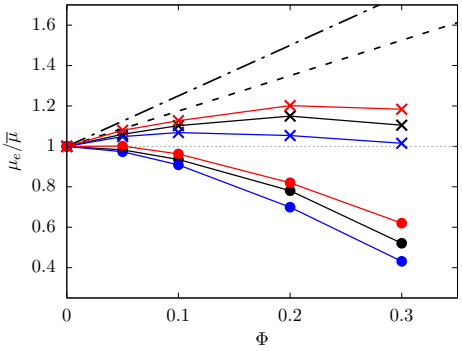

Figure 1: Normalised effective viscosity μ_e as a function of the droplets volume fraction Φ for different fluids and viscosity ratios. The blue, black and red colors indicate $n = 0.5$, 1 and 1.5, while the cross $\times$ and circle $\bullet$ symbols are used to distinguish λ equal to 1 and 0.01.

In this equation, μ_∞ and μ_0 indicate the lower and upper limits of fluid viscosity at infinite and zero shear rates. The flow index n characterizes the behaviour of the fluid: for $n < 1$ the fluid is shear thinning and the material time constant k represents the degree of shear-thinning.

RESULTS

We study the rheology of a droplet suspension immersed in power law fluids and compare the results with those obtained in a Newtonian fluid. The suspended fluid is Newtonian with uniform constant viscosity μ_1, while three different kinds of carrier fluids are studied: Newtonian fluids with viscosity $\mu_2 = \overline{\mu}$, shear-thickening fluids with viscosity $\mu_2 = \mu_{pl}$ defined by equation (1) and shear-thinning fluids with viscosity $\mu_2 = \mu_{ca}$ defined by equation (2). We consider the effective viscosity μ_e which is the viscosity of a Newtonian fluid that gives the same shear stress at the same shear rate, and is thus defined as $\mu_e = \langle \sigma_{12}^w \rangle_{xz,t} / \dot{\gamma}$. σ_{12}^w is the shear component of the stress tensor evaluated at the walls. In general, we expect the rheology of a two fluid system to be a function of the Reynolds number Re, the capillary number Ca, the viscosity ratio λ, the solute volume fraction Φ, the confinement ratio $2\mathcal{R}/2h$ and the non-Newtonian property of the carrier fluid here summarised by the power flow index n. In the present work, we limit our analysis to inertialess flows, i.e., $Re \lll 1$, the capillary number Ca is not varied and fixed to be in a range where breakup is avoided, and the domain size is chosen such that confinement effects are negligible. Thus, we can simply the analysis to $\mu_e \approx \mathcal{F}(\Phi, \lambda, n)$.

Figure 1 shows the effective viscosity μ_e as a function of the droplet volume fraction Φ for two different viscosity ratio λ and for three different power flow index n. In the Newtonian carrier fluid (black color), the behaviour is the same observed by [5]: when the viscosity of the two fluids is the same, i.e., $\lambda = 1$, the effective viscosity μ_e first grows with the volume fraction similarly to a rigid particle suspension, then reaches a maximum value for an intermediate Φ and then starts decreasing again. When the viscosity of the dispersed phase is reduced, i.e., λ decreases, the volume fraction for which the maximum effective viscosity is reached reduces, and for a sufficiently low λ the maximum is reached at $\Phi \approx 0$ and the effective viscosity curve decreases with Φ. Note that, the effective viscosity μ_e can be even smaller than the carrier fluid one $\overline{\mu}$ in the case of $\lambda < 1$. The non-monotonic behaviour of μ_e with Φ is a direct consequence of the limiting behavior for $\Phi \to 0$ and $\Phi \to 1$ where μ_e is equal to μ_2 and μ_1 by definition [6]. When the carrier fluid is non-Newtonian the situation is further modified. In general, for all the power law index n and viscosity ratio λ considered in the present study, we observe that the non-monotonic behaviour is preserved and that the effective viscosity μ_e is larger for shear-thickening fluids with $n > 1$ and smaller for shear-thinning fluids with $n < 1$ than their Newtonian counterparts with $n = 1$. The difference in μ_e between the Newtonian and non-Newtonian fluids grows with the volume fraction Φ and larger difference are evident between the Newtonian and shear-thinning fluids than what observed with the shear-thickening fluid for both the viscosity ratio λ considered.

DRYING OF ELEMENTARY NETWORKS WITHIN AN ARTIFICIAL LEAF

Philippe Marmottant[1], Benjamin Dollet [1]
[1]Laboratoire Interdisciplinaire de Physique, CNRS and University Grenoble Alpes, France

Summary The hydraulic networks of leaves are of prime importance to supply water for photosynthesis. This function is at risk when a cavitation bubble develops in the case of excessive evaporative stress, leading to an embolism, which dries the network. We have designed elementary networks in artificial microfluidic leaves to understand the speed at which the drying occurs. We found that in the case of an intersection leading to several branches, the interface between air and water divides into two several parts. The drying rate is reduced just after the splitting since axial fluxes of water vapour interact. We have developed a model to qualitatively predict this behaviour.

INTRODUCTION

Leaves are the pumping elements in plants since they drive sap water in the hydraulic circuit. Evaporation results in a strong negative pressure that tends to pull the water upwards, until it reaches the leaves and participates into photosynthesis. Unfortunately the pressure becomes so negative, of the order of tens of bars, that cavitation bubbles can occur, forming a so-called embolism, and grow. Here we are interested in the growth of the embolism in the hydraulic circuit of the leaf under evaporation. When the embolism is growing several menisci move into the conduits of the leaf. Here we are interested in unravelling the basic physical laws that drive the menisci in complex architectures.

ELEMENTARY NETWORKS

For this purpose we have developed microfluidic experiments using artificial leaves in transparent PDMS elastomer bounded on glass (method by [1]), under a continuous flux of dry air. Such networks are visible on figure 1. The networks are filled from the large disc, cut with a scalpel to create an opening. To reproduce the normal function of a leaf, water would be supplied to this entrance and would then flow, diffuse through the very thin layer of PDMS and evaporate, which mimics water transport between the sap network and the atmosphere through the body of real leaves.

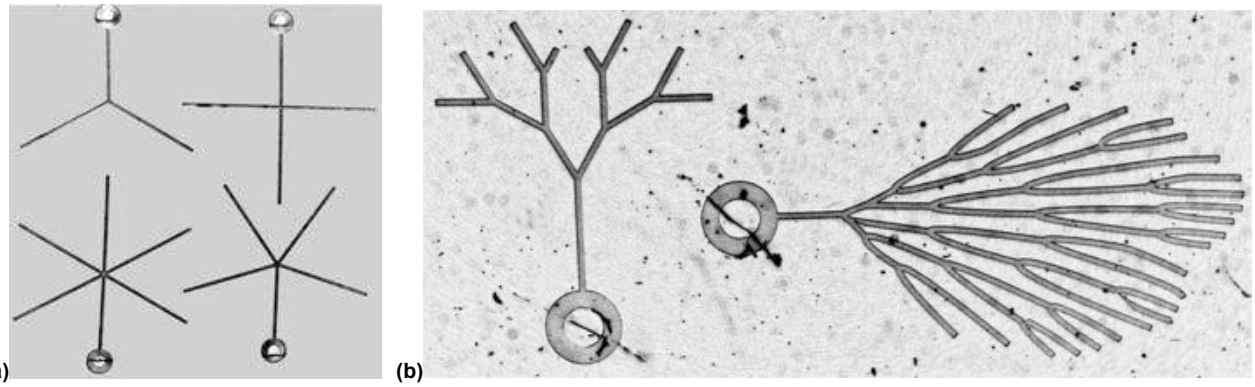

Figure 1. Microfluidic artificial leaves of thin PDMS with elementary networks with: (a) simple intersections. (b) trees of intersections inspired from Adiantum ferns leafs. In all networks, the drying starts from the disk, open to air.

We simulate an embolism by stopping the injection of water through the open disc and let an air bubble enter and invade the drying network. In biological leaves it was indeed found that embolism always starts at the base of the leaf (the petiole [2]).

DRYING IN A SINGLE CHANNEL

In simple single straight channels (not shown here) we found that the remaining length L of water in a dead end decreases during drying decreases with a velocity given by $\frac{dL}{dt} = -\frac{L+L_g}{\tau}$, where τ is a characteristic time linked to the diffusivity of water though the cover layer of PDMS, and to its thickness, and where L_g is a characteristic length due to the axial flux of evaporation through the air in the channel before diffusion in PDMS elastomer [3].

DIVISION INTO MULTIPLE MENISCI AT INTERSECTIONS

Here we first consider branched channels, as on figure 1a. When bubble grows, arriving from the left from a branch to a junction into two secondary branches, the meniscus divides into two menisci (figure 2ab and 2ef). In junction with more branches, the meniscus equally divides in several menisci (figure. 2cd).

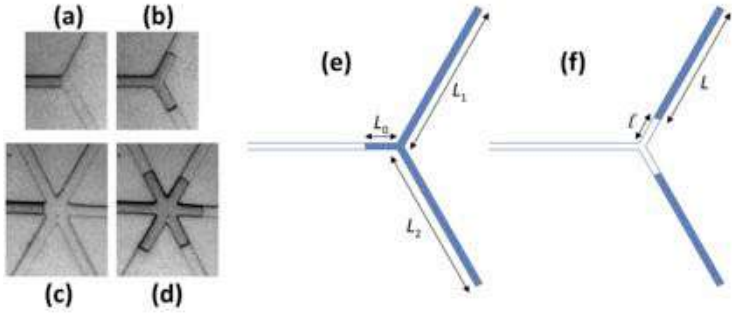

Figure 2. Division of a bubble when arriving at a intersection leading to N other branches.

The menisci velocity reduces abruptly after the junction, as seen on figure 3a. It is explained by the fact that all the evaporative flux was driving the initial single meniscus before the division. After division the velocity in each branches obeys a law that is very close to that of a single branch, see figure 3b, except at the beginning when menisci are close to each other and interact. Indeed the presence of neighbour menisci decreases the evaporative flux in the axis of the channel. We predict that the drying velocity writes $\frac{\mathrm{d}L}{\mathrm{d}t} = -\frac{L+fL_g}{\tau}$, where f is geometrical prefactor ($f < 1$) that writes $f = \frac{\cosh[\ell/L_g]+N\sinh[\ell/L_g]}{\sinh[\ell/L_g]+N\cosh[\ell/L_g]}$ using ℓ the distance to junction. This prediction qualitatively describes the observation that the velocity is smaller just after the division, when the secondary branches are full with a water length of about 4 mm.

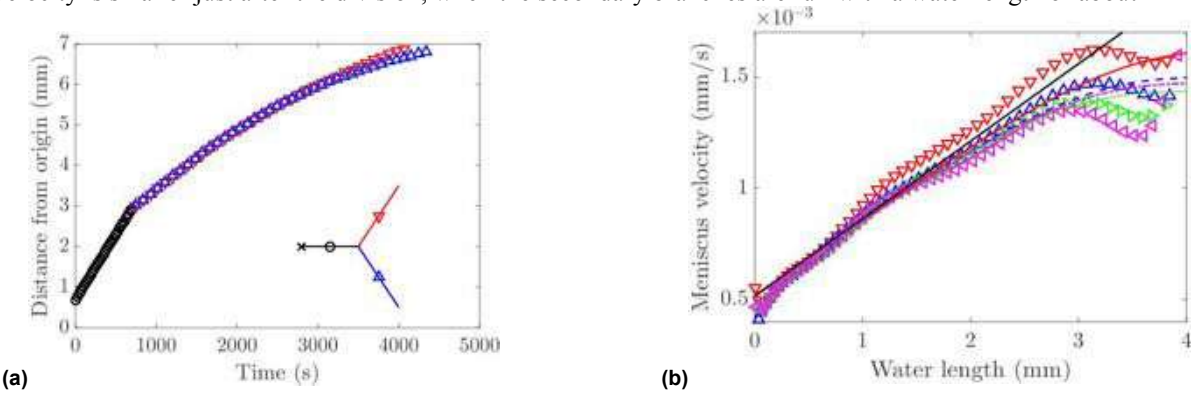

Figure 3. (a) Position of the meniscus as a function of time. (b) Velocity as a function of the remaining water length (initially 4mm), after the junction into two (◦), three (∗), four (+) and five (×) branches. Prediction for a meniscus in a single channel (black line), and taking into account the interaction between branches (colored lines).

This model helps deriving precisely the motion of water in even more complex networks such as the ones of figure 1b.

DIVISION IN THE CASE OF CONNECTED ENDS

In real leaves channels presents loops. If the secondary channels after the junction are topologically connected (imagine the ends of channels in figure 2ef being connected by water), we found surprisingly there is an inequality of velocities in secondary branches, with sometimes pinning of one meniscus due to a slight imperfection. But the total flux of water evaporating is conserved and the sum of velocities $\frac{\mathrm{d}L_1}{\mathrm{d}t} + \frac{\mathrm{d}L_2}{\mathrm{d}t}$ after the junction is evolving smoothly.

CONCLUSION AND PERSPECTIVES

We found that the axial evaporative flux is dependant on the proximity of other interfaces. Having understood the basic laws driving the motion of menisci in simple configurations we aim to tackle more complex geometries, in particular channels presenting constrictions, as is the case in real leaves. Preliminary experiments showed stop and go behaviour at constriction, with fast jumps when the pinned interface is released, consistently with biological observations.

FLOW-INDUCED VIBRATIONS DUE TO THE FLOW OF A VISCOELASTIC FLUID BETWEEN TWO CANTILEVERED MICROCYLINDERS

Cameron C. Hopkins*[1], Simon J. Haward[1], and Amy Q. Shen[1]
[1]Micro/Bio/Nanofluidics Unit, Okinawa Institute of Science and Technology Graduate University, Onna-son, Okinawa, Japan

Summary In this work, the flow of a viscoelastic wormlike micellar solution between two cantilevered microcylinders and their resulting flow-induced vibrations is studied. At moderate Weissenberg number, the microcylinders are laterally deflected due to elastic forces and undergo highly periodic and synchronized oscillations in time that are governed by the relaxation time of the fluid. At high Weissenberg number, one of the posts is dramatically deflected towards the other post, ultimately resulting in them sticking together and vibrating erratically due to elastic turbulence. The study on the motion of the posts is analyzed together with the flow behaviour of the fluid measured using micro-Particle Image Velocimetry and Flow-Induced Birefringence experiments.

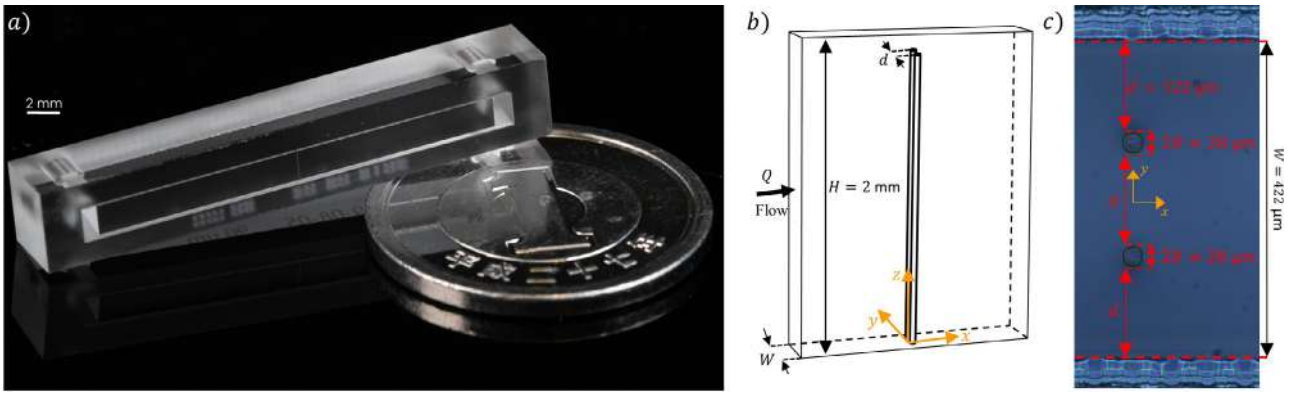

Figure 1: a) Photograph of a glass microfluidic channel with a single microcylinder in the center of the channel. 1-yen coin included for scale. b) Schematic diagram of the microfluidic channel used in this work with two cantilevered microcylinders situated at the same streamwise (x) position in the channel with equal spacing in the y direction between the cylinders and walls of the channel. c) Micrograph of the glass microchannel focused on the tips of the microcylinders.

INTRODUCTION

Microfluidics has recently emerged as a promising new technique for use in fluid dynamics and rheology [1]. One system of particular interest to this work is flow around a cylinder. The flow of a Newtonian fluid around a cylinder is characterized by the ratio of inertial to viscous forces in the fluid using the Reynolds number $\mathrm{Re} = \rho U R/\eta$, where ρ and η are the fluid density and viscosity, respectively, U is a characteristic flow velocity, and R is the radius of the cylinder. Many fluids however, including biological fluids (e.g., mucus, synovial fluid, semen), are not Newtonian, but are viscoelastic, meaning they possess a combination of solid-like (elastic) and liquid-like (viscous) properties. Elasticity in viscoelastic fluids arises from the deformation and relaxation of macromolecules in the fluid, and the elastic response of the fluid depends on the timescale for the relaxation of these molecules. The flow of a viscoelastic fluid around a cylinder can be characterized by the ratio of elastic to viscous forces in the fluid using the Weissenberg number $\mathrm{Wi} = \lambda U/R$ where λ is the relaxation time of the fluid. Due to the small lengthscale achieved in a microchannel ($R = O(10\mu\mathrm{m})$), it is therefore possible to study flows that are simultaneously inertia-less ($\mathrm{Re} \ll 1$) with high elasticity ($\mathrm{Wi} \gg 1$).

Using state-of-the-art selective laser-induced etching of glass [1], we fabricated microchannels containing slender cantilevered microcylinders. Fig. 1a shows a photograph of an example glass microchannel with height $H = 2$ mm and width $W = 400$ μm that contains a single microcylinder. For the work presented here, the microchannel used contains two cantilevered microcylinders with heights ≈ 1.95 mm positioned at the same streamwise (x) position in the channel, with equal spacing between the cylinders and walls, as in the schematic diagram shown in Fig.1b. A micrograph focused on the tips of the cylinders is shown in Fig 1c along with the dimensions of the channel.

In a previous study, we investigated the flow of a viscoelastic wormlike micellar solution around a rigid microcylinder that is fixed at both the top and bottom of the microchannel [2] as in Fig. 1a. Above a critical Wi, the flow destabilizes and the fluid preferentially flows around one side of the cylinder. At higher Wi, the flow becomes time dependent and pulses with a period equal to λ. If the microcylinder is cantilevered, the same flow instability exerts a force on the cylinder, deflecting it off the flow axis and causes complex two-dimensional oscillations [3].

In this work, we present a study on the flow of a viscoelastic wormlike micellar solution between two cantilevered microcylinders located at the same streamwise position in the channel with equal gaps between the cylinders and walls. The flow of the fluid will be investigated using micro-Particle Image Velocimetry and Flow-Induced Birefringence imaging techniques. The behaviour of the cantilevered microcylinders will be studied using high-speed video microscopy.

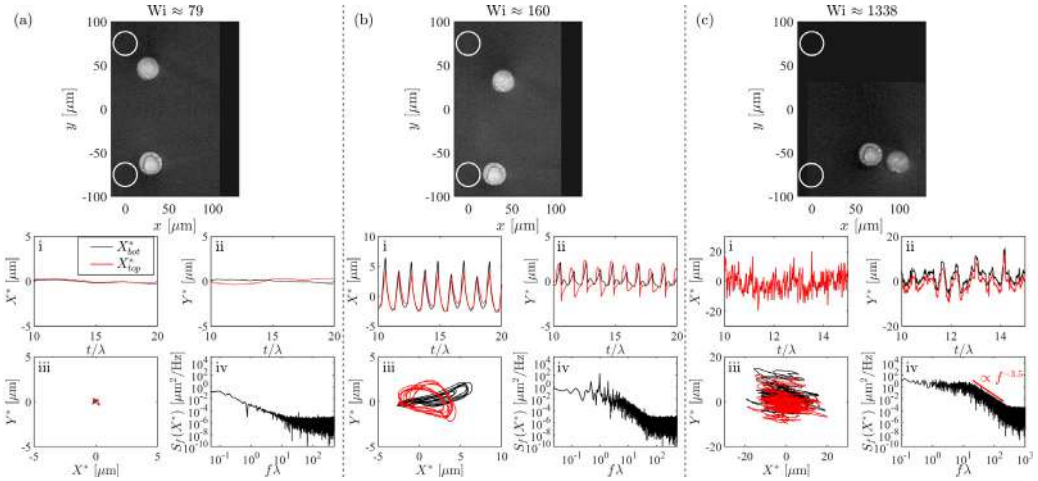

Figure 2: High-speed video microscopy and cylinder tracking. The three columns show data at three Weissenberg numbers (a) Wi $\approx$ 79, (b) Wi $\approx$ 160, and (c) Wi $\approx$ 1338. In each column, a video snapshot at each Wi is shown in the top panel. Flow is from left to right. The white circles show the initial rest positions of the cylinders. In the lower four panels, i) and ii) show X^* and Y^* for both posts, where the black curve is the bottom post and the red curve is the top post. iii) shows the $X^* - Y^*$ orbits of the posts, and iv) shows $S_f(X^*)$ for the bottom cylinder.

RESULTS

Figure 2 shows high-speed video microscopy of the motion of the microcylinders at three Weissenberg numbers illustrating distinct behaviour. At the lowest Wi (Fig 2a), the posts deflect downstream by approximately the same distance and are also deflected in the y direction, compressing the posts together. Their x and y positions with their means subtracted, denoted X^* and Y^*, are plotted vs. normalized time t/λ in Figs. 2 a-i and a-ii; they are steady in time. The posts' $X^* - Y^*$ orbits, shown in Fig. 2 a-ii are effectively points at the origin. The power spectrum of the top cylinder's x-position, $S_f(X^*)$, is plotted vs normalized frequency $f\lambda$ in Fig. 2 a-iv. In this case, $S_f(X^*)$ shows no notable features.

At slightly higher Wi, shown in Fig. 2 b, compared to the previous case, both posts are deflected more significantly in the $-y$ direction, with the top post deflecting the most. As shown by their x and y positions in Fig. 2 b-i and b-ii, the posts undergo highly periodic and synchronized oscillation in time. Their x positions follow sawtooth-like oscillations, while their y positions trace out a much more irregular, but still periodic, shape. Their orbits, plotted in Fig. 2 b-iii, trace our complex two-dimensional oval-like shapes. The power spectrum plotted in Fig. 2 b-iv reveals a strong primary peak at normalized frequency $f\lambda \approx 1$ along with higher integer harmonics in agreement with previous work [3]. In addition, half-integer harmonics are also present that were not observed in previous work, which may be evidence of a period doubling cascade towards elastic turbulence, or a modification of the flow instability due to the arrangement of the posts.

At the highest Wi shown here, in Fig. 2 c, both posts deflect more significantly downstream, with the top post deflecting over 100 μm in both the x and $-y$ directions. Note that the post that is furthest in the x direction in the top panel of Fig. 2c is the top post. The posts' x and y trajectories, plotted in Fig. 2 c-i and c-ii, are highly erratic in time, showing no clear periodicity. The posts' trajectories are virtually identical because they are effectively stuck together, showing only a slight separation in the y direction due to their relative displacement. Their orbits shown in Fig. 2 c-iii are also identical with a slight y offset, and trace out a random back-and-forth path. The power spectrum shown in Fig. 2 c-iv reveals strong broad-spectrum amplitude at low-frequency with a power-law decrease in amplitude with increasing frequency that follows a -3.5 slope which is evidence of elastic turbulence, similar to that observed in previous work [3].

OUTLOOK

The results presented above reveal that the flow of a viscoelastic wormlike micellar system between two cantilevered microcylinders results in complex spatiotemporal oscillations of the posts. The analysis of the Wi-dependent behaviour of the posts was presented in terms of their $x - y$ oscillations. Further insight can be obtained by casting the geometry of the problem in terms of the separation vector $\vec{r}$, and the angle θ, between the posts. In addition, using micro-Particle Image Velocimetry and Flow-Induced Birefringence data, the motion of the posts can be correlated with the flow behaviour of the fluid.

CONFIGURABLE DEFORMATIONS OF A THIN LIQUID FILM GENERATED BY THE THERMOCAPILLARY EFFECT

Summary: We present a novel method for deforming thin liquid-films into desired topographies, driven by a photo actuated thermocapillary effect. Our system consists of a thin liquid film, resting on a flat substrate patterned with an array of metal pads, and a DMD-based illumination system that projects light onto the metal array. Upon projecting a desired pattern, light absorbed by the array is converted to a heat pattern on the bottom surface. This heat pattern induces surface tension gradients at the liquid-air interface, which deform the free surface. By using this effect, we can achieve complex structures with deformations as large as 10 µm over cm-scale actuation regions. The deformed liquid can be dynamically modulated from one configuration to another or be polymerized to yield extremely smooth solid structures. We believe that this method opens the door to generating complex structures that can be leveraged to rapidly create phase masks and other freeform optical components.

INTRODUCTION

The Marangoni effect describes the motion of a liquid due to tangential stresses induced by surface tension gradients on one or more of its liquid-fluid interfaces. A subset of Marangoni flows, where the surface tension gradients are induced by non-uniform temperature is known as the thermocapillary effect. If a non-uniform temperature profile is imposed (for example) on a gas-liquid system, liquid will spontaneously flow along the free-surface from warmer regions with lower surface tension to colder regions with higher surface tension [1]. Since at the microscale, effects of capillary forces become dominant over convective and gravitational forces, thermocapillary flow has the potential to serve as an effective method for the control and manipulation of liquids at such scales. The study of induced deformations on horizontal liquid films dates back to Davis et al. who first derived an evolution equation of the interface of a uniformly heated but perturbed liquid film, and later provided both an analytical model and experimental results for the steady-state deformation of a thin liquid film subjected to a spatially periodic temperature distribution [2,3]. A number of studies have considered the use of the thermocapillary effect for patterning of polymers, and those are discussed extensively in a recent review by Singer [4]. In particular, McLeod and Troian demonstrated deformations of nanoscale films using temperature-controlled structural elements brought in close proximity to the film. Nejati et al. [5] demonstrated shaping of thin polymer films into periodic arrays of lenses by suspending a thick layer of another liquid on top of a thin polymer film and leveraging the Benard-Marangoni instability of the top interface to drive short-wavelength deformation in the polymer, followed by successful UV-polymerization of the structure. In this work, we demonstrate for the first time a thermocapillary-based system, which allows for reconfigurable patterning of a thin liquid (polymer) film in real time, using arbitrary light-projected actuation. We provide details of its concept and design, characterize its performance, and demonstrate its use for creation of useful phase masks and other structural elements.

EXPERIMENTAL SYSTEM

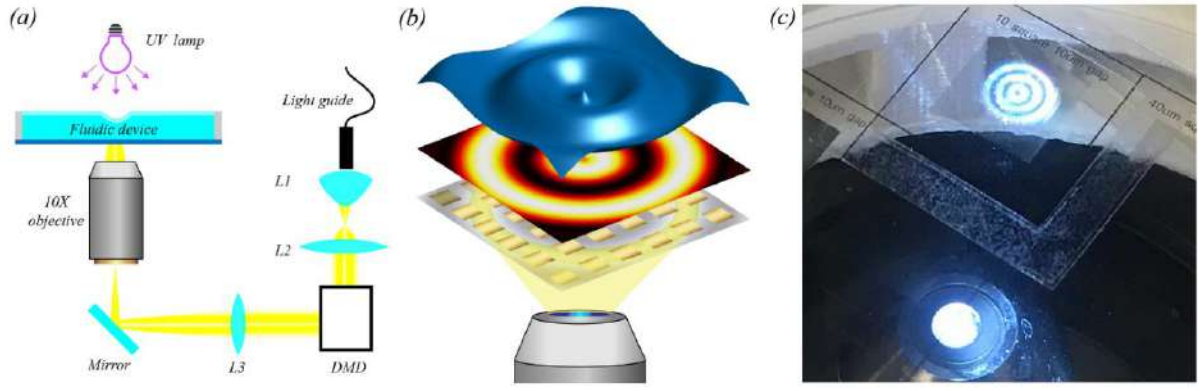

Figure 1. (a) Schematic illustration of the experimental setup. The fluidic device consists for 2x2 cm frame made of 60um thick tape, attached to a glass wafer patterned with absorbing metal squares and with a UV light curable polymer. A desired heating pattern is irradiated onto the surface using a DMD-based projection system. The light originates from a LED source coupled to a liquid guide, and we collimate it onto the DMD using a 25 mm aspheric condenser f=16 mm (L1) and a 50.8mm bi convex lens f=60mm (L2). The DMD is imaged onto the patterned surface of the chamber using a microscope objective and Kohler lens f=300 mm (L3) that focuses the light onto its back focal plane. (b) Schematic illustration of fluidic shaping via light illumination. The pattern is projected on the metal squares, which absorb the light and generate the thermal pattern to induce the thermocapillary effect, which deforms the interface between the liquid polymer and the air. We polymerize the UV curable polymer using a UV lamp located above the device. (c) An image of the device on top of the projection system.

Figure 1 presents a schematic illustration and image of the experimental setup we used to generate the thermocapillary deformations. The device consists of a 2 cm x 2 cm x 60 µm (WxLxH) fluidic chamber whose floor is made of a glass wafer patterned with an array of metal squares that absorb the light projected from below. We fabricated the squares using a standard photolithography process where we deposited a 100 nm of chrome followed by another 100 nm of gold, yielding good absorption of light in the visible spectrum. The size and spacing of the squares provide a tradeoff between spatial resolution and efficiency of heating. A desired temperature pattern is achieved by using a high intensity (4W output) LED source collimated onto a digital mirror device (DMD). We fill the chamber with a UV curable liquid polymer, and after obtaining the desired shape, we cure the polymer to obtain the final shape. To measure the topography of the resulting polymerized surface we use a digital holographic microscope (DHM) [6].

RESULTS

Figure 2 presents the experimental results of projection of three concentric rings onto wafer patterned with 20 um x 20 um metallic squares, spaced at a distance of 80 um (edge to edge), using a projection intensity of approximately 0.67 W/cm^2. The projected rings heated the surfaces on the bottom of the chamber, which then induced a gradient in the surface tension above the rings. The topography of the resulting surface, captured by the DHM, shows a set of concentric rings, whose 'valleys' correspond, as expected, to heated region where surface tension is reduced, with a deformation magnitude of several micrometers

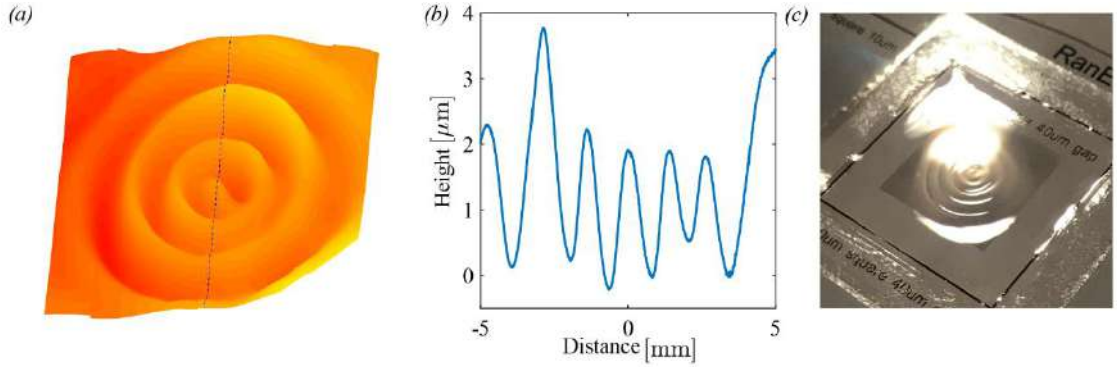

Figure 2. Experimental results showing the polymerized pattern resulting from the projection of three concentric rings. (a) A 3D view of the surface over a field of view of 10by 10 mm, as captured by a DHM. (b) The deformation pattern across the centerline of the pattern, as indicted by a dash line in 'a' (c) An image of the polymerized surface, taken using a consumer-grade camera.

Summary The presence of microparticles (MPs) in fluids may affects the flow properties and dictate MP distribution and transport, which are important in industrial, biological and environmental flows. To understand the underlying mechanisms affecting MP distribution in flows, we disentangle their response to specific element of flows. Here, a microfluidic cross-slot geometry, configured for observations over the cross-section of streamwise planes, is used to generate a stationary streamwise vortex at moderate Reynolds numbers to study MP distribution and dynamics in Newtonian and complex fluids. Findings from this study provide fundamental contributions about MP–flow interactions, improving techniques for particle sorting and transport with applications in medicine and environmental measurements and may provide insights to turbulence attenuation mechanisms.

INTRODUCTION

Microparticles (MPs) are prevalent in different flows such as biological (as cells and microorganisms in blood flow and lymph system [1]), industrial (as plastic MPs scrubbers for cleaning products [2] and textile fibers [3]) and environmental processes (such as dust, sand and degraded plastic debris [4]). Natural and synthetic MPs are a risk for human health due to the constant exchange of water and air flows between the environment and the human body (via ingestion and inhalation) [5]. Due to their high prevalence in diverse flow regimes, it is important to understand the fundamental interaction between MPs and their suspending fluids, particularly non-Newtonian fluids which are common in biological and industrial flows. Vortices are a main building block of turbulent flows, but they also represent an intermediate flow regime that is common in flows involving corners and obstacles (i.e., flows in the heart and vein intersections). Due to the unstable and dynamic nature of vortices, it is challenging to create and study them under controlled and precise conditions. Hence, most current studies focus is on laminar [6] or fully turbulent [7-8] flows. In this ongoing study we aim to explore the interaction between MPs and intermediate vortex flows of both Newtonian and complex fluids. For this purpose, a microfluidic cross-slot geometry, configured for observations over the cross-section of the outflow, is used to generate a well-controlled, stationary vortex. This vortex will serve as a model to study the dynamics of MPs in both Newtonian and complex fluids. Findings from this study provide fundamental contributions to the knowledge about MP–flow interactions, improving techniques for particle sorting and transport with applications in medicine and environmental measurements and potentially provide new insights to turbulence attenuation mechanisms by MPs.

FORMATION AND PROPERTIES OF A STEADY ISOLATED STREAMWISE VORTEX

Intersecting flows, such as the flow in the cross-slot geometry, tend to become unstable and break symmetry at low Reynolds numbers ($\mathrm{Re} = \rho U w/\eta$ where ρ is the density and η is the viscosity of the fluid) resulting in the formation of vortices. In a cross-slot geometry with a low aspect ratio ($\alpha = d/w$ where d and w are the depth and width of the geometry), a single streamwise vortex forms around a stagnation point at the center of the geometry for Re above a moderate critical value (Re_c, Fig. 1 a) [9-10]. By employing the selective laser induced etching micro-fabrication technique in fused silica (Lightfab$^{\mathrm{TM}}$) it is possible to fabricate a fully transparent, highly resistant cross-slot channel, that can be vertically mounted on an inverted microscope (Fig. 1 b). The microscope is equipped with a long working distance objective, enabling a direct observation of the formation of a streamwise vortex (Fig. 1 a-b). The device is washable, reusable, withstands high pressure and is completely transparent, allowing the observation from different planes.

One of the ways to control the vortex properties is by adding elastic forces to the fluid with flexible polymers (4 MDa polyethyleneoxide, PEO). While Newtonian fluids have no elastic properties, even slight addition of polymers, in parts per million (ppm by weight) concentration, increases the relaxation time of the fluid and hence its elasticity increases ($El = (1-\beta)(\lambda\eta/\rho w^2)$), where β is the solvent-to-total viscosity ratio and λ is the relaxation time of the polymer). Slight changes in fluid elasticity may have strong effects on the flow field which lead to a reduction in Re_c and in vortex intensity [11]. Additionally, when $El > 0.011$, the vortex flow becomes unsteady and when El approaches 1, the vortex formation is suppressed.

PARTICLE ARRANGEMENT IN VORTEX FLOW OF NEWTONIAN AND COMPLEX FLUIDS

In order to study the response of MPs to vortex flows, we control the significant factors that influence these interactions. By controlling fluid properties (i.e., density, viscosity and elasticity) and particle properties (i.e., size, shape, density and flexibility) we are able to determine the nature of the interaction between the MPs and the underlying flow. The relative importance of the influencing parameters is commonly described by the non-dimensional Stokes number ($St = t_0 U/w$

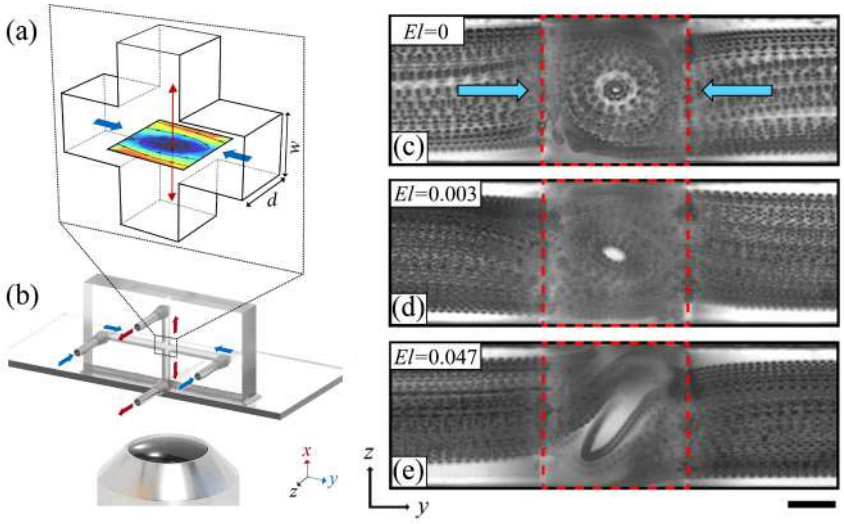

Figure 1: (a) Streamwise vortex formation at the $x = 0$ plane of the cross-slot geometry; (b) A schematic diagram of a microfluidic cross-slot device, used for streamwise vortex visualization, vertically mounted on an inverted microscope. The device is fabricated using laser induced etching technique in fused silica (Lightfab™). Stacks of 500 images of the $x = 0$ plane of the cross-slot channel. Red dashed line marks the borders of the outflow channel. Fluids are 25 wt% glycerol in water with (c) 0 ppm PEO ($El = 0$, $St = 0.03$); (d) 100 ppm PEO ($El = 0.003$, $St = 0.02$) and; (e) 400 ppm PEO ($El = 0.047$, $St = 0.01$). Inflow and outflow are indicated by blue and red arrows, respectively. Scale bar 300 μm.

where t_0 is the time scale of the particle, U is the average flow velocity and w is the characteristic length scale of the flow). The time scale of the particle is estimated by $t_0 = R^2/3\nu$, where R is the diameter of the MP and ν is the dynamic viscosity. Note that St does not account for the changes in the elasticity of the fluid.

MPs response to a single vortex flow is first studied by changing the levels of El of the fluid. We conduct a series of experiments using a microfluidic cross-slot channel with dimensions of $w = d = 1100$ μm ($\alpha = 1$). The flow is driven by 4 individually controlled neMESYS syringe pumps (Cetoni GmbH, Germany) fitted with Hamilton Gastight syringes, ensuring equal volumetric flow rates in the inlets and outlets. Neutrally buoyant spherical polystyrene MPs ($d_p = 80$ μm) are added to 25 wt% glycerol in water at a low concentration (0.2 wt%) in order to avoid interaction between particles. Re is set above Re_c, leading to formation of a stable and steady vortex at Re = 55. Images are captured with a high speed "Photron" camera at a rate of 1000 fps. A single figure is assembled from a stack of all captured images, providing an indication of the path of the MPs in the flow (Fig. 1 c-e). The flow field is shown for three different cases in Fig. 1 c-e with $El = 0$ ($St = 0.03$), $El = 0.03$ ($St = 0.02$) and $El = 0.047$ ($St = 0.01$), respectively. These initial observations demonstrate the effect of weak elasticity on the flow field and the MPs response, leading to non-homogeneous distributions of MPs in a vortex flow field. Although we might expect that particles with $St < 1$ will follow the streamlines of the flow, this is clearly not the case when elastic forces are at play. These experiments provide a simplification for turbulent flows and they represent the possible distribution of particles in intersections of biological flows.

CONCLUSIONS

In this study, a single steady streamwise vortex is formed around a stagnation point in the cross-slot geometry upon exceeding a critical Re for Newtonian and weakly elastic fluids. Adding elasticity to the fluid results in a decrease of the critical Re and in vortex intensity. Although the fluid elasticity is weak (i.e. $El \ll 1$), the non-Newtonian effects lead to distinctly non-homogeneous particle distributions in the vortical flow fields resulting in absence of particles within the vortex core.

REVERSIBLE ACCUMULATION OF COLLOIDAL PARTICLES IN MICROGROOVES BY DIFFUSIOPHORESIS

Naval Singh[1],Goran Vladisavljević[1],Francois Nadal[2],Cecile Cottin-Bizonne[3],Christophe Pirat[3],and Guido Bolognesi[*1]

Summary This work presents a new strategy, based on solute-driven transport mechanism, for the accumulation of colloidal nanoparticles in microgrooves under steady-state and continuous flow settings. Experimental and numerical analysis show how colloids can be steadily accumulated within the grooves of a microfluidic device due to combined hydrodynamics and diffusiophoresis effects.

INTRODUCTION

In recent years, the transduction of chemical energy in the form of solute concentration gradient into particle motion (i.e. diffusiophoresis) and liquid motion (i.e. diffusioosmosis) has been exploited by researchers for the manipulation of nano-/micro-particles in microfluidic devices [1, 2, 3]. Transient salt concentration gradients within dead-end microchannels have been successfully used to achieve enhanced particle transport, into these dead-end structures, driven either by diffusioosmosis [2] or diffusiophoresis [3]. Alternatively, the combination of pressure-driven multicomponent flows and diffusiophoresis directed against these flows was exploited to enable particle accumulation near a junction [4] and within open-ended nanochannels [6].

Here, a novel mechanism for particle accumulation in dead-end micro-structures in continuous flow settings is proposed [5]. Multicomponent flows past transverse microgrooves were used to generate a steady-state salt concentration gradient, which caused the particles to be directed by diffusiophoresis towards the grooves and get trapped therein by recirculation flows induced by the microstructured surface.

METHODS AND MATERIALS

A Ψ-junction microchannel, made of an adhesive polymer (NOA-81), was fabricated and glued to a silicon substrate with parallel microgrooves. Syringe pumps were used to inject an aqueous solution of fluorescent polystyrene nanoparticles (PS-NP), 200 nm in diameter, into the inner channel of the junction, and either deionised (DI) water or an aqueous solution of 10 mM LiCl salt into the outer channels. The outer flow was switched between the DI water and electrolyte solution by means of a flow valve (Figure 1a). A confocal microscope was used to measure the 3D particle concentration field within the main channel and the grooves (Figure 1b). Numerical simulations were performed in Comsol Multiphysics to solve the following PDEs for adimensional pressure p, velocity $\mathbf{u}$ and salt concentration c fields

$$\mathrm{Re}\,\mathbf{u}\cdot\nabla\mathbf{u} = -\nabla p + \nabla^2\mathbf{u} \quad ; \quad \nabla\cdot\mathbf{u} = 0 \quad ; \quad \mathrm{Pe_s}\,\mathbf{u}\cdot\nabla c = \nabla^2 c \tag{1}$$

The adimensional quantities were calculated according to the following scaling relationships: $u \propto U_0$, $x \propto W$, $p \propto \frac{\mu U}{W}$, $c \propto c_{max}$, with U_0 the average fluid velocity, W the channel and groove width, μ the fluid viscosity, c_{max} the salt

concentration of the LiCl solution injected into the device. Reynolds and salt Peclet number are defined as $\mathrm{Re} = \frac{\rho U_0 W}{\mu}$ and $\mathrm{Pe}_s = \frac{W U_0}{D_c}$, respectively, with ρ the fluid density and D_c the salt diffusivity. No salt flux boundary condition and diffusioosmosis slip velocity $\mathbf{v_{DO}} = -\xi_{DO}\frac{\nabla c}{c}$ were imposed at all solid walls, with ξ_{DO} the diffusioosmosis coefficient normalised by $U_0 W$. The nanoparticle's diffusiphoresis (adimensional) velocity field was calculated as $\mathbf{v}_{DP} = \xi_{DP}\frac{\nabla c}{c}$ with ξ_{DP} the particle's diffusiophoresis coefficient normalised by $U_0 W$.

RESULTS AND DISCUSSION

In the absence of salt gradient, particles were simply advected by the flow and the high particle Peclet number hampered their passive diffusion into the grooves (Figure 2a,c). Conversely, when a salt gradient was established by injecting the LiCl solution into the outer channels, particles were accumulated at the entrance of the microgrooves (Figure 2b,d). This phenomenon was stationary and ceased only when the salt gradient was removed. The numerical simulations show that particles were driven by diffusiophoresis from the centre of the main channel downwards towards the grooves and then outwards towards the groove sides (Figure 3c). At the same time, recirculation flows occurring right at the entrance of the grooves, as shown in the blue close-up in Figure 2, trapped the particles within the closed flow streamlines, thereby causing their accumulation at the center of the recirculation region. By alternating electrolyte flows with different and same salinity levels, it is possible to cyclically accumulate and release the particles within the grooves.

To conclude, a new approach for the manipulation of charged nanoparticles in microgrooves based on the combined effects of diffusiophoresis and hydrodynamics (i.e. flow recirculations) was presented. This method offers great potential for microfluidic bio-analytical testing applications, including bio-particle pre-concentration and sorting, signal amplification and highly sensitive biomarker detection. This work was supported by EPSRC grant (EP/S013865/1).

INSECT MICROFLUIDICS: HEARING AND BREATHING WHILE TINY

Anne E. Staples*[1] and Maxwell R. Mikel-Stites[1]
[1]Engineering Mechanics Program, Department of Biomedical Engineering and Mechanics, Virginia Tech,Blacksburg, VA, USA

Summary Insects have evolved to handle fluids using strategies that vary significantly from those used by larger animals since, by virtue of their size, they interact with fluids in the microscale regime, where surface forces dominate. Here we discuss two examples from insect microfluidics: flow actuation in insect respiration, and the amplification of acoustic sound localization cues in a parasitoid fly. We review behavioral data and present the mathematical, computational, and microfluidic device models we have developed to represent idealized versions of these systems that retain the salient features. In both examples, the insects appear to make use of finely tuned structural and material properties in the organs that come into contact with the fluids in question. In the case of the fly, we show that a tympanal asymmetry of just 5% may lead to order-of-magnitude gains in its hearing abilities.

INTRODUCTION

Bioinspired engineering has been a flourishing field of research for decades. From a mechanics perspective, much bioinspired research occurs in the realm of bioinspired materials and locomotion. Bioinspired fluid dynamics has primarily dealt with external flows at the macroscale, where inertial and viscous forces are both important. There are fewer examples of bioinspired internal and microscale flows, in which viscous and surface tension forces dominate. As integrated circuit cooling and lab-on-a-chip technologies develop, it may be fruitful to look to nature for inspiration for handling fluids efficiently at the microscale. Insects provide a particularly relevant group of model organisms. Here, we present two examples from insect microfluidics that we have studied in our laboratory, insect respiratory pumps and the hearing apparatus of the parasitoid fly, *Ormia ochracea*.

Fluid pumping in insect respiratory systems

Insects have the highest metabolic range in the animal kingdom, owing to their unique respiratory systems that do not use blood as an intermediate oxygen carrier. Instead of using lungs, insects take air in through pairs of openings around their body called spiracles. The air passes through the spiracles into a complex network of tracheal tubes that ramify and eventually reach the tissues (See Figure 1). Although the size of the largest tracheal tubes depends on the size of the insect, the size of the smallest tracheal tubes, located next to the tissues, is fixed at around $0.5 - 1$ μm.

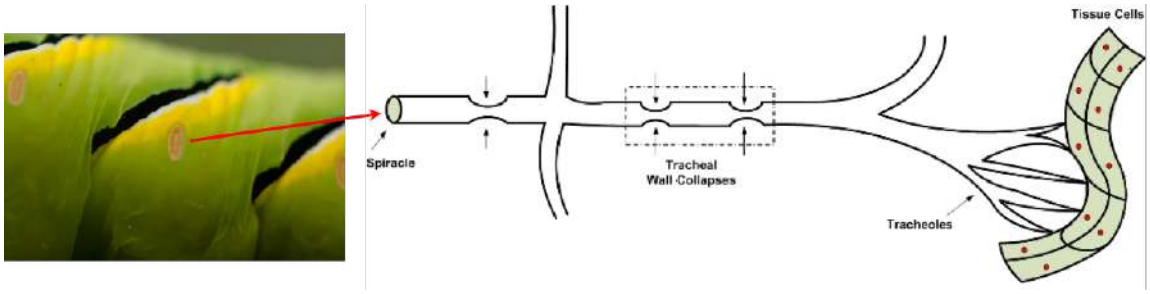

Figure 1: (Left) Close-up of spiracles on a *Manduca sexta* caterpillar. [Steve Begin, Spiracles, Creative Commons (2009); used in accordance with the Creative Commons Attribution (CC BY-NC-SA 2.0) license [1].] (Right) A schematic of the insect pathway for oxygen from spiracle to tissues. Modified with permission from [2].

It has been determined that in many insect species, portions of the tracheal tubes collapse rhythmically during active ventilation [3]. This is indicated by the boxed section labeled "Tracheal Wall Collapses" In Figure 1 (Right). We have developed mathematical, computational, and microfluidic device models that capture the salient features of tracheal-collapse driven respiratory flows (see, e.g., [2, 4]).

Sound localization in a parasitoid fly

Ormia ochracea is a parasitoid fly that relies on phonotaxis to locate its hosts in the horizontal plane. Gravid females locate their cricket hosts with astonishing precision, equal to that of horizontal sound localization in humans, though their small size should preclude this due to fundamental constrains from the physics of sound propagation [6]. Miles *et al.* demonstrated that the fly's two tympanal membranes (highlighted in Figure 2, Left) are mechanically coupled via a cuticular bridge, which increases the interaural time delay (ITD) between the tympana, allowing her to resolve nanosecond time differences, and greatly increasing the precision with which she can locate her larval hosts [5]. Below, we present new experimental and mathematical modeling results that demonstrate that small asymmetries in the tympanal system may lead to large gains in *O. ochracea*'s sound localization abilities.

METHODS

The classical model for hearing in *O. ochracea* can be written as:

$$\begin{bmatrix} k_1+k_3 & k_3 \\ k_3 & k_2+k_3 \end{bmatrix} \mathbf{x} + \begin{bmatrix} c_1+c_3 & c_3 \\ c_3 & c_2+c_3 \end{bmatrix} \dot{\mathbf{x}} + \begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \ddot{\mathbf{x}} = \mathbf{f}, \tag{1}$$

where $\mathbf{x} = (x_1(t), x_2(t))$ is the unknown tympanal amplitude vector, the force applied from the incident sound pressure wave is $\mathbf{f} = (f_1(t), f_2(t))$, and $\dot{(\,)}$ represents differentiation with respect to time, t. The parameters k_i and c_i are spring stiffnesses and dash-pot constants, respectively, and the parameter m is the effective mass of all the moving parts of the auditory system and is assumed to be concentrated at the ends of the intertympanal cuticular bridges. The subscripts 1 and 2 refer to the ipsi- and contralateral tympanal membranes, respectively. [5].

We introduced a size asymmetry between the left and right tympanal membranes into the mathematical model of hearing in *O. ochracea*. Additionally, we made 38 tympanal measurements of 19 *O. ochracea* specimens obtained from the Virginia Tech Insect Collection and the collection of the Smithsonian Museum of Natural History. The specimens were decapitated in order to expose the tympana, photographed with a high resolution camera (Canon 6D dSLR camera with a 65mm MP-E macro lens) and the tympanal areas were measured using ImageJ analysis software [7].

RESULTS

Measurements of the 38 *O. ochracea* tympana demonstrated a mean left-right asymmetry in tympanal area of approximately 5.6% (Figure 2, Center). With the modified mathematical model, we demonstrated that an asymmetry of just 5% in tympanal area can increase the ITD by a factor of 15 compared to the symmetric case (see Figure 2, Right). An additional result from the model, not shown here, is that a 5% asymmetry can also introduce interaural amplitude differences (IAD) four times greater than for the symmetric case, depending on the incident angle of the sound, θ.

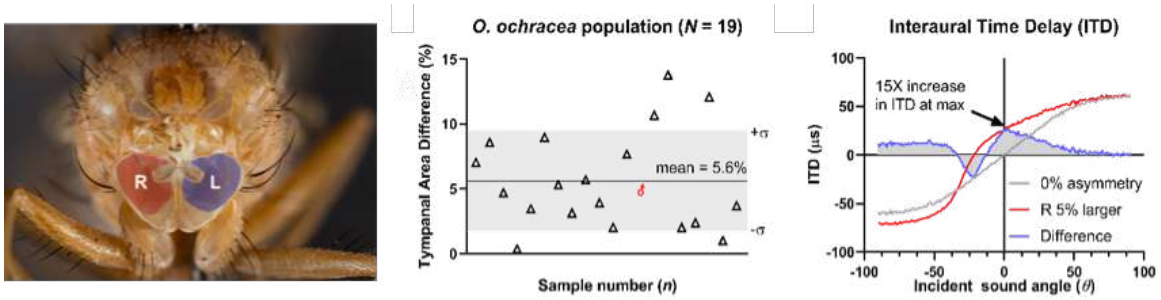

Figure 2: (Left) A headless *O. ochracea* fly with left (L) and right (R) tympanal membranes highlighted. (Center) Percent difference between left and right tympanal membrane areas for 19 *O. ochracea* samples. (Right) Interaural time delay (ITD) between the two tympana as a function of incident sound angle. An asymmetry of just 5% in tympanal area can increase the ITD by a factor of 15.

CONCLUSIONS

The mechanical coupling of the tympana in *O. ochracea* provides a significant advantage to the animal, allowing it to overcome fundamental physical constraints in locating its prey with precision. Here we demonstrate that 1) *O. ochracea*'s tympanal membranes have an average asymmetry of approximately 5.6% in area, and 2) that this asymmetry may allow for an order-of-magnitude additional increase in *O. ochracea*'s ITD and a similarly significant increase (factor of 4) in O. ochracea's interaural amplitude differences (IAD), the two quantities used by the fly to determine its prey's azimuthal location.

DYNAMICAL WETTING IN HYDROPHOBIC NANOPORES DOWN TO ANGSTROM SCALE

Loïc Michel[1],Valentin Gérard[1],Romain Bey[1],Benoit Coasne[1],Elisabeth Charlaix[1],and Cyril Picard*[1]
[1]Laboratoire Interdisciplinaire de Physique, Université Grenoble Alpes, Grenoble, France

Summary Water in hydrophobic confinement is a topic of general importance for industrial applications. Ordered hydrophobic nanoporous materials have been used to study water confined between hydrophobic surfaces in well defined geometries. These materials behave as anti-sponges. The liquid, that can be forced to enter the nanopores at high pressure, is spontaneously expelled out of the pores when the pressure is released. To study the filling and emptying of hydrophobic nanopores, a high pressure apparatus has been built that covers three decades of intrusion/extrusion time at pressures up to 100 MPa. Considering several materials with pore sizes comprised between 0.3 nm to a few nm we study quantitatively the dynamics of filling and drying of the pores and illustrates specificity when going beyond the limits of continuous medium world.

Hydrophobic nanoporous material behave as anti-sponges when immersed within aqueous solutions. The liquid, that can be forced to enter the nanopores at high pressure, is spontaneously expelled out of the pores when the pressure is released. Based on forced intrusion and spontaneous extrusion, the process converts mechanical energy into interfacial energy (see figure 1(a)). Such systems have been envisioned for energy damping or recovery at the macroscale for applications in automotive transport or aerospace [1]. They are appealing for quick operations with a power density larger than the one of supercapacitors. According to the nature of the solid matrix and the fluid, the cycle may have a negligible hysteresis with an extrusion pressure close from the intrusion pressure, of interest for energy storage, or may present a significant hysteresis with an extrusion pressure much smaller than the intrusion pressure of interest for energy damping (see figure 1(b)). In the end, these systems make a bridge between nano or even angstrofluidic phenomena and macroscopic world. The physical grounds of the various observed behaviors are of interest as they are related to general questions concerning transport and wetting phenomena in hydrophobic confinement. Water in hydrophobic confinement is a topic of major importance for industrial applications, such as boiling, heat or mass transfers at interfaces, but also for the general understanding of hydrophobic interactions mediated by water in biological matter and biomolecular responses under osmotic stress.

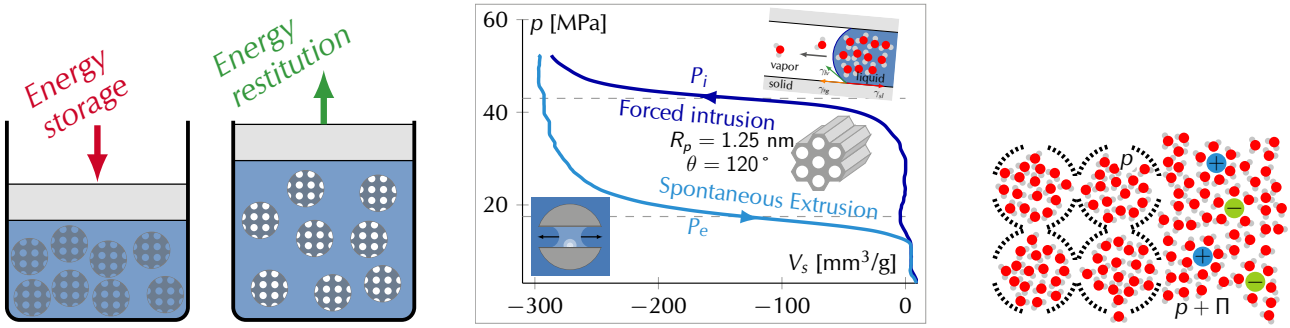

Figure 1: (a) Schematic of the intrusion extrusion process within pulverulent nanoporous material for energy applications. (b) Pressure dependence according to volume during an intrusion/extrusion cycle within hydrophobic nanopore with a radius of 1.2 nm. (c) Schematic of exclusion effect with subnanometric pores.

In this presentation we will focus on ordered nanoporous materials coupled with water or aqueous solutions. Such systems with crystalline structures are well suited to get quantitative insight on the transport of water confined between hydrophobic surfaces. Selecting the nanopore size, the impact of the confinement can be studied down to the limit of validity of the continuum approach and beyond. Among the large family of nanoporous structure, we consider Micelle Templated Silica (MCM-41) developed in the early 90's through condensation of alcoxysilicates and Periodic mesoporous organosilicas (PMOs) a new class of organic-inorganic nanocomposites. These two materials form honeycomb structures of ordered cylindrical parallel nanochannels with pore diameter which can be tuned between 1 to 10 nm. The length of the pore is of the order of 1 micron (see inset of figure 1(b)). These materials, which are natively hydrophilic, are functionnalized with silanol chains to become ultra hydrophobic. The typical intrusion pressure for pure water is of the order of 50 MPa. Additionally we worked with subnanometric pores using a metal organic frameworks (ZIF 8) which presents 1.2 nm spherical cavities interconnected through 0.3 nm gates. This material stable with water is known for its natural hydrophobicity and does not require any functionnalisation. For this material the intrusion pressure is of the order of 25 MPa.

To finely characterize the filling and emptying of hydrophobic nanopores, a specific apparatus has been built working up to pressures larger than 100 MPa in dynamical regime. This apparatus gives access to the time dependence of the bulk pressure of the liquid surrounding the pores and the volume of the system during an intrusion/extrusion cycle. Three decades of time scale down to intrusion/extrusion duration of the order of a few ms are covered. Moreover temperature can be varied between -5° to 70° C. The measured bulk pressure is directly linked to average forces required to promote the liquid flow within the nanopores. The volume variation is related to the amount of liquid stored into the pores. This experimental tool allows to study the dynamics of aqueous complex liquids under strong hydrophobic confinement.

For naporous materials of pore diameter larger than typically ten water molecules, macroscopic concepts still hold. For instance in the cylindrical pores of hydrophobic mesoporous silicas, such as silalized MCM41 interfacial phenomena control both the forced wetting and spontaneous drying of the pores (figure 1(b)). The intrusion pressure p_i obeys mainly the Laplace-Washburn law of classical capillarity and scales as the inverse of the pore radius $1/R_p$ [2]. Intrusion characterized on a large range of intrusion time, in MCM41 and recently PMOs, gives access to the excess pressure to be overcome beyond the Laplace static pressure to force the liquid into the pores. This additional contribution gives the ability to study quantitatively dynamical wetting in model hydrophobic confinement and can be related to theoretical description of contact line dynamics The spontaneous extrusion at pressure p_e, on the other hand was shown to be triggered by the heterogeneous nucleation of nanobubbles in the pore, with a strong contribution of line tension[3]. Incidentally, the study of this process provide a novel technique to measure line tension up to values much lower than the measurement limit, of the order of 100 pN, of current dedicated experimental tools. The negative line tension obtained in MCM-41 is consistent with recent numerical simulation carried out in our group [4].

With sub nanometric pores, such as ZIF-8, a breakdown occurs. Macroscopic concepts, especially the notion of bidimensional interface becomes blur as the range of interactions produced by the wall becomes comparable with the pore diameter. From mechanical measurements done in dynamical regime at various temperature, the pure water case shows intriguing behavior such as a strong impact of isotopic composition. Moreover we demonstrate from macroscopic measurements on electrolyte solutions that molecular sieving of hydrated ions leads to giant osmotic pressures that have to be overcome to be able to fill the pores [5] (see figure 1(c)). This fundamental understanding provide a way to control intrusion and extrusion pressures. Concerning the intrusion process in dynamical regime, a major change with respect to nanometric cylindrical pores is observed, with an excess pressure which presents an unexpected dependence with the intrusion duration and a major dependance on temperature.

PARTICLE MIGRATION IN A MICROFLUIDIC DEVICE ROAD TO CHARACTERIZE VISCOELASTIC LIQUIDS

X. Salas-Barzola[1], A. Naillon[1,2], W. Chevremont[1], C. De Loubens[1] and H. Bodiguel[*1]
[1]Laboratoire Rhéologie et Procédés (UMR 5520), Université Grenoble Alpes, Grenoble, France
[2]Laboratoire sols, solides, structures, risques (UMR 5521), Université Grenoble Alpes, Grenoble, France

Summary Microparticles suspended in liquids are often used to characterize fluids, having a lot of applications in several fields of science *i.e physical, chemical, biological processes*. Polymer solutions are non newtonian viscoelastic solutions. Contrary to Newtonian fluids for which the particles follow the streamlines while flowing in a confined channel, in those liquids they migrate transversely, due to the gradient of normal force at the scale of the particle. The scope of this project is to characterize the viscoelastic properties of very dilute polymer solutions by approaching the behavior of the normal force N_1 through microparticle migration experiments. These experiments are sensitive to very small normal forces (Weissenberg numbers on the order 10^{-3} to 1), a range which is not accessible in traditional rheometry. We have developed for that purpose a dedicated 3D particle tracking velocimetry technique, which allows to determine efficiently the probability density function of the particle position (PDF) and thus lead to a quantitative characterization of the viscoelastic migration phenomenon.

THERORETICAL DEFINITIONS

In 1974, Ho and Leal [1] derived for a second order fluid a theoretical prediction of the transverse viscoelastic force acting on a particle in a confined pressure driven flow. This expression can be rewritten in the following form

$$F_{e,th} = -K\eta\bar{v}_x a Wi \beta^2 z^* \qquad \textbf{Eq. 1}$$

where $\beta = 2a/H$ is the confinement ratio (particle diameter over channel height), a is the particle diameter, v_x is the mean velocity, η is the solution viscosity, $z^* = z/H$ is the reduced height of the particle and Wi is the Weissenberg number, defined as the ratio of the first normal stress difference over the shear stress. Balancing Eq. 1 with the viscous drag force $F_v = 6\pi\eta a V_z$ and assuming that particles flow at liquid velocity in x direction, using Poiseuille law and describing $N_1 = 2\eta\tau\dot{\gamma}^2$, the trajectories of the particle is found to be:

$$\frac{dz}{dx} = \frac{V_z}{V_x} = 2K\beta^2 Wi \frac{z^*}{(1-4z^{*2})} \qquad \textbf{Eq. 2}$$

With this expression we are able to predict the migration phenomena knowing the viscoelastic properties of the polymer solutions. In this work, we first test the above prediction accurately, before enlarging the scope of the problem towards shear-thinning solutions.

EXPERIMENTAL SET-UP

The experimental set-up implemented in this work consists in a thin rectangular capillary channel (Figure 1) mounted in an inversed microscope [2]. Mixing the different viscoelastic solutions with polystyrene fluorescence particles (with different sizes) and letting them flowing imposing a pressure drop with a pump we will be able to track the particles (using a PTV technique) as a function of the travelled distance along the channel.

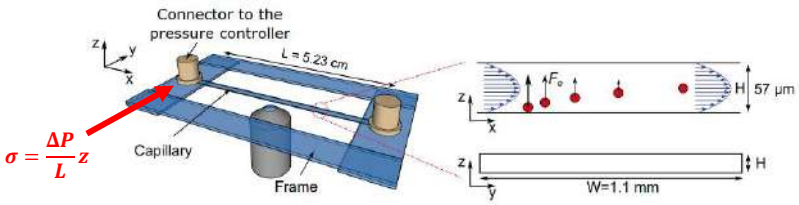

Figure 1. Microfluidic device implemented in particle migration experiments.

In practice, we compute the Probability Density Function of the position of the particles (PDF) at several location, and vary the pressure drop, the particle size and the polymer solutions.

RESULTS

Testing Bogger fluids (Polyacrylamide (PAM) : 150 kDa, 8 to 10% and Polyvinylpyrrolidone (PVP) : 360 kDa, 5 to 10%), we find that the theoretical definitions for the trajectories of the particles well described the migration phenomena, up to a prefactor which is 20% slower than predicted. This discrepancy is probably due to the fact that the theory is valid only for very small confinement. As shown in Figure 2, we are able to account for the evolution of the PDF of the z-

*Corresponding author. E-mail: hugues.bodiguel@univ-grenoble-alpes.fr

position of the particles along the without any fitting parameter. As expected, we find that the greater the pressure drop and the bigger the particles, the quicker the focalisation of the particles in the midplane of the channel.

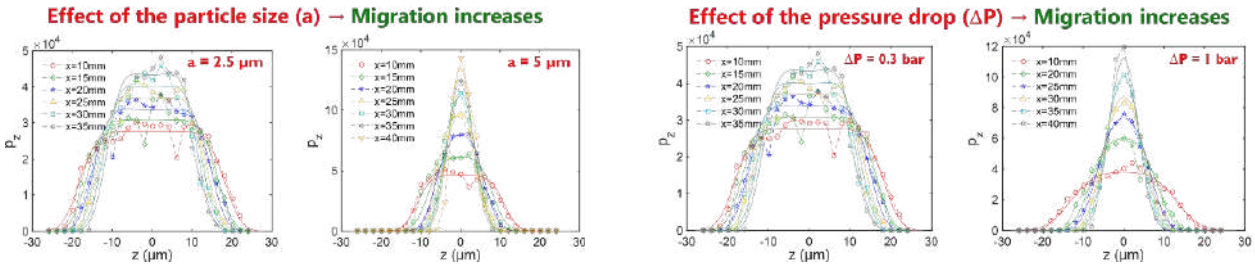

Figure 2. Effect of the particle size (a) and the pressure drop in the dynamics of the migration for Bogger fluids.

To analyse the imprint of the pressure drop in the dynamics of the particle migration, we compute the relative standard deviation of the particle z-position (which is a direct measure of the focalisation efficiency) in function of the pressure gradient. Here, we realise that the tendency is to increase the focalization when the pressure drop is higher for all the tested solutions (Figure 3).

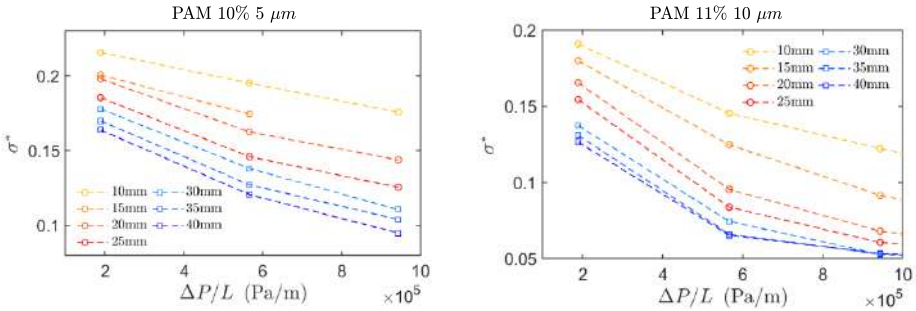

Figure 3. Relative standard deviation of the particle z-position, function of the pressure drop for tested Bogger liquids.

The dynamics of particle migration in shear thinning fluids are quite different from Bogger fluids. Testing FLOPAAM 3630s 6 g/l Na Cl: 18 MDa, 500 1000 and 2000 ppm, we find that the relative standard deviation of the particle is non-monotonic and eventually increases when increasing the pressure drop, as shown in Figure 4. We also found some rolling and sticking particles close to the walls.

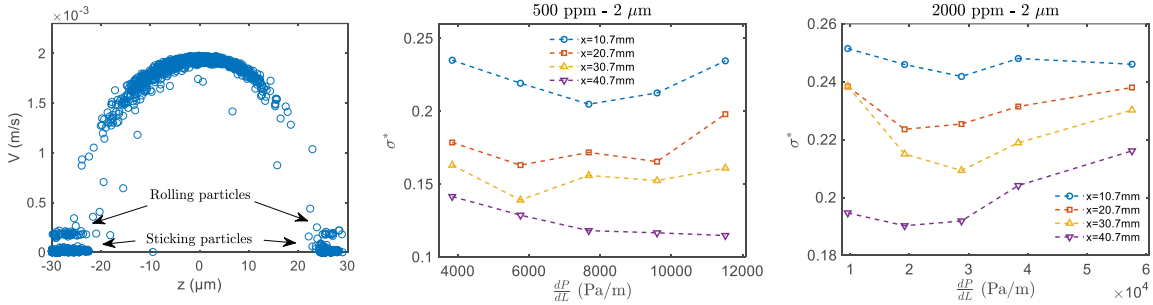

Figure 4. Left: Rolling and sticking particles. Right: Effect of the pressure drop on the migration for shear thinning solutions.

CONCLUSIONS AND OUTLOOKS

All the results presented in this work let us to conclude that the PTV3D method is well suited to study particle migration. We have performed a quantitative experimental validation of the theory for Bogger fluids, where the prediction of the evolution of the PDF along the channel could be used for a range of small $Wi \approx [10^{-3}3–3]10^{-1}]$.
For shear thinning solutions, the fact that the focalization exhibits a minimum when varying the pressure drop is puzzling. We will perform advanced rheometric characterization and direct numerical simulations to better understand these observations.

DEVELOPMENT OF UNSTEADY HYDRODYNAMIC STRESS FIELD MEASUREMENT METHOD USING PHOTOELASTIC TECHNIQUE

Masakazu Muto*[1] and Yoshiyuki Tagawa [1]
[1]Department of Mechanical Systems Engineering, Tokyo University of Agriculture and Technology, Tokyo, Japan

Summary The experimental system for measuring the unsteady stress field in the liquid bulk is required to clarify the mechanism of the aneurysm which induces the human brain damage. In this study, the focus is on photoelasticity, which enables the measurement of the retardation that is proportional to the stress. This manuscript explains the process of the established visualization of the stress field in the fluids. The unsteady retardation field in the liquid polymer is measured by using a Venturi-shaped channel while the normalized values of retardation and stress calculated using numerical simulation under the same condition as the experiment are compared. In addition, the retardation field of the polymer liquid column extended by a CaBER-Dos system is also measured. From these examples of the experiment, the proposed method indicates to be a versatile hydrodynamic stress measurement system for various purposes.

INTRODUCTION

The measurement of hydrodynamic stress field is crucial in numerous situations. In medical field, clarifying the mechanism of aneurysm is critical for early diagnosis of brain damage. Recent work [1] suggested that the wall shear stress at the inner wall of aneurysm may be the principal cause of brain injury. Therefore, the development of experimental visualization of real-time stress field is necessary. This study proposes liquid polymers with photoelastic effects for the visualization of the hydrodynamic stress field. Photoelasticity is an optical method based on the retardation obtained by changes in the polarization state of the polymer solution, which results in proportional stress field values [2]. This method is a non-contact optical measurement with the potential to overcome current problems. However, the proposed method can only measure the retardation proportional to the principal stress difference (i.e., the total of vectors of normal stress and shear stress). Here, the visualization of the retardation field using two different target objects is reported.

METHOD

Figure 1(a) shows a schematic of the experimental setup. The proposed method requires a simple system: a target object located between a high-speed polarization camera (CRYSTA PI-1P, Photron Ltd.) and an incident LED light source (520 nm). The high-speed polarization camera contains an array of micro linear polarizers with four incident angles (0°, 45°, 90°, 135°). Each polarizer is attached to each pixel of the image sensor. Therefore, the polarization camera is capable of capturing the photoelasticity phenomena at frame rates up to 1.55 Mf.p.s. The visualization of photoelasticity requires a liquid polymer with a relatively long molecular chain. When external stress is imposed on the liquid polymer, an increase of the retardation is observed. This is generally known as the effect of the orientation state of the molecular chain [3]. In this experiment, xanthan gum and CNC (cellulose nanocrystal) are used as photoelastic materials. In addition, two different target objects are measured. The first target object is the unsteady flow field of the polymer liquid at the flow rate of 30 ml/min in a Venturi-shaped milli-channel as shown in Figure 1(b). On the other hand, the second target object is the polymer liquid column during the extension due to pure extension stress (normal stress) exerted by a CaBER-Dos (the dripping-onto-substrate capillary breakup extensional rheometry) system [4] as shown in Figure 1(c).

RESULTS & DISCUSSION

The result of the retardation distribution using the xanthan gum solution in the milli-channel is shown in Figure 2 (a). It is confirmed that by the proposed method, retardation can be observed in the fluid flow, as the effect of increased stress in the liquid. Moreover, this method can reveal the area of hydrodynamic stress concentration in the liquid. In addition, the retardation near the inner wall is the highest because of the large wall shear stress. Here, in order to investigate whether both have the same spatial intensity distribution, the normalized retardation measured with the proposed method and the normalized stress calculated with numerical simulation using COMSOL Multiphysics® are compared. From the comparison, at the same measurement area of the center cross-section of the channel, it is confirmed that normalized values and slopes are in close agreement. Therefore, the spatial intensity distribution of the phase difference corresponds to the hydrodynamic stress field.

Figure 2 (b) shows the visualization result of the polymer liquid column during extension with the retardation map in the y- and x-direction. It is confirmed that there is inconsistency in the intensity of retardation between the center and the other parts of the liquid column. The red-shaded regime in the retardation map in the y-direction shows a fixed value of retardation. However, there is a big error in the other regime, because the high curvature of the liquid column prevents the camera from capturing the transmitted light from the light source. On the other hand, the red-shaded regime in the retardation map in the x-direction shows a curve. This is due to the change of the optical length of transmitted light along the circular cross-section. From these results, for the target object with curvature, it is necessary to extract the appropriate area including the correct value of retardation.

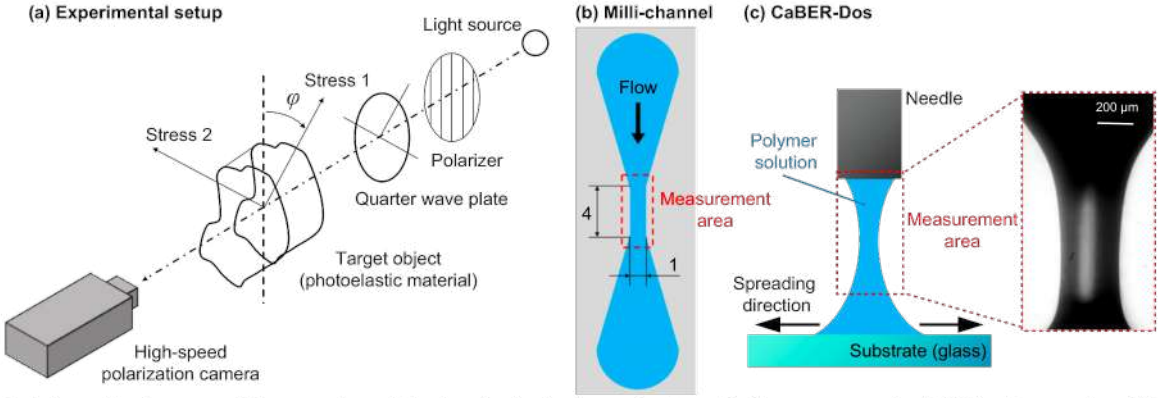

Figure 1. Schematic diagram of the experimental setup for hydrodynamic stress field measurements. (a) The frame rate of the high-speed polarization camera is 5,000 f.p.s. The backlight consists of a green LED light with a wavelength of 520 nm and circular polarization sheet. (b) The liquid polymer flows into the milli-channel is designed with a Venturi-structure with a narrow segment of a rectangular cross-section (1×1 mm^2). The flow is controlled by a syringe pump with a maximum flow rate of 30 ml/min. (c) A CaBER-Dos system generally used for the measurement of elongational viscosity that has a correlation for the neck diameter of liquid column spreading on substrate. Here, pure normal stress field at the state of extension before pinch-off is visualized.

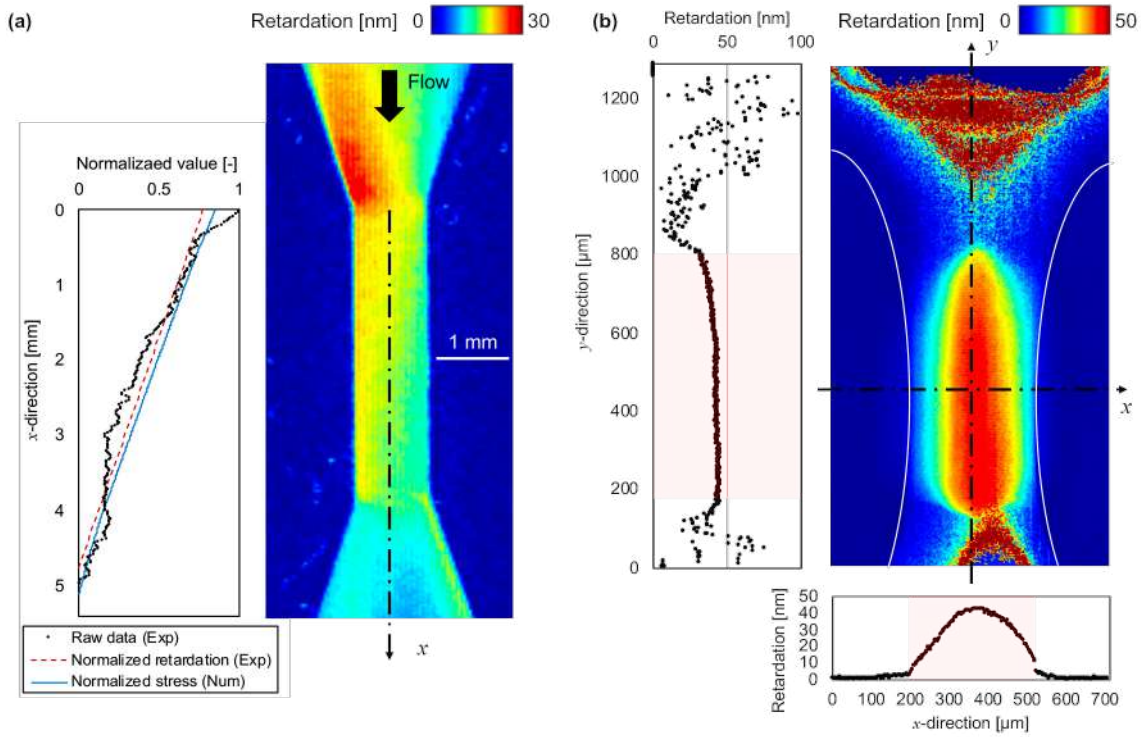

Figure 2. Visualization results of retardation distribution in (a) steady flow field of xanthan gum solution (0.5 wt% in ultrapure water) and (b) extensional stress of the polymer liquid column (mixture of xanthan gum of 0.1 wt% and CNC of 1 wt% in ultrapure water).

CONCLUSIONS

Experimental visualization of retardation proportional to hydrodynamic stress is implemented by the proposed photoelastic technique with a high-speed polarization camera and polymer solution. For the stress visualization using the milli-channel, the calibration between the experimentally measured retardation and the numerically simulated stress is required. However, with the new measurement technique using the CaBER-Dos system, even without numerical simulation, calibration is possible because both retardation and pure normal stress can be measured experimentally.

SURFACTANT INDUCED BACKFLOW ON UNDERWATER LIQUID-GAS INTERFACE

Huiling Duan[1,*], Pengyu Lv[1], Hongyuan Li[1],
[1]State Key Laboratory for Turbulence and Complex Systems, Department of Mechanics and Engineering Science, College of Engineering, Peking University, Beijing, P. R. China

Summary Particle image velocimetry (PIV) is regarded as a typical nonintrusive method for fluid measurements. However, the current work demonstrates that trace amounts of surfactant added to the tracing particle solution induce an unexpected backflow at the liquid-gas interface, which results in an "observer effect" that significantly influences the accuracy of PIV measurements. Here, we reveal the formation mechanism of the backflow, characterize the backflow behavior, and evaluate the quantitative impact of the backflow on the PIV measurements. Our work draws attention to the potential deviations between the measurements and the reality in fluid measurements, especially for studies on liquid-gas interfaces such as slip boundaries, drag reduction, and superhydrophobicity.

INTRODUCTION

"Observer effect" refers to the influence of an observer on reality by the act of watching in the process of experiments, which results in a deviation between the measured value and the true value. The observer effect has been widely demonstrated in both the natural and social sciences, such as quantum mechanics, psychology, sensor performance, and material characterization. Specifically, in fluid measurements, intrusive methods (e.g., Pitot static, hot wire) that involve placing a probe as the observer in the flow field invariably affect the measured value, reflecting the observer effect. Thus, nonintrusive methods (e.g., laser Doppler velocimetry, PIV) are employed to visualize and quantify the flow field, which are presumed to introduce negligible effects on the characteristics of the flow.

Particle image velocimetry (PIV) is a typical nonintrusive method. Through the addition of flow-tracing particles in PIV measurements, the fluid motion becomes observable and measurable. Properties of particles, such as the size, density, following behavior, light scattering, and dispersity in the fluid, are essential to the PIV measurements. For most commercial flow-tracing particles, surfactants must be added to the particle solution to inhibit the agglomeration of particles and ensure stable and well-dispersed particles. However, even trace amounts of surfactant have been demonstrated to have a significant influence on the local flow near the boundary. At the liquid-gas interfaces in the flow, surfactants accumulate at downstream stagnation points, which induces Marangoni stresses opposite to the mainstream direction and thus limits the drag reduction. The slippage is also sensitive to the presence of surfactants, which causes the measured local slip length to be two orders of magnitude smaller than the theoretical prediction. As the flow field is changed by adding surfactants, the accuracy of PIV measurements is significantly affected, which should no longer be ignored, especially for studies on liquid-gas interface phenomena such as the slip boundary, drag reduction, and superhydrophobicity [1-3]. Although previous attempts have been made to investigate the influence of surfactants on the flow, the underlying mechanisms for this strong observer effect are still not clear, and a well-designed experiment is required to systematically visualize, quantify, and evaluate this effect, which is the scope of the current work.

"OBSERVER EFFECT" IN FLUID MEASUREMENTS: BACKFLOW AT LIQUID-GAS INTERFACES

In this work, backflow at the liquid-gas interface is directly observed during PIV measurements, which changes the original flow field and thus reveals a strong observer effect. The surfactant in the particle solution along with the geometric features of the microchannel is demonstrated to be crucial to the formation of this backflow. The backflow behavior is also characterized, in which a kinematic similarity is characterized to predict the backflow behavior under different flow rates. Importantly, the observer effect of the backflow on the PIV measurements is evaluated through quantification of the local slip length. The negative local slip length indicates the loss of accuracy of the PIV measurements. The current work can serve as a model system for investigating the backflow and aims to attract attention to the observer effect in fluid measurements.

MASS PRODUCTION OF MULTI-SCALE FEATURES FOR MICROFLUIDIC AND NANOFLUIDIC APPLICATIONS

Michael D. Gilchrist*and Nan Zhang
School of Mechanical & Materials Engineering, University College Dublin,Ireland MiNAN Technologies, Dublin,Ireland

Summary Injection moulding of polymers with sub-micron and nanometre scale features is an ideal process for the mass production of microfluidic and nanofluidic devices for life science applications. However manufacturing tool inserts with inverted sub-micron and nanometre scale features is a challenge for industry. Recent research has led to the development of a method of using Bulk Metallic Glasses (BMGs) as tool materials that allow for nano-features to be incorporated into a replicating mould tool. BMGs have similarly high strength and wear resistance to Nickel, but they have no minimum microstructural size limits because of their amorphous nature. These tools can be used for manufacturing for over 20,000 moulding cycles while retaining the definition of sub-micron sized features. The smallest features that we have machined in BMGs are 85nm.

MOTIVATION

Compared to conventional tool steels, Ni is softer and develops pitting defects during moulding cycles, which may transfer toxic elements to moulded plastic devices. Furthermore, electroforming of Ni is not an environmentally friendly manufacturing process. Bulk Metallic Glasses (BMGs) are a class of amorphous metals without an intrinsic grain structure. FIB milling (focussed ion-beam) can be used to machine metallic glasses as mould tools to prototype multi-scale features that range in size from microns to nanometers.

A traditional disadvantage of manufacturing with BMG tools is the higher cost of raw materials and the need for a master, when compared to Ni electroforming. This prohibits the large uptake of BMG tools. In methods that we have developed recently, an environmentally friendly BMG tool can be used in batch manufacturing production of micron-scale features while also reducing tool cost dramatically, matching commercial Ni tool prices. We have demonstrated the use of these newly developed methods to manufacture microfluidic features with complex shapes that are tens of microns in size. This provides new opportunities to produce polymeric microfluidic and nanofluidic devices suitable for life science applications targeted at bacteria and viruses with dimensions that correspond to these sizes, as indicated in Figure 1.

FOCUSSED ION-BEAM MILLING

Figure 2 (left and middle) shows FIB milled patterns on BMG tools. The minimum feature that was successfully replicated was c. 85 nm on the UCD logo pattern (spacing between individual harp strings). The maximum aspect ratio of the corresponding ridges is c. 2. The mean height of ridge 3 was selected to indicate the quality of replication [1].

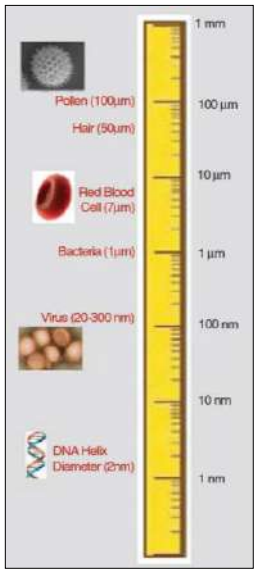

Figure 1: Biological length scales

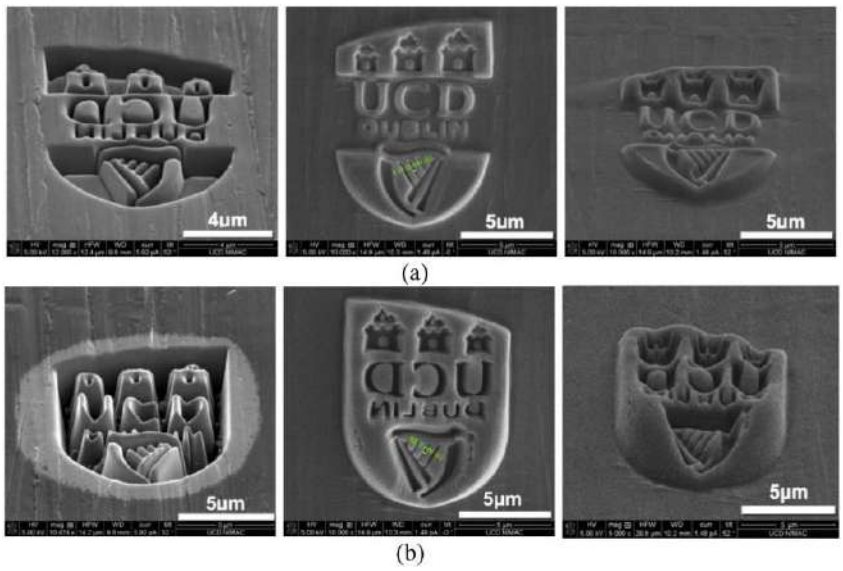

Figure 2 Surface patterns of BMG and replica: positive (a) and negative (b).

THERMOPLASTIC FORMING

Except for FIB milling, BMGs can be hot-embossed like plastics in their super cooled liquid region. Figure 3 (left) shows thermoplastically formed BMG ridge patterns that are 100 um high and that are spaced 300 um to 1 um apart. Ridges are well replicated when the spacing is larger than 10 um. Figure 3 (right) is an array of 10x10x10 um pillars embossed using BMG with a Si master.

Conventional thermoplastic forming process of BMGs uses a Si master and etches Si away after hot embossing; the master is not reusable. Si is brittle and easy to break when subjected to non-uniform pressure. Etching Si using KOH solutions causes tool surface oxidation and reduces tool life. Relatively expensive raw materials, a disposable Si master and the risk of breakage make it expensive to manufacture reliable BMG tools. Recently, however, we have developed a process to manufacture BMG tools via a reusable master and high pressures at moderate cost and without any risk of etching-induced oxidation, as shown in Figure 4. This technology is potentially useful for producing nanometer-scale fluidic tool inserts.

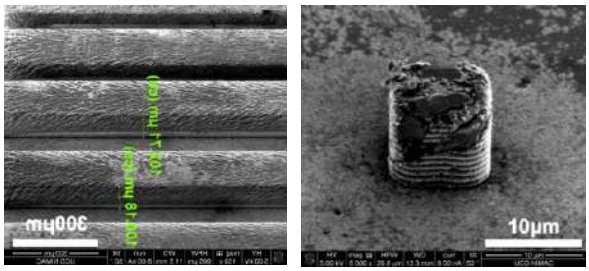

Figure 3. BMG tools embossed using Si master: ridges (left) and pillar (right).

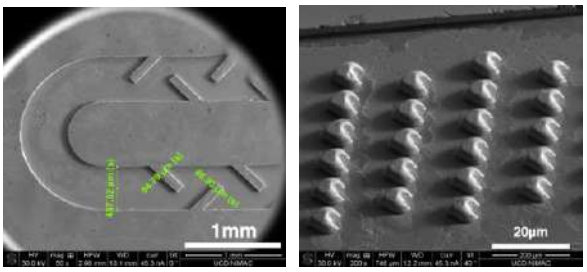

Figure 4. BMG tools produced using developed technology.

Figure 5 compares the hardness of various tool materials. Unhardened Stavax stainless steel tool had a hardness of 223HV and was hardened to 649HV. Nickel tool mechanical properties relies on electroforming conditions with hardness from 166~257HV. BMG has a hardness of 509HV and shows better mechanical properties than Ni. When used in injection moulding, a BMG tool with features smaller than 10 um can sustain ~20000 cycles [2]. By comparison, Ni inserts start to exhibit surface pitting defects and fracture after 130 moulding cycles, depending on process conditions [1].

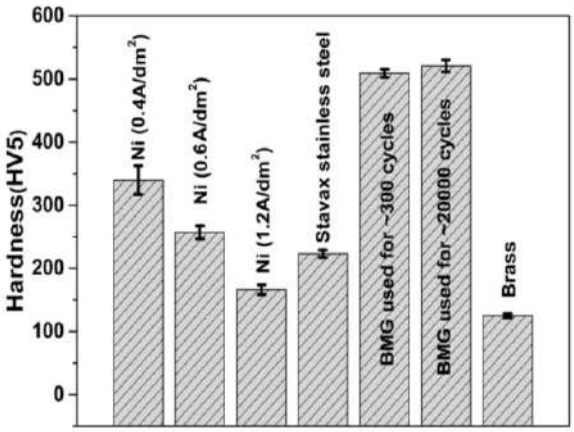

Figure 5. Hardness of various microfluidic tool insert materials.

CONCLUSIONS

Multi-scale mould tools that can be used for the mass manufacturing of polymer microfluidic and nanofluidic devices require precise definition of features that range in dimensions from c. 100 nm to centimeters. We have shown how the use of amorphous metals, specifically BMGs, are appropriate tool materials that allow for nanometer scale features to be incorporated into a mould tool, and that such a tool can be used to replicate more than 10,000 moulding cycles with high accuracy and repeatability, both quickly and cost-effectively.

ANOMALOUS DIFFUSION OF NANOPARTICLES IN LIPID MONOLAYERS

Xu Zheng*[1], Yang Liu[1], Dongshi Guan[1], Xikai Jiang[1] and Guoqing Hu [2]

[2]School of Aeronautics and Astronautics, Zhejiang University, Hangzhou, China

Summary The diffusion of membrane inclusions is crucial for various cell functions; however, its physical mechanism remains ambiguous due to the complex membrane structures. Herein, we investigate the diffusive motions of two different nano inclusions in dipalmitoylphosphatidylcholine (DPPC) monolayers. The first inclusion is the self-assembled microdomains of DPPC molecules, by which we can measured two-dimensional diffusion of an inclusion with molecular thickness. The second case is polystyrene nanoparticles embedded in DPPC monolayers, by which we can simulate nanoparticles dynamics in various biological membranes. Our results show that the diffusion of nanoparticles in lipid monolayer not only presents behaviour distinct from previous hydrodynamic prediction, but also manifests intriguing statistical features.

INSTRUCTION

Lipid membranes, such as cell membranes or lung surfactant membranes, are ubiquitous in biological systems. Despite their different functions, lipid membranes have a common structure - a thin film consisting of lipid and protein molecules. An early fluid-mosaic model treated the live cell membrane architecture as a two-dimensional (2D) fluid matrix in which the lipids and proteins are randomly dispersed. These membrane inclusions are inherently dynamic; thus, deciphering their diffusion is essential for understanding many cellular processes, such as signal propagation, membrane trafficking, and protein sorting [1]. From a physical perspective, the viscosity of the membrane and the mobility of membrane inclusions can both be determined from the lateral diffusions of the inclusions in the plane of the membrane.

The hydrodynamic description of the flow resistance of diffusive inclusions in a two-dimensional (2D) membrane has been a critical challenge [2-3]. The diffusion coefficient of membrane inclusions was initially given by Saffman-Delbrück (SD) [2]. By assuming that a uniform membrane at air-water interface has a 2D viscosity, the diffusion coefficient of a membrane inclusion in the SD model has been proposed. However, the SD model is a linear approximation. Later, Hughes, Pailthorpe, and White (HPW) extended the SD model [3] and applied it to describe the diffusion of larger inclusions, such as condensed microdomains in synthetic lipid membranes. However, it was recently found that the dispersed condensed domains formed by phase separation appeared not only on the micrometer scale but also on the nanometer scale that are in the continuous fluid phase [4-5]. Unless the membrane can be treated as homogeneous, the diffusions in membranes with heterogeneity will become more complicated than the descriptions of the SD and HPW models. Hence, it is vital to study the diffusion of membrane inclusions by considering the dynamic impact from the surrounding heterogeneous structures.

In this study, we first measured the diffusion of microdomains in the monolayers of DPPC, which is the predominant constituent of a lung surfactant film. As a well-controlled 2D model membrane system, the DPPC monolayer can help disentangle the out-of-membrane effects that are difficult to avoid in live biological membranes. After that, we dispersed polystyrene nanoparticles in the DPPC membrane on the air-liquid interface.

RESULTS

1. The 2D diffusion of DPPC domains

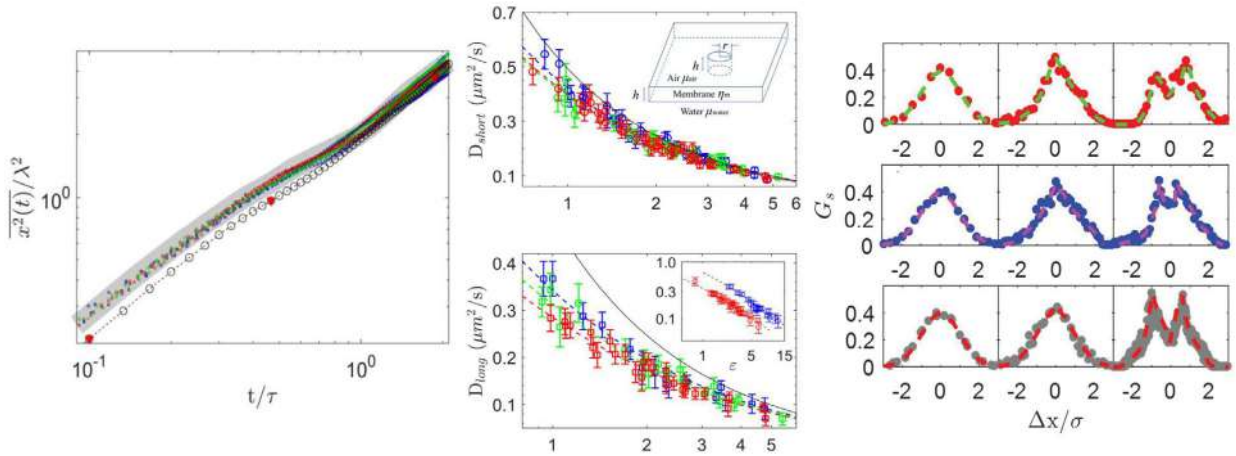

Figure 1. The characteristics of 2D membrane diffusion. (a) two-staged MSD; (b) the long-time and short-time diffusivity; and (c) the double peaked displacement probability distribution (DPD).

*Corresponding author. E-mail: zhengxu@lnm.imech.ac.cn

We find that the self-asembled domains nearby significantly impact the hydrodynamic mobility and the statistical feature of the diffusion, which are different from the existing theories considering the membrane as homogeneous. The diffusion can be divided into multiple stages (Fig.1a): short-time linear motion, then confined diffusion, and finally "anomalous yet Brownian" behavior that shows a linear MSD but an unusual double-peaked DPD. Thus, two membrane viscosities (Fig.1b, viscosity can be calculated from diffusivity) are needed to describe the hydrodynamic mobility of the microdomains: the short-time one describes the local continuous phase, which is found to be independent of the surface density of DPPC; while the long-time one describes the global phase taking into account the nanodomains, which is approximately three times larger than the local viscosity and increases with the DPPC density. Despite of the multistage MSD, the short-time or long-time diffusion coefficient can be described by HPW's hydrodynamic theory respectively (Fig.1b). Our results also unveil unusual displacement probability distributions (DPDs) of the diffusion in DPPC monolayer with heterogeneous nanodomains, which contain valuable information of the diffusion dynamics and domain-domain interactions. The temporal evolution of the DPD demonstrates that the interaction between a microdomain and the surrounding nanodomains varies at different time scales. In the early stage, the confinement from nearby nanodomains dominates, which can be described and quantified by the energy barrier theory. In the late stage, the dynamic nature of the nanodomains induces a disturbance of the positions of the nanodomains relative to the microdomain, and the nonuniformity of nanodomains causes a net dipolar repulsive force on the microdomain and generates the double-peaked DPD. We unveil the double-peaked DPD as a distinct feature of the "anomalous yet Brownian" behavior in monolayer, which differs from previously reported non-Gaussian DPDs in other complex systems that exhibit a central sharp peak or heavy tails.

Diffusion of nano polystyrene particles in the DPPC monolayer

We still use the same DPPC monolayer, and disperse polystyrene nanoparticles (radius R is from 50 nm to 500 nm) in the membrane. By particles tracking, we measure the MSD, diffusivity, and DPD of the nanoparticles based on the same experimental method as before. As the diffusivity D can be expressed as $D = k_BT/f\mu R$, we can estimate the drag coefficient f from diffusivity, and compare it with previous theory [6]. We found that the drag coefficient f is consistent with the theoretical prediction when R = 500 nm. However, the drag coefficients f of R =50 nm and R =100 nm are found to be 5-10 times larger than the theoretical prediction. We attribute the deviation to the microscopic moving contact line of the interface on the particle and the dynamically variation of the interface.

CONCLUSIONS

The diffusion of nanoparticles in biological membranes remains unclear, especially due to the complex structure of the membrane. Our results show that the diffusion of nanoparticles in lipid monolayer not only presents behaviour distinct from previous hydrodynamic prediction, but also manifests intriguing statistical features.

A SCALING LAW FOR THE NECK-SHAPE IN MICROFLUIDIC FLOW-FOCUSING DEVICE

Tetuko Kurniawan[1,2], Piotr M. Korczyk[1*]
[1]Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, Poland.
[2]President University, Bekasi, Indonesia.

Summary Droplets in microfluidic devices are generated by crossing flows of two immiscible fluid in a confined space. The core point of models describing droplet detachment process from a stream of the droplet phase is the formation of the so-called neck – the constriction of the droplet phase, which finally breaks, releasing a new droplet. In low Capillary number (Ca) range, the neck shrinks through a series of quasi-static shapes that were determined by the instantaneous volume behind the neck and the geometrical confinement of the junction. Surprisingly, the squeezing model predicts that the droplet size is independent of the shear. Here, we reveal that in flow-focusing device, the geometrical confinement is unable to ensure the evolution of quasi-static shapes, such that the neck becomes dramatically prone to the magnitude of shear. We provided a scaling analysis to explain this dependency.

DEPENDENCY OF AREA UNDER THE NECK TO CAPILLARY NUMBER

The squeezing model, firstly introduced in the seminal paper of Garstecki et. al.[1], is the formation of droplet at low Ca (= $\mu_C Q_C / \gamma HW$, where μ_C and Q_C are the viscosity and flow rate of continuous phase respectively, γ is interfacial tension, H and W is the height and width of channel respectively). It is understood that droplet size produced in this squeezing regime, either in T-junction or in flow-focusing device (FFD) is insensitive to Ca, as long as flow rate ratio $q = Q_C / Q_D$ (where Q_D is the droplet phase flow rate) is kept constant, as stated by its scaling law: $\ell_D = \ell_0 + v_{N0} q$ (where ℓ_D is the dimensionless droplet length, with ℓ_0 and v_{N0} as constant parameters represent droplet's initial volume filling the outlet channel and total volume displaced by the neck, respectively). The insensitivity to flow rate parameters makes the squeezing regimes convenient for microfluidic application. However, earlier reports[2], [3]have shown that at some point the droplet size increases greatly as Ca is decreased further. This leads to the new leaking model[4]:

$$\ell_D = \ell_0 + q\, v_{N0} + \frac{\phi}{\mathrm{Ca}} . \qquad (1)$$

The strong dependency to Ca (see last term of Eqn. 1) is due to the leaking process, where the continuous-phase flows around the droplet through the corners of the channel (the so called gutter).

Our experimental analysis of the formation of droplet in FFD revealed that besides the effect of leaking there is another source of Ca dependence – the variation of the size of the neck. In case of T-junction the neck evolution is well localized and the break-up always occurs in the edge of T-junction. So in the case of T-junction the parameter v_{N0} associated with the volume of the continuous phase accumulated behind the neck is assumed to be constant. In contrary, in case of FFD, we observed that the neck is much longer than the width of the channel and it's final length (prior to break-up) becomes very large at very low Ca (see Fig. 1(a)). This behavior is allowed in FFD because the edges in the cross-junction does not play any role in the development of neck, supported by the observation that the position of break-up does not seems to be correlated to the edge position. As a consequence, in FFD the coefficient v_{N0} in Eqn. 1 is not constant and increases sharply as Ca decreases. This is confirmed by measurement of ℓ_D as a function q at fixed value of Q_C (i.e. constant Ca) as shown in Fig. 1(b). Assuming that v_{N0} is solely function of Ca, we can approximate it as the slope of the linear relation ℓ_D versus q . Fig. 1(c) shows the v_{N0} extracted using this assumption and taken from the experimental data of five distinct rectangular cross-section devices (shown as different aspect ratio(W/H)) and one

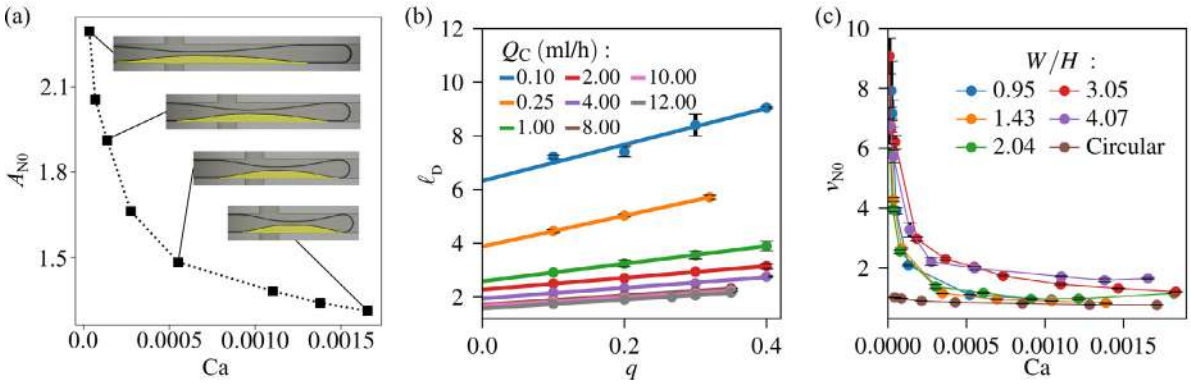

Fig. 1. (a) Visualization and measurement of neck area, A_{N0} , that drastically increases at vanishing Ca. (b) the slope of ℓ_D versus q at fixed Q_c can be use to approximate v_{N0} . The slope is higher for lower Q_c (i.e. lower Ca). Data is taken from device with W/H = 4.07. (c) Comparison of v_{N0} at low Ca from various rectangular cross-sectional devices and single circular device with radius of cross-section 0.2 mm.

* Corresponding author: piotr.korczyk@ippt.pan.pl

circular cross-section channel. v_{N0} increases drastically at decreasing Ca in rectangular cross-section devices but not in a circular cross-section device. This confirms the importance this effect in the leaking regimes of commonly used rectangular cross-section microfluidic devices. Note that although dependency of v_{N0} to flow rate parameters were indicated in previous T-junction[5] and FFD[6]literature, the changes of v_{N0} is not very significant at higher Ca flows (squeezing or dripping regime), such that it's effect is usually neglected. The non-negligible dependency of v_{N0} to Ca in the leaking regime has lead us to revise the previous assumption and modify the scaling law.

SCALING ANALYSIS OF v_{N0}

To explain the observations of v_{N0} variation we explored the simplified model of the evolution of the cosine-like profile of the neck (see Fig. 2). The analysis of the distribution of the capillary stress on such a profiles reveals that such a shape tends to increase its width for the relaxation of the stored potential energy. We Assume that the magnitude of capillary action depends on the maximal amplitude of the curvature - λ/ω^2 (where λ and ω are the height and the width of the profile respectively). The motion of the side edge points of the profile is supposed to be slowed by the viscous friction proportional to the speed of the edge propagation. Finally, balancing both interactions acting on the profile we obtained the following relation $\mathrm{d}\omega/\mathrm{d}t = c\,\lambda/\omega^2$, where $c = \xi\gamma/\mu_C$ and ξ is a constant coefficient of the length dimension corresponding to the height of the channel. Further analysis revealed Ca-dependency of neck shape as:

$$v_{N0} \propto \mathrm{Ca}^{-1/2} . \tag{2}$$

The scaling law was able to describe the exponential increase of v_{N0} at low Ca regime, as shown in Fig. 3 (a). Introduction of this relation into Eqn. 1 gives the extended leaking model, which is in very good agreement with the experiment results, as shown in Fig. 3 (b).

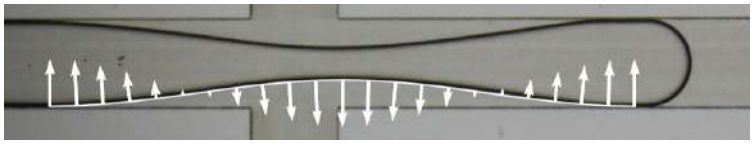

Fig. 2. The cosine-like neck profile shown as the white curve. The arrows are the $\kappa\hat{\mathbf{n}}$ vectors, where κ is the instantaneous curvature at any point along the curve and $\hat{\mathbf{n}}$ is the unit normal vector.

COLLABORATIVE DRAG REDUCTION OF MIXED SURFACTANTS AND POLYMERS

Jinjia Wei*[1,2], Dongjie Liu[2] and Fei Chen[1]
[1] School of Chemical Engineering and Technology, Xi'an Jiaotong University, Xi'an 710049, China.
[2] State Key Laboratory of Multiphase Flow in Power Engineering, Xi'an Jiaotong University, Xi'an 710049, China.

Summary Drag reduction performance and mechanism of mixed cationic surfactant and nonionic polymer were studied by using experiments and coarse-grained molecular dynamics simulation. The results showed that the mixed solutions have an intensified drag reduction performance, especially in low and high Reynolds number ranges. The addition of polymers can facilitate the coalescence of small micelles to form larger size micelles, and it can also help to share the shear action and balance the energy distribution of the micelle, to postpone the appearance of the energy extreme point and delay the rupture of the micelle structures, thus leading to the strengthened drag reduction performance.

INTRODUCTION

It is well known that the addition of small amounts of additives can cause a significant drag reduction effectiveness in turbulent flow[1].The phenomenon can reduce energy consumption and has immense applied value in industry. Polymers and surfactants are two most efficient types of additives in drag reduction. However, they have their own advantages and disadvantages. Polymers cause a drag reduction effectiveness by adding few parts per million by weight, but subject to mechanical degradation. The greatest strength of surfactants is its revisable mechanical degradation characteristics, however, surfactants need concentration above the critical micelle concentration (CMC) to form micelle structures, and showed deteriorated drag reduction performance under high Reynolds numbers due to the destruction of micelle structures. Because of the complementarity between polymers and surfactants, we want to combine them to form a mixed solution for a better drag reduction effect. It is generally believed that the formation of complexes or aggregates of polymer and surfactant is the main reason for drag reduction. For revealing the mechanism of surfactant-polymer drag reduction, some investigations have been performed on the microstructures and dynamic properties of surfactant-polymer aggregates by modern experimental techniques, such as light scattering, NMR spectroscopy surface tensiometry, viscometry and so on. However, most of the relative research is at the macro-level. To explore the phenomenon in surfactant-polymer systems at a molecular-level. The molecular dynamics (MD) simulation is an effective research method and a powerful tool to investigate such phenomena from molecular scale [2,3]. The aim of this work is to investigate the intensification of drag reduction effect caused by the mixtures of cationic surfactant and nonionic polymer solution, and to reveal the corresponding mechanism by simulating the microstructures of the mixed solution.

MEASUREMENT AND SIMULATION

Test facility

The experimental apparatus was a closed loop system consisted of a storage tank, a heater, a centrifugal pump, a setting chamber, a smooth two-dimensional (2D) channel, a diffuser and other measurement instruments. The fluid was pumped into the smooth channel and the flow rates were measured by electromagnetic flowmeters. The 2D channel was 10mm in height(H),125mm in width(W) and 3m in length. The pressure drop of the test section was measured by a differential pressure transmitter.

Surfactant and Polymer

A cationic surfactant - cetyltrimethyl ammonium chloride (CTAC) was used,and Sodium salicylate (NaSal) was used as the counter-ion salt with the same weight concentration as that of surfactant. Both solutes were added to the tap water and the mixed solution was left to stand at least 24 hours before mixing with the polymer solution. A kind of nonionic polymer - nonionic polyacrylamide (PAM) with the molecular weight of $Mv=6*10^6$g/mol was used. PAM was swelled in water for 12 hours first and then stirred in the 50℃water bath at a constant speed for 4 hours until it was dissolved. Then these two solutions (polymer and surfactant) were mixed by a stirrer and left to stand for 24h.

Molecular model

A Coarse-grained (CG) model was employed to simulate the microstructures and rheology of surfactant/polymer solution. Each site represents a group of atoms and the rank of CG sites is based on the MARTINI force field. Four main types of interaction sites are considered in this force field: polar (P), nonpolar (N), apolar (C) and charged (Q).The simulations are performed with LAMMPS simulation package. The simulations started from a random distribution of surfactants, salts, polymers and water molecules in a 23.1nm*23.1nm*23.1nm simulation box. The original distribution was obtained from PACKMOL. The system was minimized and then NPT simulation was performed. At last, the NVT simulation was performed to obtain the final structures. The temperature was 300 K and the pressure was maintained at 1 bar. Particle-Particle Particle-Mesh (PPPM) solver was used to compute long-ranged electrostatic interactions.

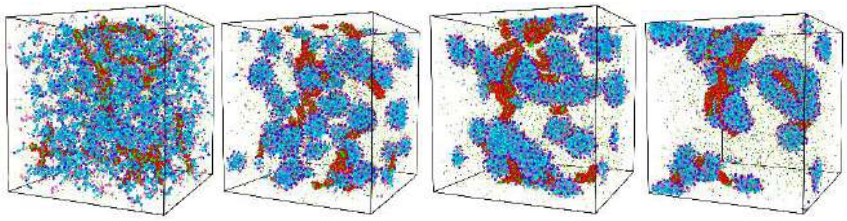
RESULTS AND DISCUSSION

Drag reduction of mixed surfactant and polymer solutions

Four concentration combinations of mixed solution were tested at 6 different temperatures range from 25℃ to 50℃ at different Reynolds numbers. The mass concentration of polymer solution is 60ppm and that of CTAC solution is 100ppm. The results indicate that the curve of mixed solution is similar to that of pure CTAC solution, but different to that of pure PAM solution. Before the critical Reynolds number, surfactant micelles play a leading role in drag reduction while after the critical Renolds number, the micelles play a supporting role, on the contrary, polymer molecules dominate the rest experiment. The drag reduction behavior can be divided into three parts: enhanced drag reduction zone, stable drag reduction zone and destroyed drag reduction zone.

Coarse-grained molecular dynamics of mixed surfactant-polymer solutions

Figure 1 shows the sequential snapshots of microstructures. Initially, CTAC and polymer randomly distribute in the box (Figure 1(a)). At the first stage, CTAC molecules aggregate each other and PAM chains curl up, shown as Figure 1(b). This behavior is similar to the CTAC/PAM system. In the second step (Figure 1(c)), CTAC molecules form bigger spherical micelles and conglutinate with PAM chains. The presence of NaSal makes the both hydrophilic head groups arrange more closely as the charges are neutralized. In the third stage, PAM polymer chains drive CTAC micelles get closer to each other and worm like micelles form. Finally, the PAM polymer chains entangle with CTAC surfactant micelles and form surfactant-polymer complex interconnected network structures, reducing contact area with water (Figure 1(d)). Figure 2 shows Cyro-TEM image of the mixed solution, we can clearly see that the polymer can condense the surfactant micelle structures locally, which validates the molecular dynamics simulation.



(a) 0 ns (b) 40 ns (c) 190 ns (d) 460 ns

Figure 1 Snapshots of the mixed solution.

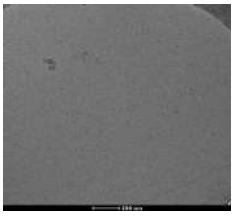


Figure 2. Cyro-TEM image of the mixed solution

Mechanism of the formation of surfactant-polymer network structures and drag reduction

It is found in the mixed solution that the CTAC micelles and PAM chains can form interesting complexes with interconnected network structures. The mechanism of the formation of the aggregates can be attributed to the the attraction between acylamino group and the head of CTAC, and the attraction between Sal^- and acylamino group. The addition of PAM can help facilitate larger size micelles, help to share the shear action and balance the energy distribution of the micelle, to postpone the appearance of the energy extreme point and delay the rupture of the micelle structures, thus leading to the strengthened drag reduction performance.

CONCLUSIONS

We investigated the intensification of drag reduction performance caused by mixtures of cationic surfactant and nonionic polymer solutions by experiments, and revealed the corresponding mechanism by simulating the microstructures of the mixed solution. The mixed solution systems can increase drag reduction efficiency by providing a wider range of Reynolds numbers, especially in enhanced zone and destroyed zone. It was found in the mixed solution that the CTAC micelles and PAM chains can form interesting complicated network structures, in which the polymer helps to form larger micelles and strengthen the network and protect surfactant micelles from being destroyed by shear stresses, improving the drag reduction performance.

CONTROLLING PURELY-ELASTIC INSTABILITIES

Robert J. Poole*[1], and Mahdi Davoodi[1,2]
[1]School of Engineering, University of Liverpool, Liverpool, L69 3GH, UK
[2]Schlumberger Cambridge Research, High Cross, Madingley Road, Cambridge, CB3 0EL, UK

Summary Complex fluid flows are ubiquitous in both the natural and man-made worlds. For such complex fluids the underlying microstructure can give rise to flow instabilities which are often totally absent in "simple" Newtonian fluids such as water or air. For example, beyond a critical flow speed in viscoelastic fluids, driven by elastic normal-stresses, the flow may break symmetry, become time dependent or even chaotic (so-called "elastic turbulence") in the total absence of inertia i.e. creeping-flow. Often such instabilities are unwelcome, for example in rheometric devices when the aim is to measure material properties or in simple pumping operations when they can give rise to unacceptably large pressure drops and prevent pumping. In the current paper we discuss a number of ways such onset conditions can be altered in order to control their onset.

INTRODUCTION

Complex fluids such as emulsions, colloidal gels, polymer or surfactant solutions are all characterized by the existence of an internal "microstructure". Often the timescales associated with this microstructure (a relaxation time say) are sufficiently large – on the order of milliseconds to seconds – that they may couple with every day processing or flow time scales (say the reciprocal of a typical shear rate in the process) and lead to instabilities. These instabilities, so-called "purely-elastic" flow instabilities, may arise even under relatively weak shear flows that correspond to vanishingly small Reynolds numbers where equivalent simple (Newtonian) fluids remain laminar and stable. Such purely-elastic flow instabilities, which are transitions in flow stability driven by elastic normal stresses in the absence of significant inertial effects, have been observed, primarily for dilute polymer solutions, in a range of flows both viscometric and complex. In this regime the Reynolds number is small and the Deborah, or Weissenberg (Wi) numbers, which characterize the degree of elasticity in the flow, large. It is now well known that such instabilities can arise as a consequence of the combination of elastic stresses and streamline curvature captured in what is known as the "Pakdel-McKinley" criterion [1]. The aim of the current paper is to understand, via studying two different prototypical geometries, if it is possible to "control" – either delaying or enhancing – the onset conditions of such instabilities. Such control is, practically, of importance in various technological applications. For example, a number of microfluidic rheometers have been proposed to measure material properties of complex fluids, see e.g. viscometers [2] and rheometers to measure time-dependent or extensional properties by [3]. In such microfluidic rheometer geometries, purely-elastic instabilities are often unwanted as they will modify the assumed (viscometric) flow and corrupt any attempt to extract meaningful material properties through them via pressure-drop measurements for example. Alternatively, it may be possible to use the fundamental understanding of the instability to relate the onset conditions to a given material property such as Zilz et al [4] where the flowrate at onset of the time-dependent instability in a microfluidic serpentine channel was used to measure relaxation times down to 1 ms for dilute polymer solutions. Creating instabilities in microfluidic geometries – to enhance heat or mass transfer for example – is also a strong motivation for better fundamental understanding in this area [5]. Firstly, we investigate Taylor-Couette flow, but with a finite aspect ratio, such that the flow is shear-dominated (but not, strictly, viscometric outside of the one-dimensional "infinite" aspect ratio case) and a modified "cross-slot" geometry with a cylinder at the geometric centre of the domain, which can be characterised as being a flow of mixed kinematics. In both cases we show how an understanding of the scaling mechanisms, coupled with the ability to vary the geometry of each problem, allows passive control of the onset conditions.

CONSTITUTIVE EQUATIONS AND NUMERICAL METHODS.

The governing equations for this problem are conservation of mass, assuming incompressibility, and momentum:

$$\nabla \cdot \tilde{\boldsymbol{u}} = 0,$$
$$\tilde{\rho}\left(\frac{\partial \tilde{\boldsymbol{u}}}{\partial \tilde{t}} + \tilde{\boldsymbol{u}} \cdot \nabla \tilde{\boldsymbol{u}}\right) = -\nabla \tilde{p} + \nabla \cdot \tilde{\boldsymbol{\tau}} + \tilde{\eta}_s \nabla^2 \tilde{\boldsymbol{u}},$$

where ρ is the density of the fluid, $\boldsymbol{u}$ is the velocity vector, η_s is the solvent viscosity and $\boldsymbol{\tau}$ is the extra-stress tensor containing the polymeric contribution to the stress which is determined using the simplified Phan-Thien and Tanner model (sPTT):

$$f_1 \tilde{\boldsymbol{\tau}} + \tilde{\lambda} \overset{\nabla}{\tilde{\boldsymbol{\tau}}} = \tilde{\eta}_p (\nabla \tilde{\boldsymbol{u}} + \nabla \tilde{\boldsymbol{u}}^{\mathrm{T}}),$$

where λ is the relaxation time of the fluid and η_p is the polymeric contribution to the viscosity. $\overset{\nabla}{\tilde{\boldsymbol{\tau}}}$ is the usual upper-convective derivative of the extra-stress tensor (see e.g. [6]). Here we use the linear form of the f_1 function:

*Corresponding author. E-mail robpoole@liv.ac.uk.

$$f_1 = 1 + \alpha \frac{\tilde{\lambda}}{\tilde{\eta}_p} Tr(\tilde{\tau}),$$

where α is the extensibility parameter. This constitutive equation was originally derived from network theory by Phan-Thien & Tanner [7]. Here we use the rheoFoam solver in the OpenFOAM platform which was previously introduced by Pimenta & Alves [8] to solve the above equations using a finite-volume methodology.

RESULTS AND DISCUSSION

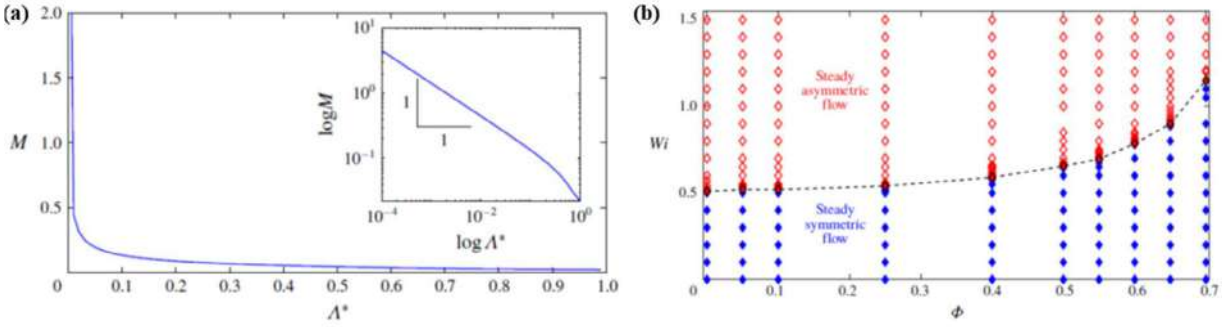

Figure 1. (a) Effect of normalised aspect ratio Λ* on the Pakdel-McKinley [1] "M" parameter for the Taylor-Couette geometry. Oldroyd-B fluid (α=0) , solvent-to-total viscosity ratio β=0.5 and radius ratio= Wi = 0.1. (b) Modified cross-slot flow; boundary between the symmetric and asymmetric flow states for different Wi and blockage ratio for α = 0.02 and β=1/9.

