Message of IUTAM President

Dear IUTAM colleagues, Dear Friends,

On behalf of IUTAM, including the Congress Committee and the Executive Committee, we write to extend a very warm welcome to you as participants of ICTAM2020+1. As we all realise, this Congress is unique in the history of IUTAM in many ways, and we have every expectation that it will be long remembered in IUTAM history as extraordinary in quality and impact in addition to its unique nature. It is, for example, the first ICTAM that has straddled the time of office of two IUTAM presidents, and so this welcoming address is a double-act.

We are extremely grateful to the local organisers who have worked tirelessly for several years on the project of bringing ICTAM to Milano, and although many of us are not be able to travel to Italy at this time, nonetheless we can be present together, in real-time, for many of the events of ICTAM2020+1. Mechanics in Italy is thriving, and so it is exciting for this large international congress in mechanics to gravitate to Milano. The organisers have overcome many challenges in these uncertain times, and we are deeply appreciative of their dedication and agility in organising such a large virtual gathering.

It requires only a glance at the program to realise that ICTAM2020+1 has a very fine collection of presentations across an enormous range of topics in mechanics. It is particularly pleasing to see participation by a highly diverse group of scientists, over at least 16 hours of difference in time-zone.

We wish you a very successful ICTAM2020+1, and would like to ask that you participate as fully as you can. Once again, we wish to recognize the organising team, in particular Professor Alberto Corigliano, as President of the Congress, and Professor Umberto Perego, as Secretary-General of the Congress, for all their hard work and commitment without which the congress would not have been possible. Many thanks to them, and a warm welcome to you!

With our best wishes for a most enjoyable and productive ICTAM2020+1,

Nadine Aubry
IUTAM President (2016-2020),
IUTAM Vice President (2020-2024)

Norman Fleck
IUTAM President (2020-2024)

Message of AIMETA President

On behalf of the Italian Association of Theoretical and Applied Mechanics (AIMeTA), welcome to the 25th International Congress of Theoretical and Applied Mechanics ICTAM 2020+1 in Milano. After Stresa in 1960, the ICTAM is back to Italy, and the Italian community of mechanics is proud of this and very happy to host you.

Mechanics in Italy has a long and important tradition, with giants in the past and major scholars and relevant contributions nowadays. We are very active, perfectly integrated in the international environment, which recognize the quality of our work. We are doing research in all fields of mechanics, in traditional and new frontiers area, and we are ready for future challenges.

Unfortunately, the pandemic forced the organizers to go online, which is the best that could have been done. As a consequence, you will be missing the occasion to visit Milano and Italy, with their lovely atmosphere, climate, culture, history, and science! But I am sure you will have soon the opportunity to visit us in person.

In spite of the very unwanted situation, the organizers "accepted the challenge" and showed their resilience and flexibility, organizing this event in the best possible way. The fact that a very large number of colleagues from all parts of the world, many more than what expected for an online congress, confirmed their submissions is the proof of the success of the organizers, as well as of the importance of ICTAM for the international community. Thanks to them and to all of you for attending this very special conference, which I am sure you will remember in any case.

Enjoy ICTAM now and Milano in the nearest future..

Stefano Lenci

President of AIMeTA

Welcome message of the 25° ICTAM President

The 25th ICTAM was initially scheduled from 23 to 28 August 2020 and should have taken place in Milano, Italy. Due to the covid-19 pandemic, the Organizing Committee decided to postpone this important event by one year and finally decided to transform the 25th ICTAM into a fully virtual Congress. This decision was considered to be the most reasonable for the organization of an ICTAM Congress, maximizing the active participation of Authors with high quality scientific works. This virtual meeting has the full support of both the President of IUTAM and the Executive Committee of the Congress Committee who very much look forward to the event.

In view of the high number of registered participants and the 1500 extended abstracts included in this book, that decision seems to have been the right one.

Participation in the 25th ICTAM-Virtual will allow you to appreciate the high quality scientific program that has been setup by the IUTAM Congress Committee, full of very interesting and innovative contributions on all aspects of Mechanics.

I hope you will enjoy the various ways in which you will be able to reach and take advantage of the scientific content of the Congress. For instance, you can explore the on-demand area, where you will find the pre-recorded full presentations that will remain available until the end of the year. You can also participate in the live sessions, where you will have the possibility to interact with Authors. Furthermore, you can make use of the chat lines to further interact with Colleagues. Finally, I hope you will appreciate the wonderful set of live Plenary and Sectional Lectures given by top scientists in the field of Mechanics.

The 25th ICTAM is a big event, and can only exist and can only be organized as a result of the numerous institutions and persons that work hard for the final result.

At an international level, IUTAM, the IUTAM Congress Committee (CC) and, more specifically, the Executive Committee of the Congress Committee (XCCC) and the Bureau have fully supported all phases of the Congress Organization. The International Paper Committee (IPC) reviewed more than 3400 extended abstracts in two successive calls. We all owe them a debt of gratitude.

Due to the change of dates, a new IUTAM President and new member of IUTAM Committees were appointed while the congress organization was in progress. Therefore, the responsibility of the 25th ICTAM is shared between the two Presidents, Nadine Aubry and Norman Fleck, the two Secretaries of the CC, Robert McMeeking and Sanjay Mittal, and all members of the previous and current Committees and Bureau. To all of them my special thanks for the great help received, in particular during the initial phases of the Congress organization. A special mention goes to Bruno Eckhardt, a valuable member of the XCCC, who unexpectedly passed away in the summer of 2019. He will always remain in my memory.

At a National level, the organization of 25th ICTAM was supported by AIMETA, the Italian Association of Theoretical and Applied Mechanics, in collaboration with Politecnico di Milano and Università di Pavia, which provided the highly experienced and motivated Local Organizing Committee. Politecnico di Milano also provided a motivated group of young researchers who integrated into the staff of the local organizing committee.

The technical organization was managed by the team of the professional congress organizer AIM Group International, who provided an excellent service.

To the organizing teams of AIMETA, Politecnico di Milano, Università di Pavia and AIM Group, I would like to express my most sincere thanks for the continuous support during the preparation of the Congress.

Finally, I would also like to thank my Colleagues Umberto Perego, Secretary General of 25th ICTAM and Carlo Cinquini, representative of AIMETA, for their constant support and collaboration given to this enterprise starting from the initial idea to submit a bid to IUTAM.

On behalf of the Local Organizing Committee and of the IUTAM Congress Committee, I would like to convey to you my warmest welcome to the 25th ICTAM.

Milano, August 2021

Alberto Corigliano
25th ICTAM President

BIOINSPIRED NANOMECHANICS: A CONTRIBUTION FOR THE CENTENARY OF THE GRIFFITH'S THEORY

Nicola Maria Pugno
Laboratory for Bioinspired, Bionic, Nano, Meta, Materials & Mechanics, Department of Civil, Environmental and Mechanical Engineering, University of Trento, Via Mesiano, 77, 38123 Trento, Italy
School of Engineering and Materials Science, Queen Mary University of London, Mile End Road, London E1 4NS, United Kingdom;
(nicola.pugno@unitn.it, extended abstract of the opening plenary lecture of the XXV ICTAM)

Summary The Italian artist, inventor and scientist Leonardo da Vinci (1452-1519) can probably be considered the father of bio-inspired design, as illustrated for example by his artificial wings and flying machines, based on bird observation and dissection. Five centuries from his death, bioinspiration is attracting widespread attention worldwide, both in academia and industry. This paper, related to the planned opening plenary lecture at XXV ICTAM, provides 3 new ideas in line with Griffith's theory of Linear Elastic Fracture Mechanics (LEFM): (i) a simple proposal to further generalize Dynamic/Quantized Fracture Mechanics theory and thus LEFM; (ii) the introduction of multiscale 3D Ashby's plots, to account for the role of size-effects on material properties for an improved material/structural selection and comparison; (iii) a new fundamental toughening mechanism that we -with Massimiliano Fraldi and colleagues- believe could be the key to better understand the fracture of bones, including related diseases (e.g. osteoporosis) and treatments; it is based on the evidence of stress alternating in sign in lamellae, thanks to symmetry breaking and hierarchy, simultaneously helping the crack opening needed for bone remodeling and the crack arrest needed for preserving its integrity and thus life, also suggesting new bio-inspired designs for tough composites. The inspiration for this work derives not only from Nature (and from da Vinci), but also from fundamental papers published by estimated colleagues of our community, all of whom I cannot mention here for brevity, starting from A. A. Griffith, who 100 years ago published his seminal paper. The following considerations thus represent my contribution for the centenary of Griffith's theory.

GRIFFITH/GENERALIZED DYNAMIC QUANTIZED FRACTURE MECHANICS

In 1921 Griffith published his seminal paper, submitted in 1920, basically describing the theory of Linear Elastic Fracture Mechanics (LEFM) [1], Fig. 1.

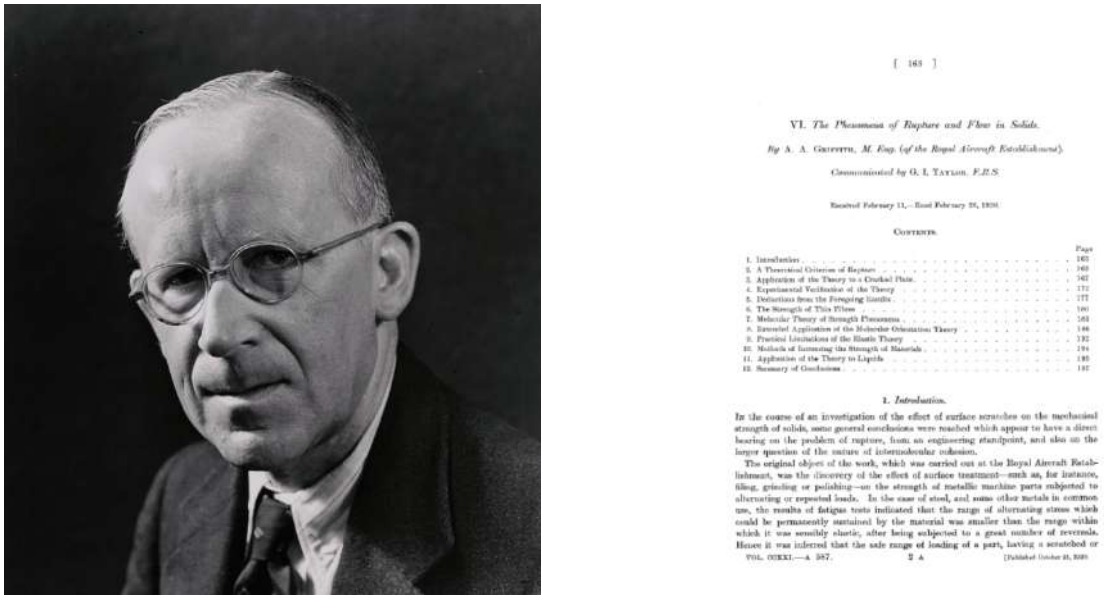

Figure 1. (left) Sir A. A. Griffith published his pioneering paper 100 years ago: The phenomena of rupture and flow in solids. Philosophical Transactions of the Royal Society of London. Series A, Containing Papers of a Mathematical or Physical Character. 1921 IV. 221: 163-198. (right) The first page of his pioneering paper.

According to LEFM, not the (maximal) stress but the energy release rate, or equivalently the stress intensity factor, must reach a critical value for the onset of crack propagation. In order to solve some limitations of LEFM, including the remaining paradox of infinite strength for vanishing crack length, I extended LEFM by introducing Quantized Fracture Mechanics (QFM, [2]): mathematically, differentials are simply substituted by finite differences in Griffith's energy balance. This corresponds to considering the onset of crack propagation not when the energy release rate reaches a critical value (the fracture energy per unit area of the material) but when its mean value along a fracture quantum of crack surface area ΔA -the previously introduced finite difference- reaches the material fracture energy. Equivalently, it is not the

stress intensity factor (for the different crack propagation modes) $K \equiv K_{LEFM}$ that must reach a critical value (the fracture toughness of the material, K_C) for crack propagation, but instead the square root of the mean value of the square of the stress intensity factor along a fracture quantum, which is by definition the quantized stress intensity factor K_{QFM}. This theory is thus based on the removal of the hypothesis of continuous crack growth, i.e. on the existence of a quantum of energy dissipation/crack advancement, as postulated in the stress-analogue approach by Novozhilov [3]. In dynamic fracture, and considering the existence of a quantum of action, the mean value must be considered also along a quantum of time Δt -thus defining the dynamic quantized stress intensity factor K_{DQFM} [4]- as introduced again by the Russian's School in the stress-analogue incubation time fracture mechanics approach [5].

The exponent of 2 can in principle be generalized to a positive real number α, thus proposing a Griffith/Generalized (Dynamic) Quantized Fracture Mechanics (GQFM), predicting crack propagation according to:

$$K_{GQFM}^{(\alpha,\Delta A,\Delta t)} \equiv \sqrt[\alpha]{\frac{1}{\Delta A \Delta t}\int_{t-\Delta t}^{t}\int_{A}^{A+\Delta A} K(A,t)^{\alpha}\mathrm{d}A\mathrm{d}t} = K_C \qquad (1)$$

Note that $K_{GQFM}^{(\alpha,\Delta A=0,\Delta t=0)} = K_{LEFM}$, $K_{GQFM}^{(\alpha=2,\Delta A,\Delta t=0)} = K_{QFM}$, $K_{GQFM}^{(\alpha=2,\Delta A,\Delta t)} = K_{DQFM}$ and $K_{GQFM}^{(\alpha=1,\Delta A=0,\Delta t)} = K_{ITFM}$, where K_{ITFM} is the equivalent stress-intensity factor according to the incubation time fracture mechanics [5]. Accordingly, all these limiting-case theories, which have been proved to capture experimental observations that LEFM cannot describe, are recovered and thus the correspondence principle is satisfied, as expected in the limit of vanishing fracture energy and action quanta.

The generalized stress intensity factor in (1) could also extend stress-intensity factor based laws such as those of fatigue, as proven for $\alpha = 2$ to capture both long and short crack behaviours even in fatigue (thus from the Wöhler to the Paris regimes) [6]. With the criterion (1), apparent R-curve behaviours and strain-rate effects emerge naturally as a consequence of the existence of fracture and time quanta, rendering fracture toughness no longer, or less crack-length and strain-rate dependent, and thus a more realistic material property, as it must be by definition. This could also help in the formulation of more realistic Ashby's plots.

MULTISCALE 3D ASHBY'S PLOTS

Asbhy's plots are fundamental for material selection [7]. As is well known, simply assuming in Griffith's theory a crack length $a \propto l^k$, where l is the structural size, would result in a scaling law for the strength of the type $\sigma \propto l^{-k/2}$, as similarly predicted by Weibull's statistics [8] or by other interpretations, e.g. fractal geometry [9]. I do not wish to comment here about the details of size-effect laws, but rather to emphasize that with the advent of nanotechnology, it is not infrequent to see papers reporting the fabrication of a new material using an Ashby's plot, even if it has been tested at a smaller size-scale. The need to adopt different Ashby's plots at the micro- and nano-scales has already been highlighted [10]. Here, I propose to use 3D Asbhy's plots for an improved multiscale representation, material/structural selection and comparison.

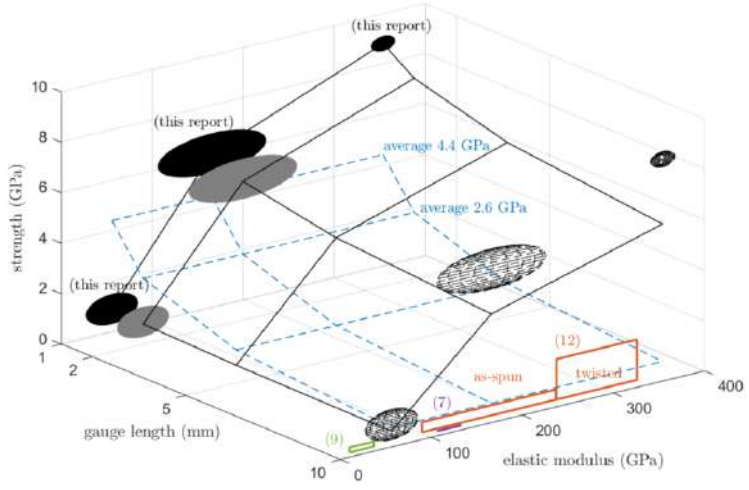

Figure 2. The black ellipses represent the strength vs elastic modulus data collected by the authors in [11] corresponding to samples with 1-mm gauge length (their fig. 4B). The overall average of this data is 4.4 GPa, while I have computed a total average of 2.6 GPa for the data at 2-mm gauge length (their fig. 3A). The corresponding scaling law, considering in a first approximation the independence of the elastic modulus, is of the type $\sigma \propto l^{-k/2}$ with a large value of $k/2 \cong 0.75$ (blue dashed lines). This scaling law predicts strength values comparable to those taken from the literature (green, purple or red areas, 1-cm gauge length). When considering the low- and high-strength regions (peaks in their fig. 3A), the average for the ellipse centred at a strength of 6.2 GPa for 1-mm gauge length falls to 5.6 GPa for a 2-mm gauge length, thus giving a scaling law with $k/2 \cong 0.15$ (black solid lines). The dashed ellipses are the projections at 10-mm gauge length of those at 1-mm gauge length, as reported in [11], whereas mean or maximal predictions at 10-mm are those reported with the blue dashed or black continuous lines, respectively. This case study must be considered just a preliminary example, such as the deduced size-effects.

As an example, I treat the case reported in Figure 2, where nanotube bundles are considered according to the paper in [11]. Asbhy's plot presented by the authors was inevitably classical, i.e. 2D, without considering the role of the bundle/gauge length, even if these authors perfectly recognized the role of size-effects and thus tested samples at different gauge lengths. A 3D Asbhy's plot, with a new axis corresponding to the size-scale (here gauge length) could thus be a better choice for comparison with other experiments, as described in Fig. 2. The experiments from the literature reported for comparison in [11] where performed at a gauge length of 1 cm, which I have considered in the 3D plot. I have also reported their experiments [11], not in the same plane but in their correct positions (1-mm or 2-mm gauge length planes). According to the same authors' experiments at different gauge lengths and assuming the simple mentioned scaling law of $\sigma \propto l^{-k/2}$, I could predict mean or maximal strength values expected at larger gauge lengths, including 10 mm, as reported respectively with the blue dashed or black solid lines.

The need for multiscale 3D Asbhy's plots is thus evident if we wish to move towards a standardization in material property comparisons. Regarding fracture toughness, the use of criterion (1) could further help the standardization, as previously mentioned. In general, the understanding of the toughness mechanisms is fundamental in Nature and Engineering. We believe that we have discovered a new fundamental one in bones.

A RECENTLY DISCOVERED TOUGHENING MECHANISM IN BONES

Bone tissue is a hybrid material made of an inorganic calcium phosphate phase nucleated into a collagenous matrix and organized hierarchically, from nanofibrillary components, to osteons (hundreds of micrometers in size), up to the cortical/trabecular macrostructure. It behaves as a complex composite able to adapt its internal organization to optimize the mechanical response under externally applied loads, contemporarily minimizing weight and resisting severe impacts and fatigue stress cycles by exhibiting surprising and not yet completely understood crack arresting mechanisms to avoid catastrophic fracture. In particular, it seems to be suitably designed to resist fracture at multiple size scales, thus achieving remarkable strength and toughness. However, the exceptional mechanical properties of bone can deteriorate with ageing and/or diseases: therefore, it is necessary to fully understand the mechanisms that confer these properties, also to develop therapies able to preserve or even rescue tissue functionality. Osteons, the fundamental bone units (Fig. 3a), are nearly hollow cylinders made of several concentric layers (lamellae) comprising helically arranged fibres wrapped nearly alternately clockwise and counterclockwise. With the Basic Multicellular Unit (BMU) osteocytes sense mechanical signals and activate and coordinate osteoblasts and osteoclasts for bone remodelling, i.e. resorption of preexisting bone by osteoclasts followed by *de novo* bone formation by osteoblasts (this process being impaired during ageing and diseases). It is ascertained that micro-damaging occurring across the scales plays a crucial role in bone mechanobiology, the micro-cracks opening at the osteon-matrix interfaces and within osteons working to trigger the BMU activities and the level of damage being an indicator of the need to locally increase mineral content through bone remodelling processes. However, how the crack propagation is triggered and arrested nearly simultaneously, both in compression and in tension (and thus also in bending) in such a stiff material, is still a partially unsolved enigma.

The most recognised hypothesis to explain the crack stopping/slowing phenomenon is based on the material inhomogeneity and anisotropy and the layered architecture of osteons: after nucleating, cracks would be halted when radially travelling across the osteon lamellae since they encounter the nearly alternating and in any case different arrangement of the wrapped fibres that make them decelerate at the lamellar interfaces and deviate along the circumferential direction. This leads to the dissipation of energy by increasing the length of the crack path, as well as by breaking micro-bridge elements and encountering a number of micro-voids and discontinuities generating micro-cracking. This mechanism surely plays an important role in arresting cracks in bone, but both theoretical calculations to estimate stress intensity factors at the crack tips and numerical analyses simulating crack propagation within osteons under static/cyclic loads as well as experimental findings [12], highlight that this is not sufficient to hinder fracture, suggesting that some yet undiscovered mechanisms should cooperate with (or exploit) bone hierarchy to halt crack progression [13]. Theoretical results also suggest that tensile hoop stresses in the lamellae, responsible for micro-crack opening in the radial direction, would occur only in case of compressive loads, while experimental observations show diffuse radial micro-cracks generated by tensile loads too [14].

Motivated by these incomplete and somehow contradictory results, we (the authors of ref. [15]) deeply explored an additional crack opening and stopping thus smart toughening mechanism with respect to those widely accepted in the literature, for which we have now clear theoretical evidences as well as experimental confirmation on 3D printed artificial hierarchical bones. For the occasion of this XXV ICTAM conference, we have rendered the paper public in the *Arxiv* [15]. Our results, obtained from an accurate mechanical model (Fig. 3a) of elastic anisotropy (Fig. 3b), show a counterintuitive radially distribution alternating in sign of both hoop and shear stresses in the lamellae and sub-lamellae (Fig. 3c,d), which could simultaneously act to open and halt cracks (Fig. 3e) thanks to hierarchy and symmetry breaking (Fig. 3f). This could also better stimulate the osteocyte activity by amplifying the mechanical signal, thus finally producing a "perfect" system capable to work both under compression or tension and thus bending.

Accordingly, this indeed unveils a powerful crack opening and simultaneously arresting mechanism, mediated by both the helical microstructure of the collagen fibrils in lamellae and sub-lamellae and the currently neglected small discrepancy in the nearly symmetric staggered angles of their wrapping in adjacent lamellae/sub-lamellae. The latter symmetry breaking generates this mechanism of Alternating Stresses in Lamellae (ASL, Fig. 3f), also occuring in sub-lamellae (ASL2) and hierarchy is shown to further enhance its power (Fig. 3c,d). Thus if ASL plays a fundamental role in bone toughening, its disappearance could be strictly related with bone ageing and common bone degenerative diseases, such as osteoporosis. Therefore, investigating the mechanosignaling pathways linking ASL to cellular response(s) and

tissue remodelling could have important and wide-ranging implications for both the comprehension of bone disorders and the conception of new therapies, essentially based on the idea of restoring ASL when lost. Additionally, with this ASL*n*-based toughening mechanism, a new design of bio-inspired *n*-level hierarchical composites is envisioned, e.g. in the next generation of self-healing materials where both crack opening and arrest could be required.

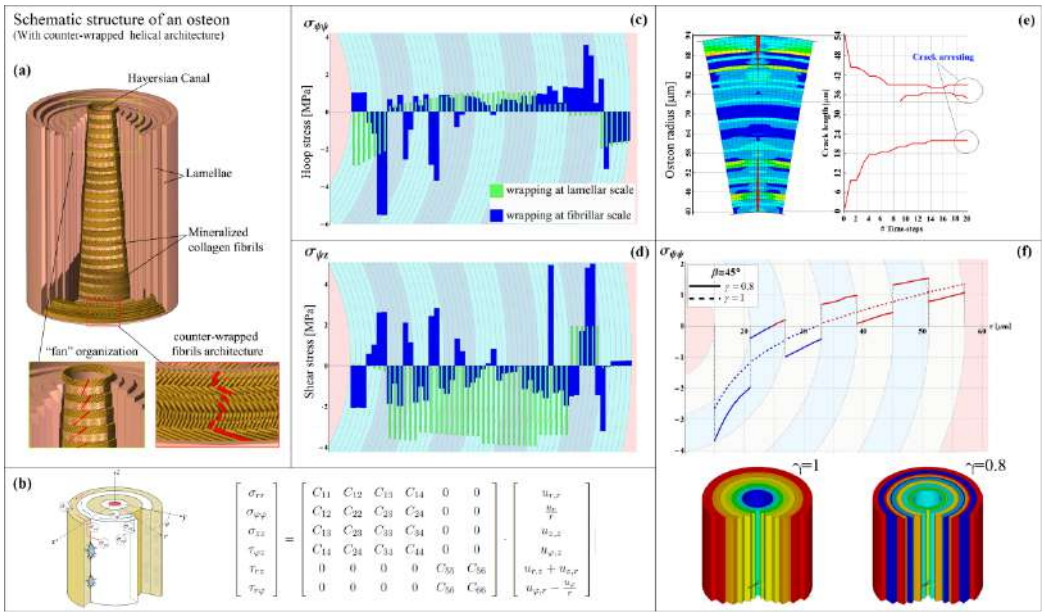

Figure 3. a) Osteon schematic structure. b) Anisotropic (monoclinic) elastic global equations resulting from the local helicoidal transversal isotropy (5 elastic constants). c)-d) Alternating in sign hoop and shear stresses without or with the presence of sub-lamellae, with stress jump amplification in the latter hierarchical case. e) Numerically (finite element) simulated crack progression and halting across osteon lamellae. f) Alternating in sign hoop and shear stresses in adjacent lamellae with fibril wrapping angles of β and $-\gamma\beta$ respectively and related stress jump amplification for symmetry breaking ($\gamma \neq 1$). For details see [15].

CONCLUSIONS

To celebrate the centenary of Griffith's theory (1921), in this paper -related to the opening plenary lecture at XXV ICTAM- I have presented 3 new concepts in the field of fracture: (i) a new extension of Griffith's theory, following the previous proposals by the author on Dynamic/Quantized Fracture Mechanics; (ii) the proposal of multiscale 3D Asbhy's plots, to include in these plots the fundamental role of the size-scale on the strength and in general on the mechanical properties of materials, for an improved material/structural selection and comparison; (iii) a new fundamental bone toughening mechanism, deriving from evidence of stress alternating in sign in osteon lamellae, emerging from the rupture of the symmetry of fibrils and empowered by hierarchy of sub-lamellae, suggesting also inspired solutions in Leonardo da Vinci's spirit [16].

As our lamellae, alone we are fragile but altogether we are resilient: this is why the pandemic is not stopping us, thanks to the new frontiers of Science and Technology and especially solidarity among peoples.

RHEOLOGY OF DENSE GRANULAR SUSPENSION

Élisabeth Guazzelli
Matière et Systèmes Complexes, CNRS, Université de Paris, France

Summary Suspensions consisting of mixtures of particles and fluids are materials with broad applications both in natural phenomena and in industrial processes. The present talk focusses on the rheology of concentrated suspensions of non-colloidal particles and shows that it can be tackled by a diversity of approaches depending on the flow configuration and on the parameters that one wishes to describe.

INTRODUCTION

Suspensions are composed of mixtures of particles and fluid and are ubiquitous in many natural phenomena (e.g. sediment transport in rivers and oceans, landslides, debris and lava flows) and in industrial processes (e.g. food and cosmetic, pulp and paper, materials for civil and petroleum engineering), see e. g. [1]. Due to their relevance to so many common situations, it is of utter importance to understand their response to imposed forces or motions at their boundaries. The problem is then to determine the rheological properties of these media (usually considered as equivalent homogeneous materials) from a knowledge of the mechanics of the particles and the interstitial fluid. In other words, the issue is to understand the relationship between the macroscopic or bulk properties of the flowing medium and its microscopic structure, see e. g. [2] .

This talk concerns the rheology of non-Brownian suspensions, meaning that the particles of interest are sufficiently large (i.e. have radius much larger than a micrometer) for Brownian or colloidal forces (such as electric double layer or van der Waals forces) to be ignored. It is mostly restricted to the condition of vanishingly small Reynolds numbers. It also focusses on the dense regime of large particle concentrations which is far from being completely deciphered. The major impediment to this understanding stems from the complex nature of the interactions between the particles. The grains can interact both by hydrodynamic interactions through the liquid but also by direct mechanical contact as the concentration increases. This is why these suspensions have been coined 'dense granular suspensions' as they somehow belong to an intermediate regime between pure Stokesian (inertialess) suspensions for which long-range hydrodynamics interactions or lubrication forces between the particles are essential and granular flows for which only direct contact interactions are present, see e. g. [3].

There are multiple avenues to study dense suspension rheology. Dense suspensions can be seen as a fluid with effective rheological properties but also as a two-phase system wherein the fluid and particles can experience relative motion. They can be described with constitutive laws in which the control parameter is the normal stress imposed to the particle phase rather than the volume fraction. This alternative description inspired by the frictional approach of dry granular media is particularly suited to yield examination of the rheology close to the jamming transition. Also, when the suspensions are confined, e.g. by interfaces, the discrete nature of the suspension comes into play.

THE SUSPENSION VIEWED AS A SINGLE EFFECTIVE FLUID

Provided the length scale of the flow is large compared with the average spacing between the particles, the suspension may evidently be regarded as a continuous effective fluid. It is well known since the seminal work of Einstein [4, 5] that the effect of adding particles results in an increase of the viscosity of the mixture above that of the suspending fluid. For the simplest case of a suspension of monodisperse hard spheres under simple shear, see figure 1 (a), the shear stress, τ, scales linearly with the shear rate, $\dot{\gamma}$, in the Stokes regime of vanishingly small Reynolds numbers. In other words, the scaling of the stress is viscous, $\tau = \eta_s \eta_f \dot{\gamma}$, where η_f is the viscosity of the suspending fluid and η_s is the relative viscosity of the suspension. This suspension viscosity, η_s, only depends on the particle volume fraction, ϕ, and increases with increasing ϕ. It is seen to diverge at the jamming transition where the particle concentration reaches a maximum value, ϕ_c, for which the suspension ceases to flow. This maximum flowable volume fraction generally differs from the maximum close random packing fraction (≈ 0.64) and varies depending on the size distribution of the particles and also their surface interactions, more precisely their frictional interactions. In practice it may be difficult to flow a suspension for $\phi > 0.52 - 0.62$.

A viscous suspension of hard spheres can be seen as a quasi Newtonian fluid with a shear viscosity increasing with increasing volume fraction. This however does not account for the existence of normal stress differences, i.e. for normal stresses which are no longer isotropic under shear, which appear for non dilute suspensions. This non-Newtonian feature is intimately linked to the loss of isotropy of the suspension microstructure due to the irreversible dynamics (due to contact interactions between the rough spheres) that develop under shear. Similarly to the shear stress, normal stresses scale viscously in Stokes flows and are proportional to the modulus of the shear stress. They also present the same divergence as the shear stress when approaching the jamming transition. Normal stress differences are difficult to be measured as they happen to be much smaller than the shear stress at small ϕ. For suspensions of hard spheres, the second normal stress difference is observed to be negative and to increase with increasing ϕ while the first normal stress difference is much smaller and its sign more elusive, see e. g. [6, 7].

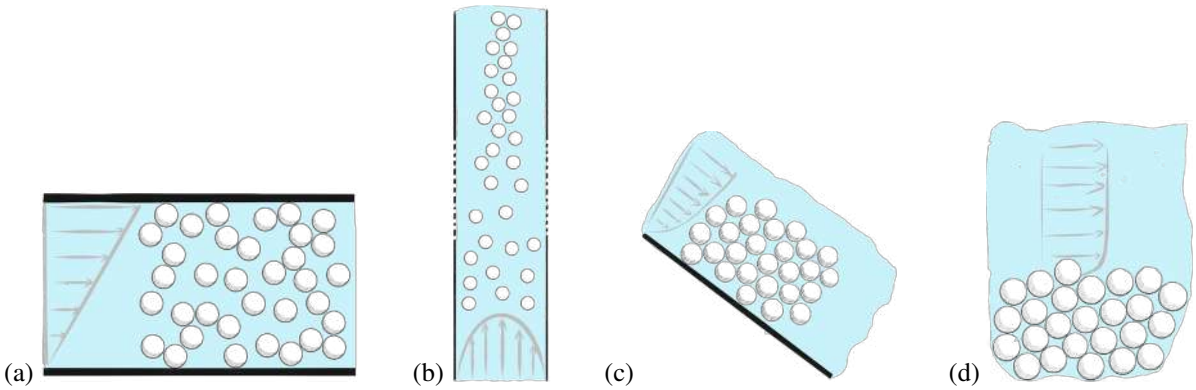

Figure 1: Some suspension flow configurations: (a) shearing flow of a suspension of neutrally-buoyant hard spheres between two plates, (b) shear-induced migration of neutrally-buoyant spheres in pressure-driven Poiseuille flow in a tube, (c) flows of immersed heavy particles down an inclined plane, (d) erosion of sedimented particles under the action of viscous fluid shearing flows.

BEYOND A SINGLE PHASE VIEW: TWO-PHASE SUSPENSION FLOWS

In many flow configurations, the fluid and the particles experience relative motion. It is then necessary to go beyond the single phase description presented in the preceding section and to consider two separate fluid and particle phases. An archetypal example is the phenomenon of shear-induced migration, e. g. the observed irreversible migration of neutrally-buoyant spheres in a pipe flow [8]. The particles have a tendency to move from the high shear region at the wall toward the low shear region at the centre line, see figure 1 (b). A key concept of the two-phase description is that of particle pressure. Whereas the whole suspension, i. e. the mixture of the particles and the fluid, is incompressible, the particle phase is not. There exists a pressure coming from the dispersed particulate phase that can develop in particular in the concentrated regime. It has been termed particle pressure (or more generally particle normal-stress) and has been considered an analog to the osmotic pressure exerted by colloidal particles or dissolved molecules and ions, where here the shear rate plays the role of the temperature to induce agitation and collisions between the particles. This particle normal stress P also scales viscously and is linear in the modulus of the shear rate. It can be written as $P = \eta_n(\phi)\,\eta_f\dot{\gamma}$ (where $\dot{\gamma}$ is conveniently defined in an invariant form as $\dot{\gamma} = \sqrt{2\,\mathbf{E}:\mathbf{E}}$ where $\mathbf{E}$ is the rate of strain). The dimensionless effective normal viscosity η_n is again a sole function of ϕ and presents the same divergence as $\eta_s(\phi)$ when approaching jamming at ϕ_c. Particle normal stress produces the driving force for the motion of the particles and is fundamental in the physical understanding of the migration process [9, 10, 11, 12].

AN ALTERNATIVE FRICTIONAL APPROACH

Up to now we have discussed situations where the control parameter is the particle volume fraction, ϕ. However, under some flow configurations, ϕ is not controlled and is a free adjustable parameter. This is the case of flows where gravity controls the level of stress experienced by the particle phase such as flows of heavy particles down an inclined plane [13] or transport of sedimented particles under the action of viscous fluid shearing flows [14, 15] depicted in figure 1 (c) and (d), respectively. The control parameter is then the stress imposed to the particle phase, P, and no longer the volume fraction, ϕ. This alternative description, coined 'pressure-imposed rheology' by contrast to the classical 'volume-imposed rheology' (see figure 2) is derived from the rheological approach developed to describe dry granular flows and hinges on a frictional view of the problem, see e. g. [16]. When the suspension is subjected to steady shear under a confining particle pressure P, there is only one dimensionless control parameter, a dimensionless shear rate which can be interpreted as the ratio of the time scale for particles to rearrange due to the pressure P to the time scale of the flow, $\dot{\gamma}^{-1}$. The effective friction coefficient $\mu = \tau/P$ and the volume fraction ϕ are sole function of this dimensionless number. In the case of suspensions for which viscous forces are dominant, the dimensionless number is $J = \eta_f\dot{\gamma}/P$ and is viscous in contrast to dry granular flows where it is inertial. Suspensions and granular materials can thus be described with a common frictional framework [17]. In the case of viscous suspensions, this frictional formulation is equivalent to the classical description of the rheology of suspensions in terms of effective viscosities discussed earlier: the shear, $\eta_s(\phi) = \tau/\eta_f\dot{\gamma} = \mu/J(\phi)$, and normal, $\eta_n(\phi) = P/\eta_f\dot{\gamma} = 1/J(\phi)$, relative viscosities where $J(\phi)$ is the inverse function of $\phi(J)$ which is perfectly defined since $\phi(J)$ is monotonic. This alternative frictional approach is particularly suitable to infer the singular rheological properties at the jamming transition as it circumvents the divergence observed in volume-imposed rheometry.

APPROACHING JAMMING

As the jamming transition is approached, particles form an extended network of contacts, and the rheology is then dominated by contact forces, even in the case of viscous suspensions for which contact interactions prevail over long-range

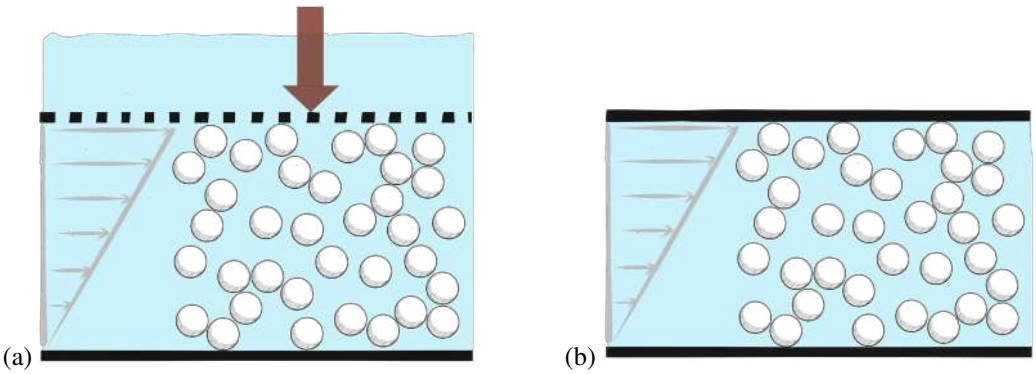

Figure 2: Pressure-imposed versus volume-imposed rheometry: (a) in pressure-imposed rheometry, the neutrally-buoyant particles are sheared at a given shear rate under a confining pressure applied to a top porous plate which enables the fluid to flow through it but not the particles (the height of the top plate can adjust in response to dilatation or compaction of the sheared suspension), (b) in volume-imposed rheometry, the neutrally buoyant particles are sheared at a given shear rate and constant volume fraction as the gap between the plates is kept constant.

hydrodynamics interactions or lubrication forces. There is not yet an accepted microscopic description of the transition and the current description, while remaining rather empirical, aims at understanding the properties of the contact network between the particles close to jamming [18, 19]. Experiments for suspensions of frictional spheres show similar algebraic divergences of the shear and normal viscosities in $(\phi_c - \phi)^{-2}$ close to the transition, see e. g. the pressure-imposed rheometry measurements of [17, 20]. This asymptotic behavior is not changed by an increase in particle roughness, or equivalently interparticle friction [21]. The quasistatic value of the effective friction coefficient, μ_c, is not significantly affected either. It is also similar to that obtained for dry granular spheres showing that hydrodynamic interactions are inconsequential and contact forces are prevailing in this quasistatic limit. Only the critical volume fraction at jamming, ϕ_c, is impacted as it decreases with increasing roughness. Conversely, the influence of the particle shape seems to have a profound impact on the singular behavior near the jamming transition. For suspension consisting of rod-like particles (i. e. fibers), the critical volume fraction, ϕ_c, decreases with increasing aspect ratio, A, and when rescaling with $\phi_c(A)$ is done, the shear and normal viscosities present a divergence in $(\phi_c - \phi)^{-1}$, in stark contrast with the divergence observed for spheres [22].

WHEN CONTINUUM BREAKS DOWN: SUSPENSIONS CONFINED BY INTERFACES

Not everything is yet elucidated but, as discussed in the preceding sections, the bulk flow rheology of granular suspensions is beginning to be well documented. Much less is known in the case of confined flows where the discrete nature of the suspension comes into play and the continuum description breaks down. In particular, suspensions confined by mobile interfaces raise new questions which are entirely unexplored.

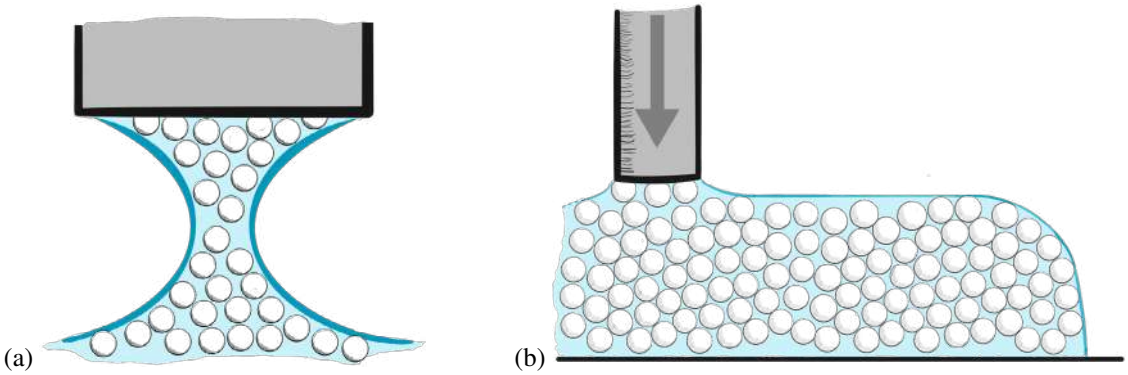

Figure 3: Two capillary flows of a suspension: (a) the pinch-off of a viscous suspension thread, (b) the wetting of a viscous granular suspension on a solid surface

Two classical capillary flow configurations are depicted in figure 3: (a) the pinch-off of a viscous suspension thread and (b) the wetting of a viscous granular suspension on a solid surface. Adding spheres to a viscous liquid thread has a drastic influence on its break-up. In the early stage of the pinch-off, the dynamics is independent of the size of the particles and the suspension behaves as an effective viscous fluid. But, there is a subsequent discrete regime in the late stage of the pinch-off, in which the thinning dynamics accelerates significantly and is dominated by discrete particle effects [23]. The spreading of a suspension on a solid surface also presents non-trivial behavior in particular in the vicinity of the moving contact line. The spherical particles remain at a finite distance from the contact line and there is consequently a region

devoid of particles in the vicinity of this contact line. This leads to an unexpected behavior as the apparent viscosity during spreading depends both on the size and volume fraction of the particles and thus profoundly differs from the bulk viscosity.

CONCLUSIONS

While long-range hydrodynamics interactions or lubrication forces are essential for dilute suspensions, contact interactions between particles become of fundamental importance for the understanding of concentrated suspension. This talk gives an overview of the different approaches that can be followed to tackle suspension rheology in this dense regime. Beyond the classical problem of the bulk flow of dense suspensions of hard spheres in a Newtonian fluid, there are entirely novel avenues of study concerning more complex mixtures of particles and fluid in more complex flowing geometries.

This work emanates from a long-term collaboration with O. Pouliquen on the rheology of granular suspensions at IUSTI (Aix Marseille Université and CNRS) and is part of the doctoral and postdoctoral studies of F. Boyer, E. Couturier, S. Dagois-Bohy, S. Hormozi, and F. Tapia. It also owes much to scientific interactions with J. F. Morris and P. R. Nott. Studies on sediment transport have been started with P. Aussillous and also come from collaboration with J. Chauchat, M. Médale, M. Ouriemi, M. Pailha, and Y. Peysson. Studies of fiber suspensions stem from a long-lasting collaboration with J. E. Butler (University of Florida) which has given rise to the jointly-advised doctoral studies of B. Snook, S. Shaikh, and S. Strednak. Finally, the more recent studies of granular suspensions confined by interfaces have been initiated with H. Lhuissier and M. Roché and are part of work undertaken with J. Château, L. Limat, M. Oléron, A. Pelosse, M. Zhao.

MEASUREMENTS IN WALL-BOUNDED TURBULENCE

Alexander J. Smits
Department of Mechanical and Aerospace Engineering, Princeton University, Princeton NJ 08540, U.S.A.

Summary Our understanding of turbulent boundary layer scaling and structure has advanced greatly in the past 20 to 30 years. On the computational side, direct numerical simulations and large-eddy simulations have made extraordinary contributions as methods and computational resources have burgeoned, while on the experimental side major advances in instrumentation have made available imaging and quantitative techniques with unprecedented accuracy and detail. Here, I illustrate how our progress has been aided by the development of such experimental methods by reference to three particular questions on the scaling of turbulent boundary layers: (1) the similarity behavior in supersonic and hypersonic flows; (2) the structure of the outer layer in subsonic flows at high Reynolds number; and (3) the scaling of the turbulent stresses in the near-wall region. I close by discussing the likely role of computation and experiment in future studies.

TURBULENT BOUNDARY LAYERS IN SUPERSONIC AND HYPERSONIC FLOWS

There are two basic differences between boundary layers in subsonic and supersonic or hypersonic flows. First, there is always a region of subsonic flow near the surface, separated from the external flow by the point where the Mach number reaches one, that is, the sonic line. This region becomes smaller relative to the boundary layer thickness with increasing Mach and Reynolds number, but it also depends on the wall temperature in that it is larger on a heated wall than on a cooled one. Second, temperature gradients become important. For example, in a Mach 10.3 helium boundary layer over an adiabatic wall ($T_w/T_r = 1$), the temperature increases by a factor of about 33 across the boundary layer [1]. Hence the viscosity near the wall can be many times larger than that in the external flow, and a single Reynolds number no longer describes the flow state. As a result, the extent of the viscous layer as a fraction of the boundary layer thickness can increase significantly with Mach number. In addition, when the Mach number is high enough, the high temperatures experienced near the wall will lead to real gas effects including vibrational excitation, dissociation, and even ionization of the gas. Surface ablation effects may also become important. The onset of these real gas effects effectively marks the beginning of the hypersonic regime.

Prior to about 1985, it was generally believed that turbulence high-speed boundary layers was fundamentally different from that in subsonic flows. In particular, hot-wire measurements had shown that the level of the velocity fluctuations $\sqrt{\overline{u^2}}/u_\tau$ decreased with increasing Mach number, and that in the outer region of the boundary layer the turbulence was considerably less intermittent than in comparable subsonic flows [2, 3]. Flow visualization by schlieren or shadowgraph methods were not very helpful in this regard because they integrate across the flow, and do not generally give much information on the turbulent-non-turbulent interface. Also, the accuracy of hot-wire measurements in high-speed flows was often compromised by inadequate temporal or spatial resolution [4]. High-speed flow experiments make strict demands on hot wire anemometry in that the frequency content of the turbulent fluctuations is very high (100s of kHz), spatial resolution requirements are strict in that boundary layers are typically thin, and the aerodynamic loads on the wire can be severe. In addition, the calibration is complicated by the fact that the wire is sensitive to both density and velocity fluctuations [5].

The development of improved hot wire techniques in general [6], and in supersonic applications in particular [7, 8, 9, 10, 11] helped turn this around. In addition, the use of laser sheets and droplet seeding [12], and the development of filtered Rayleigh scattering methods [13, 14, 15] allowed planar visualizations of the flow field for the first time, as illustrated in figure 1. Superficially, therefore, a turbulent boundary layer in supersonic flow appears to behave much like its subsonic counterpart, in that its outer interface is highly intermittent, and it displays a large range of scales that increase with Reynolds number. The dynamic effects due to temperature gradients generally appear to be small, and over a large range of Mach numbers the mean velocity profile can be rescaled by accounting for the density changes induced by the temperature differences (as is the case for subsonic flows, the mean pressure across the boundary layer can be taken to be constant). This is the essence of the van Driest transformation, where, broadly speaking, the scaling variable for the velocity is taken to be $u^* = \sqrt{\tau_w/\rho}$ rather than the classic friction velocity $u_\tau = \sqrt{\tau_w/\rho_w}$.

A similar approach may be taken in scaling the turbulence profiles. It was Morkovin who first suggested using the local stress rather than the wall stress as a scaling variable [16], that is u^* rather than u_τ, and this is now known as Morkovin scaling. Recent PIV data obtained in a Mach 7.5 boundary layer confirms the usefulness of Morkovin scaling [4], as do DNS of similar flows [17]. These comparisons are given in figure 2.

As to the structure of the turbulence in high-speed flows, recent work suggests that, in contrast to previous understanding, it is largely independent of Mach number. For example, the streamwise length scales derived from velocity correlations were seen to decrease much more slowly with Mach number than suggested by older studies [4]. Similarly, the characteristic angle of inclination of the correlation contours of streamwise velocity is relatively insensitive to Mach number, whereas previous studies suggested that this angle increased with Mach number. These new observations also

imply that there are significant differences in the properties of velocity and density fields at high Mach number. Other measures, such as the number of Uniform Momentum Zones (UMZ), do not appear to demonstrate any Mach number dependence, and they appear to match the logarithmically scaling with Reynolds number observed for subsonic flows, as illustrated in figure 3.

SCALING OF THE OUTER LAYER

Despite many decades of work, it was not until relatively recently that the turbulence distributions in incompressible flows were accurately documented. For example, [19] collected a large number of experimental results on pipe flow, which illustrated the general lack of certainty in 2010 (see figure 4a). This lack of clarity has now largely been resolved by two major developments: the development of special-purpose, high-quality, high Reynolds number laboratory facilities, and major improvements in hot-wire anemometry.

We now consider the scaling of the outer layer, that is, the region where $y^+ > 100$. Townsend's [21] attached eddy hypothesis predicted that, in the overlap or logarithmic layer of the boundary layer at a sufficiently high Reynolds number, the streamwise turbulence intensity follows a logarithmic variation such that

$$\overline{u^{2+}} = B_1 - A_1 \ln(y/\delta) - V(y^+) \tag{1}$$

where the function $V(y^+)$ was introduced by Perry et al. [22] to account for viscous effects at lower Reynolds numbers. For the logarithmic term to emerge, it is clear that we need $V(y^+)$ to become negligible, which will only happen at high Reynolds number. Since the energy content in the outer layer is dominated by the larger scales of motion, any shortfall in either temporal or spatial resolution of the instrumentation is generally not the main issue, but high Reynolds numbers are essential. To develop high Reynolds number, high-quality boundary layers in conventional wind tunnels requires purpose-built large scale facilities, which are expensive. However, using high pressure as a means of increasing the unit Reynolds number is a cost-effective way to achieve very high Reynolds number flows (pipe or boundary layer). The Princeton Superpipe [23] yielded the results shown in figure 4b, up to $Re_\tau = 98,000$. The results for the outer layer are shown in figure 4c, and the logarithmic variation predicted by Townsend is clearly seen.

SCALING OF THE INNER LAYER

To reveal the scaling of the inner layer, in addition to having high Reynolds number facilities, we need instrumentation with sufficient temporal and spatial resolution to resolve the near-wall, small-scale motions accurately. Of these two, the

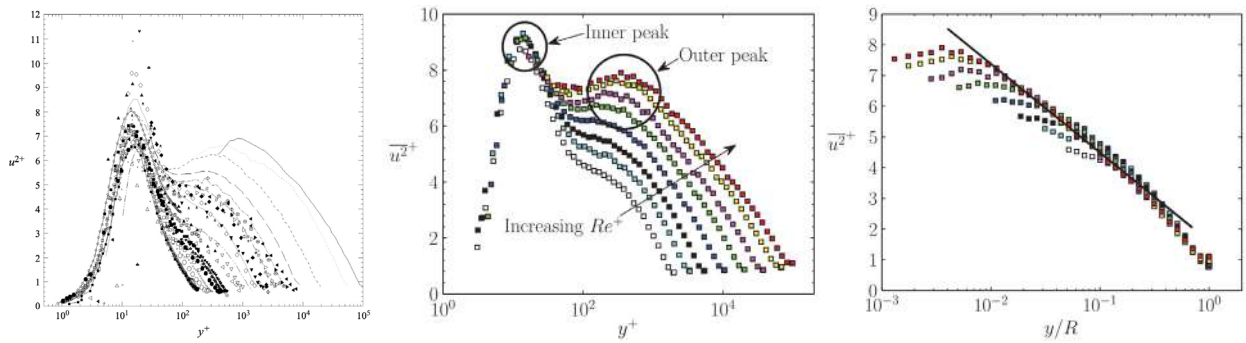

Figure 4: Streamwise turbulence intensity in pipe flow. (a) Data are from 13 experiments using LDV and hot wires. From [19], where sources are given. (b) Data from Superpipe in inner layer coordinates. From [20]. (c) Data from Superpipe in outer layer coordinates for $y^+ > 100$. The solid line is equation 1 with $A_1 = 1.25$, $B_1 = 1.61$. From [20].

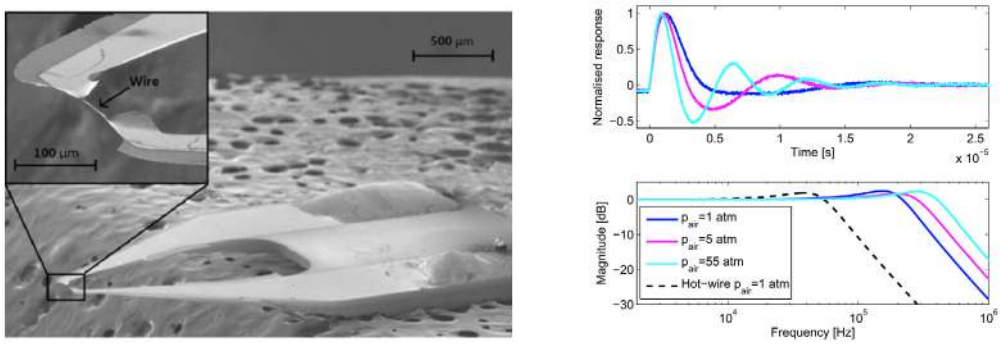

Figure 5: Configuration and performance of NSTAP ($\ell = 60$ μm, $w = 1$ μm, $t = 0.1$ μm). (a) Scanning electron microscope images. The probe is mounted on a wax substrate (seen in the background) for imaging. From [27]. (b) Temporal response of the NSTAP at different ambient air pressures. a) Square-wave response; (c) attenuation in signal with frequency (Bode diagram), where 0 dB indicates unity gain (estimated using square wave response). From [28].

spatial resolution was the more difficult criterion. It was widely held that hot wires or LDV with a maximum dimension $\ell^+ < 20$ would be sufficient to accurately measure the level of the near-wall peak in $\overline{u^{2+}}$, as long as $\ell/d \geq 200$ [24]. It was obvious, however, even from the data of [24] that the peak value continued to increase with decreasing ℓ^+ (see also [25]), as was made very clear by the work of Hutchins et al. [26].

In an effort to improve the spatial resolution of thermal anemometry, the NSTAP probes were developed at Princeton. These probes were made using MEMS techniques, and yielded ribbon-shaped sensors typically measuring 2 μm wide, 0.1 μm thick, and either 60 or 30 μm long (see figure 5)a. The sensors, therefore, have characteristic lengths about 10 times smaller than conventional hot wires, and, as evident from figure 5)b, they also have a typical frequency response about 10 times higher.

In this respect, the Superpipe data shown in figure 4b was taken using both 60 and 30 μm NSTAP probes, but even with these probes the peak could not be accurately resolved at the highest Reynolds number, despite corrections [29]. The measurements were, however, successful at unambiguously establishing the presence of the outer peak. It was not until NSTAPs were used in the Melbourne wind tunnel, where the boundary layer is about 350 mm thick, that measurements could be made in the near-wall region at high Reynolds number while maintaining $\ell^+ < 2.1$. The data are shown in figure 6, and they support a logarithmic correlation with Reynolds number, as also indicated by DNS.

SUMMARY

Our current understanding of turbulent boundary layers at all Mach and Reynolds numbers has been enabled by major advances in measurement techniques, especially in hot-wire anemometry and PIV. It is also clear that DNS and LES are beginning to take a leading role in the exploration of turbulence, and I expect that for canonical flows DNS will become the primary investigative tool within a decade.

THE MECHANICS OF LIVING CELLS — ORDER AMONGST DISORDER

Vikram Deshpande
Cambridge University Engineering Department, Cambridge, United Kingdom

Summary Living cells evade thermodynamic decay aided by the exchange of nutrients with their environment and are quintessential examples of out-of-equilibrium systems. These nutrient exchanges also fuel large non-thermal fluctuations, but cells nevertheless maintain a homeostatic state over a timescale of hours to days. We use these observations to motivate a statistical thermodynamic theory for the "equilibrium" of adherent cells. Numerous, sometimes counterintuitive observations, of cell behavior can be rationalized using this formalism and we shall discuss phenomena where cells attain a specific type of order by maximizing their overall disorder. Examples that will form the focus of the talk include: (i) "contact guidance" — the widely known phenomenon of alignment of single cells induced by anisotropic environmental features and (ii) the spatial organization of cells within micro-tissues which serves as the precursor to morphogenesis.

INTRODUCTION

Cellular organization plays a crucial role in the micro-architecture of tissues and dictates their biological and mechanical functioning [1]. This organization is often the result of the response of cells to the anisotropy of their micro-environment, which induces cells to migrate preferentially along the direction of anisotropy - a phenomenon called contact guidance. Indeed, contact guidance is known to affect various downstream cell behaviors, including survival, motility, and differentiation. Uncovering the origins of cellular contact guidance is therefore critical, not only for understanding tissue morphogenesis and regeneration, but also for predicting disease progression such as cancer invasion.

METHODS

We aim elucidate the general biophysical mechanisms underlying contact guidance of individual cells. Various *in-vitro* chemical micropatterning approaches have been developed to study cellular contact guidance, as model systems to simplify the highly complex *in vivo* environments. We followed such an approach [2] and seeded a low density of myofibroblasts (specifically, Human Vena Saphena Cells; see Methods) on effectively rigid substrates microprinted with fibronectin stripes of widths w, ranging from greater than $1.5\ \text{mm}$ (resembling a homogeneous 2D substrate) to $50\ \mu\text{m}$ (Fig. 1a). This enabled us to investigate contact guidance as affected by ECM proteins in the absence of short-range cell-cell interactions and long-range interactions via substrate elasticity. Surprisingly, we observed that even in this highly simplified model system, contact guidance commences at stripe widths much greater than the average cell size.

To interpret our unanticipated experimental observations, we combined detailed morphometric analysis of cells (and their subcellular components) with a novel statistical framework [3] that models the non-thermal fluctuations of living cells (Fig. 1b). These fluctuations, fueled by the exchange of nutrients between the cell and the surrounding nutrient bath, allow the cell to explore a large number of morphological microstates. However, these fluctuations are constrained by the fact that the cell maintains a homeostatic state and by environmental cues such as, in our case, adherence to fibronectin stripes. In our approach, we assume that the distribution of observed microstates is the one that satisfies these constraints and contains the overwhelming number of morphological microstates (i.e., the distribution that maximizes the morphological entropy). Then the statistics of biological observables such as cell shape, orientations and spatial distributions of cytoskeletal proteins is derived from that maximum entropy distribution of morphological states of the cell.

RESULTS

To investigate the origins of cellular contact guidance, we seeded myofibroblasts on micropatterned fibronectin stripes of width w, ranging from $50\ \mu\text{m}$ to homogeneous substrates with $w \to \infty$. Outside the stripes, cell adhesion is prevented by treatment with a 1% solution of Pluronic F-127. A schematic illustration of our experimental setup is shown in Fig. 1a, where the fibronectin stripes are represented in maroon and the cells in green. The cells were fixed and stained for actin, vinculin and the nucleus 24 hours after seeding. Representative immunofluorescence images (from at least 50 observations over three independent experiments) of the actin cytoskeleton (green), nucleus (blue), and focal adhesions (vinculin in magenta) of cells on fibronectin (maroon) stripes of width $w = 50\ \mu\text{m},\ 160\ \mu\text{m}$ and $390\ \mu\text{m}$ are shown in Fig. 1c. These images suggest that while the orientation of the actin cytoskeleton and nucleus are reasonably coordinated to the cell shape, the focal adhesions

are spread nearly evenly throughout the cells. A picture that consistently emerges from these images is that cells align more on the narrower fibronectin stripes than on wider stripes, demonstrating the emergence of contact guidance due to the fibronectin micropatterns. In fact, contact guidance emerges at stripe widths much greater than the cell size

To understand the origins of this surprising observation, we combined morphometric analysis of cells and their subcellular components with a novel statistical framework [3] for modelling non-thermal fluctuations of living cells. This modelling framework is shown to predict (Fig. 1d) not only the trends but also the statistical variability of a wide range of biological observables including cell (and nucleus) shapes, sizes and orientations, as well as stress-fibre arrangements within the cells with remarkable fidelity. By comparing observations and theory, we identified two regimes of contact guidance: (i) guidance on stripe widths smaller than the cell size, which is accompanied by biochemical changes within the cells, including increasing stress-fibre polarisation and cell elongation, and (ii) entropic guidance on larger stripe widths, which is governed by fluctuations in the cell morphology. Overall, our findings suggest an entropy-mediated mechanism for contact guidance associated with the tendency of cells to maximise their morphological entropy through shape fluctuations.

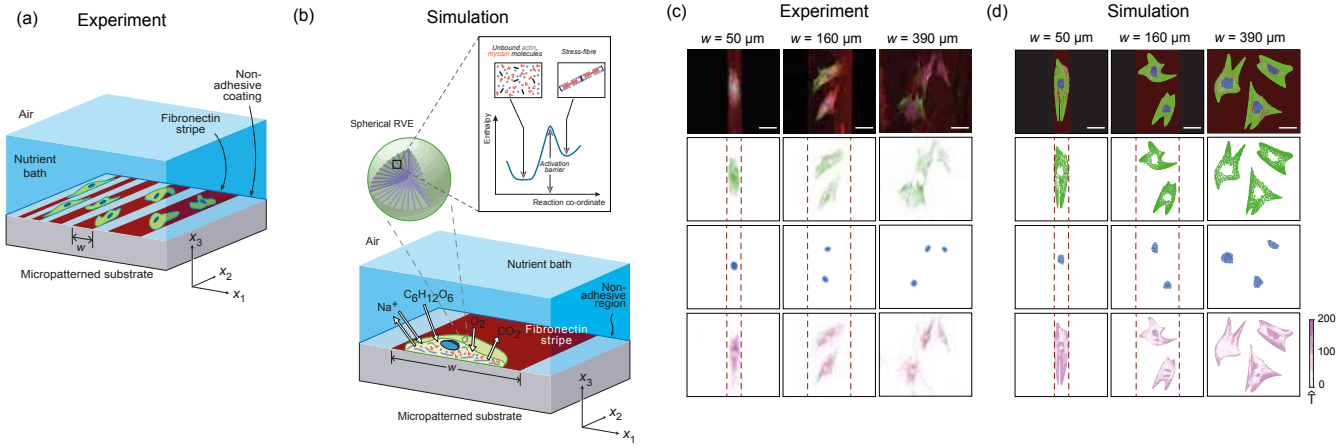

Figure 1: Experimental setup and representative images of the experimental data and simulations. (a) Sketch of the experimental setup of myofibroblasts seeded on a flat substrate micropatterned with fibronectin (red) stripes of width w. (b) An illustration of the cell model employed in the simulations using homeostatic mechanics framework. The sketch shows a section of a cell on a fibronectin stripe of width w and exchanging species with the nutrient bath. The inset shows a representative volume element (RVE) of the cell cytoplasm containing polymerized acto-myosin stress-fibers and the unbound proteins along with the energy landscape that governs the equilibrium of these proteins. (c) Immunofluorescence images of myofibroblasts on fibronectin stripes of 50, 160, and 390 μm showing the actin cytoskeleton (green), nucleus (blue), and focal adhesions (magenta); the edges of the stripes are indicated by dashed lines. (d) Corresponding predictions from the homeostatic mechanics framework with focal adhesions parameterized by the magnitude of the normalized traction $\hat{T}$. The scale bar in (c) and (d) $= 60$ μm and the width of the fibronectin stripes is indicated by the red dashed lines for the two narrowest stripes.

CONCLUSIONS

Most tissues in the human body exhibit a specific spatial organization of cells. This cellular organization plays a crucial role in the micro-architecture of tissues and dictates their biological and mechanical functioning. Despite the importance of cellular organization in all facets of tissue biology, the fundamental question of how a cell organizes itself in an anisotropic environment is still poorly understood. We show that similar to nematic ordering in liquid crystals, orientational ordering of cells on micropatterns is driven, rather counter-intuitively, by the tendency of cells to maximize morphological disorder. This finding reveals an alternative, entropy-mediated mechanism for explaining the response of cells to anisotropic environmental cues besides the often-invoked mechanisms that are predicated on very specific biochemical feedback pathways.

WHAT MAKES OCEAN WAVES GO ROGUE IN THE REAL WORLD?

Frédéric Dias
School of Mathematics and Statistics, University College Dublin, Ireland
Université Paris-Saclay, ENS Paris-Saclay, CNRS, Centre Borelli, 94235, Cachan, France

Summary The study of extreme ocean waves is a rapidly expanding area of research worldwide. Although much work in this area is based on modelling and experiments in controlled wave tanks, the starting point of all studies is wave observation in the natural world. During this talk, we will provide some evidence of extreme wave events, describe the main mechanisms for their generation and conclude with what we believe makes ocean waves go rogue in the real world.

INTRODUCTION

Extreme ocean waves occur under a variety of shapes and origins. First, we need to define what we mean by extreme. In this talk, the word "extreme" relates to wave events that the community cares about because of their potential destructive power. Extreme wave events are often linked to tsunamis, storm surges, storm waves, overtopping and freak waves. Extreme waves are often accompanied with wave breaking but in the past their study has often neglected wave breaking.

Extreme wave events occur worldwide on the ocean. They link together sailors, fishermen, marine officers, surfers, ship builders, coastal engineers, marine renewable energy developers, oceanographers, physicists and mathematicians around a common aim of understanding the formation, dynamics and impact of large ocean waves and currents. Tsunamis occur every year. There have been at least four major tsunamis in the last 20 years. The most recent ones are those of Krakatau (22 December 2018), which followed an eruption and partial collapse of the Anak Krakatau volcano in the Sunda Strait, and Sulawesi (28 September 2018), which was generated by a large earthquake and subsequent landslides. While the emphasis has been given to wave run-up and inundation to characterize tsunamis, the community has recently acknowledged the role of currents in evaluating the risk associated with tsunamis. The role of debris has also been emphasized. The swell generated by hurricane type storms can lead to waves larger than 20 meters in height. When these waves start feeling the sea bottom, extreme breakers that surfers try to surf can develop. Phenomenal barrels occur a few times every year in various locations around the world. The key ingredient is the local bathymetry for the focusing of wave energy. Storm's winds can push water onshore, causing a storm surge. Several times every year, catastrophic flooding can occur in low lying areas. On the other hand, it is less known that high lying areas such as cliff tops can also be temporarily flooded. Incident waves result in large runup amplifications at coastal cliffs. This is especially evident during storms in Ireland [1]. In the first part of the talk, we provide evidence of extreme wave events.

Freak waves are different in the sense that they are not necessarily associated with extreme conditions. Freak waves are localized both in space and in time. They can occur in calm seas as well agitated seas. The fact that they seem to be coming from nowhere is what makes them dangerous. Calm seas can mislead people that fish or walk dangerous rocky coasts: even in small seas, a single rogue wave can be enough to wash a person into the sea. After we give evidence of the type of rogue wave events described above, we review the physical mechanisms that can lead to rogue wave events.

OBSERVATIONS OF EXTREME OCEAN WAVES

Extreme ocean waves being rare events are difficult to observe or more precisely to measure accurately. When the waves are extreme, even if some instrument is available to measure them, there is always the possibility that the instrument is outside its normal range of operation. That means that it can either be damaged or not record the true value of the wave characteristics. After giving some evidence of carefully selected extreme wave events that have been measured by wave buoys, acoustic Doppler current profilers (ADCPs), satellite altimetry or lasers mounted on a bridge (the Andrea wave is one such example – see below), we will focus on the natural laboratory provided by the Aran Islands off the west coast of Ireland, where a lot of coastal boulder deposits (CBD) are present. These CBD, which are transported by waves at elevations above sea level and substantial distances inland, are markers for marine incursions. CBD on the Aran Islands are well-documented. Boulder transport was recorded using before-and-after photography (Figure 1), at surveyed sites for which elevation and inland distance were also measured. More than a thousand boulders, ranging in mass from 0.01 to 620 t, have been dislodged during the winter of 2013/2014 [2]. The 2013–2014 winter was the stormiest on record in the Ireland-UK region, with numerous Atlantic storms scourging the Irish seaboard. The winter-averaged significant wave height (H_s) was $\approx$ 40% higher than average, and off the west coast of Ireland there was a 5-fold increase (relative to the 67-year average) in the number of days with extreme sea states Central pressures for several events were <950 hPa (equivalent to category 3 hurricanes), and one reached as low as 927 hPa, putting it in the category 4 hurricane equivalent range. In combination with substantial storm duration and the large effective fetch, which predispose the North Atlantic region to extreme wave building, the stage was set for dramatic conditions. We will describe several scenarios that explain how CBD can be transported.

Figure 1. Examples of Aran Islands coastal boulder deposits that underwent change during the 2013–2014 winter storms. The photos A and B show repeat photography of a site on Inishmaan. The photos C and D show a site on Inishmore. The boulder weights about 210 t and from a starting location 10m above sea level 27m inland, it moved 22m in the 2013–2014 storms, to its current location 49m inland (adapted from [2]).

MECHANISMS OF EXTREME OCEAN WAVE GENERATION

The environment of the open sea involves multiple physical processes such as currents, dissipation, wind forcing and wave breaking. Aside from wave breaking, which is by nature nonlinear, currents, dissipation and wind forcing can be either linear or nonlinear. Despite this complexity, however, it has been possible to describe many aspects of large-amplitude ocean wave dynamics in regimes in which the physics is dominated by distinct linear or nonlinear mechanisms. For example, the linear processes of random wave superposition and dispersive focusing are both well-understood mechanisms that can lead to increased wave amplitude, and nonlinear focusing from modulation instability has been particularly studied because of its driving influence on wave localization and decay [3]. It is important to note, however, that although nonlinear focusing has certainly attracted much attention in the context of ocean rogue wave formation, determining the relative contribution of linear and nonlinear effects in driving extreme wave dynamics remains a subject of much study [4].

The characteristics of several extreme ocean wave events have been analysed in detail using an approach known as hindcasting. Such studies use archived meteorological and wave data at the location of the event under study to determine initial conditions for a forward-propagating wave model. The aim is to use the model to simulate the wave-field characteristics at later times and compare them quantitatively with a measured wave record. By varying the initial conditions and parameters of the model (particularly the directional wave energy spectrum), it is possible to draw conclusions as to which processes may be responsible for the emergence of the observed rogue waves. Studies of this type include the analysis of the maritime accidents of the fishing boat Suwa-Maru [5], the cruise ship Louis Majesty [6], the tanker Prestige [7], the merchant vessel El Faro [8], and modelling of the Draupner and Andrea waves and rogue waves generated during Typhoon Lupit in 2009 [9]. As an example, we illustrate the case of the Andrea wave, which, and its modelled profile using the hindcasting approach (Figure 2). The main conclusion of our work on extreme waves occurring in deep or intermediate water is that the wave shaping is found to be dominated by directional superposition, with a minor enhancement from the second order bound (Stokes) nonlinear contribution [10]. Modulational instabilities are ineffective and third-order resonant effects are negligible.

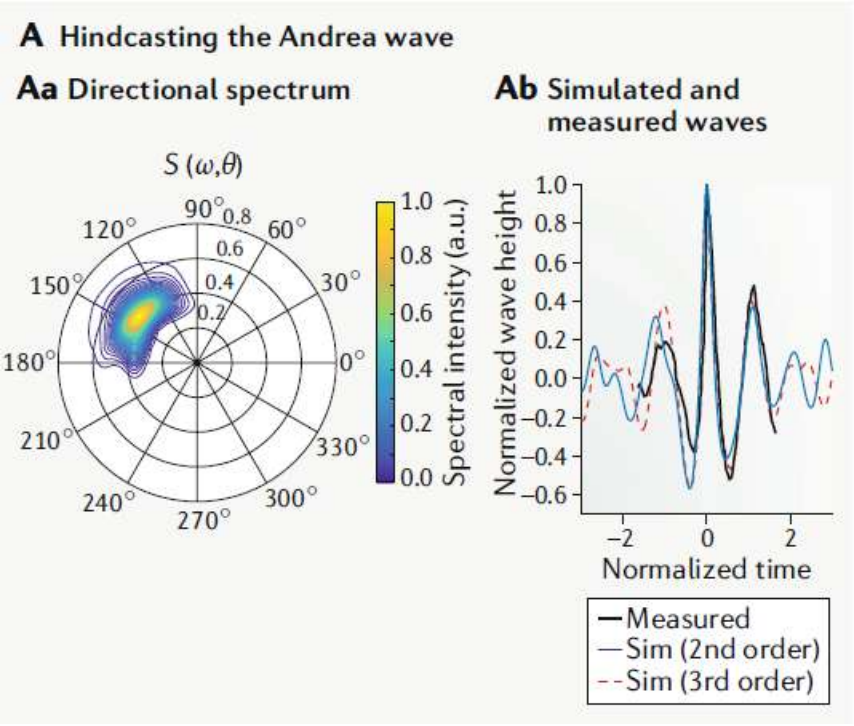

Figure 2. Hindcasting results for the Andrea wave. The directional wave energy spectrum $S(\omega,\theta)$ is used in numerical simulations, where ω is angular frequency and θ is direction in degrees (panel Aa). The measured Andrea wave (black) is compared with simulations including up to second order (blue) and third-order contributions (red) (panel Ab). The minor differences between the simulations point to a negligible role from third-order nonlinear focusing (adapted from [4]).

When it comes to extreme waves hitting the shoreline, the situation is even more complex. We also used hindcasting to recreate waves near the Aran Islands during the major storms of the 2013/2014 winter. The modelled wave heights are far from precise. They provide some sense of possible conditions at the coast but should be taken as indicator values only. Seas at some locations may have been more intense; other places will have seen lower wave activity. Bathymetric and topographic variation below the scale of the model will have focused and intensified wave heights in some areas and dampened them in others. The ways in which waves interact with the coast are determined not simply by the wave-generating mechanism, but also by complex interplay with bathymetry, and wave-wave interactions during shoaling. Infragravity waves and/or surf beat can add additional long-period components to storm-wave activity.

An interesting question is to compare the energy that tsunamis and storm waves can have to dislodge boulders. Our recent study [2] concludes that onshore flows generated by storm waves and by tsunami overlap considerably in terms of key parameters such as Froude number and flow-front velocity. Hydrodynamic equations have been derived to estimate the flow velocities required to move boulders both in the context of tsunamis and in the context of storm waves. We showed that these hydrodynamic equations systematically undervalue the power of storm waves. Therefore, while some CBD may indeed be tsunami deposits, or may have a tsunami component in their history, we emphasize that storms should be considered the default interpretation, which needs to be refuted, before a tsunami interpretation can be preferred.

DISCUSSION

Coming back to freak waves, we observe that a particular focus of the latest studies has been the relative contributions of linear and nonlinear effects in driving the emergence of rogue waves. However, although nonlinear focusing has been shown to be a dominant mechanism of rogue wave formation in wave tanks, it has not been possible to draw the same conclusion in the more complex environment of the ocean. As a result, our view is that it is not useful to focus on any single cause of all rogue waves. Rather, we believe that an objective interpretation of the current literature is that rogue waves on the ocean probably arise from several linear and nonlinear processes that contribute separately or in combination, depending on the ocean conditions at play.

We anticipate that progress in unravelling the complexity of ocean waves will require both more precisely targeted studies using wave tanks and improved in situ spatio-temporal measurements of ocean waves in their natural environment. We expect that wave tank experiments will be vital to continued efforts to understand dynamical processes such as dissipation, wave breaking and air–sea interaction, and will remain a major area of research for decades to come. Concerning the role played by nonlinearity, even in addition to potential contributions to rogue wave formation, much effort is still required to improve our understanding of how nonlinear focusing may contribute to phenomena such as wave run-up or wave overtopping.

We said above that we relate the word "extreme" to wave events that can have destructive power. Numerous marine structures are damaged by the violent impacts of extreme waves that are either breaking or very close to breaking. Design formulae for estimating the magnitude of the impulsive pressures generated by breaking waves are largely derived from the results of laboratory tests rather than from an in-depth analysis of the fundamental mechanics. Under extreme wave conditions, results are uncertain due to scale effects: the hydrodynamics requires different model scales and the influence of the various effects is difficult to infer from small-scale experiments. In the past ten years, a mathematical and computational modelling framework based on elementary loading processes (ELP) has been developed for the analysis of slamming of wave energy converters and inside the tanks of liquefied natural gas carriers [11] (Figure 3). Soon, we will use ELP to analyse overtopping.

Scaling remains the most important open question for all wave breaking impact applications. Impact pressures are strongly influenced by local phenomena such as local geometry, gas/liquid mixture and surface tension. Surface tension effects, which are quite subtle, have been largely ignored until now. Indeed, surface tension affects impact pressures not directly but indirectly. Surface tension leads to drastic changes in the geometry of the free surface.

Extreme breaking wave impacts belong to the class of extreme phenomena, such as freak waves. Extreme phenomena usually follow fat-tailed probability distributions. The topic of statistics/probability is clearly relevant to breaking wave impacts but is left aside in the present talk.

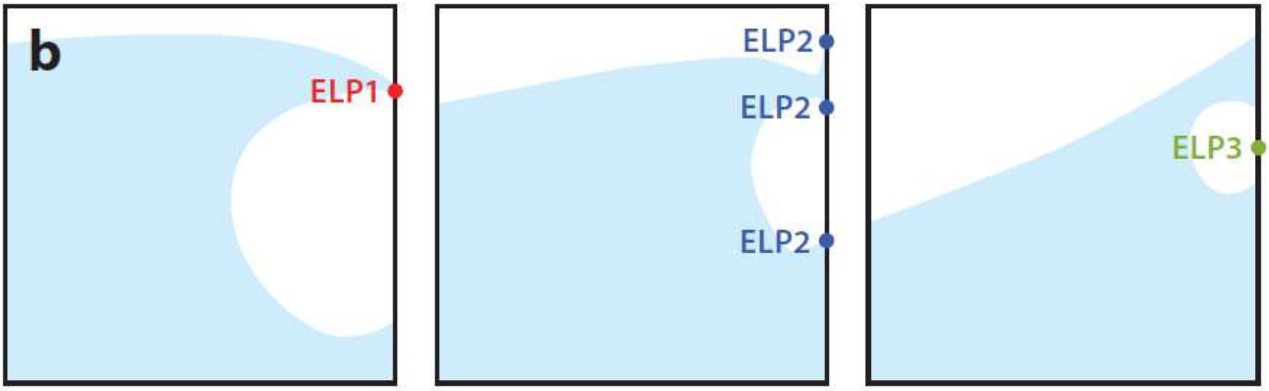

Figure 3. Qualitative description of the elementary loading processes (ELPs) that can occur when a wave hits a vertical wall. The contribution of each ELP is indicated: direct impact (ELP1, red), building jet (ELP2, blue), and compression of entrapped or escaping gas (ELP3, green) (adapted from [12]).

FRAGMENTATION VERSUS COHESION

Emmanuel Villermaux
Aix Marseille University, CNRS, Centrale Marseille, IRPHE UMR 7342, 13384 Marseille, France

LECTURE CONTENT

Capillarity is the familiar manifestation of the cohesion of liquids [1]. Since Laplace (1805), we know that intense attractive forces between the molecules *bridge the small with the large* as they shape liquid/vapor interfaces at the macroscopic scale through the concept of surface tension (menisci, drops, bubbles, puddles, liquid rise in tubes, etc...).

This lecture will concentrate on situations where liquids 'disgregate', following the neologism of R. Clausius (1862), meaning that they fragment by the action of deformations stresses whose intensity competes with that of cohesion forces. Various examples, including explosions, blow-ups, hard and soft impacts, and shears applied to liquid jets, sheets and drops will be reviewed. They concern applications ranging from liquid propulsion, agricultural spraying, to the formation of ocean spray, raindrops, and human exhalations by violent respiratory events.

In spite of their diversity, the various modes of fragment production share an ultimate common phenomenology – the ligament dynamics–, suggesting that the final stable droplets size distribution can be interpreted from elementary principles [2, 3].

The lecture will incorporate elements about:

- Origin and concept of surface tension. Founding idea of Laplace (1805).
- Tradeoff between cohesion and fragmentation: The shattered necklace example.
- Savart's sheets, bursting soap films and bubbles, receding rims and cusps.
- Paradigm of the corrugated ligament, inverse cascade of aggregations, fractional convolutions, Gamma distributions, fragments sizes, generalizations and analogies.
- Mechanisms for the formation of 'fines', direct cascades.

Figure 1: Rome, Piazza del Popolo, the lions of the central fountain expectorate a turbulent water sheet. Random velocity fluctuations and possible bubbles inclusions in the liquid nucleate holes which, driven by surface tension, grow and merge, leaving the sheet as a set of connected corrugated ligaments, which further breakup into a collection of disjointed droplets broadly distributed in size.

NONLINEAR DYNAMICS: A JOURNEY THROUGH EXPERIMENTS AND COMPUTATIONS

Balakumar Balachandran
Department of Mechanical Engineering, University of Maryland, College Park, MD 20742, USA

Summary Dynamics of a variety of mechanical and structural systems need consideration of nonlinearities. In this paper, a collection of experiments and computations conducted to further our understanding of nonlinear dynamics of a range of systems is presented. The experimental and computational findings are explained with the help of analytical studies. Grazing dynamics, energy localization, slow-scale and fast-scale decompositions, and buckling influenced oscillations are considered to illustrate the ubiquitous presence of nonlinearity influenced phenomena across length scales. The relevance of the work to different systems, including large scale structures, atomic force microscope systems, drilling systems, and rotary systems will be discussed.

INTRODUCTION

Nonlinear systems are ubiquitous across length scales, with representative examples including nano-scale systems [1], systems with flapping wings [2], manufacturing systems [3], and large scale aeroelastic systems [4]. While the sources of nonlinearities and the manifestations of nonlinear behaviour and nonlinear instabilities are different across these different systems, similar nonlinear phenomena have been observed in different physical systems. The elucidation of selected phenomena through experimental and computational means is one of the goals of this work. To that end, in the sections that follow, selected findings are drawn from the author's work with his collaborators.

SYSTEMS WITH SLOW AND FAST SCALE DYNAMICS

Dynamics of several systems can be described in terms of slow time scale and fast time scale components. These include flexible structural systems (e.g., [5-7]) and rotary systems (e.g., [8]). In these systems, sometimes, high-frequency input energy is transformed into a low-frequency response component (e.g., Figure 1), and in other instances, low-frequency input energy is transformed into a high-frequency response component (e.g., Figure 2). These systems have been extensively studied through experiments, computations, and analysis. For the nonlinear analysis, different singular

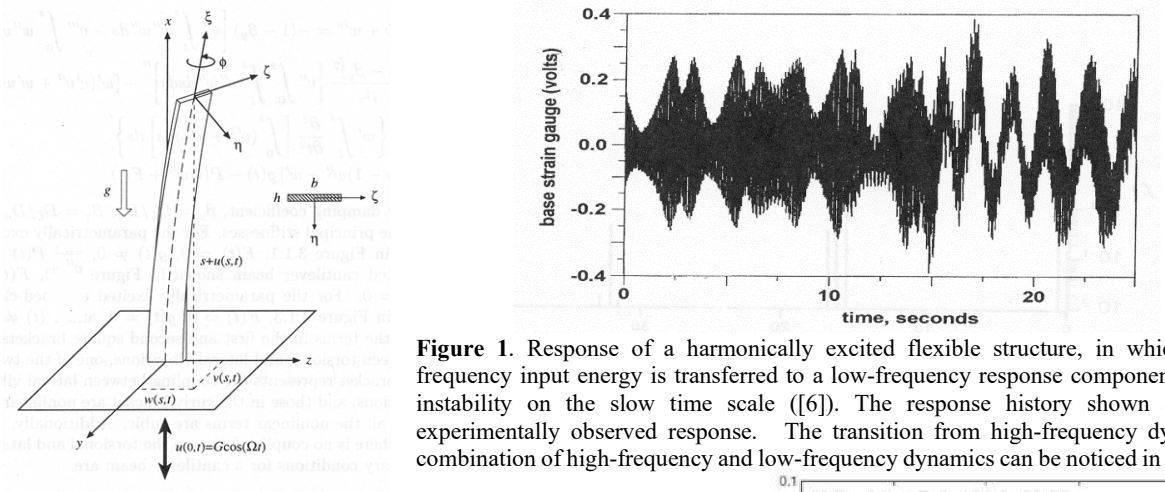

Figure 1. Response of a harmonically excited flexible structure, in which the high-frequency input energy is transferred to a low-frequency response component through an instability on the slow time scale ([6]). The response history shown above is an experimentally observed response. The transition from high-frequency dynamics to a combination of high-frequency and low-frequency dynamics can be noticed in the response.

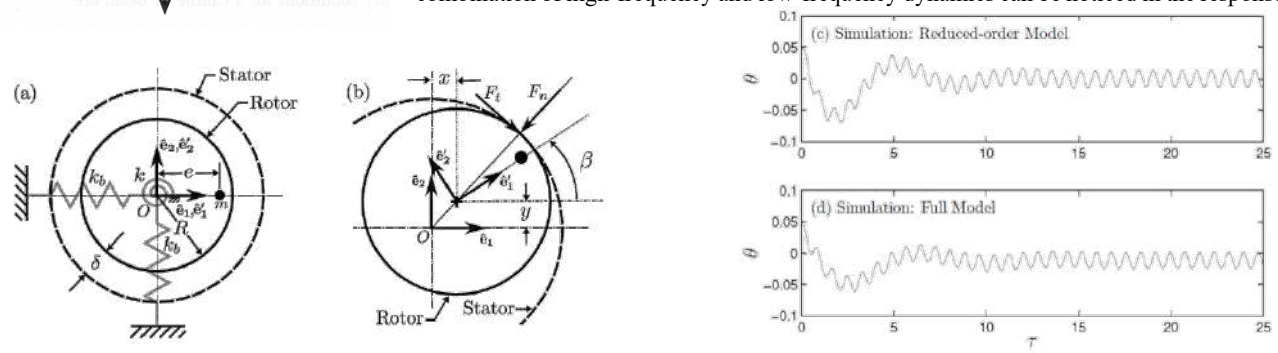

Figure 2. a) and b) Model used to torsional response of an extended, Jeffcott rotor. c) and d) Numerical results obtained by using the full system model and a reduced-order model [8]. The rotor is subjected to a low-frequency input. When a backward whirling instability occurs, the torsional response of the rotor includes a high-frequency component associated with backward whirling of the rotor. The presence of slow and fast scales can be discerned from the time histories. High-frequency backward whirling motion of a rotor subjected to a low-frequency input torque has been observed in laboratory scale experiments. This type of rotor dynamics studies is helpful for understanding drill-string dynamics.

SECTIONAL LECTURES

perturbation methods have been used, including the method of multiple scales and method direct partition of motions.

GRAZING DYNAMICS

Grazing dynamics can occur in many different scenarios, where is contact. Examples include metal cutting operations, rotor-stator dynamics, and tapping mode atomic force microscopy. For illustration, grazing contact is depicted in Figure 3.

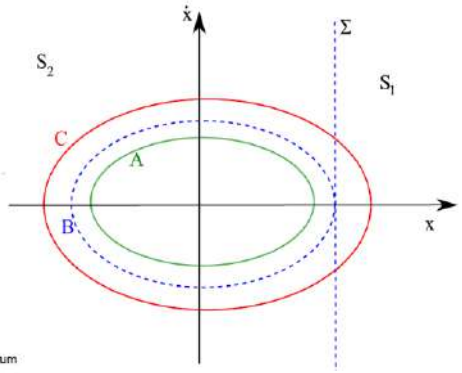

Figure 3. Orbits A, B, and C shown above are representative system responses, which are obtained as a scalar control parameter is quasi-statically varied. S_1 and S_2 are two regions separated by a boundary Σ, and orbit B represents the system response at grazing contact, which occurs when a periodic orbit grazes (makes tangential contact with a separating boundary). Post-grazing contact response can be a periodic oscillation, a quasi-periodic oscillation, a period added oscillation, or a chaotic oscillation.

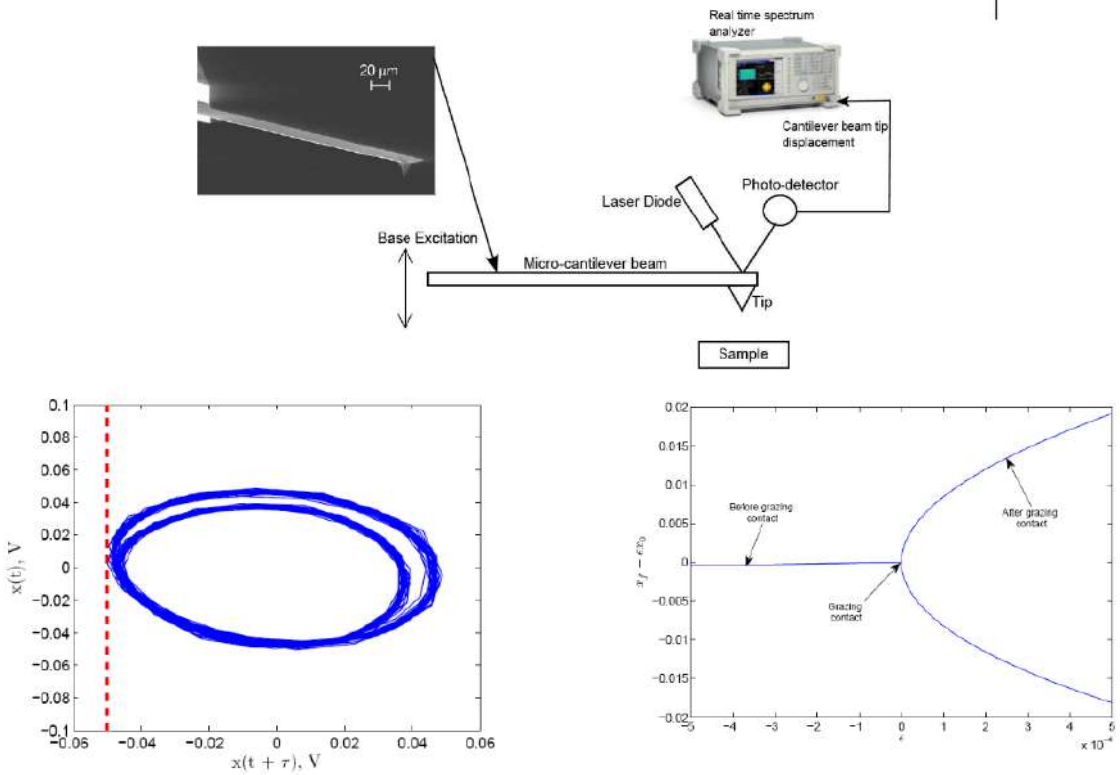

Figure 4. Experimental results obtained during tapping mode studies with a Silicon micro-cantilever are shown. When one taps delicate samples with a base excited cantilever, one would like to avoid damaging the sample. Typically, in these operations, the cantilever is excited at a frequency close to the cantilever's first natural frequency. From macro-scale studies [9], it is known that grazing contact is possible when the cantilever is excited at special frequency values between the first and second natural frequencies of the cantilever. Close to grazing contact, there is a period-doubling bifurcation in the system response. The macro-scale findings are applied to the micro-scale atomic force microscope cantilever. The corresponding experimental observation is shown in the left figure of the second row. In the right figure of the second row, results obtained from a discontinuity map analysis close to the grazing contact point are shown. A pitchfork structure can be seen emanating from the grazing contact point, supporting the occurrence of the period-doubling bifurcation observed in the experiments. Related work is reported in references [10, 11]. Based on these studies, it is conceivable that a nonlinear dynamics scheme can be used to detect near-grazing situations in experiments.

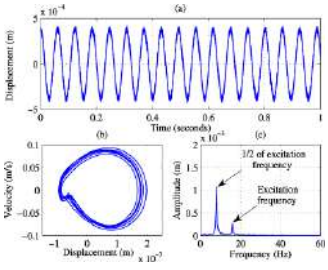

Figure 5. (a) Combined input with harmonic and noise components applied to the base of a cantilever. (b) Response phase portrait. (c) Response spectrum with a dominant peak at ½ of the input harmonic component frequency along with the input harmonic component frequency. When the noise component is turned off, the response spectrum contains only a component at the harmonic component frequency and the tip of the cantilever is contact free. The introduction of a low level of noise induces grazing contact and a period-doubling instability follows [12].

Noise can be used to influence contact dynamics, as discussed by Chakraborty and Balachandran [12].

DYNAMICS ABOUT A BUCKLED POSITION

Structures at different length scales can undergo a buckling instability. Here, an example is provided of a system a micro-scale. In Figure 6, a microelectromechanical system [14] is illustrated. This system has a curved cross-section as shown in the figure. Buckling of the microresonator results in a non-flat equilibrium position about which the system undergoes oscillations. This non-flatness is believed to be stress induced and it occurs due to the fabrication process. The corresponding modelling efforts are discussed in the work of the author and his collaborators [13, 14].

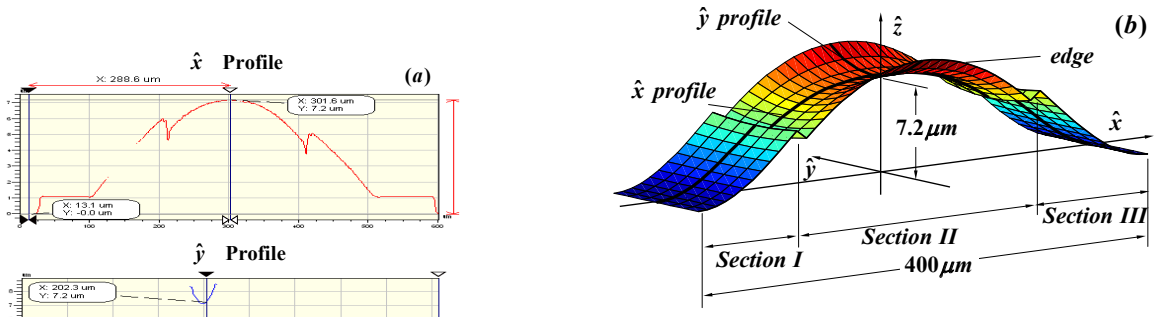

Figure 6. Static displacement profile of a 400 μm microresonator, which is essentially a clamped-clamped composite structure: (*a*) 2-D view of the measured 400 μm microresonator profile along *x*-axis and *y*-axis and (*b*) 3-D view of the resonator static profile showing that the structure has a saddle-shape displacement profile [14].

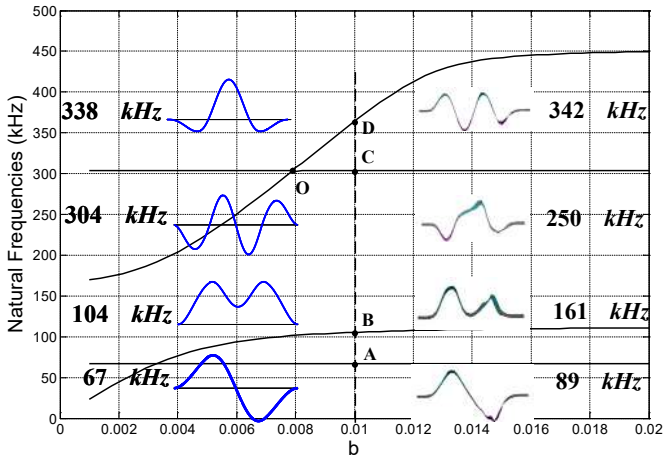

Figure 7. Forced oscillation displacement patterns of 400 μm piezoelectric resonator: predictions from model with rectangular cross-section are shown on the left and measured responses are shown on the right. The variations of natural frequencies with respect to the static non-flatness amplitude *b* are also shown in this figure. Locations A, B, C, D correspond to the predicted frequencies for the experimentally measured static amplitude *b* of 0.01 [14].

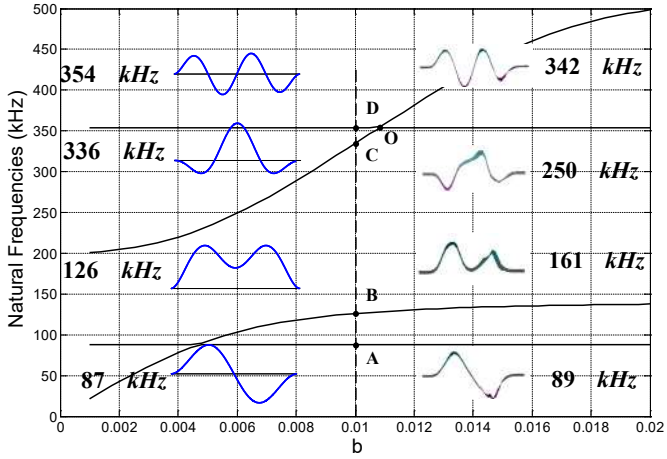

Figure 8. Free-oscillation response predictions for the 400 μm piezoelectric resonator are shown on the left and the experimental observations of spatial responses are shown on the right. The model takes curved cross-sections into account. The variations of natural frequencies with respect to the static non-flatness amplitude *b* are also shown in this figure. Locations A, B, C, D correspond to the predicted frequencies for the experimentally measured static amplitude *b* of 0.01 [14].

The experimentally observed spatial profiles of the considered resonator are shown in Figure 7 for different harmonic excitation frequencies. From the results shown in Figures 7 and 8, it is clear that if one were to just consider rectangular cross-sections, then, one cannot capture the experimentally observed spatial profiles. However, with consideration of the curved cross-section data from experiments, one can predict the spatial profiles observed in the experiments [14].

CONCLUSIONS

A collection of experimental and numerical results obtained for a range of nonlinear systems has been presented in this paper. In the talk, in addition to the nonlinear phenomena discussed here, additional phenomena will be presented and discussed.

MODELING FLOWS OVER NATURAL OR ENGINEERED SURFACES

Alessandro Bottaro
Department of Civil, Chemical and Environmental Engineering, Universit`a di Genova, Genova, Italy

Summary Natural and engineered surfaces are never smooth, but irregular, rough at different scales, compliant, possibly porous, liquid-impregnated or superhydrophobic. The correct numerical modeling of fluids flowing through and around them is important but poses problems. For media characterized by a periodic or quasi-periodic microstructure of characteristic dimensions smaller than the relevant scales of the flow, multiscale homogenization can be used to study the effect of the surface, avoiding the numerical resolution of fine-grained details. The homogenization strategy needed to model the interaction between a fluid in motion and regularly micro-textured, permeable or impermeable walls is revisited and examples are provided to demonstrate the accuracy and versatility of the approach.

INTRODUCTION

The study of the fluid motion above and through natural and engineered surfaces is a challenging task, particularly if the surface possesses small-scale features which exert some fluid-dynamics-related role, whose effect often cannot be captured directly by a numerical simulation because of the difficulty in addressing all the fine-grained details of the fluid/wall coupling. Such details might include the effect of the surface texture, its porosity, compliance and the interactions between the flow of the outer fluid and that of a different fluid which may be trapped within near-wall microcavities. It then becomes useful to employ an approach capable of replicating the important features near the wall at a fraction of the computational cost of a full, detail-resolving simulation; one such approach is multiscale homogenization. In the next section the mathematical description of the theory is limited to the case of rough surface, neglecting aspects related to the system porosity or elasticity, addressed, e.g., by Bottaro [1]. The equations are developed up to second order in terms of a small parameter, ϵ, to be able to account for those cases in which there is poor separation of scales.

MATHEMATICAL FORMULATION

A regularly structured three-dimensional rough wall is considered, with cartesian macroscale dimensionless coordinates $X_i = (X_1, X_2, X_3) = (X, Y, Z)$, Y being orthogonal to the mean surface plane. These independent variables are scaled by L, a characteristic macroscopic length. The surface $Y = 0$, tangent to the roughness elements, defines a fictitious wall on which *effective* boundary conditions should be imposed, as an alternative to the expensive alternative of computing all details of the flow field within the rough pattern. A unit cell is defined in a box which extends vertically from $y = y_{wall}(x, z)$ to $y \to \infty$; along the mean-wall parallel directions it is assumed that the representative roughness element is contained in a rectangular box, with periodic conditions which apply along x and z (cf. fig. 1). All microscale coordinates $x_i = (x_1, x_2, x_3) = (x, y, z)$ are normalized with a small length scale l and are thus dimensionless. The dependent variables are expressed as power series of the small parameter $\epsilon = l/L$, and denoted by

$$f = f^{(0)} + \epsilon f^{(1)} + \epsilon^2 f^{(2)} + ... \tag{1}$$

In general, capital letters will be used for macroscopic variables, and small letters will be employed for microscopic ones.

The whole physical domain is divided into two regions: a inner region goes from the wall to $y \to \infty$ and the outer region sits above, i.e. it goes from $Y = 0^+$ to $Y = Y_{max}$, with Y_{max} a function of the problem considered. In the inner region the equations are

$$\frac{\partial u_i}{\partial x_i} = 0, \tag{2}$$

$$\mathcal{R}\left(\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j}\right) = -\frac{\partial p}{\partial x_i} + \frac{\partial^2 u_i}{\partial x_j^2}, \tag{3}$$

and in the outer region they are

$$\frac{\partial U_i}{\partial X_i} = 0, \tag{4}$$

$$\frac{\partial U_i}{\partial t} + U_j \frac{\partial U_i}{\partial X_j} = -\frac{\partial P}{\partial X_i} + Re^{-1} \frac{\partial^2 U_i}{\partial X_j^2}. \tag{5}$$

In the equations above, $\mathcal{R} = \mathcal{U}l/\nu$ is the microscopic Reynolds number, $Re = U_{out}L/\nu$ is the macroscopic Reynolds number; the pressure in the near-wall region is normalized with the viscous pressure, $\mu\mathcal{U}/l$, and in the outer region the

SECTIONAL LECTURES

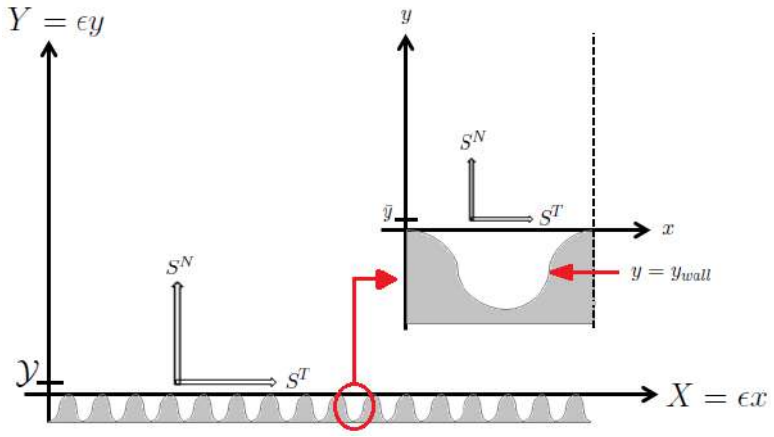

Figure 1: Sketch of regularly micro-structured rough wall, with close-up of a generic unit cell.

pressure scale is the dynamic pressure, ρU_{out}^2. Inner ($\mathcal{U}$) and outer (U_{out}) velocity scales are related by $\mathcal{U} = \epsilon U_{out}$; we also have $X_i = \epsilon x_i$. The two systems are matched at some interface plane (positioned for numerical purposes at a finite distance from the solid surface, in $y = y_\infty$, sufficiently far from the wall so that u_i and p there become independent of the microscale coordinates), and there it is imposed that velocity and traction are continuous, i.e.

$$U_i = \epsilon u_i, \tag{6}$$

$$-p\,\delta_{i2} + \frac{\partial u_i}{\partial x_2} + \frac{\partial u_2}{\partial x_i} = -Re\,P\,\delta_{i2} + \frac{\partial U_i}{\partial X_2} + \frac{\partial U_2}{\partial X_i}. \tag{7}$$

To simplify notations, the outer forcing terms will be denoted as follows:

$$S^{T_x} = \frac{\partial U}{\partial Y} + \frac{\partial V}{\partial X}, \tag{8}$$

$$S^{T_z} = \frac{\partial W}{\partial Y} + \frac{\partial V}{\partial Z}, \tag{9}$$

$$S^N = -Re\,P + 2\,\frac{\partial V}{\partial Y}. \tag{10}$$

For more details on formulation and scalings refer to Bottaro & Naqvi [2].

Equations at leading order

The problem at order ϵ^0 has already been addressed in several papers (see, e.g., [3, 4] and references therein), and will not be repeated here. The unknowns have the form

$$u_i^{(0)} = u_i^\dagger\,S^{T_x} + u_i^\ddagger\,S^{T_z}, \tag{11}$$

$$p^{(0)} = p^\dagger\,S^{T_x} + p^\ddagger\,S^{T_z} - S^N, \tag{12}$$

with the coefficients $u_i^\dagger$, $u_i^\ddagger$, $p^\dagger$ and $p^\ddagger$ function only of microscale variables. They arise out of Stokes problem, by considering alternatively S^{T_x} or S^{T_z} as forcing term.

Equations at first order

The equations at $\mathcal{O}(\epsilon)$ are:

$$\frac{\partial u_i^{(1)}}{\partial x_i} = \frac{\partial u_i^{(0)}}{\partial X_i}, \tag{13}$$

$$-\frac{\partial p^{(1)}}{\partial x_i} + \frac{\partial^2 u_i^{(1)}}{\partial x_j^2} = \frac{\partial p^{(0)}}{\partial X_i} - 2\,\frac{\partial^2 u_i^{(1)}}{\partial x_j \partial X_j}, \tag{14}$$

together with no-slip at the wall and no-traction at y_∞, i.e.

$$-p^{(1)}\,\delta_{i2} + \frac{\partial v^{(1)}}{\partial x_i} + \frac{\partial u_i^{(1)}}{\partial y} = 0. \tag{15}$$

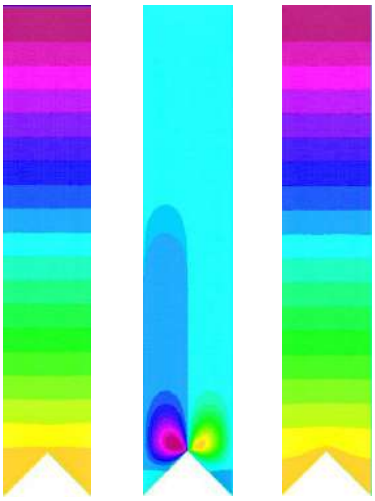

Figure 2: Order zero microscopic fields for riblets, computed for $y_\infty = 5$. From left to right, $u^\dagger$, $v^\dagger$ and $w^\ddagger$.

By using (11-12) we obtain:

$$\frac{\partial u_i^{(1)}}{\partial x_i} = -u_j^\dagger \frac{\partial S^{T_x}}{\partial X_j} - u_j^\ddagger \frac{\partial S^{T_z}}{\partial X_j}, \tag{16}$$

$$-\frac{\partial p^{(1)}}{\partial x_i} + \frac{\partial^2 u_i^{(1)}}{\partial x_j^2} = p^\dagger \frac{\partial S^{T_x}}{\partial X_j}\delta_{ij} + p^\ddagger \frac{\partial S^{T_z}}{\partial X_j}\delta_{ij} - \frac{\partial S^N}{\partial X_j}\delta_{ij} - 2\frac{\partial u_i^\dagger}{\partial x_j}\frac{\partial S^{T_x}}{\partial X_j} - 2\frac{\partial u_i^\ddagger}{\partial x_j}\frac{\partial S^{T_z}}{\partial X_j}. \tag{17}$$

The linear equations (16-17) admit a solution in the form

$$u_i^{(1)} = \hat{u}_{ij}\frac{\partial S^{T_x}}{\partial X_j} + \tilde{u}_{ij}\frac{\partial S^{T_z}}{\partial X_j} + \breve{u}_{ij}\frac{\partial S^N}{\partial X_j}, \tag{18}$$

$$p^{(1)} = \hat{p}_j\frac{\partial S^{T_x}}{\partial X_j} + \tilde{p}_j\frac{\partial S^{T_z}}{\partial X_j} + \breve{p}_j\frac{\partial S^N}{\partial X_j}, \tag{19}$$

so that three sets of auxiliary systems arise, one related to the gradient of S^{T_x} (and involving $\hat{\cdot}$ variables), one due to the gradient of S^{T_z} ($\tilde{\cdot}$ variables), and a last one induced by the gradient of S^N ($\breve{\cdot}$ variables). All of these microscopic problems involve inhomogeneous Stokes equations; for all, the boundary conditions are simply no-slip at y_{wall} and vanishing traction at y_∞, plus periodicity in x and z. Once these microscopic problems are solved, the solutions can easily be assembled to yield an *effective* condition for the macroscopic problem at $Y = \epsilon y_\infty$. It is very easy (and convenient) for this condition to be transferred onto the plane $Y = 0$, tangent to the roughness rims, as will be shown below for a representative case.

APPLICATION OF THE THEORY: RIBLETS

The case is now considered of longitudinal riblets, infinitely elongated in z. The unit cell becomes a simple two-dimensional domain in the (x, y) plane, with all microscopic variables invariant in z. As initially shown by Bechert and Bartenwerfer [5], the z-components of the microscopic equations reduce to the Laplace equation at leading order; at next order the problem in z is ruled by a set of Poisson equations. All equations at order zero and one have been solved accurately by the use of FreeFEM [6]. For the riblets displayed in fig. 2, the results of interest are reported in table 1; all the coefficients which are not reported in the table simply vanish.

It is simple to see that, up to a small error of order 10^{-5} the variables evaluated at the top boundary of the unit cell can be written, for any value of y_∞, as

$$u^\dagger = y_\infty + \lambda_x,$$
$$w^\dagger = y_\infty + \lambda_z,$$

Table 1: Microscopic variables evaluated at different y_∞'s.

y_∞	$u^\dagger$	$w^\ddagger$	$-\hat{u}_{21} = \breve{u}_{11}$	$\hat{u}_{12}$	$\tilde{u}_{32}$	$-\tilde{u}_{23} = \breve{u}_{33}$
4	4.07797	4.13965	8.31769	16.62980	17.13760	8.57542
5	5.07796	5.13966	12.89560	25.78570	26.41610	13.21510
6	6.07797	6.13965	18.47364	36.94172	37.69530	18.85470

$$
\begin{aligned}
-\hat{u}_{21} = \breve{u}_{11} &= \frac{1}{2}(y_\infty + \lambda_x)^2 + \beta_x, \\
\hat{u}_{12} &= (y_\infty + \lambda_x)^2, \\
\tilde{u}_{32} &= (y_\infty + \lambda_z)^2, \\
-\tilde{u}_{23} = \breve{u}_{33} &= \frac{1}{2}(y_\infty + \lambda_z)^2 + \beta_z.
\end{aligned}
$$

From table 1 we obtain $\lambda_x = 0.07797$, $\lambda_z = 0.13965$, $\beta_x = 0.00276$, and $\beta_z = 0.00706$. The results for the so-called *transverse* (λ_x) and *longitudinal* (λ_z) *protrusion heights* coincide with those given by Luchini et al. [7]. The additional coefficients β_x and β_z permit to correct the leading order solution when there is poor separation of scales.

The *effective* conditions

The *effective* conditions for the outer flow can be imposed by choosing any value of y_∞ and, in particular, they can be enforced at $\mathcal{Y} = \epsilon y_\infty \to 0^+$. In this case we end up with

$$U\big|_{\mathcal{Y}} = \epsilon\lambda_x \frac{\partial U}{\partial Y}\bigg|_{\mathcal{Y}} + \epsilon^2 \lambda_x^2 \frac{\partial^2 U}{\partial Y^2}\bigg|_{\mathcal{Y}} - \epsilon^2 Re \left(\frac{\lambda_x^2}{2} + \beta_x\right) \frac{\partial P}{\partial X}\bigg|_{\mathcal{Y}} + \mathcal{O}(\epsilon^3), \tag{20}$$

$$V\big|_{\mathcal{Y}} = -\epsilon^2 \left[\left(\frac{\lambda_x^2}{2} + \beta_x\right) \frac{\partial^2 U}{\partial X\, \partial Y}\bigg|_{\mathcal{Y}} + \left(\frac{\lambda_z^2}{2} + \beta_z\right) \frac{\partial^2 W}{\partial Y\, \partial Z}\bigg|_{\mathcal{Y}}\right] + \mathcal{O}(\epsilon^3), \tag{21}$$

$$W\big|_{\mathcal{Y}} = \epsilon\lambda_z \frac{\partial W}{\partial Y}\bigg|_{\mathcal{Y}} + \epsilon^2 \lambda_z^2 \frac{\partial^2 W}{\partial Y^2}\bigg|_{\mathcal{Y}} - \epsilon^2 Re \left(\frac{\lambda_z^2}{2} + \beta_z\right) \frac{\partial P}{\partial Z}\bigg|_{\mathcal{Y}} + \mathcal{O}(\epsilon^3); \tag{22}$$

Navier's slip holds at order ϵ, but effects related to the second derivatives of the slip velocity components and to the horizontal pressure gradient cannot be dismissed, particularly when ϵ and/or Re are not so small. Furthermore a transpiration velocity (blowing/suction) is present at $\mathcal{O}(\epsilon^2)$.

CONCLUDING REMARKS

The final macroscopic conditions (20-22) can be used to study the flow over riblets, without the need to carry out expensive feature-resolving simulations. These $\mathcal{O}(\epsilon^2)$ conditions remain valid under the same constraints which apply when using the simple Navier conditions, i.e. the riblets must be confined to the viscous sublayer of the turbulent boundary layer. The same applies to the case of a generic rough surface, for example with three-dimensional dimples. When the rough pattern protrudes outside the viscous sublayer, inertial terms cannot be neglected any longer. The effect of advection requires at the very least the extension of the theory to order three, when non-linear terms make their appearance in the equations [2]. This would also require the adoption of extended (wider and longer) unit cells over which to solve auxiliary problems. Further complications arise when considering some of the other effects (wall compliance, permeability, presence of a lubricant fluid, etc.) mentioned in the introduction of the present extended abstract, whose description is outside the scope of this brief contribution.

DYNAMICS OF COLLECTIVE CELLS AND BIOLOGICAL TISSUES

Xi-Qiao Feng
Institute of Biomechanics and Medical Engineering, AML, Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China

Summary Experimental and theoretical efforts are directed toward studying the dynamic behaviours of biological tissues at multiple length scales. A modified cell division rule is proposed on the basis of comprehensive consideration of mechanical forces in the cell. Statistical laws of energies and velocities of collective cell migrations are derived. We find that the spontaneous oscillation of collective cells in such biological tissues as *Drosophila* amnioserosa stems from dynamic Hopf bifurcation induced by the feedback between mechanical strains and chemical cues. A nonlinear continuum mechanics theory is established to investigate the volumetric growth, surface wrinkling, and morphological evolutions of soft tissues (e.g., tumors) under physiological and pathological conditions.

INTRODUCTION

Most tissues and organs in our body are very soft and can undergo large deformation. This mechanical characteristic is advantageous for them to achieve a wealth of biological functions, such as motion, aspiration, metabolism, mass and energy transport. Physiological and pathological processes of soft tissues always involve complicated and coupled interactions among mechanical, physical, chemical, and biological factors. The rapidly developing mechanobiology integrates the experimental and theoretical methods in biology and mechanics to investigate the physiological and pathological responses of biological molecules, cells, and tissues to mechanical, physical and chemical factors at different length scales. In this paper, we briefly summarize some recent advances in the theoretical and experimental efforts toward understanding the biomechanical mechanisms underlying some important dynamic behaviours of cells and tissues.

DYNAMICS OF COLLECTIVE CELLS

Collective cell dynamics play a crucial role in vast physiological or pathological processes including embryo development, wound healing, tissue regeneration, and tumor invasion. It involves self-assembly and self-organization of intercellular cytoskeleton, regulation of biochemical signalling pathways, cell–cell and cell–microenvironment interactions. We combine experiments, theory, and simulations to study the division, migration, oscillation and other dynamic processes of collective cells in two-dimensional (2D) confluent cell monolayers and three-dimensional (3D) cell systems.

Cell division rule

Cell division is central for embryonic development, tissue morphogenesis, and tumor development. The well-known Hertwig's cell division rule suggests that cells tend to divide along their long axes. However, this rule was established merely on the basis of geometrical statistics, rather than the analysis of mechanical forces, and thus does not fit well with some experimental observations of cell divisions. Experiments have evidenced that mitotic cell division relies on instructive signals from cellular microenvironments to coordinate the division plane. However, it still remains unclear how the biophysical cues such as cell geometry and cell–cell junctions coordinate to steer spindle position and orientation along with other influencing factors. We establish a mesoscopic dynamic cell division model to explore the integrated regulations of cortical protein polarity, microtubule kinetics, cell deformability and boundary constraints. This model can correlate division-plane orientation with cell geometry and nucleus stress. Besides the effects of cell geometry, the concentration of cortical anchoring protein is also taken into account in our model. We show that through the mechanical linkage between cortical LGN/NuMA/dynein complex and astral microtubules, the intercellular cues induced by cell–cell junctions are transmitted into the spindle orientation machinery to steer cell division. Besides predicting spindle orientation and positioning with different cortical polarities, the dramatic morphological evolutions of cell rounding is also captured. The present model can not only explain various cell division phenomena observed in cell monolayers but also account for the effects of boundary constraints, demonstrating the extensive applications of our work. It is concluded that the final division plane is perpendicular to the maximal principal stress acting on the nucleus, consistent with all relevant experiments. This new rule of cell division is referred to as the maximal principal stress rule [1].

Thermal effects on cell division

Furthermore, we investigate the effects of heat stress on the divisions of human cancer cells [2]. Multipolar divisions of heated cells has long been thought to stem from centrosome aberrations of cells directly caused by heat stress. Through long-term live-cell imaging, we provide direct cellular evidences to demonstrate that heat stress can promote multiple multipolar divisions of, for instance, MGC-803 and MCF-7 cells. Our results show that, besides facilitating centrosome aberration, polyploidy induced by heat stress is another mechanism that causes multipolar cell divisions, in which

polyploid cancer cells engendered by mitotic slippage, cytokinesis failure, and cell fusion. Furthermore, we also find that the subsequent fates of theses polyploid cells depend on their experience of these events: the polyploid cells generated by mitotic slippage experience bipolar divisions with a higher rate than multipolar divisions, while those polyploid cells induced by both cytokinesis failure and cell fusion have a higher frequency of multipolar divisions than bipolar divisions. We also show that heat stress-induced multiple multipolar divisions of cancer cells usually produce aneuploid daughter cells, and might lead to genetically unstable cancer cells and facilitate tumor heterogeneity. These findings on the thermal effects on cell division should be helpful for the design of thermotherapy strategies of cancers.

Oscillation of Collective Cells

Nest, we investigate shape oscillations of collective cells which may occur in the morphogenesis and organogenesis of various tissues and organs. Owing to their collective nature, these processes require robustly coordinated dynamics of individual cells, which are often separated too distantly to directly communicate with each other through biomaterial transportation. Although it is known that the mechanical balance generally determines the morphologies of cell systems, it remains elusive whether and how the mechanical components may contribute to the collective cell morphodynamics. Taking the collective cell oscillation in *Drosophila* amnioserosa as an example, we study the dynamic features and underlying mechanisms of collective shape oscillations in 2D cell monolayers (Fig. 1) [3]. Considering the negative chemical–mechanical feedback between cell deformation and intracellular myosin activity (Fig. 1c), a chemomechanical model is established to describe collective morphodynamics in cell monolayers. Using this model, we study collective oscillations in *Drosophila* amnioserosa to elucidate the regulatory roles of mechanical components. The tensile stress is identified as a key activator that switches collective cell oscillations on and off. This regulatory role is shown analytically using the Hopf bifurcation theory. We find that the physical properties of the tissue boundary are directly responsible for synchronizing the oscillatory intensity and polarity of cells and for orchestrating the spatial oscillation pattern in the tissue.

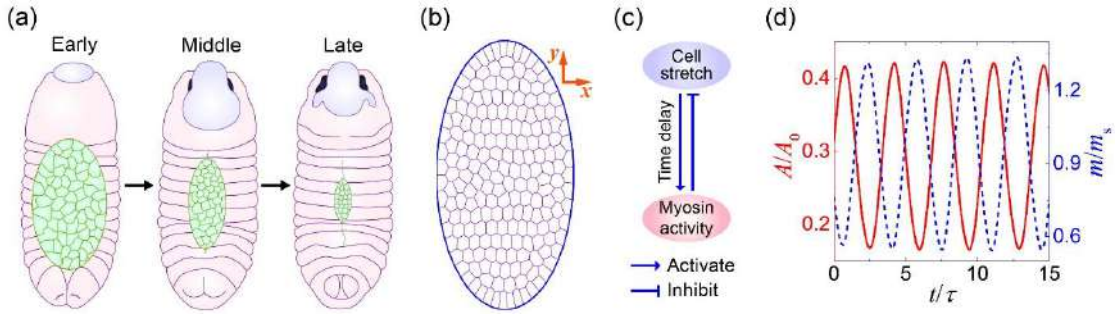

Figure 1. Collective cell oscillation in *Drosophila* amnioserosa. (a) Schematic of *Drosophila* dorsal closure. The central eye-shaped region is amnioserosa, surrounded by the lateral epidermis; (b) Geometric description of amnioserosa cells by connected polygons within an elliptic domain; (c) Interactive regulation between myosin activity and cell deformation; (d) Oscillations of normalized area (A/A_0) and myosin activity (m/m_0) of a representative cell, obtained from the chemomechanical model.

Migration of Collective Cells

Collective cell migration occurs in a diversity of physiological and pathological processes such as wound healing, cancer metastasis, and embryonic morphogenesis. In the collective context, cohesive cells may move as a translational solid, swirl as a fluid, or even rotate like a disk, with scales ranging from several to dozens of cells. By considering active cell motility and two typical social interactions among cells—local alignment (LA) and contact inhibition of locomotion (CIL), we establish an active vertex model to study collective cell migration on both planar and curved substrates. This model can well reproduce experimentally observed turbulent motion patterns in 2D cell monolayers. The regulating roles of LA and CIL on collective migration modes, characteristic scales, and density fluctuations are revealed. An intrinsic scale of cell monolayers is proposed to account for the mode transition of collective cell migration in confined spaces, and the corresponding patterns are attributed to the competition between the intrinsic scale of cell monolayers, geometric confinements, etc. A new dimensionless parameter, referred to as cell motility number, which involves the effects of cell motility, cell crowdedness, cell stiffness and confinement size, is defined to quantify the migration mode transition of collective cells.

For systems containing a large number of cells, the statistical features of forces, velocities, energies, shapes and other parameters at the meso scale are of significance for understanding the collective dynamics behaviours. To this end, we performed large-scale and long-time experiments to investigate the statistics of velocities and energies in diverse confluent cell monolayer systems that spontaneously orchestrate into mesoscale cell turbulence under certain conditions. We discover a linear relation between the variability and the mean of cell speeds as the monolayer matures, which reveals a time-invariant statistical rule. Through experimental and theoretical approaches, we demonstrate that cell velocities obey the non-canonical q-Gaussian statistics, with universality across different cell types and substrate stiffness. We further show that such universal velocity distribution statistics can be captured by the Tsallis statistical theory.

As to the energies of individual cells, the enstrophy is found to scale linearly with the kinetic energy as the monolayer matures, defining a characteristic length scale of vortices. The kinetic energies over time collapse to a family of probability

distributions, which deviate from the classic Maxwell–Boltzmann distribution and actually can be described by the q-Gaussian distribution of cell velocities. The energy spectra under larger wavenumbers exhibit a power-decaying law, with a scaling exponent markedly different from that in the classic 2D Kolmogorov–Kraichnan turbulence. Our experiments show that the obtained scaling relations of energies and velocities are nearly universal for all types of cells and substrates we measured. These findings provide physical insights into fundamental aspects of self-organization in biological tissues.

Furthermore, we investigate the relation between the collective motility and shape of human cancer cells under heat stress. Collective dynamics of MGC-803 cells in a confluent monolayer subjected to heat stress at 48 °C for 10 min are observed and analyzed using the long-term live imaging technique. It is found that the normal cell motions slow down with the increase in cell density and cell–cell adhesion, and the decrease in the average aspect ratio of cell shape and cell–substrate traction. Heat stress can speed up cellular motions accompanied with almost unchanged cell density, almost unchanged cell–cell adhesion, and the increase in the cell shape index and the tractions exerted by cells on the substrate. An approximately linear relation is revealed between the collective migration velocity and the shape index of the heated cells. This work provides inspirations for regulating cell motion with such factors as temperature.

THERMODYNAMIC MODEL OF TUMORS

In the recent years, continuum and discrete mechanobiological models have been proposed to investigate the mechanical properties and constitutive relations of soft tissues, e.g., brain and tumor. Our attention is focused on theoretical modelling of heterogeneous growth, angiogenesis, morphological and structural evolutions, invasion and metastasis of cancers. There are many mechanistic factors that might potentially collude with oncology to drive cancer progression. A solid tumor is an aggregate of cells, extracellular matrix (ECM), and interstitial space, where the cells and ECM provide mechanical integrity and act as a supporting skeleton, while the interstitial space is filled with fluids. Hence, a solid tumor is can be considered as a porous medium at the tissue level, and the theory of poroelasticity can be applied to characterize its mechanical behavior. The development and therapeutics of solid tumors are complex processes involving both biochemical regulations and mechanical interactions. We have developed a mechano-chemo-biological coupling poroelastic model to study some fundamental and clinical issues of tumors, e.g., volumetric growth, morphological evolution, vascular collapse, mechanical stiffening, and evaluation of therapeutic strategies.

In the initial development phase, a solid tumor is avascular and its growth induced by cell proliferation relies on the diffusion of oxygen and nutrients from surrounding host tissues. The gradients of these chemicals lead to heterogeneous tumor growth, which further engenders residual stresses. These stresses can modulate tumor growth both directly, by compressing tumor cells, and indirectly, by compressing the interstitial space and hinder nutrition diffusion. Based on the consideration of thermodynamics, a nonlinear poroelastic theory with a stress-modulated growth law is established to model the coupling among the mechanical, chemical, and biological mechanisms governing avascular tumor growth. The poroelastic theory can account for the interactions between the solid and fluid phases and reveal the regulating role of stresses on nutrient transport. The model shows that the mechano-chemo-biological coupling triggers anisotropic and heterogeneous growth, leading to the formation of a layered structure consisting of a necrotic core and a proliferative rim, in consistency with clinical observations. The inhibitory effect of external confinements on tumor growth is also verified by comparing the theoretical and experimental results for tumor growth under different conditions. For example, the model can reproduce the observation that there exists a steady state in which tumor growth is balanced by resorption and the effects of stresses on tumor growth may be, to some extent, reversible.

Tumor development is often accompanied with the evolution in mechanical properties. Although cancer cells generally have lower elastic moduli than the corresponding normal cells, experiments showed that tumor tissues are often stiffer than the surrounding tissues and can sustain higher compressive stresses. This contradiction is mainly attributed to the mechanical resistance capacity of tumor ECM. ECM is primarily composed of collagen fibrils and glycosaminoglycan (GAG) chains, where the collagen network maintains the mechanical integrity of ECM, and GAG chains can imbibe water and carry fixed negative charges, resulting in a gel-like phase. The poroelastic model is applied to study the chemo-mechanical behaviors of tumor ECM, which is treated as a polyelectrolyte consisting of a collagen network and GAG chains [4]. The deformation of collagen network is described by the eight-chain hyperelastic model, while the free energy due to the mixing of GAG chains and water is estimated by Flory-Huggins theory. The poroelastic model reveals that osmosis is primarily responsible for the compressive resistance of ECM. Considering that aggregated cells and collagen fibrils act as a solid skeleton and GAG chains immerse in fluids, this poroelastic model can be extended to the whole tumor tissue. The extended model fits well with the experimental data of tumor tissues under compression, and also reveals that over-expressed GAGs can stiffen the tumor tissue. Besides, GAG chains also influence the transient mechanical response of ECM and tumor tissues by modulating permeability.