Taylor Couette flow

The effect of finite depth aspect ratio (Λ) on Taylor-Couette flow [9] shows that the shear rate along the centreline can be significantly influenced by the effect of the confining walls. In Fig. 1(a) the effect of the modified aspect ratio (Λ/(Λ+1)) on the Pakdel-McKinley "M" parameter [1] is depicted along the centreline (based on a zeroth-order analytical solution) for a nominal situation of radius ratio and Wi both equal to 0.1. For this particular case, the M parameter for modified aspect ratios of 0.2, 0.5 and 0.8 are calculated as 0.02745, 0.0448 and 0.08941, respectively. Here, setting a constant M_{cr} = 5.92 (i.e. the value calculated from a linear stability analysis in the 1D limit) provides an estimate of the critical values of Wi for instability onset, which are 26.56, 21.57, 13.21 and 6.62 for modified aspect ratios of 1 (1D case), 0.8, 0.5 and 0.2, respectively. The strongly destabilising effect of confining side walls is apparent.

Cross-slot flow

The effect of adding a cylinder of diameter D to the geometric centre of cross-slot width W [10] shows that the critical Wi for the onset of a steady symmetry-breaking instability is modified by this cylinder as characterised by a "blockage" ratio (D/W) as shown in Fig. 1(b). At higher blockage, i.e. a larger cylinder, steady-symmetric conditions can be maintained until much higher Wi which, all else being equal, corresponds to a direct increase in the critical flowrate through the geometry before symmetric conditions are lost.

CONCLUSIONS

For Taylor-Couette flow, our analysis would indicate that purely elastic instabilities are more likely to occur at lower Weissenberg numbers for lower-aspect-ratio geometries. Thus, if one wanted to promote such instabilities, for example to enhance mixing, this could be achieved via small-aspect-ratio geometries. This result may also have important applications for small-angle neutron scattering or flow birefringence studies, which tend to use smaller-aspect-ratio devices. For cross-slot flow, a cylinder added to the geometric centre can enable an increase in the critical flowrate of about two before symmetry is lost. The negligible effect of a vanishingly small cylinder in this geometry highlights the importance of shear-dominated flow away from the central stagnation point as being the driving mechanism for instability in this geometry, suggesting this flow too falls under a "Pakdel-McKinley" curved streamlines paradigm.

OPENFOAM FRAMEWORK FOR PARTIALLY MISCIBLE LIQUIDS

A .Ghaemi[1],M. Hübner[2],M.Mincheva[2],and N. Germann*[1]
[1]Fluid Dynamics of Complex Biosystems, School of Life Sciences Weihenstephan, Technical University of Munich, Germany
[2]Biothermodynamics, School of Life Sciences Weihenstephan, Technical University of Munich, Germany

Summary We present a robust and versatile OpenFOAM framework for partially miscible binary systems. Our solver was successfully validated using prior numerical benchmark studies and in-house microfluidics experiments. We found that this toolbox can reliably predict the interfacial dynamics and mixing characteristics of binary viscous systems. Future work will focus on ternary systems as well as viscoelasticity.

INTRODUCTION

Many flows encountered in industrial applications are composed of multiple components. Important factors affecting the mass- and momentum transport of mixtures include the physicochemical and microstructural characteristics of the individual components as well as their degree of miscibility. An important application where partial miscibility plays a crucial role is liquid-liquid extraction (LLE). This is a purification technique used to separate compounds based on their relative solubilities in two immiscible (or partially miscible) solvents. As an industrial process, LLE is frequently employed in the downstream recovery of proteins and other biomolecules because of its low cost and ease of scale-up. The industrial design of such types of processes requires a proper understanding of the flow kinematics and mass transfer characteristics of the individual components in the mixtures, which can be gained by physical modeling and numerical simulations.

Phase-field methods are well suited to describe the interfacial kinematics of multicomponent systems. Contrary to interface-tracking techniques, e.g., volume-of-fluid (VOF), level-set, and front-tracking, the diffusion of the components is adequately addressed by assuming a diffusive interface layer of finite thickness. This helps with avoiding the non-physical assumption of abrupt changes of the properties at the interface and allows for mass transfer across it. Whereas it has become standard practice to simulate systems with immiscible or fully miscible viscoelastic components, partial miscibility has not been a major focus so far.

In this talk, we present our latest developments in this area. Based on the generalized bracket approach of nonequilibrium thermodynamics, we formulated a phase-field modeling framework for viscoelastic materials. The chemical potential is expressed through a nontrivial velocity difference between the components. In this manner, the transport of the phase fractions can be accurately solved without excessive numerical diffusion by employing a multidimensional universal limiter with explicit solution method. In addition to stress-induced migration, the inertial terms are kept in the final formulation as they can be of relevance in specific applications. The nonideal part of the mixing energy, described by, e.g., a non-random-two-liquid (NRTL)-type equation, controls the phase behavior. Comparison with other numerical studies and in-house microfluidics experiments confirmed the accuracy and reliability of our numerical implementation. Future simulation work will focus on applications involving viscoelasticity, multiple components, and living microorganisms.

METHODS

Based on previous non-equilibrium thermodynamic modeling work [3, 4, 5], we proposed a new phase-field framework to explain the phase dynamics of viscoelastic mixtures with partial miscibility while accounting for the influences of inertia and gravity. In this framework, the chemical potential is expressed through nontrivial velocity differences between the components. By doing so, we can implicitly account for diffusion and obtain more accurate numerical solutions. In the limit of two viscous immiscible components, our framework yields a model similar to NSCH (Navier-Stokes-Cahn-Hillard). We implemented the model equations into the OpenFOAM finite-volume solver. A multidimensional universal limiter with explicit solution method is used to evolve the phase fractions in time accurately.

BENCHMARKING WITH NUMERICAL STUDIES

As a first assessment of our framework, we focused on viscous binary systems with immiscible, partially miscible, and fully miscible components. For the immiscible scenario, we considered the well-known rising bubble problem and compared our predictions with published VOF data [1, 2]. The benchmark setup is displayed along with the comparison in Fig. 1. A two-dimensional rectangular domain whose width to length ratio is $x/y = W/L = 0.5$ is filled with phase-1. The other phase, phase-2, is taken to be a circular bubble of radius ratio $r_{b0}/W = 0.25$. This bubble is placed inside the matrix fluid at the initial position $(x/W, y/W) = (0.5, 0.5)$. The comparison was performed at a dimensionless

*Corresponding author. E-mail: natalie.germann@tum.de

time $\tilde{t} = tU_g/W = 3$, where $U_g = \sqrt{2gr_{b_0}}$ is the characteristic velocity with g being the gravitational acceleration. We find that the rise and deformation of the bubble are accurately captured in both immiscible cases. The formation of the filaments and the satellite bubbles in the system with more significant density and viscosity contrast indicate good agreement.

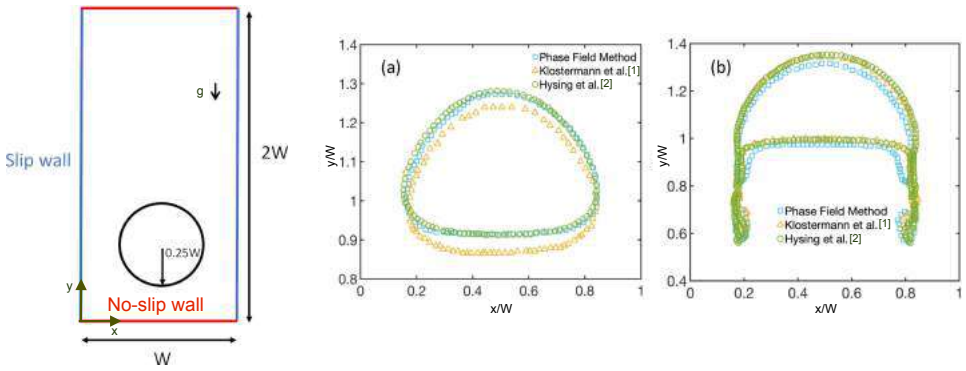

Figure 1: Rising bubble benchmark setup (left) and validation results (right). Comparison of our phase-field predictions with VOF benchmark data at the time instant $\tilde{t} = 3$. a) Bubble rise and deformation. b) Bubble breakup in a system with more significant density and viscosity contrast.

COMPARISON WITH IN-HOUSE MICROFLUIDIC EXPERIMENTS

For the more complicated case of partially and fully miscible viscous components, we compared the numerical results of our solver with in-house microfluidics data. The laboratory data were obtained at room temperature near the inlets and outlet of a Y-shaped microchannel using an optical microscope. For the miscible system, the numerical results are in full agreement with experimental observation. The interface of the two components dissolves along the channel until it disappears, showing complete mixing. The selected partially miscible system is immiscible at room temperature and miscible at an elevated temperature of 330 K. The solver nicely reproduces the experimental data at room temperature. Artificially increasing the temperature in the numerical simulation makes this system miscible, as expected from the binary phase diagram.

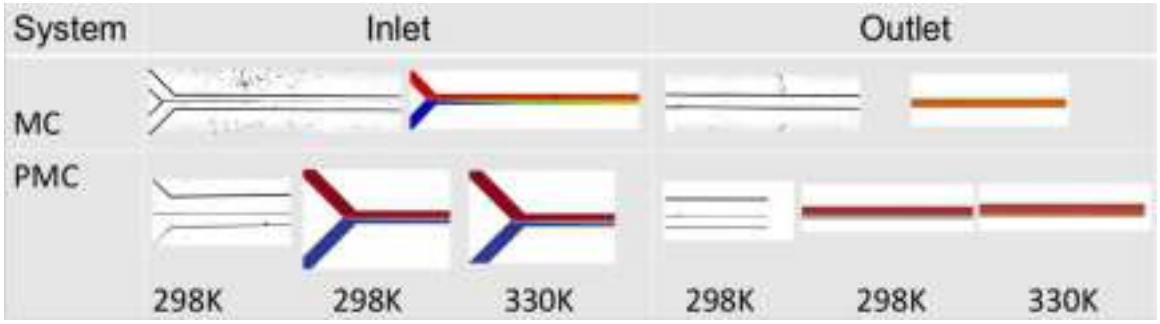

Figure 2: Validation of our solver with optical data recorded near the inlets and outlet of the Y-shaped microchannel. Miscible case (MC): Water/MeOH. Partially miscible case (PMC): MeOh/n-Hexane. All laboratory experiments were conducted at room temperature. An additional simulation was performed at an increased temperature of 330 K to capture the single-phase behavior of MeOh/n-Hexane.

TWO-DIMENSIONAL NUMERICAL SIMULATIONS OF VISCOELASTIC JETS

K. Zinelis*, T. Abadie, R. Constante-Amores, and O. K. Matar
Department of Chemical Engineering, Imperial College London, London, UK

Summary The numerical simulation of spray formation in a non-Newtonian fluid offers substantial challenges and is central to numerous industrial applications such as spray-drying. The aim of the present work is to set out the basis for the numerical examination of viscoelastic spray systems. To achieve this, we begin with two-dimensional axisymmetric numerical simulations of a impulsive jet into a stagnant gaseous phase using the volume-of-fluid technique to capture the interface and the log-conformation transformation for the solution of the viscoelastic constitutive equation. This permits the exploration of parameter space, capturing the effect of the elastic, viscous, and inertial forces on the ejected droplet size. In particular, the dependence of the rate of thinning on the injected flow rate, the relaxation time, as well as the finite extensibility of the polymeric chains is investigated.

BACKGROUND

Sprays are the result of atomisation processes, following a number of different types of instabilities, which occur when a jet of liquid discharges into a gaseous phase. The ultimate objective of the present research is the development of numerical simulations about the atomisation process of viscoelastic (i.e. dissolved polymers) fluids. The first step towards this direction is the thorough investigation and capture of phenomena of smaller length-scales that take place during a spray formation. An indicative example of these physical phenomena is the ligament breakup into smaller droplets, which leads to the typical "beads-on-a-string" morphology in the case of viscoelastic jets [1]. The viscoelastic filament thinning and breakup is one of the major problems which exhibit strong complexities due to the emerging non-linearities derived from elastic stresses and gradients of stresses and velocity. Specifically, capillarity is the driving force for the process of breakup. The filament breakup of a Newtonian liquid is a really fast process due to a delicate interplay among viscous, elastic and inertia stresses enhancing the resistance to the action of capillarity. However, in the case of viscoelastic materials, the temporal evolution of a thread is governed by the balance between elastic and capillary forces. Consequently, it is crucial to develop an adequate understanding of the emerging visco-elasto-capillary thinning process [2].

Both experimental and numerical work has been carried out so far on the breakup of a viscoelastic filament. In particular, the thinning dynamics of a viscoelastic thread has been extensively examined through the capillary breakup extensional rheometry (CaBER) and the Rayleigh-Ohnesorge jetting extensional rheometer (ROJER), which are the two predominant experimental methods for jetting processes of viscoelastic fluids [3]. Moreover, several Computational Fluid Dynamics (CFD) simulations have confirmed the CaBER measurements, as well as the effect of elasticity and inertia [4,5], but there is still a lack of advanced and robust numerical tools for studying the jetting process of viscoelastic filaments in both low (ROJER experiment) [6] and high (turbulent jets) Reynolds (Re) numbers.

FORMULATION AND PROBLEM STATEMENT

Using a Volume-of-Fluid (VOF) approach, we solve the two-dimensional (2D) axisymmetric, two-phase, incompressible Navier-Stokes equations with surface tension [7]. The polymeric contribution in the total stress balance is modelled with a constitutive equation, $\boldsymbol{\sigma_p} = (\mu_p/\lambda)\,(\mathbf{f_R}(\mathbf{A})\mathbf{A} - \mathbf{I})$, where $\boldsymbol{\sigma_p}$ is the polymeric stress, μ_p is the polymeric viscosity, λ is the relaxation time of the polymer, $\mathbf{A}$ is the conformation tensor of the viscoelastic fluid and $\mathbf{f_R}(\mathbf{A})$ is the relaxation function equal to $\mathbf{A} - \mathbf{I}$ for the often used Oldroyd-B model and to $\frac{\mathbf{A}}{1-\mathrm{tr}(\mathbf{A})/L^2} - \mathbf{I}$ for the non-linear FENE-P model with L being the finite extensibility of the polymeric chains. For overcoming the numerical challenges emerging in the case of high relaxation times, known as the "High-Weissenberg number problem" (HWNP), the log-conformation formulation is implemented, where the aforementioned equations account for the logarithm of the conformation tensor $\mathbf{A}$ instead, $\boldsymbol{\Psi} = \log \mathbf{A}$ [8].

The complexity of the viscoelastic fluids arises from the different macroscopic and microscopic time-scales that characterise the flow. Specifically, the jetting process of a viscoelastic fluid can be thoroughly described by the following non-dimensional groups, which can be obtained from the governing equations normalised by using the initial filament radius R_0 as length scale, the capillary time scale, $t_c = \sqrt{\rho R_0^3/\gamma}$, with γ being the surface tension, $u_s = R_0/t_c$ as characteristic velocity scale, and finally $\sigma_s = \rho u_s^2$ as characteristic stress scale:

$$De = \frac{\lambda}{t_c} = \frac{\lambda}{\sqrt{\rho R_0^3/\gamma}}, \quad Oh = \frac{t_v}{t_c} = \frac{\mu_0}{\sqrt{\rho\gamma R_0}}, \quad \beta = \frac{\mu_s}{\mu_0}, \quad \frac{\rho_a}{\rho_s}, \frac{\mu_a}{\mu_s}, \quad We = \frac{2\rho u_{jet}^2 R_0}{\gamma}, \tag{1}$$

where De is the Deborah number determining the elasticity effects, Oh is the Ohnesorge number which characterises the relevant importance of the viscous and the inertial forces, t_v is the viscous-capillary time scale, β is the solvent viscosity ratio accounting for the contribution of the polymeric viscosity in the total zero shear viscosity μ_0 of the fluid, μ_a/μ_s and ρ_a/ρ_s are the air-liquid viscosity and density ratios, We is the Weber number which determines the transition between dripping and jetting regime, and u_{jet} is the average jet velocity.

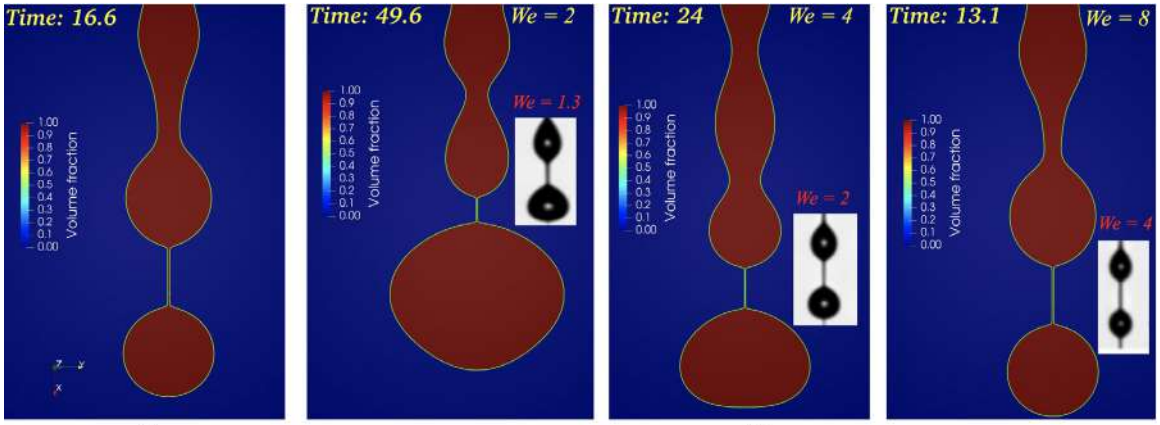

Figure 1: *(a)* The "beads-on-string" morphology of a viscoelastic jet of $De = 1$, $Oh = 0.2$, $\beta = 0.85$, $\rho_a/\rho_s = 0.01$, $\mu_a/\mu_s = 0.01$ and $We = 8$, where *Time* = t/t_c. *(b)* Qualitative comparison of CFD simulations and experimental data for different We numbers [3].

RESULTS

In this study, we perform 2D axisymmetric numerical simulations using the open source code *basilisk* [9], which permits the application of an Adaptive Mesh Refinement (AMR) for a highly-resolved development of the very thin viscoelastic thread. We manage to capture the typical "beads-on-a-string" structure, as Figure 1(a) indicates, that a viscoelastic jet exhibits during a ROJER experiment defined by the parameters shown in Table 1. The size of the simulation domain is $0 \leqslant z/R_0 \leqslant 20$, the jet is injected with a velocity perturbation $u(z,0)/u_s = u_{jet}/u_s + \sin(0.5\pi(t/t_c))$ and the maximum level of AMR is 12. Subsequently, we investigate the effect of the flow rate by applying three different We numbers ($We = 2, 4, 8$) and comparing qualitatively the results of the CFD simulation with available experimental data [3], as Figure 1*(b)* presents. We observe that for lower We number, which is indicative of the "dripping to jetting transition" regime ($We \approx 1$), there is a strong coalescence of the formed droplets just before the breakup time, leading to a large droplet size and a breakup closer to the inlet. For a large We number, the coalescence is less pronounced and thus the jet breaks into droplets over a longer distance from the nozzle and in shorter times. Finally, during this research, the effect of De and L on the thinning dynamics of a viscoelastic jet are also examined. More specifically, in the first case as De increases, thin viscoelastic threads of longer length, as well as larger lifespan are expected, whilst when FENE-P model is applied, for larger L (i.e. $L >$100) a FENE-P filament approaches the Oldroyd-B dynamics, which provides the best agreement with the theoretical predictions so far.

De	Oh	β	ρ_a/ρ_s	μ_a/μ_s	We
1	0.2	0.85	0.01	0.01	8

CONCLUSIONS

2D axisymmetric CFD simulations are performed for studying the thinning dynamics of a ROJER experiment. The numerical simulations can effectively capture the "beads-on-string" structure of the viscoelastic fluids, but also how the thinning dynamics change due to the Weber and Deborah numbers, as well as the finite extensibility of the polymer. A remaining challenge is the development of fully three-dimensional Direct Numerical Simulations where all the scales in space and time are resolved, especially for viscoelastic flows of high Re numbers.

CONSTRAINING THE ORIGIN OF FORE-AFT ASYMMETRICAL SHAPE OF BUBBLES RISING IN YIELD STRESS FLUIDS

Marjan Zare*[1], Ali Pourzahedi[2], and Ian Frigaard[1,2]
[1]Department of Mathematics, University of British Columbia, Vancouver, BC, Canada
[2]Department of Mechanical Engineering, University of British Columbia, Vancouver, BC, Canada

Summary A series of novel experiments are conducted exploring a potential cause of fore-aft asymmetry of a rising bubble in a simple yield stress fluid. It has been believed that the yield stress could prevent bubbles injected from a nozzle to freely adjust their shape and smooth the developed cusp on their lower side. This possibility is investigated by introducing a bubble, with controlled shape, and speed, into a yield stress fluid, Carbopol, without direct injection from a nozzle. Our results rule out this possibility and show that a slight change in the rheology can have significant effect on the shape of rising bubbles, though still fore-aft asymmetric.

INTRODUCTION

A significant number of fluids used in our daily life like toothpaste, hair gel and peanut butter, as well as working fluids in geophysical and industrial settings, such as magma and cement slurry, are categorized as viscoplastic fluids. The key feature of viscoplastic fluids is their characteristic yield stress. More precisely if such fluids are subjected to a stress more than their yield stress they deform and flow, otherwise they exhibit a solid-like behavior. The transition from a solid-like regime to a fluid-like regime is often approximated using rheological models such as Bingham, and Herschel-Bulkley constitutive laws. In these models, the build-up and breakdown of structure are assumed to be reversible and instantaneous, i.e., the material regains its value of the yield stress upon the flow reversal. This ideal yield-stress behavior implies that elastic and thixotropic effects are negligible. Upon adopting this assumption, the rise of a bubble and creeping motion of a sphere settling in a yield stress fluid have been studied numerically, e.g. [1, 2]. Their results confirmed that the developed flow in the yielded envelope zone enclosing moving objects or bubbles is symmetric, when the particles/bubbles are symmetric.

However, the experimental observations published in [3, 4, 5, 6] started researchers thinking that real yield stress fluids might not be as simple as predicted from the aformentioned constitutive laws. The results published in [3, 4] dramatically illustrated the fore-aft asymmetry of flow around a spherical particle settling in a yield stress fluid. And the cusp shape at the bubble's lower side, observed in [6], markedly contradict the fore-aft symmetry expected theoretically in Stokes flows. These results were more surprising since the yield stress fluid used in those experiments, Carbopol, was often assumed to be a simple yield-stress fluid, with negligible thixotropic behaviour.

The inverted teardrop shape could be attributed to a number of reasons. One of which is the elasticity of the Carbopol before yielding and a little sign of thixotropy/hysteresis in its flow curves around the yielding point. There have been many studies aiming to address this shortcoming by including time-dependent parameters into the constitutive law equations. Assuming the bubble is injected from a nozzle, one other possibility is that the shape is formed at the origin and the yield stress of material prevents evolution of bubble's shape and causes the shape to remain 'frozen' [2]. The goals in this paper are to explore the potential contribution of the entry point on the bubble shape in a yield stress fluid and constrain the origin of fore-aft asymmetry. We have investigated this potential cause in a series of experiments. In the following sections, we will describe the experimental setup and the rheological characterization of fluids which have been used. We end the paper with a brief summary of results and conclusion.

EXPERIMENTAL SETUP AND MATERIAL

A simple experimental setup is used to introduce a bubble into a yield stress fluid without injecting direclty from a nozzle. We designed a three-layer fluid system as shown in Fig. 1. A bubble is injected to the lower layer and then in accordance with the properties of fluids in the lower and middle layers develops its shape, speed and volume as it rises. The lower layer is to control the size of bubble injected. The shape and speed are adjusted in the middle layer. Using this setup a bubble with a specified shape, size and speed enters the upper layer which is our test section. A syringe pump is used to inject air into the lower layer and fluids are placed inside a long plexiglas box of width $\hat{W} = 9.525$ cm $(3.75'')$ and length $\hat{L} = 63.5$ cm $(25'')$, with sealed base. The injection point for the invading fluid is via a hole of radius $\hat{R}_h \approx 0.32$ mm $(r_h \approx 0.01)$ positioned centrally in the base of the column.

We used carbopol, densified with Glycerin and sugar, in the lower layer to control the volume of the bubble. The bubble then deforms to an ellipsoidal shape in the middle layer consisting of pure glycerin. We are interested to see

*Corresponding author. E-mail: marjan.zare@math.ubc.ca

how the bubble's shape varies as it enters a yield stress fluid. Hence, the top layer which is our test section is filled with Carbopol. The experiments have been repeated for three concentrations of carbopol and various other parameters. The Herschel-Bulkley (see eq. 1) fits of the yield stress $\hat{\tau}_y$, consistency $\hat{\kappa}$ and power-law index n of the Carbopol in the test section are summarized in table . The Herschel-Bulkley model describes the constitutive equation of a yield stress material after yielding with the following equation:

$$\hat{\boldsymbol{\tau}} = (\hat{\kappa} + \frac{\hat{\tau}_y}{\hat{\dot{\gamma}}})\hat{\dot{\boldsymbol{\gamma}}}^{n-1}, \quad \Leftrightarrow \hat{\tau} > \hat{\tau}_y \tag{1}$$

where $\hat{\boldsymbol{\tau}}$ and $\hat{\dot{\boldsymbol{\gamma}}}$ are the deviatoric stress tensor and the rate of deformation tensor, respectively.

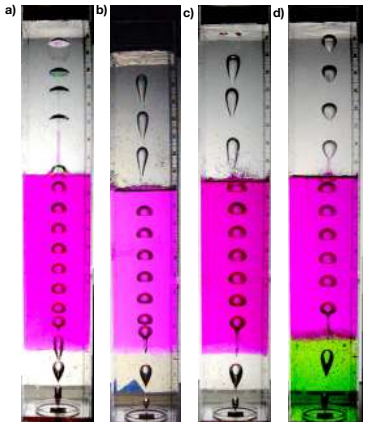

Figure 2: Spatiotemporal images of bubble's motion through our 3-layer fluid system comprising a densified Carbopol (DC) (lower layer), pure Glycerin (middle layer) and Carbopol (C) (upper layer): a) DC=0.15, C=0.06, b) DC=0.15 , C=0.2; c) DC=0.18, C=0.15; and d) DC=0.18, C=0.1 $wt/wt\ \%$.

RESULTS

Some experimental results showing how the shape of a bubble changes as it rises in Glycerin and moves up into a Carbopol solution are presented in Fig. 2. Given the properties of Glycerin,$\hat{\mu} = 0.4Pa.s$ and $\hat{\rho} = 1.18g.m^{-3}$, the bubble develops an ellipsoidal shape at each pair of (Bo, Re) and reaches a steady state before crossing the Glycerin-Carbopol interface. Interestingly, once the bubble enters the Carbopol it adjusts its shape and develops a cusp at the lower side in concentrations above 0.1 $wt/wt\ \%$. Results clearly confirm the fore-aft asymmetry of a bubble in Carbopol is not a nozzle effect. The shape of bubble also varies in Carbopol solutions with different concentrations as well; the bubble becomes elongated as it rises in higher concentrations of Carbopol.

CONCLUSIONS

A novel set of experiments was performed to investigate the 'nozzle effect' on the formation of a cusp at the tail of bubbles rising in Carbopol solution, which is often used as a simple yield stress fluid. Our results restrain potential causes of fore-aft asymmetrical bubble shape and confirm that it is not related to the injection method and the shape of entry point. It might originate from the temporal structure and elasticity of fluid which leads to development of time-dependant behaviours.

COEXISTING INERTIA-DRIVEN AND ELASTO-INERTIAL TURBULENCE DURING MULTISTAGE TRANSITIONS IN POLYMER DRAG REDUCTION

Lu Zhu[1] and Li Xi*[1]
[1]Department of Chemical Engineering, McMaster University, Hamilton, Ontario, L8S 4L7, Canada

Summary Elasto-inertial turbulence (EIT) has been believed to be the state responsible for maximum drag reduction (MDR). We show that EIT can coexist with inertia-driven turbulence starting from much lower Weissenberg number Wi and only takes over when the latter is suppressed. Different from the common belief, MDR is not converged EIT but involves more complex dynamical cycles that are non-asymptotic in nature. Relationship between EIT and other transition stages in turbulent drag reduction is our ongoing focus.

INTRODUCTION

A small amount of polymer additives are known to cause significant turbulent drag reduction (DR). At constant Re and with increasing fluid elasticity, measured by the Weissenberg number Wi, turbulence undergoes several transitions between different dynamical stages [1]. At lowest Wi, no DR is observed. After the onset of DR, the flow enters a low-extent DR (LDR) regime where DR is confined to the buffer layer. At higher Wi, transition to high-extent DR (HDR) occurs where DR is felt across the flow domain. Finally, it converges to an asymptotic upper limit called the maximum DR (MDR). MDR indicates the existence of a new self-sustaining turbulent state with lower drag than Newtonian turbulence, whose mean flow, surprisingly, becomes invariant with polymer elasticity (and all polymer solution properties). Understanding these transitions, in particular, the mysterious MDR asymptote, has motivated researchers for decades.

Recent discovery of the so-called elasto-inertial turbulence (EIT) [2] provided promising leads for the new self-sustaining process (SSP) of MDR. This is a unique state of turbulence where both elasticity and inertia support turbulence. It is self-sustaining even in 2D [3]. Later experiments [4] found that at relatively low Re close to the laminar-turbulent transition for Newtonian flow, classical inertia-driven turbulence (IDT) will first be suppressed by polymer elasticity, causing the laminarization of the flow. Turbulence would resurge in a new form at higher Wi, which was presumed to be EIT. Mean flow was found to reach an asymptotic level in this resurgent regime, which has supported a now prevailing view that MDR reflects the complete suppression of IDT and convergence to EIT.

Recently, we have shown [5] that EIT itself does not give asymptotic DR. Rather, it shows continued drag enhancement with increasing Wi. Asymptotic DR requires 3D flow where IDT grows intermittently from EIT. In this study, we further explore the coexistence between IDT and EIT as well as the role of EIT in various stages of DR.

METHODOLOGY

The Navier-Stokes equation is coupled with the FENE-P constitutive equation

$$\frac{D\boldsymbol{v}}{Dt} = -\boldsymbol{\nabla} p + \frac{\beta}{\mathrm{Re}}\nabla^2\boldsymbol{v} + \frac{2\,(1-\beta)}{\mathrm{ReWi}}\left(\boldsymbol{\nabla}\cdot\boldsymbol{\tau}_p\right), \quad \boldsymbol{\nabla}\cdot\boldsymbol{v} = 0, \tag{1}$$

$$\frac{\mathrm{Wi}}{2}\left(\frac{D\boldsymbol{\alpha}}{Dt} - \boldsymbol{\alpha}\cdot\boldsymbol{\nabla}\boldsymbol{v} - (\boldsymbol{\alpha}\cdot\boldsymbol{\nabla}\boldsymbol{v})^{\mathrm{T}}\right) = -\frac{b}{b+5}\boldsymbol{\tau}_p, \quad \boldsymbol{\tau}_p = \frac{b+5}{b}\left(\frac{\boldsymbol{\alpha}}{1-\frac{\mathrm{tr}(\boldsymbol{\alpha})}{b}} - \left(\frac{b}{b+2}\right)\boldsymbol{\delta}\right) \tag{2}$$

and solved for plane Poiseuille flow (domain size in inner units: $L_x^+ \times L_y^+ \times L_z^+ = 720 \times 2\mathrm{Re}_\tau \times 230$) under fixed pressure drop, where $\boldsymbol{\tau}_\mathrm{p}$ and $\boldsymbol{\alpha}$ are polymer stress and conformation tensors. $\mathrm{Wi} \equiv 2\lambda U/l$ is the product between polymer relaxation time and mean wall shear rate. The friction Reynolds number $\mathrm{Re}_\tau = 84.85$, viscosity ratio $\beta \equiv \eta_\mathrm{s}/\eta = 0.97$ (ratio between solvent "s" and solution zero-shear viscosities), and $b = 5000$ (b is the upper limit of $\mathrm{tr}(\alpha)$, which measures the extent of polymer extension) are constant for all simulations. A finite-difference/pseudo-spectral hybrid scheme is used where the $\boldsymbol{v}\cdot\boldsymbol{\nabla}\boldsymbol{\alpha}$ term is discretized with a conservative total variation diminishing (TVD) method and all other terms use a pseudo-spectral approach. The scheme avoids the need for artificial diffusion. Details on the numerical method and other numerical details are found in [6].

RESULTS AND DISCUSSION

Since IDT only exists in 3D, 2D DNS can completely preclude IDT and obtain EIT in its cleanest form. One such solution at $\mathrm{Wi} = 64$ is shown in fig. 1(a), which, compared with IDT (see 3D DNS of $\mathrm{Wi} = 30$) has much reduced Reynolds shear stress (RSS) and a mean velocity (measured by A_{25}^*) higher than MDR. As reported in [5], EIT solution is not invariant with polymer properties and with increasing Wi, the drag will increase – i.e., the solution will move left in the plot. At high Wi, its mean velocity will be significantly lower than MDR. This indicates that MDR cannot be a single converged EIT state.

*Corresponding author. E-mail: xili@mcmaster.ca

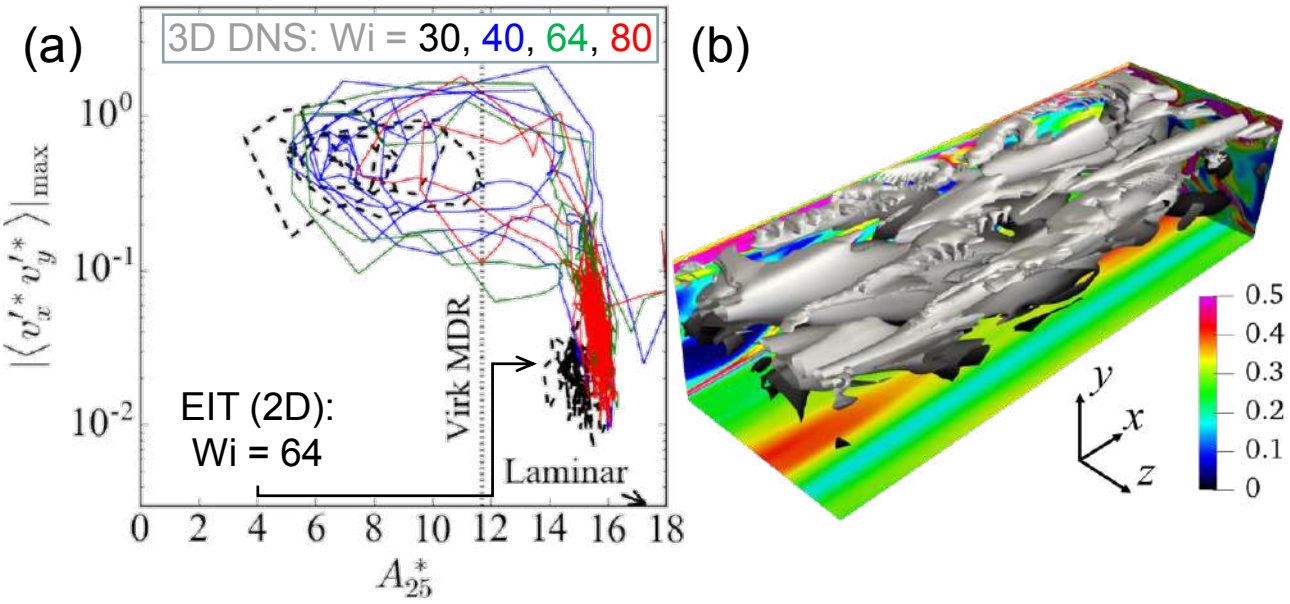

Figure 1: (a) state-space projection of 2D EIT and 3D DNS trajectories: $A^* \equiv y^*(\partial U_{\mathrm{m}}^*(y^*,t)/\partial y^*)$ is the slope in a logarithmic relation of $U_{\mathrm{m}}^* = A^* \ln y^+ + \text{const.}$ (A_{25}^* is its value at $y^* = 25$) and $|\langle v_x'^* v_y'^* \rangle|_{\max}$ is the instantaneous Reynolds shear stress profile peak [7]; (b) vortex configuration at $Q = 0.004$ [8] (top half channel only; darker color for larger wall distance) and color contours of $\mathrm{tr}(\alpha)/b$ for a typical instant of active turbulence ($\mathrm{Wi} = 40$).

Solutions from 3D DNS represent realistic turbulent dynamics and are shown for several Wi. At $\mathrm{Wi} = 30$, the trajectory samples frequently a well-defined region of strong turbulence (high RSS), which represents the kernel of IDT or active turbulence [9]. Occasional excursions away from the kernel can be found, sometimes reaching the MDR level. This is the earlier-studied hibernation phenomenon [9] and is termed type A cycles in [5]. At $\mathrm{Wi} = 40$, some excursions extend far over the MDR level and clearly approach the EIT region (type B cycles [5]), indicating that polymer elasticity is strong enough to disrupt the SSP for IDT and EIT must act as a barrier that blocks the flow from laminarization. With further increasing Wi, the IDT kernel moves toward lower drag (higher A_{25}^*) and the trajectory spends less time therein. At $\mathrm{Wi} = 80$, the highest reported here, the trajectory spends most time in a region near the EIT without fully converging to it. Rather, it frequently jumps back and forth between EIT and a state of higher drag (higher RSS and lower A_{25}^*). This state, according to [5], is also IDT and such cycles were classified as type C.

What we have observed so far is the coexistence of multiple solution objects in the state space, including the kernel of IDT (active turbulence [9]), EIT, and a yet unknown IDT state that forms type C cycles with EIT. Results from higher Wi would show that visits of active turbulence (i.e., types A and B cycles) eventually diminish but type C cycles persist. This transition occurs within the asymptotic DR regime: i.e., flow states with the same average drag display different dynamical characteristics, which indicates that despite the converging mean velocity, MDR is fundamentally underlay by non-asymptotic dynamics [5].

A representative moment when the trajectory returns to active turbulence is shown in fig. 1(b). The flow field shows streamwise vortices which are typical of IDT at this Re. Interestingly, structures near the wall show small protrusions extending sideways. Spanwise vortices in the form of rolls and threads are typical of EIT [2, 5] and our finding indicates that EIT can coexist with IDT not only at different moments of the trajectory, but at different regions of the same moment.

It appears that EIT occurs upon a critical Wi. An EIT layer occurs at Wi much lower than those shown here. When IDT dominates, EIT is confined in a thin-layer near the wall where shear is high and IDT is insignificant. At higher Wi, where active turbulence is suppressed, EIT can spread to the whole channel to keep turbulence sustained. Active turbulence becomes intermittent (for Wi shown here) and eventually disappears (for higher Wi shown in [5]), but another form of IDT still exists. We have so far revealed the role of EIT in the transition to MDR, but its existence at lower Wi makes it possible to affect earlier transitions, which is a focus of our ongoing research.

WATER ENTRY OF VISCOPLASTIC DROPLETS

Anselmo Pereira[1], Mazi Jalaal[2], Romain Castellani[1], Elie Hachem[1], and Rudy Valette[1]
[1]MINES ParisTech, PSL Research University, CEMEF, CNRS UMR 7635, Sophia-Antipolis, France
[2]University of Cambridge, Dept. of Applied Mathematics and Theoretical Physics, Cambridge, UK

Summary We study through experiments and direct numerical simulations the water entry of viscoplastic (yield-stress fluid) droplets. Following the impact on water free surfaces, these Non-Newtonian fluids undergo at least three stages: a spreading one (1), related to the formation of a water crater, driven by viscous dissipation in the droplet and during which the droplet reaches its maximum deformation; a droplet-water interaction stage (2) along which the viscoplastic material tends to recover, at least partially, a spherical shape due to the crater reclosing, before sedimentation (3), being finally dominated by the yield-stress, which prevents further deformations. Different final shapes are observed as a function of the inertial, capillary, viscous and plastic effects. Their link with the fluid rheology is discussed in the light of scaling laws, kinematic and energy exchange analyses.

CONTEXT

The impact of non-Newtonian fluids (microgels, suspensions, emulsions etc.) on free liquid surfaces represents a fundamental and scarcely explored topic in interfacial hydrodynamics and soft matter rheology directly related to extremely important environmental and industrial situations, such as pesticides deposition, ceramic beads production, as well as encapsulation processes [1]. Typically impact flows involve, as illustrated in figures 1-left and 1-right, a falling non-Newtonian drop passing through a liquid-air interface and forming an air cavity, which later retracts, while the non-Newtonian material penetrates the liquid. During the penetration, the drop undergoes deformations as a consequence of the impact on the liquid surface and its interactions with the aforementioned air cavity, inducing different final shapes. These final morphologies vary from pears, Mexican hats (figure 1-left), bowls, up to capsules (figure 1-right) depending on the impact velocity, U_0, and the rheological properties of the drop.

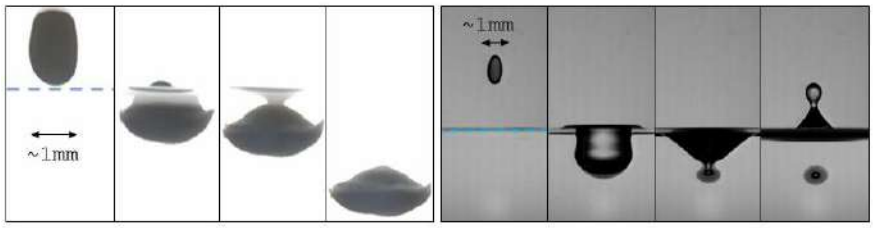

Figure 1. Deformation of viscoplastic drops at different times (typical timescale is 10 *ms*) during and after penetrating a water bath (bath surfaces are shown in blue dashed lines), forming a Mexican hat (left) at low impact velocitiy $U_0 = 0.5m.s^{-1}$ of an alumina suspension and a capsule (right) at a larger impact velocity $U_0 = 2.0m.s^{-1}$ of a Carbopol gel.

A recent attempt to highlight the impact of non-Newtonian drops on liquids was reported by Jalaal et al. [2], who performed experiments on the water-entry of Carbopol solutions (polymer microgels), obtaining a variety of final shapes, similar to the ones displayed in figure 1. Despite the importance of their study, the physical mechanism correlating the viscoplasticity with the drop final morphologies has not been addressed.

MODELLING

In the current work, the relevance of the viscoplastic nature of this phenomenon is demonstrated using both numerical simulations from a homemade finite element code [3, 4] and scaling arguments related to the three aforementioned key-stages (figure 2-left): (1) the drop impact; (2) the formation and retraction of the air cavity; and (3) the descent of the drop. Numerical simulations were performed for different drop diameters D_0, impact velocities U_0, Herschel-Bulckley rheological parameters (consistency k, power law exponent m and yield stress τ_0) and air/bath surface tension σ in order to obtain a large screening of Reynolds numbers $Re = \rho U_0^2/\bar{\tau}$, where ρ and $\bar{\tau}$ are the drop density and characteristics Herschel-Bulckley stress ($\bar{\tau} = k[U_0/D_0]^m + \tau_0$), capillary numbers $Ca = \bar{\tau}D_0/\sigma$, Froude numbers $Fr = U_0^2/gD_0$ (g being the gravity acceleration) and Bingham numbers $Bi = \tau_0/k[U_0/D_0]^m$.

An example of the simulation of an initially spherical viscoplastic drop after its impact at large velocity on a water bath is shown on figure 2-left at different instants within each key-stage, showing that its dimensionless diameter increases in the first stage, deceases in the second one up to 1, meaning that a capsule was formed, and finally kept constant in the last

stage, which preserves the capsule shape. When using low to high impact velocities in numerical simulations, we were able to retrieve all the final shapes observed experimentally (bowls, Mexican hats etc..), as shown on figure 2-right.

Finally, using dimensional arguments similar to previous studies on drop impacts [5, 6], we show and validate through numerical simulations that the drop shape is controlled by the Reynolds number in stage 1, its diameter decreasing in stage 2 is obtained if $Re > Fr^{1/5}/Ca$ and its final shape is preserved if the Reynolds number in the last stage is bounded by the Bingham number. These criteria lead to a single master curve giving the final aspect ratio D_f/D_0 as a function of all Re, Ca, Fr and Bi non-dimensional numbers.

.

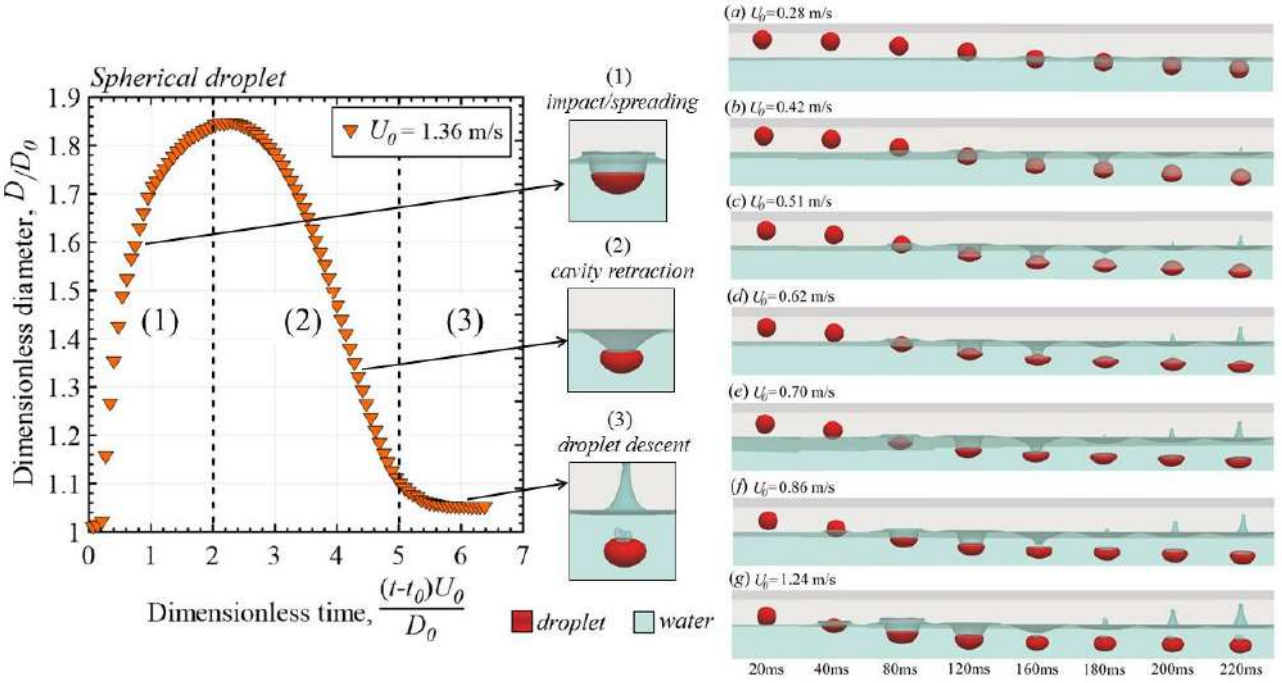

Figure 2. Left: simulation of an initially spherical viscoplastic drop after its impact on the water surface at large velocity and corresponding dimensionless diameter vs. dimensionless time curve. Right: simulations of viscoplastic drops after their impact on the water surface at different velocities, leading to different final shapes (spherical, bowl, Mexican hat, capsule, from low to high velocity).

MULTILAYER FLOWS OF VISCOPLASTIC FLUIDS IN AXIALLY ROTATING PIPES

Shan Lyu and Seyed-Mohammad Taghavi*
Department of Chemical Engineering, Université Laval, Quebec, QC, Canada

Summary This experimental work studies the removal of a viscoplastic fluid by a Newtonian fluid in an axially rotating pipe, with applications in the cementing process of oil and gas wells. The experiments are performed in a long inclined pipe. The fluids involved are of different rheological properties, they are miscible and they have different densities. The key parameters are the physical properties of the fluids, such as the density difference, the rheological properties, the imposed flow velocity, and the pipe rotation. The results reveal that the pipe rotation changes the flow patterns significantly, namely from inefficient to efficient removal flow regimes, as the rotating speed increases. The critical transition is well described by dimensionless groups, i.e. the modified Froude number (Fr) and the Rossby number (Rb).

INTRODUCTION

Multilayer displacement flows of viscoplastic fluids have a variety of industrial applications, an example of which is the cementing process in the construction/completion of oil and gas wells. One of the main objectives of this process is the zonal isolation, to hydraulically seal the well. A key step in this process is to completely displace/remove viscoplastic drilling mud by another fluid (e.g. cement slurry, spacer, etc) within the casing (i.e. a pipe) and the annulus parts of the well. To improve the displacement process, casing rotation can be used. However, a significant lack of solid laboratory studies limit our understanding of this process with casing rotation and constrain the wide application of casing rotation in the oil and gas industry. Thus, extending the previous works on viscoplastic displacements in static flow geometries [1, 2], we experimentally analyze the effects of a pipe rotation on the flow features, using the dimensionless groups that describe the flow.

EXPERIMENT

The displacement flow experiments were performed in an acrylic inclined pipe, mounted on a robust frame. The dimensions and some of the flow parameters can be found in Figure 1. An automated gate valve was used to initially separate the displacing and displaced fluids. A system of a stepper motor and various connectors, controlled by LabView, produced stable pipe rotations. A high-resolution digital camera (Basler acA2040) was used to acquire image sequences of the displacement flow process at the frequency of 5 Hz. The post-processing image analysis was done via in-house Matlab codes.

The preparations of the test solutions strictly followed the technical instructions. The displaced fluid was a Carpobol gel, i.e. viscoplastic fluid (i.e.a shear-thinning and yield stress fluid). The displacing fluids were simply salt-water. Fluid characterization was made using a rheometer DHR-3 (TA Instruments). For all cases studied, the temperature was held constant at room temperature.

RESULTS AND DISCUSSIONS

The experiments are performed at various flow parameters, such as the density difference ($At = \frac{\hat{\rho}_H - \hat{\rho}_L}{\hat{\rho}_H + \hat{\rho}_L}$ with $\hat{\rho}_H$ and $\hat{\rho}_H$ being the heavy and light fluid's densities, respectively, 0.0035 - 0.016), pipe inclination angle (β, 83° and 60°), yield stress ($\hat{\tau}_y$, 1.14, 3.80, and 9.20 Pa), imposed flow velocity ($\hat{V}_0$, 10 - 60 mm/s), and rotating speed ($\hat{\omega}$, 0 - 6.28 rad/s).

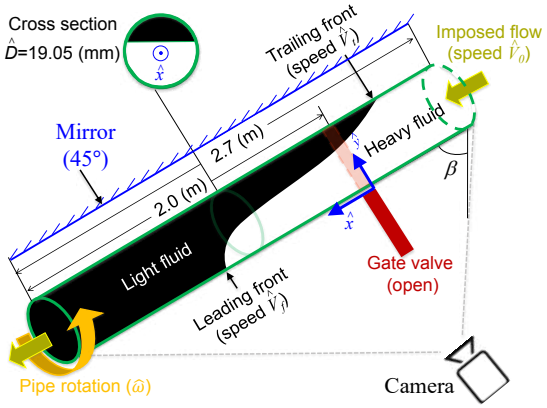

Figure 1: Schematic view of the experimental set-up. The interface is illustrative only.

*Corresponding author. E-mail: Seyed-Mohammad.Taghavi@gch.ulaval.ca

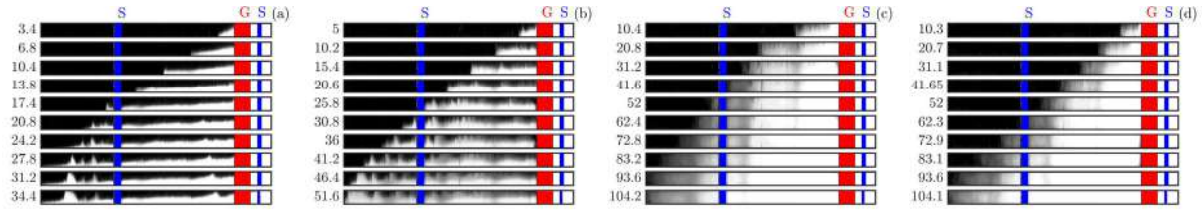

Figure 2: Sequence of experimental snapshots at $\beta = 83°$, $\hat{V}_0 = 20$ mm/s, and $At = 10^{-2}$, with pipe rotating speeds: $\hat{\omega} =$ (a) 0, (b) 2.09, (c) 3.14, and (d) 4.19 rad/s. The yield stress of the displaced fluid is 3.80 Pa. Experimental times in seconds, $\hat{t}$, are indicated beside each snapshot. Field of view in each snapshot is 19.05×2000 mm^2. Displacement is from right to left in each snapshot. Gate valve and pipe supports are marked by G and S, respectively.

The effects of the pipe rotation on the flow patterns of viscoplastic fluid displacement flows are shown in Figure 2. When the pipe is kept static ($\hat{\omega} = 0$), a clear slumping interface exists between the displacing and displaced fluids. A fast leading front leads to the breakage of the viscoplastic layer and flows underneath it. The unyielded viscoplastic gel with an irregular thickness remains immobile on the upper part of the pipe wall. The formation of the ripped displacement is shown in Figure 2a. As the Carbopol gel cannot be removed by the displacing fluid, an "inefficient removal regime" is observed in this figure. By introducing a weak pipe rotation (e.g. $\hat{\omega} = 2.09$ rad/s, see Figure 2b), the weak rotational inertia notches the immobile viscoplastic gel in unsteady bursts. Once the initial burst of the gel layer has occurred, the segments of the Carbopol gel are non-uniform. Figure 2c-d shows continuous unsteady bursts of the Carbopol gel at moderate-high rotating speeds. Some of the large pieces of the Carbopol gel are isolated and they remain as stationary residual deposits; however, the large isolated segments can also be pushed downstream by the slower trailing front. It appears that the pipe rotation can promote an *efficient* displacement regime. In this regime, called "efficient removal regime", the yield stress effect is negligible and the buoyant effects seem to be less relevant. All the Carbopol gel is removed by the displacing fluid.

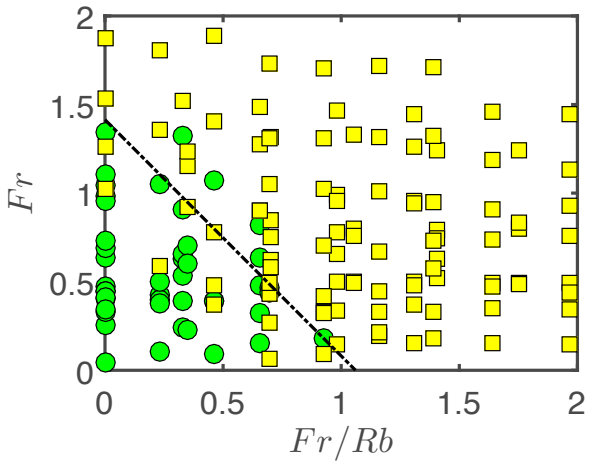

Figure 3: Displacement flow regime classification of viscoplastic fluid. The inefficient (●) and efficient flow regime (■) are roughly separated by the dashed line (empirical) passing through $Fr = \sqrt{2}$ and $Fr/Rb = \frac{3\sqrt{2}}{4}$.

Appropriate dimensionless groups are used to classify our results into efficient and inefficient removal flow regimes (see Figure 3), i.e. Fr and Fr/Rb, where the modified Froude and Rossby numbers are defined as $Rb = \hat{V}_0/\hat{\omega}\hat{R}$ and $Fr = \hat{V}_0/\sqrt{(At)\,\hat{g}\hat{R}\sin\beta}$, respectively, where $\hat{R}$ is the pipe radius and $\hat{g}$ is the gravitational acceleration. Note that Fr shows a balance of the imposed inertia and buoyancy while Fr/Rb represents the balance between rotational inertia and buoyancy. This regime classification can bring novel insights to improve the displacement efficiency using the pipe rotation in the cementing process.

VISCO-PLASTICALLY LUBRICATED TRIPLE-LAYER CORE-ANNULAR FLOWS

Parisa Sarmadi[1], Sarah Hormozi[2], and Ian A. Frigaard *[3]
[1]Department of Mechanical Engineering, University of British Columbia, Vancouver, Canada
[2]Department of Mechanical Engineering, Ohio University, Athens, USA
[3]Department of Mechanical Engineering and Mathematics, University of British Columbia, Vancouver,Canada

Summary We present a novel triple-layer core-annular flow method in which we purposefully position an unyielded skin of a visco-plastic fluid between the core and the lubricating fluid to eliminate the possibility of interfacial instabilities, see [1, 2, 3, 4]. Specifically, the skin layer is shaped which allows for lubrication force to develop as the core rises under the action of buoyancy forces. The objective is to reduce the frictional pressure gradient while avoiding interfacial instabilities [5, 6]. Here we address the issue of how in practice to develop a triple-layer flow with a sculpted/shaped visco-plastic skin, all within a concentric manifold by control of the flow rates of the individual fluids. An axisymmetric triple-layer simulation establishes that these flows may be stably established in a controlled way with a desired interface shape. Then, we extend the feasibility of the method to large pipes and higher flow rates by considering the effects of inertia and turbulence in the lubricating layer [7].

MODELING FLOW DEVELOPMENT

Our aim in this paper is to establish the feasibility of developing steady periodic triple-layer flows with a shaped interface of the type illustrated in Fig. 1 as studied in [5]. The development flow is assumed to occur in an inflow manifold, with a concentric arrangement, through which the three fluids may be pumped at controlled flow rates. We consider a horizontal pipe which is periodic in streamwise $\hat{z}$-direction, with period $\hat{l}$. Figure 1 indicates schematically the positions of the 3 fluids, within a cross-section of the pipe at fixed $\hat{z}$. Fluid 1 denotes the core fluid (viscous Newtonian heavy oil), with viscosity $\hat{\mu}^{[1]}$ and density $\hat{\rho}^{[1]}$. The skin layer is fluid 2, modeled simply as a Bingham fluid, with $\hat{\mu}^{[2]}$, $\hat{\tau}_y^{[2]}$, and $\hat{\rho}^{[2]}$ denoting its viscosity, yield stress, and density, respectively. Fluid 3 is the lubrication layer (a low viscosity Newtonian fluid) with viscosity $\hat{\mu}^{[3]}$, and density $\hat{\rho}^{[3]}$.

The outer radius of the skin may vary with $\hat{z}$: $\hat{r}_2 = \hat{r}_{2,0} + \Delta\hat{r}_2\Phi(\hat{z})$, i.e. $\Phi(\hat{z})$ captures the sculpted streamwise skin profile. The inner radius ($\hat{r} = \hat{r}_1$) is assumed to be uniform. The skin fluid is assumed to have a sufficiently high yield stress that it remains rigid (unyielded), except during a flow development region in which the interface shape is sculpted, as studied by [6]. Thus, fluids 1 and 3 remain separated. In general, we might assume that the required yield stress is moderately large (estimated later) and that surface tension effects are negligible in comparison to the other stresses; note that the radii of curvatures are relatively large.

The governing equations for the flow are the Navier-Stokes equations, in each fluid domain. The core fluid is assumed lighter than the lubricant. As shown by [8], both eccentricity and axial variation in lubrication layer are necessary to generate a transverse lift force via viscous lubrication. The lubrication pressure generated is larger where the gap is smaller and hence eccentricity towards the top of the pipe results in a net downward force to balance the buoyancy.

EXTENSIONAL MODEL

Here we exploit the aspect ratio of the flow to derive a simplified model to estimate the minimal yield stress required to maintain the skin rigid. We derive the model under the assumption of small aspect ratio. We suppose that the desired

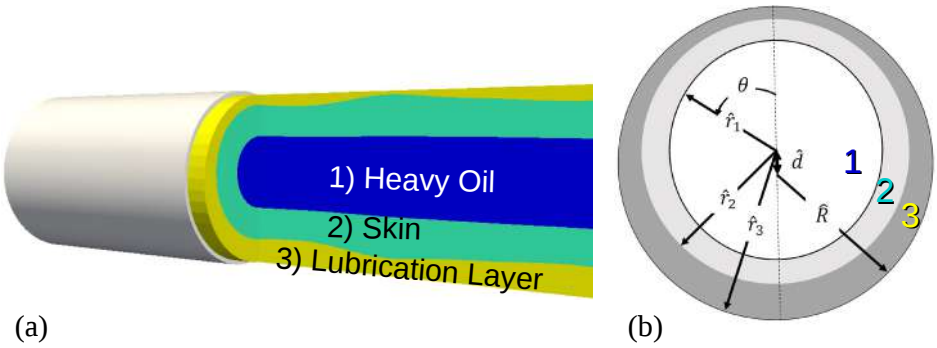

Figure 1: a) Shaped skin profile in 3D; b) cross section of the pipe with triple-layer configuration, illustrating the coordinates.

*Corresponding author. E-mail: frigaard@math.ubc.ca.

sculpted interface is to be periodic in $\hat{z}$, with period $\hat{L}$. Variations in the downstream flow of the skin and lubricant occur due to variations in interface shape, hence layer thickness, which have amplitude $\hat{R}(1-r_{2,0})$. Therefore, an appropriate aspect ratio ϵ to consider is $\epsilon = \frac{\hat{R}(1-r_{2,0})}{\hat{L}}$. We scale $\hat{z}$ with $\hat{L}$: $\tilde{z} = \hat{z}/\hat{L}$. In the lubricant and skin layers we scale radial distances onto x:

$$\hat{r} = \hat{r}_{2,0} + (\hat{R} - \hat{r}_{2,0})x \quad \Rightarrow \quad x = \frac{r - r_{2,0}}{1 - r_{2,0}}.$$

In terms of the x-coordinate the skin occupies $x_1 \leq x \leq x_2$. The lubricant occupies $x_2 \leq x \leq 1$. The core fluid layer is not assumed thin: hence $r = \hat{r}/\hat{R}$ for fluid 1.

We split the pressure into two parts: $\hat{P} = -\hat{G}\hat{z} + \hat{P}_l$, where the constant axial pressure gradient $\hat{G}$ drives the flow and $\hat{P}_l$ is the lubrication pressure. For the latter we use a classical lubrication scaling of the equations. Core and lubrication layers are mainly shear flow and velocity scaling implies $\hat{\tau}_{xx} \sim \hat{\tau}_{zz} \sim \epsilon\hat{\tau}_{xz} \sim \epsilon^2\hat{P}_l^*$. Within the skin layer, as we are interested in large yield stresses where the skin is unyielded or just yielded, we expect an extensional flow. The pressure in the Newtonian layers is balance by the total normal stress, i.e. part of the pressure generated in the lubrication layer may be absorbed by $\hat{\tau}_{rr}^{[2]}$, i.e. $\hat{\tau}_{rr}^{[2]} \sim \hat{\tau}_{zz}^{[2]} \sim \hat{P}_l^*$.

Leading order momentum equations and leading order constitutive equation of the skin result in a system of equations for skin velocity and normal stresses within the skin.

INERTIAL EFFECTS

The effect of inertia can be neglected for long-thin geometries when the product of aspect ratio and Reynolds number is small. However, inertial effects can become important both for large Reynolds numbers and in trying to balance larger core fluid density differences with larger amplitude sculpting. Both effects occur in larger pipelines and with higher flow rates: common industrial objectives. Thus, extension of the triple-layer concept to wider parameter regime means that we need to understand the main effects of inertia and turbulence in lubricating layer in particular on the generated lubrication force. For this purpose, we investigate a single periodic wavelength of fully developed flow, in which the buoyancy of the core fluid is balanced by the generation of hydrodynamic lubrication pressures. Different scaling for different flow regimes of the lubricating layer is used and leading order N-S equations are derived. We have used an analytical method to estimate inertial effects by assuming self-similarity of the velocity profile in thin layer flow. The study shows that inertia can have a significant effect on the pressure field and consequently lubrication force. In addition, careful choice of the waveshape can result in counterbalancing lubrication force.

CONCLUSIONS

We introduced a novel methodology for efficient transport of heavy oil via a triple-layer core-annular flow. We positioned a shaped unyielded skin of a visco-plastic fluid between the transported oil and the lubricating fluid layer. We addressed the important issue of how in practice to develop a triple-layer flow with shaped viscoplastic skin. Computational studies of [6] showed that these flows may be stably established and the shaped interface induces extensional stresses in the skin layer. We studied this directly by developing a long-wavelength analysis of the extensional flow. This allowed us to predict the minimal yield stress required to maintain the skin rigid.

We extended the feasibility of the method by considering the effects of inertia and turbulence in the lubrication layer. We showed that the method can generate enough lubrication force to balance the buoyancy force for wide range of density differences and pipe sizes if the proper shape is imposed on the unyielded skin.

TURBULENT DRAG REDUCTION WITH SURFACTANT SOLUTIONS AT A HIGH CONCENTRATION

Rodrigo S. Mitishita*[1], Jordan MacKenzie[2], Gwynn J. Elfring[1], and Ian A. Frigaard[1,3]
[1]Department of Mechanical Engineering, University of British Columbia, Vancouver, Canada
[2]Department of Chemical and Biological Engineering, University of British Columbia, Vancouver, Canada
[3]Department of Mathematics, University of British Columbia, Vancouver, Canada

Summary We present a comparative experimental investigation of turbulent drag reduction with surfactant based micellar solutions at high concentrations. Experiments are performed with a rotational rheometer and a flow loop in the fully turbulent regime. We analyse the rheology of the micellar fluid in order to characterize its viscoelastic behaviour and compare with that of xanthan gum and Carbopol solutions. The surfactant shows a gel-like response to oscillatory shear that is consistent with entangled gel systems, which is further corroborated by a scaling of G' with concentration, as well as Cryo-TEM visualizations. We analyse these results with LDV measurements of turbulent, drag reducing flows to characterize and better understand the mechanisms of drag reduction with high concentration viscoelastic systems.

INTRODUCTION

As it is well known from the experimental results by Toms, the addition of a few ppm of polymers or surfactants to water can reduce drag in turbulent flows by as much as 70% [1]. Such small additions grant viscoelasticity to the fluid but do not alter the shear viscosity significantly, in most cases. This discovery has brought significant energy savings in practical applications such as fire fighting, HVAC systems and hydraulic fracturing [2,3]. Industrial applications in the oil and gas industry such as gravel packing seek to benefit from both turbulent drag reduction (TDR) as well as high shear viscosities, useful for gravel suspension [4]. While the mechanisms of TDR with dilute polymer or surfactant solutions have been extensively investigated over the years with experimental and computational methods [5], fewer studies have been performed with high viscosity micellar viscoelastic fluids. Considering this gap in literature, we present an experimental investigation of turbulent flows with high viscosity polymer and surfactant fluids. In this study, we compare a Carbopol solution (an ideal yield stress fluid with negligible elasticity after the yielding point [6]),with a mostly shear-thinning fluids (xanthan gum) and a viscoelastic, shear thinning surfactant solution. We present rheological results for the fluids, turbulent friction factor, pressure drop and velocity measurements from Laser Doppler Velocimetry (LDV), and other turbulence characteristics.

EXPERIMENTAL SETUP

Turbulent flow experiments are conducted in a horizontal, pump driven flow loop with two transparent 7.5 *m* test sections, with both cylindrical and rectangular cross sections, as presented in Figure 1. The rectangular test section ("Channel") is made of three 2.5 *m* long, clear acrylic channels with dimensions of (W x H) 50.8 *mm* by 25.4 *mm*, and hydraulic diameter $D_h = 2WH/(W+H)$ of 33.8 *mm*. The circular test section ("Pipe") is composed of five 1.5 *m* borosilicate glass pipes with outer diameter (OD) of 60 *mm* and inner diameter (ID) of 42 *mm*. The fluid in the 200 *L* storage tank is driven by a Netzsch NEMO progressing cavity pump, capable of a maximum flow rate of 1000 *L/min*. An Omega FMG 606 magnetic flow meter is used to measure the average flow rate. The pressure drop along 2.5 *m* of the rectangular test section and 3.1 *m* of the circular test section is measured by an Omega DPG 409 differential pressure transducer (*DP1* and *DP2*). The temperature of the fluid in the tank is measured by an Omega TC-NPT pipe thermocouple. Two-component velocity measurements are performed with an LDV system (*FlowExplorer, Dantec Dynamics*) in the *measurement box* (a rectangular tank surrounding the pipe filled with glycerol to minimize the effects of beam refraction), and also the channel test section.

RESULTS AND FUTURE WORK

Rheological measurements are performed with a Malvern Kinexus Ultra+ rheometer, with a C34 roughened Couette geometry. The surfactant employed in this study is EDAB (erucic dimethyl amidopropyl betaine + isopropanol) mixed with tap water. The rheology of the surfactant system is initially probed by frequency sweeps in the linear regime at different concentrations from 1%w to 10%w concentrations, after a pre-shear of 100 s^{-1} for 6 *mins* and a resting time of 30 *mins* for a reproducible initial condition. We note here that the range of concentrations for industrial applications is usually from 3% to around 6% [4]. The data from Figure 2 (a) indicates that the surfactant system behaves as a viscoelastic solid at room temperature, with storage modulus G′ at least an order of magnitude greater than the loss modulus G″. This also implies very long relaxation times at room temperature and also the presence of a yield stress, which is confirmed by steady flow curves. In the inset of Figure 2 (b), we see that G′ scales with concentration with a power law index of approximately 2.2, which is also seen in other entangled gel-like materials, such as actin. More evidence of an entangled system is seen through Cryo-TEM analysis in Figure 2 (b), which shows a structure of very long micelles greater than 1μm in length. The structure seems to be exclusively formed by entanglements without crosslinks or branching. This evidence of highly elastic material could help to explain drag reduction such as measured by Goyal et al [4] with high concentration surfactant solutions.

Rheology data, as well as comparisons with better known polymers such as a Carbopol fluid, which is an inelastic gel-like material in the linear viscoelastic regime, is used to interpret flow loop experiments with surfactants at concentrations between 1 and 4.5 %w, performed with the setup described in the previous section. Experiments are executed at a Reynolds number of over 10000 to ensure a fully turbulent flow. We present friction factor measurements over a range of turbulent Reynolds numbers in both pipe and channel test sections, for both Carbopol and the surfactant fluid. The percentage of drag reduction is calculated as $\%DR = (\Delta P_{water} - \Delta P_{measurement})/\Delta P_{water}$. In order to quantitatively investigate TDR with polymers and surfactant fluids, we present Reynolds stress measurements as well as spectra of velocity fluctuations near the wall, to show how the additives affect the energy cascade and thus energy dissipation during a statistically steady turbulent flow.

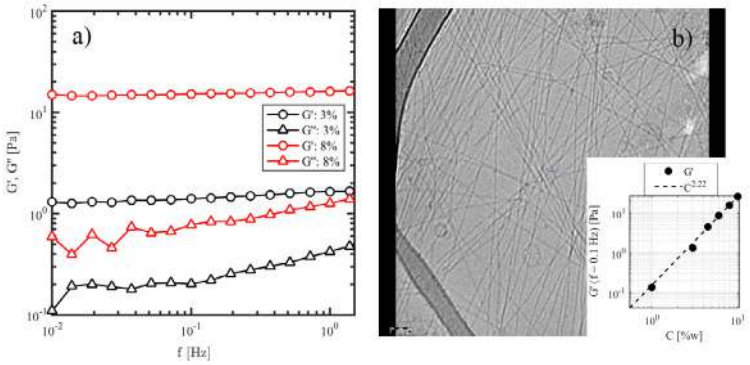

Figure 2: (a) Storage (G′) and loss modulus (G″) vs frequency, showing only results for 3%w and 8%w concentrations. (b) Cryo-TEM of 4.5% EDAB along with scaling of G' with concentration, at a frequency of 0.5 Hz.

A LAGRANGIAN VORTEX MODEL FOR VISCOELASTIC FLUID FLOWS

Fumihiko Mikami*[1]
[1]Department of Mechanical Engineering, Chiba University, Chiba, Japan

Summary A Lagrangian vortex model is proposed that describes the vorticity transport in a two-dimensional flow of a Maxwell fluid in which elastic shear waves propagate. A point vortex created at the surface of the body translates with the uniform flow velocity, and its vorticity occupied area expands at the shear wave speed according to the two-dimensional Green's function of the telegraph equation. The viscoelastic Mach number determines the size of the expanding area. In contrast, the Deborah number determines the radial distribution of the vorticity that can be classified into diffusion type and traveling-wave type. The model offers an intuitive understanding of the viscoelastic fluid flows around a body.

INTRODUCTION

Vorticity plays an important role in fluid dynamics. In the case of a two-dimensional incompressible flow, the vorticity form of the Navier-Stokes equations describes the convection and diffusion of the vorticity, which provides useful insights into the understanding of the flow of a Newtonian fluid. In contrast, a clear explanation of the vorticity transport mechanisms in the flow of a viscoelastic fluid has not been found, in particular, the one corresponding to the viscous diffusion. In a viscoelastic fluid, elastic shear waves or vorticity waves propagate in certain conditions. Joseph[1] studied the problem of the flow of a viscoelastic fluid past a body, which is the viscoelastic analog to the aerodynamic flow problem associated with sound waves. With linearization around uniform flow, he obtained an equation that describes the propagation of vorticity. Such an equation was shown by Joseph et al. [2] to change type in steady flow depending on the viscoelastic Mach number M defined as the ratio of the uniform flow speed U to the shear wave speed c in the fluid. Besides, the problem depends on another parameter, such as the Deborah number De, the ratio of the fluid relaxation time τ to characteristic flow time. It is thus desirable to understand the vorticity transport in the flow of viscoelastic fluids in terms of these parameters. In this study, a Lagrangian vortex model is proposed based on the linearized equations of a Maxwell fluid, with which we discuss the vorticity transport mechanisms in the flow around a body.

VORTICITY TRANSPORT IN A MAXWELL FLUID

A vortex model

Based on the governing equations linearized around a uniform flow, and with the notation $D_0/Dt = \partial/\partial t + U \cdot \partial/\partial x$, Joseph[1] has derived the following vorticity equation for a Maxwell fluid,

$$\frac{D_0^2 \boldsymbol{\omega}}{Dt^2} + \frac{1}{De}\frac{D_0 \boldsymbol{\omega}}{Dt} = \frac{1}{Re\, De}\nabla^2 \boldsymbol{\omega}, \tag{1}$$

where $\boldsymbol{\omega}$ is the vorticity. This equation describes the propagation of vorticity waves in a medium moving with uniform speed U. From equation (1), the shear wave speed relative to the surrounding fluid is given by $c = 1/\sqrt{ReDe} = 1/M$. By using the coordinate system moving with the fluid and by including a source term $\gamma(\boldsymbol{x}, t)$ introduced in this study to denote creation of vorticity at the body surface, equation (1) is now replaced by the following telegraph equation,

$$\left(\nabla^2 - M^2\frac{\partial^2}{\partial t^2} - \frac{M^2}{De}\frac{\partial}{\partial t}\right)\boldsymbol{\omega}(\boldsymbol{x}, t) = -\gamma(\boldsymbol{x}, t). \tag{2}$$

In the case of two-dimensional flow, a point vortex created at the point $\boldsymbol{x} = \boldsymbol{x}'$ on the body surface at $t = t'$ translates with the uniform flow velocity U, and its vorticity occupied area expands at the wave speed c according to the two-dimensional Green's function of equation (2), which is described, with $t - t'$ replaced by t, as[3]

$$G_2(r, t) = \frac{1}{2\pi\sqrt{t^2 - M^2 r^2}}\exp\left(-\frac{t}{2De}\right)\cosh\left(\frac{\sqrt{t^2 - M^2 r^2}}{2De}\right)H(t - Mr), \tag{3}$$

where $r = |\boldsymbol{x} - \boldsymbol{x}'|$. This Green's function for a Maxwell fluid is essentially different from that of seismic S waves[4, 5]. Figure 1 shows a schematic of this process. The viscoelastic Mach number $M = U/c$ determines the radius of the area occupied by the vorticity as it is observed at a fixed point of the domain downstream of the body. The vorticity occupied areas are assumed to retain the same shape for all times.

On the other hand, the Deborah number De determines the radial profile of vorticity. Figure 2 shows the plots of equation (3) for two different Deborah numbers, presenting the difference in the feature of the point vortex. At $De = 0.1$ (Figure 2(a)), the vorticity spreads, keeping the feature of the vortex core, like viscous diffusion in a Newtonian fluid, with the exception that the vorticity occupied area is restricted within a non-dimensional radius $r = t/M$, whereas at $De = 0.4$ (Figure 2(b)), traveling waves with tails are readily observable, where the wave carries the vorticity with its maximum at the wavefront. The radial profile of vorticity is attenuated with time due to a loss term in the equation (2) and tends to the profile of the Newtonian case.

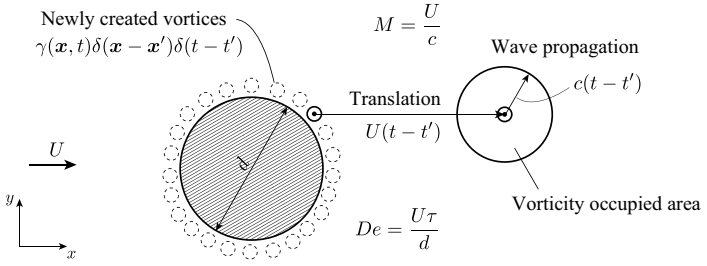

Figure 1: A Lagrangian vortex model for vorticity transport in the flow of a Maxwell fluid.

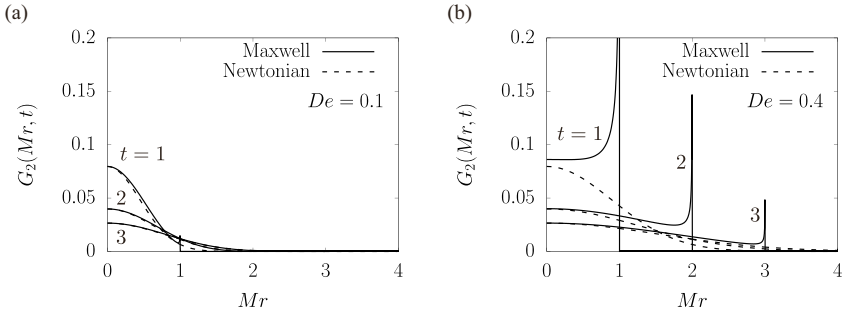

Figure 2: Equation (3) at various non-dimensional times $t = 1, 2$ and 3, showing the expansion of the vorticity occupied area. The dashed lines denote the Newtonian cases at the equivalent Reynolds number $Re = M^2/De$. (a) $De = 0.1$. (b) $De = 0.4$.

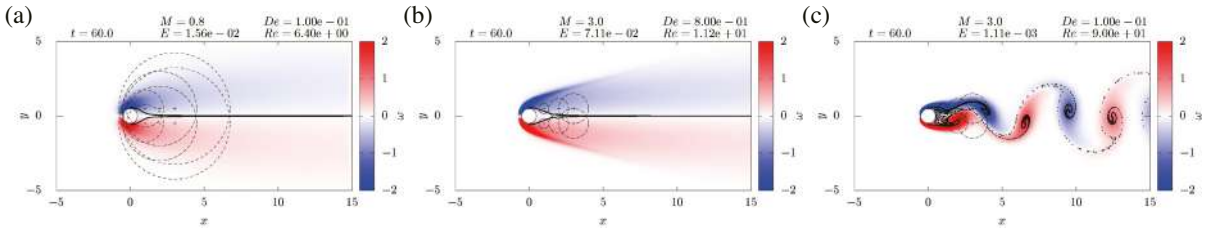

Figure 3: Snapshots of vorticity contours and streaklines. The dashed lines denote examples of the wavefronts of the previously created vortices, only showing those originated from the top and bottom of the circular cylinder and at positions corresponding to the times shown in Figure 2. (a) The flow exhibits a low Reynolds number character at $M = 0.8, De = 0.1$. (b) A clear Mach cone is observed at $M = 3.0, De = 0.8$. (c) The flow exhibits a vortex street wake at $M = 3.0, De = 0.1$.

Comparison with numerical results

The impulsively started flow of a UCM (upper convected Maxwell) fluid around a circular cylinder is numerically simulated using a finite-difference method, with a Cartesian mesh and the staggered variable arrangement. The solid obstacle is taken into account by the penalization method. The governing equations are the stream function-vorticity formulation of the momentum equation and the constitutive relations for the UCM fluid.

The flow exhibits a steady and low Reynolds number character at $M = 0.8$ and $De = 0.1$ (Figure 3(a)), where the vorticity in the wake is located near the center, as shown in Figure 2(a), of a larger expanding area, whereas at $M = 3.0$ and $De = 0.8$ (Figure 3(b)), a formation of a Mach cone, i.e., a V-shaped wake is observed, where the peak vorticity is located at the wavefront as shown in Figure 2(b). The flow exhibits a vortex street wake at $M = 3.0$ and $De = 0.1$ (Figure 3(c)), where the vorticity is located near the center of an expanding area of relatively small radius displaying low dissipation (that is, high Reynolds number).

CONCLUSIONS

A vortex model which describes the vorticity transport in a two-dimensional flow of a Maxwell fluid is proposed. The viscoelastic Mach number determines the size of the expanding area occupied by the vorticity, whereas the Deborah number determines the radial distribution of the vorticity, which can be classified into diffusion type and traveling-wave type. The model successfully describes the main characteristics of the numerical results based on the specified parameters, which offers an intuitive understanding of the viscoelastic fluid flows around a body.

YIELD STRESS EFFECTS ON FLOW ONSET AND ARREST

Kunal D. Jadhav[1], Pietro Rossi[1], and Ida Karimfazli*[1]
[1]Department of Mechanical, Industrial & Aerospace Engineering, Concordia University, Montreal, QC, Canada

Summary We conduct experimental studies of internal buoyancy-driven flow of yield stress fluids to characterize the effect of the yield stress on flow features. We compare our findings with theoretical predictions to assess the accuracy of hydrodynamic models. We verify the existence of a critical yield stress (sufficient to prevent steady flow) but identify other phenomenological differences in the predicted and observed flow development patterns.

BACKGROUND

Yield stress fluids (*YSF*), first introduced by Bingham [1], are characterized by their solid-body-like behaviour below a certain shear stress known as the yield stress. Above the yield stress, the material *yields* and starts to flow.

For any flow setup there is, inevitably, a critical yield stress below which the fluid does not flow. Energy stability analysis and numerical studies [2, 3] have shown that the motionless background state is always linearly stable and that, if disturbed, stable disturbances decay and the motionless state is recovered within a finite time. Although these initial studies focused on unidirectional shear flows, more recent studies demonstrated the same results in different multidimensional buoyancy-driven flows (see e.g. [4, 5, 6]). Numerical results also revealed episodic flow development in yield stress fluids (including delayed flow onset and temporary flow arrest) [7, 8].

Figure 1: Illustration of the flow domain.

Contrary to the plethora of theoretical studies on buoyancy-driven flows of YSF, experimental studies are quite scarce and the distinct features of YSF predicted theoretically have not been validated with experimental studies. We consider natural convection in a square cavity with differentially heated sidewalls and use time resolved Particle Image Velocimetry (*PIV*) to investigate the existence of a critical yield stress and flow development and arrest in YSF (see Fig.1).

EXPERIMENT SETUP

A square box of size $15cm$ was made of acrylic. The sidewalls (on the hot and cold side) are made of Aluminum to facilitate heat transfer. Hot and cold side temperatures were maintained using feedback-controlled Peltier modules. See Fig.2 for an illustration of the setup. Temperature variation on each wall was monitored and found to be always less than 1^oC. Carbopol solutions of concentration 0.3 to $0.4g/L$ with yield stress values ranging from 0.05 to $0.2Pa$ were used as the working fluid. Experiment was started with the system at room temperature and the fluid at rest. Peltier modules were turned on and data collection started at $t = 0s$. Once the flow reached steady state, the Peltier modules were turned off while data collection continued until flow stoppage.

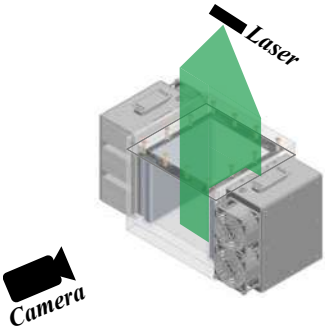

Figure 2: Schematic of the experimental setup.

CRITICAL YIELD STRESS

For each carbopol solution, the temperature difference across the cell was changed between 3^oC and 30^oC. The L^2 norm of the velocity field, $||u||$, was used as a measure of the kinetic energy of the flow to determine the existence of steady advective currents. Figure 3 illustrates the outcome of the experiments. When the ratio of the yield stress to the buoyancy stresses is above a certain *critical* value, the steady state is motionless; however, when the ratio is below the critical value, steady flow is observed (see Fig.3).

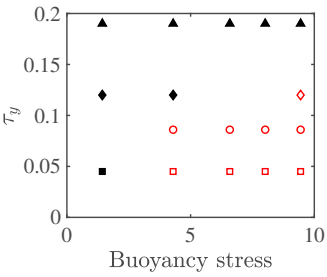

Figure 3: Effect of the yield stress on development of advective currents. Filled (empty) markers indicate motionless (flowing) regimes.

FLOW ONSET AND ARREST

An illustrative case of flow development is presented in Fig.4: (a,b,c,d) show snapshots of the velocity field at different stages of flow development and (e,f) flow decay (after the Peltier modules are turned off). Figure 4 (g) and (h) show the evolution of the temperatures of the hot and cold walls and the velocity norm during the experiment. In an apparent contrast with the theoretical predictions, flow appears to start immediately, initially developing slowly before accelerating and approaching the steady state.

*Corresponding author. E-mail: ida.karimfazli@concordia.ca.

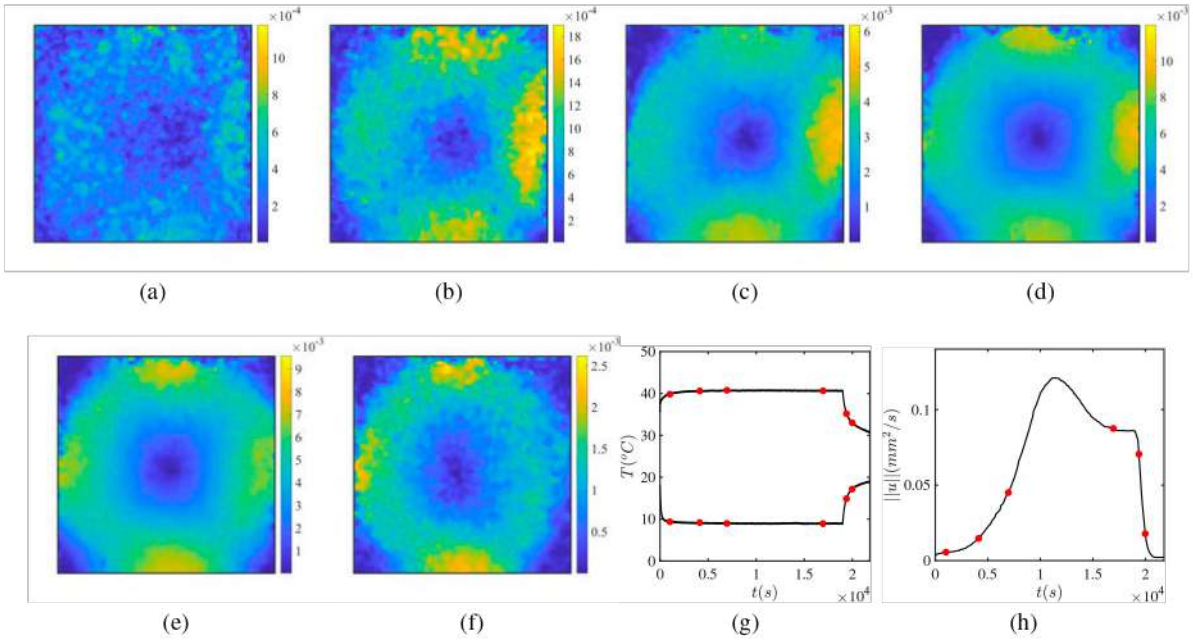

Figure 4: (a-f) show snapshots of the velocity field (in mm/s). (g) and (h) show the time evolution of hot and cold wall temperatures and the velocity norm, respectively. The red circles indicate the times of the snapshots (carbopol concentration $0.38g/L$).

We present different quantitative measures of advective currents to show that, although some experiments comply with the theoretical predictions (see e.g. Fig.5), depending on the magnitude of the yield stress there can also be marked differences between experiment and theory.

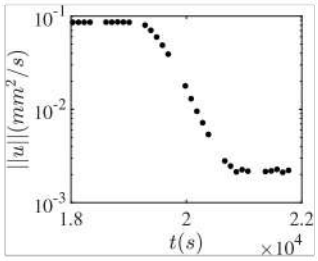

Figure 5: Decay of the velocity norm after the heating and cooling units are turned off. Carbopol concentration $0.38g/L$; for temperature boundary conditions see Fig. 4g.

CONCLUSIONS

We conduct experiments to investigate buoyancy-driven flow in a square cavity. We use time-resolved PIV to characterize flow onset, development and arrest. Experimental observations confirm the existence of a threshold yield stress above which there is no steady flow. Contrary to the theoretical predictions, however, below the critical limit flow onset appears to be immediate; this does not seem to depend on the value of the yield stress. Flow arrest is theoretically expected to take place within a finite time. Our experimental observations contradict this prediction. Increasing the yield stress, however, decay trends appear to approach the theoretical predictions.

CHOCOLATE FOUNTAIN: MULTI-PHYSICS, MULTI-PHASE, AND MULTI-SCALE MODELING

Lyes Kahouadji*[1], Seungwon Shin[2], Jalel Chergui[3], Damir Juric[3], and Omar K. Matar[1]
[1]Department of Chemical Engineering, Imperial College London, South Kensington Campus, London SW7 2AZ, UK
[2]Department of Mechanical and System Design Engineering, Hongik University, Seoul 121-791, Republic of Korea.

Summary We present a three-dimensional direct numerical simulation of a heated chocolate fountain using physical properties of melted chocolate (60°C) flowing in an ambient atmosphere (20°C). We solve both the Navier-Stokes and the energy equation using a front-tracking-based multiphase method that accounts for both the Newtonian (ambient air) and Non-Newtonian (melted chocolate) fluids, and a direct forcing method technique for fluid-structure interaction. The numerical framework employed circumvents numerous meshing issues normally associated with constructing complex geometries within typical computational fluid dynamics packages. The device considered in the present work, a static chocolate fountain structure with a rotating vertical Archimedes Screw that are both constructed via a module that defines solid objects by means of two distance functions, which are positive for the fluid and negative for the solid. The construction combines primitive objects, such as a cylinder, a plane, and an ellipsoid, for instance, using simple geometrical operations. Finally, we present a new approach to explore the resulting computational fluid dynamics data through a virtual reality environment in which it will be possible to 'dive' inside the chocolate fountain and explore the underlying physics through a multi-sensory process.

INTRODUCTION

A chocolate fountain encompasses many topics in fluid mechanics such fluid-structure interactions, heat-transfer, and multiphase flow. A typical chocolate fountain is composed of (*i*) a large plate at the bottom filled with molten chocolate, (*ii*) a central vertical tube in which a vertical Archimedes Screw is rotating in order to pump up the heated molten chocolate from the bottom plate, and (*iii*) some domes fixed to the vertical tube over which the molten chocolate flows. When the chocolate fountain is activated, people enjoy dipping pieces of fruit (strawberries, bananas,...) and also some sweets such as marshmallows through the falling chocolate curtain between two domes. Townsend and Wilson [1] have considered both Newtonian and Non-Newtonian types of molten chocolate and studied the flow occurring in a chocolate fountain by isolating three mechanisms in it: (*i*) the pumped pipe flow as a traditional Poiseuille flow, (*ii*) a chocolate film flowing on a typical dome, and finally (*iii*) the curtain flow between two domes. Our approach is to combine all these isolated mechanisms through a single numerical setup that also takes into account heat-transfer effects and a complex type of pumping mechanism via the rotation of an Archimedes screw.

CONFIGURATION, PROBLEM FORMULATION, AND DISCUSSION

The specific Chocolate Fountain configuration used in this study is a 4-tier device illustrated in Figure 1-(a), represented in a cubical Cartesian domain (x, y, z) of size $0.5m \times 0.5m \times 0.5m$. Our approach for the construction of a similar structure circumvents the need for time-consuming construction, meshing, and remeshing of this geometry. Instead, we proceed in a modular manner that enables us to build the geometry from primitive geometrical objects using a static distance function that takes into account the interaction of these objects with the flow for both single and two-phase flows. The final structure in the computational domain, viz. Fig. 1-(a) and (d) to (j), consists of the iso-value $\psi(x, y, z) = 0$; the static distance function, $\psi(x, y, z)$, is positive for the fluid part and negative for the solid part. In a similar way, the Archimedes screw is also constructed with a distance function (see figure 1-(c)) and its rotational motion via a direct forcing method technique [3]. The temporal evolution of the chocolate fountain exhibits many physical mechanisms such as Poiseuille flow (see Fig 1-(d)), laminar falling film during the dome envelopment (g), radial retraction of the chocolate curtain (g and h), curtain coiling when reaching a larger dome (h and i) followed by an interfacial instability in the azimuthal direction (i), and finally curtain breakup (j).

The Archimedes screw shown in figure 1-(c) is also built using distance functions. The rotation of its helicoid geometry provides an axial motion that pumps the molten chocolate from bottom to top. The activation of the Archimedes screw rotation requires the implementation of the so-called Direct Forcing Method, which is a technique that incorporates a fluid-solid interaction force defined numerically using the latest step of the temporal integration [3] for two types of molten chocolate rheology (a highly viscous Newtonian and a shear-thinning non-Newtonian model [1]).

When the chocolate fountain is activated, the molten chocolate falls from one dome to a larger dome and the liquid curtain becomes thinner and colder (see figure 1-(b)). Moreover, the simulation correctly predicts the inward falling of the chocolate curtain due to the presence of a pressure difference between its external and internal sides, the gravity, and the surface tension force.

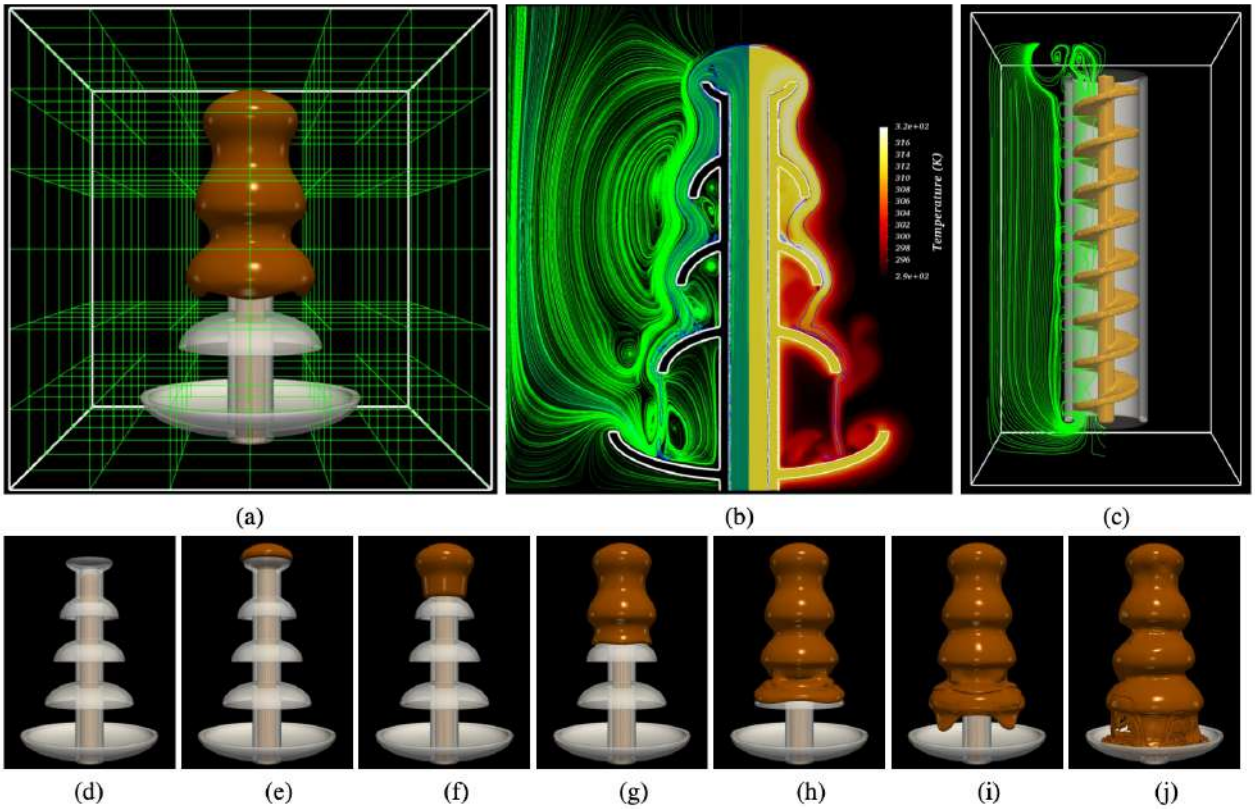

Figure 1: Typical chocolate fountain (a): Computational domain of 0.5^3 m^3 divided onto $216 = 6 \times 6 \times 6$ subdomains. Each subdomain has a resolution of 64^3 grid cells which gives a global resolution of 384^3. (b): A typical vortical structure and temperature field in the solid, liquid and in the gas. (c): A vertical Archimedes screw confined inside a cylindrical tube. (d-j): Temporal evolution of chocolate fountain flow until reaching the bottom plate.

CONCLUSIONS

This work studies the dynamics of a chocolate fountain in a single computation that combines fluid structure interaction, heat-transfer, and in the context of a front-tracking based multiphase method for both Newtonian and non-Newtonian fluids.

ENERGY TRANSFER IN VISCOELASTIC DILUTE POLYMER SOLUTIONS MODELED BY A HYBRID CONTRAVARIANT-COVARIANT DUMBBELLS

Kiyosi Horiuti*[1], Carlos B. da Silva[1], and Fernando T. Pinho[2]
[1]LAETA/IDMEC/Instituto Superior Técnico, Universidade de Lisboa, Portugal 2CEFT, FEUP, Universidade do Porto, Portugal

Summary We conduct an analysis of the energy transfer and polymer configuration in homogeneous isotropic turbulent flow (HIT) of dilute polymer solutions. The polymer chains are modeled by new nonlinear elastic dumbbells in which the constraint of affinity of motion of the bead-spring configuration with the macroscopic deformation of the solvent fluid is removed. Slippage of the strand and variation in the slip parameter α are allowed. When the complete affine dumbbell ($\alpha = 0$) is rotated to the maximum non-affine ($\alpha = 1$) direction, the value of α is adjusted to represent the renewed orientation. Assessment is numerically conducted by dispersing the dumbbells in HIT, where their motion is pursued by Brownian dynamics. The macroscopic motion of solvent fluid is determined by DNS and with the proposed model with variable slip, enhancement of drag reduction is achieved in comparison to the complete affine case. This is associated with the conversion of the connector vector of dumbbell between contravariant ($\alpha = 0$) and covariant ($\alpha = 1$) states, which takes place alternately and quasi-periodically in time with an interval comparable to the relaxation time. The largest elastic energy production is achieved in the elongated covariant dumbbells ($\alpha \approx 1$) with the elastic energy accumulating in the region adjacent to the vortex sheets. Large elastic energy is attained in the dumbbells aligned in the direction normal to the vortex sheets. When $\alpha \approx 0$, the elastic energy accumulates along the vortex sheets, and large elastic energy is attained in the dumbbells oriented in the direction transverse to the vorticity.

Drag reduction (DR) by addition of small amounts of long-chain polymers into Newtonian solvent is an important theoretical and practical problem. Molecules of polymer in dilute solution are commonly modeled as dumbbells, i.e. sets of two beads connected by a nonlinear spring. It is generally assumed that the fluid surrounding this bead-spring configuration moves affinely with an equivalent continuum. The polymer chains, however, may slip through the solvent which is normally observed with rigid particles [1]. Actually, when complete affinity is assumed, the elasto-inertial turbulence (EIT) regime arises as shown in [2] using the FENE-P constitutive equation for the polymer stress. Molecular motions may not precisely correspond to the macroscopic deformation when straining is large [3], and slip may be accounted for through slip parameter α $(0 \leq \alpha \leq 1)$. This rigidity effect was considered in [4] assuming that α may not be fixed but variable subjected to elongation and reorientation of the dumbbells. This paper aims to develop a new dumbbell model in which the variation of α is incorporated and to elucidate its impact on the energy transfer and DR.

We utilize the multi-scale BDS-DNS in which a mesoscopic description of an ensemble of dumbbells is connected to a macroscopic DNS of the solvent [5]. Non-affinity is introduced by allowing the slippage of strand motion in the dumbbell model. When $\alpha = 0$, the governing equation for the end-to-end vector of the dumbbell $\boldsymbol{R}$ becomes $dR^i/dt = R^j \partial_j u^i$, and $\boldsymbol{R}$ is contravariant. $\boldsymbol{R}$ tends to become parallel to the vorticity vector $\boldsymbol{\omega}$ and distributes along the vortex sheet. When non-affinity is maximum $(\alpha = 1)$, it becomes $dR_i/dt = -R_j \partial_i u^j$, and $\boldsymbol{R}$ is covariant. $\boldsymbol{R}$ aligns orthogonally to the vortex sheet [6].

Using the steady solution for the governing equation of the conformation tensor $c_{ij}(\equiv R_i R_j)$, the production term for c_{ii}, $P_c(= (1-2\alpha)c_{ij}S_{ji})$, is approximated as $P_c \approx 4\tau_s(1-2\alpha)^3 S_{ik}S_{kj}S_{ji}$ [6], where S_{ij} is the strain rate tensor and τ_s is the relaxation time. The generation term of the solvent dissipation rate (ε) is given as $P_\varepsilon \approx -\nu S_{ik}S_{kj}S_{ji}$, where ν is the viscosity. Since $\mathcal{S}_\mathrm{S}(\equiv -S_{ik}S_{kj}S_{ji})$ is predominantly positive [7], when $\alpha = 0$, $P_c \propto$ -$\mathcal{S}_\mathrm{S} < 0$ and $P_\varepsilon \propto \mathcal{S}_\mathrm{S} > 0$. Thus, the contravariant dumbbells transfer the elastic energy back into the solvent where it is then dissipated and EIT arises. This energy transfer can be reversed only when $\mathcal{S}_\mathrm{S} < 0$. We use the eigenvalues of S_{ij}, $\sigma_+, \sigma_-, \sigma_s$. σ_s corresponds to the eigenvector $\boldsymbol{e}_s$ maximally aligned with $\boldsymbol{\omega}$, the largest remaining ones as σ_+ and $\boldsymbol{e}_+$, and the smallest ones as σ_- and $\boldsymbol{e}_-$. $\boldsymbol{e}_s \parallel \boldsymbol{\omega}$, and $\boldsymbol{e}_s$ and $\boldsymbol{e}_+$ span the vortex sheet, while $\boldsymbol{e}_-$ is perpendicular to the vortex sheet [6]. When $\alpha = 0$, $\boldsymbol{R} \parallel \boldsymbol{e}_s$ or $\boldsymbol{R} \parallel \boldsymbol{e}_+$ and $\mathcal{S}_\mathrm{S} < 0$ is achieved when $\sigma_+ > 0, \sigma_- < 0, \sigma_s < 0$. By altering the orientation of $\boldsymbol{R}$ from $\boldsymbol{e}_s$ to $\boldsymbol{e}_+$, large P_c is restored [7]. When $\alpha = 1$, $\boldsymbol{R} \parallel \boldsymbol{e}_-$, $P_c \propto \mathcal{S}_\mathrm{S} > 0$ and $P_\varepsilon \propto \mathcal{S}_\mathrm{S} > 0$. The energy transfer can proceed to both elastic energy and dissipation.

Evolution of $\boldsymbol{R}$ is governed by the $\Omega_{ij}R_j$ term which gives rotation of $\boldsymbol{R}$ but preserves the length of $\boldsymbol{R}$, and the $S_{ij}R_j$ term which yields stretching of $\boldsymbol{R}$, where Ω_{ij} is the vorticity tensor. Noting that the $\Omega_{ij}R_j$ term is independent on α, we incorporate the effect of reorientation of $\boldsymbol{R}$ due to $\Omega_{ij}R_j$ term into the renormalized value of α. The increment of α in time can be determined as $\delta\alpha = -C_\alpha(\Delta t/\tau_s)(R_pR_jS_{ip}\Omega_{ij})/2(R_pR_jS_{ip}S_{ij})$ (Variable-α model) where Δt is the time increment.

The polymer stress tensor τ_{ij} due to the force acting on the fluid from the dumbbells and solvent is directly obtained by averaging over the dumbbells in the configurational space as $\tau_{ij} = C_\tau \sum_{n=1}^{N_t}(1-2\alpha)\left\{f(|\boldsymbol{R}|^*)(R_i^{(n)}R_j^{(n)})/r_{eq}^2 - \delta_{ij}\right\}\delta(\boldsymbol{x} - \boldsymbol{r}_g^{(n)})$, where N_t is the number of dumbbells, r_{eq} is the equilibrium length of the dumbbell and $\boldsymbol{r}_g$ is the vector connecting the center of $\boldsymbol{R}$. The FENE damping function $f(x) = 1/(1-x^2)$ is applied. The linear interpolation scheme is applied for averaging [5]. Transfer of the solvent energy to the polymers is evaluated by the production term $P_e(\equiv \tau_{ij}S_{ij})$.

We carried out three cases in HIT with 128^3 grid points, $\tau_s = 2.4$s, Weissenberg number $W_i = 10$ and $N_t = 10^9$: α was fixed to 0 in case Fix-B, fixed to 1 (case Fix-A) and allowed to vary between 0 and 1 (Variable-α). Figure 1 (a) compares the p.d.f. of the length of the dumbbells $|\boldsymbol{R}|$ in the three cases. Not only is Variable-α not intermediate to the two fixed cases, but the largest elongation is attained in Variable-α. In this study, steady state is maintained by imposition of external random force f_i. Figure 1 (b) shows the p.d.f. of the work provided by the external force f_i, $u_i f_i$. The tails of p.d.f. obtained in all cases are decimated compared with the Newtonian case, i.e., steady state is sustained by supplying smaller work due to f_i in viscoelastic cases and DR is achieved. Solvent dissipation (ε) was smaller in Fix-A (0.226) than in Fix-B (0.263) and P_e was larger in Fix-A (0.149) than in Fix-B (0.115). In Variable-α, P_e was close to Fix-A (0.146), while ε was between Fix-A and Fix-B (0.243). DR exceeding Fix-B is obtained in Variable-α.

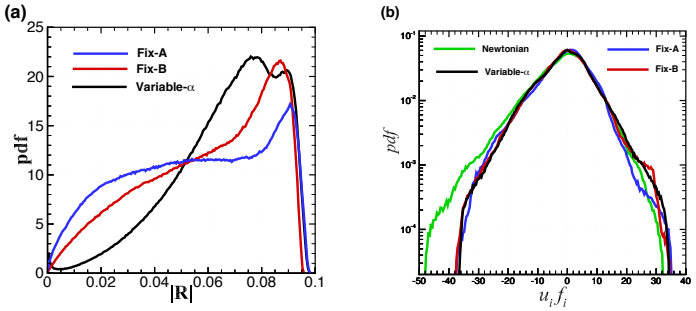

Figure 1: (a) Distributions of p.d.f. of the dumbbell length $|\boldsymbol{R}|$ obtained in Fix-A (blue line), Fix-B (red), Variable-α (black).; (b) Distribution of p.d.f. of the $u_i f_i$ term obtained in Newtonian (green line), Fix-A (blue), Fix-B (red), Variable-α (black).

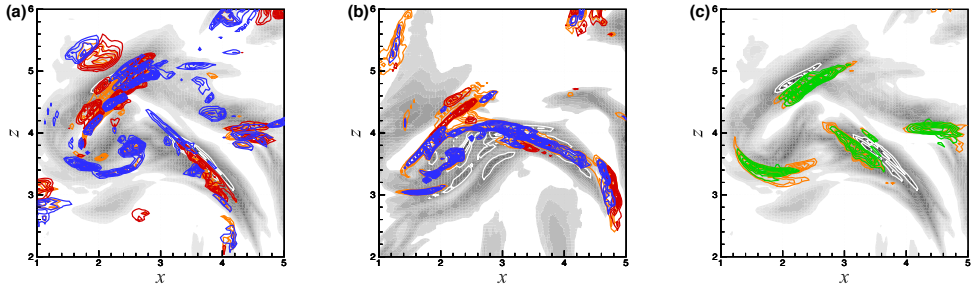

Figure 2: Contours of vortex sheets (gray flood and white lines), the polymer energy τ_{kk} (orange lines) and the polymer energy production term P_e (blue, red, green lines) in the $x-z$ plane at $y = 2.21$ at (a) $t = 586.5$, (b) $t = 587.0$, (c) $t = 586.5$.

Figure 2 show the distributions of vortex sheets (gray flood), the polymer energy τ_{kk} (orange lines) and P_e in which conditional sampling of $|\boldsymbol{R}|^2 \geq 0.75 L^2_{\max}$ is applied on the dumbbells to derive τ_{ij}, where $L_{\max}$ is the maximum dumbbell length. In Fig. 2 (a) and (b), P_e is sampled on $0 \leq \alpha \leq 0.2$, and Fig. 2 (c) on $0.8 \leq \alpha \leq 1$. Blue, red and green lines show P_e further sampled on the dumbbells with $\boldsymbol{R} \parallel \boldsymbol{e}_+$, $\boldsymbol{R} \parallel \boldsymbol{e}_s$, $\boldsymbol{R} \parallel \boldsymbol{e}_-$, respectively. In the contravariant dumbbells, initially in (a), the dumbbells with $\boldsymbol{R} \parallel \boldsymbol{e}_s$ are responsible for large P_e, but later in (b), P_e by $\boldsymbol{R} \parallel \boldsymbol{e}_s$ annihilates and P_e by $\boldsymbol{R} \parallel \boldsymbol{e}_+$ becomes predominant. Large P_e is restored by turning $\boldsymbol{R}$ from $\boldsymbol{e}_s$ to $\boldsymbol{e}_+$, and τ_{kk} distributes upon the vortex sheets. In the covariant dumbbells in Fig. 2 (c), τ_{kk} concentrates in the region outside and adjacent to the vortex sheets and P_e by $\boldsymbol{R} \parallel \boldsymbol{e}_-$ is predominant. The dumbbells are orthogonal to the vortex sheets and the sheet is under tension, leading to large DR [6].

CONCLUSIONS

We proposed new dumbbell model with variable α. Its impact on the motion of polymers and energy transfer is studied using BDS-DNS in HIT. Correlation between the alignment of the dumbbells and polymer energy production is presented. Contravariant polymers release the polymer energy back into the solvent when highly stretched and dissipation increases. This transfer is alleviated by altering the orientation of the dumbbell to the transverse direction. Covariant polymers distribute orthogonally to the vortex sheets and the largest elastic energy is retained when highly elongated, which leads to larger DR.

SLIPPERY WEISSENBERG EFFECT?

Udita U. Ghosh,[1] Navin K. Chandra,[1] and Aloke Kumar*[1]
[1]Department of Mechanical Engineering, Indian Institute of Science, Bangalore, India.

Summary We investigate the effect of a slippery interfacial layer on the climbing of a viscoelastic fluid onto a partially immersed rotating rod (Weissenberg effect). The bare rods are replaced by silicone and castor oil dipped rods and the maximum free surface deformation ($\bar{h}$) of the polymeric suspensions is used as a characterization parameter. It is found that the polymeric suspensions not only continue their ascent onto the rod but can also exhibit rod-dipping state for polymeric concentration $c = 0.5$ (w/w%) for a range of rod rotation velocity of $\omega = 400$ to $\omega = 1000$ RPM. Thus, fluid behavior has been demarcated into three regimes (rod-climbing, rod-dipping, absence of Weissenberg effect) as a function of type of oil, polymeric concentration and rod-rotation velocity.

INTRODUCTION

Weissenberg effect [1] is the 'climbing' by a fluid onto a partially immersed rotating shaft. Weissenberg [1] postulated that such deformation in the meniscus profile is driven by the non-zero value of the normal stress differences under shear flow [2-4]. There are multiple parameters that influence the magnitude of climb and can be enumerated as the properties of the fluid properties like surface tension, viscosity, experimental variables (angular velocity) and geometrical parameters (rod radius, extent of rod immersion in fluid) [5]. However, the effect of altering the interfacial condition (rod-fluid interface) on the climbing is still unexplored. In this article, we alter the interfacial condition by introducing an oil layer at the rod-fluid interface and outline its effect on the maximum free surface deformation, h of the fluid as a response to the applied angular velocity ω.

Aqueous polymeric suspensions of polyethylene oxide (PEO, viscosity average molecular weight ~ 5×10^6, *Sigma Aldrich*) are employed as a model fluid in the present study and subjected to rotating rods dipped in castor/silicone oils. The polymer concentration is varied as $c_{0.5}, c_1$ where represent the 0.5 and 1 are the polymer weight percentage (w/w) resp. in the suspension. Effect of such 'slippery-rods' on the occurrence of the Weissenberg effect are outlined as a function of two parameters, (i) polymer weight concentration in the fluid, c and (ii) varying angular rotation speed, ω. It is surprisingly found that the polymeric fluid not only exhibits the rod-climbing in presence of oily rods but can also show rod-dipping for $c_{0.5} + castor\ oil$!

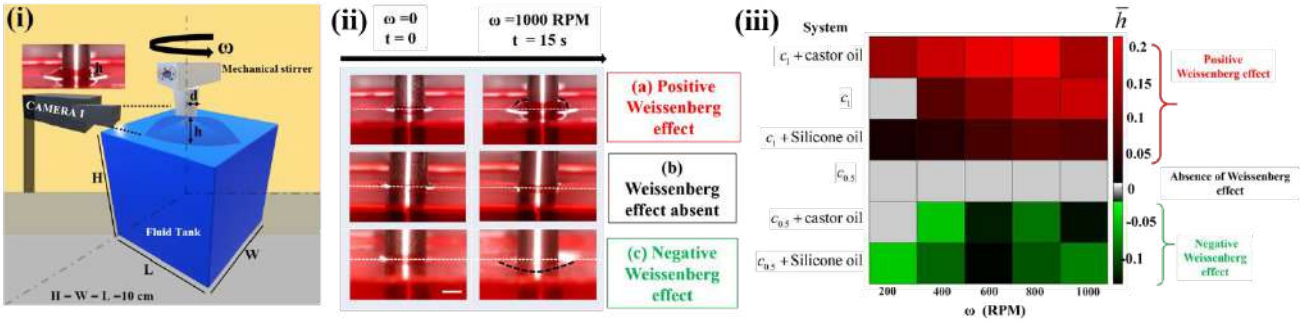

Figure 1. (i) Schematic of the experimental setup, h is the height of rod climbed/dipped by the fluid on a rod of diameter, d (= 1 cm) (ii) Image sequence demarcating the three states of (a) classical rod-climbing/ positive Weissenberg effect shown by aqueous suspension of 1% (w/w) of polyethylene oxide (c_1) (b) absence of Weissenberg effect shown by aqueous suspension of 0.5% (w/w) of polyethylene oxide ($c_{0.5}$) (c) dipping of the meniscus or the negative Weissenberg effect shown by ($c_{0.5}$ + castor oil). All the three regimes are shown for $\omega = 1000$ RPM. Scale bar: rod diameter, d = 1 cm (iii) Heat map display demarcating the observed regimes based on the absence/occurrence of Weissenberg effect (positive and negative) in presence of oil coated (slippery) rod surface as a function of rod rotation rate, ω and polymer concentration ($c_{0.5}, c_1$). The maximum deformation, $\bar{h} = h/d$ of the fluid meniscus (climbing or dipping) is used as the characterizing parameter in the heat map display.

The experimental setup comprises of a cuboid acrylic tank of dimensions (H =W= L = 10 cm) as shown in Figure 1(i), placed symmetrically with respect to an overhead stirrer. A digital camera (Camera I) was aligned with the stirrer axis to track the interfacial profile at 50 fps (front view). Polymeric fluid in the tank (fluid level ~ 4 cm) in the tank, rod immersion depth ~ 3.5 cm was kept constant) was dyed with Phenol red (*Sigma Aldrich*) and the maximum free surface deformation, h of the fluid is quantified via image analysis (*ImageJ v:1.52a*). It is non-dimensionalized ($\bar{h} = h/d$) by the rod diameter, d to classify the three regimes (positive, absence, negative Weissenberg effects) of polymeric response observed in the experiments. Figure 1(ii) shows these regimes for an applied angular velocity $\omega = 1000$ RPM.

*

RESULTS AND DISCUSSIONS

A heat map (Figure 1(iii)) is constructed to classify the systems into these three states based on the maximum free surface deformation, $\bar{h}$ over the range of the applied angular velocity ω provided by the overhead stirrer, ramped externally from 200 to 1000 RPM in increments of 200 RPM. The first regime of classical rod-climbing can be observed for c_1 for $\omega \geq 400$ till $\omega = 1000$ RPM. It is expected intuitively that an oil layer will promote slip allowing the polymer molecules to slip over the rod which in turn acts as a hindrance to the upward climb of the fluid. However, we found that the polymeric fluid continued to exhibit rod-climbing even for an oily-rod for c_1. Also, a decrease in the rod-climbing angular velocity from $\omega = 400$ RPM for a bare rod to $\omega = 200$ RPM is observed for an oily rod. The influenced the magnitude of climb, $\bar{h}$ is found to be dependent on the type of the oil layer. Specifically, castor oil enhanced the magnitude of climb, for e.g., at $\omega = 800$ RPM, it increased from ~ 0.1 to ~ 0.2. Silicone oil had an opposite influence on the rod-climbing magnitude, it decreased the climbing height e.g., at $\omega = 800$ RPM from ~ 0.1 to ~ 0.05. The second regime is the control state which is the absence of either rod-climbing /rod-dipping observed uniformly for $c_{0.5}$ for the entire range of ω and for c_1 at $\omega = 200$ RPM. This control state remains unaltered on introduction of oily-rod for $c_{0.5}$ only at the lowest operational velocity, $\omega = 200$ RPM for castor oil. At the rest of the operational velocities, an oily-rod with either of the oils (Silicone and castor) changes the control state to third regime of rod-dipping in $c_{0.5}$ systems! The trend in the magnitude of dip for a specific angular rotation speed can be stated as, $\left|\bar{h}_{(c_{0.5}+silicone\ oil)}\right| > \left|\bar{h}_{(c_{0.5}+castor\ oil)}\right|$ except for the highest operational speed, $\omega = 1000$ RPM. To summarize the effect of oily-rod for the range of operating velocities, $\omega = 200$ to $\omega = 800$ RPM, castor oil assists in maintaining the existing state of rod-climbing in c_1 system and also increases the magnitude of climb whereas in $c_{0.5}$ system, it changes the fluid response from absence of Weissenberg to rod-dipping or Negative Weissenberg state. Therefore, alteration in the interfacial condition affects the free-surface response in terms of its directionality i.e. rod-climbing, rod-dipping, control as well as the magnitude of the response, $\bar{h}$.

CONCLUSIONS

Weissenberg effect in the presence of an oil-dipped rod is investigated and the interfacial dynamics is represented by a heat map. This heat map demarcates three states of positive (rod-climbing), negative (rod-dipping) and absence of Weissenberg effect on the basis of polymer concentration and applied shear rates (rod rotational velocity). Thus, the alteration of the interfacial condition by introduction of an oily rod affects the rod climbing phenomenon in terms of the magnitude of the response.

LOCAL NORMAL STRESSES MEASUREMENT IN NON-NEWTONIAN FLUIDS

Anaïs Gauthier*[1], Michaël Pruvost[1], Olivier Gamache[1] and Annie Colin [1]
[1]MIE,Chemistry,Biology and Innovation Laboratory (CBI) UMR8231,ESPCI Paris,CNRS,PSLR esearch University, 10 rue Vauquelin, Paris,France

Summary We present a new experimental approach to obtain a local measurement of normal stresses in non-Newtonian fluids. We use a 4x4 cm^2 array of 25 highly sensitive sensors (with a precision of 5 Pa) that we built and integrated to the bottom plate of a rheometer. We use this system to characterize the flow of a shear-thickening liquid: a non-Brownian suspension of cornstarch particles. We demonstrate that the flow becomes heterogeneous in the discontinuous shear thickening region. Intriguingly, the sensors evidence the presence of a single, stable object rotating with the surrounding fluid. We characterise in detail this heterogeneity: we show how its shape and its relative velocity varies with the solid fraction of the suspension, the gap height and the nature of the particles. We finally discuss its origin.

INTRODUCTION

The flow of complex fluids is often associated with highly non-linear phenomena, such as the development of normal stresses, with dramatic effects. Polymer suspensions, for example climb along spinning rods (the well-known Weissenberg effect), which is a consequence of the elasticity of the polymer chains. Another example is the growth of normal stresses in shear-thickening suspensions, which is an important industrial issue: strong and local normal stresses can break mixers or blenders. The characterisation of these complex flows is greatly improved by local measurements, which can be used to measure the pressure profile in the geometry [1], or to detect heterogeneities [2]. Here, we develop a new capacitive sensor, inspired from "soft electronics" and adapt it to a rheology geometry to measure the local normal stresses. The sensors are sensitive to the pressure $P = -\sigma_{zz}$, with σ_{zz} the zz component of the stress deviator tensor. Pressures as small as 5 Pa can be detected, so that a precise 2D mapping of the normal stress can be established. We use this system to characterize the flow of a shear-thickening liquid: a cornstarch suspension, at high solid fraction ϕ.

MATERIALS AND METHODS

The core of the sensor is a piezo-capacitive soft solid foam, filled with carbon black particles [3]. The dielectric material is placed between two electrodes: a soft one, at the top and a solid electrode network, at the bottom. When a pressure P is applied on the sensor, the foam slightly bends and compresses, which increases its capacitance C. We measure C by applying a low-voltage AC current (1V, 1000 Hz) between the top electrode and one of the bottom electrodes. As presented in Figure 1a, 25 of these sensors are built into a 4x4 cm^2 matrix (figure 1b), which replaces the bottom plate of a torsional rheometer. The blue disk on Figure 1b indicates the size and position of the upper plate (with diameter 4 cm). In a typical experiment, the suspension is sheared between two parallel plates separated by a distance h = 1 mm. Using the sensor array, we record the normal stress measured by each of the 12 sensors covered by the fluid. The suspension considered here consists of a large volume fraction of solid particles of cornstarch (here, 40% in weight) in an isodensity salt of CsCl in water. This suspension exhibits a discontinuous shear thickening, for applied shear stress $\sigma > 20$ Pa. In each experiment, we apply a series of step-like shear stresses σ of increasing values and record the pressure measured by each sensor. In the following, we focus on two points placed diagonally in the geometry, as indicated in Figure 1b, in red and blue.

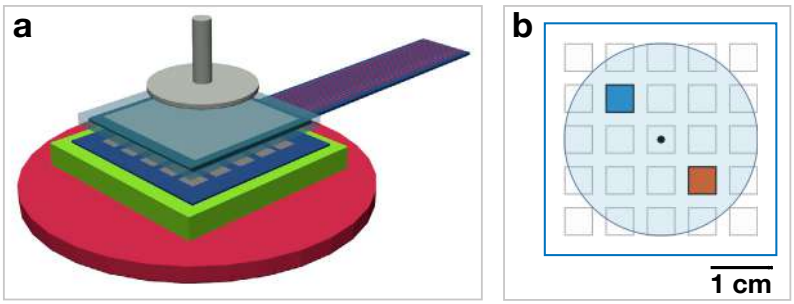

Figure 1. **a.** Schematic of a capacitive pressure sensor. It consists of two layer: the top one is a soft solid polymeric foam filled with conductive carbon black particles, and covered with a soft electrode. At the bottom, an electrode network of 25 measurement points, with size 4x4 mm^2. The sensor is placed on the bottom plate of the rheometer (in red), in a parallel plate configuration. **b.** Array of 25 sensors: the circle in blue shows the position and size of the upper disk, with a diameter of 4 cm. The two measurement points (used in Figure 2) are shown in red and blue.

RESULTS

Figure 2a shows the viscosity η of a 40% (in weight) cornstarch suspension for increasing shear stresses $\dot{\gamma}$: this system is shear-thinning at low shear rates ($\dot{\gamma} < 5$ s^{-1}) and strongly shear thickening above at critical shear rate $\dot{\gamma}_c = 40$ s^{-1}, with a viscosity η increasing by more than one order of magnitude. As reported earlier [4], the shear thickening is associated with a strong increase of the mean normal stress, associated with very large fluctuations. For the first time, our sensor arrays give access to the local normal stresses associated with these fluctuations. We use here two sensors, placed at opposite directions below the rotating plate (see Figure 1b, in red and blue), and record the pressure at a high frequency of 100 Hz. We present in Figure 2b and c the sensors measurement during steps of constant shear stress σ, either before the discontinuous shear thickening region (Figure 2b, for $\sigma = 1$ and 16 Pa) or in the discontinuous shear thickening region (Figure 2c, $\sigma = 125$ Pa).

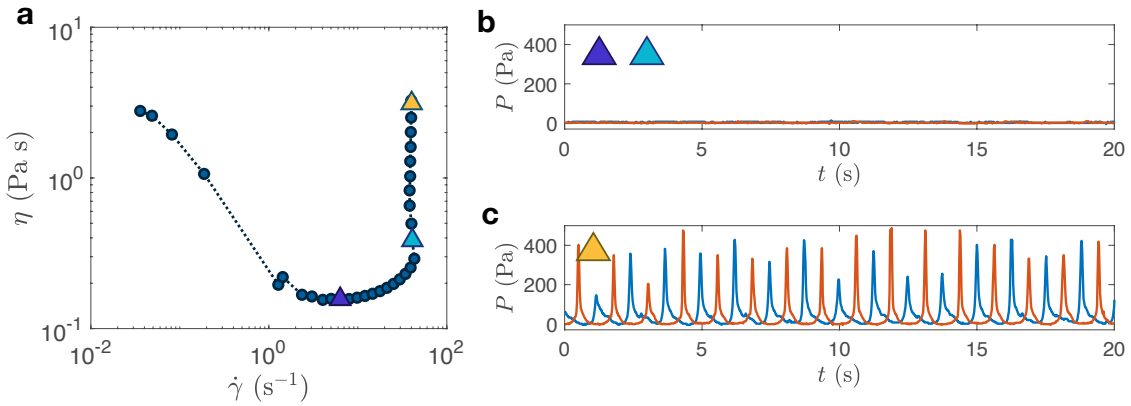

Figure 2. **a.** Viscosity η of a 40% cornstarch suspension as a function of the shear rate $\dot{\gamma}$. The triangles indicate the points in the plot where the pressure is recorded by the sensors. **b-c**. Pressure measurement of the sensors as a function of time, for varying imposed constant stresses σ. Two 4x4 mm^2 sensors (red and blue lines) are placed in opposite directions on a diagonal (as shown in Figure 1b). **b**: σ = 16 Pa and **c**: σ = 125 Pa.

Below the discontinuous shear-thickening region, the pressure is constant, close to zero and identical for both sensors (figure 2b). However, as soon as the discontinuous shear thickening region is reached, normal stress oscillations become visible, as presented in Figure 2c. Very interestingly, the pressure fluctuations are extremely regular: the red and blue signals exhibit perfectly out of phase peaks, of similar amplitude. This indicates the presence of one large structure, rotating here at a velocity $\Omega_a \approx 5$ rad/s, which is 60% faster than the angular velocity of the geometry. Our experiments show that this signal is extremely stable, and that its relative velocity (with respect to the geometry) does not depend on the imposed stress. However, the peak pressure P_{max} does increase with σ, from $P_{max} \approx 10$ Pa for $\sigma = 50$ Pa to $P_{max} \approx 400$ Pa for $\sigma = 125$ Pa (Figure 2c). This unique structure is observed in every experiment we performed. It also appears when varying the solid fraction ϕ of the suspension (from 37% to 42%) as long as the system undergoes discontinuous shear thickening. Its size (measured by the width of the signal) and velocity, however, do vary with ϕ, which might indicate a different nature or origin.

CONCLUSION

The sensor array that we present here is a new tool that brings a new insight into heterogeneous flows. It gives access to the local value of σ_{zz}, an important parameter that is much less studied than the shear components of the stress tensor. We use here the sensors to characterize the flow of a cornstarch suspension, a popular shear thickening system. We evidence for the first time a unique normal stress front propagating within the flow, in the discontinuous shear thickening regime. Its exact nature and origin (is it an aggregate with a larger density, a stress front propagating within the flow?), and their stability are still to be understood. It would also be interesting to see if such objects are specific of cornstarch suspensions or if they can also be detected in other non-brownian, shear-thickening systems.

FLOW AND STABILITY OF A VISCOELASTIC LIQUID CURTAIN

Antoine Gaillard*[1,2], Matthieu Roché [1], Sandra Lerouge[1], Cyprien Gay[1], and Laurent Limat[1]
[1]Universitéde Paris,Laboratoire MSC-CNRSUMR 7057,Paris,France
[2]MCND and Department of Physics & Astronomy, University of Manchester, UK

Summary Liquid curtains are sheets of liquid falling freely from an extrusion die. We investigate the flow of curtains made of polymer solutions and we show that gravity is initially balanced by the elastic stress arising from the stretching of polymer chains, after which the classical free-fall behaviour is recovered. We show how this is analogue to Newtonian curtains in which gravity is initially balanced by viscous dissipation. We also describe a varicose modulation of the sheet observed for the most shear-thinning solutions, which is linked to a unsteady three-dimensional flow instability at the planar contraction in the extrusion die.

INTRODUCTION

Liquid curtains are used in industry for precision coating of surfaces. This curtain coating technique consists in forming a liquid sheet by extruding a liquid from a slot, and let it impact on a substrate moving underneath. This free-surface extensional flow has been investigated in the case of Newtonian liquids [1]. The evolution of the liquid velocity U with the distance z from the slot outlet is given by the force balance equation

$$U\frac{\mathrm{d}U}{\mathrm{d}z} = g + \frac{4\eta U}{\rho}\frac{\mathrm{d}}{\mathrm{d}z}\left(\frac{1}{U}\frac{\mathrm{d}U}{\mathrm{d}z}\right) \tag{1}$$

where g is the gravitational acceleration and ρ and η are the liquid density and dynamic viscosity respectively. Viscosity affects the flow over a characteristic distance $z_v = ((4\eta/\rho)^2/g)^{1/3}$ from the slot outlet. Within this distance, the liquid acceleration is less than g. More precisely, for extrusion velocities $U_0 \ll \sqrt{gz_v}$, the flow close to the slot ($z \ll z_v$) is a balance between gravitational acceleration and viscous dissipation where $U \propto \rho g z^2/8\eta$ and the flow far from the slot ($z \gg z_v$) is a free-fall where inertia dominates over viscosity, i.e. $U \propto \sqrt{2gz}$.

In most Newtonian industrial curtains, $z_v \ll L_c$ due to low liquid viscosity where L_c is the distance over which the liquid falls before impacting the substrate. The flow can then be approximated by a free fall $U^2 = U_0^2 + 2gz$. Since most industrial coating liquids are non-Newtonian, a natural question is whether or not z_v is still the relevant length scale of the transition to free-fall. The case of viscoelastic liquids is of particular importance. Recent experimental works have been dedicated to the study of curtains made of polymer solutions, but they mainly consider the effect of viscoelasticity on the stability of the sheet without fully exploring its effect on the liquid velocity field [2].

In this work, investigate the effect of viscoelasticity on the flow and stability of curtains made of polymer solutions.

EXPERIMENT

We use aqueous solutions of polyethylene oxide (PEO) of varying polymer concentration. We also use solutions of partially hydrolysed polyacrylamide (HPAM) in salted water of varying salt concentration to tune the flexibility of the polymer chains. The liquid is extruded at constant flow rate Q from a die sketched in figure 1 (a) where the flow undergoes a planar contraction of ratio 14 before entering a slot of thickness $2a = 1$ mm. The liquid then forms a rectangular curtain falling vertically in ambient air over a distance $L_c > 15$ cm before impacting a motionless horizontal solid substrate. The liquid velocity in the curtain is measured by particle image velocimetry.

Liquid shear viscosity is measured by a shear rheometer equipped with a cone-plate geometry and the experimental data is fitted by a Carreau law of the form $\eta = \eta_0(1 + (\dot\gamma/\dot\gamma_c)^{a_1})^{(n-1)/a_1}$ where η_0 is the zero-shear viscosity and n represents the degree of shear-thinning. Our solutions range between Boger-like liquids with $n = 1$ (dilute PEO solutions) to strongly shear-thinning solutions with $n = 0.2$ (HPAM solution in unsalted water). Extensional rheology measurements are performed using a Capillary Breakup Extensional Rheometer (CaBER) which is a filament thinning technique allowing the measurement of the polymer relaxation time τ_{fil} relevant in strong extensional flows [3].

RESULTS

Curtain flow

Like in Newtonian curtains, we observe that the liquid acceleration is initially less that g close to the slot, and finally reaches the classical free-fall regime of constant acceleration g beyond some characteristic distance from the slot outlet, provided that the sheet is long enough and doesn't impact the substrate before reaching this regime. This characteristic length z_e is however much larger than the Newtonian viscous length $z_v = ((4\eta_0/\rho)^2/g)^{1/3}$ based on the zero-shear viscosity η_0 of the liquid. Among all rheological parameters, we show that the flow is mostly influenced by the value of the extensional relaxation time τ_{fil} of the polymers.

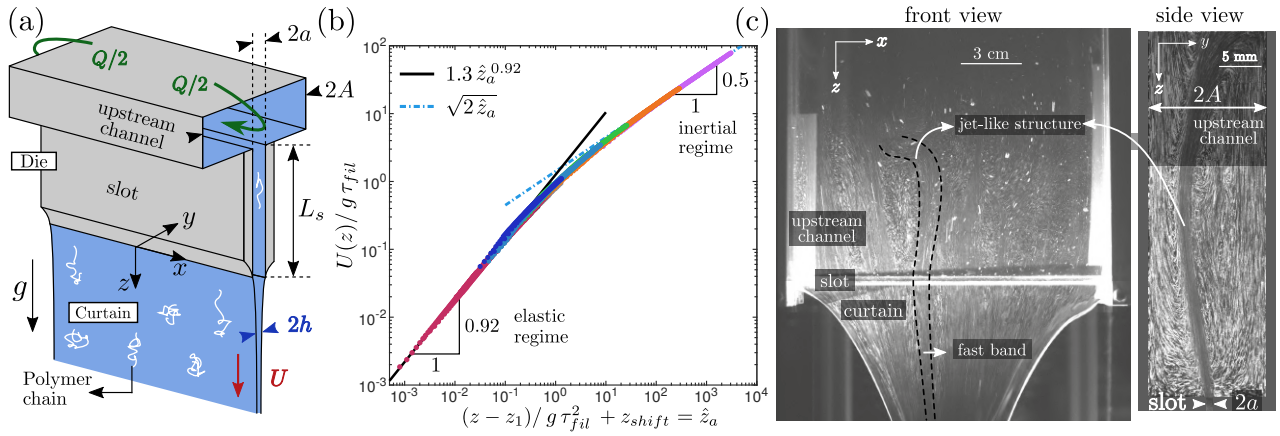

Figure 1: (a) Schematic of the slot die. (b) Master curve for the flow of viscoelastic curtains, showing an initial elastic regime followed by an inertial free-fall regime. Velocity profiles $U(z)$ (where z is the distance from the slot outlet) are scaled by length and velocity scales $g\tau_{fil}^2$ and $g\tau_{fil}$, where τ_{fil} is the polymer extensional relaxation time, and translated along the x-axis by a quantity z_{shift} linked to the dimensionless extrusion velocity. (c) Front and side views of the unsteady and three-dimensional instability observed in the die for a solution of HPAM in unsalted water. "Jet-like" portions of fluid move faster than their surrounding, leading to a modulation of the curtain thickness and velocity field downstream. Note that the transparent die used in (c) is not the one sketched in (a) and that for lighting purposes, the curtain in (c) is exceptionally not guided by the edge wires normally used to get a rectangular sheet.

As displayed in figure 1 (b), all experimental velocity profiles $U(z)$ collapse on a single master curve when using $z_e = g\tau_{fil}^2$ and $\sqrt{gz_e}$ as characteristic length and velocity scales of the problem. This scaling can be explained by simple physical arguments. A polymer molecule following a free-fall trajectory $U \propto \sqrt{2gz}$ is in a spatially decreasing strain-rate field $\dot{\epsilon} = \mathrm{d}U/\mathrm{d}z \propto \sqrt{g/2z}$. Polymer chains are expected to exhibit large stresses for $\dot{\epsilon}\tau_{fil} > 1/2$ which corresponds to the coil-stretch transition value [4]. This translates into $z < z_e = g\tau_{fil}^2$ (without prefactor). Hence, for extrusion velocities $U_0 \ll \sqrt{gz_e}$, the flow is characterised by an initial elastic regime where gravity is balanced by the elastic stresses arising from the stretching and unravelling of polymer molecules. As shown in figure 1 (b), the flow in this regime is close to a linear velocity field where $U \propto z/\tau_{fil}$ with a prefactor close to 1, which gives $\dot{\epsilon}\tau_{fil} = O(1)$. These results are fairly well predicted by a simple model using the Oldroyd-B constitutive equation for polymer molecules. See [5, 6] for details.

Curtain stability

We show that polymer addition enhances the stability of the curtain by reducing the minimum flow rate required to maintain a continuous sheet. However, our results suggest no significant influence of viscoelasticity on the dynamics of sheet retraction after being punctured. Indeed, a continuous sheet forms when the extrusion velocity exceeds the classical Taylor-Culick velocity $\sqrt{\gamma/\rho h}$ where γ is the surface tension and h is half the sheet thickness [7].

We also report a flow instability characterised by an unsteady and horizontally modulated curtain, both in thickness and velocity [6]. This varicose instability is only observed for the most shear thinning solutions with typically $n < 0.7$. Visualisation of the flow inside the die reveals that this phenomenon is linked to a flow instability at the contraction plane upstream of the slot where the flow is unsteady and three-dimensional. Figure 1 (c) shows the typically observed "jet-like" structures formed in the die where the liquid is faster than its surrounding. This leads to an non-uniform feeding of the slot and therefore to a horizontal modulation of the curtain downstream.

CONCLUSIONS

The flow of viscoelastic liquid curtains is characterised by an initial balance between gravity and the elastic stresses arising from the stretching of polymer molecules, followed by the classical free-fall behaviour with constant acceleration g. The characteristic transition length between these two regimes is $g\tau_{fil}^2$ where τ_{fil} is the polymer extensional relaxation time measured by a filament thinning technique. Polymer addition has a stabilising effect on the sheet, unless the solution is too shear-thinning as it may trigger a flow instability in the extrusion die, leading to non-uniform curtains.

EFFECT OF BLOOD THIXOTROPY AND VISCOELASTICITY ON THE HEMODYNAMICS IN LARGE VESSELS: ADVANCED HEMORHEOLOGICAL MODELLING AND SIMULATION

Konstantinos Giannokostas[1], Pantelis Moschopoulos[1], Yannis Dimakopoulos[*1], Andreas Anayiotos[2] and John Tsamopoulos[1]

Summary Blood exhibits pronounced non-Newtonian behaviour that comes from the proteinic and lipidic structure of the red blood cell (RBC) membrane along with its interaction with the ionic environment of the blood plasma and the shear-rate dependent bridging of neighboring cells. Thus, RBCs can deform and consequently store elastic energy, and also, they can form aggregates that break in quite high shear-rates. The current work deals with the advanced constitutive modelling of human blood samples using the mesoscopic theory proposed by Varchanis et al. (2019) for thixo-elasto-visco-plastic complex materials. The proposed model provides accurate calculations of the yield stress, the shear module, the relaxation time, the dependence of the rouleaux aggregation and the disaggregation rates on the hemodynamic environment as well as realistic predictions of the blood response under different non-linear rheometric protocols (e.g., LAOS, Triangular Ramp experiments). Finally, we apply the model in multidimensional flows where the effect of viscoelasticity and thixotropy is critical due to the development of normal stresses that affect the configuration of the tissue layers or the local viscosity (e.g., flow in a saccular aneurysm).

INTRODUCTION

Human blood is a suspension in plasma of formed elements, mainly erythrocytes, that exhibits plasticity, elasticity, shear-thinning, and thixotropic behaviors[1,2]. Thus, it can be classified as a thixo-elasto-visco-plastic (TEVP) material. Complications in its flow are more pronounced when the size of the vessel, wherein blood flows, is comparable to the radius of a Red Blood Cell (e.g., microvessels and aneurysms). Also, the non-Newtonian effects arise in rheometric flows even under steady or transient conditions, and they are responsible for the development of structural and kinematic instabilities that cannot be represented by previous hemorheological models[3,4,5]. Specifically, for low shear-rates, blood kinematic can never reach a steady-state, and experimental measurements depend strongly on the initial configuration of the blood sample[6,7]. Moreover, under steady flow conditions, there is a non-linear relationship between stresses and velocity-gradient, dependence of the viscosity on the shear rate, existence of a finite yield stress value, and development of slip phenomena due to the formation of plasma layer[8]. Also, under transient flow conditions (e.g., startup shear flow), there is a lag shear-stress and velocity gradient, formation of stress-overshoot in sudden start-up, and hysteretic responses. In the present work, we test previous hemorheological models[3,4,5], which can selectively represent some of the mechanisms mentioned above, and employ our recently proposed macroscopic model for TEVP materials[9], which fits non-linear hemorheological data perfectly. After the successful rheological characterization of various samples of human blood from different donors, we perform flow simulations in large vessels where the effect of thixotropy and viscoelasticity play significant roles (e.g., hemodynamics in and around terminal aneurysm).

MODEL and RESULTS

The TEVP model[9] is an extension of the Elasto-Viscoplastic Model by Saramito[10], accounting for the transient response of the microstructure (e.g., individual RBCs and rouleaux) according to the principles introduced by Dimitriou and Mckinley[11], We et al.[12] and Armstrong et al.[13]. In particular, our model couples the tensorial constitutive model by Saramito for EVP materials with thixotropy, extending the ideas of Isotropic Hardening (IH), and with Kinematic Hardening (KH). We also adopt a scalar variable that describes the level of structure at any instance and a modified Armstrong-Frederick KH equation, thus providing rules governing the dynamics of the apparent yield stress. The material viscosity, yield stress, and back stress modulus feature a nonlinear dependence on the structural parameter, enabling the model to make accurate predictions with a single structural parameter.
We apply the constitutive model in the rheometric data of all donors presented in Ref. [1]. In all cases, the model provided very realistic predictions of basic hemorheological parameters. Indicatively, the basic properties for Donor 1 are: shear model G = 0.597 Pa, viscosity η_p=0.084 Pa s, and yield stress τ_y=0.004 Pa. The predictions of the TEVP model against the experimental data under steady and transient conditions are shown in Figures 1 (a) & (b), respectively. Apart from the excellent capability of the model on reproducing the data, it can also provide an accurate prediction of the transient response of blood under homogenous rheometric conditions. Figure 1(c) depicts the variation of the shear stress in a sequence of shear-rate pulses. The initial response before the overshoot corresponds to the reorganization of the rouleaux, while the overshoot represents the maximum stress value before the breaking up of the rouleaux, while the plateau represents an equilibrium state where RBCs are isolated particles. The cessation of the flow at t=2.5 s causes the gradual formation of new three-dimensional structures. The latter is a long-lasting process causing the reduction of the maximum stress when a second shear pulse is applied at t =5.0 s.

(a) (b) (c)

Figure 1. The TEVP model ([9]) can accurately capture the rheometric data for all Donors in Ref. [1]. (a) & (b) depict the predictions of the model (solid lines) and experimental measurements (hollow symbols) of Donor 1 at steady-state conditions and in time-dependent triangular ramp, respectively. (c) depicts the thixotropic response of blood sample of Donor 1 in a sequence of shear-rate pulses ($\dot{\gamma} = 14.1\ s^{-1}\big(H(t) - H(t-2.5s)\big) + 14.1s^{-1}(H(t-4.5s) - H(t-7.5s))$.

Also, we apply the model in flow domains (e.g., saccular aneurysm) where the structural dynamics and the distribution of the rouleaux vary significantly (e.g., inside and outside the aneurysm). In particular, Figure 2 shows snapshots of the velocity and the Wall-Shear-Stress fields in the cardiac circle under physiological flow conditions. The results are mesh-size independent and they are based on the hemorheological properties of Donor 1 in Ref. [1].

EXPERIMENTAL STUDY OF ROLL WAVES IN MUD

Simon Dagois-Bohy*[1],Djibrilla Noma[1],Séverine Millet[1],Valéry Botton[1],Daniel Henry[1],and Hamda Ben Hadid[1]
[1]Laboratoire de Mécanique des Fluides et d'Acoustique,CNRS,UMR 5509,Université Claude Bernard Lyonl,Ecole Centrale de Lyon,INSA Lyon, 43 boulevard du 11 novembre1 918,F-69100,VILLEURBANNE, France

Summary We study experimentally the stability of a film of a viscoplastic fluid down an incline. We set up a model experiment to measure the primary instability of these roll waves : in an inclined channel ($5° - 15°$ slope angle), we established a permanent flow of viscoplastic fluid. By perturbing the inlet flow rate, we generated surface waves at a controlled frequency, and we observed their evolution downstream with direct thickness measurement. Growth rates and wave numbers were calculated, and neutral frequencies were determined, from which a critical Reynolds number was extracted. We found this experimental Reynolds number to be in good agreement with existing theoretical work, provided that the Bingham number is carefully calculated.

Introduction

Viscoplastic fluids are characterized by a yield stress, under which no flow can occur. They usually also exhibit shear-thinning properties. In many engineering applications (coating processes in paint, paper, food, plastic, etc. industries) or geophysical phenomena (glaciers, mud and debris flows), the liquids involved present this viscoplastic behavior. In particular, during mud or debris flows, the surface can destabilize and develop into roll waves, that should be taken into account in any risk assessment study. In this study, we focus on the primary stability of viscoplastic fluids that follow the Herschel-Bulkley law $\sigma = \sigma_y + k\dot{\gamma}^n$, with σ the total shear stress, $\dot{\gamma}$ the shear rate, σ_y the yield stress, k the constistency, and n the rheological index. Such surface waves, also called Kapitsa waves, are well known when the fluid is Newtonian. It is known since the pioneering work of Benjamin (1957) and Yih (1963) that the critical Reynolds number, under which the waves are always stable, is given by $Re_c = \frac{5}{6}\cot\phi$, with ϕ the slope angle. This result has been later confirmed experimentally by Liu and Gollub (1990). To our knowledge, no experimental work on the stability of Herschel-Bulkley fluids has been performed yet, there is only the theoretical study of Balmforth and Liu in 2004. They proposed a linear stability analysis, at the order 0 in the thickness parameter, and they found a critical Reynolds number that depends solely on B, the Bingham number, and n, the fluid power index.

Experiment setup

The experiments were carried out in an inclined channel of length 2 m and width 0.5 m, in which a flowing film of carbopol 980 was perturbed at the inlet, and waves recorded further downstream, as presented figure 1-a). In each experiment, we imposed the frequency f, the flow rate q and the angle ϕ. The perturbation was recorded by measuring the local thickness with a laser position sensor at various positions along the flow direction. A careful Fourier analysis allowed us to extract both the wave number k and attenuation factor α. The rheological properties of the fluid were measured with a cone-plate rheometer several times during the experiments, and found constant over the relevant time scales (1 day).

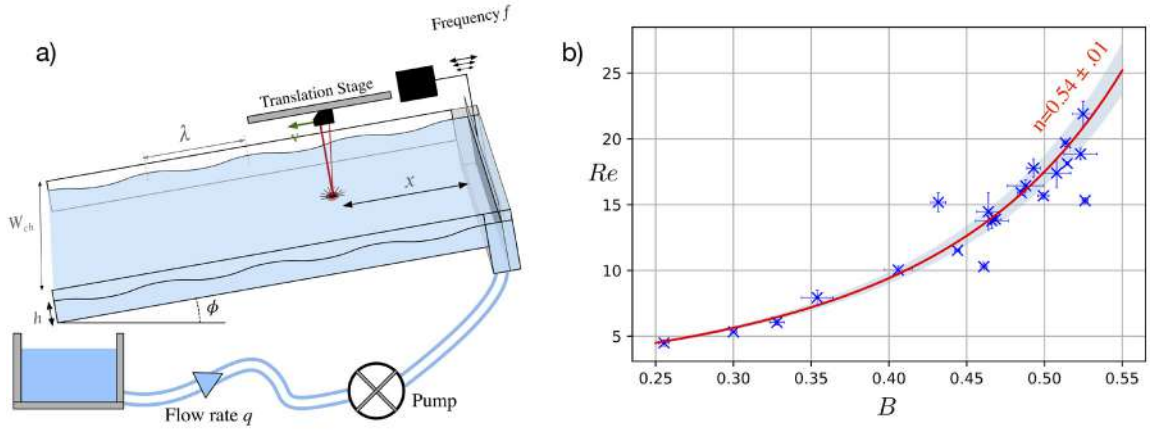

Figure 1: a) scheme of the experimental setup. b) Critical Reynolds number vs Bingham number. Blue crosses : experimental points. Red line : theory by Balmforth and Liu for $n = 0.54$.

*Corresponding author. E-mail: simon.dagois-bohy@univ-lyon1.fr.

Results

By varying the frequency at constant flow rate and angle, we determined the neutral frequency for a given flow rate (i.e. the frequency for which waves are neither amplified nor damped). By repeating these measurements for different flow rates, we were able to determine a critical Reynolds number Re_c and Bingham number B_c, for which this neutral frequency drops to zero. When $Re < Re_c$ or when $B > B_c$, the film is always stable. Finally, we repeated this analysis at different angles and for different concentration of carbopol, in order to measure different couples of (Re_c, B_c). In figure 1-b), we present our measurements together with the prediction of Balmforth and Liu for $n = 0.54$, showing a very good agreement between the two.

ANISOTROPIC EFFECTIVE VISCOSITY OF SHORT-FIBER SUSPENSIONS

Róbert Bertóti*[1], Daniel Wicht[1], Matti Schneider[1], and Thomas Böhlke[1]
[1]Chair for Continuum Mechanics, Institute of Engineering Mechanics, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

Summary For mold filling simulations of short-fiber suspensions, it is efficient to model the fiber-matrix mixture as a homogenized fluid with effective tensorial viscosity which can be anisotropic. Mean-field homogenization theories, based on different assumptions, can be used to predict the anisotropy of the effective viscosity depending on the microstructure parameters: matrix shear viscosity, fiber length to diameter aspect ratio, fiber volume content and fiber orientation distribution. But as far as the authors know, there are no real experiments – because of complexity – which could be used to evaluate the predicted anisotropy of these theories. For this reason numerical experiments, i.e. full-field simulations are performed. The numerical results are used to evaluate and improve the analytical predictions of a mean-field homogenization theory.

ANISOTROPIC EFFECTIVE VISCOSITY

For mold filling simulations of incompressible fiber suspensions the effective, deviatoric Cauchy-stress $\bar{\boldsymbol{\sigma}}'$ is assumed to be the linear mapping of the effective viscosity tensor $\bar{\mathbb{V}}$ and the deviatoric strain rate tensor $\bar{\boldsymbol{D}}'$, noted in tensor and in index notation as

$$\bar{\boldsymbol{\sigma}}' = \bar{\mathbb{V}}[\bar{\boldsymbol{D}}'], \qquad \bar{\sigma}'_{ij} = \bar{V}_{ijkl}\bar{D}'_{kl}, \tag{1}$$

respectively. The effective viscosity tensor $\bar{\mathbb{V}}$ can be parameterized with the help of four variables [1], namely the effective scalar viscosity $\bar{\eta}$, the shear number $\bar{N}_\mathrm{s}$, the particle number $\bar{N}_\mathrm{p}$ and the fourth-order fiber orientation tensor $\bar{\mathbb{N}}$ as

$$\bar{\mathbb{V}}(\bar{\eta}, \bar{N}_\mathrm{s}, \bar{N}_\mathrm{p}, \bar{\mathbb{N}}) = \mathbb{P}_2 \left(2\bar{\eta}\left(\mathbb{P}_2 + \bar{N}_\mathrm{s}\left(\bar{\boldsymbol{N}}\square\mathbf{1} + \mathbf{1}\square\bar{\boldsymbol{N}}\right) + \bar{N}_\mathrm{p}\bar{\mathbb{N}}\right)\right)\mathbb{P}_2, \tag{2}$$

where $\mathbb{P}_2$ is the deviatoric identity tensor of fourth order, $\bar{\boldsymbol{N}} = \bar{\mathbb{N}}[\mathbf{1}]$ is the second-order fiber orientation tensor, $\mathbf{1}$ is the second-order identity tensor and the boxproduct $\square$ is defined by $(\boldsymbol{A}\square\boldsymbol{B})[\boldsymbol{C}] \mathrel{\widehat{=}} A_{ij}C_{jk}B_{kl}$. The viscosity parameters $\bar{\eta}$, $\bar{N}_\mathrm{s}$ and $\bar{N}_\mathrm{p}$ depend on the microstucture of the suspension, i.e. on the matrix viscosity η_m, on the fiber volume fraction $\bar{c}_\mathrm{f}$ and on the fiber aspect ratio l/d, where l denotes the fiber length and d the fiber diameter.

MEAN-FIELD HOMOGENIZATION

Let $\bar{\mathbb{V}}^\mathrm{mf}$ note the viscosity tensor determined by mean-field homogenization [2]. The directional dependency of the effective elongational viscosity $\bar{\eta}_\mathrm{el}$ and of the effective shear viscosity $\bar{\eta}_\mathrm{sh}$ qualifies and quantifies the anisotropy of $\bar{\mathbb{V}}^\mathrm{mf}$. The dimensionless $\bar{\eta}_\mathrm{el}/\eta_\mathrm{m}$ and $\bar{\eta}_\mathrm{sh}/\eta_\mathrm{m}$ are depicted in Fig. 1, considering horizontally aligned short-fibers in the suspension.

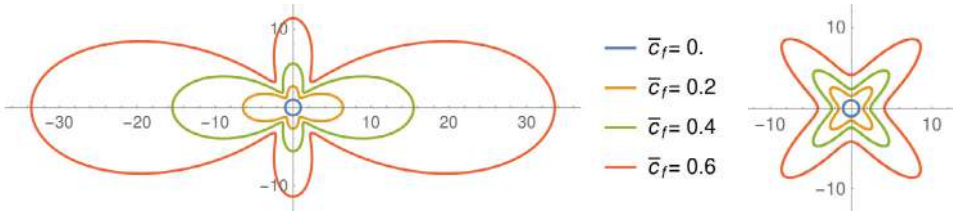

Figure 1: The directional dependency of the effective elongational viscosity $\bar{\eta}_\mathrm{el}$ (left) and of the effective shear viscosity $\bar{\eta}_\mathrm{sh}$ (right) relative to η_m, considering horizontally aligned short-fibers in the suspension, for $l/d = 10$ and different $\bar{c}_\mathrm{f}$ fiber volume fractions. The polar angel corresponds to the direction and the radius to the value.

FULL-FIELD HOMOGENIZATION

To involve more information about the microstrocture in $\bar{\mathbb{V}}$, it is also determined through numerical full-field homogenization based on [3]. With the full-field approach the spatial distribution of the fibers and the effect of the investigated volume element size can also be considered. For the full-field homogenization 128 representative microstructures are generated based on [4], see for examples Fig. 2, depicting the three extreme, i.e. unidirectional (ud), planar isotropic (piso), isotropic (iso), and a frequently formed (7715) fiber orientation state [5]. The corresponding fiber orientation tensors are

$$\boldsymbol{N}_\mathrm{ud} \mathrel{\widehat{=}} \mathrm{diag}(1,0,0),\ \boldsymbol{N}_\mathrm{piso} \mathrel{\widehat{=}} \mathrm{diag}(0.5,0.5,0),\ \boldsymbol{N}_\mathrm{iso} \mathrel{\widehat{=}} \mathrm{diag}(0.33,0.33,0.33),\ \boldsymbol{N}_{7715} \mathrel{\widehat{=}} \mathrm{diag}(0.77,0.15,0), \tag{3}$$

respectively. The numerically determined viscosity tensor $\bar{\mathbb{V}}^\mathrm{num}$ is considered as reference solution. Assuming that the viscosity tensor has the form (2), a fitted viscosity tensor $\bar{\mathbb{V}}^\mathrm{fit}(\bar{\eta}, \bar{N}_\mathrm{s}, \bar{N}_\mathrm{p}, \bar{\mathbb{N}})$ and the errors e^fit and e^mf are determined through

$$e^\mathrm{fit} := ||\bar{\mathbb{V}}^\mathrm{fit} - \bar{\mathbb{V}}^\mathrm{num}||/||\bar{\mathbb{V}}^\mathrm{num}|| \to \min_{\bar{\eta}, \bar{N}_\mathrm{s}, \bar{N}_\mathrm{p}}, \quad e^\mathrm{mf} := ||\bar{\mathbb{V}}^\mathrm{mf} - \bar{\mathbb{V}}^\mathrm{num}||/||\bar{\mathbb{V}}^\mathrm{num}||, \tag{4}$$

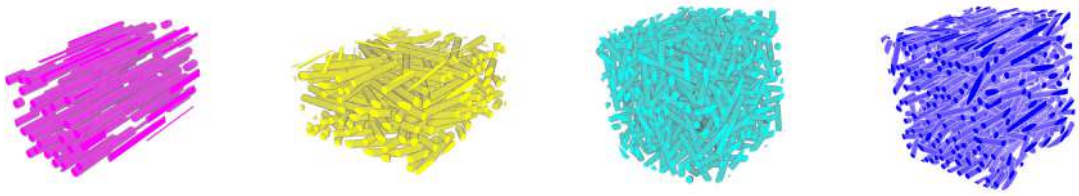

Figure 2: Examples for synthetic microstructures, from left to right: unidirectional (ud), planar isotropic (piso), isotropic (iso) and a frequently formed (7715) fiber orientation state, belonging to the fiber orientation tensors of (3).

respectively, where $\bar{\mathbb{V}}^{\mathrm{mf}}$ is the viscosity tensor determined by mean-field homogenization [2]. The viscosity parameters $\bar{\eta}$, $\bar{N}_{\mathrm{s}}$ and $\bar{N}_{\mathrm{p}}$ of the fitted viscosity tensor $\bar{\mathbb{V}}^{\mathrm{fit}}$ are determined through minimizing the error e^{fit} (4) by a sequential least square algorithm.

COMPARISON OF THE MODELS

The fast predictions of the mean-field approach and the expensive results of the full-field simulations will be compared in the presentation. The similarities and the differences will be shown on hand of the viscosity parameters and the errors e^{mf} vs. e^{fit}. The results considering all four orientation states of Fig. 2 will be discussed in the talk.

CONCLUSIONS

The expensive, numerically determined $\bar{\mathbb{V}}^{\mathrm{num}}$ is almost exactly reproduced by fitting the parameters of (2) to the numerical solution. Through the fitting a relative error $e^{\mathrm{fit}} < 3.5\%$ is reached which is notably smaller than the relative error of the mean-field model $e^{\mathrm{mf}} < 18\%$, considering all investigated orientation cases. Further investigations are needed for higher aspect ratios and to judge, whether the performance of the fitted model is similarly good in the case of non-Newtonian matrix material as in the investigated Newtonian case.

THE EFFECT OF VISCOELASTICITY IN LUBRICATED CONTACTS

Humayun Ahmed*[1] and Luca Biancofiore[1]
[1]Department of Mechanical Engineering, Bilkent University, Ankara, Turkey

Summary Lubrication is essential to improve the performance of sliding surfaces. Lubricants are carefully designed to account for thermodynamic and *flow* conditions. Particularly, they can exhibit strong viscoelastic effects, if polymers are added. In this study a novel 1D viscoelastic Reynolds equation is derived based on the Oldroyd-B constitutive relation. The model is compared with direct numerical simulations of thin films for a parabolic slider. The results are in good qualitative and quantitative agreement indicating that the simplified model is valid within the context of lubrication theory. The load carrying capacity of the film increases as the lubricant elasticity becomes significant, but stagnates as the polymer relaxation time becomes large compared to the characteristic flow time.

INTRODUCTION

Viscoelasticity within the context of lubrication has received some attention within the past few decades. It has been demonstrated both experimentally [1] and theoretically [2] that the load carrying capacity of the film can be enhanced in the presence of viscoelastic effects. For these reasons, there is a need to improve the models describing viscoelastic lubricants.

Continuum models of viscoelastic fluids consist of a coupling between the Navier-Stokes equations and a constitutive relation describing the growth of the polymeric stress. Hence, the direct numerical simulation (DNS) involves a highly non-linear system of equations and requires special numerical techniques, such as e.g. the Log Conformation Representation (LCR) to obtain accurate solutions if viscoelastic effects are reasonably strong [3].

A linearized model can be achieved by an asymptotic expansion of the Navier-Stokes equations and the constitutive relation, see for example Ref. [2]. However, the only known non-linear model available is the generalized Reynolds equation (an integral-differential equation) [5] which considers only a portion of the material derivative [4]. In this work, a new 1D (spatial) model is proposed which can accurately describe the temporal evolution and spatial distribution of the polymeric stress across the contact and the allowable load for fluids obeying the Oldroyd-B constitutive relation.

MODEL AND NUMERICAL METHOD

The full set of coupled equations for an incompressible, isoviscous fluid consist of the continuity equation (1a), the momentum equation (1b) and the Oldroyd-B constitutive relation (1c)

$$\nabla \cdot \mathbf{u} = 0, \tag{1a}$$

$$Re\frac{D\mathbf{u}}{Dt} = -\nabla p + \beta\nabla^2\mathbf{u} + \nabla\cdot\boldsymbol{\tau}, \tag{1b}$$

$$\boldsymbol{\tau} + De\left(\frac{D\boldsymbol{\tau}}{Dt} - (\nabla\mathbf{u}\boldsymbol{\tau} + \boldsymbol{\tau}\nabla\mathbf{u}^T)\right) = (1-\beta)(\nabla\mathbf{u} + \nabla\mathbf{u}^T), \tag{1c}$$

where $\mathbf{u}$ is the velocity vector, p is the pressure, $\boldsymbol{\tau}$ is the polymeric stress tensor, $\beta = \frac{\mu_s}{\mu_0}$ is the solvent concentration, $Re = \frac{\rho U h_0}{\mu_0}$ is the Reynolds number, μ_s is the solvent viscosity, μ_0 is the total viscosity, h_0 is the maximum height of the film, ρ is the density and U is the surface speed. The Deborah number $De = \lambda\frac{U}{h_0}$, i.e. the ratio of the polymer relaxation time (λ) and characteristic flow time ($\frac{h_0}{U}$), is used to measure the strength of the viscoelastic effects.

Firstly, we assume that (i) the film thickness h is much smaller than the contact length ℓ and (ii) $Re << 1$, hence inertial effects are ignored. Our proposed model stems from the thin film approximation (lubrication theory) of Eqs. 1a-1c, in which we retain the polymer normal stress unlike the GR model (see Ref. [5]). The reduced x-momentum equation is integrated and an explicit equation for pressure is obtained via the reduced continuity equation

$$\frac{d}{dx}\left(\frac{h^3}{12}\frac{dp}{dx}\right) = \frac{\beta}{2}\frac{dh}{dx} + \frac{d}{dx}\left(\int_0^h \frac{y}{h}\int_0^h\int_0^y \frac{d\tau_{xx}}{dx}dy''dy'dy - \int_0^h\int_0^y\int_0^y \frac{d\tau_{xx}}{dx}dy''dy'dy\right)$$
$$+ \frac{d}{dx}\left(\int_0^h \frac{y}{h}\int_0^h \tau_{xy}dy'dy - \int_0^h\int_0^y \tau_{xy}dy'dy\right). \tag{2}$$

where p is the film pressure, τ_{xx} is the normal stress, τ_{xy} is the shear stress and h is the channel height. The integral form of Eq. 2 is further simplified via two key numerical simplifications: (i) we approximate the stress components via polynomials in y ($\tau_{xx} = \sum_{i=1}^{n} F(x,t)y^{i-1}$, $\tau_{xy} = \sum_{i=1}^{n+1} G(x,t)y^{i-1}$ and $\tau_{yy} = \sum_{i=1}^{n+1} K(x,t)y^{i-1}$) and (ii) decouple the stress from the pressure by assuming that the velocity field does not depend on De. Therefore, we obtain the stresses by solving the thin film constitutive equation and obtain the pressure from Eq. 2.

To test the quality of our new model, we have conducted direct numerical simulations of the Eqs. (1a-1c) via *rheoTool* an OpenFOAM based C++ library which takes advantage of LCR [6].

RESULTS

We simulate the lubricant behaviour in a typical parobolic slider, illustrated in fig. 1a. Particularly, we compare for different models the film pressure and the maximum allowable load (L) in Figs. 1b and 1c respectively. The film pressure increases due to an increase (i) in the bulk pressure distribution and (ii) a shift in the positive pressure region. This difference is significant since the pressure within the contact can reach several MPa in magnitude. Finally, a noticeable distortion is symmetry manifests due to the viscoelastic polymers is observed.

Furthermore, all models predict an increase of the load adding viscoelasticity (see Fig. 1c), at least at moderate De. However the degree of increase varies significantly depending on the models. In addition, it should be noted that DNS do not converge at high De due to (i) the high non-linearity of Eqs. 1a-1c and (ii) the strong aspect ratio of the geometry ($\frac{h_0}{\ell} \sim 10^{-3}$). Moreover for the same reasons DNS present some uncertainty as $De \geq 30$ depicted by the gray region in Fig. 1c.

At small De the linearized model predicts the variation accurately but departs from the DNS as De increases, whereas, the generalized Reynolds equation (GR) strongly underestimates the load. Our proposed model (VR) provides excellent quantitative and qualitative agreement with DNS for low to moderate values of De. At large values, it remains within the estimated tolerance region (gray band). From VR, we find a strong non-linear trend in the load which exhibits a maximum value around $De \approx 55$ and eventual saturation at high De. The proposed viscoelastic model imposes no restriction on (i) the value of Deborah number, (ii) the complexity of the surface profile and (iii) mesh size, hence it is computationally appealing.

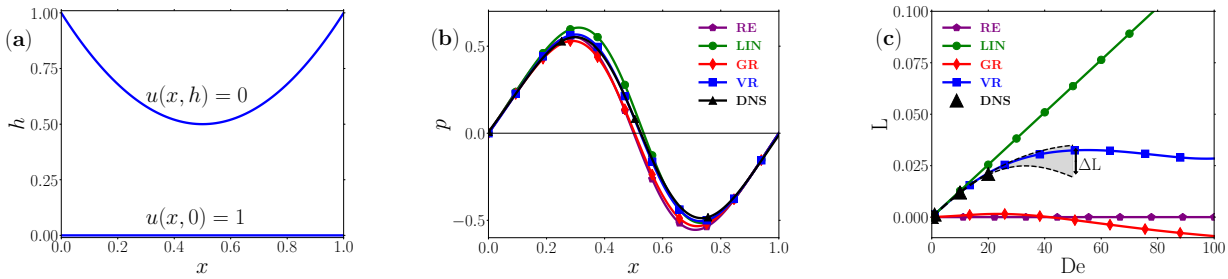

Figure 1: (a) A typical parabolic profile mimicking a lubricated contact in a roller bearing. (b) The film pressure along the channel for $De = 40$ and (c) the load versus De for different models: the Newtonian Reynolds equation (RE), the linearized model (LIN, Ref. [2]), generalized Reynolds equation (GR, Ref. [5]), viscoelastic Reynolds equation (VR) and DNS for $\beta = 0.8$.

CONCLUSIONS

Viscoelasticity can increase the load carrying capacity of the lubricant film. While for small De the linearized model accurately captures the viscoelastic behavior, it fails at moderate to strong De. The new viscoelastic model can capture high-order effects without the complexity, and so with significantly less computational cost, of the existing non-linear models. Furthermore, VR can couple other complex phenomena that can be found in lubricated contacts such as piezo-viscosity (viscosity variation due to pressure), compressibility (density variation) and shear thinning (viscosity variation due to shear stress).

INFLUENCE OF POLYMER ADDITIVES ON INVARIANTS OF THE VELOCITY GRADIENT NEAR A TURBULENT/NON-TURBULENT INTERFACE STUDIED BY DIRECT NUMERICAL SIMULATIONS

Hugo Abreu*[1], Fernando T. Pinho[2], and Carlos B. da Silva[1]
1LAETA,IDMEC,Instituto Superior Técnico,Universidade de Lisboa,Lisboa,Portugal2CEFT,FEUP, Universidade do Porto, Porto, Portugal

Summary The motivation for this work is study the influence of the polymer additives on the microscales of a turbulent flow, namely on the turbulent entrainment process. In order to achieve this, the attention is given to the T/NT interface separating the turbulent and the irrotational flow regions. The objective is perform a DNS simulation of a shear free turbulence (SFT) and observe the physical mechanisms and dynamics present at this interface, the ones responsible for turbulent entrainment. The study of the invariants across this interface allows a detailed characterization of the dynamics, geometry and topology of the flow during the entrainment. Viscoelastic solutions simulated by means of the FENE-P model, show to produce interfaces with smoother features and larger scales, more importantly turbulent fronts in dilute polymer solution propagate less than their Newtonian equivalents.

DNS: SHEAR FREE TURBULENCE WITH AND WITHOUT POLYMER ADDITIVES

In order to gain physical insight into the phenomenon the use of Direct Numerical Simulations (DNS) has gained prominence with the evolution of computational resources, since DNS of viscoelastic fluid flows is significantly more expensive than its Newtonian counterpart for a number of reasons. Most of these simulations have been carried out for fluids described by the Finitely Extensible Non-linear Elastic[1] constitutive equation with the dumbbell spring force described through the simplified Peterlin's closure[2], henceforth denoted as the FENE-P model.

More recent investigations on the effect of viscoelasticity upon inertial turbulence has benefited from a more fundamental approach in which the effects of walls and inhomogeneities have been removed in order to focus on the inherent turbulent processes, as in the DNS investigations of forced homogeneous isotropic turbulence of Liberzon et al. [3], De Angelis et al. [4], Ouellette et al. [5] and Valente et al. [6]. In particular, the most recent investigations of FHIT with polymer solutions have shown the reduction of the classical energy cascade with a concomitant increase of the energy directly dissipated by the polymer[6],[7].

Our current understanding of these polymer-induced modifications has not been accompanied by equally relevant issues that have been poorly investigated. Specifically, if the turbulence exists in a sea of irrotational fluid how does the propagation of the turbulence of polymer-laden fluid takes place and how are the mechanisms of entrainment modified by the presence of the polymer? These are important issues to understand, amongst others, the growth rate of a turbulent jet of a polymer solution, its rates of mixing, heat or momentum transfer. Through DNS of viscoelastic fluids described by the FENE-P model, in this work, we precisely investigate the effects of flow viscoelasticity upon the characteristics of the turbulent/ non-turbulent interface, its propagation and the inherent mechanisms associated with turbulence entrainment.

Figure 1 shows that as compared with Newtonian fluid case, much less but wider tube-like vortex structures in the SFT for the polymer solution cases. This appearance of vortex tube structure also reflects a decrease in enstrophy, since the enstrophy indicates the strength of the tube-like vortex structures and mainly is generated by the stretching of the tube-like vortex structures.

(a) (b) (c)

Figure 1: (Isometric view) Constant Q isosurface ($Q = 100s^{-2}$) for a Newtonian fluid (a), viscoelastic fluid with $\tau_p = 0.025$s (b), and viscoelastic fluid with $\tau_p = 0.200$s (c).

Through the analysis of the physical meanings represented by Q and R, clear physical images for the topological dynamics characteristics can be obtained, such as the joint PDFs plots of Q and R in Figure 2. However, it can be seen that the tails of the teardrop shapes have been changed for the polymer solution cases compared its Newtonian fluid counterpart: the large-R and Q regions have shrunk greatly, which indicates the inhibition of small-scale vortices.

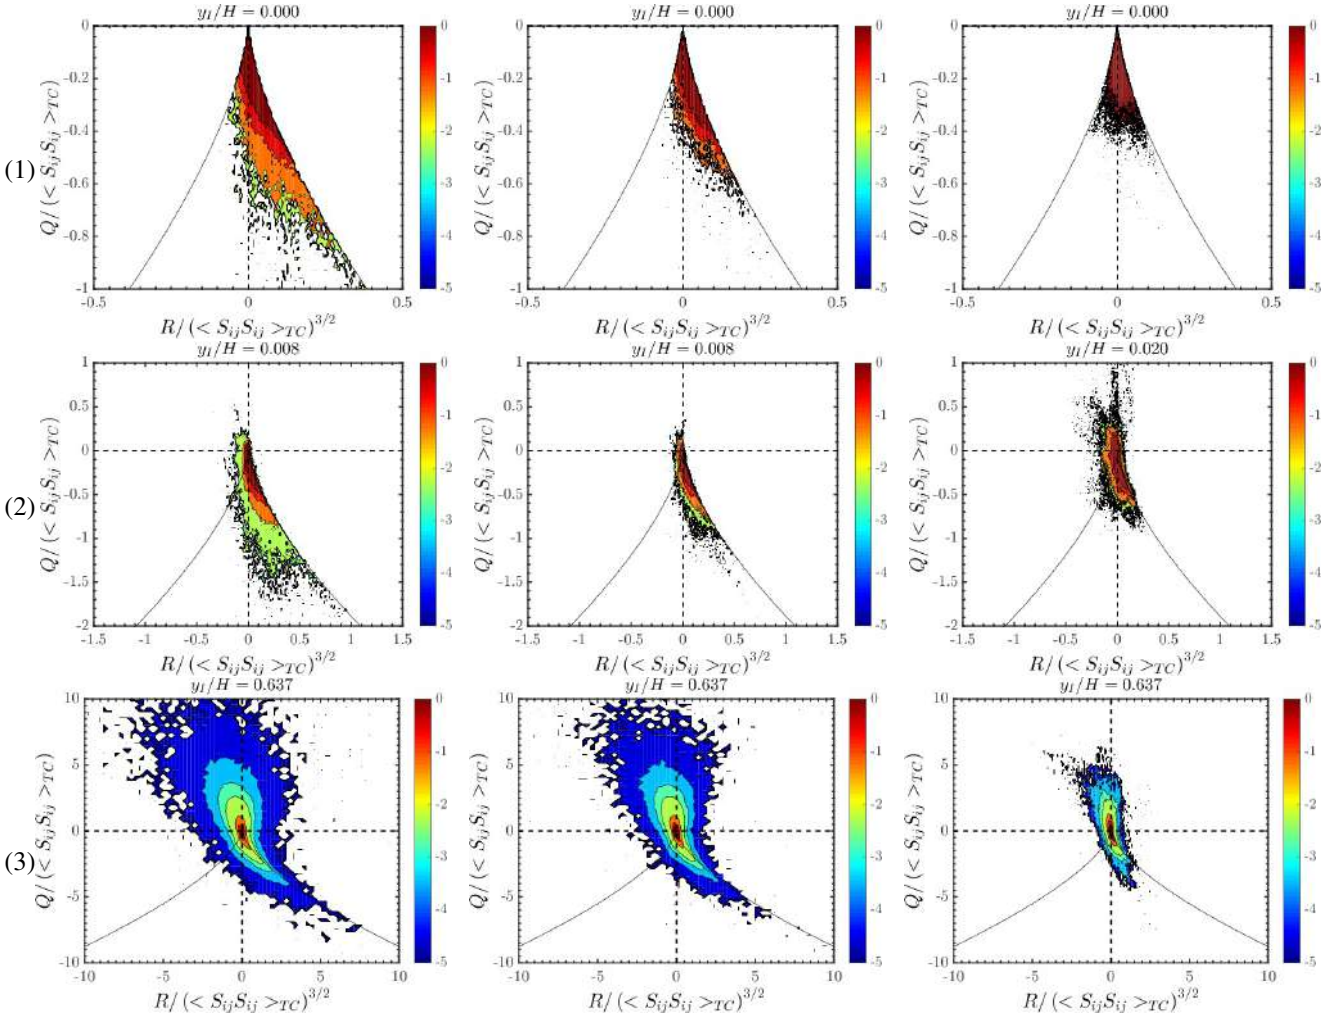

Figure 2: Joint PDFs of R and Q at turbulent non-turbulent (T/NT) interface (1), point of maximum diffusion of the enstrophy (2) and turbulent core (3), for a Newtonian fluid (a), viscoelastic fluid with $\tau_p = 0.025$s, and a viscoelastic fluid with $\tau_p = 0.200$s (c).

CONCLUSIONS

The topological dynamics analysis for the velocity gradient tensor of the shear free turbulence with/without polymer additives has been performed in this paper to the explore the effect of viscoelasticity on the turbulence structures near of the turbulent/non-turbulent interface.

AN IDEA FOR NON-INVASIVE IN-LINE RHEOMETRY BASED ON SPATIO-TEMPORAL VELOCITY INFORMATION

Yuji Tasaka*[1], Taiki Yoshida[1], Kohei Ohie[1], and Yuichi Murai[1]
1Laboratory for Flow Control, Faculty of Engineering, Hokkaido University, Sapporo, Japan

Summary A novel algorithm for realizing non-invasive in-line rheometry was proposed based on spatio-temporal velocity information that will be measured by ultrasonic velocity profiling. The main concept is substituting velocity data into the equation of motion and a constitutive equation describing rheology, on frequency domain, and thus the rheological properties are determined by minimizing the residual in the equations. The algorithm was evaluated using theoretically derived velocity data of pulsatile pipe flows.

INTRODUCTION

Rheological evaluation of complex materials in manufacturing processes is one of the important issues of rheology, and development of rheometry that is able to do the evaluation in-line and real time has great importance to improve productivity, quality and safety in the processes. Recent developments of ultrasonic velocity profiling provided invention of UVP-PD method that evaluates non-Newtonian viscosity utilizing time-averaged velocity profile information measured by ultrasonic velocity profiling (UVP) and pressure difference (PD) along a pipe [1]; rheological properties are determined as best fit parameters on a constitutive equation of rheology by comparing between the measured velocity profiles and those derived from the equation of motion, the constitutive equation and PD information. The method is, however, still in development for practical use in industry; PD measurement requires insert of pressure transducers in a pipe getting avoided in factories for safe issue; using time-averaged velocity profile cannot access viscoelastic characteristics of materials. Here we propose a novel algorithm of ultrasonic in-line rheometry to avoid PD measurement and to allow characterization of viscoelastic materials using unsteadiness of fluid motion. Main concept of the algorithm is from our recent development of ultrasonic spinning rheometry [2, 3] that evaluates rheology of test fluids by analyzing spatio-temporal velocity information measured by UVP in an oscillating cylindrical vessel on the equation of motion for unsteady flows.

ALGORITHM OF IN-LINE RHEOMETRY

Unsteady laminar pipe flows of general fluids with density ρ under assumption of one-directional flow can be described by following equation of motion,

$$\rho\frac{\partial u}{\partial t} = \alpha(t) + \frac{\partial \tau}{\partial r} + \frac{\tau}{r}, \tag{1}$$

where $\alpha(t) = -\partial p/\partial x$ demotes unsteady pressure gradient in the flow direction. Relation between Shear stress τ and shear rate $\dot{\gamma}$ is expressed by rheological model as constitutive equation,

$$\tau = h(\dot{\gamma}; \Pi_1, \Pi_2, \Pi_3, \cdots), \ \dot{\gamma} = \frac{\partial u}{\partial r} \tag{2}$$

with some constants, $\Pi_1, \Pi_2, \Pi_3, \cdots$, as rheological properties. Assuming that the velocity profile $u(r,t)$ is given by measurements, the equation system on Eq. (1) and (2) has unknowns, $\alpha(t)$ and rheological properties; Given information of the velocity profiles cannot close the system. Here we take Fourier transform on Eq. (1), and assuming that the unsteady flow has dominant frequency component $\omega = \omega_0$. The equation of motion is reduced into ordinal differential equation,

$$i\rho\omega_0\hat{u}(r;\omega_0) = \hat{\alpha}(\omega_0) + \left(\frac{d}{dr} + \frac{1}{r}\right)\hat{\tau}(r;\omega_0), \tag{3}$$

where $\hat{}$ denotes Fourier-transformed function, and $\hat{\alpha}(\omega_0)$ is complex constant. Velocity profiles are given as N-points discrete data in the radial direction, $u(r_n,t),\ n = 1, 2, \cdots, N$, and thus the equation can be closed. To determine the multiple unknowns, cost function,

$$F[\hat{\alpha}(\omega_0), \Pi_1, \Pi_2, \Pi_3, \cdots] = \sum_{n=0}^{N}\left| i\rho\omega_0\hat{u}(r_n;\omega_0) - \hat{\alpha}(\omega_0) - \left(\left.\frac{d}{dr}\right|_{r_n} + \frac{1}{r_n}\right)\hat{\tau}(r_n;\omega_0)\right|^2 \tag{4}$$

is used, and thus the unknowns are determined by minimizing the function, i.e.,

$$\min F[\hat{\alpha}(\omega_0), \Pi_1, \Pi_2, \Pi_3, \cdots] \Longrightarrow \Re[\hat{\alpha}(\omega_0)], \Im[\hat{\alpha}(\omega_0)], \Pi_1, \Pi_2, \Pi_3, \cdots .$$

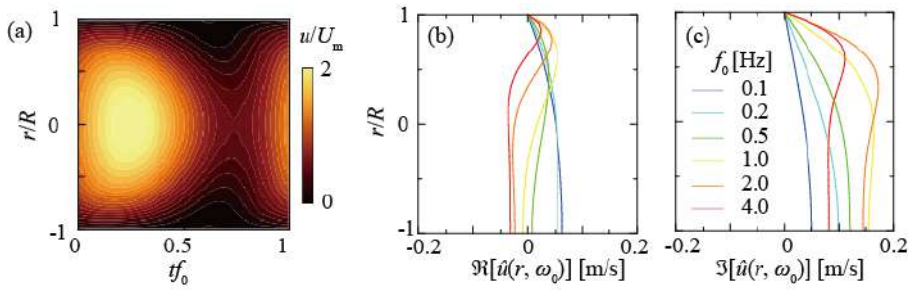

Figure 1: Samples of velocity information calculated from analytic solution of pulsatile flow ($\nu = 100$ mm^2/s, $U_\mathrm{m} = 0.2$ m/s, $U_\mathrm{o} = 0.1$ m/s); (a) spatio-temporal velocity map for one period ($f_0 = 0.5$ Hz), radial profiles of (b) real and (c) imaginary part of Fourier component corresponding to $f = f_0$ for different f_0

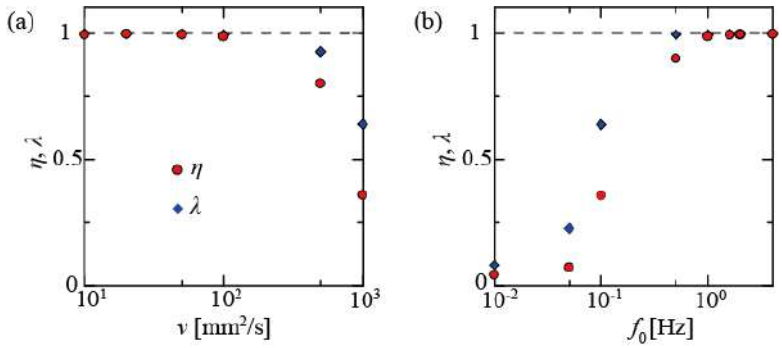

Figure 2: Influence of (a) viscosity and (b) oscillation frequency on estimated values of viscosity and pressure amplitude for $f_0 = 1$ Hz and $\nu = 100$ mm^2/s in each investigation

DEMONSTRATION OF VISCOMETRY ON IDEAL NUMERICAL VELOCITY DATA

We demonstrate the algorithm adopting Newton's law of viscosity, $\tau = \rho\nu\partial u/\partial r$ with kinematic viscosity ν, in this system, as viscometry to simplify the problem. Numerical data sets of velocity are calculated from analytically derived unsteady velocity profile of pulsatile flow, combination of steady Poiseuille flow $u_\mathrm{m}(r)$ and periodically oscillating flow $u_\mathrm{o}(r,t)$ as $u(r,t) = u_m(r) + u_\mathrm{o}(r,t)$. In the data set, maximum velocities of u_m and u_o are set constant, $U_\mathrm{m} = 0.2$ m/s and $U_\mathrm{o} = 0.1$ m/s, respectively, while ν and oscillation frequency of the pulsatile flows $f_0 = \omega_0/(2\pi)$ are modified to evaluate capability of the algorithm. Two normalized values, $\eta = \nu_\mathrm{est}/\nu_\mathrm{set}$ and $\lambda = |\hat{\alpha}_\mathrm{est}|/|\hat{\alpha}_\mathrm{set}|$, are investigated as indicators of successful evaluation of rheology, where subscripts "set" and "est" are given and evaluated values.

A sample of spatio-temporal velocity data and Fourier components of velocity information, real $\Re$ and imaginary $\Im$ part, calculated for $\nu = 100$ mm^2/s and different frequencies are shown in Fig. 1, where R (= 25.4 mm) denotes radius of the pipe. It is easily deduced that velocity data obtained at out of viscous layer, $r > \delta_\mathrm{v} \approx \sqrt{\nu/\omega_0}$, has less information about viscosity, while the pressure estimation is not affected. Here we evaluate applicability of algorithm; how large viscosity or how low frequency conditions can be dealt with. Results of evaluation for influences of the viscosity and the frequency are summarized in Fig. 2, where f_0 and ν are kept constant at 1 Hz and 100 mm^2/s in each evaluation. The both fractions η and λ detach from unity around ν =100 mm^2/s and 1 Hz for high viscosities and low frequencies, where the points are close to conditions $\delta_\mathrm{v} \approx R$ in the set conditions. These results suggest that cases of viscosities dominating behaviors of the frequency modes reduce the quality of estimation.

CONCLUSIONS

We proposed a novel algorithm to realize non-invasive in-line rheometry utilizing spatio-temporal velocity data, and applicability of the algorithm was evaluated in viscosity estimation using velocity data calculated from theoretically derived formula of pulsatile flows. The algorithm has certain measurable range of viscosity determined by thickness of viscous layer. More detailed discussions will be given in the corresponding talk.

A NOVEL MULTIPLE RHEOLOGY MAPPING BY ULTRASONIC SPINNING RHEOMETRY

Kohei Ohie*[1], Taiki Yoshida[2], Hyun Jin Park[2], Yuji Tasaka[2] and Yuichi Murai[2]
[1]Laboratory for Flow Control, Graduate School of Engineering, Hokkaido University, Sapporo, Japan
[2]Laboratory for Flow Control, Faculty of Engineering, Hokkaido University, Sapporo, Japan

Summary We propose a novel rheological property map representing both shear rate and frequency dependence of viscoelasticity evaluated by ultrasonic spinning rheometry, which can extract rheological properties from velocity distribution in an oscillating cylindrical vessel through the equation of motion. Rheological properties of carboxymethyl cellulose aqueous solution were evaluated as a typical demonstration of rheological evaluations using the map. Usefulness of the map on evaluations is discussed through considering complex rheological properties of the solution.

INTRODUCTION

Rheological properties measurement has great importance on design optimization of industrial plants, quality control of food processing and performance evaluation of working fluids. Fluidity materials targeted by rheology have complexities which have risks to collapse ideal conditions regarded in conventional torque rheometer, such as wall slip, shear banding and jamming. Ultrasonic spinning rheometry (USR), which is based on velocity information obtained by ultrasonic velocity profiler (UVP), has conquered these fatal problems. Success stories of USR have been reported for measurement of fluids with yield stress and temporal change of rheological properties [1, 2]. These complex fluids have microscopic inner structures, and they induce shear rate and frequency dependence of rheological properties. For better understanding rheology of complex fluids, we propose a novel rheological property map by USR. The map reveals both shear rate and frequency dependence of rheological properties.

EXPERIMENTAL APPARATUS AND ANALYTICAL METHOD

An acrylic cylindrical vessel (diameter: 154 mm, height: 300 mm, thickness: 3 mm) filled with a test fluid up to 240 mm from the bottom is installed centre of a water bath for propagation of ultrasonic wave and for temperature control [Fig. 1]. The vessel is driven by a stepping motor with oscillation frequency f_0 and angle Θ. Spatiotemporal velocity distribution u_ξ along propagation line of the wave is obtained by UVP, where the ultrasonic transducer is installed at off-axis Δy. Linear viscoelastic analysis, an analytical method to quantify viscoelasticity from velocity distribution [3] is adopted, and here, essence of the method is summarized below. Assuming that the flow in the vessel is axisymmetric and radial velocity component is negligible, u_ξ is converted to the azimuthal velocity u_θ along the radial direction by geometric relation $u_\theta = u_\xi\, r/\Delta y$, where the velocity should satisfy Cauchy's equation of motion, $\rho \partial u_\theta/\partial t = (\partial/\partial r + 2/r)\,\tau$; τ indicates the shear stress. Maxwell model, $\tau + (\mu/E)\,\partial\tau/\partial t = \mu\,(\partial/\partial r - 1/r)\,u_\theta$ is utilized just for separation of viscous and elastic contributions to the shear stress, where μ and E denote viscous coefficient and elastic modulus, respectively. Fourier transform is utilized for suppression of measurement noise of UVP. Combining these equations, cost function $F(\mu, E; r) = [i\omega\rho\hat{u}_\theta - (\partial/\partial r + 2/r)\hat{\tau}]^2_{\omega = 2\pi f0}$ is defined where $\hat{u}_\theta$ and $\hat{\tau}$ indicate Fourier-transformed velocity and shear stress, $\mathscr{F}[u_\theta(r, t)]$ and $\mathscr{F}[\tau(r, t)]$, respectively. In optimization problems based on the cost function, μ and E making the cost function minimum are the most proper rheological properties. Solving the optimization problems at every radial position, spatial distributions of μ and E are acquired. Spatiotemporal distribution of shear rate is derived as $\dot{\gamma} = (\partial/\partial r - 1/r)\,u_\theta$, and effective shear rate $\dot{\gamma}_{\mathrm{eff}}(r)$ is obtained by taking effective value of $\dot{\gamma}$ as a representative shear rate at each radial position.

EXAMPLE OF RESULTS

As a demonstration of rheological evaluation using the property map, a viscoelastic fluid, carboxymethyl cellulose (CMC) 1.0 wt.% aqueous solution (Daicel Chemical Co., Ltd., Japan) was chosen as a test fluid. Temperature of the fluid was kept at 25.0 °C by a thermostatic chamber during experiments. Fine particles of highly porous polymer (CHP 20P, Mitsubishi Chemical Co., Ltd., Japan, diameter: 75−150 μm) were added a little to the test fluid as tracer particles for ultrasonic reflection. Ultrasonic transducer (emission frequency is 4 MHz) was set at Δy = 15 mm and 150 mm height from bottom of the vessel. The set height is an adequate height for assumptions in linear viscoelastic analysis. The effective shear rate $\dot{\gamma}_{\mathrm{eff}}(r)$ takes the maximum $O(10\ \mathrm{s}^{-1})$ on the side wall and decreases to $O(1\ \mathrm{s}^{-1})$ toward inner region. USR therefore can obtain $\dot{\gamma}_{\mathrm{eff}} - \mu$ and $\dot{\gamma}_{\mathrm{eff}} - E$ curves which express shear rate dependence only by a set of oscillation parameters (f_0, Θ). Frequency dependence of the rheological properties can be examined by increasing oscillation frequency little by little. Five oscillation conditions were selected as (f_0, Θ) = (0.25 Hz, 480°), (0.50 Hz, 240°), (0.75 Hz, 160°), (1.00 Hz, 120°), (1.25 Hz, 96°). Integrating the results of linear viscoelastic analysis, the rheological property map was obtained [Fig. 2. (a)]. Continuous lines in the map indicates contour of E.

Based on the map, mainly five typical characteristics of the CMC solution can be confirmed. (1) The isolines rising to the right means that the CMC solution expresses more elastic behaviour in higher frequency oscillations. (2) Horizontal

colour strips of viscosity coefficient are confirmed, which indicates that the CMC solution has no frequency dependence of viscosity in oscillation frequency from 0.25 Hz to 1.25 Hz. (3) Monotonous decrease of viscous coefficient toward high shear rate direction reflects shear thinning characteristic. (4) The CMC solution can be treated as pure viscous fluid on the area surrounded by dotted line [Fig. 2. (b)]. (5) Viscous coefficient on top side of pure viscous area is constant, which means that the CMC solution behaves like a Newtonian fluid in the area.

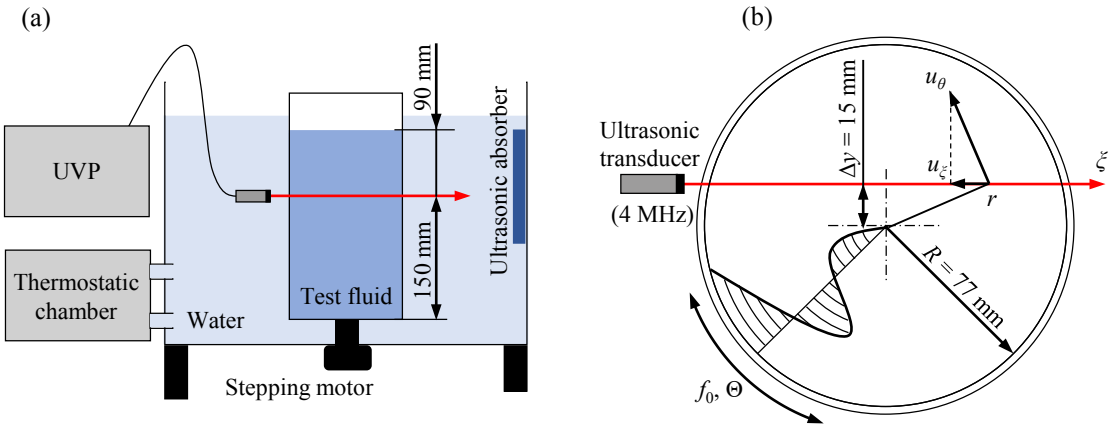

Figure 1. A schematic diagram of experimental setup: (a) side view, and (b) top view.

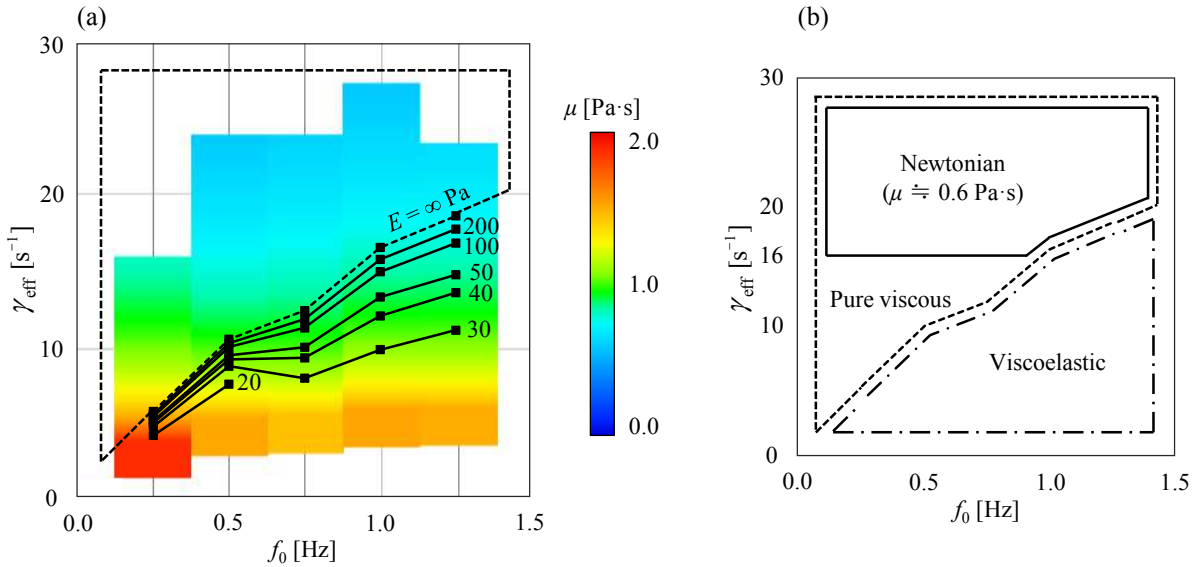

Figure 2. Rheological property map of CMC 1.0 wt.% aqueous solution at 25.0 °C: (a) distribution of viscosity coefficient and elastic modulus, and (b) classification of flow characteristics.

CONCLUSIONS

The CMC solution has usually been treated as a simple shear thinning fluid. However, it widely expresses from viscoelastic to pure viscous, Newtonian behaviours, depending on shear rate and oscillation frequency [Fig. 2]. USR can acquire these rheological properties by measurements with a few oscillation parameters, whereas conventional torque rheometer needs to set not only oscillation frequency conditions but also shear rate conditions. Furthermore, the map obtained by USR is applicable to evaluate more complex fluids such as fluids containing solid or gas phases and fluids with yield stress. Evaluations using the map have high potential for better understanding rheology of complex fluids.

SOLUTION OF TRANSIENT VISCOELASTIC FLOW PROBLEMS APPROXIMATED BY A VMS STABILIZED FINITE ELEMENT FORMULATION USING TIME-DEPENDENT SUBRID-SCALES

Laura Moreno[1], Ramon Codina[1,2], and Joan Baiges *[1]
[1]UniversitatPolitècnicadeCatalunya,JordiGirona1-3,EdificiC1,08034,Barcelona,Spain

Summary Recent studies indicate that classical residual-base stabilized methods for unsteady incompressible flows may experience difficulties when the time step is small in relation with the spatial grid size. The aim of this work is the design of finite element stabilized techniques based on the Variational Multiscale (VMS) method that allow to compute time-dependent viscoelastic flow problems with high elasticity and considering an anisotropic space-time discretization. Although the main advantage is achieve stable solutions for anisotropic space-time discretizations, other benefits related with elastic problems are proved in this study. In particular, the proposed methods are designed for the standard and logarithmic formulations in order to deal with high Weissenberg number problems, ensuring stability in all cases. A comparison between formulations and stabilization techniques will be performed to demonstrate the efficiency of time-dependent sub-grid scales and the term-by-term methodologies.

INTRODUCTION

Bochev et al. [1] argue that spatial stabilization in conjunction with finite differencing in time implies destabilizing terms and that $\delta t > Ch^2$ (where δt is the time step size, C a positive constant and h the spatial grid size) is a sufficient condition to avoid instabilities. Nevertheless, for anisotropic space-time discretizations, this inequality is not necessarily satisfied, and in fact complications in residual-based stabilized methods are reported. These problems can happen, for instance, when small time steps result from the necessity of accuracy to solve transient problems due to the presence of non-linear terms in the differential equations, a very common issue in viscoelastic flow formulations. In particular, the approximations used in Variational Multiscale (VMS) methods [2] usually neglect the time derivative of the sub-grid scales, resulting in the inequality $\delta t > Ch^2$ being required to obtain stable solutions. Consequently, anisotropic space-time discretizations cannot guarantee stability, as it is argued by Codina et al. [3]. By following these ideas, the present work pursues to expand transient subgrid-scale methods to the viscoelastic flow problem, such as it is presented in [4] for the Navier-Stokes incompressible problem using a split term-by-term method. The computation of viscoelastic flows leads to its own difficulties, especially when elasticity becomes dominant, i.e., when the dimensionless number known as the *Weissenberg number* is high: the so called High Weissenberg Number Problem (HWNP). A new formulation was proposed by Fattal and Kupferman in order to deal with these shortcomings: the so called Logarithmic Conformation Representation. In this sense, in [5] the authors apply this reformulation using a stabilized formulation based on the VMS method.

VISCOELASTIC FLOW PROBLEM

The governing equations for the viscoelastic flow problem in incompressible and isothermic conditions, are the conservation of momentum and mass and a constitutive equation which can be expressed as

$$\rho\frac{\partial \boldsymbol{u}}{\partial t} + \rho\boldsymbol{u}\cdot\nabla\boldsymbol{u} - \nabla\cdot\boldsymbol{T} + \nabla p = \boldsymbol{f} \text{ in } \Omega, t \in]0, t_{\mathrm{f}}[, \tag{1}$$

$$\nabla\cdot\boldsymbol{u} = 0 \text{ in } \Omega, t \in]0, t_{\mathrm{f}}[, \tag{2}$$

$$\frac{1}{2\eta_p}\boldsymbol{\sigma} - \nabla^s\boldsymbol{u} + \frac{\lambda}{2\eta_p}\left(\frac{\partial\boldsymbol{\sigma}}{\partial t} + \boldsymbol{u}\cdot\nabla\boldsymbol{\sigma} - \boldsymbol{\sigma}\cdot\nabla\boldsymbol{u} - (\nabla\boldsymbol{u}^T)\cdot\boldsymbol{\sigma}\right) = \boldsymbol{0}, \text{ in } \Omega, t \in]0, t_{\mathrm{f}}[, \tag{3}$$

where Ω is the domain considered of $\mathbb{R}^d$ (d=2 or 3), whose boundary is $\partial\Omega$, during the time interval $[0, t_{\mathrm{f}}]$, where ρ denotes the constant density, p is the pressure field, $\boldsymbol{u}$ is the velocity field, $\boldsymbol{f}$ is the force field and $\boldsymbol{T}$ is the deviatoric stress tensor. In general, $\boldsymbol{T}$ is defined in terms of a viscous and a viscoelastic contribution as $\boldsymbol{T} = 2\eta_e\nabla^s\boldsymbol{u} + \boldsymbol{\sigma}$. Effective (or solvent) viscosity is denoted by η_e and the polymeric viscosity by η_p. The third equation of the system is the constitutive equation for the viscoelastic stress tensor. We have considered the Oldroyd-B model where λ is the relaxation time. The logarithmic reformulation of the equations is derived basically from a change of variables, where the stress tensor is replaced by $\boldsymbol{\sigma} = \frac{\eta_p}{\lambda_0}(\exp(\boldsymbol{\psi}) - \mathbf{I})$ in (1), (2) and (3). Particularly, λ_0 is linearly dependent with λ and is defined as $\lambda_0 = \max\{k\lambda, \lambda_{0,\min}\}$, being $k \leq 1$ a constant and $\lambda_{0,\min}$ a given threshold. Note that the complete development employed is extensively explained in [5].

STABILIZED FINITE ELEMENT FORMULATION

The stabilization method departs from the framework described in [2], which consists in splitting the unknowns $\boldsymbol{U}$ in the sum of two components, $\boldsymbol{U}_h$ (component which can be captured by the finite element space) and $\tilde{\boldsymbol{U}}$ (the remainder, called sub-grid scale). Let us suppose that $\mathcal{L}(\hat{\boldsymbol{u}};\cdot)$ is a linear operator for a given $\hat{\boldsymbol{u}}$. Introducing the sub-grid scale decomposition and integrating by parts, the method leads to find $\boldsymbol{U}_h :]0, t_{\mathrm{f}}[\longrightarrow \boldsymbol{\mathcal{X}}_h$ such that

$$\mathcal{G}(\boldsymbol{U}_h, \boldsymbol{V}_h) + B(\boldsymbol{u}_h; \boldsymbol{U}_h, \boldsymbol{V}_h) + \sum_K \langle \tilde{\boldsymbol{U}}, \mathcal{L}^*(\boldsymbol{u}_h; \boldsymbol{V}_h) \rangle_K = L(\boldsymbol{V}_h), \tag{4}$$

for all $\boldsymbol{V}_h \in \boldsymbol{\mathcal{X}}_h$, where B is the bilinear form of the problem and $\mathcal{G}$ the temporal terms, $\mathcal{L}^*(\boldsymbol{u}_h; \boldsymbol{V}_h)$ is the formal adjoint of the operator $\mathcal{L}(\hat{\boldsymbol{u}};\cdot)$ typically without considering boundary conditions, $\tilde{\boldsymbol{U}}$ is the sub-grid scale, which needs to be approximated and has components $\tilde{\boldsymbol{U}}$=$[\tilde{\boldsymbol{u}}, \tilde{p}, \tilde{\boldsymbol{\sigma}}]$. Particularly, $\mathcal{L}(\hat{\boldsymbol{u}};\cdot)$ is the operator associated to the viscoelastic flow problem and $L(\boldsymbol{V}_h)$ comes from the RHS terms in (1) - (3). Once operators $\mathcal{G}$ and $\mathcal{L}$ are defined for both formulations, the sub-grid scales are now the solution of this equation, written in terms of the finite element component:

$$\mathcal{D}_t(\tilde{\boldsymbol{U}}) + \boldsymbol{\alpha}^{-1}\tilde{\boldsymbol{U}} = \tilde{P}[\boldsymbol{F} - \mathcal{G}(\boldsymbol{U}_h) - \mathcal{L}(\boldsymbol{u}_h; \boldsymbol{U}_h)], \tag{5}$$

where we denote $\tilde{P}$ as the L^2 projection onto the space of sub-grid scales, $\mathcal{D}_t(\tilde{\boldsymbol{U}})$ is defined as the temporal derivative of the sub-grid scale and $\boldsymbol{\alpha}$ is taken as a diagonal matrix of stabilization parameters. Apart from the purely residual-based stabilization (denoted by OSS), we propose a term-by term stabilization motivated by the fact that not all the terms of some products provide stability, denoted by S-OSS. The idea of this method is to replace the solution of (5) in (4) but keep only the terms of the form one operator term applied to the unknown by the same operator term applied to the test function, thus neglecting the products of different operators.

NUMERICAL RESULTS AND CONCLUSIONS

The flow over a cylinder problem is used to achieve several objectives: firstly, to compare the various stabilization methods proposed (dynamic and quasi-static formulations) in terms of stability when the time step is small, and when the Weissenberg number increases. In first case, Table 1 shows us that the dynamic method is the most efficient. In the second study, Table 2 we can conclude that dynamic formulations are more effective avoiding elastic instabilities, allowing the computation of fluid flows with a higher Weissenberg number.

The results obtained are particularly remarkable due to the high Weissenberg number reached with the dynamic formulation, which remains stable even if the standard formulation is considered, apart from evident benefits in anisotropic space-time discretizations when the time step is small. The combination of dynamic sub-grid scales and the logarithmic formulation is capable of solving problems with higher elasticity.

A PHENOMENOLOGICAL EQUATION FOR THE FRICTION FACTOR OF TURBULENT FLOW OF VISCOELASTIC FLUIDS: FROM THE NEWTONIAN TO THE MAXIMUM DRAG REDUCTION LIMIT

H.R. Anbarlooei[1], C.M.M.Santos[2], F. Ramos[1], and D.O.A. Cruz*[2]

[2]Mechanical Engineering Program, Federal University of Rio de Janeiro (COPPE/UFRJ), Brazil

Summary A novel friction equation is developed for the fluids which follow Oldroyd-B model, using the phenomenological model of Gioia and Chakraborty [1] which connects the Kolmogorov's micro-scales to the wall shear stress. To accomplish this, the kolmogorov's micro-scales for the Newtonian case are extend to the non-Newtonian visco-elastic Oldroyd-B model. The resulted friction equation is then compared with experimental data, where very good agreement has been observed. Finally, the developed friction equation reduces to Blasius equation (Newtonian) and maximum drag reduction asymptote in the limits.

INTRODUCTION

It is well known that the friction coefficient of a turbulent flow, can be reduced by the addition a small amount of some substances to the liquid. Despite the extensive research done since that phenomenon was discovered in the late 40's , no definite explanation for the friction factor drop or even a theoretical approach was developed, that can provide a useful friction equation for this type of flow. In their work of Gioia and Chakraborty (GC) [1], proposed a phenomenological approach that can be used to formulate a variety of frictions equations for different types of non Newtonian fluids turbulent flows [2]. In this work, a friction factor equation is proposed for the turbulent flow of viscoelastic fluids using the Oldroyd B model. The resulting expression is valid from the Newtonian to the maximum drag reduction regime.

PHENOMENOLOGICAL MODEL

In the present work, the phenomenological model developed by Gioia and Chakraborty [1] is extended for the viscoelastic Oldroyd-B model. This model is a combination of the upper convected maxwell (UCM) model with the solvent contribution. The UCM model is described as:

$$\lambda\dot{\tau_p} + \tau_p = \eta_p\dot{\varepsilon}, \tag{1}$$

where λ, η_s, τ and $\dot{\varepsilon}$ are the relaxation time, polymer viscosity, shear stress and strain rate respectively. Assuming a scale analysis of the equation (1) such as $\lambda\tau_p\omega + \tau_p \approx \eta_p\varepsilon\omega$, with frequency scale as $\omega \approx 1/t$, the shear stress can be expressed as:

$$\tau_p \approx \frac{\omega\eta_p}{1+\omega\lambda} \tag{2}$$

Equation (2) represents the polymer stress equation. The solvent stress contributions (τ_s) is given by $\tau_s \approx \omega\eta_s$ (η_s is the solvent viscosity). Therefore, the total shear stress would be:

$$\tau_T \approx \tau_p + \tau_s \approx \frac{\omega\eta_p}{1+\omega\lambda} + \omega\eta_s \tag{3}$$

Following the lines of [2] to obtain Kolmogorov's microscales for the Oldroyd-B model, two conditions must be met: 1- balance between the inertial and the viscous effect ($Re \sim 1$), and 2- dissipation of the input energy at viscous scale ($\varepsilon \sim \tau_T\omega$). Using these two, one could find the following equations for the ω and velocity at Kolmogorov's microscale.

$$\beta\left(\frac{1+\omega\lambda}{1+\beta\omega\lambda}\right)\frac{u^2}{\nu_s\omega} \approx 1 \tag{4}$$

$$\frac{U^3}{L} = \varepsilon = \left(\frac{\omega\eta_p}{1+\omega\lambda} + \omega\eta_s\right)\omega \tag{5}$$

Here, ν_s, u, U and L are the solvent kinematic viscosity, Kolmogorov's velocity scale, integral velocity and integral length scale, respectively. Also the parameter β is defined as $\beta = \eta_s/(\eta_s+\eta_p)$.

Finally, defining the solvent Reynolds number as $Re = \frac{UL}{\nu_s}$, and Deborah number as $De = \frac{\lambda U}{L}$, equations (4) and (5) can be solved for ω_k and u_k as follows:

$$\omega_k^2\left(\frac{1+\beta\omega_k\,De}{1+\omega_k De}\right) = \beta Re \tag{6}$$

$$\frac{u_k}{U} = \sqrt{\frac{\omega_k}{Re\,\beta}\left(\frac{1+\beta\omega_k\,De}{1+\omega_k De}\right)} \tag{7}$$

*Corresponding author. E-mail: doac@mecanica.coppe.ufrj.br.

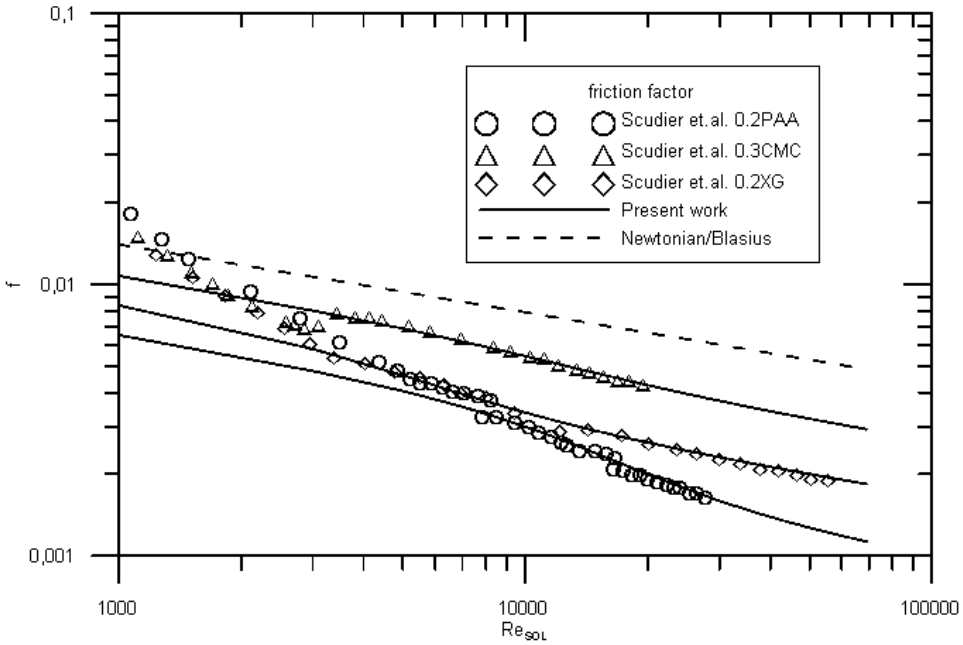

Figure 1: The predictions of the friction factor equation for the visco-elastic fluids compared with experimental data.

According to the phenomenological model of [1], the wall shear stress in pipe can be expressed as $\tau \sim \rho u_k U$. Therefore, the friction factor will be

$$f = \frac{2\tau}{\rho U^2} = \alpha \frac{u_k}{U} = \alpha \sqrt{\frac{\omega_k}{Re\,\beta}\left(\frac{1+\beta\omega_k\,De}{1+\omega_k De}\right)} \tag{8}$$

Figures (1) shows the predictions of the this friction factor, compared with the experimental data of [3]. Here the horizontal axis is the Reynolds based on the wall viscosity. As evident, this simple friction predicts the behaviour of such a complicated fluid successfully. It must noticed that the cases shown here did not reach to the maximum drag reduction limit.

As evident in Equation (8), for the case $De = 0$ this equation reduces to the well-known Blasius equation for the Newtonian fluids ($f \propto Re^{-1/4}$). On the other hand, for $\beta \ll 1$, $De > 1$ and $\omega > 1$, the equation (8) reduces to:

$$f_{MDR} \propto \sqrt{\frac{1}{Re}} \tag{9}$$

This result is similar to the empirical equation proposed in [4] for the maximum drag reduction, and also by Virk's asymptote.

BLOOD RHEOLOGICAL MODELING: UNCERTAINTY QUANTIFICATION OF THE REGRESSION CALIBRATED PARAMETERS

Christos Psevdos[1], George Makrigiorgos [2], Yannis Dimakopoulos [1*], John Tsamopoulos[1]
[1]Department of Chemical Engineering, University of Patras, Patras, Greece
[2]Chemical and Biomolecular Engineering Department, University of California, Berkeley, USA

The following work presents a start-to-finish procedure for performing uncertainty quantification tasks on a tensorial differential hemorheological model that accounts for blood thixotropy, elasticity and viscoplasticity, utilizing open-source tools that researchers and professionals can expect to use with relative ease. This study is based on a specific model but can also provide a detailed roadmap for conducting uncertainty quantification related tasks on similar models encountered in several areas of science and engineering.

INTRODUCTION

Being a complex suspension of various types of cells and proteins, blood demonstrates a profoundly non-Newtonian rheological behaviour [1]. Due to its importance in human physiology, this behaviour has been under heavy scrutiny over the last decades, resulting in the development of multiple rheological models that describe it from different aspects and to various degrees of accuracy. Despite the undeniably great effort put into developing such models, there seems to be a relatively small number of works focused on validating their ability to discriminate between healthy and pathological cases via means of sensitivity analysis (SA). This is especially true for the more complex models that encompass a large number of adjustable parameters in order to accurately depict the changes in blood shear and normal stresses as well as in viscosity under a plethora of varying conditions. Unlike simple constitutive models, whose few parameters are usually acquired directly from experimental data, the tuning of most multi-parametric differential models relies on some form of regression. While this procedure aids greatly in selecting a suitable set of parameters for the given experimental conditions, it provides no readily available information about their statistical properties (distribution shape, confidence intervals, etc.). This lack of information discourages the usage of powerful and widely available SA tools, which, no matter how sophisticated, are heavily reliant on such knowledge [2]. In this work, we present a methodology of conducting uncertainty quantification (UQ) tasks on flows utilizing a thixo-elastoviscoplastic hemorheological model [3,4] that has been calibrated through Least-Squares Regression (LSR) on steady-state and transient experimental data of blood under different shear regimes.

ESTIMATING PARAMETER DISTRIBUTIONS FROM REGRESSION DATA

The data utilized for the LSR of the model parameters originate from three types of experiments, namely: simple shear steady-state, rectangular shear step, and triangular shear step. Accordingly, the shear stress calculated by the model under these experimental conditions is fitted on the aforementioned data. It should be noted that the model also outputs the normal stress along with a blood structure parameter, both of which indirectly affect the shear stress profiles.

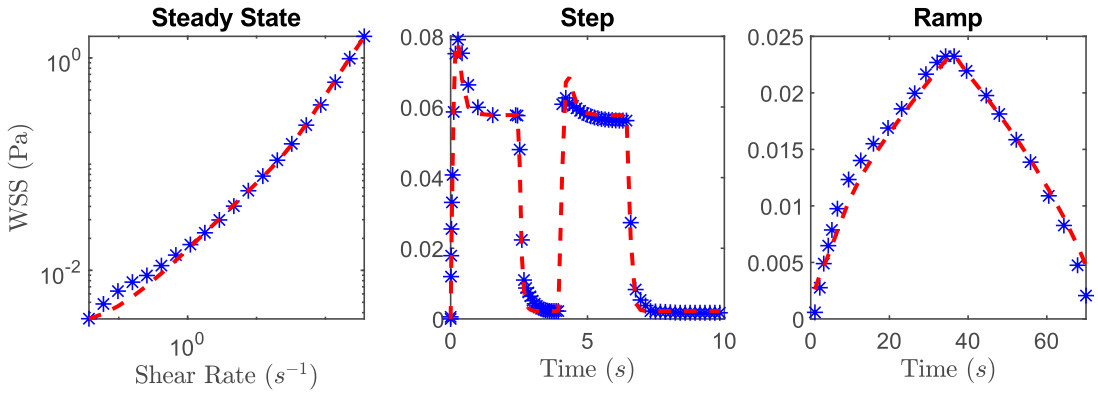

Figure 1: Model predictions (red) vs. experimental data (blue) after calibration with LSR

When performing LSR, it is possible to calculate the estimated parameters' variances, under the assumption that the model error is independent and normally distributed [5]. As expected, the usage of such assumptions leads to a crude approximation of the parameters' probability distributions (PDs). Nevertheless, this is the only source of information on the uncertain parameters' PDs, it is therefore imperative to improve these estimates if they are to be used for SA purposes.

Bayesian Inference (BI)

BI enables the update of *prior* knowledge of uncertain parameters as more data becomes available (*evidence*). In our case, the prior PDs are considered to be gaussian, characterized by the variance that has been computed from the LSR results.

*Corresponding author: **dimako@chemeng.upatras.gr**

The same experimental data used for the LSR serve as the evidence. Using the same data to obtain a first estimate of the PDs and then improve them may seem paradoxical, but the logic is very similar to solving a system of nonlinear equations using an iterative method that requires an initial guess of the solution: The experimental data are first used to perform the LSR and derive the prior PDs. Then, utilizing both the data and the priors, the posteriors are calculated through BI. All computations regarding the BI are carried out using the UQLab Matlab toolbox [6], which offers a user-friendly interface to perform such tasks without requiring from the user to be familiar with the complex mathematical concepts involved.

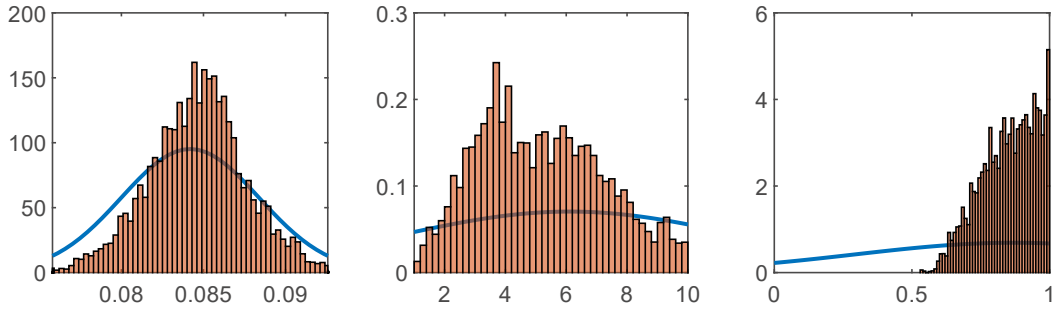

Figure 2: Prior (solid line) and posterior (histogram) PDFs for 3 of the model parameters

GLOBAL SENSITIVITY ANALYSIS (GSA)

Having extracted the PDs of the uncertain parameters, we opt to perform GSA via variance-based methods, to quantify their impact on model predictions. The first step in this endeavour is deciding which model outputs are to be studied (termed Quantities of Interest – QoIs) and the conditions under which the study will take place. Obviously, conditions similar to those encountered in the experimental data used for LSR have to be avoided since it is expected that highly identifiable parameters (parameters that showed minimal variance during LSR) will also be deemed as the most important by GSA. Instead, it is of more substance to perform the GSA under steady-state and transient extensional flow regimes, allowing for the evaluation of model fidelity in drastically different conditions to the ones it has been calibrated on. As for the QoIs, we consider all 3 model outputs.

The next step lies in choosing the most suitable method. The PDs calculated through BI indicate a strong correlation between some of the model parameters. We choose to proceed with Analysis of Covariance (ANCOVA), whose results offer a relatively approachable and clear interpretation [7]. The main disadvantage of ANCOVA is that its current realizations only take into account first-order effects, leaving out the interaction effects that occur due to the model's structure. Luckily, the magnitude of parameter correlation effects on the variance of the output is shown to be minimal, meaning that we can safely utilize methods designed for GSA of models with uncorrelated parameters. We calculate the 1st order and Total order Sobol' indices for each parameter in the set of conditions discussed previously, presenting a clear view of their effects on the variation of the QoIs.

Surrogate Models - Metamodeling

Variance-based methods require a relatively large number of model evaluations in order to produce accurate results. This feature can be problematic when the simulation is computationally expensive, resulting in prohibitively long runtimes to perform a single analysis. A possible solution is to use data from a small number of model evaluations in order to develop a much simpler model that sufficiently mimics the original model's behaviour. This obstacle can be overcome by deriving a data-driven mapping between the predicted QoIs and the uncertain parameters, based on polynomial chaos expansions of the original model and using it to perform the analysis. We utilized this approach to great effect, reducing the total runtime of all the analyses performed from a few days to overnight, achieving an almost 10-fold time saving (including the time needed to train the PCE surrogates).

FROM MICROSTRUCTURE TO RHEOLOGY OF SOFT DENSE SUSPENSIONS

Nicolas Cuny*[1], Romain Mari[1], and Eric Bertin[1]
[1]Université Grenoble Alpes,CNRS,LIPhy,38000 Grenoble,France

Summary Our work aims to develop a constitutive model allowing for the description of the rheology of soft dense suspensions below and above jamming. While most attempts to get such a constitutive model are purely phenomenological ones, based on symmetries like frame indifference, we developed such a constitutive model from the particle-level dynamics, using statistical physics tools to get a non-linear tensorial equation linking the stress tensor to the strain-rate and vorticity tensors. The coefficients appearing in this equation are expressed in terms of particle-level parameters. We are thus able to describe the behaviour of dense suspensions under simple shear deformation and to get predictions on various rheological protocols.

CONTEXT

Soft dense suspensions, as microgels for example, cover a large spectrum of materials made of soft particles immersed in a liquid phase. Although the nature of those solid particles can be very different, dense suspensions share some common rheological properties under simple shear. We distinguish two density regimes for the rheology of those materials. For low enough density, particles at rest have enough space to organize themselves without developping contact one with another. Applying shear to the material, the latter flows with a viscosity decreasing with the shear-rate, a phenomenon known as shear-thinning[1]. When increasing the density, particles have to overcome elastic energy barriers to move and the material thus exhibits a yield-stress: for shear-stress above this threshold materials behave as solid materials whereas overcoming this yield-stress makes the materials flow according to the Herschel-Bulkley law linking stress and shear-rate[2]. The transition density between these two regimes is known as the jamming density.

Establishing an evolution equation for the stress tensor as a response to a given time-dependent deformation is of great importance in order to describe the flow of such systems. Most attempts to obtain a constitutive model are phenomenological. They are typically based on symmetries, such as frame indifference[3, 4, 5], and while usually motivated by a microscopic physical picture, they do not directly relate the parameters they rely on to microscopic (i.e., particle-level) quantities. The goal of our work is to derive a constitutive model directly from the microscopic dynamics.

METHOD

In this work we are interested in getting such a constitutive model starting from the particle dynamics in order to connect the microscopic particle properties to the rheology. We assume two-dimensional, athermal and overdamped particles interacting one with another by radial contact repulsion forces only. We consider the influence of fluid through a Stokes drag and the external deformation of the material is assuming to generate a velocity field $\mathbf{U}^\infty$ in the fluid. The gradient of this velocity field is assumed to be homogeneous, for simplicity.

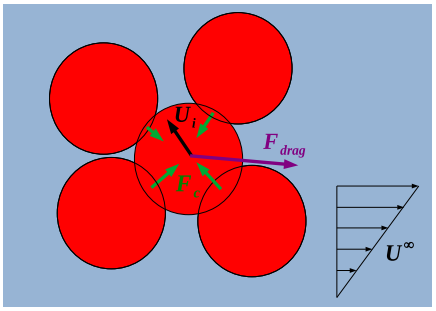

Figure 1: Illustration of the microscopic model used to describe our material.

Inspired by some similar work on hard sphere suspensions[6], we write the equation of conservation of the N-body probability density function associated to this microscopic description. We derive from the latter an equation on the pair correlation function g, thus reducing the number of variables of the equation, g being only function of $\mathbf{r}$ the center-to-center vector between two particles. However, this equation is not closed because of the presence of the three-body correlation function $g^{(3)}$. We solve this problem using a simple and standard closure relation between $g^{(3)}$ and g, known as the Kirkwood closure[7]. In order to translate this equation describing the microscopic structure into an equation on the macroscopic rheology, we use the virial relation linking the stress-tensor to the pair-correlation function.

Then, using a parameterization of the pair correlation function in terms of the deviatoric part $\mathbf{\Sigma}'$ of the stress tensor $\mathbf{\Sigma}$, we eventually obtain a tensorial equation on $\mathbf{\Sigma}$ that we can decompose into two equation. The first equation is a Ginzburg-Landau-type tensorial equation on $\mathbf{\Sigma}'$ with advection terms satisfying frame indifference. This first equation is

*Corresponding author. E-mail: nicolas.cuny@univ-grenoble-alpes.fr.

coupled to a non-linear evolution equation for the pressure, thereby providing a full characterization of the stress tensor. The pressure equation has a fixed point which depends on density and shear rate. All the coefficients appearing in these two coupled equations are expressed in terms of microscopic parameters, through a systematic approximation scheme motivated by observations made in LAMMPS simulations. Note that the cases below and above the jamming density have to be considered separately. One of the originalities of our approach is that it naturally provides a non-linear term in the tensorial equation on $\mathbf{\Sigma}'$ that induce a yield-stress behaviour above jamming.

The resulting macroscopic equations describing the rheology are quite promising. We display in Fig. 2 some preliminary results. By numerically integrating the macroscopic equations above the jamming density, we get a time evolution of the shear-stress qualitatively similar to what one can observe in simple shear experiments, with the presence of an overshoot before the shear-stress tends to some stationnary value. Turning to the steady-state rheology, we obtain a flow-curve with the presence of a yield-stress and a linear dependence of shear-stress with shear-rate for low shear-rate, resulting in a Bingham-fluid behavior.

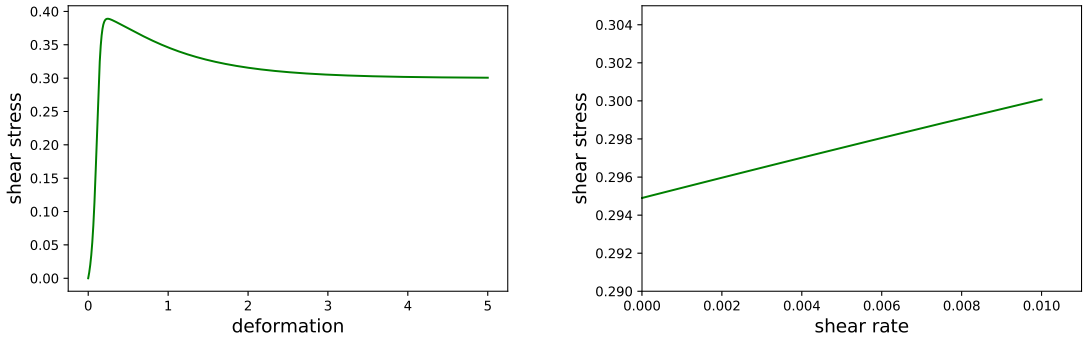

Figure 2: *(left)* Evolution of the shear-stress with time for a shear-rate of 10^{-2} and area fraction of 1.3 obtained by numerical resolution of our model, *(right)* Flow-curve obtained by numerical resolution of our model for area fraction of 1.3. Shear-rate is adimensionned by $f_{\text{el.}}/3\pi\eta a^2$ and stress by $f_{\text{el.}}/a^2$, where $f_{\text{el.}}$ is the caracteristic elastic contact force, a the radius of particles and η the viscosity of the Newtonian fluid.

IMMERSED METHOD AND ANISOTROPIC MESH ADAPTATION FOR MULTIPHASE FLOW DYNAMICS

Thierry Coupez[1],
[1]CEMEF, Mines-ParisTech, Sophia Antipolis, France

Summary CFD is still strongly depending on the construction of meshes. Moreover, the flow equations are containing different scales filtered by the local mesh size, adding difficulties to tailor accurately the mesh a priori. For complex flow situation as liquid gas or fluid structure interaction involving discontinuity in the primal variables the sensitivity to the mesh can become a bottleneck. Mesh adaptation is a way of to simplify both the initial mesh construction, as the a posteriori dependency of solution to the mesh. In order to simplify CFD simulation, in particular for multiphase flows, we present here a general approach that combines immersed method and anisotropic mesh adaptation with an error estimate original technique in view to embed completely the mesh construction into the solution calculated with a stabilised optimally Finite element solver. . .

INTRODUCTION AND CONTEXT

A wider use of numerical simulation is still depending on meshing and adaptive meshing capabilities when complex geometry, multi-domain, moving interface and multiphase flow are involved. This task becomes more and more difficult when it is combined with a posteriori adaptive meshing or/and dealing with moving interfaces and boundary layers and also when running on massively parallel computers. In order to overcome the lack of flexibility of the common body fitted method, the alternative proposed here, is based on an implicit representation of the interfaces by a local distance function using a hyperbolic tangent filter. Therefore, the geometries can be interpolated and contribute to the numerical error which is detected by an a posteriori error estimator technique. This approach favours the full usage of anisotropic adaptive meshing techniques providing an optimal capture of the interfaces within the volume mesh, whatever is the complexity of the involved geometries. From the flow solver side, unstructured meshes with highly distorted elements (however solution aligned) need to rely on a robust solution framework. The interface condition transfer is enforced by following the immersed boundary/volume (IVM) methodologies for fluid/fluid and or fluid/structure interaction. The proposed multiphase flow solver, including a related local level set technique is based on a stabilized finite element method (VMS with residual based stabilisation) that can afford with anisotropic meshing with high aspect ratio elements. For transient flow a complete stabilization approach including the interface stabilization term and the dynamic of the subscales will be proposed with a quasi-optimal calculation of the stabilization parameter. The error estimation and the metric calculation will be presented and various application examples will be proposed.

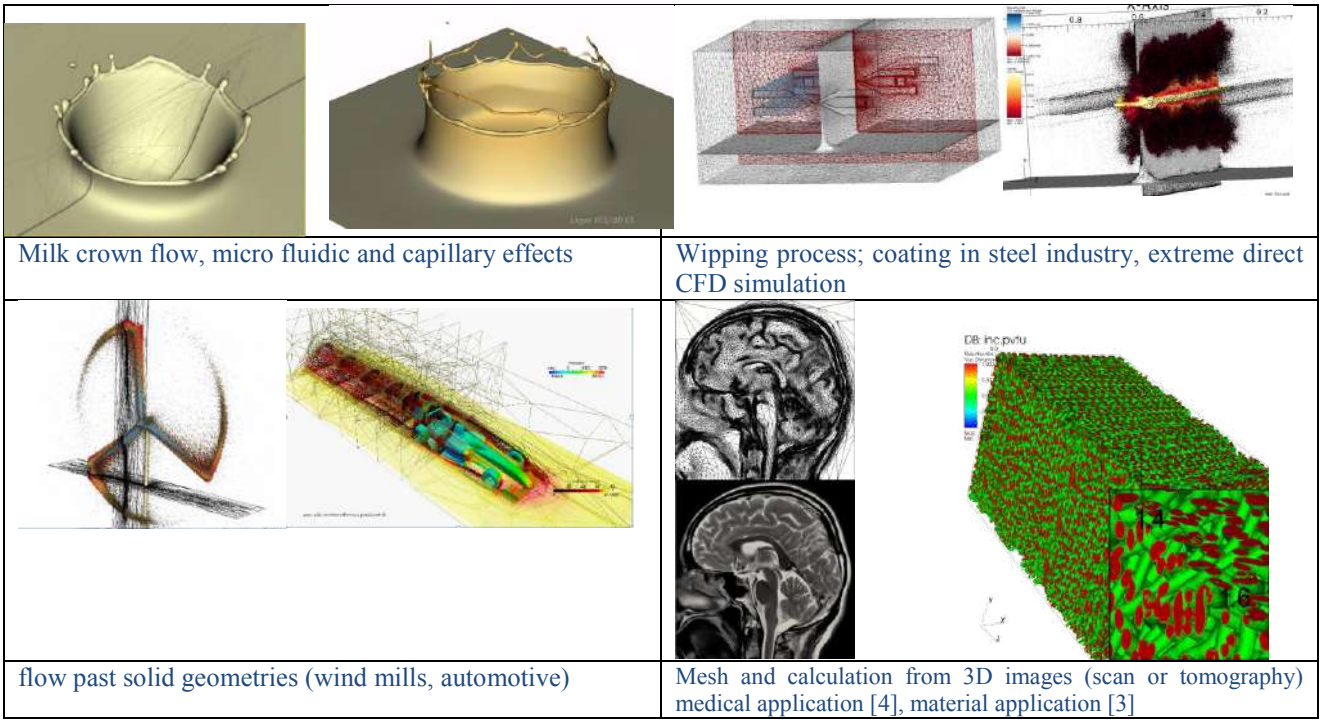
METRIC STABILITY APPROXIMATION ERROR AND IMMERSED METHOD

The presentation will follow the following issues:
First we go back to the definition of a metric field, denoted by M, following the technique introduced in [5] to calculate a unit continuous metric field associated with a certain class of meshes. Moreover, we will show that the metric provides a very simple recovery operator and it enables on one hand, to retrieve the classical interpolation error and to elaborate an approximation erro on the other hand. We focus on the numerical calculation of the incompressible Navier-Stokes equation by using a mixed velocity pressure formulation with equal order finite element, mainly P1/P1 at this stage because of the current unstructured anisotropic meshing technology, well established for straight simplex elements and being under development for curved tetrahedra. The stabilisation theory gives rise to a unique framework to fulfil the infsup condition and to control the convective term. In brief, we introduce the Petrov-Galerkin formulation in which the stabilisation parameter providing the stability condition will depend on h, a mesh size field. In fact, and it is part of the novelty of this presentation, by using a duality argument (looking at the adjoint problem) h can be defined as the square root of the trace of the metric, $\text{trace}(M)^{-1/2}$, which is clearly dominated by the smallest height of elements and consequently opening clearly the door to anisotropic meshing. Indeed, the added artificial diffusion is controlled by the smallest width of the element and consequently at the least possible level.

This leads to a convergence between the residual based stabilisation method and the approximation error estimate.
The basic idea of immersed method is to represent the interfaces between domains or phases by an implicit function, here the zero value of a level set function. The parameter jumps are averaged by a smooth Heaviside function depending on thickness parameter [2]. The classical way to choose the thickness is to account for a certain number of elements. We change this point of view by fixing a priori the thickness and expecting that the mesh adaptation will give the right number of element we need to achieve the best possible accuracy. Here again it requires a well suited metric construction that must combine the solver error and the interpolation of the geometry? exactly evaluated by the a posteriori error estimate of the interpolated or calculated distance fields.

APPLICATIONS

In order to show the calculation possibility of this approach, several examples will be presented in order to explain the methodology and results obtained for challenging applications. We will focus on a target industrial process in which the spatial scales and time scales can be considered as extreme for the actual state of the art. The process is the coating of an iron strip by a liquid (molten zinc) with impacted by a very high speed air jet. It combines high Reynolds effect with high capillary effect with air liquid interaction and liquid solid interaction with jump in rheology parameters at more than one to thousands. Moreover, the target layer of the liquid film is about ten micron meters related to the meter which is the scale of the entire process and effectively, the meshes can vary from one to the micron meter in certain direction.



Milk crown flow, micro fluidic and capillary effects

Wipping process; coating in steel industry, extreme direct CFD simulation

flow past solid geometries (wind mills, automotive)

Mesh and calculation from 3D images (scan or tomography) medical application [4], material application [3]

Figure 1. Various applications using a monolithic approach for fluid-fluid or fluid-solid with a single adapted mesh and the implicit representation of interfaces. Dynamic anisotropic parallel mesh adaptation.

CONCLUSIONS

Immersed method can be combined with anisotropic mesh adaptation providing a unique mesh on which a monolithic formulation can be written for various multiphase applications. In that case, the geometries involved can be integrated in the error estimate for Navier stokes by using an extension of our earlier work on the metric construction.
The inherent thickness of the interfaces of immersed methods can be well controlled a priori and the mesh adaption process delivers the optimal mesh size in the vicinity of the interfaces. Clearly, this artificial thickness gives rise to certain regularity to the solution that aims to ensure a mesh convergence. 3D complex applications show the potential of this framework.

REDUCED ORDER METHODS FOR FLUID-STRUCTURE INTERACTION PROBLEMS

Gianluigi Rozza*[1], Monica Nonino[1], and Francesco Ballarin[1]
[1]SISSA, International School for Advanced Studies, Mathematics Area, mathLab, Trieste, Italy

Summary This work focuses on overcoming the problem of slowly decaying Kolmogorov n-widths in the framework of reduced basis method (RBM). This slow decay represents an additional difficulty since it decreases the efficiency of reduction methods: this happens, for example, in transport dominated problems. In this work we implemented a preprocessing procedure, to be carried out during the offline phase of the reduced basis method; this procedure has been introduced in [1], and it has mainly been studied in the 1D framework. We tested its performance in the 2D setting, on three different test cases [2], the representative one being a transport dominated FSI problem. The multiphysics problem has been solved with a monolithic procedure; future work will concern partitioned procedures for RBM in FSI [3].

INTRODUCTION AND MOTIVATION

Let $\mathcal{M}$ be the solution manifold of the problem of interest, embedded in some normed linear space $(X, ||\cdot||_X)$. A fundamental assumption of the reduced basis method is that $\mathcal{M}$ can be well approximated by a sequence of finite dimensional linear spaces. This assumption translates in the mathematical hypothesis that the Kolmogorov n-width D_n of $\mathcal{M}$ decays fast, as a function of n, being D_n defined as:

$$D_n(\mathcal{M}, ||\cdot||_X) = \inf_{E_n} \sup_{p\in\mathcal{M}} \inf_{q\in E_n} ||p-q||_X,$$

where E_n is any linear subspace of X of $\dim(E_n) = n$. Unfortunately hyperbolic or convection dominated problems represent quite a challenge for the reduced basis method, since a linear setting is not suited to represent complex phenomena such as shocks or wave propagation. Our investigation focuses on transport dominated problems, and it aims at overcoming the problem of the slow decay of D_n by implementing an additional feature in the offline phase of the reduced basis method, called 'preprocessing procedure', which has been first introduced in [1].

FLUID–STRUCTURE INTERACTION PROBLEM FORMULATION

Given the time interval $[0, T]$, we have a thin (1D) structure Σ_t, situated at the top and at the bottom of a 2D rectangle filled with a newtonian fluid Ω_t^f. We adopt an Arbitrary Lagrangian Eulerian (ALE) formulation for the coupled problem, which now reads as follows: find $\mathbf{u}_f(\cdot;t)\colon \Omega_t^f \to \mathbb{R}^2$, $p_f(\cdot;t)\colon \Omega_t^f \to \mathbb{R}$ and $d_s(\cdot;t)\colon \Sigma \to \mathbb{R}$ such that:

$$\begin{cases} J\rho_f(\partial_t \mathbf{u}_f + F^{-1}(\mathbf{u}_f - \partial_t d_f \mathbf{e}_y)\cdot\nabla)\mathbf{u}_f) - \mathrm{div}(J\sigma^f F^{-T}) = \mathbf{b}_f & \text{in } \Omega^f \times [0,T], \\ \mathrm{div}(JF^{-1}\mathbf{u}_f) = 0 & \text{in } \Omega^f \times [0,T], \\ \rho_s h_s \partial_{tt} d_s - c_0 \partial_{xx} d_s + c_1 d_s = -\sigma^f \mathbf{n}\cdot\mathbf{n} & \text{in } \Sigma, \end{cases}$$

subject to the coupling conditions:

$$\begin{cases} d_f = d_s & \text{in } \Sigma_t, \quad \text{continuity of the displacement} \\ \mathbf{u}_f = \partial_t d_s \mathbf{e}_y & \text{in } \Sigma_t, \quad \text{continuity of the velocity.} \end{cases}$$

Here σ_f is the fluid Cauchy stress tensor and d_f is a suitably defined extension of the structure displacement on the whole domain. F is the gradient of the map T that maps the reference fluid domain Ω^f to the current domain Ω_t^f, and J is the determinant of F. Figure 1 shows three snapshots for the fluid pressure, for which we clearly see that there is a dominating transport phenomenon.

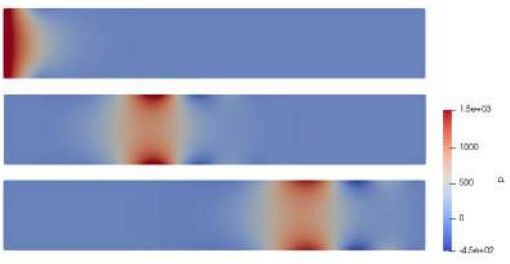

Figure 1: Fluid pressure p_f behaviour at different timesteps. The peak of the pressure wave (red) propagates in the domain: we have a transport dominated behaviour.

*Corresponding author. E-mail: gianluigi.rozza@sissa.it

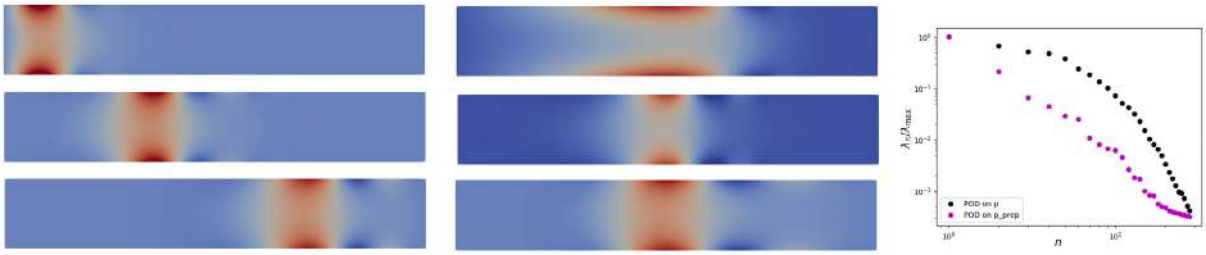

Figure 2: Example of snapshots of p_f before (left column) and after (central column) the preprocessing. The peaks of the waves are all aligned at the same point. Right column: comparison of the rate of decay of eigenvalues given by POD on $\mathcal{M}_{p_f}$, and on $\mathcal{M}_{p_f,\mathcal{F}}$.

PREPROCESSING PROCEDURE

For the sake of the simplicity of the exposition we briefly outline the preprocessing procedure applied on the solution manifold $\mathcal{M}_{p_f}$ for the fluid pressure p_f. The idea is to build a family of *smooth* and *invertible* maps $\mathcal{F} = \{F : \Omega^f \to \Omega^f\}$ s.t. $\forall t \in [0;T]$, $\exists F_t \in \mathcal{F}$ s. t.

$$\mathcal{M}_{p_f,\mathcal{F}} = \{p_f(F_t^{-1}(\cdot), t); t \in [0;T]\}$$

has a smaller Kolmogorov n-width.
We outline in the following the entire algorithm:

Reduction method with the preprocessing procedure
Offline phase

- FEM: compute M snapshots $p_f(t_1), \dots, p_f(t_M)$, where $\{t_1, \dots, t_M\}$ is a discretization of the time interval $[0, T]$;
- $\forall n = 1, \dots, M$, compute a preprocessing map $F_n^{-1}\colon \Omega^f \to \Omega^f$ that alignes the peaks of the wave at the same point;
- run a POD on the set of preprocessed snapshots and obtain N basis functions $\{\Phi_1^{p_f}, \dots, \Phi_N^{p_f}\}$, N small.

Online phase

- at timestep $n+1$ look for coordinates $\{\alpha_k^{n+1}\}_{k=1}^N$ and a suitable map $F_{n+1} \in \mathcal{F}$ such that $p_f(\cdot, t^{n+1})$ is well approximated by:

$$p_N^{n+1} = \sum_{k=1}^{N} \alpha_k^{n+1} \Phi_k^{p_f} \circ F_{n+1}.$$

RESULTS

In the test case considered results show that we are able to gain an important improvement in the efficiency of the RBM by adding the preprocessing of the snapshots in the offline phase. This is shown in Figure 2, where we have plotted the decay of the eigenvalues returned by the POD, normalized by the greatest eigenvalue, against the number N of modes, with (magenta) and without (black) the preprocessing procedure. As we can see the results are promising: with just $N = 5$ modes we obtain an improvement of more than one order of magnitude, and with just $N = 15$ modes we reach a magnitude of 10^{-3} thanks to the preprocessing procedure. Other remarkable results have been obtained for other two test cases, as detailed in [2]. The undergoing extension of this work is in collaboration with Efthymios Karatzas (NTUA Athens, Greece), and Yvon Maday (Sorbonne Université, Paris, France).

A COMPUTATIONAL FLUID DYNAMICS STUDY OF BLOOD FLOWS IN THE HUMAN LEFT HEART

Luca Dede'*[1], Alberto Zingaro[1], Marco Fedele[1], and Alfio Quarteroni[1,2]
[1]MOX–Modeling and Scientific Computing, Department of Mathematics, Politecnico di Milano, Milano, Italy
[2]Institute of Mathematics,E´cole Polytechnique Fédérale de Lausanne,Switzerland (Emeritus Professor)

Summary We propose a computational fluid dynamics study of blood flows in the human left heart. Our model considers the incompressible Navier-Stokes equations in the ALE framework where domain displacement is prescribed, or possibly obtained from cardiac electromechanics simulations. We use the Variational Multiscale method within the Large Eddy Simulation paradigm to model turbulence, the finite element method for space discretization, and BDF formulas for time discretization. Our numerical study highlights that, in healthy hearts and normal conditions, the cardiac blood flows are transitional and characterized by complex and peculiar features.