As a novel anticancer strategy, nanomedicine uses nanoparticles for drug delivery. However, the transport of nanoparticles, whose sizes are normally tens or even hundreds of nanometers, may be hindered by a dense tumor ECM. Both collagen fibrils and GAG chains affect drug diffusion and fluid convection in the tumor ECM. By using the principle of maximum energy dissipation rate, we also propose a general thermodynamic framework of poroelastic solids with degradation effects [5]. This framework is specified to evaluate the enzymatic degradation of tumor ECM. The permeability of ECM is predicted by considering the hydraulic drags engendered by the collagen network and GAG meshwork, and the diffusivity of nanomedicines in ECM is estimated by considering the obstruction of collagen fibrils, which cause an increase in the diffusive length, and the frictions between GAG chains and nanoparticles. In consistency with experiments, our results reveal that the diffusion of nanoparticles in tumors is mainly hindered by collagen fibrils,

while the weakened fluid convection in ECM is due to GAG chains. Therefore, degradation of tumor ECM could be an effective strategy to improve the efficacy of drug delivery.

MORPHOMECHANICS OF SOFT TISSUES

Biological morphomechanics addresses the formation and evolution of morphologies induced by growth, deformation, damage and reshaping of various tissues and organs under physiological and pathological conditions. A challenging issue in biomechanics and medical engineering is to build the intrinsic relationship between biological specificity and mechanical principles in the morphogenesis of soft tissues. Using the growth-induced wrinkling theory and the pseudodynamic method we have investigated the surface instability and morphological evolution of soft tissues with different geometric configurations. First, the critical conditions for the buckling, period-doubling buckling, and creasing in such soft tissues as airway and esophageal mucosa are derived. The coupling mechanisms between mechanical and chemical factors (e.g., gene) underlying the morphogenesis of these soft tissues are unraveled. Pattern evolutions under different physiological and pathological conditions are predicted and experimentally verified.

Morphogenesis of tumors holds significant applications in biomedical engineering, treatment and diagnosis of cancers. During development, solid tumors and brains always stratify into layered or core-shell structures and evolve into diverse surface morphologies [6]. It is found that the surface wrinkling of spherical core–shell tissues exhibit complicated and 3D features, strong nonlinearity, and multiple pattern transitions. We derive the analytical solution for the critical buckling and pattern formation of spherical core–shell tissues due to differential growth. It is revealed that the spherical surface can buckle into a surface pattern consisting of pentagons and hexagons, named the buckyball-like mode. This wrinkling mode in core–shell structures has been further validated by the experiments. During subsequent morphological evolution, the buckyball-like wrinkling pattern can switch to labyrinth folding morphologies akin to animal brains. The energetic mechanisms underpinning the wrinkle-to-fold transition has been elucidated. In addition, the period-doubling folding, labyrinthine folding, and spiral wrinkling of cylindrical core-shell tissues are also identified. These findings provide a new perspective toward understanding the morphogenesis of brains and tumors.

The development of tissues and organs involve not only wrinkling and morphological evolution on their surfaces but also structural variation and instability in the interior. For a tumor beyond the avascular phase, for example, angiogenesis is required to supply more oxygen and nutrients needed by tumor growth and metabolism. However, blood vessels may buckle and even collapse, characterized as lumen closure, during cancer development. Vascular collapse may lead to hypoxia, which promote cancer metastasis, and hinder the delivery of drug. The buckling and collapse of blood vessels are closely associated with mechanical microenvironment in tumors, such as elevated interstitial fluid pressure, over-proliferation of perivascular cells, and abnormal osmotic pressure. It can be expected that, by exerting an outer pressure on the vessel wall, the overgrowth of perivascular cells and elevation of interstitial fluid pressure and osmotic pressure may lead to the buckling and collapse of blood vessels. We have investigated the stability of blood vessels embedded in a growing tumor, described by the biochemomechanical poroelastic model [7]. Linear stability analysis is first made to give the critical condition of vascular buckling. The analysis shows that interstitial fluid pressure tends to drive blood vessels to buckle with a lower buckling mode, while perivascular cell proliferation favors a higher mode. Furthermore, a nonlinear biochemomechanical finite element method is formulated to track the morphological evolution of blood vessels during postbuckling. The blood vessels with the second mode of buckling may readily evolve into a crack-like shape. This theory can reproduce the essential features of vascular collapse observed in *in vivo* tumors.

CONCLUSIONS

Physiological and pathological processes of living tissues involve complicated interactions of mechanical, biological and chemical cues at different length scales. Combined experimental and theoretical efforts are required to understand the dynamic behaviours of cells (e.g., deformation, division, motion, migration and oscillation) and tissues (e.g., growth, regeneration, reshaping, damage, morphogenesis). We have studied the division, migration, oscillation and some other dynamic behaviours of collective cells through the combination of experiments, theory and simulations. A biochemomechanical poroelastic model is established to investigate the stress-modulated avascular growth, surface wrinkling and vascular buckling in growing tumors, mechanical properties of cancerous tissues, and nanomedicine therapy. These models may not only deepen our understanding of evolutionary processes of cells and soft tissues but also hold promise for clinical applications.

SIMPLE INVARIANT SOLUTIONS REPRESENTING FLUID TURBULENCE

Genta Kawahara
Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka, Japan

Summary Theoretical approaches using simple invariant solutions (equilibrium and periodic solutions) to the Navier–Stokes equations are presented to the problems of subcritical transition and developed turbulence. Considering turbulent flows as dynamical systems, stable and unstable manifolds of invariant solutions could represent flow instability and thus turbulence dynamics, while the simple solutions themselves exhibit coherence in turbulent flows. In this paper we attempt to quantitatively characterize turbulent flow and its onset in terms of invariant solutions. Specifically, the intensity of turbulence-driven mean secondary flow in a square duct is evaluated using the three-dimensional steady traveling-wave solution (Uhlmann, Kawahara & Pinelli 2010), and the scaling law of the Nusselt number (dimensionless wall-to-wall heat flux) with the Rayleigh number observed in thermal convective turbulence is reproduced by the three-dimensional steady solution (Motoki, Kawahara & Shimizu 2020). The onset Reynolds number of transient turbulence is also determined by the first tangency of homoclinic orbits to the known three-dimensional periodic edge state (Kawahara & Kida 2001) in minimal plane Couette flow (Lustro *et al*. 2019).

1. INTRODUCTION

The motion of a viscous fluid is governed by the Navier–Stokes equations, i.e., a set of partial differential evolution equations, apparently implying that fluid flow is an infinite-dimensional dynamical system. However, the turbulent motion in a finite domain is considered to be finite-dimensional. The physical reason is that small-scale motions are smoothed by viscosity. There is a mathematical proof of the existence of approximate inertial manifolds for the Navier–Stokes equations, providing a relation between the dominant modes and the higher-order ones that can be truncated (see e.g. Foias 2001). Within such a manifold, the Navier–Stokes equations can be rigorously approximated by a finite-dimensional system of ordinary differential equations.

Dynamical systems theory suggests that coherent structures in turbulent flows may be thought of simple invariant sets in phase space, in the neighborhood of which the system spends a substantial fraction of time. Spatio-temporally organized structures appear when a turbulent state approaches such an invariant set. Possible simple invariant sets in phase space are a fixed point and a periodic orbit. Recently dynamical-systems approaches have been taken widely to the problems of subcritical transition (see e.g. Kerswell 2005; Eckhardt *et al*. 2007; Eckhardt *et al*. 2008) as well as to developed low-Reynolds-number turbulence (see e.g. Kawahara, Uhlmann & van Veen 2012). Many of recent studies in this approach are concerned with qualitative characterization of flow properties in transition and turbulence. In this paper, on the other hand, we shall attempt to quantitatively reproduce statistical properties of turbulent flows and evaluate the onset Reynolds number of transient turbulence using simple invariant solutions.

In section 2 three-dimensional steady traveling-wave solutions to the Navier–Stokes equation is presented for square-duct flow (Uhlmann, Kawahara & Pinelli 2010). This traveling-wave solution not only exhibits eight-vortex secondary flow consistent with that observed in turbulent square-duct flow but also reproduces a secondary flow intensity comparable with turbulence-driven secondary flow. We also discuss a three-dimensional steady solution to the Boussinesq equation for Rayleigh–Bénard convection in section 3 (Motoki, Kawahara & Shimizu 2020). This steady solution represents the scaling law of the Nusselt number Nu with the Rayleigh number Ra, $Nu \sim Ra^{0.31}$, commonly observed in turbulent thermal convection. In section 4 we identify the onset of transient turbulence eventually relaminarizing as the first tangency of a pair of distinct homoclinic orbits to the known periodic edge state (Kawahara & Kida 2001) in minimal plane Couette flow (Lustro *et al*. 2019). A brief summary and the outlook for future studies are given in section 5.

2. TRAVELING WAVE REPRESENTING MEAN SECONDARY FLOW

Mean secondary (cross-sectional) flow is widely observed in turbulent flow through straight ducts with non-circular cross-section. Theoretical interpretation of the generation of such (turbulence-driven) mean secondary motion of Prandtl's second kind has long been a significant issue in fluid mechanics. In this section we shall discuss turbulence-driven secondary motion in the flow through a square duct. The mean flow in the cross-section consists of four pairs of counter-rotating vortices on four walls (a total of eight vortices per cross-section). There are several phenomenological explanations of the formation of the secondary vortices based on inspection of the dominant terms in the averaged streamwise-vorticity equation (Gavrilakis 1992), identification of preferential locations of instantaneous quasi-streamwise vortices (Pinelli *et al*. 2010), and so on.

Here we theoretically interpret the generation of the mean secondary flow in terms of three-dimensional steady traveling-wave solutions to the Navier–Stokes equation (Uhlmann, Kawahara & Pinelli 2010). Figure 1 shows the flow field on the upper-branch traveling wave at the bulk Reynolds number $Re = 1404$ (see the cross on the blue curve in figure 2). It can be seen that a wavy low-speed streak as well as staggered streamwise vortices appear in the vicinity of all

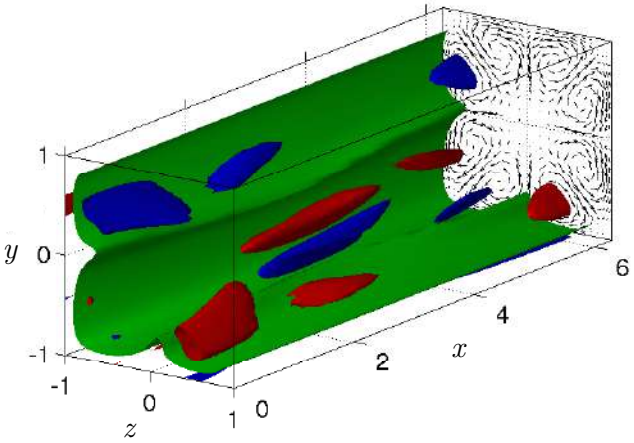

Figure 1: The upper branch of steady traveling waves (Uhlmann, Kawahara & Pinelli 2010) in pressure-driven square-duct flow at Reynolds number $Re = 1404$. The flow is visualized by green iso-surfaces of the streamwise velocity $0.55\,\max(u)$ and by red and blue iso-surfaces of the streamwise vorticity $\pm 0.65|\max(\omega_x)|$. The surfaces are cut away on one side of a diagonal of the duct cross-section for improved clarity. Streamwise-averaged velocity vectors are projected upon the cross-sectional plane of a square duct.

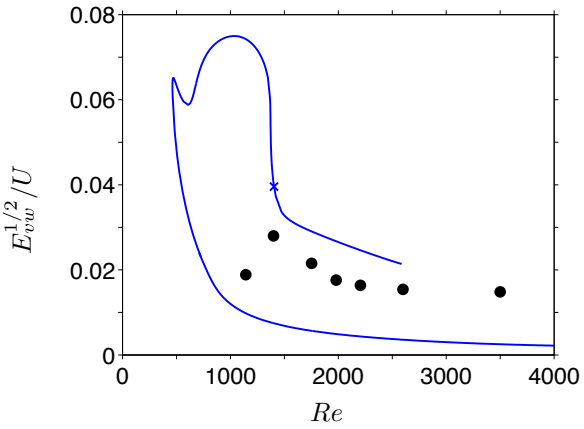

Figure 2: The intensity of the mean secondary flow $E_{vw}^{1/2}$ for Uhlmann, Kawahara & Pinelli's (2010) traveling waves normalized by the bulk velocity U as a function of the Reynolds number Re. $E_{vw} = \langle\langle v\rangle_x^2 + \langle w\rangle_x^2\rangle_{yz}$, where $\langle\cdot\rangle_m$ denotes the average with respect to m. The blue curve represents the upper- and lower-branch traveling-wave solutions on which the cross corresponds to the field visualized in figure 1. The closed circles stand for long-term averaged turbulent flow (Uhlmann *et al.* 2007).

four wall planes. The streamwise-averaged velocity of the traveling wave exhibits a secondary flow pattern with eight vortices, consistent with the mean secondary motion observed in turbulent square-duct flow. The traveling wave is quantitatively compared with turbulence data in figure 2, where the intensity of the secondary flow is shown as a function of the bulk Reynolds number Re. It is demonstrated that the upper-branch traveling wave has a comparable intensity with the turbulence-driven secondary flow at least up to $Re \approx 2500$, suggesting that the mean secondary flow can be identified as nonlinear equilibrium given by the invariant solution around which a turbulent system spends a substantial fraction of time.

3. STEADY SOLUTION REPRODUCING SCALING LAW IN TURBULENT CONVECTION

Rayleigh–Bénard convection is one of the most canonical turbulent flows. It is thermal convection driven by buoyancy, and dimensionless parameters in this system are the Rayleigh number Ra and the Prandtl number Pr. At low Ra wall-to-wall heat flux is given by thermal conduction. When Ra is increased, thermal convection arises and eventually convective turbulence appears to drastically enhance the heat flux. The dimensionless wall-to-wall heat flux normalized with thermal

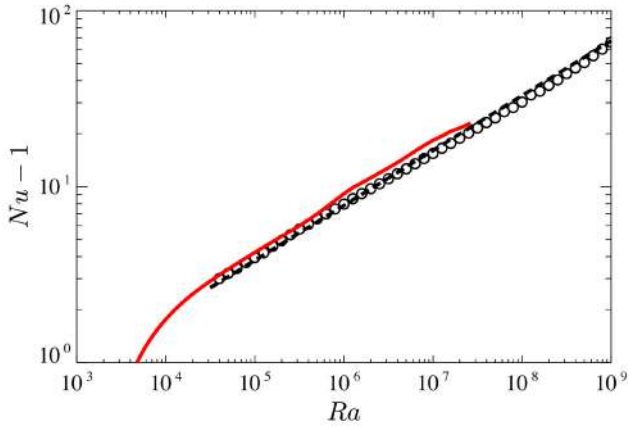

Figure 3: The Nusselt number Nu of Motoki, Kawahara & Shimizu's (2020) three-dimensional steady solution to the Boussinesq equation for $Pr = 1$ as a function of the Rayleigh number Ra. The red curve represents the invariant solution while the open circles denote the temporal average of the corresponding turbulent solution. The dashed line is the empirical correlation of the scaling law of Nu with Ra, $Nu - 1 = 0.105Ra^{0.312}$ (He *et al.* 2012).

conduction heat flux is the Nusselt number Nu. A large number of experiments and numerical simulations have been performed, and the scaling law $Nu \sim Ra^{0.31}$ has been commonly observed at $Ra \sim 10^8 - 10^{11}$ (see e.g. He *et al.* 2012). Grossmann & Lohse (2000) have proposed phenomenologically the scaling theory of Nu with Ra and Pr. Their theory gives us the scaling $Nu \sim Ra^{1/3}$ in the high-Ra range $Ra \sim 10^8 - 10^{14}$ for $Pr \sim 1$.

Here we aim at theoretically reproducing this well-known scaling law of Nu with Ra using a three-dimensional steady solution to the Boussinesq equation (Motoki, Kawahara & Shimizu 2020). Figure 3 shows the Nusselt number Nu of the steady solution for $Pr = 1$ as a function of the Rayleigh number Ra. In this figure the temporal average of Nu is also shown for a turbulent solution to the Boussinesq equation with consistent conditions with the steady solution. It is significant that Nu for the steady solution increases with increasing Ra, implying that at higher Ra, smaller-scale thermal plumes appear closer to the walls to enhance the wall heat flux in the simple invariant solution. It can be seen that the steady solution excellently reproduce the behavior of the corresponding turbulent solution, and what is remarkable in the figure is that the invariant solution exhibits the well-known turbulent scaling law $Nu \sim Ra^{0.31}$ (see e.g. He *et al.* 2012).

4. HOMOCLINIC TANGENCY LEADING TO TRANSIENT TURBULENCE

Recent studies have shown that transient turbulence eventually relaminarizing appears at the onset of subcritical transition to turbulence before (or without) the linear instability of laminar flow (see e.g. Eckhardt *et al.* 2008). It is indispensable for theoretical prediction of the transition to turbulence to determine the onset Reynolds number for such transient turbulence. Dynamical systems theory tells us that the onset of chaos can be identified by the emergence of the Smale horseshoe and that if transversal intersections of stable and unstable manifolds of a periodic orbit, i.e., homoclinic orbits, exist in our system, we can find a horseshoe map on its Poincaré section. Therefore, the onset of transient turbulence is rigorously determined as the first emergence of homoclinic orbits to a periodic edge state, i.e., the first homoclinic tangency.

Here we theoretically determine the onset Reynolds number of transient turbulence in minimal plane Couette flow by identifying the first homoclinic tangency to Kawahara & Kida's (2001) periodic edge state (Lustro *et al.* 2019). Figure 4 shows the two-dimensional projection of the two homoclinic orbits, which have been observed to exist down to the lowest (tangency) Reynolds number. Even at the highest Reynolds number $Re = 245$ the former of the two large-amplitude temporal oscillations are almost consistent between the two homoclinic orbits while the latter are significantly distinct (see figure 4 (*e*)). As Re is decreased these two homoclinic orbits get closer to each other and eventually merge to disappear in tangency at $Re \approx 240.88$. Below the tangency Reynolds number $Re \approx 240.88$ we have not observed transient turbulence eventually relaminarizing, implying that $Re \approx 240.88$ is the onset Reynolds number of transient turbulence in minimal plane Couette flow.

5. SUMMARY AND OUTLOOK

Recently dynamical-systems approaches have been taken to enrich our understanding of subcritical transition and developed turbulence with a focus on qualitative characterization of flow properties in transition and turbulence. In this paper, by using simple invariant solutions to the Navier–Stokes equations we have attempted to quantitatively reproduce the intensity of turbulence-driven secondary motion in square-duct flow and the scaling law of the Nusselt number with the Rayleigh number in turbulent Rayleigh–Bénard convection as well as to evaluate the onset Reynolds number of transient

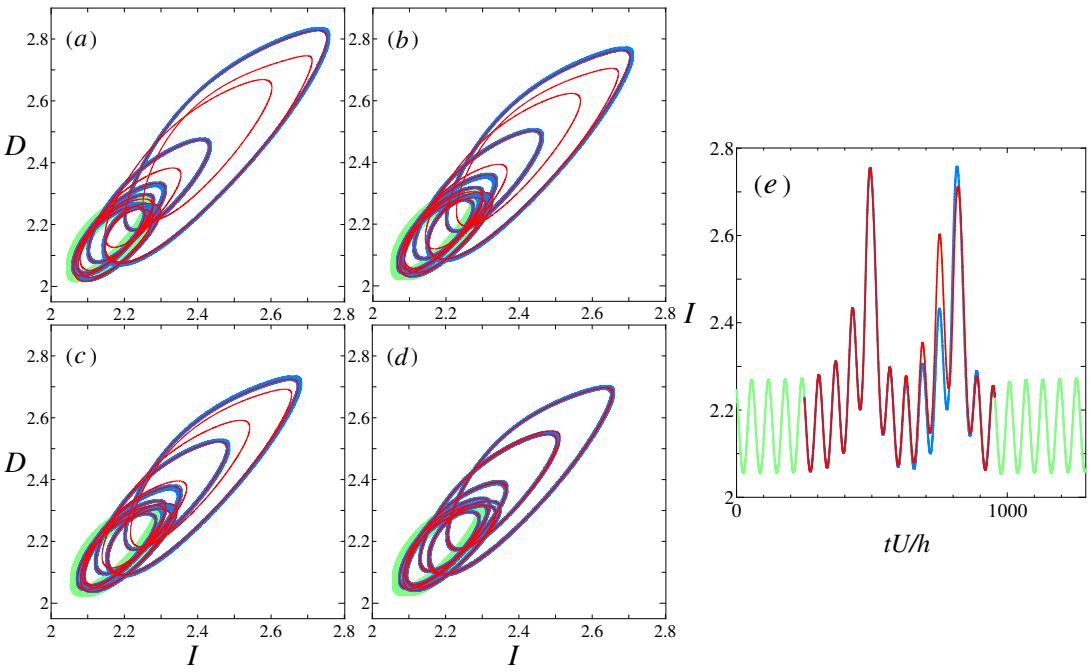

Figure 4: A pair of distinct homoclinic orbits that exhibit tangency in the two-dimensional projection defined by energy input rate I and energy dissipation rate D normalized with the corresponding laminar values. The light green line represents Kawahara & Kida's (2001) periodic edge state. The blue and red lines correspond to the family of homoclinic orbits. Starting from (a) the pair move closer to each other with decreasing Reynolds number until they merge to tangency at (d). (a) $Re = 245$, (b) $Re = 242.5$, (c) $Re = 241.4$, and (d) $Re \approx 240.88$. The value of I of the two orbits is shown as a function of time at $Re = 245$ in (e).

turbulence in minimal plane Couette flow. Such quantitative characterization in terms of simple invariant solutions to the Navier–Stokes equations could be the key to theoretical description of transition and developed turbulence. However, since the numerical computation of invariant solutions is much tougher at higher Reynolds numbers, representative statistical laws of turbulence, e.g., the inertial range in isotropic turbulence and the logarithmic layer in wall turbulence, are still beyond the quantitative characterization in terms of invariant solutions. In order to take a dynamical-systems approach to high-Reynolds-number turbulence using invariant solutions, we need to develop novel numerical schemes for invariant solutions and/or to obtain invariant solutions to the model equations for high-Reynolds-number turbulence, such as the LES (Large Eddy Simulation) equations, rather than the Navier–Stokes equations. More recently there are a few studies on the LES invariant solutions (see e.g. van Veen, Vela-Martín & Kawahara 2019 for an attempt on the inertial-range dynamics using a periodic solution to the LES equation).

WHEN BIOLOGY INSPIRES FLUID MECHANICS

Eric Lauga
Department of Applied Mathematics and Theoretical Physics, University of Cambridge, Cambridge CB3 0WA, United Kingdom

Summary Research in fluid mechanics has long been motivated by the desire to understand the world around us. Biology, in particular, is dominated by transport problems involving fluids, from diffusion of nutrients and locomotion at the cellular level to flows around plants and the circulatory system of animals, and as such the biological realm is a constant source of inspiration for fluid mechanicians. In this talk I will highlight recent work in my group where fluid mechanics problems are inspired by small-scale biology. I will first focus on motile bacteria, from their individual and collective dynamics to their interactions with viruses. I will then highlight our research on the distribution of swimming speeds for eukaryotic organisms. Finally, I will show how cell locomotion can be used as a source of inspiration to design and optimise artificial swimmers and pumps.

INTRODUCTION

Fluid dynamics plays a crucial role in numerous biological processes, from the largest animals to the smallest cells, and research activity at the intersection of fluid dynamics and biology has been steadily growing since the pioneering work of Taylor in the 1950's. Over the last twenty years, fluid mechanics conferences and journals have seen a stark increase in research relevant to, or inspired by, biology.

An area of particular interest is the role of low Reynolds number flows in cellular life. Enabled by advances in microscopy and micromanipulation, experimental data have been used to inspire new models and enable hydrodynamic discoveries while in turn quantitative theories using fluid mechanics have been precisely tested. One area where this back and forth between theory and experiments has been very successful is the study of cell motility. Exemplified by the swimming of microorganisms such as bacteria and spermatozoa, this is an area where fluid dynamics has not only helped explain many natural phenomena but also one where biology has lead to a new understanding of hydrodynamics.

In this talk I will highlight recent work in my group where fluid mechanics problems are inspired by small-scale biology. I will first focus on motile bacteria, from their individual and collective dynamics to their interactions with viruses. I will then highlight our research on the distribution of swimming speeds for eukaryotic organisms. Finally, I will show how cell locomotion can be used as a source of inspiration to design and optimise artificial swimmers and pumps. Throughout the talk, I will attempt to focus on the basic mathematical modelling tools and emphasise the key physical ideas.

FLUID MECHANICS OF BACTERIA

Bacterial magneto-convection

Dense suspensions of swimming bacteria are known to self-organise and display unsteady dynamics. In work done in collaboration with the groups of Cécile Fradin and Kari Dalnoki-Veress from McMaster University, I will report on a new type of collective motion observed in a population of confined magnetotactic bacteria induced by application of a magnetic field perpendicular to the confining walls in a microfluidic setup. We find that a uniform distribution of bacteria

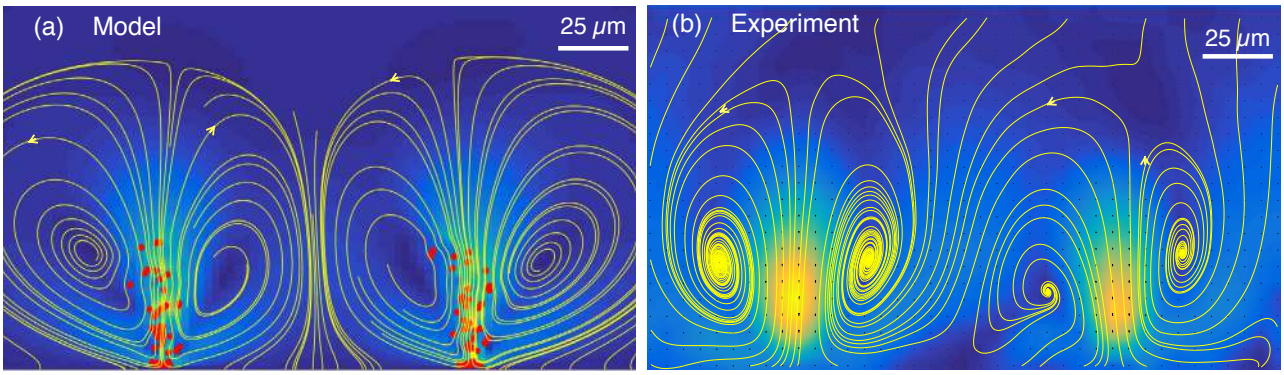

Figure 1: Convection cells created by two plumes in a 200 μm glass capillary. (a) Experimental measurements showing magnitude and streamlines of the flow field. (b) Convection cells and flow from theoretical model, where red dots represent cells [1].

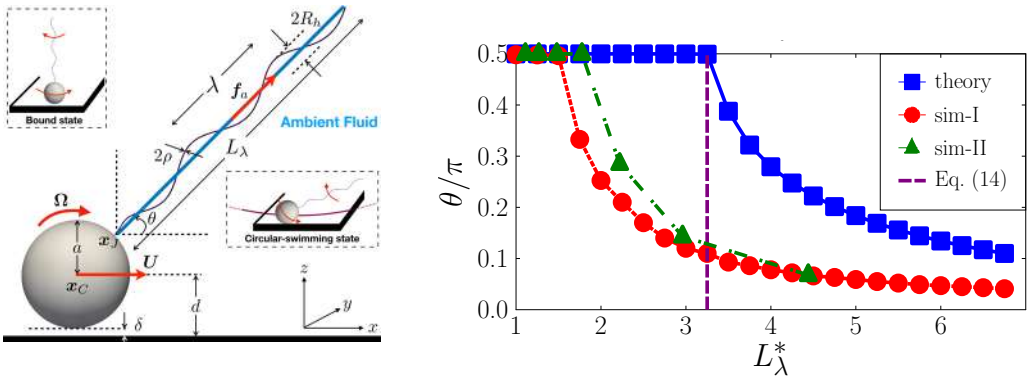

Figure 2: Left: Schematic diagram of a flagellated bacterium swimming near a plane surface. The cell body is modelled as a rigid sphere and the flagellar filament as a rigid right-handed helix rotating along its axis (numerical simulations) or a rod placed along the helix axis with an active force acting along it (theoretical model). The flagellum tilt angle is denoted by θ. The two possible final steady states of a bacterium near a surface are shown in the insets: the surface-bound state ($\theta = \pi/2$) and circular-swimming state ($\theta \neq \pi/2$). Right: Pitchfork bifurcation of the tilt angle, θ/π, plotted against the dimensionless flagellum axial length, L^*_λ, for the numerical simulations (red dashed lines/circles for sim-I and green dash-dotted lines/triangles for sim-II) and the theoretical model (blue solid lines/squares) [2]. The critical flagellum axial length below which bound state is possible is shown in purple dashed line for the analytical model.

self-organises spontaneously into bacterial plumes perpendicular to the wall, resulting in self-sustained flow convection cells (Fig. 1).

The observed plumes are reminiscent of bioconvection patterns and the flow generated resembles Rayleigh-Benard convection cells while the dynamics bears similarities with porous media flows. However, an essential difference exists between the phenomenon reported here and these well-studied instabilities. Both bioconvection and the Rayleigh-Benard instability rely on a density mismatch between layers of the fluids. In contrast, for the phenomenon reported here, no external forces are applied on the fluid and the magnetic field only exerts an external torque aligning magnetotactic bacteria with the field – the plumes result thus only from hydrodynamic interactions between the oriented cells and the confining walls.

Using a theoretical model based on hydrodynamic singularities, we are able to capture quantitatively the instability and the observed long-time growth of the plumes [1]. We use the model to show that the self-sustained state, which we term bacterial magneto-convection, results from the balance between the ordered state of the cells and both cell-cell and cell-wall hydrodynamic interactions.

Stability of bacteria bacteria near surfaces

It is well known that flagellated bacteria, such as the oft-studied *Escherichia coli*, swim in circles near surfaces. However, recent experiments have shown that a sulfide-oxidizing bacterium named *Thiovulum majus* can transition from swimming in circles to a dynamical surface-bound state where it stops swimming while remaining free to move laterally along the surface. In this bound state, the cell body continuously rotates around its centre in the direction perpendicular to the surface while its flagellar filaments point away from the surface, rotating in the opposite direction. Mathematically, we define the cell to be in the surface-bound state when the flagellum axis is perpendicular to the surface, i.e. $\theta = \pi/2$, and consequently, the radius of circular trajectory is $R = 0$ (see Fig. 2, left).

In the bound state, a small perturbation in the tilt angle of the flagellum is expected to destabilise the cell and cause it to swim parallel to the surface in circles. What makes this state stable? Using two different numerical simulations together with a theoretical analysis, we demonstrate the existence of a fluid-structure interaction instability that causes cells with relatively short flagella to become surface bound [2]. Specifically, we show that the flagellum of a freely swimming *T. majus* cell undergoes slow tilt angular dynamics near a rigid wall. If the distance between the cell's surface and the wall becomes sufficiently small, drag forces acting on the translating flagellum (which tend to align the flagellum parallel to the surface) are unable to compensate the large lubrication torque exerted on the cell body (which tends to align the flagellum perpendicular to the surface). In this case, the cell eventually points perpendicular to the wall and thus stops swimming, while the cell body and flagella continue rotating as seen in experiments. This bound state is stable only below a certain critical flagellum axial length, L_λ, normalised by the radius of the spherical cell body, a, consistent with experiments (see Fig. 2, right).

Hydrodynamics of bacterial phages

Bacteriophage viruses, one of the most abundant entities in our planet, lack the ability to move independently. Instead, they crowd fluid environments in anticipation of a random encounter with a bacterium. Once they land on the cell body of their victim, they are able to eject their genetic material inside the host cell. Many phage species, however, first attach to the flagellar filaments of bacteria. Being immotile, these so-called flagellotropic phages still manage to reach the cell

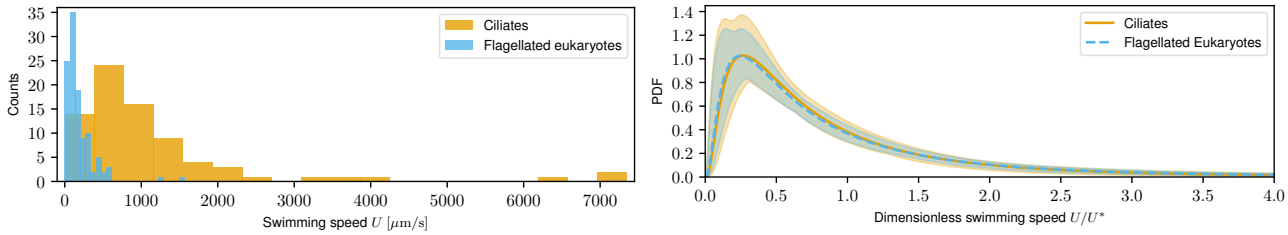

Figure 3: Left: Histograms of swimming speed for ciliates and flagellates demonstrate a similar character but different scales of velocities. Right: Test of rescaling hypothesis. Shown are the two fitted log-normal curves for flagellates and ciliates, each multiplied by the distribution median M, plotted versus speed normalized by M. The distributions for show remarkable similarity and uncertainty of estimation [5].

body for infection, and the process by which they move up the flagellar filament has intrigued the scientific community for decades. Back in 1973, Berg and Anderson [3] proposed the nut-and-bolt mechanism in which, similarly to a rotated nut that is able to move along a bolt, the phage wraps itself around a flagellar filament possessing helical grooves (due to the helical rows of flagellin molecules) and exploits the rotation of the flagellar filament in order to passively travel along it. One of the main pieces of evidence for this mechanism is the fact that immotile mutants of bacterial species such as *Escherichia coli* and *Salmonella typhimurium* equipped with straight, but rotating, flagellar filaments with a preserved helical groove structure are still infected by their relative phages.

Using two distinct theoretical approaches for the short-range interactions between phages and flagellar filaments, I will show the derivation of a first-principles theoretical model for the nut-and-bolt mechanism applicable to mutants possessing straight flagellar filaments [4]. Our model is fully analytical, is consistent with past experimental observations, and is able to predict the speed of translocation of a bacteriophage along a flagellar filament as a function of (i) the geometry of both phage and bacterium, (ii) the rotation rate of the flagellar filament and (iii) the handedness of the helical grooves.

FLUID MECHANICS OF EUKARYOTIC CELLS

Distribution of swimming speeds and a database of cell motility

One approach to quantifying biological diversity consists of characterising the statistical distribution of specific properties of a taxonomic group or habitat. Microorganisms living in fluid environments, and for whom motility is key, exploit propulsion resulting from a rich variety of shapes, forms, and swimming strategies. In joint work with the group of R. E. Goldstein in Cambridge, I will present our effort to explore the variability of swimming speed for unicellular eukaryotes based on published data (Fig. 3, left). The data naturally partitions into that from flagellates (with a small number of flagella) and from ciliates (with tens or more). Despite the morphological and size differences between these groups, I will show that each of the two probability distributions of swimming speed are accurately represented by log-normal distributions, with good agreement holding even to fourth moments. Scaling of the distributions by a characteristic speed for each data set leads in fact to a collapse onto an apparently universal distribution (Fig. 3, right). These results suggest a universal way for ecological niches to be populated by abundant microorganisms [5].

I will next present a thorough survey of the available experimental data produced to date on the characterisation of motile behaviour of unicellular microswimmers. We have assembled from the available literature empirical data on the motility of five broad categories of organisms: bacteria, archaea, flagellated eukaryotes, spermatozoa and ciliates. Whenever possible, we gathered the following parameters: species, geometry and size of the organisms, swimming speeds, actuation frequencies, actuation amplitudes, number of flagella and properties of the surrounding fluid. We analyse the results in the light of the established fluid mechanics principles for propulsion at low Reynolds numbers. We reproduce expected scalings for the locomotion of cells within the same taxonomic groups of organisms while demonstrating the variability for organisms of different species within the same group. We also obtain a number of new, unexpected scalings, for which we propose biophysical rationalisations. The material gathered in our work is a summary of the established knowledge in the domain, providing a convenient and practical reference point for future studies while highlighting uncharted territories [6].

FLUID MECHANICS OF ARTIFICIAL SWIMMERS

Quincke swimmers

Limitations in nanofabrication have thus far hindered the ability to design and program synthetic swimmers with the same abilities as self-propelled biological cells, so scientists have taken advantage of other physical mechanisms in order to design self-propelled artificial swimmers. Dielectric particles suspended in a weakly conducting fluid are known to spontaneously start rotating under the action of a sufficiently strong uniform DC electric field due to the Quincke rotation instability. This rotation can be converted into translation when the particles are placed near a surface providing useful

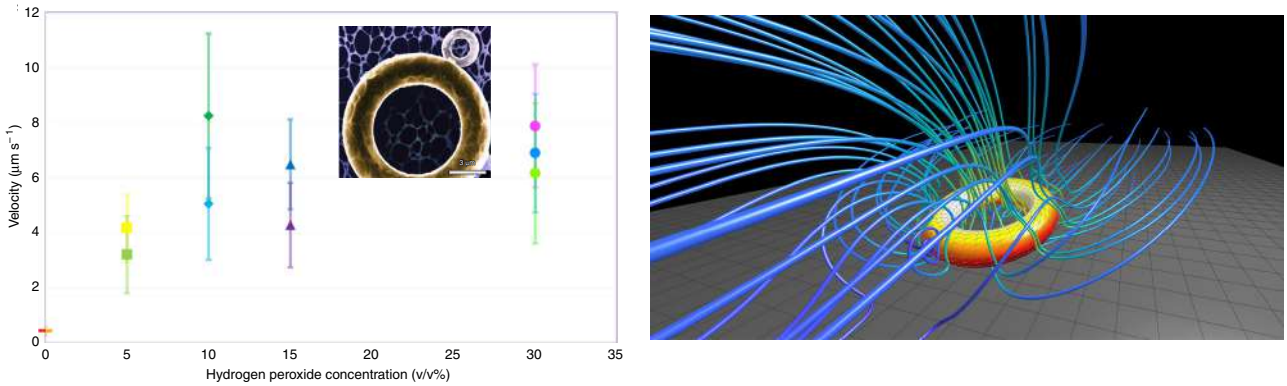

Figure 4: Left: Propulsion velocity of a catalytic Janus torus as a function on the concentration of hydrogen peroxide (Inset: High-resolution transmission electron microscope image of Janus torus; scale bar is 3 μm). Right: Flow streamlines and surface concentration of a steady gliding catalytic torus, at an angle of 12°, shown in the frame in which the torus is stationary [8].

model systems for active matter. Using a combination of numerical simulations and theoretical modeling, we demonstrate that it is possible to convert this spontaneous Quincke rotation into spontaneous translation in a plane perpendicular to the electric field in the absence of surfaces by relying on geometrical asymmetry instead [7].

Phoretic swimmers and pumps

Phoretic mechanisms, whereby gradients of chemical solutes induce surface-driven flows, have recently been used to generate directed propulsion of patterned colloidal particles. I first present experimental and theoretical work where, in collaboration with the groups of A. Sen and I. Aronson at Penn State, we encode multi-behavioural responses in microscopic self-propelled tori using nanoscale 3D printing. We show experimentally and theoretically that the tori continuously transition between two primary swimming modes in response to a magnetic field (see Fig. 4). The tori also manipulate and transport other artificial swimmers, bimetallic nano-rods, as well as passive colloidal particles, and have the potential to interact with biological active matter, e.g. bacteria or cells [8].

We next consider the case of confined phoretic flows, which provide efficient means to drive fluid motion on very small scales. Colloidal particles covered with chemically-active patches with nonzero phoretic mobility (e.g. Janus particles) swim using self-generated gradients and similar physics can be exploited to create phoretic pumps. In work carried in collaboration with the group of S. Michelin at Ecole Polytechnique (France), I will present a detailed analysis of the design principles of phoretic pumps and show that for a minimal phoretic pump, consisting of three distinct chemical patches, the optimal arrangement of the patches maximising the flow rate is universal and independent of chemistry [9].

In collaborative work in collaboration with the groups of E. Keaveny and D. Papageorgiou at Imperial College London and S. Michelin, I finally show theoretically that, in a mechanism analogous to Bénard-Marangoni convection, phoretic phenomena can create spontaneous and self-sustained wall-driven mixing flows within a straight, chemically-uniform active channel. Such spontaneous flows do not result in any net pumping for a uniform channel but greatly modify the distribution of transport of the chemical solute. The instability is predicted to occur for a solute Péclet number above a critical value and for a band of finite perturbation wave-numbers. We solve the perturbation problem analytically to characterise the instability, and use both steady and unsteady numerical computations of the full nonlinear transport problem to capture the long-time coupled dynamics of the solute and flow within the channel [10].

SIZE-EFFECTS IN POROUS METAL PLASTICITY

Christian F. Niordson
Department of Mechanical Engineering, Technical University of Denmark, Kgs. Lyngby, Denmark

Summary A model for the incorporation of micron scale size-effects in the plastic response of porous metals is proposed. Strain gradient plasticity theory is employed in a finite element setting in order to quantify size effects on the yield surface of porous metals. It is quantified how void growth on the micron scale is suppressed, and it is proposed to account for void-size effects in established conventional models by decreasing the sensitivity to porosity and mean stress. A simple simple transformation of conventional yield surfaces is proposed to obtain size-dependent yield surfaces.

MOTIVATION

Size-effects in metals have been confirmed in numerous small scale experiments. Whenever large strain gradients are imposed on micron scale samples, such as in torsion of thin wires or bending of thin films, the plastic response exhibits size-dependence with the general trend that 'smaller is stronger'. Similarly, micro- and nano-indentation tests show increased hardness for smaller indentation depths, where large densities of geometrically necessary dislocations accompany large plastic strain gradients.

Under macroscopically homogeneous deformation, size-effects may arise due to passivation layers or at internal microstructural interfaces causing inhomogeneous plastic strain. This includes the well known Hall-Petch effect where plastic strain gradients increase with decreasing grain size leading to higher yield strength. This paper focuses on how size-effects may be included in models for micron scale void growth and in homogenized theories of porous metal plasticity.

COMPUTATIONAL MODEL

The strain gradient plasticity theory by Gudmundson [1] is implemented in a finite element framework based on the minimum principles developed by Fleck and Willis [2] in finite strain generalization [3]. A homogeneous distribution of voids in layers (Figure 1b) with a hexagonal pattern (Figure 1a) is analysed using an axi-symmetric approximate representative volume element (RVE) (Figure 1c) of length L_c, radius R_c and with the void size R_v. Boundary conditions are imposed through displacements of the RVE sides (U_1 and U_2) such that a constant axi-symmetric stress ratio is maintained. For spherical voids the initial porosity is defined in terms of the RVE geometry by $f = 2R_v^3/(3R_c^2 L_c)$.

RESULTS

For equal in-plane and out-of-plane void spacing ($R_C = L_c$) and a porosity of $f = 0.04$ Figure 2a shows RVE predictions for macroscopic yield surfaces in mean stress - effective stress space (σ_m-σ_e space). The axes are normalized

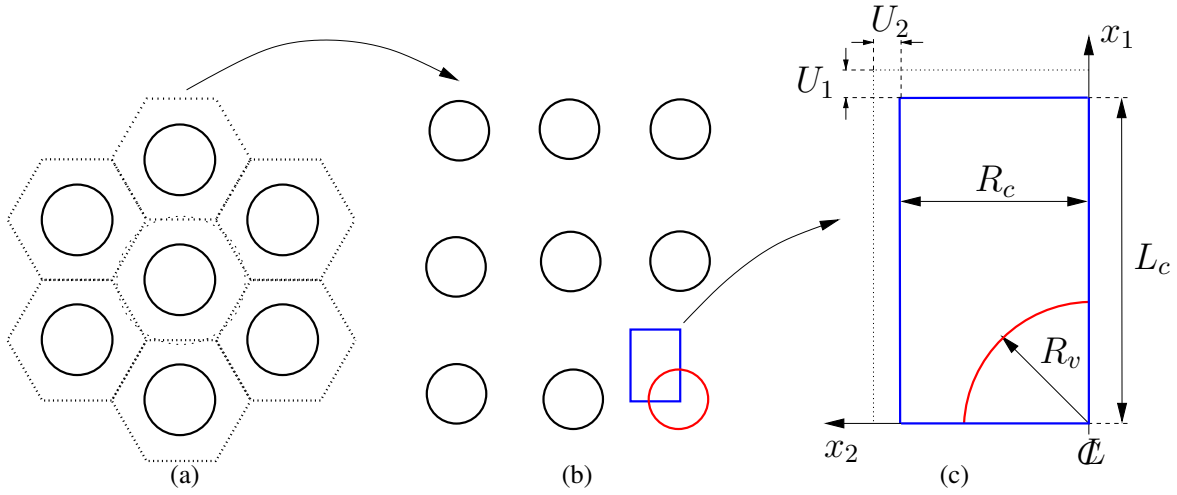

Figure 1: Hexagonal pattern of spherical voids (a) in layers (b). (c) Axi-symmetric representative volume element approximation including a single void.

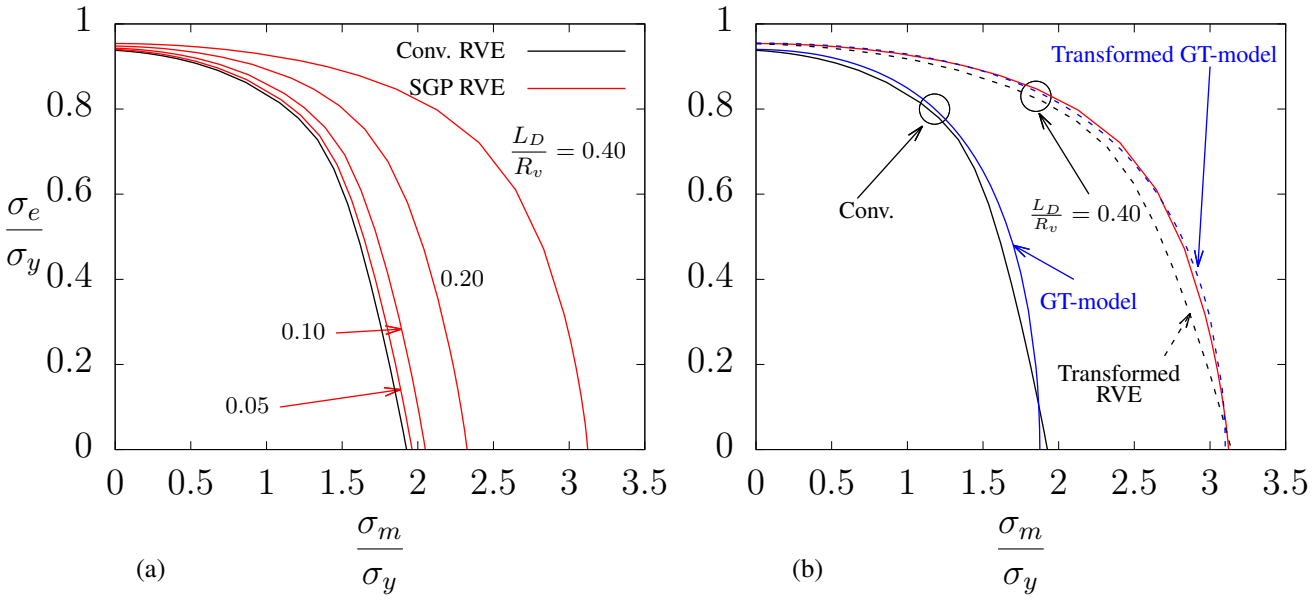

Figure 2: (a) Size dependence of yield surfaces. (b) Transformed conventional yield surfaces capture size effects well.

by the yield stress of the matrix material, σ_y. The black curve shows the conventional yield surface and the red curves show size-dependent yield surfaces for different ratios of the material length parameter in the strain gradient plasticity model, L_D, to void radius, R_v. For the fixed porosity of $f = 0.04$, the figure shows how the yield surface expands for decreasing void size. For each void size the yield surfaces presented may be expressed by yield functions of the form $F(\sigma_e, f, \sigma_m, \sigma_y) = 0$. Figure 2b shows the conventional yield surface and that for $L_D/R_v = 0.4$. Based on the notion that the yield surface of a size-dependent material corresponds to that of a conventional material with a smaller void volume fraction and a smaller mean stress sensitivity the yield surface for a conventional material may be transformed to that of the size-dependent material throug the transformation

$$F(\sigma_e, f, \sigma_m, \sigma_y) \rightarrow F(\sigma_e, Q_1 f, Q_2 \sigma_m, \sigma_y) \tag{1}$$

where $Q_1 \leq 1$ and $Q_2 \leq 1$ are positive parameters that depend on the size scale of the voids. By using $Q_1 = 0.75$ and $Q_2 = 0.67$ a yield surface for a conventional material may be transformed to be in close agreement of the size-dependent material for $L_D/R_v = 0.4$, as shown by the black dashed curve in Figure 2b. The figure also includes yield surfaces based on the conventional Gurson-Tvergaard model (GT-model) [4] (blue curve) and that of a transformed GT-model (dashed blue curve). It is seen that the same transformation parameters work well also for the Gurson-Tvergaard model.

CONCLUSIONS

Based on strain gradient plasticity investigations, it is shown how a simple transformation of yield surfaces (1) may be employed to transform yield surfaces conventional porous metals to the size-dependent scale. A systematic study shows that the transformation parameters may be well approximated by the following explicit expressions

$$Q_1 \approx \frac{0.364}{1 + 1.8\left(\frac{L_D}{R_v}\right) + 10\left(\frac{L_D}{R_v}\right)^2} + 0.636 \qquad Q_2 \approx \frac{1}{1 + 1.8\left(\frac{L_D}{R_v}\right)^{3/2}} \tag{2}$$

In the context of ellipsoidal voids the same transformation has also been found to give good predictions. However, care must be taken when choosing the relevant void size measures in the transformation.

INTRODUCTION

Due to the volatile development of storage capacities as well as suitable soft- and hardware, the amount of available data has increased by many orders of magnitude over the last decades. This influences almost all parts of practical life but also science and technology. In particular, the area of computational mechanics has a significant role in it, since it seeks for physically relevant models validated by meaningful data. The question arises as to whether the challenging step of setting up parametric constitutive models can be left out completely. Is it possible to represent and numerically predict the material behaviour purely by means of data? On the one hand, the presentation shall focus on data-driven approaches for inelastic material behaviour, where loading and unloading paths in a stress-strain diagram do not coincide. An important point is to clarify which data sets are needed to obtain a physically reasonable material description. What are today's limitations – also in comparison to standard continuum mechanical modelling? Another field of interest concerns the important question how the computational efficiency of such approaches can be improved. In the talk, several ideas to reduce the computational effort and to deal with large amounts of data are discussed. Of high significance are also connections to machine learning algorithms or other surrogate approaches including model order reduction.

DATA-DRIVEN INELASTICITY

A new paradigm in computational mechanics was recently introduced by Kirchdoerfer and Ortiz [1] as well as Conti et al. [2] which is called data-driven computing. The approach enables the usage of experimental data in the fundamental form of pairs of stress and strain directly in a computation. As a consequence, no explicit material law has to be formulated or fitted to experimental results. In this kind of data-driven approach the classical boundary value problem is reformulated by means of distances between states satisfying equilibrial and kinematic relations and states from a data set. The procedure started new ways of thinking and opened a new field of research.
One essential question concerning the extension to inelastic material behavior is answered by the authors in [3]. This formulation differs from data-driven problems in elasticity in that the material data set includes histories of prior stresses and strains or even history variables. As a result the relevance of a certain data point changes from one time step to another. As to mention a simple example of a data set which can represent time-dependent viscoelastic material behavior, we simply extend the data set in the following format: $D = \{\varepsilon_i^k, \sigma_i^k, \varepsilon_i^{k+1}, \sigma_i^{k+1}\}_{i=1}^N$. Here, the N stresses and strains

SECTIONAL LECTURES

indexed by $k+1$ are measured at time $t_{k+1} = t_k + \Delta t$ which is one time increment Δt after the measurements at time t_k. Further types of inelasticity, like elastoplasticity or viscoplasticity can be recovered in a very similar manner. As initially proven for elasticity, also for inelastic material behavior, the classical solution is approached with increasingly fine data sets (see Fig. 1). The central challenge for algorithms solving problems in inelasticity concerns the formulation of practical representational paradigms for the evolving material data set. An essential point to remain computationally efficient when handling large data sets is the usage of extremely fast search algorithms which interact with the solver. Further challenging issues arise from noisy data sets, see e.g. [4] and [5].

DATA-DRIVEN IDENTIFICATION OF MATERIAL RESPONSE

Meanwhile, a different field of research contrived, which can be understood as an inverse formulation of the data-driven paradigm. This field of research might solve a crucial issue. As the name suggests, the key in data-driven computing is the availability of large numbers of data. Leygue et al. [6] initially introduced an algorithm for solving inverse problems based on full-field strain measurements by digital image correlation (DIC). The goal is to identify the stresses which cannot be obtained by DIC. This is performed without the necessity to formulate a constitutive law a priori. The algorithm is based on minimizing the distance to a data set which is created during the solution procedure and is of a predefined size. In [7] and [8], among other examinations, the applicability to real experimental measurements is shown. In the present work we focus on a formulation that generalizes the initially proposed algorithm and makes it more robust, accurate and applicable to data sets of higher dimensions. The data are generated by means of a standard computation of the specimen plotted in Fig. 2. In the left part, the von Mises stress obtained from this computation is seen. These stress values are taken as reference. Fig. 2b and Fig. 2c show contour plots of the difference between the identified von Mises stress and the reference von Mises stress. It is clearly seen that the generalized identification algorithm reduces the error noticeably. Further investigations regarding noisy measurements and unknown Neumann boundary conditions show very promising results.

Figure 2: Stress identification problem: (a) reference von Mises stress [MPa], (b) stress error [MPa] of initially proposed identification algorithm, and (c) stress error [MPa] of generalized identification algorithm.

DATA-DRIVEN COMPUTATION ENHANCED BY TENSOR VOTING

Another important issue of data-driven computing occurs, when the amount of data is not high enough or the dimensionality of the data set is too high to sample the necessary phase space adequately. For these cases a new plug-in method for the data-driven solver is developed which makes use of local tangent spaces associated with each data point (see Fig. 3. Those tangents can be computed in an offline step by the tensor voting method introduced by Medioni and Mordohai [9]. Now, during the solution of a boundary value problem, in addition to the classically performed nearest neighbor search, the point in the local tangent space is computed which minimizes the actual distance. By this additional step, the convergence speed of the solver and the accuracy can be increased (see Fig. 4). The method shows promising results for data sets with homogeneous as well as for inhomogeneous data densities.

MULTI-SCALE COHESIVE ZONE MODELLING SUPPORTED BY MACHINE LEARNING

Grain boundary (GB) characteristics play an important role in the determination and prediction of material behavior, especially when it comes to nanocrystalline metals and ceramics (see [10] and [11]). Molecular dynamics simulations serve to gain deeper insight into the behavior of different grain boundaries. In the context of the present investigations of

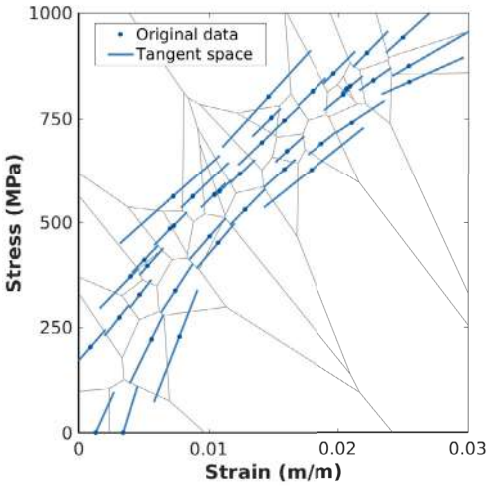

Figure 3: Voronoi tesselation of the phase space due to a given data set and corresponding tangent spaces computed by the tensor voting method.

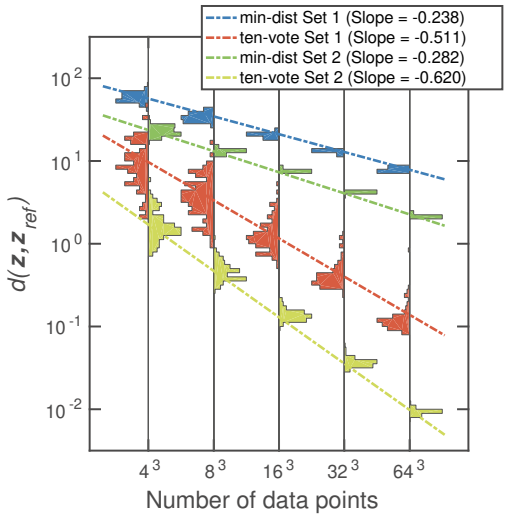

Figure 4: Comparison of convergence with respect to data set size of min-dist data-driven methods for noise-free data sets with random equally distributed (set 1) and random normally distributed (set 2) data points. Error histograms generated from 100 material set samples.

$\Sigma 5$ grain boundary of aluminum [12], it turns out that the behaviour in mode II differs noticeably from the one in mode I. In fact, the cyclic behaviour in mode II resembles rather elasto-plastic material behaviour than classical damage behavior. This shows that also the relations for the tractions in normal and shear direction must be chosen to be qualitatively different from each other.

It is, however, difficult to transfer the knowledge about the behavior at the atomistic level to a macroscopic cohesive zone formulation. For this purpose a new quantity called "traction density" is introduced. When it comes to the grain boundary (GB) behavior, the proposed methodology is able to represent intergranular fracture, grain boundary sliding as well as their mixed-mode behavior [13]. Interestingly, the calculations from current MD simulations show size-dependent traction-separation relation for the GB. By introducing a healing parameter in the new interface model, it is now possible to explain and predict possible GB size-dependent behavior. In order to cut short the scale transition, the traction-separation behavior at the atomistic scale can also be represented by means of artificial neural networks (see [14] and Fig. 5).

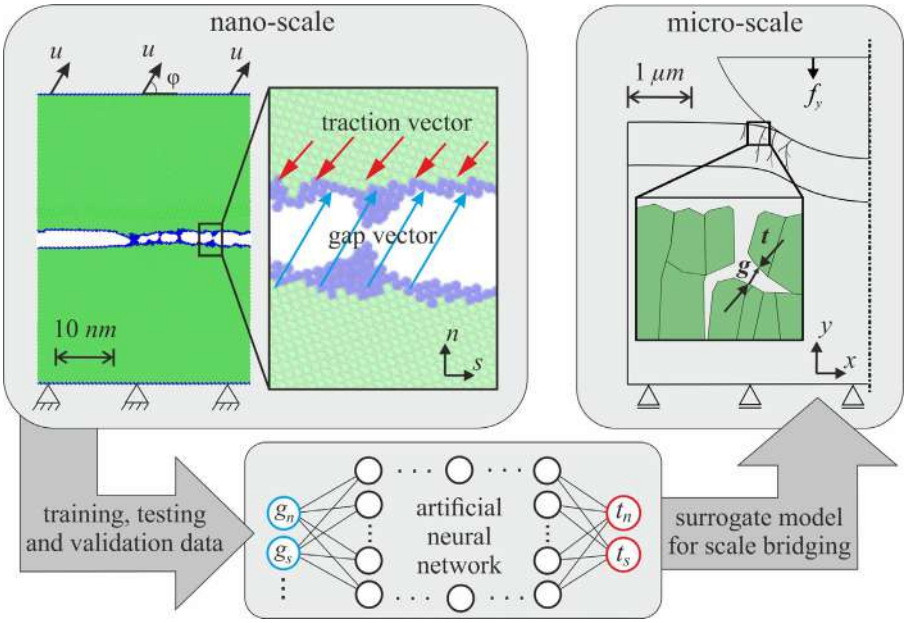

Figure 5: Scale bridging utilizing an artificial neural network trained by molecular dynamics simulation results.

Here, a Resnet like architecture with feed forward neural networks (FFNN) and a physics-guided model completion has been used. The approximation of the FFNN model is very good and can be also applied to temperatures and load angles which were not part of the training (see the results in Fig. 6). The next step is to implement the functions $t_n\,(g_n, g_t)$ and $t_t\,(g_n, g_t)$ directly into a macroscopic cohesive zone formulation.

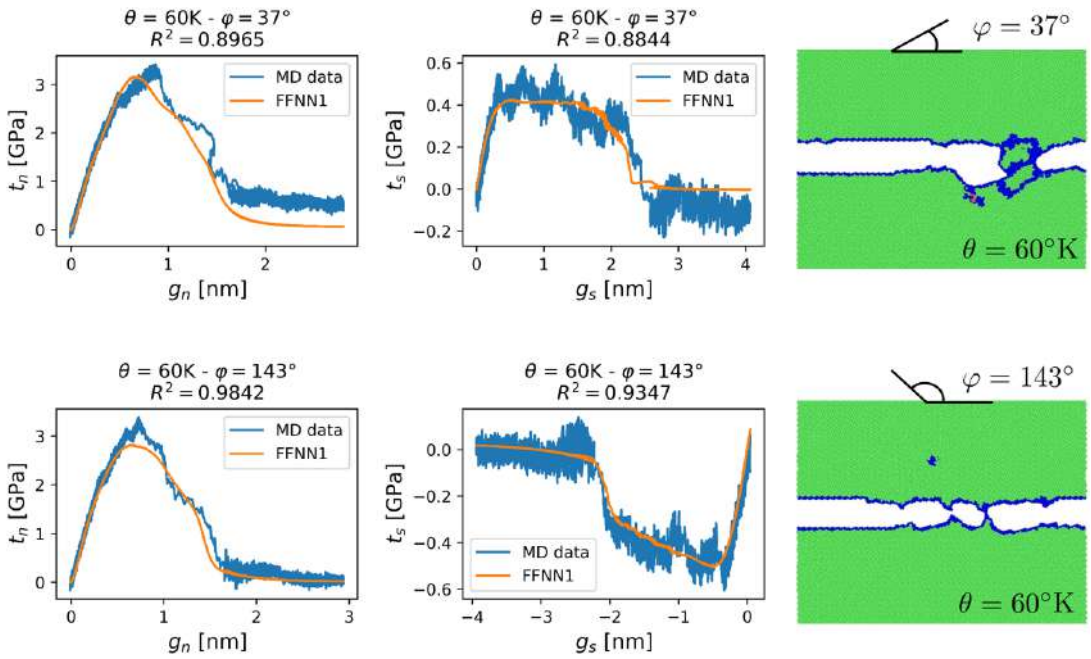

Figure 6: Evaluation of FFNN for unseen loading angles and temperature.

CONCLUSIONS

It is shown in the presentation that data-driven approaches are well suited to complement and improve constitutive modeling. This is carried out in various respects. One idea is to circumvent the development of complex phenomenological constitutive equations and to work only with the data available. Obviously, this requires sophisticated algorithms to reduce the CPU time effort of such data-based computations to an acceptable level. Another interesting application of data-driven mechanics is the identification of full-field stress data on the basis of measured strains. Having the complete information about the stress-strain behavior in complex structures available, might significantly support the development of constitutive models with good predictability. Finally, approaches such as machine learning can be well used to bridge scales. It is conceivable that for instance ANN models replace the classical microscopic boundary value problems in a homogenization procedure.

ACKNOWLEDGEMENTS

We acknowledge the support of F. Fritzen in discussions within the scope of machine learning. Also discussions with J. R. Mianroodi in conducting the molecular dynamics simulations are acknowledged.