INTRODUCTION

Recent years have seen an increasingly use of *in-silico* studies to assess and characterize blood flows in the cardiovascular system. While hemodynamics of arteries, its interaction with the arterial walls (both in physiological and several pathological conditions) have been extensively addressed, numerical studies of blood flows in the human heart as an organ are less common. Indeed, the focus is often on a single chamber – typically the left ventricle or atrium [4, 11] – or, even more commonly, numerical studies target valvular dynamics and their pathological conditions [2, 7]. As a matter of fact, computational fluid dynamics of the heart is a very challenging task [1, 8], mainly due to: i) the very large and complex deformations of the cardiac chambers during the heartbeat; ii) the topological changes occurring in the domain wherein the equations are defined when valves open and close; iii) the very large pressure gradients across chambers and changes occurring over time, mainly related to cardiac electromechanics and valve dynamics [10]; iv) the blood flow dynamics exhibiting multiscale behavior both in space and time, thus namely calling for a intensive use of computational resources. Moreover, as blood flows in the heart can reach in physiological conditions Reynolds numbers around 5000 or above, cardiac hemodynamics is characterized by a distinguishing behavior; this can be further exacerbated in pathological conditions or simply under exercise. As a matter of fact, blood flows in the left heart appear to be neither laminar nor fully turbulent, but rather transitional. The latter is a peculiar condition that has received so far a limited attention in computational fluid dynamics studies of internal flows.

We propose in this work a detailed computational fluid dynamics study of the whole left heart including the left atrium and ventricle, the mitral and aortic valves, the pulmonary veins, and the aortic root. In particular, we characterize the blood flows developing in a healthy heart that operates in normal conditions; our study takes into consideration the whole heartbeat and, for a more complete assessment, several heart cycles. In addition, we study blood flows through meaningful fluid dynamics indicators in cardiac configurations and working conditions that are departing from the reference one.

MATHEMATICAL MODELS

As our focus is on blood flow dynamics in the heart chambers, we model it by means of the incompressible Navier-Stokes equations in the Arbitrary Lagrangian Eulerian (ALE) framework, wherein the displacement of the chambers' walls in prescribed. In this respect, we consider two approaches. In the first one, the endocardium wall displacement is assigned compatibly with the behavior of the chambers' volume vs. time that is depicted in a typical Wiggers diagram. In the second one, the wall displacement is instead obtained as output of electromechanical simulations [9] for which the Navier-Stokes equations are surrogated by 0D models of the chamber and the whole circulation.

Accounting for the valves and their dynamics is an essential part of blood flow modeling in the heart. In particular, for the left heart, the aortic and mitral valves take a leading role in shaping cardiac hemodynamics. In this work, we account for valve leaflets and their dynamics by means of surrogate models. In addition, we use the resistive method [5] to mimic the effect of the valves on the blood flows; this boils down adding to the Navier-Stokes equations a (zero order) term that weakly enforces blood velocity adherence to that of the valve leaflets.

NUMERICAL METHODS

In principle, turbulence should be taken into account in cardiac hemodynamics. This can be done according to Direct Numerical Simulations, for which the whole range of spatio-temporal scales of the velocity and pressure fields are numerically solved by using space and time discretizations that fully match Kolmogorov lengths. Instead, Large Eddy Simulations (LES) directly solve only the largest scales of the velocity and pressure fields, whereas the smaller scales are modeled. In this work, we define a sub-grid model for LES by means of the Variational Multiscale (VMS) method [6], a stabilization technique for the Navier-Stokes equations that: i) yields inf-sup stable approximations when considering the same finite element spaces for velocity and pressure fields; ii) controls numerical oscillations in flow regimes at locally large Reynolds numbers; and iii) provides LES modeling of turbulence.

*Corresponding author. E-mail: luca.dede@polimi.it

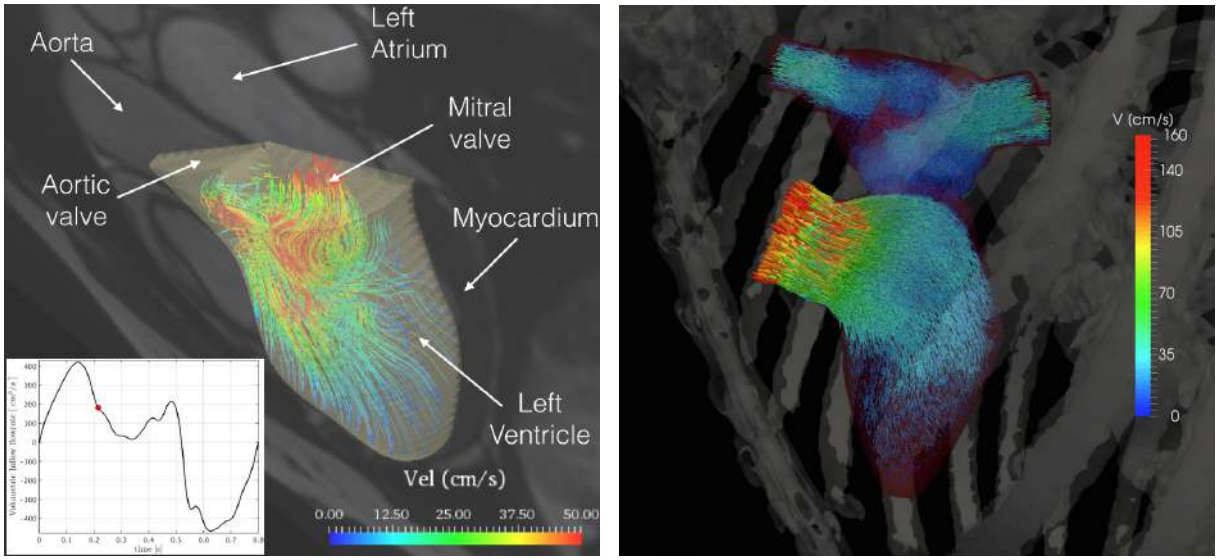

Figure 1: Blood flows in a patient-specific left ventricle during diastole (left) and in an idealized left heart during systole (right); colors highlight the magnitude of the velocity field.

Our numerical approximation scheme is therefore based on the VMS-LES method for which we consider space discretization by the finite element method and semi-implicit or implicit schemes involving BDF formulas for the time discretization [6]. We consider for our VMS-LES formulation both quasi-static and dynamic modeling of the sub-grid (fine) scales of the velocity and pressure fields.

NUMERICAL RESULTS AND DISCUSSION

We use our VMS-LES computational models to assess and characterize the blood flow dynamics in a realistic left heart in normal conditions (Figure 1). Our study involves both instantaneous and phase averaged quantities, other than several clinically meaningful fluid dynamics indicators as kinetic energy, fluctuating kinetic energy, enstrophy, and Wall Shear Stress [3]. In particular, we confirm that the blood flow regime in a healthy heart is transitional or nearly turbulent. Indeed, fully developed turbulence does not sustain for a significant amount of time during the heartbeat; moreover, we highlight that blood flows are characterized by instabilities and complex interactions of vortexes involving different spatio-temporal scales. In this respect, we finally critically compare and assess the numerical performances of VMS-LES formulations with quasi-static and dynamic approximations of sub-grid scales.

HIGH FIDELITY COMPUTATIONAL FRAMEWORK FOR CONTROL CO-DESIGN OF UTILITY SCALE WIND FARMS: REDUCING THE LEVELIZED COST OF ENERGY VIA ADVANCED TURBINE CONTROLS

Xiaolei Yang[1], Christian Santoni[2], and Fotis Sotiropoulos*[2]
[1]Institute of Mechanics, Chinese Academy of Sciences, Beijing, China
[2]Department of Civil Engineering, College of Applied Sciences, Stony Brook University, Stony Brook, United States

Summary A large-eddy simulation approach incorporating advanced turbine controls is developed for control co-design of large wind farms. The methodology is employed to evaluate the effect of individual blade pitch control (IBPC) on the fatigue loads of wind turbine blades for 1) a finite-size wind turbine array, 2) an infinitely-large wind turbine array and 3) a utility-scale wind farm. It is shown for the first time that IBPC can significantly reduce the fluctuations of blade bending moments for all three cases.

INTRODUCTION

With the increase in penetration of wind energy in the world's energy portfolio, the levelized cost of energy (LCOE) has to be further reduced for wind energy to remain competitive [1]. Advanced turbine controllers have the potential to greatly reduce the LCOE by lowering the capital and operational expense of wind farms. However, such advanced controllers have to be designed taking into account the nonlinear aerodynamics, hydrodynamics (for offshore wind) and structural dynamics of wind turbines that cannot be taken into account by existing engineering design tools (e.g. FAST, Bladed, HAWC2, etc.). The goal of our work is to use high-fidelity numerical simulations to develop and evaluate the performance of advanced turbine controllers for the nonlinear dynamics of wind turbines following the concept of the control co-design (CCD) approach [2], which integrates turbine control in the design process of wind turbines and wind farms.

In general, at wind speeds below rated, the turbine controller varies the generator torque to keep the angular velocity at optimum to maximize the power extraction (region 2). For higher wind speeds, region 3, the blades are pitched to mitigate mechanical and electrical loads. As it rotates, the turbine blade loads fluctuate due to the heterogeneity of the wind speed at the rotor caused by the vertical shear and large-scale turbulence structures. The collective blade pitch control (CBPC) commonly used in Region 3 cannot reduce such load fluctuations as it pitches all the blades together to the same angle. On the other hand, the individual blade pitch control (IBPC) has the potential to reduce the blade load fluctuations. However, the effectiveness of the IBPC on reducing blade load fluctuations cannot be tested easily in the field. As a first step towards developing advanced turbine controllers using the CCD approach, we evaluate the performance of IBPC on reducing blade load fluctuations using high-fidelity simulations.

METHODOLOGY

Large-eddy simulations of a finite-size turbine array, an infinitely large turbine array and a utility-scale wind farm have been performed using the Virtual Flow Simulator (VFS) code [3, 4]. Fully developed turbulent flow is applied at the inlet of the finite-size turbine array with periodic boundary conditions along the crosswind direction. For the infinitely large wind turbine array, periodic boundary condition was given along the streamwise and crosswind direction. The utility-scale wind farm consists of 100 turbines located in a complex terrain at Pleasant Valley, Minnesota, United States. The wind turbines are modeled using the actuator line/surface for the rotor and nacelle. For all cases the turbines operate in Region 3, where the blade pitch control is activated. Both CBPC and IBPC are tested for each case. A description on the IBPC of the EOLOS turbine can be found in [7]. VFS has been successfully validated and applied to utility-scale wind farm including the Horns-Rev offshore wind farm [5] and a wind farm in complex terrain [6] located in Vantage, Washington, United States.

RESULTS

Figure 1 show the contours of the instantaneous downwind velocity and the temporal variation of the blade bending moment for the finite-size turbine array case. As seen, the fluctuations of the bending moments are reduced significantly by using IBPC. Similar levels of reductions on the fluctuations of the blade bending moments are observed for the infinitely-large turbine array case as shown in figure 2. Figure 3 show the results from the utility-scale wind farm case. The wind blows from left to right in figure 3. The bending moments from two turbines, turbine T98 located in the upwind and the turbine T11 located deep in the farm, respectively, are examined. Reduction on the fluctuations of blade bending moments are observed for both turbines, although the temporal variations of the bending moment of T11 are more complex because of the terrains and the upwind turbine wakes.

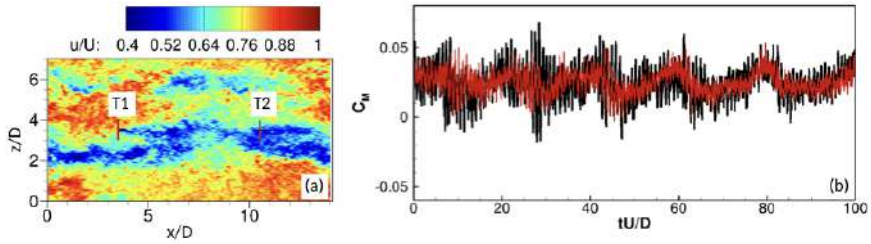

Figure 2: Infinitely-large turbine array case for (a) contour of instantaneous downwind velocity at turbine hub height and (b) temporal variations of blade bending moments. In (b), the black and red lines are for CBPC and IBPC, respectively.

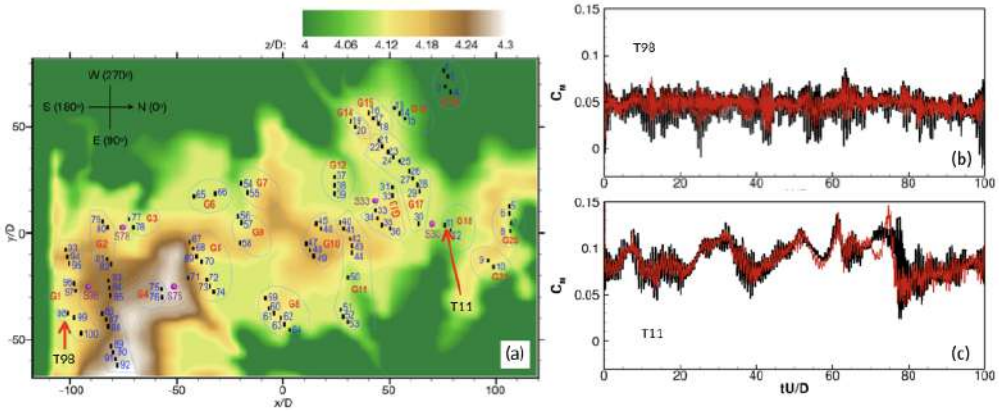

Figure 3: Utility-scale wind farm case for (a) contour of terrain elevations, and (b) and (c) temporal variations of blade bending moments for turbines T98 and T11, respectively. In (b) and (c), the black and red lines are for CBPC and IBPC, respectively.

CONCLUSIONS

We have performed large-eddy simulations with actuator line/surface to model the wind turbine rotor to investigate the effect of IBPC on the blade bending moment fluctuations. A finite-size turbine array case, an infinitely large turbine array case and a utility-scale wind farm case are considered. Comparison of the IBPC against CBPC have shown that the fluctuations of the bending moment are reduced. This study suggests the possibility of using IBPC to reduce the maintenance cost of wind farms, shows the importance of considering IBPC in the design process of wind farms and paves the way for significant reduction in the levelized cost of energy by incorporating advanced control strategies in large wind farms.

EFFECT OF ASPECT RATIO ON THE INTERACTION BETWEEN WING-TIP VORTEX AND VORTEX SHEDDING AT LOW REYNOLDS NUMBER

Jawahar Sivabharathy Samuthira Pandi[1], Yuvraj[1], and Sanjay Mittal*[1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Kanpur, INDIA

Summary The effect of aspect ratio ($0.5 \leq AR \leq 10$) on the flow past a rectangular wing with NACA 0012 section is studied numerically. The angle of attack of the wing to the freestream is 14 deg and the Reynolds number based on its chord is 1000. The flow is steady for very low AR. Cellular shedding is observed on the wing for higher AR; one cell for $AR \leq 6$ and two cells for larger AR. The dislocations at the boundary of the cells as well as the end-cell structures are studied. Very interesting variations in flow structure with change in AR are observed. Contrary to the flow at large Re, $\overline{C_D}$ increases with an increase in AR, and it is lower than that for an airfoil.

INTRODUCTION

The wing is the main lifting body in an aircraft. The parameters that govern the flow of wing are: Reynolds number (Re), angle of attack (α), section of the wing (airfoil profile), wing planform and aspect ratio (AR). An interesting feature of the flow is the wing-tip vortex which is generated due to the pressure difference between the lower and upper surface of the wing. The wing-tip vortex leads to downwash and reduction in the effective angle of attack. There have been several experimental and computational studies on flow past wing, but mostly at larger Re. Taira and Colonius [1] studied the flow past flat plate low aspect ratio wing at $0^o \leq \alpha \leq 60^o$ for $Re = 300$ and 500. It was found that the wing-tip vortex plays a significant role in the stability and shedding frequency of the primary vortices. Jantzen *et al.* [2] carried out numerical and experimental investigation on pitching rectangular flat plates for $AR = 2$ and 4 at $Re = 300$. It was found that the fully developed wing-tip vortex significantly affects the vortex structures in the flow. The vortices remain relatively close to the surface at the mid-span for $AR = 2$ due to the stronger influence of the wing-tip vortex while for $AR = 4$ the vortices remain separated. Six wing planforms were investigated by Chen and Qin [3] at various α and $Re = 10^5$. The tapered wing with high sweep angle experiences a drastic stall. On the other hand the low sweep angle wing exhibits a gradual stall. Among all the planforms considered in their study the Zimmerman planform achieves high lift to drag ratio. The present study is conducted on rectangular wing in the pre-stall regime and for $\alpha = 14^o$. The governing flow equations are solved using a stabilized finite element method [4].

EFFECT OF ASPECT RATIO

At $Re = 1000$, strong vortex shedding is observed for an end-to-end/infinite wing. However, a wing-tip vortex is expected to weaken the shedding. Figure 1 shows the $Q(= 0.1)$ iso-surface for the fully developed unsteady flow for various aspect ratio. The presence of wing-tip vortex is evident from the picture. The wing-tip vortex completely suppresses the vortex shedding and steady flow is observed for $AR = 0.5$. Cellular vortex shedding is observed at larger AR. The frequency of vortex shedding recorded by probes placed at certain spanwise locations is used to identify the cell structures in the flow. One cell structure is observed for $AR \leq 6$ whereas two cell structures are observed for larger AR. The primary vortices observed in $AR = 10$ are almost parallel to the wing-axis at the mid-span of the wing (Figure 1(c)).

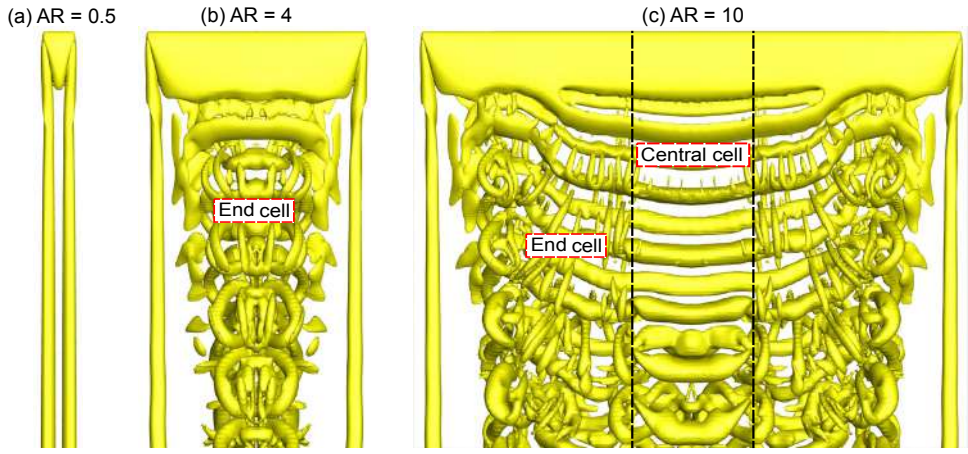

Figure 1: Flow past wing at $Re = 1000$ and $\alpha = 14^o$: $Q(= 0.1)$ iso-surface for various AR. Also marked in the picture are the cellular structures. The dashed black line in (c) is used to show the central cell region.

*Corresponding author. E-mail: smittal@iitk.ac.in

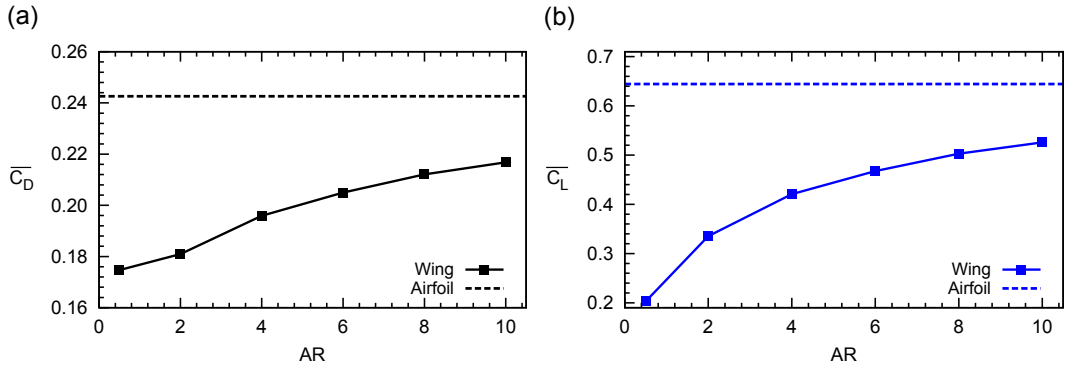

Figure 2: $Re = 1000$ and $\alpha = 14^o$: variation of (a) $\overline{C_D}$ and (b) $\overline{C_L}$ with AR. Also plotted is the data of NACA 0012 airfoil.

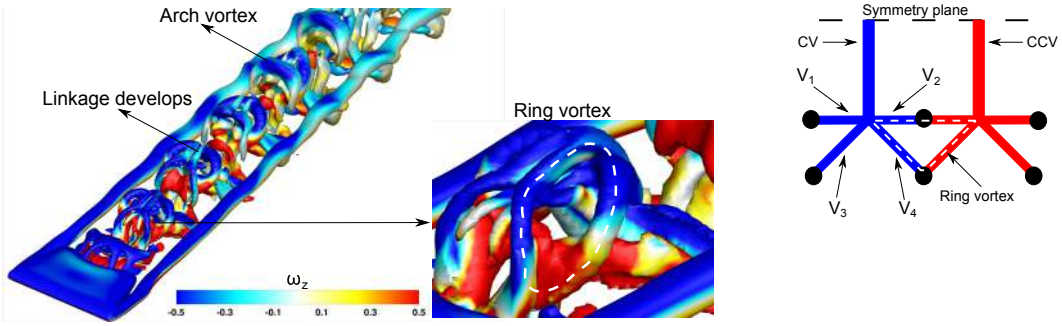

Figure 3: $Re = 1000$, $\alpha = 14^o$ and $AR = 2$: Q(= 0.1) iso-surface of the flow colored with spanwise vorticity. A schematic representation of the connectivity observed between the spanwise vortices is also shown. CV and CCV represents clockwise and counter-clockwise vortices.

The variation of aerodynamic force coefficient with AR is presented in figure 2. Also plotted is the data for airfoil. Both $\overline{C_D}$ and $\overline{C_L}$ increase with an increase in AR. According to the finite wing theory, at large Re, the wing-tip vortices create downwash which are responsible for induced-drag and lowering the lift. The effect of wing-tip vortex decrease with increase in AR of the wing. Therefore, for large Re wing, the induced-drag as well as the total drag experienced by a wing reduces with increase in AR. In contrast the present study shows that drag of wing is lower than the airfoil and with an increase in AR the value approaches airfoil. It is found that the unsteadiness in the flow increases with AR.

Q iso-surface colored with spanwise vorticity (ω_z) and schematic representation of the connectivity between the spanwise vortices is presented in figure 3 for $AR = 2$. The primary vortices (CV and CCV), near the wing-tip, split into four branches V_1, V_2, V_3 and V_4 and form a ring vortex. The ring vortex present on either side of the symmetry plane forms an additional linkage as the vortex is shed. This results in the formation of arch vortex in the far wake. Unlike $AR = 2$, the ring vortex in $AR = 4$ (please refer figure 1(b)) collapses and forms loop like structure in the far wake. The undulations in wing-tip vortex is dominant in $AR = 2$ (Figure 1 and 3). For $AR \geq 6$, the vortices split into V_1 and V_2 and forms linked vortex structure. Details of the Reynolds stress distribution across the span, along with the variation of strength of wing-tip vortex for various AR and dislocations observed at large AR will be presented in the conference. In addition the data obtained for steady flow simulation will be compared with the unsteady results.

CONCLUSIONS

The flow past rectangular wing for various aspect ratio placed at $Re = 1000$ and at $\alpha = 14^o$ has been numerically investigated via a stabilized finite element method. The wing-tip vortex weakens the vortex shedding, specially near the wingtip. The $AR = 0.5$ flow remains steady. Cellular vortex shedding is observed for wing with larger AR. Two cell vortex shedding occurs for $AR > 6$. The drag coefficient of wing is found to be lower than the airfoil. Ring vortex structures are seen for $AR \leq 4$. The linkages between the counter-rotating vortices at the end cell show complex structures for $AR \geq 6$.

DEFINING A NEW VARIABALE-ORDER TEMPERED FRACTIONAL DERIVATIVE FOR MODELING TURBULENT FLOWS

Pavan P. Mehta[1] andGeorge Em Karniadiakis *[1]
[1]Division of Applied Mathematics, Brown University, Providence, United States of America

Summary A fractional derivative is used to model non-local effects in turbulence. However, as the second moment does not exist, tempering the Levy distribution leads to finite moments, and thus, a new tempered fractional derivative free from all assumptions is formulated for non-local modelling of turbulent flows. The total shear stress is modelled here as opposed to commonly modelled unclosed terms in turbulence modelling; also, working in wall units does not introduce any coefficient for representing the shear stresses. We demonstrate this new concept for turbulent Couette flow, where the error found in total shear stress is very low compared to results of direct numerical simulations.

INTRODUCTION

In an experiment for a rotational flow, for long enough time, the tracer particles exhibited Levy distribution [1]. In the context of non-Fickian law, it is a super-diffusion phenomenon where the spatial scales spreading are larger than the temporal scales, a rather non-local phenomenon. Furthermore, Kolmogorov's 5/3 spectra described the inertial ranges [2]. The Hurst scaling, $H = 1/3$ with fractional Brownian motion, a stochastic process models the Kolmogorov's 5/3 spectra [3], while, a tempered fractional derivative, with a fixed order and a tempering length models the entire spectra [4]. Despite this evidence of non-locality in turbulence, modelling has mostly received local treatment. Thus, in this study a non–local closure model is established with the use of fractional derivatives.

Fractional derivatives were first introduced by Leibniz soon after their integer counter parts [5]. Chen speculated that the Reynolds Stresses behaved as fractional laplacian of fixed order 2/3 [6]. Our group extended it to a variable-order fractional derivative to address the multiple scales [7][8], whilst discovering a *universal scaling law*. A variable-order as a function of the distance from the wall, provides further robustness to model it, as the energy containing wave-numbers will vary. Furthermore, our group also modelled the total shear stress as opposed to Reynolds stresses using one sided Caputo fractional derivative for turbulent Couette flow [7]; the advantage of working in wall units was emphasised as modelling required no additional scaling coefficient. In the present study, a new approach for the fractional Reynolds-averaged Navier-Stokes equations (F-RANS) is established for turbulent flows.

TEMPERED FRACTIONAL TWO SIDED DERIVATIVE

For an infinitely long turbulent Couette flow, the Reynolds-averaged Navier-Stokes (RANS) equations reduce to (1) in wall units [7]. Upon integration and using the fact that $\overline{uv}^+ \approx 0$ near the wall, while $U^+ \approx y^+$, the constant of integration is then elevated as $\left.\frac{\partial U^+}{\partial y^+}\right|_{y^+=03} = \tau^+ = 1$, thus we have (2).

$$\frac{\partial}{\partial y^+}\left(\frac{\partial U^+}{\partial y^+} - \overline{uv}^+\right) = 0^33 \tag{1}$$

$$\frac{\partial U^+}{\partial y^+} - \overline{uv}^+ = \tau^+ = 1^33 \tag{2}$$

The newly formulated definition for tempered F-RANS is given by (3), where λ_l and λ_r are associated with the tempering length of the left- and right-sided fractional derivative, respectively (4,5). The total shear stress is modelled directly with the use of these derivatives (3). As $\lambda \to 0$, the tempered definition becomes a standard fractional Caputo derivative. Tempering the Levy distribution ensures that the second moment exists, thus a finite variance, as observed in real world phenomenon. In contrast to a sharp cut-off, the exponential term appearing in (4,5) is smoother cut-off.

$$\left({}_0^C D_{y^+}^{\alpha(y^+),\lambda_l} - 3\,{}_{y^+}^C D_{2Re_\tau}^{\alpha(y^+),\lambda_r}3\right)U^+ = \tau^+ = 1; 3\alpha(y^+) \in (0,1], 3\lambda_l, \lambda_r \in [0,\infty)3 \tag{3}$$

$${}_0^C D_{y^+}^{\alpha(y^+),\lambda_l} U^+ = 3\frac{1}{\Gamma(1-\alpha(y^+))}3\int_0^{y^+} 3(y^+ - \xi)^{-\alpha(y^+)}3U^+(\xi)'3e^{-\lambda_l(y^+-3\xi)/Re_\tau}3d\xi 3 \tag{4}$$

$${}_{y^+}^C D_{2Re_\tau}^{\alpha(y^+),\lambda_r} = 3-\frac{1}{\Gamma(1-\alpha(y^+))}3\int_{y^+}^{2Re_\tau} 3(\xi - y^+)^{-\alpha(y^+)}3U^+(\xi)'3e^{-\lambda_r(\xi 3-3y^+)/Re_\tau}3d\xi \tag{5}$$

The variable order ($\alpha(y^+)$) appearing in (3) is found by employing the fractional – physics informed neural networks [9] for a fixed tempering length on both sides ($\lambda_l = \lambda_r = \lambda$) as shown in [7] with the aid of velocity data from direct

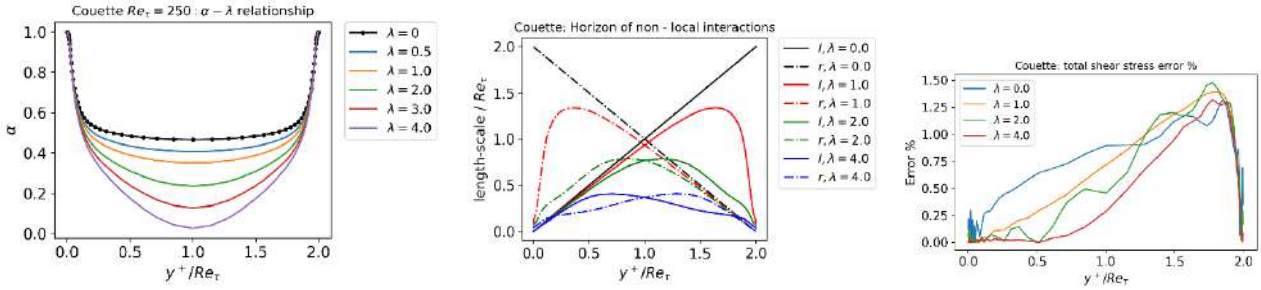
numerical simulations (DNS) of turbulent Couette flow [10]. The horizon of non-local interactions is computed by decomposing the integral appearing in (4, 5) into a sum of integrals over infinitesimally small domains. The fraction of the original domain associated with first n-integrals computed to 0.99999 times the original value of the fractional derivative is where the non-local interactions take place. Since the fractional order is a variable, the horizon then can be determined for all points in space.

RESULTS

Beyond the viscous sub-layer, the flow is non-local as indicated by the low fractional order values (figure 1(a)). While in the viscous sub-layer the fractional order (α) converges to unity, irrespective of the tempering length (figure 1(a)), as the flow is dominated by the *local interactions* governed solely by the viscous forces. Thus, the horizon near wall for both left- and right-length-scale are negligible (figure 1(b)). However, for $\lambda = 0$ (standard definition) the horizon shows other than zero; this is due to the fact that the second moment for a Levy distribution does not exists, or in other words, there could be infinite jump lengths, hence it takes the information of the entire available domain. However, for real applications there are only finite jump lengths and tempering the Levy distribution thus addresses real world phenomenon. The linear regions observed for $\lambda = 13$(figure 1(b)) indicates that the tempering length is too large to have an effect and it returns to a standard Levy distribution. The error in total shear stress is appreciably low (figure 1(c)) for any given tempering length. The error is primarily due to the use of first-order schemes for evaluating the integral (4, 5).



(a) (b) (c)

Figure 1: Results for Couette flow, $Re_\tau = 250$ (a) The effect of tempering length (λ) over fractional order (α). (b) Horizon of non-local interaction for various tempering lengths (λ), here, the length-scale, l and r are associated with the left- and right-sided fractional derivative, respectively. (c) The percentage error in total shear stress when compared to DNS [10] for various λ.

One of the major advantages of the tempered F-RANS is that it can be readily applied to unbounded flows, where the tempering length is tuned for the free stream beyond which non-local interactions do not occur. This has useful consequences, as a large number of engineering flows also uses free stream boundary conditions, such as a flow over an aerofoil. In a nutshell, this new model represents a generalized approach applicable to any type of flow.

CONCLUSIONS

Turbulence is governed by both local and non-local phenomenon, thus it has been cumbersome on a mathematical standpoint to address it with proper mathematical objects. The introduction of a variable–order fractional derivative is thus highly suitable to address such complex phenomenon, while tempering ensures its variance is finite, mimicking the real world. As a first step its merit is shown for turbulent Couette flow, however, this model does not inherently use any assumptions, thus this new definition is a general one and can be applied to any flow, which includes unbounded flows too.

USING COMPUTATIONAL PHYSISCS TO PERFORM QUALITY CONTROL OF 4D FLOW MRI SYSTEMS

Franck Nicoud*[1], Thomas Puiseux [2], Anou Sewonu[2], Ramiro Moreno[2] andSimon Mendez[1]
[1]IMAG, Univ Montpellier, CNRS, Montpellier, France
2ALARA Expertise, Strasbourg, France

Summary A numerical pipeline is developed to compute the outcome of Phase Contrast Magnetic Resonance Imaging, a modality able to characterize the hemodynamics of large vessels under *in vivo* conditions. The methodology requires solving the Navier-Stokes (for the flow dynamics) and Bloch (for the spins magnetisation) equations simultaneously and makes use of a semi-analytic solution for the Bloch equations as well as an original particle re-injection strategy. After being validated, the methodology is applied to the pulsatile flow within an *in vitro* experiment designed to represent the typical flow features in the largest vessels of the cardiovascular system. The simulated Magnetic Resonance Images compare favourably with the experimental and computational unsteady 3D flow and allows explaining some of the systematic errors related to Phase Contrast Magnetic Resonance Imaging.

MOTIVATION

Hemodynamics in large vessels is closely related to several diseases of the cardiovascular systems such as aneurysm generation and rupture, stenosis or thromboembolism. Time-resolved 3D phase-contrast Magnetic Resonance Imaging (or 4D Flow MRI) is a promising tool for non-invasive blood flow quantification under *in vivo* conditions [1]. As for its morphological counterpart, the basic principles of 4D flow MRI arise from the magnetic properties of the protons. This imaging technique takes advantage of the nuclear spin of the hydrogen atoms, widely present in tissues like vessels or blood, and consists in analyzing the response of the spins after they are excited by the Radio-Frequency signal (RF) and immersed in a properly designed time-dependent and inhomogeneous magnetic field (the so-called MRI sequence). If morphological MRI is now part of the clinical routine, the 4D flow modality still belongs to clinical research and requires more assessment/characterization before it can be widely used by non-experts. Several artifacts have been identified which are related to either MRI principles (e.g.: partial volume effect, acceleration induced error, intra-voxel phase dispersion, spatial misregistration) or technology (e.g.: Gibbs artifacts, magnetic field distortion, coil sensitivity profile). A way to better understand and quantify these measurement errors consists in numerically simulating the MRI experiment in order to reconstruct synthetic images in which technological errors are either absent or controlled. On top of identifying the effects of the different types of errors on the velocity measurements, the ability to build *in silico* 4D flow images could serve as a support to optimize MRI sequences at low price. The main objective of this work is thus to develop an efficient numerical pipeline able to represent the outcome of actual 4D flow MRI systems.

METHODS

The macroscopic behaviour of a collection of spins is governed by the Bloch equations [2] which read

$$\frac{d\mathbf{M}}{dt} = \gamma \mathbf{M} \times \mathbf{B} + \frac{M_0 - M_z}{T_1}\mathbf{e_z} - \frac{M_x}{T_2}\mathbf{e_x} - \frac{M_y}{T_2}\mathbf{e_y} \qquad (1)$$

where $\mathbf{B}(t) = B_0\mathbf{e_z} + \mathbf{B_1}(t)$ is the magnetic field generated by the MRI system to excite the spins, γ is the gyromagnetic ratio which equals 267.513×10^6 rad $s^{-1}T^{-1}$ form the hydrogen atoms, T_1 and T_2 are the longitudinal and transverse relaxation times of the tissues and $\mathbf{M}(t) = M_x\mathbf{e_x} + M_y\mathbf{e_y} + M_z\mathbf{e_z}$ is the magnetization vector expressed in the cartesian basis $(\mathbf{e_x}, \mathbf{e_y}, \mathbf{e_z})$. When submitted to the stationary magnetic field $B_0\mathbf{e_z}$, the spins rotate around the z-axis at the Larmor angular frequency γB_0 and generate the magnetization vector $M_0\mathbf{e_z}$. A common approach is to solve the Bloch equations within the Eulerian framework in order to avoid solving for a very large number of particles and reduce the computational time [3], [4]. Since the equations for fluid mechanics are most often solved within the Eulerian framework as well, this choice also simplifies accounting for the spins convection by the blood motion when phase contrast MRI is dealt with. In turn, the Lagrangian formalism offers the possibility to use analytical solutions for the Bloch equations once the MRI sequence has been properly idealized [5], but requires to track a large number of particles to avoid spurious images due to spins density inhomogeneity. In any case, the usual strategy is to decouple the magnetization and fluid problems, solving and storing the information from the Navier-Stokes equations in a first step and solving Eq. (1) in a second round [6]. This approach is well suited for stationary cases but requires a huge amount of data storage when dealing with pulsatile flows. Indeed, the 4D flow MRI acquisition requires simulating several (a few tens or hundreds) cardiac cycles; it turns out that, to the best of our knowledge, no *in silico* 4D MRI of complex flow configuration has been presented so far.

* Corresponding author. E-mail: franck.nicoud@umontpellier.fr

An Eulerian (fluid) - Lagrangian (spins) simulation strategy is proposed to generate *in silico* the kind of images that a 4D Flow MRI system would produce. The data storage issue is avoided by solving the Bloch equations on Lagrangian particles with "on the fly" coupling to the flow solver. In this view, each Lagrangian particle represents a sample of spins (isochromat) transported by the turbulent velocity field, as computed by Large Eddy Simulation with proper sub-grid scale model [7]. For each isochromat, a semi-analytic formulation of Eq. (1) is then used to speed up the computation of the magnetization vector. Eventually, an original volume particle reinjection strategy is implemented that mimics the periodic removal of the transverse magnetization (the RF-spoiling in actual 4D Flow MRI) and allows keeping the particle distribution homogeneous in space, independently of the number of particles considered. This allows generating non-spurious images while tracking less than 50 particles per voxel while 1000 was recently recommended [6] in the classical framework without reinjection. The pipeline was implemented in the in-house YALES2BIO solver (imag.umontpellier.fr/~yales2bio/) dedicated to the computation of blood flows [7-8] and verified by considering several elementary configurations (e.g.: [10]).

RESULTS AND CONCLUDING REMARKS

The *in vitro* flow phantom designed and studied by computational fluid dynamics (CFD) as well as experimentally by 4D flow MRI in [11] was then simulated by the numerical pipeline proposed. As illustrated in Fig. 1 (left), the configuration includes an aneurysm, a curved channel as well as a bifurcation; it produces, under pulsatile conditions, a complex flow with several features typical of the cardiovascular hemodynamics (recirculation, periodic turbulence generation, shear layer, boundary layer separation, jetting flow). Fig. 1 (middle) shows that the outcome of the proposed pipeline (the reconstructed hemodynamics from *in silico* 4D flow MRI) is in very good agreement with the phase-averaged CFD velocity field. Note that the latter is very well correlated (approx. 97 %, [11]) with the flow measurement obtained with an actual imaging system (1.5 T Siemens) operated at University Hospital of Toulouse-Rangueil. Fig. 1 (right) shows that the largest discrepancies are located near the exit of the collateral vessel. A deeper analysis suggests that this large error site is a consequence of neglecting acceleration in 4D Flow MRI sequences (not shown). Overall the discrepancies are larger for the experimental 4D Flow MRI, reflecting that the experimental noise due to magnetic field inhomogeneities and off-resonance effects are not present in the MRI simulations. This illustrates how the pipeline can be used to better understand and control the different sources of errors when measuring the hemodynamics of large vessels.

Summary Simulation-based biomedical engineering relies on a variety of physical and physiological models to represent the reality. In addition to macro-scale biomechanics, models extend now increasingly to cellular and molecular scales. For prediction of blood damage, the averaged red blood cell behavior is modeled in the form of coupled partial differential equations, exhibiting certain similarities to macroscopic models of constitutive behavior of microstructured fluids. The numerical approaches also follow the paths established in the viscoelastic flow community, from stabilized finite element formulations to logarithmic transformation of primary variables.

INTRODUCTION

Modeling and computational analysis play an increasingly-important role in bioengineering, particularly in the design of implantable ventricular assist devices (VAD) and other blood-handling devices. Numerical simulation of blood flow and associated physiological phenomena has the potential to shorten the design cycle and give the designers important insights into causes of blood damage and suboptimal performance [1,2].

METHODOLOGY

A set of modeling techniques is presented which are based on stabilized space-time finite element formulation of the Navier-Stokes equations. An Arbitrary Eulerian Lagrangian (ALE) moving mesh approach combined with a limited remeshing technique – shear-slip mesh update method – are used to represent the movement of the rotating parts of the pump. Alternate methods that represent the rotating components in an averaged sense using a rotating frame of reference have been compared to the high-fidelity ALE approach, and showed adequate representation of the flow field at a greatly reduced computational cost [3].

Tensor morphology model

In order to obtain quantitative hemolysis prediction, cumulative tensor-based measures of strain experienced by individual blood cells must be developed; red blood cells under shear can be modeled as deforming droplets, and their deformation tracked along pathlines of the computed flow field. Originally, these models were based on integrating the evolution of the droplet shapes over a representative sample of pathlines. Although this approach has some advantages, such as the possibility to account for the tank-treading motion of the membrane, it was relatively inefficient, and it was difficult to provide adequate coverage of the entire flow volume. An efficient continuum-based approach was developed as an alternative, where a tensor field is undergoing an evolution in every part of the fluid domain. As such, this continuum representation of the RBC shape shows similarities to some common viscoelastic constitutive models (Fig. 1).

Log-morph transformation

A reformulation in terms of logarithm of the morphology tensor, analogous to the log-conf formulations which are finding use in flow rheology [4], is shown to improve the numerical behavior of the hemolysis quantification tools. This reformulation is able to represent the very sharp boundary and internal layers which tend to develop in the tensor field. Moreover, it guarantees by construction the positive definiteness of the conformation tensor, precluding the numerical difficulties normally associated with the local loss of such definiteness. A downside is that the morphology equation in the log-morph form becomes relatively complex.

Stabilized finite element formulation

A critical aspect is the proper stabilized formulation of this transport equation. Here, a Variational Multiscale (VMS) approach was found to be beneficial, allowing for the first time robust simulation of the blood cell deformation across the broad range of flow fields, including those found in actual devices which are of engineering and clinical interest.

Concentration equation transformation

Another area where reformulation of the governing equations may be useful is the hemoglobin concentration equation. Regardless of modeling approach to quantify release (source) of hemoglobin, local concentration and accumulation is governed by a strongly non-linear advection-diffusion-reaction equation. The standard form of such an equation does not guard against non-physical values of concentration, such as negative or extremely high concentrations which may result from numerical artifacts. A restating of the equation in terms of tailored functions of concentration [5] improves the numerical behavior, and often makes the model more suitable for model order reduction.

*Corresponding author. E-mail: behr@cats.rwth-aachen.de.

RESULTS AND CONCLUSIONS

The methods are applied to several rotary blood pump configurations. One of them is a simplified centrifugal pump, which was recently the subject of an FDA round-robin study. A second device undergoing computational analysis with these tools is a prototype centrifugal blood pump now in development and in clinical trials [6]. For both the FDA and the prototype pump, a variety of experimental data is becoming available, ranging from PIV-generated averaged flow fields, to the measures of hemolysis.

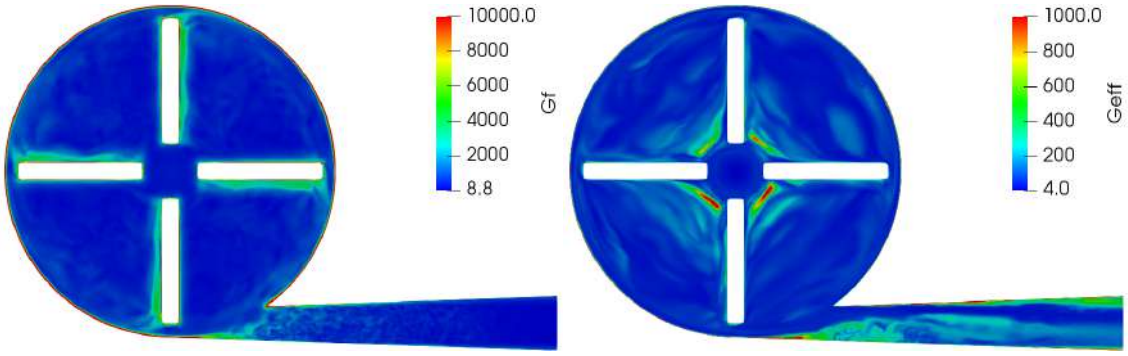

Figure 1. Actual shear rate in a cross-section of a simplified centrifugal blood pump (left) shows potential hemolysis areas but does not take into account the delay between flow shear stress and red blood cell deformation. The cell deformation is correlated to the effective shear rate in a morphology model (right). This more accurately identifies the areas where excessive shear and higher residence time combine to deform red blood cells, thus promoting pore formation and hemoglobin release.

HYBRID LEVEL-SET/EMBEDDED BOUNDARY NUMERICAL METHOD FOR THE SIMULATION OF SOLIDIFICATION/MELT PROBLEMS

Alexandre Limare*[1], Stéphane Popinet[2], and Christophe Josserand[1]
[1]Laboratoire d'Hydrodynamique de l'Ecole polytechnique, Institut Polytechnique de Paris, Palaiseau, France
[2]Institut Jean lerond d'Alembert, CNRS & Sorbonne Université, Paris, France

Summary In this paper, we present a novel way to represent the interface for two-phase flows with phase change. We combine a level-set method with an embedded boundary method and take advantage of both. This is part of an effort to obtain a numerical strategy relying on Cartesian grids allowing the simulation of complex boundaries with possible change of topology while retaining a high-order representation of the gradients on the interface and the capability of properly applying boundary conditions on the interface. This new numerical method is then applied to some validation test cases.

INTRODUCTION

Flows with moving interfaces between two phases are quite commonly encountered in engineering and fundamental fluid physics studies and are of interest to a wide community of researchers. Having a computational tool able to deal with such flows accurately and efficiently has been the goal that gave birth to several families of numerical methods which started with Harlow and Welch's marker and cell (MAC) method [1], Volume of Fluid [2] (VOF), phase field [3] and level-set methods [4]. Most of the time, in a two-phase flow simulation, one method is best suited, depending on the main properties of the flow: possible phase change, shear of the interface, complex topological changes of the interface (splitting/merging). This is because they treat the interface differently by construction. Thus, the development of numerical methods combining the best properties of the aforementioned techniques is still an open field of research. Levelset methods are for example known to provide simple access to geometric quantities while not exactly conserving mass, in contrast to VOF methods. This lead Sussman and Puckett [5] to combine a VOF method with a level-set in order to remove this limitation. Our work is the direct continuity of such endeavours. We developed a numerical approach combining a level-set function used as an embedded boundary method [6] for phase change simulations. We present a few preliminary results on validation test cases.

NUMERICAL METHOD

Let ϕ be a level-set function, whose zero level-set is a hypersurface which represents the interface Γ. Subscripts $_L$ and $_S$ will denote the liquid and the solid respectively. The equation describing the motion of the interface is the following:

$$\partial_t \phi + \mathbf{u_{pc}}|_\Gamma \cdot \nabla \phi = 0 \tag{1}$$

$\mathbf{u_{pc}}|_\Gamma$ is the phase-change velocity which is given by a Dirichlet boundary conditions on the interface, the so-called Stefan condition:

$$L_H \ \mathbf{u}_{pc}|_\Gamma = k_L \ \nabla T_L|_\Gamma - k_S \ \nabla T_S|_\Gamma \tag{2}$$

where L_H is the latent heat, k_i are the thermal diffusivities. The normal derivative of the temperature, are obtained by imposing the interface temperature following the relation:

$$T_\Gamma = T_m - \epsilon_\kappa \kappa - \epsilon_u u_{pc}, \tag{3}$$

where κ is the curvature of the interface, ϵ_κ is the surface tension coefficient and ϵ_u is the molecular kinetic coefficient. This condition consists of imposing the temperature of the interface to be the melting one, corrected by the Gibbs-Thomson (curvature term) and kinetic (velocity term) corrections [7].

A level-set approach requires solving the heat equation in a complex domain with Dirichlet boundary conditions on the interface Eq. (3), then computing the jump in the normal derivative of the temperature, and then extending this to the region around the front. The extension of the velocity off the interface is necessary to obtain a continuous field that can be used in Eq. (1). In our approach the level-set function is used as an embedded boundary method [6]. Thus, this can be seen as two-fluid approach where, from the perspectibe of each phase, the embedded boundary is the interface between the two fluids. Therefore each phase has its own set of variables. The embedded boundary method gives us the tools needed to compute high-order approximations of the gradients on the interface (Fig. 1(a)) and, Eq. (2) and Eq. (3) :

$$\nabla \phi|_\Gamma = \frac{1}{d_2 - d_1} \left(\frac{d_2}{d_1}(\phi_f - \phi_1) - \frac{d_1}{d_2}(\phi_f - \phi_2) \right) \tag{4}$$

In our method u_{pc} is a cell-centered velocity defined in both phases. The initial values on the interface centroids in red on Fig. 1(b) are given by relation (3) and the method of Chen *et al.* [8] is then used to extend the velocity off the interface. We use an iterative method to correct the cell-centered values u_{pc} (in black) so that their bilinear interpolation matches the correct interfacial boundary condition $u_{pc}|_\Gamma$.

Figure 1: Embedded boundary approach

TEST CASES

We validated our method with some test cases, such as 1D solidification, the stable solidification of a Gaussian bump and the melting of a starry-shaped ice particle. We show the evolution of the interface at different times on Fig. 2(a) and 2(b) . We are planning to do a proper stability analysis corresponding to the Mullins–Sekerka instability and we also would like to study dendrite growth and run a few cases combining solidification and convection.

ONLINE REDUCED-ORDER MODEL AND ITS APPLICATION ON ADJOINT-BASED MESH ADAPTATION FOR LARGE EDDY SIMULATION

Xiaodong Li*, Steven John Hulshoff, and Stefan Hickel
Department of Aerodynamics, Wind Energy, Flight Performance and Propulsion, Delft University of Technology, Delft, the Netherlands

Summary We present a mesh adaptation strategy based on adjoint method to improve the performance of Large Eddy Simulation (LES) so as to address the difficulties of mesh generation in high-fidelity simulations. The adjoint method is employed to facilitate Adaptive Mesh Refinement (AMR) by controlling local contributions to an physical quantity of interest (such as lift, drag). Since solving the adjoint problem for unsteady simulations requires the access to flow states, an online reduced-order model, which is implemented by an enhanced incremental singular value decomposition, is considered to tackle this issue instead of storing them. The ROM-enabled AMR approach is verified in a Burgers problem with a multiple-frequency forcing term compared to those from full-order flow solutions. Numerical results validate the efficiency and effectiveness of the ROM-enabled AMR approach for LES.

INTRODUCTION

Large Eddy Simulation (LES) has the potential to deliver reliable flow predictions for cases involving mixing layers, large pressure gradients or high unsteadiness. The main challenge of LES for practical applications is how to make its computing cost tractable while keeping a good accuracy of the Quantity of Interest (QoI), e.g. lift or drag. Constructing such meshes, however, usually involves experience and trial even for engineering experts. Adaptive Mesh Refinement (AMR) [1] provides the ability to automatically change the computational mesh, resulting in a considerable reduction of computing cost. Thus, it has been widely used to improve the computing efficiency. On the other hand, adjoint methods can be used to facilitate the AMR by connecting local mesh contributions with the error of approximating a QoI so that the adapted mesh can provide the highest accuracy per degree of freedom. Through doing this, a posterior estimation can be developed for AMR, which has been investigated largely in steady laminar and turbulent flow problems [2].

In unsteady simulations, the primal flow problem is advanced forward in time, while the adjoint problem needs to be solved backward in time. Due to the non-linearity of Navier-Stokes equations, flow states from LES are required for completely solving the adjoint problem. Unfortunately, the resources required to record these solutions would be very huge, even prohibitive, for practical problems. Hence, a Reduced-Order Model (ROM) is considered to address this difficulty, which will be elaborated in following sections.

AN AMR STRATEGY BASED ON ADJOINT METHOD AND ROM FOR LES

In present work, the Proper Orthogonal Decomposition (POD) is utilized to build ROM because POD is capable of extracting optimal low-dimensional bases, viz. POD modes, to represent the high-dimensional flow field while retaining important dynamic features of the full-order system [3]. The procedure of building a ROM is stated as follows, (i) POD analysis to obtain POD modes, (ii) computing the coefficients of ROM, and (iii) reconstructing the flow solution in a low-order space. In order to make it feasible for practical problems, the POD implemented by incremental Singular Value Decomposition (SVD) [4] is introduced to achieve an online ROM as shown in Algorithm 1. One improvement of this algorithm is that an enhanced step is added by truncating the number of selected POD modes on-the-fly as well (stated in Line 5).

Algorithm 1 Incremental weighted SVD

Input: $V \in \mathbb{R}^{n\times k}, \Sigma \in \mathbb{R}^{k\times k}, W \in \mathbb{R}^{m\times k}, c \in \mathbb{R}^{n}, \mathrm{tol}, \mathrm{tol}_{\mathrm{sv}}, \mathrm{nModes}$

1: **Get the dimension:** $k = \mathrm{nColumns}(V)$.
2: **Project of a new column into an existing space:** $d = V^{\intercal}c, \quad p = \|c - Vd\|_2$.
3: **Neglect the small projection** ($< \mathrm{tol}$)**.**
4: **Apply standard SVD analysis on an updated matrix** Q**:** $V_Q, \Sigma_Q, W_Q = \mathrm{SVD}(Q)$.
5: **Truncation 1: truncate on the selected number of POD Modes** (nModes)**:**
$k = \mathrm{nModes}, \quad \Sigma = \Sigma_{(1:\mathrm{nModes},1:\mathrm{nModes})}, \quad V = V_{(:,1:\mathrm{nModes})}, \quad W = W_{(:,1:\mathrm{nModes})}$.
6: **Truncation 2: neglect small singular values** ($< \mathrm{tol}_{\mathrm{sv}}$)**.**
7: **Re-orthogonalize the modes if necessary.**

The QoI used here is chosen as an volume-integrated function of flow variables. Variational Multiscale Method (VMM) is applied as a LES model and the error estimation is accomplished by representing the actual solution by resolved and

*Corresponding author. E-mail: X.Li-12@tudelft.nl.

unresolved scales. The error estimation is constrained on each element to form elemental error indicator by which the cell will be marked in whether to be refined or not. We use a mesh adaptation strategy to refine 10% cells with largest errors and an auxiliary algorithm to keep the smoothness of the adapted mesh. Finally, a novel AMR strategy is formulated based on adjoint method and ROM for LES.

NUMERICAL RESULTS

This novel technique is validated on an 1D unsteady Burger problem with a multiple-frequency forcing term, which is designed to produce flow solutions with large fluctuations. Figure 1 shows the approximation of a QoI by uniform, full-order solution-based and one-mode ROM-enabled AMRs. These results demonstrate that the AMR-based computation is more efficient than the uniform refinement and the ROM-enabled AMR has a reasonable agreement with full-order solution-based AMR although only one POD mode is used to construct the ROM. Furthermore, online POD analysis does not alter the convergence of the computation, which has the same accuracy of calculations from the AMR technique based on a standard ROM. Overall, ROM-driven AMR does not affect the computing accuracy of the QoI and online ROM can keep this property as long as the significant modes are considered. Figure 2 depicts the comparison of first eigenvalue between standard and online ROMs. We can observe that they tally well with each other except for the last two AMR levels. This results from the limited number of selected POD modes, which means that one POD mode is not enough to capture significant flow features on fine meshes. Thus, the discrepancy of computations occurs. This can be improved by increasing the number of selected POD modes, as shown from the results of a four-mode ROM in this figure.

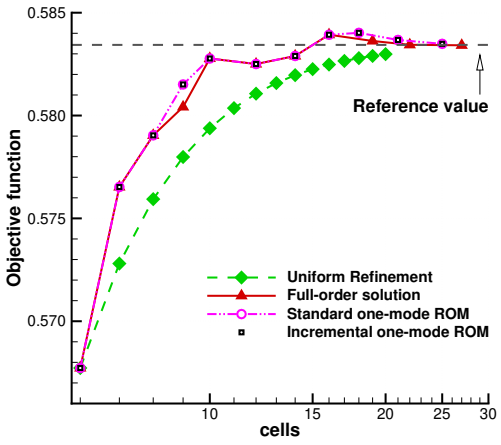

Figure 1: QoI's approximations by different AMRs. Green, red and purple lines and black square denote results from the uniform refinement, full-order solution-based AMR, ROM-based AMR, and online ROM-based AMR, respectively.

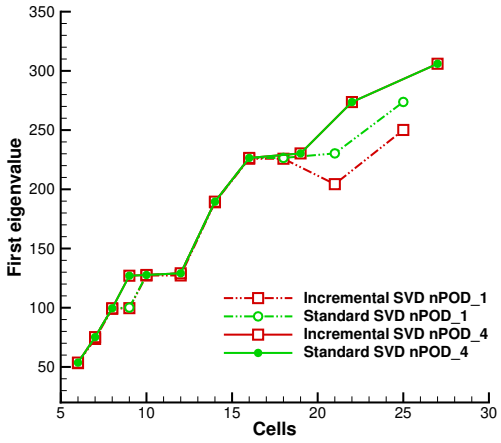

Figure 2: Eigenvalue evolutions of one-mode (dashdotdot lines) and four-mode (solid lines) ROMs during AMR from online (red) and standard (green) SVD

CONCLUSIONS

To summarize, adjoint-based AMR can be used to significantly reduce the computing cost of LES regarding to an interested output function. The ROM-driven AMR preserves the efficiency of solution-driven AMR in the current case and reducing the number of POD modes has a slight impact on QoI's convergence. Thus, ROM can give a correct prediction of primal flow solutions. As long as the POD modes are able to capture major flow structures, the ROM-driven AMR is effective and will acquire a good accuracy of the QoI. The online algorithm further improves the feasibility of ROM-enabled AMR for more challenging problems without losing the accuracy of the computation.

COUPLING ADJOINT SENSITIVITY ANALYSIS WITH THE POLYNOMIAL CHAOS EXPANSION FOR EFFICIENT UNCERTAINTY QUANTIFICATION

Kyriakos D. Kantarakias[1] andGeorge Papadakis *[1]
[1]Department of Aeronautics, Imperial College London, London, United Kingdom

Summary We present a method for Uncertainty Quantification (UQ) that uses the Polynomial Chaos Expansion (PCE) coupled with the adjoint method. In contrast to the standard PCE, where the computational cost scales in a power law with the number of stochastic parameters, N, in the coupled method the cost is independent of N. The method works for small input uncertainties, and takes advantage of widely available software for solving PDEs and the corresponding adjoint problem. The method is applied to a transonic airfoil with uncertain geometry, and results are compared with traditional UQ methods, such as Monte Carlo.

UNCERTAINTY QUANTIFICATION WITH THE POLYNOMIAL CHAOS EXPANSION

In Computational Fluid Dynamics, as well as in general mechanics problem, we consider systems in the form

$$\frac{d\mathbf{u}}{dt} = \mathbf{f}(\mathbf{u}, \mathbf{s}) \tag{1}$$

where $\mathbf{u}$ are the field variables and $\mathbf{s}$ denotes a set of design parameters. In many practical cases, such as turbulent flows, it is of interest to compute quantities that are integrals of the field $\mathbf{u}$, in the form

$$J = \int_{\Omega} h(\mathbf{u}, \mathbf{s}) d\Omega \tag{2}$$

In the case of fluid mechanics, (1) represents the Navier–Stokes equations and J is for example the drag or lift coefficients of an airfoil. If the vector $\mathbf{s}$ is of stochastic nature, uncertainty will propagate through the flow field $\mathbf{u}$ and introduce uncertainties into the Quantity of Interest (QoI) of eq. 2. These uncertainties are of interest since they characterise the performance of the system. In real world applications, spectral approaches such as the PCE, are the state of the art for conducting UQ, due to their low cost for a small number of uncertain variables. In such methods, the QoI is written in spectral form

$$J(\xi) = \sum_{i=0}^{\infty} J^i \Psi_i(\xi) \tag{3}$$

where ξ is a vector modelling the stochastic behavior of $\mathbf{s}$ and Ψ_j refers to polynomials that are orthogonal to the PDF of $\mathbf{s}$. Here J^i is computed by the the Galerkin integral

$$J^i = \int_{\mathcal{E}} J \Psi_i d\xi \approx \sum_{j=1}^{\alpha} \omega_j J(\xi_j) \Psi_i(\xi_j) \tag{4}$$

where the value of a depends on the integration grid chosen. This method, first presented in [2] is accurate, however its computational cost has a power law scaling with the number of uncertain parameters.

DECOUPLING THE COST OF THE PCE FROM THE NUMBER OF UNCERTAIN VARIABLES

The computational cost of conducting UQ with the PCE can be decoupled from the number of uncertain parameters, by employing the adjoint sensitivity analysis, as in [1]. The sensitivities of 2 with respect to $\mathbf{s}$ can be computed by solving the adjoint equation of 1 to find the Lagrange multipliers of $\mathbf{u}$. The adjoint sensitivity analysis can compute the sensitivity of the QoI (2) with respect to multiple parameters, with a computational cost that is decoupled from the dimension of $\mathbf{s}$. This property can be employed to compute the statistics of the QoI, by approximating the spectral coefficients of the expansion in eq. 4 using the information from the sensitivities, namely

$$J(\xi_j) = J_\mu + (\xi_j - \xi_\mu)^T \nabla J_\mu \tag{5}$$

Where ∇J_μ is computed with adjoint sensitivity analysis at the mean value of the stochastic inputs, ξ_a. With eq. 5, we approximate the values of J at eq. 4, while ω_j and Ψ_j are given by the PCE. This approach implies the locality of the adjoint and is therefore not suitable for UQ of large uncertainties. However, in most aerodynamic applications, such as the quantification of uncertainties in the geometry of airfoils uncertainties are usually small and global UQ is of no practical interest, therefore implying an equivalence between local UQ and sensitivity analysis.

TRANSONIC INVISCID 2D NACA0012 WITH UNCERTAIN GEOMETRY

This test case for the method deals with the inviscid flow around a NACA0012 airfoil, at $M_\infty = 0.8$ and $a_\infty = 1.25°$, which is a common benchmark problem for methods focusing on aerodynamics. The geometry of the airfoil is written as

$$y_{airfoil} = y_{base} + \sum_{i=1}^{N} a_i f_i(x) \tag{6}$$

where $f_i(x)$ are the Hicks–Henne bump functions, commonly used in shape optimization problems in aerodynamics [3]. For the purposes of demonstration, we consider Gaussian uncertainties in the set of weights $(a_1, a_2, \dots a_N)$, with a standard deviation equal to 1% of their mean value. In figure 1 we see that the Monte–Carlo simulation converges to the mean value and standard deviation predicted by the adjoint enhanced PCE. A comparison of the moments predicted by

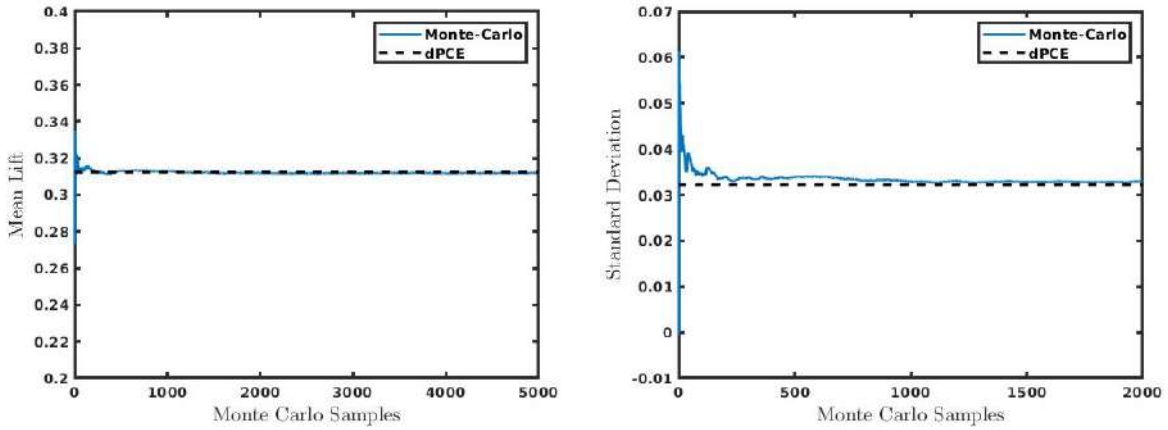

Figure 1: Monte–Carlo convergence and comparison with adjoint–enhanced PCE.

the adjoint enhanced PCE and the Monte–Carlo is seen in table 1. Notice that results are in very good agreement with the compared methods, with the computational cost of the adjoint-PCE approach being orders of magnitude smaller than the PCE and the MC. As an example, in the case of $N = 19$ uncertain variables, for a full tensor product computation of the integral of eq. 4, $a = 524288$ CFD runs would be required for the PCE, while in the adjoint enhanced PCE only one CFD and one adjoint evaluation were conducted.

Parameters N	μ_{C_L}		σ_{C_L}		Error (%) μ_{C_L}	Error (%) σ_{C_L}
	MC	adjoint PC	MC	adjoint PC		
1	0.3339	0.3289	0.0333	0.0326	1.51	2.06
2	0.3451	0.3421	0.0352	0.0358	0.86	1.70
3	0.3128	0.3144	0.0313	0.0317	0.53	1.39
19	0.3156	0.3124	0.0316	0.0322	1.01	1.92

Table 1: UQ in the NACA0012 airfoil. The QoI is the lift coefficient. Uncertainty is introduced through the coefficients of the Hicks–Henne bump conditions. A comparison is made with the Monte–Carlo simulation.

CONCLUSIONS

A new method, capable of conducting accurate UQ for a high number of uncertain variables is introduced. It is found that the statistical moments of a QoI can be computed, provided that the input uncertainties are relatively small. The method, introduces small errors due to the linear approximations introduced by the adjoint, but at a massively reduced computational cost.

DEMONSTRATION OF MACHINE LEARNING-BASED REDUCED ORDER MODELING USING UNSTEADY FLOWS AROUND BLUFF BODIES WITH VARIOUS SHAPES

Kazuto Hasegawa*[1,2], Kai Fukami[1], and Koji Fukagata [1]
[1]Department of Mechanical Engineering, Keio University, Japan
[2]Dipartimento di Scienze e Tecnologie Aerospaziali, Politecnico di Milano, Italy

Summary We use machine learning (ML) methods to build a framework of reduced order modeling for complex flows. Two ML methods are unified for the present modeling: a convolutional neural network-based autoencoder (CNN-AE) and long short term memory (LSTM). The CNN-AE is utilized to map a high-dimensional flow field into low-dimensional latent space. The LSTM is then employed to predict a temporal evolution of low-dimensionalized field via the CNN-AE. By combining these methods, a temporal evolution of high-dimensional dynamics can be represented by following only that of low-dimensionalized vector, because a CNN decoder which is part of the CNN-AE can re-map to original dimension. The present scheme is demonstrated using a flow around bluff bodies with various shapes. The reconstructed fields show statistical agreement with the reference data obtained by a direct numerical simulation.

INTRODUCTION

In recent years, the enthusiastic uses of machine learning have been seen in fluid dynamics due to its great affinity between accumulated fluid big data generated under complex and chaotic nature, and machine learning which is good at dealing with a large amount of data while considering nonlinearlity [1]. In particular, the applications to reduced order modeling (ROM) have been attracting attention. Srinivasan *et al.* [2] demonstrated the ability of a multi-layer perceptron and a long short-term memory (LSTM) by predicting a temporal evolution of nine-shear turbulent flow equation. A spatial low-dimensionalization with a customized convolutional neural network-based autoencoder (CNN-AE) was presented by Murata *et al.* [3]. These works reported that considering nonlinearity into the internal schemes of machine learning enables us to have a possibility to overcome drawbacks of the conventional linear-theory based ROM.

Here, we present a new framework of machine learning based reduced order modeling (ML-ROM) unifying a CNN-AE and an LSTM, then demonstrate its ability using a flow around bluff bodies with various shapes defined randomly.

MACHINE LEARNING METHODS

Let us first introduce a CNN-AE utilized for dimension reduction of the present study. With the use of the autoencoder (AE) [4], the problem setting is usually set to output the same data as the input data $\boldsymbol{q}$ through the model $\mathcal{F}$ such that $\boldsymbol{q} \approx \mathcal{F}(\boldsymbol{q};\boldsymbol{w})$, where $\boldsymbol{w}$ denotes the weights of the AE. Although it looks like a copy machine now, the noteworthy structure of the AE here is to have the intermediate latent space $\boldsymbol{r}$ which has lower dimension than input or output data. In other words, $\boldsymbol{r}$ can be a low-dimensionalized representation of input high-dimensional data $\boldsymbol{q}$ if we can obtain the same data as the output with the input data. The parts of the AE for dimension reduction and extension are called an encoder $\mathcal{F}_e$ and a decoder $\mathcal{F}_d$, respectively. In this study, we use a convolutional neural network (CNN) [5]-based model called multi-scale CNN [6] to construct the AE so that a multi-scale nature of complex flows can be considered [7].

An LSTM [8] is known as a prominent data-driven tool to apply to time-series prediction, e.g., speech recognition [9]. We here utilize the LSTM $\mathcal{F}_L$ to predict the temporal evolution of the latent dynamics. Although the details are skipped here, a flag map of the bluff body (i.e., 1 for the bluff body region, 0 for the fluid region) is also utilized as the input of the LSTM model to give the information of boundary condition.

The present combination of CNN and LSTM for reduced order modeling are shown in figure 1. A high-dimensional flow field $\boldsymbol{q}$ is mapped into a low-dimensional latent vector $\boldsymbol{r}$ using the CNN-AE. Then, the temporal evolution of latent dynamics are predicted by the LSTM with recursive input so that the temporal evolution of high-dimensional flow can be also represented with the use of CNN decoder. Summarizing above, the proposed modeling can be mathematically expressed as

$$\boldsymbol{q} \approx \mathcal{F}(\boldsymbol{q}) = \mathcal{F}_e(\mathcal{F}_d(\boldsymbol{r})), \tag{1}$$

$$\boldsymbol{r}^{(n+1)\Delta t} = \mathcal{F}_L(\boldsymbol{r}^{n\Delta t}). \tag{2}$$

RESULTS

Let us consider flows around various bluff bodies, whose shapes are defined randomly. Training data is prepared with a two-dimensional direct numerical simulation by solving incompressible Navier–Stokes equations,

$$\nabla \cdot \boldsymbol{u} = 0, \quad \frac{\partial \boldsymbol{u}}{\partial t} + \nabla \cdot (\boldsymbol{u}\boldsymbol{u}) = -\nabla p + \frac{1}{Re_D}\nabla^2 \boldsymbol{u}, \tag{3}$$

where $\boldsymbol{u}$, p, and t denote the velocity, pressure, and time, respectively. All variables are made dimensionless by the fluid density ρ^* , the uniform velocity U^*_∞, and the frontal length D^* of the body, where the superscript $*$ represents dimensional variables. The Reynolds number is set to $Re_D = U^*_\infty D^*/\nu^* = 100$, where ν^* is the kinematic viscosity. The length of computational domain is set to $(L_x, L_y) = (25.6D, 20.0D)$. The number of grid points is $(N_x, N_y) = (1024, 800)$ and the time step is set to $\Delta t = 2.5 \times 10^{-3}$. A ghost-cell method [10] is used to satisfy the no-slip boundary condition on the bluff body surface. To investigate whether the proposed model can learn the Navier-Stokes equation under various conditions as a proof concept for unseen flow data, we consider various bluff bodies, whose shapes are defined as

$$r = 0.5 + \sum_{n=1}^{4} a_n \sin n\theta + \sum_{n=1}^{4} a_{n+4} \cos n\theta, \quad \sum_{n=1}^{8} a_n = 0.5, \tag{4}$$

where r is the distance between the center and the surface, θ represents the angle from the inflow (i.e., x) direction, and a_n denotes random numbers normalized to satisfy equation (4). Fifty different shapes are generated for training data and the generated fields are rotated around the x-axis symmetry to increase the amount of training data, i.e., 100 kinds of flows.

Let us present in figure 2 an example of flow fields around bluff bodies with untrained shapes. As the data attributes, we use velocities and pressure $\boldsymbol{q} = \{u, v, p\}$. The dimension of the latent space here is set to 72 which corresponds to 0.03% compression against original data dimension. The flow fields reconstructed by the present ML-ROM show excellent agreement with the reference DNS data. In addition, the mean centerline velocity profiles of the present model are also in good agreement with the DNS data. Note that we can see nice agreement for the other test shapes and other attributes, i.e., v and p, although not shown here.

CONCLUSIONS

We presented machine-learning based reduced order modeling by unifying a CNN and an LSTM. The CNN was employed to map a high-dimensional flow field into low-dimensional latent space. The LSTM was then utilized to predict a temporal evolution of latent dynamics. By combining the predicted latent vectors with the CNN decoder, the time-evolved high-dimensional dynamics can be represented. The proposed method was demonstrated unsteady flows around bluff bodies with various random shapes. The reconstructed flow fields were in excellent agreement with the reference data. We refer enthusiastic readers to Hasegawa *et al.* [11] for more details.

IMMERSED BOUNDARY PROJECTION METHOD FOR THE IMCOMPRESSIBLE NAVIER-STOKES EQUATION WITH ARBITRARILY SHAPED NAVIER SLIP BOUNDARIES

Takehiro Fujii*[1], Takeshi Omori[2], and Takeo Kajishima[1]
[1]Department of Mechanical Engineering, Osaka University, Suita, Japan
[2]Department of Mechanical and Physical Engineering, Osaka City University, Osaka, Japan

Summary Immersed boundary methods that have been used to simulate flows with arbitrary-shaped boundaries on the Cartesian grid have not been established for the Navier slip boundary condition. We present a new method to impose the Navier boundary condition based on the immersed boundary projection method by introducing the regularization operator which is the sum of the conventional regularization operator and its gradient. Using the present regularization operator to regularize the boundary forces, the velocity gradient in the Navier boundary condition is appropriately evaluated with interpolation. Results from the simulations of the plane Poiseuille flow and Couette flow inside the two concentric cylinders with Navier slip walls show good agreement with the analytical solutions.

INTRODUCTION

In recent progress in the micro- and nanofluidics, the prediction of the flow confined by intricately shaped walls with slip velocity plays a significant role [1,2], and the numerical methods for the flows around the arbitrarily shaped Navier slip walls are needed.

The immersed boudary method is one of the most popular method to simulate the flows around the arbitrarily shaped surfaces where the no-slip conditions are imposed. However, the immersed boundary methods for the Navier boundary conditions have not been established. In this study, we present a new method that imposes the Navier boundary conditions on the immersed surfaces, based on the immersed boundary projection method by Taira and Colonius [3], which is appropriate for simulating the flows with rigid bodies. We present a discrete description of the Navier boundary condition using interpolations and introduce a new regularization operator, which smears the boundary forces on the Cartesian grid, to appropriately evaluate the velocity gradient in the Navier boundary condition using interpolation. To validate the present method, the plane poiseuille flow and the Couette flow inside the two concentric cylinders are calculated.

GOVERNING EQUATIONS

We consider the two dimensional imcompressible flow of Newtonian fluids around the arbitrarily shaped walls. The wall position and velocity are assumed to be known. The non-dimensional governing equations are the Navier-Stokes equation $\partial \boldsymbol{u}/\partial t + \boldsymbol{u}\cdot\nabla\boldsymbol{u} = -\nabla P + (1/\mathrm{Re})\nabla^2\boldsymbol{u} + \boldsymbol{f}_{ext}$, together with the continuity equation $\nabla\cdot\boldsymbol{u} = 0$. Here P is the non-dimensionalized pressure, Re is the Reynolds number and $\boldsymbol{f}_{ext}$ is the acceleration due to external forces. The boundary conditions on the walls are the Navier boundary conditions [4]

$$(1+\mathcal{L}_s\kappa)u_t - u_t^B = \mathcal{L}_s\left(\frac{\partial u_t}{\partial x_n} + \frac{\partial u_n}{\partial x_t}\right), \tag{1}$$

together with the impermeability conditions $u_n = u_n^B$, where the subscripts t and n indicate tangential and normal, respectively, the superscript B represents the quantities defined on the walls, $\mathcal{L}_s$ is the non-dimensional slip length, and κ is the curvature of the walls. For the second term on the right hand side of the Eq. (1), $\partial u_n/\partial x_t = \partial u_n^B/\partial x_t$ holds using the impermeability conditions $u_n = u_n^B$.

NUMERICAL METHODS

In the immersed boundary projection method [3], the immersed boundaries are described as the sequence of Lagrange points, where the boundary condisions are imposed, and the positions and the velocities of these points are assumed to be known. The discretized no-slip boundary condition is described as $\hat{E}\boldsymbol{u} = \boldsymbol{u}^B$, where $\hat{E}$ is the interpolation operator which interpolates the quantities defined on the Cartesian grid onto the Lagrange points. In order to enforce the discretized no-slip conditions on the immersed boundaries, the boundary forces $\boldsymbol{F}^B$ defined on the Lagrange points act on the Cartesian grid via the regularization operator $\hat{H}$. Both $\hat{E}$ and $\hat{H}$ are linear operators and constructed from the regularized discrete delta function.

In case of the Navier boundary condition, the evaluation of the tangent velocity and its normal gradient at the Lagrange points is needed. The velocity profile near the immersed boundaries depends on the distribution of the boundary forces on the Cartesian grid, namely, the regularization operator. The conventional combination of the operators $\hat{E}$ and

*Corresponding author. E-mail: fujii@fluid.mech.eng.osaka-u.ac.jp

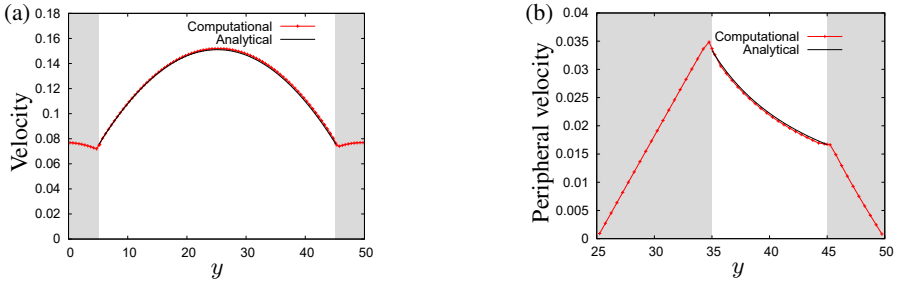

Fig. 1: The velocity profile for the case (a) the plane Poiseuille flow at $t = 10$ and (b) the Couette flow inside the two concentric cylinders at $t = 200$. The shaded regions represent the walls.

$\hat{H}$ underestimates the velocity gradient. We introduce a new regularization operator $\hat{H}^* = \hat{H} + \Delta\hat{G}_n\hat{H}$, where Δ is the grid space, to appropriately evaluate the tangent velocity and its gradient at the Lagrange points using interpolation. $\hat{H}^*$ regularizes the tangential boundary force corresponding to the Navier boundary condition, and the normal boundary force imposing the impermeability condition is regularized with $\hat{H}$. The Navier boundary condition and the impermeability condition are described as $(1 + \mathcal{L}_s\kappa)\hat{E}u_t - \mathcal{L}_s\hat{E}\hat{G}_n u_t = u_t^B + \mathcal{L}_s(\partial u_n^B/\partial x_t)$ and $\hat{E}u_n = u_n^B$, respectively, and these descriptions are reduced to an equation $\hat{B}\boldsymbol{u} = \boldsymbol{u}^B$, where $\hat{B}$ is a linear operator. For the discrete delta function constructing the interporlation and regularization operator, we use the three-grid cell delta function by Roma et al. [5], which is appropriate for the staggered grids.

The discretized governing equations and the boundary conditions are described as follows:

$$\frac{\boldsymbol{u}^{n+1} - \boldsymbol{u}^n}{\Delta t} = \frac{1}{2}\left(3\boldsymbol{A}^n - \boldsymbol{A}^{n-1}\right) - \hat{G}P^{n+1} + \frac{1}{2\mathrm{Re}}\left(\hat{L}\boldsymbol{u}^{n+1} + \hat{L}\boldsymbol{u}^n\right) + \boldsymbol{f}_{ext}^{n+1} + \hat{K}\boldsymbol{F}^{B,n+1}, \tag{2}$$

$$\hat{D}\boldsymbol{u}^{n+1} = 0, \tag{3}$$

$$\hat{B}\boldsymbol{u}^{n+1} = \boldsymbol{u}^{B,n+1}, \tag{4}$$

where $\hat{G}$, $\hat{L}$ and $\hat{D}$ are gradient, Laplacian and divergence operators, respectively, $\hat{K}$ composes of $\hat{H}^*$, $\hat{H}$ and coodinate transformation, and $\boldsymbol{A}^n = -\boldsymbol{u}^n \cdot \hat{G}\boldsymbol{u}^n$. Eqs. (2), (3) and (4) are solved in the same way as the immeresed boundary projection method [3].

RESULTS

For a two-dimensional test problem, we simulate (a) the plane Poiseuille flow driven by the constant external force $\boldsymbol{f}_{ext} = 0.04\boldsymbol{e}_x$ and (b) the Couette flow inside the two concentric cylinders with peripheral velocity $U = 0.1$ of the inner cylinder. The flows are initially stationary. We take a periodic computational domain of size $[0, 50] \times [0, 50]$, spatial resolution $\Delta x = \Delta y = 0.5$, Reynolds number $\mathrm{Re} = 0.01$ and non-dimensional slip length $\mathcal{L}_s = 10$ for the both cases, and time step $\Delta t = 1 \times 10^{-2}$ for the case (a) and (b) $\Delta t = 1 \times 10^{-1}$. The positions of the Lagrange points are $(0.25 + (i-1)\Delta x, 4.65)$ and $(0.25 + (i-1)\Delta x, 44.65)$, $(i = 1, 2, \cdots, 100)$ for the case (a). For the case (b), the 372 Lagrange points are located on the circumferences $(x-25)^2 + (y-25)^2 = 10^2$ and $(x-25)^2 + (y-25)^2 = 20^2$ at the equal intervals.

Fig. 1 shows the velocity profile for the case (a) at $t = 10$ and (b) along $x = 25$, $y \in [25, 50]$ at $t = 200$. The results are in good agreement with the analytical solutions.

CONCLUSIONS

We presented a new numerical method that imposes the Navier boundary condition on the immersed surface, based on the immersed boundary projection method. In order to appropriately evaluate the velocity gradients using interpolation, the regularization operator which is the sum of the conventional regularization operator and its gradient was introduced. To validate this method, the plane Poiseuille flow and the Couette flow inside the two concentric cylinders with Navier slip walls were computed. The resulting velocity profile shows a good agreement with the analytical solution.

Summary This work presents a reduced order modeling technique built on a high fidelity embedded mesh finite element method, as proposed in [1]. Such methods, and in particular the CutFEM method, are attractive in the generation of projection-based reduced order models thanks to their capabilities to seamlessly handle large deformations of parametrized domains and in general to handle topological changes. The combination of embedded methods and reduced order models allows us to obtain fast evaluation of parametrized problems, avoiding remeshing as well as the reference domain formulation, often used in the reduced order modeling for boundary fitted finite element formulations. The resulting novel methodology is presented on linear elliptic and Stokes problems, together with several test cases to assess its capability. The role of a proper extension and transport of embedded solutions to a common background is analyzed in detail. We will then further discuss ongoing extensions to fluid-structure interaction problems [2], in collaboration with M. Nonino and Y. Maday.

INTRODUCTION AND MOTIVATION

A wide variety of numerical methods for the solution of problems governed by partial differential equations is nowadays available. However, in many cases either the solution of the governing equations or the solution of associated inverse problems becomes impractical or unfeasible using standard discretization techniques, such as the Finite Element Method. For instance, complicated topology of the problem or a complex geometry may pose a challenge in the discretization of complex phenomena, and ultimately affect the quality of the resulting simulation. Moreover, repeated queries to the underlying solver in the context of an iterative solution of inverse problems may result in unbearably large computational times. Such situations occur, for example, when a large number of different configurations are in need of being tested, such as in uncertainty quantification, optimal control and shape optimization. The overall objective of this presentation (and the associated manuscript [1]) is to investigate how the recently introduced unfitted mesh finite element methods can be used in combination with reduced order modeling techniques for parametrized partial differential problems. Indeed, unfitted methods are very useful in cases characterized by complex geometrical configurations; however, as their Finite Element counterparts, they usually require large computational efforts. A combination with reduced order methods, able to widely decrease the overall computational time, would result in a very compelling methodology to be possibly applied in several different fields.

HIGH FIDELITY CUTFEM APPROXIMATION

For simplicity, for most of the presentation we will tackle stationary (but parametrized) problems, of the form find $u(\mu) \in V(\mu)$ such that

$$a_\gamma(u(\mu), v; \mu) = \ell_\gamma(v; \mu) \text{ in } V(\mu), \tag{1}$$

where $a_\gamma(\cdot, \cdot; \mu)$ is the weak form of an operator defined on a domain $\mathcal{D}(\mu) \subset \mathcal{B} \subset \mathbb{R}^d$, for $d = 2, 3$, while $\ell_\gamma(\cdot, \mu)$ is the right hand side of the system of equations related to the forcing term. The forms $a_\gamma(\cdot, \cdot; \mu)$, $\ell_\gamma(\cdot, \mu)$, the domain $\mathcal{D}(\mu)$, as well as the Sobolev space $V(\mu)$, depend on the parameter $\mu \in \mathcal{K}$, being $\mathcal{K} \subset \mathbb{R}^K$ the set of possible outcomes, which we assume to be a compact set in $\mathbb{R}^K$, $K \in \mathbb{N}$. In contrast, the bounding box $\mathcal{B}$ is not parameter dependent. Since CutFEM discretizations usually require suitable penalty and stabilization procedures, for the sake of exposition we will denote by $a_\gamma(\cdot, \cdot; \mu)$ and $\ell_\gamma(\cdot, \mu)$ the forms with penalty and stabilization, where γ represents the penalty and stabilization coefficients. We refer to e.g [1] for the expressions of the forms $a_\gamma(\cdot, \cdot; \mu)$ and $\ell_\gamma(\cdot, \mu)$ for common problems in fluid dynamics.

REDUCED ORDER MODELS FOR EMBEDDED METHODS

Using embedded methods, such as CutFEM, as high fidelity method of projection based reduced order models is certainly attractive, e.g. because (i) it offers a more versatile shape parametrization (for instance, based on level sets), (ii) which is capable of seamlessly handle large deformations, (iii) and which does not require a reference domain formulation typical of standard reduced basis methods (see for instance [3]). The main challenge however comes from the need to efficiently reduce (possibly localized) snapshots moving (due to parametric dependence) throughout the global domain. We will compare the two following options:

*Corresponding author. E-mail: fballarin@sissa.it.

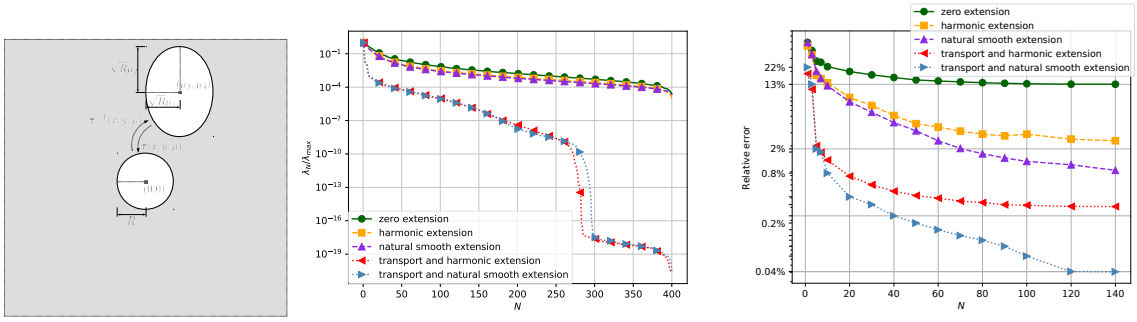

Figure 1: Example of transport map (left), comparison of POD eigenvalue decay (middle) and comparison of error analysis (right) between linear and nonlinear POD-Galerkin methods

Standard (linear) POD-Galerkin methods

Offline phase (POD):

- query CutFEM for $M \gg 0$ representative values $\mu^1, \dots, \mu^M$ of the parameter μ;
- note that $u(\mu^m) \in V_h(\mu^m)$, where the FE space $V_h(\mu^m)$ is defined *just* over (a neighbrood of) $\mathcal{D}(\mu^m)$, $m = 1, \dots, M$,
- introduce the background FE space $\widehat{V}_h$ defined over $\mathcal{B}$, of dimension $\mathcal{N}_h$;
- extend $u(\mu^m) \in V_h(\mu^m)$ to $\widehat{u}(\mu^m) \in \widehat{V}_h$ (three simple options will be presented);
- compute a POD of the (extended) snapshots $\mathcal{S} = [\widehat{u}(\mu^1), \dots, \widehat{u}(\mu^M)] \in \mathbb{R}^{\mathcal{N}_h \times M}$;
- collect the first POD modes $\varphi_1, \dots, \varphi_N$ and define the RB space $\widehat{V}_N = \text{span}\{\varphi_1, \dots, \varphi_N\}$;
- note that $V_h = V_h(\mu)$ depends on μ, $\widehat{V}_N$ *does not*.

Online phase (Galerkin):

- seek a RB solution of the form $u_N(\mu) = \sum_{i=1}^N \alpha_i(\mu)\, \varphi_i$, such that $\sum_{i=1}^N \alpha_i(\mu) a_\gamma(\varphi_i, \varphi_j; \mu) = \ell_\gamma(\varphi_j; \mu), \quad \forall j = 1, \dots, N$.

Nonlinear variant of POD-Galerkin methods

The nonlinear variant is based on the following assumption: for a fixed $\overline{\mu} \in \mathcal{K}$, assume to have $\boldsymbol{\tau}(\mu) : \mathcal{B} \to \mathcal{B}$ be a bijective map chosen such that $\mathcal{D}(\overline{\mu})$ is mapped into $\mathcal{D}(\mu)$, and let $\boldsymbol{\tau}^{-1}(\mu)$ denote its inverse with respect to the spatial coordinates (see e.g. Figure 1 (left)).

Offline phase (POD + transport^{-1}):

- query CutFEM for $M \gg 0$ representative values $\mu^1, \dots, \mu^M$ of the parameter μ;
- extend $u(\mu^m) \in V_h(\mu^m)$ to $\widehat{u}(\mu^m) \in \widehat{V}_h$;
- transport^{-1} $\widehat{u}(\mu^m) \in \widehat{V}_h$ to $\widehat{u}_{\boldsymbol{\tau}}(\mu) = \widehat{u}(\mu) \circ \boldsymbol{\tau}^{-1}(\mu)$;
- compute a POD of the (extended and transported^{-1}) snapshots and collect the first POD modes $\varphi_1, \dots, \varphi_N$

Online phase (Galerkin + transport):

- define the RB space $\widehat{V}_N^{\boldsymbol{\tau}}(\mu) = \text{span}\{\varphi_1 \circ \boldsymbol{\tau}(\mu), \dots, \varphi_N \circ \boldsymbol{\tau}(\mu)\}$, by transporting the computed POD modes;
- note that $\widehat{V}_N^{\boldsymbol{\tau}}(\mu)$ now depends on μ;
- seek a RB solution via Galerkin projection on the space $\widehat{V}_N^{\boldsymbol{\tau}}(\mu)$.

Numerical results

Numerical results on elliptic and fluid dynamics cases show that the nonlinear variant outperform the linear one. The results of the offline stage for a representative test case are shown in Figure 1 (middle) where POD eigenvalues (normalized to the maximum eigenvalue) are plotted against the number of modes. Results show that small reduced basis spaces cannot be obtained relying only on linear methods; indeed, Figure 1 (middle) shows a very slow eigenvalue decay, with negligible differences among the different extension options. A faster decay is obtained instead thanks to the transportation introduced by the nonlinear variant. In particular an improvement of almost three orders of magnitude is obtained for $N = 100$, more than four for $N = 200$; furthermore, the transport POD drops below numerical precision at $N = 300$. Results of the online stage are then shown in Figure 1 (right), where the average of the relative error over the testing set is plotted against the reduced basis size. The reduced solution obtained from the best linear method results in relative errors that are of the order of 10^{-2} for the maximum value of N. In contrast, the combination with inverse transportation of nonlinear methods allows to sensibly improve results, up to errors of 10^{-4} for $N = 140$. Ongoing extensions to fluid-structure interaction problems will be mentioned as well [2].

A MULTISCALE MODEL FOR PREDICTING THE VASCULAR TRANSPORT AND ADHESION MECHANICS OF NANOMEDICINES

Summary In the Nanomedicine community, there is a pressing need for predictive, quantitative tools to rationally design and optimize carriers for therapeutic and imaging applications. Current nano/micro-fabrication technologies allow us to control a large number of parameters, namely size, shape, surface properties and mechanical stiffness (4S parameters). Indeed, the biophysical behavior of such nanomedicines is greatly affected by these parameters. Reliable, multiscale and multiphysics computational models are crucial to guide the fabrication process towards optimal delivery systems. Here, a computational model for describing blood flow in the microvasculature, particle transport and molecular interaction with the vascular walls is presented. The model predicts particle deposition within a tumor microvasculature as a function of different design parameters.

INTRODUCTION

THE MULTISCALE COMPUTATIONAL MODEL

The aim of the present work is to study the dynamics of injectable particles (nanomedicines) within a microvascular network. Such particles travel along the vascular tree and interact with the endothelial cells. The vascular transport and adhesion of particles depend on various factors, over different scales. These include the geometry of the vascular network, the local Reynolds number, Re (which governs the hydrodynamic forces) and the ligand-receptor interaction (which modulates vascular adhesion). Here, a hierarchical, multiscale computational approach is developed, based on continuum and statistical mechanics, to predict and quantify the vascular concentration of blood-borne particles and their vascular deposition as a function of the above factors. Our long term vision is to develop a computational model consisting of three different modules: the organ level module, the vascular transport module and the particle-wall interaction module. These three modules with their characteristic governing equations and the exchange parameters are schematically shown in **Figure.1**.

In this work, we explicitly address the vascular transport module and the particle-wall interaction module only. A top-down strategy is used starting from the continuum macroscale description of the fluid flow and particle transport at the level of the whole network [1] to the molecular scale with the individual particle-wall interactions [2]. The model is formulated as a particle transport problem regulated by the blood flow. For this reason, the blood flow problem is first studied in terms of hydrodynamic velocities and pressures. Then, the actual particle transport problem in the vascular network is addressed. To combine these models with the organ level module, we are planning to adopt an approach based on numerical homogenization in order to upscale the current simulations to the level of the whole organ. Very encouraging preliminary results based on this strategy are obtained in the work by Vidotto et al. [3]. We believe that models based on averaged tissue-vasculature should be used in combination with the approach presented here, with the ultimate aim to tackle organ level simulations.

In particular, the present model couples two numerical approaches for different length scales. The detailed dynamics of micro-carriers with different stiffness and surface properties is computed by an Immersed-BoundaryLattice Boltzmann approach. On the other hand, larger scales are carried out by means of a finite element (FE) discretization of a real vasculature and the within flow filed (taken from http://physiology.arizona.edu/people/secomb/network). These two computational schemes are off-line coupled and hierarchical multiscale approach is obtained.

Vascular and extra-Vascular Transport

To model a network of arterioles, we start form the vascular data for R3230AC mammary carcinoma developed in a rat dorsal skin flap preparation. Precisely, the dataset named rat93 is chosen, which describes a network of 28 branches, with variable diameters. The network is embedded into a biological tissue modeled as a homogeneous continuum. This material is called the interstitial volume. The fluid dynamic problem is defined in a three-dimensional domain, which is split in two subdomains: the tissue and the vasculature. The tissue is assumed to be an isotropic porous medium and the flow is governed by the Darcys law combined with mass conservation for incompressible fluids. The blood is considered ad a non-Newtonian biphasic suspension consisting of plasma and blood borne cells. Precisely the model provides the flow of plasma and haematocrit on the basis of conservation of mass and momentum principles, combined with constitutive laws for the blood rheology such as Fahraeus-Lindqvist effect, plasma skimming and variable apparent viscosity. To mitigate the computational cost of such model, a dimensionality reduction technique is adopted and the full 3D vessels are replaced by their central axis.

Micro-transport and particle-wall interaction module

A dynamic-Immersed–Boundary (IB)/Lattice Boltzmann (LB) scheme is employed to analyze particle transport and adhesion mechanics with micro-and meso-lenght scales. Such membranes are modeled as a collection of mass-spring elements responding to a bending potential, a worm-like chain potential and the area conservation constraint. Furthermore, on particles' surfaces are uniformly distributed adhesive molecules (ligands) interacting with their counterpart (receptors) disposed on vascular walls. For the lattice Boltzmann modeling, a Gauss-Hermite projection is used to derive the lattice equation; wall boundary conditions are imposed through the Zou-He framework; and a moving least squares algorithm accurately reconstructs the forcing term accounting for the immersed boundary.

CONCLUSIVE REMARKS

The present model has the unique ability to combine a physically sound mechanistic description of micro-particles transport and adhesion dynamics with an affordable computational cost. It represents an ideal framework to optimize the such carriers rational design. Moreover, it has to be stressed that the model is open to interesting generalizations without changing its general structure. It has to be stressed that the present model is based on fundamental physical laws of particle dynamics, which are put into action through advanced computational models. In perspective the aim of the work is twofold; firstly, this technique can be adapted on a number bio-inspired problems, then such approach as it is could significantly foster the development of nanomedicine, for more effective and personalized treatments.

A FINITE VOLUME METHOD FOR NAVIER-STOKES EQUATIONS ON OVERSET GRID

Michele Giuliano Carlino*[1,2], Michel Bergmann[1,2], and Angelo Iollo[1]
[2,1]MEMPHIS team, INRIA Bordeaux Sud-Ouest, Talance, France

Summary In the present work, we propose a Finite Volume (FV) approach for the solution of Navier-Stokes equations for incompressible flows over a Chimera configuration of meshes. In particular, a Chimera configuration (or overset grid) is a composition of meshes allowing to overcome the problem of the geometrical adaptation of the computational domain with a unique block of mesh. These meshes overlap each other and can move and deform during the simulation. The Navier-Stokes equations are solved through a projection method (*Chorin-Temam*). For this reason, we present two solvers for the steady diffusive problem and the unsteady advection-diffusion problem. For the last problem we present a proper adaptation of the ADER method.

INTRODUCTION

One of the difficulties in the simulation of a fluid flow problem is the representation of the computational domain with a unique block mesh. As a matter of fact, not only the geometry could be particularly complex in itself, but it could change during the simulation and this necessary involves an *in itinere* geometrical adaptation of the mesh, with consequent high computational costs. One of the ways to overcome this problem is to use multiple overlapping mesh blocks that together define a *Chimera* or *overset* grid [1]. Once the different mesh blocks are generated, they are properly composed by the creation of holes and, consequently, an *overlapping zone* between two overlapping blocks is defined. In our simulations, the Chimera grid is composed of a background and a foreground mesh (see Figure 1). In particular, the foreground mesh can move and deform (consequently, the hole in the background mesh can change its configuration).
Let $\Omega \subset \mathbb{R}^2$ be the computational domain and let us consider the Navier-Stokes equation for incompressible flow

$$\partial_t \boldsymbol{u} - \nu \Delta \boldsymbol{u} + (\boldsymbol{u} \cdot \nabla)\boldsymbol{u} + \nabla p = \boldsymbol{f} \quad \text{in } \Omega \times [0, T], \tag{1}$$

with $\nabla \cdot \boldsymbol{u} = 0$ in $\Omega \times [0, T]$ and properly completed with initial and boundary conditions; with $\boldsymbol{u}$ and p the fluid velocity field and pressure, respectively, $\nu = 1/Re$ the inverse of Reynolds number and $\boldsymbol{f}$ the force term. System (1) is solved through a projection method (*Chorin-Temam*) [2, 3], thus we propose in the sequel a finite volume (FV) method for the steady diffusion equation and the unsteady advection-diffusion (AD) equation on a Chimera configuration. For both methods, the error of the mismatch between the exact solution and its FV approximation in L^∞- and L^2-norm shows schemes are second order accurate. The overlapping zone is necessary for the the communication and data transfer from one mesh to another. With respect to the methods available in the literature for overset grids, the ADER approach allows to transmit data from one mesh to another through fluxes and not through strong conditions on the boundary of the overlapping zone, by improving computational costs and timing.

THE POISSON EQUATION AND ADER METHOD FOR ADVECTION-DIFFUSION EQUATION

Let the Poisson equation be $\Delta u = f$ in $\Omega \subset \mathbb{R}^2$, completed with adequate boundary conditions. Let Ω_i be the quadrilateral i-th cell (either in the background or foreground mesh); thus its boundary is denoted by $\partial\Omega_i = \bigcup_{l=1}^4 \Gamma_{il}$. By integrating the Poisson equation over cell Ω_i, it reads

$$\sum_{l=1}^{4} \int_{\Gamma_{il}} \nabla u \cdot \boldsymbol{n}_{il} \, \mathrm{d}\Gamma = \int_{\Omega_i} f \, \mathrm{d}\Omega, \tag{2}$$

where $\boldsymbol{n}_{il}$ is the outer unit normal to Γ_{il}. For the computation of the gradient, we adopt two different strategies: if the cell is not at the boundary of the overlapping interface, the reconstruction is *geometrically* achieved, otherwise, an *analytical* reconstruction is employed. The analytical approach consists of an interpolation of the gradient by using the information of neighboring cells to Ω_i by minimizing a convex functional [4]. On the other hand, the geometrical approach is based on the projection of the gradient along the direction $\boldsymbol{n}_{il}$ by using the approximations of the gradient along the directions linking the cell centers and the extremes of sides Γ_{il}.
Regarding the unsteady advection-diffusion equation, let us consider problem

$$\begin{aligned} \partial_t u + \nabla \cdot \mathcal{F}(u, \nabla u) &= f \quad \text{in } \Omega \times [0, T]; \\ \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} &= \boldsymbol{V}(\boldsymbol{x}, t; u); \end{aligned} \tag{3}$$

properly completed with initial and boundary conditions. In the above system, $\mathcal{F}(u, \nabla u)$ is the advective-diffusive term and the second line is the *motion equation* for the foreground mesh. In order to solve (3), we adapted the ADER method

*Corresponding author. E-mail: michele-giuliano.carlino@inria.fr.

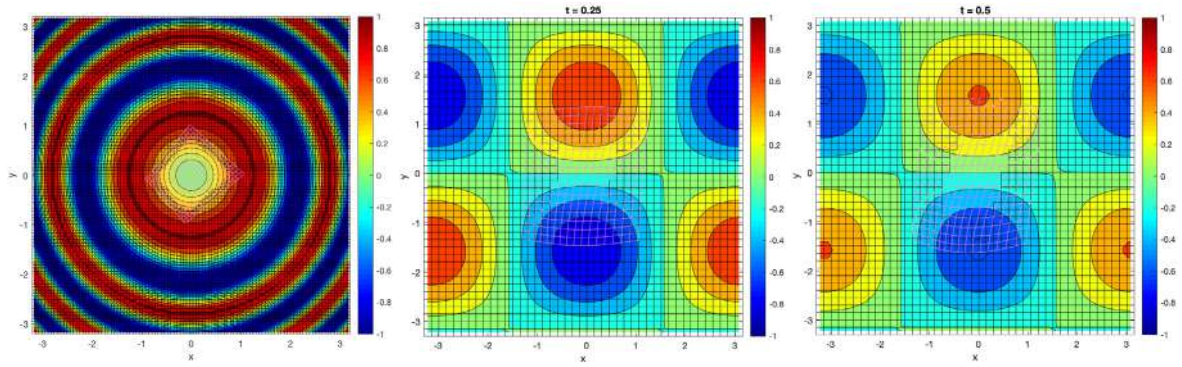

Figure 1: First figure in the left corresponds to the Poisson equation case test. The central and right figures show two time instants of the advection-diffusion case test.

[5, 6] for a Chimera configuration. First, we solve the motion equation in the space-time cell $\mathcal{C}_i^n = \Omega_i(t) \times [t^n, t^{n+1}]$, with Ω_i the usual spatial cell, in a weak sense by a Galerkin projection. This allows to both solve $(3)_2$ and define a map $\mathcal{M}_i$ from the physical space-time cell $\mathcal{C}_i^n$ to the reference space-time cell $\hat{\mathcal{C}} = [0,1]^3$. Through map $\mathcal{M}_i$, we first find a **local predictor solution** of $(3)_1$ in $\mathcal{C}_i^n$ as a Galerkin projection employing the same Lagrangian basis used for solving $(3)_2$ (*isogeometric approach*). Successively, by writing equation $(3)_1$ in a hyperbolic sense, namely $\tilde{\nabla} \cdot \tilde{\boldsymbol{u}} = f$, with $\tilde{\nabla} = [\nabla, \partial_t]^T$ and $\tilde{\boldsymbol{u}} = [\mathcal{F}, u]^T$, we integrate it over $\mathcal{C}_i^n$. Since the boundary $\partial\mathcal{C}_i^n$ of the space-time cell is $\partial\mathcal{C}_i^n = \Omega_i^n \cup \Omega_i^{n+1} \cup \bigcup_{j=1}^4 \Gamma_{ij}^n$, with $\Omega_i^\mu \equiv \Omega_i(t^\mu)$ and Γ_{ij}^n the j-th space-time side of $\mathcal{C}_i^n$, equation $(3)_1$ turns into

$$-|\Omega_i^n| U_i^n + |\Omega_i^{n+1}| U_i^{n+1} + \sum_{j=1}^{4} \int_{\Gamma_{ij}^n} \tilde{\boldsymbol{u}} \cdot \tilde{\boldsymbol{n}}_{ij} \, \mathrm{d}\Gamma = \int_{\mathcal{C}_i^n} f \, \mathrm{d}\mathcal{C}, \tag{4}$$

with $U_i^\mu = |\Omega_i^\mu|^{-1} \int_{\Omega_i^\mu} u(\boldsymbol{x}, t^\mu) \mathrm{d}\boldsymbol{x}$ the spatial average of the solution and $\tilde{\boldsymbol{n}}_{ij}$ the unit outer normal of Γ_{ij}^n. In equation (4), the unknown is U_i^{n+1} and the last term of the left side is the space-time flux to be computed. For this reason, the integral function $\tilde{\boldsymbol{u}} \cdot \tilde{\boldsymbol{n}}_{ij}|_{\Gamma_{ij}^n}$ is approximated through a Local Lax-Friederichs (LLF) formula by using the local predictor solutions over $\mathcal{C}_i^n$ and its neighboring space-time cells. Equation (4) with the approximation of the space-time flux is called **correction stage** of the ADER method. Finally, in order to manage the cells at the boundary of the overlapping zone and the evolution of the cells in the hole of the background mesh, a local polynomial reconstruction over those cells is performed.

Here we present the study of the order of convergence with two test cases for the two problems, respectively. For both test cases, the computational domain is $\Omega = [-\pi, \pi]^2$. For the Poisson equation (see Figure 1 left), the exact solution is $u_{ex} = \sin(x^2 + y^2)$ and Dirichlet boundary conditions are imposed, i.e., $u \equiv u_{ex}$ on $\partial\Omega$. For AD problem, we considered a linear advective-diffusive term, i.e. $\mathcal{F}(u, \nabla u) = \nu \nabla u + \boldsymbol{\beta} u$, where $\nu = 0.1$ is the viscous term and $\boldsymbol{\beta} = [3, 4]^T$ is the advective field. The exact solution reads $u_{ex} = e^{-\nu t} \sin(x) \cos(y)$ and the last time is $T = 1$. We imposed initial and boundary conditions as $u(\boldsymbol{x}, 0) = u_{ex}(\boldsymbol{x}, 0)$ and $u \equiv u_{ex}$ on $\partial\Omega \times [0, T]$, respectively. The foreground mesh fulfills $(3)_2$ with velocity $\boldsymbol{V} = [u, u]^T$ (see Figure 1 center and right). Table 1 resumes the errors and rates of convergence for both problems, confirming the second order accuracy of the methods.

Table 1: Errors (second and third columns) and convergence rates (last two columns) for Poisson (left) and advection-diffusion equations (right). For AD problem, the errors refer to final time $T = 1$.

A NEURAL-NETWORK-BASED SYNTHETIC BOUNDARY CONDITION FOR THE SIMULATION OF CHANNEL TURBULENCE

Heesik Yoo[1], Bérengère Podvin*[1], Yann Fraigneau[1], and Alexandre Allauzen[1]
[1]Université Paris-Saclay, CNRS, LIMSI

Summary We describe a method combining Proper Orthogonal Decomposition (POD) and an artificial recurrent neural network to implement an inlet boundary condition for a turbulent channel flow. The boundary condition is reconstructed from POD modes, the amplitudes of which are predicted using a neural network (LSTM). We first assess the quality of the LSTM prediction in POD space. The reconstructed velocity is then used as an inlet boundary condition in a spatially developping channel. Statistics are compared with the reference and are found to be in relatively good agreement.

MOTIVATION

The generation of turbulent inlet boundary conditions is an important question for the simulation of flows around aerodynamic immersed bodies or a spatially developing boundary layer. Fully developed turbulent channel flow can be obtained using periodic boundary conditions, but in general turbulent flows such as boundary layers develop in the spatial direction and more effort is required to construct an inlet velocity condition.

Pamiès *et al.* [1] used a combination of structures to construct the inlet condition - synthetic eddy method. Proper Orthogonal Decomposition (POD) provides a natural reconstruction framework as the velocity field can be approximated as a linear combination of POD spatial modes, the amplitudes of which vary in time. The question of determining inlet boundary conditions thus boils down to predicting the temporal evolution of a relatively limited number of amplitudes. In this framework the issue is to predict the behavior of the amplitudes of the POD spatial modes. Druault *et al.* [2] combined linear stochastic estimation with POD to construct an inlet boundary condition for a spatially developing mixing layer. Perret *et al.* [3] used experimental data to construct a low-order model for the amplitudes of the POD modes and build an inlet condition for large-eddy-simulation (LES) of a mixing layer. In the present work, we predict POD amplitudes using a special type of neural network called a long-term short-term memory network (LSTM) [4]. We first describe the method and show how the network is able to predict the POD amplitudes of the velocity field in a turbulent channel flow. The method is then implemented to reconstruct the velocity field on a plane which is used as an inlet boundary condition for the numerical simulation of a turbulent channel flow. Turbulent statistics in the channel are then compared with those of a reference one.

RECONSTRUCTION METHOD

Description

We consider the numerical simulation of an incompressible turbulent channel flow characterized by a bulk velocity U and a half-height h. The Reynolds number based on channel half-height h and friction velocity u_τ is $Re_\tau = 194$, which corresponds to the reference channel. Application of Proper Orthogonal Decomposition to the velocity field yields

$$\underline{u}(\underline{x}, t) = \sum_n a_n(t)\underline{\phi}_n(\underline{x}) \tag{1}$$

The spatial eigenfunctions $\underline{\phi}_n$ are determined *a priori* from a reference simulation. We consider 300 snapshots separated by a time scale of $\delta t = h/U$, which can be reorganized into a hierarchy of 300 modes.

Constructing an inlet condition at all times consists in predicting the amplitude of these modes. In order to this we use a LSTM. The network is trained on a subset of the snapshots and validated on the remaining subset. The goal of the LSTM is to predict the next values of the amplitudes at $t + \delta t$, given the values at t. It is a recursive procedure, so that the amplitudes can be predicted over a long period of time.

Once the predicted values obtained at regular intervals of δt, the amplitudes can be interpolated in the simulation at any instant within the range spanned by the prediction.

Results

In the results shown below, the LSTM was trained on 180 snapshots. The remaining 120 snapshots constitute the validation basis. The LSTM was iterated over 640-180=480 snapshots - 120 of which can be compared with the reference and 360 of which correspond to entirely new times. We consider only the 100 most energetic POD modes, which capture about 85% of the energy.

We first compare the amplitude of the POD modes predicted with the LSTM to those the reference simulation.

Figure 1 represents respectively the energy content and frequency spectrum of the amplitudes (frequencies are expressed in wall units, denoted with a $+$). Overall the LSTM predicts relatively well the characteristics of the modes.

INLET BOUNDARY CONDITION

In this section we simulate a spatially developing turbulent channel using as an inlet condition the velocity field reconstructed using the POD eigenfunctions and the amplitudes predicted by the LSTM. A convective boundary condition is used at the outlet of the channel. The dimensions of the channel are $L_x = 2\pi, L - z = 4\pi, L_y = 1$ in respectively the streamwise (x), wall-normal (y) and spanwise (z) direction. The statistics are computed over 24 time units based on channel half-height and bulk velocity in cross-planes at the following streamwise locations: the inlet, the mid-channel $x = \pi$ and the outlet. They are compared with those of a reference simulation at the same Reynolds number with periodic boundary conditions in the streamwise direction.

Figure 2 shows the turbulent intensities (or normal components of the Reynolds stresses). The normal stresses components of the reconstructed velocity condition are slighty under-predicted, which corresponds to the fact that only 85% of the kinetic energy is captured in the reconstruction. However at the outlet of the channel, the stresses are in much better agreement with the reference.

CONCLUSIONS

A new method combining Proper Orthogonal Decomposition and neural approaches was developed in order to build an inlet condition for an turbulent channel flow. The boundary condition was reconstructed using POD modes determined *a priori*. The amplitudes of the POD modes were predicted using a LSTM network. The characteristics of the amplitudes were satisfactorily captured by the LSTM. The statistics of the channel with the synthetic inlet boundary condition were found to match relatively well those of a turbulent channel flow with standard periodic boundary conditions.

AN OPTIMAL, FAST, PARALLEL SOLVER FOR THE INCOMPRESSIBLE NAVIER–STOKES EQUATIONS ON COLOCATED GRIDS

Franco Auteri*[1], Alessandro Chiarini[1], and Maurizio Quadrio[1]
[1]Department of Aerospace Sciences and Technologies, Politecnico di Milano, via La Masa 34, 20156 Milano, Italy

Summary A novel colocated finite difference solver for the incompressible Navier-Stokes equations is presented, based on the direction-splitting fractional step method proposed in [Guermond & Minev 2010]. High computational efficiency is obtained using the direction-splitting method; high scalability is obtained thanks to the Schur complement method used for parallelisation. The checkerboard pressure modes have been stabilised using the approach introduced by [Rhie & Chow 1983], which consists in adding a fourth order term to the right-hand side of the pressure equation and using a short stencil for second derivatives in the left-hand side. The obtained solver is found to be second order accurate in time and space. As expected, the new solver is faster than the staggered version and its parallel performance scales extremely well with the number of processors.

The large increase in CPU and memory performance of recent computers leads to new opportunities for Direct Numerical Simulations (DNS) of turbulent flows. An example is the DNS of complex biomedical flows such as the flow in the nasal cavities [2] or the blood stream [3]. These new possible applications of the DNS require large grids – up to 10^9 points – and high geometrical flexibility. Therefore, together with improving computer performance, suitable new DNS programs need to be developed capable of taking advantage of the hardware performance and allowing an increased geometrical flexibility. In this respect, the time and space discretisation methods can be key to fully exploit the available performance to solve problems still elusive. In particular, when fluid structure interaction problems within complex geometries are concerned, such as in biomedical applications, not only high geometrical flexibility is needed, but also the capability to cope with a shape that changes with the flow. Finite elements, despite providing high geometrical flexibility and good accuracy, lack the necessary efficiency when the mesh must be modified in each time step. Finite differences, able to deal with such complex geometries by the immersed boundary method, seem to provide the best trade-off between accuracy and efficiency in these applications.

A very efficient finite difference solver for the incompressible Navier–Stokes equations on staggered grids has been recently introduced by Guermond and Minev [1], the solver has an optimal computational complexity and is highly scalable. The efficiency of this solver hinges on a novel fractional-step method used to decouple the viscous step from the incompressibility constraint that allows the use of the ADI algorithm [4] for both the viscous and the pressure step. Using a Crank–Nicolson time discretisation, the viscous step reads:

$$\frac{\boldsymbol{\xi}^{n+1}-\boldsymbol{u}^n}{\Delta t}-\frac{1}{\mathrm{Re}}\nabla^2\tilde{\boldsymbol{u}}^n=f^{n+1/2}-\nabla p^{*,n+1/2}-\mathbf{nl}(\boldsymbol{u}^{n+1/2}) \tag{1}$$

$$\frac{\boldsymbol{\eta}^{n+1}-\boldsymbol{\xi}^{n+1}}{\Delta t}-\frac{1}{2\mathrm{Re}}\frac{\partial^2}{\partial x^2}\left(\boldsymbol{\eta}^{n+1}-\boldsymbol{u}^n\right)=0 \tag{2}$$

$$\frac{\boldsymbol{\zeta}^{n+1}-\boldsymbol{\eta}^{n+1}}{\Delta t}-\frac{1}{2\mathrm{Re}}\frac{\partial^2}{\partial y^2}\left(\boldsymbol{\zeta}^{n+1}-\boldsymbol{u}^n\right)=0 \tag{3}$$

$$\frac{\boldsymbol{u}^{n+1}-\boldsymbol{\zeta}^{n+1}}{\Delta t}-\frac{1}{2\mathrm{Re}}\frac{\partial^2}{\partial z^2}\left(\boldsymbol{u}^{n+1}-\boldsymbol{u}^n\right)=0 \tag{4}$$

where $\boldsymbol{u}^n$ is the velocity at time t_n, $p^{*,n+1/2}=p^{n-1/2}+\phi^{n+1/2}=2p^{n-1/2}-p^{n-3/2}$ is the pressure prediction at time $t_{n+1/2}$, Re is the Reynolds number and **nl** the nonlinear term. Instead, the pressure step reads:

$$\psi-\frac{\partial^2\psi}{\partial x^2}=-\frac{1}{\Delta t}\nabla\cdot\boldsymbol{u}^{n+1}, \qquad \frac{\partial\psi}{\partial x}|_{x=0,1}=0, \tag{5}$$

$$\varphi-\frac{\partial^2\varphi}{\partial y^2}=\psi, \qquad \frac{\partial\varphi}{\partial y}|_{y=0,1}=0, \tag{6}$$

$$\phi^{n+1/2}-\frac{\partial^2\phi^{n+1/2}}{\partial z^2}=\varphi, \qquad \frac{\partial\phi^{n+1/2}}{\partial z}|_{y=0,1}=0. \tag{7}$$

This method retains the efficiency of $1D$ solvers with banded matrices, hence an optimal computational complexity, in a direct solver. The high scalability is guaranteed by the use of the Schur-complement method [1].

While the capabilities of this solver have been extended to complex geometries by a Moving Least Square immersed boundary procedure [6], the use of a staggered grid to enforce the LBB condition prevents the potential of the solver to be fully exploited when moving geometries and fluid-structure interaction problems are concerned. Indeed, when applying the immersed boundary procedure, the calculation of all the coefficients necessary for the involved interpolations must be computed on the four staggered grids, leading to a significant performance degradation.

*Corresponding author. E-mail: franco.auteri@polimi.it.

These problems motivated us to develop a colocated version of the aforementioned fractional-step solver. The instability related to pressure spurious modes has been cured by the method proposed by Faure et al. [8] which heavily relies on the well known method first proposed by Rhie and Chow [7]. It consists in adding a stabilisation term in the form of a fourth derivative term multiplied by an under-relaxation coefficient in the right-hand side of the equivalent of the Poisson equation for pressure. The stabilisation term reads:

$$\alpha c(\nabla_L^2 p - \nabla_s^2 p) \tag{8}$$

where $\nabla_s^2 p$ is the pressure Laplacian computed on the small stencil – in 2D $(p_W - 2p_C + p_E)/\Delta x^2 + (p_S - 2p_C + p_N)/\Delta y^2$, see fig 1 – and $\nabla_L^2 p$ is the pressure Laplacian computed on the large stencil – $(p_{WW} - 2p_C + p_{EE})/4\Delta x^2 + (p_{SS} - 2p_C + p_{NN})/4\Delta y^2$– and $\alpha \in [0, 1]$ and c a constant.

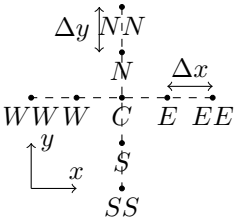

Figure 1: Colocated grid in the 2D case.

The stabilisation term partially substitutes the large-stencil Laplacian of the pressure implicitly present in the right-hand side of the pressure equation with its small-stencil counterpart, thus coupling all grid points.

As expected, the colocated program is slightly less accurate than the staggered one, but second order convergence is obtained in both time and space for velocity and pressure (see figure 2). Moreover, the colocated program displays faster

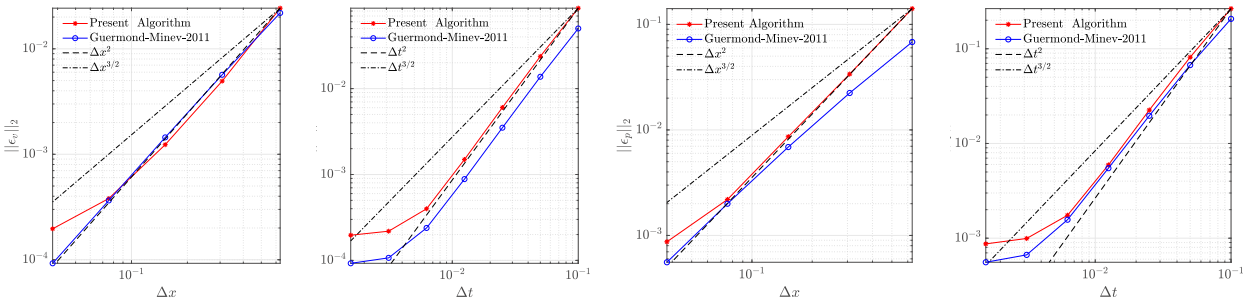

Figure 2: Convergence curves. Top-left panel: spatial convergence of the velocity; top-right panel: time convergence of the velocity; bottom-left panel: time convergence of the velocity; bottom-right: time convergence of the pressure

convergence in space with respect to the original staggered one (see bottom-left in figure 2).

In addition, the colocated version of the program is about 30% faster than the staggered one, and still presents high scalability by virtue of the Schur complement method used for parallelisation.

A HIGH ORDER COMPACT MESHLESS METHOD FOR MOVING BOUNDARY FLOWS

Y. YAO[1]*, D. Shyam Sundar[2], K.S. Yeo[2]
[1]Midea Corporate Research Center, Midea Group, Foshan, China
[2]Department of Mechanical Engineering, National University of Singapore, Singapore

Summary This article presents the application of a high order meshless method with compact support in moving boundary flow problems. The high order meshless method is applied to a mix of Cartesian and meshless nodes to construct an efficient hybrid high-order scheme. The present scheme was then applied to solve complex moving boundary problems including the ground effect of flapping airfoils and the flow phenomena in clap-and-fling motion.

INTRODUCTION

The meshless or meshfree methods have generated considerable interest among researchers for the treatment of problems with complex geometry [1-3]. Meshless methods are a class of methods that do not rely on a mesh for solution process. These methods require relatively lower cost of geometric and data administration, especially with problems involving complex deforming geometries. However, meshless methods are sensitive to the distribution of support nodes selected for data reconstruction. The problem of instability increases rapidly with increase in the order of meshless methods. In practice, additional supporting nodes are added until the set of nodes result in a valid interpolation.

The requirement for large supporting node set and the sensitivity of interpolation techniques to the distribution of support nodes have restricted the general application of meshless methods. Shyam Sunder et al. [4] presented a high order meshless method with compact support. The utilization of the increased degrees of freedom and corresponding high-order information at nodes results in a significant reduction in the number of support nodes needed for solution reconstruction. High-order accuracy of up to the 6th order was demonstrated in their work.

This research work is an extension and development based on what Shyam Sundar et al. [4] has done. We extended the compact meshless method to Cartesian grid system and constructed a hybrid high-order scheme with a mix of Cartesian and meshless nodes. The high order scheme was then applied in complex moving boundary problems. The results showed that the high order scheme can produce accurate results in small gap and proximity with lesser number of nodes.

NUMERICAL METHODS

Theoretical Formulation of High Order Meshless Method with Compact Support

Consider a meshless grid, where there exists at each node a solution data set, which describes the solution in the vicinity of the node. For a reference node i, N_s supporting nodes will be used to interpolate data set Q^i at node i. Thus, the solution data may be represented in terms of a finite linear expansion in a set of basis functions $Q^i = [\alpha^i]^T[\phi^Q]$. With proper selection of $[\phi^Q]$, we could get the derivatives of Q^i of any order in terms of and their derivatives. Conversely, the same equation can be used to find the coefficient $[\alpha^i]$ if we know the derivatives of solution data.

Let $\mathrm{I}^i = [\beta^i]^T[\phi^I]$ denotes a p_I order interpolant of Q^i. With sufficient number of support nodes, the interpolant coefficients $[\beta^i]$ can be obtained by solving the system of equations

$$\left[\frac{\partial^p \phi^I}{\partial \xi_i^m \partial \eta_i^{p-m}}\right]^T_{(\xi_i,\eta_i)=(\xi_{ij},\eta_{ij})} \left[\beta^i\right] = \left[\frac{\partial^p Q^j}{\partial \xi_i^m \partial \eta_i^{p-m}}\right]^T_{(\xi_i,\eta_i)=(\xi_{ij},\eta_{ij})}, (p \le p_Q) \quad (1)$$

where (ξ_{ij},η_{ij}) denotes the local coordinate of the *j*-th support node for the node *i*. In the present work, we adopt the singular-value decomposition (SVD) method to solve weighted Eq. (1) for $[\beta^i]$. The estimated $[\beta^i]$ then gives the interpolant I^i and its relation with the solution data. With M_Q number of derivatives available at a node, and N_s supporting nodes, $M_Q \times N_s$ number of equations can be constructed for Eq. (1). Thus, the supporting region of reference node could shrink to contain a moderate number of nodes, which allows stable reconstruction at high order of interpolation. The computation procedure for $[\beta^i]$ has been discussed in details by Shyam Sundar et al. in [1].

Governing Equations and Discretization

In this study, we investigate the moving boundary problems in incompressible viscous fluid flow. The present methodology is adopted to discretize the Arbitrary Lagrangian-Eulerian (ALE) form of the incompressible Navier-Stokes equations. Fractional step method is used to integrate the governing equations in time.

The discretized equations are solved on a hybrid Cartesian-cum-messfree grid system. The formulation described in the last section is used to obtain the derivatives on both kinds of nodes. The interpolation on the Cartesian nodes is

*Corresponding author. E-mail: yaoyang@u.nus.edu.

equivalent to that derived in the compact finite difference methods. At time step *n*, the Cartesian nodes overlapped by meshfree nodal cloud or moving body will not participate in the computation. For the overlapped Cartesian nodes that may emerge in the computation in the next time step, the field values on the nodes will be updated with the high meshfree scheme, thus to maintain the order of accuracy of the solution. More details of the 'nodal refreshing' process can be found in [2].

NUMERICAL EXPERIMENTS

Flapping Airfoil

We first studied the aerodynamics of a single 2D flapping elliptic airfoil. The numerical results were compared the experimental results of flapping wings in a free-steam velocity reported by Zhang et al. [4]. The single wing undergoes simple harmonic motion with exactly the same kinematics described in [5]. The time dependent thrust and lift coefficients are compared in Figure 1. The results clearly show that the good agreement between the numerical and experimental results was achieved.

Flapping in Ground Effect

We further studied the performance of the present computational method in ground effect simulation. Numerical results with the 2D flapping wing results of Gao & Lu [6] and experimental results of Lu et al. [7] were compared with the current CFD results. As shown in Figure 2, the variations of resultant lift and drag coefficients in all the three studies follow similar trend and can be categorized into the three regimes: force enhancement, force reduction and force recovery. However, the magnitudes of the resultant force coefficients are different from each other. The lift and drag coefficients obtained in the present study were substantially higher than those in the other flights.

Aerodynamic Effects in Clap-and-Fling

Aerodynamic effects of 2D clap-and-fling flapping motion were investigated at Re=150. The numerical method was carefully modified to allow the stable and accurate computations of rigid wings to be in extreme close proximity and even with physical clap occurring at the wing tips. The lift peak captured and aerodynamic force computed have shown good agreement with existing published results in [10].

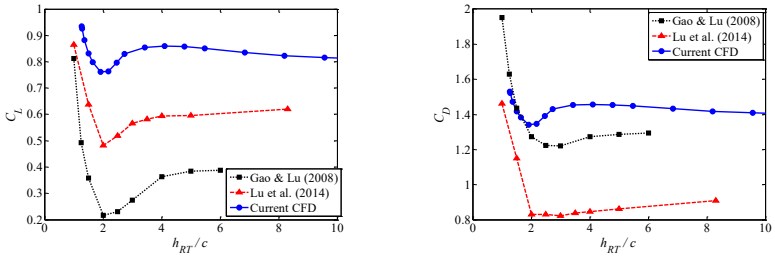

Figure 2. Force coefficients of a flapping wing in ground effect. (a) Lift coefficient, (b) Thrust coefficient.

CONCLUDING REMARKS

In this work, we extended the high order compact meshless method to hybrid meshfree-Cartesian grid with a unified interpolation scheme. The hybrid high order scheme was then applied in complex moving boundary problems involving small gaps. The numerical results proved that the present method could capture fine flow structures with high accuracy in moving boundary flows.

NUMERICAL MODEL OF THE COLLECTIVE FLIGHT OF METEOROID FRAGMENTS IN THE ATMOSPHERE

Vladislav Lukashenko, Fedor Maksimov
Institute for Computer Aided Design of RAS, Moscow, Russia

Summary We present a numerical model to simulate a collective flight of meteoroid fragments in the atmosphere. The calculation method is based on the system of grids and allows to consider the bodies of different shapes and sizes placed in different positions relative to each other. Collisions of the bodies are simulated with the help of 'billiard balls' model with impact recovery coefficient. Using this method, we studied the dynamics of the system consisting of ten bodies. Initially bodies were placed on the line perpendicular to the flight direction with a short distance between them. It was observed that two head formations appeared from initial configuration and in these formations multiple collisions of the bodies occurred. Eventually the formations merged together into a conical shape that continued to spread apart.

INTRODUCTION

The development of observational technologies shows that the fall of meteor bodies is not as rare occurrence as it was assumed before. It is important to construct accurate models to simulate the events of meteoroids entering Earth's atmosphere and their flight. Initially meteoroid may enter the atmosphere as a single body however it often cracks under the load due to inner defects and heterogeneity of the structure [1]. As a result, fragmentation occurs and a group of closely spaced fragments is formed in the stead of the singular body. These fragments continue their flight together however the difference in forces, acting on each body, should result in the restructuring of these fragments: some fragments may get separated from the group, while others may continue their flight together.

The studies concerning the dynamics of multiple bodies are often carried out by determining aerodynamic properties of the bodies at different relative positions [2]. This approach works relatively well for small number of bodies but becomes inconvenient for big systems due to a large number of potential positions of the bodies and time-consuming calculations. Alternative approach is to solve adjoint aerodynamic and ballistic problems [3]. At first the aerodynamic problem is solved for the current configuration of the bodies, and then coordinates and velocities of the bodies are changed according to the acting forces and moments. In this work we present a newly developed method [4] that allows to simulate dynamics of the collective flight of multiple bodies and can be used to determine the possible change in the trajectory of the fragments. Using this method we studied the problem of the expansion of a system of ten meteoroid fragments that initially formed a line perpendicular to the flight direction and results show that the bodies will restructure and eventually form a conical shape.

METHODOLOGY

A uniform grid with rectangular cells is used to describe the external non-viscous flow field. A set of other smaller grids is used to simulate the flow near the surfaces of the bodies. These grids are connected with each corresponding body and take into account their shape and size (Figure 1). Thin-layer approximation to the Navier-Stokes equations is used to describe the flow field on these grids (i.e. viscous flow is considered). An information exchange is established between the external grid and the grids built in the proximity of the bodies.

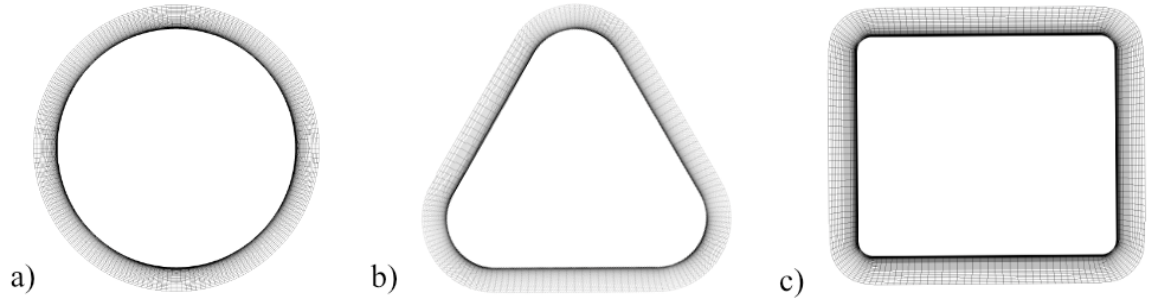

Figure 1. Grids that are built around cylindrical bodies with different shape of the cross section: (a) – circle, (b) – triangle, (c) – rectangle with elongation $\lambda = 1.2$.

Flow field is calculated using a two-step predictor-corrector method. The aerodynamic forces and moments acting on each body are determined from the pressure distribution, and then the state of the whole system is recalculated after a small time interval. Each body is moved together with its own grid to the distance that it should have passed. The flow field is recalculated over the given time interval with bodies having new positions. A new pressure distribution is calculated on the surfaces of the bodies. The whole process is repeated multiple times until calculations are completed.

If one body appears in the area behind another then it will have reduced resistance from the flow and, as a result, it will catch up with the body flying ahead. A collision is bound to occur in this situation as was shown by Barri [3]. The model of 'billiard balls' is used to simulate such collisions. Fragments are considered to be rigid bodies; the impact recovery coefficient is used to calculate the energy exchange and loss.

CALCULATIONS AND RESULTS

Using the method [4] we studied the dynamics of the system consisting of ten bodies that were initially placed near each other on the line perpendicular to the flight direction (Figure 2a). Due to time consuming calculations, two-dimensional plane problem was considered with bodies having a cylindrical shape with circular cross section. It was assumed that each body is an iron fragment with a mass of 1 kg and the flight was happening with a speed of 2 km/s at an altitude of 10 km. The distance between bodies was a variable parameter.

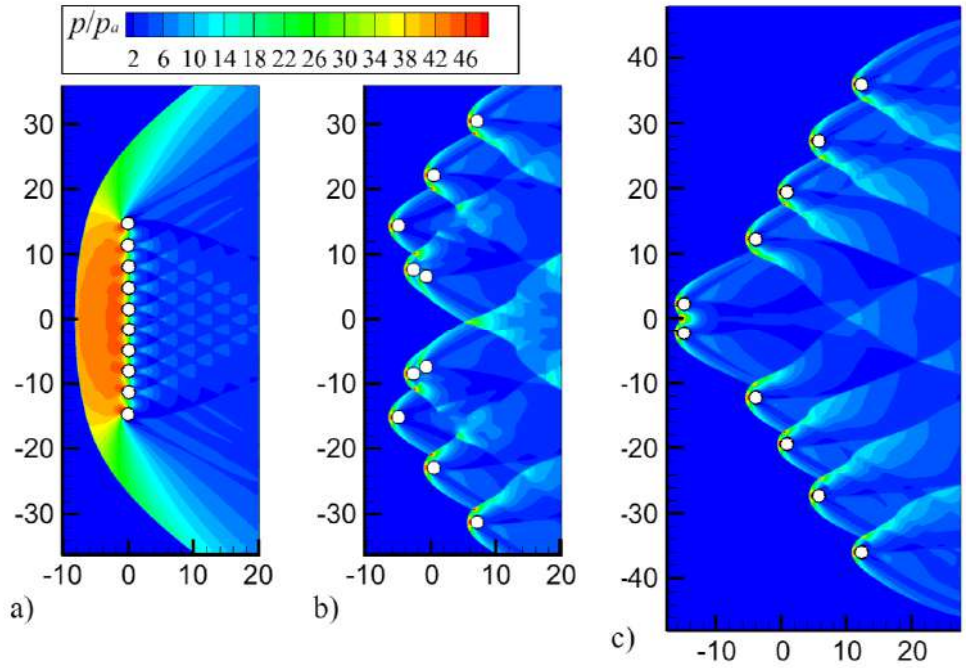

Figure 2. Pressure patterns for the expansion of a system of ten bodies: (a) – initial configuration with a collective head shock wave; (b) – appearance of two head formations in which collisions of the bodies occur; (c) – final configuration of the system that resembles a conical shape and continues to spread apart.

The results of the calculations show that outer bodies of the initial configuration (Figure 2a) fly apart from the group due to the asymmetry of the pressure on their surface, while the bodies in the center get pushed back due to the highest amount of pressure on their front. As the result the central bodies get dragged into the trail of the bodies located further from the middle of configuration and two head formations emerge (Figure 2b). Multiple collisions of the bodies occur in these head formations, however eventually the formations merge together forming a conical shape (Figure 2c). This conical shape remains relatively stable with bodies slowly spreading apart.

CONCLUSIONS

A new comprehensive method has been developed to study dynamics of complex systems of meteoroid fragments. The method allows to consider fragments of different shapes and sizes placed in different positions. The dynamics of the system consisting of ten bodies was studied. Initially bodies were placed near each other on the line perpendicular to flight direction. As a result of restructuring, two head formations appeared in which collisions of the fragments occurred. Eventually these formations merged together forming a conical shape that continued to spread apart.

COUPLED COOLING CHARACTERISTICS ANALYSIS FOR LAMINATED COOLING CONFIGURATION

Honglin Li[1], Lei Li1[1], Wenjing Gao[1], Zhonghao Tang[1], Fujuan Tong[1]
[1]School of Mechanics, Civil Engineering and Architecture, Northwestern Polytechnical University, Xi'an, China

Summary. The coupled cooling, internal cooling and film cooling of laminated cooling configuration are simulated under different blowing ratios using a new method that internal coolant air flows out computational domain at the film hole to decoupled internal cooling and remain the same flow pattern. Results indicate that while the coupled cooling contains the cooling characteristics of internal cooling and film cooling, its performance cannot directly derive from the superposition of internal cooling and film cooling, they will counteract part of cooling performance. Cooling effectiveness analysis under different blowing ratios shows that the internal cooling and film cooling effectiveness are about 98% and 25% that of coupled cooling separately.

Introduction and background

As the increasing requirement of gas turbine engines and aeroengines performance, the turbine inlet temperature gets dramatically raised and thus requires more advanced cooling method for turbine blade. The newly laminated cooling configuration can achieve larger temperature decrease than traditional cooling method since it integrates the advantages of film cooling, impingement cooling and pin fin cooling. Coolant air impinges into the laminated configuration and then flows through pin fins. Finally, it exhausts from film holes and forms the protective film. The external film cooling will influence the heat that transferred into blade from gas and the internal impingement cooling and pin fin cooling will also influence the formation of protective film. Therefore, the cooling process of laminated cooling configuration is a typical coupled cooling including internal cooling and external cooling.

It would be beneficial for the design of laminated cooling configuration to clarify the characteristics of internal and external cooling separately and their coupling property. Limited publications addressed this issue previously. Zhou, et al. [1] obtained the internal cooling effectiveness through directly minus the film cooling effectiveness from coupled cooling effectiveness. They found that the optimum coupled cooling effectiveness does not represent the optimum film cooling effectiveness or internal cooling effectiveness due to their interaction. Rao, et al. [2] conducted the coupled cooling numerical simulation and internal cooling calculations using constant temperature boundary conditions. Result shows that internal heat transfer is insensitive to the external flow. Though their studies have revealed the coupling property of laminated cooling to some extent, furtherly intensive investigation are still needed.

This study presents a new numerical method to calculate internal cooling considering the external flow and retaining the same flow pattern as coupled cooling. Combined with external cooling and coupled cooling calculation, three series of numerical simulations are conducted under different blowing ratios. The temperature distribution of outside surface and the cooling effectiveness under different blowing ratios are analyzed to clarify the coupling property, internal cooling characteristics and external cooling characteristics.

Numerical method

In this paper, a laminated cooling configuration is established which contained 7 cooling units as shown in Fig.1. Based on it, a fluid numerical model is also established which extended the gas flow channel to form gas inlet and outlet boundary, thus to eliminate the influence of boundary condition. In order to study cooling characteristics of internal cooling, external cooling and coupled cooling, three series of numerical method are employed. Simulating the flow and heat transfer between fluid and solid domains to obtain coupled cooling, simulating the flow and heat transfer only in fluid domain to obtain external cooling, simulating the flow and heat transfer both in fluid domain and solid domain with a coolant air outlet near the outside surface as shown in Fig.1 to obtain internal cooling.

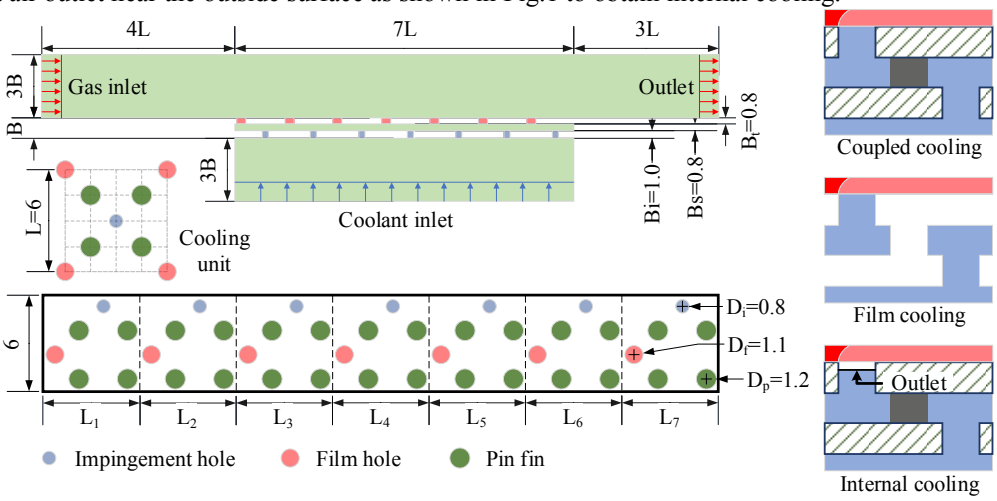

Fig.1 The dimension and three numerical calculation methods of laminated cooling configuration

Hot gas flows into fluid domain at 500 m/s and total temperature of 1800K. Coolant air flows into fluid domain at total temperature 800K and its total pressure varies among 111325Pa~171325Pa to obtain different blowing ratios. The outlet pressure is set to be 101325Pa. Hexahedron grid is used for fluid domain and tetrahedron grid is used for solid domain. SST turbulence model is employed and results shows Y+ value is less than 1 which satisfies requirement. Present numerical method has been verified by grid independence analysis and comparison with experiment.

Results & Discussion

Temperature distribution and effectiveness are analyzed under different blowing ratios which can be calculated by:

$$BR = \rho_c v_c / \rho_g v_g \quad (1) \qquad effectiveness = (T_g - T_w)/(T_g - T_c) \quad (2)$$

Fig.2 presents the temperature distribution of outside surface for three kinds of cooling calculations. When the laminated cooling configuration only has external cooling (film cooling), the film only covers a relatively small region behind film holes. Therefore, only a narrow low temperature region would be formed. At L1~L3 coolant units, when coolant air exhausts from film holes, it will attach outside surface firmly and cause an obviously low temperature region. However, at L4~L7 coolant units, the coolant air jet will penetrate the bulk flow and hence decrease the cooling performance. The low temperature region will disappear. When there is only internal cooling, the temperature distribution of outside surface appears clearly characteristics that it gets lowest at corresponding impingement region and then decreases along radial direction. The overall temperature is significantly lower than that of external cooling and it decreases from left to right due to the effect of hot gas flow. It can be clearly seen that the outside surface temperature distribution of coupled cooling distinctly shows the characteristics of internal cooling and external cooling. The overall temperature level is similar with that of internal cooling.

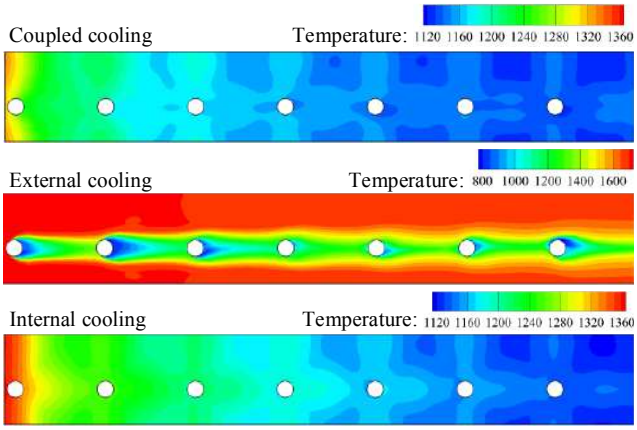

Fig.2 The outside surface temperature distribution (BR=0.62)

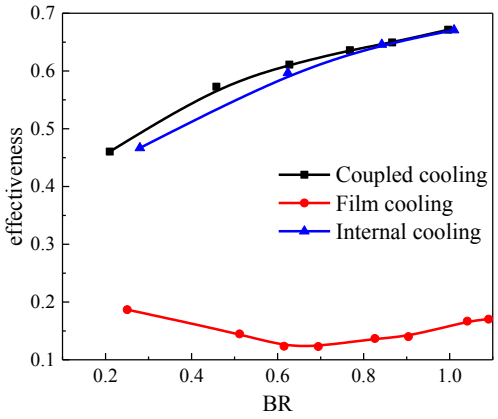

Fig.3 Cooling effectiveness under different blowing ratio

Fig.3 presents the outside surface area-averaged cooling effectiveness of L5~L6 cooling units. Corresponding to the temperature distribution as shown in Fig.2, the internal cooling has similar cooling effectiveness with coupled cooling while there is slightly difference when blowing ratio is lower than 0.6. The film cooling effectiveness is significantly lower than Internal and coupled cooling. When blowing ratio is lower than 0.6, the jet will gradually detach outside surface so that the cooling effectiveness decreases with the blowing ratio rises. When blowing ratio is higher than 0.6, the cooling effectiveness will increase because rising coolant air mass flow rate will furtherly enhance heat transfer. In general, the internal cooling effectiveness is about 98% of that of coupled cooling, meanwhile, the film cooling is about 25% of that of coupled cooling under all calculated blowing ratio. It indicates that coupled cooling performance cannot directly derived from the superposition of internal cooling and film cooling and they will counteract part of cooling performance.

Conclusions

The coupled cooling, internal cooling and film cooling of laminated cooling configuration are simulated under different blowing ratios using a new method that internal coolant air flows out computational domain at the film holes to decoupled internal cooling with the same flow pattern. The results show that coupled cooling contains the cooling characteristics both of internal cooling and film cooling and the internal cooling has similar temperature distribution with coupled cooling. Cooling effectiveness analysis under different blowing ratios shows that the internal cooling and film cooling effectiveness are about 98% and 25% that of coupled cooling separately. Coupled cooling performance cannot directly derive from the superposition of internal cooling and film cooling, they will counteract part of cooling performance.

SUPER-RESOLUTION RECONSTRUCTION OF UNPAIRED TURBULENCE USING GENERATIVE ADVERSARIAL NETWORKS

Junhyuk Kim[1], Hyojin Kim[1], and Changhoon Lee*[1,2]
[1]Department of Mechanical Engineering, Yonsei University, Seoul, Republic of Korea
[2]Department of Computational Science and Engineering, Yonsei University, Seoul, Republic of Korea

Summary We investigated super-resolution reconstruction of turbulent flows using an unsupervised learning method, generative adversarial networks (GANs). Unlike previous studies that have applied supervised learning to predict direct numerical simulation (DNS) data from filtered DNS data, the present study has novelty in the use of unpaired turbulence data. We found that an unsupervised learning adopting GAN model has statistically similar reconstruction capability of turbulent flows to that of supervised learning one. Therefore, super-resolution reconstruction of turbulence could be extended to much wider applications such as translation from large-eddy simulation (LES) to DNS, connection between experiment and simulation, and de-noise.

INTRODUCTION

The equations governing turbulence have long been established as the Navier-Stokes equations, but their solutions are difficult to predict due to their nonlinearity and multi-scale nature. Recently, deep learning has been rapidly developed to find a function that represents the nonlinear correlation of turbulence. In particular, convolutional neural networks (CNNs) effectively represent spatial correlation with fewer trainable parameters than fully connected neural networks (FCNNs). As a result, in addition to turbulence closure modelling, they were applied to various fields such as unsteady flow prediction, super-resolution reconstruction of turbulent flows[1], analysis of spatial relation between turbulence variables[2], and inflow turbulence generation[3].

Especially, super-resolution flow reconstruction is very important in a direct application in simulations and experiments as well as in a fundamental study related to the large-scale motions and their effect on the small-scale modulation. If a high-resolution reconstruction from low-resolution turbulence is possible, it means that there is a connection between the relatively large-scale structures and the small-scale structure. It could be a basis for the sub-grid scale modelling of large-eddy simulation (LES). In addition, from an experimental viewpoint, it will help to overcome the environment where only some data can be measured due to the limitation of measuring equipment.

The CNN model used by Fukami et al.[1] showed the reconstruction ability of isotropic turbulence from filtered one. However, with an increase in resolution ratio, poor representation of small-scale structures was observed because there are too many possible high-resolution solutions from low-resolution data. To overcome this, generative adversarial networks (GANs) proposed by Goodfellow et al.[4] could be used to give a possible high-resolution solution with realistic small-scale structures. Using the GAN training framework, Xie et al.[5] proposed a super-resolution reconstruction model for smoke flows. Deng et al.[6] also applied GAN to high resolution reconstruction of turbulent flow around cylinders and showed statistically accurate results similar to DNS.

However, most studies are restricted to supervised learning frame that low-resolution data is obtained from DNS, and the input (filtered DNS) and the output (DNS) are paired. It is unlikely that the trained model developed under these frames could well reconstruct high-resolution flow field from the LES data or experimental data which were not used for training. That is, there is a strong need for an unsupervised learning methodology that can learn unpaired turbulence data, such as LES data and DNS data, and sparse-measured data and dense-measured data, and could be used in realistic environments.

In this study, we apply GAN, one of the unsupervised learning methods, to reconstruction of super-resolution using unpaired turbulence data. Kim and Lee[3] found that GAN can learn the similarity in turbulence data obtained with different simulation parameters. From this experience, we expect that performance of unsupervised learning might be similar to that of supervised learning by learning the similarity of turbulence structure in unpaired data.

METHODOLOGY

In unsupervised learning, the most different thing from supervised learning is that input (X) and output (Y) data are not paired. Therefore, there is no clear loss such as mean-squared-error (MSE) between predicted field and targeted one. The basic GAN objective function without MSE could be expressed as follows.

$$\min_G \max_D \mathbb{E}_Y\left[\log\left(D(Y)\right)\right] + \mathbb{E}_X\left[\log\left(1 - D(G(X))\right)\right]$$

In our problem, X and Y are low-resolution turbulent flow fields and high-resolution ones which are not paired. After training, $G(X)$ could give a high-resolution flow field. However, $G(X)$ is less dependent on X and has low prediction accuracy compared to supervised learning method because desirable correlation between X and $G(X)$ is not considered in the above objective function. To reflect correlation between low-resolution flow fields and high-resolution ones, an inverse mapping $F : Y \rightarrow X$ is added and a cycle consistency loss is enforced [7].

*Corresponding author. E-mail: clee@yonsei.ac.kr.

RESULTS AND CONCLUSIONS

The framework was applied to two test cases. In the first one, DNS and filtered DNS data of homogeneous isotropic turbulence were used as Y and X, respectively. For the purpose of comparison, supervised learning using direct MSE between reconstructed field and DNS one with GAN was carried out. As a result, unsupervised GAN model could give statistically high reconstruction ability compared with DNS flow fields. It also achieved low MSE between reconstructed field and DNS one, similar to the supervised learning GAN model. In other words, we found that unsupervised GAN model could reflect physical correlation between low-resolution and high-resolution turbulent flows with a level similar to supervised learning.

In second test case, DNS and LES data of fully developed turbulent channel flow were used. Supervised learning framework could not be used for this unpaired problem. Our unsupervised learning model also showed high statistical accuracy with DNS. We could observe high similarity between the LES field and the DNS-like one reconstructed from LES one. Our results indicate that it is possible to match unpaired turbulence data, which was thought to be impossible so far. In addition to changing LES field to DNS one, unsupervised GAN could be applied to connect experiment and simulation, to reconstruct dense-measured data from sparse-measured one, and to reduce noise in the measured data.

CFD MODELING OF TWO-PHASE FLOWS IN CONCRETE CRACKS

Germain Davy*[1,2,3], Etienne Reyssat[3], Stéphane Vincent[2], and Stéphane Mimouni[1]
[1]R&D Division, Electricité de France (EDF), Chatou, France

Summary In the event of a pressurized water reactor loss-of-coolant accident, hot water vapor would infiltrate and condensate into cracks present in the concrete containment structure. The liquid water could form capillary bridges, which would probably modify the leakage rate. This paper presents the latest developments to the NETPUNE_CFD code in the context of the modeling of two-phase flows in concrete cracks under LOCA conditions. Water vapor condensation is affected by the presence of non-condensable gases. Liquid bridges dynamics depends on wettability. Two physical models are proposed. The first one is a condensation model allowing to take into account non-condensable gases. The second one is a wettability model allowing for the imposition of a given contact angle. The results of these numerical models are compared with analytical and experimental studies.

CONTEXT

In the event of a pressurized water reactor loss-of-coolant accident (LOCA), a large amount of water vapor, as well as fission products, would be released in the containment building. The large pressure involved would open up preexisting cracks in the concrete walls, through which potentially dangerous fission products could escape.

The flow of water vapor inside the relatively colder cracks would induce condensation. The liquid water would form drops, films and eventually capillary bridges (see Figure 1), which would counteract the primary flow and thus probably modify the leakage rate of the containment building [1].

This paper aims to present the latest advances in the modeling of gas-liquid flows in concrete cracks with the NEPTUNE_CFD code in the context of a LOCA.

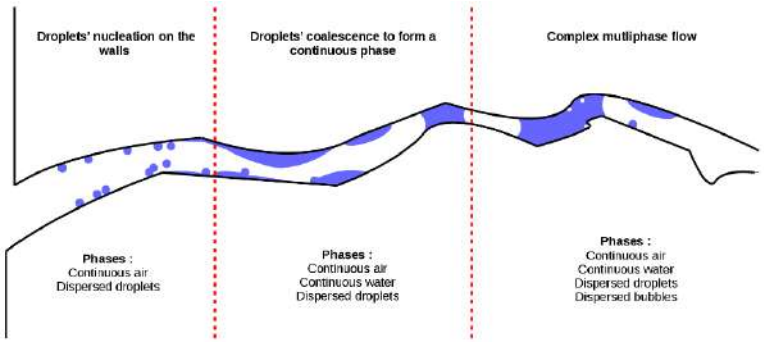

Figure 1. Crack in which water vapor has condensed.

NEPTUNE_CFD

NEPTUNE_CFD is Electricité de France's (EDF) in-house multiphase computational fluid dynamics code. It is based on the two-fluid model of [4] extended to n-fields and allows for three-dimensional calculations of compressible and turbulent flows.

In NEPTUNE_CFD, in the context presented above, the liquid phase can be modeled as a dispersed or as a continuous field. In the latter case, which corresponds to the modeling approach adopted in this paper, the gas-liquid interface is explicitly captured and surface tension can be taken into account [2].

CONDENSATION

Two condensation models are available in NEPTUNE_CFD. The first one is specific to wall condensation. Dispersed liquid droplets nucleate at the wall and grow due to heat and mass transfer in the core flow [5]. The second one is specific to explicitly captured interfaces [2].

Unlike the model by [5], the model by [2] was originally not developed to deal with non-condensable gases. An adaptation of this model for cases involving such gases is proposed. The adapted model has been successfully validated on several test cases, including one corresponding to the well-known Stefan problem.

DYNAMICS

The presence of a capillary bridge in a model crack can lead to a no-flow state, depending on the orientation of the walls and on the contact angle (CA) made by the liquid on the solid [6].

Based on the work of [3], a model allowing for the imposition of a given CA of the liquid on the solid has been implemented in NEPTUNE_CFD (see Figure 2). While most of the existing models consist in correcting the interface normal at each time step to match the imposed CA, the model proposed here simply consists in adding a penalization term in one of the equations solved and thus does not require any correction step. This model has been successfully validated both in statics, by comparison with Jurin's law, and in dynamics, by comparison with Wang's experimental data [7].

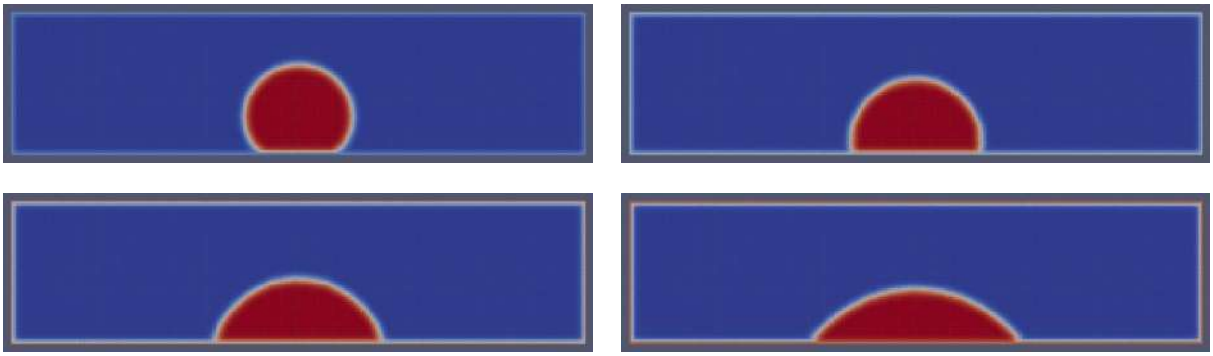

Figure 2. Water droplet at equilibrium. From top to bottom and left to right: $CA = 138°, 111°, 72°, 37°$.

CONCLUSIONS

Two new physical models have been implemented in the NEPTUNE_CFD code in the context of the modeling of two-phase flows in concrete cracks under LOCA conditions. The first one is a condensation model allowing to take into account non-condensable gases. The second one is a wettability model allowing for the imposition of a given contact angle. Both models have been successfully validated by comparison with analytical and experimental results.

Future work will focus on the development of a model for thermal expansion of concrete, phenomenon resulting from condensation and causing the cracks opening to decrease. The three models (condensation, wettability and thermal expansion) will then be coupled. 3D representative calculations at the scale of the cracks will finally be performed and the impact of the flow structures such as the capillary bridges on the leakage rate will be assessed.

A POSTERIORI STABILIZATION OF CONVECTION-DOMINATED FLOWS. SOME APPLICATIONS TO REDUCED ORDER MODELING

Summary We present a simple general procedure to stabilize the spurious oscillations due to convection-dominance in the numerical solution of fluid flow problems. We apply it to Finite Element and Proper Orthogonal Decomposition discretizations, for both convection-diffusion problems and Navier-Stokes equations.

INTRODUCTION

The numerical solution of fluid flow problems generates well-known spurious numerical instabilities when the convection term dominates the diffusion one at the discrete level, provoking the failure of the discrete maximum principle. We address in this talk the treatment of this difficulty with conformal discretizations. Typically, to avoid these instabilities, the numerical discretizations need to be modified by means of complex stabilization (projection stabilization, method of characteristics or variational multi-scales among others) techniques, that ultimately need to be non-linear if all spurious oscillations are to be eliminated. These techniques have experienced a vast development in the last decades (Cf. for instance [1, 2, 4]).

In the last years the solution of parametric PDEs by reduced order models (ROM) has experienced a fast development due to its ability to dramatically reduce the computing times to solve the PDE. These ROM are Galerkin methods constructed on structurally-fitted discrete spaces of very low dimension, able to accurately represent the dominant features of the parametric range of the flows to be solved. The construction of the ROM basis requires the solution of the parametric PDE with an accurate numerical method (the full order method, FOM) for a well chosen set of parameters. The solution of flows with convection-dominance by ROM similarly faces the presence of spurious oscillations, that needs to be stabilized as well. Many efforts are being addressed in this sense to let really useful the reduced order solution of fluid flows. The strategy again is to modify the discrete equations by introducing stabilization terms (Cf. [3, 5]).

In this talk we follow a different approach. Our intention is to act on the numerical solution polluted by spurious oscillations, applying a post-processing procedure aimed at damping them. This is not based upon a pure filtering technique that does not take into account the PDE, but rather it is consequence of a self-stabilizing effect that is present in the Galerkin discretization of fluid flow equations on any discrete space. Indeed, the large scales of the discrete solution satisfy a modified variational formulation with additional diffusive terms. The strength of these diffusive terms depends on the actual decomposition of the discrete solution as sum of a large and a small scale component. This lets a large range of possibilities to the user to optimize the post-processed solution.

This post-processing procedure may be applied to any Galerkin method. We here present applications to Finite Element and Proper Orthogonal Decomposition (POD) discretizations. In this last case we will also show the interplay between the a-priori stabilization of the FOM and the a-posteriori stabilization by our method.

We at first describe the post-processing procedure in an abstract framework, then apply it to the finite element solution of Navier-Stokes equations and finally to POD solution of convection-diffusion equations.

A POSTERIORI STABILIZATION

Let us describe the process of a-posteriori stabilization in an abstract framework. Let us consider an elliptic variational problem: Find $x \in X$ such that $b(x,w) = l(w) = \langle f, w\rangle, \quad \forall w \in X$, where X is a Hilbert space. The form b is defined on $X \times X$ and $l \in X'$, being X' the topological dual of X. Consider a family of sub-spaces of finite dimension of X, $\{X_i\}_{i\in\mathcal{I}}$, for some set of indices $\mathcal{I}$. Let us assume that we solve the problem by the Galerkin method on X_i: Find $x_i \in X_i$ such that $b(x_i,w_i) = l(w_i), \quad \forall w_i \in X_i$. Assume that the space X_i is decomposed into $X_i = Y_i \oplus Z_i$, where Y_i and Z_i are subspaces of X_i. Let $x_i = y_i + z_i$ be the unique decomposition that x_i admits with $y_i \in Y_i$ and $z_i \in Z_i$. The Galerkin discretization may be recast as a variational problem for the only unknown y_i, as follows. Denote by $\mathcal{A}$ the operator from X on X' defined by the form b; that is for $v \in X$, $\mathcal{A}v$ is the element of X' defined by: $\langle \mathcal{A}v, w\rangle = b(v,w), \quad \forall w \in X$. Denote by $\mathcal{R}_i : X' \mapsto Z_i$ the "static condensation"operator on Z_i generated by the form b, defined for $\varphi \in X'$ by: $b(\mathcal{R}_i(\varphi), w_i) = \langle \varphi, w_i\rangle, \quad \forall w_i \in Z_i$. Let us introduce the "condensed" variational formulation to the Galerkin discretization: Find $y_i \in X_i$ such that $b_c(y_i,v_i) = l_c(v_i), \quad \forall v_i \in Y_i$, with $b_c(y,v) = b(y,v) - b(\mathcal{R}_i(\mathcal{A}^*v), \mathcal{R}_i(\mathcal{A}y)), \quad l_c(v) = l(v) - b(\mathcal{R}_i(\mathcal{A}^*v), \mathcal{R}_i(f)), \quad \forall y, v \in X$; where $\mathcal{A}^*$ is the adjoint of $\mathcal{A}$.

Let us consider a family of finite-dimensional spaces $\{(Y_i, Z_i)\}_{i\in\mathcal{I}}$, where $\mathcal{I}$ is a set if indices, satisfies the saturation property $\|y_i\|_X + \|z_i\|_X \leq \alpha \|x_i + y_i\|_X, \quad \forall y_i \in Y_i, z_i \in Z_i, \quad \forall i \in \mathcal{I}$, for some $\alpha > 0$. Assume in addition that

*Corresponding author. E-mail: chacon@us.es.

$Y_i \cap Z_i = \emptyset$. Let $x_i = y_i + z_i$ be the unique decomposition of some $x_i \in X_i$, with $y_i \in Y_i$ and $z_i \in Z_i$. Then, x_i is the solution of the Galerkin method if and only if y_i is the solution of the condensed variational formulation, and $z_i = \mathcal{R}_i(l - \mathcal{A}(y_i))$. Moreover, there exists a constant $C > 0$ such that $\|y_i\|_X + \|z_i\|_X \leq C\,\|l\|_{X'}, \quad \|c_i\|_X \leq C\,\|l\|_{X'}$, where $c_i = \mathcal{R}_i(\mathcal{A}(y_i))$. Note that c_i is a representation on Z_i (by means of the static condensation operator) of the small-scale components of the operator $\mathcal{A}$ acting on y_i. Due to the last estimate, c_i is uniformly bounded in X norm. We interpret this bound as an a-posteriori stabilization effect.

In practice, if X_i is a FE space, Y_i could be a subspace of X_i constructed on a sub-grid with coarser elements, or with polynomials of lower degree. This construction may be local in space, acting only on the elements located in a sub-set of the computational domain. Also, if X_i is a POD space, or a more general ROM space, then Y_i could be a subspace formed by a truncated set of basis functions of low frequency. In both cases, Z_i will be a space containing the small scales (or high frequency) components of the space X_i. Anyhow only the restriction operator from X_i onto Y_i is needed to construct the post-processing, space Z_i is not needed. For evolution problems, the post-processing procedure may be applied at a given time step, without need of post-processing the preceding ones.

APPLICATIONS

Figure 1 depicts the effect of the post-processing procedure to the piecewise finite element solution of the steady Navier-Stokes equations in a channel with an obstacle, at $Re = 1000$. The computational domain is$[0, 10] \times [0, 1]$. Fig. 1 shows the stabilized y_i of x_i (the computed velocity) after locally applying the procedure on the domain $[0, 1.2] \times [0, 1]$. The degrees of freedom of y_i are the "even" nodes of the grid. The values of y_i at those nodes are the same as the values of x_i. We observe that all oscillations have disappeared, and that the quality of the numerical solution is improved.

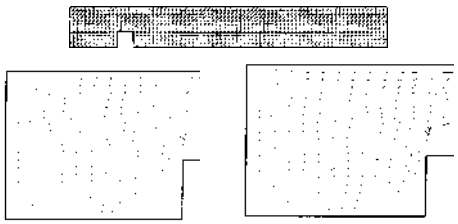

Figure 1: Post-processing of convective instabilities for Navier-Stokes FE produced by a frontal obstacle in a channel

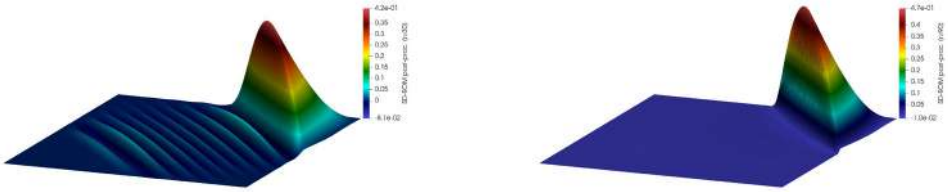

Figure 2: Numerical solution for SD-POD with stabilizing post-processing at $T = 1$ for $r = 30, 90$ (from left to right).

Figure 2 displays the effect of post-processing the POD solution to the evolution convection-diffusion equation with a traveling inner front, with Péclet number 10^8, applied at $T = 1$. The POD basis are constructed from the solutions provided by the FOM: a finite element discretization that, despite including a local projection stabilization of the advection operator, still present large spurious oscillations. We observe that when space Y_i is formed by the $r = 30$ more energetic basis functions out of 100 large oscillations still remain, while when it is formed by the $r = 90$ most energetic basis functions, these are largely reduced. These basis respectively contain 99.71% and 99.96% of the kinetic energy of the POD. The L^2 error is reduced from 0.12 for the Galerkin solution to 0.06 with the post-processed POD solution.

THEORETICAL AND NUMERICAL ANALYSIS OF A MEMBRANELESS REDOX FLOW BATTERY

Désirée Ruiz-Martín[1], Daniel Moreno Boza[1], Marcos Vera[1], Rebeca Marcilla[2], and Mario Sánchez-Sanz*[1]
[1]Departamento de Ingeniería Térmica y de Fluidos, Universidad Carlos III de Madrid, 28911, Leganés, Madrid, Spain

Summary In this work we present the first mathematical model for the description of a membrane-free redox flow battery formed by two co-flowing immiscible electrolytes. The interface separating the liquid-liquid system is well defined once the physical fluid properties (viscosity and density ratios), Reynolds and mass flow rate are specified. Here we focus on testing the feasibility of a flow battery working in laminar regime. In particular we present the variation of the cell voltage with the state of charge (SoC) for different current intensities I_{app}, to show that the operational range of SoC becomes narrower as I_{app} increases. The performance of the cell is thoroughly assessed varying the flow rate of the electrolytes to show a steady working power of around 1 mW/cm^2 at Reynolds numbers $Re = 20$, comparable to the experimental values reported by [1].

INTRODUCTION

The increasing concern about climate-related issues has stimulated the demand of energy-storage systems to increase the penetration of green energy into sectors that could no benefit yet from the utilization of renewable energy. In this regard, electrochemical storage (batteries) are widely used in stationary applications. In particular, Redox Flow Batteries (RFBs) present several advantages, among which is worth mentioning the total decoupling of power and energy densities and the rapid mechanical charging easily achieved by substituting spent electrolytes with fresh ones. However, most RFBs use an expensive ion-selective membrane to separate the electrolytes and prevent the crossover of active species while providing the exchange of the active charge carriers. The high cost of these membranes has motivated the development of membrane-free designs with two immiscible electrolytes that form a separating interface which allows the exchange of active species [1, 2].

DESCRIPTION OF THE PROBLEM

In this work we present a two-dimensional model of a membrane-less battery formed by two immiscible liquids. The flow geometry under consideration is depicted in Fig. 1. We consider a channel of width h and length $L \gg h$ fed with two liquid streams at flow rates per unit spanwise length Q_1 and Q_2. The traditional vanadium compounds have been replaced with organic molecules in accordance with the previous work of Navalpotro et. al [1]. Thus, the catholyte consists of an acidic solution of hydroquinone (H_2Q), with viscosity μ_2 and density ρ_2, while for the anolythe we considered the redox-active organic molecule parabenzoquinone (pBQ) dissolved in hydrophobic ionic liquid with viscosity μ_1 and density ρ_1. The viscosity ratio between both fluids is large, $\mu_1/\mu_2 = 80$, while the density ratio ρ_1/ρ_1 is assumed to be unity. The interface Γ separating both fluids has been tracked using the Arbitrary Lagrangian-Eulerian (ALE) method [3]. For the sake of simplicity, the dilute solution theory is assumed to decouple the velocity and the species concentration field. Therefore, we first computed the velocity field and, in a second step, we determined the distribution of mobile ionic species as well as the current and electric potential field of the electrolyte. Both geometrical and flow parameters are carefully chosen to avoid the emergence of shear and viscosity driven instabilities that could perturb the shape of the interface $Re = \rho_1 Q_1 h_0/\mu_1 \leq 20$. For this purpose, before obtaining the electrochemical parameters of the RFB, we performed a complete study of the stability of the two-layer, viscosity-stratified Poiseuille flow following the approach used by [4, 5].

CONCLUSIONS

Unlike previous membrane-less designs, limited to work in laminar conditions to avoid the crossover of active species, the operation of the proposed design is not restricted to low Reynolds numbers. Besides, the device can be applied to both aqueous and non-aqueous electrolytes. The model developed provides, under a particular set of fluid and electrochemical parameters, the current-voltage polarization curves as well as the species concentration and ionic potential fields both during charge and discharge. We have verified that the limiting current density increases with Reynolds number both under charge and discharge conditions. Accordingly, higher power densities are achieved as the flow rate increases. The effect of the flow only becomes evident at larger flow rates, when the limiting current density is shifted towards larger values as the gradient concentrations near the electrode surface are reduced. Our results are qualitatively consistent with previous studies, showing during discharge operation a dependency of the limiting current density with the flow rate similar to the $Re^{1/3}$ predicted by Braff et al [2] (see Fig. 2). Besides, the maximum power density obtained at $Re = 20$ is around 1 mW/cm^2, comparable to the experimental values reported by [1]. The effect of the State of Charge (SoC)

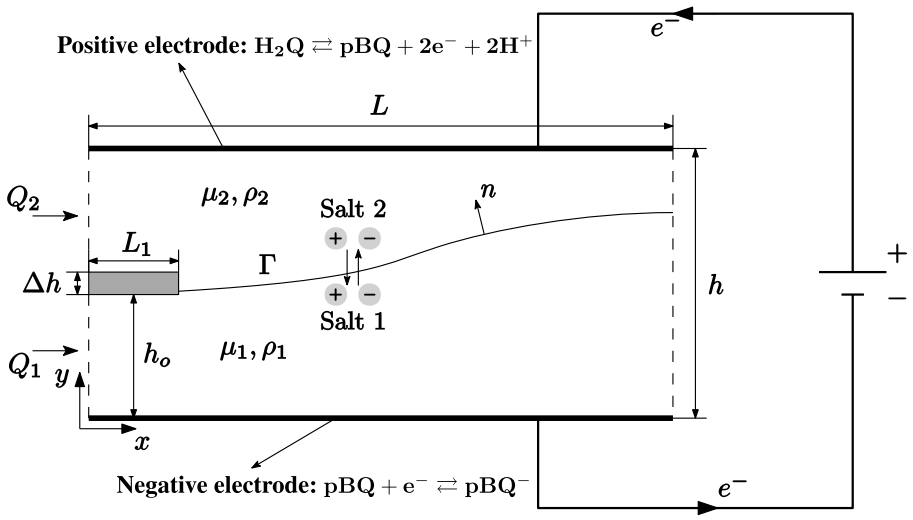

Figure 1: Schematics of the problem, including the geometrical, fluid-dynamical and electrochemical relevant parameters.

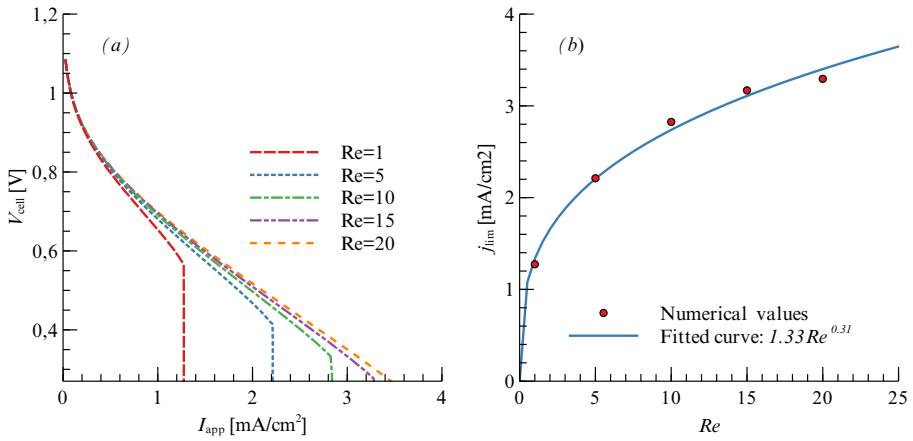

Figure 2: (a) Discharge polarization curves for different Reynolds numbers: 1 (red dashed dotted line), 5 (blue dashed line), 10 (green dotted line), 15 (purple dotted line), 20 (yellow dotted line) . (b) Value of the limiting current density as a function of Reynolds number. Both figures are calculated at 50% SoC.

has also been analysed. Low SoC values lead to fuel depletion at the anode whereas at SoC close to unity the absolute values of the overpotentials at the anode and cathode increase as a result of the high gradient concentrations. Thus, the performance of the device relies closely on the suitable reactant supply to the electrodes.

EFFECT OF AN IMPULSIVELY-ACCELERATED FLOW ON THE PIPE BEND FORCES

Feroz Ahmed *[1], Emad Moeendarbary[1], and Alireza Azarbadegan[2]
[1]Department of Mechanical Engineering, University College London, London, WC1E 7JE, UK
[2]BP Exploration Operating Company Limited, Chertsey Road, Middlesex, TW16 7NL, UK

Summary We studied the influence of strongly impulsively-accelerated flow on the forces in 90-degree pipe bend. This force is characterised by a step change due to high Strouhal number flow. The problem is analytically and numerically analysed at $Re = 2000$, $St = 1$ and $R_c/D = 1.5$. Various contributions to the total bend forces are found: momentum flux (ρU_b^2), time-acceleration ($\rho \mathrm{d}U_b/\mathrm{d}t$), pressure at the bend inlet (p_{bi}) and outlet (p_{bo}).

INTRODUCTION

Unsteady flows (positive branch of sine function $|\sin \Omega_p t|$) along circular pipes are one of the most studied problems in fluid mechanics encompassing a type of geometry (the circular tube) and a type of flow driven by a heart [1] or a pump [2] common in nature and industry. Unlike smoothly varying acceleration in sinusoidal flows ($\sin \Omega_p t$), these flows exhibit an impulsively-accelerated components, and are characterised by large jumps in the acceleration. Impulsively-accelerated flows are especially common in high-pressure high Strouhal number flow systems in the energy sector where high static pressures can only be achieved with reciprocating pumps. The purpose of this paper is to understand the effect of an impulsively-accelerated flow on the forcing characteristics in the pipe bend. These forces are problematic with respect to the stress, vibration and hence fatigue.

MATHEMATICAL FORMULATION

We analyse a duplex configuration of reciprocating pump that consists of a periodic volume flux (see figure 1 (a)) and focus on a 90-degree bend (see figure 1 (b)), a geometry common in the energy sector.

Fluid Mechanical Model

The three-dimensional fluid flow $\boldsymbol{u}$ is driven by the gradient of a pressure field p and resisted by viscous stresses $\boldsymbol{\tau}$. The dynamics of an incompressible Newtonian fluid are described by the Navier-Stokes and the continuity equations,

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}\right) = -\boldsymbol{\nabla}p + \boldsymbol{\nabla}\cdot\boldsymbol{\tau}, \qquad \boldsymbol{\nabla}\cdot\boldsymbol{u} = 0, \tag{1}$$

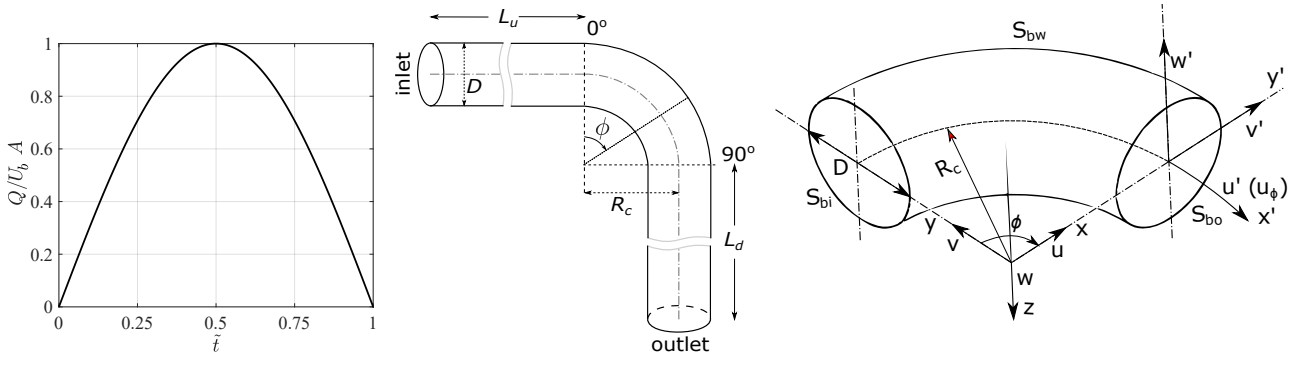
where ρ is the fluid density. The velocity field is set on the pipe inlet through a volume flux (Q), and by imposing a kinematic constraint on the velocity at the pipe wall surface. The periodic volume flux is set as

$$Q(t) = AU_b|\sin \Omega_p t|, \tag{2}$$

where U_b is the maximum velocity, Ω_p is angular frequency, and A is the pipe cross-sectional area (see figure 1 a). On the pipe outlet surface, the pressure is set as $p = 0$. The key parameters are

$$Re = \frac{U_b D}{\nu}, \quad St = \frac{\Omega_p D}{2\pi U_b}, \quad \frac{R_c}{D}. \tag{3}$$

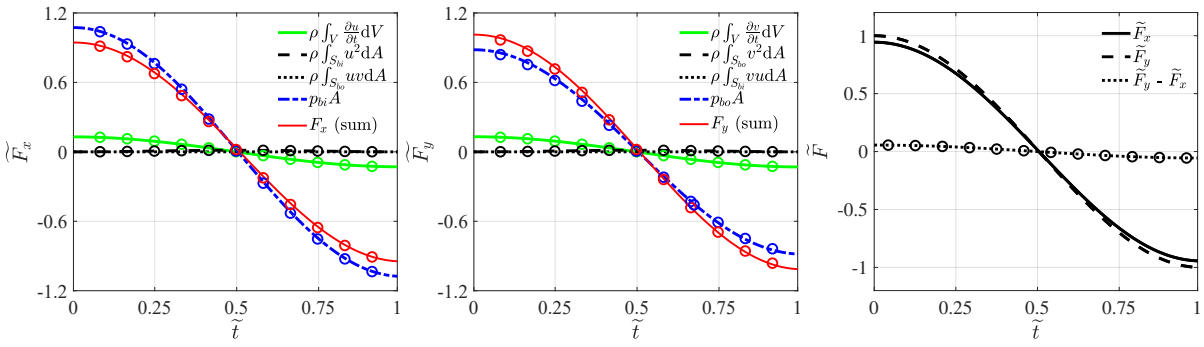
where Re is Reynolds number, St is Strouhal number, R_c/D is the curvature ratio, ν is kinematic viscosity, R_c is radius of curvature, and D is pipe diameter. Numerically, equation (1) were solved within ANSYS FLUENT 19.0.



(a) (b) (c)

Figure 1. (*a*) The variation of an inlet volume flux (Q/U_bA) with dimensionless time ($\widetilde{t} = \Omega_p t/\pi$) is shown for one cycle. (*b*) A schematic of the computational domain is shown along with the geometrical length scales. (*c*) The coordinates along with the bend surfaces are shown. The surfaces includes the curved wall (S_{bw}), inlet (S_{bi}) and outlet (S_{bi}) surfaces.

*Corresponding author. E-mail: ucemfah@ucl.ac.uk



(a) (b) (c)

Figure 2. The pipe bend force in the (a) x- and (b) y- direction are decomposed into integral components and evaluated numerically (solid lines, (4)) and estimated analytically (circular makers, (6)). In (c), the difference in $\widetilde{F}_x$ and $\widetilde{F}_y$ are plotted. The dimensionless force is $\widetilde{F}_x(\text{ or } \widetilde{F}_y) = F_x(\text{ or } F_y)/\rho A\Omega_p U_b(L_d + R_c)$.

Analytical Model

Using the momentum integral approach, the force can be expressed in terms of an integral over the pipe bend inlet and outlet surfaces (S_{bi} and S_{bo}) (see figure 1 (c)), and the pipe bend fluid volume (V)

$$\begin{aligned}\boldsymbol{F}_p\big(=(F_x,F_y)\big) = -\Big(p_{bi}A + \rho\int_{S_{bi}} u_\phi^2\mathrm{d}A + \rho\int_{S_{bo}} u_\phi v'\mathrm{d}A\Big)\hat{\boldsymbol{n}}_i \\ -\Big(p_{bo}A + \rho\int_{S_{bo}} {u_\phi}^2\mathrm{d}A + \rho\int_{S_{bi}} u_\phi v'\mathrm{d}A\Big)\hat{\boldsymbol{n}}_o - \rho\int_V \frac{\partial \boldsymbol{u}}{\partial t}\mathrm{d}V - \int_{S_{bi}+S_{bo}} \boldsymbol{\tau}\cdot\hat{\boldsymbol{n}}\mathrm{d}S,\end{aligned} \tag{4}$$

where p_{bi} and p_{bo} are bend inlet and outlet pressure and $\hat{\boldsymbol{n}}_i\big(=(-1,0)\big)$, $\hat{\boldsymbol{n}}_o\big(=(\cos\phi,-\sin\phi)\big)$ are unit vectors normal to the pipe bend inlet and outlet. [3] applied a momentum approach to evaluate the unsteady forces on a pipe bend due to slugs passing, where the V changed with time due to the slug movement, but the Q was constant. In our example, the V is constant, but Q changed with time. At high Reynolds numbers, the main contributions to the bend force is due to the deflection of the pipe flow arising from the change in $\hat{\boldsymbol{n}}$ and the integral along the bend (from $\int \hat{\boldsymbol{s}}\mathrm{d}V$), with weaker contributions from the secondary flow and viscous effects. At high St, the pressure gradient is dominated by the fluid acceleration $p = -\rho(\mathrm{d}U_b/\mathrm{d}t)\hat{\boldsymbol{s}}$. The pipe bend force is, to leading order,

$$\boldsymbol{F}_p \simeq -(p_{bi}+\rho U_b^2)A\hat{\boldsymbol{n}}_i - (p_{bo}+\rho U_b^2)A\hat{\boldsymbol{n}}_o - \rho\frac{\mathrm{d}U_b}{\mathrm{d}t}\int_V \hat{\boldsymbol{s}}\mathrm{d}V, \tag{5}$$

where $\hat{\boldsymbol{s}}\big(=(\cos\phi,-\sin\phi)\big)$ is the tangential unit vector. The force components for a 90-degree bend ($\phi_m = \pi/2$) are

$$\begin{aligned}F_x &= \Big(p_{bi} - p_{bo}\cos\phi_m + \rho U_b^2(1-\cos\phi_m) - \rho\frac{\mathrm{d}U_b}{\mathrm{d}t}R_c\sin\phi_m\Big)A, \\ F_y &= \Big((p_{bo}+\rho U_b^2)\sin\phi_m - (\cos\phi_m - 1)\rho\frac{\mathrm{d}U_b}{\mathrm{d}t}R_c\Big)A.\end{aligned} \tag{6}$$

RESULTS AND DISCUSSIONS

Figure 2 (a, b) shows a decomposition of the bend force components ($\widetilde{F}_x$ and $\widetilde{F}_y$) into the various terms shown in (4) and compared with with the analytical predictions based on one-dimensional model (6). This shows the relative calculation of pressure at the inlet/outlet of the bend (p_{bi} and p_{bo}), flow acceleration ($\rho\int_V \frac{\partial \boldsymbol{u}}{\partial t}\mathrm{d}V$), momentum flux changes ($\rho\int_{S_{bi}} u^2\mathrm{d}A$ and $\rho\int_{S_{bo}} v^2\mathrm{d}A$) to the total bend force. These bend loading components are dominated by the unsteady impulsive pressure field. The agreement between predictions and computations give a strong justification that the key physics are encapsulated in the simple one-dimensional model (6). The analysis indicates that the force components depend on the length of the pipe exit L_d since this largely determine the pressure in the vicinity of the bend. The model also predicts an asymmetry between $\widetilde{F}_x$ and $\widetilde{F}_y$ (see figure 2 c), and it depends on the bend length.

CONCLUSIONS

The effect of a high St impulsively-accelerated flow on pipe bend forces has been studied using numerical and detailed one-dimensional prediction model. Various force contributions and asymmetry in the force components were found.

Summary A direct numerical simulation of a Poiseuille turbulent channel flow was performed at a friction Reynolds number of 10000, in a small box of dimensions $(2\pi h, 2h, \pi h)$. This value is large enough to allow the study of high Reynolds numbers effects. The streamwise mean velocity presents a long logarithmic region, extending from $y^+ \approx 150$ to $y/h \approx 0.2$. The von Kármán constant has a value of $\kappa = 0.389$, which seems to be very close to the final value for this constant. The first maximum of the intensity u' keeps growing and the second maximum is still not present. Mean velocities and intensities can be downloaded from the web page of the FDY

Wall turbulence is probably one of the open problems in physics with most applications in daily life. Even if the equations ruling out these flows have been known for 150 years, we still lack of complete theory. As wall-bounded turbulence is responsible of the 5% of the CO2 dumped by mankind into the atmosphere every year, this is a problem of the uttermost importance. Research of turbulent flows has been dominated by experimental techniques until the eighties of the last century, where supercomputers started to be powerful enough to solve turbulent flows. However, due to the highly non-linear behavior of wall-turbulent flows, Direct Numerical Simulation (DNS) of these flows are restricted to simplified geometries. The most successful of these idealized flows are Poiseuille turbulent channels, where the fluid is confined between two parallel plates and the flow is driven by pressure. Since the seminal paper of Kim, Moin, and Moser, [1], the friction Reynolds number Re_τ has grown steadily. Here, a simulation reaching the $Re_\tau = 10000$ frontier is presented, which would allow the study of high Reynolds numbers effects. This Re_τ is still less than the largest realization of the flow obtained by experimental means, [2], reaching $Re_\tau = 20000$. However, the main advantage is that the DNS allows one to compute any imaginable quantity in the whole domain.

As it is said before, the main control parameter is the friction Reynolds number, defined as $Re_\tau = u_\tau h/\nu$, where h is the semi-height of the channel and ν is the kinematic viscosity. Superscript (+) indicates that the quantities have been normalized by u_τ and ν. h is equivalent to the radius in pipes and δ_{99} in boundary layers. This computation has been performed in a computational box of sizes $L_x = 2\pi$ and $L_z = \pi$. This box is large enough to accurately describe the statistics of the flow [3]. The streamwise, wall-normal, and spanwise coordinates are x, y, and z. The corresponding velocity components are U, V, and W or, using index notation, U_i with $i = 1, 2, 3$. Statistically averaged quantities in x, z, and time t are denoted by an overbar $\overline{\cdot}$, whereas fluctuating quantities are written in lowercase letters, i.e. $U = \overline{U} + u$. Primes are reserved for intensities, e.g. $u' = \overline{(uu)}^{1/2}$.

The flow can be described by means of the momentum and mass balance equations. They have been solved using the LISO code [4]. Briefly, the code uses the same strategy as [1], but using seven-point compact finite differences in y direction with fourth-order consistency and extended spectral-like resolution [6]. The temporal discretization is a third-order semi-implicit Runge-Kutta scheme [7]. The wall-normal grid spacing is adjusted to keep the resolution at $\Delta y = 1.5\eta$, i.e., approximately constant in terms of the local isotropic Kolmogorov scale $\eta = (\nu^3/\epsilon)^{1/4}$, where ϵ is the dissipation rate. In wall units, Δy^+ varies from 0.3 at the wall, up to $\Delta y^+ \simeq 12$ at the centerline. The resolution in x and z is similar to the largest simulations of turbulence.

To accelerate the compilation of statistics, three initial files were prepared and thus three simulations were run at the same time. The initial file of every run was taken from a smaller Reynolds number simulation. In every case, the code was run until some transition phase has passed and the flow had adjusted to the new set of parameters. Once the flow was in a statistically steady state, which can be very time consuming, statistics were compiled. Comparisons are shown with data coming from [4] ($Re_\tau = 2000$, blue),[3] ($Re_\tau = 4200$, red), and [8]($Re_\tau = 5000$, green).

In order to further validate the simulation, figure 1(a) shows the error in the momentum equation,

$$\overline{uv}^+ = \frac{d\overline{U}^+}{dy^+} + y^+ - 1. \tag{1}$$

As the difference between both sides of this equation is still not below $5 \cdot 10^{-3}$, similar to the other large simulations, the simulation is still running. However, we do not expect any major change in the statistics of the simulation.

The mean velocity profile is shown in figure 1(b) in terms of the indicator function, $\Xi = y^+ \partial_y U^+$. This function should show a plateau if the classical scaling for the logarithmic layer, $U^+ = \kappa^{-1} \log(y^+) + B$, holds. Here, κ is the von Kármán constant. For every case, the minimum is reached around $y^+ \approx 70$ calling into question the possibility, or even the relevance, of estimating the extent of the logarithmic layer in this way. The flatter region of the profile starts at $y^+ \approx 150$. The logarithmic layer extends to around $y^+ \approx 2000$ or $y/h = 0.20$. To obtain the values of κ and B, we have restricted ourselves to the region where the indicator function is even flatter, $y^+ = 350$ to $y/h = 0.15$, obtaining $\kappa = 0.389$ and $B = 4.47$. This value for κ is only 0.005 units larger than the one given by [8].

The intensity of the streamwise velocity is shown in figure 2(a). The well known, [4], scaling failure in the buffer layer is still present. The first maximum is still growing, and its value $u'^+ = 3.06$ is in agreement with the experimental

*Corresponding author. E-mail:serhocal@mot.upv.es

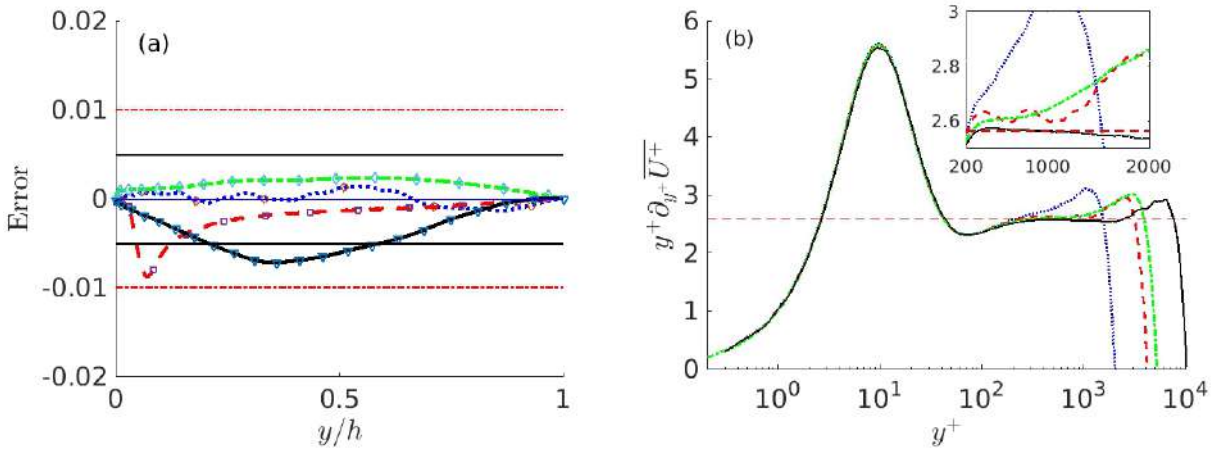

Figure 1: (a) Error in the computation of momentum equation 1 (b). Indicator function, showing an extended log layer, ranging from $y^+ \approx 150$ to $y/h \approx 0.2$

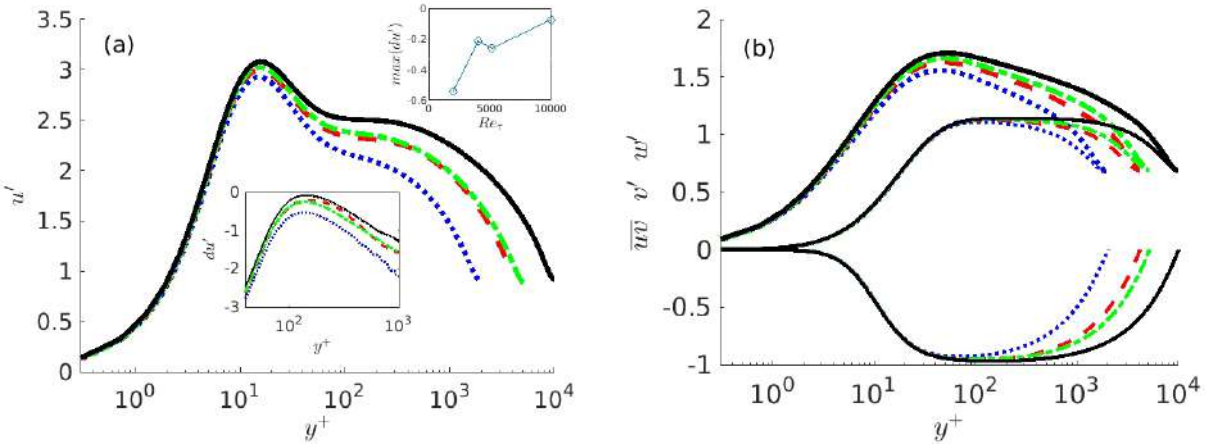

Figure 2: (a) $u'^+ = \sqrt{\overline{uu}}$ for the four cases. The lowest box shows the value of the derivative of u'^+ and the top one the evolution of the maximum with Re_τ. (b) From bottom to top, $\overline{uv}^+$, v'^+ and w'^+.

results of [2]. About the uncertain second maximum of the velocity, located around $y^+ = 120$, the situation is shown in the lowest box of this figure. The derivative of u' is still not zero, and is not clear if the second maximum will ever exist. Again, this is also in agreement with the results of [2].

The collapse of v' and $\overline{uv}$ in the viscous region, figure 2(b), is almost perfect. Also, v' presents a flat behavior in the logarithmic layer. It is remarkable that the maximum of w', first spotted in [4], is still growing. This is possibly the reason of the scaling failure of w'.

As conclusion, a DNS of a Poiseuille turbulent channel has been made at a $Re_\tau = 10^4$. Using symmetry theory, the log layer has been delimited from $y^+ = 150$ to $y/h = 200$. Using this interval a value for $\kappa = 0.389$, has been obtained. Doing the same procedure in previous simulations, κ has basically the same value. About the streamwise intensity, u', its first maximum is still growing and the second one is not yet present. A study of the first derivative of u' shows that is possible that this maximum would never exist. Funally, DNS results suggest that there actually exists a logarithmic scaling of $\overline{U}$ while at the same time this is not true for higher moments. This is the subject of another talk in this session. Mean velocities and intensities can be downloaded from the web page of the FDY. More data will be made available as the postprocessing advances.

DROP BREAKUP IN HOMOGENEOUS ISOTROPIC TURBULENCE

Alberto Vela-Martín[1] and Marc Avila*[2]
[1]School o fAeronautics, Universidad Politénica de Madrid, Madrid, Spain
[2]Center of Applied Space Technology and Microgravity (ZARM), University of Bremen, Bremen, Germany

Summary The formation and breakup of drops in turbulent flows is of key importance in chemical, mechanical and aerospace engineering, but their physical mechanisms and time scales remain poorly understood. We investigate drop breakup in homogeneous isotropic turbulence with direct numerical simulations, thereby resolving all temporal and spatial scales. A new GPU code solving the Cahn–Hilliard–Navier–Stokes equations enables the simulation of thousands of independent cases and a detailed analysis of the breakup process. We find that drop breakup is a memoryless process, whose rate depends on the Weber number. Our results allow estimating the evolution of drop-size distributions in the dilute regime and can be used to parametrize population-balance equations.

INTRODUCTION

The emulsification of a disperse phase in a continuous phase under turbulent flow conditions is central in the food and pharmaceutical industries. In stirred tanks, a statistically steady state characterized by the probability density function (pdf) of drop sizes, is approached after initial transients. This pdf is determined by the competition of drop breakup and coalescence processes [6], which are notoriously difficult to parametrize. In this paper, we focus on the breakup of a single drop in homogeneous isotropic turbulence.

The theoretical background of drop breakup in turbulent flows was developed by Kolmogorov[3] and Hinze[2]. Their main assumption was that a drop breaks when the kinetic energy of velocity fluctuations on the drop scale $\overline{u^2(d)}$ (where d is the drop diameter) exceeds the interfacial energy. This happens when the Weber number $We = \rho \overline{u^2(d)} d/\sigma > 1$, where ρ is the fluid density of the continuous phase and σ is the surface tension. In isotropic turbulence the so-defined Weber number can be rewritten as

$$We = 2\rho\epsilon^{2/3} d^{5/3},$$

where ϵ is the average energy dissipation – which is equal to the power input in stirred tanks. The breakup criterion $We \approx 1$ is extremely useful in engineering because it allows to estimate the maximum drop size in an emulsion. However, it does not provide any information on the dynamics of the system and size distributions. In this work, the spatiotemporal dynamics of drop breakup are investigated with direct numerical simulation and statistics are extracted.

METHOD AND SETUP

The Navier–Stokes equations are solved with the pseudo-spectral method of Cardesa *et al.* [1], which was extended to simultaneously solve the Cahn–Hilliard equations governing the conservation of a phase-field variable. Our highly efficient GPU code enables a statistical study of the inherently stochastic breakup process. For simplicity, density- and viscosity-matched fluids are considered, which allows a qualitative comparison with experiments using water as continuous phase and certain oils as disperse phase [4].

The breakup process was investigated by varying the Reynolds number Re_λ and Weber We independently. The initial conditions were taken as snapshots from single-phase turbulence in which a spherical drop was introduced. Numerical resolutions of 128^3 and 256^3 were used and several thousands of independent runs were performed. Results were found to be independent of the interface thickness and numerical convergence was also verified.

RESULTS

The temporal evolution of an initially spherical drop until its breakup is shown in Figure 1. The drop evolves from a sphere to a cigar shape, as described by Hinze [2] in his theoretical considerations. Subsequently the drop progressively stretches until in the final stages it consists of a filament connecting two bulgy bulbous ends – precursors to two large drops emerging after the breakup process. In addition, several small satellite drops form out of the filament. Noteworthy the process is remarkably similar to that of a spherical drop placed in a steady extensional (Stokes) flow [7] and our conditional analysis of velocity gradients close to the interface highlights indeed the importance of the rate-of-strain in the breakup process.

Because of the turbulent nature of the flow, the number and size of daugther drops obey a stochastic process. We found that the breakup times scale with the characteristic drop time

$$t_d = (d^2/\varepsilon)^{1/3}.$$

Surprisingly, at lower Weber numbers the distribution of breakup times is exponential, implying that drop breakup is a memoryless process. The breakup rate diminishes as We is decreased, but remains finite. By contrast, at high Weber numbers the process is fast and sudden (as documented in recent simulations [5]) and the memoryless property is lost. The number of drops increases as We increases.

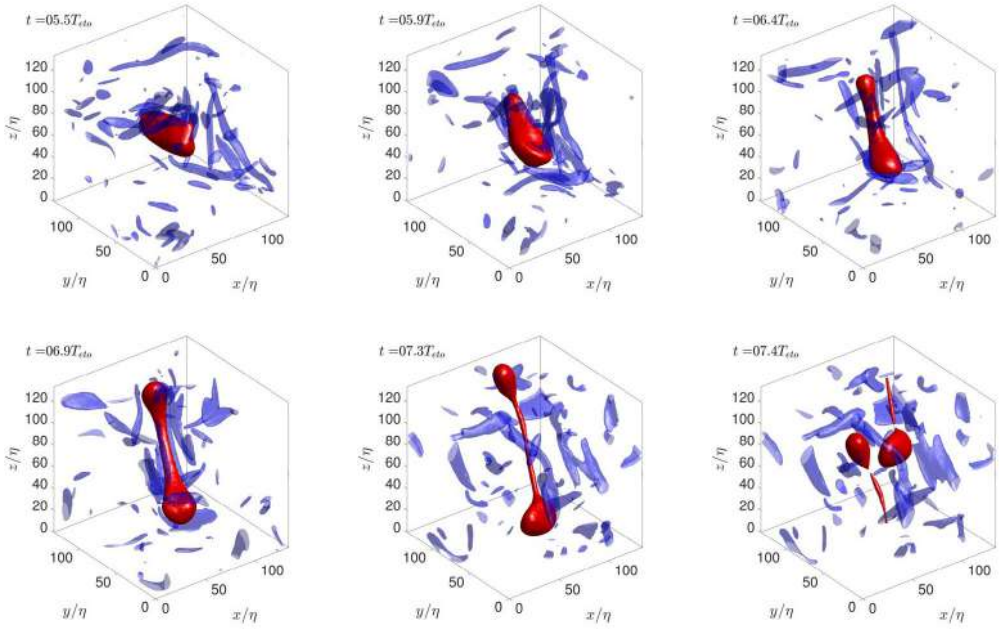

Figure 1: Snapshots of a direct numerical simulation of drop breakup in homogeneous isotropic turbulence with Reynolds number $Re_\lambda = 58$ and Weber number $We = 1.2$. In blue, isosurfaces of intense enstrophy are shown. The box size is 134η, where η is the Kolmogorov scale and time is eddy turnover units, $T_{eto} = L/u'$, where L is the integral scale and u' is the standard deviation of the velocity fluctuations. At $t = 0$ a spherical drop is placed in the turbulent flow and left to evolve until its breakup.

DISCUSSION

The results presented in this work have implications for the physical modeling of binary mixtures. For example, population-balance models require parametrizations of the probability of drop breakup and of the number of children droplets and their surfaces, which were obtained here through direct numerical simulation. Finally, the memoryless property discovered at low Weber numbers implies that in the dilute regime drop size distributions continue to evolve as time passes without reaching steady state.

MEMORY EFFECT AND QUASI-CYCLIC FRONT PROPAGATION SPEED OF TURBULENT SPOTS DURING PIPE FLOW TRANSITION

Xiaohua Wu*[1], Parviz Moin [2] and Ronald J. Adrian [3]
[1]Department of Mechanical and Aerospace Engineering, Royal Military College of Canada, Kingston, Canada

[3]Arizona State University, Tempe, USA

Summary We present direct simulation results on a blob of inlet turbulence developing spatially through a 1000 radii-long fully-developed laminar pipe flow at $Re = 2150, 2300$ and 2500, respectively. We observed turbulent spot packet entering processes of splitting, reconnection and re-splitting, indicating a surprising memory and hysteresis effect. Splitting is found to be driven by a sustained zonal axial velocity differential between a spot's downstream front and its center, which causes an elongated zone being frequently shed from the spot leading edge. Viscous dissipation often prevents the detached elongated zone (child embryo) from developing into a child spot (hence full splitting), resulting in a quasi-cyclic peak-valley variation of the spot packet's front instantaneous propagation speed with the axial distance. This suggests that splitting and dissipation are coupled processes rather than two totally independently factors; and mean front propagation speed masks important instantaneous pipe flow transition physics. The constitutive elemental vortex structure of turbulent spots in low Reynolds number pipe flow is primarily reverse hairpin vortex.

BACKGROUND, OBJECTIVE AND METHOD

Compared to pipe transition, boundary layer bypass transition in the narrow sense, a superposition on a Blasius boundary layer by freestream homogeneous isotropic turbulence at an initial turbulence intensity of 1%–4%, has received much more attention from the aeronautical fluid dynamics community. Since pipe transition and boundary layer bypass transition in the narrow sense are both wall-bounded shear flows initiated by finite-amplitude disturbances, it is instructive, and perhaps even imperative, to establish connection between these two branches of study. Much of the pipe transition research to date can be categorized as the Schubauer-Klebanoff type in that the focus was often placed on mean statistics concerning the propagation, development, evolution and fate of deliberately imposed turbulent spots in laminar pipe flow, as was done in [1] for the boundary layer bypass transition in the narrow sense. A more complete investigation of pipe transition should also incorporate the Klebanoff-Tidstrom-Sargent approach to consider both the amplification of inflow three-dimensional disturbance prior to laminar pipe flow breakdown, and the inception of turbulent spots during breakdown, as was done in [2] for the boundary layer by examining the causality of key instantaneous structures in transition.

Lindgren [3] discovered that, at low Reynolds numbers such as $Re = 2800$, based on the bulk velocity V and pipe radius R, some turbulent spots developed a tendency to split into two units with the child spot always appearing downstream of the parent. Avila et al [4] considered turbulent spot splitting in pipe flow as an example of spatial proliferation of chaotic domains. The central underpinning of their idea is that, for $Re < 2400$, turbulent spot splitting is the only mechanism for turbulence to spread; splitting is memoryless, independent of, and competing with, dissipation. A balance between spot decay and splitting yields a critical Reynolds number $Re = 2040$ for pipe flow transition. Barkley et al [5] developed a one-dimensional model to describe the mean front propagation speeds of pipe turbulent spot as a function of the Reynolds number. The essence of the advection-reaction-diffusion model of is one-dimensional transition modeling of certain mean global quantities in pipe flow.

Our objectives here are to examine the hypothesis introduced in the spatial proliferation idea [4] that pipe spot splitting is a memoryless process independent of dissipation, and the underlying assumption made in the advection-reaction-diffusion model [5] that the mean front propagation speeds of turbulent spot encapsulate the pipe transition physics. Such a critical re-examination, in the laboratory reference frame, is also necessary considering the fact the nearly all the previous computer simulations of pipe transition, including [4] and [5], used the numerically expedient axially-periodic boundary condition. The degree of inaccuracy associated with long duration, axially periodic, turbulent spot simulations using short pipe domain $(< 200R)$ can be discerned from [6]. The temporal simulations in [6] correspond to a non-standard situation of imposed turbulent spots developing into an already perturbed (by itself earlier in time) chaotic pipe flow environment. When spot life-time statistics are extracted from such short-length pipe simulations running for very long time, they may be contaminated, see [6]. Our direct simulation design corresponds to the standard and idealized situation of turbulent spot developing spatially into a pristine fully-developed laminar pipe flow environment that has not been perturbed prior to the arrival of the spot. The governing equations are the continuity and the Navier-Stokes equations for incompressible flow in cylindrical coordinates, and they are solved using the fractional step method. The pipe length is $1000R$. Three cases were simulated at $Re = 2150$, 2300 and 2500, respectively. The computational mesh size is $32768 \times 200 \times 256$, $\Delta t = 0.01R/V$. The inlet base flow has the fully-developed parabolic laminar velocity profile, except for $0 \le t \le 20R/V$, within a 60^o numerical wedge, the exact laminar parabolic velocity profile is replaced by a time-dependent, fully-developed turbulent pipe DNS velocity field at $Re = 5300$ to trigger disturbance to generate a spot. For $t > 20R/V$, the laminar velocity profile is restored inside the wedge.

RESULTS

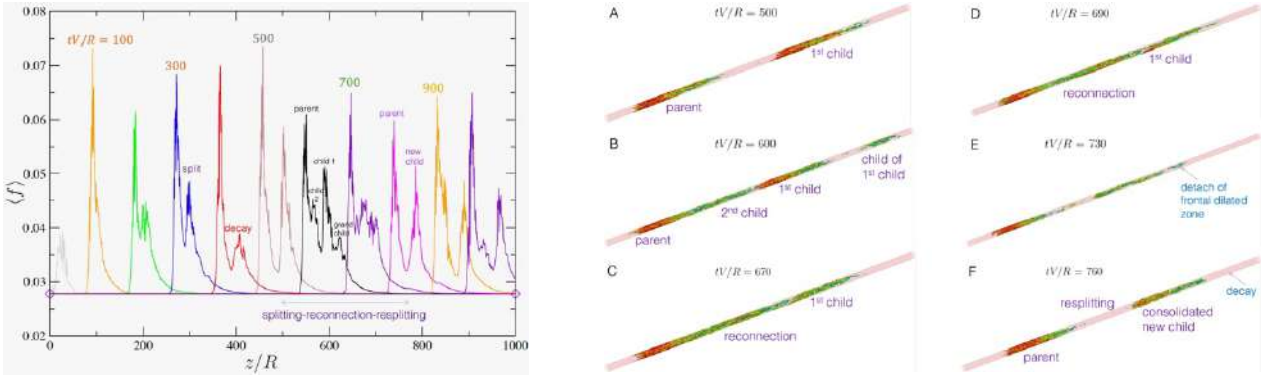

Figure 1. Splitting-reconnection-resplitting at $Re = 2300$ revealed by circumferentially-averaged friction factor $\langle f \rangle$ (Left) and by iso-surfaces of swirling strength $\lambda_{ci} = 0.3V/R$ (Right). Diamond symbols are fully-developed laminar pipe solution. This composite process suggests that after a full splitting event, child spot can still have contact and interaction with its parent; it may also merge and consolidate with other children. Thus, pipe spot splitting may not be memoryless. This is at odds with the prevailing spatial proliferation idea [4] which considers that, for $Re < 2400$, spot splitting is memoryless in the sense that, once split, a child spot has no contact (memory) with its parent and behaves entirely as a standalone new parent. The splitting-reconnection-resplitting process also suggests that, for the purpose of collecting lifetime statistics, it is important to carefully track child spots through three-dimensional vortex structures (as opposed to one-dimensional signals) because their identities can change due to reconnection and re-splitting.

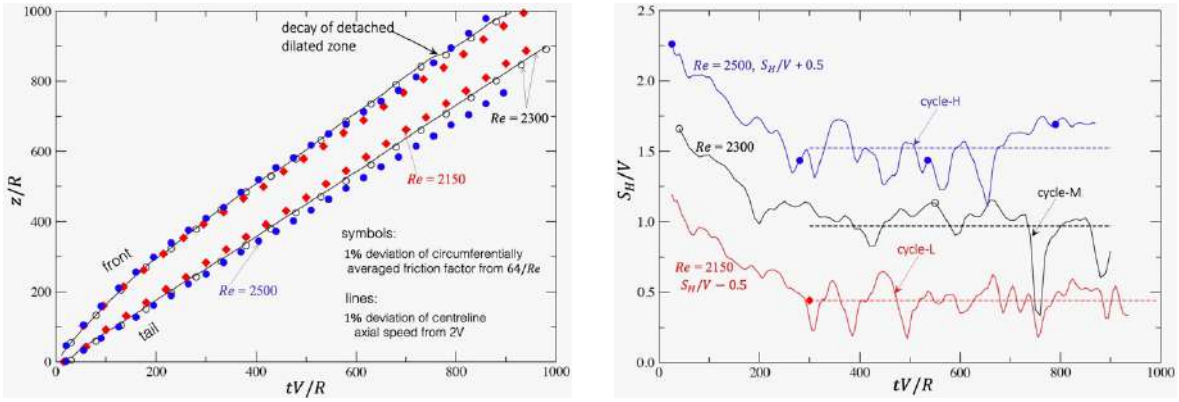

Figure 2. Propagation of turbulent spot packet: Left: Front and tail positions. Right: Instantaneous speed S_H/V of the front. Note the S_H/V profiles exhibit a quasi-cyclic peak/valley characteristic – this is not random stochastic fluctuation. In particular, the deep valley labeled as 'cycle-M' at $Re = 2300$ corresponds to the kink highlighted on the Left pane. The valley at $Re = 2500$, marked as 'cycle-H', is due to the decay of a detached frontal dilated zone. Similarly, the valley labeled as 'cycle-L' at $Re = 2150$ is a result of the decay of a detached frontal dilated zone. Averaged front propagation speed values are represented using the dashed lines. Clearly, the averaged propagation speed misses the important transition physics information conveyed by the quasi-cyclic peak/valley characteristic in the instantaneous front speed data: the frequent development, detachment, decay or growth of a frontal elongated zone. Furthermore, in the event of growth rather than decay, the frontal elongated zone is in essence the embryo of a child spot which will lead to a full splitting. This scenario is somewhat inconsistent with the notion of splitting and dissipation being two completely independent factors in pipe transition [4] because the present results suggest that dissipation may also be an integral part of the splitting process itself.

CONCLUSIONS

Pipe spot splitting at low Reynolds number can have memory and hysteresis effect, splitting and dissipation are coupled rather than totally independent. Variation of a spot-packet's instantaneous front speed with axial distance reflects the physical development processes of splitting, reconnection, re-splitting and decay. Mean propagation speed of spot-packet fronts masks important pipe transition physics. Conditional sampling results demonstrate that the fluid dynamics mechanism of splitting is a sustained zonal axial velocity differential between a pipe spot's leading front and the core.

DISENTANGLING LAGRANGIAN TURBULENCE

Lukas Bentkamp[1], Cristian C. Lalescu[1], and Michael Wilczek*[1]
[1]Max Planck Institute for Dynamics and Self-Organization, Am Faßberg 17, 37077 Göttingen, Germany

Summary Lagrangian particles frequently encounter extreme acceleration events in fully developed turbulence. Intense small-scale structures such as vorticity filaments can give rise to acceleration events exceeding the typical root-mean-squared fluctuations by orders of magnitude (see Fig. 1). Here, we introduce the notion of persistent Lagrangian acceleration, quantified by the squared Lagrangian acceleration coarse-grained over a viscous time scale. Conditioning Lagrangian particle data from direct numerical simulations on this coarse-grained acceleration, we find remarkably simple, close-to-Gaussian statistics for a range of Reynolds numbers. Based on this observation, we develop a theory of Lagrangian single-particle statistics covering the acceleration, velocity increments as well as single-particle dispersion.

Introduction A recurrent idea for modeling turbulence is to seek decompositions into simpler sub-ensembles. This idea underlies various modeling approaches such as superstatistics and multifractals. In these approaches, the full ensemble statistics is obtained by superposing simpler statistics characterized by a parameter, which varies statistically across the ensemble. To obtain a physically meaningful description for turbulence, the challenge is to identify the quantity that separates the full statistical ensemble into simpler sub-ensembles.

For the description of the spatial (i.e. Eulerian) statistics of turbulence, the refined similarity hypothesis [1, 2] states that the scale-dependent Eulerian statistics can be reduced to a universal form, solely depending on the dissipation rate volume-averaged (i.e. coarse-grained) on the given scale. Indeed, conditional probability density functions (PDFs) of velocity increments were observed to take a self-similar, or even an approximately Gaussian form when conditioning on the coarse-grained energy dissipation [3, 4] or energy transfer rate [5, 6].

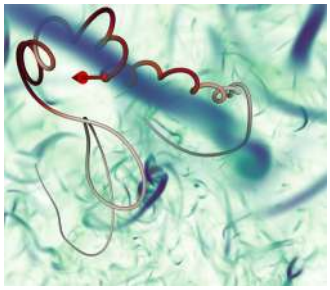

Figure 1: Tracer particle (trajectory color-coded by acceleration magnitude) encountering an intense vortex (blue volume rendering). Figure adapted from [14].

In the analogous Lagrangian refined similarity hypothesis [7–10], it is assumed that Lagrangian statistics can be formulated in a universal form in terms of a locally averaged (in time or space) dissipation rate along tracer particle trajectories. However, conditional statistics appear to remain intermittent and generally depart from Gaussianity [3, 11]. This raises the question whether a physically meaningful quantity exists that separates the intermittent statistics of Lagrangian turbulence into simpler, Gaussian statistics. In this contribution, we provide an answer to this question. We introduce the squared acceleration, coarse-grained over a typical viscous time scale, as a measure of persistence of the Lagrangian acceleration, and show that it decomposes the strongly non-Gaussian and scale-dependent statistics of Lagrangian turbulence into much simpler, close-to-Gaussian sub-ensembles. Based on this observation, we develop a comprehensive theoretical framework of Lagrangian single-particle statistics.

Results The central quantity, which allows us to disentangle the complex Lagrangian statistics, is $\alpha(t)$ – the squared acceleration coarse-grained along Lagrangian tracer trajectories over a few Kolmogorov time scales. On a general level, $\alpha(t)$ can be perceived as a Lagrangian analogue of the coarse-grained dissipation rate in the Eulerian refined similarity hypothesis [1, 2], which essentially measures the degree of small-scale turbulence encountered by a particle.

We find that conditioning Lagrangian statistics on α leads to approximately Gaussian statistics, which implies a significant reduction of complexity. As an example, Fig. 2 shows the PDFs of an acceleration component a both unconditional (red line) and conditional on α (colored lines) from our direct numerical simulations of homogeneous isotropic turbulence at a Reynolds number of $R_\lambda \approx 350$. Whereas the unconditional PDF is extremely heavy-tailed, the conditional acceleration PDFs display a close-to-Gaussian form for all values of α.

Based on this observation, we develop a comprehensive framework of Lagrangian single-particle statistics. The complete statistical information of a Lagrangian trajectory is contained in its characteristic functional $\phi[\vartheta]$, which has been introduced in Hopf's functional approach to turbulence [12]. Exploiting our observation that conditioning on α leads to approximately Gaussian statistics, we propose that the characteristic functional of the full ensemble takes the form [13, 14]

$$\phi[\vartheta] = \int_0^\infty \mathrm{d}\alpha\, f(\alpha)\, \phi_\alpha^{\mathrm{G}}[\vartheta]. \tag{1}$$

Here, $f(\alpha)$ is the PDF of α, and $\phi_\alpha^{\mathrm{G}}[\vartheta] = \exp\left[-\frac{1}{2}\int_{-\infty}^{\infty}\mathrm{d}t\int_{-\infty}^{\infty}\mathrm{d}t'\,\vartheta(t)C_\alpha(t-t')\vartheta(t')\right]$ is a Gaussian characteristic functional, which is fully determined by the conditional autocorrelation function $C_\alpha(\tau)$. The test function $\vartheta(t)$ can be chosen, for example, to project the complete statistics to single- or two-time statistics etc. Overall, this means that the

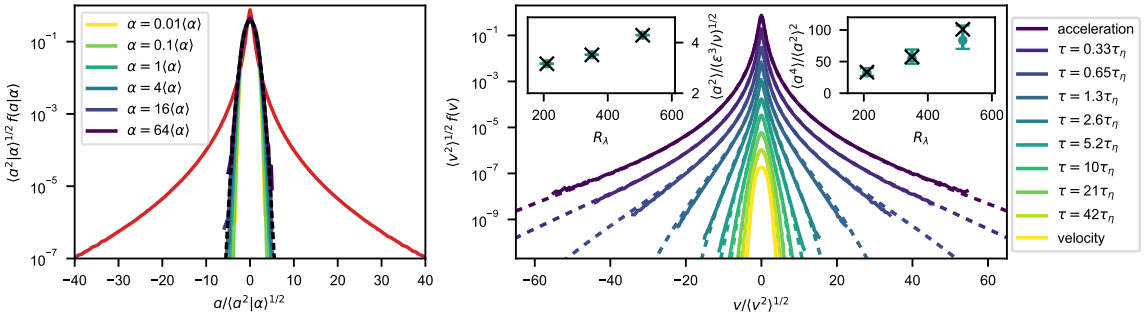

Figure 2: **Left:** The PDFs $f(a|\alpha)$ of an acceleration component conditional on α (colored lines) are all close to Gaussian. The unconditional PDF (red line) and a Gaussian distribution (black, dashed line) are plotted for comparison. **Right:** Comparison of PDFs derived from the model (dashed) with DNS data (solid) ($R_\lambda \approx 350$). From top to bottom: acceleration PDF, velocity increment PDFs, velocity PDF (vertically shifted for clarity). Insets: Acceleration variance (in Kolmogorov units) and flatness from model (dots) compared to DNS (crosses) as a function of Reynolds number. The error bars are obtained by varying the coarse-graining time scale between 1.5 and 4.5 Kolmogorov time scales. Figure adapted from [14].

full Lagrangian ensemble can be considered as a probabilistic mix of Gaussian sub-ensembles with varying correlations. Since the characteristic functional offers a comprehensive statistical description, the complete single-particle statistics of Lagrangian turbulence can be determined from our framework once the PDF of the coarse-grained squared acceleration $f(\alpha)$ and the conditional correlation functions $C_\alpha(\tau)$ are given. For the present results, we take these quantities directly from our DNS data without resorting to further modeling assumptions.

The main challenge in capturing Lagrangian single-particle statistics is intermittency, which can be studied in terms of the statistics of the velocity increment $v = u(t+\tau/2) - u(t-\tau/2)$ taken over a time lag τ. Intermittency manifests itself in a pronounced scale dependence of the PDF $f(v;\tau)$ of the Lagrangian velocity increments. It exhibits heavy tails for small time lags but relaxes to an almost Gaussian distribution for large time lags. These PDFs can be directly computed from our framework [14]. As a quantitative benchmark, we compare the PDFs obtained from (1) to the ones obtained from DNS. Fig. 2 shows the velocity increment PDFs along with the PDFs of velocity and acceleration at $R_\lambda \approx 350$. Very good agreement is found at all scales, which supports our hypothesis that Lagrangian intermittency can be perceived as a consequence of the statistical mixture of different regions of the flow, each characterized by a particular coarse-grained squared acceleration.

Conclusions We showed that Lagrangian single-particle statistics can be decomposed into approximately Gaussian sub-ensembles when trajectories are discriminated with respect to the coarse-grained squared acceleration α. Physically, high values of α correspond to events in which particles encounter intense small-scale structures such as vorticity filaments. Hence the decomposition intuitively separates regions of highly turbulent activity from more quiescent regions.

Based on this, we developed a theoretical model of Lagrangian single-particle statistics, which requires the PDF of α and the conditional Lagrangian velocity autocorrelation functions as input. Formulated in terms of the characteristic functional, our framework offers a comprehensive statistical description of Lagrangian single-particle statistics, which constitutes a conceptual generalization of previous approaches. By projecting it to finite-dimensional statistics such as velocity increment distributions, we find very good agreement with simulation results across a range of Reynolds numbers.

[2]Department of Physics, Indian Institute of Technology Guwahati, Guwahati, India

Summary We present the dynamics of corner vortices during flow reversals of large-scale circulation (LSC) in turbulent Rayleigh-Bénard convection (RBC) of air inside a cubic cell in the range $2 \times 10^6 \leq Ra \leq 10^9$ using direct numerical simulations. The plane containing LSC is generally aligned along one of the diagonals of the box accompanied by a four-roll structure in the other. In addition to the primary roll, two secondary corner-rolls are also observed in the LSC plane, which grow in size and destabilize the LSC resulting in partial and complete reversals. We observe that these corner vortices are not restricted to the LSC plane, as observed in two dimensional simulations, but they extend much beyond.

INTRODUCTION

Reorientation of large-scale flow, such as wind reversals in atmospheric flows and the change in polarity of magnetic field in Earth and Sun have been an interesting field of research in turbulence since last couple of decades. Understanding the genesis of large-scale circulation and the mechanism that leads to change in its direction still remains a challenge. Although flow reversals have been extensively studied over the years in 2D/quasi-2D systems [1] and cylindrical [2] domains, origin and dynamics of such large-scale structures in a Cartesian box are not well understood, especially for highly turbulent flow. In the present study, we examine the dynamics of LSC with prime focus on its orientation and subsequent reversals in high Rayleigh number range $2 \times 10^6 \leq Ra \leq 10^9$.

NUMERICAL DETAILS

The mathematical model of RBC using Boussinesq approximation consists of the momentum, mass, and energy conservation equations written as

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}\cdot\nabla\boldsymbol{u} = -\nabla p + \sqrt{\frac{Pr}{Ra}}\nabla^2\boldsymbol{u} + \theta\hat{\boldsymbol{k}} \quad (1)$$

$$\nabla\cdot\boldsymbol{u} = 0 \quad (2)$$

$$\frac{\partial \theta}{\partial t} + \boldsymbol{u}\cdot\nabla\theta = \frac{1}{\sqrt{PrRa}}\nabla^2\theta \quad (3)$$

where $\boldsymbol{u}$ represents the velocity vector, p pressure, and θ non-dimensional temperature, while Ra and Pr are the Rayleigh number and Prandtl number, respectively. The above coupled Eqs. 1-3 are solved using a predictor-corrector based finite volume formulation with collocated arrangement of variables. No-slip velocity condition is applied on all the boundaries, while for temperature isothermal and adiabatic conditions are applied on the horizontal and vertical walls, respectively. The non-linear convective term is approximated using the 2nd-order Adams-Bashforth scheme, while the buoyancy, pressure and diffusive terms are approximated by the 2nd-order Crank-Nicolson scheme. All the resulting sparse linear systems are solved using BiCGSTAB technique preconditioned by a highly scalable diagonalised version of Stone's Strongly Implicit Procedure. For details of the numerical procedures, readers are referred to Vishnu *et al.* [3].

RESULTS

One of the striking features of turbulent RBC is the presence of LSC, which is a large-scale discernible convection pattern comprising thermal plumes sustained by its own dynamics, depending not only on the state of the turbulence but also on the geometric constraints. In cubic cells LSC is generally aligned along a diagonal plane [4]. It is observed that, with time, the plane containing LSC switches between the diagonals resulting in flow reversals. Here we classify these reversals as partial, where the LSC reorients from one diagonal to another and complete in which the LSC stays in a single diagonal plane but changes its direction of circulation.

Figure 1(a) shows the iso-surfaces of instantaneous temperature for $Ra = 10^9$, where hot plumes erupt from the boundary layer and cold plumes sink along the opposite corners giving rise to a large-scale coherent structure aligned along the diagonal labeled as d_1. The planar view of this diagonal plane is shown in Fig. 1(b) which shows the apparent large-scale circulatory motion of the flow. For better visualization of the large-scale flow structure, time-averaged velocity vectors superimposed on the temperature contours at the diagonal planes are shown in Fig. 2 for $Ra = 10^7$. In the diagonal plane containing LSC, a counter-clockwise rotating primary roll (LSC) along with two corner rolls are observed [see Fig. 2(a)]. Note that the direction of circulation of the corner rolls (clockwise) is opposite to that of the LSC. In the opposite diagonal, a four-roll structure is identified, as shown in Fig. 2(b). It has been well established that these corner vortices play a crucial role in the stability and dynamics of LSC in 2D Rayleigh-Bénard flows. However,

*Corresponding author. E-mail: vishnu.t@iitg.ac.in

in 3D RBC, such dynamics are less explored. To quantify these vortices, the second invariant of the velocity gradient tensor, Q, is shown in Fig. 2(c). Here $Q > 0$ represents regions of strong local rotation, i.e., high vortical motions. It is apparent from Fig. 2(c) that the corner vortices are not restricted to the LSC plane (as are limited in 2D RBC), but they extend along the adjacent faces sharing the diagonal plane to yield a "boomerang" shape.

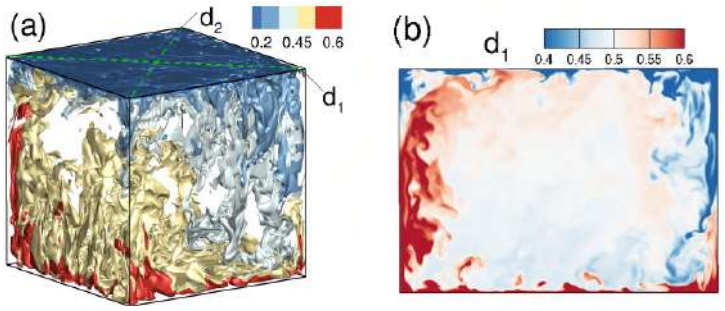

Figure 1: (a) Instantaneous temperature iso-surfaces indicating LSC oriented along the diagonal plane d_1 for $Ra = 10^9$. (b) The contours of temperature in the diagonal plane containing LSC.

Mechanism of flow reversals

Previous 2D/quasi-2D studies [1] on the dynamics of LSC have emphasized the role of corner rolls in flow reversals, though, in such a set-up, LSC is forced to coexist with the rolls at all times in a plane. Alleviating such limitations, we discuss dynamics and reversal of the mean wind in a 3D Cartesian box. At the outset, LSC is oriented along d_1 as a counter-clockwise primary roll accompanied by two clockwise secondary rolls near the corners, while in d_2 a four-roll structure is noticed [see Figs. 2(a) and 2(b)]. During a reversal, the corner rolls in d_1 grow in size and they induce the primary roll to break into two, which results in a four-roll structure. On the other hand, only a set of rolls with same sense of rotation appear to grow and merge in d_2 only to form an LSC retaining the sense of rotation. This effectively shrinks and constricts the remaining two rolls towards the corners. Thus, the LSC and four-roll structure switch between the diagonal planes during a partial reversal. In addition, we observe complete reversals in which the corner rolls in the LSC plane grow in size to yield a four-roll structure which further merge to produce an LSC with opposite sense of rotation. However, on the other diagonal plane, the same four-roll structure is maintained during the entire reversal process. The sequence of flow structures and vortex reconnection in the LSC-plane during a complete reversal is very much similar to that observed in 2D/quasi-2D [1] cases. On the contrary, partial reversals are only realized in 3D geometry.

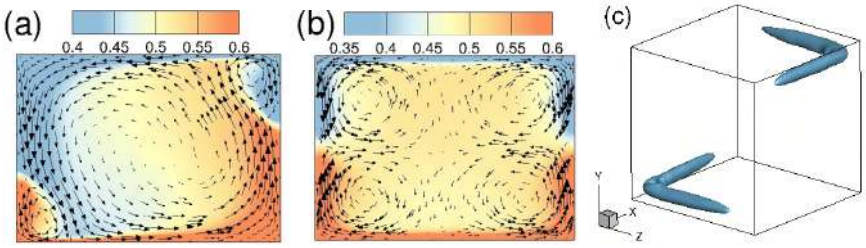

Figure 2: Time-averaged velocity vectors superimposed on the temperature contours at the diagonal planes containing (a) LSC and (b) four-roll structure for $Ra = 10^7$. (c) Time averaged Q structures showing three dimensional structure of the corner vortices.

CONCLUSIONS

Using a series of DNS calculations, dynamics of LSC in turbulent RBC inside a cubic box has been investigated for $2 \times 10^6 \leq Ra \leq 10^9$. LSC is primarily aligned along one of the diagonal planes accompanied by a four-roll structure in the other diagonal. The present study reveals that the corner vortices are not just restricted to the plane containing LSC, but extend much beyond, thus forming a "boomerang" topology. Further, we have analyzed the flow structures in different planes for partial and complete reversals. During a partial reversal, the LSC weakens at the expense of growth of the corner-rolls to form a four-roll structure, while in the opposite plane, two rolls merge together to form LSC.

TURBULENT POLY-DISPERSED BUBBLY CHANNEL FLOWS: EFFECTS OF SOLUBLE SURFACTANT AND VISCOELASTICITY

Outi Tammisola*[1], Zaheer Ahmed[2], Daulet Izbassarov[4], M Nufail Farooqi[3], and Metin Muradoglu[2]

Summary Interface-resolved direct numerical simulations are performed to examine the combined effects of soluble surfactant and viscoelasticity on the structure of poly-dispersed bubbly turbulent channel flows at $Re_\tau = 250$. A soluble surfactant and FENE-P viscoelastic models are coupled to the incompressible flow equations. In the clean case, small bubbles move toward the wall due to the inertial lift force, resulting in the formation of wall-layers and a significant reduction in the flow rate while larger bubbles tend to move toward channel center. An addition of strong enough surfactant alters the direction of lateral migration, i.e., the contaminated bubbles move toward the core region and spread out across the channel. For the viscoelastic case, shear-thinning effects and elastic forces promote formation of bubbly wall-layers leading to a strong decrease in the flow rate. Formation of a wall-layer is determined by the interplay of the inertial lift, elastic and Marangoni forces when they coexist.

NUMERICAL METHOD

The incompressible flow equations are solved in both phases using a second-order finite-difference/front-tracking (FD/FT) method [4]. Following [4] and [1], a single set of governing equations can be written for the entire computational domain provided the jumps in the material properties are taken into account and the effects of the interfacial surface tension are treated appropriately. The momentum equation, accounting for interphase coupling, is given by

$$\begin{aligned}\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot (\rho \mathbf{u}\mathbf{u}) &= -\nabla p + (\rho - \rho_{av})\mathbf{g} + \nabla \cdot \boldsymbol{\tau} + \nabla \cdot \mu_s(\nabla \mathbf{u} + \nabla \mathbf{u}^T) \\ &+ \int_A \left[\sigma(\Gamma)\kappa \mathbf{n} + \nabla_s \sigma(\Gamma)\right]\delta(\mathbf{x} - \mathbf{x_f})dA, \end{aligned} \quad (1)$$

where $\mathbf{u}$, $\boldsymbol{\tau}$, p, $\mathbf{g}$ ρ, μ_s and σ are the velocity vector, the polymer stress tensor, the pressure, the gravitational acceleration, the density, the solvent viscosity, and the surface tension coefficient, respectively, and A is the surface area. In the last term of Eq. (1), κ is twice the mean curvature, $\mathbf{n}$ is a unit vector normal to the interface and ∇_s is the gradient operator along the interface. The present soluble surfactant methodology is developed by Muradoglu and Tryggvason [4]. The FENE-P model is adopted as the constitutive equation for the polymeric stress $\boldsymbol{\tau}$. The FENE-P model and its numerical solution are described in [1, 2].

COMPUTATIONAL SETUP

We consider vertical turbulent channel flow as shown in Fig. 2. The flow is periodic in the spanwise (x) and streamwise (y) directions, with no-slip/no-penetration boundary conditions at the walls in the z direction. In all the cases, bubbles were placed randomly in a vertical channel with a fully developed turbulent flow. The flow is driven upward by an imposed constant pressure gradient dp/dy with the gravitational acceleration $\mathbf{g}$ acting in the opposite direction. The size of computational domain is $4 \times 8 \times 2$ and it is resolved by a $640 \times 1280 \times 384$ grid in x, y and z directions, respectively. The grid points are uniformly spaced in the spanwise and streamwise direction but stretched in the wall-normal direction. In terms of wall units, defined by $l_0^+ = h/Re_\tau$ (i.e., $l_0^+ = 1/250 = 0.004$ in the present setup), the size of the channel is $1000 \times 2000 \times 500$. For the poly-dispersed flow case, the physical parameters are selected such that the total void fraction is 3%. Further, the void fraction is divided into four equal portions of 0.75% for four different sizes of bubbles, yielding the Eötvös numbers (Eo) ranging from 0.5 to 2.5. The details of this configuration and governing parameters are given in Table 1.

RESULTS

First, simulations are perfomed to achieve fully developed single phase turbulent flow for $Re_\tau = 250$. Statistically steady state results are compared with the DNS data of Lu and Tryggvason [3]. Figure 1 shows that the results are in excellent agreement. Extensive simulations are then performed to investigate the the effects of surfactant and viscoelasticity on the dynamics of turbulent bubbly channel flow. For this purpose, in addition to the clean case ($C_\infty = 0$), computations are carried out for two bulk surfactant concentrations, i.e., $(C_\infty = 0.25 \text{ ppm}, 0.5 \text{ ppm})$ of TritonX-100 to examine the

Table 1: (left) The governing parameters (right) Configuration of poly-dispersed flow. Eo, R_b , V_b and N_b denote the Eötvös number, the initial bubble radius, the bubble volume and number of bubbles.

Parameter	Definition	value
Density ratio	ρ_i/ρ_o	0.1
Viscosity ratio	μ_i/μ_o	0.1
Morton Number	$M = g{\mu_o}^4/\rho_o\sigma^3$	5.75×10^{-10}
Langmuir Number	$La = k_aC_\infty/k_d$	0/0.6/1.2
Elasticity Number	$\beta_s = RT\Gamma_\infty/\sigma$	0.5
Weissenberg Number	$Wi = \lambda W_b/h$	0/10/20
Solvent viscosity ratio	$\beta = \mu_s/\mu_o$	0.9
Extensibility parameter	L	60

Eo	R_b	V_b	N_b	$N_b \times V_b$
0.5	0.08	0.0021	224	0.48
1.0	0.11	0.0055	86	0.48
1.5	0.14	0.0114	42	0.48
2.5	0.18	0.0244	20	0.48

effects of surfactant on the poly-dispersed bubbly flows without viscoelasticity. Then the simulations are performed for the viscoelastic case at Weissenberg numbers of Wi = 0, 10 and 20 in the absence of surfactant to examine the sole effects of viscoelasticity. Finally the combined effects of surfactant and visoelasticity are investigated. Figure 2 shows the results of the clean case ($C_\infty = 0, W_i = 0$). Although the flow has not yet reached to a statistically stationary state (Fig. 2), the clean spherical bubbles move towards the wall due the strong inertial lift force and the formation of a horizontal bubble clusters has already emerged. The formation of these clusters results in the reduction of the flow rate in the channel. The most deformable bubbles are distributed around the core as expected.

WAKES AND TURBULENCE PROPERTIES IN WIND FARMS

Jens N. Sørensen*[1] and Søren J. Andersen [1]
[1]Department of Wind Energy, Technical University of Denmark, Lyngby, Denmark

Summary Large Eddy Simulations (LES) are performed to analyse the influence of turbulence on wakes and power production of wind turbines located in a wind farm. Three farm simulations with different degrees of imposed atmospheric turbulence is presented and compared to results using an analytical wake model. The analytical wake model, which was originally developed for infinite wind farms, is validated against the LES computations in order to check its generality for coping with power production in finite-sized wind farms subject to different levels of inflow turbulence.

INTRODUCTION

Modern wind turbines are often clustered in wind farms in order to reduce the overall installation and maintenance expenses. An unwanted but inevitable side-effect, however, is that the downstream turbines, depending on the wind direction, often operate in the wake of upstream located turbines. A wind turbine operating in the wake of one or more wind turbines yields less power and is subject to greater loadings from the induced turbulence, leading to increased fatigue. The increased turbulence originates from the vorticity created by the rotor loading on the passing rotor blades. Understanding this highly dynamic wake interaction is very important for wind farm optimization. Although large eddy simulations reveal many details regarding wakes and turbulence in a wind farm, for layout optimization of wind farms one has to resort to semi-analytical techniques based on simplified modelling of the wake dynamics, such as those proposed by Jensen [1] and Frandsen et al. [2]. Generally, these models are based on simple assumptions regarding steady state considerations, and are developed with the aim of predicting mean quantities, e.g. the mean velocity deficit in the wake. Therefore, the models exclude the details of the dynamic wake interaction and turbulence properties needed to assess the turbine performance and loadings. Frandsen [3] proposed both a model for the array-effect of the wind farm on the atmospheric boundary layer, and a model for fatigue loading on rotors using the effective turbulence intensity as the only governing parameter, arguing that the various changes in turbulence properties usually correlates with the standard deviation of wind speed fluctuations. The present work concerns an extension of the models by Frandsen, taking the effective turbulence intensity as a design variable, which will be tested against controlled LES results.

NUMERICAL TECHNIQUE

The LES computations presented in this paper are carried out using the 3D flow solver *EllipSys3D* (Michelsen [4]), Sørensen [5]). This code solves the discretized incompressible Navier-Stokes equations in general curvilinear coordinates using a block structured finite volume approach. *EllipSys3D* is formulated in pressure-velocity variables in a non-staggered grid arrangement. In the present work, the pressure correction equation is solved using the PISO algorithm and pressure decoupling is avoided using the Rhie/Chow interpolation technique. The convective terms are discretized using a hybrid scheme combining the third order accurate QUICK scheme and the fourth order CDS scheme. The time discretization is specified such that the tip of a rotor blade during a time step moved less than a half grid spacing. The flow field around the wind turbine rotor is simulated using the actuator line technique developed by Sørensen and Shen [6]. In this model the three-dimensional Navier-Stokes equations are solved with body forces distributed along rotating lines representing the blades of the wind turbine. The flow field is thus determined by solving the three-dimensional Navier-Stokes equations using Large Eddy Simulation (LES), whereas the loading on each blade is computed by calculating the local angle of attack to determine the local forces from tabulated airfoil data.

RESULTS

Three simulations are presented, which all are computed on the same grid. The grid is 200R × 20R × 20R in the streamwise, lateral, and vertical direction, respectively. The grid is constructed of 640 blocks of 803 cells corresponding to a total of approximately 328·106 cells. The grid is uniform in all directions with a resolution corresponding to 17 cells per rotor blade. The lateral boundary conditions are cyclic to simulate wind farms of infinite extent in the lateral direction. The vertical boundary conditions are symmetry planes. Inlet/outlet conditions are applied in the streamwise boundaries. Three LES have been performed with a row of 16 turbines of constant turbine spacing of 12R. The same inflow of 8m/s at hub height has been applied, but the turbulent fluctuations are imposed using body forces, which have been scaled to yield different turbulent intensities of approximately 0%, 3%, and 15%. For more details on the simulation setup, please see Andersen et al. [7]. As an illustration of the flow and turbulence characteristics about the turbines, Fig. 1 depicts instantaneous iso-vorticity contours around the 16 wind turbines that are located around a common line.

*Corresponding author. E-mail: jnso@dtu.dk.

Fig. 1 Vorticity contours showing the wake structure along the wind turbines.

Figure 2 shows box plots of the power production of 51 different 10-min periods of the 16 turbines normalized by the rated power of 2750 MW. The influence of atmospheric turbulence is mainly seen in two aspects. First, the power production of the second turbine is greatly affected by the inflow turbulence, which helps the wake breakdown and recover, see Sørensen et al. [8]. Secondly, the converged level deep inside the farm increases with increasing turbulence as the entrainment is enhanced.

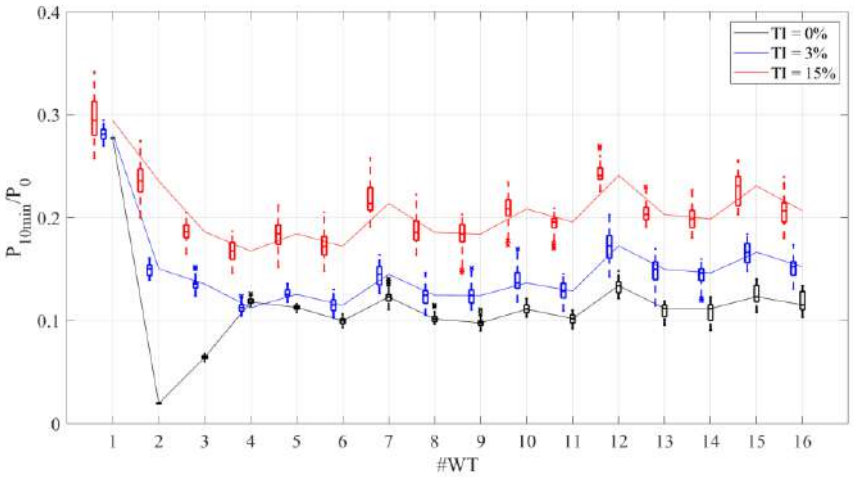

Fig. 2 Averaged power production of the wind turbines for different turbulence intensities.

CONCLUSIONS

Large eddy simulations have been performed to analyse the influence of inflow turbulence on the power production in a wind farm. The turbulence is seen to have a big impact on the power production, in particular on the power produced by the second wind turbine in the array. In the final presentation these results will be compared to an analytical wake model.