EULERIAN FORMULATION OF INELASTICITY – FROM METAL PLASTICITY TO GROWTH OF BIOLOGICAL TISSUES

Miles Rubin
Faculty of Mechanical Engineering, Technion-Israel Institute of Technology, 32000 Haifa, Israel

Summary An Eulerian formulation of inelasticity is required to remove unphysical arbitrariness of choices of the reference configuration, an intermediate configuration, a total deformation measure and an inelastic deformation measure that are introduced in the Lagrangian formulation. It is shown that the Eulerian formulation can be used to model metal plasticity and growth of biological tissues.

INTRODUCTION

The need for an Eulerian formulation of inelasticity, in contrast to a Larangian formulation, can best be understood by Gillman's comment [5]

> "It seems very unfortunate to me that the theory of plasticity was ever cast into the mold of stress-strain relations because 'strain' in the plastic case has no physical meaning that is related to the material of the body in question. It is rather like trying to deduce some properties of a liquid from the shape of the container that holds it. The plastic behaviour of a body depends on its structure (crystalline and defect) and on the system of stresses that is applied to it . . . "

and the notion of an internal state variable by Onat [11] as a history-dependent variable that must be measurable in the current state of the material. Eckart [3] seems to be the first to propose an Eulerian evolution equation directly for an elastic deformation tensor for elastically isotropic solids, which was also done for polymeric liquids by Leonov [10].

The standard Lagrangian formulation introduces deformation tensors measured relative to a reference configuration or an intermediate configuration. For example, the total deformation gradient $\mathbf{F}$ from the reference configuration to the current configuration is determined by the evolution equation

$$\dot{\mathbf{F}} = \mathbf{L}\mathbf{F}\,, \tag{1}$$

where $(\dot{})$ denotes the material time derivative and $\mathbf{L}$ is the velocity gradient. The formulation proproped by Green and Naghdi [6] uses the right Cauchy-Green total deformation tensor $\mathbf{C} = \mathbf{F}^T\mathbf{F}$ and introduces a plastic deformation tensor $\mathbf{C}_p$ relative to a reference configuration by the evolution equation

$$\dot{\mathbf{C}}_p = \overline{\mathbf{A}}_p\,, \tag{2}$$

with $\overline{\mathbf{A}}_p$ being the inelastic deformation rate. The Bilby-Kröner-Lee multiplicative formulation [2, 8, 9] introduces a plastic deformation tensor $\mathbf{F}_p$ from a reference configuration to an intermediate configuration and an elastic deformation tensor $\mathbf{F}_e$ from the intermediate configuration to the current configuration by the evolution equation and definition

$$\dot{\mathbf{F}}_p = \mathbf{\Lambda}_p\mathbf{F}_p\,, \quad \mathbf{F}_e \equiv \mathbf{F}\mathbf{F}_p^{-1}\,, \tag{3}$$

where $\mathbf{\Lambda}_p$ is the inelastic deformation rate. Besseling [1] introduced an elastic deformation tensor $\mathbf{F}_e$ from an intermediate configuration to the current configuration directly by the evolution equation

$$\dot{\mathbf{F}}_e = (\mathbf{L} - \mathbf{L}_p)\mathbf{F}_e\,, \tag{4}$$

where $\mathbf{L}_p$ is the inelastic deformation rate. Also, Rodriguez et. al [13] modeled grow of biological tissues using the muliplicative formulation (3) by replacing p by g and identifying $\mathbf{F}_g$ as a growth tensor. However, letting $\mathbf{A}$ be an arbitrary second order tensor with positive determinant and $\mathbf{O}$ be an arbitrary proper orthogonal tensor, it follows that

$$\mathbf{F}_e = (\mathbf{F}\mathbf{A})(\mathbf{F}_p\mathbf{A})^{-1}\,, \quad \mathbf{F} = (\mathbf{F}_e\mathbf{O}^T)(\mathbf{O}\mathbf{F}_p)\,, \tag{5}$$

which demonstrates that the Lagrangian formulation exhibits arbitrariness in the choice of the reference configuration and the intermediate configuration, as discussed in [16]. This means that the tensors $\mathbf{F}, \mathbf{F}_e, \mathbf{F}_p$ and $\mathbf{F}_g$ are not internal state variables in the sense of Onat [11] since they exhibit unphysical arbitrariness that cannot be measured by experiments on identical samples of the material in its current state.

A FULLY ANIOSTROPIC ELASTIC-INELASTIC MATERIAL

In [16] it was proved that when the unphyiscal arbitrariness of the Lagrangian formulation is removed, the formulation must reduce to the Eulerian formulation in [14], which proposes evolution equations for a triad of linearly independent micostructural vectors $\mathbf{m}_i$

$$\dot{\mathbf{m}}_i = (\mathbf{L} - \mathbf{L}_p)\mathbf{m}_i \,, \tag{6}$$

that characterize elastic deformations and material orientations. Moreover, the elastic dilatation J_e and elastic metric m_{ij} are defined by

$$J_e = \mathbf{m}_1 \times \mathbf{m}_2 \cdot \mathbf{m}_3 > 0 \,, \quad m_{ij} = \mathbf{m}_i \cdot \mathbf{m}_j \,, \tag{7}$$

which satisfy the evolution equations

$$\dot{J}_e = J_e\,(\mathbf{D} - \mathbf{D}_p) \cdot \mathbf{I} \,, \quad \dot{m}_{ij} = 2(\mathbf{D} - \mathbf{D}_p) \cdot (\mathbf{m}_i \otimes \mathbf{m}_j) \,, \quad \mathbf{D} = \frac{1}{2}(\mathbf{L} + \mathbf{L}^T) \,, \quad \mathbf{D}_p = \frac{1}{2}(\mathbf{L}_p + \mathbf{L}_p^T) \,. \tag{8}$$

In these equations, $\mathbf{D}$ is the total deformation rate, $\mathbf{D}_p$ is the inelastic deformation rate, $\mathbf{I}$ is the second order identity tensor, $\mathbf{A} \cdot \mathbf{B} = \mathrm{tr}(\mathbf{A}\mathbf{B}^T)$ is the inner product betweeen two second order tensors $\mathbf{A}, \mathbf{B}$, and $\mathbf{a} \otimes \mathbf{b}$ denotes the tensor product of two vectors $\mathbf{a}, \mathbf{b}$. For later reference, $\mathbf{L}'$ and $\mathbf{D}'$ denote the deviatoric parts of $\mathbf{L}$ and $\mathbf{D}$, respectively.

Within the context of the purely mechanical theory, the strain energy function Σ per unit mass and the Cauchy stress $\mathbf{T}$ are given by

$$\Sigma = \Sigma(m_{ij}) \,, \quad \mathbf{T} = 2\rho \frac{\partial \Sigma}{\partial m_{ij}} (\mathbf{m}_i \otimes \mathbf{m}_j) \,, \tag{9}$$

where ρ is the current mass density and the usual summation convention is implied for repeated indices. Moreover, the microstructural vectors can be specified so that they form an orthonormal triad in any zero-stress state, with Σ restricted so that

$$\frac{\partial \Sigma}{\partial m_{ij}} = 0 \quad \text{and} \quad m_{ij} = \delta_{ij} \quad \text{whenever} \quad \mathbf{T} = 0 \,, \tag{10}$$

where δ_{ij} is the Kronecker delta. It also follows that the rate of material dissipation $\mathcal{D}$ requires inelastic deformation rate to be dissipative

$$\mathcal{D} = \mathbf{T} \cdot \mathbf{D} - \rho \dot{\Sigma} = \mathbf{T} \cdot \mathbf{D}_p \geq 0 \,. \tag{11}$$

Furthermore, it is noted that in the absence of inelastic deformation rate ($\mathbf{L}_p = 0$) the evolution equations (6) cause $\mathbf{m}_i$ to deform as material line elements so the constitutive equations (9) characterizes a general anisotropic hyperelastic material.

ELASTICALLY ISOTROPIC MATERIALS

For elastically isotropic materials it is not possible to distinguish between the microstructural vectors $\mathbf{m}_i$ so it is meaningful to use the work of Flory [4] to define the unimodular elastic distortional deformation tensor $\mathbf{B}'_e$ by

$$\mathbf{B}'_e = J_e^{-2/3} \mathbf{m}_i \otimes \mathbf{m}_i \,, \quad \det \mathbf{B}'_e = 1 \,. \tag{12}$$

In [15] an evolution equation was proposed directly for $\mathbf{B}'_e$ of the form

$$\dot{\mathbf{B}}'_e = \mathbf{L}'\mathbf{B}'_e + \mathbf{B}'_e\mathbf{L}'^T - \Gamma \mathbf{A}_p \,, \quad \mathbf{A}_p = \mathbf{B}'_e - \left(\frac{3}{\mathbf{B}'^{-1}_e \cdot \mathbf{I}} \right) \mathbf{I} \,, \quad \Gamma \geq 0 \,, \quad \mathbf{A}_p \cdot \mathbf{B}'^{-1}_e = 0 \,, \tag{13}$$

where Γ controls the inelastic deformation rate and $\mathbf{A}_p$ controls its direction, with $\mathbf{A}_p$ being restricted to ensure that $\mathbf{B}'_e$ remains unimodular. The two non-trivial invariants α_1 and α_2 of $\mathbf{B}'_e$ satisfy the equations

$$\alpha_1 = \mathbf{B}'_e \cdot \mathbf{I} \,, \quad \dot{\alpha}_1 = 2\mathbf{B}''_e \cdot \mathbf{D} - \Gamma \mathbf{A}_p \cdot \mathbf{I} \,, \quad \alpha_2 = \mathbf{B}'_e \cdot \mathbf{B}'_e \,, \quad \dot{\alpha}_2 = 4(\mathbf{B}'^2_e - \frac{1}{3}\alpha_2 \mathbf{I}) \cdot \mathbf{D} - 2\Gamma \mathbf{A}_p \cdot \mathbf{B}'_e \,, \tag{14}$$

where $\mathbf{B}''_e$ is the deviatoric part of $\mathbf{B}'_e$. Also, for isotropic materials the strain energy Σ and stress $\mathbf{T}$ are given by

$$\Sigma = \Sigma(J_e, \alpha_1, \alpha_2) \,, \quad \mathbf{T} = -p\,\mathbf{I} + \mathbf{T}'' \,, \quad p = -\rho J_e \frac{\partial \Sigma}{\partial J_e} \,, \quad \mathbf{T}'' = 2\rho \Big[\frac{\partial \Sigma}{\partial \alpha_1} \mathbf{B}''_e + 2 \frac{\partial \Sigma}{\partial \alpha_2} (\mathbf{B}'^2_e - \frac{1}{3}\alpha_2 \mathbf{I}) \Big] \,, \tag{15}$$

where p is the pressure, $\mathbf{T}''$ is the deviatoric part of $\mathbf{T}$ and the rate of material dissipation $\mathcal{D}$ requires

$$\mathcal{D} = \mathbf{T} \cdot \mathbf{D} - \rho \dot{\Sigma} = -p\,(\mathbf{D}_p \cdot \mathbf{I}) + \Gamma \left[\rho \frac{\partial \Sigma}{\partial \alpha_1} (\mathbf{A}_p \cdot \mathbf{I}) + 2\rho \frac{\partial \Sigma}{\partial \alpha_2} (\mathbf{A}_p \cdot \mathbf{B}'_e) \right] \geq 0 \,. \tag{16}$$

Moreover, Σ satisfies restrictions so that zero-stress states require

$$J_e = 1 \quad \text{and} \quad \mathbf{B}'_e = \mathbf{I} \quad \text{whenever} \quad \mathbf{T} = 0 \,. \tag{17}$$

Consequently, from (13) it follows that inelastic deformation rate causes a tendency for $\mathbf{B}'_e$ to approach the identity tensor, which causes a tendency for deviatoric stress to vanish. Also, it was shown in [15] that

$$\mathbf{A}_p \cdot \mathbf{I} \geq 0\,, \quad \mathbf{A}_p \cdot \mathbf{B}'_e \geq 0\,. \tag{18}$$

In the absence of inelastic deformation rate, the evolution equations (8) and (13) cause J_e to be the total dilatation and $\mathbf{B}'_e$ to be the unimodular part of the left Cauchy-Green deformation tensor $\mathbf{B} = \mathbf{F}\mathbf{F}^T$ from zero-stress states, so the constitutive equations model general isotropic hyperelastic response.

METAL PLASTICITY

For metal plasticity inelastic deformation rate is isochoric so that

$$\mathbf{D}_p \cdot \mathbf{I} = 0\,, \quad J_e = \frac{\rho_z}{\rho}\,, \tag{19}$$

where ρ_z is the zero-stress density. Moreover, following the work in [7, 12, 15, 19, 21], it is possible to develop a robust, strongly objective numerical integration algorithm for J_e and $\mathbf{B}'_e$. Specifically, consider a time step which begins at $t = t_n$, ends at $t = t_{n+1}$ with increment $\Delta t = t_{n+1} - t_n$. Given values of $J_e(t_n)$ and $\mathbf{B}'_e(t_n)$ at the beginning of the time step, the numerical algorithm produces estimates $J_e(t_{n+1})$ and $\mathbf{B}'_e(t_{n+1})$ at the end of the time step. Next, it is recalled that the relative deformation gradient $\mathbf{F}_r$, the relative dilatation J_r and the unimodular part $\mathbf{F}'_r$ of $\mathbf{F}_r$ satisfy the equations

$$\dot{\mathbf{F}}_r = \mathbf{L}\mathbf{F}_r\,, \quad J_r = \det \mathbf{F}_r\,, \quad \dot{J}_r = J_r\,(\mathbf{D} \cdot \mathbf{I})\,, \quad \mathbf{F}'_r = J_r^{-1/3}\mathbf{F}_r\,, \quad \dot{\mathbf{F}}'_r = \mathbf{L}''\mathbf{F}'_r\,, \quad \mathbf{F}_r(t_n) = \mathbf{F}'_r(t_n) = \mathbf{I}\,. \tag{20}$$

Then, using (19), the exact solution of the evolution equation (8) for J_e yields

$$J_e(t_{n+1}) = J_r(t_{n+1})J_e(t_n)\,. \tag{21}$$

Also, the elastic trial value $\mathbf{B}'^*_e$ and its deviatoric part $\mathbf{B}''^*_e$ are defined by

$$\mathbf{B}'^*_e = \mathbf{F}'_r\mathbf{B}'_e(t_n)\mathbf{F}'^T_r\,, \quad \mathbf{B}''^*_e = \mathbf{B}'^*_e - \frac{1}{3}(\mathbf{B}'^*_e \cdot \mathbf{I})\,\mathbf{I}\,, \tag{22}$$

where $\mathbf{B}''^*_e$ satisfies the evolution equation

$$\dot{\mathbf{B}}''^*_e = \mathbf{L}''\mathbf{B}'^*_e + \mathbf{B}'^*_e\mathbf{L}'' - \frac{2}{3}(\mathbf{B}'^*_e \cdot \mathbf{D}'')\,\mathbf{I}\,. \tag{23}$$

Next, from (13) it can be shown that the deviatoric part $\mathbf{B}''_e$ of $\mathbf{B}'_e$ satisfies the evolution equation

$$\dot{\mathbf{B}}''_e = \mathbf{L}''\mathbf{B}'_e + \mathbf{B}'_e\mathbf{L}'' - \frac{2}{3}(\mathbf{B}'_e \cdot \mathbf{D}'')\,\mathbf{I} - \Gamma\mathbf{B}''_e\,, \tag{24}$$

which can be approximated by

$$\dot{\mathbf{B}}''_e = \dot{\mathbf{B}}''^*_e - \Gamma\mathbf{B}''_e\,. \tag{25}$$

This equation yields the exact solution for elastic response ($\Gamma = 0$). Furthermore, using a backward Euler approximate of the derivative, (25) can be integrated implicitly do deduce that

$$\mathbf{B}''_e(t_{n+1}) = \frac{\mathbf{B}''^*_e(t_{n+1})}{1 + \Delta\Gamma}\,, \quad \Delta\Gamma = \Delta t\Gamma(t_{n+1})\,. \tag{26}$$

Once $\mathbf{B}''_e(t_{n+1})$ is known, the value of $\mathbf{B}'_e(t_{n+1})$ is determined by solving the cubic equation

$$\det \mathbf{B}'_e(t_{n+1}) = \det\left[\frac{1}{3}\alpha_1\mathbf{I} + \mathbf{B}''_e(t_{n+1})\right] = 1\,, \tag{27}$$

for α_1 as discussed in [7, 15]. Moreover, it was shown in [19] that this algorithm is simpler than the one for the evolution equation in [22]. Furthermore, this numerical algorithm is strongly objective to Superposed Rigid Body Motions ($SRBM$) since the quantities $J_e(t_{n+1})$ and $\mathbf{B}'_e(t_{n+1})$ transform like the exact values J_e and $\mathbf{B}'_e$ for all $SRBM$.

GROWTH OF BIOLOGICAL TISSUES

A unified theoretical structure for modeling interstitial growth and muscle activation in soft tissues was proposed in [17]. This model treats the tissue as an open system with a rate of mass supply, but with a single velocity for material

points in the tissue. Specifically, this model modifies the evolution equations for elastic dilatation and elastic distortional deformation of metals to take the forms [18]

$$\dot{J}_e = J_e \left[\mathbf{D}\cdot\mathbf{I} - \Gamma_m \ln\left(\frac{J_e}{J_h}\right) \right] , \quad \dot{\mathbf{B}}'_e = \mathbf{L}''\mathbf{B}'_e + \mathbf{B}'_e\mathbf{L}''^T - \Gamma \left[\mathbf{B}'_e - \left(\frac{3}{\mathbf{B}'^{-1}_e \cdot \mathbf{H}} \right) \mathbf{H} \right] . \tag{28}$$

For purely mechanical elastically isotropic response, the strain energy function Σ and the stress $\mathbf{T}$ take the forms (15). In contrast with the evolution equations for metal plasticity, the evolution equations (28) model the process of homeostasis which causes the elastic dilatation J_e to approach its homeostatic value J_h with the rate controlled by Γ_m and which causes the elastic distortional deformation $\mathbf{B}'_e$ to approach its homeostatic value $\mathbf{H}'$ with the rate controlled by Γ where

$$\mathbf{H}' = (\det \mathbf{H})^{-1/3}\mathbf{H} , \quad \det \mathbf{H}' = 1 . \tag{29}$$

The homeostatic values J_h and $\mathbf{H}'$ as well as the homeostasis rates Γ_m and Γ require constitutive equations. In particular, it is noted that the homeostatic value of stress need not be zero

$$\mathbf{T}(J_e, \mathbf{H}') \neq 0 , \tag{30}$$

which allows for modeling phenomena like the homeostatic value of tension in the skin as cells are being replaced over time.

In [17] equations were developed for growth of a fiber, growth of a material surface and volumetric growth. Also, in [20] structural tensors were used for anisotropic growth including torsion observed in early cardiac morphogenesis during c-looping.

CONCLUSIONS

It has been shown that the Eulerian formulation of inelasticity proposes evolution equations for elastic deformations based on internal state variables which are measurable by experiments on identical samples of a material in its current state. This formulation removes unphysical arbitrariness of choices of the reference configuration, an intermediate configuration, a total deformation measure and an inelastic deformation measure that are introduced in the Lagrangian formulation. The Lagrangian formulation of inelasticity is not necessarily incorrect but it has arbitrariness that can and should be removed.

TRANSIENT SPRAY COOLING

Jan Breitenbach[1], Ilia V. Roisman[1], Fabian M. Tenzer[1], and Cameron Tropea*[1]
[1]Institute for Fluid Mechanics and Aerodynamics, Technische Universität Darmstadt, Germany

Summary Spray cooling is a very efficient technology, surpassing all other conventional cooling methods, especially those not involving phase change and not exploiting the latent heat of vaporization. However, the effectiveness of spray cooling is dependent on a large number of parameters, including spray characteristics like drop size, velocity and number density, the surface morphology, but also on the temperature range and thermal properties of the materials involved. Indeed, the temperature of the substrate can have significant influence on the hydrodynamics of drop and spray impact, an aspect which is seldom considered in model formulation. This process is extremely complex, thus most design rules to date are highly empirical in nature. Transient spray cooling adds complexity by the fact that the substrate temperature is continually cooling, thus the hydrodynamics occur in different thermodynamic regimes: film boiling, transitional boiling and nucleate boiling. On the other hand, significant theoretical progress has been made in recent years about the interaction of single drops with heated walls and improvements to the fundamentals of spray cooling can now be anticipated. The present contribution has the objective of summarizing some of these recent experimental and theoretical advances and to establish a framework for future development of more reliable and universal physics-based correlations to quantitatively describe and predict quantities involved in spray cooling.

INTRODUCTION

Spray cooling technology is a promising technique for the cooling of devices with very high heat flux densities [6, 7, 2], as encountered in the fields of metal production such as die forging and hot rolling, cooling of electronic modules, light-water reactors or of diode laser arrays. As shown by the large number of industrial applications spray cooling covers a wide variety of boundary conditions, e.g. the temperature range of spray cooling lies between cryogenic temperatures (80 K) to about 1300 K. An important demand in general, but in particular for spray cooling of electronic equipment, is the uniform heat removal from the surface and avoidance of hot spots. Compared to other heat transfer mechanisms, such as forced air or jet impingement, spray cooling has the highest heat transfer coefficient [9].

Current approaches, usually presented in the form of empirical correlations or developed as a simple superposition of single drop impacts, disregard to a large extent the physics of drop/spray wall interaction [4]. No universal model predicting the effectiveness of spray cooling over a significant range of operating parameters has been developed to date. The main difficulty in spray research is the fact that most sprays are usually polydisperse. Their behavior is governed by a large number of parameters which cannot be varied and controlled independently. Thus, it is not easy to identify the main influencing parameters or their combinations which define the problem.

The present study has the objectives to enhance the understanding of non-isothermal spray/wall interactions and to establish more reliable physics-based correlations for the various regimes in order to describe the quantities involved in the non-isothermal transient spray cooling process. For this purpose, non-isothermal single drop and spray impact experiments have been conducted leading to various physic-based theoretical considerations for the various heat transfer regimes.

HEAT FLUX MEASUREMENTS AND OBSERVATION OF SPRAY IMPACT

Figure 1 shows the evolution of the instantaneous heat flux $\dot{q}$ as a function of the surface temperature T_i for an exemplary spray cooling experiment. The results were obtained by solving the inverse heat conduction problem using temperature readings from thermocouples embedded in the target slightly below the surface where the spray impact takes place. The underlying spray parameters are: mass flux $\dot{m} = 1\,\mathrm{kg/m^2s}$, mean droplet diameter $D_{10} = 54\,\mu\mathrm{m}$ and mean droplet velocity $U = 7.6\,\mathrm{m/s}$. The substrate is initially heated to $450\,^\circ\mathrm{C}$, then the heating is switched off and the spray is turned on. Since the substrate continuously cools, the time t increases following the curve in Fig. 1 from right to left (or with decreasing surface temperature). The dashed part indicates the first instants of the cooling experiments when the precision of the results is not sufficient due to the temporal response of the thermocouples. The measured curve exhibits the well-known boiling regimes, in the order from high to low temperatures: film boiling regime at very high surface temperatures where the heat flux decreases in a linear fashion with decreasing surface temperature. This regime ends at the Leidenfrost point, corresponding to the minimum heat flux. The following transition boiling regime features an increasing heat flux until the maximum heat flux is reached (called the critical heat flux). Subsequently, in the nucleate boiling regime the heat flux again decreases until the surface temperature reaches the saturation temperature.

The images in Fig. 1 show pictures of the surface during spray impact and allow the identification of the corresponding hydrodynamic behavior. The equivalent instants are marked on the curve. At very high temperatures above the Leidenfrost point (right picture) we identify single drop impact onto a dry surface. The droplets impact at the surface, rebound or atomize and form secondary droplets due to inertia or thermal atomization [10]. In contrast to common expectations, a

SECTIONAL LECTURES

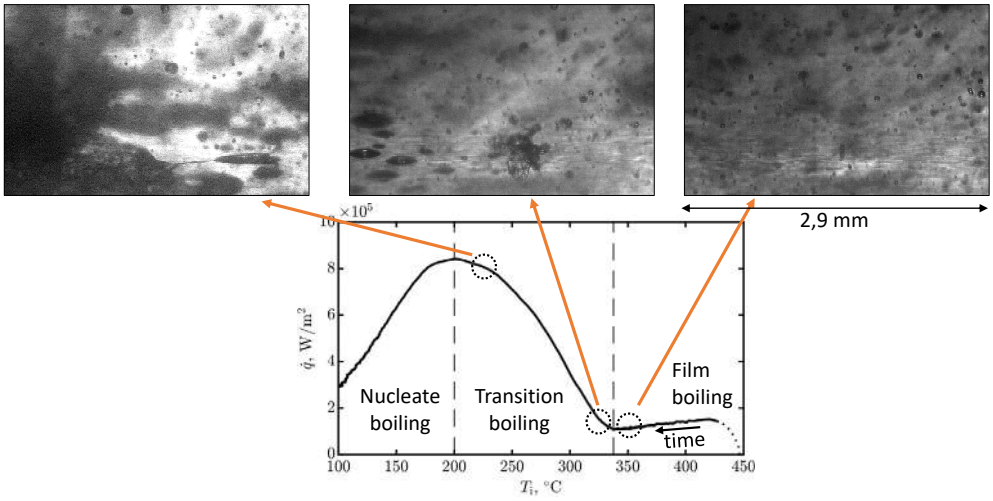

Figure 1: Heat flux as a function of the surface temperature. Images show pictures of the hydrodynamics during spray impact in different spray cooling regimes.

liquid film separated from the surface by a vapour layer cannot be observed [16]. Instead, spray impact can be regarded as a superposition of single drop impacts onto a dry wall [3]. At surface temperatures slightly below the Leidenfrost point (picture in the middle) we identify first small liquid patches on the surface. At even lower surface temperatures, approaching the critical heat flux, (left picture) the number of wetted patches increase, larger ligaments form and finally the entire surface is covered by liquid.

The broad variation of spray impact parameters (droplet diameter, droplet velocity and mass flux) - measured by a phase Doppler measurement system and a patternator - and substrate materials allows the validation of novel analytical models describing the heat transfer during spray cooling, which we present in the following section.

ANALYSIS AND MODELING OF HEAT TRANSFER

Film boiling regime

Consider the impact of a single liquid drop onto a flat solid substrate in the developed film boiling regime [3]. In this regime a vapor layer develops between the liquid and solid regions. Therefore, the heat transfer during film boiling includes heat conduction in an expanding thermal boundary in the solid wall, heat convection in an expanding thermal boundary in the liquid region and heat convection in the vapor layer. The heat flux is continuous at the solid/vapour interface. The jump in the heat flux at the vapor/liquid interface is caused by the energy required for evaporation and is described by the Stefan boundary condition. Solving the energy balance equation the heat flux of an impacting single droplet in the film boiling regime can be estimated, where ϵ_w is the thermal effusivity of the wall, T_w0 the the initial wall temperature and T_sat the saturation temperature

$$\dot{q}_1(t) = \frac{2G\,\epsilon_\mathrm{w}\,(T_\mathrm{w0} - T_\mathrm{sat})}{\sqrt{\pi}\,(K + 2G)\,\sqrt{t}}, \tag{1}$$

and the expression for the evolution of the vapor thickness is obtained in the form

$$h(t) = K\frac{\epsilon_\mathrm{w}\,(T_\mathrm{w0} - T_\mathrm{sat})}{\rho_l L}\sqrt{t}. \tag{2}$$

Here ρ_l is the density of the liquid, L the latent heat of evaporation and K a dimensionless coefficient, determined as

$$K = \sqrt{(B-G)^2 + \frac{4G}{\sqrt{\pi}}} - B - G, \tag{3}$$

with

$$G = \frac{\sqrt{\pi}\lambda_\mathrm{v}\rho_\mathrm{f} L}{2\,(T_\mathrm{w0} - T_\mathrm{sat})\,\epsilon_\mathrm{w}^2}; \quad B = \frac{\sqrt{5}\,(T_\mathrm{sat} - T_{f0})\,\epsilon_\mathrm{f}}{\sqrt{\pi}\,(T_\mathrm{w0} - T_\mathrm{sat})\,\epsilon_\mathrm{w}}. \tag{4}$$

Here the dimensionless parameter G is analogous to the inverse Stefan number, λ_v the thermal conductivity of the vapour, T_f0 the initial fluid temperature of the droplet and ϵ_f the thermal effusivity of the fluid. A comparison of the predicted model (2) for the vapor layer thickness with experimental data from [5] is shown in Fig. 2. The agreement between the data and the model is rather good, although no adjustable constant is used in the model. Noteworthy is the fact, that

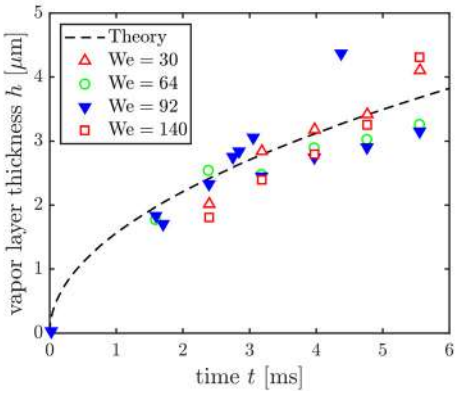

Figure 2: Vapor layer thickness $h(t)$ calculated with the theoretical predication (2) in comparison with experimental data obtained in [5] for an impacting water drop onto a hot saphire substrate at various impact Weber numbers. The drop diameter is constant for all cases.

the theoretical prediction (2) for the vapor layer thickness is not influenced by the impact velocity of the drop, again in excellent agreement with the experimental results.

The previously described model for single drop impact in the film boiling regime can be additionally extended to spray impact as shown in [3]. Additionally, neglecting drop-drop interaction and assuming a semi-infinite wall allows to derive a theory to predict the temporal evolution of the heat flux as well as the surface temperature during transient spray cooling of an initially homogeneously heated target. Some further simplifications and mathematical transformations lead to the following model for the dimensionless heat flux $\Phi(\xi)$ and dimensionless surface temperature $\Theta(\xi)$ as functions of the dimensionless time ξ, which can also be found in [15]:

$$\Phi(\xi) = -\int_0^{\xi} \frac{\Theta'(\zeta)}{\sqrt{\xi-\zeta}}\mathrm{d}\zeta, \quad \Theta'(\zeta) = \frac{1}{2}\sum_{i=1}^{\infty} a_i i \zeta^{i/2-1}, \quad \Theta(\xi) = 1 + \sum_{i=1}^{\infty} a_i \xi^{i/2}. \tag{5}$$

with a_i being a series that converges after a few steps i and the dimensionless quantities

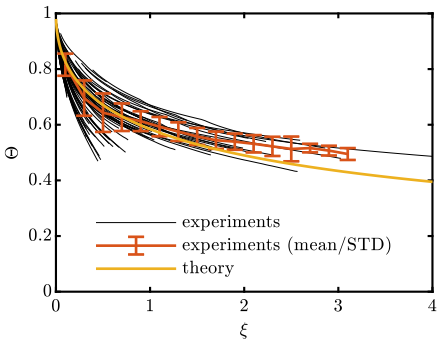
$$\Theta = \frac{T_\mathrm{i}(t) - T_\mathrm{sat}}{T_\mathrm{w0} - T_\mathrm{sat}}, \quad \xi = t\pi S^2, \quad \zeta = \tau\pi S^2, \quad \Phi = \frac{\dot{q}}{S\epsilon_\mathrm{w}(T_\mathrm{w0} - T_\mathrm{sat})}, \tag{6}$$

and

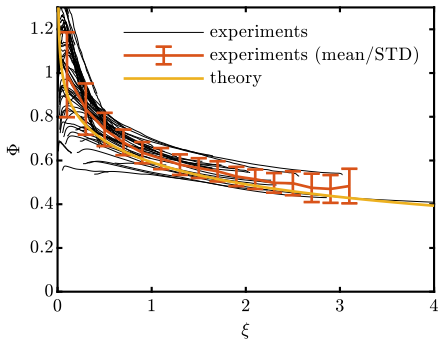
$$S = 8.85\chi \frac{\dot{m}}{\rho_\mathrm{f} D_{10}^{1/2} U^{1/2}\left[1 - b + \sqrt{(1-b)^2 + w}\right]}, \quad w = \frac{8(T_\mathrm{i} - T_\mathrm{sat})\epsilon_\mathrm{w}^2}{\pi\lambda_\mathrm{v}\rho_\mathrm{f} L}, \quad b = \frac{2\sqrt{5}\epsilon_\mathrm{w}\epsilon_\mathrm{f}(T_\mathrm{sat} - T_\mathrm{f0})}{\pi\rho_\mathrm{f}\lambda_\mathrm{v} L}. \tag{7}$$

Here χ is a dimensionless fitting parameter depending, amongst others, on the surface properties approximately equal to unity. This predictive model obviously accounts for the different surface materials, spray properties (hydrodynamic and thermodynamic), spray temperatures and initial wall temperatures.

For validation, we calculate the dimensionless quantities for a variety of experimental data spanning the following ranges: $\dot{m} = 0.6 - 29.5\,\mathrm{kg/m^2 s}$, $D_{10} = 41 - 117\,\mu\mathrm{m}$, $U = 5.2 - 23.7\,\mathrm{m/s}$, $T_\mathrm{w0} = 300 - 462\,^\circ\mathrm{C}$ and $T_\mathrm{f0} = 18 - 23\,^\circ\mathrm{C}$. The corresponding measured evolution of the dimensionless surface temperature $\Theta(\xi)$ and dimensionless heat flux $\Phi(\xi)$ as



(a) Dimensionless surface temperature $\Theta(\xi)$.



(b) Dimensionless heat flux $\Phi(\xi)$.

Figure 3: Evolution of the dimensionless quantities for the nickel target as a function of the dimensionless time ξ for experimental data in the film boiling regime compared to the theoretical solution.

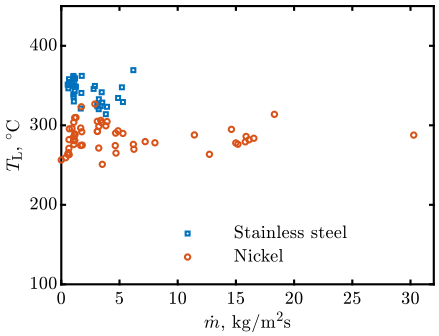


Figure 4: Dependence of the Leidenfrost temperature T_L on the mass flux $\dot{m}$ for different materials ([14].)

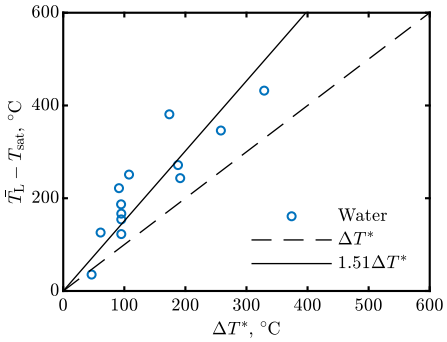

Figure 5: Mean substrate superheat at the Leidenfrost point $\overline{T}_L - T_{sat}$ as a function of ΔT^* for data from this study and from literature ([14].)

a function of the dimensionless time ξ for various experiments is shown in Fig. 3. Additionally, the single red line showing the experiments is the mean and standard deviation computed over all experiments and the yellow line corresponds to the theoretical prediction. We identify a very good agreement between experimental data and theory.

Leidenfrost point

The Leidenfrost point can be identified in experimental data as the minimum heat flux. Understanding and predicting the Leidenfrost point in sprays are of ongoing interest. There is some agreement that this point is influenced by the spray properties, having the mass flux as the main influencing factor [12, 11, 1]. However, the overall picture is rather diffuse [8]. Astonishingly, the present study leads to completely different results and insights into the Leidenfrost [14]. Figure 4 shows the dependence of the Leidenfrost temperature T_L on the spray mass flux $\dot{m}$ for two different substrate materials. Here the substrate material and not the mass flux is the major influencing factor. Spraying a nickel target, which has a higher thermal effusivity ϵ_w, results in a lower Leidenfrost temperature, whereas stainless steel, having a lower thermal effusivity, leads to a higher Leidenfrost temperature.

To explain this observation, imagine the appearance of a vaporization front between drop and wall, which expands along the surface immediately upon impact. This front develops instead of local nucleation bubbles if the surface temperature is sufficiently high. As derived in detail in [14], we can define a Reynolds number Re_v associated with the vaporization front and a characteristic superheat ΔT^*

$$Re_v = \frac{\epsilon_w \sqrt{\alpha_f}(T_{w0} - T_{sat})}{\nu_f L}, \quad \Delta T^* = \frac{\nu_f L}{\epsilon_w \sqrt{\alpha_f}}, \tag{8}$$

where α_f is the thermal diffusivity and ν_f the kinematic viscosity of of the fluid.

In Fig. 5 we plot the mean substrate superheat at the Leidenfrost point $\overline{T}_L - T_{sat}$ of the present experimental data and those found in literature as a function of the characteristic superheat ΔT^*. The literature data is based on experiments performed with various substrate materials from glass or ceramic, having very low thermal effusivities, to copper haven a very high one. The superheat associated with the Leidenfrost temperature follows a linear dependence on ΔT^*. The best fit of the data is $\overline{T}_L - T_{sat} = 1.51\Delta T^*$. This good agreement indicates a new understanding of the Leidenfrost point in sprays and allow the prediction of its temperature for various spray cooling applications.

Nucleate boiling

The temporal evolution of the heat flux and surface temperature indicate that the transition boiling regime lasts only a short time. Therefore, and based on the fact that the Leidenfrost point is the inception of wetting on the surface, we can image this regime to be replaced by a jump of the heat flux towards a very high value. For this reason we skip any further discussion of the transition boiling regime and move on to the nucleate boiling regime.

Upon wetting of the surface the contact temperature at the surface immediately decreases to the saturation temperature. Indeed, this corresponds to the hypothetical maximum cooling. Assuming again a semi-infinite target having the undisturbed initial temperature T_{w0} far away from the surface from where the spray impact takes place and the constant saturation temperature at the wetted surface, we can calculate the temporal evolution of the heat flux as [15]:

$$\mathcal{T} \equiv k \frac{\epsilon_w^2 \Delta T^2}{\pi \dot{q}(t)^2} \approx t - t_L. \tag{9}$$

Figure 6 shows $\mathcal{T} = k\epsilon_w^2 \Delta T^2 / \pi \dot{q}^2$, measured for various spray parameters and different initial substrate temperatures, as a function of $t - t_L$. Here t_L corresponds to the instant of the Leidenfrost point and is derived from the experimental data as the minimum heat flux, k is a constant which can be determined from the experiments and $\Delta T = T_{w0} - T_{sat}$. We can identify a very good agreement between experimental data and theoretical prediction. Furthermore, this leads to

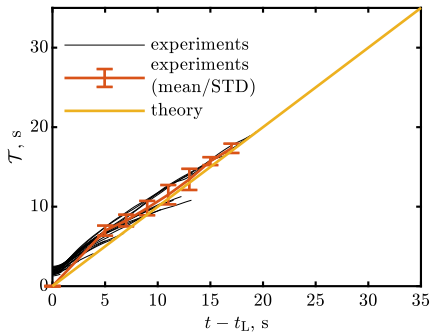

Figure 6: Scaling of the heat flux plotted as a function of time for the nickel target [13].)

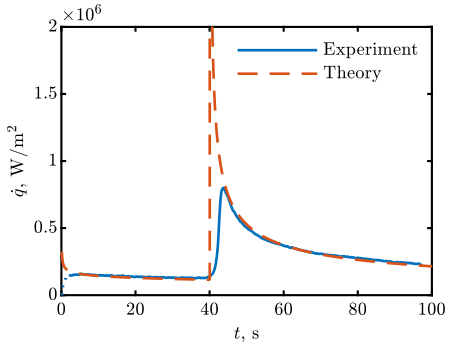

Figure 7: Exemplary comparison between one experiment and the theoretical prediction of the entire cooling process. Heat flux evolution with time [13].)

a new understanding of spray cooling in the nucleate boiling regime: The heat flux is independent of the spray properties and only depends on the substrate material, temperature difference and time. In other words, the heat flux is limited by the thermal inertia of the substrate material

CONCLUSIONS

The previously discussed overview of new models for the different regimes of transient spray cooling lead to new insights and provide a predictive capability to develop and improve spray cooling processes. As a conclusion Fig. 7 shows the application of the model for the film boiling and nucleate boiling regime to an example experiment. The Leidenfrost temperature was calculated from the experimental data. The excellent agreement between theory and experiment impressively illustrates the universality and performance of the developed models.

[3]DM, DII, Uniroma2, Roma, IT
[4]GSSI, L'Aquila, IT

Summary We present the results from a multi–physics computational model capable of tackling the electrophysiology, the elasto–mechanics and the fluid dynamics of the heart, including their multi–way coupled interactions. The developed tool embodies accuracy, versatility and computational efficiency thus allowing cardiovascular simulations in realistic conditions without resorting to large–scale supercomputers. The model has been verified and validated through comparisons with the literature, ad–hoc experiments and clinical data. We show results for physiologic and pathologic configurations with the aim of assessing the reliability of the model and proving its predicting capabilities that could be used to anticipate the outcome of surgical procedures and to aid clinical decisions.

INTRODUCTION

The human heart is a hollow muscular organ that pumps blood throughout the body, to the lungs and to its own tissue. It drives the systemic–, the pulmonary– and the coronary–circulation, to bring oxygen and nutrients to every body cell and to remove the waste products. The heart achieves these fundamental goals by two parallel volumetric pumps, the right and the left, which beat approximately 10^5 times per day to deliver a continuous flow rate of about 5 l/min with an outstanding reliability. This is possible because of the highly cooperative and interconnected dynamics of the heart in which every element is key for the others. In a few words, each heart beat is triggered by specialized pacemaker cells that generate rhythmical electrical impulses propagating along well defined paths and with precise timings thus stimulating a sequence of contractions driving the blood from atria to ventricles and eventually to the arteries. The resulting hemodynamics yields shear stresses and pressure loads on the endocardium and on the valves, whose opening/closing ensures the correct flow direction across heart chambers: only the synchronized and synergistic action of the myocardium electrophysiology, mechanics of the tissues and hemodynamics allows the heart of an adult human to operate on a power of only 8 W, lifelong. Such a perfect and highly sophisticated mechanism, in which even a minor malfunctioning impairs its pumping efficiency, calls for a complete study on account of the scientific, social and economic implications.

Concerning the latter we note that cardiovascular disorders (CVD) are the main cause of population death and health care costs of developed Countries and, despite the advances of medical research, CVD expenditure projections for the next decades are predicted to become unsustainable. This scenario requires novel approaches that improve the effectiveness of the available diagnostic tools without concurrently increasing further the costs: computational science can be key for this purpose since it can add predicting capabilities and improve the precision of many evidence based [1] current procedures.

On the other hand, accurate and reliable CVD simulations involve the interconnected multi–physics dynamics of the whole heart and this is a formidable task from the modelling and computational point of view.

This paper shows the progress of the present research group towards the fully–coupled multi–physics computational model for the heart.

THE MODEL

The multi–physics computational model used in this study is thoroughly described in [2] where also verification and validation tests are reported; here only the main features are summarised.

One of the challenges of cardiovascular simulations is the definition of the initial configuration owing to the extreme variability among humans; even leaving apart differences related to gender, age, race or pathologies, also homogeneous cohorts of people (say male, adult, Caucasic, healthy) show differences. The two possible approaches are then either tackle a *patient specific* case or rely on an idealised setup which is representative of a broad class of people but of none in particular: the first approach is usually adopted when a particular case (such as a prosthesis implantation to a specific human) has to be anticipated while the second is preferred for research and development purposes.

In the present study we have adopted the latter possibility; starting from tens of high–resolution CT or MRI clinical images and medical atlas [3, 4] that have been ensemble–averaged and, relying on modeling software, the geometries for each heart chamber, valve and main vessel, have been built and assembled to form a 'standard' heart (figure 1a).

The hemodynamics is governed by the Navier–Stokes equations, which in non–dimensional form read:

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u} = -\nabla p + \nabla\cdot\tau + \mathbf{f}, \qquad \nabla\cdot\mathbf{u} = 0. \tag{1}$$

SECTIONAL LECTURES

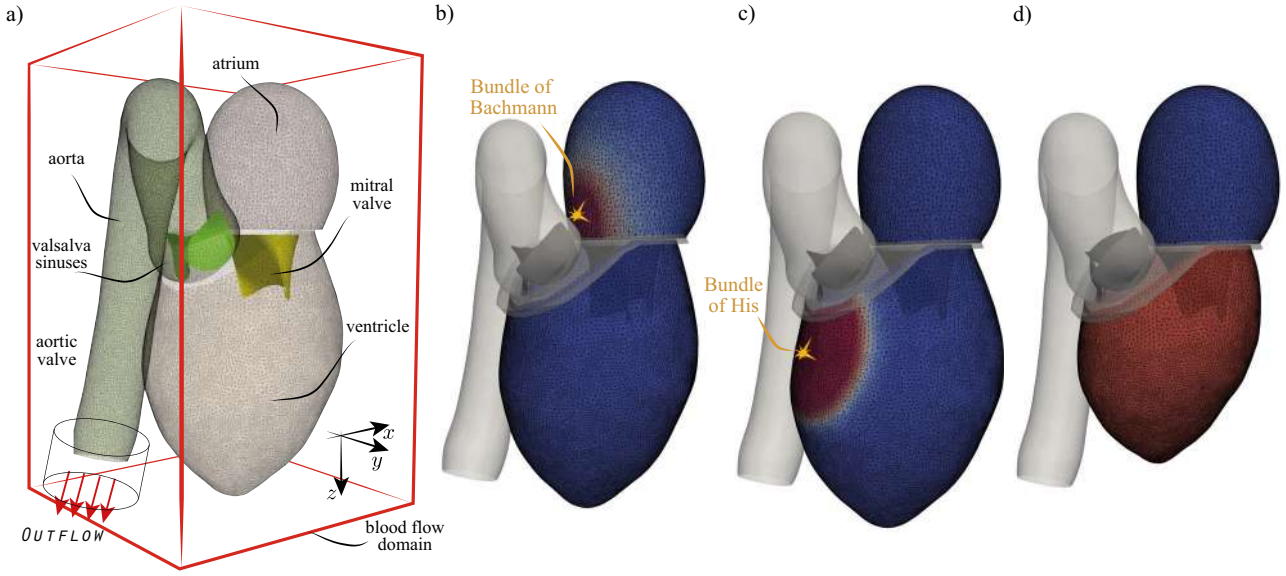

Figure 1: a) Geometry of the left heart assembly with ventricle, atrium, mitral and aortic valve and a tract of the aorta. All these deformable elements are anchored to rigid valvular planes that mimic the fibrous trine. b), c) and d) Snapshots of the transmembrane potential propagation in the left heart; the levels range from -85mV (blue) to $+20$mV (red). b) early atrial systole, corresponding to the time $t/T = 0.85$, c) early ventricular systole $t/T = 0.005$; d) peak ventricular systole $t/T = 0.23$. $T = 0.86$s is the heartbeat period.

Here $\mathbf{u}$ is the blood velocity and p the pressure; in the case of a Newtonian fluid, the viscous stress tensor τ is given by $Re^{-1}(\nabla\mathbf{u} + \nabla^T\mathbf{u})$, whereas non–Newtonian fluids call for more complex constitutive relations as done in [5]. The Reynolds number is defined as $Re = Ud/\nu$ being $d = 2.4$ cm the mitral annulus diameter, $U = 60$ cm/s the averaged velocity in the mitral annulus during diastole and $\nu = 4.8 \times 10^{-6}$ m^{2}s^{-1} is the effective kinematic viscosity for human blood with an hematocrit of 40%: the resulting Reynolds number is $Re = Ud/\nu = 3000$.

The dynamics of the heart tissues is integrated using the Fedosov's interaction potential approach [6, 7, 8]. Any structure is modeled as an elastic shell and discretized by triangular meshes. The mass is lumped at the nodes proportionally to the area of the triangles sharing a given node. Nodes sharing an edge are connected by elastic links oriented as the mesh edges and the former give back an in–plane force as a response to an in–plane stretching. Additionally, the bending stiffness is provided by torsional springs acting between two adjacent faces sharing an edge; the relative rotation of two adjacent triangles generates a restoring moment. When the hydrodynamics loads and the active muscular contraction (described below) are applied to the network, the latter deforms and generates internal elastic forces that are applied to the mesh nodes.

Although this model is typically used in the framework of linear elastic materials [9, 7], biological cardiac tissues are strongly nonlinear and anisotropic, thus requiring more complex constitutive relations. To simulate the response of an hyperelastic and orthotropic material, a Fung–type relation [10, 7] is adopted with the resulting tissue properties that are stiffer in the direction of the fibers than in the cross–fibre direction and an hyperelastic stress–strain behaviour.

The propagation of the electrophysiologic signal is obtained by modeling the myocardium as an intracellular and an extracellular overlapping continuum media (*bidomain* model) separated by the cell membrane which acts as an electrical insulator [11, 12]. The status of each domain is determined by its electrical potential whose gradient yields the electric field from which the current densities are computed. Considering the conservation of charges and the absence of external current sources, the transmembrane current is given by the gradient of the current density, which depends on the potential difference across the membrane (transmembrane potential) and on its permeability to the ions.

Once the activation potential at every point and every instant is available, the active tension τ_{act} of the tissue is computed [13] and translated in internal nodal active forces oriented as the local muscular fiber direction: according to the physiologic myocardium model by [14], here the fibers are assumed to spiral clockwise in the ventricle from the apex to the basis and back with a constant angle of $\pm 45^o$ while in the atrium fibers are aligned with its vertical axis.

The contraction and relaxation of the heart chambers along with the aorta and valve leaflets kinematics come from the dynamic balance between inertia, external and internal (passive and active) forces acting on each triangular vertex. For each node the second Newton law of motion, integrated twice in time, yields the instantaneous tissue configuration at each time step. The new geometry can then be used as input for the fluid and electrophysiology to to obtain the new active and external forces for the successive step.

Owing to the strongly interconnected dynamics of the three models it is not obvious whether they should be solved simultaneously or sequentially and, in the latter case, which one has to be integrated first.

Each of the two approaches (strong– or loose–coupling) have advantages and drawbacks and both have been implemented in the computational model. Unfortunately the most efficient choice depends on the specific problem and its

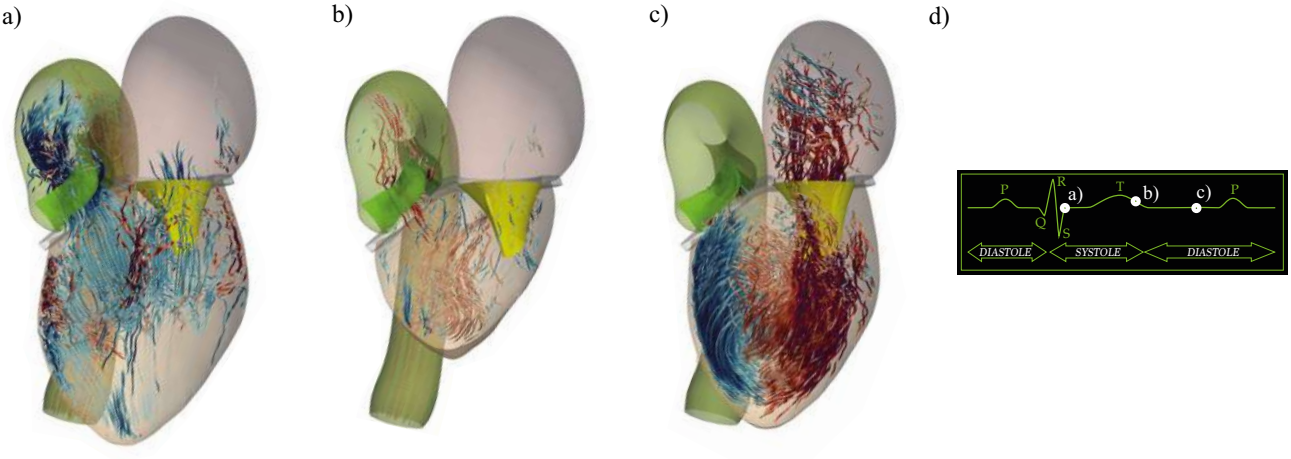

Figure 2: Instantaneous left heart configuration with streamtraces coloured by the local vertical velocity. The colour coding is -0.6 (dark blue), 0.6 (dark red). a) Snapshot at early ventricle systole $t/T = 0.14$, b) end of ventricle systole/beginning of isovolumic relaxation $t/T = 0.43$, c) early atrial systole (ventricle diastole) and passive filling phase $t/T = 0.60$. d) Sketch of an electrocardiogram with the instants of the three snapshots of the figure.

parameters; for the present cardiovascular simulations it appears that the time step size is physically limited by the elastic frequency of the stiffer tissue, the ventricle myocardium, rather than by the other physical systems or stability features of the integration scheme.

RESULTS

A series of preliminary simulations have been run to assess the time step and mesh needed for convergence. Eventually it was determined that the left–heart assembly of figure 1a could be properly simulated using a mesh of about 19 million nodes and 2 million time steps per heartbeat; more details about validations, comparison with experiments, other simulations and clinical data can be found in [2].

In the heart, each heartbeat is initiated by the sino–atrial node in the right atrium that 'sparks' an electrical impulse to initiate the propagation of the activation potential throughout the heart. This propagation occurs along specific directions and with precise timings and delays to allow the efficient filling and emptying of the various heart chambers.

Our computational model allows to consider the fully inhomogeneous and anisotropic electric conduction properties of the myocardium and therefore also the preferential directions and and different velocities of the signal propagation. However, since in this example we are considering only the left half of the whole organ, part of the 'electrical circuit' is not physically present and the activation potential has to be triggered separately at specific times and points. The latter are indicated in figure 1bc as Bundle of Bachmann and Bundle of His that are the position in which the fast conduction fibers intersect the left atrium and ventricle, respectively. Figure 1d finally shows the setup at the peak of the ventricular systole, when the electrical signal has fully propagated across the ventricle and activated the myocardium contraction that has reduced the volume of the chamber to about 30% of its initial value.

The asynchronous active contraction of the myocardium pushes the blood from the atrium to the ventricle and then to the aorta to feed the systemic circulation. The correct flow direction is assured by the heart valves that passively open and close owing to the hydrodynamic loads produced by the fluid structure interaction.

In figure 2 we report three representative snapshots of the blood motion within the left heart visualised by streamtraces coloured by the local value of the vertical velocity. Among the various features we note the large–scale recirculation generated in the relaxed ventricle by the mitral jet (figure 2c). This large vortex is very beneficial for the endocardium that, being constantly swept by the recirculating blood prevents its stagnation, especially within the trabeculae, and the formation of clots.

Although the results in figures 1, 2 are plausible and consistent with the mechanics of the heart, we can not consider them as a validation of the model since they are only qualitative and do not allow any quantitative comparison. In this respect, the graph of figure 3 is much more useful since it reports the time evolution of the pressure in the atrium, ventricle and aorta during a heart cycle. This is usually referred to as 'Wiggers diagram' and it is considered a standard of cardiac physiology to assess the health status of the organ. Our results show that not only the shape of the profiles but also the pressure value agree very well with the literature and this is particularly meaningful for the present computational model in which every quantity is obtained from the computation of the complex interconnected dynamics without imposing ad hoc conditions.

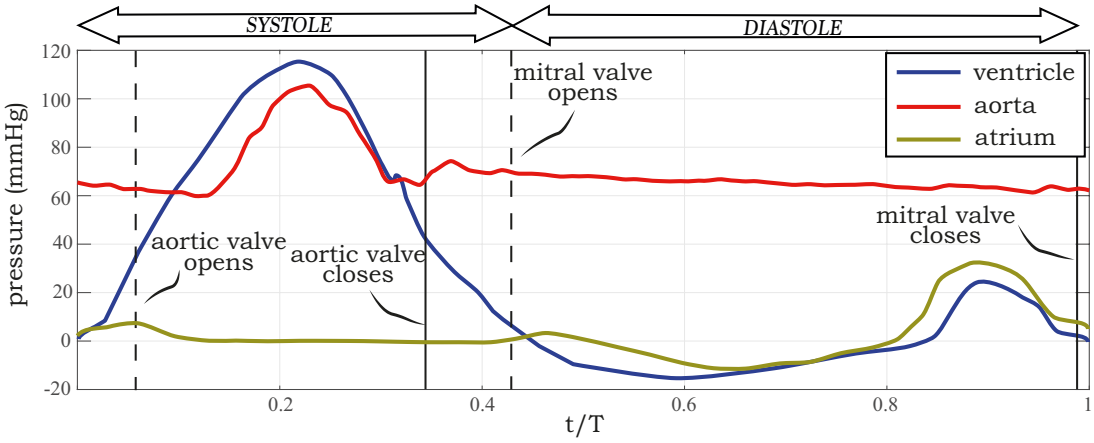

Figure 3: Wiggers diagram obtained by the present computational model.

CONCLUSIONS

In this paper we have presented a recently developed multi–physics model for cardiovascular simulations that has been used to simulate the full dynamics of the left heart. The model solves the three–dimensional incompressible hemodynamics coupled with the active contraction and passive deformation of the tissues via a fluid/structure interaction procedure. The active contraction, in turn, is activated by the electrophysiology that is computed by a bidomain electrophysiology model fully coupled with the other two.

The computational framework yields realistic results in terms of myocardium activation, hemodynamics and wall shear stresses (not shown here). Among the quantitative data we have computed the total volume variation of the ventricle in a cycle that gives an ejection fraction of about 60% and a cardiac output of 5.06 l/min, which are typical physiological values for the heart of a healthy adult.

Owing to the formidable computational effort required by this model, it has been parallelized using both, openMP and MPI directives and, more recently, also also GPU architectures; the parallelization strategies and the speed–up obtained are being reported elsewhere.

Another research activity is aimed at accounting the considerable variability of the input parameters; for this reason uncertainty quantification analysis is being performed either for evaluating the robustness of the model to errors affecting the inputs and for assessing the level of confidence to be given to the results.

Finally, the model is being extended to the full heart (left and right) to perform large simulation campaigns for inputs defined by probability distributions rather than deterministic values: the full set of simulations therefore could be considered as a virtual clinical trial to be analysed statistically.

THEORETICAL ANALYSES OF CONFIGURATIONAL STABILITY OF CRACK PROPAGATION IN MIXED-MODE I+III OR I+II+III: A REVIEW

Jean-Baptiste Leblond*[1], Alain Karma[2], and Laurent Ponson[1]
[1]Institut Jean Le Rond d'Alembert, Facult des Sciences et Ingénierie, Paris, France
[2]Physics Department and Center for Interdisciplinary Research on Complex Systems, Northeastern University, Boston, Massachussetts, USA

Summary The instability of coplanar propagation of cracks loaded in mixed-mode I+III conditions, leading to splitting of the front and formation of small disconnected tilted facets, is well documented experimentally. This presentation reviews some recent analyses of this instability, based on (i) theoretical formulae of Gao and Rice (1986) and Movchan et al. (1998), providing general expressions of the stress intensity factors along the front of a semi-infinite crack slightly perturbed both within and out of its initial plane; (ii) a "double" propagation criterion, applied at all times all along the front, combining Griffith (1920)'s energetic condition and Goldstein and Salganik (1974)'s principle of local symmetry.

INTRODUCTION

Cracks loaded under mixed-mode I+III conditions are well known not to propagate along a plane, but in the form of small tilted facets, leading to splitting of the crack front. Figure 1 illustrates the behavior of this front, initially coinciding with the axis Oz, as it propagates under such conditions. The front splits into small facets of "type A" rotating around the direction Ox of propagation so as to minimize the mode III component of the local stress field, and facets of type B rotating in the opposite direction. Facets of type A are "privileged" over facets of type B in the sense that their length (in the direction of propagation) is larger (this is not represented in Figure 1 for legibility).

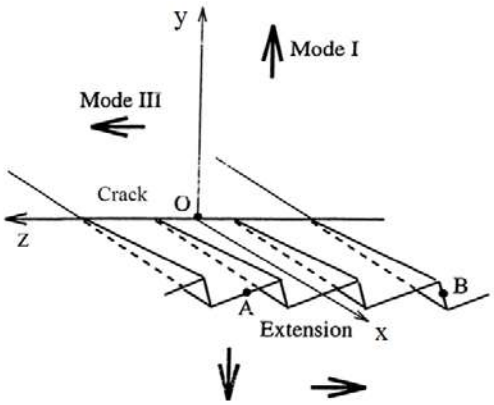

Figure 1. Schematic geometry of a crack propagating in mixed-mode I+III.

The aim of this presentation is to present and discuss some recent theoretical analyses of the formation of such twisted fracture facets under mixed-mode I+III loading conditions. These analyses were inspired by Pons and Karma's numerical simulations [1], based on a phase-field model, of crack propagation in mode I+III, which evidenced a "helical" instability of the propagating crack front. The common basis of these analyses consisted of two combined elements:

1) Theoretical formulae of Gao and Rice [2] providing the expressions of the first-order variations of the stress intensity factors (SIFs) along the front of a semi-infinite crack resulting from an arbitrary *in-plane* perturbation of the crack *front*; and of Movchan et al. [3] for the variations of the SIFs resulting from an arbitrary *out-of-plane* perturbation of the crack *surface*.
2) A "double" propagation criterion, which itself combined Griffith's energetic condition [4] and Goldstein and Salganik's "principle of local symmetry" (PLS) [5]. This criterion was assumed to apply at all times and all positions along the crack front.

The three analyses considered however differed in the hypotheses made on the loading and the fracture energy, as will be seen.

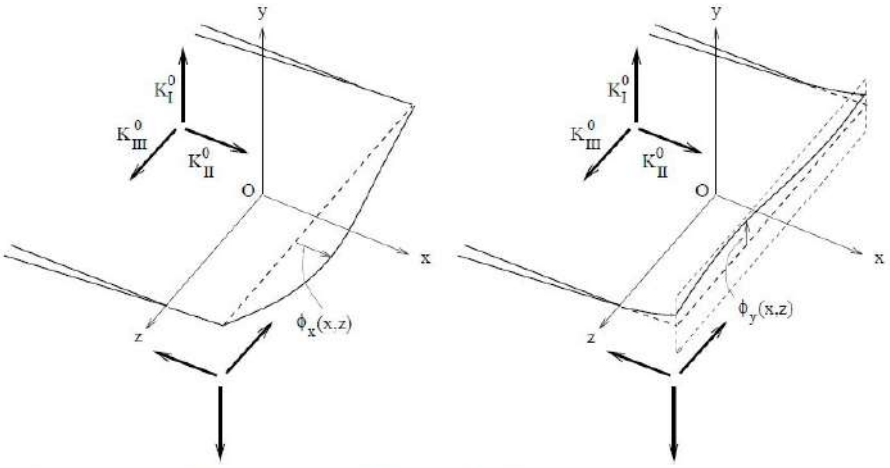
SECTIONAL LECTURES

GENERAL PRINCIPLES OF THEORETICAL STABILITY ANALYSES

A semi-infinite crack embedded within an infinite isotropic elastic body is considered in two configurations (Fig. 2). In the first, unperturbed one, the crack is planar and its front is straight. A Cartesian frame $Oxyz$ with axes oriented according to the standard convention is introduced. The crack is loaded under general mixed-mode I+II+III conditions, with uniform SIFs K_I^0, K_{II}^0, K_{III}^0 along the front. In the second, slightly perturbed configuration, the front of the crack is displaced in the direction x by a small distance $\phi_x(x,z)$ (Fig. 2, left), and its surface is displaced in the direction y by a small distance $\phi_y(x,z)$ (Fig. 2, right).



(a) In-plane perturbation of the crack front. (b) Out-of-plane perturbation of the crack surface.

Figure 2. Unperturbed and perturbed configurations of a semi-infinite crack loaded in mode I+II+III.

In this new configuration, the perturbation $\delta K_p(x,z)$ of the p-th SIF is given, to first order in the pair (ϕ_x, ϕ_y), by the formula $\delta K_p(x,z) = \delta_x K_p(x,z) + \delta_y K_p(x,z)$ where the contributions $\delta_x K_p(x,z)$ and $\delta_y K_p(x,z)$ arise from ϕ_x and ϕ_y, respectively. With some mildly restrictive hypotheses, the expressions of the contributions $\delta_x K_p(x,z)$ are given in the work of Gao and Rice [2], and those of the contributions $\delta_y K_p(x,z)$ in the work of Movchan et al. [3].