MALL SCALE UNIVERSALITY IMPRINTED IN THE ENTRAINMENT CHARACTERISTICS OF FREE SHEAR FLOWS

Marco Zecchetto[1] and Carlos B. da Silva*[1]
[1]LAETA,IDMEC,Instituto Superior Ténico,Universidade de Lisboa,Lisboa,Portugal

Summary It is well known that different turbulent flows such as jets, wakes, mixing layers, boundary layers, exhibit different entrainment characteristics as attested by their different spreading rates and entrainment velocities. Several direct numerical simulations (DNS) of free turbulent flows, attaining Reynolds numbers of the order of $Re_\lambda \approx 400$, show that when properly normalised, the small scale turbulence quantities governing the entrainment are universal. Specifically, normalised by the local Kolmogorov scales, the profiles of the small scale turbulence statistics within the so called turbulent/non-turbulent interface (TNTI) layer - which separates the flow into a turbulent and a non-turbulent (or irrotational) region - display exactly the same shape and magnitude in jets, wakes and shear free turbulence.

INTRODUCTION

Turbulent entrainment takes place in free shear flows (jets, wakes, mixing layers) and also in boundary layers, and results in some of the most visible features observed in these flows, namely the growth of the shear layer (or turbulent region). It is well known that the entrainment characteristics in these flows are very different *e.g.* planar jets entrain more fluid than circular jets. This can be attested by the very different spreading rates and entrainment velocities that are observed in different turbulent flows [1]. The turbulent entrainment (TE) mechanism occurs across the so called *turbulent/non-turbulent interface* (TNTI), which is a very thin and highly contorted layer, that separates regions of turbulent and non-turbulent (or irrotational) flow [2]. TE can be described by the mechanism by which packets of non-turbulent flow acquire vorticity across the very thin TNTI layer [3]. The turbulence characteristics vary significantly moving from the irrotational region towards the turbulent bulk *e.g.* the enstrophy and viscous dissipation display extremely high spatial gradients inside the TNTI layer, and become statistically uniform once the turbulent bulk of the flow is reached. However, it has been recently established that the TNTI layer possesses a two layers structures: a viscous superlayer (VSL) where viscous effects dominate, and a turbulent sublayer (TSL) where inertial effects dominate and that the thickness of these two sublayers (as well as the total TNTI layer) scales with the Kolmogorov micro-scale, for sufficiently high Reynolds numbers [4]. This result, together with the close relation between the local shape of the TNTI layer and the intense vortices in its vicinity [5] suggests that the Kolmogorov scales can be the key to describe the characteristics of the TNTI layer arising from very different flows, such as wakes and jets.

The entrainment characteristics of turbulent planar jets (PJET), planar wakes (PWAKE) and shear free turbulence (SFT) are assessed by comparing several turbulence statistics across the TNTI layers in these flows, obtained from direct numerical simulations (DNS) which attain Reynolds numbers, based in the Taylor micro-scale, of up to $Re_\lambda \approx 400$.

Figure 2: Conditional mean profiles of enstrophy (normalised by the Kolmogorov velocity u_η, and lenght scale η), in relation to the distance from the irrotational boundary (IB) at the edge of the TNTI layer, y_I, for planar jet (JET), planar wake (WAKE), and shear free turbulence (SFT), normalised by the Kolmogorov micro-scale η: (a) Using a constant Kolmogorov micro-scale η_T taken from the turbulent core region; (b) using a (conditional) mean local Kolmogorov micro-scale $\langle\eta\rangle_I$.

RESULTS AND DISCUSSION

To analyse the TNTI layer it is crucial to use a metric which provides an unambiguous separation between turbulent and irrotational flow data (samples). This is achieved by using conditional statistics in relation to the distance from a given reference point within the TNTI layer. These conditional statistics are obtained rearranging the calculated 3D field as function of the distance from the irrotational boundary (IB), which is the outer surface delimiting the TNTI layer (figure 1 (a)). The conditional mean profiles are then computed in a local coordinate system positioned at the IB (at the edge of the the TNTI layer), and the averaging is computed as function of the distance from the IB. Figure 1 (b) shows the conditional mean profiles of enstrophy and velocity fluctuations normalised by the center line velocity ($\sqrt{\langle u'^2\rangle + \langle v'^2\rangle + \langle w'^2\rangle}/U_c$). The distance to the IB, y_I is normalised by the Kolmogorov length scale η calculated in the turbulent core region of the flow. The IB is fixed at $y_I = 0$, while the irrotational and turbulent regions correspond to $y_I < 0$ and $y_I > 0$ respectively. The enstrophy is zero in the NT region and roughly constant in the T core region, the two regions being linked by characteristic sharp vorticity jump with a thickness close to $\sim 15\eta$. In contrast, the velocities exhibit a very smooth variation across the TNTI layer [6].

Figure 2(a) shows typical conditional mean profiles of vorticity magnitude ($\omega_i\omega_i$) normalised with the mean Kolmogorov time scale obtained from the turbulent core region $\langle\tau_\eta\rangle^2$. In the non-turbulent region, $\omega_i\omega_i$ is zero but advancing towards the turbulent core it grows sharply when crossing the initial part of the TNTI ($\sim 10\eta$). A smoother rise follows until a constant plateau is reached in the turbulent bulk of the shear layer. A relatively good collapse is achieved by normalising these conditional means as $\langle\omega_i\omega_i\rangle_I \cdot \langle\tau_\eta\rangle^2 \approx 1$ due to kinematic constraints. However the profiles obtained from different flows (jets, wakes, shear free turbulence) with different initial conditions, diverges in the proximity of the TNTI layer (i.e. for values of $y_I/\eta \lesssim 150$) due to the different local dynamics of the different flows analysed here. Figure 2(b) plots the conditional profiles of $\langle\omega_i\omega_i\rangle_I$ using local conditional mean Kolmogorov scales $\langle\tau_\eta\rangle_I^2$. It is clear that an excellent collapse is achieved in these figures, which underscores the universality of the small scale motions of different flows within the TNTI layer. Here again $\langle\omega_i\omega_i\rangle_I \cdot \langle\tau_\eta\rangle_I^2 \approx 1$ deep into the turbulent core while it is virtually zero in the non-turbulent region. The steep profiles increment that occur after the IB continue much further until a pronounced peak of $\langle\omega_i\omega_i\rangle_I \cdot \langle\tau_\eta\rangle_I^2 \approx 1.2$ is reached. Afterwards they start decreasing slowly to 1. The peaks location occur in a very narrow range of $y_I/\langle\eta\rangle_I \approx 15$.

More evidences of the universality of small scale motions during the entrainment will be discussed during the presentation.

Summary In the last century, the study of turbulence has been approached following the great Kolmogorov's physical insights on the inertial energy cascade and, more recently by investigating the geometry of the state space of the Navier-Stokes equations treated as a dynamical system. Such novel geometric approach arises from the evidence that what is observed in physical space sometimes is not always suggestive of the hidden laws of physics of the turbulent motion. Thus, looking at the turbulent dynamics in state space may lead to new understanding of the associated physical processes. In particular, vortices in a channel flow change shape as they are transported by the mean flow at the Taylor speed, or dynamical velocity. Reducing the translational or Toric symmetry in state space reveals that the shape-changing dynamics of vortices influences their own motion and it induces an additional self-propulsion velocity, the so-called geometric velocity. Thus, in strong turbulence the Taylor's hypothesis of frozen vortices is not satisfied because the geometric velocity can be significant.

RESULTS

Symmetry reduction approaches [1, 2, 3] provide a new way to understand the vortical motion of turbulence. This depends on the inertia of the flow and on its own shape-changing form over time. Because of the inertia of the flow, vortices are transported at roughly the Taylor speed, the so-called dynamical velocity V_{dyn} [2]. If turbulent fluctuations are significant, vortices change shape over time as they are transported by the mean flow. Their shape-changing dynamics induces an additional self-propulsion velocity, the so-called geometric velocity V_{geom} [2]. Thus, in strong turbulence the Taylors hypothesis of frozen vortices is not satisfied since the geometric velocity is not negligible over the Kolmogorov's inertial range.

The Navier-Stokes (NS) equations for channel flows have translational symmetry, that is if the fluid velocity $u(x,t)$ and associated pressure $p(x,t)$ fields are solutions, so are the space-shifted $u(x+L,t)$ and $p(x+L,t)$, where L is the shift. From a dynamical system perspective, if symmetry is present, the velocity V of the vortical motion can be uncoupled in the sum of dynamical and geometric components [2]

$$V = V_{dyn} + V_{geom}. \tag{1}$$

Such uncoupling is clearly observed in state space, and symmetry can be reduced or quotiented out to reveal the pure motion solely due to turbulence. The desymmetrized state space reveals how i) vortices change shape over time and how ii) their shape-changing influences their own motion. The Fourier representation of the velocity field is

$$u(x,t) = \sum_{-N}^{N} z_n(t) e^{ik_0 n x} \tag{2}$$

and the NS state space is $\mathbb{C}^N = \mathbb{R}^{2N}$, where N is the number of Fourier modes. We collect the Fourier modes z_n in a vector z and the NS equations can be rewritten as

$$\dot{z} = F(z), \tag{3}$$

where $F(z)$ is a nonlinear operator of z. Translational symmetry in physical space becomes a Toric symmetry (T-symmetry) in Fourier space, i.e. if the set (z_n) of Fourier modes is a solution of Eq. (4), so is $(z_n \exp(ik_0 L))$, for any shift L. The state space $\mathbb{C}^N$ has the geometric structure of a fiber bundle (see [2] and references therein). The bundle is made of a base or shape manifold $B = \mathbb{C}^N|\mathbb{R}$ of dimensions $\mathbb{R}^{2N-1}$ and 1D fibers along the direction of T-symmetry that attach to any point of B as shown in Figure 1a.

The T-symmetry can be reduced by devising a reduction map π that maps trajectories or orbits $z(t)$ of $\mathbb{C}^N$ onto desymmetrized orbits $Z_D(t)$ of the base manifold B, as illustrated in Figure 1a. The map π is invariant under the T-symmetry and it can be interpreted as a coordinate change transformation that allows for a map representation of the abstract base manifold. There are infinite ways to represent such manifold, i.e Mercatore projection, stereographic projections, etc. The desymmetrized orbit $Z_D(t)$ depends only on the shape-changing dynamics of vortices as in the motion of a jellyfish. Geometric and dynamical velocities allow studying the motion of the vortical motion in the desymmetrized frame. Figure 1b shows the mean velocity profile V of a turbulent channel flow at $Re = 3300$ $(Re_\tau = 180)$. The regime of turbulence is strong and the Taylor hypothesis is not satisfied. The dynamical velocity V_{dyn} is estimated as if vortices are transported by and frozen in the flow. V_{dyn} underestimates the observed mean velocity and the geometric component V_{geom} is not negligible, indicating that the shape-changing of vortices affects their own speed.

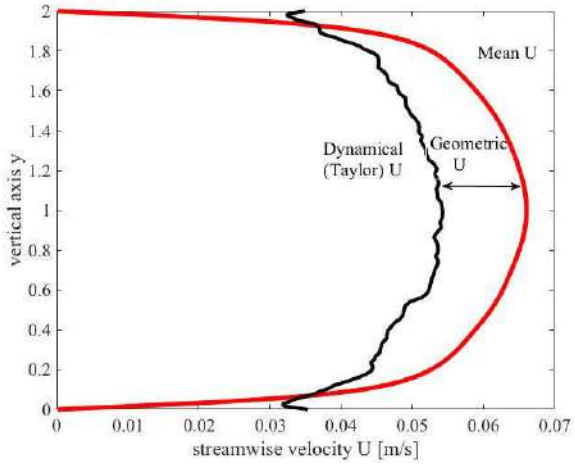
(a) Desymmetrization concepts



(b) Dynamic and geometric velocity components

The group orbit of a trajectory $z(t)$ is a sheet of the fiber bundle and it is defined as

$$\begin{cases} G(z) = \{G_\alpha(z(t)) \quad \forall\, t\} \\ G_\alpha(z(t)) = \left\{z_n(t)e^{in\alpha}, \quad \alpha \in [0\ 2\pi]\right\} \end{cases} \tag{4}$$

Typical group orbits of $\mathbb{C}^N$, visualized in a 3D subspace, are depicted in Figures 2a and 2b. The simulated full trajectory or orbit $z(t)$ (black line), the orbit in the comoving frame (yellow line) and the desymmetrized orbit $Z_D(t)$ (blu line) are also shown. The comoving frame trajectory is that seen from a frame that moves with the dynamical velocity V_{dyn}. The desymmetrized trajectory is seen from a frame that moves at the total speed $V = V_{dyn} + V_{geom}$, sum of the dynamical and geometrical velocities.

CONCLUSIONS

Symmetry reduction approaches are new ways to study the anatomy of the vortical motion in channel flows. Because of the inertia of the flow, vortices are transported at the Taylor speed, the so-called dynamical velocity [2]. When the vortex shape changes over time, it induces an additional self-propulsion velocity, the so-called geometric velocity [2]. Thus, in strong turbulence the Taylor's hypothesis of frozen vortices is not satisfied since the geometric velocity is not negligible.

NETWORK-BASED INVESTIGATION OF TURBULENT MIXING IN AN INHOMOGENEOUS FLOW

Summary To date, many aspects of turbulent mixing require a better and more detailed understanding. Added clarity may be provided by the use of novel approaches such as those based on complex networks, one of which will be presented in this work. The network here proposed aims specifically to describe turbulent mixing in the inhomogeneous direction of a numerically resolved channel flow at $Re_\tau = 950$; this is done using as a starting point Lagrangian data, in the form of the trajectories of a set of tracers released in the channel. Such an approach makes it possible to thoroughly analyse the transient phase before the Taylor regime, the spatial heterogeneities of tracers and the formation of spatial and temporal zoning.

INTRODUCTION

Turbulent mixing is a primary constituent of a huge variety of different phenomena, such as the diffusion of pollutants in the atmosphere or the blending of chemical reactants. Further investigation is needed to better understand its properties, especially its ability to enhance transport [1]. The Lagrangian perspective appears appropriate for this kind of study, since it makes it possible to directly follow the motion of tracers which experience mixing [4]. Complex networks have been already successfully applied to a range of different fields, including biology and social network [2][3]. Their exploitation in the study of turbulence is rather recent but promising, since they allow one to properly represent the temporal and spatial complexity of turbulent flows and are an innovative tool to enrich classical statistical analysis [5][6][7].

DATASET AND NETWORK DEFINITION

The Lagrangian dataset employed in this work consists of the trajectories of $N_p = 10^4$ non inertial tracers released in a turbulent channel flow. The channel flow is simulated by means of direct numerical simulation at a frictional Reynolds number $Re_\tau = \delta u_\tau/\nu = 950$, where δ, u_τ, and ν are the channel half height, the friction velocity and the kinematic viscosity, respectively [8]. The trajectories are integrated for the entire simulation time, which is $T^+ = 15\,200$. At their release, tracers are disposed in $N_l = 100$ equispaced levels along the inhomogeneous direction, which is y; their position is shown in Figure 1(a). The network is specifically designed to describe the mixing of tracers starting from different levels. Indeed, each level constitutes a node in the network, while a connection between nodes is established according to the motion of tracers along y^+. In details, a link between levels i and j exists at any given time if a tracer, released at $t^+ = 0$ inside level i, reaches level j. This leads to the definition of a network composed by $N_l = 100$ nodes, which is *directed* since it retains information about the directional motion of tracers. Moreover, a weight is associated to each link, namely the number of tracers moving between different levels (normalized by the number of tracers present in each level at their release, that is 100). Figure 1(b) contains a simplified representation of the trajectories of particles in and out of levels located at different y coordinates. The mixing process can be fully described by the transport network $\mathbf{W}(t^+)$; the weight matrix of this simplified representation is shown in 1(c), along with the ingoing strength $s_i^{\mathrm{IN}} = \sum_{j=1}^{N_l} W_{ji}$ of the four nodes, which is the sum of weights of incident links and is proportional to the number of tracers moving inside a node at a given time.

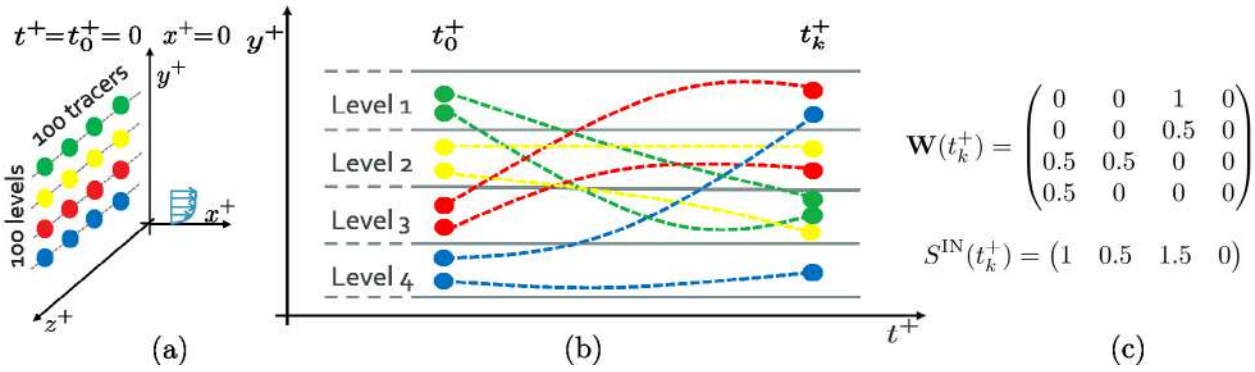

Figure 1: (a) Schematics of the release pattern of tracers, organized in N_l equispaced levels on the $x^+ = 0$ plane; (b) schematics of the motion of tracers between different levels, leading to the definition of the network weight matrix $\mathbf{W}$; (c) network weight matrix $\mathbf{W}$ and ingoing strength s^{IN} for the simplified representation of 1(b). All values in $\mathbf{W}$ are normalized by 2 (*i.e.* the number of particles originally present in each level); the values on the main diagonal are always zero since nodes cannot have self loops.

RESULTS

The geometrization of the particle dynamics provided by the network definition allows us to highlight several features of the mixing phenomenon. The time dependent weight matrices $\mathbf{W}(t^+)$ immediately characterize the extent of mixing between initially distant levels. While for short times (Figure 2(a), $t^+ = 240$) the motion of tracers is confined to levels close to the release location and thus only the elements of $\mathbf{W}$ close to the diagonal are non-zero, for longer times (Figure 2(b), $t^+ = 14\,250$) particles are diffused everywhere across the channel and any information about their starting coordinates is lost. Applying metrics designed for directed networks to the weight matrix $\mathbf{W}$ enables us to thoroughly describe the motion of particles. For instance, the ingoing strength of each node $s^{\mathrm{IN}}(t^+)$ is directly related to the concentration of tracers at any time. As it is shown in Figure 2(c), two main phases in the evolution of the flow are evident: for short times ($t^+ < T_d^+$, $T_d^+ \approx 4000$) the concentration of tracers is highly inhomogeneous, while for larger times ($t^+ > T_d^+$) the vertical mixing of particles is completed and the Taylor dispersion regime is reached. The network formalism is able to capture both the complexity of the irregular, transient phase, and the onset of the asymptotic behaviour. The tools introduced by graph theory may also be exploited to highlight non trivial features which are difficult to notice using statistical methods. The analysis of the physical length of links measures the spatial extent reached by diffusion and also signals the presence of tracers trapped near the channel walls and far away from their starting level. The increase in link length is related to the displacement of tracers towards the channel walls during the initial transient, as can be seen in Figure 2(c). Additionally, common and fast tools developed to find communities in graphs may be used to partition the network into regions of the channel that exchange a reduced amount of tracers between them. Community detection performed in the channel flow is useful to determine the spatial extent of turbulent mixing at different times and highlights the existence of two separate regions near the channel walls.

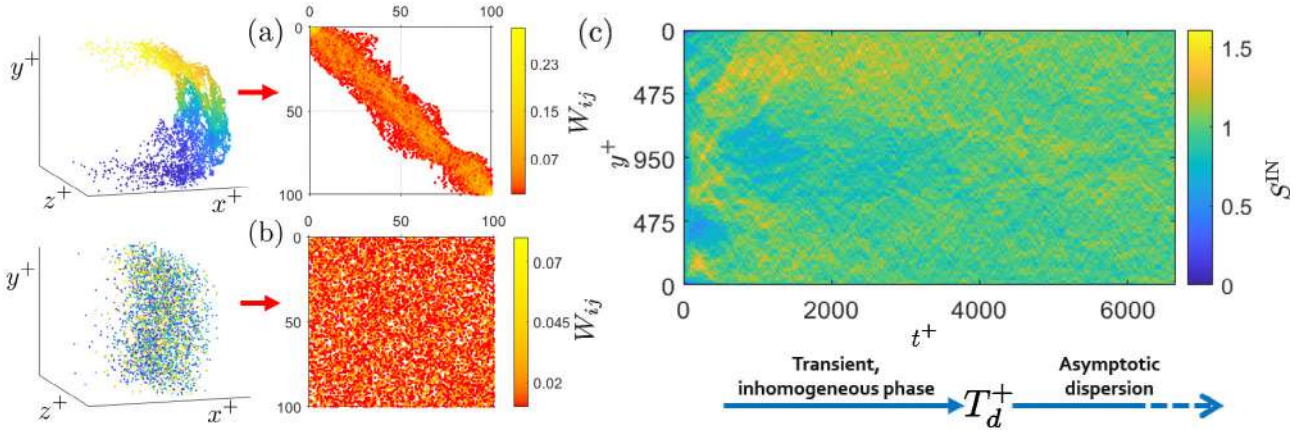

Figure 2: (a) Distribution of particles and network weight matrix at $t^+ = 240$; (b) Distribution of particles and network weight matrix at $t^+ = 14\,250$; (c) the evolution of the ingoing strength s^{IN} of nodes emphasizes both the details of particle motion across the channel and the presence of different regimes in the dispersion process; the onset of the Taylor asymptotic regime ($T_d^+ \approx 4000$) marks the shift between a highly irregular concentration of tracers and a more homogeneous one.

CONCLUSIONS

These findings show both the effectiveness of methods based on network theory and the suitability of the Lagrangian framework for the analysis of turbulent mixing. The complexity of the starting transient and the shift to the asymptotic dispersion regime are well outlined by the network representation of vertical motion inside the channel. Exploitation of the capabilities of the tools presented here offers an in-depth look on the collective and individual behaviour of diffusing tracers in wall bounded turbulence, highlighting their concentration, their trapping in persistent flow structures and their presence in isolated communities [9].

DYNAMICS OF SHEAR-LAYER COHERENT STRUCTURES IN A FORCED WALL-BOUNDED FLOW

Petrônio A.S. Nogueira[1] and André V.G. Cavalieri*[1]
[1]Divisaõ de Engenharia Aeronáutica, Instituto Tecnológico de Aeronáutica, São José dos Campos, SP, Brazil

Summary A model problem for analysing the interaction between coherent structures in shear flows with the presence of a convective instability is proposed. Starting from Couette flow, a permanent forcing in the shape of a hyperbolic tangent is introduced, leading to a wall-bounded flow with an inflection point, triggering a Kelvin-Helmholtz (KH) hydrodynamic instability. Due to the presence of shear, streaks and rolls are also present in the flow, and these structures interact with KH-vortices via oblique waves. Results from direct numerical simulation exhibit a limit cycle involving streaks, vortices, rolls and oblique waves. The flow dynamics reproduce some of the features of jets and mixing layers, such as jitter and translational instability, showing that the present simplified flow model can potentially clarify some of the phenomenon involved in turbulence dynamics.

INTRODUCING THE FLOW MODEL

The present work focuses on analysing the interaction between streamwise elongated, spanwise organised structures (rolls and streaks) and Kelvin-Helmholtz-like vortices, both coherent structures present in turbulent jets [2, 4]. For that, we introduce a novel flow model in which both structures are present, but with a simpler wall-bounded configuration that prevents streamwise inhomogeneity. We consider a laminar Couette flow between two walls at $y = \pm h$, moving with velocity $\pm U_e$. In this flow we introduce a steady forcing, independent of span and streamwise coordinates, in the shape of a hyperbolic tangent in the wall-normal direction y, which is given by the expression $f_P = P_A \tanh(P_B y)$. By introducing this forcing in the laminar streamwise momentum equation, subject to no-slip boundary conditions, the laminar solution can be directly obtained as a function of the parameters P_A and P_B, and the Reynolds number Re. The body force leads to positive (respectively negative) streamwise forcing for $y > 0$ (respectively $y < 0$), which increases velocity gradients in the central region of the flow and creates an inflection point at the centre of the channel. For the present case, we chose P_A such that $\partial U/\partial y = 0$ on the walls, and $P_B = 5$ for a sharp gradient of the body force around $y = 0$, which may nonetheless be numerically resolved with a low number of grid points, and $Re = 200$. The base flow and its wall-normal derivatives for the present choice of parameters can be seen in figure 1(a).

Despite the simplicity of the model, this is a new baseflow and should be appropriately characterised, especially concerning its stability and the amplification of flow disturbances. This was be assessed by means of linear stability analysis and resolvent analysis, pointing to unstable Kelvin-Helmholtz vortices for streamwise/spanwise wavenumbers $(k_x, k_z) = (0.5, 0)$, which leads to structures with zero phase velocity, and highly amplified streaks for $(k_x, k_z) = (0, 1)$.

DIRECT NUMERICAL SIMULATION

From the results of locally parallel analyses, a computational box for a direct numerical simulation (DNS) was designed. Since we are interested in evaluating the interaction between vortices, streaks and other structures, the computations should allow for the growth of the unstable mode at this Reynolds number. Therefore, a box size of $(L_x, L_y, L_z) = (4\pi, 2, 2\pi)$ was chosen, enabling the growth of modes associated to $k_x = 0.5$, which is the sole unstable mode for this case. The box size also enables structures related to $(k_x, k_z) = (0, 1)$, related to the energetic streaks found using resolvent analysis. The present simulation was performed with $(N_x, N_y, N_z) = (32, 65, 32)$ collocation points before dealiasing.

The simulation was started with spatial white-noise, and velocity fields were stored for post-processing. The importance of streaks and vortices in this flow is reinforced by simply looking at the streamwise/wall-normal velocity field at a given simulation time. Isocontours of 60% of maximum streamwise velocity at a sample time ($t = 1930$) are shown in figure 1(a), and streaky structures similar to the ones found in the analysis of [3] can be clearly spotted; the high energy of such structures facilitate their identification in the raw velocity field. At this time, Kelvin-Helmholtz vortices are less energetic, and can only be seen by taking the spanwise mean of the velocity field. Contours of this structure are depicted in the slices shown in figure 1(b).

Looking at the energy of each combination of wavenumbers in the simulation, a limit cycle could be identified, and the energy of the most relevant modes for a single cycle can be seen in figure 2. Clearly, the streaky mode $(k_x, k_z) = (0, 1)$ has most of the energy of this flow for almost all times, with some regions of sharp decay, pointing to an intermittent cancellation of this mode, with alternating positive and negative streaks in a given position of the channel. The vortex, i.e. $(k_x, k_z) = (0.5, 0)$, on the other hand, has intervals of exponential growth and decay, and is never totally damped in the flow. Other modes are also important in the flow dynamics: the oblique wave mode $(0.5, 1)$, for instance, has a higher energy growth at some times compared to the vortex mode, even though it is also subject to a cancellation at other parts of the cycle. Isolating the (v, w) components of mode $(0, 1)$, the energy related to rolls (streamwise vortices) can be extracted; considering that these structures are closely linked to streaks via the lift-up effect, it is expected that these also

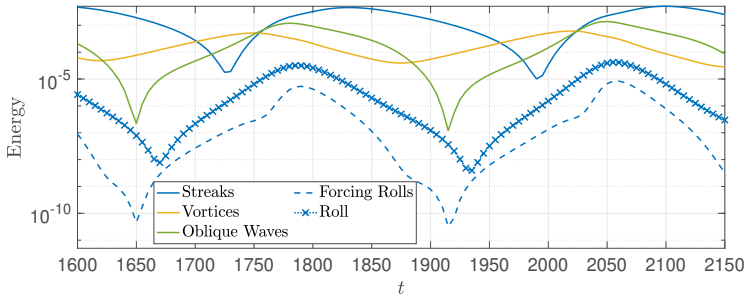

Figure 2: Energy of the different modes involved in the dynamics as a function of time. Dashed line represents the energy related to the forcing of mode $(k_x, k_z) = (0, 1)$ and the symbols depicts the energy related to the (v, w) velocity field of mode $(k_x, k_z) = (0, 1)$.

play a role in this case. Figure 2 also depicts the energy related to the $(0, 1)$ component of the non-linear terms, which also affects directly the time-evolution energy of the rolls. Our current analysis of the limit cycle shows a self-sustaining process, where non-linear interactions of vortices and oblique waves excite rolls of opposite sign of existing ones; rolls cancel existing streaks and create new streaks of opposite sign; and stability of the streaky mean flow leads to new oblique waves of opposite phase, restarting the cycle with a π phase jump.

CONCLUSIONS AND PERSPECTIVES

The present work introduces a flow model that includes the most important coherent structures in jets and mixing layers. To study such flow, a computational box for direct numerical simulation was designed based on the optimal wavenumbers from stability and resolvent analyses. Results from the simulation display a limit cycle involving streaks, vortices, oblique waves and rolls, and a clear dynamics between these modes is observed. We plan to further study this limit cycle by using linear analyses and by computing directly the relevant non-linear terms, so that all the steps of the cycle are clarified. The present results already show several similarities with the behaviour of jets and mixing layers, reproducing a simplified jitter phenomenon [1] and keeping some of the characteristics of a translational instability mechanism [5]. Considering the simplicity of the model and its characteristics (which could be compared to a "minimal jet unity"), such study has considerable potential for the study of coherent structures in free-shear turbulence.

HIERARCHY OF COHERENT STRUCTURES AND ENERGY CASCADE IN WALL-BOUNDED TURBULENCE

Yutaro Motoori*and Susumu Goto
Graduate School of Engineering Science, Osaka University, 1-3 Machikaneyama, Toyonaka, Osaka, 560-8531, Japan

Summary By applying a Gaussian filter to the velocity fields in turbulent channel flow at the friction Reynolds number $Re_\tau \approx 4200$, we decompose the turbulence into different scales. Then, we identify the hierarchy of vortices and low-speed structures depending on the scale and height from the wall. For examining its generation mechanism, we also quantify the inter-scale energy transfer. The largest-scale structures at each height (wall-attached structures) are composed of quasi-streamwise vortices and low-speed streaks. Since these are similar to the well-known coherent structures in the buffer layer, they are likely to be maintained by the hierarchical self-sustaining process, in which the source of the energy is the mean flow. On the other hand, structures smaller than the height are generated by the energy cascade; the energy of these small-scale structures is transferred predominantly from twice-larger-scale structures and reduced by half-scale structures.

BACKGROUND AND SCOPE

The sustaining mechanism of wall-bounded turbulence at low Reynolds numbers is well known (for example, Ref. [1]). However, as the Reynolds number increases, the sustaining mechanism becomes complicated due to the appearance of the hierarchy of multiscale vortices. This is the reason why we must identify the hierarchy of coherent vortices to understand the sustaining mechanism of high-Reynolds-number turbulence. However, the extraction of multiscale vortices is difficult because the magnitude of the velocity gradient is predominantly determined by the smallest scale. In our previous studies [2, 3], by coarse-graining turbulent fields, we overcame this difficulty and identified the hierarchy in a turbulent boundary layer at $Re_\tau \approx 1000$. In the present study, for turbulent channel flow [4] at a higher Reynolds number ($Re_\tau \approx 4200$), we identify the hierarchical structures to understand their sustaining mechanism. For this purpose, we extract the hierarchy of vortices, and also quantify the real-space energy transfer.

HIERARCHY OF VORTICES AND LOW-SPEED STREAKS

To extract the hierarchy in turbulence, we use a band-pass filter, which was also used in our previous study [3]. First, we apply the Gaussian filter

$$u_i^{(\sigma)\mathrm{low}} = C(y) \int_{V(\boldsymbol{x}|\sigma)} u_i'(\boldsymbol{x}') \exp\left(-\frac{2}{\sigma^2}(\boldsymbol{x}-\boldsymbol{x}')^2\right) \mathrm{d}\boldsymbol{x}' \quad (1)$$

to the fluctuating velocity fields u_i', where C is the coefficient to ensure that the integration of the filter gives unity and σ denotes the filter scale. For the wall-normal direction y, we use the method proposed by Lozáno-Durán *et al.* [5]. Next, we take the difference between the low-pass filtered fields $u_i^{(\sigma)\mathrm{low}}$ at two different scales, i.e.

$$u_i^{(\sigma)} = u_i^{(\sigma)\mathrm{low}} - u_i^{(2\sigma)\mathrm{low}}. \quad (2)$$

This filter corresponds to a band-pass filter of the Fourier modes because $u_i^{(\sigma)}$ has the contributions only from around the scale σ. All the scale-decomposed quantities $\cdot^{(\sigma)}$ (e.g., the second invariant $Q^{(\sigma)}$ of the velocity gradient tensor) are evaluated from $u_i^{(\sigma)}$. Figure 1 shows positive isosurfaces of $Q^{(\sigma)}$ at three different scales $\sigma^+ = 960$ (red), 240 (yellow) and 60 (blue). Here, $\cdot^+$ denotes the wall unit. We see that the identified structures are approximately in the filter scale. We emphasize that these hierarchies cannot be identified without a scale-decomposition (see figures 3 and 4 in Ref. [2]).

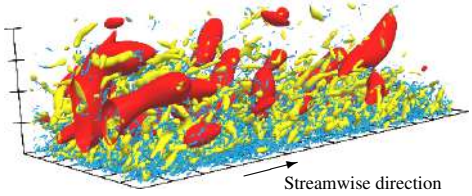

Figure 1: Hierarchy of vortices identified by positive isosurfaces of $Q^{(\sigma)}$ at three scales $\sigma^+ = 960$ (red), 240 (yellow) and 60 (blue). The grid width indicates 1000 wall units.

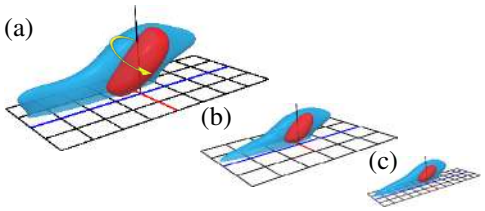

Figure 2: The hierarchy of quasi-streamwise vortices and low-speed streaks identified by isosurfaces of conditional averages of $Q^{(\sigma)}$ (red) and $u^{(\sigma)}$ (blue) at (a) $y_c^+ = \sigma^+ = 960$, (b) 240 and (c) 60. The grid width indicates the filter scale σ.

The analysis of the scale-decomposed fields enables us to reveal the nature of the hierarchy. To show that the largest-scale structures at each height ($\sigma = y$) are similar to coherent structures in the buffer layer, we take conditional averages. When $Q^{(\sigma)}$ at a height y_c is larger than the standard deviation and the streamwise vorticity $\omega_x^{(\sigma)}$ is positive, we take averages of $Q^{(\sigma)}$ and $u^{(\sigma)}$ around the point satisfying these conditions. This conditional averaging leads to the average distributions of $Q^{(\sigma)}$ and $u^{(\sigma)}$ around the largest-scale vortices. Figure 2 shows the isosurfaces of the conditional averages of $Q^{(\sigma)}$ (red) and $u^{(\sigma)}$ (blue) for (a) $\sigma^+ = y_c^+ = 960$, (b) 240 and (c) 60. We see that visualized structures are a quasi-streamwise vortex (red) and low-speed streak (blue), which implies that they are likely to be maintained by the self-sustaining process (SSP). Since such processes occur simultaneously at different heights, we call them the hierarchical SSP.

SUSTAINING MECHANISM OF THE HIERARCHY

To investigate the sustaining mechanism of the hierarchy, we quantify two types of the scale-dependent energy transfers. First, we define the energy transfer at the scale $\sigma_{\rm to}$ from the mean flow as

$$Pr(\mathrm{M} \to \sigma_{\rm to}; y) = -\overline{u_i^{(\sigma_{\rm to})} u_j^{(\sigma_{\rm to})}} \frac{\partial \overline{u_i}}{\partial x_j} = -\overline{u^{(\sigma_{\rm to})} v^{(\sigma_{\rm to})}} \frac{\partial \overline{u}}{\partial y}, \tag{3}$$

where $\bar{\cdot}$ denotes the average in the spanwise and streamwise directions and time. We then define the inter-scale energy transfer from $\sigma_{\rm fr}$ to $\sigma_{\rm to}$ as

$$Tr(\sigma_{\rm fr} \to \sigma_{\rm to}; y) = -\overline{u_i^{(\sigma_{\rm fr})} u_j^{(\sigma_{\rm fr})} \frac{\partial u_i^{(\sigma_{\rm to})}}{\partial x_j}} - \left(\overline{-u_i^{(\sigma_{\rm to})} u_j^{(\sigma_{\rm to})} \frac{\partial u_i^{(\sigma_{\rm fr})}}{\partial x_j}} \right). \tag{4}$$

Since these are scale-dependent quantities, they are not in the equation of the (mean) turbulent kinematic energy. However, as Kawata and Alfredsson [6] showed, these terms are in the equation of the scale-dependent energy, which is derived by decomposing the velocity into two scales with an orthogonal filter. Although our decomposition is not orthogonal, similarly to Ref. [6], we interpret $Pr(\mathrm{M} \to \sigma_{\rm to})$ as the energy transfer to the scale $\sigma_{\rm to}$ from the mean flow and $Tr(\sigma_{\rm fr} \to \sigma_{\rm to})$ as the inter-scale energy transfer from $\sigma_{\rm fr}$ to $\sigma_{\rm to}$.

We show, in figure 3, Tr (open circles) and Pr (closed circles) for $\sigma_{\rm to}^+ = 960$ (red), 240 (yellow) and 60 (blue) in the log layer ($y^+ = 960$). Looking at Tr, we see that the contributions from the larger scale ($\sigma_{\rm fr} > \sigma_{\rm to}$) are positive, whereas those from the smaller scale ($\sigma_{\rm fr} < \sigma_{\rm to}$) are negative. This implies that the energy is forwardly transferred on average. Among the contributions, those from the twice larger scale $Tr(2\sigma_{\rm to} \to \sigma_{\rm to})$ and half one $Tr(\sigma_{\rm to}/2 \to \sigma_{\rm to})$ are most important. Note that Pr (closed circles) is larger for larger scales. To investigate the generation mechanism of the energy for a given scale $\sigma_{\rm to}$ and a given height y, we show in figure 4 the ratio Γ of $Tr(2\sigma_{\rm to} \to \sigma_{\rm to})$ to $Pr(\mathrm{M} \to \sigma_{\rm to})$. If $\Gamma > 1$, the energy for the scale $\sigma_{\rm to}$ at height y is generated by the energy cascade; otherwise, the energy is directly produced by the mean flow. The blue dashed line indicates $y = 3\sigma$. We can see that this line is in good agreement with $\Gamma = 1$, which corresponds to the qualitative change of the generation mechanism. Therefore, we conclude that, in the log and buffer layers, the largest-scale ($\sigma \gtrsim y/3$) energy is directly produced by the mean flow, which is related to the SSP, whereas small scales ($\sigma \lesssim y/3$) are generated by the energy cascade.

We have shown that the spatial structures and sustaining mechanism of the hierarchical structures in turbulent channel flow [7]. The keys to these analyses are the scale-decomposition defined by (2) and the quantification of the real-space energy transfer defined by (3) and (4). The main result is the qualitative change (from the hierarchical SSP to the energy cascading process) of the sustaining mechanism at the scale $\sigma \approx y/3$ of vortices of the scale σ at height y (figure 4).

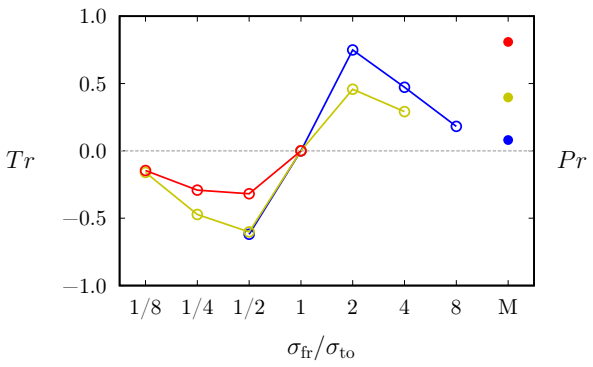

Figure 3: Tr (open circles) and Pr (closed circles) for scales $\sigma_{\rm to}^+ = 960$ (red), 240 (yellow) and 60 (blue) at $y^+ = 960$. Larger-scale energy tends to be produced by the mean flow, whereas smaller-scale energy is transferred from the twice-larger scale.

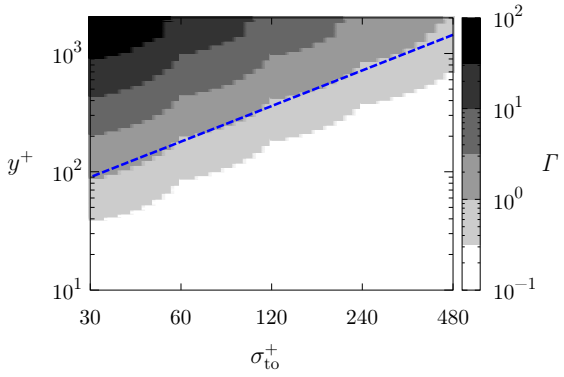

Figure 4: The ratio Γ of $Tr(2\sigma_{\rm to} \to \sigma_{\rm to})$ to $Pr(\mathrm{M} \to \sigma_{\rm to})$. $\Gamma = 1$ indicates the qualitative change of the generation mechanism, which corresponds to $y = 3\sigma$ (blue dashed line). The large-scale ($\sigma \gtrsim y/3$) energy is produced by the mean flow, whereas small-scale ($\sigma \lesssim y/3$) energy is generated by the energy cascade.

SYMMETRY INDUCED TURBULENT MOMENT SCALING LAWS OF ARBITRARY ORDER AND ITS VALIDATION USING CHANNEL FLOW DNS DATA AT $Re_\tau = 10^4$

Martin Oberlack*[1], Sergio Hoyas[2], Stefanie Kraheberger[1], and Francisco Alcántara-Ávila[2]
[1]Chair of Fluid Dynamics, TU Darmstadt, Otto-Berndt-Str.2, 64287 Darmstadt, Germany
[2]Instituto de Matemática Pura y Aplicada, UP València, Camino de Vera, 46024 València, Spain

Summary Using the symmetry-based turbulence theory we derive turbulent scaling laws for arbitrarily high moments of the streamwise velocity U_1. In the region of the log-law, the theory predicts an algebraic law with the exponent $\omega(n-1)$ for moments $n > 1$. The exponent ω of the 2^{nd} moment determines the exponent of all higher moments. Moments here always refer to the instantaneous quantities and not to the fluctuations. For the core region of a Poiseuille flow we find a deficit law for arbitrary moments n of algebraic type with a scaling exponent $n(\sigma_2-\sigma_1)+2\sigma_1-\sigma_2$. Hence, the moments of order one and two with its scaling exponents σ_1 and σ_2 determine all higher exponents. To validate the new theoretical results we have conducted a Poiseuille flow DNS at $Re_\tau = 10^4$. All of the latter theoretical findings could be verified with high accuracy using DNS data.

THE MULTI-POINT CORRELATIONS EQUATIONS AND ITS SYMMETRIES

The basic equations of the following analyses are the infinite set of multi-point correlations equations

$$\frac{\partial H_{i_{\{n+1\}}}}{\partial t}+\sum_{l=0}^{n}\left[\frac{\partial H_{i_{\{n+2\}[i_{(n+1)}\mapsto k_{(l)}]}}[\boldsymbol{x}_{(n+1)}\mapsto\boldsymbol{x}_{(l)}]}{\partial x_{k_{(l)}}}+\frac{\partial I_{i_{\{n\}[l]}}}{\partial x_{i_{(l)}}}-\nu\frac{\partial^2 H_{i_{\{n+1\}}}}{\partial x_{k_{(l)}}\partial x_{k_{(l)}}}\right]=0 \quad \text{for} \quad n=1,\ldots,\infty \ , \tag{1}$$

which directly result from the Navier-Stokes equations (see e.g. [1]), to be extend by continuity, and where $H_{i_{\{n+1\}}} = H_{i_{(0)}i_{(1)}\ldots i_{(n)}} = \overline{U_{i_{(0)}}(\boldsymbol{x}_{(0)},t)\cdot\ldots\cdot U_{i_{(n)}}(\boldsymbol{x}_{(n)},t)}$. $I_{i_{\{n\}[l]}}$ obeys a similar defintion as $H_{i_{\{n+1\}}}$, but at the l-th position the velocity is replaced by the pressure P. Most important it is to note that other than in classical statistical approaches both velocity and pressure refer to the instantaneous and not to the fluctuating quantities. We may note that $H_i = \bar{U}_i$.

For the results to be derived below we need to define symmetries, which indicate a transformation of the independent $\boldsymbol{x}$ and dependent variables $\boldsymbol{y}$ to new variables $\boldsymbol{x}^* = \boldsymbol{\phi}(\boldsymbol{x},\boldsymbol{y})$ and $\boldsymbol{y}^* = \boldsymbol{\psi}(\boldsymbol{x},\boldsymbol{y})$, which map a differential equation (DE) $\boldsymbol{F}(\boldsymbol{x},\boldsymbol{y},\boldsymbol{y}^{(1)},\boldsymbol{y}^{(2)},\ldots,\boldsymbol{y}^{(p)}) = 0$ onto itself, i.e. concretely after the transformation the DE has an identical form, so $\boldsymbol{F}(\boldsymbol{x}^*,\boldsymbol{y}^*,\boldsymbol{y}^{*(1)},\boldsymbol{y}^{*(2)},\ldots,\boldsymbol{y}^{*(p)}) = 0$. The Lie algorithm allows to rigorously calculate the symmetry transformations $\boldsymbol{\phi}$ and $\boldsymbol{\psi}$ from a given DE, which denote a continuous transformation that depends on one or several continuous parameter out of $\mathbb{R}$ and possesses certain group properties. Since the equations (1) is derived from the Navier-Stokes they admit the classical Galilei transformation group, and in the limiting case of large Reynolds numbers, the two scaling symmetries

$$t^* = \mathrm{e}^{a_2}t, \quad \boldsymbol{x}^*_{(l)} = \mathrm{e}^{a_1}\boldsymbol{x}_{(l)}, \quad \mathbf{H}^*_{\{n\}} = \mathrm{e}^{n(a_1-a_2)}\mathbf{H}_{\{n\}}, \quad \mathbf{I}^*_{\{n\}[l]} = \mathrm{e}^{(n+2)(a_1-a_2)}\mathbf{I}_{\{n\}[l]}, \tag{2}$$

which are scaling of space (a_1) and time (a_2). Additionally, the equations (1) admit two statistical symmetries, i.e.

$$t^* = t, \quad \boldsymbol{x}^*_{(l)} = \boldsymbol{x}_{(l)}, \quad \mathbf{H}^*_{\{n\}} = \mathrm{e}^{a_s}\mathbf{H}_{\{n\}}, \quad \mathbf{I}^*_{\{n\}[l]} = \mathrm{e}^{a_s}\mathbf{I}_{\{n\}[l]}, \tag{3}$$

and

$$t^* = t, \quad \boldsymbol{x}^*_{(l)} = \boldsymbol{x}_{(l)}, \quad \mathbf{H}^*_{\{n\}} = \mathbf{H}_{\{n\}} + \mathbf{A}_{\{n\}}, \quad \mathbf{I}^*_{\{n\}[l]} = \mathbf{I}_{\{n\}[l]} + \mathbf{B}_{\{n\}[l]}, \tag{4}$$

where a_s, $\mathbf{A}_{\{n\}}$ and $\mathbf{B}_{\{n\}[l]}$ are group parameter. These statistical symmetries are not admitted by the Navier-Stokes equations and in [2] it has been shown that (3) and (4) respectively define a measure of intermittency and non-gaussianity.

SYMMETRY INDUCED TURBULENT SCALING LAWS

From the above symmetries and using the notion of infinitesimal transformation, we may construct invariant solutions using the invariant surface condition (for details see e.g. [1]), which specifically for plane shear flows reads

$$\frac{\mathrm{d}x_2}{a_1x_2+a_3}=\frac{\mathrm{d}H_1}{[a_1-a_2+a_s]H_1+A_1}=\cdots=\frac{\mathrm{d}H_{1_{\{n+1\}}}}{[n(a_1-a_2)+a_s]H_{1_{\{n+1\}}}+A_{1_{\{n+1\}}}}, \tag{5}$$

where we presently focus on moments of the U_1 velocity, $H_{1_{\{n+1\}}} = H_{\underbrace{11\ldots1}_{n}}$ and, further, we remind that $H_1 = \bar{U}_1$.

Since the equation (1) is a multi-point equation, the moments $n \geq 2$ depends on further points, so that in the general case in (5) further invariant parts of coordinates occur. In the present case we consider only one-point moments, so that the integration constants are true constants. For the integration of (5) we consider two cases.

For the log-law, the friction velocity $u_\tau = \sqrt{\tau_w/\rho}$ is the determining parameter. If we combine the scaling symmetries (2) and (3), which for the mean velocity reads $\bar{U}_1^* = \mathrm{e}^{a_1-a_2+a_s}\bar{U}_1$, u_τ turns out to be symmetry-breaking and hence

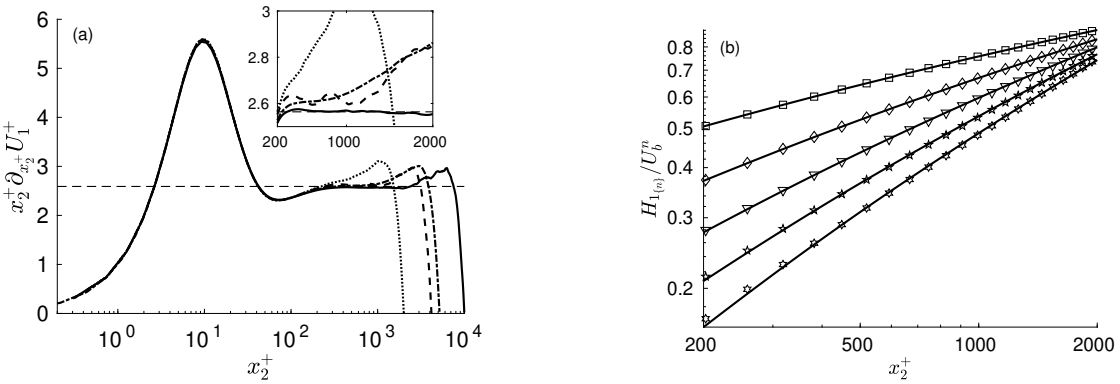

Figure 1: *Left*: Log-indicator function $x_2^+\partial_{x_2^+}\overline{U}_1$ at different Re, with zoom on the log-region. ------ : $Re_\tau = 2000$, – – – : $Re_\tau = 4000$, – - – - : $Re_\tau = 5200$, ——— : $Re_\tau = 10^4$. Horizontal line $\kappa \approx 0.384$. *Right*: Higher moments $H_{1_{\{n\}}}$. From top to bottom: $H_{1_{\{n\}}}$ of order $n = 2, ...6$. ——— : DNS data at $Re_\tau = 10^4$, symbols: Eq. (6) with coefficients fitted to DNS data.

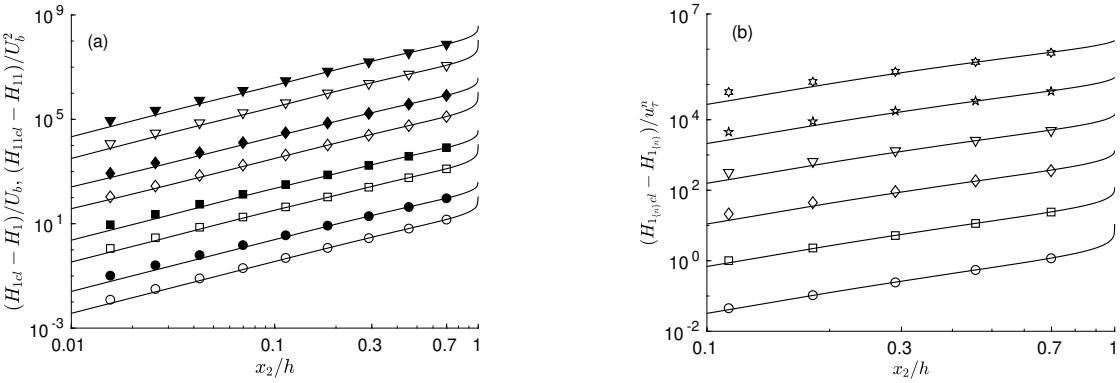

Figure 2: Results refer to the channel core, as x_2 is anchored to the channel center. Solid lines link to DNS data. Symbols are according to Eq. (7). *Left*: 1^{st} and 2^{nd} moments H_1 (open symbols) and H_{11} (closed). From bottom to top: $Re_\tau = 2000, 4000, 5200, 10^4$. Profiles are shifted to increase visibility. *Right*: $H_{1_{\{n\}}}$ of order $n = 1, ...6$, DNS data are at $Re_\tau = 10^4$.

$a_1 - a_2 + a_s = 0$. Using this in (5) and integrate the ODE, we obtain the classical log-law for the mean velocity and an algebraic scaling law for the higher moments

$$\bar{U}_1^+ = \frac{1}{\kappa}\ln\left(x_2^+ + A\right) + B, \quad \text{for } n = 1 \quad \text{and} \quad H_{1_{\{n\}}} = C_{1_{\{n\}}}\left(x_2^+ + A\right)^{\omega(n-1)}, \quad \text{for } n \geq 2 \tag{6}$$

where κ, A, ω, are function of the group parameter defined in (2)-(4) and $C_{1_{\{n\}}}$ are constants of integration. For the deficit-law in the channel center, which was first suggested to be algebraic in [3], we may not invoke a symmetry breaking scale ab initio, and integration of (5) leads to

$$\frac{H_{1_{\{n\}}cl} - H_{1_{\{n\}}}}{u_\tau^n} = D_{1_{\{n\}}}\left(\frac{x_2}{h}\right)^{n(\sigma_2-\sigma_1)+2\sigma_1-\sigma_2} \quad \text{for } n \geq 1. \tag{7}$$

σ_1 and σ_2, which are the scaling exponents of the 1^{st} and 2^{nd} moments, determine all higher moments, and have their origin in the group parameter given in (2)-(4). $H_{1_{\{n\}}cl}$ is the n^{th} moment at the channel center and $D_{1_{\{n\}}}$ are constants of integration.

TURBULENT SCALING LAW VALIDATION USING DNS DATA

Validation of these new scaling laws (6) and (7) have been done using the data of [4], [5], [6] and a new simulation at $Re_\tau = 10^4$ using the code LISO [4]. All computations were conducted on SuperMUC-NG at LRZ in Munich/Garching.

A clear confirmation of (6), especially for the new algebraic law for $n > 2$, is done using the new DNS data at $Re_\tau = 10^4$. Results are shown in figure 1b, leading to the following values $\kappa = 0.386$, $A = 4.487$ and $\omega = 0.12$. Further, the evaluation of the scaling law (7) in the channel centre, even at lower Reynolds numbers, can be taken from the figures 2a and 2b, where the DNS data yield the following values $\sigma_1 = 1.76$ and $\sigma_2 = 1.74$.

REGENERATION OF THE SMALL SCALES IN TURBULENCE WITH 4DVAR: COMPARISON BETWEEN DNS AND LES

Yi Li*[1], Jianlei Zhang[2], and Gang Dong[2]
[1]School of Mathematics and Statistics, University of Sheffield, UK
[2]National Key Laboratory of Transient Physics, Nanjing University of Science and Technology, P. R. China

Summary Variational data assimilation has been applied to CFD research in a number of applications, including inflow condition generation, fields reconstruction, sensor placement, dispersion source identification etc. Here the method is applied to recover small scale fluctuations in 3D turbulent velocity fields from a given time sequence of the velocity data obtained at the large scales. The 4DVAR formalism is used, where the initial velocity field serves as the control, to be chosen to minimize the difference between the measure data and the simulated velocity. Both DNS and LES as the model for the data are considered. The adjoint method is used to find the optimal solutions. The results show that satisfactory recovery can be achieved with DNS as the model. As expected, the recovery with LES as the model is lower, although the accuracy might still be sufficient for some applications.

THE GOVERNING EQUATIONS

Data assimilation (DA) refers to the process where experimental data are merged with simulation data to improve the prediction of a numerical model. In the four-dimensional variational (4DVAR) method, the available data are usually 3D field data given as a time sequence over a time period. The assimilation is accompolished by solving an optimization problem, where a problem-specific control variable is optimized to reduce the error between simulation and measurements. The method has been used, e.g., for field reconstruction [2, 1], to obtain optimal reduced order models [3], to find optimal sensor placement [4] and to reconstruct scalar sources [5]. In this paper, it is assumed some measurements of a time sequence of 3D turbulent velocity fields $\mathbf{v}(\mathbf{x},t)$ are known over a time period $t\in[0,T]$. The measurements are denoted by $\mathcal{F}\mathbf{v}(\mathbf{x},t)$, and is assumed to contain only the large scale velocity field. The question is if it is possible to reconstruct the small scales in $\mathbf{v}(\mathbf{x},t)$ solely based on the large scale data $\mathcal{F}\mathbf{v}$ and the knowledge that $\mathbf{v}(\mathbf{x},t)$ is a solution of either the Navier-Stokes equations (NSEs) or the filtered NSEs. Let $\widetilde{\mathbf{u}}(\mathbf{x},t)$ be the solution of the filtered NSEs with initial condition $\widetilde{\mathbf{u}}(\mathbf{x},0)=\boldsymbol{\phi}(\mathbf{x})$. The problem is thus reduced to finding $\boldsymbol{\phi}(\mathbf{x})$ such that $\mathcal{F}\mathbf{u}(\mathbf{x},t)$ agrees with $\mathcal{F}\mathbf{v}(\mathbf{x},t)$. Since $\widetilde{\mathbf{u}}$ is a solution of the filtered NSEs and $\mathcal{F}\widetilde{\mathbf{u}}$ matches $\mathcal{F}\mathbf{v}$, the small scales of $\widetilde{\mathbf{u}}$ are thus the reconstruction of $\mathbf{v}$. Because 3D turbulent flows are highly chaotic, this problem has not been fully resolved.

Mathematically, we define a cost functional to quantify the difference between $\mathcal{F}\widetilde{\mathbf{u}}(\mathbf{x},t)$ and the measurement data:

$$J\equiv\frac{1}{2}\int_0^T\int_B||\mathcal{F}\widetilde{\mathbf{u}}(\mathbf{x},t)-\mathcal{F}\mathbf{v}(\mathbf{x},t)||^2d^3\mathbf{x}dt, \tag{1}$$

where T is the optimization horizon and B is the solution domain. The initial field $\boldsymbol{\phi}(\mathbf{x})$ is found from a constrained optimization problem in which J is minimized subject to the constraint that $\widetilde{\mathbf{u}}(\mathbf{x},t)$ is the solution of the filtered NSEs given $\boldsymbol{\phi}(\mathbf{x})$ as the initial condition.

Using the adjoint method, the optimal solution can be found as the solution of the KKT conditions. The KKT conditions includes the filtered NSEs:

$$\partial_t\widetilde{\mathbf{u}}+\widetilde{\mathbf{u}}\cdot\nabla\widetilde{\mathbf{u}}+\nabla\widetilde{p}+\nabla\cdot\boldsymbol{\tau}-\nu\nabla^2\widetilde{\mathbf{u}}-\widetilde{\mathbf{f}}=0,\quad\nabla\cdot\widetilde{\mathbf{u}}=0,\quad\widetilde{\mathbf{u}}(\mathbf{x},t=0)=\boldsymbol{\varphi}(\mathbf{x}). \tag{2}$$

where $\boldsymbol{\tau}=\widetilde{\mathbf{u}\mathbf{u}}-\widetilde{\mathbf{u}}\widetilde{\mathbf{u}}$ is the SGS stress tensor. The KKT conditions also include the adjoint equations:

$$\partial_t\boldsymbol{\xi}+\mathbf{u}\cdot\nabla\boldsymbol{\xi}-\nabla\mathbf{u}\cdot\boldsymbol{\xi}+\nabla\mu+\nabla\cdot\boldsymbol{\tau}^{\xi}+\nu\nabla^2\boldsymbol{\xi}=-\mathcal{F}^{+}\mathcal{F}[\widetilde{\mathbf{u}}(\mathbf{x},t)-\mathbf{v}(\mathbf{x},t)],\quad\nabla\cdot\boldsymbol{\xi}=0,\quad\boldsymbol{\xi}(\mathbf{x},t=T)=0, \tag{3}$$

where $\boldsymbol{\xi}$ and μ are the adjoint velocity and pressure, respectively. Using the standard Smagorinsky model, we obtain:

$$\boldsymbol{\tau}=2(C_s\Delta)^2|\widetilde{\mathbf{s}}|\widetilde{\mathbf{s}}\quad\text{and}\quad\boldsymbol{\tau}^{\xi}=2(C_s\Delta)^2\left\{|\widetilde{\mathbf{s}}|^{-1}[(\widetilde{\mathbf{s}}:\widetilde{\mathbf{s}})\boldsymbol{\Sigma}+(\widetilde{\mathbf{s}}:\boldsymbol{\Sigma})\widetilde{\mathbf{s}}]\right\},$$

where $\Sigma=(\nabla\boldsymbol{\xi}+\nabla\boldsymbol{\xi}^T)/2$. It can be shown that the gradient of J is given by

$$\frac{dJ}{d\boldsymbol{\varphi}}=\boldsymbol{\xi}(\mathbf{x},0). \tag{4}$$

If $\mathbf{v}$ is assumed to be the solution of the NSEs instead, the KKT condtions would be the same except that $\boldsymbol{\tau}$ and $\boldsymbol{\tau}^{\xi}$ will be absent. The above sysmtem of equations are solved iteratively using a forward-backward loop. For this investigation, a 3D Kolmogorov flow is considered, so that all equations are solved in the Fourier space with a pseudo-spectral scheme. A second order time stepping is used. The Reynolds number of flow is $Re_\lambda\approx 75$. $\mathcal{F}\mathbf{v}(\mathbf{x},t)$ is assumed to include the Fourier modes of a sequence of DNS data with wavenumbers not bigger than $k_m=4$.

*Corresponding author. E-mail: yili@shef.ac.uk.

RESULTS

The reconstruction quality can be measured by the energy spectrum E_D of the velocity difference $\widetilde{\mathbf{u}} - \mathbf{v}$, as well as the spectral correlation between the Fourier modes of $\widetilde{\mathbf{u}}$ and $\mathbf{v}$, which is defined by

$$\hat{\rho}_{\mathbf{uv}}(k) \equiv \frac{\oint \langle \hat{\mathbf{u}}^*(\mathbf{k},t) \cdot \hat{\mathbf{v}}(\mathbf{k},t) \rangle dS_k}{2\sqrt{E_{\mathbf{u}}(k) E_{\mathbf{v}}(k)}}, \tag{5}$$

where $E_{\mathbf{u}}(k)$ and $E_{\mathbf{v}}(k)$ denote the energy spectrum of the reconstruction $\widetilde{\mathbf{u}}$ and the target velocity $\mathbf{v}$, respectively. The left panel in Fig. 1 plots the integral $\int_0^{k_\Delta} E_D(k)dt$ normalized by a similar integral of $E_{\mathbf{v}}(k)$. The ratio meaures the total difference up to wavenumber k_Δ. The result shows that the reconstruction with DNS as the model is uniformly better, as expected. Nevertheless, the reconstruction with LES can reduce the error down to about 2%. The error is smaller for smaller k_Δ, which implies larger scales are reconstructed better, which again is expected.

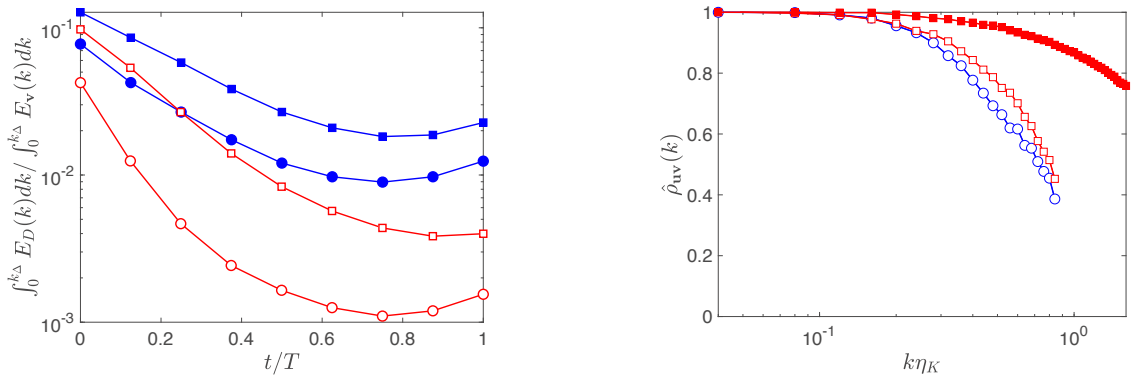

Figure 1: Left: The integrated $E_D(k)$ normalized the integrated $E_{\mathbf{v}}(k)$. Solid symbols: LES; open symbols: DNS. Squares: $k_\Delta \eta_K = 0.5$; circles: $k_\Delta \eta_K = 0.25$. T equals the large eddy turn-over time scale. Right: $\hat{\rho}_{\mathbf{uv}}$ for LES (open symbols) and DNS (solid symbols). Squares: $t/T = 1$; circles: $t/T = 0.5$.

The right panel of Fig. 1 shows the spectral correlation as different times for the LES model, which is compared with the result for DNS at $t = T$. Good correlation is observed for DNS down to the Kolomogorov scale. For LES, the correlation coefficient at the filter scale is approximately 0.4, which shows there is not much correlation with the target data. Good correlation at twice the fitler scale is observed, with the coefficient at about 0.8.

DISCUSSION AND CONCLUSIONS

The ability of the 4DVAR method to reconstruct the small scales of a 3D turbulent field from large scale measurement is investigated. For the given parameters, accurate reconstruction can be obtained if DNS is used as the model and the optimization horizon is approximately one large eddy turn-over time scale. However, to ascertain whether full reconstruction is possible, a longer optimization horizon is needed. The reconstruction with LES has larger errors, which is not unexpected. However, as LES is less expensive, in principle it is possible to extend the optimization horizon to compensate, to some extent, for the error induced by the SGS model. This scenario and the generalization to problems with higher Reynolds number are on-going research.

SPECTRAL ANALYSIS OF REYNOLDS SHEAR STRESS IN WALL-BOUNDED TURBULENT FLOWS

Myoungkyu Lee*[1] and Robert D. Moser[2,3]

[2]Oden Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, Texas, USA
[3]Walker Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas, USA

Summary We perform spectral analysis of terms in the transport equation of the Reynolds shear stress (RSS), $\langle u'v' \rangle$, in wall-bounded channel flows to study the dynamics of RSS in the overlap region. It had previously been observed [1], that the RSS spectrum is highly concentrated in streamwise elongated modes with spanwise length scales that grow linearly with wall distance in the overlap region. The RSS transport spectra are studied to identify the reason for this, and investigate other characteristics of the RSS dynamics. Also, to facilitate interpretation, we will revisit the definition of terms in conventional Reynolds stress transport equations.

The wall-bounded flows at high Reynolds number (Re) are important in science and engineering applications, such as atmospheric flows and high-speed transportation system. Yet, our understanding of wall-bounded turbulence is still limited despite recent advances in experimental and computational techniques. As with all turbulent flows are, turbulent fluctuations at different length scales occur in wall-bounded turbulence and their dynamics vary with the distance from the wall. The dynamics of the near-wall turbulence is relatively well explained by the autonomous self-sustaining cycle model [2]. On the other hand, the interaction between the near-wall and outer flows are not well-understood. In this study, we investigate the "life-cycle" of the Reynolds shear stress (RSS) in the overlap region between near-wall and outer layer turbulence. In particular, we perform spectral analysis of the terms in the transport equation of RSS, $\langle u'v' \rangle$.

For this study, we used a set of direct numerical simulations (DNSs) of turbulent channel flows up to friction Reynolds number, Re_τ, 5200 [3]. Here, x, y, and z denote the streamwise, wall-normal and spanwise directions and u, v and w denotes velocity components in each direction, respectively. Using the analysis outlined in [1], we examine the two-dimensional spectra at various distances from the wall of terms in the transport equation for the RSS computed from this DNS. The two-dimensional spectral densities are visualized in polar-log coordinates, as defined in [1].

To start, consider the spectral density of $\langle u'v' \rangle$ itself, as shown in Figure 1a for selected locations in the overlap region. The RSS is highly concentrated in the streamwise elongated modes, that is the spectral density is concentrated along the $k_z^\#$ axis. Further the z wavenumber at which it is concentrated increases linearly with distance from the wall, as expected. Because of the role of the RSS in the production of turbulent kinetic energy, this structure has a profound effect on the spectral dynamics of the turbulence [1].

In Figure 1b-d we examine the spectra of terms in the RSS transport equation to determine what gives rise to this structure. First, as in the $\langle u'v' \rangle$ spectrum, a large portion of production occurs in streamwise elongated motions (near the $k_z^\#$ axis), and the spanwise grows linearly with y (Figure 1b). There is however also production in modes with other orientations consistent with the spectra of the wall-normal fluctuations. The spectrum of the scale transfer term $E^{T^\parallel}_{u'v'}$ indicates the redistribution of RSS from streamwise elongated modes toward more spanwise elongated modes (Figure 1c), which is acting to make the RSS spectrum more isotropic in scale, contrary to structure of the RSS spectrum. Note that the scale-transfer acts from large to small scales or to change orientation. It does not exhibit transfer from small to large scales as suggested in one-dimensional spectral densities [4]. The wall-normal transport of RSS by both turbulent and viscous processes (not shown) is relatively weak, and so does not significantly impact the structure of RSS. Similarly, the dissipation of $\langle u'v' \rangle$ (not shown) is small and in fact acts to strengthen spanwise elongated modes. The only process that provides a significant sink of RSS in the spanwise elongated modes that could produce the observed structure of $\langle u'v' \rangle$ is the pressure-strain (Figure 1d). Of course, the pressure terms arise due to the continuity constraint, and so the rapid and slow pressure strain contributions can be understood as the response to the continuity constraint of the turbulent processes that result in production and scale transfer, respectively.

In summary, the spectral analysis of the RSS transport equation shows detailed pathways for the RSS in length-scales and wall-normal locations. The rich information obtained from spectral transport analysis allows a number of open questions regarding the structure and dynamics of the Reynolds stress to be addressed, where the results outlined above are an example. In this presentation we will discuss the spectral RSS transport analysis in detail and revisit the definition of terms in the Reynolds stress transport equation.

SOLUTION PROPERTIES OF THE TURBULENT CHANNEL FLOW MEAN EQUATION

Joe Klewicki[1]
[1]Department of Mechanical Engineering, University of Melbourne, Melbourne, Australia

Summary Multiscale analysis reveals that, under a key assumption, the mean momentum equation for turbulent channel flow admits similarity solutions for the mean velocity and Reynolds shear stress. The solutions are found via analytical integration. High resolution numerical simulations up to friction Reynolds numbers of 8,000 are used to assess the analyses and solutions. At $\delta^+ = 8{,}000$ the key assumption is satisfied to within less than 0.1%. Mathematically well-defined criteria for the start and end points of the log layer are found via use of the leading balances and Reynolds stress similarity solution. The present results indicate that the mean flow structure arises from a self-similar hierarchy of scales, and that this hierarchy is reflected in the shape of the Reynolds stress profile. Ramifications of this structure on the asymptotic value of the von Karman constant are briefly discussed.

BACKGROUND AND MOTIVATION

The broad and lasting technological relevance of turbulent wall-flows motivates developing reliable ways to predict their statistical property variations with Reynolds number [1]. Owing to the dynamical complexity of wall-flows, their Re dependencies occur in ways that are often difficult to anticipate from empirical evidence alone. This study investigates the analytical prediction of turbulent channel flow statistics and their associated scaling behaviours.

Predicting time averaged behaviours typically begins the mean momentum equation, and subsequently seeks to determine the structure of the mean flow – a primary need for engineering applications. This leads to the classical closure problem that inherently accompanies methods founded on the Reynolds Averaged Navier-Stokes (RANS) equations. Indeterminacy, which is addressed herein, results from averaging the nonlinear advective acceleration terms. The inherent non-uniqueness of RANS solutions presents an apparently insurmountable challenge.

Fully developed turbulent channel flow is one of the canonical wall-flows. The simplified form of the mean momentum equation for this flow retains indeterminacy through a single Reynolds stress gradient term. The literature on mean flow prediction approaches for this flow is extensive, with the predominant methods including those that *i*) assume some sort of phenomenological or mathematical closure hypothesis, *ii*) implement (at least partially) the methods of matched asymptotic expansions, or *iii*) exploit the symmetry properties of the equations themselves.

Because scaling is such a prevalent issue in fluid dynamics, symmetry methods hold special importance, e.g., [2]. Approaches that leverage the symmetry properties of the RANS equations retain a clear mathematical basis for describing the solutions to these equations [3]. Central aims of symmetry methods involve identifying and exploiting the invariant forms of the governing equation(s), which also inherently informs Re scaling. To date, however, general methods that address the full RANS equations continue to face a variant of the classical closure problem.

The present study builds upon a multiscale analysis aimed at determining the scaling properties of indeterminate equations. This analysis reveals that the mean equation simplified for the channel asymptotically admits an invariant form over a large wall-normal portion of the flow [4]. Because the analysis yields a self-similar relationship between the derivatives of the mean velocity, U, and the Reynolds shear stress ($T = -\langle uv \rangle$), the indeterminacy of the equation is addressed. As a result, a single invariant form simultaneously yields similarity solutions for both U and T via direct integration. These solutions hold over well-defined subdomains, and for asymptotically large Re simplify to those found via asymptotic matching. Owing to the spatial hierarchy of length scales shown to underlie these solutions, significantly more can be said, and herein some of these findings are described.

ANALYSIS OUTLINE AND THE KEY ASSUMPTION

The mean momentum equation for turbulent channel flow involves three terms that sum to zero; a mean viscous force (VF), a Reynolds shear stress gradient or turbulent inertia (TI), and a mean pressure gradient (PG). The multiscale analysis employed herein begins with an empirical step that reveals how the leading balances of the mean equation are structured across the channel. With this information one can analytically determine how to rescale the equation such that it formally reflects the leading balances. Employing a change of variables and invocating a well-supported assumption yields an invariant form of the mean momentum equation that is operative from a position that is $O(\nu/u_\tau)$ from the wall to a position that is $O(\delta)$. Here, ν is the kinematic viscosity, u_τ is the friction velocity, and δ is the half-channel height.

The invariant equation holds on a continuous hierarchy of scaling layers whose structure depends on the decay rate of the TI term with wall distance. At any position on the hierarchy, TI takes on some value. This TI value uniquely prescribes the wall-normal location, y, and the finite layer width, W(y), anchored at the given y location. The layer widths increase in size with distance from the wall. The local length scale used in the variable normalizations that yield the invariant form on any and all hierarchy layers is this layer width. Thus, the analysis shows that the mean equation admits an invariant form on the layer hierarchy domain when u_τ and W(y) are used as the normalizing parameters.

The analysis uses one key assumption. It is analytically known that on the layer hierarchy the normalized second derivative (curvature) of the T profile remains O(1) for all Re. In addition, from the formulation leading to the invariant form one can surmise that on an interior inertial portion of the hierarchy this derivative should attain constancy at large

Re. The key assumption is that this constancy is realized. Given this, the equation can be integrated to yield solutions for U and T. Results that speak to the asymptotic geometric structure of the flow also emerge.

RESULTS

Results herein pertain to an assessment of the analysis, and the predictive capability of the theory. In the space remaining we describe a few of these using the high-resolution DNS of Yamamoto and Tsuji [5].

The constancy of the normalized Reynolds stress curvature is analytically equivalent to the W(y) profile attaining constant slope on the interior inertial domain (inertial sublayer) noted above. Direct evaluation of dW/dy at $\delta^+ = \delta u_\tau/\nu = 8{,}000$ reveals an interior region where the profile is linear to within less that 1 part in 1000. Use of the leading balance structure and the solution for T(y) allows one to independently identify the beginning and ending locations of the inertial sublayer. Consistently, this region identically coincides with where $dW/dy = 1/\phi_c$ attains constancy. The theory specifies that dW/dy is also directly related to the von Karman constant, $\kappa = 1/\phi_c^2$. On the domain where dW/dy is constant, $U^+(y^+)$ is logarithmic to within a fraction of a percent with a slope that is accurately determined using dW/dy.

Comparisons between the similarity solutions for U and T are made across the range of friction Reynolds numbers, $1{,}000 < \delta^+ < 8{,}000$. These solutions are shown to closely adhere to the finite δ^+ solutions, and with increasing δ^+ increasingly approximate the accepted asymptotic forms. The finite δ^+ form for U^+ is used to clarify why use of the indicator function, $\Xi = ydU^+/dy$, for discerning logarithmic dependence can be misleading.

The scaling on any layer of the hierarchy layer holds over the finite extent of that local W(y). This analytical result lead to a discrete representation of the layer hierarchy. This allows one to algebraically develop new results pertaining to the geometric structure of the flow. One such result is exemplified in Fig. 1, which shows that on the constant dW/dy portion of the hierarchy the geometric mean of the y^+ locations of any fixed T^+ value is equal to y_m^+, the position of maximum T^+. Among other findings, this result affords an alternative means of estimating the von Karman constant.

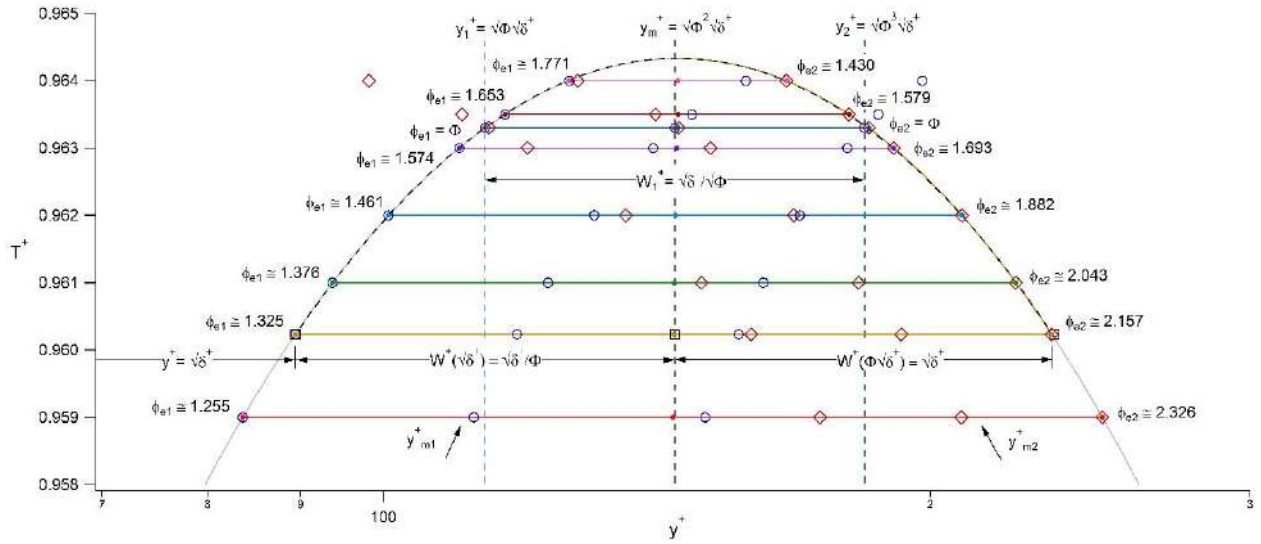

Figure 1. Inner-normalized Reynolds shear stress profile in the vicinity of the peak at $\delta^+ = 7996$. Small dot symbols along the vertical line at y_m^+ are the geometric mean of the points on the solution curve at the same T^+ value.

CONCLUSIONS

An invariant form of the mean momentum equation in channel flow is developed and validated. This invariant form leads to similarity solutions for U and T over an interior portion of the flow, while the mathematical properties underlying its construction provides a basis for understanding the scaling structure of the flow.

TWO-TIME VELOCITY CORRELATION FUNCTION FOR TWO LAGRANGIAN PARTICLES IN TWO-DIMENSIONAL INVERSE ENERGY-CASCADE TURBULENCE

Tatsuro Kishi*[1], Takeshi Matsumoto[1], and Sadayoshi Toh[1]
[1]Division of Physics and Astronomy, Graduate School of Science, Kyoto University, Kyoto, Japan

Summary We investigate both numerically and analytically a two-time correlation function of two Lagrangian particles in two-dimensional inverse energy-cascade turbulence. From our direct numerical simulation data, we propose a self-similar form of the correlation function and the scaling exponents, one of which is not obtainable from dimensional analysis. We then show the non-Kolmogorov scaling law is consistent to the Richardson law of dispersion, t^3.

INTRODUCTION

Correlation function is a fundamental tool of physics. Here our focus is on two-time correlation function of two Lagrangian particles in turbulence,

$$C_{ij}(t_1, t_2) = \langle \delta v_i(t_1) \delta v_j(t_2) \rangle, \tag{1}$$

which is intrinsic to turbulent dispersion and mixing. Here the Lagrangian velocity increment $\delta v_i(t)$ is defined by $\delta v_i(t) \equiv v_i(\boldsymbol{x} + \boldsymbol{r}_0, s|t) - v_i(\boldsymbol{x}, s|t)$, where $v_i(\boldsymbol{x}, s|t)$ is the i-th component of the velocity of a Lagrangian particle at time t, which passed a point $\boldsymbol{x}$ at time s. Notice that it is different from the Lagrangian velocity autocorrelation for a single particle which has been studied and well-understood recently, see, e.g. [1]. In contrast, the property of the particle-pair correlation, Eq.(1), remains open. A notable exception is one measurement in direct numerical simulation (DNS) of three-dimensional homogeneous and isotropic turbulence [2], to the best of our knowledge. Obviously, obtaining converged data of the correlation (1) is more difficult than the single-particle correlation or Eulerian correlation. However with two-dimensional (2D) turbulence, this difficulty can be alleviated.

SELF-SIMILARITY IN TIME OF CORRELATION FUNCTION

We investigate scaling properties of the correlation function, Eq.(1) in detail in the 2D inverse-cascade turbulence. Based on the numerical result, we propose a self-similar form of $C_{ij}(t_1, t_2)$ and determine two scaling exponents. In particular, both of the exponents are different from those obtainable with the Kolmogorov's phenomenology.

We investigate the correlation function, $C_{ij}(t_1, t_2)$, in two-dimensional inverse energy-cascade turbulence both numerically and analytically. Although $C_{ij}(t_1, t_2)$ has four components for two-dimensional turbulence, we here deal only with a longitudinal component, $C(t_1, t_2) \equiv r_i(t) C_{ij}(t_1, t_2) r_j(t) / r^2(t)$, as a first step. Here $r_i(t)$ is a i-th component of relative separation of two Lagrangian particles and $r(t) \equiv |\boldsymbol{r}(t)|$. Also we define the longitudinal relative velocity as $v_l(t) \equiv \delta v_i(t) r_i(t) / r(t)$. This component is directly related to the squared relative separation of Lagrangian particle pairs, namely,

$$\langle r^2(t) \rangle \sim \int_0^t \int_0^t C(t_1, t_2)\, dt_1 dt_2. \tag{2}$$

The celebrated Richardson law [3] is $\langle r^2(t) \rangle \propto \varepsilon t^3$, where ε is the energy flux in the inertial range for the 2D inverse-cascade turbulence.

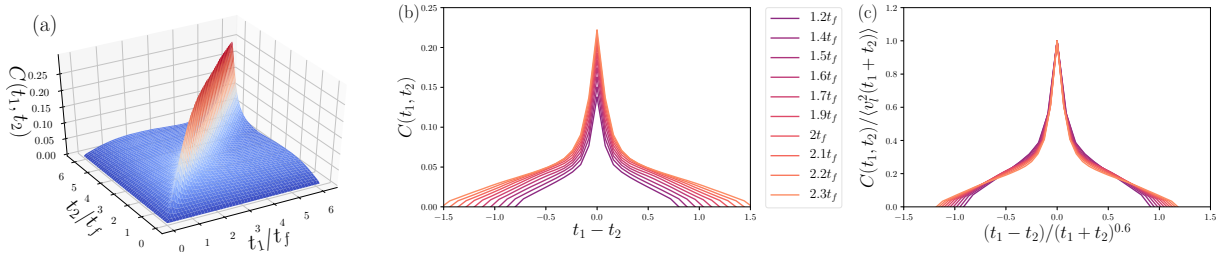

Figure 1: (a) Bird's view of the correlation function, $C(t_1, t_2)$. (b) $C(t_1, t_2)$ vs. $t_1 - t_2$ at different time $(t_1 + t_2)/2$ as shown in the legend. Here t_f is a forcing time scale. (c) Rescaled two-time correlation function by the second-order moment, $\langle v_l^2(t_1 + t_2) \rangle$. The time, $t_1 - t_2$, is also rescaled by $(t_1 + t_2)^{0.6}$.

First, we perform DNS of two-dimensional inverse energy-cascade turbulence with Lagrangian particle tracking involving a velocity interpolation. Our numerical setup of the 2D turbulence is the same as [5]. Figure 1(a) shows DNS

*Corresponding author. E-mail: tatsuro@kyoryu.scphys.kyoto-u.ac.jp

results of the correlation function. Horizontal axis represents the time lag between a two particle, $t_1 - t_2$. As shown in figure 1(b), the correlation function is likely to have a self-similar form,

$$C(t_1, t_2) = r_0^{\frac{2}{3}(\alpha-1)} \varepsilon^{\frac{\alpha+2}{3}} (t_1 + t_2)^{\alpha} F\left(\frac{t_1 - t_2}{r_0^{1-\beta} \varepsilon^{\frac{\beta-1}{2}} (t_1 + t_2)^{\beta}} \right). \tag{3}$$

Here, r_0 is an initial separation of particle pairs. The two scaling exponents of this self-similar form cannot be determined uniquely by dimensional analysis unlike the Kolmogorov's phenomenology. This indeterminancy of the scaling is induced by the fact that $C(t_1, t_2)$ depends on not only $t_1 + t_2$ but also $t_1 - t_2$. The self-similar form, Eq.(3), can be supported by the incomplete similarity analysis. According to figure 1(b), we can determine the scaling exponents as follows:

$$\alpha \simeq 1.3, \quad \beta \simeq 0.6. \tag{4}$$

Note that the exponent α is determined by looking at $\langle v_l^2(t) \rangle$ shown in figure 2(b).

We performed the same DNS but with three different Reynolds numbers. This suggests that the above results are insensitive to the Reynolds number.

RICHARDSON LAW OF SEPARATION & NON-KOLMOGOROV SCALING OF VELOCITY

Now we show numerically that the above results of the correlation function are consistent with the Richardson law, $\langle r^2(t) \rangle \propto t^3$. In figure 2(a), we show $\langle r^2(t) \rangle$ calculated with our DNS data, which indeed show the t^3 law. Combining Eq.(2) with Eq.(3), the observed t^3 law imposes a constraint on the exponents α and β as $\alpha + \beta + 1 = 3$. Our measured exponents (4) are consistent with this constraint.

Contrastively, if we adopt the Kolmogorov's dimensional analysis, the second-order moment of the relative velocity becomes $\langle v_l^2(t) \rangle \propto \varepsilon t$. This is different from our result $\langle v_l^2(t) \rangle \propto t^{1.3}$ (figure 2(b)). This difference is caused by the temporal correlation in $t_1 - t_2$ as shown in figure 1.

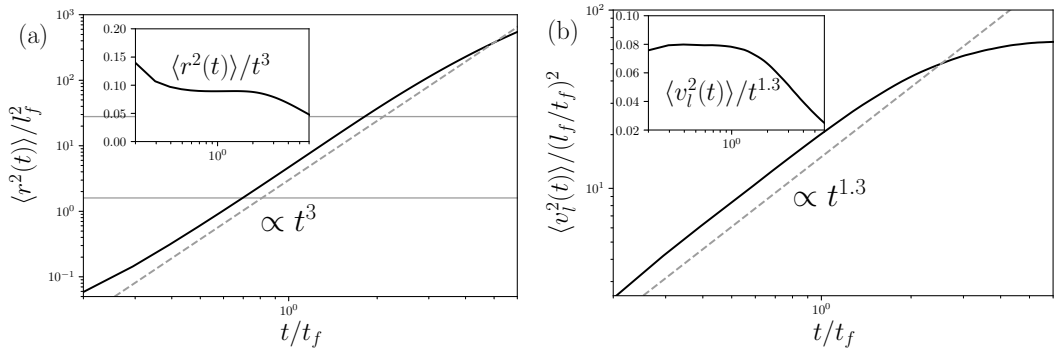

Figure 2: (a) Second-order moments of the relative separations, $\langle r^2(t) \rangle$. The dashed line represents the Richardson t^3 law. The range between the two horizontal gray solid lines is the inertial range estimated with the mean exit time [4]. Inset: the compensated plot by t^3. (b) Second-order moments of the longitudinal relative velocity, $\langle v_l^2(t) \rangle$. The dashed line represents the non-K41 $t^{1.3}$ scaling law. Inset: the compensated plot by $t^{1.3}$.

These DNS results imply that another theoretical consideration beyond the Kolmogorov's phenomenology is needed to understand the scaling behavior of the correlation function. As one way to shed some light, we adopt the Lagrangian renormalized approximation (LRA) [6] to study the above scaling exponents, Eq.(4), which will be reported in the conference. This is different from [2], where they substitute a Lagrangian velocity autocorrelation (single particle) for the correlation function, $C(t_1, t_2)$.

CONCLUSIONS

In this study, we have revealed the self-similar properties of the Lagrangian two-particle, two-time correlation function, $C(t_1, t_2)$, for the first time. We estimated the scaling exponents from DNSs. They are consistent with incomplete similarity analysis and the Richardson law. Moreover the scaling relation leads to the non-Kolmogorov scaling law of the relative velocity.

Summary Turbulence statistics concerning the vorticity and the advective and viscous terms of the Navier-Stokes equations are studied by analysing the data of high-resolution direct numerical simulation of forced turbulence in a periodic box. The analysis shows that the conditional average of the magnitude of the advective term and that of the viscous term for a given magnitude ω of the vorticity increase with ω at large ω, but the conditional average of the ratio, say R_{loc}, of the former to the latter is almost independent of ω. The analysis also shows that the Reynolds number given by $Re \equiv UL/\nu$ is much larger than the average of the ratio R_{loc}, where U and L are respectively the characteristic velocity and length of the energy containing eddies, and ν is the kinematic viscosity.

INTRODUCTION

High Reynolds number turbulence exhibits strong intermittency at small scales. The magnitude ω of the vorticity $\boldsymbol{\omega}$ is high in some regions and low in others. It would not be surprising if the statistics of the flow field are different in the high- and low-vorticity regions. Among the statistics are those of the advective term $(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}$ and the viscous term $\nu\boldsymbol{\nabla^2 u}$, which are the key ingredients of the Navier-Stokes (NS) equations. Here $\boldsymbol{u}=\boldsymbol{u}(\boldsymbol{x},t)$ is the fluid velocity at position $\boldsymbol{x}$ and time t. In order to get some idea on the relation between ω and the statistics, we consider here the joint probability distribution functions (pdf's) $P(\omega^2,|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|)$, $P(\omega^2,\nu|\boldsymbol{\nabla^2 u}|)$, and $P(\omega^2,R_{loc})$, on the basis of the data of high-resolution direct numerical simulation (DNS), where R_{loc} is the local Reynolds number defined at each position as the ratio of $|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|$ to $\nu|\boldsymbol{\nabla^2 u}|$.

STATISICS OF ADVECTIVE AND VISCOUS TERMS

The following shows some results of the DNS of forced incompressible turbulent flow obeying the NS equations and the incompressibility condition in a periodic box. The Taylor micro-scale Reynolds number R_λ is 730, and $k_{\max}\eta \approx 2$ in the DNS, where η is the Kolmogorov micro-scale given by $\eta=(\nu^3/\epsilon)^{1/4}$, ϵ is the average of the energy dissipation rate per unit mass, and $k_{\max}$ is the maximum wavenumber retained in the DNS. Readers may refer to Ishihara et al. (2007) for some details of the method of DNS.

Figures 1(a), (b) and (c) show the pre-multiplied joint pdf's $xyP(x,y)$ for $x=\omega^2/|\omega^2|$ and $y=|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|$, $\nu|\boldsymbol{\nabla^2 u}|$, and R_{loc}, respectively. The solid lines show the conditional averages of y, for a given ω^2. These figures can be compared with Figs. 1 (d), (e) and (f), which plot the same statistics as Figs. 1 (a), (b) and (c), respectively, but for an artificial random field generated by randomizing the phases of the Fourier velocity components $\hat{\boldsymbol{u}}(\boldsymbol{k})$ of the DNS field.

As regards the advective term, the normalized averages $\langle|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|\rangle/[(u'v_\eta)/\eta)]$ are 0.707 in the DNS and 0.812 in the random field, where u' is the characteristic velocity of the energy containing range given by $3(u')^2=\langle\boldsymbol{u}\cdot\boldsymbol{u}\rangle$, v_η is the Kolmogorov micro-scale given by $v_\eta=(\epsilon\nu)^{1/4}$, and $\langle\boldsymbol{u}\rangle=0$. Thus the average is smaller in the DNS field. The smallness in the NS field is consistent with the phenomenon known as the depression of nonlinearity. A comparison of Fig. 1(a) with Fig. 1(b) shows that the depression of the conditional average $\langle|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}||\omega^2\rangle$ for a given ω^2 occurs only for small $c\equiv\omega^2/\langle\omega^2\rangle$, e.g. $c<1$, but not for large c.

As regards the viscous term, the normalized averages $\langle\nu|\boldsymbol{\nabla^2 u}|\rangle/[\nu v_\eta/\eta^2]$ are 0.283 and 0.405 in the DNS and random fields, respectively. Thus the average is again smaller in the DNS field. A comparison of Fig. 1(b) with Fig. 1(e) shows that the conditional average $\langle\nu|\boldsymbol{\nabla^2 u}||\omega^2\rangle$ is smaller in the DNS than in the random field for small c, e.g., $c<1$, but not for large c. For large c, the conditional average sharply increases with ω^2 in DNS; in the random field, in contrast, the average is almost independent of ω^2.

As regards the local Reynolds numbers, the averages $\langle R_{loc}\rangle$ are 53.6 and 34.9 in the DNS and random fields, respectively. Thus the average $\langle R_{loc}\rangle$ is larger in the NS field. It is remarkable that the conditional average $\langle R_{loc}|\omega^2\rangle$ is almost independent of ω^2 in the DNS field, in contrast to the random field. This implies that there is a certain mechanism in the NS dynamics which suppresses the increase of $\langle R_{loc}|\omega^2\rangle$ with ω^2 at large c as observed in Fig. 1(f).

It is often mentioned in the literature that the Reynolds number $Re\equiv UL/\nu$ is a representative ratio of the advective term to the viscous term, where U and L are respectively the characteristic length and velocity of the flow filed. Given this, one might expect that $\langle R_{loc}\rangle \sim Re$. But this is not so. In fact, the DNS data used in Fig. 1 give $Re\approx 14800$. (Here we used $U=u'$ and $L=$ the integral length scale.) The value 14800 is much larger than $\langle R_{loc}\rangle = 53.6$. This implies that

$$Re\equiv UL/\nu \neq |advective\ term|/|viscous\ term|. \quad (1)$$

The (incorrect) expectation $\langle R_{loc}\rangle \sim Re$ could be derived by assuming $|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|\sim U^2/L$ and $\nu|\boldsymbol{\nabla^2 u}|\sim\nu U/L^2$ as often assumed in the literature. However, the large difference between $\langle R_{loc}\rangle$ and Re implies it to be wrong or misleading for turbulence. A better estimate of $\langle R_{loc}\rangle$ can be obtained by assuming $|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|\sim u' v_\eta/\eta$ and $\nu|\boldsymbol{\nabla^2 u}|\sim\nu v_\eta/\eta^2$. We thereby obtain $\langle R_{loc}\rangle\sim u'\eta/\nu \propto (Re)^{1/4}$, which is consistent with an estimate by Orszag (1977). This gives $\langle R_{loc}\rangle\sim$ 13.7 for the DNS data used in Fig.1.

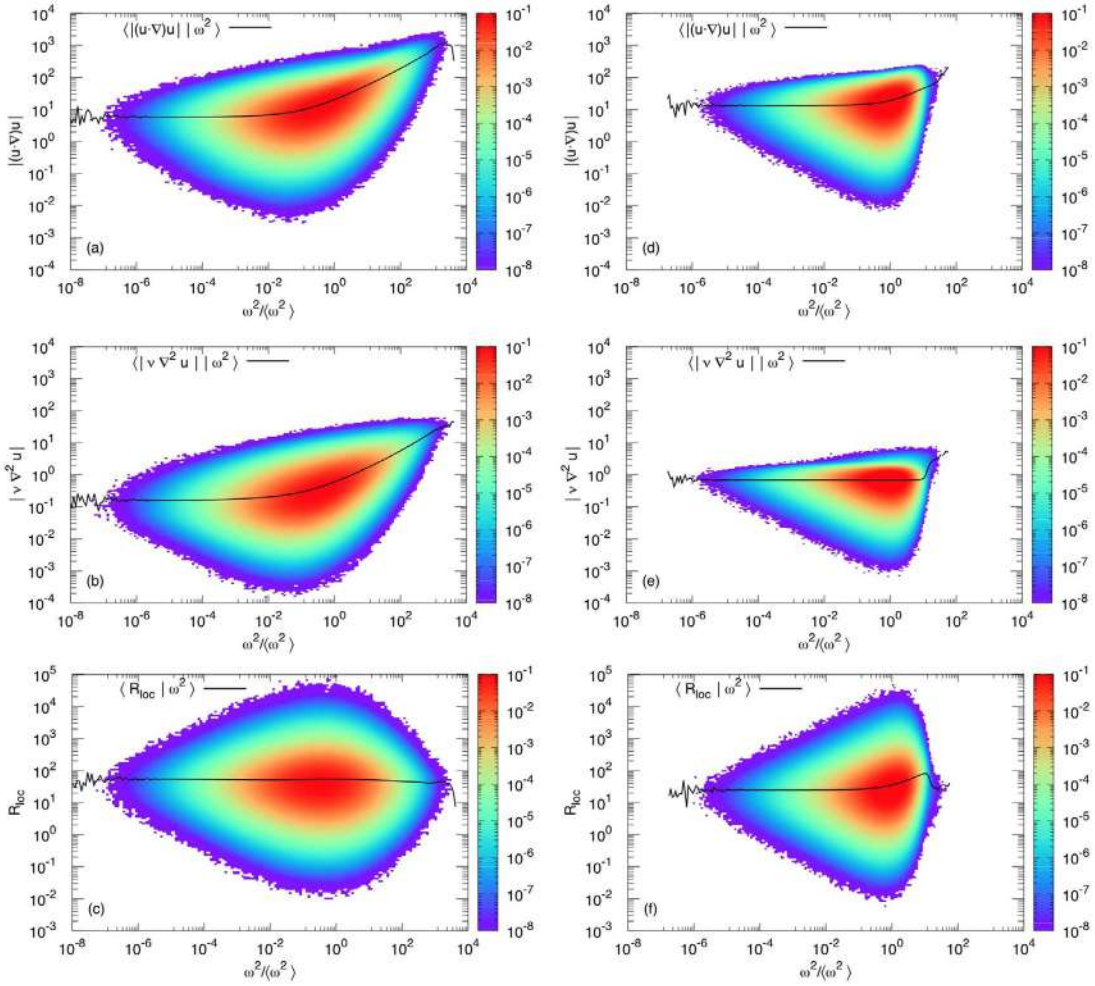

Figure 1. Pre-multiplied joint pdf's of (a)$(\omega^2, |(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|)$, (b)$(\omega^2, \nu|\boldsymbol{\nabla^2 u}|)$, and (c) (ω^2, R_{loc}) at $R_\lambda = 730$. (d), (e), (f): The same as (a), (b), (c), respectively, but for the random field.

CONCLUSIONS

The DNS data suggest the following:
(i) Both of the conditional averages $\langle|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}||\omega^2\rangle$ and $\langle\nu|\boldsymbol{\nabla^2 u}||\omega^2\rangle$ increase with ω^2 at large $\omega^2/\langle\omega^2\rangle$.
(ii) The conditional average $\langle R_{loc}|\omega^2\rangle$ is almost independent of ω^2 in the DNS field, in contrast to the random field.
(iii) The estimates $|(\boldsymbol{u}\cdot\boldsymbol{\nabla})\boldsymbol{u}|\sim U^2/L$, $\nu|\boldsymbol{\nabla^2 u}|\sim\nu U/L^2$, as well as the idea that the Reynolds number $Re \equiv UL/\nu$ is a measure of the ratio of the advective term to the viscous term, are incorrect or misleading for turbulence. (see Eq. (1))
Some results of the analysis of DNS data at lower R_λ were reported at a meeting [3].

SCALE-SIMILAR ANALYSIS ON MAXIMALLY HELICAL HOMOGENEOUS TURBULENCE

Kazuhiro Inagaki[1]
[1]Institute of Industrial Science, The University of Tokyo, Tokyo, Japan

Summary In the conventional three-dimensional homogeneous turbulence, the direction of energy cascade is forward or large to small scales. Recent studies showed that inverse energy cascade or small to large scale energy transfer occurs even in three-dimensional homogeneous turbulence when the turbulence is highly helical. Through the analysis employing the detailed balance, we can show a possibility that the Navier–Stokes equations have a scale-similar structure accompanied by an inverse cascade of energy under the maximally helical condition. However, the closure approximation does not allow the maximally helical condition. Thus, we conclude that the maximally helical condition cannot be realized through the purely nonlinear dynamics of the Navier–Stokes equations.

SCALE-SIMILAR SPECTRA IN HELICAL TURBULENCE

As the two-dimensional Navier–Stokes equations have two inviscid invariants, energy and enstrophy (squared vorticity), the three-dimensional Navier–Stokes equations also have two inviscid invariants; namely, energy and helicity. Helicity is defined by the inner product of velocity and vorticity. In analog with the enstrophy cascade range in two-dimensional turbulence, Brissaud *et al.* [1] suggested the existence of the following energy spectrum in helicity cascade range:

$$E(k) \propto (\varepsilon^H)^{2/3} k^{-7/3}, \tag{1}$$

where $E(k)$ denotes the energy spectrum which satisfies $\langle \boldsymbol{u}^2 \rangle/2 = \int_0^\infty \mathrm{d}k\, E(k)$, $\langle \cdot \rangle$ denotes the statistical average, and ε^H denotes the dissipation rate of helicity. However, what we often observe in three-dimensional homogeneous turbulence is the conventional Kolmogorov spectrum of $E(k) \propto \varepsilon^{2/3} k^{-5/3}$ where ε denotes the energy dissipation rate (see, e.g., ref. [2]). Moreover, the direction of the energy cascade is forward.

Recently, Biferale *et al.* [3, 4] showed that an inverse energy cascade with Kolmogorov spectrum $E(k) \propto k^{-5/3}$ occurs when we restrict the nonlinear interaction to that inducing the single sign of helical mode. In such a case, the helicity spectrum must satisfy

$$E^H(k) = 2kE(k), \tag{2}$$

where $\langle \boldsymbol{u} \cdot \boldsymbol{\nabla} \times \boldsymbol{u} \rangle = \int_0^\infty \mathrm{d}k\, E^H(k)$. Equation (2) gives the maximally helical condition [1, 5]. They also observed the energy spectrum of the helicity cascade range given by Eq. (1) [4]. Although it is interesting that the inverse cascade occurs even in three-dimensional homogeneous turbulence, there remains a question: does the Navier–Stokes equations without any modulation on the nonlinear interaction also provides an inverse cascade solution? Sahoo *et al.* [6] suggested that inverse cascade occurs only when the nonlinear term is modulated to an almost fully homo-chiral condition. In this study, we investigate the scale-similar laws and the direction of cascade through the statistical property of the Navier–Stokes equations without any modulation.

STATISTICAL PROPERTY OF NAVIER–STOKES EQUATIONS IN MAXIMALLY HELICAL CONDITION

The Navier–Stokes equations with the continuity equation lead to the following energy and helicity spectra equations:

$$\left(\frac{\partial}{\partial t} + 2\nu k^2\right) E(k) = \frac{1}{2}\int_0^\infty \mathrm{d}p \int_0^\infty \mathrm{d}q\, S(k,p,q), \quad \left(\frac{\partial}{\partial t} + 2\nu k^2\right) E^H(k) = \frac{1}{2}\int_0^\infty \mathrm{d}p \int_0^\infty \mathrm{d}q\, S^H(k,p,q), \tag{3}$$

$$S(k,p,q) = -16\pi^2 kpq \Delta_{kpq} M_{ij\ell}(\boldsymbol{k}) \Im[\langle \tilde{u}_i(\boldsymbol{k},t)\tilde{u}_j(-\boldsymbol{p},t)\tilde{u}_\ell(-\boldsymbol{q},t)\rangle], \tag{4}$$

$$S^H(k,p,q) = -16\pi^2 kpq \Delta_{kpq} \left(\epsilon_{ijm}k_\ell + \epsilon_{i\ell m}k_j\right) k_m \Re[\langle \tilde{u}_i(\boldsymbol{k},t)\tilde{u}_j(-\boldsymbol{p},t)\tilde{u}_\ell(-\boldsymbol{q},t)\rangle], \tag{5}$$

where $\tilde{u}_i(\boldsymbol{k},t)$ denotes the Fourier coefficient of the velocity field, $M_{ij\ell}(\boldsymbol{k}) = [k_j P_{i\ell}(\boldsymbol{k}) + k_\ell P_{ij}(\boldsymbol{k})]/2$, $P_{ij}(\boldsymbol{k}) = \delta_{ij} - k_i k_j/k^2$, and Δ_{kpq} takes unity only when k, p, and q can form the sides of a triangle. Note that $S(k,p,q)$ and $S^H(k,p,q)$ satisfy the detailed balance equations,

$$S(k,p,q) + S(p,q,k) + S(q,k,p) = 0, \quad S^H(k,p,q) + S^H(p,q,k) + S^H(q,k,p) = 0, \tag{6}$$

which guarantee the conservation of energy and helicity for the inviscid condition. Now, we assume that the helicity spectrum is given by Eq. (2). In such a case, $S(k,p,q)$ and $S^H(k,p,q)$ satisfy

$$S^H(k,p,q) = 2kS(k,p,q). \tag{7}$$

Thus, the detailed balance for helicity spectrum equation yields

$$kS(k,p,q) + pS(p,q,k) + qS(q,k,p) = 0. \tag{8}$$

This is the analog of two-dimensional turbulence, which yields $k^2S(k,p,q) + p^2S(p,q,k) + q^2S(q,k,p) = 0$. Through the two detailed balance equations (6) and (7) and the scale-similarity assumption,

$$\frac{E(ak)}{E(k)} = a^{-n}, \quad \frac{S(ak,ap,aq)}{S(k,p,q)} = a^{-(1+3n)/2}, \tag{9}$$

we can analyze the scale-similar structures of the Navier–Stokes equations [7, 8]. Consequently, we can show a possibility of an inverse cascade of energy under the maximally helical condition.

STATISTICAL PROPERTY OF CLOSURE EQUATIONS IN MAXIMALLY HELICAL CONDITION

To discuss the scale-similarity of the Navier–Stokes equations, closure theories may be helpful. Now, we consider the helical decomposition of the velocity field [8]:

$$\tilde{\boldsymbol{u}}(\boldsymbol{k},t) = \tilde{u}^+\boldsymbol{h}^+_{\boldsymbol{k}} + \tilde{u}^-\boldsymbol{h}^-_{\boldsymbol{k}}, \quad \boldsymbol{h}^\pm_{\boldsymbol{k}} = \boldsymbol{e}^{(2)} \mp \mathrm{i}\boldsymbol{e}^{(1)}, \quad \boldsymbol{e}^{(1)} = \frac{\boldsymbol{k}\times\boldsymbol{n}}{|\boldsymbol{k}\times\boldsymbol{n}|}, \quad \boldsymbol{e}^{(2)} = \frac{\boldsymbol{k}\times\boldsymbol{e}^{(1)}}{|\boldsymbol{k}\times\boldsymbol{e}^{(1)}|}, \tag{10}$$

where $\boldsymbol{n}$ denotes an arbitrary vector. Under the maximally helical condition where $\tilde{u}^-(\boldsymbol{k},t) = 0$, the equation for $Q^-(k,t)(= \langle|\tilde{u}^-(\boldsymbol{k},t)|^2\rangle)$ yields

$$\frac{\partial}{\partial t}Q^-(k,t) = -\frac{1}{4}\int \mathrm{d}^3p \int \mathrm{d}^3q\, \delta(\boldsymbol{k}-\boldsymbol{p}-\boldsymbol{q})(p-q)\boldsymbol{h}^+_{\boldsymbol{k}}\cdot\boldsymbol{h}^+_{\boldsymbol{p}}\times\boldsymbol{h}^+_{\boldsymbol{q}}\left\langle\tilde{u}^{-*}(\boldsymbol{k},t)\tilde{u}^+(\boldsymbol{p},t)\tilde{u}^+(\boldsymbol{q},t)\right\rangle = 0. \tag{11}$$

However, the closure approximation, e.g., the eddy-damped quasi-normal Markovian (EDQNM)[8, 9] yields

$$\frac{\partial}{\partial t}Q^-(k,t) = \int \mathrm{d}^3p \int \mathrm{d}^3q\, \delta(\boldsymbol{k}-\boldsymbol{p}-\boldsymbol{q})\theta_{kpq}(t)\frac{(k-p-q)^2}{16R^2}(p-q)^2Q^+(p,t)Q^+(q,t) \neq 0, \tag{12}$$

even in the maximally helical condition where $Q^-(k,t) = 0$. Here, $R^2 = (kpq)^2/[2(p^2q^2+q^2k^2+k^2p^2) - k^4 - p^4 - q^4]$ and $\theta_{kpq}(t)$ is the function characterizing a probabilistic relaxation time. The same situation occurs in the direct-interaction approximation based closures [10]. Hence, the maximally helical condition cannot hold in the closure equations. This is because the closure approximations take into account the dynamics of the Navier–Stokes equations that tends to recover the mirror symmetry [2, 11]. Some special helical forcing may alter this situation [12].

CONCLUSIONS

The analysis through the detailed balance equations shows that the Navier–Stokes equations possibly have the scale-similar structures accompanied with an inverse cascade of energy under the maximally helical condition. However, the closure analysis suggests that the maximally helical condition cannot be a root of the statistically averaged Navier–Stokes equations. This is because the dynamics of the Navier–Stokes equations tends to recover the mirror symmetry [2, 11]. Hence, we conclude that the maximally helical condition cannot be realized through the purely nonlinear dynamics of the Navier–Stokes equations. Employing some special helical forcing is a candidate that realized the maximally helical spectra [12].

ANGULAR MOMENTUM TRANSPORT IN TURBULENT TAYLOR–COUETTE FLOW MODIFIED BY SURFACTANT ADDITIVES

Yasufumi Horimoto*, Taisei Hayama, Hiroki Matsukawa, Yosuke Imai, and Yasuo Kawaguchi
Department of Mechanical Engineering, Tokyo University of Science, Noda, Chiba, Japan

Summary To understand the most enhanced angular momentum transport in turbulent Taylor–Couette flow, we conduct laboratory experiments of turbulence suppression by surfactant additives. Turbulent eddies are drastically suppressed by the viscoelasticity of the surfactant solution. Systematic experiments of flow visualization, torque measurements, and particle image velocimetry for this suppressed turbulence provide important information to consider the transport mechanism of turbulence of water.

INTRODUCTION

Experimental approaches are necessary to understand the physics in fully developed turbulence as well as numerical simulations. Taylor–Couette flow, the flow between two concentric cylinders which independently rotate about their axes, is one of the most popular closed flow systems and has been used for fundamental researches of turbulence [1]. In turbulent Taylor–Couette flow where the rotation of the inner cylinder is dominant, it is well-known that there exist large-scale vortical structures, so-called turbulent Taylor vortices which play a quite important role in transport phenomena in this flow system. On the other hand, the rotation of the outer cylinder suppresses these vortices and makes laminar flow more stable. However, interestingly, angular momentum transport is enhanced for the case that the outer cylinder rotates slowly in the opposite direction to that of the inner cylinder, rather than the case of pure inner cylinder rotation [2]. In the present study, we investigate this enhanced turbulence by using a very large experimental apparatus.

Here, we introduce control parameters of Taylor–Couette flow. Note that once we fix geometric parameters such as the radius ratio $\eta = r_o/r_i$ and aspect ratio $\Gamma = L/(r_o - r_i)$ [r_i (r_o) is the radius of the inner (outer) cylinder; L is the length of the inner cylinder], only two independent parameters exist reflecting the fact that we control only the angular velocities of the two cylinders. Although the Reynolds numbers defined by the angular velocities and radii of the cylinders are easy to understand, we use the Taylor number Ta and the ratio a of the angular velocities defined as

$$Ta = \frac{1}{4}\left(\frac{1+\eta}{2\sqrt{\eta}}\right)^4 \frac{(r_o^2 - r_i^2)^2(\omega_i - \omega_o)^2}{\nu^2} \quad \text{and} \quad a = -\frac{\omega_o}{\omega_i}. \tag{1}$$

ω_i (ω_o) is the angular velocity of the inner (outer) cylinder and ν is the kinematic viscosity of a working fluid, respectively. Ta characterizes the magnitude of the centrifugal force relative to the viscous force. A positive value of a means a counter-rotation of the cylinders. As an indication of the magnitude of angular momentum transport, we define a Nusselt number Nu_ω as the ratio of torque T on the surface of the inner cylinder to its value for the laminar case,

$$Nu_\omega = \frac{T}{4\pi L\rho\nu r_o^2 r_i^2(\omega_i - \omega_o)/(r_o^2 - r_i^2)}. \tag{2}$$

ρ is the density of a working fluid.

For a sufficiently high Taylor number, turbulence is sustained in not only a bulk region but also boundary layers on both the cylinders. This turbulence is called *ultimate turbulence* and a scaling law,

$$Nu_\omega \sim Ta^{0.39}, \tag{3}$$

holds [2]. A similarity between this turbulence and the most enhanced heat transfer in Rayleigh–Bénard convection is predicted [3]. Thus, there are many investigations to understand the transport mechanism. We also focus on this problem.

In this study, we employ a strategy based on the view of the rheological properties of fluid. More concretely, we examine turbulence suppression caused by additives. This is an easy method for turbulence control because even a dilute solution of additives has viscoelasticity and turbulent eddies are strongly suppressed [4, 5]. Furthermore, we can drive important information about a physical mechanism of turbulence by systematically investigating this phenomenon [6].

METHODS AND PRELIMINARY RESULTS

We conduct flow visualization, torque measurements, and particle image velocimetry (PIV) by using a large experimental apparatus whose inner and outer cylinders rotate independently. The radii of the inner and outer cylinders are respectively 150 mm and 205 mm, radius ratio η being 0.732. The length of the inner cylinder is 990 mm while that of the outer cylinder is 1014 mm. That is, the aspect ratio Γ of the gap between the cylinders is 18. The end surfaces of the outer cylinder rotate together with it.

As working fluids, we use water and an aqueous solution of cationic surfactant, cetyltrimethyl ammonium chloride (CTAC; the molecular weight 160.10). We add sodium salicylate (NaSal; the molecular weight 320.00) to the solution to

*horimoto@rs.tus.ac.jp

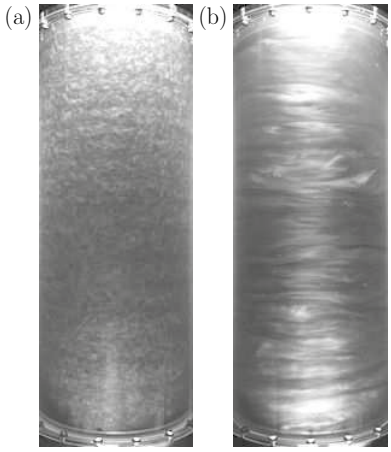

Figure 1: Visualized turbulences of (a) water and (b) the CTAC solution (100 ppm) for $Ta = 2.4 \times 10^8$ and $a = 0.33$. We can observe turbulence suppression by the addition of surfactant in spite of the existence of Taylor vortices which are implied by horizontal stripe patterns.

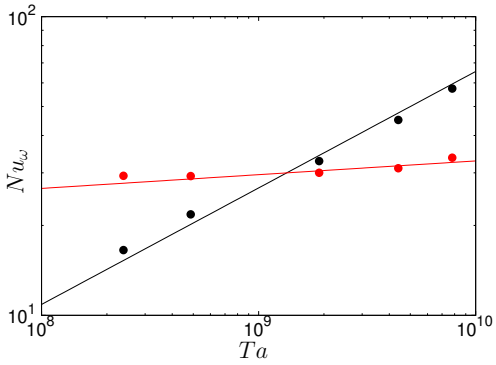

Figure 2: Taylor-number dependence of normalized torque Nu_ω at $a = 0.33$. Black: water; Red: the CTAC solution (100 ppm). Black and red lines are proportional to $Ta^{0.39}$ and $Ta^{0.046}$, respectively. Viscoelasticity of the solution drastically reduces the dependence of angular momentum transport on the effect of the centrifugal force.

supply counterions which stabilize micellar structures of surfactant. Both concentrations of the CTAC and NaSal are 100 ppm by mass (the molar ratio of NaSal to CTAC is 2). Because the solution is quite dilute, we estimate the Taylor number and the Nusselt number for the solution by using the physical property values of water at the same temperature.

The outer cylinder consists of acrylic resin so that we can observe flow visualized by using minute mica flakes and three light sources surrounding the apparatus. Figure 1 shows turbulences of water and the CTAC solution for $Ta = 2.4 \times 10^8$ and $a = 0.33$. For water [Fig. 1(a)], developed turbulence is sustained and angular momentum transport between the two cylinders is the most enhanced by Taylor vortices at this value of a [2]. On the other hand, we can observe the remarkable suppression of turbulent eddies in the CTAC solution [Fig. 1(b)]. Very interestingly, nevertheless, we also see horizontal stripe patterns which imply that Taylor vortices still exist even in such suppressed turbulence.

Figure 2 shows the results of torque measurements. For the CTAC solution, the Taylor-number dependence of the Nusselt number is much weaker than that for water which well coincident with the previous study [see Eq. (3) and Ref. [2]]. This implies that the effect of the centrifugal force is drastically reduced by the viscoelastic property of the solution such as first normal stress difference. To consider these results in more detail, we are conducting parametric experiments which show that the above results also occur for other values of a (results will be shown at the conference).

CONCLUDING REMARKS

To investigate the physical mechanism of angular momentum transport in ultimate turbulence in Taylor–Couette flow, we conduct flow visualization, torque measurements, and PIV for turbulences of water and a dilute surfactant (CTAC) solution by using a large apparatus. Eddies in turbulence of water are strongly suppressed even by a very small amount of surfactant additives. We can consider the dynamics of fully developed turbulence by examining the suppressed turbulence because it is a response of turbulence to the addition of surfactant.

Turbulent eddies are almost vanished by the viscoelasticity of the CTAC solution although Taylor vortices still exist (Fig. 1). Torque measurements reveal that the Taylor-number dependence of the non-dimensional torque, the Nusselt number Nu_ω, is also reduced by the addition of surfactant (Fig. 2). These results imply that angular momentum transport which sustains fully developed turbulence is drastically suppressed due to decreasing the relative magnitude of the centrifugal force by surfactant additives in spite of the existence of Taylor vortices. We are now conducting PIV as well as the methods described above in a more higher Ta-regime. At the conference, we will present a more detail discussion by showing distributions of turbulence statistics obtained by PIV.

REYNOLDS STRESS ANISOTROPY IN CANONICAL SHOCK / TURBULENCE INTERACTIONS

Nathan E. Grube[1] and M. Pino Martín *[1]
[1]Department of Aerospace Engineering, University of Maryland, College Park, MD, USA

Summary The disagreement between predictions of linear interaction analysis (LIA) and observations in direct numerical simulation (DNS) and experiments regarding the anisotropy of turbulence emitted by shock/turbulence interactions is a longstanding question. The disagreement arises from nonlinear terms which are neglected by LIA. These terms usually promote isotropy, but here the nonlinearities actually generate the observed anisotropy. We propose that this behavior is due to the wavelengths of vortical waves emitted from the interaction at different inclination angles. The wavelength disparity implies a timescale disparity which in turn causes the waves carrying the transverse Reynolds stress to return to isotropy faster than the waves that carry the streamwise Reynolds stress. A simple model based on this physical understanding agrees with the DNS and experimental observations.

CANONICAL SHOCK / ISOTROPIC TURBULENCE INTERACTIONS (SITI)

Super- and hypersonic flows of engineering interest are complicated by unsteady two-way interactions between shock waves and turbulent fluctuations; the general shock / turbulence interaction is too complicated to be studied theoretically with much success. Instead, the simpler, statistically axisymmetric interaction between isotropic turbulence and a nominally planar shock wave offers a theoretically tractable problem that retains a large subset of the physics of the more general interaction.

This so-called canonical shock / isotropic turbulence interaction (SITI) is characterized by four flow parameters based on the pre-shock conditions: the convective Mach number in the shock-normal direction (M), the turbulence Mach number ($M_t \equiv q'_{\rm rms}/\overline{c}$) based on the r.m.s. velocity fluctuation magnitude $q'_{\rm rms}$ and the mean speed of sound $\overline{c}$, a Reynolds number such as the Taylor microscale Reynolds number Re_λ, and the ratio χ of dilatational turbulent kinetic energy to total TKE.

The interaction leads to the amplification of turbulence and the emission of sound and entropy spots as well as a modification of the mean jumps across the shock. An example is shown in Figure 1 for the case with $(M, M_t, Re_\lambda, \chi) = (2.98, 0.504, 48, 0.026)$. Instantaneous contours of density gradient magnitude are shown at left and Reynolds stress amplification (and isotropy) profiles at right.

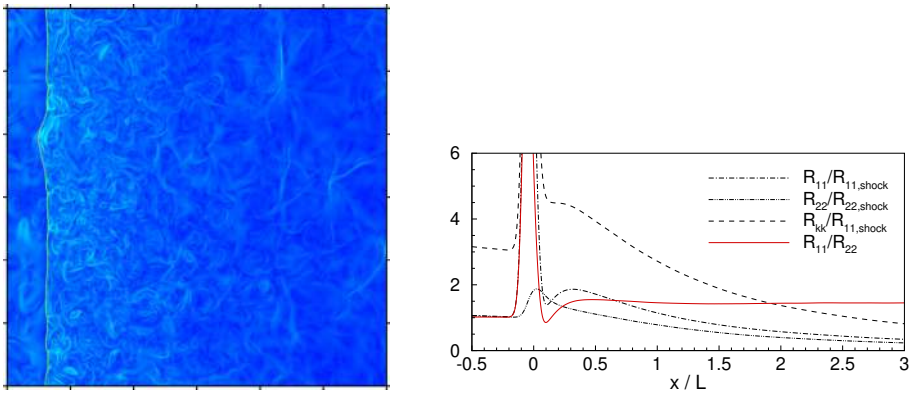

Figure 1: DNS of shock / isotropic turbulence interaction: instantaneous contours of density gradient magnitude (left) and Reynolds stress profiles (right). Distance is normalized by pre-shock turbulence scale L.