The prediction of the successive configurations of the crack, resulting from its mixed-mode propagation, are based on a double criterion enforced all along the crack front and at all instants during propagation, consisting of:

1) Griffith's condition [4] $G(x,z) = G_c(x,z)$ where $G(x,z)$ denotes the local energy-release-rate and $G_c(x,z)$ its local "critical value" inducing propagation of the front (that is, the fracture energy).
2) Goldstein and Salganik's PLS [5] according to which the local SIF $K_{II}(x,z)$ of mode II must be zero.

STABILITY ANALYSIS: BASIC VERSION

In the first, simplest version of the stability analysis [6], the loading is in mode I+III ($K_{II}^0 = 0$), and the fracture energy is assumed to be an absolute constant, depending only on the material. The instability mode (ϕ_x, ϕ_y) satisfying the double criterion is looked for in the form $\phi_x(x,z) = e^{\lambda x}\psi_x(z)$, $\phi_y(x,z) = e^{\lambda x}\psi_y(z)$ where λ (> 0) is an unknown parameter (the growth rate of the perturbation), and $\psi_x(z)$, $\psi_y(z)$ unknown functions (specifying the shape of the in-plane and out-of-plane perturbations).

The method used consists of introducing the Fourier transforms of all functions in the direction z of the unperturbed crack front, expressing the perturbations of the SIFs in Fourier's space for the perturbations of the crack front and surface considered, and then enforcing the double criterion. This yields a relation that ties together the Fourier transforms $\widehat{\psi_x}(k)$, $\widehat{\psi_y}(k)$ of $\psi_x(z)$, $\psi_y(z)$, plus a condition involving the "unperturbed mixity ratio" $\rho^0 = \frac{K_{III}^0}{K_I^0}$ and the "reduced growth rate" $\xi = \frac{\lambda}{|k|}$.

One finds that for the reduced growth rate ξ to be positive (as required for an instability mode), the unperturbed mixity ratio ρ^0 must be larger than some "critical value" given by

$$\rho^{cr} = \left[\frac{(1-\nu)(2-3\nu)}{3(2-\nu)-4\sqrt{2}(1-2\nu)}\right]^{1/2}$$

where ν denotes Poisson's ratio. This quantity is plotted as a function of ν in Fig. 3 below.

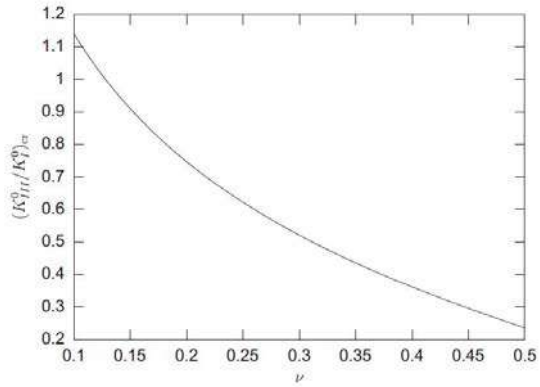


Figure 3. The critical mixity ratio as a function of Poisson's ratio.

Also, the geometry of instability modes - present when ρ^0 exceeds ρ^{cr} - is deduced from the relation connecting $\widehat{\psi_x}(k)$ and $\widehat{\psi_y}(k)$. It is found that the initially straight front becomes an elliptic helix the axes of which grow proportionally and exponentially with the distance x of propagation (Fig. 4). This result is fully compatible with the observations made numerically by Pons and Karma [1] using a phase-field model.

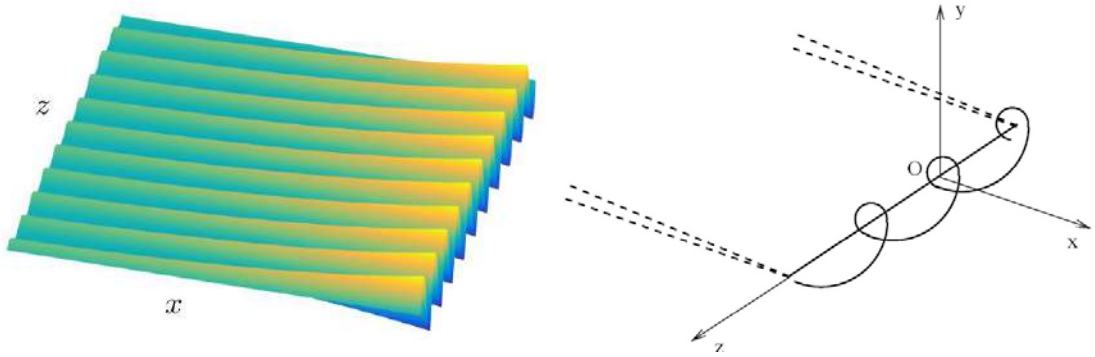

Figure 4. Geometry of the perturbed crack surface (left) and front (right).

STABILITY ANALYSIS: FIRST EXTENSION INCORPORATING A MODE-DEPENDENT FRACTURE ENERGY

One serious problem with the preceding analysis is that the value of the critical mixity ratio ρ^{cr}, being of the order of 0.5 for standard values of ν, is generally much larger than that actually observed, see for instance Sommer [7] and Pham and Ravi-Chandar [8].

One possible solution to this problem was proposed by Leblond et al. [9]. It consisted in heuristically assuming the local fracture energy $G_c(x,z)$ to be a function of the local "mixity ratio" $\rho(x,z) = \frac{K_{III}(x,z)}{K_I(x,z)}$, in agreement with some observations of Lin et al. [10]. The heuristic formula $G_c(\rho) = G_c^{\text{mode I}}(1+\gamma|\rho|^\kappa)$, with γ and κ being material parameters, was adopted by Leblond et al. [9].

Repeating the preceding analysis with this new hypothesis, Leblond et al. [9] found critical values ρ^{cr} of the unperturbed mixity ratio depending on γ and κ. With the values $\kappa = 2$ and $\gamma = 25$ providing a good fit of the heuristic formula for $G_c(\rho)$ with Lin et al.'s measurements [10], they found the value $\rho^{cr} \approx 0.1$, which is within the range of loadings considered in the experiments.

STABILITY ANALYSIS: SECOND EXTENSION INCORPORATING A SMALL MODE II LOADING COMPONENT

Small mode II loading components, arising from various imperfections, are bound to be present in actual experiments. It is therefore a natural idea to repeat the preceding analysis with such an extra loading component.

However the introduction of a small mode II components raises some new issues. The first arises from the resulting general kink of the crack, which is assumed to occur only once a certain position of the crack front is reached. We thus consider an initially flat semi-infinite crack obtained for instance through propagation in mode I fatigue. A static load including mode II and III components is applied henceforward. A general kink of the crack ensues, with possibly superimposed perturbations of the crack front and surface growing in an unstable manner.

Also, instability modes of the form $\phi_x(x,z) = e^{\lambda x}\psi_x(z)$, $\phi_y(x,z) = e^{\lambda x}\psi_y(z)$, with *real* parameter λ and *real* functions $\psi_x(z)$, $\psi_y(z)$, happen not to be compatible any more with continuous satisfaction of the double criterion. More general modes of the form $\phi_x(x,z) = \mathrm{Re}\left[e^{\lambda x}\psi_x(z)\right]$, $\phi_y(x,z) = \mathrm{Re}\left[e^{\lambda x}\psi_y(z)\right]$ with *complex* λ, $\psi_x(z)$, $\psi_y(z)$, must be considered. The calculations required to enforce the double criterion then become more complex, but still remain feasible.

The results are as follows. First, the presence of some mode II tends to stabilize the crack front in the sense that it slightly increases the value of the critical unperturbed mixity ratio ρ^{cr}. But the major effect is on the geometry of instability modes, which now *drift along the crack front as it propagates*. This motion is represented schematically in the left part of Fig. 5 (to be compared to the left part of Fig. 4). The right part of the same figure shows a photograph of a fracture surface recently observed by Vasudevan [11] in some experiment which involved small components of mode II and mode III. Ridges propagating obliquely with respect to the (vertical) main direction of propagation of the crack are apparent in this photograph; deciding whether or not this phenomenon may be explained by the theory developed requires further, more detailed investigations.

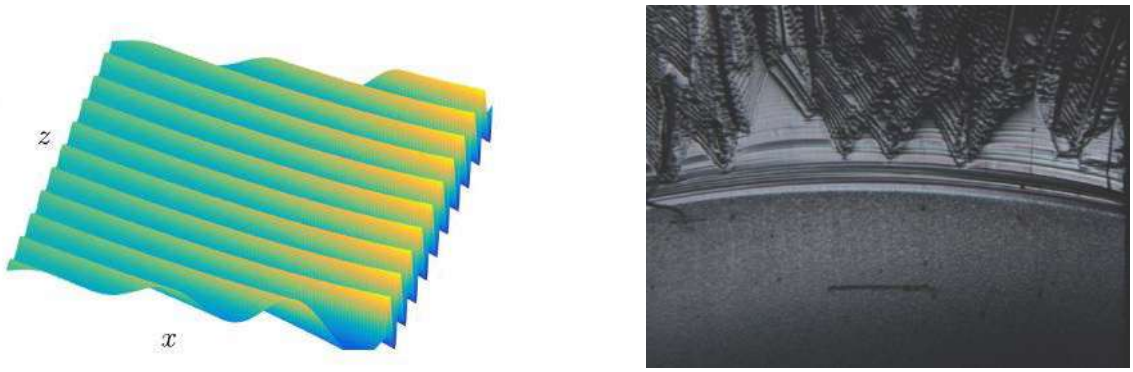

Figure 5. Drifting motion of instability modes in mode I+II+III. Left: theoretical predictions; right: experimental observations of Vasudevan [11].

Summary Neurodegeneration will undoubtedly become a major challenge in medicine and public health caused by demographic changes worldwide. Recent studies have reinforced the hypothesis that the prion paradigm, the templated growth and spreading of misfolded proteins, could help explain the progression of a variety of neurodegenerative disorders. However, our current understanding of prion-like growth and spreading is rather empirical. Here we show that a physics-based reaction-diffusion model can explain the growth and spreading of misfolded protein in a variety of neurodegenerative disorders. We combine the classical Fisher-Kolmogorov equation for population dynamics with anisotropic diffusion and simulate misfolding across the human brain and use Bayesian approach to infer our model parameters from a longitudinal study of 76 human brains. Our continuum model correctly predicts amyloid-beta deposits and tau inclusions in Alzheimer's disease, alpha-synuclein inclusions in Parkinson's disease, and TDP-43 inclusions in amyotrophic lateral sclerosis. To reduce the computational complexity, we replace the continuous brain through a connectivity-weighted Laplacian graph created from 418 brains of the Human Connectome Project. Our brain network model simulates the key characteristic features of whole brain models at a fraction of their computational cost. Our results suggest that misfolded proteins in various neurodegenerative disorders grow and spread according to a universal law that follows the basic physical principles of nonlinear reaction and anisotropic diffusion. Our model has important clinical implications, from estimating the socioeconomic burden of neurodegeneration to designing clinical trials and pharmacological intervention.

More than 45 million people are living with dementia today and this number is expected to triple by 2050. A major challenge of age-related neurodegenerative diseases is that the initial symptoms of cognitive decline become noticeable only one or two decades after the first pathological abnormalities have started to affect the brain. For several decades, researchers have tried to establish early predictive indicators of neurodegeneration and identify common pathological themes of neurodegenerative disorders. Recent evidence suggests that the key to understanding common features of neurodegeneration could lie in the unusual biology of prion diseases [8]. Prions, proteinaceous infectious particles, are unconventional infectious agents that consist of misfolded proteins that act as corruptive seeds to initiate a chain-reaction of misfolding, growth, and spreading [2]. Prion diseases have some unique kinetic features: Disease progression is inevitable after initial seeding; the duration of the incubation period depends on both the initial seeding concentration and the rate at which prions amplify; and disease progression is characterized by a long, clinically silent incubation period during which prions grow and spread, followed by a brief and invariably fatal clinical disease [4]. Interestingly, these characteristics are similar to the progression of a wide variety of age-related neurodegenerative disorders including Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis [9]. While the clinical and pathological symptoms of these disparate disorders may vary, at the molecular level, they share with prions the unique properties of nucleation, templating, growth, and spreading [3]. Each of these phenomena presents a potential target for therapeutic intervention; yet, our quantitative understanding of protein misfolding remains rather limited.

Here we illustrate how to model and simulate the spatio-temporal progression of neurodegenerative diseases within the human brain [5]. We have recently fit a network diffusion model based on a weighted Laplacian graph of the axonal connectome to longitudinal tau PET data of 46 subjects using a deterministic optimization approach [6]. We now use Bayesian hierarchical modeling to systematically infer the model paramters from longitudinal imaging data of 76 subjects from the Alzheimer's Disease Neuroimaging Initiative [7]. This probabilistic approach allows us to account for potential uncertainties in image acquisition and processing, and, at the same time, quantify the uncertainty in model calibration [1]. Identifying the uncertainty in our model parameters is essential to determine the accuracy of our personalized model predictions. Our results can have important implications in accurate study design and improved personalized diagnostics.

MORPHING AND SHAPE CONTROL: FROM MECHANO-BIOLOGY TO ENGINEERING

Antonio De Simone

Locomotion strategies employed by unicellular organism are a rich source of inspiration for studying mechanisms for shape control. These strategies are particularly interesting because the organisms and the mechanisms they exploit are invisible to the naked eye, and offer surprising new solutions to the question of how shape can be controlled.
In recent years, we have studied locomotion and shape control in unicellular organisms using a broad range of tools ranging from theoretical and computational mechanics, to experiment and observations at the microscope, to manufacturing of prototypes. The physical models used to demonstrate the mechanisms exploited by biological organsism naturally suggest new solutions for adaptable and deployable structures, morphable devices, robotic applications, smart shape-shifting materials and structures. We will survey our most recent findings within this stream of research.

DATA-DRIVEN MODELING OF FLUIDS

Clarence W. Rowley

Fluid flows can be extraordinarily complex, and even turbulent, yet often there is structure lying within the apparent complexity. Understanding this structure can help explain observed physical phenomena, and can help with the design of control strategies in situations where one would like to change the natural state of a flow. This talk addresses techniques for obtaining simple, approximate models for fluid flows, using data from simulations or experiments. We discuss and compare a number of methods for obtaining linear or nonlinear models, and apply the methods to several flows with complex behavior.

RESOLVENT ANALYSIS OF SEPARATED FLOWS OVER AIRFOILS

Kunihiko Taira* [1] and Chi-An Yeh[1]
[1] Department of Mechanical and Aerospace Engineering, University of California, Los Angeles, CA, USA

Summary Resolvent analysis, founded on transfer function from modern linear control theory, reveals the input-output characteristics of the base flow. This linear analysis technique is able to identify the most amplified flow structures and the required forcing input over a range of frequencies through the singular value decomposition of the resolvent operator. In this talk, we will discuss the use of resolvent analysis to study separated flow over a NACA 0012 airfoil. Examples will include the analysis of turbulent separated flows, active flow control, and transonic buffet over a range of Reynolds numbers. We will also discuss our efforts on incorporating data-science and network-science-based techniques to extend the applicability of resolvent analysis for fluid flows at higher Reynolds numbers and those with time-varying base states.

INTRODUCTION

A variety of aerodynamic flows exhibit sustained fluctuations about their base states, providing dynamical richness to the flow physics. Resolvent analysis offers the foundation to reveal the input-output relationship between the sustained perturbations and the flow response with respect to the base flow [1, 2]. As a companion to the global stability analysis that offers insights based on the homogeneous solution to initial value problems, the resolvent analysis describes the system response as the particular solution to the harmonic forced system [1, 3]. One of the key features of the resolvent analysis is its close connection to the pseudospectral analysis that captures the non-normality of the flow [1, 4].

In recent years, the refreshing perspective of McKeon and Sharma [5] has enabled the use of resolvent analysis for time-averaged turbulent base flows, assuming that the flow is statistical stationary. In their formulation, the nonlinear term in the Navier–Stokes equations is treated as intrinsic forcing in a feedback loop about the linearized operator. This perspective has enabled resolvent analysis to analyze turbulent flows, which has been a challenge for linearized techniques that assume small-amplitude perturbations about an equilibrium state. Resolvent analysis has in recent years been applied to reveal the input-output characteristics of a variety of flows [4]. In this presentation, we will focus on the applications of resolvent analysis on low and high-speed separated flows over a NACA 0012 airfoil. Towards the end of the talk, we discuss techniques to extend resolvent analysis to analyze complex high-Reynolds-number and time-varying base flows.

CHARACTERIZATION AND CONTROL OF SEPARATED FLOW

Resolvent analysis reveals the most amplified forcing or perturbation profile over a range of frequencies by performing the singular value decomposition (SVD) of the resolvent operator. The modal profiles determined from resolvent analysis can be used to develop control design metrics that can point to effective choices of control parameters, including forcing location, direction, and frequency. We consider the application of resolvent-based control to suppress flow separation over a NACA 0012 airfoil at Reynolds number of $23,000$, as shown in Fig. 1 [6]. For this flow, we take the resolvent modes to determine an effective control approach for enhancing mixing near the separation point to direct high-momentum fluid towards the airfoil surface. The guidelines developed from this resolvent-based approach are tested in full LES. The trend for control effectiveness predicted by the resolvent-based metric is found to be in excellent agreement with the results obtained from an exhaustive set of parametric LES runs. Because the present approach only requires the baseline flow and the discretized resolvent operator, the optimal set of control parameters can be found with significantly lower computational cost and time compared to a large number of LES cases.

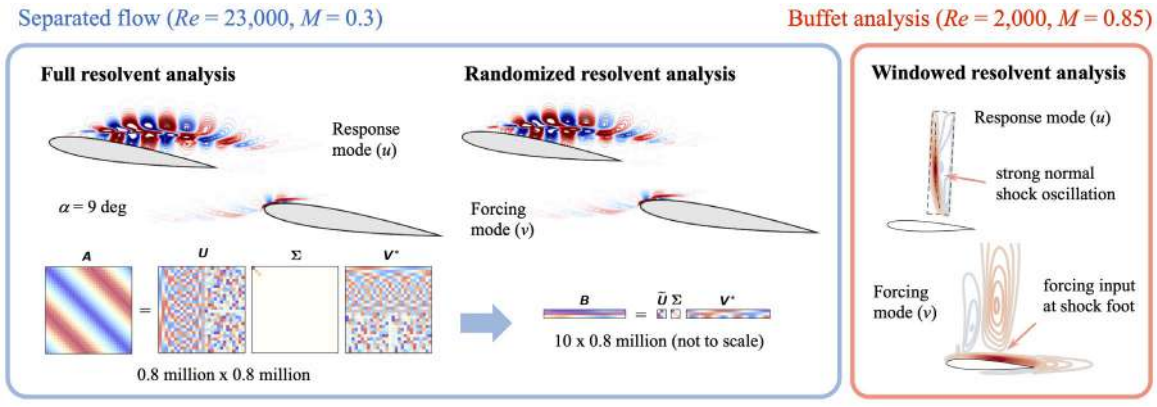

Figure 1: (Left) Resolvent analysis of turbulent separated flow over an airfoil at $Re = 23,000$ and $M = 0.3$. Comparison of full and randomized resolvent analysis shows excellent agreement. (Right) Resolvent analysis of transonic buffet at $Re = 2,000$ and $M = 0.85$ using spatial windowing revealing the source of 2D buffet at shock foot. This overview figure is compiled from [11, 8].

*Corresponding author. E-mail: ktaira@seas.ucla.edu

ANALYSIS OF TRANSONIC BUFFET

We can direct the focus of resolvent analysis to certain regions of the flow field to shed light on particular flow phenomena [7]. Spatial windowing can be incorporated into the resolvent formulation to identify the causal relations of particular flow phenomena. In this example, we apply spatial windowing to the region where standing shock appears over an airfoil in transonic flow to understand the origin of two-dimensional buffet [8], as shown in Fig. 1. Through this analysis, we reveal that the cause of the low-frequency buffet oscillation lies at the foot of the shock. What is noteworthy with this type of analysis is its ability to uncover such mechanism even for flow regimes that are not typically associated with buffet. The findings from the study is validated by actuating the transonic flow with the forcing mode profile to stimulate the predicted response in DNS. The results suggest that low-Reynolds number compressible flows encountered in Martian flight condition may be susceptible to buffet-induced low-frequency oscillations.

EXTENDING RESOLVENT ANALYSIS

Performing resolvent analysis requires the availability of the discretized Navier–Stokes operator, whose size is dependent on the spatial discretization scheme and the number of spatial grid points. The size of the resolvent operator becomes very large for turbulent base flows at high Reynolds numbers and for two- and three-dimensional base flows. To ease the handling of such high-dimensional resolvent operators and extend the applicability of resolvent analysis, we consider the use of randomized numerical linear algebra [9, 10, 11]. Randomized methods can provide a low-rank operator through a technique called sketching, which retains the dominant properties of the full operator. This reduction enables the use of the randomized singular value decomposition within the resolvent framework to achieve computational speedup and memory relief [11]. We provide guidelines on the use of randomized resolvent analysis and demonstrate its use for turbulent separated flows over the airfoils at $Re = 23,000$ and $500,000$ [11, 12], as shown in Fig. 1 for the lower Re. We also will discuss efforts to incorporate data-science and network-inspired inspired techniques into resolvent analysis to extract additional physical insights for complex fluid flows.

CONCLUSIONS

Resolvent analysis have become an invaluable modal analysis technique to reveal the input-output relationship for a variety of flows. One particularly attractive feature of resolvent analysis is its ability to analyze turbulent base flows, which has been an open question for global stability analysis. As many flows are under sustained perturbations or possess flow unsteadiness in turbulent conditions, resolvent analysis holds tremendous potential to analyze a range of flows for their characterization, modeling, and control.

LOW-COMPLEXITY MODELS FOR PASSIVE CONTROL OF WALL TURBULENCE

Andrew Chavarin, Christoph Efstathiou, Shilpa Vijay, and Mitul Luhar*
Department of Aerospace and Mechanical Engineering, University of Southern California, Los Angeles, USA

Summary The use of riblets is one of the most effective ways to reduce skin friction in wall-bounded turbulent flows. Recent simulations for anisotropic porous materials show promise as well. However, the design space for such functional surfaces is vast. We present a low-complexity modeling framework that enables efficient exploration of this design space for skin friction reduction. This framework uses a gain-based decomposition of the Navier-Stokes equations to identify a single mode that serves as a surrogate for the energetic near-wall cycle. Comparison against prior results shows that the gain of this one mode is a good predictor of performance for both riblets and porous materials. The framework is also able to predict when spanwise-coherent structures that lead to performance deterioration emerge over such surfaces. These developments provide a pathway for future optimization efforts.

INTRODUCTION

A great amount of effort has been expended on the development of passive skin friction reduction techniques for wall-bounded turbulent flows over the past few decades. Experiments and simulations have shown that streamwise-aligned *riblets* can yield as much as 10% skin friction reduction in wall-bounded flows [1, 5]. More recent efforts suggest that porous substrates with streamwise permeability (K_x) that is higher than the spanwise (K_z) or wall-normal permeability (K_y) could be even more effective than riblets. Direct numerical simulation (DNS) results show reductions in skin friction of up to 25% over idealized anisotropic permeable substrates [4]. It is generally accepted that the drag-reducing ability of riblets and permeable substrates arises from their anisotropy [6]. The mean flow is unimpeded in the riblet grooves and within streamwise-preferential permeable materials. However, turbulent cross-flows are blocked and displaced further from the wall. This weakens the quasi-streamwise vortices associated with the near-wall (NW) cycle and reduces turbulent momentum transfer in the wall-normal direction. Simple physical and theoretical arguments show that the initial decrease in skin friction over riblets and permeable materials depends on the difference between the effective slip length felt by the streamwise mean flow, l_x, and the spanwise turbulent cross-flow, l_z [6, 4]. For riblets l_x and l_z are determined by the shape and size. For porous materials, these slip lengths depend on the corresponding permeabilities, $l_x \sim \sqrt{K_x}$ and $l_z \sim \sqrt{K_z}$, though substrate thickness can also play a role. Skin friction reduction increases initially with increasing $(l_x - l_z)$. However, performance deteriorates beyond a certain riblet size or threshold permeability. For riblets, early studies attributed this deterioration of performance to the NW streamwise vortices lodging within the riblet grooves. Recent efforts suggest that a Kelvin-Helmholtz instability also plays a role in driving this deterioration of performance over riblets and porous materials [5, 3, 4].

In this talk, we present a unified low-complexity modeling framework that can (i) account for both riblet surfaces and anisotropic porous materials, (ii) determine whether riblets of specified geometry or porous materials with known permeability are likely to weaken or strengthen the NW cycle, and (iii) predict when Kelvin-Helmholtz type spanwise rollers emerge over such complex surfaces. These models require minimal computation, i.e., they can be implemented on standard laptop or workstation computers. As advances in manufacturing technology enable the development of increasingly complex functional materials and surfaces, such low-cost models can be very useful design tools.

MODELING FRAMEWORK

The low-complexity modeling framework is grounded in resolvent analysis [8]. For wall-bounded turbulent flows, the resolvent formulation interprets the Fourier-transformed Navier-Stokes equations as a forcing-response system. The nonlinear convective terms are interpreted as the forcing that acts on the remaining linear terms to generate a velocity and pressure response. For each wavenumber-frequency combination $\mathbf{k} = (\kappa_x, \kappa_z, \omega)$, a gain-based singular value decomposition of the forcing-response transfer function—the resolvent operator—yields a set of velocity and pressure response modes (singular vectors) that are ranked based on their forcing-response gain (singular values). These response modes, termed *resolvent modes*, are flow structures with streamwise and spanwise wavelength $\lambda_x = 2\pi/\kappa_x$ and $\lambda_z = 2\pi/\kappa_z$, respectively, traveling at speed $c = \omega/\kappa_x$. Previous work shows that the highest-gain (rank-1) resolvent modes obtained at specific $\mathbf{k}$ combinations serve as useful surrogates for energetic structures such as the NW cycle [7].

To account for the presence of riblets in this framework, we use a volume penalization method [3]. The presence of anisotropic permeable substrates is incorporated by extending the resolvent formulation to the volume-averaged Navier-Stokes equations, which include a generalized version of Darcy's law for flow through porous media [2]. The permeable medium is characterized by the porosity ϵ and a permeability tensor $\mathbf{K}$. Resolvent analysis proceeds as follows. First, the volume penalized or volume-averaged governing equations are Fourier-transformed and expressed as $[\mathbf{u_k}, p_\mathbf{k}]^T = H_\mathbf{k}\mathbf{f_k}$. Here, $\mathbf{u_k}$ and $p_\mathbf{k}$ denote the velocity and pressure fields, the forcing $\mathbf{f_k}$ represents the nonlinear terms, and $H_\mathbf{k}$ is the resolvent operator representing the linear forcing-response dynamics. Next, a singular value decomposition of the discretized resolvent operator is used to identify high-gain forcing and response modes as well as the forcing-response gain (singular values, $\sigma_\mathbf{k}$). Here, we focus on resolvent modes resembling the NW cycle (i.e., with $\mathbf{k}$ corresponding to $\lambda_x^+ = 10^3$, $\lambda_z^+ = 10^2$, and $c^+ = 10$) and spanwise-constant structures similar to Kelvin-Helmholtz vortices.

*Corresponding author. E-mail: luhar@usc.edu.

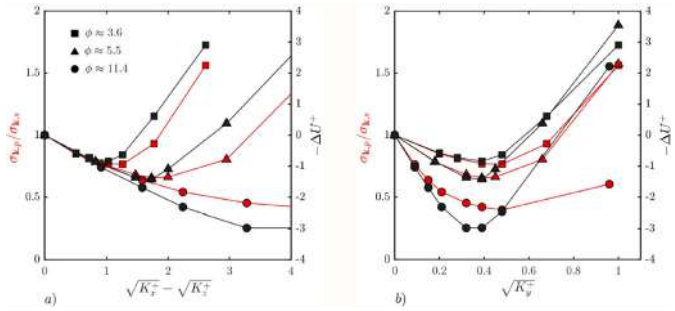

Figure 1: Comparison of the change in singular values for modes resembling the NW cycle (red) with the drag reduction observed in DNS (black; from [4]) over anisotropic porous materials. Symbols denote substrates with different anisotropy ratios, $\phi = K_x/K_z$.

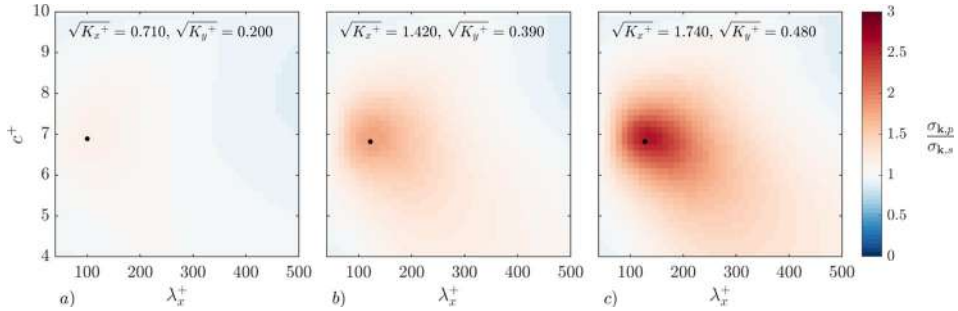

Figure 2: Change in singular values for spanwise-constant modes ($\kappa_z = 0$) of varying streamwise wavelength and mode speed. Wall-normal permeability $K_y(= K_z)$ increases from (a)-(c) but the anisotropy ratio is fixed, $\phi = K_x/K_z \approx 3.6$.

SAMPLE RESULTS AND DISCUSSION

The predictive power of the modeling framework is showcased by the sample results shown in Figs. 1-2 for flow over anisotropic porous materials with permeability $\mathbf{K} = \mathrm{diag}(K_x, K_y, K_z)$, where $K_y = K_z$. Fig. 1(a) shows that the forcing-response gain for the NW resolvent modes is a very good predictor of the friction reduction observed in DNS [4]. Material properties that lead to a suppression in gain relative to the smooth wall case ($\sigma_{\mathbf{k},p}/\sigma_{\mathbf{k},s} < 1$) yield an outward shift in the mean velocity profile ($-\Delta U^+ < 0$) and, hence, drag reduction in DNS. Further, the initial decrease in singular values is linearly proportional to $\sqrt{K_x} - \sqrt{K_z}$ across all cases, which is consistent with the slip length models proposed previously. Fig. 1(b) shows that the gain for the NW resolvent mode alone does not predict the exact conditions in which performance deteriorates. DNS data show that performance deteriorates as the wall-normal permeability increases beyond $\sqrt{K_y}^+ \approx 0.35$, irrespective of K_x and K_z. In DNS, this coincides with the emergence of spanwise-coherent rollers that resemble Kelvin-Helmholtz vortices and have a streamwise length scale of about 150 viscous units. Fig. 2 shows that the resolvent framework is able to predict the emergence of such structures as well. A region of high amplification is observed for spanwise-constant resolvent modes with $\lambda_x^+ \approx 100 - 150$ for the materials with $\sqrt{K_y}^+ \geq 0.39$. Results obtained for riblets are similarly encouraging [3].

The full presentation will include results for both riblets and anisotropic porous materials. Additional evaluation of model predictions against DNS results and a discussion of the predicted changes in flow structure will be provided as well. Time permitting, the presentation will also cover preliminary efforts on model-based geometry optimization and laboratory testing of such designed functional surfaces.

RESTRICTED NONLINEAR MODELING FOR HIGH REYNOLDS NUMBER WALL-BOUNDED TURBULENCE

Dennice F. Gayme* [1] and Benjamin A. Minnick[1]
[1] Department of Mechanical Engineering, Johns Hopkins University, Baltimore, Maryland, USA

Summary The restricted nonlinear (RNL) model provides a reduced order representation of low to moderate Reynolds number wall-bounded turbulent flows that accurately predicts low-order statistics, spanwise energy spectra, and turbulent kinetic energy budgets at greatly reduced computational costs. Here, we introduce the additional large-scales required to capture higher Reynolds number behavior through an augmented RNL (ARNL) model. This flow representation permits additional nonlinear interactions in a manner consistent with generalized quasilinear (GQL) models, while enforcing the dynamical restrictions that maintain the computational benefits of the RNL framework. The ARNL model thus represents a hybrid approach that we show to be promising in representing wall-bounded turbulence at Reynolds numbers as high as $Re_\tau = 5200$.

BACKGROUND

The well-documented prevalence and importance of coherent motions in wall-bounded turbulent flows, see e.g. [1], has motivated the use of reduced order models to both isolate and interrogate the flow physics, see e.g. [2, 3]. The restricted nonlinear (RNL) model is one such approach that decomposes the flow field into large-scale $\mathbf{U}(y, z, t)$ streamwise constant (mean) dynamics and perturbations defined about that mean $\mathbf{u}(x, y, z, t)$. Order reduction is achieved through a dynamical restriction of its nonlinear interactions to those of the streamwise constant mean flow dynamics and interactions between perturbations that contribute to the mean. The model is parametrized by limiting the resulting linear perturbation equations to a small set of streamwise varying wavenumbers (nonzero streamwise Fourier coefficients $k_x \neq 0$) that maximize dissipation in the outer layer. This model reproduces low-order statistics, spanwise energy spectra, and turbulent kinetic energy budgets at $Re_\tau = 180$, even when restricted to a single nonzero streamwise mode interacting with the mean flow [2]. However, the RNL dynamics supported by only the small-scale streamwise varying modes associated with peak outer-layer dissipation are insufficient to capture the scale separation that emerges with increasing Reynolds number.

A similar reduction in accuracy has been seen with increasing flow complexity in closely related quasilinear (QL) models that are popular in the atmospheric sciences, see e.g. [4]. QL models employ a horizontally averaged large-scale and neglect the corresponding perturbation-perturbation nonlinearity, but do not parametrize the small-scale perturbations as in the RNL formulation discussed above. The fidelity of these models has been improved through the generalized QL (GQL) model which employs a spectral filter to define the 'mean' or large-scale dynamics rather than averaging, thereby allowing nonlinear interactions between non-zero streamwise and spanwise modes modes [5]. However, the improved predictions of the flow statistics are achieved at the cost of increasing computational expense due to the resulting energy scattering introduced through nonlinear modal interactions.

Here, we take a hybrid approach. The mean flow field is expanded to allow select non-zero modes to interact nonlinearly in the spirit of the GQL model, but the dynamics are limited to a small number of streamwise modes, saving computational resources as in the RNL model. We simulate these augmented (ARNL) dynamics supported by three non-zero streamwise modes, one scaling with the half-channel height that is treated as a large-scale, and two small-scale modes associated with the outer-layer peak of the surrogate dissipation spectra, see Figure 1. Our results demonstrate that the ARNL model reproduces low-order statistics and structural features of a channel flow at Reynolds numbers as high as $Re_\tau = 5200$, thereby increasing the range of applicability of the RNL modeling paradigm by a factor of 10.

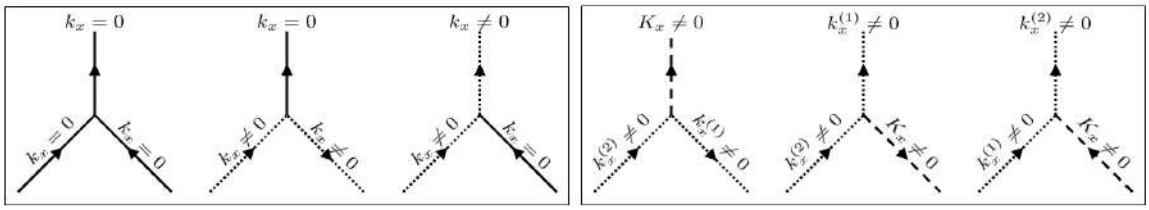

Figure 1: The nonlinear interactions between the streamwise varying ($k_x \neq 0$) modes retained in the RNL (left) and ARNL (both panels). The zero wavenumber ($k_x = 0$) is represented by the solid lines, small non-zero wavenumbers by dashed lines, and large non-zero wavenumbers by dotted lines. The wavenumbers used in the ARNL (right panel) triads are related by $k_x^{(2)} - k_x^{(1)} = K_x$, where K_x is a large-scale non-zero mode and $k_x^{(1)}, k_x^{(2)}$ are small-scale modes. In the ARNL convolution, K_x, $k_x^{(1)}$, and $k_x^{(2)}$ all interact with the zero wavenumber according to the left panel triads.

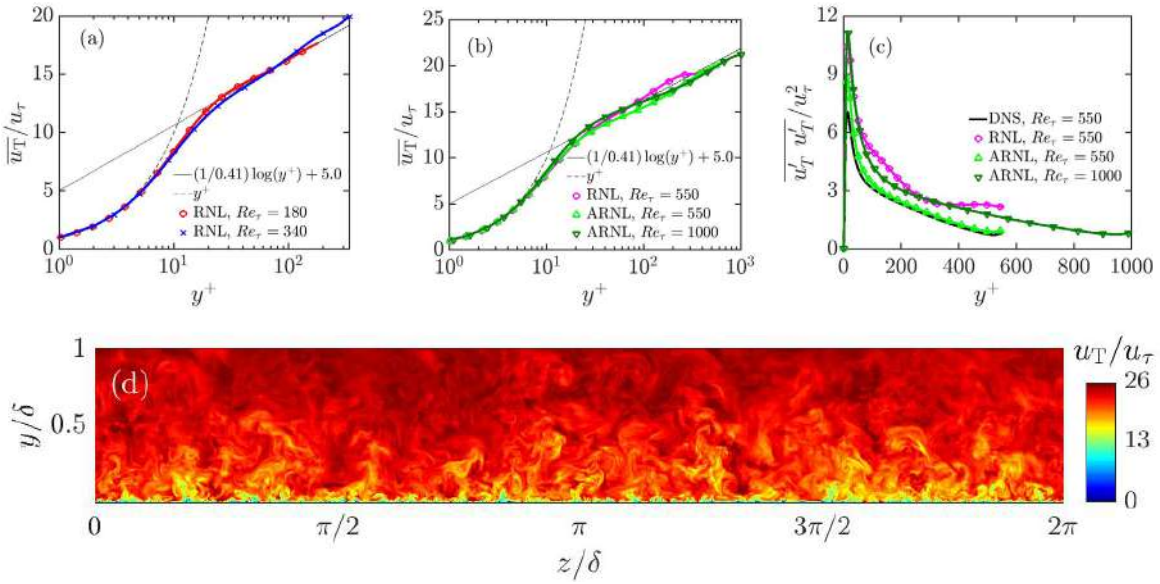

Figure 2: (a) RNL mean velocity profiles at $Re_\tau = 180$ ($k_x\delta = 0, 7$) and $Re_\tau = 340$ ($k_x\delta = 0, 14$). (b) Mean velocity and (c) streamwise Reynolds stress profiles from RNL simulations at $Re_\tau = 550$ ($k_x\delta = 0, 23$), and ARNL simulations at $Re_\tau = 550$ ($k_x\delta = 0, 7, 19.5, 26.5$), and $Re_\tau = 1000$ ($k_x\delta = 0, 7, 38.5, 45.5$). (d) An ARNL cross-plane snapshot at $Re_\tau = 5200$ ($k_x\delta = 0, 7, 214.5, 221.5$).

RESULTS

We consider a half-channel flow configuration of size $[L_x, L_y, L_z]/\delta = [4\pi, 1, 2\pi]$ with no-slip and stress-free boundary conditions imposed on the bottom ($y = 0$) and top ($y = \delta$) walls respectively, and periodic boundary conditions in the streamwise and spanwise directions. The RNL equations are solved using a modified version of the open source code LESGO (https://lesgo.me.jhu.edu) where wall-normal derivatives are discretized using second-order central finite differencing, and Fourier transforms de-aliased by the 3/2 rule are applied in the streamwise and spanwise directions. The temporal derivative is treated using the second-order Adams-Bashforth method.

The restriction placed on the RNL and ARNL dynamics significantly reduces perturbation-perturbation interactions between streamwise modes as shown in Figure 1. These limited interactions naturally permit simulating the governing equations in the streamwise Fourier space (k_x, y, z, t) where the simplified nonlinear term is treated as a convolution rather than performing a transformation to physical space, as is traditionally done. This framework is not only computationally efficient but also allows prescribes structures, represented as Fourier modes, to be isolated. In this manner, the dynamics of streamwise structures and their interactions can be readily studied, see [6] for further details of this implementation.

Figure 2 demonstrates the accuracy of the RNL mean velocity profiles at $Re_\tau = 180$ and 340 in panel (a), while panel (b) shows the decreased fidelity of the model at $Re_\tau = 550$. Panels (b) and (c) indicate that adding the energetic streamwise mode associated with the half channel height into the large-scale mean dynamics of the ARNL improves the low-order statistics at this Reynolds number and that they continue to be well represented at $Re_\tau = 1000$. Panel (d) provides a cross-plane snapshot of the instantaneous streamwise velocity of ARNL turbulence at $Re_\tau = 5200$, where the scale interactions typical of high Reynolds number wall-bounded turbulence are shown to be captured in this reduced order model. The computational savings of the ARNL simulations versus direct numerical simulations (DNS) represent a speed up by a factor of 26 at $Re_\tau = 550$, which increases to 200 at $Re_\tau = 5200$.

CONCLUSIONS

The ARNL modeling framework reproduces low-order statistics and structural features of high Reynolds number wall-bounded turbulence at vastly reduced computational cost over DNS. Ongoing work to better understand the required range of scale interactions will determine the full potential of the ARNL investigations of high Reynolds number flows.

EXPERIMENTS AND MODELLING OF SYNTHETIC JETS IN CROSS-FLOW

Bharathram Ganapathisubramani * [1], Girish Jankee[1], and Tim Berk[1]
[1] University of Southampton, UK

Summary The interaction between a synthetic jet actuator and a turbulent boundary layer is critically important in a variety of flow control applications. The ability to predict the trajectory of the jet in the presence of the cross flow will enable us to design flow control techniques for efficient and targeted usage of such actuators. In this investigation, we examine the effects of a synthetic jet issued into a crossflow from rectangular orifices through PIV and hot-wire measurements. Experiments are carried out over a large range of Reynolds numbers, jet exit geometries, frequencies and velocity ratios. An assessment of the trajectories obtained from experimental data results in identification of relevant non-dimensional numbers, the velocity ratio, momentum ratio and the Strouhal number, that dictate the behaviour of this interaction. There trajectories can be modelled using data-driven vortex models where the strength of the vortices are derived from data.

INTRODUCTION

Jets in crossflow have attracted considerable interest over the past decades with singular emphasis on flow control applications as they involve interaction of a jet with an incoming boundary layer. Knowledge of the jet trajectory is of paramount importance as it describes the depth of penetration as well as the streamwise range over which the actuator can be considered as effective. Jet trajectory can be computed using various parameters which include the positions of local velocity maxima, local scalar maxima, vorticity maxima or time-averaged streamline originating at the jet exit [1]. In this study, we focus on synthetic jet actuators and compute the trajectory based on the location of maximum velocity deficit.

The trajectory is commonly described using a power law:

$$\frac{y/D}{g(...)} = B(\frac{x/D}{g(...)})^n, \tag{1}$$

where y is the wall-normal trajectory (m), x is the streamwise location (m), D is the corresponding orifice dimension (m), $g(...)$ represents non-dimensional scaling factors and B and n are constants.

For steady jets, various scalings for $g(...)$ have been put forward and demonstrate that the jet trajectory depends on the velocity ratio and the diameter of the orifice [2, 3, 4]. However, [1] provides evidence that rd is not sufficient to scale such a wide range of data. Considerable variations in jet trajectories were observed, even for similar velocity ratios. This highlights that the velocity ratio and the orifice dimensions are not sufficient to completely describe the trajectory. Rather, it is important to account for the distribution of momentum in the jet and in the incoming boundary layer [5]. Additionally, synthetic jets are characterised by the forcing frequency which can take the form of a Strouhal number. However, there exists a certain level of ambiguity concerning the exact form of this Strouhal number. It is hypothesised that the Strouhal number could be either a function of the outer units of the boundary layer, the inner units of the boundary layer or the passing frequency of the crossflow over the jet [6]. In this study, we define a momentum ratio which uses the orifice dimensions and the momentum thickness of the boundary layer:

$$\mu = \frac{\rho \bar{U}^2 dl}{\rho U_\infty^2 d\theta} = r^2 \frac{l}{\theta} \tag{2}$$

where $\bar{U}$ is the jet exit velocity, U_∞ is the freestream velocity, l is the length of the orifice, d is the width of the orifice and θ is the momentum thickness of the boundary layer. In this study is to identify the parameters considered important for describing the synthetic jet trajectory in crossflow and determine the appropriate scaling factors. The investigation also considers constraints associated with the use of a single scaling law to describe the complete trajectory. These involve the interaction of vortical structures and the near field and far field regions of the flowfield. Finally, we examine the utility of vortex-based models in determining the trajectory of these flows with information about the strength/size of the vortices determined from experimental measurements.

EXPERIMENTAL SETUP

The study consisted of 2 experiments. High Reynolds number experiments were performed in the high-Reynolds-number boundary layer wind tunnel (HRNBLWT) at the University of Melbourne. A rectangular orifice with an aspect ratio of 13 was used and the actuator was operated over a range of frequencies between 60 and 400 Hz while the freestream velocity was varied between 10 and 25 m/s. Hot wire anemometry was used for velocity measurements from which the jet trajectories were derived. Experiments at lower Reynolds numbers were carried out in a 3 x 2 ft suction wind tunnel facility at the University of Southampton. Orifices with aspect ratios 3, 6 and 12 were tested between 100 and 600 Hz and velocity ratios of 0.25, 0.5 and 1.0. The freestream velocity was kept constant at 8 m/s. Planar- and stereo-PIV measurements were performed to capture the flowfield.

*Corresponding author. E-mail: G.Bharath@soton.ac.uk

RESULTS

Initial results demonstrated that the trajectory of a synthetic jet cannot be determined using a single scaling law. Rather, it is possible to categorise the flowfield of a synthetic jet and obtain appropriate scaling laws for each class by considering constraints such as vortex interaction, the near field behaviour, dominated by the synthetic jet or the far field behaviour which is defined by the crossflow properties.

There has been numerous attempts to define what constitutes the near-field or the far-field regions. Although [4] suggested a far-field definition of $x/r^2D > 0.3$, the threshold between the near-field and far-field behaviour still remains ambiguous. [7] defined a far field limited by $x \gg \sqrt{\pi D^2 4}$. However, application of this definition to the current datasets led to inconclusive results and a more adequate definition was needed, specifically for synthetic jet actuators. Using the gradient of the trajectory and the convergence of the fitting coefficients, the near field is found to occur when the jet is at an angle greater than 17° and the far-field region is defined by a jet angle less than 14° with the transition region lying in between. The following equation was subsequently derived for the streamwise location corresponding to the far-field:

$$\frac{x_{thresh}}{\delta} = 1.75\left(\frac{U_j}{U_\infty}\right)^{0.5}\left(\frac{fl}{U_j}\right)^{0.1}\left(\frac{l}{\delta}\right)^{0.4} \tag{3}$$

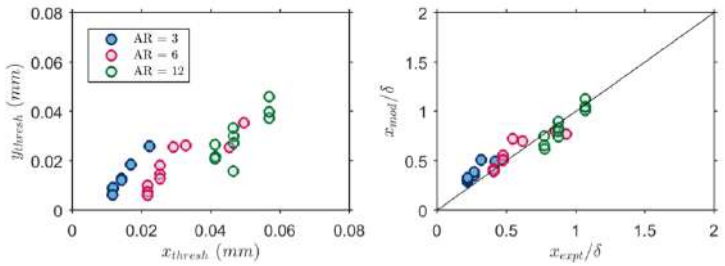

Figure 1: Left subplot shows the streamwise threshold values delimiting the far-field region for all the test cases. Right subplot compares the normalised experimental threshold values against the values derived from the model.

Application of the above-defined constraints leads to the emergence of four categories of synthetic jet behaviour, governed by different combinations of Strouhal numbers, velocity ratios and momentum ratios. In the presence of vortex interaction, in the near-field, the only parameters that are important are the velocity ratio and the jet-based Strouhal number ($St = fl/U_j$). In the far-field, together with the momentum ratio, it is observed that the Strouhal number now depends on the boundary layer thickness and the freestream velocity ($St = f\delta/U_\infty$). When there is no vortex interaction, the near field depends only on the velocity ratio and the crossflow-based Strouhal number while the far field trajectory is determined by a combination of the velocity ratio and the momentum ratio with the Strouhal number not significant. The talk will cover these and other aspects in greater detail.

NETWORK-BASED RESOLVENT ANALYSIS FOR MODIFICATION OF ISOTROPIC TURBULENCE

Chi-An Yeh*[1], Muralikrishnan Gopalakrishnan Meena[1], and Kunihiko Taira[1]
[1] Department of Mechanical and Aerospace Engineering, University of California, Los Angeles, U.S.A.

Summary We present a network-based resolvent analysis that identifies the key dynamical paths along which perturbations amplify in a time-evolving isotropic turbulent flow. This formulation is built upon the Katz centrality, which reveals the flow structures that can effectively spread perturbations over a time-evolving network of vortical elements. Moreover, due to the resolvent form of the Katz function, we take the SVD of the resulting communicability matrix, complementing the resolvent analysis for fluid flows. The left-singular vector, or broadcast mode, gives insights into the hot spots from which perturbations can be effectively spread over the entire fluid-flow network when it evolves in time. This broadcasting structure infers that the opposite-sign vortex pairs, acting like local 'jets,' are the important structures in spreading perturbations. We observe that the forcing based on the broadcasting mode obtained from the longer time-horizon is more effective in modifying the evolution of the isotropic turbulence than that from the shorter time-horizon.

INTRODUCTION

Identifying structures that are significant in changing the dynamical evolution of a turbulent flow has been an important yet challenging task in fluid mechanics. A recent study by Jiménez [1] aimed to identify these structures as sub-volumes in 2D isotropic turbulence by blanking out sets of sub-volumes and tracking the change of the flow field evolution from that of the unperturbed flow. The sub-volumes that are flagged as significant structures contain strong vortices, rendering high levels of modification in turbulence evolution when these sub-volumes are blanked out.

Our goal is to identify these structures in 2D isotropic turbulence [2] using the modern toolsets of resolvent and network analyses. Resolvent analysis for fluid flows can be traced back to Trefethen et al. [3] and has been extended to turbulent flows by McKeon & Sharma [4]. Network analysis has demonstrated its strength in providing insights into the interactions amongst flow structures [2, 5, 6]. In this study, we seek a formulation that combines these two toolsets to identify the significant structures for modifying time-evolving 2D isotropic turbulence.

APPROACH

Network-based modeling of vortical interactions

We model the interaction dynamics of isotropic turbulence by a time-evolving network of vortical elements. In the turbulent flow field, the vorticity at each Eulerian grid point is treated as a vortical element, which constitutes a vertex of the network. The interactions between the vertices, or vortical elements, form the edges of the network. According to these interactions we construct the adjacency matrix $\boldsymbol{A} \in \mathbb{R}^{n\times n}$, where n is the number of Eulerian grid points and each edge-strength element a_{ij} in $\boldsymbol{A}$ quantifies vertex j's influence on vertex i.

The edge strength is defined in two manners. The first one is based on the induced velocity magnitude at i by j according to Biot–Savart's law and defines $a_{ij} = \omega_j \Delta s/2\pi|\boldsymbol{x}_i - \boldsymbol{x}_j|$, where Δs is the area of the cell. The second definition considers the perturbation perceived at $\boldsymbol{x}_i$ when a spatial vorticity pulse is introduced at $\boldsymbol{x}_j$ as $a_{ij} = |\,[\,\mathcal{N}(\omega + \epsilon\delta(\boldsymbol{x}_j)) - \mathcal{N}(\omega)\,]_i\,|/\epsilon$, according to the right-hand-side of the vorticity transport equation, $\partial_t\omega = \mathcal{N}(\omega)$. In what follows, we refer to the former as B–S (Biot–Savart) network and the latter as the N–S (Navier–Stokes) network. With a snapshot of vorticity field at time t_k, the adjacency matrices $\boldsymbol{A}_k$ can be determined using both definitions.

Katz centrality and network-based resolvent analysis

Network centralities deduced from adjacency matrices give valuable insights into important vertices to seed and broadcast information over the entire network. One of the centrality measures is called the Katz centrality [7]. This centrality can be viewed as a Markov chain process where a distributed piece of information, $\boldsymbol{f} \in \mathbb{R}^n$, is transferred through the vertices of a network by infinite amount of walks. Along each walk, the intensity of the information transferred from vertex j to i is characterized by the edge strength a_{ij} and a walk-downweighting parameter α as $\boldsymbol{q} = (\boldsymbol{I} + \alpha\boldsymbol{A} + \alpha^2\boldsymbol{A}^2 + \cdots)\boldsymbol{f}$. For the fluid-flow network, the information $\boldsymbol{f}$ can be interpreted as a forcing to be spread and amplified globally. Moreover, when α is chosen such that $\alpha < 1/\rho(\boldsymbol{A})$, where $\rho(\boldsymbol{A})$ is the spectral radius of $\boldsymbol{A}$, the infinite series converges as

$$(\boldsymbol{I} + \alpha\boldsymbol{A} + \alpha^2\boldsymbol{A}^2 + \cdots) = (\boldsymbol{I} - \alpha\boldsymbol{A})^{-1}. \tag{1}$$

With this formula, the traditional Katz broadcasting centrality is computed as $b_j = \Sigma_i(\boldsymbol{I} - \alpha\boldsymbol{A})^{-1}$, which quantifies vertex j's capability of broadcasting information to all other vertices in the network.

We note that the Katz function $(\boldsymbol{I} - \alpha\boldsymbol{A})^{-1}$ is in the form of a resolvent matrix of $\boldsymbol{A}$. It is also featured in the input–output process between $\boldsymbol{q}$ and $\boldsymbol{f}$. Therefore, instead of performing the column-sum to compute the broadcasting centrality, we follow the resolvent analysis in fluid flows [3, 4] and take the SVD of the Katz function as

$$(\boldsymbol{I} - \alpha\boldsymbol{A})^{-1} = \boldsymbol{Q}\boldsymbol{\Sigma}\boldsymbol{B}, \tag{2}$$

where we refer the leading right-singular vector $\boldsymbol{b}_1$ as the broadcasting mode. The broadcasting mode also complements the concept of forcing mode in resolvent analysis, as it identifies the most influential vertices, or sensitive regions, that can effectively spread perturbations over the vortical network.

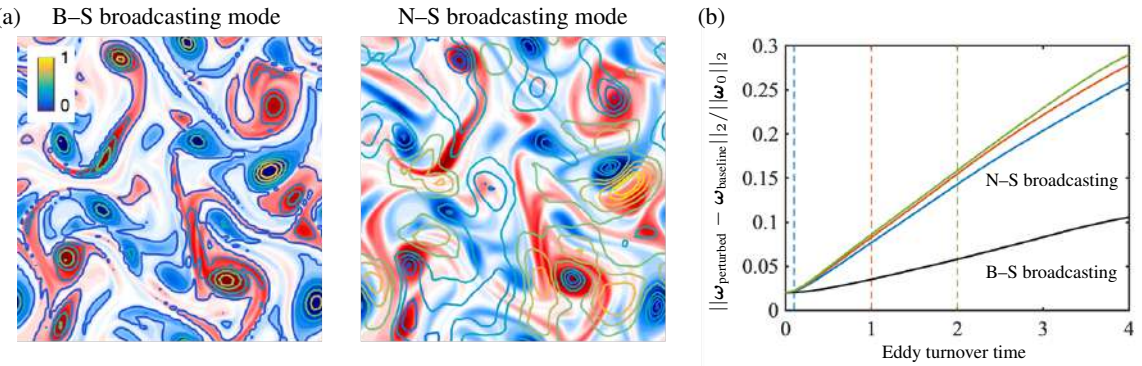

Figure 1: (a) B–S and N–S broadcasting modes (green-yellow contour lines) over the instantaneous vorticity field (blue-red solid contour). (b) Flow modifications using perturbations based on B–S and N–S broadcasting modes. For N–S network, three time-horizons, marked by the same-colored dashed lines, are examined in their influences on the flow modification.

Time-evolving network model

We aim to extract the broadcasting mode that further accounts for the time evolution of the vortical network. In a time-evolving network, the transfer of information over vertices can either kinematically occur in a time-frozen $\boldsymbol{A}$ or due to the time evolving nature of $\boldsymbol{A}$. This propagation of information over the time horizon $t \in [t_0, t_k]$ can be described as

$$\boldsymbol{q}(t_k) = \underbrace{(\boldsymbol{I} + \alpha \boldsymbol{A}_k + \alpha^2 \boldsymbol{A}_k^2 + \cdots)}_{t=t_k} \cdots \underbrace{(\boldsymbol{I} + \alpha \boldsymbol{A}_1 + \alpha^2 \boldsymbol{A}_1^2 + \cdots)}_{t=t_1} \underbrace{(\boldsymbol{I} + \alpha \boldsymbol{A}_0 + \alpha^2 \boldsymbol{A}_0^2 + \cdots)}_{t=t_0} \boldsymbol{f}(t_0), \tag{3}$$

where the identity matrix allows the information to 'stay' at the same vertex at a certain time instant [8]. Note that each infinite series can be further reduced to the associated Katz form. Similar to the walk-downweighting parameter α, we consider the formulation by Grindrod & Higham [9] where an age-downweighting parameter γ is introduced in

$$\boldsymbol{S}_{k+1} = \left[\boldsymbol{I} + e^{-\gamma \Delta t}(\boldsymbol{S}_k - \boldsymbol{I})\right](\boldsymbol{I} - \alpha \boldsymbol{A}_{k+1})^{-\Delta t} \tag{4}$$

to account for the decaying intensity of the information due to its aging in time. The communicability matrix $\boldsymbol{S}_k$ can be recurrently computed over the time horizon of $t \in [t_0, t_k]$. By taking the SVD of $\boldsymbol{S}_k = \boldsymbol{Q}\boldsymbol{\Sigma}\boldsymbol{B}$, we refer the leading right-singular vector $\boldsymbol{b}_1$ as the broadcasting mode for the time-evolving vortical network .

RESULTS

We show the broadcasting modes for the B–S and N–S networks determined for an instantaneous vorticity field in figure 1 (a). The B–S broadcasting mode suggests that the vortex cores, featured by high vorticity, are the regions of high broadcasting efficiency (yellow contour lines) in the 2D turbulence. This observation aligns with that made by Jiménez [1]. The N–S broadcasting mode tells an entirely different story. The volumes of high broadcasting efficiency are found to occupy the regions between opposite-sign vortex pairs. These vortex pairs locally build up highly oriented shear layers and act like local 'jets', which are known to be receptive to perturbations. Meanwhile, the vortex cores are the regions of the lowest broadcasting efficiency.

In the time-evolving network model, we choose the walk- and age-downweighting parameters $\alpha = e^{-\gamma t^*} = e^{-1}$, where t^* is the eddy turnover time at t_0. The broadcasting modes obtained from the time-evolving networks are found to be similar to their kinematic counterparts, highlighting the paths of either vortices or opposite-sign vortex pairs. To explore how these broadcasting modes can be used to target the sensitive regions in the turbulence, we add these broadcasting modes as initial vorticity disturbances, $\boldsymbol{\omega}(t_0) = \boldsymbol{\omega}_0 + \epsilon \boldsymbol{b}_1$, evolve the turbulent flow and track the differences from the unperturbed case in figure 1 (b). We find that the N–S broadcasting mode is more effective in modifying the turbulence, as its formulation is based on perturbation dynamics. Moreover, with the extended time-horizon over which the broadcasting modes are computed, higher levels of flow modification is achieved by the initial disturbances.

CONCLUSIONS

We perform network-based resolvent analysis of 2D isotropic turbulence and seek the broadcasting modes based on the Katz centrality as optimal initial disturbances. While the B–S and N–S broadcasting modes reveal different structures as the sensitive regions in 2D turbulence, the findings are physical intuitive and align with those from literature. The time-evolving network model shows that higher levels of modification can be achieved with the longer time-horizon, providing a framework to analyze time-varying base flows.

TRAVELING-WAVE PROPAGATION IN THE SWEPT LEADING-EDGE BOUNDARY LAYER AT HIGH REYNOLDS NUMBER

Aiko Yakeno *[1] and Shigeru Obayashi[1]
[1] Institute of Fluid Science, Tohoku University, Japan

Summary Transition characteristics around the leading-edge of a swept-back airfoil shape have been investigated numerically. We identified the generation of two coherent modes, i.e., the stationary and traveling waves in the swept direction. The existence of the traveling-wave mode has already been mentioned in previous studies, and we succeeded in observing that propagation through direct numerical simulations (DNS) in a swept-wing shape, at the practically high Reynolds number of $Re_c = 2.0 \times 10^6$ based on the chord length. Additionally, we analyzed the optimal transient-energy growth for the present leading-edge boundary layer. The wavelength of the optimal mode generated in a short-time and traveling in the swept direction corresponds to the results obtained through the DNS.

BACKGROUND

Commercial aircraft often have their main wing swept-back to suppress a shock wave. Around the swept wing, the boundary layer becomes three-dimensional and different types of laminar-turbulence transitions occur. Researchers have focused on studying the occurrence of turbulence, to increase viscous drag and delay transition [1, 2, 3, 4, 5]. Further, regarding the boundary-layer transition, several studies have been conducted both theoretically and experimentally. Most conventional-flow stability analyzes have discussed asymptotic behavior [6, 1]. In recent years, attention has been focused on the temporary energy amplification in finite time and transient growth due to a system's nonorthogonality [7, 8, 9]. Corbett and Bottaro (2001) analyzed the optimal perturbation in the Falkner–Skan–Cooke similarity solution and stated that the highest energy-amplification mode took the form of vortices and almost aligned with the external streamline to evolve streaks. Guegan *et al.* (2006, 2007) investigated the temporal energy growth based on the Görtler–Hämmerlin assumption for the swept Hiemenz flow and confirmed the spanwise traveling chordwise vortices as the most amplified instability mode at large Reynolds numbers. Discussion on the transition scenario is still ongoing, and not many examples exist for the application of the analysis to the actual flow field.

PROBLEM SETTINGS

We numerically investigated flow instabilities to cause a transition in the attachment-line boundary layer of a swept-back airfoil at the practically high Reynolds number of $Re_c = 2.0 \times 10^6$ based on the chord length of the airfoil. A DNS of the three-dimensional compressible Navier–Stokes equations was conducted for the leading-edge region of an airfoil shape, NACA0030, with swept angle $\alpha = 70$ [deg]. The Mach number was set to 0.2 in the present study; it was assumed to be incompressible. The schematic of the swept-back wing model and input flow direction, x, are shown in Fig.1. The original coordinate, (x, y, z), was rotated around the swept wing in the chord-wise, swept, and wall-normal directions, (x^*, y^*, z^*), respectively. The distributed random roughness was set at the wall to excite the flow instability in the swept upstream direction, which covers 20 [%] of the surface in the present study; it was switched on once and retained, similar to a step function. The governing equation was solved using the generalized curvilinear coordinates (ξ, η, ζ). At the ξ direction boundaries, we set a fixed pressure, which was obtained through a two-dimensional full wing computation at the same flow condition. The computational-grid number is $(470, 892, 179)$, in the ξ, η, and ζ directions, respectively, that is, 75 million in total.

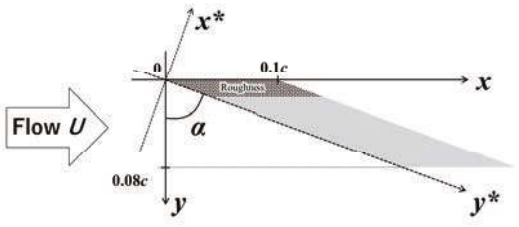

Figure 1: Top view of the swept wing and input flow direction. Distributed roughness is set at the wall in the swept upstream, covering 20 [%] of the surface.

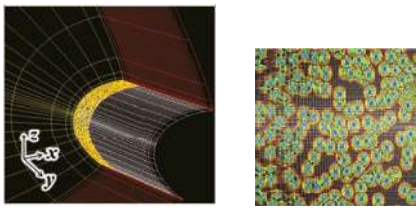

(a) (b)

Figure 2: (a) The grid at every 20 points. White grids represent the wall surface, while red and yellow grids are the boundaries at ξ and η, respectively. Local body force at the wall surface is shown as contour lines. (b) Body force distribution with a grid at every point.

STATIONARY- AND TRAVELING-WAVE PROPAGATIONS

The DNS results identify as many as two unstable modes around a swept wing: steady and traveling downstream. The steady mode is elongated in the external-flow directions, and the traveling mode moves in the sweep direction with a wavelength of approximately $\lambda_{y^*}/c = 0.008$, which is distributed to the upper and lower surfaces of the airfoil around an attachment line. The *two modes coexist*; this answers the question by Guegan *et al.*(2006, 2007) [4, 5] which mode is dominant based on the Görtler–Hämmerlin assumption for the swept Hiemenz flow.

(a) $tU/c = t_0U/c + 2.5$ (b) $tU/c = t_0U/c + 7.5$ (c) $tU/c = t_0U/c + 12.5$

Figure 3: The traveling-wave propagation in the swept leading-edge boundary layer. The isosurface is the second invariant of deformation tensor $Q = 2.5$ with span-wise velocity v of -0.3(red) to 0.3(blue).

OPTIMAL TRANSIENT-ENERGY GROWTH

Next, we analyzed the optimal transient-energy growth for the leading-edge swept boundary layer. The temporal energy growth at target time τ is calculated as

$$G_{rate}(\tau) = E(\tau)/E(0) = \|\boldsymbol{u}'^*(\tau)\|^2 = (\boldsymbol{A}(\tau)\boldsymbol{u}_0'^*, \boldsymbol{A}(\tau)\boldsymbol{u}_0'^*) = (\boldsymbol{u}_0'^*, \bar{\boldsymbol{A}}(\tau)^T\boldsymbol{A}(\tau)\boldsymbol{u}_0'^*), \tag{1}$$

where the energy is defined as the kinetic energy of velocity perturbations, assuming that the flow is incompressible. This is the same as the inner vector with the self-adjoint operator, $\bar{\boldsymbol{A}}^{\boldsymbol{T}}\boldsymbol{A}$. Therefore, the maximum perturbation growth rate of $G_{max}(\tau)$ is described as the maximum eigenvalue of the self-adjoint operator:

$$G_{max}(\tau) \equiv \max_{\|\boldsymbol{u}_0'^*\|=1} E(\tau)/E(0) = \max_j \kappa_j, \quad \bar{\boldsymbol{A}}(\tau)^T\boldsymbol{A}(\tau)\boldsymbol{u}_j'^* = \kappa_j\boldsymbol{u}_j'^*, \quad \|\boldsymbol{u}_j'^*\| = 1. \tag{2}$$

Perturbations are of the following form when we assume periodicity in the swept x^* and chord directions y^*: $\boldsymbol{u}'^*(x^*, y^*, z^*, t) = \hat{\boldsymbol{u}}'^*(z^*, t)\exp(i\alpha x^* + i\beta y^*)$. We obtained initial value $\boldsymbol{u}_0'^*$ for the most amplified energy at each target time. The program code was validated by comparison with references ([7, 10]).

The energy growth for each target time are shown in Fig. 4. Two groups were realized: the short-time transient growth ($0.02 \leqq \tau U/c \leqq 0.08$) and the long-time exponential growth ($0.1 \leqq \tau U/c$); the optimal modes are $0.006 \leqq \lambda_{y*}/c \leqq 0.02$ and $\lambda_{y*}/c \approx 0.03$, respectively. Although G_{max} of the long-time exponential growth is much larger than that of short-time growth, its amplification takes significant time. In the short-time growth, the modes of $0.006 \leqq \lambda_{y*}/c \leqq 0.02$ grow much larger than that of $\lambda_{y*}/c \approx 0.03$, and the short-time optimal wavelength corresponds to the DNS results, $\lambda_{y*}/c \approx 0.008$. Therefore, we conclude that the traveling-wave generation in the present attachment-line boundary layer is strongly related to the short-time transient energy growth of the nonorthogonal basis.

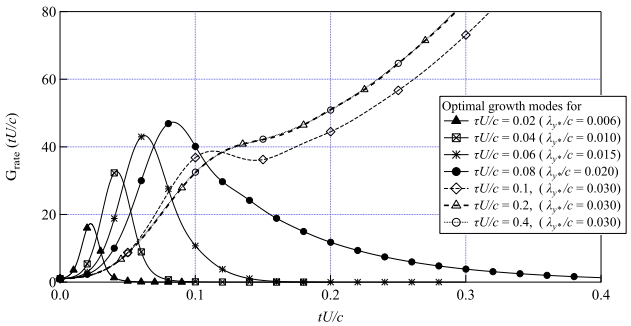

Figure 4: $G_{rate}(tU/c)$ of the short- and long-time optimal growth for each target times $\tau U/c$.

FLOW-INDUCED MOTION OF A SINGLE BEAD AT SMALL SUPERCRITICAL SHIELDS NUMBERS

N. Topic[1], J. R. Agudo[1,2], G. Luzi[3], and A. Wierschem[1,3]
[1] Institute of Fluid Mechanics, Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Erlangen,Germany
[2] Anton Paar Germany GmbH, Ostfildern, Germany
[3] LSTME Busan Branch, Busan, Republic of Korea

Summary We study the flow-induced motion of a single bead on regular substrates made of spherical particles at small particle Reynolds numbers. At near supercritical Shields numbers, the bead moves along the substrate. The average bead velocity increased approximately linearly with the Shields number and decreased as the spacing between substrate particles increases. We develop a model to describe the experimental findings. It shows good agreement with the experimental results and allows a collapse of the experimental data onto a master curve.

INTRODUCTION

Prediction of particle motion is important in a wide variety of industrial and natural processes like cleaning of surfaces, assembling of particles, conveying as well as sediment transport in rivers, granular beds erosion and dune formation [1]-[6]. Given its wide range of applications, onset of particle motion has been studied intensively during the last century. There have been many approaches to study flow induced particle motion at surfaces and in bedload transport, see e.g. [7] and references therein. Studying flow-induced motion of beads on regularly arranged monolayers of spheres as substrates, we found a strong impact of the substrate geometry on the incipient motion [1]-[3]. We proposed a model that takes into account the substrate geometry. It covers the entire range of angles of repose [3] and of size ratios between mobile beads and substrate spheres [6]. Although our study focusses on small particle Reynolds numbers, we remark that even in high Reynolds number flows, the particle Reynolds numbers may be of order one or smaller [7]. The particle motion is typically characterized by rolling, sliding, and bouncing [9], [10]. Here, we extend our study to the particle motion at small supercritical Shields numbers.

SYSTEM

We consider a single sphere of diameter D_P and density ρ_S deposited on a regular substrate and exposed to a steady shear flow (see Figure 1) with shear rate $\dot{\gamma}$ of a viscous incompressible Newtonian fluid of constant density ρ and kinematic viscosity ν. The substrate consists of a layer of fixed spheres of same size that are regularly arranged in quadratic configurations. In experiments, the spacing was achieved using sieves of different mesh size [1], [2], [6]. It has been shown that the shear flow penetrates slightly into the substrate [10]-[12]. Extrapolating the linear shear flow results in an effective zero level z_0 below substrate protrusions [3], [6].

We study the system at particle Reynolds numbers of about 1 and smaller, where the particle Reynolds number is given by $\mathrm{Re}_P = \dot{\gamma} D_P^2 / \nu$. The incipient motion is characterized by the critical Shields number θ_C, which compares the characteristic shear force acting on the particle to the resistant specific particle weight that retains the particle in its place. The Shields number is defined by $\theta = \nu\dot{\gamma} / \left[(\rho_S / \rho - 1) g D_P\right]$, where g is the acceleration of gravity.

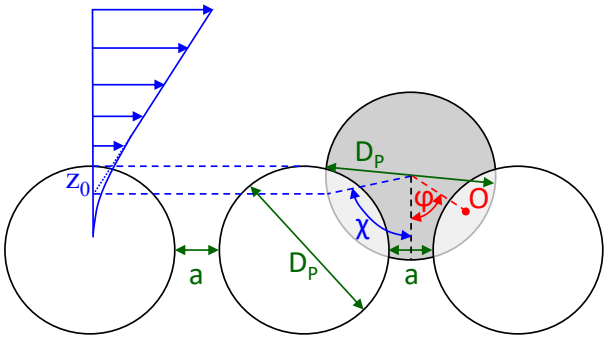

Figure 1. Sketch of the system: Single bead resting on a quadratic substrate exposed to a shear flow. D_P: particle diameter; a: substrate spacing; z_0: effective zero level below the top of the substrate; O: downstream contact point between mobile bead and substrate; ϕ: angle of repose; χ: angle between bead surface at effective zero level and vertical axis.

RESULTS

Beyond the critical Shields number, the bead leaves its equilibrium position in the substrate pocket and rolls along the substrate, slowly uphill and faster downhill. Figure 2(a) shows an experimental example at small supercritical Shields number. At larger Shields numbers, the modulation of the velocity diminishes. At the particle Reynolds numbers considered, the bead achieves a constant mean equilibrium velocity in the early stage of its motion. As the spacing between the substrate spheres increases, the mobile bead is located deeper in substrate. It has to climb steeper slopes and is stronger

shielded from the shear flow. This results in lower average velocities. Figure 2(b) shows this as a result of our model, where we scaled the average velocity with the settling velocity.

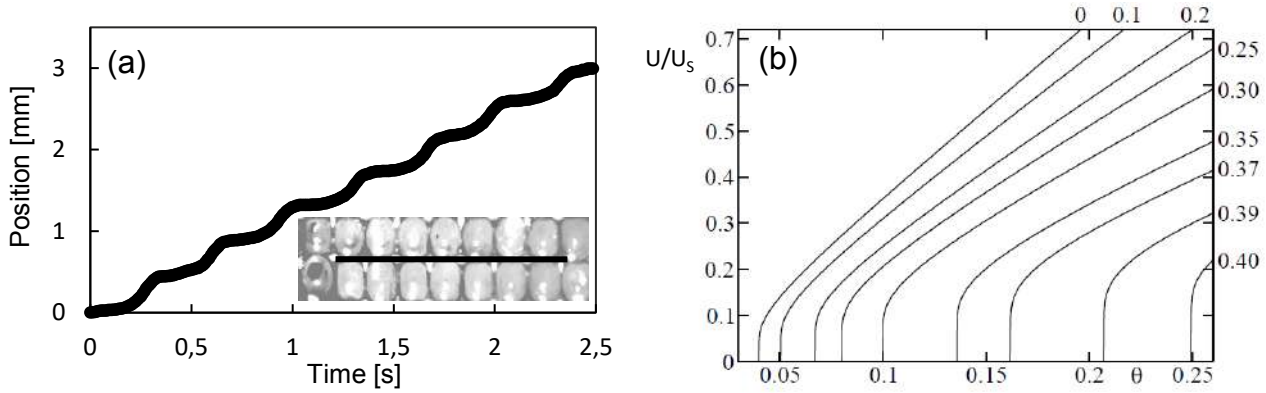

Figure 2. Experimental particle position during its motion along 7 substrate pockets on the quadratic substrate at $\theta/\theta_C = 1.3$ (a) and result of the model for the average bead velocity for different spacings a/D_P as a function of the Shields number (b). The respective values for a/D_P in (b) are printed at the end of the curves. The inset in (a) shows a top view of the path along the substrate; particle diameter: 0.4 mm.

To describe the experimental findings, we develop a model based on expressions for the forces and torques acting on the moving bead near a wall. Our model for the supercritical motion is an extension of the analytical description for the critical Shields number [3], [6]. It provides a quantitative description of the experimental results for the bead motion and allows a collapse of the experimental data onto a single curve. It also provides a threshold for detachment of the bead from the substrate.

CONCLUSIONS

At small supercritical Shields numbers, a bead exposed to the steady shear flow rolls along the substrates. Its velocity depends on the substrate geometry. It is modulated due to the local slope. The average bead velocity appears to be a linear function of the Shields number for all substrates studied. The slope of the curve and intercept depend on the substrate geometry. Our model recovers the experimental findings. It shows good quantitative agreement with the experimental results and allows a collapse of the experimental data onto a master curve. The master curve permits to forecast the bead velocity according to the sediment bed topography at low particle Reynolds numbers.

STRUCTURE OF CONTROLLED FLOW SEPARATION

Curtis J. Peterson[1], Bojan Vukasinovic *[1], and Ari Glezer [1]

[1] Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA 30332-0405, USA

Summary Natural separation of turbulent flow by an adverse pressure gradient along a diverging surface within a duct is delayed using a spanwise array of surface-integrated fluidically-oscillating jets. The interaction of the jets with the local cross flow leads to the formation of a spanwise array of counter-rotating streamwise vortex pairs that are characterized by alternating induced downwash and upwash flows along the jet centerlines and between adjacent jets, respectively. The presence of the vortices delays separation proportionally to the magnitude of the actuation. In the presence of actuation induced vortices, the attached flow exhibits nominally spanwise-periodic turbulent structure in which enhanced turbulent kinetic energy as well as turbulent production and dissipation are coupled to the induced upwash and appear to be suppressed within the downwash domains.

The present experimental study focuses on the streamwise evolution of a surface vorticity layer that separates in an adverse streamwise pressure gradient along a diverging surface within a duct as flow attachment is incrementally extended by fluidic actuation of increasing intensity. Of particular interest is the spanwise structure of the attached flow in the presence of actuation with emphasis on the turbulent characteristics. The experiments are conducted within an open-return, subsonic wind tunnel with a square test section ($H = W = 127$ mm, and length $L = 660$ mm) implemented with a spanwise-uniform converging-diverging insert along the surface of the bottom wall (Figure 1a). The maximum cross stream protrusion of the insert is $H' = 17.6$ mm, and the Mach number at the upstream entrance of the test section is $M_o = 0.25$. The diverging insert contour is based on the suction surface of a VR-12 airfoil ($c = 62.2$ mm) at $\alpha = 13^o$, and a trip wire having diameter $d \approx 0.007c$ is placed upstream of the insert's apex at $x/c = 4.8$. Flow control actuation is effected using a spanwise array of 17 laterally oscillating fluidic actuator jets issuing nearly tangentially to the surface 7 mm apart at $x/c = 5.1$ and having rectangular orifices that measure 0.5 × 1 mm in the cross stream and spanwise directions, respectively (Peterson et al., 2019, Figure 1b). The jet thrust J is measured independently and is used to compute the jet momentum coefficient $C_\mu = J/(\rho_o A_o U_o^2)$. The cross-stream flow structure at multiple spanwise y-z planes is investigated using stereoscopic particle image velocimetry (SPIV) for which the CCD imagers are arranged as shown in Figure 1b and are traversed in the streamwise direction along with the laser sheet optics.

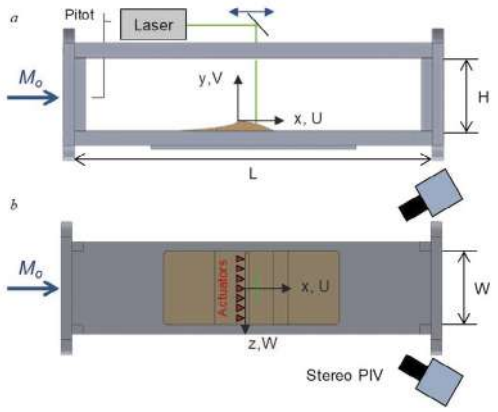

Figure 1. Side (a) and top (b) views of the flow insert in the bottom surface and the SPIV cameras and the laser sheet. The coordinate system is centered at the protrusion's apex.

The time-averaged flow over the ramp was investigated by Peterson et al. (2019) with emphasis on the characteristic features of separation and reattachment within a closed recirculation bubble. The flow structure ($M_o = 0.25$) is depicted in Figure 2 using raster plots of the time-averaged spanwise vorticity (overlaid with velocity vectors, 2a, c) and of the corresponding turbulent kinetic energy (TKE) (2b, d) in the absence (2a, b) and presence (2c, d) of actuation. In the absence of actuation (Figures 2a and b), the time-averaged flow exhibits the formation of a closed recirculating bubble that is bounded from above by a separating shear layer that originates at $x/c \approx 5.2$ downstream of the apex and its streamwise mixing and entrainment lead to cross stream spreading and transport of the spanwise vorticity and the formation of a hierarchy of vortical structures of decreasing scale as marked by TKE concentrations. The flow becomes reattached near the downstream edge of the field of view ($x/c \approx 6.4$), and the attached flow is characterized by a thick surface vorticity layer owing to separation. When C_μ is increased beyond some threshold, separation is streamwise-delayed progressively, and the respective length and width of the recirculating flow domain and the bounding vorticity layer diminish. When $C_\mu = 2.1 \cdot 10^{-3}$, the time-averaged flow becomes fully attached (Figures 2c and d) throughout the aft flow domain with significantly thinner surface vorticity layer that is characterized by much reduced TKE.

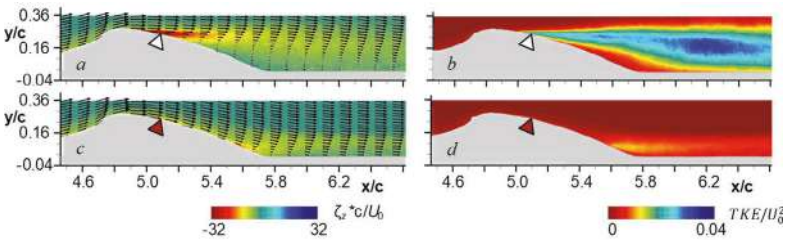

Figure 2. Color raster plots of (a, c) the time-averaged spanwise vorticity (overlaid with velocity vectors) and (b, d) the turbulent kinetic energy in the absence (a, b) and presence (c, d) of actuation: $M_o = 0.25$, $C_\mu = 2.1 \cdot 10^{-3}$.

*Corresponding author. E-mail: bojan.vukasinovic@me.gatech.edu

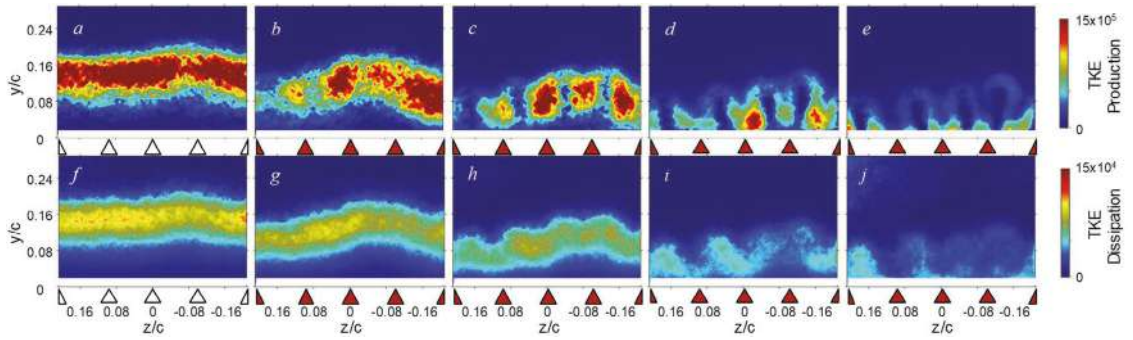

Figure 3. Color raster plots of turbulent production (a-e) and dissipation (f-j) in the absence (a, f) and presence (b-e, g-j) of actuation at the *y*-*z* plane $x/c = 5.72$ for $C_\mu \cdot 10^3 = 0.36$ (b, g), 0.96 (c, h), 1.5 (d, i), 2.1 (e, j). The respective spanwise positions of the inactive and active actuation jets are marked by white and red triangles.

The interaction of the actuation jets with the cross flow is assessed from stereo PIV (cf., Figure 1) measurements in the *y*-*z* plane at the streamwise location of separation in the absence of actuation ($x/c = 5.72$). The evolution of rates of turbulent production $-\langle u_i u_j \rangle \overline{S_{ij}}$ and dissipation $2\nu\langle s_{ij} s_{ij} \rangle$ with increasing levels of actuation $0 < C_\mu \cdot 10^3 < 2.1$ is shown using color raster plots in Figure 3 (since earlier measurements in the *y*-*x* plane indicated weak dependence on *x*, these estimates omit the variation with respect to *x*). As expected, Figures 3a and f show that the turbulent production and dissipation in the base flow are reasonably spanwise-uniform, peak within the separating shear layer and diminish precipitously towards the surface. The most salient features of the distributions of the turbulent production (b-e) in the presence of actuation is the formation of spanwise–regular concentrations that are roughly aligned with the centers of the actuation jets (marked by triangles in Figure 3) and move closer to the surface and weaken as the actuation level increases and the flow becomes more attached. It is noteworthy that as the flow becomes fully attached ($C_\mu = 2.1\ 10^{-3}$, Figure 3e), the production levels form discrete spanwise-periodic 'halo' patterns between the centers of the jets. As discussed in connection with Figure 4, these concentrations are associated with the formation of a spanwise array of alternating counter-rotating streamwise vortex pairs between adjacent actuation jets that are formed within the separating vorticity layer and are advected towards the surface as the actuation level is increased. The corresponding distributions of the dissipation show the evolution of higher concentrations between adjacent actuation jets that are nominally aligned with the centerlines of the vortex pairs and weaken as the flow becomes attached.

Spanwise alternating streamwise vortices that are induced by adjacent actuation jets are shown in Figure 4 along with the corresponding concentrations of TKE and turbulence production and dissipation. As noted in connection with Figure 3, jet actuation leads to the formation of a spanwise array of counter-rotating vortex pairs on each side of the jet orifice. The sense of these vortices is such that the induced vertical flow in the *y*-*z* plane is downwelling and upwelling along the center of and between adjacent jets, respectively (shown schematically in Figure 4). The downwelling flow along actuators' centerlines results in advection of entrainment of fluid from the high-speed side of the separating shear layer (cf., Figure 2a) and low-speed fluid from the near-wall region. The advection of the high-speed, low-turbulence fluid is marked by low TKE concentration above the jet centerline (Figure 5b) while the spanwise transport of low-speed fluid and its upwelling between the counter-rotating vortices results in halo-like concentrations between the jets. Figure 4c show shat turbulent production is primarily concentrated along the surface below and within the cores of the vortices, while dissipation (Figure 4d) is primarily associated with opposite spanwise motions at their upper edges coupled with shear with the higher speed streamwise flow above. The present investigations indicate that the actuation induced streamwise vortices within the nominally 2-D separating shear layer and their interactions with the layer's spanwise vortices result in enhanced entrainment from its low-speed side and thereby lead to gradual re-attachment of the surface vorticity layer that is able to overcome the increase in adverse streamwise pressure gradient.

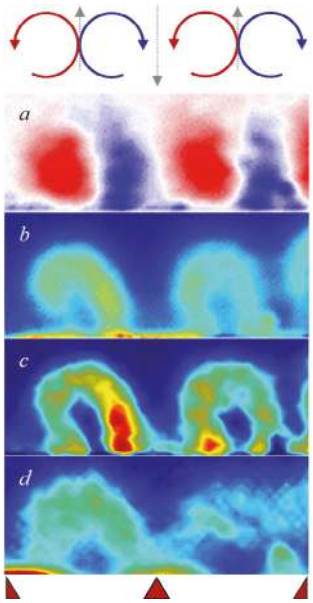

Figure 4. Color raster plots composite of the streamwise vorticity (*a*), TKE (*b*) and turbulent production (*c*) and dissipation (*d*) induced by neighboring actuation jets (marked by triangles) for $C_\mu = 1.5 \cdot 10^3$ at $x/c = 5.54$. The sense of rotation of the streamwise vortices is shown schematically at the top.

CONTROL OF JET MIXING USING DEEP REINFORCEMENT LEARNING

Koichi Tsujimoto[1] and Tsubasa Tanoue[1]
[1] Division of Mechanical Engineering, Graduate School of Engineering, Mie University, Tsu, Mie, Japan

Summary In order to develop a new jet mixing procedure, we explore the possibility of DRL (deep reinforcement learning). First, we conduct some cases of open-loop control in which a main jet is manipulated by a pair of sub jet being actuated at the inlet of main jet, and examine the effect of actuating frequency on the mixing performance of main jet. Then, we select a DDPG (deep deterministic policy gradient) scheme among of the present DRL schemes, and apply it to the above-mentioned jet control problem. Compared the the results of DDPG with that of OLC (open-loop control), the DDPG scheme turns out the useful performance of jet mixing control, $i.e.$,both the entrainment of fluid from surroundings and statistical entropy are enhanced through the DRL while the main jet behaves like a flapping jet.

NUMERICAL PROCEDURE

Active flow control

The flow is assumed to be incompressible. Thus, the governing equations are the continuity and momentum equations. The Cartesian coordinate system is employed. Computational conditions such as the size of the computational domain, and Reynolds number are $(H_x, H_y) = (16D, 20D)$, where D is the nozzle diameter, Re = 100 , respectively. The spatial discretization involves a sine or cosine series expansion in the x direction and sixth-order compact scheme in the streamwise direction. Figure 1 is schematic drawing of the flow field. The inlet velocity distribution is assumed to be top-hat type. As well as the reference[1] a main jet is manipulated by a pair of sub jet being actuated at the inlet of main jet. Each sub jet is driven in opposite phase. In order to evaluate the results obtained by DRL, OLC (open loop control) is performed in which the sub jet is driven with a sine wave ($u_1 = -u_2 = u_0 sin(\omega t)$, ω: angular velocity).

DRL (deep reinforcement learning)

In reinforcement learning, learning is conducted with combining the concepts of environment (state), action, and reward. That is, under a certain environment, an action is selected based on a policy, and a state and a reward are obtained. The environment changes state due to action and rewards are immediately determined. It then finds a policy that maximizes rewards. In this study, such concepts are connected to the actual jet mixing control as follows; the action: the blowing of the sub jet at every moment, the policy: how to drive the sub jet, the state: the velocity of the main jet at monitoring locations and the reward: the entrainment due to the main jet. Although there are some proposals for the DRL scheme, DDPG (deterministic policy gradient) [2] is adopted because it is capable of dealing with continuous action such as blowing from sub jet. As shown in Fig, 2, DDPG consists of two networks, the critic network and the actor network, which promote learning while complementing each other. The distance between the sub jet and the location where mixing occurs are far apart. Therefore, there is a time lag between the state at the observation point and the action. In this study, the problem of time lag is solved by arranging multiple observation points at the downstream position. Specifically, a total of 20 observation points were arranged at a distance of 2D toward the downstream.

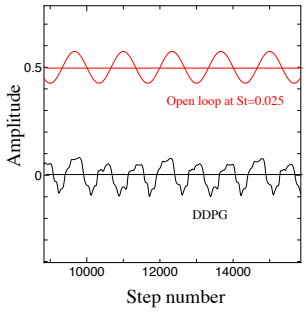

Figure 5. Amplitude of actuator input

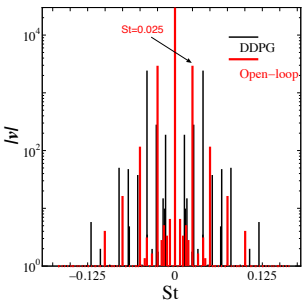

Figure 6. Frequency Characteristics with DMD

RESULTS

Entrainment of the surrounding fluid due to the main jet has been one of the measure of mixing performance. Figure 3 (a) shows the distribution of the entrainment E_{mean}. The red line in the figure is the result of OLC, and the black line is the value obtained by DRL. In the OLC, a peak appears at a low control frequency. In the literature[1], the same OLC is conducted, and St = 0.03 was shown as the optimal St number. This values is almost consistent with the results obtained in this OLC. At the same time, the value obtained by DRL is almost the same as the optimum value in the OLCs. Thus it reveals that the sufficient mixing performance is realized with the DRL. As another mixing meaure, Everson et al. [3] proposed a statistical entropy based on scalar concentration, and we verified this mixing measure based on the DNS data of active controlled jet[4]. Figure 3 (b) shows the distribution of statistical entropy. Similar to entrainment, the statistical entropy of the OLC is highest at St = 0.025, and the DRL shows higher mixing performance than that of OLC. Figure. 4 shows the instantaneous velocity vector field obtained by the DRL. Although the OLC induces the flapping jets due to the sub jets as shown in the literature[1], even in the DRL, the qualitatively similar structures are formed. Figure 5 shows the input waveform of the sub jet. In the case of OLC at St = 0.025, the waveform becomes a given sine waveform, while the distorted waveform is quasi-periodically generated in the DRL. We analyze the difference of the waveform using DMD (dynamic mode decomposition) method [5] which is easily capable of extracting the temporally periodic mode. Figure 6 shows the frequency characteristics. In the case of OLC at St = 0.025, first peak occurs at the control frequency, and second and third peaks occur at integer multiples of the first peak. On the other hand, in the DRL, the first peak has a higher frequency than the first peak of OLC, but the second and third peaks occur at lower frequencies than the primary frequency of OLC. Thus, unlike the OLC, obviously different frequencies are mixed in the DRL.

CONCLUSION

As a result of active control of jet mixing by open-loop control and DRL, there is an optimal control frequency at low frequency in OLC; the DRL results in the distorted waveforms that cannot be artificially determined. Furthermore, as a result of evaluating the entrainment and the statistical entropy, it was clarified that the DRL can achieve the same or better performance than the optimal mixing control in OLCs. From the jet structure, the mixing of DRL is activated by flapping, similar to that observed in the case of OLC. As a result of the analysis by DMD, the frequency characteristics of DRL show that the mode at the lower frequency is activated than the optimum result in the OLC, which is thought to contribute to the improvement of the mixing performance.

A SPECTRAL POD–GALERKIN REDUCED–ORDER MODEL FOR TURBULENT SHEAR FLOWS

Aaron Towne [1]
[1] Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, USA

Summary Nonlinear reduced-order models for fluid systems are often obtained via Galerkin projection of the Navier-Stokes equations in a spatial inner product onto proper orthogonal decomposition (POD) modes. While popular, this approach has well-documented limitations, especially for turbulent flows. We develop an alternative approach based on a space-time Galerkin projection of the equations onto spectral proper orthogonal decomposition (SPOD) modes. By minimizing errors over a time window of interest, this approach has the potential to outperform and overcome limitations of standard POD-Galerkin models for turbulent shear flows.

INTRODUCTION

The high diensionality of the spatially discretized Navier-Stokes equations needed to simulate turbulent flows has spurred considerable effort to obtain reduced-order models capable of providing accurate approximate solutions at reduced computatinal cost. The most common approach used to obtained nonlinear reduced-order models of the Navier-Stokes equations is Galerkin projection [4]. In this approach, the discretized state vector $\boldsymbol{q}(t)$ is written as a summation of orthogonal spatial modes $\boldsymbol{\phi}_j$, each weighted by a time-varying expansion coefficient $a_j(t)$, i.e.,

$$\boldsymbol{q}(t) = \sum_{j=1}^{N} \boldsymbol{\phi}_j a_j(t). \tag{1}$$

A coupled set of nonlinear ordinary differential equations (ODEs) for the expansion coefficients is obtained by inserting (1) into the governing equations and subsequently projecting the governing equations onto the modes. Finally, a reduced order model is obtained by retaining only a subset of the modes, leading to a smaller set of coupled nonlinear ODEs for the remaining expansion coefficients.

While in general the modes could correspond to any orthogonal basis, they are most often chosen to be proper orthogonal decomposition (POD) modes [5]. A defining property of POD modes is that they optimally reconstruct the flow energy, computed in a spatial norm and averaged over time, for any order of the expansion in (1). However, this gaurentees neither optimality nor accuracy of the POD-Galerkin reduced-order model solution. In general, POD-Galerkin projection suffers from a number of well-known issues [4]. Errors within the approximation accumulate at every time step, leading to solutions that are often accurate only over short temporal horizons. Indeed, POD-Galerkin systems are sometime unstable.

METHOD

To alleviate these issues, several recent studies have proposed the use of various space-time reduced-order modeling approaches [1, 3]. In the present work, we develop a new framework for developing nonlinear reduced-order models based on a space-time Galerkin projection of the governing equations using spectral proper orthogonal decomposition (SPOD) modes [2, 7]. In place of (1), we consider the expansion

$$\boldsymbol{q}(t) = \sum_{j=1}^{N} \boldsymbol{\psi}_j e^{i\omega_j t} b_j. \tag{2}$$

Each SPOD mode $\boldsymbol{\psi}_j$ is associated with a single temporal frequency ω_j. SPOD modes are the solution of a space-time POD optimization problem for stationary flow, and therefore optimally capture the flow energy in a space-time norm [2, 7]. In this sense, they are the natural space-time equivalent of standard spatial POD modes. There exists a complete set of spatially orthogonal modes at each frequency, and the space-time modes $\boldsymbol{\psi}_j e^{i\omega_j t}$ are orthogonal in a space-time inner product. Physically, SPOD modes can be interpreted as coherent structures – portions of the flow that are self-correlated in space and time and uncorrelated with all other modes.

Using the expansion (2) and projecting the equations onto the modes using the space-time inner product leads to a set of coupled algebraic equations for the expansion coefficients b_j, which are time-independent scalars. This space-time projection of the equations naturally minimizes error over the full time window for which the modes are defined, providing a means to control the solution error over a desired time window and prevent the error accumulation and instability typical of POD-Galerkin methods. Additionally, we have developed a SPOD-Petrov-Galerkin variant that optimally captures linear amplification mechanisms with the Navier-Stokes equations.

*Corresponding author. E-mail: towne@umich.edu

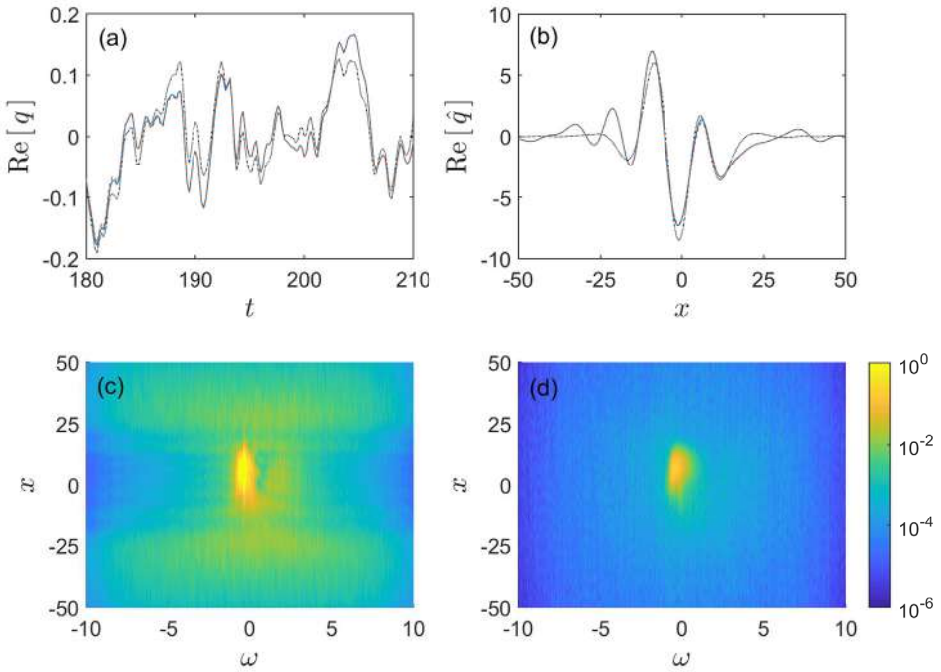

Figure 1: Results for the Ginzburg-Landau problem: (a) Sample time series for true solution (blue solid line), POD-Galerkin model (black dotted line), and SPOD-Galerkin model (dashed orange line); (b) Fourier mode of each solution (lines same as in (a)) at frequency $\omega = 1$; (c-d) PSD of error for the POD-Galerkin and SPOD-Galerkin modes, respectively. In all cases, the SPOD-Galerkin model yields lower error levels.

RESULTS

We demonstrate our method using two example problems. First, we consider the complex Ginzburg-Landau equation subject to random excitation [6]. This produces a simple model that mimics the non-normal energy amplification present in real shear flows and produces quasi-random time series reminiscent of turbulent flow. We construct both POD-Galerkin and SPOD-Galerkin reduced-order models, and choose the order of each model such that they have equal computational cost (i.e., we compare accuracy at fixed cost). Figure 1(a) shows an example time trace produced by the Ginzburg-Landau equation and the two reduced-order models, and Figure 1(b) shows the corresponding Fourier modes at a particular frequency, $\omega = 1$, as a function of the spatial coordinate x. In both cases, the POD-Galerkin solution contains noticeable errors, while the SPOD-Galerkin solution is essential indistinguishable from the true solution. Figure 1(c,d) shows the power spectral density of the error of the POD-Galerkin and SPOD-Galerkin reduced-order models, respectively, as a function of frequency and spatial location. The error for the SPOD-Galerkin model is consistenyly lower, by several orders-of-magnitude over most of the domain. In addition to the Ginzburg-Landau model, the conference presentation will include results for a turbulent channel flow.

CONCLUSIONS

Improved nonlinear reduced-order models are needed to enable low-cost prediction and control of turbulent shear flows. The proposed space-time SPOD-Galerkin projection approach has the potential to overcome issues commonly encountered when using traditional POD-Galerkin reduced-order models, such as error accumulation and instability, by minimizing errors over a desired time interval. While further testing is needed, our results demonstrate the considerable potential of the method to deliver accurate solutions at low computational cost.

INTERMITTENT TURBULENT STRUCTURES IN SUBCRITICAL TRANSITION OF ANNULAR COUETTE FLOW WITH/WITHOUT IMAGINARY DOMAIN

Kazuki Takeda[1] and Takahiro Tsukahara *[1]
[1] Department of Mechanical Engineering, Tokyo University of Science, Chiba, Japan

Summary In the subcritical transition of annular Couette flow (aCf), the global-stability Reynolds number Re_g increases with the decreasing radius ratio η, which is the ratio of inner- to outer radii. With low η, the small circumferential extent of the domain restricts the patterning of localized turbulence that may spread two-dimensionally. In such a case, the intermittently turbulent state settles down rapidly in the laminar state. However, aCf with an artificially-extended domain ($L_\theta > 2\pi$) exhibits two-dimensional patterns of localized turbulence by relaxing the circumferential confinement, even keeping a low η. The patterning and spreading of localized turbulence allows Re_g to be lower than that with the nominal domain of 2π. The newly found transitional process shows a good agreement with (1+1)-dimensional directed-percolation universality class.

INTRODUCTION

Annular Couette flow (aCf) is a wall-bounded shear flow between two concentric cylinders driven by a steady sliding motion of the inner cylinder, as illustrated in Fig. 1(a). This system is characterized by the radius ratio defined by the two radii of the inner and outer cylinders: that is, $\eta = r_{in}/r_{out}$. In aCf with $\eta \geq 0.1415$, the linear-stability Reynolds number Re_L goes to infinity and, even for $\eta = 0.1$, $\mathrm{Re}_L = 8.0 \times 10^5$ [1]. However, below Re_L, aCf can sustain turbulent state steadily. Especially, for low Reynolds numbers close to Re_g, the flow exhibits intermittently-turbulent structures of the localised turbulence that coexists with laminar regions. In plane Couette flow regarded as aCf with $\eta \to 1$, the intermittency shows two-dimensional pattern spreading in the streamwise and spanwise directions with a regular interval between oblique turbulent bands, the so-called turbulent stripe, near $\mathrm{Re}_g = 324$ [2]. The case with a low η can be regarded as a pipe flow and has actually exhibited a puff-like structure having the one-dimensional intermittency only in streamwise direction [3]. This fact indicates that spatial intermittency would be limited by the closed boundary condition of short circumferential extent. Recently, different types of directed percolation (DP) universality classes were found in various wall-bounded shear flows such as plane Poiseuille flow and Taylor-Couette flow with high η, by the experimental and DNS (direct numerical simulation) studies in huge domains [4, 6, 5]. In such flows, there occur splitting and decaying of localised turbulence frequently. The DP universality classes are characterized by some critical exponents about the spatiotemporal dimensions of the intermittency. For aCf with $\eta = 0.1$ and artificially-extended circumferential length ($L_\theta = 16\pi$) as the "imaginary domain", the subcritical transition revealed a trend of the DP universality class because of the relaxed closed boundary conditions [3]. The aCf with the imaginary domain is a good test system to investigate the competition between two effects of the closed circumferential length and the curvature.

In this study, we have performed DNS of aCfs at various η values to examine η-dependency of the intermittent structures, in particular the switching from stripe to puff. In addition, low-η aCfs with with imaginary domains have been also simulated to assess the intermittently-turbulent state as a DP universality class.

NUMERICAL METHOD AND CONDITION

We performed DNS of calculating the incompressible Navier-Stokes and continuity equations described in the cylindrical coordinate system, without using any turbulence model, for aCf with a huge computational domain. We calculated, from fully turbulent to laminar state in subcritical transition for low value of the radius ratio $\eta = 0.1$–0.3, aCf with a nominal domain ($L_\theta = 2\pi$) and that with a large enough imaginary domain for the circumferential direction ($L_\theta > 2\pi$) in order to relax the closed boundary condition in the circumferential direction. The details of computational conditions are summarized in Table 1. The control Reynolds number is $\mathrm{Re} = U_w h/4\nu$, where U_w is the speed of the sliding inner cylinder, h is the gap width between the concentric cylinders, and ν is the kinematic viscosity.

Table 1: Computational conditions. The superscript (*) represents a non-dimensionalized quantity by h.

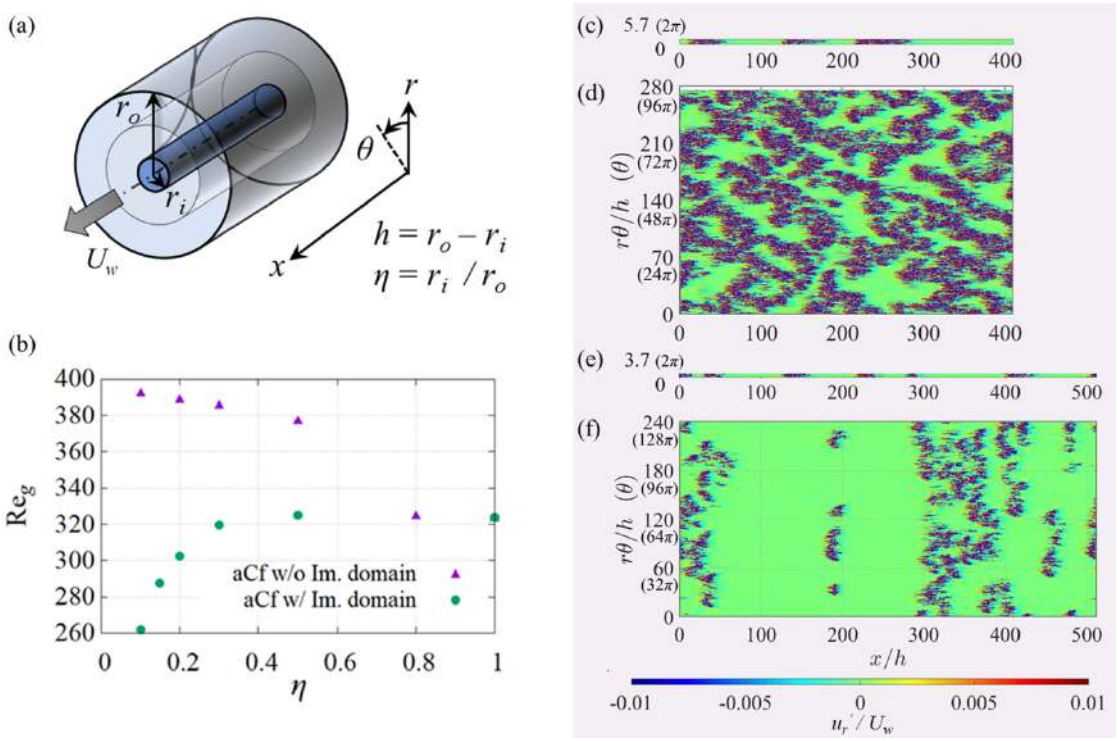

Figure 1: (a) Schematic of the annular Couette flow (aCf). The gray curved plane in the gap is the visualized (x, θ)-plane at the central gap $(r^* = (r^*_{in} + r^*_{out})/2)$. (b) Dependency of the global-stability Reynolds number Re_g on the radius ratio η, including the value at $\eta = 1$ cited from Duguet *et al.* [2], and from Kunii *et al.* for $\eta = 0.5, 0.8$ [3]. (c)–(f) Instantaneous flow fields with the intermittent structures of localized turbulence in aCf for $\eta = 0.3$; (c) without imaginary domain for $\mathrm{Re} = 388$, (d) with imaginary domain for $\mathrm{Re} = 325$ and $\eta = 0.1$; (e) without imaginary domain for $\mathrm{Re} = 402.5$, and (f) with imaginary domain for $\mathrm{Re} = 262.5$. Contours show radial (wall-normal) velocity fluctuation in the central gap $(x,\ \theta)$-plane, which is marked with a gray plane in (a). Red and blue as $|u_r^{'}/U_w| \geq 0.01$ indicate turbulent regions, while green as $|u_r^{'}/U_w| < 0.01$ corresponds to laminar region.

RESULTS AND DISCUSSION

In subcritical transition, for high η, the nominal aCf and artificial-extended aCf with an imaginary domain exhibit same intermittency with the stripe structure, while for low–middle η they have different structures of the puff-like and stripe structures. In the nominal aCf without an imaginary domain for $\eta < 0.7$, the intermittent structure cannot form the helical shape like the turbulent stripe and exhibits puff-like structures, as shown in Fig. 1(c,e). Figure 1(b) shows that Re_g increases from 324 for $\eta > 0.7$. On the other hand, in aCf with an imaginary domain, the stripe structures are not collapsed for $\eta \geq 0.3$: see Fig. 1(d). However, aCf with an imaginary domain and $\eta \leq 0.2$ forms the helical structure even far from Re_g, while near Re_g it collapses and forms turbulent spots that extend only in the circumferential direction, i.e., the transverse structures, as shown in Fig. 1(f). Interestingly, Re_g greatly decreases from 324, as plotted in Fig. 1(b).

We now introduce the turbulent fraction $F_t = (\text{Turbulent area})/(\text{Turbulent area} + \text{Laminar area})$ on the central gap plane. Although figure not shown, the temporal change of F_t and the Reynolds number dependency of time-averaged $\bar{F}_t$ can each be scaled with power laws: $F_t \sim t^{-\alpha}$ and $\bar{F}_t \sim (\mathrm{Re} - \mathrm{Re}_g)^{\beta}$. These scaling exponents show good agreements with the critical exponents of (1+1)d DP universality class; $\alpha_{\mathrm{DP}} = 0.159$ and $\beta_{\mathrm{DP}} = 0.276$. This result implies the universality in the turbulence spreading and developing.

CONCLUSIONS

We found the subcritical transition of annular Couette flows (aCf) with imaginary circumference domains exhibit different intermittent structures compared with the nominal aCf: for $\eta \geq 0.3$ the stripe structures form, while for $\eta \leq 0.2$ the transverse or spot structures occur. Re_g of the nominal aCf for $\eta < 0.8$ increases as η decreases ($\mathrm{Re}_g > 324$), while Re_g of aCf with imaginary domains for $\eta \leq 0.3$ decreases ($\mathrm{Re}_g < 324$).

DATA-DRIVEN LINEAR ESTIMATORS FOR TURBULENT CHANNEL FLOW AT $Re_\tau = 2003$

Sean Symon *[1], Anagha Madhusudanan[1], Simon J. Illingworth[1], and Ivan Marusic[1]
[1] Department of Mechanical Engineering, University of Melbourne, Parkville, Australia

Summary We investigate the minimum number of flow measurements required to estimate the large scales of turbulent channel flow at a friction Reynolds number of $Re_\tau = 2003$. Time and space-resolved measurements, known at discrete wall-normal locations, serve as inputs to linear estimators based on the linearised Navier-Stokes equations. The nonlinear terms are treated as white noise in space and time forcing. The estimation is improved significantly when the input data are known at two wall-normal locations as opposed to a single wall-normal location. The estimated velocity fields are in good agreement with those of DNS in the buffer and logarithmic regions and can be used to infer statistics of the unknown nonlinear forcing terms.

INTRODUCTION

A practical limitation of controlling wall-bounded flows is the ability to measure them experimentally. The hardware needed to obtain measurements of high Reynolds number turbulence, for example, is costly in order to resolve the wide range of scales present. Recent work [1, 2] has focused on converting partially known measurements into estimates of flow states that are not measured. The work of Illingworth et al. [1] converted knowledge of time-resolved velocity measurements at one wall-normal location into estimates at other wall heights. This Kalman-filter-based approach relied on the linearised Navier-Stokes equations which, when linearised around the turbulent mean velocity profile, was able to reproduce key features of wall-bounded turbulent flows [3].

An alternative estimation technique is to relate the velocity field between two wall-normal planes using spectral linear stochastic estimation (SLSE) [2]. The performance of the linear estimator, however, was hindered by treating the unknown nonlinear terms as white in space and time forcing [4]. The linear estimator overemphasised small scales relative to large scales and overestimated the magnitude of velocity fluctuations below the measurement plane. In this work, estimation is improved by adding one additional measurement plane to counteract deficiencies of the linear model. It is also shown that a suitable nonlinear forcing can be derived from the input measurements to improve predictions of second-order velocity statistics and, consequently, estimates obtained from SLSE.

METHODS

Two methods are used to estimate turbulent channel flow: the Kalman filter and SLSE. Figure 1(a) outlines the components in the Kalman filter. The objective is to design a filter $\boldsymbol{F}(s)$ that minimises the error $\boldsymbol{e}$ between the estimated quantities $\boldsymbol{z}_e$ and filter estimate $\boldsymbol{z}$. The filter takes as input the measured quantities $\boldsymbol{y}$ contaminated by noise $\boldsymbol{n}$. The plant $\boldsymbol{P}(s)$ is derived from the linearised Navier-Stokes equations where $\boldsymbol{d}$ represents unmodelled nonlinear terms that are assumed to be white noise in space and time.

SLSE is illustrated in Figure 1(b) and provides an estimate at wall-normal location z_1 using a transfer kernel H_L and known input data at z_2. H_L is wavenumber-dependent and can be constructed from second-order velocity statistics $\boldsymbol{X}(k_x, k_y)$. In the first row (eLNS), the second-order statistics of the unknown forcing are assumed to be white in time and space, i.e. $\boldsymbol{S}_{\hat{d}\hat{d}} = \boldsymbol{I}$. The second row (sLNS) denotes the case when velocity correlations are known between multiple input planes. The unknown forcing statistics $\boldsymbol{S}_{\hat{d}\hat{d}}$ may be estimated from a projection-based approach [5] and used to compute updated velocity correlations $\boldsymbol{X}_f$ to improve estimation accuracy.

RESULTS

The linear estimators are tested on the large scales of turbulent channel flow at a friction Reynolds number of $Re_\tau = 2003$, which have been obtained by direct numerical simulation (DNS) [6]. In Figure 2, the DNS is compared to two

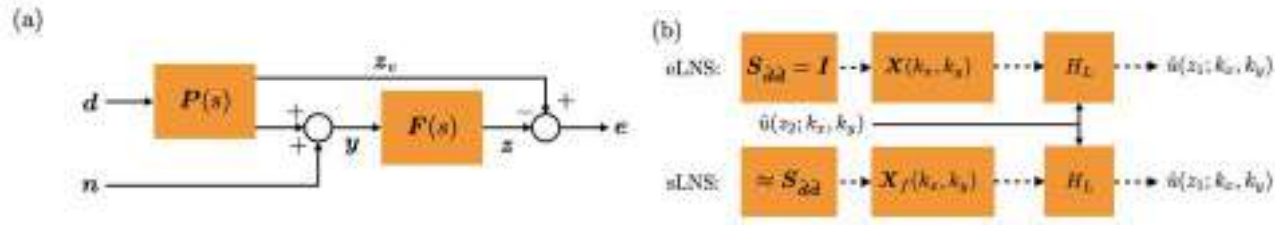

Figure 1: Schematic of the (a) Kalman filter and (b) SLSE-based linear estimators.

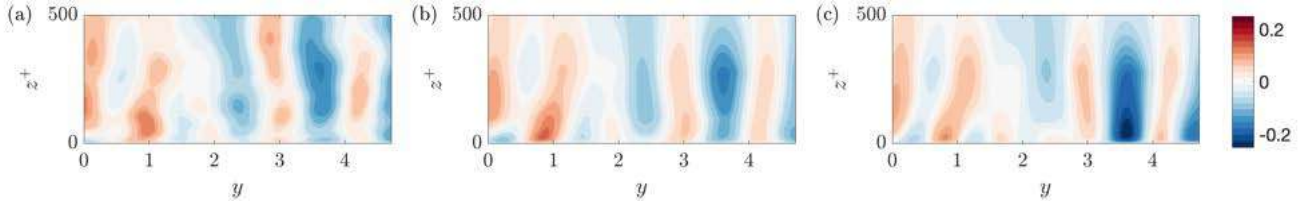

Figure 2: Streamwise velocity from (a) DNS, (b) Kalman filter using two input planes and (c) Kalman filter using one input plane.

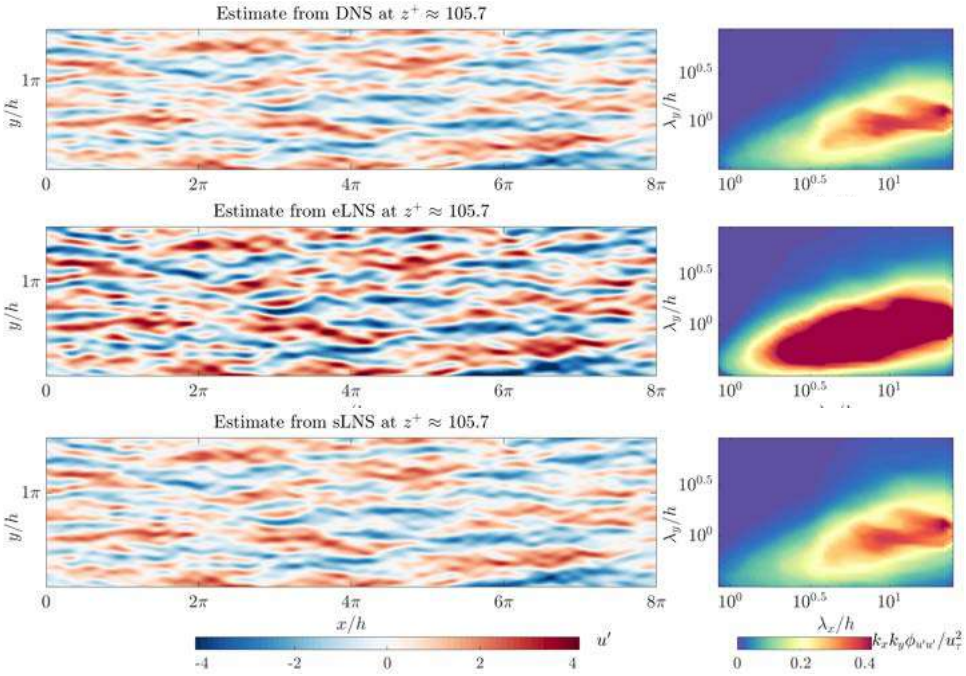

Figure 3: SLSE velocity estimates obtained from DNS (top), eLNS (middle) and sLNS (bottom).

Kalman filter-based estimators. The first, which will be referred to as the 2-plane case, has knowledge of the velocity field at two wall-normal locations: $z^+ = 100$ and $z^+ = 300$. The second has knowledge of the velocity field at $z^+ = 300$ only and will be referred to as the 1-plane case. There is good agreement between the DNS and 2-plane velocity fields in Figure 2(a) and (b) although it deteriorates above $z^+ = 500$. The 1-plane case in Figure 2(c) overestimates the velocity fluctuations near the wall. This is particularly apparent in Figure 2(c) where it can be seen that the 1-plane case predicts an intense $-u'$ fluctuation at $y = 3.5$. The addition of the second plane, therefore, is necessary to prevent overestimation near the wall.

Similar improvements can be observed in the estimates obtained using SLSE in Figure 3. Unlike the Kalman filter, SLSE does not yield the actual velocity field at the estimate location z_1. Instead, it predicts the velocity fluctuations that are coherent with the measurement plane at z_2 [2]. Hence, the best case scenario is referred to as the DNS estimate in Figure 3. eLNS, which assumes forcing that is white in time and space, overestimates the magnitude of fluctuations and overemphasises smaller scales relative to larger scales. sLNS, on the other hand, has limited knowledge of the forcing from the input measurements and is in very good agreement with the DNS estimate.

The financial support of the Australian Research Council is gratefully acknowledged and we thank the Fluid Dynamics Group of the Polytechnic University of Madrid (UPM) for the DNS dataset [6].

MEAN MOMENTUM BALANCE IN ADVERSE PRESSURE GRADIENT TURBULENT BOUNDARY LAYERS

Sylvia Romero*, Spencer Zimmerman , Jimmy Philip, and Joseph Klewicki
Department of Mechanical Engineering, University of Melbourne, Parkville, Australia

Summary The mean momentum balance is used to analyze large eddy simulation data of adverse pressure gradient (APG) boundary layers (of Bobke et al., 2017), as well as newly acquired experimental data at higher Reynolds numbers. The structure of the mean momentum balance is compared relative to the zero pressure gradient case. Zero pressure gradient boundary layer data is obtained from the direct numerical simulations of Schlatter and Örlü, 2010 and Sillero et al., 2013, and experimental data from Zimmerman et al., 2019. Changes in the layered structure are seen to affect the emerged properties of the APG flow. We will discuss changes in the inner and outer interactions in terms of (for example) the location where the viscous force loses dominance, the skewness, and amplitude modulation.

Mean momentum balance

The mean momentum balance (MMB) is the time averaged statement of Newtons second law. We first consider the MMB for the channel flow since its force balance stucture is well-characterized (see [5], [6], and [7]). For channel flows the equation is a balance of three terms: viscous force (VF), turbulent inertia (TI), and pressure gradient (PG).

$$\underbrace{\frac{\partial^2 U^+}{\partial y^{2+}}}_{\text{VF}} - \underbrace{\frac{\partial \overline{uv}^+}{\partial y^+}}_{\text{TI}} - \underbrace{\frac{1}{\delta^+}}_{\text{PG}} = 0. \tag{1}$$

The VF term is the gradient of the viscous stress and the TI term is the gradient of the Reynolds stress. The zero-crossing of the TI term corresponds to the peak location of the Reynolds stress. Prior to the zero-crossing the TI term acts as a source, whereas after the zero-crossing the TI term becomes negative and acts as a momentum sink. The PG term is a function of Reynolds number and remains constant with wall-normal distance y. The superscript '$+$' denotes inner normalization.

For the two-dimensional zero pressure gradient boundary layer (ZPG BL) the equation is still a balance of three terms. Here, the PG term is replaced by the mean inertia (MI) term, which is still a function of Reynolds number, but no longer a constant in y or streamwise distance x.

$$\underbrace{\frac{\partial^2 U^+}{\partial y^{2+}}}_{\text{VF}} - \underbrace{\frac{\partial \overline{uv}^+}{\partial y^+}}_{\text{TI}} - \underbrace{[U^+\frac{\partial U^+}{\partial x^+} + V^+\frac{\partial U^+}{\partial y^+}]}_{\text{MI}} = 0. \tag{2}$$

Near the wall the VF and TI terms are dominant. Because of this the MMB structure for the ZPG BL and channel flow is very similar. The main difference is that a small outer peak forms in the MI and TI terms of the ZPG BL.

The MMB for the APG BL is comprised of four terms. Like the ZPG BL the mean momentum equation includes a non-constant MI term. Like the channel flow case, however the relevant equation also includes a constant PG term. For the APG BL this term is constant and negative, while for the channel flow it is positive.

$$\underbrace{\frac{\partial^2 U^+}{\partial y^{2+}}}_{\text{VF}} - \underbrace{\frac{\partial \overline{uv}^+}{\partial y^+}}_{\text{TI}} - \underbrace{[U^+\frac{\partial U^+}{\partial x^+} + V^+\frac{\partial U^+}{\partial y^+}]}_{\text{MI}} + \underbrace{U_\infty^+\frac{\partial U_\infty^+}{\partial x^+}}_{\text{PG}} = 0. \tag{3}$$

Due to the additional PG term the balance has changed from the ZPG BL to the APG BL as shown in Figure 1. For the APG BL, the VF term is now balanced by the PG term very near the wall, while away from the wall the PG term balances the MI term. Furthermore in the ZPG BL flow the position where the VF term loses leading order nominally coincides and scales with where the TI term crosses zero. In the APG BL flow, however, the TI term crosses zero beyond where the VF term loses dominance. Beyond the location where the VF term approaches zero, a new inertial balance emerges where the remaining three terms (the TI, MI, and PG) are balanced. This new structural feature suggests a change in the nature of the interaction between the inner and outer regions.

Experiments

The value of the Clauser pressure-gradient parameter $\beta = (\delta^*/\tau_w)(dP/dx)$, where δ^* is the displacement thickness, τ_w is the wall shear stress, and dP/dx is the streamwise pressure gradient, characterizes the boundary layer between ZPG: $\beta = 0$, APG: $\beta > 0$, and favourable pressure gradient (FPG): $\beta < 0$ cases. A boundary layer will behave differently depending on how rapidly β is changing and whether β is decreasing or increasing with Reynolds number. Large eddy simulation (LES) data of a quasi-equilibrium APG BL (where β is nominally constant) was studied. From direct numerical simulation (DNS) and LES data a range of low Reynolds numbers were analyzed for the ZPG BL ($670 \leq Re_\theta \leq 6.5\times10^3$)

*Corresponding author. E-mail: sylviar@student.unimelb.edu.au

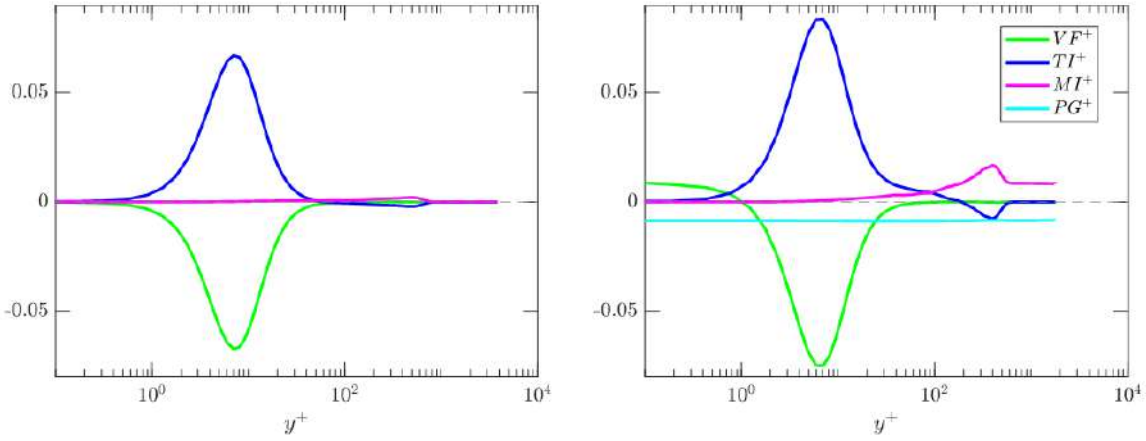

Figure 1: (Left) MMB of ZPG BL at $Re_\theta = 2000$, data from [2]. (Right) MMB of APG BL at $Re_\theta = 2000$, data from [1].

and APG BL cases ($1.3 \times 10^3 \leq Re_\theta \leq 3.2 \times 10^3$), respectively. To observe an APG BL at higher Reynolds numbers hot-wire anemometry experiments were conducted in the Flow Physics Facility (FPF) at The University of New Hampshire. A ramp structure was installed on the ceiling of the FPF. Extending approximately 15m downstream, this ramp creates a FPG region followed by a ZPG ramp (where the flow relaxes back to equilibrium), and that is followed by an APG ramp. The flow is then allowed to develop downstream of the ramp system back to equilibrium over a ∼20m fetch. Hot-wire measurements were taken in the region of the APG ramp as well as downstream of the ramp to observe this relaxation. In the APG region, the measured Reynolds numbers ranged from $2.1 \times 10^4 \leq Re_\theta \leq 2.7 \times 10^4$ and downstream of the ramp from $2.9 \times 10^4 \leq Re_\theta \leq 3.8 \times 10^4$.