Post-Shock Turbulence Anisotropy

In 1998, some forty-five years after the initial publication of his pioneering work on the linear analysis of this problem (so-called linear interaction analysis or LIA), Ribner [5] reflected on the state of agreement between direct numerical simulation (DNS), experiment, and LIA theory. Although experimental results and DNS generally agreed with LIA predictions, Ribner noted that, above Mach 2, a severe qualitative disagreement between the Reynolds stress anisotropy observed by experiment and DNS on the one hand ($R_{11} > R_{22}$) and LIA predictions on the other hand ($R_{22} > R_{11}$) "remain[ed] a puzzle." Here R_{11} and R_{22} denote streamwise and transverse Reynolds stresses, respectively.

DNS profiles of the budget terms for the Reynolds stress equations show that the nonlinear pressure terms (pressure–strain and pressure-diffusion) redistribute TKE from R_{22} to R_{11} until $R_{11} > R_{22}$. These terms are usually observed to drive the turbulence toward isotropy; in fact the slow pressure–strain term is often called the *return-to-isotropy* term. Why, then, do these nonlinear effects drive the Reynolds stress *away* from isotropy in these SITI flows?

An answer to this question would help clarify the acceptable applications for LIA, and the resulting physical insights might aid in the development of turbulence models for STIs. The following section proposes an explanation.

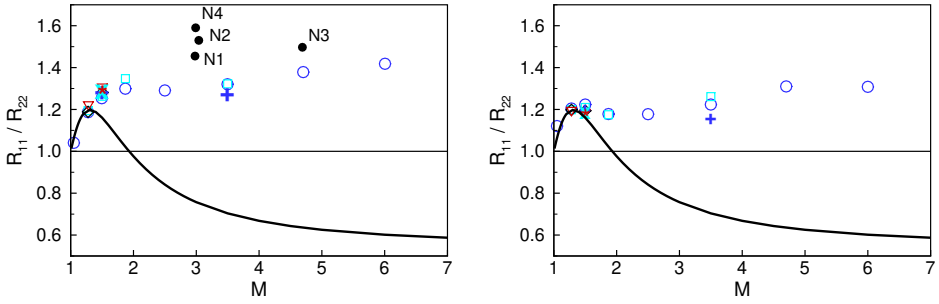

Figure 2: DNS results (left) and model predictions (right) of post-shock Reynolds stress anisotropy R_{11}/R_{22} for the cases of [2] (circles, squares, diamonds, and triangles) and the N-series cases of [1] (+). The LIA prediction is shown as a solid line.

Proposed Explanation

Consider the turbulence field as a superposition of elementary Fourier waves. The angle and wavenumber of an incident vortical wave are linked to those of the resulting emitted wave by a refraction law. The ratio of wavenumber magnitudes for emitted and incident vortical waves (k_2 and k_1, respectively) can be written as

$$\left(\frac{k_2}{k_1}\right)^2 = 1 + \alpha_1^2(\check{m}^2 - 1) = \frac{\check{m}^2}{\check{m}^2 - \alpha_2^2(\check{m}^2 - 1)} \tag{1}$$

where $\alpha_1 \equiv \cos\theta_1$ is the cosine of the incident wave angle, $\alpha_2 \equiv \cos\theta_2$ is the cosine of the emitted wave angle, and $\check{m} \equiv \bar{\rho}_2/\bar{\rho}_1$ is the compression ratio across the shock. The incidence angles θ of the wavevectors are defined relative to the mean flow (x) direction. It follows from (1) that the spatial compression k_2/k_1 of the emitted wavefronts ranges from unity to $\check{m} \equiv \rho_2/\rho_1$ for wavefronts perpendicular ($\alpha_2 = 0$) and parallel to the shock ($\alpha_2 = \pm 1$), respectively. For a specific heat ratio $\gamma = 1.4$ and high Mach number M, the wavefront compression varies from unity to as much as six.

According to LIA, the Reynolds stress in the immediate post-shock region is anisotropic in two senses: First, without regard to lengthscale (and for $M > 2$), there is more energy in R_{22} than in R_{11}. We might call this *global* anisotropy. It also follows from (1) that the energy in R_{22} (i.e., modes with $\alpha_2 \approx \pm 1$) is concentrated at smaller scales than the energy in R_{11} (i.e., modes with $\alpha_2 \approx 0$). In the wavenumber range where R_{22} is concentrated, there is a *local* anisotropy in the sense $R_{22} > R_{11}$, which is in the same direction as the global anisotropy. By contrast, in the largest post-shock scales, those which have not been spatially compressed as much by the shock, the local anisotropy is in the sense $R_{11} > R_{22}$.

In the near post-shock region, the majority of R_{11} lies at lower wavenumbers than the majority of R_{22}. From dimensional analysis, each vortical wave can be associated with a timescale based on its wavelength and perturbation velocity. The result is that the smaller scales isotropize more rapidly, and this process transfers TKE from R_{22} to R_{11}. The largest scales evolve more slowly, and their anisotropy in the sense $R_{11} > R_{22}$ persists longer, resulting in a global anisotropy in the same sense that is observed in DNS.

Based on this understanding, we develop a quantitative model starting with the LIA solution at the shock and using an eddy viscosity representation for the subsequent nonlinear interactions. Figure 2 compares the model predictions against DNS results of Larsson *et al.* [2] and Grube and Martín [1]. The LIA prediction is shown in black. The present model is applicable only to solenoidal incident turbulence; cases N1 through N4, which feature significant incident dilatational TKE, are included to show that the presence of dilatational TKE increases the anisotropy. Note that the simple model offers a vast improvement over LIA; this improvement supports the physical argument based on different timescales for the return to isotropy of the different Reynolds stress components.

REALIZABILITY AND METRICS FOR COARSE GRAINED SIMULATION OF THE TURBULENT MIXING TRANSITION

Fernando F. Grinstein* and Filipe S. Pereira
Los Alamos National Laboratory, MS F644, Los Alamos, NM 87545, USA

Abstract In many areas of practical interest we are interested in detailed understanding of the late-time consequences of mixing driven by hydrodynamical instabilities promoted by initial conditions at accelerated material interfaces. Under-resolved simulations of turbulent mixing driven by under-resolved velocity fields are unavoidable, Coarse Grained Simulation is typically the strategy of choice, and there is a practical need to characterize the simulated turbulence and assess macroscopic convergence of quantities of interest. Recently proposed turbulent mixing transition metrics are examined for representative examples of both, fundamental and practical applications.

BACKGROUND

Turbulent mixing can be characterized by the length scales of the fluid physics involved: 1) large-scale entrainment in which advection brings relatively large regions of the pure materials together, 2) an intermediate length scale associated with the convective stirring due to velocity gradient fluctuations, and, 3) much smaller scale interpenetration resulting from molecular diffusion. At high Reynolds number (Re) -- when convective time-scales are much smaller than those of molecular diffusion -- and for Schmidt number, Sc~ 1, primary concern is with the simulation of advection and stirring. The complexity of the high-Re turbulent flow typically requires achieving accurate and dependable large-scale predictions of highly nonlinear processes with under-resolved computer simulation models. All scale-resolving simulation models reduce the range of scales, and presume scale separation between resolved and unresolved scales: Direct Numerical Simulation (as typically practiced) leaves out the longest scales, and CGS [1] (classical and implicit LES) models the effects of the shortest scales.

Transition to turbulence is traditionally viewed in terms of rapid increase in the energy and the enstrophy production by mode coupling of a spectrum of smaller length scale motions. Transition can lead to an inertial range exhibiting Kolmogorov -5/3 power-law in the turbulence kinetic energy spectrum for sufficiently high Re [2,3] above the mixing transition threshold, Re ~ 1-2x10^4 based on the integral scale L (or Re ~ 1-1.4x10^2 based on the Taylor microscale λ) [2]. A higher threshold, Re ~ 1.6x10^5, was proposed to achieve a minimum turbulent state [3] having enough scale separation to ensure robustness of macroscopic flow characteristics. Cascade mechanisms for high Re are believed to be mainly driven by Re-independent equilibrium dissipation, e.g., as indicated by the high-Re constancy of the non-dimensional quantity $D = \varepsilon L / u^3 \sim 1$ [4]. Equilibrium dissipation is regarded as basis for the fundamental turbulence scaling relation $\varepsilon \sim u^3 / L$, where u and L denote characteristic velocity fluctuation magnitude and length scale. However, there is also reported evidence for significant high-Re non-equilibrium dissipation regimes existing in various turbulent flows in which the energy spectrum has Kolmogorov -5/3 wave-number scaling over a wide wave-number range, for which distinctly different scaling relations supporting asymptotically non-constant D apply [5].

TO BE PRESENTED AT XXV ICTAM

On dimensional grounds, if the dissipation rate ε can be estimated the simulated turbulence can be characterized by an effective viscosity defined in terms of strain-rate or enstrophy [6,7], $\nu_{eff} \sim \varepsilon / [2 < s_{ij} s_{ij} >] \sim \varepsilon / \Omega$.

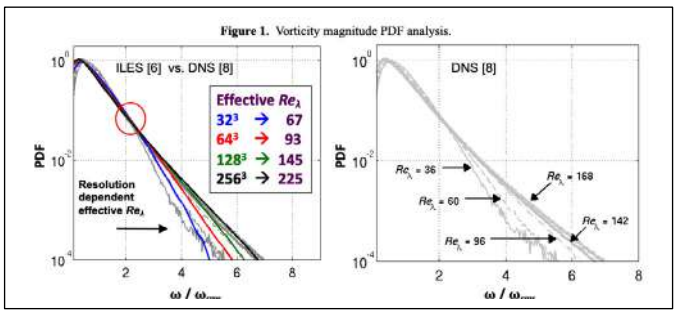

Figure 1. Vorticity magnitude PDF analysis.

The dissipation ε is determined by the prescribed momentum forcing for the homogeneous isotropic turbulence case; it relates to the kinetic energy dissipation for unsteady turbulence, and can be estimated through $\varepsilon \sim u^3 / L$ in the high-Re limit [7]. Effective turbulence Re, is then computed as $\mathrm{Re}_\lambda = u\lambda / \nu_{eff}$, where u is the *rms* value of the velocity and λ is the Taylor microscale of the velocity fluctuations characterizing the CGS cutoff – both evaluated from raw velocity data. Evaluation of ν_{eff} as computed ratio of dissipation and mean squared strain-rate [6,7] is distinct from residual local numerical viscosity (as Newtonian viscosity) associated with algorithm specifics through modified equation analysis. For high-Re inertially dominated flow, ν_{eff} characterizes the simulated turbulence dissipation in the inertial subrange whereas the local (grid level) numerical viscosity characterizes the simulated viscous dissipation subrange.

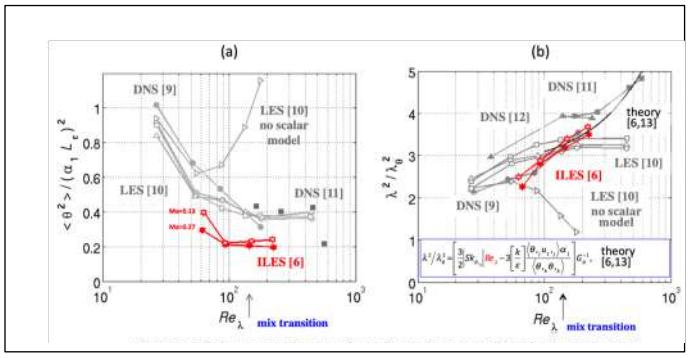
In [6], we used established turbulence metrics and DNS data [8] to show that a well-designed ILES can accurately capture the mixing transition and asymptotic high-Re self-similar behaviour (Fig.1), in terms of this effective turbulence Re. Mixing of a passive scalar θ by a fluctuating flow field is a classical problem in turbulence and relevant in many industrial flow applications. Overholt and Pope [9] conducted DNS of Sc~1 mixing of a passive scalar in the presence of a mean scalar gradient, by forced, spatially periodic, isotropic turbulence. In this flow, a statistically steady-state scalar variance is achieved by balancing scalar variance production and dissipation. This problem was first investigated in the LES context by Pullin [10], who predicted that the normalized scalar variance asymptotically approaches a constant value as a function of Re (Fig.2); however, non-constancy of the highest-Re DNS predictions [11] in Fig.2 are clearly apparent, and uncertainties due to sampling time –between 27 and 2.3 eddy-turnover times for Re_λ between 174-586 in [11], remain to be established. The squared-ratio of Taylor microscales – proportional to the velocity-to-scalar dissipation time ratio $\mathcal{R}$, was also reported to be asymptotically constant as function of Re in [10], albeit comparisons with the early DNS [9,12] were inconclusive. Analysis of subsequent results from theory [13], DNS [11], and ILES in [6], shows continued growth of $\mathcal{R}$ consistent with high-Re non-equilibrium dissipation variability [5].



Associated with equilibrium dissipation *built* into the LES modeling, Re-independence of $\mathcal{R}$ for high Re is predicted by Pullin's LES. On the other hand, equilibrium dissipation *not built* into DNS, theory, and ILES, allows variability of $\mathcal{R}$ as function of Re for high-Re. Figures 2 also show that when the explicit scalar SGS model is turned off in LES [10], scalar variance and the ratio predictions rapidly diverge with increasing Re – reflecting inadequacy of the (dispersive) numerics in [10] to ensure by itself correct physical asymptotic behaviour. In contrast, we find that a well-designed ILES allows for asymptotic growth behaviour with Re consistent with the predictions from theory [13], early [9] and more recent DNS [11]. Thus, fundamental constraints appear naturally built into a numerically well-designed ILES, but not necessarily in the mainstream classical LES – *suggesting that further realizability requirements for LES are needed*. More accurate high-Re reference data is also needed to elucidate these issues.

Capturing a target late-time turbulence Re threshold characteristic of the laboratory experiments is crucial in qualifying the impact of the discretization specifics on the simulated flow accuracy for many transitional flows of interest. For example, consider recently revisited ILES of shocked Gas-Curtain experiments with LANL's xRAGE code [14,15]. Simulations agree well with experiments on flow patterns & growth rates before reshock with 2nd order Godunov xRAGE (Fig.3) [14] but are unable to capture the late-time mix-transition after reshock – i.e., late-time Re is too low – as fairly diffusive 2nd order numerics inhibit vortex stretching driving transition. On the other hand, enhanced "smaller-scale" mixing with less-diffusive low-Mach corrected 3rd order xRAGE [15] – allows capturing higher late-time turbulence Re.

Los Alamos National Laboratory is operated by TRIAD National Security, LLC for the US DOE NNSA.

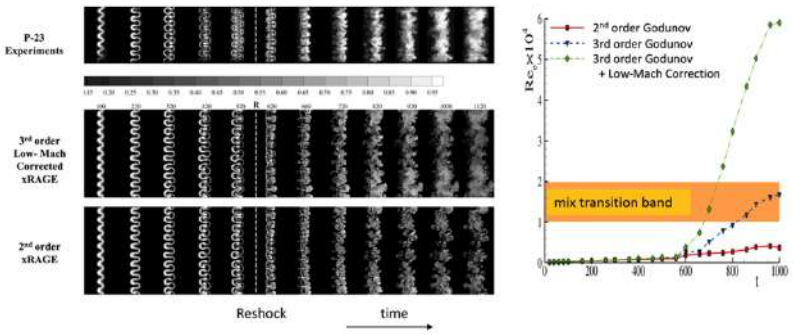


Figure 3: ILES of shocked Gas-Curtain experiments; Re is computed based on a mix width L, and a high-Re effective viscosity as in [15].

TRANSITION OF GRADIENT MOMENTS OF PASSIVE VECTOR IN RANDOMLY STIRRED FLUID

T. Gotoh*[1], J. Yang[1], H. Miura[2], and T. Watanabe[1]
[1]Department of Physical Science and Engineering, Nagoya Inst. Tech., Nagoya, Japan [2]National Institute for Fusion Science, Oroshi, Toki city, Gifu, Japan

Summary Variation of the normalized moments of the gradients of an incompressible passive vector as well as passive scalar and turbulent velocity against the Reynolds number is numerically studied. It is found that the transition of the moments from that of the Gaussian statistics to that of the turbulence occurs at the almost same Reynolds number for three fields and that the power law exponents in the Reynolds number for the passive vector are larger than those of the velocity.

INTRODUCTION

It is recognized that the scaling exponents of passive scalar at high order are smaller than those of the velocity and less universal [1, 2]. In order to explore the physics behind this difference, we have recently studied the statistcial properties of the incompressible passive vector $\boldsymbol{w}$ convected by the isotropic turbulence which obeys an equation very similar to the Navier Stokes equation except the linearity of the convective term [3, 4]. Findings are (1) the spectrum obeys $k^{-5/3}$ in the inertial convective range, (2) the intense pseudo enstrophy $(\nabla \times \boldsymbol{w})^2$ is sheet-like unlike the tube like for the enstrophy as seen in Fig.1, (3) the scaling exponents are in between the velocity and the passive scalar, (4) the pseudo pressure suppresses the intermittency but not as effective as the pressure, and (5) the differences result from whether or not the convective term is nonlinear, (6) the differences bewteen linear and nonlinear become more appreciable at small scales. It has recently been reported that when the Reynolds number R_λ is increased the n-th order moments of the velocity derivatives change from the Gaussian value to increase as a power law $R_\lambda^{\rho(n)}$ and that $\rho(n)$ is related to the scaling exponents in the inertial range [5, 6, 7]. Since the universality of the scaling exponents of the passive scalar is weaker than in the velocity, it is interesting and important to see whether or not such relationship holds for the passive scalar and passive vector.

PASSIVE VECTOR

An incompressible passive vector $\boldsymbol{w}(\boldsymbol{x}, t)$ convected by the homoegenous isotropic turbulence of an incompressible fluid velocity $\boldsymbol{u}(\boldsymbol{x}, t)$ is assumed to obey the following equations:

$$\left(\frac{\partial}{\partial t} + \boldsymbol{u} \cdot \nabla\right) \boldsymbol{w} = -\nabla q + \alpha \nabla^2 \boldsymbol{w} + \boldsymbol{f}^w, \qquad \nabla \cdot \boldsymbol{w} = 0, \tag{1}$$

where α is the diffussive coefficient of the passive vector, and $q(\boldsymbol{x}, t)$ the pseudo-pressure to assure the incompressibility of the passive vector. The external force $\boldsymbol{f}^w$ obeys the Gaussian statistics with zero mean and white in time. Also a passive scalar θ is assumed to be convected by the same turbulent flow. The direct numerical simulation (DNS) of the velocity, passive vector and scalar is performed for very low to moderate Reynolds numbers as $0.126 \leq R_\lambda \leq 120$. In order to assure the enough spatial resolution for high order moments of the gradient fields $k_{\max}\eta$ is kept quite large as $3.73 \leq k_{\max}\eta \leq 67.6$ depending on the Reynolds number. The statistical average is taken as the volume and time average.

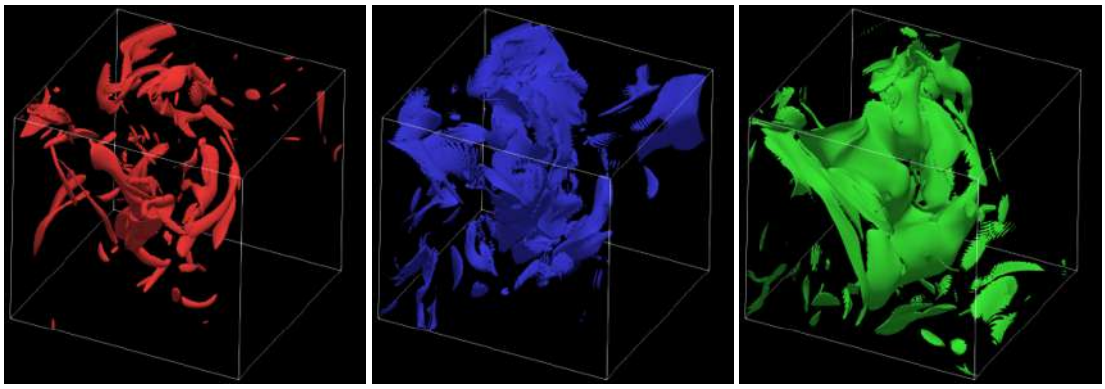

Figure 1: Visualization of $(\nabla \times \boldsymbol{u})^2$ (left), $(\nabla\theta)^2$ (center), and $(\nabla \times \boldsymbol{w})^2$ (right) at $R_\lambda = 120$, respectively.

*Corresponding author. E-mail: gotoh.toshiyuki@nitech.ac.jp.

RESULTS

Figure 1 shows the visularization of $(\nabla \times \boldsymbol{u})^2$, $(\nabla\theta)^2$, and $(\nabla \times \boldsymbol{w})^2$ at $R_\lambda = 120$ in the domain $(L/4)^3$, where L is the box size. It is seen that $(\nabla \times \boldsymbol{u})^2$ is tube like while $(\nabla\theta)^2$ and $(\nabla \times \boldsymbol{w})^2$ are sheet like as reported in [4]. The nth-order normalized moments of the longitudinal and transverse derivatives of the velocity are defined as

$$M_n^{u_L} = \left\langle \left(\frac{\partial u_1}{\partial x_1}\right)^n \right\rangle \Big/ \left\langle \left(\frac{\partial u_1}{\partial x_1}\right)^2 \right\rangle^{n/2}, \qquad M_n^{u_T} = \left\langle \left(\frac{\partial u_1}{\partial x_2}\right)^n \right\rangle \Big/ \left\langle \left(\frac{\partial u_1}{\partial x_2}\right)^2 \right\rangle^{n/2}, \tag{2}$$

respectively. Similarly, the nth-order moments of the corresponding derivatives of the passive vector and passive scalar are defined as

$$M_n^{w_L} = \left\langle \left(\frac{\partial w_1}{\partial x_1}\right)^n \right\rangle \Big/ \left\langle \left(\frac{\partial w_1}{\partial x_1}\right)^2 \right\rangle^{n/2}, \qquad M_n^{w_T} = \left\langle \left(\frac{\partial w_1}{\partial x_2}\right)^n \right\rangle \Big/ \left\langle \left(\frac{\partial w_1}{\partial x_2}\right)^2 \right\rangle^{n/2}, \tag{3}$$

$$M_n^{\theta} = \left\langle \left(\frac{\partial \theta}{\partial x_1}\right)^n \right\rangle \Big/ \left\langle \left(\frac{\partial \theta}{\partial x_1}\right)^2 \right\rangle^{n/2}, \tag{4}$$

For the multivaliate Gaussian statistics, the above moments are $M_{2n}^G \,/\, (M_2^G)^n = (2n-1)!!$. Figure 2 shows the variation of the normalized moments M_n^A, where A denotes $u_L, u_T, w_L, w_T, \theta$, with respect to the Reynolds number. The curves are constant at the Gaussian values M_n^G for $R_\lambda < 2$, begin to rise at around $R_\lambda \approx 5$, and increase as $R_\lambda^{\rho_n^A}$ for $R_\lambda > 30$. Since the transition is not sharp but the trend is clear, it is interesting and worthwhile to estimate the transition point as $R_\lambda \approx 5$ for n up to 10, which is not inconsistent with the previous studies [5, 6]. Corresponding to this transition in the moments, we found that when the Reynolds number increases the probability density functions (PDFs) for the gradient fields change their functional forms and their tails begin to expand. Close examination finds the facts that the curves $M_n^{W_T}$ and M_n^{θ} are close to each other and the same for $M_n^{W_L}$ and $M_n^{u_T}$, while the curve $M_n^{u_L}$ is lowest. The exponents $\rho_n^{u_L}$ are smaller than other ones for up to $n = 8$ but not certain for high order. Careful examination of the exponents and PDFs are now under way and will be reported.

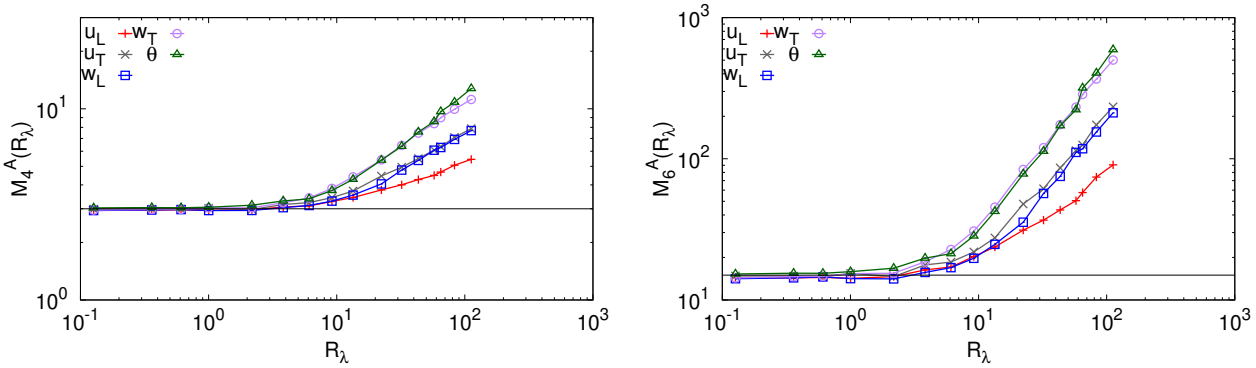

Figure 2: Variation of moments of gradients M_4^A (left) and M_6^A (right) against R_λ for $A = u_L, u_T, w_L, w_T, \theta$. Thin black lines denote the Gaussian values, 3 and 15, respectively.

EMERGENCE OF TRANSPORT DISSIMILARITY BY GROWING TURBULENT SPOT IN PLANE COUETTE FLOW

Koji Fukudome*[1], Takahiro Tsukahara[1], Hiroya Mamori[2], and Makoto Yamamoto[1]
[1]Department of Mechanical Engineering, Tokyo University of Science, Tokyo, Japan
[2]Department of Mechanical and Intelligent Systems Engineering, The University of Electro-Communications, Tokyo, Japan

Summary Direct numerical simulations (DNSs) were performed to study the dissimilarity between the heat and momentum transfer of turbulent spot structures developing in a laminar plane Couette flow. The turbulent spot was generated by pair vortices, and the boundary conditions for velocity and thermal fields were set to be consistent with each other. The Reynolds and Prandtl numbers were 450 and unity, respectively. As a result, we confirmed that the effective heat transfer state is obtained for developing a turbulent spot rather than a fully developed state. It attains the maximum when the turbulent spot grows the half size of the computational domain. Moreover, much effective heat transfer state was obtained for developing in streamwise direction rather than in spanwise direction.

INTRODUCTION

From the engineering view point, there are many concerns for the flow achieving the dissimilarity between heat and momentum transfer because the dissimilarity under higher heat transfer with lower hydraulic friction would improve the efficiency of heat exchangers. Although the transport between heat and momentum has a strong similarity as known as Reynolds or Colburn analogies, the origin of the dissimilarity is coming from the pressure terms of momentum transfer equation, i.e. Navier-Stokes equations [1]. Recently, the authors [2] studied the turbulent stripe in a plane Couette flow, and reported that the more effective heat transfer state is slightly obtained for the turbulent stripe in comparison to the fully-developed turbulence. Here, the turbulent stripe is one of the large-scale intermittent flow structures observed in the transitional region between laminar and turbulence. More recently, the authors [3] reported that the effective heat transfer state is obtained by developing turbulent spot, where the magnitude of dissimilarity is almost proportional to the size of the developing turbulent spot which keeps effective heat transfer state, where the spot grows in both streamwise and spanwise directions. In this study, we perform the DNSs of developing turbulent spot in a plane Couette flow to reveal which is more dominant for the effective heat transfer state of the spot growing in streamwise or spanwise direction.

NUMERICAL PROCEDURE

Objective flow is a plane Couette flow driven by the walls moving in opposing directions at a speed of $\pm U_W$ in the streamwise (x-) direction, where the wall-normal and spanwise directions are y- and z-directions, respectively. The governing equations are incompressible continuity, Navier-Stokes, and energy equations, where the temperature is treated as a passive scalar. For spatial discretization, the spectral method [2] is adopted with Fourier series in the streamwise and spanwise directions, respectively, and the Chebyshev polynomial expansion in the wall-normal direction. The collocation grid used to compute the nonlinear terms in physical space has 1.5 times finer resolution to remove aliasing errors. For time integration, the second-order Adams–Bashforth and Crank–Nicolson schemes are adopted for the nonlinear and viscous terms, respectively, though the explicit Euler scheme is adopted for the first step of the nonlinear terms to compute from the initial flow field. In this study, the Reynolds and Prandtl numbers are 450 and unity, respectively, where the Reynolds number is defined by the wall speed U_W and the channel half width δ. For the thermal boundary condition, the top and bottom walls are set to a constant temperature of $\Theta_H = 1$ and $\Theta_C = -1$, respectively. The computational domains as well as the grid systems are listed in Table 1. Time step size is $\Delta t = 0.01\delta/U_W$. Thereafter, the parameters are normalized by U_W, δ, and the half of the temperature difference, $(\Theta_H - \Theta_C)/2$.

As the initial flow field, we mimic a transient jet from the wall, as a single disturbance, introduced by Lundbradh and Johansson [4]. The flow field is formulated as

$$\Psi = A(1-y^2)^2 z \exp(-x^2-z^2), \quad (1)$$

where Ψ is the stream function. In addition, A is set to be 1.2 where A represents the magnitude of the jet, and the jet position is located at the centre of the computational domain (but note the periodic boundary conditions in x and z). This initial field (as shown in figure. 1(a) discussed later) comprises two vortices near the channel centre, and the initial distribution of temperature T is set to be same with streamwise velocity, so that both the velocity and thermal fields are precisely matched. We would focus on onset of any mismatch, i.e., dissimilarly, between the velocity and thermal fields as the spot disturbance grows with time.

Table 1 Computational domains and the grid system

Cases	Box size	Grid points
2-1	$20\pi\delta \times 2\delta \times 10\pi\delta$	256×65×256
2-2	$20\pi\delta \times 2\delta \times 20\pi\delta$	256×65×512
4-1	$40\pi\delta \times 2\delta \times 10\pi\delta$	512×65×256

(a) $t = 0$ (b) $t = 100$ (c) $t = 200$ (d) $t = 300$

Figure 1. Temporal evolution of the developing turbulent spots for Case2-1.

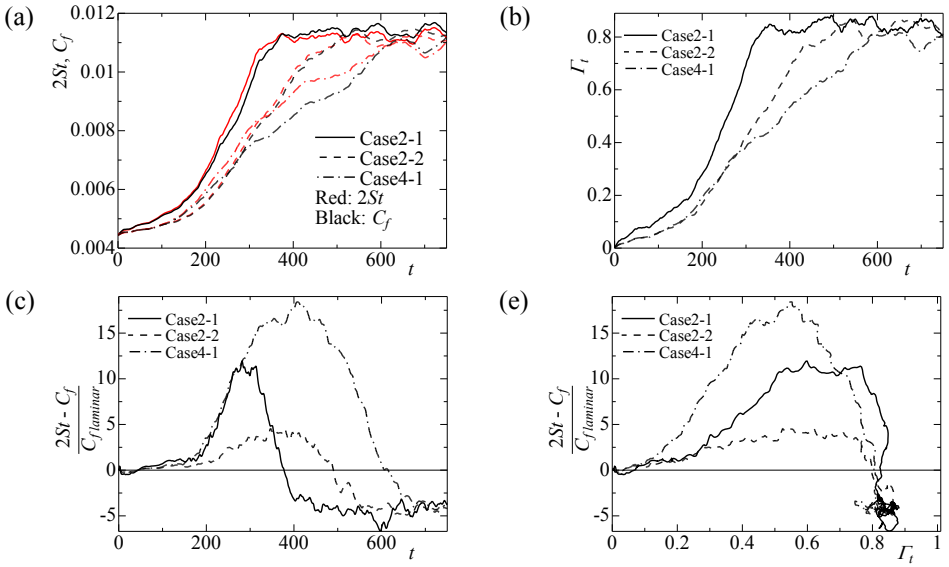

Figure 2. Statistics evolution of the developing turbulent spots.

RESULT AND DISCUSSION

Figure 1 shows the temporal evolution from the pair vortices disturbance as shown in figure 1(a) for Case2-1. Red and blue iso-surfaces represent clockwise and anti-clockwise vortical structures, respectively, identified by second invariant of deformation tensor. The vortices develop and elongated in the streamwise direction at $t = 100$ in figure 1(b). Then, the turbulent spot consists of many small-scale vortices and spatially develops in the streamwise and spanwise directions, as shown in Figure 1(c) at $t = 200$. Thereafter, its dimension becomes comparable with the domain size at t = 300 in figure 1(d). Figure 2 shows the temporal statistics of the developing turbulent spots. The Stanton number St and friction coefficient C_f as shown in figure 2(a) increase with time for all cases and reach to the fully-developed turbulence at $t \approx 400$, 550 and 650 for Case2-1, Case2-2 and Case4-1, respectively. Figure 2(b) represent the temporal evolution of the turbulent fraction Γ_t estimated by the turbulent dissipation [2], and the evolutions show the same trends with the temporal evolutions of St and C_f in each case. Figure 1(c) represents the effectiveness of the heat transfer against the hydraulic friction normalized by the laminar friction coefficient $C_{f\,laminar}$. Here, the equation of $2St = C_f$ is derived by Colburn analogy as the Prandtl number is unity, thus we can judge the effectiveness of the heat transfer by $2St - C_f$. The effectiveness rapidly increases from $t \approx 200$ except Case 2-2 and almost same evolution for Case2-1 and Case4-1 is clearly seen in $t < 250$, thereby much effective heat transfer state was obtained for developing in the streamwise direction rather than in the spanwise direction. Eventually, they become almost constant value of –5 for all cases when Γ_t is saturated in each case. Figure 1(d) shows the effectiveness as a function of Γ_t. The effectiveness increases for $\Gamma_t < 0.5$ in all cases and thereby the effective heat transfer state appears until when the spot grows the half of the computational domain, and it attains the much effective state for growing in the streamwise direction because of the results of Case2-1 and Case4-1.

CONCLUSION

We confirmed the effectiveness of the heat transfer of developing turbulent spot. As a result, it attains the maximum when the turbulent spot grows the half size of the computational domain, and much effective heat transfer state was obtained for developing in the streamwise direction rather than in the spanwise direction.

TOWARD MACHINE LEARNING BASED CONTROL OF TURBULENCE

Koji Fukagata[1]
[1]Department of Mechanical Engineering, Keio University, Yokohama, Japan

Summary Application of machine learning techniques is one of the hottest topics in the fluid mechanics community. In the present talk, some of our recent efforts to establish the building blocks required to achieve machine learning based control of turbulence are introduced. We adopt the convolutional neural network to extract lower order dynamics of flows, and its performance is demonstrated through some examples such as the spatio-temporal regression of cross-sectional velocity field in a turbulent channel flow and the super-resolution reconstruction of a two-dimensional isotropic turbulence. In addition to the machine learning of turbulent flows, the methodology to extract the lower dimensional dynamics is introduced through simpler flow problems involving laminar vortex shedding.

INTRODUCTION

Modern turbulence research has a history of more than 100 years. Although numerical prediction of turbulence at the laboratory level has made remarkable progress in the recent 50 years, true understanding of turbulence phenomena and their control are still challenging issues due to their inherent strong nonlinearity and multi-scale nature.

Until now, various numerical simulations and experimental measurements have been performed to understand the essence of turbulence. Direct numerical simulations (DNS) can now be performed with billions of degrees of freedom, which produce *big data* of turbulence. In order to understand the dynamics of turbulence from those *big data* and to control it, many attempts have been made primarily based on the linear theory. However, nonlinear mechanisms such as vortex deformation and breakdown, which should be as important as the linear mechanisms such as streak formation in the self-sustaining process, cannot be extracted by the methods based on the linear theory. For instance, in our group, the resolvent analysis [1] has been utilized to analyze and improve the performance of the suboptimal control law developed for turbulent friction drag reduction [2]. In this example, the resolvent based analysis of the control law in the wavenumber-frequency space [3] was successfully utilized to design an improved control law [4], but the amount of improvement was limited likely due to the nonlinearity accounted for just as an external forcing in the resolvent framework. Therefore, development of methods that can directly deal with the nonlinearity of turbulence is awaited. If such methods are successfully developed, those methods can also be applied to construct more efficient control laws.

In the present talk, we introduce some of our recent efforts to establish some building blocks required to achieve machine learning (ML) based control of turbulence. We adopt the convolutional neural network (CNN) to extract lower order dynamics of flows, and its performance is demonstrated through some examples such as spatio-temporal regression of cross-sectional velocity field in a turbulent channel flow [5] and super-resolution reconstruction of a two-dimensional isotropic turbulence [6]. In addition to the machine learning of turbulent flows, the methodology to extract the lower dimensional dynamics [7, 8] is introduced through a simpler flow problem involving laminar vortex shedding. For the recent studies in this field conducted by other research groups, readers are referred to the very recent review paper by Brunton et al. [9].

APPLICATIONS OF CONVOLUTIONAL NEURAL NETWORK TO TURBULENT FLOWS

Spatio-temporal regression of cross-sectional velocity field in a turbulent channel flow [5]

We used an autoencoder-type CNN with a fully connected multilayer perceptron in the middle, as schematically shown in Fig. 1 for spatio temporal regression of the cross-sectional velocity field in a turbulent channel flow at the friction Reynolds number of $Re_\tau = 180$. The ML model was trained using the DNS data so as to work as a surrogate model to the discretized Navier-Stokes equation. From the *a priori* test, the spatio-temporal evolution of cross-sectional structure is found to be reasonably well reproduced only by recycling the output to the input within this ML model. As an *a posteriori test,* we utilized this ML model as the spatio-temporally varying inflow condition for DNS of inflow-outflow turbulent channel flow. It was demonstrated that the present ML model can be used as a turbulent inflow generator with much lower computational cost than the conventional driver DNS.

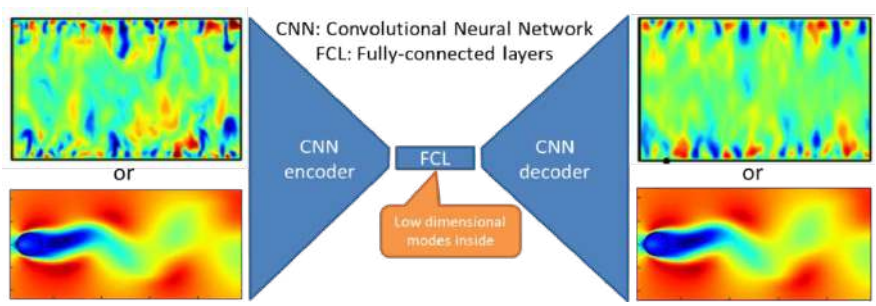

Figure 1. Schematic of the generic structure of the neural network models introduced in the present talk.

Super-resolution reconstruction of two-dimensional isotropic turbulence [6]

In this example, we used a similar CNN-based network for super-resolution reconstruction of flow field from grossly under-resolved flow field data of two-dimensional decaying isotropic turbulence. To account for the multiscale nature of the flow field, a variant of CNN structure called the hybrid downsampled skip-connection/multi-scale (DSC/MS) model was proposed. The present ML-based super-resolution technique was found to be able to reconstruct the flow field with 192×192 resolution with a reasonable accuracy even from an extremely coarse input of 4×4 pixels, in contrast to other reconstruction methods such as the bicubic interpolation and the conventional CNN. The present results imply a great potential of CNN-based networks for revealing subgrid-scale physics.

MACHINE LEARNING BASED REDUCED ORDER MODELING

Nonlinear mode decomposition using CNN autoencoder [7]

Using another variant of CNN autoencoder, called MD-CNN-AE, we proposed a new nonlinear mode decomposition method to visualize the decomposed flow fields. A flow around a circular cylinder at Re = 100 was mapped into two nonlinear modes in the latent space and then these two modes are visualized in the physical space. It was found that each single mode decomposed using the MD-CNN-AE with nonlinear activation contains multiple POD modes in a physically interpretable manner. The same was confirmed for a slightly more complicated problem involving a transient wake. The present results suggest a great potential for the MD-CNN-AE to be used for feature extraction of flow fields in lower dimensions than POD, although its applicability for turbulent flow needs further investigation.

Extracting dynamics of low dimensional nonlinear modes [8]

We also attempted to extract the governing equations for the two extracted nonlinear modes for the above cylinder flow problem using SINDy [10]. It was found that the dynamics of the flow can be successfully extracted as a state equation when the parameter for L_1 regularization is properly chosen. The optimal choice of the parameter, however, is not known *a priori* and needs to be asessed *a prosteriori*, which gives some technical difficulties in using SINDy for extracting nonlinear reduced order dynamics.

OUTLOOK TOWARD MACHINE LEARNING BASED CONTROL OF TURBULENCE

Once a turbulent flow is successfully represented with reasonably few nonlinear modes, it may not be so difficult to extract their dynamics by using either the sparse nonlinear regression techniques such as SINDYc [11] which accounts for control input or an ML based technique such as the long short term memory (LSTM), which has been demonstrated to excellently reproduce the chaotic behaviour of the nine-equation shear flow model [12]. Control using sparsely placed sensors will also be straightforward [13]. However, the major problem is how to drastically reduce the number of nonlinear modes to successfully represent a turbulent flow. Therefore, the key issue toward successful machine learning based control of turbulence should be further improvement in the low dimensionalization part.

RECOVERY OF TURBULENT PIPE FLOW DOWNSTREAM OF A SQUARE BAR ROUGHNESS

Liuyang Ding*[1] and Alexander Smits[1]
[1]Mechanical and Aerospace Engineering, Princeton University, Princeton, New Jersey 08544, USA

Summary The recovery of turbulent pipe flow at $Re_D = 156,000$ downstream of an axisymmetric square bar roughness is studied. Two bar sizes are tested: $h/D = 0.05$ and 0.1 (bar height h, pipe diameter D). Particle image velocimetry (PIV) is utilized to measure turbulence statistics in an axial-radial plane and over a downstream distance of $100h$. Three stages of recovery are identified: the self-similar development of the shear layer, the diffusion of turbulence towards the center region of the pipe, and the decay of turbulence throughout the pipe cross-section. h is shown to be the length scale governing the flow evolution in the first two stages. R is potentially the length scale for the third stage, which is to be confirmed with data further downstream ($h/D \sim 200$). The recovery is found to be long-lasting and non-monotonic.

INTRODUCTION

Wall-bounded turbulent flows subjected to step or impulse changes in surface conditions are commonly encountered in laboratory experiments and engineering applications. We are interested in small perturbations, i.e. the length scale of the perturbation is small as compared to the integral length scale of the flow. Examples include the flow over the surface of a vehicle where there is a small height mismatch between two panels, a screw, or a change in surface roughness; the flow over the joint of two sections in a pipe or channel. Such flows have been largely overlooked in the past. Scaling laws for the downstream evolution of the flow are lacking. We do not know to what extent these small perturbations challenge the validity of well established experimental methods. Also, it is unclear whether classical modeling approaches for RANS and LES would succeed in predicting the flow.

Past investigations have manifested some intriguing but not fully understood aspects of flows subjected to abrupt changes in surface conditions. First, the recovery to equilibrium is a long-lasting process. For example, a turbulent boundary layer over a fence or step of height h does not return to the ordinary boundary-layer state even at a downstream distance of a few hundreds of h [1]. The length scale on which the flow evolves far downstream is still an open question. Second, the recovery is non-monotonic. Quantities such as the Reynolds shear stress and the friction coefficient typically evolve like a damped harmonic oscillator, with the valley noticeably below the equilibrium-state value [2, 3]. The physical mechanism driving the non-monotonic recovery has not been thoroughly explained.

We study in this work a fully developed turbulent pipe flow over an axisymmetric square bar roughness. The flow recovery to equilibrium is of our primary interest. This flow possesses the advantage of having well defined boundary conditions. Therefore, it provides an ideal test case for computational approaches such as RANS and LES.

EXPERIMENTAL METHOD

The experiment is conducted in a recirculating pipe facility with an inner diameter of D = 19.05 mm in the development and test sections. The development length is approximately $200D$, ensuring the flow being fully developed upstream of the square bar roughness. With water being the working fluid, the bulk Reynolds number is $Re_D = U_b D/\nu = 156,000$, and the friction Reynolds number is $Re_\tau = u_\tau R/\nu = 3,550$. Here, U_b, u_τ, ν and R are, respectively, the bulk velocity, the friction velocity, the kinematic viscosity of water, and the pipe radius. The axisymmetric square bar is held in position by friction, and three bar sizes are tested: h/D = 0.02, 0.05, and 1. The schematic of an axial-radial slice of the test geometry is depicted in figure 1.

Particle image velocimetry (PIV) is utilized to measure the in-plane velocity components in an axial-radial plane. The measurement domain spans over a distance of $100h$ downstream of the square bar roughness. A single PIV camera (LaVision Imager sCMOS) is deployed at multiple downstream stations with a magnification of 0.32 (49 pix/mm). Statistics of the flow are computed with 10,000 realizations.

RESULTS AND BRIEF DISCUSSION

We identify three stages for the evolution of the flow downstream of the square bar roughness. The first stage features the self-similar development of the shear layer arising directly from the separation on the square bar. As seen in figure

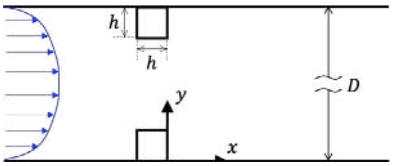

Figure 1: Schematic of an axial-radial slice of the test geometry.

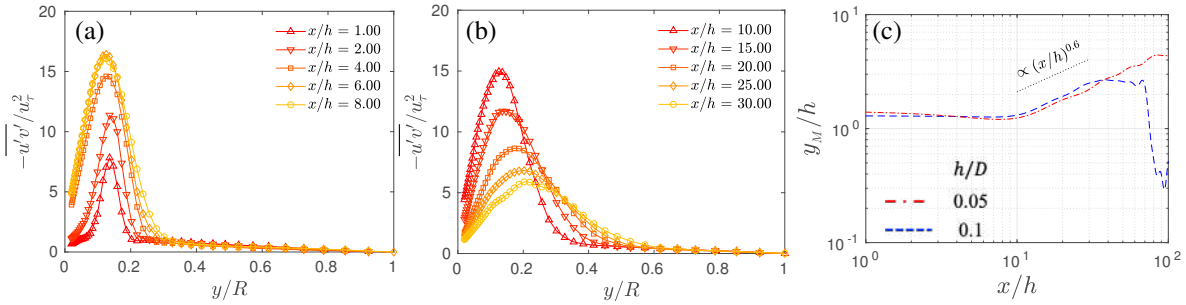

Figure 2: Development of the Reynolds shear stress distribution for $h/D = 0.05$: (a) the self-similar growth of the shear layer until $x/h \approx 10$; (b) the diffusion of turbulence towards the center region of the pipe; (c) the location of peak shear stress, y_M, against the downstream distance, x, suggesting that h is the correct length scale for the early stage of the flow evolution. u_τ is the friction velocity of the upstream fully developed flow.

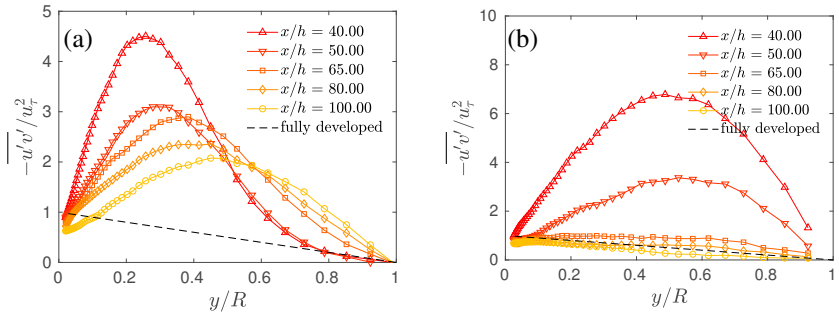

Figure 3: The far-field ($40 < x/h < 100$) evolution of the Reynolds shear stress for h/D = 0.05 (a) and 0.1 (b). u_τ is the friction velocity of the upstream fully developed flow.

2a, the distribution of the Reynolds shear stress ($-\overline{u'v'}$) for $h/D = 0.05$ grows in both its strength and width. The peak location is slightly above $y/D = 0.05$ ($y/R = 0.1$) and moves slowly towards the wall until $x/h \approx 10$. $x/h \approx 10$ marks the beginning of the second stage, during which the shear layer starts to interact with the wall. It is evident in figure 2b that the region of strong turbulence near the wall gradually diffuses into the center region of the pipe. The peak value of $-\overline{u'v'}$ decreases, and the peak location moves away from the wall. Flow evolution in the above two stages originates from the perturbation of scale h on the wall. The presence of the perturbation and the wall directly affects the evolution of the flow, but the confined geometry of the pipe does not. Therefore, it is reasonable to expect h to be the length scale governing the flow evolution in these two stages. This postulation is supported by the result in figure 2c, in which the peak location of $-\overline{u'v'}$, y_M, is plotted against the downstream distance, x. When both quantities are scaled by h, the curves for $h/D = 0.05$ and 0.1 collapse upstream of $x/h \approx 30$. The plot also distinctly shows the two stages divided by $x/h \approx 10$, and the diffusion of turbulence in the second stage follows a power law of $(x/h)^{0.6}$.

The confined geometry of the pipe, i.e. the radius R (or diameter D), kicks in after the second stage. Following the diffusion of turbulence, the third stage is initiated by the merging of turbulence in the center region of the pipe. Thereby, the onset location of the third stage is a function of h/D. It is clear in figure 2c that the second stage for $h/D = 0.05$ continues until at least, and probably beyond, $x/h = 100$, while for $h/D = 0.1$ the third stage starts after $x/h \approx 30$. Consequently, the evolutions of $-\overline{u'v'}$ for the two bar sizes are fundamentally different in the far field ($x/h > 30$). For $h/D = 0.05$, the diffusion of turbulence is still ongoing in $40 < x/h < 100$, as seen in figure 3a. However, $-\overline{u'v'}$ of $h/D = 0.1$ is noticeably dissipated throughout the cross-section of the pipe. At $x/h = 100$, $-\overline{u'v'}$ of $h/D = 0.05$ is significantly above the equilibrium state, whereas $-\overline{u'v'}$ of $h/D = 0.1$ falls below the equilibriums state. These observations are consistent with previous findings that the flow recovery is a long-lasting and non-monotonic process.

Ongoing effort is focused on the length scale of the far-field recovery. R is a potential candidate, which is to be justified with data further downstream ($x/h \sim 200$). Also, the data for the smallest bar size, $h/D \approx 0.02$, is being analyzed to provide more insights into the flow recovery downstream of weak perturbations. We expect to finish data processing in February and have all presentable results ready in May, well before the conference (Aug. 23 – 28, 2020).

LARGE EDDY SIMULATION WITH A MACHINE-LEARNING-BASED SUBGRID-SCALE MODEL

Jongwhan Park[1] and Haecheon Choi[1]
[1]Department of Mechanical Engineering, Seoul National University, Seoul, Korea

Summary We apply a neural network (NN) to model the subgrid-scale (SGS) stress and perform large eddy simulation (LES). NNs are trained to predict the SGS stress for two turbulent flows: forced isotropic turbulence and turbulent channel flow. For isotropic turbulence, an NN-SGS model using stencils of velocity components performs better than the Smagorinsky model for the prediction of the energy spectrum. For turbulent channel flow, an NN-SGS model using stencils of velocity components shows the highest correlation coefficient between true and predicted SGS stresses. In actual LES, however, this NN-SGS model provides inaccurate statistics due to overpredicted backscatter. On the other hand, an NN-SGS model using the strain rate tensor shows excellent agreements with the filtered mean velocity and Reynolds shear stress from DNS data, even without any wall damping function or *ad hoc* clipping.

Large eddy simulation (LES) resolves only large-scale turbulent flows, and the effect of subgrid-scale (SGS) flow on the resolved one is modeled. The aim of SGS modeling is to find the relation between the resolved flow and SGS stress. A conventional approach for the SGS modeling is to approximate the SGS stress with the resolved flow in an arithmetic form based on a turbulence theory and hypothesis. For example, the Smagorinsky model assumes that the SGS stress is linearly correlated with the strain rate tensor (Smagorinsky [1]). However, the Smagorinsky model is purely dissipative and cannot predict the energy transfer from unresolved to resolved scale flows (backscatter). In addition, the Smagorinsky model provides low correlations between the SGS stress and the true SGS stress from DNS data. To overcome these limitations, machine-learning-based SGS models without any assumption on the model form have been developed. In the case of two- or three-dimensional isotropic turbulence (Wang *et al.* [2]; Maulik *et al.* [3]; Xie *et al.* [4]), SGS models based on neural networks (NN) showed better performances than the physics-based SGS models. In the case of turbulent channel flow, Gamahara & Hattori [5] conducted LES with an NN using the velocity gradient tensor and wall-normal location and showed high correlations between the SGS stresses from the model and DNS data in *a priori* test. However, this NN-SGS model had no advantages over the Smagorinsky model in the actual LES for predicting the mean velocity and Reynolds stresses.

In the present study, we apply NNs for SGS modeling and conduct LES of two canonical turbulent flows: forced isotropic turbulence at Re_λ=73 and turbulent channel flow at Re_τ=180, respectively. We use NNs to predict pointwise SGS stress (τ_{ij}) with a resolved flow variable: $\tau_{ij}=\overline{u_iu_j}-\bar{u}_i\bar{u}_j=f(\bar{x})$, where $u_i(=u_1, u_2, u_3)$ is the velocity, an overbar denotes a filtering operation, and $\bar{x}$ (resolved flow variable) is a user-defined input variable of NNs. Direct numerical simulations of forced isotropic turbulence at Re_λ=73 and turbulent channel flow at Re_τ=180 are conducted to obtain instantaneous τ_{ij} and $\bar{x}$. We use NNs consisting of two hidden layers and 128 neurons per layer, and optimize them to minimize the mean-squared-error between the SGS stresses from NN-SGS model and DNS data. We test several input flow variables ($\bar{x}$) such as the strain rate tensor, velocity gradient tensor and local stencils of velocity components at 3×3×3 grids. *A priori* and *a posteriori* tests are conducted to investigate the performances of NN-SGS models considered.

For isotropic turbulence, the NN-SGS model with stencils of the velocity components as an input variable outperforms the Smagorinsky model for the predictions of the SGS dissipation, energy spectrum, and vortical structures (figure 1). The NN-SGS model trained is also applied to the LES of different grid resolution and higher Reynolds number (Re_λ=115), resulting in more accurate solution than the dynamic Smagorinsky model (Germano *et al.* [6]; Lilly [7]). The results from other NN-SGS models with the input variables of the strain rate and velocity gradient tensors will be also discussed in the presentation.

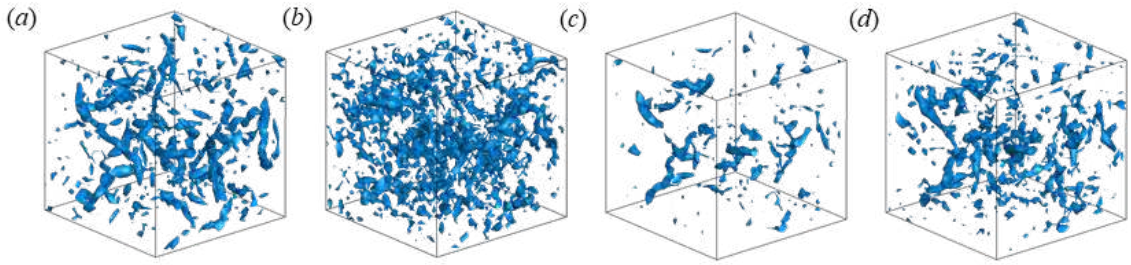

Figure 1. Instantaneous vortical structures of isotropic turbulence: (*a*) filtered DNS; (*b*) coarse DNS; (*c*) LES with dynamic Smagorinsky model; (*d*) LES with an NN-SGS model using stencils of the input velocity components

For turbulent channel flow, an NN-SGS model with stencils of input velocity components provides highly correlated SGS stresses with those from DNS data, and predicts backscatter more accurately than other models considered in *a priori* test. In the actual LES, however, the NN-SGS models that predicted the backscatter very well in *a priori* test severely overpredict the backscatter, resulting in inaccurate statistics. On the other hand, an NN-SGS model with the strain rate tensor as an input variable shows excellent predictions of the filtered mean velocity and Reynolds shear stress, even

without any wall damping function or *ad hoc* clipping (figure 2). The NN-SGS model trained at Re_τ=180 is also applied to the LES at $Re_\tau \approx 720$, and shows a good prediction capability.

EXPLORING ISOTROPIC TURBULENCE RELATIONS WITH CENTERLINE TURBULENCE

Clayton P. Byers*[1], Matt K. Fu[2], Ivan Marusic[3], and Marcus Hultmark[4]
[1]Department of Engineering, Trinity College, Hartford, CT 06106 USA

Summary Isotropic relations form a cornerstone of turbulence research, but the exact extent of their validity in different flow configurations is always elusive. An investigation of multiple isotropic relations for high Reynolds number turbulence has been performed along the centerline of a turbulent pipe flow. Utilizing a nanoscale crosswire, simultaneous measurements of the streamwise and radial component of velocity were acquired and the consistency of several different isotropic dissipation estimates were evaluated. The estimations indicate that isotropic dissipation relations can work in limited regions, and no universality is found at the moderate Reynolds numbers of the experiments performed. A correction for inhomogeneity is shown to be necessary for increasing separation of the structure functions, but is less prominent with increasing Reynolds number.

INTRODUCTION

The study of high Reynolds number turbulence and turbulence theory often relies upon the assumption of local isotropy of the small scales in the flow. This assumption allows for the estimation of the viscous dissipation, ϵ, from fully resolved measurements of a single fluctuating component of the velocity field. Two commonly obtained examples are the streamwise estimate, ϵ_u, and radial estimate, ϵ_v, both of which are given in equation 1:

$$\epsilon_u = 15\nu \int_0^\infty k_1^2 \phi_{11}(k_1) \mathrm{d}k_1, \quad \epsilon_v = \frac{15}{2}\nu \int_0^\infty k_1^2 \phi_{22}(k_1) \mathrm{d}k_1. \tag{1}$$

Here, k_1 is the streamwise wavenumber, ϕ_{ii} corresponds to the spectrum function in the i direction, u is the $i = 1$ streamwise velocity fluctuation, v is the $i = 2$ radial velocity fluctuation, and ν is the kinematic viscosity of the flow. The refined similarity hypothesis of Kolmogorov [3], seen in equation 2, provides another dissipation estimate:

$$\epsilon_{\langle(\Delta u)^3\rangle} = -\frac{5}{4}\frac{\langle(\Delta u)^3\rangle}{r}, \tag{2}$$

where $\Delta u = u(x + (r/2)) - u(x - (r/2))$ is the streamwise velocity increment at location x with streamwise separation r, and $\langle\cdot\rangle$ indicates ensemble averaging. Though derived in the limit of high Reynolds number turbulence, this relation is often applied to finite Reynolds number flows. More recently, a generalization of equation 2 was proposed by Danaila et al. [1], shown in equation 3, to incorporate the large scale anisotropic contributions from flow inhomogeneities:

$$\underbrace{-\frac{\langle(\Delta u)^3\rangle}{\epsilon r}}_{\text{Term I}} + \underbrace{\frac{6\nu}{\epsilon r}\frac{\mathrm{d}}{\mathrm{d}r}\langle(\Delta u)^2\rangle}_{\text{Term II}} + \underbrace{\frac{6}{\epsilon r^5}\int_0^r s^4 \left(-\frac{\partial\langle v(\Delta u)^2\rangle}{\partial y}\right)\mathrm{d}s}_{\text{Term III}} = \frac{4}{5}. \tag{3}$$

The estimates for dissipation in equations 1 to 3 will be compared and evaluated with Taylor's dissipation estimate of $\epsilon = Au^3/l$, where u and l are relevant velocity and length scales, respectively, and A is a constant, argued to be universal at sufficiently high Reynolds number. These comparisons will provide an indication of the applicability of local isotropy. The five different estimates of ϵ will be calculated by obtaining high resolution measurements of u and v along the centerline in a turbulent pipe flow. A nanoscale crosswire probe (X-NSTAP) with enhanced spatial and temporal resolution is utilized to obtain these measurements [2].

RESULTS

A test of the universality of A is shown in figure 1, following the methodology of Morrison et al. [4]. In this plot, the relevant velocity and length scale is u_τ, the friction velocity, and R, the pipe radius, respectively. Included in figure 1 is the data presented by Morrison et al. in hollow symbols [4].

The spectral dissipation estimates from the nanoscale crosswire measurements and equation 1 (shown in $\triangle$ and $\triangledown$ symbols) demonstrate good agreement with the data of [4], indicating a nearly linear increase in A with Re_λ. Interestingly, the agreement in the evolution of A with Re_λ for the different spectral measurements is significant and consistent with the assumption of local isotropy, indicating that either streamwise or radial velocity fluctuations provide similar estimates, so long as the resolution is sufficient. Similar agreement between the current and previous study is found with equation

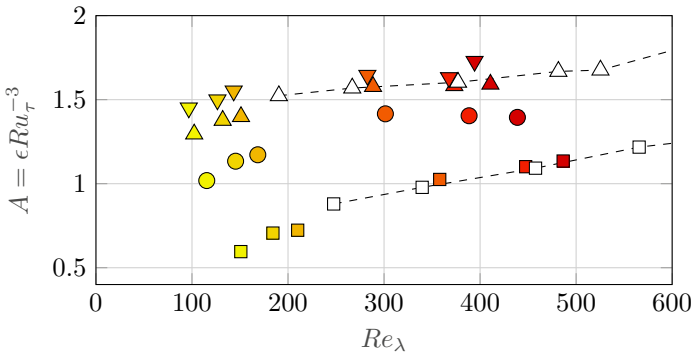

Figure 1: Nondimensional dissipation rate $A = \epsilon R u_\tau^{-3}$. $\triangle$ and $\triangledown$: equation 1. $\square$: equation 2. $\circ$: equation 3 evaluated at the maximum value of the third order structure function. Colors indicate increasing Re_λ from yellow to red. Hollow symbols represent the same parameter from Morrison et al. [4].

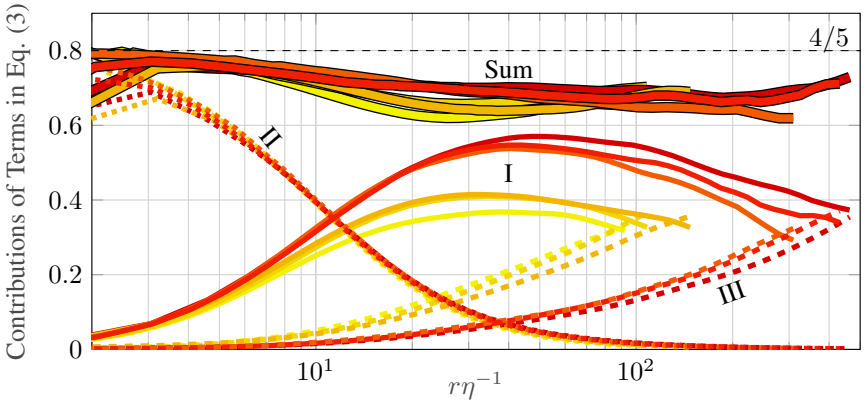

Figure 2: The three terms in equation 3 and their sum as a function of the non-dimensional separation $r\eta^{-1}$, where $\eta = (\nu^3\epsilon^{-1})^{1/4}$ is the Kolmogorov scale. Term I shown in solid lines; Term II shown in dotted lines; Term III shown in dashed lines; the sum of the three terms shown in thick solid lines. Colors of yellow to red indicate increasing Re_λ.

2, shown with $\square$ symbols. A new estimate of A that utilizes equation 3 to extract ϵ at the maximum value of $\langle(\Delta u)^3\rangle$ is shown in $\circ$ symbols and indicates an intermediate estimate between the three other methodologies.

The three terms on the left hand side of equation 3 and their sum are plotted in figure 2. At sufficiently high Reynolds numbers, the sum should equate to $4/5$. Here, we assume that the dissipation in equation 3 is given by the integrated streamwise spectra using equation 1. Consequently, a sum of 4/5 is only observed at the smallest separation where the behavior is entirely dominated by Term II. As the separation increases, the contributions of Term I, representing the inertial contributions, become dominant as predicted by refined similarity hypothesis of Kolmogorov [3]. However, at the abscissa of the maximum value of Term I, the contributions from Terms II and III are non-negligible at these moderate Reynolds numbers.

Despite being able to account for the large scale inhomogeneity along the centerline, the corrected dissipation estimate from equation 3 does not agree with the those obtained from equation 1. The disagreement between the various dissipation estimates even for this nearly isotropic centerline flow motivates the need for further investigation, in particular, measurements of additional velocity components at higher Reynolds number.

Summary Turbulent entrainment is classically studied in flows for which the background is non-turbulent. Whilst the majority of environmental/industrial flows exist within a turbulent background, entrainment for flows exposed to freestream turbulence is not well understood. In particular, when the background turbulence is particularly intense it is not yet clear whether a turbulent/turbulent interface exists demarcating the primary turbulent flow from the background or whether the entrainment rate is enhanced relative to a non-turbulent background. Here we present results proving the existence of such an interface. Further, we show that the presence of freestream turbulence reduces the entrainment rate with the key parameter being the intensity of the freestream turbulence. We show that intense freestream turbulence promotes powerful detrainment events explaining this finding.

INTRODUCTION

Turbulent entrainment is the process by which mass/energy is transferred into a body of turbulent fluid from the background. The rate of entrainment is determined by the dynamics of the flow in the proximity of the outermost boundary of the turbulent portion, which is characterised by a sharp contorted interface of thin, but finite thickness. When the turbulent fluid is surrounded by irrotational fluid, this boundary is known as the turblent/non-turbulent interface (TNTI) which has been extensively studied over the past two decades [e.g. 1]. The seminal work of Corrsin and Kistler [2] postulated that the mechanism by which vorticity is transferred from the turbulent to the irrotational fluid, and hence the entrainment mechanism, is via the direct action of viscosity; a result that has been verified in more recent years [e.g. 3].

In practical applications, however, entrainment rarely takes place from an irrotational background since most industrial/environmental flows exist within a turbulent background. In such cases the boundary between the primary flow, e.g. a turbulent wake, and the background is no longer the TNTI but the turbulent/turbulent interface (TTI). In such circumstances the intuition of Corrsin and Kistler [2] no longer holds since inertial mechanisms may also be responsible for transferring vorticity/mass across the TTI. At present there is no consensus as to whether the presence of freestream turbulence increases [e.g. 4] or decreases [e.g. 5] the rate of entrainment relative to that from an irrotational background. Our uncertainty of the understanding of turbulent/turbulent entrainment (TTE) is particularly acute when the background turbulence intensity is high. In the review paper of da Silva et al. [6] it was even suggested that when the turbulence intensity of the background becomes comparable to that in the primary turbulent flow the TTI breaks down entirely.

EXPERIMENTAL METHODS

Two experimental datasets are presented in this abstract, both of which were acquired using simultaneous particle image velocimetry (PIV) and planar laser induced fluorescence (PLIF) in the Imperial College London hydrodynamics flume [e.g. 7]. In both datasets in excess of 2,500 combined PIV/PLIF snapshots were collected. The two configurations are a two dimensional multi-scale array of rectangular bars (of three different thicknesses) and a circular cylinder exposed to freestream turbuulence produced by an assortment of turbulence-generating grids. The freestream turbulence was categorised into three groups (1, 2 and 3) according to the intensity of the freestream turbulence in the field of view, which was 37-41 cylinder diameters downstream of the cylinder. This abstract specifically considers group 3 in which the freestream turbulence intensity was greater than the turbulence intensity in the wake when no grid was used (9.8%). The first configuration gives us access to TTE between different sized wakes in which there is a strong coherent aspect to the "background" turbulence and the second configuration yields TTE in which the background turbulence is intense but incoherent. A high Schmidt number scalar (Rhodamine 6G, $Sc \approx 2.5 \times 10^3$ in water) is used to mark the primary portion of the flow, which is seeded isokinetically through a small pinhole into the wake of interest (the smallest rectangular bar and the circular cylinder, respectively). More details on the experimental methods can be found in Baj and Buxton [7].

RESULTS AND DISCUSSION

Figure 1(a) shows the mean enstrophy ($\omega^2 = \boldsymbol{\omega} \cdot \boldsymbol{\omega}$, where $\boldsymbol{\omega}$ is the vorticity vector) conditioned on distance normal to the location of the TTI, γ. $\gamma = 0$ corresponds to the outermost boundary between the wake and the background and was determined using a threshold on $|\nabla\phi|$, where ϕ is the signal recorded by the PLIF camera. This threshold detection was validated against the no-grid run and detection of the TNTI using the classical enstrophy threshold technique reported frequently in the literature [e.g. 6]. In a result that is reminiscent of the classical TNTI result it can be seen that there is a jump in the conditional mean enstrophy across the TTI, regardless of the level of the background turbulence - even for the

(a) (b) (c)

Figure 1: (a) Conditional enstrophy jump across the TTI for various experimental runs. Note group 3 refers to the runs with intense background turbulence. (b) Probability density functions for the computed normalised entrainment mass flux per snapshot. (c) Phase-averaged velocity and scalar fields for TTE between adjacent wakes in the multi-scale array.

group 3 cases in which the background turbulence intensity is higher than the "natural" turbulence intensity of the wake, i.e. for the wake in which the cylinder was not exposed to any freestream turbulence (no-grid run). This result proves the existence of the TTI even for cases with extreme freestream turbulence intensity, and thereby refutes the postulation in da Silva et al. [6] that the interface may break down entirely in such cases.

The specific "runs" in figure 1(a) correspond to an exploration of the two-dimensional $\{\mathcal{L}, u'\}$ freestream turbulence parameter space, where $\mathcal{L}$ corresponds to the integral length scale and u' corresponds to the rms velocity fluctuation (or turbulence intensity) of the freestream turbulence. Our results (not shown in this abstract for brevity) show that the entrainment mass flux is a decreasing function of u' but it is uncorrelated to $\mathcal{L}$. This is despite the fact that an increase in $\mathcal{L}$ and u' are both correlated to an increased contortion of the TTI and hence an increase in surface area over which entrainment may take place. The explanation for why an increasingly contorted TTI, and hence increased surface area, corresponds to a reduction in entrainment rate is provided in figure 1(b). This shows probability density functions (PDFs) of the normalised entrainment mass flux per snapshot for the reference no-grid run and the group 3 (intense freestream turbulence) runs. It can be seen that whilst the right tails (entrainment events) of the PDFs are similar there is a large discrepancy between the left tails of the group 3 runs and the no-grid run. This shows that intermittent, but powerful detrainment events (fluid is transported across the TTI from the wake to the background) occur significantly more frequently when there is intense freestream turbulence. Multi-scale analysis (again not presented for brevity) shows that the entrainment mass flux is virtually constant as a function of length scale, a result that mirrors classical entrainment from a non-turbulent background. This explains the dependence of the entrainment rate on u' but not $\mathcal{L}$, since the complete spectrum of turbulent length scales are involved in the entrainment processes, not simply the energy-containing scales.

Figure 1(c) shows the phase-averaged combined scalar and velocity fields for the intersection between the wakes produced by the small and medium bars in the multi-scale array. In this configuration the scalar was seeded into the wake of the small bar and the medium wake acts as intense "freestream turbulence" with a periodic/coherent component to it associated with the vortex shedding. The phase averaging is done with respect to the periodic velocity fluctuation of the medium wake, i.e. the "freestream turbulence" as far as the seeded, small wake is concerned. Our results indicate that the coherence of the freestream turbulence drives powerful detrainment events in which fluid is transported from the space occupied by the small wake to that occupied by the medium wake, analogous to the powerful detrainment events evidenced in figure 1(b). Our final paper will present analysis based on a multi-scale triple decomposition, i.e. $\boldsymbol{u} = \overline{\boldsymbol{u}} + \sum_j \tilde{\boldsymbol{u}} + \boldsymbol{u}''$ [see, e.g. 7], which tracks the decomposed scalar and energy exchanges that take place during this detrainment.

WALL-BOUNDED TURBULENCE OVER HIGHLY POSITIVELY AND NEGATIVELY SKEWED ROUGHNESS

Angela Busse*[1] and Thomas O. Jelly[1,2]
[1]James Watt School of Engineering, University of Glasgow, Scotland
[2]Department of Mechanical Engineering, University of Melbourne, Australia

Summary While most engineering rough surfaces have only moderately skewed height distributions, examples of irregular rough surfaces with very high positive or negative skewness are not unusual. In the current study, the fluid dynamic properties of a set of seven irregular rough surfaces with skewness varying from -2.3 to $+2.3$ are investigated using direct numerical simulations of turbulent channel flow. We observe that the roughness function saturates both for very high positive and very high negative skewness, showing that extrapolation of existing empirical correlations for moderate skewness will overpredict the roughness effect for extremely skewed cases.

INTRODUCTION

The fluid dynamic effects of a rough surface are known to increase with the roughness height but are also influenced by a number of other topographical parameters. Amongst these, the skewness of the height distribution Ssk has been identified as a key topographical parameter [1]. The effect of surface skewness on wall-bounded turbulence has been the subject of both experimental [2] and numerical [3] investigations. However, the skewness values covered in these studies encompass only a relatively narrow range for this parameter not exceeding $Ssk \approx \pm 1$. When surveying the skewness and kurtosis Sku values of typical engineering rough surfaces (see map shown in figure 1(a)), we observe that while many rough surfaces have only moderately skewed height distributions, cases with $Ssk \gg 1$ or $Ssk \ll -1$ commonly occur. For example, surfaces affected by light calcareaous tubeworm-fouling display high skewness and kurtosis [4], as the sparse tubeworm features cause sharp local deviations relative to surrounding smaller-scale roughness features. The aim of the current study is a systematic investigation of rough surfaces with extreme skewness values, and to test existing empirical correlations developed in the context of previous studies for more moderately skewed roughness [1, 2].

NUMERICAL METHOD

The fluid dynamic properties of seven different rough surfaces with Ssk ranging from -2.3 to $+2.3$ have been investigated using direct numerical simulations of turbulent channel flow.

All rough surfaces have been generated using the surface generation algorithm of Patir [5, 6]. The heightmaps are then passed through a low-pass Fourier filter to generate smoothly-varying rough surfaces [7]. Two representative examples of the resulting rough surfaces are illustrated in figure 1(b). All surfaces have been scaled to the same mean-peak to valley height and have closely matched values in effective slope ($ES \approx 0.2$) to allow the current study to focus on the effects of the higher moments of the height distribution. The skewness and kurtosis values of the investigated cases are representative of values typically found for engineering rough surfaces (see figure 1(a)).

For each surface, a direct numerical simulation of turbulent channel flow at $Re_\tau = 395$ with constant mean streamwise pressure gradient has been conducted. Uniform grid spacing ($\Delta x^+ = \Delta y^+ = 4.94$) and periodic boundary conditions were applied in the streamwise and spanwise directions. In the wall-normal direction, uniform grid spacing was used within the roughness layer ($\Delta z^+_{\text{min}} = 0.67$). Above the highest roughness peak, the wall-normal grid spacing was gradually increased reaching $\Delta z^+_{\text{max}} \approx 5$ at the channel centre.

RESULTS

The roughness function, ΔU^+, and mean streamwise velocity profiles (see figure 2) show that the roughness effect increases with Ssk for moderate values of Ssk consistent with trends observed in previous studies. Outer-layer similarity of the mean streamwise velocity profile is recovered in all cases. However, for very highly positively and negatively skewed cases, the roughness effect saturates - no significant further increase in ΔU^+ is observed as Ssk is increased above 1; similarly, ΔU^+ stays constant for high negative values of $Ssk \leq -1.5$. The observed behaviour can be approximately fitted by a $\tanh$-function. Extrapolation of existing empirical correlations for positively and negatively skewed surfaces [2] to $Ssk > 1$ or $Ssk < -1$ would predict an increase in the roughness function for both high positive and high negative skewness. This difference in behaviour between moderately and extremely skewed surfaces could be attributed to the fact that very highly skewed surfaces are typically characterised by a sparse distribution of extreme roughness peaks or very deep roughness pits embedded into a 'background roughness' composed of smaller roughness features. In contrast, moderately skewed surfaces typically display a much more dense distribution of pits ($Ssk < 0$) or peaks ($Ssk > 0$).

CONCLUSIONS

Direct numerical simulations of turbulent channel flow over highly positively and negatively skewed surfaces were performed at a friction Reynolds number of 395. The highly skewed surfaces show a saturation in the roughness function for both very high positive and negative values of Ssk (see figure 2). This demonstrates that the fluid dynamic behaviour of highly skewed surfaces cannot be extrapolated from results obtained for more moderately skewed surfaces [1, 2]. A detailed analysis of the turbulent velocity fluctuations, the surface pressure statistics, and their dependence on surface skewness is currently ongoing.

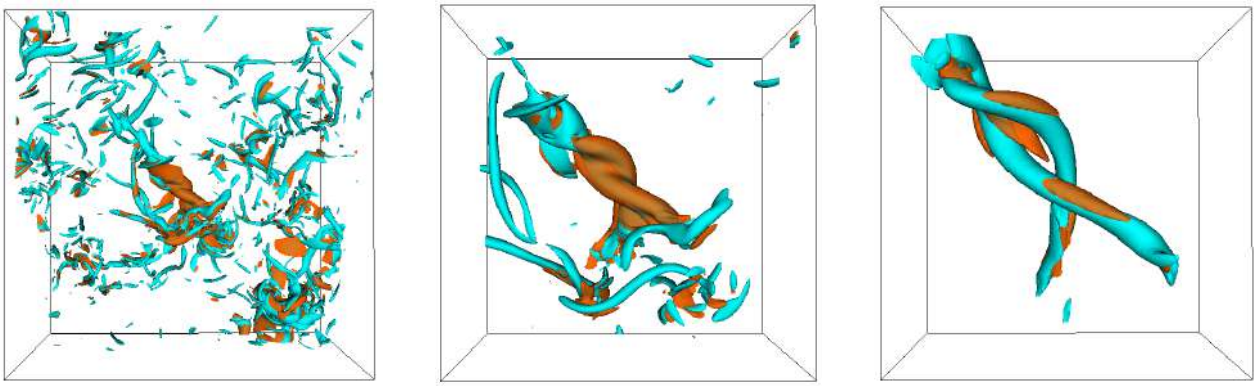
NON-LOCALITY OF VORTICITY AMPLIFICATION IN TURBULENT FLOWS

Dhawal Buaria*[1,2], Alain Pumir[3,2], and Eberhard Bodenschatz[2,4]
[1]Department of Mechanical and Aerospace Engineering, New York University, New York, USA [2]Max Planck Institute for Dynamics and Self-Organization, Göttingen, Germany
[3]Laboratoire de Physique, Ecole Normale Supérieure de Lyon and CNRS, Lyon, France
[4]Institute for Nonlinear Dynamics, University of Göttingen, Göttingen, Germany

Summary Using highly resolved direct numerical simulations of stationary isotropic turbulence, we investigate the non-local contributions to the process of vortex stretching. In particular, expressing the strain-rate as a Biot-Savart integral over the vorticity field, we decompose it as a sum of a local and a non-local component, and characterize their respective roles in amplifying vorticity. Our results suggest a characteristic length scale of about ten times the Kolmogorov length scale for the non-local effects. We also consider statistics conditioned on vorticity magnitude to understand formation of extreme events.

BACKGROUND AND APPROACH

Small-scale intermittency, which refers to intermittent formation of very localized and intense velocity gradients, is a key characteristic of fluid turbulence [1]. The physical mechanism responsible for the formation of these extreme events is vortex stretching, which results from a non-linear coupling between vorticity and strain-rate. An essential aspect of this coupling is non-locality, whereby vortex stretching in one region of space is affected by the entire flow field, resulting in severe mathematical difficulties. The complexity of the problem is highlighted in Fig. 1, which shows the organization of the intense regions of vorticity and strain rate. Consistent with known results, intense vorticity is found arranged in tube-like structures, surrounded by regions of intense strain, which non-locally amplify the tubes. Thus, a natural question arises, as to what proportion of the stretching acting at a spatial point arises from non-local effects. The objective of the present contribution is to characterize quantitatively this non-locality. To this end, we utilize direct numerical simulations (DNS) of isotropic turbulence with an unprecedented small-scale resolution, going up to 8192^3 grid points and Taylor-scale Reynolds number (R_λ) of 650 [2].



(a) $(250\eta)^3$; $C = 50$ (b) $(100\eta)^3$; $C = 100$ (c) $(50\eta)^3$; $C = 300$

Figure 1: 3D contour surfaces of squared-norm of vorticity (cyan) and strain-rate (red) normalized by their mean-values, from direct numerical simulation at Taylor-scale Reynolds number of $R_\lambda = 650$ on 8192^3 grid (or $(4096\eta)^3$, where η is the Kolmogorov length scale). Panels (a-c) show sub-domains of decreasing size, and increasing contour threshold, C, as indicated in sub-captions. All sub-domains are centered around the same intense vorticity event.

NON-LOCAL STRAIN AND VORTICITY AMPLIFICATION

Quantitatively, the non-locality discussed earlier can be explicitly expressed by writing the velocity $\mathbf{u}(\mathbf{x})$ and hence the strain rate, defined as $\mathbf{S}(\mathbf{x}) = \frac{1}{2}\left[\nabla\mathbf{u} + (\nabla\mathbf{u})^T\right]$, as a global Biot-Savart integral over the vorticity field $\boldsymbol{\omega}(\mathbf{x})$:

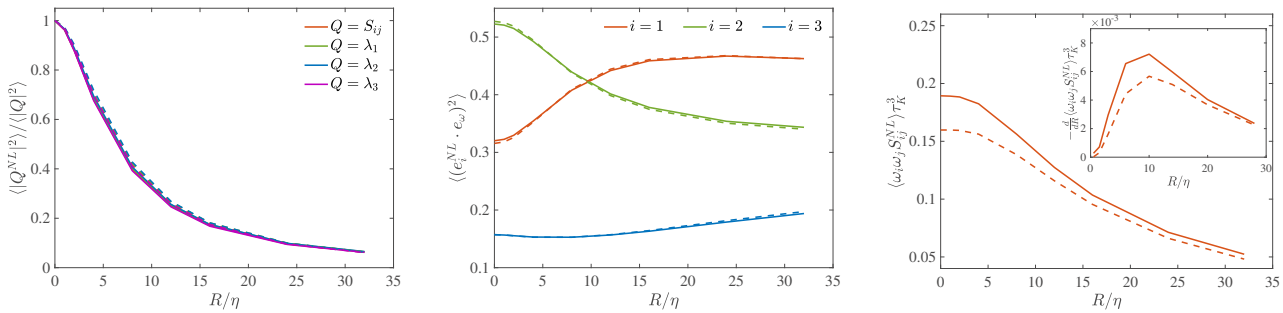
$$\mathbf{u}(\mathbf{x}) = \frac{1}{4\pi}\int_{\mathbf{x}'} \boldsymbol{\omega}(\mathbf{x}') \times \frac{\mathbf{x}-\mathbf{x}'}{|\mathbf{x}-\mathbf{x}'|^3} d^3\mathbf{x}' \,. \tag{1}$$

Thereafter, we can decompose the strain-rate at each spatial point as $\mathbf{S}(\mathbf{x}) = \mathbf{S}^L(\mathbf{x}) + \mathbf{S}^{NL}(\mathbf{x})$ [3], where $\mathbf{S}^L(\mathbf{x})$ is the local contribution, obtained by evaluating the Biot-Savart integral in the neighborhood $|\mathbf{x}' - \mathbf{x}| \leq R$, and $\mathbf{S}^{NL}(\mathbf{x})$

*Corresponding author. E-mail: dhawal.buaria@nyu.edu

is the non-local contribution over the background $|\mathbf{x}-\mathbf{x}'| > R$. This allows us to separate the local and the non-local contributions to the strain, hence to the stretching acting on vorticity as a function of the distance R. Note, by definition $\mathbf{S}^L(\mathbf{x}) = \mathbf{0}$ and $\mathbf{S}^{NL}(\mathbf{x}) = \mathbf{S}(\mathbf{x})$ when $R = 0$. Extending the theoretical framework of [3], we show that the non-local strain $\mathbf{S}^{NL}(\mathbf{x})$ can be exactly determined by applying a simple filter to the total strain $\mathbf{S}(\mathbf{x})$, resulting in a very efficient numerical implementation than an explicit computation of the Biot-Savart integral.

Fig. 2a shows the relative amplitude of non-local strain, $\langle|\mathbf{S}^{NL}|^2\rangle/\langle|\mathbf{S}|^2\rangle$, as a function of R at two different R_λ. The relative contribution of $\mathbf{S}^{NL}$ appears to depend only on R/η, (where η is the Kolmogorov length scale, regarded as the size of the smallest eddies), almost independently of R_λ. The local and non-local contribution become comparable for $R \approx 10\eta$. We further diagonalize $\mathbf{S}^{NL}$ into an orthonormal basis, with its eigenvalues given by λ_i, and sorted in decreasing order: $\lambda_1 \geq \lambda_2 \geq \lambda_3$, with $\lambda_1 + \lambda_2 + \lambda_3 = 0$ due to incompressibility; the corresponding eigenvectors are denoted as $\mathbf{e}_i$. Fig. 2a also shows that the ratio between the variances of the eigenvalues of $\mathbf{S}^{NL}$ and those of $\mathbf{S}$ remarkably follows the same decay with R as the strain magnitudes, again without any appreciable dependence on R_λ.



(a) (b) (c)

Figure 2: (a) Relative magnitude of non-local strain and its eigenvalues as a function of R/η (where η is the Kolmogorov length scale), normalized by their respective values corresponding to total strain; (b) Alignment of vorticity with the eigenvectors of the $\mathbf{S}^{NL}(\mathbf{x})$, as a function of R/η; (c) Enstrophy production term normalized by Kolmogorov time scale τ_K as a function of R/η. The rate of production as a function of R (shown in inset), peaks at $\approx 10\eta$. In all plots, solid lines correspond to $R_\lambda = 650$ and dashed lines correspond to $R_\lambda = 140$.

The alignment between $\mathbf{e}_\omega$ $(= \boldsymbol{\omega}/|\boldsymbol{\omega}|)$ and the eigenvectors of $\mathbf{S}^{NL}$, can be characterized by the cosines $\langle(\mathbf{e}_i \cdot \mathbf{e}_\omega)^2\rangle$ (which by definition, add up to unity), and is shown in Fig. 2b as a function of R. Vorticity preferentially aligns with the intermediate strain eigenvector for $R = 0$ ($\mathbf{S}^{NL} = \mathbf{S}$), consistent with know results [4], and with the most extensive eigendirection of $\mathbf{S}^{NL}$ when R exceeds $\approx 10\eta$, consistent with [5]. Finally, the dependence of vortex stretching by $\mathbf{S}^{NL}$, normalized by τ_K^3, and shown as a function of R/η in Fig. 2c, shows an inflexion at $R \approx 10\eta$. Fig. 2 therefore reveals a qualitative change of the properties of $\mathbf{S}^{NL}$ with scale, occurring around $R/\eta \simeq 10$. To summarize, the results presented in Fig. 2 point to a length of about 10η that characterizes the region where non-local effects are important.

CONCLUSIONS

We have documented here the feasibility of decomposing the strain $\mathbf{S}$ as a sum of a local, $\mathbf{S}^L$, plus a non-local contribution, $\mathbf{S}^{NL}$ in a systematic and efficient manner. The preliminary results reveal the existence of a characteristic length scale, $\ell_S \approx 10\eta$, for which the local and non-local contributions are equal. When $R \gtrsim \ell_S$ (respectively $R \lesssim \ell_S$), vorticity aligns with eigenvector corresponding to the most extensive (respectively intermediate) eigenvalue of $\mathbf{S}^{NL}$. Extending the analysis presented here by conditioning on strain or vorticity magnitude will provide new insights on the (local and non-local) mechanism(s) of production of very large gradients in turbulent flows – as we will further discuss in the presentation at the Congress.

We gratefully acknowledge the Gauss Centre for Supercomputing (GCS) for providing the necessary computing time for this work on the GCS Supercomputers JUQUEEN and JUWELS at Jülich Supercomputing Centre (JSC).

PASSIVE SCALAR TRANSPORT IN ROTATING COUETTE FLOWS

Geert Brethouwer*[1]
[1]FLOW, Engineering Mechanics, KTH, Stockholm, Sweden

Summary The transport of a passive scalar in rotating plane Couette and Taylor-Couette flow is investigated by DNS. In non-rotating Couette flows the passive scalar transport and (angular) momentum transport are similar, in accordance with the Reynolds analogy. However, if Couette flow is subject to anti-cyclonic system rotation passive scalar transport can be much faster than (angular) momentum transport. The Reynolds analogy can thus be broken if a Coriolis force induced by system rotation is imposed on the flow.

INTRODUCTION

Reynolds [1] postulated almost one and a half century ago that turbulence transports heat and momentum at a similar rate in shear flows. Experiments and numerical simulations have confirmed that this analogy applies to heat and mass transfer in many shear flows. This concept has been very valuable for turbulence modelling and deriving relations between the skin friction and heat or mass transfer in wall-bounded flows. The Reynolds analogy can be physically motivated and is suggested by the similarity between the governing equations for the streamwise velocity and e.g. temperature or concentration. However, the latter similarity is absent if a body force acts on the flow, therefore, the Reynolds analogy applies less obviously to transport processes in flows subject to e.g. buoyancy or Coriolis forces. Indeed, turbulent Prandtl numbers much smaller than unity have been observed in DNS of mixed convection in turbulent channel flow [2] and in turbulent channel flow subject to spanwise system rotation [3, 4]. Also in recent theoretical studies it has been shown that a body force can alter transport processes and make the transport of a passive scalar much faster than the transport of momentum in channel and plane Couette flows [5, 6]. This result is interesting because it implies that it is perhaps possible to make heat and mass transport more efficient and reduce the power consumption by applying a body force in engineering applications with heat and mass transfer. However, the body force was arbitrary in the aforementioned theoretical studies. Consequently, it is not obvious how this body force can be generated and how efficient transport can be realized in practice. The purpose of the present study is to demonstrate that rotation significantly affects the transport of a passive scalar in Couette flows and can make the scalar transport much more efficient in real flows.

DIRECT NUMERICAL SIMULATIONS

To investigate the effect of rotation on transport in Couette flows, I have carried out DNS of incompressible plane Couette flow (PCF) and Taylor-Couette flow (TCF) with a passive scalar. From now on the passive scalar is called temperature for convenience, but note that there are no buoyancy forces. The PCF system rotates about the spanwise direction whereas the TCF system rotates about the axial direction. The governing equations for TCF are solved in cylindrical coordinates using a similar setup as in [7], and the ratio of the radius of the inner and outer cylinder $\eta = r_i/r_o = 0.71$. PCF can be viewed as the limit $\eta \to 1$ of TCF. The velocity at the no-slip and isothermal inner and outer wall is $\pm U_w$, respectively, while the temperature at the inner and outer wall is $\pm T_w$, respectively. The momentum and heat transport are thus driven by a velocity and temperature difference between the plane or cylindrical walls. The Reynolds number is now defined as $Re = \Delta U d/\nu$ and the rotation number as $Ro = 2\Omega d/\Delta U$, where $\Delta U = 2U_w$ is the velocity difference and d the gap width between the walls, ν viscosity and Ω the rotation rate. In PCF the Prandtl number $Pr = 1$ whereas in TCF $Pr = 0.7$. To study the effect of rotation on the transport, I have carried out DNS at a constant Re and varying Ro. I have repeated this procedure at several Re, from low values of Re up to $Re = 40\,000$.

RESULTS

In the statistically stationary state the mean transverse (angular) momentum flux J^m and mean heat flux J^h through a unit area (PCF) or cylindrical shell (TCF) are constant. To quantify the (angular) momentum and heat transport the Nusselt numbers $Nu_m = J^m/J^m_{lam}$ and $Nu_h = J^h/J^m_{lam}$, respectively, are used. Here, J^m_{lam} and J^h_{lam} are the (angular) momentum and heat flux, respectively, when the flow is fully laminar.

PCF and TCF are very suitable systems to study the influence of rotation on momentum and heat transport because the momentum and heat transport are forced in the same way, i.e. by a velocity and temperature difference between the walls. Figure 1(a) and (c) shows Nu_m and Nu_h, respectively, for PCF at $Re = 400$, 1600, 6400, 17 200 and 40 000 as function of Ro while Fig.1.(b) and (d) shows Nu_m and Nu_h, respectively, for TCF at $Re = 400$, 2593, 8750, 19 688 and 40 000 as function of Ro. In both PCF and TCF $Ro > 0$ corresponds to anti-cyclonic rotation whereas $Ro < 0$ corresponds to cyclonic rotation. Fig. 1 shows that both Nu_m and Nu_h increase with Re, as expected, but also change if the rotation rate, i.e. Ro, changes. Starting from $Ro = 0$, i.e. no rotation, the (angular) momentum transfer and, accordingly, Nu_m at first increases with Ro and reaches a maximum at approximately $Ro = 0.2$ in PCF and between $Ro = 0.1$ and 0.3 in TCF.

*E-mail: geert@mech.kth.se

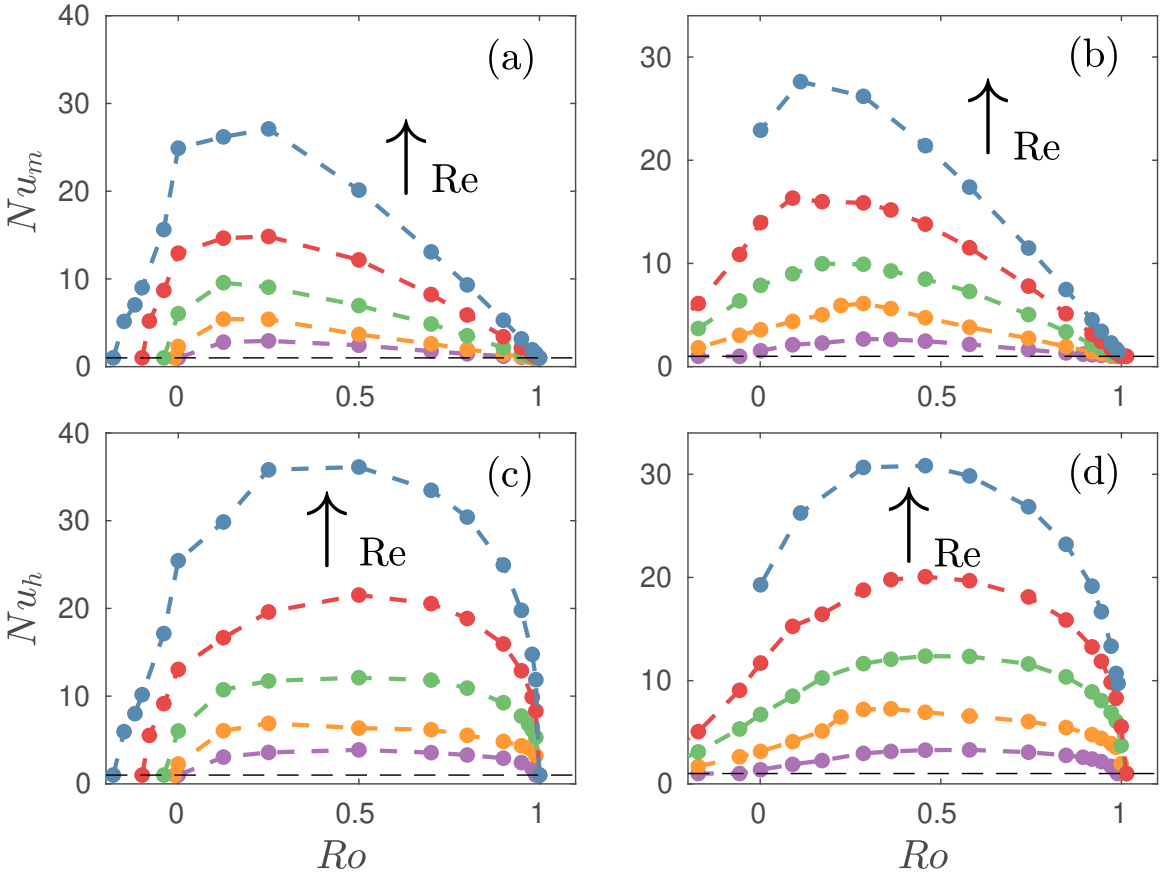

Figure 1: (a) Nu_m and (c) Nu_h for PCF. (b) Nu_m and (d) Nu_h for TCF. Each line/colour represents a different constant Re and dots denote simulation results. Arrows show trends for increasing Re.

Thereafter Nu_m declines and approaches unity when $Ro \to 1$ and the flow becomes laminar. When $Ro \gtrsim 1$ Couette flows are linearly stable and turbulence cannot be sustained. These results for the (angular) momentum transfer are consistent with e.g. the DNS of [7, 8]. At low Re Couette flows are steady and contain large streamwise vortices but at high Re both PCF and TCF are turbulent. The heat transfer expressed in terms of Nu_h is similar to Nu_m at $Ro = 0$ and $Ro < 0$ in PCF and TCF, which implies that the Reynolds analogy is approximately valid for non-rotating and cyclonic rotating Couette systems. However, if $Ro > 0$ and the rotation is anti-cyclonic Nu_m and Nu_h start to differ. The maximum of Nu_h is higher and occurs at a higher $Ro \approx 0.5$ in both PCF and TCF. When Ro further increases the ratio Nu_h/Nu_m increases until Ro approaches unity and both Nu_m and Nu_h become one because the flows becomes laminar. This means that the heat transfer becomes increasingly fast compared to the (angular) momentum transfer until about $Ro = 0.8$ to 0.99, which implies that rapid anti-cyclonic rotation induces a strong violation of the Reynolds analogy in PCF and TCF. At these Ro the mean temperature profiles deviate clearly from the mean streamwise or azimuthal velocity profiles (not shown here). Further analysis reveals that at high Ro the Coriolis force strongly suppresses the streamwise or azimuthal velocity fluctuations and this leads to weak momentum transport. However, Taylor vortices or turbulent eddies are still present and are able to effectively transport the heat across the flow from one wall to the other.

To summarize, anti-cyclonic rotation can lead to a strong violation of the Reynolds analogy between heat and (angular) momentum transfer in Couette flows and can make the heat transport very efficient compared to (angular) momentum transfer. Care should therefore by exercised when modelling heat and mass transfer in flows affected by body forces like the Coriolis force because the Reynolds analogy is not necessarily valid.

FROM ISOTROPIC TURBULENCE TO TRANSITION IN PLANE CHANNEL FLOW

Wouter Bos*[1], Faouzi Laadhari[1], and Wesley Agoua[1]
[1]CNRS, LMFA, Ecole Centrale de Lyon, UCBL, INSA Lyon, Univ Lyon

Summary In plane Poiseuille flow, somewhat beyond a critical value of the Reynolds number, laminar flow co-exists with turbulent stripes. We transpose modeling concepts, which were derived for the case of statistically isotropic turbulence, to this case. Thereby it is shown that the kinetic energy balance around the onset of turbulent flow in plane channel flow can be described by a simple model-equation. We first validate our ideas in the isotropic setting using direct numerical simulation (DNS) and two-point closure technique. Subsequently we assess the ideas applied to channel flow using high resolution DNS.

INTRODUCTION

Transitional shear flows and the modeling of isotropic turbulence are two seemingly different research subjects. Recently, however, it was realized that isotropic turbulence and the laminar-turbulent transition in wall-bounded shear flows share certain features [1]. For instance, it was shown that relaminarization, a feature generally associated with shear flows, such as flow through pipes driven by a pressure gradient, can also be observed in statistically isotropic periodic box turbulence. In the present investigation we first investigate the transitional dynamics of isotropic turbulence. In particular, we will show that in the case of linear forcing a critical Reynolds number exists above which a turbulent flow can be sustained.

ISOTROPIC TURBULENCE

The global kinetic energy of a closed or periodic turbulent flow is fully determined by the production (p) and dissipation (ϵ) mechanisms. Its volume-averaged balance is simply given by the equation

$$\frac{dk}{dt} = p - \epsilon. \tag{1}$$

We consider the Navier-Stokes equations to which we add a linear forcing term [2],

$$\frac{D\boldsymbol{u}}{Dt} = -\boldsymbol{\Pi} + \nu\Delta\boldsymbol{u} + \alpha\boldsymbol{u}. \tag{2}$$

with $\boldsymbol{u}$ the velocity, $\boldsymbol{\Pi}$ the density-normalized pressure gradient and ν the kinematic viscosity. The parameter α determines the strength of the linear forcing. This system allows the exact determination of the energy injection as a function of the kinetic energy. Using an in-depth analysis of triadic closure and comparison with DNS we refine and assess an existing model for the dissipation as a function of the kinetic energy. We show that the analytical solutions to the modeled equation describe accurately the asymptotic behavior of the Reynolds number dependence of the kinetic energy near the onset [3]. Results of this study are shown in figure 1.

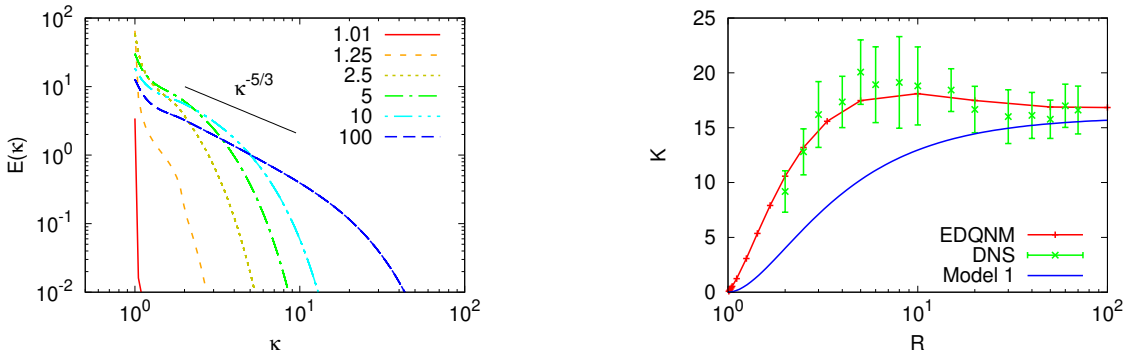

Figure 1: DNS and closure analysis of the linearly forced Navier-Stokes equations allow to assess a simple model for the kinetic energy in steady states above a critical value of the Reynolds number. Left: closure results for energy spectra for forcing-rate-based Reynolds numbers $R = \alpha L^2/\nu = [1.01 : 100]$. Right: kinetic energy as a function of R. A basic model of the dissipation rate leads to an under-prediction of the kinetic energy. We improve the model [3].

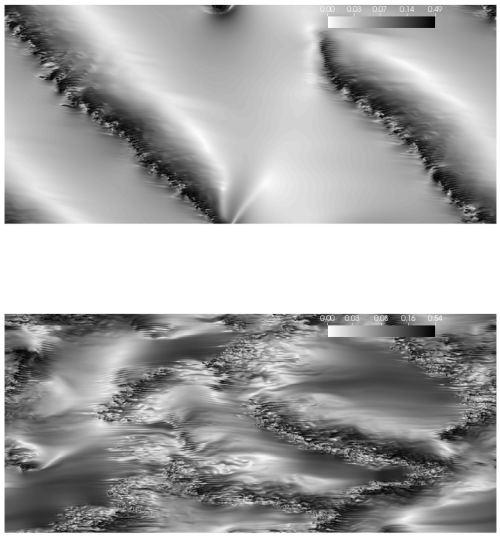

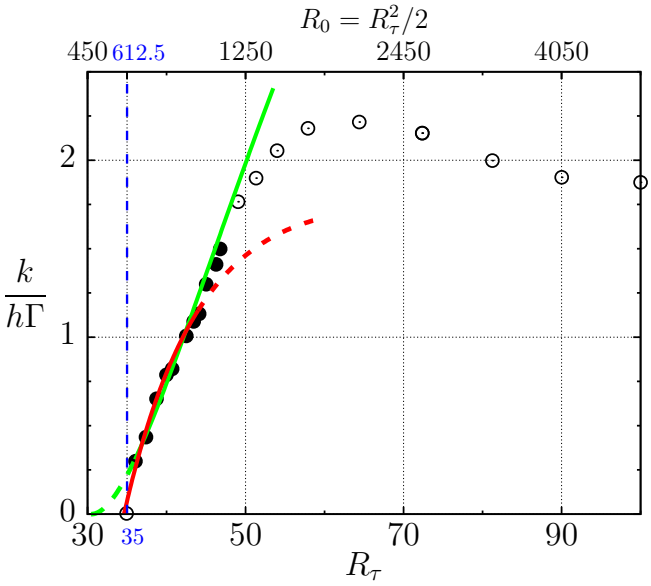

Figure 2: Left: DNS results of velocity-fluctuations in the center-plane of plane Poiseuille flow. The mean flow is directed from left to right. Right: kinetic energy as a function of the Reynolds number $R_\tau = \Gamma^{1/2}h^{3/2}/\nu$. Two distinct models (lines) are compared to the data.

PLANE POISEUILLE FLOW

Subsequently we transpose the ideas to the case of plane Poiseuille flow, i.e. flow between two parallel walls driven by a mean pressure gradient. In this case the evolution of the system is also given by equations (1) and (2), but the forcing of the system is now not determined by the linear forcing term ($\alpha = 0$) but by the imposed pressure gradient which we will call $-\Gamma$. Using the same type of model as for the isotropic case, we can obtain a closed expression for the kinetic energy as a function of the Reynolds number. We checked our ideas by means of a series of 25 pseudo-spectral simulations in a domain of size $L_x \times L_y \times L_z = 350h \times 2h \times 155h$ with periodic boundary conditions in the streamwise (x), and spanwise (y) directions. The domain is discretized using approximately 7×10^8 grid-points. Steady state values were obtained by decreasing stepwisely the Reynolds number starting from a turbulent initial condition.

In Figure 2 (left), we show the RMS velocity fluctuations in the centerplane between the two walls for a Reynolds number close to the critical value below which the flow relaminarizes and a Reynolds number somewhat larger. Coexistence of laminar and turbulent regions is observed in the flow, in particular for the lowest value of the Reynolds number. In Figure 2(b), we show the prediction of our simple models for the kinetic energy as a function of the Reynolds number and good agreement is observed with the numerical results.

CONCLUSIONS

It is shown that the behaviour of the turbulent kinetic energy in both isotropic turbulence and plane Poiseuille flow, near the critical Reynolds number above which turbulence can be sustained, can be described by a simple model equation. What is still to be explored is how the results depend exactly on the size of the domain, and how the shape of the turbulent production term can be derived from the Navier-Stokes equations. Furthermore, in future work we want to assess our ideas in different systems which show subcritical transition, such as plane Couette flow.

ASSIMILATION & CLASSIFICATION OF TURBULENCE DATA: PHYSICS-INFORMED AND MACHINE LEARNING TOOLS

L. Biferale[1], F. Bonaccorso[1], M. Buzzicotti[1]and P. Clark di Leoni[2]
[1]Dept. Physics and INFN University of Rome Tor Vergata, Italy
[2]Dept. Mechanical Engineering, Johns Hopkins University, Baltimore, USA

We provide a side-by-side comparison of modern techniques to assimilate, classify and control turbulent data by using equation-based tools, as Nudging, or big-data Machine Learning approaches. We discuss applications to rotating turbulence and fully developed isotropic turbulence. Both Eulerian and Lagrangian cases will be discussed, including optimal navigation problems [1-4].

INTRODUCTION

Measuring, reconstructing, and then predicting the evolution of turbulent flows are highly important tasks for fundamental and applied goals. A key example is given by the problem of state estimation in geophysics, important for numerical weather prediction. The chaotic and complex nature of turbulence makes these tasks very difficult, as any small error in the initial conditions will make predictions impossible on the long run, and as it is impossible to access all active modes in the flow. This is particularly worrying when we consider that in a turbulent flow the number of active degrees of freedom (dof) grows with the Reynolds number as $Re^{9/4}$. Data assimilation (DA) is the family of tools used to reconstruct the states of a dynamical system, out of a series of partial and noisy data, in order to improve future predictions. The key questions that need to be answered are: what is the quality and quantity of information that we need to provide to ensure a perfect (or optimal) data reconstructions? In other words, where, when and what we need to measure to exploit the maximum information from the field data? In this paper we will compare two modern and popular tools to attack this problem. One based on an equation-informed protocol, known as Nudging. The second is a Machine-Learning approach, where (many) partial data are supplied to a machine (a Neural Network) to train the output to reproduce as faithfully as possible the missing data. The final goal is to set-up a series of optimal Eulerian and Lagrangian protocols to reconstruct and control turbulent flows, as well as to learn how to navigate and design optimal measuring campaign in flows of geophysical interest [1-4].

NUDGING

Nudging is a general data-driven algorithm to learn from sparse measurements in a dynamical way and with a broad range of applications. The idea is to use the Navier-Stokes equations with a Newton relaxation feedback term, which imposes a linear reward/penalisation depending if the evolved velocity and/or temperature fields are close/far from the data to be assimilated [1-2]. In our Eulerian and Lagrangian implementation (see Fig. 1 right panel), the Nudging control terms are defined on fixed spatial positions (Eulerian) or along the trajectory, $\mathbf{X}(t)$, of tracer probes passively advected by the flow. In applications triggered from the field, data are affected by errors and one does not know the precise intensity and properties of the forcing mechanisms. As a result, it is key to perform an optimisation of the nudging coefficient (e.g., varying its intensity depending on the space/time probes position and on the quality of the local data). In our presentation, we will show the first application of Nudging to highly turbulent flows, both isotropic and anisotropic (rotating turbulence) providing a systematic assessment of reconstruction performance as a function of the quantity and quality (Eulerian/Largangian/Fourier) of data provided. Transition to full synchronization (perfect reconstruction) will be also studied.

ADVERSARIAL NEURAL NETWORKS

Machine Learning (ML) approaches provide key solutions to many different problems, especially when the goal is to extract significant information out of a large amount of data without control on the equations of motion. In the recent years, ML has been applied to problems related to flow control and modelling, demonstrating a good ability in gathering information about the chaotic and multi-scale evolution of turbulent fields [5]. In this work, we investigate the potential of the generative adversarial neural networks (GANN) to (i) identify the main features of turbulent flows (e.g. intensity of rotation, kinematic viscosity, temperature boundary conditions etc…) and (ii) reconstruct field data satisfying all the features extracted from the supplied partial measurements [6].
The GANN framework, consists in the competition of two different models, the generative model (G) that is trained to reproduce the data distributions of the training dataset and the discriminative model (D) that simultaneously learns to estimate the probability that a given input comes from the training dataset or that it is produced by the generative model. In this way, following an adversarial process the model G aims to maximize the probability of D to be mistaken. The optimal solution in the space of arbitrary G and D is for G to reconstruct exactly the full training data distribution and for D being always 1/2. Following this idea, we compare the GANN performances with the ones of Nudging in the reconstruction of the velocity field. In particular, we focus on the case of turbulent flows on a rotating reference frame,

as for the case of geophysical flows. We perform a quantitative analysis, comparing spectral properties and small-scale statistics involving gradients' distributions.

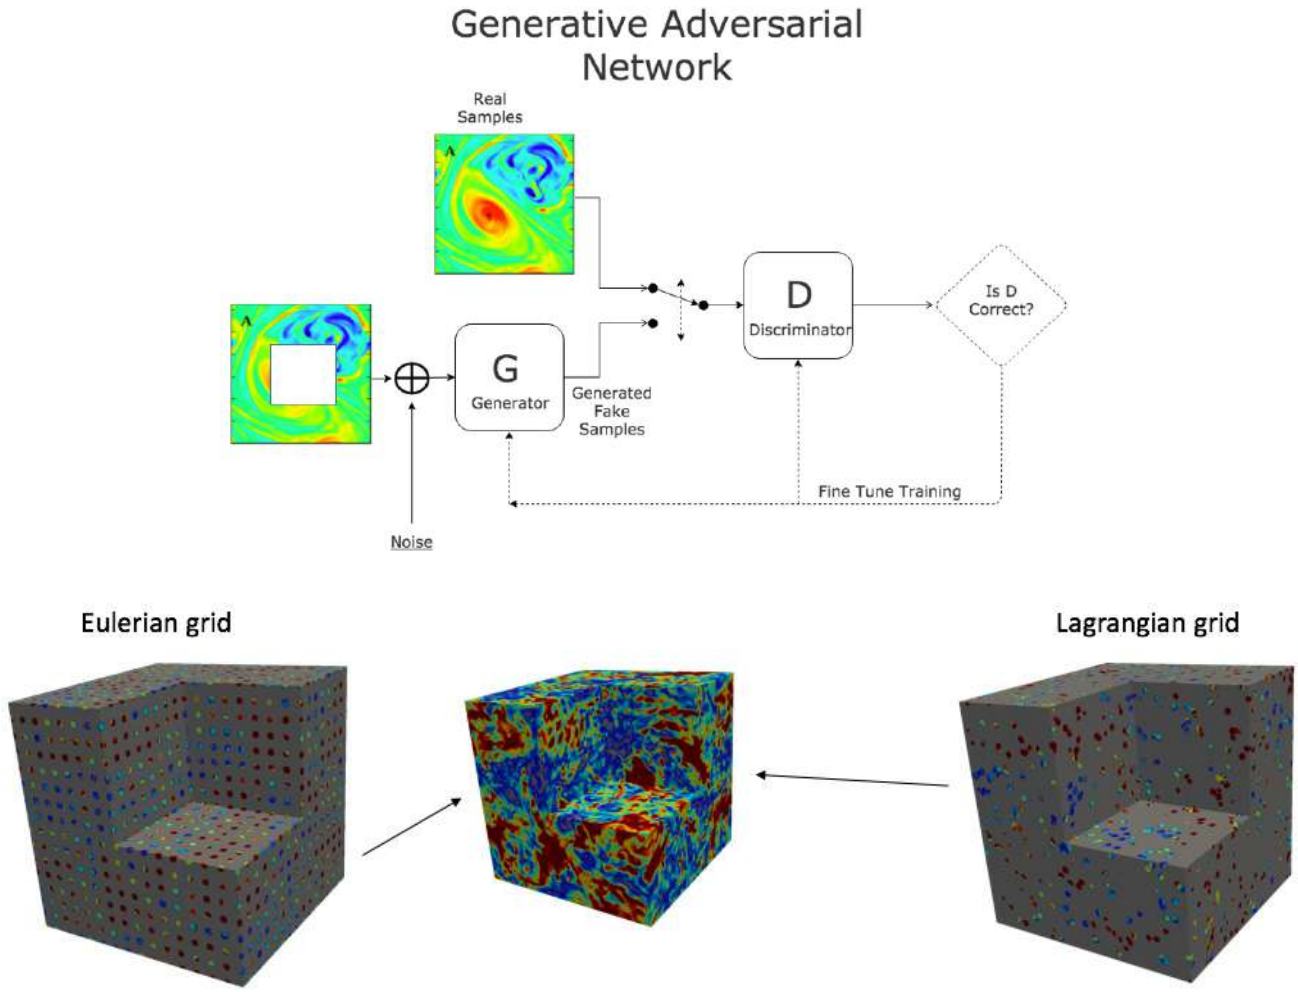

Figure 1. Top: schematic of the GANN approach for data assimilation of 2d turbulent snapshots. The aim is to fill the (squared) gap in the supplied data set. Bottom: data assimilation using Nudging [2], where two different data-sets (from partial Eulerian or Lagrangian measurements) are supplied to the Navier-Stokes equations to reconstruct the flow in the whole volume.

CONCLUSIONS

We present a quantitative comparison among physics-informed data-assimilation tools, based on Nudging techniques [1-2], and ML approaches without imposing any prior knowledge on the equations of motion [6]. We discuss pluses and minuses of both techniques and potential application to flow control using either Eulerian or Lagrangian actuators. The latter problem being also connected to optimal swimming/navigation in complex flows [3-4].

Summary We address the question as to whether turbulence contains vortex knots in a context which is simpler that ordinary fluids: superfluid helium. Unlike what happens in ordinary Navier-Stokes fluids where vorticity is a continuous field, in superfluid helium quantum mechanics constraints the vorticity to individual vortex lines, aiding the characterization of knots in terms of Alexander polynomials. Numerical simulations confirm that superfluid turbulence is indeed knotted.

INTRODUCTION

The controlled generation of vortex knots in the laboratory [1] motivates this work on knots in turbulent flows. Numerically, turbulent field lines display a high degree of spatial disorder, and appear to be coiled, twisted, even knotted. Our aim is to explore direct ways to quantify this complexity beyond existing measures such as helicity [2], $\mathcal{H} = \int_V \boldsymbol{\omega}(\mathbf{r})\cdot\mathbf{v}(\mathbf{r})d^3\mathbf{r}$, where $\mathbf{v}$, $\boldsymbol{\omega} = \nabla \times \mathbf{v}$, $\mathbf{r}$ and V are respectively the velocity field, the vorticity, the position and the volume of fluid. In the case of thin vortex tubes, $\mathcal{H}$ can be interpreted in terms of writhe, link and twist of the tubes [3], combining geometrical and topological information. Here we seek a measure which is directly related to the knottiness of the vortex lines. In principle, this requires precise identification of instantaneous vortex lines from the numerical solution of the incompressible Navier-Stokes equation; however, starting from the initial position, numerical noise across regions of large and small vorticity may prevent the traced vortex line from joining with itself, forming a closed loop as required by $\nabla \cdot \boldsymbol{\omega} = 0$.

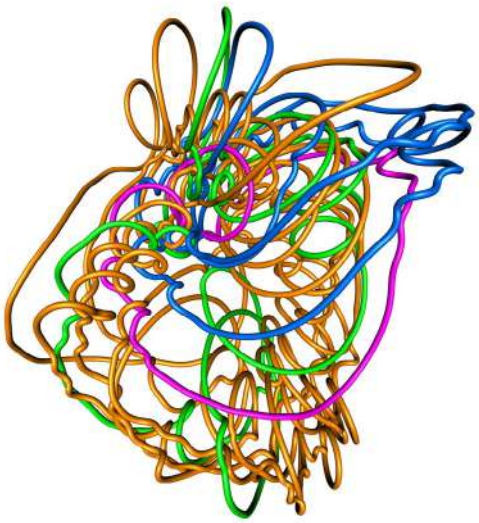

Figure 1: Snapshot of numerically computed turbulent tangle of vortex lines. For clarity, a tubular region of arbitrary radius has been drawn around the axis of each vortex line; the colours distinguish the different vortex loops.

Fortunately there is a fluid, superfluid helium, in which the vorticity is not an unconstrained continuous field, but is concentrated in discrete, physically distinct vortex lines, hence the identification of vortex lines is not a problem (indeed individual vortex lines and their reconnections have been experimentally visualized [4]). Superfluid helium is created in the laboratory by cooling liquid helium to temperatures below the critical temperature for Bose-Einstein condensation, $T_c = 2.17$ K at saturated vapour pressure. For $T < T_c$, a macroscopic fraction of the atoms form a condensate (which, for simplicity, we identify with the superfluid); the remaining thermal atoms form the so-called normal fluid, whose density drops rapidly as T is lowered. The key property [5] of a superfluid vortex line is that its circulation κ takes the fixed value $\kappa = h/m \approx 10^{-7}$ m^2/s where h is Planck's constant and m is the mass of one atom. This property is a consequence of the existence and the uniqueness of a macroscopic wavefunction $\Psi(\mathbf{r})$ governing the system. Physically, a vortex line is a small tubular region of radius $a_0 \approx 10^{-10}$ m around the vortex axis (defined by $\Psi = 0$); the azimuthal velocity around the axis corresponds to the phase of Ψ which changes from 0 to 2π.

Superfluid turbulence, easily generated by mechanical or thermal stirring, consists of a disordered tangle of vortex lines which interact and reconnect when they collide. Because of the discrete nature of vortex lines, this is an ideal context to study the knottiness of turbulence. Additional interest arises from the fact that superfluid turbulence satisfies key properties of ordinary turbulence, for example the same Kolmogorov energy spectrum. Thus what we learn about the knottiness of superfluid turbulence is probably relevant to ordinary turbulence too.

MODEL

In most helium experiments, the average distance between vortex lines, $\ell \approx 10^{-4}$ to 10^{-2} m, is orders of magnitude larger than the vortex core radius a_0, hence vortex lines can be modelled as space curves $\mathbf{s}(\xi, t)$ (where ξ is arclength and t is time) which move according to the classical Euler equation. We are interested in experiments in which the vortex tangle is generated in the centre of the helium sample away from boundaries; in this way all vortex lines form closed loops, which simplifies the analysis. Each vortex line is advected by all other vortex lines (Helmholtz Theorem), and, at $T \neq 0$, interacts with the normal fluid, gaining or losing energy depending on the relative difference between the local normal fluid and superfluid velocities (an effect akin to a positive or negative friction). The governing equation of motion is [6]

$$\frac{d\mathbf{s}}{dt} = \mathbf{v}_s(\mathbf{s}, t) + \alpha \mathbf{s}' \times \mathbf{w}(\mathbf{s}, t) - \alpha' \mathbf{s}' \times [\mathbf{s}' \times \mathbf{w}(\mathbf{s}, t)], \tag{1}$$

where α and α' are small temperature-dependent friction coefficients, $\mathbf{w}(\mathbf{s}, t) = \mathbf{v}_n(\mathbf{s}, t) - \mathbf{v}_s(\mathbf{s}, t)$, $\mathbf{v}_n(\mathbf{s}, t)$ is the normal fluid's velocity, $\mathbf{s}' = d\mathbf{s}/d\xi$ is the unit tangent vector to the vortex line at $\mathbf{s}$, and

$$\mathbf{v}_s(\mathbf{s}, t) = -\frac{\kappa}{4\pi} \int_{\mathcal{L}} \frac{(\mathbf{s} - \mathbf{r}) \times d\mathbf{r}}{|\mathbf{s} - \mathbf{r}|^3}, \tag{2}$$

is the velocity induced by the entire vortex configuration at $\mathbf{s}$. The Biot-Savart integral (2) is desingularised in a standard way based on the core a_0 cutoff. Vortex reconnections are performed algorithmically when vortex lines collide [6, 7].

RESULTS

All numerical simulations start with few seeding random vortex lines driven by a prescribed, time-dependent, solenoidal normal fluid velocity $\mathbf{v}_n(\mathbf{r}, t)$ which is concentrated in a spherical region of radius D. After an initial transient, the vortex tangle settles down to a steady regime in which vortex length Λ and energy E fluctuate around average values which is independent of the initial condition, as driving and dissipation balance out; a snapshot of the vortex tangle in this regime is shown in Fig. (1). Small vortex loops which move away from this spherical region shrink and vanish due to friction in the quiescent normal fluid. We verify that in this regime the energy spectrum obeys the classical Kolmogorov $k^{-5/3}$ scaling (where k is the wavenumber) in the inertial range $2\pi/D < k < 2\pi/\ell$.

To characterize the knottiness of the turbulence, we compute the Alexander polynomial $\Delta(\tau) = c_0 + c_1\tau + \cdots + c_\nu\tau^\nu$ of each vortex loop. A vortex ring has Alexander polynomial of degree $\nu = 0$, a trefoil knot has degree $\nu = 2$, etc; the higher ν, the more complex the knot type [8].

We find [9] that although vortex reconnections keep breaking up long vortex loops, long loops are also continually created; therefore, at each time, the vortex tangle always contains some long, highly knotted vortex loops, with degree of Alexander polynomial ranging from $\nu \approx 10$ to 100 depending on the intensity of the drive. The probability that a vortex loop is knotted increases (and then saturates to unity) with the length of the loop, as found for macromolecules [10]. Finally, we find that the probability of finding a knot with degree ν in the turbulent vortex tangle scales as $P(\nu) \sim \nu^{-3/2}$, independently of the tangle's total vortex length.