Observations

From the APG BL LES the behavior of the VF term as it loses dominance remains largely the same as β changes from a ZPG case to mild quasi-equilibrium APG case. On the other hand, the peak in the Reynolds stress moves outwards, indicating an additional momentum source from the outer region. Despite this, the peaks of the Reynolds stress from the experimental measurements align better with the LES profiles with $\sqrt{\delta^+}$ scaling than with δ scaling. This suggests that the TI term zero-crossing still scales with $\sqrt{\delta^+}$ despite the additional PG term in the MMB.

Another indicator of inner and outer structural changes is the streamwise velocity skewness, S_u, which behaves similar to the amplitude modulation (AM) coefficient as seen in [8] and [9]. Owing to the application of an APG BL the extent of positive S_u increases. Given the connection between S_u and AM, this suggests that the AM has been modified. Similiar findings were seen by Harun et al., 2013, however AM was increased in the inner and outer regions. As the near-wall S_u increases the zero-crossing moves outwards. This was also noted for the AM in [10] at constant Reynolds number and increasing pressure gradient. Before the zero-crossing of the AM the small scales were positively correlated to large scale streamwise velocity fluctuations and afterwards negatively correlated. At high Reynolds numbers S_u commonly corresponds to the start of the inertial layer in the ZPG BL. A coupling of the S_u-zero-crossing and where the VF loses dominance was not observed in the APG BL experimental data.

Conclusion

The MMB under the addition of a pressure gradient suggests that inner and outer regions communicate differently from the ZPG BL flow. This is seen in the shift in the peak location of the Reynolds stress from where the VF loses dominance. Observations correlate with an increased S_u and amplitude modulation as the pressure gradient increases from a ZPG BL.

THE MINIMAL SEED IN A BOUNDARY LAYER FLOW: A FREQUENCY-DOMAIN APPROACH

Georgios Rigas*[1], Denis Sipp [2], and Tim Colonius[3]
[1]Department of Aeronautics, Imperial College, London, United-Kingdom
[2]Department of Aerodynamics, Aeroelasticity and Acoustics, ONERA, Meudon, France
[3]Department of Mechanical and Civil Engineering, California Institute of Technology, Pasadena, CA, USA

Summary We identify the nonlinear optimal mechanisms at the edge of the turbulent regime through solution of the frequency-domain Harmonic-Balanced Navier-Stokes equations. Specifically, we seek the optimal harmonic or multi-harmonic forcing mechanisms that maximise the skin friction coefficient asymptotically in time, which can be viewed as *the minimal forcing seed in the frequency domain*. By retaining a small and finite number of harmonics that nonlinearly interact and distort the mean flow, but also transfer energy among them, a low-dimensional self-consistent dynamical description of the turbulent regime obtained. At the edge of turbulence, the skin-friction coefficient reaches the empirical turbulent values, and the velocity profiles depart from the law of the wall by developing a logarithmic region, as predicted by the model.

INTRODUCTION

For spatially developing flows of practical interest, such as boundary layer flows, nonlinear optimisation has been recently employed to find the most amplified initial condition of the governing Navier-Stokes equations that leads to turbulent dynamics. This is known in the literature as the *minimal seed* [1, 2]. By analog with the linear approaches, and specifically the frequency-response analysis, it is experimentally more natural to model transition from laminar to turbulent flow as a stationary process where disturbances are continually supplied to the system from the environment, i.e. to consider the nonlinear receptivity problem.

A natural generalization in order to calculate finite-amplitude perturbations in the frequency domain is to seek self-consistent solutions to the full Navier-Stokes equations under the form of an expansion consisting of a mean-flow solution, a fundamental mode and p harmonics of the fundamental. Using this framework, for a given forcing, the response of the system can be calculated in a self-consistent way. Subsequently, optimal nonlinear forcing mechanisms that lead to turbulence and maximise the skin-friction coefficient are calculated using a variational method and direct-adjoint looping.

THE MINIMAL FORCING-SEED AT THE EDGE OF TURBULENCE

By increasing the finite forcing amplitude, and repeating the nonlinear optimisation, we identified the frequency-domain minimal seed and the key-mechanisms that lead to turbulent dynamics. We found that for fundamental forcing, the nonlinearly most amplified disturbances correspond to a pair of oblique waves with frequency and spanwise wavenumber close to the linear optimal one. Nonlinearity is responsible for redistributing the energy to the streamwise uniform vortex component which leads to streak growth through the lift-up mechanism. Depending on the imposed spanwise symmetry, the low-speed streaks break down to turbulence through varicose oscillations (imposing reflectional symmetry in spanwise) or sinuous ones (no symmetry imposed in in spanwise), as shown in figure 1. In each case, hairpin vortices and quasi-streamwise vortices are observed prior to breakdown and the distinct regimes during the transition process can be summarised as follows:

- At the very early stages of transition, characterised by linear growth, the velocity profiles obey the linear wall law $u^+ = y^+$, as shown in figure 2. Transition has been triggered optimally with a pair of oblique waves.
- The second stage of transition is associated with the generation of streaks through nonlinear interactions of the oblique waves. At this regime the skin friction coefficient departs from the laminar Blasius values. This new regime is reflected as well through the modification of the local velocity profile for $y^+ > 10$, in accordance with the increase of the skin friction coefficient. Depending on the symmetry of the forcing, varicose Λ-shaped streaks (symmetry in z) or sinuous streaks (no symmetry in z) are identified for $Re_x > 260,000$.
- A third regime is observed where a distinct plateau is formed in the buffer region, $15 < y^+ < 30$ for all three cases. In the symmetric cases, hairpin-like vortical structures grow around the Λ-shaped low-speed streaks. In the case without symmetry, alternate quasi-streamwise vortices grow around the sinuous low-speed streaks. Immediately after the vortical structures are formed, the skin friction coefficient overshoots to the turbulent values.
- The final transition regime is associated with the breakdown of streaks. At this regime, the skin friction coefficient reaches the empirical turbulent values and energy is transferred to all the higher harmonics.

*Corresponding author. E-mail: g.rigas@imperial.ac.uk

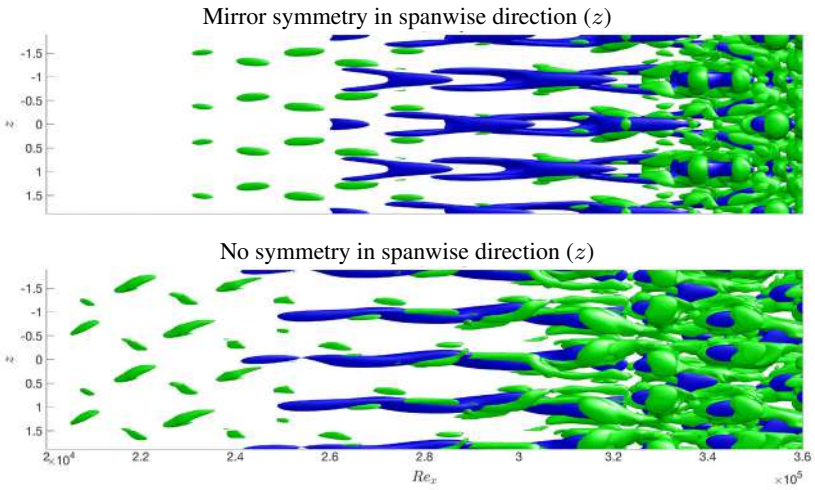

Figure 1: Nonlinear optimal response during laminar-turbulent transition on a plat plate boundary layer flow, triggered by a pair of oblique waves. Isosurfaces of low-speed streaks (blue) and vortical structures are shown. Solutions have been obtained with mirror-symmetry in z (top) and no symmetry (bottom), leading to varicose and a sinuous-like breakdown of the streaks, and the generation of hairpin and quasi-streamwise vortices, respectively.

For the case with no symmetry in z, the velocity profiles at the final stages of transition show characteristics similar to the ones observed in turbulent boundary layers. As shown in figure 2, the velocity profile appears to develops a nascent logarithmic region that extends in y^+ as Re_x increases. The skin friction coefficient, after an initial overshoot above the turbulent empirical values, drops to values close to the turbulent ones. For this specific case, we observed sinuous low-speed streaks, in contrast to the varicose streak instability that was observed for the symmetric case. The sinuous instability is a fundamental ingredient in the self-sustaining process (SSP) that has been identified in a variety of streamwise homogeneous flows [3].

The proposed *nonlinear input/output analysis* method identifies the most dangerous nonlinear mechanisms that lead to turbulent dynamics in the frequency domain, which can be viewed as *the minimal forcing seed in the frequency domain*. Advantages from the extension of the proposed framework to control applications will be discussed, specifically focusing on optimal passive geometric modifications and open-loop periodic forcing.

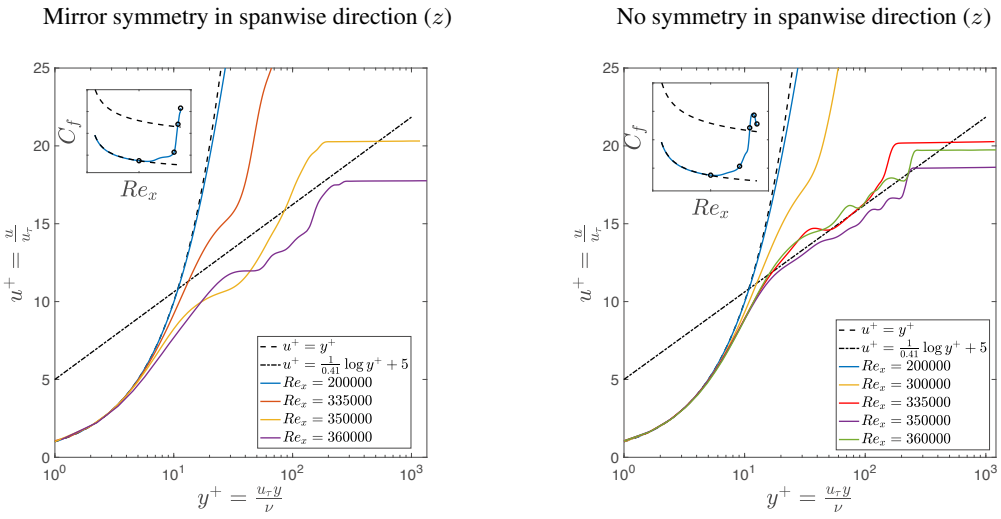

Figure 2: Mean velocity profiles during transition in innner units based on the local friction velocity u_τ. Linear (dashed) and log laws (dashed-dotted) are also shown. Then insets show the skin friction coefficient as a function of Re_x and the location where the velocity profiles are plot are marked with circles.

[3] Institut Pprime, CNRS / Université de Poitiers /ENSMA, 86962 Futuroscope Chasseneuil, France

Summary Recent studies have shown that including a linear eddy-viscosity model significantly improves the match between modes predicted by resolvent analysis (linearized about the turbulent mean flow) and those educed from data (i.e. large eddy simulation) via spectral proper orthogonal decomposition. Given this agreement and the low-rank behavior of turbulent jets, we investigate whether a truncated resolvent basis accurately reconstructs turbulent statistics. In particular, we perform resolvent analysis of a turbulent jet using mean flow quantities found via a Reynolds-Averaged Navier-Stokes (RANS) simulation and determine if the associated RANS turbulent kinetic energy may be reconstructed, therefore constituting a self-consistent jet model. We present results for a Mach 0.4, isothermal, turbulent, round jet.

INTRODUCTION

Resolvent analysis [1] continues to provide a fruitful path for creating reduced-order models for turbulent flows, both among wall-bounded and free shear flow, yet complete models remain elusive, necessitating further refinement and/or modeling of turbulent forcing statistics. Recently, studies including an eddy-viscosity model in the resolvent operator in jets have shown striking improvements in alignment between resolvent modes and modes educed via SPOD [2, 3], the optimal basis for describing turbulent statistics[4]. Considering these improvements, we ask whether a self-consistent, reduced-order model for turbulent jets may be attained.

Self-consistent models of turbulent flow have been achieved through quasi-linear approaches in bluff bodies [5], channel flow [6], and turbulent boundary layers [7], and here we assess how well our current resolvent jet model may attain self-consistent behavior. We do so by reconstructing the one-point statistics from two target simulations. The first from a LES and the second from a RANS (i.e. tuned to match the LES meanflow quantities) for utility as a predictive jet modeling tool. The key advantage of reconstructing the one-point statistics of the LES first is the ability to decompose and compare LES and resolvent quantities at discrete frequency and wavenumber pairs, whereas RANS only provides an integrated mean quantity. For each frequency-wavenumber pair, alignment of SPOD and resolvent modes can then be optimized. With sufficient alignment, the resolvent models may be integrated in frequency and wavenumber to reconstruct the mean quantities associated with turbulent fluctuations, such as the TKE and acoustic field. Once demonstrated upon the LES database, we implement the same model using only RANS-based inputs, with a condition that the turbulent kinetic energy reconstruction be self-consistent – with the goal of producing a predictive, RANS-resolvent jet model.

METHODS

The resolvent operator, $\boldsymbol{R}$, takes the form of an input-output transfer function between flow responses, $\boldsymbol{q}$, and forcings, $\boldsymbol{f}$,

$$\boldsymbol{q} = \boldsymbol{R}\boldsymbol{f}, \tag{1}$$

where $\boldsymbol{R}$ is obtained from the linearized Navier-Stokes, continuity, and energy equations about a mean flow. In this study, stationary statistics in time and an axisymmetric geometry allow the resolvent operator to be defined at individual frequency and azimuthal wavenumber, $St - m$, pairs. Taking a singular value decomposition (SVD) of the resolvent operator, $\boldsymbol{R} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^*$, provides an orthogonal set of responses, $\boldsymbol{U}$, and forcings, $\boldsymbol{V}$, along with the diagonal matrix $\boldsymbol{\Sigma}$ whose entries denote the energetic amplification between the forcing and responses, ranked from largest to smallest.

The resolvent operator may also be viewed from a statistical perspective as described by Towne et al. [4], where the expectation of equation 1 times its complex conjugate,

$$\boldsymbol{S}_{qq} = \langle \boldsymbol{R}\boldsymbol{f}\boldsymbol{f}^*\boldsymbol{R}^* \rangle = \boldsymbol{R}\boldsymbol{S}_{ff}\boldsymbol{R}^* \tag{2}$$

gives the relationship between the two-point response statistics (i.e, the cross-spectral density tensor), $\boldsymbol{S}_{qq}$, and forcing statistics, $\boldsymbol{S}_{ff}$, through the resolvent operator. Expanding the resolvent operator then gives, $\boldsymbol{S}_{qq} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^*\boldsymbol{S}_{ff}\boldsymbol{V}\boldsymbol{\Sigma}\boldsymbol{U}^*$, and if $\boldsymbol{S}_{ff}$ is assumed to be a diagonal matrix of form $\alpha\boldsymbol{I}$, where α is a scalar constant which may be a function of frequency and wavenumber, the above equation reduces to $\boldsymbol{S}_{qq} = \alpha\boldsymbol{U}\boldsymbol{\Sigma}^2\boldsymbol{U}^*$. However, the form $\alpha\boldsymbol{I}$ assumes that the forcing is present at the same amplitude throughout the entire domain. Unfortunately, this assumption is poor for turbulent jets due to differences in spatial location of forcing mechanisms (i.e. Kelvin-Helmholtz, Orr, and Lift-Up) [8] and varied forcing amplitudes in those regions. Instead we replace $\boldsymbol{\Sigma}\boldsymbol{V}^*\boldsymbol{S}_{ff}\boldsymbol{V}\boldsymbol{\Sigma}$, with the diagonal matrix $\boldsymbol{B}$, whose diagonal entries represent the effective forcing amplitude for each resolvent mode.

SPOD directly decomposes $\boldsymbol{S}_{qq}$ as $\boldsymbol{S}_{qq} = \boldsymbol{\Psi}\boldsymbol{\Lambda}\boldsymbol{\Psi}^*$, where $\boldsymbol{\Psi}$ are orthogonal responses (from the LES) and $\boldsymbol{\Lambda}$ is a diagonal matrix denoting the energy of each response, showing that the assumption of a diagonal $\boldsymbol{B}$ is valid so long as $\boldsymbol{U} \approx \boldsymbol{\Psi}$. In the case that SPOD and resolvent modes are identically aligned the optimal model for $\boldsymbol{B}$ is $\boldsymbol{\Lambda}$. In these results we use $\boldsymbol{\Lambda}$ to inspire a functional form for $\boldsymbol{B}$, but determine the precise values by fitting the resolvent approximation to the one-point statistics. Finally, for reduced-order models, it also necessary to consider truncating the basis of resolvent modes, $\tilde{\boldsymbol{U}}$, and assess how closely the truncated basis reconstructs the statistics, $\tilde{\boldsymbol{S}}_{qq}$, as, $\tilde{\boldsymbol{S}}_{qq} = \tilde{\boldsymbol{U}}\tilde{\boldsymbol{B}}\tilde{\boldsymbol{U}}^*$.

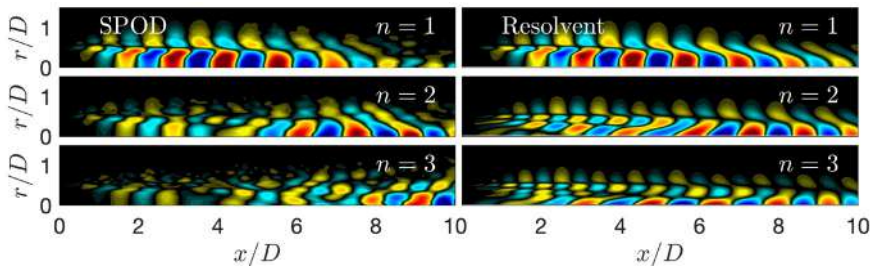

Figure 1: First three SPOD and resolvent modes (left and right columns respectively) of streamwise fluctuating velocity at $St = 0.6$, $m = 0$, for the $M_j = 0.4$ jet.

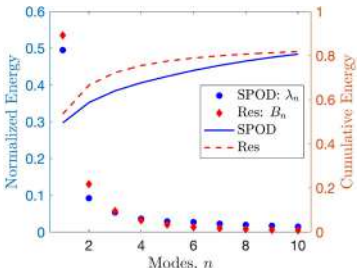

Figure 2: Normalized spectra of SPOD and fitted resolvent spectrum.

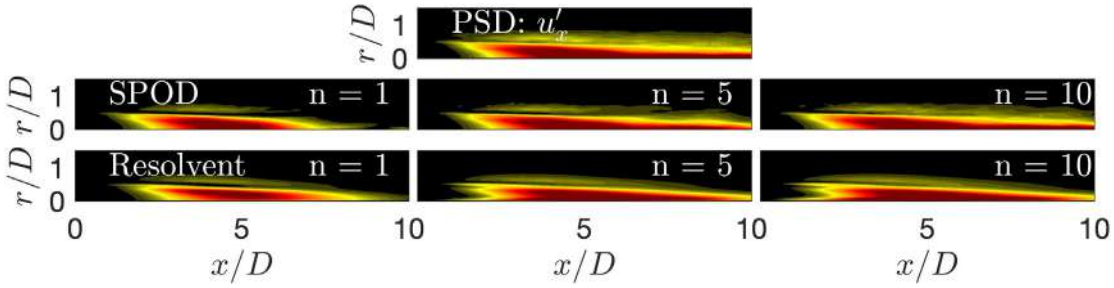

Figure 3: PSD of the LES data at $St = 0.6$, $m = 0$, for the $M_j = 0.4$ jet and the SPOD and resolvent reconstructions using 1, 5, and 10 modes from left to right.

RESULTS & OUTLOOK

The first three modes (fluctuating streamwise velocity) of the resolvent basis, found using the RANS eddy-viscosity resolvent model, are shown below for $m = 0$ and $St = 0.6$ for the $M_j = 0.4$ jet in figure 1 along with their associated SPOD modes. The resolvent modes show significant agreement with SPOD and present alignments of 92% 67% and 33% respectively. However, the resolvent spectrum suggests the first mode as containing $> 99\%$ of the energy due to the scalar forcing assumption. Therefore, we find the diagonal energy matrix $\tilde{\boldsymbol{B}}$ by performing a least-squares fit to the PSD of the chosen frequency $m - St$, by adjusting two parameters which model $\tilde{\boldsymbol{B}}$, $B_{i,i} = \alpha i^{-\beta}$. Figure 2 presents both the SPOD and modeled spectrum, each normalized by the total energy of the $St - m$ PSD. Both spectra are similar, which is expected as $\boldsymbol{U} \approx \boldsymbol{\Psi}$, however, we can also see $\tilde{\boldsymbol{B}}$ has values which are larger than the SPOD spectrum.

The resolvent and SPOD bases are then used to reconstruct the LES statistics at the given $St, m = [0.6, 0]$ pair and figure 3 presents the reconstructed PSD using a 1,5, and 10 mode basis. We can see that the first resolvent and SPOD modes account for a substantial amount of energy and reconstruct much of the overall PSD. We also see improvements in the reconstruction as further modes are added, although marginal.

We hypothesize that a truncated resolvent basis, and a simple form for the energy matrix $\tilde{\boldsymbol{B}}$, is sufficient for reconstructing the most energetic regions at each $m - St$ pair and may be integrated to construct the overall TKE field. In this talk we present the ability of the resolvent model to reconstruct the LES PSD across all $m - St$ pairs and subsequently expand the analysis to then reconstruct the overall RANS TKE. We present an optimization of the energy matrices $\tilde{\boldsymbol{B}}$ across the entire $m - St$ space constrained to best fit the RANS TKE and we discuss whether these matrices may be generalized for future RANS-resolvent predictive models.

DIRECT CALCULATION OF EDDY VISCOSITY OF TURBULENT CHANNEL FLOW AT $Re_\tau = 180$

Danah Park*[1] and Ali Mani[1]
[1] Department of Mechanical Engineering, Stanford University, Stanford, USA

Summary This study presents an exact quantification of the eddy viscosity operator for the turbulent channel flow at $\mathrm{Re}_\tau = 180$ using a statistical technique, called macroscopic forcing method. Quantification of eddy viscosity is performed in the context of the generalized momentum transport equations which allow examination of mean momentum transport in a manner non-intrusive to the underlying transporting turbulent flow. Using these tools, we quantify the eddy viscosity in a tensorial kernel form. The results indicate the following: (1) the eddy viscosity is highly anisotropic, (2) its leading-order, obtained by neglecting spatial moments of the closure kernel, generates a non-symmetric Reynolds stress tensor, (3) the eddy viscosity operator acts on all components of the mean velocity gradient including mean rate of rotation, and (4) the eddy viscosity kernel is highly nonlocal.

INTRODUCTION

The Boussinesq approximation is common in the majority of the closure models for the Reynolds Average Navier Stokes equations (RANS). This approximation leads to an eddy viscosity coefficient which is a scalar field that locally describes the ratio between the deviatoric Reynolds stresses and the mean strain rate tensor. Similar to the notion of molecular mixing, Boussinesq assumes that the eddy viscosity is isotropic and local. There have been many demonstration of violation of these two assumptions in realistic flows, but quantitative measures of the non-Boussinesq effect are still lacking [1].

We have recently developed a new technique, called the macroscopic forcing method (MFM), [2] that allows the calculation of the exact RANS closure operator for any given flow. MFM measures turbulent momentum flux in response to different scenarios of mean momentum gradients obtained via forcing of the momentum transport equation. Exact eddy diffusivity operators can be obtained by careful assembly of such solutions. In this work, we present results of such calculation for the turbulent channel flow at $Re_\tau = 180$.

Eddy Viscosity Kernel

Equation 1 shows the fourth order tensorial kernel formulation of the RANS closure which is the most general representation of the eddy viscosity as an operator [3].

$$-\overline{u_j' u_i'}\,(\mathbf{x}) = \int D_{jilk}(\mathbf{x},\mathbf{y})\left.\frac{\partial U_k}{\partial x_l}\right|_{\mathbf{y}} \mathrm{d}\mathbf{y}. \tag{1}$$

Unlike the Boussinesq model, here the tensorial components in D_{jilk} capture anisotropy, while the integral form incorporates the nonlocal effects.

Macroscopic Forcing Method

The challenge with this general representation is quantification of the kernel itself, for which we applied MFM as follows. We first obtain the space-time resolved velocity field from a direct numerical simulation (DNS) and use it as a background velocity for additional DNS of a passive momentum transport equation, which we call the generalized momentum transport equation (GMT) as discussed in [2]. This way we gain two advantages. First, the GMT equation is a linear equation and thus can benefit from analysis using specific tools including superposition methods, combined with force response analysis. Second, this method is non-intrusive to the underlying turbulence that transports the momentum, and thus a RANS operator characterization based on GMT is exact for the given specific flow.

LEADING ORDER (LOCAL) APPROXIMATION

Starting with Equation 1, one can use the Taylor series expansion to expand the velocity gradient around $\mathbf{y} = \mathbf{x}$. If the velocity gradient is smooth, one may retain the leading term in this expansion. This will lead to a simplified representation of the eddy viscosity operator reduced to a local form $-\overline{u_j' u_i'}\,(\mathbf{x}) = D^0_{jilk}(\mathbf{x})\partial U_k/\partial x_l$, where D^0_{jilk} is the spatial integral of the kernel, effectively relegating the entire non-local kernel in 1 to a Dirac delta function. We use this approximate representation of eddy viscosity (essentially the zeroth order moment of the kernel) to assess the anisotropy of the closure oeprator.

In Figure 1(b), four components of the leading order eddy viscosity tensor are shown from the bottom wall to the top wall. D^0_{2121} corresponds to the standard eddy viscosity, which is commonly estimated by taking the ratio of Reynolds stress to the mean velocity gradient. Unlike such estimates, which essentially tune an inaccurate model form, here D^0_{2121} shows the exact leading-order eddy diffusivity coefficient. Conducting RANS solutions with this local eddy viscosity shows the error of the leading-order operator (neglecting the non-local effects) to be about 1.5 percent. This indicates that

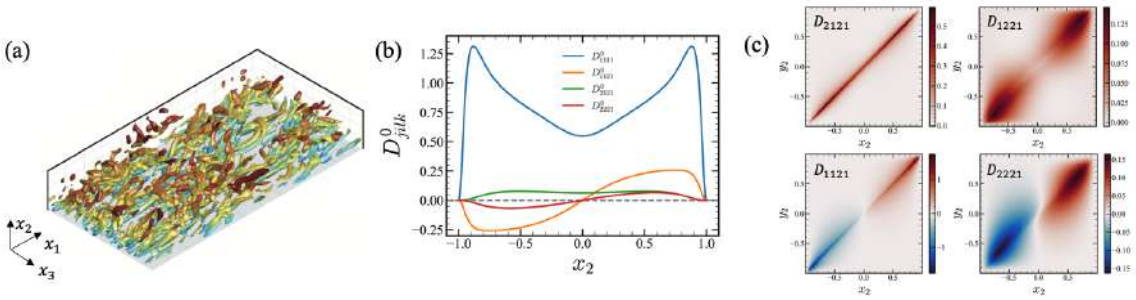

Figure 1: (a) The isocontour of the Q-criterion of the channel flow and its coordinates, (b) The distribution of the four elements in leading-order eddy viscosity tensor, and (c) the distribution of the eddy viscosity kernels.

the non-local effects are negligible for the $\overline{u_1 u_2}$ component of the Reynolds stress, which is the only important component when it comes to prediction of parallel channel flow.

Unlike parallel channel flows, spatially developing boundary layers, involve gradients in multiple directions and are thus sensitive to other components of the eddy viscosity. Using a scaling analysis, we determine four dominant eddy viscosity components which are shown in the figure. Here we use quantification of these components in the channel flow as a proxy to infer anisotropic effects in spatially developing flows. As shown, some components of the eddy viscosity tensor can be locally orders of magnitude larger than the nominal eddy viscosity, D^0_{2121} indicating drastic deviation from the Boussinesq limit.

In our presentation we will show that leading order eddy viscosity operator generates a non-symmetric Reynolds stress tensor. Moreover, our results suggest that leading-order Reynolds stress can be generated by both mean strain rate and mean rotation. This violates the mainstream modeling assumption of Reynolds stress to be only function of the mean strain rate tensor.

FULL KERNEL ANALYSIS

The capture of Reynolds Stress in the channel centerline requires the inclusion of nonlocal terms in the eddy viscosity operators. Hence, for a subset of these tensorial components, we calculated the full non-local eddy viscosity operator, specifically the kernel components that multiply $\mathrm{d}V_1/\mathrm{d}x_2$ in equation 1. We measure D_{ji21} as a function of both $x_2$and y_2. As shown in Figure 1(c), our results indicate that D_{2121} is highly local as the kernel is non-zero only when $\mathbf{x} \simeq \mathbf{y}$. This explains the earlier observation of small error of the leading-order approximation. In contrast, for other components of eddy viscosity, the results indicate significant nonlocality, which invalidate the intrinsic assumption in the Boussinesq hypothesis. Lastly, we confirm that incorporating the full kernel provides exact Reynolds Stresses recovering the symmetry that was lost in the leading order approximation.

CONCLUSION

In summary, we present an exact measurement of the eddy viscosity of the turbulent channel flow along with a quantification of non-Boussinesq effects, and its implications in modeling. For the parallel flow, only one Reynolds stress and one velocity gradient is important and hence anisotropy does not influence the predictions. In such case, the narrow kernel of D_{2121} indicates the validity of the local assumption. These two findings explain why Boussinesq approximation works well for parallel flows. However, our quantification suggests that this conclusion does not hold for spatially developing wall-bounded flows where the non-parallel effects become important. Our measurements reveal that the eddy viscosity is highly anisotropic and highly nonlocal, when it comes to components other than D_{2121} indicating a clear need to include non-Boussinesq effects in RANS models.

INPUT-OUTPUT ANALYSIS OF A TURBULENT SEPARATION BUBBLE VIA THE HARMONIC RESOLVENT

Alberto Padovan*[1] and Clarence W. Rowley[1]
[1] Department of Mechanical and Aerospace Engineering, Princeton University, Princeton, NJ, USA

Summary We study the input-output characteristics of a turbulent separation bubble at $Re_{\theta_0} = 490$ based on the momentum thickness. At these flow conditions, a low-frequency "breathing" mode is present, in addition to oscillations at higher frequencies, and we are interested in understanding their interplay. We perform a frequency-domain linearization of the dynamics about a time-periodic representation of the large, coherent structures that are observed in the flow. This allows us to compute the harmonic resolvent [3], which is a linear operator that governs the dynamics of time-periodic perturbations about a time-periodic base flow, in response to some external time-periodic input. The SVD of the harmonic resolvent shows that the low-frequency breathing mode interacts most strongly with perturbations at 3/2 and twice the breathing frequency, while perturbations at lower frequencies have little effect.

THE HARMONIC RESOLVENT

We apply the harmonic resolvent framework described in [3] to study the input-output characteristics of a turbulent separation bubble at $Re_\theta = 490$ based on the momentum thickness. The direct numerical simulations performed by Wu *et al.* [4] reveal the presence of three distinct unsteady motions: a low-frequency expansion/contraction (*breathing*) of the separation bubble, and two high-frequency modes associated with the shedding of spanwise vortical structures downstream of the separation bubble. For notational clarity, we henceforth let ω be the frequency associated with the breathing mechanism, while the frequencies of the downstream spanwise vortical structures are 2ω and $5\omega/2$.

In order to understand the nature of the coupling between the flow structures at the aforementioned frequencies, we proceed as follows. We write the velocity $\boldsymbol{u}$ and pressure p together in a single state variable $\boldsymbol{q} = (\boldsymbol{u}, p)$ and write the Navier-Stokes equation and continuity in the compact form

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix}\mathbf{I} & 0\\ 0 & 0\end{bmatrix}\boldsymbol{q} = \boldsymbol{f}(\boldsymbol{q}), \tag{1}$$

where $\mathbf{I}$ is the identity matrix. We linearize the dynamics about a time-periodic base flow $\boldsymbol{Q}(t)$ over the set of frequencies $\Omega_b = \{-\frac{3}{2}\omega, -\omega, \ldots, \frac{3}{2}\omega\}$, and we consider time-periodic perturbations $\boldsymbol{q}'(t)$ over the set of frequencies $\Omega = \{-3\omega, -\frac{5}{2}\omega, \ldots, 3\omega\}$. It can be shown that performing the linearization in the frequency domain leads to an input-output system

$$\hat{\boldsymbol{q}}' = \mathbf{H}\hat{\boldsymbol{w}}' \tag{2}$$

where $\mathbf{H}$ is the harmonic resolvent. This is a frequency-domain, block, linear input-output operator that governs the dynamics of small perturbations about the time-periodic base flow, and it accounts for the leading-order coupling between structures at different frequencies. Here, $\hat{\boldsymbol{q}}' = \{\hat{\boldsymbol{q}}'_{k\omega/2}\}_{k=-6,\ldots,6}$ is a vector of all Fourier modes of the perturbed state, while $\hat{\boldsymbol{w}}'$ is a vector of all Fourier modes associated with perturbations (including nonlinearities) that feed back into the harmonic resolvent. We also point out that if we linearize about a steady base flow, then the harmonic resolvent reduces to the standard resolvent operator, for instance considered in [1, 2].

GLOBAL AND CROSS-FREQUENCY AMPLIFICATION MECHANISMS

Analyzing the structure of the harmonic resolvent sheds light on the underlying input-output characteristics of the flow. More precisely, we extract the global amplification mechanisms from the singular value decomposition of the harmonic resolvent. The left singular vectors are the (optimal) most amplified space-time response modes, and they identify the structures that are preferentially excited through the harmonic resolvent. The right singular vectors, on the other hand, are the optimal space-time forcing modes. These provide information about the spatio-temporal sensitivity of the flow and highlight the structures that are most effective at exciting an energetic response through the harmonic resolvent. We also perform an SVD of each block of the harmonic resolvent in order to extract information about the cross-frequency amplification mechanisms of the flow. We find the block singular values particularly informative, as they help identify the cross-frequency interactions that are dominant in the flow.

SELECTED RESULTS AND DISCUSSION

In this section we present the results for the harmonic resolvent evaluated about the previously described base flow. The time-periodic base flow is spanwise-averaged, and we consider two-dimensional perturbations about the base flow.

In figure 1 we show the singular values of the harmonic resolvent as well as the leading singular value computed for each individual block. First, we observe from figure 1a that the singular values quickly decay by more than one order of magnitude, suggesting that the amplification mechanisms about the base flow are low rank. Second, we notice from 1b

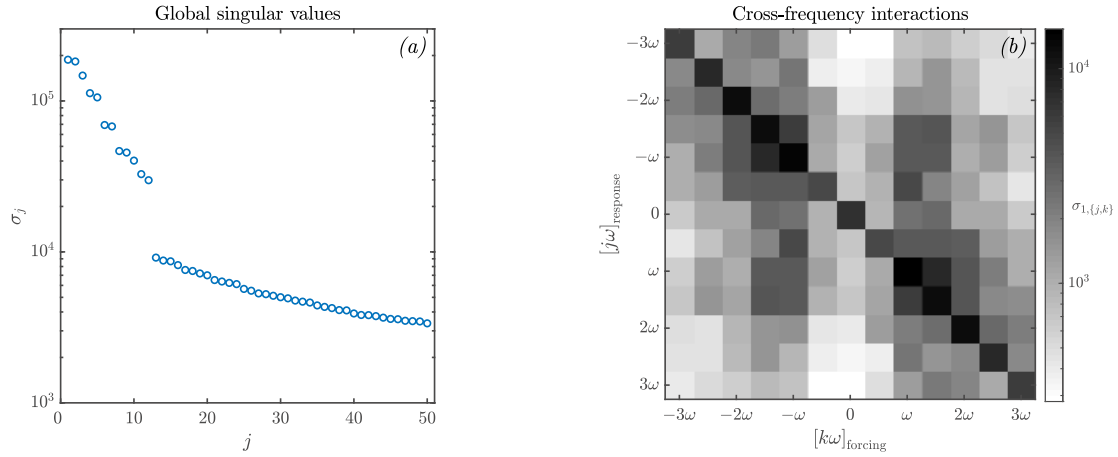

Figure 1: *(a)* singular values of the harmonic resolvent, and *(b)* first singular value, denoted $\sigma_{1,\{j,k\}}$, for each $(j\omega, k\omega)$ block of the harmonic resolvent. The block singular value identify the dominant cross-frequency input-output interactions.

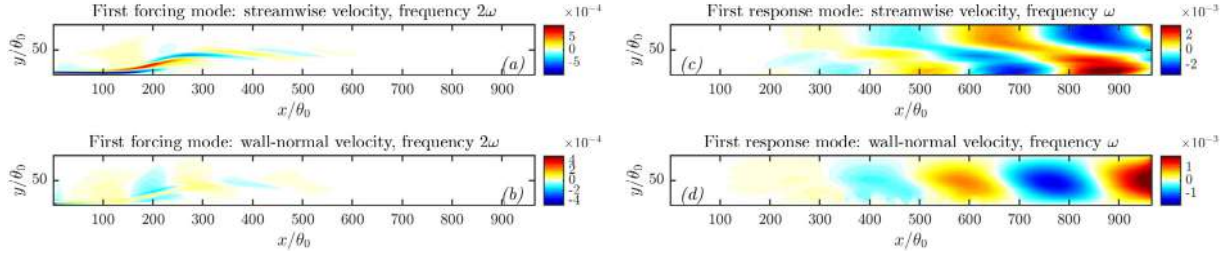

Figure 2: Real part of selected entries of the forcing and response modes associated with σ_1 in figure 1a. From the forcing mode we show *(a)* the streamwise velocity, and *(b)* the wall-normal velocity at frequency 2ω. From the response mode we show *(c)* the streamwise velocity, and *(d)* the wall-normal velocity at the breathing frequency ω.

that there is strong coupling across all frequencies. In particular, by looking at the ω row we find that the perturbations that most strongly couple to the breathing frequency are those at frequencies $3\omega/2$ and 2ω.

In figure 2 we present the optimal forcing and optimal response mode shapes associated with the $(2\omega, \omega)$ frequency pair. Figures 2a and 2b show the structures at frequency 2ω that are optimal at exciting a very energetic response through the harmonic resolvent. We observe that these structures are supported along the shear layer that forms as a consequence of separation, and we can therefore conclude that the shear layer is where this flow is most sensitive to disturbances at frequency 2ω. Figures 2c and 2d, on the other hand, show the most amplified structures at frequency ω that arise in response to a disturbance at frequency 2ω. Finally, we learn from the harmonic resolvent that the cross-frequency coupling between a disturbance at 2ω and the response at ω is sustained (linearly) by the base flow at $-\omega$.

CONCLUSIONS

We present selected results on the amplification mechanisms in a turbulent separation bubble obtained from the analysis of the harmonic resolvent. This is an input-output operator that governs the dynamics of perturbations about a time-periodic base flow in the frequency domain. We find that the flow is susceptible to perturbations along the shear layer that forms upstream of the separation bubble, and we identify the structures that form in response to perturbations along the shear layer. Furthermore, we learn that there is strong coupling across all frequencies, and that the breathing mechanisms is strongly affected by higher frequency structures that scatter back through the base flow.

BOUNDARY LAYER FLUX CONTROL USING KELVIN'S CATS' EYES

Giovanni Nino and Robert Breidenthal*
Department of Aeronautics and Astronautics, University of Washington, Seattle, USA

Summary Wind tunnel experiments are described to detect vortex position and to develop vortex actuators as part of an active control system. The position and strength of a vortex downstream from a vortex generator can be controlled by dielectric barrier discharge plasma jets and air jets at the swept leading edge of a vortex generator. It was found that the most effective location to place the actuators is on the vortex leading edge. Effects of the actuator topology on the level and type of control will be discussed.

BACKGROUND

In the free shear layer, entrainment had been thought to be controlled by small-scale nibbling at the "superlayer" edge [1]. The subsequent discovery of coherent structures revealed that entrainment instead is dominated by large-scale gulping in Roshko's engulfment tongues [2]. It was discovered that forcing the shear layer to form a regular array of vortices results in the entrainment rate going to zero [3]. Implausibly, the growth rate and the Reynolds stresses all essentially vanish when the vortices are equally spaced. Even the molecular mixing rate essentially vanishes as measured by Roberts and Roshko [4]. The vortices are rotating but accomplishing nothing. An idealized model of this behavior is Kelvin's cats' eye flow as shown in Figure 1, when a planar array of co-rotating point vortices of equal sign, strength, and spacing. The flow consists of external streamlines separated from internal streamlines about each vortex by a closed separatrix. The key concept is that the separatrix is a closed streamline, so that the outer flow is perpetually isolated from the inner flow.

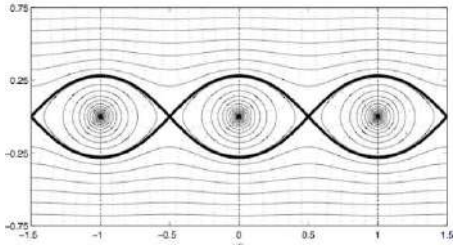

Figure 1. Kelvin's cats' eyes flow model.

A natural question is if such entrainmentless flow could be established for a boundary layer. If so, then all the wall fluxes would dramatically decline to their laminar values, which are much less than turbulent values at large Reynolds number. Based on the peculiar entrainment behavior of a vertical jet at a stratified interface, Cotel proposed that the entrainment rate due to a vortex near a surface should depend on the stationarity of that vortex [5]. If a large vortex is stationary near a solid wall, the wall fluxes would depend on the rotation period of the large vortex and be independent of any small-scale eddies. The wall fluxes would be laminar. This prediction was tested by adding large, streamwise vortices into a wall flow and attempting to stabilize them with a wavy wall, as suggested by Balle [6]. Water tunnel experiments have demonstrated that an initially turbulent boundary layer can be partially relaminarized by adding large, streamwise vortices to the flow and stabilizing them with large, streamwise grooves. The turbulent intermittency vanishes over about half the surface of the wavy wall when a streamwise vortex is deployed in a small "sweet spot" in the center of each groove. If the vortices are slightly mispositioned, the relaminarization effect disappears.

Just as the open-loop forcing of the free shear layer inhibits entrainment for only a short distance, open-loop forcing with a wavy wall relaminarizes the flow for only a short distance. Passive, open-loop control has only a limited range, as the vortices are unstable. It is natural to attempt to continuously stabilize the vortices over an entire surface with active vortex control using feedback. Such a vortex control strategy would exploit active control rather than a passive wavy wall to hold the streamwise vortices stationary. If achievable, it would in principle work for any arbitrary surface.

ACTIVE CONTROL APPROACH

With the aim to develop a boundary layer flux control over a flat or curved surface, a vortex-based active control concept has been divided in four parts: (i) vortex generator, (ii) vortex detection, (iii) actuators, and (iv) control logic. In this paper, we present recent experiments performed at the Kirsten Wind Tunnel on the vortex generation, detection and actuators. A vortex generator (VG) with a swept back leading edge was selected to be mounted on a flat plate and angled to the free stream to generate a vortex. This was the simplest and most effective way to produce reliable vortices. The angle of attack of the VG ranged from 10-25° with 5° increment for speeds between 20 m/s and 70 m/s.

Regarding the vortex detection (Figure 2), a method was developed based on the distribution of the pressure coefficients downstream of the VG. Dynamic pressures were collected with two electronic pressure scanner (Scanivalve ZOC33/64Px) modules over an array of pressure taps installed on a flat plate. The vortex center position is approximated by a fitted straight line on the pressure data using the least squares method. The resulting slope is used to calculate the vortex drift angle γ. This angle provides a good feedback to the controller.

The position and strength of a vortex downstream from a vortex generator can be controlled by actuators mounted on the VG itself. Two types of actuators were investigated: dielectric barrier discharge plasma jets and air jets. These devices are shown in Figure 3. It was found that the most effective location to place the actuators is on the vortex leading edge.

*Corresponding author. E-mail: breident@aa.washington.edu

The experiments reveal that the plasma induced electric wind results in a decrease of the vortex drift angle. It is believed that the induced body force displaces the center line of the induced vortex further away from the wall. Counter-intuitively, this corresponds to a reduction of the lift. Following the Kutta-Joukowski theorem, a reduction of the lift is associated with a reduction of the circulation and the vortex drift angle. On air jets, dynamic pressure cross sections were gathered at different stages behind a VG. Figure 4 shows the effects of air injection at three different ports on their associated dynamic pressure responses. It was found that the vortex position (direction and magnitude) changed in function of air pressure and injection location (i.e. port). For example, air injection at the lower position (Pos 1) of the VG leading edge produced a strong vortex displacement to the side. Air injection at other places (Pos 2 and 3) moved the vortex away of the surface. In addition, injectors topology affected the amount of displacement of the vortex. Divergent injectors produced longer vortex displacements than the one produced by circular injectors. It was clear, from these wind tunnel experiments, that air jets were more effective controlling the vortex position than dielectric barrier discharge plasma actuators. The next steps of the active control system are the development of the controller logic and the integration of the system.

STUDY OF INTERMITTENT STRUCTURE IN ANNULAR COUETTE–POISEILLE FLOW FROM TURBULENT PUFF TO TURBULENT STRIPE

Hirotaka Morimatsu and Takahiro Tsukahara
Department of Mechanical Engineering, Tokyo University of Science, Chiba, Japan

We performed direct numerical simulations (DNS) of annular Couette-Poiseuille flow, focusing on intermittent structures in the subcritical transitional regime. For high radius ratios, we investigated the dependence of the intermittent structures on the pressure gradient, $F(p)$. For the radius ratio of $\eta = 0.8$, the pressure-gradient dependence of the intermittent structure was not observed. For $\eta = 0.5$, the intermittent structure changed dependently on $F(p)$: large $F(p)$ provided helical patterns of localized turbulence. For η of 0.3 and 0.1, we performed DNS with long computational domains and applied $F(p)$ at which the velocity gradient on the inner cylindrical wall surface becomes zero, in order to mimic the pipe flow. One-dimensional intermittency was observed, as seen in the pipe flow, and we found splitting from one puff to several puffs as well as decay of puff.

INTRODUCTION

In wall-bounded shear flow, it is known that the flow often shows characteristic intermittent structures of localized turbulence in the subcritical transitional regime. The characteristic intermittent structure exhibits a regular large-scale pattern in which laminar regions and turbulent regions coexist spatially. The intermittent structure differs depending on the channel shape. In planar flows, an intermittent structure called “turbulent stripe” or “turbulent band” that obliquely inclined to the main flow direction occurs. On the other hand, in the pipe flow, one-dimensional intermittency called a “turbulent puff”, where turbulent regions are localized only in the axial (streamwise) direction, occurs. It is reported that the turbulent puff in the pipe flow can be split from a single puff to two puffs [1]. These intermittent structures, such as turbulent stripe and turbulent puff, are known to also occur in annular flows. In the annular flow, since the channel shape changes with the radius ratio η of inner tube to the outer tube, the intermittent structure also changes according to the radius ratio. In the annular Poiseuille flow driven by a pressure gradient in the axial direction and the annular Couette flow driven by moving of the inner cylinder to the axial direction, one-dimensional intermittency like the turbulent puff in the pipe flow was found at low radius ratio, while high η provided the intermittency like the turbulent stripe such in planar flows [2]. At $\eta = 0.5$, a difference in the type of intermittent structure was found between the annular Poiseuille flow and the annular Couette flow. In the annular Poiseuille flow, turbulent stripe occurs. On the other hand, in the annular Couette flow, a characteristic intermittent structure does not occur, an irregular intermittent structure occurs [3].

In this study, we aim at a unified understanding of intermittent structures from turbulent puff to turbulent stripe by investigating intermittent structures in annular Couette-Poiseuille flows at various radius ratios. At high η, we studied the dependence of the intermittent structure on the given pressure gradient, represented by $F(p)$. At low η, our interest is in whether the turbulent puff-like intermittent structure that was observed in the annular flow can split and decay, like the puff in the pipe flow.

NUMERICAL METHODS

We performed direct numerical simulations (DNS) of annular Couette-Poiseuille flow. The flow is driven by moving of the inner cylinder to the axial direction and the pressure gradient in the axial direction. They are described by parameters of Re_w and $F(p)$. The Reynolds number is defined by $\mathrm{Re}_w = U_w h/\upsilon$, where U_w is the inner cylinder speed, h is the gap width between the cylinders, and υ is the kinetic viscosity. The magnitude of the non-dimensionalized pressure gradient is defined by $F(p) \equiv -\mathrm{d}P^*/\mathrm{d}x^* \cdot \mathrm{Re}_w$, where $\mathrm{d}P^*/\mathrm{d}x^*$ is the mean axial pressure gradient and μ is the viscosity. For radius ratios of $\eta = 0.8$ and 0.5, in order to investigate the $F(p)$-dependence of intermittent structures, we applied three different values of $F(p) = 4$, 8, and 16 in the flow path. For $\eta = 0.3$ and 0.1, we applied $F(p)$ at which the velocity gradient at the inner cylindrical wall surface becomes zero approximately.

The governing equations are the continuity equation and the Navier–Stokes equation in the cylindrical coordinate system. Periodic boundary condition is imposed in the main flow (x) and azimuthal (θ) directions, and non-slip condition is imposed on the wall surfaces. The computational domain size in the azimuthal direction is 2π. The axial domain size is adjusted to satisfy each purpose of the high- and low-η cases. For high $\eta = 0.8$ and 0.5, we performed DNS using the minimum computational domain ($L_x = 51.2h$), which can capture one wavelength of the turbulent stripe. For low $\eta = 0.3$ and 0.1, in order to capture multiple puffs, we performed DNS using very long computational domain ($L_x = 409.6h$) in the main flow direction.

RESULTS AND DISCUSSIONS

At first, we prepared a uniformly turbulent flow as an initial field for all cases, from which the Reynolds number was gradually decreased. For $\eta = 0.8$ and 0.5, we investigated the pressure-gradient dependences of the intermittent structure by applying three different $F(p)$. In the Couette-Poiseuille flow, the flow field can be classified according to whether or not there is a position of zero local shear rate in the cylinder gap. If there is no such position, the flow field is classified as Couette-type flow, otherwise (if there is such position) the flow field is classified as Poiseuille-type flow [4]. For $\eta =$

0.8, regardless of the flow type, helical turbulence occurred for all tested values of $F(p)$: see Figure 1. In the annular flow, higher the radius ratio, the higher the spatial freedom in the azimuthal direction. For high $\eta = 0.8$, the azimuthal computational domain is sufficiently large, so the helical turbulence occurred regardless of the magnitude of $F(p)$. For high $\eta = 0.5$, different intermittent structures occurred and depended on the $F(p)$. For $F(p) = 4$, where the flow field was Couette type, the helical turbulence did not occur, and an irregular intermittent structure occurred. On the other hand, for $F(p) = 8$ and 16 supplying Poiseuille-type flows, the helical turbulence occurred. However, the helical turbulence observed at $F(p) = 8$ was not steadily present, but repeatedly formed and collapsed. This is consistent with the fact that the stripe interval in the plane Poiseuille flow should be half of that of the plane Couette flow.

For the radius ratios of 0.3 and 0.1, we performed analysis that simulated the pipe flow by adjusting $F(p)$ to achieve the nearly zero shear rate at the inner-cylinder surface. For $\eta = 0.3$, one-dimensional intermittency like the turbulent puff in the pipe flow was observed at $\mathrm{Re_w} = 1470–1460$, as shown in Figure 2. Normalization of these Reynolds numbers using the hydrodynamic equivalent diameter and the bulk mean velocity reveals that those values correspond to approximately 2500. This Reynolds number is close to the value at which the turbulent puff occurs in the pipe flow. For $\eta = 0.1$, we observed one-dimensional intermittency as seen in the pipe flow at $\mathrm{Re_w} = 1600$. The normalized Reynolds number by the hydrodynamic equivalent diameter and the bulk mean velocity is approximately 2190. This Reynolds number is also close to the range of the turbulent puff in the pipe flow. Furthermore, these turbulent puffs observed in the present annular flows were found to split from one to several turbulent puffs as time progresses (Figure 3), and also decayed without maintaining the turbulence.

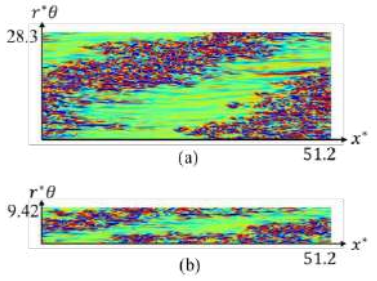

Figure 1. Instantaneous flow field in the (x, θ)-plane at the midgap for (a) $\eta = 0.8$, $F(p) = 4$ and (b) $\eta = 0.5$, $F(p) = 8$. The contour shows wall-normal fluctuation; red, $u_r' > 0.03U_w$; blue, $u_r' < -0.03U_w$.

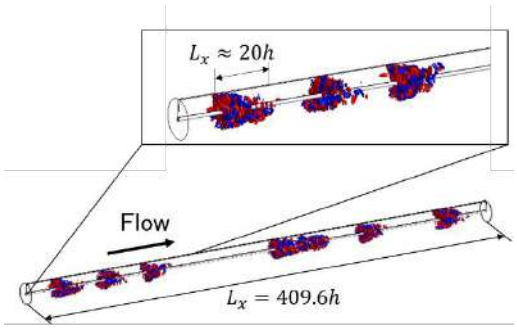

Figure 2. Three-dimensional visualization of the localized turbulent puffs for $\eta = 0.1$, $\mathrm{Re_w} = 1600$. The iso-surfaces show wall-normal fluctuation: red, $u_r' > 0.03U_w$; blue $u_r' < -0.03U_w$.

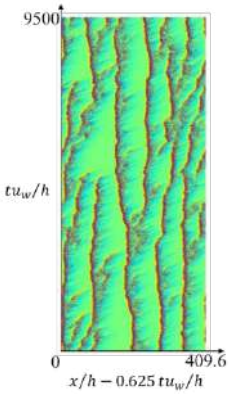

Figure 3. Space-time diagram of azimuthally-averaged wall-normal velocity $\langle u_r \rangle_\theta$ at the gap center for $\eta = 0.1$, $\mathrm{Re_w} = 1600$: red, positive value; blue, negative; green, zero.

CONCLUSIONS

We performed direct numerical simulations of annular Couette-Poiseuille flow for four different radius ratio. For the radius ratios of 0.8 and 0.5, we investigated the pressure-gradient dependences of intermittent structure by applying three different $F(p)$. By changing $F(p)$, the intermittent structures as well as the mean flow exhibited continuous variation between those in the Poiseuille-type and Couette-type flows: the helical turbulence can disappear at low $F(p)$ even with fixing $\mathrm{Re_w}$. For the radius ratios of 0.3 and 0.1, we simulated the pipe-flow-like system. In both η cases, we observed one-dimensional intermittency like the turbulent puff in the pipe flow. The one-dimensional intermittency exhibited split and decay of the turbulent puff. The present findings imply a smooth continuous transition from stripes to puffs in wall-bounded shear flows.

ACKNOWLEDGEMENTS

The present simulations were performed on an SX-ACE supercomputer at the Cybermedia Center of Osaka University and at the Cyberscience Center of Tohoku University.

Summary The instantaneous streamwise velocity in turbulent wall flows exhibits a staircase-like profile, with uniform momentum zones (UMZs) separated by regions of concentrated spanwise vorticity (vortical fissures, or VFs) across which the streamwise flow speed jumps by a few multiples of the friction velocity. One challenge is to identify a mechanism that accounts for observed properties of the UMZ/VF profiles while respecting the constraints imposed by the mean momentum balance. Measurements show that outboard of the near-wall peak in the Reynolds stress: (i) the characteristic VF thickness decreases as the friction Reynolds number increases; and (ii) the mean momentum equation is inertially dominated. Supported by a new large-Re asymptotic analysis of the Navier-Stokes equations, a multiple spatial scale self-sustaining process for UMZs and VFs is proposed that satisfies these requirements.

SINGULAR NATURE OF TURBULENT WALL FLOWS

Meinhart & Adrian [1] were the first investigators to document that the wall-normal (y) structure of the instantaneous streamwise velocity in the turbulent boundary layer exhibits a staircase-like profile: regions of quasi-uniform momentum are separated by internal shear layers across which the streamwise velocity jumps by an O(1) amount when scaled by the friction velocity u_τ, as shown in Figure 1a. This sharply-varying instantaneous profile differs dramatically from the well-known long-time mean profile, which is logarithmic over much of the boundary layer, prompting Klewicki [2] to propose that the turbulent boundary layer is singular in two distinct ways. Firstly, spanwise vorticity and mean viscous forces are concentrated in a near-wall region of thickness $O(1/\sqrt{Re_\tau})$, where Re_τ is the friction Reynolds number. Secondly, in a turbulent boundary layer, spanwise vorticity and viscous forces are also significant away from the wall (in the inertial domain, i.e. outboard of the peak in the Reynolds stress), but *only* in spatially-localized regions (i.e. within the internal shear layers). This interpretation accords with a multiscale similarity analysis of the mean momentum balance for turbulent wall flows performed by Wei *et al.*[3]. In support of this notion, Cuevas Bautista *et al.* [4] demonstrate that the logarithmic profile and other higher-order statistcal features associated with the mean streamwise flow can be recovered by ensemble averaging staircase-like streamwise velocity profiles. The objective of the present investigation is to probe the governing Navier–Stokes equations in the limit of large Re_τ in search of a mechanistic self-sustaining process (SSP) theory that (i) can account for the emergent staircase-like profile of streamwise velocity in the inertial region and (ii) is compatible with the singular nature of turbulent wall flows.

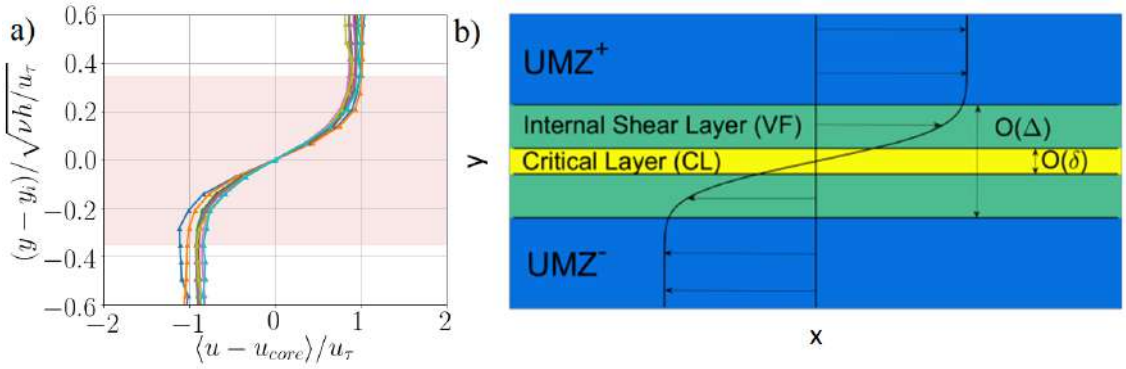

Figure 1: (a) Conditionally-averaged streamwise velocity through vortical fissures in the inertial region of a turbulent boundary layer flow (at $Re_\tau \approx 6000$) in the Flow Physics Facility at the University of New Hampshire. y_i indicates the wall normal location of the VF, u_{core} is the streamwise velocity at the center of the VF, and angle brackets indicate a conditional average. Figure 2: Two-dimensional projections of a new, inertial ECS exhibiting VFs coupled to adjacent UMZs in unbounded plane Couette flow at $Re_\tau \approx 8000$). (a) Close-up view of streamlines in a rotated-streamwise/wall-normal plane within the VF centred on $y = 0$, where the streamwise direction is rotated using Squire's transformation to highlight the appearance of the fine-scale Kelvin's cat's-eyes vortex pattern within the VF. (Arrows are also plotted to indicate in-plane velocity vectors.) (b) Mean velocity field in the fissure-normal/spanwise-plane. Color indicates the value of the streamwise-averaged streamwise velocity component while arrows show the roll velocity field. (c) Fissure-normal fluctuation velocity component in a streamwise/spanwise plane within the VF near $y = 0$. Color indicates the value of this component normalized by ${Re_\tau}^{-3/2}$. The solid black lines indicate caustics, which partition the plane into an 'illuminated region' ($-0.7 \leq z \leq 0.7$) and 'shadow zones' ($|z| \geq 0.7$).

A MULTISCALE SSP THEORY FOR INERTIAL REGION STRUCTURES

Plausible explanations for the formation and persistence of sharply-varying instantaneous streamwise velocity profiles all implicate quasi-coherent turbulent flow structures including streamwise roll motions that induce a cellular flow in the transverse (i.e. spanwise/wall-normal) plane. A possibility, explored here, is that these large–scale motions may be *directly* sustained via an inertial–layer SSP that is broadly similar to the near-wall SSP and closely-related vortex-wave interaction (VWI) theory developed by Waleffe [5] and Hall & Smith [6], respectively. It is argued that these theories cannot account for organized motions in the inertial domain, essentially because the rolls are predicted to be viscously dominated even at large Re_τ [7,8]. The target of the present investigation is an inherently multiscale SSP, in which inviscid streamwise rolls differentially homogenize an imposed background shear flow, thereby generating uniform momentum zones and an embedded internal shear layer (or 'interface'), and are sustained by Rayleigh instability modes having asymptotically smaller streamwise and spanwise length scales.

The Rayleigh mode is supported by the inflectional wall-normal profile of the streamwise–averaged streamwise velocity. Because the thickness of the internal shear layer varies comparably slowly in the spanwise direction, the Rayleigh mode is refracted and rendered fully three–dimensional. This three–dimensional mode is singular, necessitating the introduction of a critical layer within the shear layer within which the mode is viscously regularized. As in VWI theory, a jump in the spanwise Reynolds stress is induced across the critical layer, which ultimately drives the roll motions. This multiscale and three–region asymptotic structure (figure 1b) is efficiently captured using a complement of matched asymptotic and WKBJ analysis. In contrast to the near-wall SSP, the rolls are sufficiently strong to differentially homogenize the background shear flow, thereby providing a potential mechanistic explanation for the formation and maintenance of both UMZs and interlaced internal shear layers. Two-dimensional projections of a new exact coherent state (ECS) supported by the multiscale SSP and exhibiting this spatial structure are shown in figure 2.

CONCLUSIONS

In summary, a primary merit of the new SSP identified here is that it highlights the distinction between viscous and inertial ECS. The SSP also provides a plausible mechanism, derived directly from the NS equations, for the observed UMZ/VF profiles of streamwise velocity. In this mechanism, the VFs play a dynamically *active* role in the sustenance and persistence of the UMZs. Perhaps most significantly, the new SSP and associated ECS provide a concrete dynamical realization of the conceptual model of the singular nature of turbulent wall flows proposed by Klewicki, lending further support to the 'boundary-layers-within-*the*-turbulent-boundary-layer' paradigm.

AN ANISOTROPIC MODEL FOR THE TURBULENT SCALAR FLUX IN SHEAR FLOWS WITH DEEP LEARNING

Pedro M. Milani *[1] and John K. Eaton[1]
[1] Mechanical Engineering Department, Stanford University, Stanford CA, USA

Summary In the present paper, we consider a deep learning model for the closure of the turbulent scalar flux in the Reynolds averaged equations. This model utilizes a neural network with embedded rotational invariance to predict a tensorial turbulent diffusivity using mean flow quantities as inputs. Notably, the high fidelity data used for training do not explicitly contain a diffusivity tensor - the neural network architecture is designed to learn that information implicitly. The model is applied in an inclined jet in crossflow and shows significant improvement in predicting the streamwise evolution of the mean scalar concentration.

INTRODUCTION

Many turbulent shear flows of interest involve the transport of a passive scalar c by the velocity field u_i. One such example is the inclined jet in crossflow, in which a cylindrical jet releases a contaminant into the main flow. This configuration finds applications in turbomachinery film cooling [1], where the scalar concentration is analogous to temperature. To solve for the mean scalar concentration in practical flows, the Reynolds averaged equations are usually employed and closure models are needed for both the Reynolds stress (in the momentum equations) and the turbulent scalar flux (in the scalar transport equation).