CONCLUSIONS

We have demonstrated that superfluid turbulence is knotted, indeed it contains long vortex loops with high degree of Alexander polynomial. This rich topology has a physical meaning, because vortex reconnections (which create the knots in the first place) are associated with energy losses by phonon emission [11]. The natural question is whether these findings also apply to ordinary Navier-Stokes turbulence.

EVOLUTION OF THE DENSITY GRADIENTS IN BUOYANCY-DRIVEN HOMOGENEOUS VARIABLE-DENSITY TURBULENCE

Denis Aslangil*[1,2], Daniel Livescu[1], and Arindam Banerjee[2]
[1]Los Alamos National Laboratory, Los Alamos, NM, USA
[2]Department of Mechanical Engineering and Mechanics, Lehigh University, Bethlehem, PA, USA

Summary Evolution of the density gradients in buoyancy-driven homogeneous variable-density turbulence (HVDT) is studied using high-resolution direct numerical simulations (DNS) data on 2048^3 triply periodic domain size. Turbulent mixing is generated as two incompressible, miscible fluids with different densities, initially at rest and segregated in large random regions, are subjected to acceleration. Mixing is enhanced by the conversion of the potential energy to the turbulent kinetic energy which leads to an increase in density gradients during the flow evolution. We investigate the suitability of the Boussinesq approximation and validity of the incompressible assumption in variable-density (VD) turbulence for both low density ratio (1.1:1) and high density ratio (7:1) cases, as the density gradients increase due to turbulence.

INTRODUCTION

Variable-density (VD) turbulence is of fundamental research interest due to its frequent occurrence in atmospheric and oceanic flows, astrophysics, combustion, and high density energy processes such as inertial confinement fusion [1-4]. DNS studies using a triply periodic configuration of HVDT remove the edge and boundary effects from the flow and allow investigations of the VD turbulent mixing process in the core of the mixing layer [1,2,4-6]. In most engineering models, a Boussinesq kind of assumption is widely used to model density effects; the density variations are neglected except for the buoyancy term in the Navier-Stokes equations (NS). In this study, we examine the suitability of the Boussinesq approximation and the possibility that the density gradients blow up in finite time due to stirring by turbulence.

Governing Equations

The variable-density version of the non-dimensional incompressible Navier-Stokes Equations can be written as [1,4]:

$$\rho^*_{,t} + (\rho^* u^*_j)_{,j} = 0, \tag{1}$$

$$(\rho^* u^*_i)_{,t} + (\rho^* u^*_i u^*_j)_{,j} = -p^*_{,i} + \tau^*_{ij,j} + \frac{1}{Fr^2}\rho^* g_i, \tag{2}$$

where ρ^* is the instantaneous density, u^*_i is the instantaneous velocity in i direction, p^* is the instantaneous pressure term and $\tau^*_{ij,j}$ is the Newtonian stress term where $\tau^*_{ij} = (\rho^*/Re_0)(u^*_{i,j} + u^*_{j,i} - (2/3)u^*_{k,k}\delta_{ij})$, and $g_i = (-1, 0, 0)$ is the gravitational force applied to the flow. In addition, due to the mixing process, the velocity divergence is not zero and is equal to:

$$u^*_{j,j} = -\frac{1}{Re_0 Sc_0} ln\rho^*_{,jj}. \tag{3}$$

The non-dimensional numbers that appear in equations 1, 2 and 3 are the computational Reynolds number, $Re_0 = \rho_0 L_0 U_0/\mu_0$, Schmidt number, $Sc = \mu_0/\rho_0 D_0$, and Froude number, $Fr^2 = U_0^2/gL_0$; where, $\mu_0/(= \mu^*/rho^*)$ is the reference dynamic viscosity, ρ_0 is the mean density, and D_0 is the diffusion coefficient.

Computational Setup

In this study, low density ratio (1.1:1) and high density ratio (7:1) cases are compared to study the influence of the density ratio on the evolution of the density gradients in HVDT. The mean density values are ≈ 1.05 and 4, and Re_0 is equal to 20000 and 3125 respectively for the low and high density ratio cases. Details of the simulations and more information on the initializing procedure can be found in [4-6]. VD NS equations (1) and (2) are solved with periodic boundary conditions and the divergence condition (3) using the CFDNS code [1,2] developed at LANL. The spatial derivatives are evaluated using Fourier transforms and the time advancement is performed with the variable time step third order Adams-Bashforth-Moulton scheme, coupled with a fractional time method.

RESULTS

In HVDT, when the acceleration is applied to the triply periodic domain, pure light and heavy fluids start to move in opposite directions due to differential buoyancy forces. These motions generate turbulence within the flow, which in turn enhances molecular mixing between the fluids. As the pure fluids become molecularly mixed, the buoyancy production weakens and at some instance turbulence dissipation overcomes turbulence production. Hence, buoyancy driven HVDT covers birth, growth, and decay of VD turbulence. This dynamic behavior allows us to connect acceleration driven Rayleigh-Taylor and shock driven Richtmyer-Meshkov instabilities as well as VD mixing layers and jet flows to the different phases of the idealized HVDT flow evolution (more information can be found in [4,6]). Here, we focus on the evolution of the density gradients in HVDT.

*Corresponding author. E-mail: denis.aslangil@gmail.com.

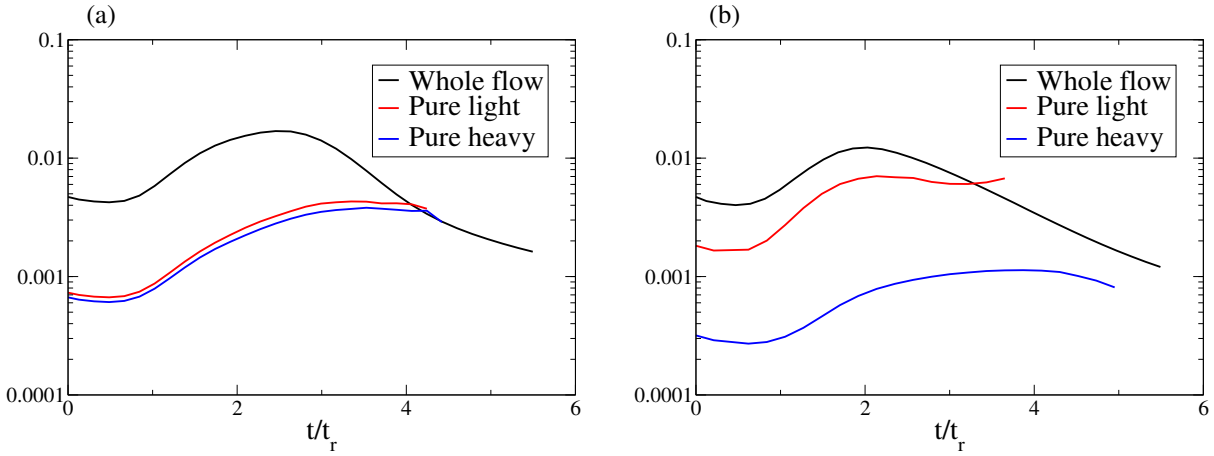

Figure 1: The evolution of the normalized Euclidean norm of the density gradients ($\Omega_{2,\nabla\theta}$) for a) low density ratio (1.1:1) and b) large density ratio (7:1) cases. The black line represents the volume average of the $\Omega_{2,\nabla\theta}$, red and blue lines represent the conditional average of the $\Omega_{2,\nabla\theta}$ for the pure light and pure heavy fluids, respectively.

Non-Boussinesq Effects

In the Boussinesq approximation, density appears in the momentum equation only in the buoyancy term. The usual underlying assumption is that the density fluctuations are much smaller than the mean and can be neglected in the rest of the terms of the momentum equations. However, even when the density fluctuations are small, density field can still have large gradients that could invalidate the Boussinesq approximation [1]. The evolution of the normalized Euclidean norm of the density gradients [$\Omega_{2,\nabla\theta} = (\int_V (\nabla(ln(\rho^*)/\theta_0)^2 dV)^{1/2}$, where θ_0 is the maximum resolved density gradient in DNS] is shown for both low and high density ratios in figure 1. The results indicate that, unlike density fluctuations that continuously decrease during the flow evolution, density gradients are not bounded by the initial conditions. This lack of non-linear depletion of the density gradients suggests that non-Boussinesq approximation may not be valid even for the low density-ratio mixing flows when the turbulence levels become high. Moreover, for the high density ratio case, the evolution of the conditional expectations of the density gradients is significantly different within the pure fluid regions. This indicates that the flow properties can locally be very different than what volume averaged statistics suggest [4] and any conclusion on the validity of Boussinesq approximation relying on the global statistics may be incorrect.

To further examine the evolution of the density gradients, the terms in the transport equations for the L^{2m}-norms of density gradient are bounded from above by simple expressions. The methodology was first used for the low density ratio (1.1:1) case by Rao et al.(2017) [7]. Here, we extend the study to the large density ratio (7:1) case. In addition, we change the normalization for a more meaningful comparison of the norms at late times and replace some of the bounds by tighter expressions. Similar to Rao et al.(2017), the results show that the analysis cannot exclude the possibility of finite time blow-up of the density gradients at sufficiently high Reynolds number, as the fluids are accelerated by differential buoyancy forces. On the other hand, at high Atwood numbers, the larger turbulence intensity in the light fluid regions also leads to much larger density gradients in these regions compared to the rest of the flow. Thus, if a blow-up does occur, it is in the light fluid regions. Of course, such an event would invalidate not only the Boussinesq approximation, but also the incompressibility assumption used to derive the VD euqations.

ALTERNATION OF VERY LARGE SCALE FEATURES IN A TURBULENT CHANNEL FLOW

Yuya Tanada[1], Yuta Akasaka[2], and Masaharu Matsubara *[3]
[1,2,3]Department of Mechanical System Engineering, Shinshu University, 4-17-1, Wakasato, Nagano, Japan

Summary It has been experimentally observed that in turbulent channel flows very large scale features(VLSF), whose scales are ten times larger than the channel width, appear at very low and very high Reynolds numbers, though it is unknown if both Reynolds numbers are classified as the same because there is no scrutiny between them. In the present study, we explore the Reynolds number range existing the VLSFs and their streamwise and spanwise length scales with increasing the Reynolds number up to 10000 (based on the mean velocity and the channel width) in the experiments with the cross spectra of the streamwise velocity fluctuations measured by hot-wire sensors separating in the spanwise direction. Between Reynolds numbers, 3400 and 5000, the VLSF of a wide spanwise scale alters into narrow structure keeping their streamwise length. The narrow VLSF is confirmed up to Reynolds number 10000 and the streamwise and spanwise length scales are in the same order of that Monty et al. (J. Fluid Mech. 289, pp. 147–156, 2007) found in a channel flow.

INTRODUCTION

In the current decade, large-scale turbulent patterns in wall-bounded shear flows have been noticed. Liu et al. [1] performed proper orthogonal decomposition (POD) for two-dimensional particle image velocimetry measurements in a turbulent channel flow at $Re_h = 5378, 29935$ (defined by the bulk velocity and the half channel width), and they demonstrated that modes of the streamwise large-scale in order of the channel width has high contribution to the total kinetic energy. Monty et al. [2] discovered a low-speed region of streamwise length scales larger than ten pipe radii or channel widths in turbulent pipe and channel flows at very high Reynolds number, and they called it 'very large-scale feature' (VLSF). Seki et al [3] observed a low-frequency peak which is very close to the frequency of the turbulent patch appearance in premultiplied frequency spectra of the streamwise velocity fluctuation at $Re = 2660$ (defined by the bulk velocity and the channel width) at which the flow is turbulent with the intermittency factor reaching unity. This peak suggested the existence of the VLSF. Horii et al. [4] conducted similar experiments to theirs using two-channel flow facilities and showed that the spectral peak of the VLSF at low Reynolds number was observed independently of the apparatus and they confirm the peak up to $Re = 4000$. They also performed flow visualization in a water channel facility and observed inclined regions filled with kinked streaks whose streamwise length corresponds to that of the spectral peak.

Though the roles of the VLSFs to a channel flow are not obvious, it is clear that VLSF gives a contribution to the statics such as the spectra of the streamwise velocity. Furthermore, since the VLSFs were observed at only both very-low and very-high Reynolds numbers it is not clear whether these are the same or not. In order to investigate the VLSFs at moderate Reynolds numbers and their streamwise and spanwise length scales, we measure the two-point correlations of the streamwise velocities by hot-wire anemometry with increasing Reynolds number from the upper marginal Reynolds number at which the channel flow sustains a fully turbulent state.

RESULTS AND DISCUSSION

In the present experiment, the channel facility is the same as the larger facility used by Horii et al. [4]. The channel width d is 25 mm. The streamwise and spanwise dimensions of the channel part are about 14 m and 1 m, respectively. The coordinates are defined as x and y in the streamwise and wall-normal directions. Hot-wire anemometry is used for the streamwise velocity measurements. The measurements are conducted at the channel center with a sampling frequency of 20 kHz, and a sampling time of 600 s. The two-point correlations of the streamwise velocity fluctuations are obtained with fixing one hot-wire sensor and moving the other hot-wire in the spanwise direction. All length scales here are normalized by the channel width d.

Figure 1 shows the color maps of the cross-correlation coefficient at $Re = U_b d/\nu = 3400$, 5000 and 10000, where U_b is the bulk velocity and ν is the kinematic viscosity. ΔZ is the non-dimensional distance between the hot-wire sensors and λ_x is the non-dimensional streamwise scale estimated in Taylor's frozen-flow hypothesis with the velocity spectra. Blue shows a negative cross-correlation coefficient and red is positive. It can be estimated that the ΔZ at which the correlation coefficient has a negative minimum is about half the spanwise length scale of the dominant structures. It is inferred that negative minimum regions around $\Delta Z = 0.7$, $\lambda_x = 3$ at all Reynolds numbers are caused by turbulent vortices because their streamwise length scale is in order of the magnitude of d.

At $Re = 3400$, a negative region distributes around $\Delta Z = 3.1$ and $\lambda_x = 20$ indicating the VLSF that has the streamwise and spanwise length scales of about $20d$ and 6, respectively. These sizes correspond to those of the VLSF observed by Seki et al. at $Re = 2660$. Furthermore, the length scales are very close to the scales of the large structure observed by Horii et al. [4]. It is considered that VLSF observed from this experiment is the same as the structure observed by Horii et al. [4] in their flow visualization, suggesting that this VLSF is a cluster of the streaky structures forming an inclined local band.

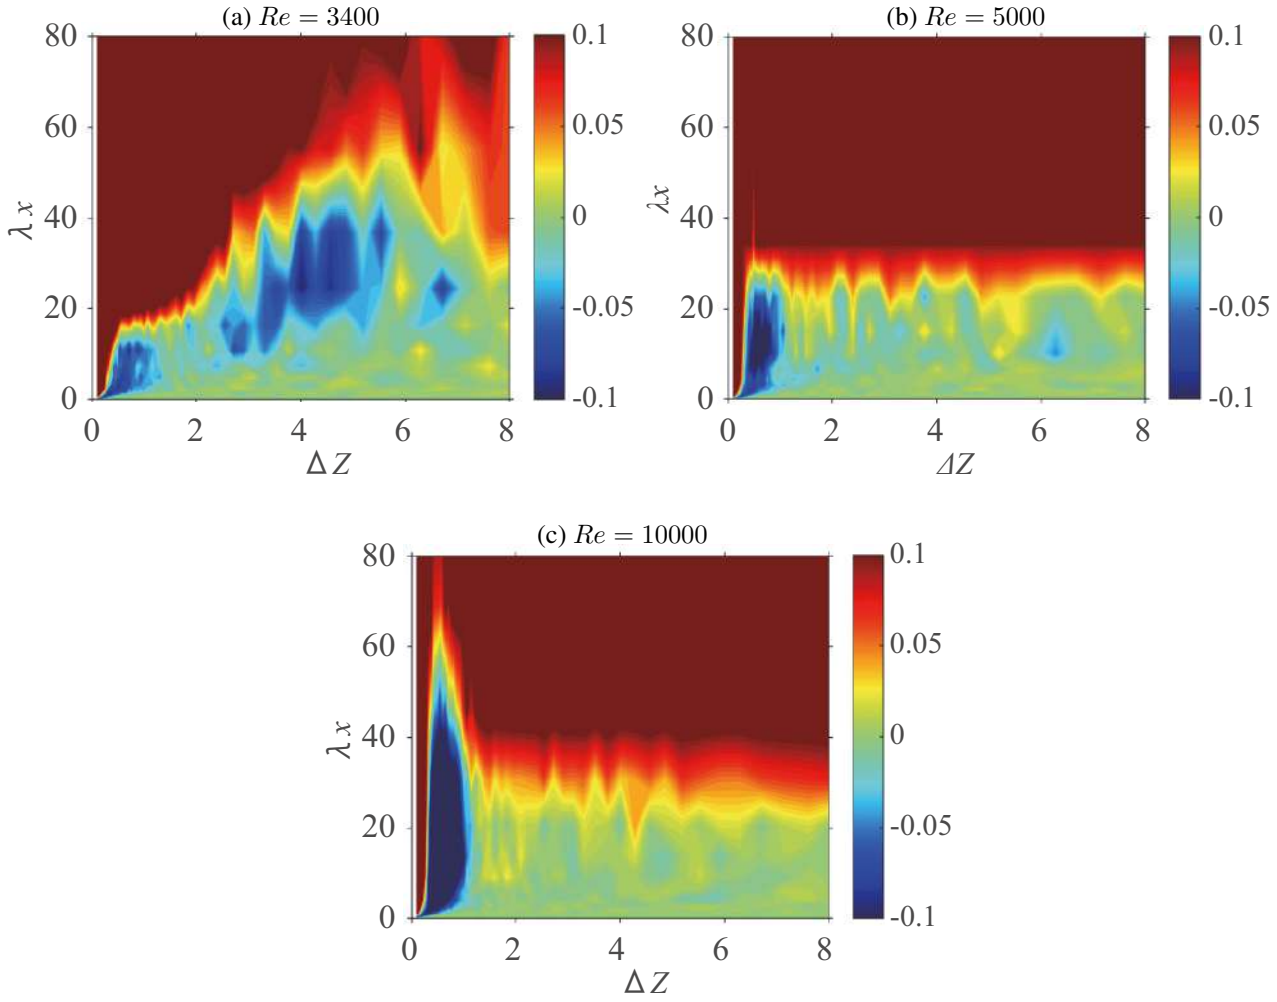

Figure 1: Color maps of the cross correlations of the streamwise velocities.

The negative peak at $Re = 5000$ in the region of $\Delta Z = 0.7$ and $\lambda_x = 10$-20 indicates another VLSF that has the spanwise length scale of $1.4d$ This spanwise length scale corresponds with that of the VLSF obtained by Monty et al. This negative region still exists at $Re = 10000$, though the streamwise length slightly elongates comparing with that at $Re = 5000$. Survey of the color maps with gradually increasing Re shows the drastic change of them around $Re = 4000$, indicating that the VLSF alters to the narrow VLSF. The observation at $Re = 10000$ and the investigation by Monty et al. suggest that the narrow VLSF is ubiquitous in a high Re channel flow.

THE ENERGY BUDGET AT THE OUTER PEAK OF $\overline{u^2}$ IN TURBULENT PIPE FLOW

Jonathan Morrison*and José Fernando Vicente
Department of Aeronautics, Imperial College London, London SW7 2AZ, UK.

Summary We use the NSTAP data from the Princeton superpipe [1] to examine the spatial & spectral energy fluxes close to the outer peak in $\overline{u^2}$ in the range of Reynolds numbers, $2.1 \times 10^6 \leq Re_D \leq 6.0 \times 10^6$, for which the ratio of hot-wire length to Kolmogorov length scale is $l/\eta \leq 10$. Previous results [2] suggest that the outer peak emerges at $Re_D \approx 1.1 \times 10^6$, its position exhibiting a locus $y_m^+ = 0.23(Re_\tau)^{0.67}$. We note that this is close to the position of the well-known "mesolayer", which we have also described as the intermediate layer with scaling ($y_m^+ \propto \sqrt{Re_\tau}, u_m$), where u_m is the rms velocity at $y = y_m$ – see [3, 4] and also the presentation in the minisymposium, "Modeling and Controlling Turbulent Shear Flows". It is straightforward to show that the locus of u_m is close to that for the production of $\overline{u^2}$, $P_m(\overline{u^2})$ where the local-equilibrium approximation holds. Therefore, spectral dynamics are most 'Kolmogorov-like' because spatial transport is small there. Here we examine the inertial scaling of the axial velocity spectra and low-order structure functions to help provide a rational basis for the concept of intermediate scaling.

INTRODUCTION

The logarithmic (log) variation of the streamwise mean velocity and variance in the inertial sublayer are two cornerstones in wall turbulence (Eq. 1):

$$U^+ = \frac{1}{\kappa}\ln(y^+) + C, \qquad \frac{\overline{u^2}}{u_\tau^2} = B_1 - A_1 \ln\left(\frac{y}{\delta}\right). \tag{1}$$

Here u_τ is the friction velocity, y is the wall-normal distance and $^+$ indicates scaling on wall variables. δ is the boundary-layer thickness for the turbulent boundary layer or, here, the pipe radius. κ and A_1 in Eq. (1) are the well-known von Kármán and Townsend-Perry [5] 'constants' respectively; C and B_1 are the additive 'constants'.

We have recently demonstrated [3, 4] the importance of a length scale for the intermediate region, $y_m^+ \propto \sqrt{Re_\tau}$ ($Re_\tau \equiv R^+ = u_\tau\delta/\nu$), which is the typical "mesolayer" scaling; the velocity scale is chosen to be the rms turbulence velocity at $y = y_m$. Using the intermediate length scale and velocity scale, we show that the mean-velocity defect and variance profiles achieve a Reynolds-number similarity in the intermediate region for both pipe and boundary-layer flow. This reveals a Reynolds-number invariant log region in wall turbulence, in terms of the intermediate variables. As a consequence, the classical log law is seen to emerge only at sufficiently large Reynolds numbers and the Townsend-Perry 'constant' shows a systematic Reynolds-number dependence and it is plausible that associated eddies scale on the intermediate variables which are local to the inertial sublayer. We have also discussed the consequences of this finding for the Reynolds-number behaviour of κ and A_1.

It is not immediately obvious why y_m should emerge as a natural length scale: in some sense, it is obvious simply through the identification of a maximum on which statistics close to it can be expected to scale. For a more physical reason however, we note that the three-layer asymptotic structure of pipe flow, made explicit by the use of intermediate scaling, suggests Reynolds-number independence for $Re_\tau \gtrsim 10^4$. We further note that previous results [2] suggest that the outer peak emerges with $Re_D \gtrsim 1.1 \times 10^6, Re_\tau \gtrsim 2 \times 10^4$. By extension, a simple dimensional analysis of the near-wall energy budget using wall scaling (u_τ, y) will reduce to the local-equilibrium approximation, for which spatial transport of turbulence kinetic energy is a small fraction of its (local) production and dissipation. We further suppose that, in this region, spectral flux is most 'Kolmogorov-like' because small spatial transport implies a relative absence of energy sources or sinks at each wavenumber. Here we use the turbulent pipe-flow data obtained in Princeton Superpipe using the NSTAP probe [1, 2] for $Re_\tau = 1985 - 98190$. Measurements were performed with NSTAP probes of length, $\ell = 30$ μm and 60 μm, with temporal resolution up to 300 kHz. The ratio of hot-wire length to Kolmogorov length scale is $l/\eta \leq 10$. Figure 1 shows the variance profiles scaled on wall units, the actual peak lying close to the intermediate length scale, $y_m^+ = 3.5\sqrt{Re_\tau}$ with the velocity scale $u_m = \sqrt{\overline{u^2}}(y = y_m)$ – see [3].

SCALING OF THE DISSIPATION RATE NEAR THE OUTER PEAK

We have previously examined [6] the inertial subrange scaling of the axial velocity component for the centreline of turbulent pipe flow for Reynolds numbers in the range $249 \leq Re_\lambda \leq 986$, where λ is the Taylor length scale: we noted that the dimensionless dissipation rate, $A = \epsilon R/u_\tau^3$, increases indefinitely with Reynolds number, in contrast to other similar measures [7]. Here, we extend the analysis to examine the scaling of the inertial subrange in the local-equilibrium region, $y/R = 0.052$. With the assumption of "wall" (u_τ, y) scaling, we expect the log-law and local-equilibrium regions to be approximately coincident. With the assumption of local-equilibrium, and using the momentum equation:

$$-\overline{uv}^+ = 1 - \frac{y}{R} - \frac{1}{\kappa y^+}, \qquad \epsilon^+ = (-\overline{uv}^+)/\kappa y^+. \tag{2}$$

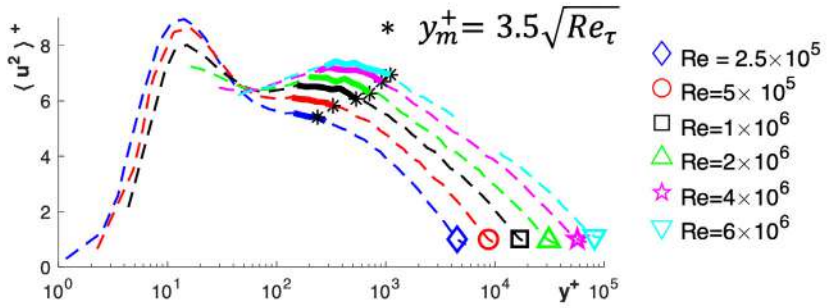

Figure 1: Streamwise variance, $\overline{u^2}^+$, $2.5 \times 10^5 \leq Re_D \leq 6.0 \times 10^6$, locus of actual peak given by $y_p^+ = 0.23 Re_\tau^{0.67}$ [2].

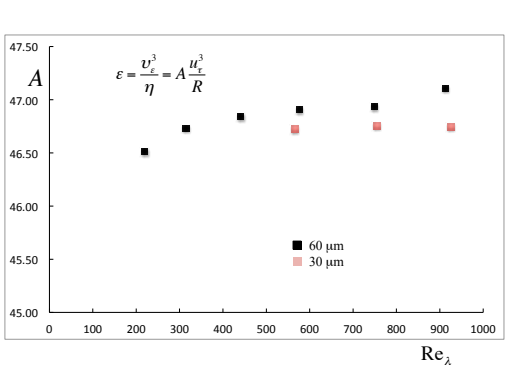
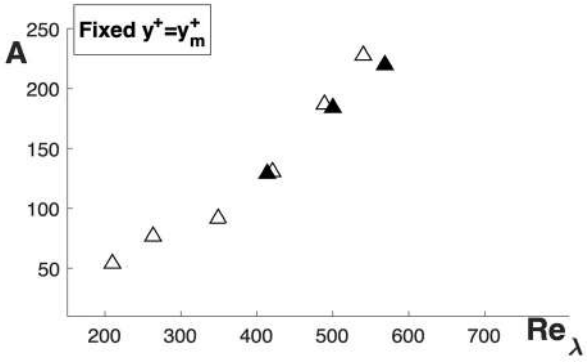


(a) Fixed y, $y^+ = 0.052 Re_\tau$



(b) Outer peak, $y_m^+ = 3.5\sqrt{Re_\tau}$. Open symbols, 60$\mu$m; closed 30$\mu$m.

Figure 2: Variation of $A = \epsilon R/u_\tau^3$ with Re_λ.

However, the spectral flux is much more spatially intermittent than either the production or dissipation spectra, and since the energy balance at any point in space is an integration over all wavenumbers, local equilibrium will only ever be an approximation. Figure 2a shows that A in the local-equilibrium region is closer to a constant value than at the centreline over a similar range of Re_λ, [6, 8]. This could be attributed to the fact that the turbulent transport in the local-equilibrium region is a somewhat smaller fraction of production and dissipation than at the centre line. With these assumptions, it is straightforward to show that $A = \epsilon^+ R^+$ and that by inspection of equation (2), A is more nearly constant at $y/R =$constant. Note also that $S = dU/dy$ nondimensionalised as $S^* = \sqrt{\epsilon/S^3}$ becomes $S^{*+} = \kappa y^+$, with the assumption of local equilibrium. With $A =$ constant therefore, the use of u_τ and R to non-dimensionalise ϵ here, suggests that the effect of the outer boundary conditions is represented by these scales, in conformity with the assumptions of local equilibrium.

Figure 2b shows the calculated variation of A following the locus of $y_m^+ = 3.5\sqrt{Re_\tau}$. To leading order, equation (2) may be written as $A = R^+/\kappa y^+$ which, with $y^+ = y_m^+$ gives $A/\sqrt{R^+} =$ constant. Noting that $\sqrt{R^+} \propto Re_\lambda$, figure 2b shows that this is indeed the case. The result is similar for y_p^+ [8]. At the outer peak therefore, we have $A = Re_\lambda \times$ constant. In the full paper, we shall discuss this result, and compare estimates of dissipation rates with locally-isotropic estimates available from integration of the one-dimensional dissipation spectra. We shall also examine the spectral and spatial distribution of energy by reference to scaled and premultiplied inertial subrange spectra as well as the second- and third-order structure functions.

CHARACTERISTICS OF GRID TURBULENCE IN THE FAR DOWNSTREAM REGION

Yulin Zheng*[1], Tomoaki Watanabe[1], and Koji Nagata[1]
[1]Department of Aerospace Engineering, Nagoya University, Nagoya, Aichi, Japan

Summary Characteristics of grid turbulence have been investigated in the far downstream region ($x/M \sim 10^3$: x is the downstream distance from the grid, M is the mesh size of the grid.) through the wind tunnel experiment. It can be concluded that the dissipation coefficient C_ε at large Re_λ (Re_λ is the Taylor microscale Renolds number, based on the r.m.s longitudinal velocity fluctuation $u_{\rm rms}$, the Taylor microscale λ, and the kinematic viscosity ν) tends to be constant and raises rapidly during the final of the transition period of decay. The construction of the vorticity $S + 2G/Re_\lambda$ (S is the skewness of the longitudinal velocity derivative, G is the destruction coefficient) rapidly increases with the streamwise distance in the far downstream region.

INTRODUCTION

Homogeneous isotropic turbulence (HIT) is probably the most fundamental turbulence which has been extensively investigated by theoretical studies, direct numerical simulation (DNS), and wind tunnel experiments[1, 2, 3]. Since grids with various geometries can generate quasi-HIT, they have been applied for the wind tunnel experiments for many decades. Although the development and the initial period of decay of grid turbulence have been analyzed experimentally and theoretically, few experiments have been conducted in the far downstream region to investigate the transition and final period of decay. In this study, the wind tunnel experiment was conducted to investigate the statistics from the initial to the transition period of decay till the far downstream, with the range of Re_λ = 5-114.

EXPERIMENT APPARATUS

The experiment was conducted in an open-type wind tunnel in Nagoya University. The test section has a width of 600 mm, a height of 600 mm and a length of 12 m. Three types of grids with difference mesh size M (Fig. 1) were used. The experiments were conducted 5 times at each point to reduce the statistical errors. The measurements were conducted up to 6 m from the entrance of the test section because of the growth of the boundary layer and secondary flow at the farther streamwise region. Experimental conditions are given in Table 1.

Constant Temperature Anemometer (CTA, DANTEC Streamline) with an I-type hot wire probe (DANTEC 55P11) was used to measure the instantaneous streamwise velocity. The sampling number and frequency are set to 524288 and 20 KHz aiming to acquire reliable derivative quantities. Low pass filter is used to remove the electronic noise.

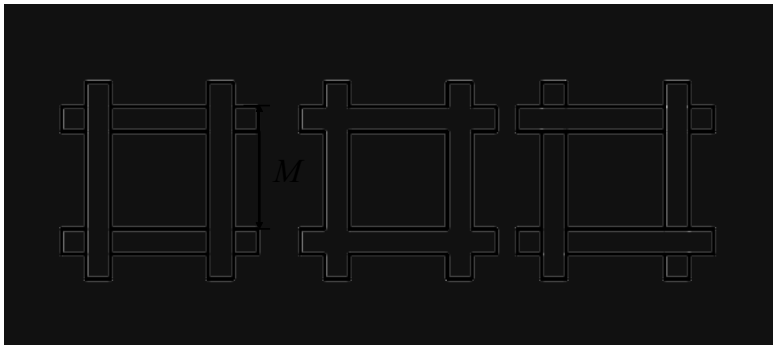

Figure 1: Sketch of (a) square grid of biplane, (b) square grid of single plane, and (c) woven-mesh grid

RESULTS

For HIT, the fundamental equations related to the dissipation rates of energy and enstrophy can be derived from the Karman-Howarth equation as Eq. (1) and Eq. (2)[1]:

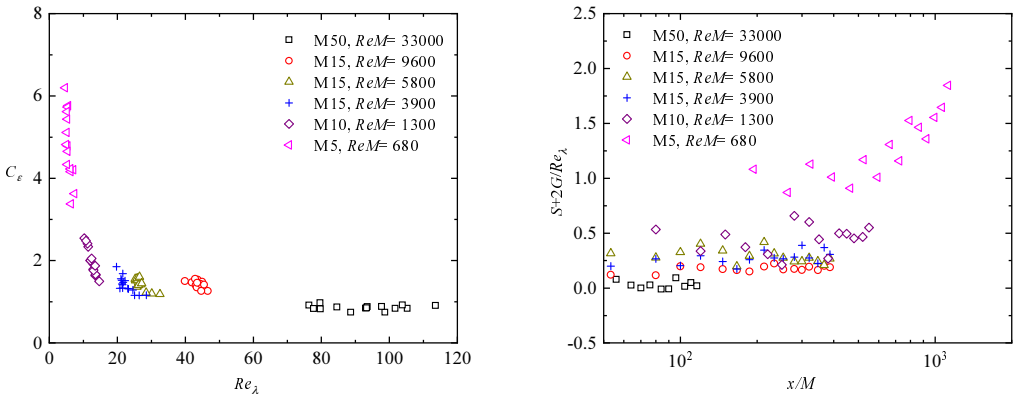
$$\varepsilon = -\frac{3}{2}\frac{{\rm d}{u_{\rm rms}}^2}{{\rm d}t} = \frac{C_\varepsilon u_{\rm rms}^3}{L_{uu}} \tag{1}$$

$$\frac{{\rm d}{\omega_{\rm rms}}^2}{{\rm d}t} = -\frac{7}{3\sqrt{5}}{\omega_{\rm rms}}^3 (S + 2G/Re_\lambda) \tag{2}$$

*E-mail: zheng.yulin@k.mbox.nagoya-u.ac.jp

Table 1: Experimental conditions

U_0 (m/s)	Re_M	M (mm)	Solidity σ	Shape
2	680	5 (M5)	0.39	woven-mesh
2	1300	10 (M10)	0.36	square (single-plane)
4	3900	15 (M15)	0.36	square (biplane)
6	5800	15 (M15)	0.36	square (biplane)
10	9600	15 (M15)	0.36	square (biplane)
10	33000	50 (M50)	0.36	square (biplane)



(a) (b)

Figure 2: (a) Relationship between C_ϵ and Re_λ. (b) Variation of $S + 2G/Re_\lambda$ with downstream.

$$S = \overline{\left(\frac{\partial u}{\partial x}\right)^3} \Big/ \left[\overline{\left(\frac{\partial u}{\partial x}\right)^2}\right]^{\frac{3}{2}}, G = {u_{\rm rms}}^2 \overline{\left(\frac{\partial^2 u}{\partial x^2}\right)^2} \Big/ \left[\overline{\left(\frac{\partial u}{\partial x}\right)^2}\right]^2 \tag{3}$$

Here, L_{uu} is the integral length scale, $\omega_{\rm rms}$ is the r.m.s of the vorticity fluctuations. S and G is defined by Eq. (3). From Eq. (1), it is of great significance to investigate the energy decay and the connection between large and small eddies. Thus, it is important to measure the dissipation coefficient C_ε ($C_\varepsilon = \varepsilon L_{uu}/u_{rms}^3$), which is associated with both the characteristics of large eddies and dissipation. The relationship between C_ε and Re_λ is shown in Fig. 2(a). For large Re_λ, $C_\varepsilon \approx 1$ can be seen clearly and this is consistent with the results of past experimental data[5]. Conversely, for small Re_λ, C_ε increases rapidly as Re_λ decreases. The variation of $S + 2G/Re_\lambda$ with the downstream distance from the grid is given in Fig. 2(b). It can be seen that $S + 2G/Re_\lambda$ grows with the downstream distance in the far downstream region only for M5, while the increasing trends of other cases do not appear apparently. This means that the balance between the production and destruction of the enstrophy has been broken down and that the process is under the domination of destruction in the far downstream region for the case M5.

CONCLUSIONS

Velocity measurements in grid turbulence were conducted in the far downstream region of $x/M \sim O(10^3)$ and $Re_\lambda \sim O(1)$. C_ε rapidly increases at the small Re_λ, and the construction of enstrophy ($S + 2G/Re_\lambda$) increases in the far downstream region.

SKIN-FRICTION DRAG REDUCTION EFFECT OF STREAMWISE LARGE-SCALE VORTEX GENERATED BY WALL HEATING AND COOLING IN TURBULENT PIPE FLOW

Koyo Tanaka[1], Hiroya Mamori [*1], and Takeshi Miyazaki [1]
[1]University of Electro-Communications, 1-5-1, Chofugaoka, Choufu, Tokyo, Japan

Summary Skin-friction drag reduction in wall-turbulence is of importance to reduce energy loss and many flow control techniques to obtain the drag reduction have been studied. It is known that streamwise large-scale vortical structure can decrease the skin-friction drag in the turbulent channel flow. In this study, we performed direct numerical simulations of the turbulent pipe flow controlled by the large-scale vortical structure to investigate its drag reduction effect. To generate the large-scale vortical structure, we impose temperature distribution to generate buoyancy force. A maximum drag reduction rate is 8.7% when two pairs of the large-scale vortices are generated. We found that the turbulent vortical structures are transported and affected by the motion of the large-scale vortical structure.

Background

Reduction of skin-friction drag is of importance in wall-turbulence. Streamwise vortical structures play important role to increase the skin-friction drag and various control techniques to decrease the vortical structures have been studied [1-3]. One of the control techniques, this study focuses on a large-scale control technique for the skin-friction drag reduction in the wall-turbulence.

Schoppa & Hussain[4] made direct numerical simulations (DNS) of turbulent channel flows with streamwise forced vortices. The forced vortices are generated by an imposed velocity distribution mimicking small jet flow from walls or assuming a vortex generator. They reported that the forced vortices decrease the wall-normal vorticity and the regeneration mechanism of the wall-turbulence is weakened. Thus, the skin-friction drag is reduced. Canton et al.[5] imposed an ideal body force distribution into the turbulent channel flow to generate the forced vortices and they confirmed 18% of the skin-friction drag reduction. Our research group, in contrast to the channel flow, has investigated the control effect in turbulent pipe flows, because the pipe flow is an important system in engineering, e.g., pipelines, and the number of forced vortices generated by control is limited due to curvature of pipe.

In this study, we make the DNS of the turbulent pipe flow with the forced vortex to investigate its skin-friction drag reduction effect. To induce the forced vortex, instead of the ideal velocity or body force distribution, we employed the buoyancy force generated by heating and cooling from the wall.

Direct numerical simulation

Figure 1 shows a pipe flow (together with the temperature distribution as discuss later). The length of the pipe was set to $10R$ where the radius R of the pipe is chosen as a reference length. A constant pressure gradient condition is imposed as the driving force of the flow. The friction Reynolds number Re_τ, defined by the friction velocity and R, is set to be 180. In addition, the reference temperature is denoted by T_{ref} in this paper.

A staggered computational grid in a cylindrical coordinate system is employed and the number of computational grid points is 64x128x128. The governing equations are incompressible continuity, Navier-Stokes, and energy equations. As boundary conditions, a non-slip condition is imposed on the wall and a periodic boundary condition is imposed in the streamwise direction. The DNS code is discretized by using a finite difference method[6].

A forced vortex is generated by buoyancy force which appears as a body force term in the Navier-Stokes equation. The buoyancy force using Boussinesq approximation reads,

$$F_b = Ri\Delta T \quad (1)$$

The buoyancy force F_b consists of the Richardson number $Ri = Gr / (\mathrm{Re}_\tau{}^2)$ (where Gr is the Grashof number) and ΔT (difference between the local temperature and the reference temperature). To induce the body force, we impose the wall temperature as the control input and it reads

$$T_{wall}(\theta) = -A\sin(\Omega_{wall}\theta) \quad (2)$$

The wall temperature varies in the azimuthal direction and homogeneous in the streamwise direction. The control parameters are the wave number Ω_{wall} and the amplitude A. In this study, the amplitude A is fixed at $A = 1$, which means the mean temperature averaged on the wall surface equals T_{ref}. To make parametric study, Ω_{wall} is varied from 2 to 4 with the Richardson number of 40, 80, 120, and 160.

Figure 1 also shows an example of the mean temperature distribution at the wavenumber of 3 and the Richardson number of 120, together with the mean velocity vectors. Due to the heating and cooling from the wall, the buoyancy force generates the upward flow (i.e., flow from the wall toward center of the pipe) at $\theta = 0$ and π and the downward flow at $\theta = \pi/2$ and $3/2\pi$. As a result, two pairs of forced streamwise vortices were generated in this case.

Simulation results

Figure 2 shows a drag reduction rate as a function of the Richardson number. The drag reduction rate R_D is defined as.

$$R_D = \frac{C_{f0} - C_f}{C_{f0}} \times 100 \quad (3)$$

Here, C_f is a friction coefficient and the subscript of zero indicates the uncontrolled flow. The skin-friction drag reduction is obtained ($R_D > 0$) for $\Omega_{wall} = 2$ and 3 and R_D is maximized ($R_D = 8.7$ [%]) at $\Omega_{wall} = 3$ and $Ri = 120$, whereas the drag increases for $\Omega_{wall} = 4$. We chose the maximum drag reduction case as a reference in the following.

Figure 3 shows turbulent vortical structures visualized by the second invariant value of the velocity deformation tensor at $Q^+ = 0.05$. The plus means wall units. In the uncontrolled case as shown in Fig. 3(a) and (c), the vortical structures are observed near the wall surface. On the other hand, in the reference case as shown in Fig. 3(b) and (d), the vortical structures are gathered around $\theta = 0$ and π. Due to upward flow induced by the buoyancy force the vortical structure is transported to the center of the pipe.

Conclusion and outlook

The skin-friction drag reduction effect by the forced vortex induced by the buoyancy force in the turbulent pipe flow is investigated by means of the direct numerical simulations. The buoyancy force is controlled by the temperature distribution on the pipe wall. The maximum drag reduction rate of 8.7 [%] was obtained at the wavenumber of 3 and the Richardson number of 120, in which two pairs of forced vortices were generated. The force vortices gather the turbulent vortical structures and they are transported toward the center of the pipe. In the presentation, we will discuss the mechanism of the drag reduction in detail.

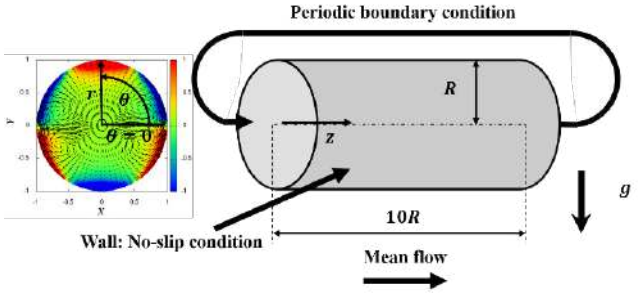

Figure 1. Computational domain.

EXPERIMENTAL STUDY ON MIXING AND ENTRAINMENT THROUGH ANISOTROPIC POROUS MEDIA DRIVEN BY A TURBULENT FLOW

Sofia Saoncella*[1], Aidan Rinehart[1], Agastya Parikh[1], Marcus Hultmark[2], and Shervin Bagheri[1]
[1]Department of Engineering Mechanics, KTH, Stockholm, Sweden
[2]Department of Mechanical and Aerospace Engineering, Princeton University, Princeton, USA

Summary This poster presents our current effort to investigate a turbulent flow over an anisotropic micro-structured porous bed. The objective is to characterize modifications in the overlying turbulent flow in terms of turbulent structures and friction drag and to describe quantitatively mixing, entrainment and diffusion of particles inside the porous bed. In particular, we want to understand the link between shear flow instabilities and the interstitial flow for different microscopic features of the porous medium. The work involves the building of water channel facility, the fabrication of a micro-structured surface and the measurement procedure through micro-PIV.

MOTIVATION

Fluid flows over porous media play a central role both in industrial applications as well as in natural settings (geological, environmental, etc). The conditions encountered in different applications are broad enough to cover a large range of Reynolds numbers, both for the overlying turbulent flow and the interstitial flow in the porous media. For example, Stokes flow in porous media may be encountered in ground water flows while turbulent flows are found in application such as heat exchangers or nuclear reactors. Despite their ubiquity, the relationship between the geometry of the porous material, porous size and shape, and the the turbulence over the porous bed is still not known in detail. The present experimental study aims to investigate the interaction between turbulent flows and porous surfaces. In particular, we will characterize surfaces with different geometries and configurations of micro-sized pores. A schematic representation of the configuration is shown in Fig. 1.

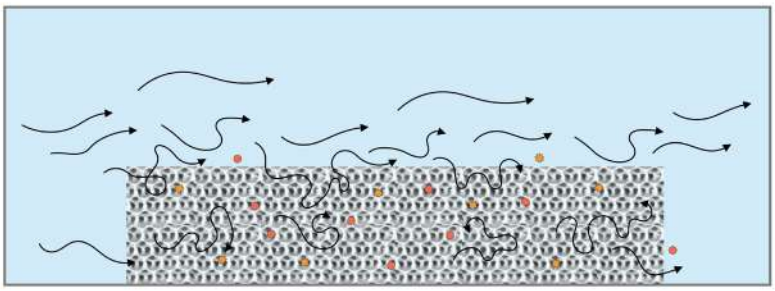

Figure 1: Schematics of the mixing and diffusion of particles induced by a flow over the porous medium. Black arrows indicates possible trajectories of the flow and consequently of the particles.

METHODS

The project involves the fabrication of a complex surface with interconnected and properly sized pores (ranging from 10 to $300\,\mu\mathrm{m}$), followed by the characterisation of its porosity, permeability and geometry and the final test inside a water channel facility. The water channel is being manufactured and designed to sustain flows with Reynolds number up to $Re_\delta \approx 5 \cdot 10^5$. To provide insight into the turbulent transport processes within the porous structure, particle image velocimetry technique at the micro scale (μPIV) will be used. A difficulty common to most optical diagnostic techniques that are applied to fluid-structure studies is the refraction of light passing through the material. This project will use refraction index matching of the liquid (NaI solution) and wall surface (PDMS) to minimize the distortion from the walls. This treatment will allow for measurements to be taken at the interface as well as within the porous structures. The channel has a cross section of $10\,\mathrm{mm} \times 200\,\mathrm{mm}$ and a length of $2160\,\mathrm{mm}$, of which $1440\,\mathrm{mm}$ are counted as the pre-test section development length. The facility has a design bulk flow velocity of $10\,\mathrm{m\,s^{-1}}$ in the test section, which yields a maximum friction Reynolds number $Re_\tau \approx 2.4 \cdot 10^3$. The test section has removable plugs to insert various surfaces as depicted in Fig. 2. The surfaces tested will cover an area of $10\,\mathrm{cm} \times 15\,\mathrm{cm}$ with a maximum of $1\,\mathrm{mm}$ height. Particular attention is dedicated to the choice of the materials which have to meet specific requirements such as; durability, robustness and easy optical access for the water channel. The complex surface must have low refractive index and manufacturing processes that are adaptable allowing for variety of complex surfaces. Several tests have been conduced in order to identify the most suitable and effective technique for surface fabrication. A promising protocol, used in other works (2), consists in the

*Corresponding author. E-mail: sofiasao@kth.se

creation of a sacrificial mold made of pressed white sugar grains which will be then impregnated with the liquid polymer. Once the polymer is cured, the sugar mould is dissolved in water and the structure of a porous scaffold will remain as solid PDMS.

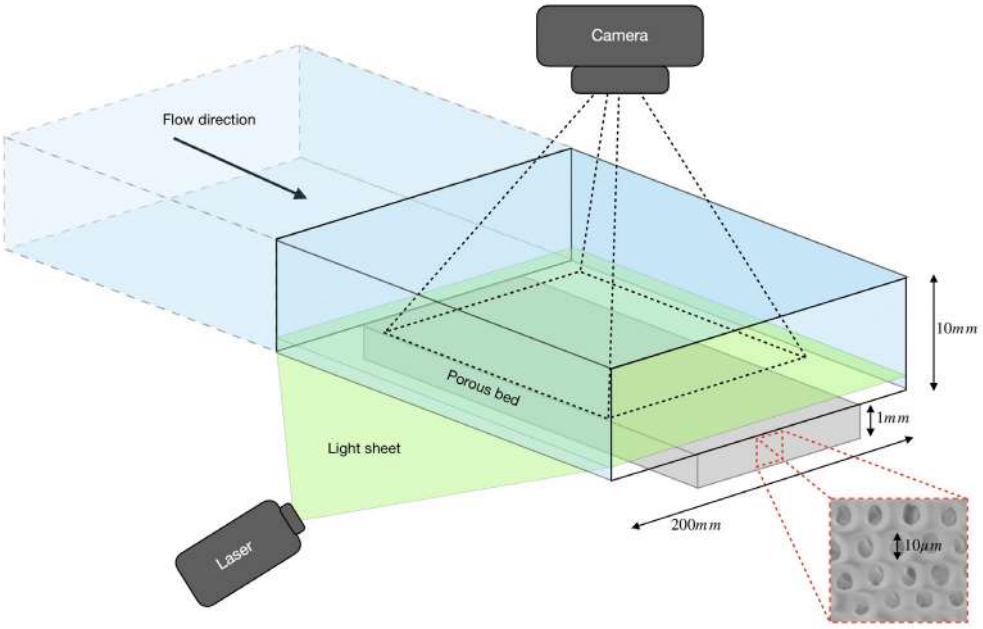

Figure 2: Representation of the water channel test section together with the main elements for the PIV acquisition system. In the sketch the dimensions of the relevant component are also indicated.

OUTLOOK

We will present our initial results of turbulent flow over index-matched porous surfaces. We seek to extend the prior research of turbulent flows over rough and porous surfaces (1) by providing greater detail of the physics near the interface as well as the internal porous flow. The ability to capture continuous flow data from the free fluid into the porous surface will provide greater understanding of the complex physics at the fluid surface interface. This research will increase our understanding of drag modification from porous surfaces. It will also elucidate the role and key parameters that control mixing and entrainment of particles inside the porous medium. These mechanisms are central in applications, such as the mixing and diffusion of marine soil nutrients in the environmental field and delivery of drugs into bone tissue in the biomedical field.

PARTICLE COLLISION STATISTICS IN MULTISCALE TURBULENT FLOW STRUCTURES

Yoshiki Sakurai*[1], Naoki Kobayashi [1], and Takashi Ishihara [2]
[1]Graduate School of Engineering, Nagoya University, Nagoya, Japan
[2]Graduate School of Environmental and Life Science, Okayama University, Okayama, Japan

Summary Collision statistics of inertial particles in multiscale vortical structures in high Reynolds number turbulence are studied using direct numerical simulation data of incompressible turbulence laden with the particles. It was shown recently by Picardo et al. that vortical regions contribute predominantly to slow side-on collisions compared to rapid head-on collisions in straining zones. In this paper, the statistics of the second invariant Q^* of velocity derivatives in coarse grained velocity field $\boldsymbol{u}^*$ at the positions of the inertial particles are studied. The data analysis shows that depending on a given coarse grained level, the PDF of Q^* at the positions of particles with a certain value of the Stokes number (St) is the most negatively skewed and also that the particles with that value of St have a tendency to collide at relatively low speeds when they are in negative Q^* regions.

INTRODUCTION

To elucidate the mechanisms of rain drop growth in cloud and planetesimal growth in protoplanetary disks, particle collision processes in high Reynolds number (Re) turbulence should be properly understood. Especially in the planetesimal formation, it is important to understand how the dust particles collide at low speeds because high-speed collision causes bouncing and fragmentation. Picardo et al. studied the correlation between particle collisions and flow structures in low Re turbulence, and showed that particles in vortical regions can collide at slower speeds than those in straining regions [1]. Recently, the method of data analysis using the eigenframe of the rate-of-strain tensor in turbulence [2] was applied to investigate the relationships between inertial particle clustering and multiscale vortical structures [3,4]. The results suggest that the distribution and the motion of inertial particles around high-vorticity regions defined in coarse-grained turbulent velocity fields have a self-similar property depending on particle inertia and coarse-graining level [4]. These results motivate us to study the relationships between particle collision statistics and coarse-grained turbulence structures. In this paper, we study the statistics of the second invariant Q^* of velocity derivatives in coarse grained velocity field at the positions of the inertial particles using a DNS dataset.

NUMERICAL SIMULATION AND ANALYSIS METHODS

In a study on the turbulent clustering [5], DNSs of incompressible homogeneous isotropic turbulence were performed using an alias-free spectral method and inertial particles were tracked in the time-dependent velocity fields in the DNSs. In this study, we use the datasets of turbulence with the number of grid points $N^3 = 2048^3$ and the Taylor microscale Reynolds number $R_\lambda \sim 730$. The values of the Stokes number (St), which is defined by the ratio of the relaxation time of the particle to the Kolmogorov time scale, are St=0, 0.1, 0.5, 1, 2, 5, 10, and 20, where St=0 corresponds to the fluid particles. For the detail of the computations, see [5] and references therein.

To characterise the multiscale structure of turbulence, we analyse the second invariant Q^* of the velocity derivatives in coarse grained velocity field $\boldsymbol{u}^*$ obtained by spectral low-pass filter. Here Q^* is given by $Q^*=(\Omega)^2-(S)^2$, where $S = (A + A^t)/2$, $\Omega = (A - A^t)/2$, and $A = \boldsymbol{\nabla u}^*$ so that $Q^*>0$ and $Q^*<0$ define the vortical regions and the straining regions, respectively, in the coarse grained field. The cut off wavenumber k_c for the coarse grained velocity $\boldsymbol{u}^*$ are set as $k_c/k_{\max}$ =1, 1/2, 1/4, 1/8, 1/16, and 1/32, where $k_{\max} = \sqrt{2}N/3$ is the maxmum wavenumber in the DNS and the unfiltered field is expressed as $k_c/k_{\max}$=1.

RESULTS

Figure 1 shows the probability density functions (PDFs) of Q^* for the turbulence field and at the particle positions. As shown in Ref [6], the PDFs are asymmetric and have St dependence. The PDF of Q^* at fluid particle positions is positively skewed and agrees well with that obtained for the turbulence field. The shape of the positive part of the PDFs of Q^* at the inertial particle positions strongly depends on the particles' inertia (St value) and the coarse-graining level (k_c). The result indicates small probability for particles with a certain St value (which depends on the value of k_c) to be found in high Q^* region. This may be well explained by considering that the particles with a certain St value are effectively ejected from the high Q^* (vortical) regions.

To quantify the St dependence of the PDFs plotted in Figure 1, we plot the skewness of the second invariant in Figure 2. Note that the positive/negative skewness of Q^* means that vorticity/strain is dominant at the positions of the inertial particles in the filtered field. Figure 2 shows that the value of the skewness is a function of St and k_c and that, for each value of k_c, the function takes the minimum at a certain St value. The fact that the St value that gives the minimum skewness is an increasing function of k_c is consistent with our previous result [4], that is, the particles with larger inertia are effectively and self-similarly ejected from coarser-grained high vorticity regions.

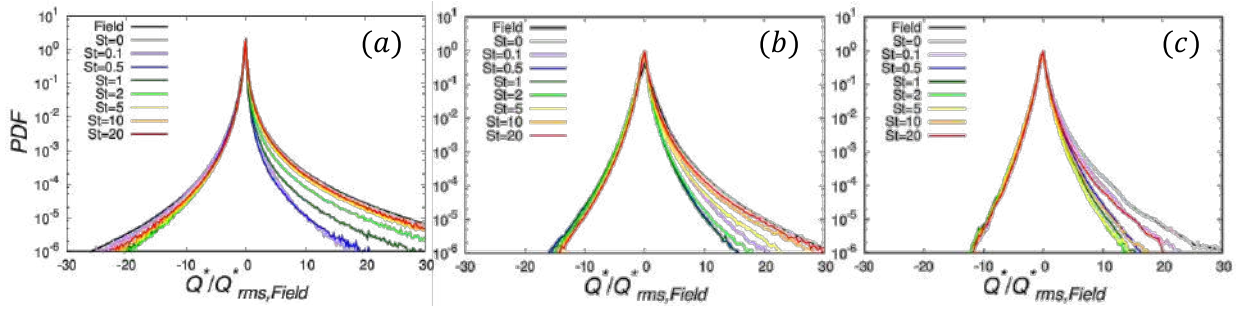

Figure 1. Probability density functions (PDFs) of Q^* for turbulence field and at particle positions. (a)$k_c = k_{\max}$, (b)$k_c = k_{\max}/8$, and (c)$k_c = k_{\max}/32$. The horizontal axis is normalized by the rms value of Q^* for the turbulent velocity field.

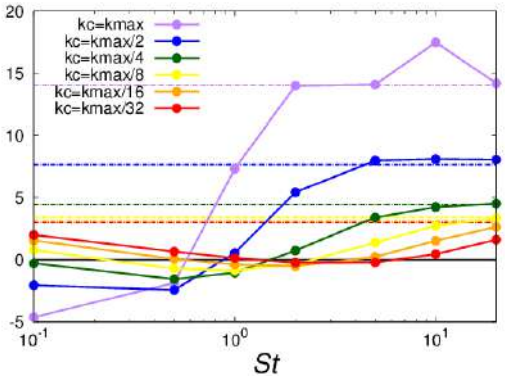

Figure 2. Skewness of the second invariant (Q^*) as a function of St. The dashed lines and solid line parallel to the horizontal axis represent the skewness of the turbulent field and zero skewness.

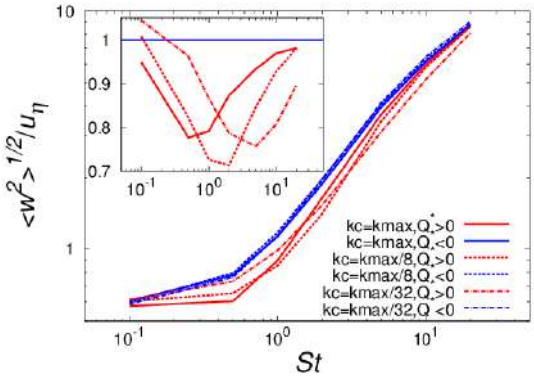

Figure 3. rms relative velocity of particles in vortical regions ($Q^* > 0$) and straining regions ($Q^* < 0$) as a function of St. The data are normalized by the Kolmogorov velocity u_η. Inset represents the ratio of rms relative velocity in vortical regions to that in straining regions.

As one of the particle collision statistics, relative velocities between particles at a distance of Kolmogorov-scale, conditionally averaged over two different zones are plotted separately in Fig. 3: one average was taken over the particles in vorticity dominant (Q*>0) zone and the other was taken over the particles in strain dominant (Q*<0) zone. The result for the case of $k_c = k_{\max}$ is consistent with that reported in [1], that is, the ratio of the average over the strain dominant region to that over the vorticity dominant region is the smallest when the value of St is approximately 0.5. Figure 3 shows that for the cases of $k_c = k_{\max}/8$ and $k_{\max}/32$, the ratios are the smallest at the different values of St: $St = 2$ for $k_c = k_{\max}/8$ and $St = 5$ for $k_c = k_{\max}/32$. Note that this correspondence between the values of St and k_c agrees well with the correspondence between the St value that gives the minimum skewness of Q* and the k_c value that determines the coarse grained level. In the cases of the smallest ratio, the rms relative velocity in vortical zone is 20-30% lower than that in straining zone. The results indicate that depending on the values of St, particle collisions at relatively slow speeds may occur in the vorticity dominant (Q*>0) zone of the corresponding coarse-grained level. In general, the particles' inertia grow due to coalescence. The above results suggest a possibility that coalescing particles may continue to collide at low speeds when they are in the appropriate vorticity dominant (Q*>0) zone at each colliding process.

TURBULENT FLUID FLOW IN A PRECESSING CYLINDER

Federico Pizzi*[1], André Giesecke[1], and Frank Stefani[1]
[1]Department of Magnetohydrodynamics, Helmholtz-Zentrum Dresden-Rossendorf, Institute of Fluid Dynamics, Bautzner Landstrasse 400, D-01328 Dresden, Germany

Summary In the framework of DRESDYN (DREsden Sodium facility for DYNnamo and thermohydraulic studies) we study the hydrodynamics of a fluid contained in a precessing cylinder. Here we focus on turbulence properties of the flow in dependence of the precession angle as well as Reynolds number and Poincaré number (ratio of the frequency of the precessional system and the cylinder itself). The main result is a characteristic peak in the dissipation around $Po = 0.1$ which goes along with a local maximum of turbulent kinetic energy.

PROBLEM DEFINITION AND METHODS USED

A precessing container performs simultaneous rotations around two different axis (Fig.1). In doing so the fluid in the container experiences a force that drives a non-axisymmetric flow, which becomes turbulent when precession is strong enough.

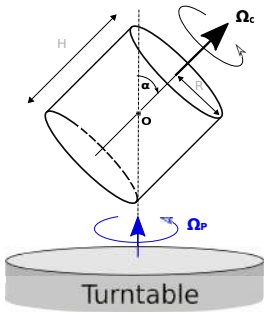

Figure 1: Schematic drawing of the precessing cylinder.

The mathematical problem is described by the Navier-Stokes equations for incompressible flows, which in dimensionless formulation in the precessing frame of reference read:

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{\partial P}{\partial x_i} - 2Po\,\Omega_j \epsilon_{ijk} u_k + \frac{1}{Re}\frac{\partial^2 u_i}{\partial x_j^2}\,, \qquad \frac{\partial u_i}{\partial x_i} = 0\,, \tag{1}$$

where u_i is the velocity field, P the (reduced) pressure and Ω_j the components of precession angular velocity. The boundary conditions are standard no-slip conditions (Dirichlet) at the wall $u_{r,z} = 0$ and $u_\phi = \Omega_C R$. The dimensionless numbers are respectively the Reynolds number $Re = \Omega_C R^2/\nu$ and the Poincaré number $Po = \Omega_P/\Omega_C$ with Ω_P, Ω_C denoting the precession angular frequency and cylinder angular frequency. We solve equations (1) using the DNS code SEMTEX which is based on a Galerkin Spectral Element Fourier method [2]. In our simulations we fix the aspect ratio, $\Gamma = H/R = 2$ (close to the resonance of the first Kelvin mode), in order to compare the results with a water experiment carried out at HZDR [6] in preparation for a large scale dynamo experiment [1], where liquid sodium will be used as a fluid.

TURBULENCE PROPERTIES

Precession provides a volume forcing that directly drives a flow with azimuthal wave number $m = 1$. Figure $2(a)$ shows the corresponding kinetic energy scaled by the energy of a rigid rotating cylinder $(\Omega_c R)^2$ for $Po = 0.095$. The flow drains energy from the rigid body rotation, and after an initial transient phase a fluctuating but, in the statistical sense, stationary state develops. There is a clear oscillating pattern for the largest precession angle. The contour plots on the right side of Fig. 2 show the correspnding time-average of the axial velocity $\langle u_z \rangle$ Fig. 2 (b) and the fluctuating components $u_z' = u_z - \langle u_z \rangle$ Fig. $2(c)$. The two magnitudes are comparable therefore the fluctuating flow is a non-negligible contribution. Figure $3(a)$ represents the total dissipation of the time-averaged flow $D = \int_V (2\nu S_{ij} S_{ij} - S_{ij} R_{ij})\, dV$, where $S_{ij} = 1/2\,(\partial u_i/\partial x_j + \partial u_j/\partial x_i)$ is the strain rate tensor and $R_{ij} = -\langle u_i' u_j' \rangle$ the Reynolds stress tensor. The discontinuity of the curve around $Po \simeq 0.1$ indicates the transition to a turbulent state, which happens independent of the precession angle. Figure $3(b)$ presents the (integral) turbulent kinetic energy $E_{turb} = \int_v \langle u_i' u_i' \rangle dV/2$ as a function of Po with a peak at $Po \approx 0.1$. The maximum of the corresponding turbulence intensity $I = \sqrt{(2/3)\ E_{turb}/2\pi}$ is around 7%, in accordance with observations performed in a spheroid [7]. For particular combinations of α, Re and Po we find a triadic resonance when free Kelvin modes become resonant simultaneously [3], indicated by the spike localized at small Po in Fig. $3(a)$.

(c) Snapshot of the fluctuating axial velocity $u_z' = u_z - \langle u_z \rangle$ ($Re = 6500,\ Po = 0.095,\ \alpha = 60°$).

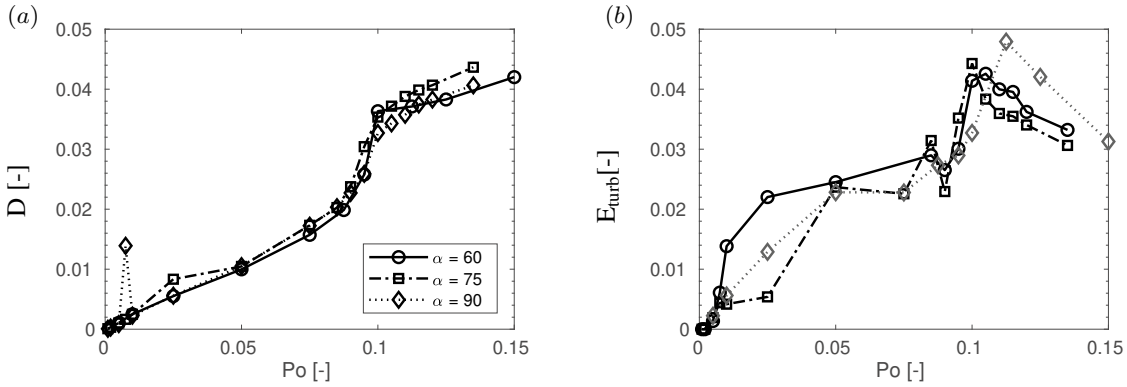

Figure 3: (a) Total Dissipation D and (b) turbulent kinetic energy E_{turb} versus precession ratio for $Re = 6500$.

CONCLUSIONS

Our simulations show that in a precession driven fluid around the transition to turbulence the chaotic fluctuations have a comparable amplitude to the mean flow itself. Moreover, in the turbulent regime the total dissipation increases almost linearly with the forcing. This behavior is found also in our experiments [8]. However Malkus experimentally [5], and Kerswell through a theoretical estimation [4], observed a plateau-shape in the turbulent regime for high precession ratios. Further studies must be done regarding this aspect. The impact of the precession angle α remains small, in contrast to preliminary experimantal studies performed with the water experiment which is probably due to the much smaller Reynolds number used in the numerical simulations compared with experiment.

ELECTROMAGNETIC FORCING OF A TIDE-LIKE FLOW IN CYLINDRICAL GEOMETRY

Peter Jüstel*[1],Sebastian Röhrborn[1],Felix Schindler[1],Frank Stefani[1],Tobias Vogt[1],and Rodion Stepanov[2]
[1]Institute of Fluid Dynamics, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany
[2]Institute of Continuous Media Mechanics, 1 Acad. Korolyov str., 614013 Perm Russia

Summary Motivated by a tidal synchronization model of the solar dynamo, we plan to study the influence of a tide-like forcing on the helicity oscillations of the large-scale circulation in a Rayleigh-Bénard experiment. The current paper reflects on preliminary experiments to investigate the flow structure arising from electromagnetic tidal forcing of a liquid metal.

INTRODUCTION

The amazing similarity of the eleven-year solar cycle and the alignment cycle of the tidally dominant planets Venus, Earth, and Jupiter has been known for a long time in the solar science community. Recent papers [1-4] have suggested that a viable synchronization effect could be accomplished by influencing the current-driven, kink-type Tayler instability (TI) with azimuthal wavenumber $m = 1$. The proposed mechanism implies that small tidal forces created by the planets might be sufficient to affect the helicity oscillations of the TI, whereby the chaotic behaviour of the entire solar dynamo could ultimately be synchronized [3]. A liquid metal experiment has been set up at Helmholtz-Zentrum Dresden-Rossendorf to investigate this mechanism. The TI flow structure is actually replaced by a Rayleigh-Bénard (RB) large scale circulation (LSC) with the same $m = 1$ azimuthal dependence. The helicity oscillations are nothing else than the well-known sloshing/torsional oscillations of the LSC. A resonance of those oscillations with external tide-like forces would hint on a rather generic mechanism. As a first step, the Lorentz-force driven m=2 flow was investigated to validate the experimental setup.

THE EXPERIMENTAL SETUP

We have chosen the liquid eutectic GaInSn alloy as the working fluid. The vessel is a cylinder with inner diameter $D = 180\,\mathrm{mm}$ and unit aspect ratio [6]. For the subsequent Rayleigh-Bénard experiments, it can be cooled at the top and heated at the bottom via a thermostat and an electric heater. The cylindrical shell is insulated. Additionally, two electromagnetic coils are situated on opposite sides of the cylinder along a horizontal axis (dashed lines in Fig. 1(a)). They can be used to induce a flow in the liquid metal. For data acquisition, ten Ultrasound-Doppler-Velocimetry probes are arranged around the vessel. They measure velocity values at multiple points on the acoustic path. Those values are projections of the velocity vector onto the path.

FLOW STRUCTURE AND STABILITY

Applying an alternating current between 5 and $49\,\mathrm{A_{RMS}}$ to the coils induces an eddy current in the fluid. The resulting Lorentz-force draws the liquid metal towards the coils and pushes it from the sides towards the centre axis. The fluid motion is generally turbulent while the average flow takes the form of Fig. 1(c). Increasing the coil current at a fixed frequency increases the turbulence and mean velocities. The frequency range of 12.5 to 200 Hz shows different optimum coupling efficiencies for each current setting. Mean flow velocities of up to $3\,\mathrm{cm/s}$ are achieved.
Since for strong forcing the two impinging jets form an unstable system, the stagnation point moves around the centre of the cylinder. This motion is random without any reproducible periodicity. But there seems to be a preference to stagnate away from the centre point. A histogram of the flow in Fig. 1(b) shows a clearly bimodal distribution.

CONCLUSIONS AND PROSPECTS

For weak forcing, the observed fluid motion bears good resemblance to the simplified Stokes flow simulation of Stepanov et al. [5]. We were able to confirm the effectiveness of a symmetric coil polarity to attain the desired flow pattern. Varying the coil current and the frequency leads to the expected behaviour: higher currents increase the Lorentz-forces and induce stronger flows. Higher frequencies tend to get shielded by the skin effect, reducing coupling effectiveness. For the future helicity synchronization experiments, the LSC should not be heavily disturbed by the tide-like forcing. Therefore a setting of around 25 Hz and below $5\,\mathrm{A_{RMS}}$ will be chosen for the Rayleigh-Bénard experiments. For those forcings, we were able to show that there are no internal frequencies present in the system yet. Therefore the chances are high to properly identify a synchronized sloshing motion, without false attribution, if such an effect is detected. Apart from that, the bi-stable impinging jets might form a system susceptible to stochastic resonance. We will further investigate this possibility. Our next step will be to apply a modulated alternating current in order to emulate the tidal forcing. The subsequent experiments with added Rayleigh-Bénard flow will then answer the question of a possible helicity synchronization by tidal forcing.

Summary We report results from the laboratory experiments investigating the possibilities to control the turbulence in the flow of viscous incompressible fluid in the gap between concentric spherical boundaries, induced by their rotation about the common axis. Turbulent flow states were subjected to periodical modulation of outer sphere rotational rates about unaltered averaged values. With an increase of modulation amplitude, a change of flow state was found to occur in the whole spherical gap: turbulent flow became laminar and exemplified the patterns, preceding the transition to turbulence.

Much attention is currently given to the invention of methods of turbulence suppression in pipes [1] and rotating flows [2]; in nature turbulence destruction can be observed in atmospheric processes, for example, cooling of the surface atmospheric boundary layer at night [3]. The spherical Couette flow (SCF) - the flow of viscous incompressible fluid in the gap between concentric spherical boundaries, induced by their rotation about common axis, is under study in the present work. In the case of turbulence, induced in SCF by periodical modulation of outer sphere rotational rate, it was numerically shown that azimuthal component of kinetic energy remains periodical [4]. In the present study we carried out the experiments to investigate the influence of periodical excitation of outer sphere rotational rate on the possibility of turbulence destruction. The initial turbulent flows in the spherical layer are formed within the gap between the two counter rotating transparent spheres with stationary in time angular velocities Ω_1 and Ω_2, and radii r_1 = 75mm for the inner sphere and r_2 =150mm for the outer sphere. The spherical gap is filled with silicone oil with viscosity $\nu = 5\times10^{-5}$ m^2/s at 22^{0}C temperature. The oil is contaminated with aluminum powder to visualize the flow. The azimuthal flow velocity u_φ measurements were conducted by using laser Doppler anemometer. The more detailed description and picture of the experimental setup are presented in [5]. The chosen turbulent flow states have the following peculiarity: with decelerating inner sphere rotational rate (or Reynolds number $Re_1 = \Omega_1 r_1^2/\nu$ decreasing at constant $Re_2 = \Omega_2 r_2^2/\nu$) the transition to periodical laminar flow state occurs, where pattern is represented by three symmetric about equatorial plane vortices propagating in azimuthal direction. In turbulent flow states, near the threshold of its formation, randomly distributed fragments of mentioned above spatial structures were observed [6]. Chosen turbulent flows (I: Re_1 =434, Re_2 =900, II: Re_1 =382, Re_2 =700, and III: Re_1 =377, Re_2 =700) are subjected to periodical modulation of the outer sphere angular rotational rate Ω_2 (t) about unaltered averaged values Ω_{20}: $\Omega_2(t) = \Omega_{20}(1+A\sin(2\pi ft + \varphi))$, where A is the modulation amplitude, f is modulation frequency. I and II turbulent flow states were received with Re_1 increasing at constant Re_2, III – was obtained from II by decreasing Re_1 at constant Re_2 and occupied the hysteretic area of Re_1 between laminar flow state and turbulent state. Each experiment began from turbulence at A=0, then for a selected value of f amplitude A was increased from 0 to a specified value (but not more than 20% of Ω_{20}). At small A the turbulence remains and its spectra look like “two-dimensional”: with slope -5/3 at lower frequencies and slope -3 at higher frequencies. An increase in A in all the considered cases was found to suppress turbulence, which is replaced by a laminar flow. The structure of the laminar flow is similar to the structure of the above-mentioned periodic flow, which under stationary boundary conditions precedes turbulence. Decrease in A for I and II leads to the restoration of turbulence. In this case, hysteresis is observed with the suppression of turbulence and its restoration. For III the flow remains laminar with A decreasing.

Figure 1 shows fragments of the time dependence Ω_2 (t) and u_φ (t), a) and b) destruction of turbulence and transition to a laminar flow after increasing A, c) turbulence restoration after decreasing A. Fig 1a and 1b present time dependence of amplitudes at the modulation frequency and at natural frequencies of laminar flow states. Amplitudes were calculated from u_φ signal using the same method as in [5] based on the Hilbert transform. The characteristic time of amplitude rising from a local minimum, preceding the stage of final increase, until the moment of turbulence destruction approximately equals to one oscillation period (Fig. 1a, 1b). Destruction of turbulence with A increasing occurs at the moment of time close to the Ω_2 (t) minimum (Fig. 1a, 1b). Turbulence is restored after decreasing A and passing Ω_2 (t) maximum (Fig. 1, c). Hence, the suppression of turbulence occurs in the region of Re that in the case of stationary rotation level of stochasticity is more intense. This result corresponds to the available data for pipe flow, where one of the possible ways to suppress turbulence is to increase its intensity at the entrance to the tube [1]. First of all, due to the limitations in maximal values of A in the experiment (A < 0.2), it was not possible to destroy the turbulence at f > 0.02 Hz. Critical A_1 values, corresponding to the suppression of turbulence, increase with f arising in the range of 0.01-0.018Hz, and the dependence of A_1 from f has a local minimum in the range of f from 0.018 to 0.02Hz. This range is close to one-third of the natural frequency of laminar flow state. Since it contains three vortices, this frequency corresponds to the passage frequency of one vortex. Therefore, we can conclude that turbulence is most sensitive to disturbances with a frequency corresponding to the passage frequency of one vortex of the preceding turbulence periodic flow state.

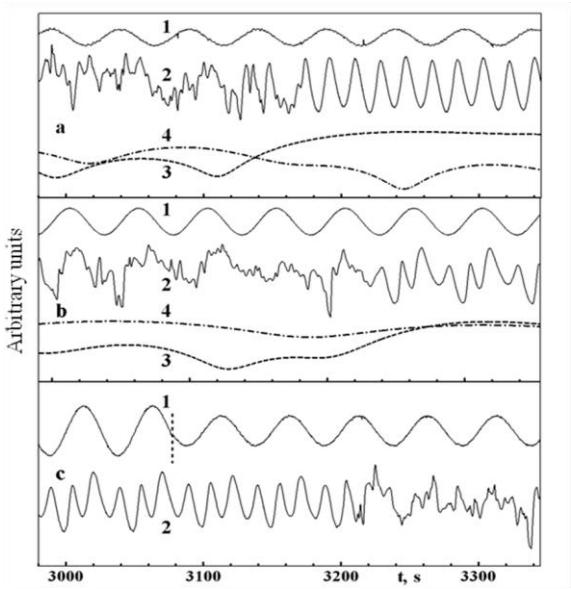

Figure 1. Time dependence of the smoothed signal Ω_2 (t)-1, u_φ (t) -2, amplitudes at the frequency of coherent structures -3, amplitudes at the modulation frequency f=0.02 Hz, a) – III, A=0.02, b)-II, A=0.15, c)- II, transition from A=0.1 to A=0.059 (the moment when A changes is indicated by the vertical dashed line).

CONCLUSIONS

Periodical excitation of outer sphere velocity at a frequency, not exceeding the transit frequency of one vortex in the laminar flow preceding turbulence, can lead to the suppression of turbulence. Turbulence destruction occurs at times near the minimums of the outer sphere rotation rates, while the turbulence recovery at values of amplitude smaller than suppression occurs at times close to the velocity maximum. Suppression of turbulence occurs in the range of Re numbers that in the case of stationary boundary conditions is more displaced from the threshold of turbulence formation compared to the range of Re numbers, corresponding to its restoration.

SPECTRAL ENERGETICS OF A QUASILINEAR APPROXIMATION IN UNIFORM SHEAR TURBULENCE

Carlos G. Hernández*[1,2] and Yongyun Hwang[2]
[1]Department of Mathematics, Imperial College London, 180 Queen's Gate, London SW7 2AZ, UK
[2]Department of Aeronautics, Imperial College London, South Kensington, London SW7 2AZ, UK

Summary A quasi-linear approximation is employed to study statistically-stationary uniform shear turbulence. The approximation is based on the decomposition of the velocity into a mean component and a two-term fluctuation: a streamwise-averaged part and a second term for the rest of the fluctuation and zero streamwise average. Direct numerical simulations removing the nonlinear product of the latter are performed and compared to resolved DNS. The premultiplied one-dimensional spectra of the velocity fluctuations and pressure-strain spectra are obtained and an energy budget analysis is carried out for production, dissipation and turbulent transport.

INTRODUCTION

The quasi-linear-type modelling incorporates some minimal roles played by the nonlinearity in the resulting self-sustaining velocity fluctuations. Common to all variations of this approach is a decomposition of the given flow into two groups: one in which all nonlinear terms are kept, and the other in which all self-interactions are ignored or suitably modelled (e.g. a stochastic forcing). In parallel wall-bounded shear flows, the former is obtained by averaging the velocity field in the streamwise direction and the latter is considered to be the remaining one. An important feature of this type of model is that it typically activates only a handful number of active streamwise Fourier modes for self-sustaining velocity fluctuations [1], thereby being capable of reducing the computational cost significantly. At high Reynolds numbers, the growing recent evidence has consistently supported that wall-bounded shear flows are composed of a hierarchical organisation of self-similar self-sustaining energy-containing motions. This feature poses an important challenge especially from the perspective of QL modelling, because the role of the nonlinearity is expected to be more important at all the integral length scales in such a high-Reynolds-number regime. The present study aims to explore spectral energy transfer in the aforementioned QL model. For the purpose of bypassing the difficulty arising from the existence of multiple integral length scales in typical high-Reynolds wall-bounded turbulent flows, we consider uniform shear turbulence. The capability of the QL model for the description of the self-sustaining process and its related energy cascade can be fully assessed using a spectral energy-budget analysis without suffering from the issue of having multiple integral length scales like in wall-bounded turbulence.

PROBLEM FORMULATION

We consider a turbulent flow under a uniform mean shear where the density and kinematic viscosity of the fluid are given by ρ and ν, respectively. The time is denoted by t, and the space is by $\mathbf{x} = (x, y, z)$ with x, y and z being the streamwise, transverse and spanwise directions, respectively. We consider the Reynolds decomposition of the velocity $\mathbf{u} = (u, v, w)$ like $\mathbf{u} = \mathbf{U} + \mathbf{u}'$ in which $\mathbf{U}(\equiv \langle \mathbf{u} \rangle_{x,z,t}) = (U(y), 0, 0)$ is the mean velocity. The turbulent velocity fluctuation is further decomposed into a streamwise-averaged and the remaining component $\mathbf{u}' = \mathbf{u}_m + \mathbf{u}_r$ with $\mathbf{u}_r = \langle \mathbf{u}' \rangle_x$. Following [3], we introduce two projection operators, which can decompose the flow variables into the streamwise-averaged part and the remaining one. The projection operators are defined as $\mathcal{P}_m[\mathbf{u}'] \equiv \langle \mathbf{u}' \rangle_x = \mathbf{u}_m$ and $\mathcal{P}_r[\mathbf{u}'] \equiv \mathbf{u}' - \langle \mathbf{u}' \rangle_x = \mathbf{u}_r$. The projection of the equations for turbulent fluctuation onto $\mathcal{P}_m$ and $\mathcal{P}_r$ leads to the equations:

$$\frac{\partial \mathbf{u}_m}{\partial t} + (\mathbf{u}_m \cdot \nabla_{yz})\mathbf{U} = -\nabla_{yz} p_m + \nu \nabla_{yz}^2 \mathbf{u}_m - (\mathbf{u}_m \cdot \nabla_{yz})\mathbf{u}_m - \mathcal{P}_m[(\mathbf{u}_r \cdot \nabla)\mathbf{u}_r] \tag{1a}$$

$$\frac{\partial \mathbf{u}_r}{\partial t} + (\mathbf{U}_m \cdot \nabla)\mathbf{u}_r + (\mathbf{u}_r \cdot \nabla)\mathbf{U}_m = -\nabla p_r + \nu \nabla^2 \mathbf{u}_r - \mathcal{P}_r[(\mathbf{u}_r \cdot \nabla)\mathbf{u}_r], \tag{1b}$$

where $\mathbf{U}_m = \mathbf{U} + \mathbf{u}_m$, and p_m and p_r are defined to enforce $\nabla_{yz} \cdot \mathbf{u}_m = 0$ and $\nabla \cdot \mathbf{u}_r = 0$, respectively, with $p' = p_m + p_r$. For the QL approximation, the self-interaction term in (1b) will be ignored: i.e. RNL model [1,3]. The TKE equation is considered in the streamwise/spanwise Fourier space, so that the inter-scale energy transfer can be studied. For this purpose, one-dimensional Fourier-mode decomposition for the turbulent velocity fluctuations is introduced: $u_j'(t, r) = \int_{-\infty}^{\infty} \widehat{u_j'}(t, k) e^{\mathrm{i}kr} \mathrm{d}k$ for $j = 1, 2, 3$, where $\widehat{\cdot}$ denotes the Fourier-transformed coefficient, $(u_1', u_2', u_3') = (u', v', w')$, $r(= x \text{ or } z)$ is the streamwise or spanwise coordinate, and $k(= k_x \text{ or } k_z)$ the corresponding wavenumber. Taking an average in time, transverse direction and the planar direction along which the Fourier transform is not taken ($r^{\perp}$), the resulting energy balance is given by

$$\left\langle \left\{ -\overline{\widehat{u'}}(k)\widehat{v'}(k)\,\frac{\mathrm{d}U}{\mathrm{d}y} \right\} \right\rangle_{r^{\perp},y,t} + \left\langle -\nu \frac{\partial \widehat{u_i'}(k)}{\partial x_j} \frac{\partial \overline{\widehat{u_i'}}(k)}{\partial x_j} \right\rangle_{r^{\perp},y,t} + \left\langle \left\{ -\overline{\widehat{u_i'}}(k) \left(\frac{\partial}{\partial x_j} \left(\widehat{u_i' u_j'}(k) - \mathcal{P}_r \left[\widehat{u_{r,i}' u_{r,j}'}(k) \right] \right) \right) \right\} \right\rangle_{r^{\perp},y,t} = 0,$$

where the first, second and last terms in the left-hand side are the rate of turbulence production, $\widehat{P}(k)$, viscous dissipation, $\widehat{\varepsilon}(k)$ and (nonlinear) turbulent energy transport, $\widehat{T}(k)$ at a given wavenumber, respectively.

QL-FULL	617	108	54	497×108	0.007	0.99	1.85	1.35	1.30
QL-NX16	628	108	5	497×108	0.006	0.99	1.75	1.35	1.25

Table 1: One-point turbulence statistics.

RESULTS AND DISCUSSION

Uniform shear turbulence is simulated following the approach in [2]. The application of the QL approximation is found to generate more anisotropic velocity fluctuations. In particular, u^*_{rms} and v^*_{rms} are increased in the QL simulations regardless $N_{x,F}$ considered, whereas w^*_{rms} is decreased. The QL simulations are also found not to show any significant changes in the one-point turbulence statistics, if $N_{x,F} \geq 5$ (see table 1). This implies that only a handful number of streamwise Fourier modes are active in the QL simulations. The premultiplied streamwise wavenumber spectra of the energy budget per unit mean shear are shown in figure 1. While the spectra of DNS show the typical features of energy cascade and turbulent dissipation observed in the spanwise spectra, QL simulations do not develop such features. Given the linear nature of (1b), it is not surprising to see the significantly damaged energy cascade in the streamwise wavenumber space. However, it should also be pointed out that there are still a non-negligible number of wavenumbers actively involved in the spectral TKE balance. For example, in the case of QL-FULL, there are still approximately five streamwise Fourier modes highly active, and they form the spectral TKE balance in the streamwise wavenumber space. Furthermore, the nonlinear turbulent transport is not completely inactive in the streamwise wavenumber space either. These observations are found to be associated with the linear instabilities of (1b), consistent with the notion of the self-sustaining process observed in this flow [2]. Finally, the componentwise of TKE transport is studied (not shown). It is found that the QL simulations show a considerable damage in the pressure-strain transport, and this is understood to the lack of slow pressure in (1b).

CONCLUSIONS

The QL model shows a healthy energy cascade in the spanwise wavenumber space. However, it completely inhibits energy cascade in the streamwise wavenumber space due to the proposed linearisation. The latter feature also results in highly elevated spectral energy intensity residing only at the integral streamwise length scale. For the same reason, the velocity field of the QL model has also been found to be anisotropic throughout the entire wavenumber space of the spectra. These features fundamentally differ from the turbulence in DNS, where the spectra in the inertial and dissipation ranges are highly isotropic. It has also been found that the streamwise wavenumber spectra of turbulent transport obtained with the classical Reynolds decomposition statistically well characterizes the instability of the linearised fluctuation equations, as they exhibit a largest intensity at $L_x/L_z = 2 \sim 3$. In the final presentation, we will discuss on how to improve the present QL model based on the understanidng gained from the present analysis.

EXTENDED ORR-SOMMERFELD STABILITY ANALYSIS MODEL

Vilda K. Markeviciute*[1] and Rich R. Kerswell [1]
[1]Department of Applied Mathematics and Theoretical Physics, University of Cambridge, United Kingdom

Summary Using Orr-Sommerfeld stability analysis on turbulent mean flows was first proposed by Malkus (1956). While commonly used to explain the appearance of large scale structures in turbulent flows, this approach can fail when applied to some systems. We extend this naive approach to the next level of sophistication and evaluate its performance by analysing turbulent 2D channel states (metastable asymmetric and symmetric states and an unstable saddle state).

MOTIVATION AND PROBLEM DEFINITION

There is a long history of examining the stability of the turbulent mean profile in shear flows. Originally this was to explore the existence of a possible selection mechanism for the particular form of the mean flow [1] and, latterly, has been used to help rationalise observed large scale structures seen in the turbulence. The stability analysis usually applied consists simply of studying the spectral properties of the Orr-Sommerfeld equation built around the turbulent mean. We extend the notion of 'statistical' stability of turbulent flows by considering the turbulent statistics (mean velocity and correlation matrices) rather than the instantaneous flow fields [2]. Using time-averaging and principal component analysis of the correlation matrices, we derive an embedding back to the primitive variable space producing an extended Orr-Sommerfeld stability model, where the perturbation vector now consists of both the mean and fluctuation fields. We test the model on turbulent 2D channel flow [3] which we found to have two metastable (symmetric and asymmetric) states.

RESULTS AND DISCUSSION

Starting with the statistical flow representation equations, we develop an extended Orr-Sommerfeld stability model in terms of the primitive flow variables (velocity and pressure) decomposed into the streamwise-mean and fluctuation components. We show that the naive Orr-Sommerfeld eigenvalue analysis fails to correctly predict the stability properties of two metastable (symmetric and asymmetric - see Figure 1.) states and one unstable (saddle) state of 2D channel flow. Preliminary application of the extended stability model shows only marginal improvement to the naive approach: the eigenspectrum still does not correctly reflect the stability of the states, but a better understanding of the most unstable eigenvector structure is obtained showing significant energy in the mean velocity component (even if an order of magnitude smaller to the dominant fluctuation component). Two possible shortcomings of the extended Orr-Sommerfeld model are suggested: time-averaging of the velocity correlation matrices neglects the time-evolution of the fluctuation field while singular value decomposition of the time-averaged correlation matrix is an oversimplification of the underlying fluctuation vector. The significance of these shortcomings is examined by performing further numerical experiments. The turbulent base flow and the linear perturbation field are advanced in full and quasi-linear models. This allows us to compute the 'true' value of the growth rate of the most unstable perturbation to the turbulent base flow and thus assess the new extended stability model. Finally, if time permits, we discuss the application of the proposed stability theory on 3D flows.

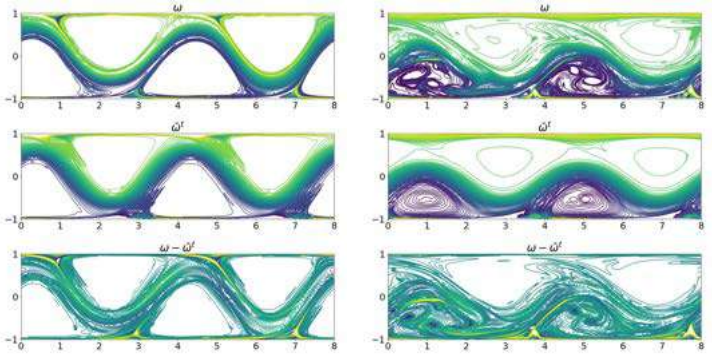

Figure 1: Metastability of states in 2D channel flow. Snapshots of: (top) the vorticity field in the channel $\omega(t)$; (middle) time-averaged vorticity field $\bar{\omega}^t$ in the travelling wave frame; and (bottom) the fluctuation field $\omega(t) - \bar{\omega}^t$ for symmetric (left) and asymmetric (right) states at $Re = 36300$. Dark blue corresponds to minimal vorticity while bright yellow to maximal vorticity levels.

ON A TURBULENT VORTEX RING

Victor Kopiev, Sergey Chernyshev
TsAGI, Moscow Branch, Moscow, Aeroacoustic Department, Russia

Summary It is generally assumed that the short-wave instability of the vortex (the wavelength of the order of the core size) is responsible for the turbulence of the flow near the vortex filaments. This paper draws attention to essentially different instabilities of vortices with a wavelength of the order of the scale of the entire vortex structure (long-wave instabilities), which may be the main reason for the transition to turbulence in vortices and other effects that have verifiable manifestations. The study is based on the theory of long-wave oscillations of a vortex ring, which shows that the eigen-frequency spectrum has a complex structure with accumulation points. Eigen-oscillations are accompanied by the formation of a system of critical layers in which, in the presence of a weak monotonically decreasing vorticity outside the core, perturbations of vorticity intensify through the formation of spiral structures. The obtained results allow to explain the following experimental facts: (i) the existence of a laminar core and turbulent flow regime in the atmosphere of a vortex ring with a sharp boundary between them; (ii) the "impossible" flow regime with the inclination of the plane of the ring; (iii) narrow-band sound radiation by a vortex ring with a main frequency corresponding to the theory prediction and the presence of peaks at multiples of fundamental frequencies; (iv) the structure of the far sound field in three azimuthal quadrupoles n=0, 1, 2. It is shown that the curvature of vortex lines plays a crucial role in the occurrence of long-wave instability.

SETTING THE PROBLEM

The study of vortex ring oscillations is of great interest, as it allows considering the non-stationary processes in the core of localized vortices. The vortex ring can easily be produced for experimental study (Figure 1a,b) and allows the theoretical description of both stationary states and oscillations within the framework of the basic equations of an incompressible ideal fluid. According to the long-wave theory [1] all eigen-oscillations are subdivided into the families of Bessel modes and isolated modes, and the discrete spectrum of eigen-frequencies can degenerate if the isolated mode frequency coincide with the frequency of the Bessel mode (Figure 1c). The influence of a weak monotonically decreasing vorticity outside the main vortex core on the properties of these oscillations was considered [2]. It is shown that the presence of vorticity outside the core leads to multiple instability of oscillations that are neutrally stable in the absence of external vorticity. The mechanism of this instability is similar to the Miles mechanism for surface waves [3]. Miles instability of the vortex ring oscillations occurs due to the complex structure of the eigen-mode shape against vortex column modes. Unstable oscillations are accompanied by the appearance of critical layers outside the vortex core, in which the displacement amplitudes of liquid particles reach a large value. Since many modes are unstable, the entire region of the vortex ring atmosphere is filled with critical layers that provide energy transfer from the average flow to the vortex oscillations (Fig. 1a).

The curvature of the vortex lines causes one more type of the long-wave instability associated with the coupling of the eigen-frequencies of the perturbations with energy of different sign (oscillations with positive and negative energy), as noted in [2]. The characteristics of this new instability were obtained in [4]. This instability is actually a direct verification of long-wave theory on the whole.

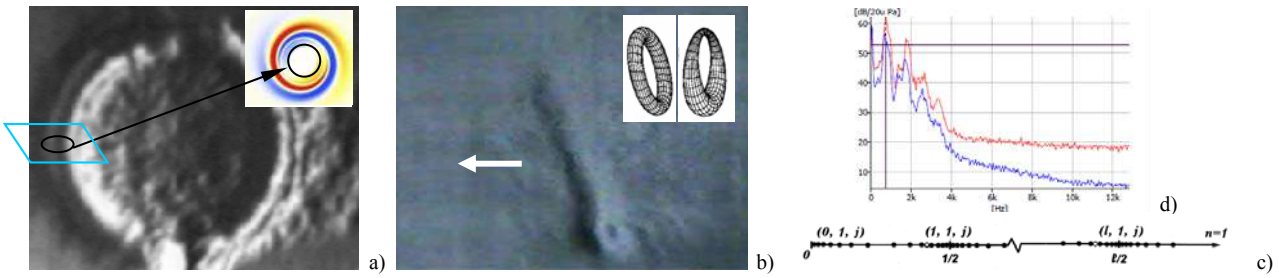

Figure 1. Turbulent vortex ring: a) visualization of laminar vortex core and transport of fluid particles to the vortex tail (front view); in the corner vorticity disturbances in critical layer with the appearance of a spiral structure; b) vortex ring (side view), tilt of the ring, the arrow shows the motion direction; in the corner two phases of slow bulging eigen-mode; c) eigen-osscilations near accumulation points; d) vortex ring noise spectra in large-scale experiment.

Based on the theoretical and experimental results obtained, the paper offers a new scenario of transition to turbulence in a vortex ring. This view is an alternative one to the currently dominant concept of short-wave instability in the cores of large-scale localized vortices [5] or the concept based on an analogy with the elasticity effects of rotating flows [6,7].

METHOD OF PROBLEM SOLUTION

The theory of long-wave oscillations of a thin vortex ring developed in [1] is the basis of the consideration. Due to the extreme complexity of the problem, all theoretical solutions are limited to the case of a thin vortex ring ($\mu \ll 1$).

In the case of short-wave three-dimensional oscillations, when the wavelength has the order of the radius of the core [8,9], the ratio of the wavelength to the vortex ring radius is an additional small parameter, the presence of which allows to obtain a solution, ignoring the mutual influence of perturbations in the distant regions of the vortex ring. In this case, one can limit himself to the main term in the decomposition of the stationary field by the thickness parameter μ, so the question of the existence and structure of the stationary flow does not raise. In contrast to that in the case of long-wave

oscillations the interaction of perturbations is non-local, so the question of the existence and structure in μ of a stationary flow is key question for the asymptotic expansion and oscillation describing.

The stationary flow with vorticity in the toroidal region was considered by Frankel [10]. He proved the existence of stationary solutions for a thin vortex ring with different vorticity distributions, and developed a procedure for obtaining a family of stationary solutions that differ in vorticity profiles in the vortex core. The choice of a stationary flow for which the stability problem would be the simplest is considered and the concept of an isochronous vortex ring was introduced [12], in the core of which the periods of circulation of liquid particles are the same.

The eigen-modes obtained in [1] for an isochronous vortex ring are determined by three integers that characterize the frequency, azimuthal and radial structures of the mode. These modes are the main instrument for turbulent vortex ring structure explanation.

MAIN RESULTS

The main result of this work is a statement and validation of a new scenario for turbulization of a vortex ring. The presented concept is based on a series of results obtained by the authors at different times. It turned out that to describe non-stationary processes in a turbulent vortex ring, it is necessary to consider the long-wave part of the spectrum, where energy can be transferred from the average flow to unstable oscillations with the formation of multiple critical layers. Consideration of the Cauchy problem shows that vorticity perturbations intensify near each critical layer with the appearance of a spiral structures [11] (Fig.1a). At the nonlinear stage, the interaction of perturbations in close critical layers will lead to the transport of vorticity across the streamlines and turbulization of the flow. Thus, for a vortex ring whose spectrum is characterized by the presence of accumulation points, the occurrence of multiple critical layers causes turbulization of the entire flow region outside the vortex core.

Since the critical layers are condensed to the boundary of the vortex core and are absent at the core itself, the boundary between turbulent and laminar domains remains sharp. It can be assumed that this mechanism is also implemented in other vortex flows with intense curved vortex filaments. This would mean that core oscillations of intense vortex filaments serve as a mechanism for turbulization via the formation of small-scale spiral structures around the core with large-scale structure along the filament (pancake like structures). Estimates of the Reynolds number are made for which such a representation can be valid (Re>1000). The proposed concept is validated primarily by experimental observations of the turbulence structure of a vortex ring with a sharp boundary between the laminar core and turbulent atmosphere [6] and an explanation of the existence of modes in which the ring inclinates to the axis of motion in one of the oscillation phase (Fig.1b). These non-trivial experimental facts are explained within the framework of the proposed theory. The theory was also validated by the sound radiation of the vortex ring [2], explaining not only the long-term radiation of the vortex and the high q-factor of the oscillator as a sound energy emitter, but also giving a quantitative comparison with the frequency of the maximum radiation and the presence of several peaks with a multiple frequencies in the radiation spectrum [12].

The new instability of the vortex ring associated with the merging of the eigen-frequencies of the modes with energy of different signs [4] also confirmed the proposed concept [2]. This instability is similar to the Fukumoto's instability obtained earlier for the short-wave disturbances [9]. In spite of the small increment, the instability can be detected in the experiment as having quite special shape. The new instability as well as Miles shear instability of the Bessel oscillations is realized due to the curvature of the vortex line in the vortex ring.

CONCLUSIONS

A new scenario for the transition to turbulence in large-scale 3D vortices with an intense laminar core is proposed. From the point of view of the considered processes, small-scale perturbations, which are certainly present in the considered flows, play the role of a kind of "cover", behind which long-wave processes that have access to the energy of the average flow are hidden. It is remarkable that at the linear stage the solution of the key problems underlying this scenario can be obtained completely analytically based on the equations of an incompressible inviscid fluid.

EFFECT OF TRAVELING DIRECTION OF WAVE CREATED BY BLOWING AND SUCTION ON RELAMINARIZATION PHENOMENA IN TURBULENT CHANNELFLOW

Minami Kishi[1] and Hiroya Mamori *[1]
[1] Department of Mechanical and Intelligent Systems Engineering, The University of Electro- Communications, Japan

Summary Control techniques for turbulent flows are of importance for improving energy efficiency in manufacturing industry. Recently, a traveling wave control is well-known to induce not only drag reduction effect but also relaminarization phenomenon. In this study, we make direct numerical simulations of turublent channel flows with the traveling wave control to investigate influence of the traveling wave direction on the control effect. In practical situations, the main flow direction may vary due to the unsteadiness of the flow and robustneess is required for the control. The results show that, in some control parameter sets, the relaminarization phenomenon and the skin friction drag reduction effect even in the obliquely traveling waves.

INTRODUCTION

Traveling wave-like blowing and suction control can not only reduce the skin-friction drag reduction but also induce relaminriazation phenomenon on a fully developed turbulent channel flow [1]. The traveling wave control technique is attractive since it is one of predetermined control techniques: apparatus is simple and it doesn't require any sensors [2]. Thus, it is expected to implementation to actual flows. The relaminarization phenomenon by the traveling wave occurs when the wave travels in the downstream direction (i.e., the wave travels in the same direction of the main flow) [3] [4]. However, in practical situations, e.g. ships, the main flow direction may vary due to the unsteadiness of the flow. Therefore, in this study, we make direct numerical simulations to investigate influence of the direction of the traveling wave control on the drag reduction effect and relaminarization phenomenon. The parametric study clarifies the relaminarization range of not only control parameters (amplitude, wavelength, and wavespeed) but also the angle between the traveling wave direction and the main flow.

DIRECT NUMERICAL SIMULATION

In this study, the flow between parallel plates driven by a constant pressure gradient was used. Then, the periodic boundary conditions were applied in the flow direction and the span direction. The calculation area is $L_x \times L_y \times L_z = 2\pi \times 2 \times 2\pi$, and the calculation grid is $N_x \times N_y \times N_z = 256 \times 96 \times 256$. The control formula for the traveling wave-like blowing and suction control is shown as

$$v_w = \mp a \sin\left(\frac{2\pi k}{L_x}(x - ct)\right). \tag{1}$$

The parameters are amplitude a, wave number k, and wavespeed c. On the wall surface, the blowing and suction are given as vertical velocities, and non-slip conditions are given for flow and span velocities. In this study, only varicose mode is investigated. The control effect is evaluated using the skin friction drag coefficient C_f and the total kinetic energy (TKE). Using the continuity equation of an incompressible flow and the Navier-Stokes equation as governing equations, we use friction velocity u_τ^*, channel half width δ^*, and viscous velocity ν^* for non-dimensionalization. The Reynolds number is defined by $Re_\tau = u_\tau^* \delta^* / \nu^*$, and a fully developed turbulent field is used as the initial field at $Re_\tau = 180$.

In this study, the direction of traveling wave control is tilted with respect to the mainstream: the mainstream direction is changed, but the direction of the traveling wave is unchanged. The angle difference between the mainstream and traveling waves is $\theta = 0°, 30°, 45°, 60°$, and $90°$. Figure 1 shows a schematic diagram of the channel flow that changes the mainstream direction.

SAMPLE RESULTS AND OUTLOOK

In previous study, the fully developed turbulent channel flow becomes the laminar flow when the traveling wave travels in the same direction with the mainstream. The relaminarization phenomenon occurred and the so-called

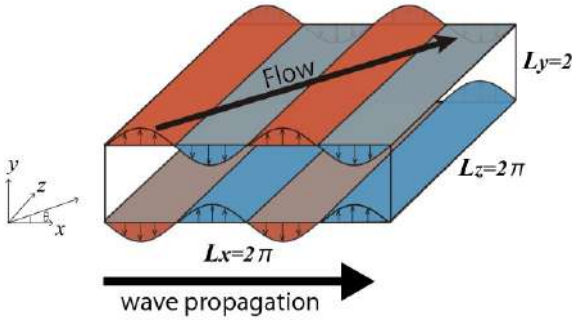

Figure 1: Coordinate system with the traveling wave.

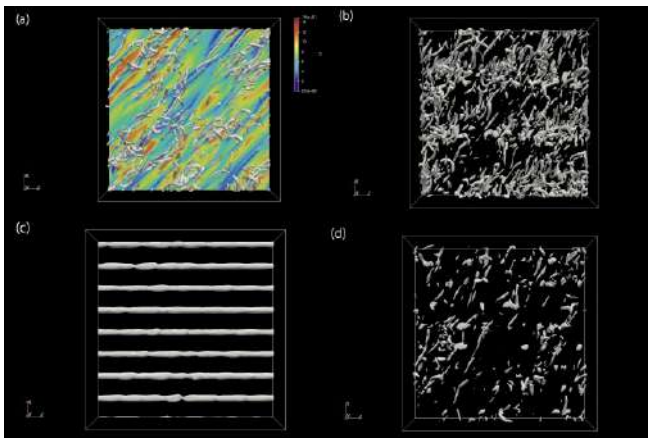

Figure 2: Vortical structure at lower-half of the channel flow: (a) Uncontrolled with $Q = 0.01$; (b) $k = 3$ and $c = 30$ with $Q = 0.03$; (c) $k = 8$ and $c = 30$ with $Q = 0.03$; (d) $k = 8$ and $c = 120$ with $Q = 0.03$. The angle of the main flow direction is $\theta = 45°$.

coherent structures decreased [3, 4]. In contrast, the present study focuses on the control effect of the wave traveling in the diagonal direction to the mainstream.

Figure 2 shows sample results: instantaneous vortical structures visualized using the second invariant of the velocity tensor (so-called the Q value) for uncontrolled and controlled cases. For all the cases, the wave travels in the diagonal direction (i.e., the difference between the direction of the mainstream and the traveling waves is $\theta = 45°$) and the amplitude of the wave is set to be $a = 8$. Figure 2(a) shows the vortical structure together the velocity in the region near the lower wall in the uncontrolled flow. We confirm the turbulent coherent structure (i.e., vortical structures and the streaky structures). Figure 2(b-d) shows controlled cases. All the wave travels in the $x+$ direction and the mainstream direction is 45° on $x - z$ plane. Figure 2(b) shows the reference case of $k = 3$ and $c = 30$. The vortical structures along the mainstream direction remained and the relaminarization phenomenon does not occur. On the other hand, for large wavenumber case as shown in Fig. 2(c) ($k = 8$ and $c = 30$), the vortical structure disappeared where relaminarization phenomenon occurred. As increase of the wavespeed ($k = 8$ and $c = 120$), shown in Fig. 2(d) the vortical structure decreased as compared with the reference case, but they remained and the relaminarization phenomenon did not occur.

In the presentation, we will discuss the flow field in detail, e.g., turbulent statistics and interaction of the control and the coherent structure. Moreover, we will carry out a parametric study to clarify the range of the relaminarization phenomenon and they will be compared with that with the previous study. According them, we will contribute to understand the mechanism of the relaminarization phenomenon by the traveling wave-like control in the fully developed turbulent channel flow.

TIME RESOLVED PIV MEASUREMENTS IN FULLY DEVELOPED TURBULENT PIPE FLOW.

Zeinab Hallol*[1], Mohamed Yousry[1], Sebastian Merbold[1], and Christoph Egbers [1]
[1]Department of Aerodynamics and Fluid Mechanics, Brandenburg University for Technology Cottbus- Senftenberg,Germany.

Summary Measurements of time-resolved high-speed particle image velocimetry (HS-PIV) are applied at moderate and high Reynolds numbers in Cottbus Large Pipe facility (CoLaPipe) in Brandenburg University for Technology Cottbus-Senftenberg. The main objective of this experiment is to capture high-spatial instantaneous snapshots of recently explored large coherent structures in log and outer regions of fully developed turbulent pipe flow. PIV measurements in stream-wise wall-normal plane are validated through comparing it with previous single hot-wire anemometry datasets that reveals a good agreement. Among visual inspection, stream-wise coherent structure features are exhibited in the middle of the log region and at the near-wall region.

BACKGROUND

Earlier experimental and numerical studies have explored and documented the existence of coherent structures among the investigation of hairpin-like vortices inclined at an angle to the free stream [7]. Subsequent studies induced that multiple structures of these hairpins are travelled at the same convective velocity forming vortex packets that create large scale structures in internal and external flows [5], [1]. The features of large structures are their alignment in the stream-wise direction to produce regions of low and high stream-wise momentums in the inner and outer layers [3]. Large coherent structures are known to prohibit the log and outer regions of the boundary layer at moderate to high Reynolds number [4] to be responsible for ejection and sweep events generation which are the major contributors to turbulent production and Reynolds shear stress [6].

EXPERIMENTAL SETUP

Although hot wire anemometry proved its effective role in measuring flow in several manners, PIV applications on turbulent flows still stand as one of the most demanding applications due to their wide range of length and time scales [8]. Recent experiment is conducted in CoLaPipe test facility of 190 mm diameter at measuring station L/D = 110 to proceed two dimensional velocity fields of stream-wise /wall-normal plane with accurate temporal and spatial resolutions at Reynolds number range ($10^3 \leq Re_\tau \leq 10^4$). Re_τ is the friction Reynolds number corresponding to the ratio between largest and smallest length scale ($Re_\tau = \mathrm{R}\, u_\tau / \nu$). In this paper, we will present the results of principle statistical moments of $Re_\tau = 1786$. Lavision PIV system is used to capture 1838 snapshots. The system consists of flow visualization by laser illumination of seeding particles, CMOS camera, laser/camera synchronization system, and analysis software (Davis8). The field of view of HS-PIV measurements is 1R in wall-normal and 2R in stream-wise direction. Where R is the pipe radius. Fig.(1) shows the experimental setup.

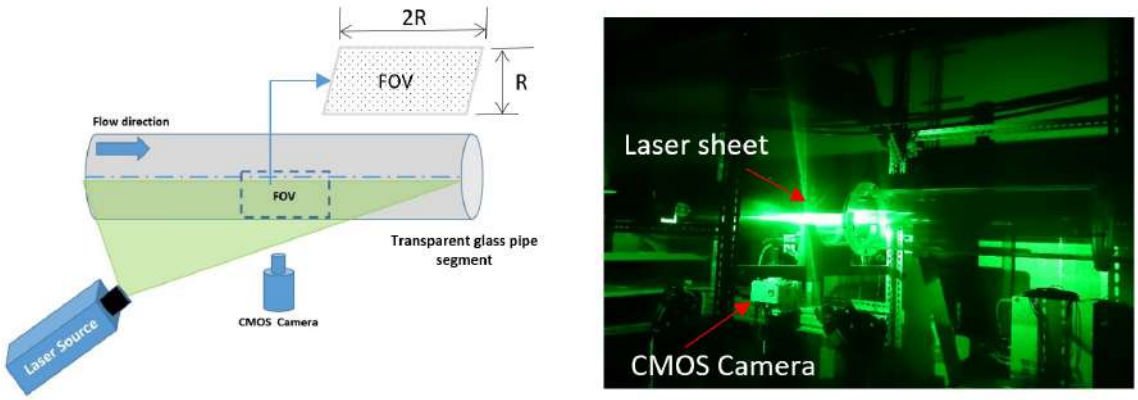

Figure 1: PIV experimental setup in CoLaPipe test facility.

RESULTS AND CONCLUSION

The flow statistics; mean stream-wise velocity profile (u^+), stream-wise Reynolds stress (u^{2+}) and Reynolds shear stress (uv^+) normalized by friction velocity (u_τ) are presented in figure (2.a). Comparisons for the first and second-order momentum statistics are drawn to single-point prior hot wire anemometry (HWA) measurements of [2] in SuperPipe test facility and recent hot wire datasets in CoLaPipe. The validation reveals good and acceptable agreement between PIV and HWA datasets for the stream-wise fluctuations. The near-wall region $y^+ < 40$ is not clearly captured by PIV system due to the wall turbulence large discrepancies which are the main influence of spatial attenuation and wall reflections. Fluctuation of stream-wise component (u_{rms}) indicates small magnitude in the core region and larger in the near wall region, this is clarified well in fig.(2.b), Also hairpin foot print can be observed near the wall. Temporal and spatial resolutions of the current measurements enable us to visualize large coherent motions known to exist in the near-wall region at moderate to high Reynolds number. Fig.(3.a) extends the instantaneous velocity field contours of stream-wise and wall-normal velocity components. The flow direction is from left to right and the pipe wall is located at the bottom of the image. The visual inspection of the velocity field indicates spatial structures and important stream-wise coherence structure features at the middle of the log region and close to the wall. Velocity fluctuation vector-map image in fig.(3.b) exhibits a high degree of complexity ranging from the smallest resolved scales to structures that are larger than the radius of the pipe. The vortical structures were found to be close to low-speed regions, being responsible to maintain these regions and to induce ejection and sweep events. Protracted flow field is required in future work to obtain sufficient spatial resolution over a longer stream-wise extent. However, large coherent structures (i.e very large scale motions) are recognized to commonly persist with a length greater than 20 R [4].

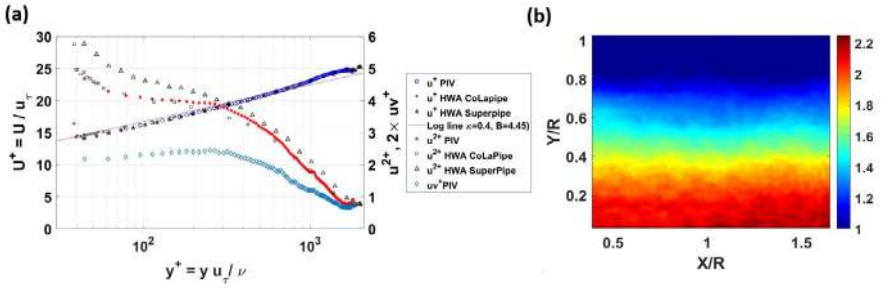

Figure 2: (a) Logarithmic velocity (u^+), stream-wise Reynolds stress (u^{2+}), and shear stress (uv^+) profiles of PIV data compared among CoLaPipe HWA measurement Re_τ= 1786 and SuperPipe HWA measurement Re_τ= 1985 [2]. (b) Contour map for u_{rms} measured by PIV.

BLOWING AND SUCTION CONTROL BASED ON DEEP REINFORCEMENT LEARNING FOR DRAG REDUCTION IN FULLY DEVELOPED TURBULENT CHANNEL flOW

Ryota Aoki[1] and Hiroya Mamori *[1]
[1]Department of Mechanical and Intelligent Systems Engineering, The University of Electro-Communications, Tokyo, Japan

Summary For energy efficiency, flow control techniques to reduce skin-friction drag in the wall-turbulence are investigated by means of direct numerical simulations (DNS). While the coherent structures dominate the near-wall turbulence, it is very difficult to design control based on them due to non-linearity. To make the flow control for the turbulent flow, the present study employs blowing and suction from the wall based on a deep reinforcement learning. The deep reinforcement learning has recently attracted much attention in the community of control. We have given a task to search for the parameters of the blowing and suction from the wall and the control scheme is examined in the turbulent channel flow by means of the DNS. As a result, we were able to learn a parameter that can achieve a 28% drag reduction effect about 600 times out of more than 3000 combinations of parameters.

INTRODUCTION

For energy efficiency, many control techniques to reduce the skin-friction drag in the wall-turbulence have been preformed. A direct numerical simulation (DNS) is powerful tool to investigate the control effect in the turbulent flow, because it can compute without using any turbulence models. For example, Choi *et al.* [1] made the DNS of turbulent flow with so-called an opposition control. The opposition control means the blowing and suction from the wall based on the near-wall velocity to decrease the activity of the vortical structures. Based on the opposition control, many study has been tried to design and construct an optimal (or better at least) control method. In the present study, we employ deep reinforcement learning (DRL) to construct the control scheme for opposition control. Recently, the DRL has been attracting attention in the control community and several studies have demonstrated the effectiveness. In contrast with previous studies, we employ the DRL for the fully developed and three-dimensional turbulent flow for the opposition control. The DRL is applied to search for the detection plane of the opposition control.

NUMERICAL METHOD

Direct Numerical Simulation

Figure 1 shows a schematic diagram of the turbulent channel flow. The governing equations are the continuity equation and the Navier-Stokes equation for incompressible flow. The computational domain size is $(2\pi \times 2 \times \pi)$ in the x, y, and z direction and the number of grid points is $(128 \times 96 \times 128)$. The grid spaces are uniform in the homogeneous directions and non-uniform in the wall-normal direction. The mean pressure gradient is set to be constant and the friction Reynolds number Re_τ based on the half channel width and the friction velocity is set to 180. A no-slip condition is imposed on the wall except the wall-velocity in the controlled case. All the simulation starts from the fully developed turbulent channel flow. In addition, the temperature is treated as a passive scalor with the uniform heat generation condition. The Prandlt number is $Pr = \nu/\alpha = 1.0$ where α is a thermal diffusivity.

Opposition Control and Deep Reinforcement Learning

Opposition control is one of the turbulence control methods performed by Choi *et al.* [1]. A schematic diagram is shown in Fig. 2. This control reduces the skin-friction drag by controlling blowing and suction from the wall to cancel the streamwise vortical structures. Specifically, the wall-normal velocity is detected at 'detecting plane' and the blowing and suction from the wall is used them with opposite sign. In this control, the drag reduction rate depends on the height of the detecting plane: the maximum drag reduction is obtained when the detecting plaine is located at $y^+ \approx 15$ [2]. In the present computational setting, when the detection plane height is set to $y^+ = 15$, the flow becomes steady in about 6 dimensionless time and the drag reduction rate of 25% was obtained.

Figure 3 shows schematic of the DRL. The DRL consists of agents and environment. The agent selects the 'action' and repeatedly tries to maximize the 'reward' based on the 'state' of the environment. In other words, the behavior is determined by the conditions and rewards of the environment. Although various algorithms have been proposed for the DPL, we employ PPO [3] and the DRL framework ChinerRL [4] for its implementation.

In this study, we divide the transitional regime (6 seconds in dimensionless time) from the initial to the steady state under the control into five segments. At the beginning of the segmented time domain, the agent selects the detection plane height and repeats the control for 1.2 seconds in 5 steps. The state-space was set to bulk velocity and bulk temperature, and the action space is set to the detecting plane height of $0 - 20$. The rewards are sum of the increment (or decrement) of the drag reduction rate of each step for one episode.

*Corresponding author. E-mail: mamori@uec.ac.jp

RESULTS

The time history of skin friction drag coefficient C_f during 600 episodes of training is shown in Fig. 4. The red line shows the case of the conventional opposition control (i.e., without using the DRL): the detection plane height is fixed at $y^+ = 15$ and blowing and suction are performed for 6 seconds. On the other hand, the blue line shows the reference DRL case: the detection plane height is changed by the deep reinforcement learning. The number in the figure represents the detection plane height selected by the DRL at each step. In this case, the detection plane height varies 4→ 15 → 15→ 14 → 15. In the conventional case, C_f significantly decreases at $t < 3$ and slightly recovers at $3 < t < 6$. For the DRL case, C_f rapidly drops at the second step when the detection height is $y^+ = 15$. From the third to fifth time steps, the detection heights of 15, 14, and 15 are selected and C_f is maintained around 0.57 where 28% drag reduction is obtained.

Instantaneous vortical structures of the uncontrolled and the DRL case (forth and fifth steps) are visualized in Fig. 5. The vortical structures, which cause the large skin-friciton drag, are observed in the uncontroleed flow. However, number of them decreases in the DRL cases, which corresponds the skin-friction drag reduction.

OUTLOOK

The control learned in this study takes longer than the conventional method to reduce the skin friction drag, so it does not completely outperform the conventional method. Also, the task of selecting the detection plane height is discrete. We are going to develop better control methods by designing the reward system according to the purpose and assigning tasks to learn continuous blowing and suction control.

VORTICES AS PARTICLES IN RAPIDLY ROTATING TURBULENT FLOWS

Ke-Qing Xia*[1,2], Kai Leong Chong[2], Jun-Qiang Shi[3], Guang-Yu Ding[1,2], Shan-Shan Ding[3], Hao-Yuan Lu[3], and Jin-Qiang Zhong[3]
[1]Center for Complex Flows and Soft Matter Research and Department of Mechanics and Aerospace Engineering, Southern University of Science and Technology, Shenzhen, China

Summary Using rotating Rayleigh-Bénard convection as a paradigmatic model system, we demonstrate through both experiment and numerical simulations that the movement of vortices in a rotating turbulent flow resembles that of inertial Brownian particles, the motion of which changes from ballistic to diffusive after certain critical time. Moreover, the transition from ballistic to diffusive behaviors is direct, free from the so-called hydrodynamic memory effect, as predicted by Langevin. The transitional timescale and the effective diffusivity of the vortices can be collapsed excellently onto a master curve for all parameters explored. When the centrifugal buoyancy is present, the cyclonic (anticyclonic) vortices are expected to move radially inward (outward). Surprisingly, as centrifugal buoyancy becomes dominant, anomalous outward motion of cyclones is observed in a centrifugation-dominant flow regime. Moreover, the relative motion of the vortices within a cluster resembles that of scale-free collective motion in systems of active particles. We interpret this phenomenon as a symmetry-breaking of both the population and vorticity magnitude of the vortices brought about by the centrifugal buoyancy.

STOCHASTIC MOTION OF COLUMNAR VORTICES

We present an experimental and numerical study of the motion of columnar vortices in rotating convective thermal turbulence, where the vortices advect horizontally in a stochastic manner. The traditional view of vortex motion is that the effect of inertia should be neglected since the vortex does not have distinct density or mass difference from their environment. Our results demonstrate that the movement of vortices resembles that of inertial Brownian particles, i.e. they initially move ballistically, and then diffusively after certain critical time. Moreover, the transition from ballistic to diffusive behaviors is direct, as predicted by Langevin, without first going through the hydrodynamic memory regime. It is also found that the transitional timescale and the effective diffusivity of the vortices can be collapsed excellently onto a master curve for all our explored parameters.

VORTEX MOTION UNDER CENTRIFUGAL FORCE

When centrifugal buoyancy becomes significant the vortices are found to undergo radial motions, i.e. cyclones move radially inward and anticyclones outward. Unexpectedly, when the centrifugal buoyancy becomes dominant anomalous outward motion of cyclones are observed. This phenomenon is interpreted as a symmetry-breaking of the vorticity field induced by the centrifugal buoyancy. Consequently the cyclones submit to the collective motion dominated by the strong anticyclones. Further studies of this anomalous vortex motion reveal that the vortices self-organize into coherent clusters, in which their velocity fluctuations exhibit scale-free correlations. Scale-free collective motions have been found in many natural systems consisting of large number of objects, such as bird flocks, fish schools, and bacteria swarms.

CONCLUSIONS

We have made systematic studies of the motion of columnar vortices in thermally-driven rotating turbulent flows from ballistic to diffusive regimes. When centrifugal force becomes dominant, anomalous outward motion of cyclones are observed, which can be interpreted as a symmetry-breaking of the vorticity field. Our study brings new perspectives on the phenomenon of collective motion, and may have broad implications in the studies of soft condensed matter, fluid physics and biological systems.