Machine learning approaches have drawn increased attention in the community as means to formulate improved closure models [2]. For example, Ling et al. [3] developed the Tensor Basis Neural Network (TBNN), which is a neural network architecture to predict the Reynolds stress tensor with rotational invariance. Most authors focus on Reynolds stress modeling for the momentum equations; by contrast, the focus of the current work is on the turbulent scalar flux.

The most common model for the turbulent scalar flux is the simple gradient diffusion hypothesis, with an isotropic turbulent diffusivity prescribed via a fixed turbulent Schmidt number [4]. Milani et al. [5] explored machine-learned models for the turbulent Schmidt number field, and obtained some improvement; however, model form errors can be significant in 3D shear flows which makes this approach insufficient. A more comprehensive model form is shown in Eq. 1, which assumes that the turbulent scalar flux vector, $\overline{u_i' c'}$, is related to the mean concentration gradient via a tensorial diffusivity D_{ij}. This model is still local, but it allows different turbulent transport properties in different directions and cross-gradient transport (whereby, for example, gradients in the y direction affect the transport in the x direction).

$$\overline{u_i' c'} = -D_{ij} \frac{\partial \bar{c}}{\partial x_j} \tag{1}$$

Some authors have proposed algebraic models for the diffusivity tensor D_{ij} based on the Reynolds stress, but such models have not gained much traction in practical codes [4]. In the current work, we apply deep learning techniques to predict the diffusivity tensor based only on mean flow quantities in hopes that this could lead to a more practical model. In particular, we adapt the TBNN of Ling et al. [3] to the scalar modeling problem, with a modified architecture which we call TBNN-s (where 's' stands for scalar flux modeling). The model is developed using the highly resolved large eddy simulations (LES) of inclined jets in crossflow that are presented and validated in Milani et al. [6], shown in Fig. 1.

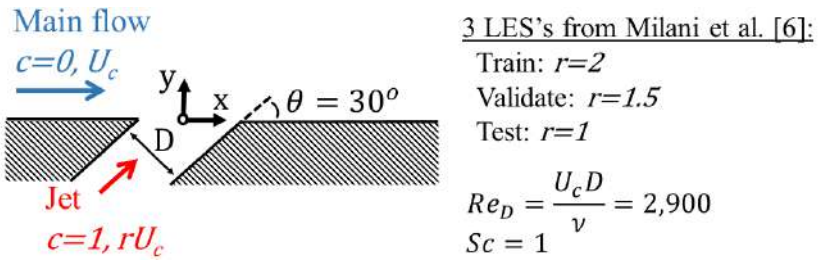

Figure 1: Schematic of the inclined jet in crossflow used in this study. This geometry is fully 3D, with a square channel main flow and a cylindrical jet. The flow is incompressible, U_c is the channel bulk velocity, and rU_c is the jet bulk velocity. Three highly resolved simulations are employed with the same Reynolds number (Re_D) and molecular Schmidt number (Sc), but different velocity ratios (r).

METHODOLOGY

The TBNN is designed to predict the Reynolds stress anisotropy tensor, which is a symmetric tensor explicitly available in the high fidelity data, as a function of the local mean flow variables. It employs a tensor basis expansion to guarantee that the turbulence model is invariant to any coordinate frame transformations. To use an analogous approach to model the turbulent scalar flux, we assume initially that it is a general function of $\mathbf{S}$ (the mean strain rate tensor), $\mathbf{R}$ (the mean rotation rate tensor), and $\nabla \bar{c}$ (the mean concentration gradient vector):

*Corresponding author. E-mail: pmmilani@stanford.edu.

$$\overline{\mathbf{u}'c'} = -\mathbf{f}(\mathbf{S}, \mathbf{R}, \nabla\bar{c}). \tag{2}$$

Then, we use an appropriate basis expansion to represent the function $\mathbf{f}$ with embedded rotational invariance. Zheng [7] shows that, for this particular case, there are 13 scalar invariants λ_i, which are ultimately the inputs to the neural network, and 6 vector elements in the integrity basis expansion, $\mathbf{t}^{(n)}$. The relevant vector basis is shown in Eq. 3:

$$\mathbf{t}^{(1)} = \nabla\bar{c}, \quad \mathbf{t}^{(2)} = \mathbf{S}\nabla\bar{c}, \quad \mathbf{t}^{(3)} = \mathbf{R}\nabla\bar{c}, \quad \mathbf{t}^{(4)} = \mathbf{S}^2\nabla\bar{c}, \quad \mathbf{t}^{(5)} = \mathbf{R}^2\nabla\bar{c}, \quad \mathbf{t}^{(6)} = (\mathbf{SR} + \mathbf{RS})\nabla\bar{c}. \tag{3}$$

Note that it is possible to factor out the mean concentration gradient $\nabla\bar{c}$ from each of the basis elements, such that they can be written as a 3x3 matrix multiplied by $\nabla\bar{c}$. Then, a weighted sum of the vector basis elements can be interpreted as a diffusivity tensor times the mean concentration gradient. Using a neural network architecture that explicitly recognizes this fact, it is possible to use high fidelity data with a known $\overline{u_i'c'}$ (but unknown turbulent diffusivity tensor D_{ij}) to train the network. The network learns a tensorial diffusivity that is most consistent with the given turbulent scalar flux and the invariance requirement. Then, for a new flow, we need only provide the quantities $\mathbf{S}$, $\mathbf{R}$, and $\nabla\bar{c}$ and the trained network is able to predict a turbulent diffusivity matrix.

RESULTS AND DISCUSSION

We train the proposed network architecture in the $r = 2$ LES and determine its hyperparameters through validation on the $r = 1.5$ LES. We use a deep neural network with 10 hidden layers and 30 nodes per layer. The network then predicts a turbulent diffusivity matrix in the $r = 1$ dataset, which is used to solve the Reynolds averaged scalar transport equation. The results are shown in Fig. 2.

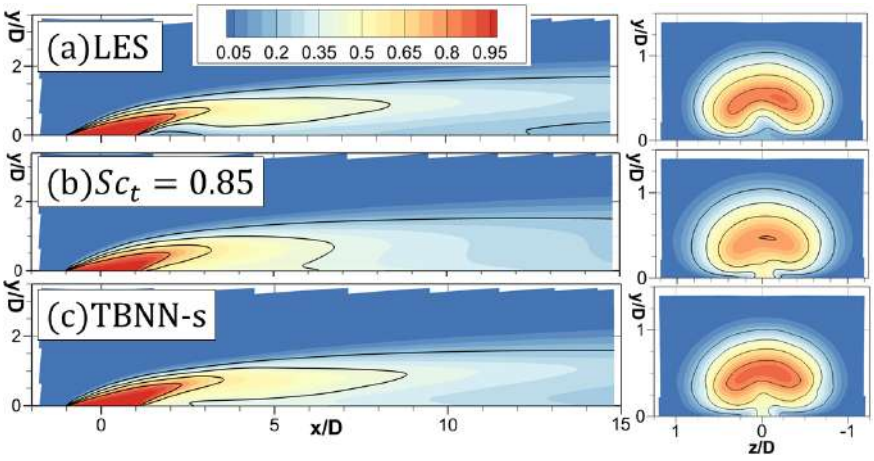

Figure 2: Mean scalar concentration in the $r = 1$ jet in crossflow. The left side shows centerplanes ($z = 0$) and the right side show axial ($y - z$) planes located at $x/D = 2$. (a) shows LES results, which are validated against experimental data. Both (b) and (c) are obtained by solving the Reynolds averaged scalar transport equation with the LES mean velocity field and distinct models for the turbulent scalar flux. (b) contains results from a baseline turbulence model, which is the isotropic gradient diffusion hypothesis with a fixed turbulent Schmidt number ($Sc_t = 0.85$). (c) shows results of the TBNN-s anisotropic model.

The resulting model is numerically stable after a simple post-processing step of the output diffusivity that forces it to be positive semidefinite. Interestingly, the TBNN-s model is able to significantly improve the mean scalar concentration field prediction in a flow that is has not been trained on. In particular, the network learns off-diagonal elements of the diffusivity matrix that are intuitively sound. So, this added cross-gradient capability of the model is able to better predict the streamwise decay compared to a baseline model. The results are also superior to those of a previously reported machine-learned isotropic model [5]. The TBNN-s proposed here can be readily applied to arbitrary 3D flows and meshes as long as relevant training data exist. Thus, future work could explore the application of this model in other turbulent flows where the concentration of a scalar contaminant is sought.

Summary As fluid system typically have large numbers of degrees of freedom, classical control strategies typically need to be obtained using reduced order models (ROMs). Obtaining such models is often is the most costly process in the development of control strategies. Alternatives using response modes from resolvent analysis, PSE solutions, and data-driven methods have been proposed as an alternative. However, none of these approaches are generalizable to large class of problems, and are mostly restricted to flows dominated by convection, and to SISO control. An approach for optimal control of complex flows, without the construction of ROMs is proposed. The method has moderate computational cost, and a matrix-free approach makes it suitable for complex flows. Force colour, which is seen to be crucial for an accurate estimation of turbulent flows, is naturally handled by the method.

INTRODUCTION

Flow control has been an active research topic, with possible applications in aircraft noise and drag reduction. Classical control methods have been successfully used in many studies. Due to the large numbers of degrees-of-freedom of unsteady shear flows, reduced order models (ROMs) are typically constructed to obtain a system for which the solution of Ricatti equations is feasible. ROMs based on Galerkin projections using proper-orthogonal decomposition (POD) modes, balanced modes, and eigen-modes have been used. All of these can be computed from time marching schemes, however in some cases the number of modes required can be large, and the procedure is not always straightforward. Moreover, ROM accuracy may be fragile, and good representation of open-loop dynamics does not guarantee an accurate representation of the closed-loop behaviour. A posteriori tests are thus needed, which often requires some trial and error in the construction of a ROM.

Some alternatives have been proposed. Eigen-system realization algorithms have much lower computational cost, and are equivalent to a ROM based on balanced modes [1]. Optimal control and estimation gains for full systems can be obtained with iterative methods [2], which can be used directly for control (which is only feasible for simulations), or for constructing ROMs a posteriori. Both these methods are in practice restricted to low-dimensional inputs.

Another approach to estimation and control is the Wiener regulator. Martinelli [3] is, to the best of our knowledge, the only work using Wiener's method for flow control. The author realized that the method can potentially lead to large computational saving, as the most costly part of the calculation scales with the number of sensors and actuators, not with the dimensionality of the flow model. However, his application was limited to the use of one sensor and one actuator, probably due to the difficulties of solving the corresponding Wiener-Hopf problems.

METHODS

Estimation methods based on the resolvent operator have been proposed as an alternative to classical estimation tools [4, 5]. Building on these works, a previous work from from the authors [6] showed that the resolvent leads to optimal non-causal estimation, which minimizes the functional

$$\boldsymbol{J} = \int_{-\infty}^{\infty} \langle (\boldsymbol{u}(\boldsymbol{t}) - \tilde{\boldsymbol{u}}(\boldsymbol{t}))^{\dagger} (\boldsymbol{u}(\boldsymbol{t}) - \tilde{\boldsymbol{u}}(\boldsymbol{t})) \rangle \boldsymbol{dt}, \tag{1}$$

with $\langle \cdot \rangle$ representing the expected value, u the flow-state, and $\tilde{u}$ the flow state estimation obtained from low-rank flow measurements, $y(t)$. It is shown that the optimal estimate can be obtained for large systems using time marching of the adjoint and direct linearized Navier-Stokes equations, which naturally handles system disturbed by coloured forces. On a turbulent channel flow, the use of the correct force colour, with forces representing non-linear interactions [7], is crucial for obtaining accurate estimations with a low number of sensors, with estimation outperforming previous approaches [8]. Although typically unknown, force colour can be efficiently estimated using the method and an auxiliary set of sensors.

The method is extended to the development of control strategies: perturbations in certain flow regions, referred to as targets, $z(t)$, are minimized using flow actuation obtained via a convolution of a control law and flow readings, $a(t) = \Gamma(t) * y(t)$. This corresponds to minimization of the cost functional

$$\boldsymbol{J} = \int_{-\infty}^{\infty} \langle \boldsymbol{z}(\boldsymbol{t})^{\dagger} \boldsymbol{z}(\boldsymbol{t}) \rangle \boldsymbol{dt} + \int_{-\infty}^{\boldsymbol{0}} \boldsymbol{\lambda}(\boldsymbol{t}) \boldsymbol{\Gamma}(\boldsymbol{t}) \boldsymbol{dt}, \tag{2}$$

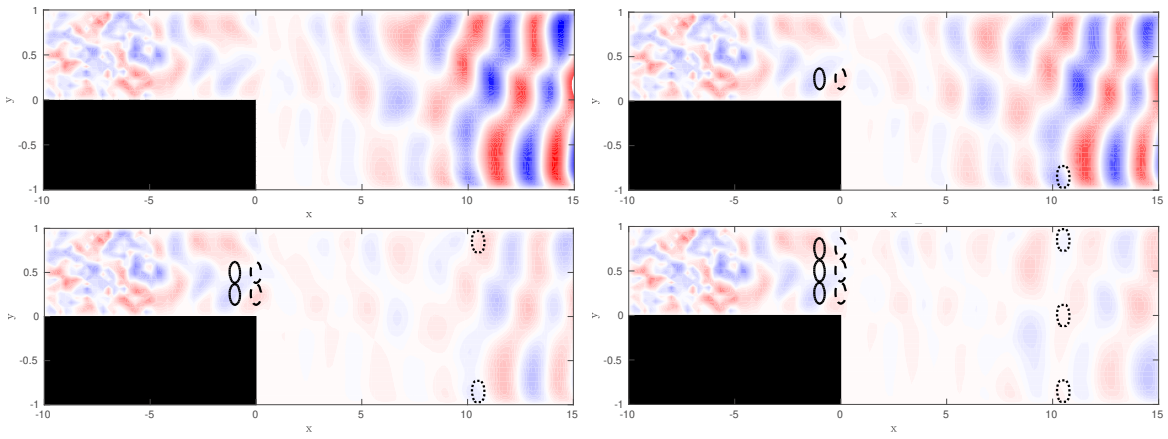

Figure 1: Flow perturbation snapshot for uncontrolled and optimally controlled systems. Colour map indicates streamwise velocity perturbations, with the same colour scale used in all plots. Solid, dashed and dotted circles represent sensors, actuators and targets used.

where the rightmost term corresponds to a Lagrange multiplier to enforce control law causality. A minimization of this functional leads to a Wiener-Hopf equation, due to the presence of the half-time-domain integral.

Solutions of Wiener-Hopf equations can be obtained with a kernel factorization as a multiplication of a causal and an anti-causal functions. Solving equation (2) requires the factorization of two kernels, of sizes $n_y \times n_y$ and $n_z \times n_z$, with n_y and n_z representing the number of sensors and targets used. Kernel factorization can only be obtained analytically for scalar kernels and special types of matrix kernels. In this work this is carried out with numerical solutions of the Fredholm equation of second kind [9]. Optimal causal control of large system is thus obtained with moderate costs, without requiring model reduction, for a system with assumed force and sensor noise statistics, via the resolvent operator: the method is thus refereed to as *Resolvent-based control*.

RESULTS

The method is applied for control of perturbations of a backward-facing step, with $Re = 500$, based on the channel width, and a unit step height. We work with the linearized Navier-Stokes system, driven by stochastic external disturbances. The spectral solver *Nek5000* is used for direct and adjoint computations. The configuration is similar to the that used by [10], where a single sensor and actuator were used to control low-rank disturbances using a data-driven approach. Here the problem is made considerably more challenging by making the external forces high rank, with spatiotemporal white forces used for $x < -5$. For this case multiple sensors and actuators are seen to be crucial for an effective control of flow disturbances, as seen in figure 1.

The proposed method is effective for developing control strategies, as the associated Wiener-Hopf equation scales with the number of sensors and targets, not with the dimensionality of the underlying problem. There is no need to form large system matrices, as all computations are carried out with the direct and adjoint time stepper. The method is thus directly applicable to complex, three-dimensional flows. The control law can easily incorporate coloured force statistics, which can be estimated using an approach proposed on a previous work [6].

ESTIMATION OF ROUGH WALLS BY THE ROUGHNESS HEIGHT AND STEEPNESS

Guozhen Ma[1], Chunxiao Xu[1] and Hyung Jin Sung[2], Weixi Huang *[1]

Summary Turbulent flows over three-dimensional sinusoidal rough walls are investigated by direct numerical simulations at $Re_\tau \approx 540$. By systematically varying the roughness height k^+ or wavelength λ^+, we introduce a new coupling scale $k^+ \cdot ES$ ($ES \sim k/\lambda$). By utilizing this scale, the roughness function collapses well to a single line. More importantly, the prediction model of wall resistance based on roughness function was established by defining a drag increasing ratio (*DI*). Thus we can estimate the wall drag coefficient directly from the given roughness height and steepness.

INTRODUCTION

The turbulent flow over a rough wall almost always produces higher drag than that of a smooth wall. The increase in drag is often quantified by the Hama roughness function ΔU^+, which reflects the downward shift of the streamwise mean velocity profile. In practice, the increase of drag usually brings a lot of harm and efficiency loss, and predicting the drag on a rough wall is therefore of crucial importance to most engineering problems. A central goal in the present study is to predict the roughness function directly from the given rough surface, and then predict the wall resistance.

The dependence of ΔU^+ on the roughness height k^+ and other geometric features, such as the density and shape has been explored in many studies (Jiménez, 2004; Flack & Schultz, 2010). Most of them mainly focused on investigating the influence of these two parameters separately. In this paper, a parameter $k^+ \cdot ES$ is defined which comprehensively considers the roughness Reynolds number and the steepness of the wall roughness, to parameterize the flow field statistics. *ES* is the mean absolute streamwise gradient of the surface (Napoli *et al*., 2008), and proportional to k/λ in the roughness form of our study.

COMPUTATIONAL SETUP

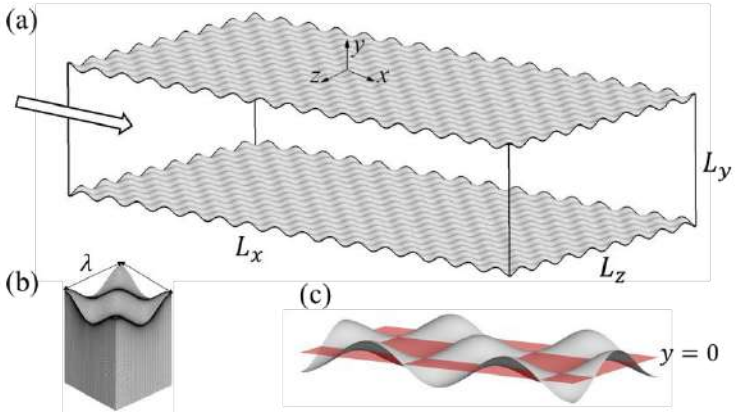

Figure 1. Schematics of the turbulent channel flow over three-dimensional sinusoidal rough walls.

The problem under consideration is the fully developed turbulent channel flow over 3D sinusoidal rough walls. The roughness form chosen is consistent with that of Chung *et al*. (2015). A schematic diagram of the channel is shown in Figure 1. A right-handed Cartesian frame fixed in the physical space is employed with *x*, *y* and *z* axes along the streamwise, vertical and spanwise coordinates, respectively. *k* is the semi-amplitude of the sinusoidal roughness and λ is the wavelength of the roughness elements. The mean height of the rough surfaces is set to zero, thus the coordinate $y = 0$ is used as the virtual origin of the bottom wall. The friction Reynolds number based on the friction velocity u_τ and the half channel height δ is about 540. The sizes of the computational domain is $2\pi\delta \times 2\delta \times \pi\delta$, and the corresponding grid number is 288×192×288. The grid sizes in the *x* and *z* directions are uniform with the resolution of $\Delta\xi_1^+ \approx 11$ and $\Delta\xi_3^+ \approx 5.5$, respectively. The grid points along the *y* axis follow a cosine distribution with $\Delta\xi_{2,min}^+ \approx 0.1$ and $\Delta\xi_{2,max}^+ \approx 8.9$. The no-slip condition is applied to the walls of the channel and a periodic boundary condition is applied in the *x* and *z* directions. The flow is driven by a mean pressure gradient, which is dynamically adjusted to keep the constant flow rate in time. We used the coordinate transformation to transform the irregular physical domain into a rectangular computational domain based on the boundary-fitted system. To identify the roughness effects, the phase average and triple decomposition are adopted in analysis of the flow fields. Further details of the numerical methods can be found in Zhang *et al*. (2019). In this work, three groups are chosen: (1) group A, k^+ is varied while k/λ is kept constant; (2) group B, λ^+ is varied while k^+ is kept constant; (3) group C, k^+ is varied while λ^+ is kept constant.

NUMERICAL RESULTS

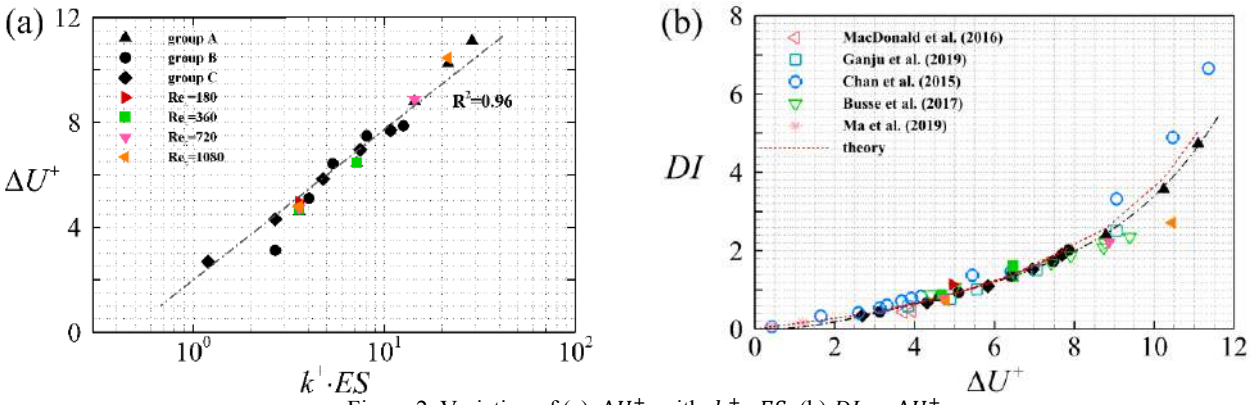

Figure 2. Variation of (a) ΔU^+ with $k^+ \cdot ES$; (b) DI *vs* ΔU^+.

A simple fitting of the present data is applied for the parametrization of ΔU^+ with k^+ and ES,

$$\Delta U^+ = 2.78 \cdot [log(k^+ \cdot ES)] + 1.35, \quad (1)$$

Figures 2(a) show the results of scaling of the roughness function ΔU^+ using new roughness paramater $k^+ \cdot ES$. All the data collapse well to a single line, that is, the rough walls constructed in different roughness heights and roughness wavelengths exhibit a similar behaviour by denoting $k^+ \cdot ES$. Here we add several cases to take into account the effect of Reynolds number. It's clear that the ΔU^+ only has to do with k^+, with little dependence on the Reynolds number. Figure 2(b) gives the prediction relationship between the drag coefficient C_f and ΔU^+. The y-axis is defined as the drag increase ratio as $DI = (C_f - C_{f,0})/C_{f,0}$, which is fitted by the fourth-order polynomial. Almost all data fall on the fitting asymptote, and the goodness-of-fit reaches 0.99. Note that C_f approaches the smooth wall result $C_{f,0}$ for $\Delta U^+ = 0$, namely DI tends to zero, which is reflected in the fit. Besides the fitting curve, DI can be derived according to its definition, i.e.

$$DI = \left(\frac{1}{1-\Delta U^+/U_{b,0}^+}\right)^2 - 1. \quad (2)$$

where $U_{b,0}^+$ denotes viscous-scaled bulk velocity of the smooth wall. The results of some published literature with different roughness forms are also putted in the figure to make comparisons, which show very good consistency.

CONCLUSIONS

In the present study, DNS with a body-conforming grid was performed for turbulent channel flow over three-dimensional sinusoidal rough walls. Three groups were chosen and the DNS data for a smooth wall was included for comparison. By systematically varying the roughness height k^+ and roughness steepness ES, we parameterize the effects of these two important parameters. The results showed the combination of k^+ and ES, i.e. $k^+ \cdot ES$, produces more reliable predictive schemes, which performs significantly better than just k^+ or ES individually. Then a resistance increasing ratio is defined to illustrate the predictive relationship between the total drag coefficient and the roughness function. The wall drag coefficient can be estimated directly from known roughness parameters of the surface, i.e. $C_f \sim f(k^+ \cdot ES)$, which is of great significance to our practical application. However, the scaling still exists the limitations. When ES is very large or small, there is a lack of the correct behaviour. This is related to the solidity of the roughness, and the current study is mainly applicable to the sparse regime.

MODELING THE TURBULENT FLOW OVER AN ANISOTROPIC POROUS WALL USING DMD MODES AND DEEP LEARNING

Summary The main goal of this work is to model the flow near an anisotropic porous wall. Two databases have been analysed, where the drag increases or decreases compared to the case of an isotropic porous wall. Higher order dynamic mode decomposition (HODMD) is applied to identify the main spatio-temporal flow structures in the flow. As expected, the drag increase is related to the presence of spanwise elongated structures, so-called 'rollers', which are related to a KH-like instability, frequently reported over permeable substrates. On the contrary, the drag reduction mechanism is related with the presence of stronger streamwise correlated structures, so-called 'streaks'. Based on this, a group of DMD modes have been selected to model the wall shear stress. Combining these modes with linear and non-linear regression models, the evolution in time of the wall shear stress is predicted with noteworthy accuracy.

INTRODUCTION

Wall-bounded turbulent flows present a wall friction higher than laminar flows. Due to their widespread applications, in natural flows and in the industry, many researchers have studied in detail the flow over complex surfaces, especially over porous walls. In particular, researchers have paid special attention to the flow over isotropic porous walls [1], although more recently the community has started to consider the flow over anisotropic walls, as these can alter the near wall dynamics. Increasing the wall normal permeability, the drag increases compared to a standard isotropic wall [2,3]. This drag increase is related to a KH-like instability, identified by the presence of spanwise elongated structures, named 'rollers' [4]. On the other hand, decreasing wall-normal permeability and increasing the streamwise one, drag reduces and the flow is more correlated in the streamwise direction. The present work studies in detail two datasets obtained from numerical simulations of the turbulent flow over an anisotropic porous wall and compares the results with a third data set modelling the turbulent flow over an isotropic porous wall. In the first case, the wall normal permeability is increased, thus the drag increases, while in the second case, the permeability along the streamwise and spanwise direction is increased, thus the drag decreases when compared to the flow over a rigid wall [2].

METHODOLOGY

Higher order dynamic mode decomposition (HODMD) [5], an extension of dynamic mode decomposition (DMD) [6] introduced for the analysis of complex and noisy databases, is used to analyse two databases modelling a turbulent anisotropic porous wall [2]. The spatio-temporal HODMD analysis [7] have been carried out with the aim to identify the main mechanism producing the drag increasing or drag reduction in the flow. Once these mechanisms, have been identified by the DMD modes in form of coherent structures, the flow field, $\boldsymbol{v}_{rec}$, composed by the three components of the velocity, streamwise $\boldsymbol{u}_{app}$, wall-normal $\boldsymbol{v}_{app}$ and span-wise $\boldsymbol{w}_{app}$ components, is reconstructed using the M highest-amplitude (most-energetic) DMD modes, following the spatio-temporal DMD modal expansion (defined in time t and along spanwise coordinate z) as

$$\boldsymbol{v}_{rec} = \sum_{m=1}^{M} a_m \boldsymbol{u}_m e^{(\delta_m + i\omega_m)t + (\nu_m + i\beta_m)z},$$

where $\boldsymbol{u}_m$ and a_m, are the DMD modes and their corresponding amplitudes; ω_m, β_m are the frequency and wavenumber in the spanwise direction of the modes, and δ_m, ν_m are their corresponding temporal and spatial growth rates. A function modelling the wall shear stress, defined as $\tau = \mu \frac{\partial \boldsymbol{u}}{\partial y} + \boldsymbol{u}\boldsymbol{v}$, where μ is the fluid viscosity, is constructed using the previous approximation of the flow field, $\boldsymbol{u}_{app}$ and $\boldsymbol{v}_{app}$, as $\tau_{app} = \mu \frac{\partial \boldsymbol{u}_{app}}{\partial y} + \boldsymbol{u}_{app}\boldsymbol{v}_{app}$. Combining this wall shear function with linear and non-linear regression techniques, it is possible to minimize the difference between the real solution and the approximation, $\min 3|\tau - \tau_{app}|$, obtaining an efficient reduced order model for the wall shear stress evolution $\frac{d\tau_{app}}{dt}$. Integrating this model in time is then possible to predict the temporal history of the wall shear stress.

RESULTS AND FUTURE WORK

Figure 1 shows a three-dimensional reconstruction of two DMD spatio-temproral modes, with high and low frequency, in the drag reduction and drag increasing case analysed. In the drag increasing flow, it is possible to identify the spanwise elongated structures, the rollers, with $\beta = 0$ (related to a KH-like flow instability), nevertheless, in the drag reduction case, the structures are not spanwise correlated. More details about the physics of the problem will be presented at the time of the conference.

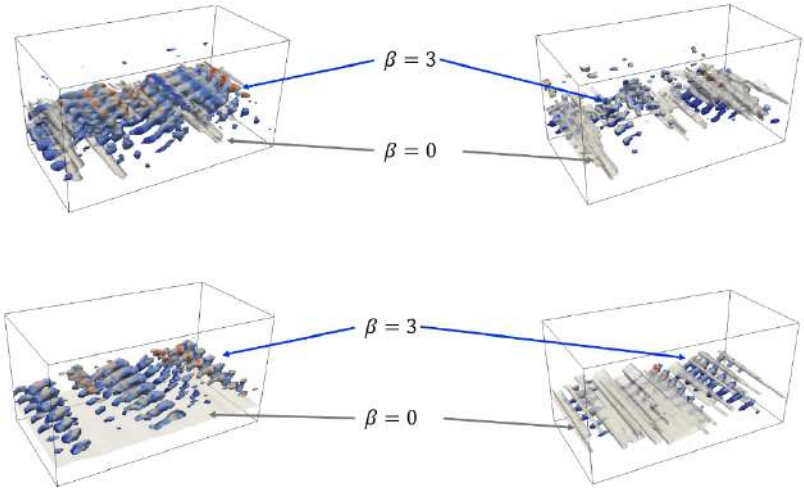

Figure 1: Three-dimensional reconstruction of two spatio-temporal DMD modes. Iso-surfaces of streamwise velocity in the module of the DMD modes. Left: low frequency mode. Right: high frequency mode. Top: drag increasing case. Bottom: drag reduction case.

Figure 2 shows the temporal evolution of the wall shear stress in the drag reducing case. The figure compares the model with the solution from the direct numerical simulations performed as described in [2]. The DMD analysis (training) is carried out in a group of data collected in the interval $t \in [0,200]$, while the prediction is carried out until the time $t \simeq 580$ with relative error smaller than 2%. More details about this model and these predictions will be presented at the conference. Similarly, a model for the shear stress in the flow of reduced drag will also be presented at that time.

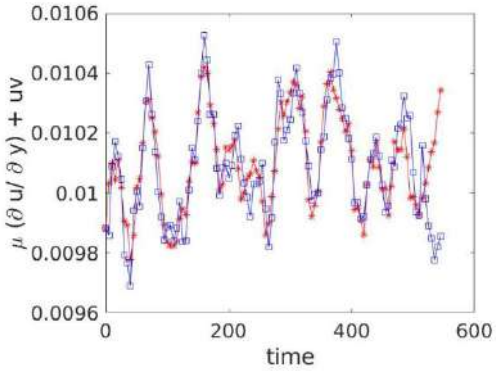

Figure 2. Temporal evolution of the wall shear stress in the drag reduction case. Blue and red lines correspond to the real solution and the model based on DMD combined with machine learning methods.

SPATIO-TEMPORAL CHARACTERISTICS OF UNIFORM MOMENTUM ZONES THROUGH EXPERIMENTS AND MODELLING

Angeliki Laskari*[1], Charitha M. de Silva[3], Nicholas Hutchins[4], and Beverley J. McKeon[2]
[1] Department of Process & Energy, Delft University of Technology, Delft, The Netherlands

Summary The probability density function (pdf) of the instantaneous streamwise velocity can be used to extract information on the presence of uniform momentum zones (UMZs) in turbulent boundary layers [1]. In this work, we present new insight into the spatio-temporal characteristics of this pdf, using different experimental datasets with very long temporal and spatial domains. When the pdf is plotted over time, repeated transitions to lower velocities are observed, while similar trends can also be observed for increasing streamwise distance. In order to examine how these trends are linked to the underlying velocity field, a simple resolvent model is employed [2]. Results show that a single resolvent mode reproduces many of the observed patterns and highlights the importance of the wavelike nature and phase characteristics of the velocity structures involved.

EXPERIMENTAL RESULTS

Time-resolved planar Particle Image Velocimetry (PIV) data from a boundary layer at $Re_\tau = 5200$ in streamwise–wall-normal planes are first analysed [3]. The pdf of the streamwise velocity U, is constructed using the full streamwise extent of the field of view ($L_x|_{pdf} = 0.5\delta$) and all vectors within the turbulent region.

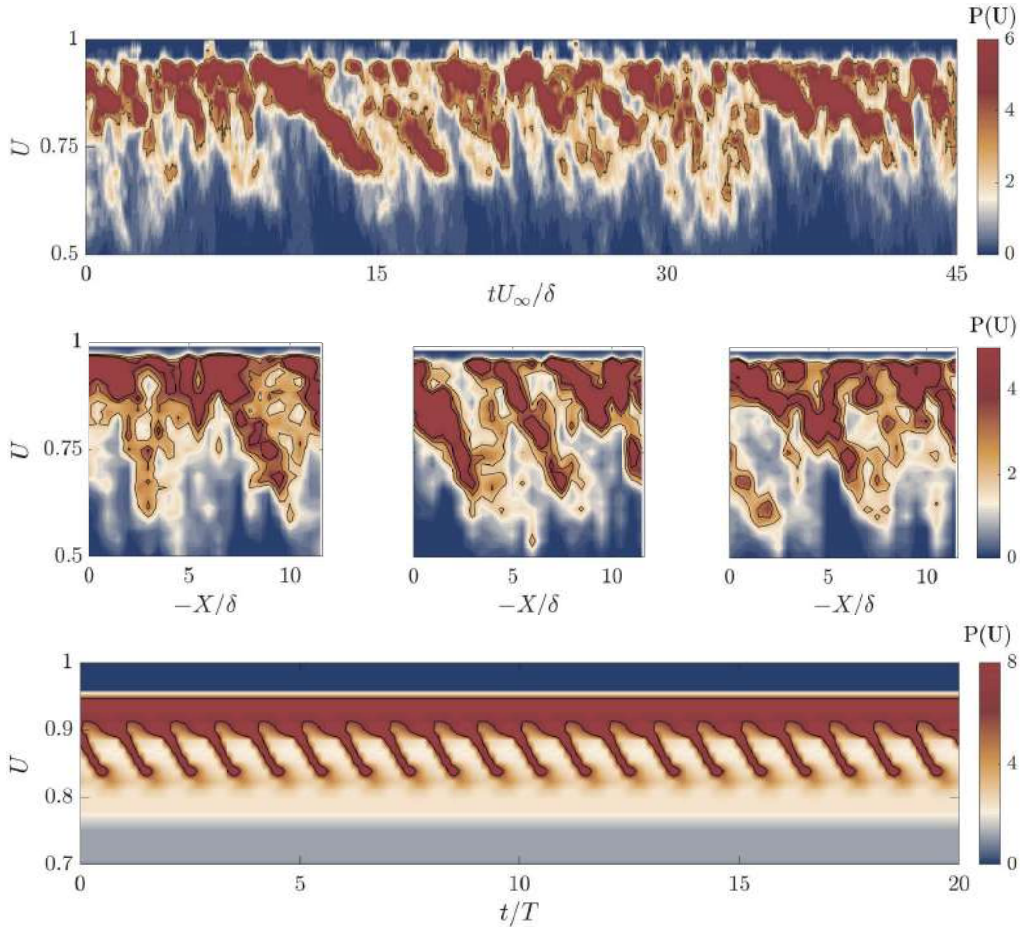

Figure 1: Contour plots of the probability density function, $P(U)$ of the full streamwise velocity, $U = u + \overline{U}$. Experimental measurements, temporal domain (Top, [3]). Experimental measurements, spatial domain, three independent snapshots (middle). Resolvent framework (Bottom, [2]).

*Corresponding author. E-mail: a.laskari@tudelft.nl.

The temporal evolution of the pdf indicates repeated transitions to lower velocities, while faster, more abrupt changes to higher velocities are also observed (figure 1, top). To quantify the rate of these temporal transitions, their slope with respect to time is estimated ($\tan\phi = \frac{\delta}{{U_\infty}^2}\frac{\Delta U_{min}}{\Delta t}$). Results show that these transitions are robust across all experimental datasets available, with $|\tan\phi_l| = 0.15\pm0.07$ and $|\tan\phi_h| = 0.35\pm0.11$, for the transitions to lower and higher velocities, respectively. When conditioned on these transitions, the number of zones present in the flow, N_{UMZ} shows a very distinct variation, increasing as $P(U)$ peaks at lower velocities, and decreasing when velocities close to the freestream are the most prominent in the flow. The corresponding velocity fluctuations also indicate a clear pattern of large-scale downstream leaning structures of alternating signs associated with both transitions observed in the pdf of U.

To compare this temporal pattern with the spatial evolution of the pdf, a second PIV dataset, with an extended streamwise field of view ($L_x = 12\delta$) at $Re_\tau = 2500$, is used. The pdf of U is computed over consecutive windows of $L_x = 0.5\delta$ along the streamwise direction of each snapshot. Preliminary results on the spatial evolution of the pdf indicate a similar trend for increasing streamwise distance as the one observed in the temporal domain (figure 1, middle).

SIMPLE RESOLVENT MODEL

In order to analyse the characteristics of the velocity structures leading to this spatio-temporal behaviour, we employ the resolvent framework [2]. Here, a simplified approach is followed where a single resolvent mode is used, located at the edge of the log region (centred at $y = 0.27$), with a wavelength λ_x and a wave period T. The mode amplitude profile for the streamwise velocity component is approximated by a Gaussian function (recently shown to be a very accurate representation of exact resolvent mode shapes in wall bounded turbulence, [4]), the phase variation in the wall-normal direction exhibits a $-\pi$ reversal across the critical layer) and the phase speed of the mode at the critical layer is $c_x = 0.89U_\infty$. The mean profile, which also informs the wall-normal extent and weighting of the mode, is from a channel flow at $Re_\tau = 15000$ (more details can be found in [5]).

Based on the temporal and spatial scales extracted from the experimental data, we select a streamwise extent $L_x|_{pdf} = 0.25\lambda_x$ for the model. The resulting temporal evolution of the pdf exhibits a very similar pattern of slower transitions to lower velocities and abrupt jumps to higher velocities as observed in the experiments, albeit periodic as expected (figure 1, bottom). Velocity fluctuations conditionally averaged on these transitions agree very well with the experimental results. Additionally, it is shown that the phase jump across the critical layer is crucial for reproducing the observed behaviour. The choice of the mode weighting with respect to the mean is another important factor in the resulting rate of these transitions and can be tuned accordingly, in order for the model to better match the experimental observations. To that end, increased complexity in the modelled pdf can also be achieved, by increasing the number of resolvent modes used, organised in a self-similar hierarchy ([6]).

CONCLUSIONS AND FUTURE WORK

Experimental datasets with long temporal and spatial domains allow a unique assessment of the evolution of the streamwise velocity pdf in wall-bounded flows, while the comparison of the dynamics observed in both space and time indicates the role and limitations of Taylor's hypothesis in connecting the two. We further exploit a simple model for the velocity fluctuations based on the resolvent approach to reproduce many of the experimental observations and highlight their link to the underlying wavelike nature and phase characteristics of the velocity structures involved.

A WALL-LAW FOR THE MEAN VELOCITY IN THE INNER PART OF TURBULENT BOUNDARY LAYERS AT ADVERSE PRESSURE GRADIENT AND APPLICATION FOR RANS TURBULENCE MODELLING

Tobias Knopp *[1], Nico Reuther[3], Matteo Novara[1], Erich Schülein[1], Daniel Schanz[1], Christian Willert[2], Andreas Schröder[1], Andreas Krumbein[1], Cornelia Grabe[1], and Christian J. Kähler[3]

Summary We present a strategy to modify turbulence models based on the Reynolds averaged Navier-Stokes (RANS) equations for flow separation on smooth surfaces due to an adverse pressure gradient. We describe two new turbulent boundary layer experiments to study the behaviour of the mean velocity profile at adverse pressure gradients and at high Re. We observe that the log-law in the mean velocity profile is a robust feature, but its region is much thinner than in zero-pressure gradient flows, and its slope is altered. A square-root law emerges above the log-law extending to the wall-ward distance the log-law typically occupies. Then we modify a differential Reynolds stress turbulence model. The modified model accounts for a change of the log-law slope and the formation of a square-root law at adverse pressure gradient, improving the agreement with the experimental data for both experiments.

GOALS, EXPERIMENTAL SETUP, AND MEASUREMENT TECHNIQUE

Turbulent boundary layers subjected to an adverse pressure gradient at high Reynolds numbers still pose many open questions regarding their statistically averaged mean flow, see [1]-[5]. At the same time, they have a high relevance in technical applications, e.g., in aerospace research. At high Re, turbulence resolving simulation methods like large-eddy-simulation (LES) and hybrid RANS/LES methods still need a near-wall model based on the RANS equations and statistical turbulence models for the foreseeable future. Therefore the prediction of flow separation on smooth surfaces due to an adverse pressure gradient is still not reliable. We pursue a strategy (i) to set-up a high-quality data base by new experiments, (ii) to find an empirical wall-law for the mean velocity in the inner layer, and (iii) to improve the turbulence models based on the empirical wall-law.

The first goal is to find a new wall-law for the mean velocity based on the following questions: Q1: Does a log-law region still exist at APG [1]-[5]? Q2: Does the slope of the log-law change with the streamwise pressure gradient in inner scaling $\Delta p_x^+ = (\partial P/\partial x)^+$, as proposed by [1]? Q3: Is there a sqrt-law region above the log-law, see e.g. [2], [3]? For this purpose we designed two new wind-tunnel experiments. The second goal is to use this knowledge of a wall law for the mean velocity to improve RANS turbulence models.

In the wind-tunnel experiments, the turbulent boundary layer flow develops on the side wall of the wind-tunnel and then follows a ramp and a long flat plate at almost zero pressure gradient. Then the flow enters into the adverse pressure gradient section, first along a curved surface and then on a flat plate, which is the focus region. The flat plate segment has an opening angle of 14.4° and 18.6° resp. relatively to the zero-pressure gradient section. The flow remains attached in the first experiment and separates in the second.

The experiments were performed at different Re by variation of the velocity up to $U_\infty = 36\,\mathrm{m/s}$. The focus region is at $8\,\mathrm{m} \leq x \leq 10.5\,\mathrm{m}$, where the test-section starts at $x = 0\,\mathrm{m}$. We obtain a significant adverse pressure gradient with $\Delta p_x^+ > 0.02$ and Rotta-Clauser pressure gradient parameter $\beta_{\mathrm{RC}} > 30$ for the first experiment and even larger values for the second, and Re_θ up to 50000 in the adverse pressure gradient region.

The measurement technique uses 2D2C large-scale particle image velocimetry (PIV) for characterising the streamwise evolution of the flow over a streamwise distance of 2.1 m or 15 boundary layer thicknesses. In the adverse pressure gradient focus region, we use 2D2C microscopic (2D μPTV) and 3D3C Lagrangian particle tracking (3D LPT) to measure the mean velocity and the Reynolds stresses down to the viscous sublayer. Oil-film interferometry is used for the complementary direct measurement of the wall shear stress.

RESULTS FOR THE MEAN VELOCITY AND DISCUSSION

For the mean velocity profile in the adverse pressure gradient region, we observe that the log-law in the mean velocity profile $u^+ = \log(y^+)/K_i + B_i$ is a robust feature, but its region is much thinner than in zero-pressure gradient flows, and its slope is altered. The value of the log-law slope coefficient K_i is found to be decreasing with increasing values of the pressure gradient parameter Δp_x^+. We find a value of $K_\mathrm{i} = 0.370 \pm 0.017$ for $\Delta p_x^+ = 0.018$, lower than for the von Kármán constant for zero pressure gradient boundary layers $\kappa = 0.4 \pm 0.02$, see Fig. 1 (a). A square-root law emerges above the log-law extending to the wall-ward distance the log-law typically occupies, see Fig. 1 (b), and the slope diagnostic function for the square-root law shows a plateau.

*Corresponding author. E-mail: Tobias.Knopp@dlr.de.

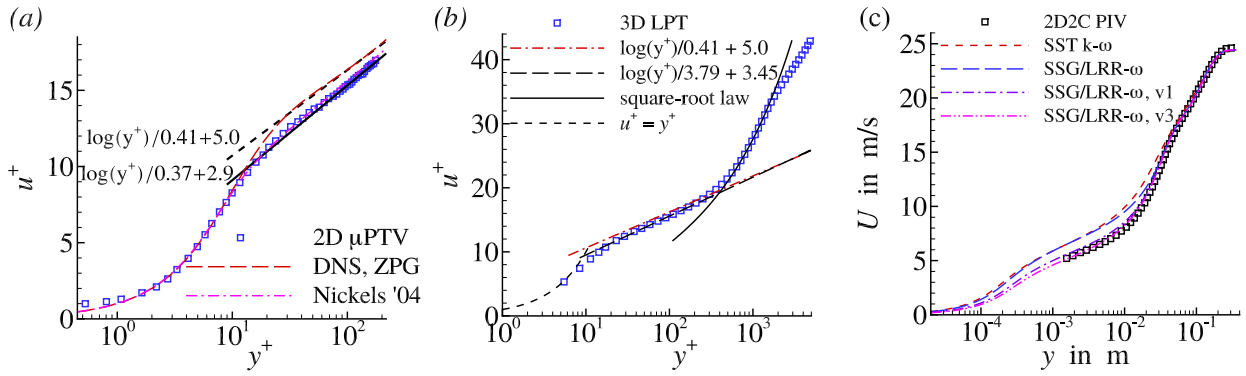

Figure 1: (a) Near wall profile of u^+ for $\Delta p_x^+ = 0.018$ and change of log-law slope. (b) Reduced extent of log-law region and square-root law for $\Delta p_x^+ = 0.011$. (c) RANS results for modified SSG/LRR-ω RSM using the square-root law modification (v1) and additional modification of the log-law slope (v3) at $\Delta p_x^+ = 0.027$.

The wall-distance, where the mean-velocity profile changes from the log-law to the square-root law, can be characterised by two similarity parameters, i.e., the pressure gradient parameter Δp_x^+ and the acceleration parameter $\Delta u_{\tau,x}^+ = (\partial u_\tau/\partial x)^+$, being the streamwise gradient of the wall shear stress velocity. Put in other words, we find mean-flow similarity in the inner layer for the present flow and other flows in the literature, provided that they are at the same values of Δp_x^+ and $\Delta u_{\tau,x}^+$ and provided that low-Re effects are small, i.e., $Re_\theta > 10000$. In the outer layer, the profiles can differ due to the different upstream history. Similarity in the inner layer and differences in the outer layer can be explained using the idea of the eddy turn over time.

RANS MODEL IMPROVEMENT FOR ADVERSE PRESSURE GRADIENTS

Then we present a RANS study for the two experiments using two popular models, i.e., the SST k-ω model and the differential Reynolds stress model (DRSM) SSG/LRR-ω. The SST model is based on the turbulent viscosity hypothesis. The SSG/LRR-ω model solves the transport equation for the Reynolds stress tensor using empirical models for redistribution and turbulent transport. For both, the dissipation ϵ is modelled using the specific dissipation rate ω, for which an additional empirical transport equation is solved. We observe that both models predict a too high velocity in the inner layer and cannot predict a square-root law, see Fig. 1 (c).

We apply the above findings for the mean velocity profile to modify the RANS models, extending the work in [5]. First, the coefficient which controls the slope of the log-law is made a function of the local value of Δp_x^+, instead of being a constant value in the standard model. Second, we add a model deficiency term so that the modified model gives a square-root law at adverse pressure gradient. The deficiency term is determined by analytical solution of an inverse boundary layer problem. Both modifications increase the dissipation in the inner part of the inner layer in agreement with the findings in [4]. This leads to a reduction of turbulent transport of momentum into the near-wall region, thus making the model more susceptible for flow separation. The modified model yields a much better agreement with the experimental data, see Fig. 1 (c).

CONCLUSIONS

In an analysis of two new turbulent boundary layer experiments, we find that the mean velocity profile at adverse pressure gradient in the inner layer shows a thin log-law region, whose slope is altered compared to the zero pressure gradient case, and a square-root law which emerges above the log-law extending to the wall-ward distance the log-law occupies at zero pressure gradient. These findings are used to modify a differential Reynolds stress RANS turbulence model to account for a change of the log-law slope and the formation of a square-root law at adverse pressure gradient, leading to improved agreement with the experimental data.

Summary The effect of a variable transformation on the linear operator that is obtained by linearizing a turbulent flow about its mean is investigated. It is shown that the characteristics of the linear operator are dependent on the state variables used and can be modified when the state vector is subjected to non-linear transformation and linearisation is not performed around a fixed point. This observation raises a uniqueness issue for mean-flow resolvent analyses. The effect of the variable transformation on the stability characteristics is demonstrated via some test cases, including a subsonic jet. The implications for the validity of mean-flow resolvent analyses and possibilities for optimizing resolvent-based approaches are discussed.

INTRODUCTION

Mean-flow-based linear analyses have been used since the 1970s to understand and model the dynamics of coherent structures in turbulent shear flow. The approach involves linearisation around the mean field and subsequent analysis of the resulting linear operator. Linear analysis performed using the mean flow has proved to be a useful way to study coherent structures in turbulent shear flows [1, 2, 3, 4, 5, 6]. However there is no rigorous mathematical justification for such a choice. The temporal mean is one of infinitely many non-fixed points about which one may linearise. This observation reveals an ambiguity in the roles that the linear operator and the remaining non-linear terms play. It is possible, for instance, to modify the linear operator via the introduction of an eddy-viscosity-based model in the linear part [7], or by directly changing the linearisation point, which change the characteristics of the linearised system.

In this paper, we discuss the validity of mean-flow resolvent analyses from the point of view of their uniqueness. By limiting ourselves to linearisation about the temporal mean, we show that, choosing two different variable sets that define a given flow yields two linearised systems with different characteristics, if the two variable sets are non-linearly related, as are, for example conservative and primitive variables. The formalisation is achieved by (*i*) considering a flow defined by Navier-Stokes equations written in two different variable sets that are non-linearly related, (*ii*) linearising the two systems around their temporal means, respectively, (*iii*) deriving a relation between the resulting linear operators.

METHODOLOGY AND RESULTS

Given a dynamical system, $\partial_t q = \mathcal{N}(q)$ with the state, q and the non-linear operator $\mathcal{N}$, linearising about the temporal mean of the state, $\overline{q}$ yields,

$$\partial_t q - \mathbf{A}_{\overline{q}} q' = f, \tag{1}$$

where q' is the fluctuating part of q, $\mathbf{A}_{\overline{q}} = \partial_q \mathcal{N}|_{\overline{q}}$ is the linear operator and f denotes the remaining non-linear terms. Given a non-linear transformation $\tilde{q}_T = \mathscr{H}(\overline{q})$, the relation between the linear operators of the original and transformed systems, $\mathbf{A}_{\overline{q}}$ and $\mathbf{A}_{\tilde{q}_T}$, respectively, is obtained as,

$$\mathbf{A}_{\tilde{q}_T} = \partial_q \mathscr{H}|_{\overline{q}} \mathbf{A}_{\overline{q}} \left(\partial_q \mathscr{H}|_{\overline{q}}\right)^{-1} + \partial_{qq} \mathscr{H}|_{\overline{q}} \left(\partial_q \mathscr{H}|_{\overline{q}}\right)^{-1} \mathcal{N}|_{\overline{q}}. \tag{2}$$

In (2), the first term on the right-hand-side denotes a similarity tranformation of $\mathbf{A}_{\overline{q}}$, which does not modify the eigenvalues. However, addition of the second term on the right-hand-side causes a change in eigenvalues. Note that second term is zero only if the transformation is linear ($\partial_{qq}\mathscr{H} = 0$) or linearisation is about a fixed point ($\mathcal{N}(q_0) = 0$). We first consider a model problem based on Ginsburg-Landau (G-L) equation, given as,

$$\partial_t q + U\partial_x q - \gamma \partial_{xx} q - \mu q = -\beta q|q|^2 + f_{ext}. \tag{3}$$

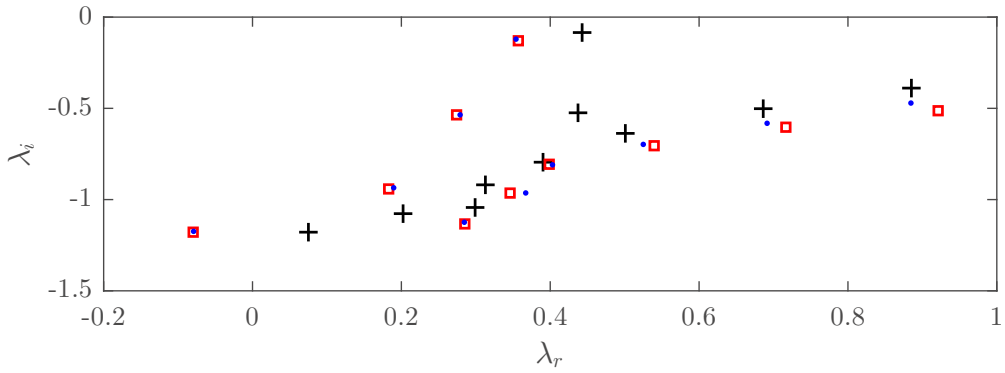

Figure 1: Eigenspectrum for the least unstable 10 eigenvalues of the original (black-plus), and the tranformed (red-square) systems and the first-order predictions of the corresponding transformed eigenvalues (blue-dot).

We limit the study to stationary systems, and bijective transformations between the variables.

The change in eigenvalues of the model problem due to a non-linear transformation of the state variable is shown in Figure 1. The transformation function used for this case has the form,

$$q_T = \frac{1}{q-a} + \frac{1}{a}, \tag{4}$$

where $a = 0.2$ is a free parameter. Eigenvalues in Figure 1 are significantly changed in the transformed system, and so are eigenfunctions. Note that $\tilde{q}_T$ does not correspond to the mean of the transformed state. We show that predicting the linear operator of the transformed system using the mean-flow information in the original system is only possible through a first-order Taylor-series expansion. In Figure 1, this first-order expansion is also shown to successfully predict the transformed eigenvalues.

CONCLUSIONS

The dependency of the characteristics of the linear operator defined for a dynamical system that is linearised about the temporal mean, (or any non-fixed point in general) on the state variables raises questions regarding the conditions for validity of mean-flow stability analysis. The validity of mean-flow resolvent analyses for jets have been justified based on the fact that for weakly non-parallel flow the resolvent of the linear operator will exhibit large gain separation [8], and associated large spatial separation between forcing and response modes, such that for the leading input-output pair the forcing is entirely localised at the upstream boundary [6]. However, we show in our analysis that using the same flow data, it is possible to obtain two different resolvent operators, with different gain separations and spatial supports for the corresponding modes. Having two different operators corresponding to the same flow indicates that one should take into account the non-linear terms for the validity of the mean-flow stability analysis, via, for instance, appropriate statistics for the forcing f in (1).

The final paper will include, in addition to discussion of the theoretical framework, demonstration of the issue using a model problem based on G-L equation, and a subsonic, compressible jet.

HIERARCHY ANALYSIS OF LARGE-SCALE COHERENT STRUCTURES IN TURBULENT WALL-BOUNDED FLOWS

Guangyao Cui, Ido Ruhman, and Ian Jacobi
Faculty of Aerospace Engineering, Technion Israel Institute of Technology, Haifa, Israel

Summary Understanding the relationships between large- and small-scale coherent motions in turbulence is crucial for developing reduced-order models of turbulent flows. We implemented a novel, spatial wavelet-based approach for identifying hierarchies of coherent motions, utilizing insights from astrophysical galaxy cluster detection. The hierarchy detection method was validated against synthetic, turbulent super-structure data and then applied to new, experimental boundary layer measurements at high Reynolds number. The phase and amplitude relationships between different scale structures of momentum hierarchies were calculated and compared with the results of traditional filtering approaches.

Very large-scale regions of coherent, streamwise momentum have long been observed in measurements of the turbulent boundary layer [1] and are dynamically significant to its kinetic energy and Reynolds stresses [2]. Although these large-scale structures have been explored via spatial and temporal filtering of velocity fields, their interpretation has remained somewhat subjective: do they represent the superposition of smaller scale motions, in a 'bottom-up' construction [3, 4] or are these large structures the 'top-down' result of dynamics at the outer edge of the boundary layer [5]? Filtering-based analysis can describe the dynamics of these super-structures, but cannot determine whether a coherent region of momentum is best understood as a superposition of smaller motions or an independent larger motion. The answer to this question has important implications for analyzing scale interactions in turbulence and modeling canonical turbulent flows.

In order to examine the composition of very-large scale motions in wall-bounded flows, we need to identify hierarchies of coherent structures and establish their inter-relationships. To define such hierarchies objectively, we adopted an analytical tool from the world of astrophysics, traditionally used to identify clusters of galaxies from telescope imagery. A field of individual galaxies is typically obtained in the form of a binary field of points. Clusters are then determined by using a continuous wavelet transform of the field [6, 7]. A statistical comparison is performed between the resulting wavelet coefficients and the coefficients of a random ('no-clustering', null-hypothesis) field. Under this approach, a cluster of galaxies can be objectively defined as an isolated collection of binary points that are statistically unlikely to appear by chance over a given length scale (i.e. the wavelet size). We applied this technique in wall-bounded flows to avoid the subjectivity otherwise inherent in labeling long, meandering regions of high or low velocity as turbulent 'super-structures' (figure 1). In addition to identifying individual structures of momentum at different scales, the spatial wavelets were also used to establish a statistically significant hierarchy of these structures and then to study their spatial distribution and the dynamical (modulating) relationships present between scales within a single hierarchy.

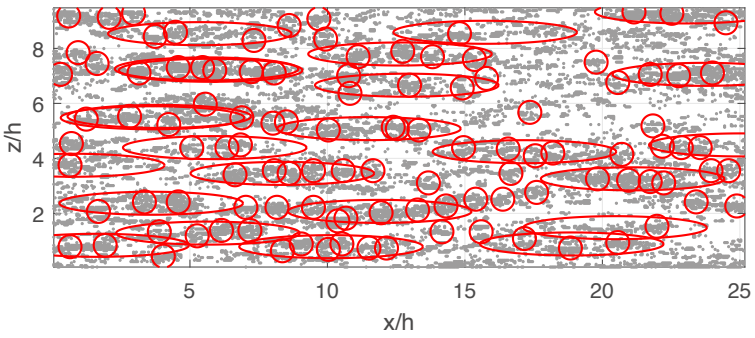

Figure 1: The wall parallel velocity field from a channel flow DNS (half-height h) [8] at $\mathrm{Re}_\tau = 1000$, sampled at $y^+ = 30$, binarized to represent the top 20% of velocities in the instantaneous PDF. Spatially coherent clusters of momentum are marked in red for wavelets with streamwise extent $0.8h$ and $6.6h$, identified with statistical significance level of 0.001 (here including overlaps), using the technique described below.

In this study, we developed a wavelet based hierarchy detection scheme for turbulent flow analysis, and applied it in two different environments: initial testing and validation of synthetic velocity fields and low Reynolds number DNS channel data; and primary application in new experimental measurements of a high Reynolds number boundary layer flow ($\mathrm{Re}_\tau \approx 6000$).

The initial validation study (figure 2) was performed using synthetic meandering velocity fields, representative of the super-structures observed in the logarithmic region of wall-bounded flows [1]. When applied to momentum measurements, the cluster detection process involved first segmenting the velocity field into binary fields (corresponding to uniform momentum zones) and transforming these fields via a continuous wavelet transform. The transform was calculated over all of the wavelet scales, aspect ratios, and orientation angles of dynamical relevance. The relative extrema of the wavelet-transformed field were then identified allowing for the detection of regions of high spatial density of coherent momentum [9]. However, the presence of a relative extremum alone does not necessarily represent a statistically significant spatial density of coherent momentum; in order to ascertain whether the extremum is significant, it must be compared with the magnitude of wavelet coefficient extrema that would be obtained via transformation of a uniform random process with the same number density as the momentum field. This statistical significance

*Corresponding author: ijacobi@technion.ac.il

thresholding was accomplished via an efficiently modeled version of a Monte-Carlo simulation. The thresholds were then applied to the extrema found in the transformed momentum field to identify statistically significant momentum clusters. The superposition of these clusters was then analyzed, under a similar statistical model, in order to group significant structures at different scales into hierarchies.

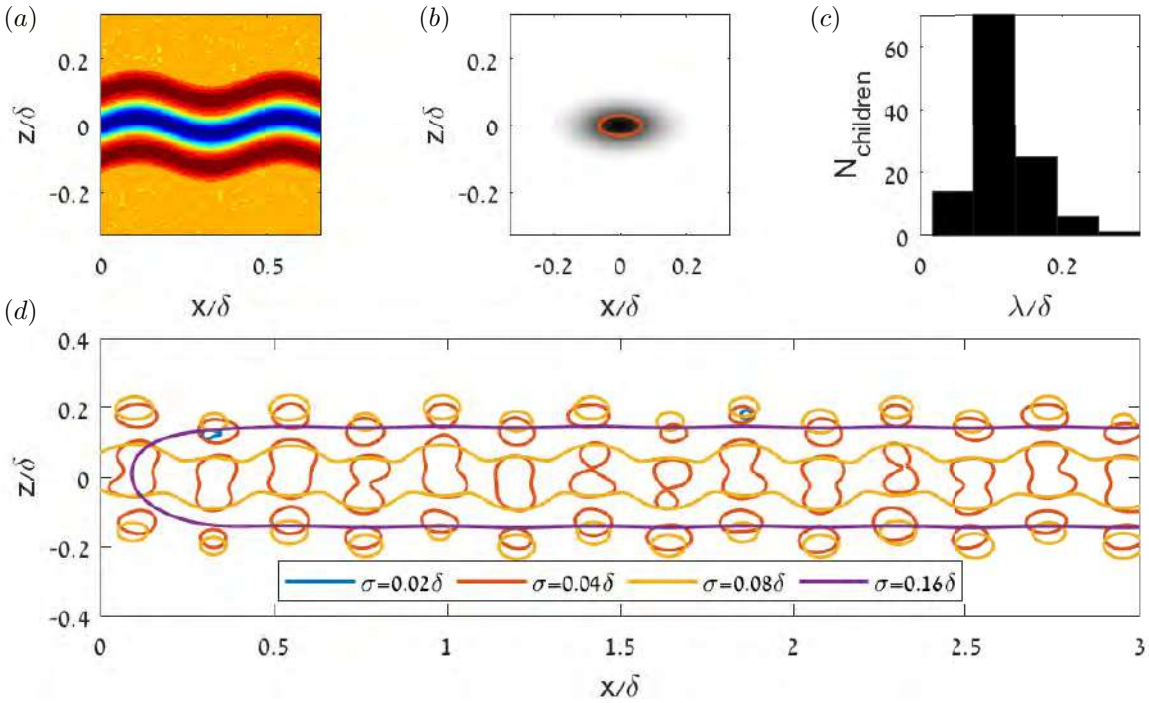

Figure 2: (a) Synthetic meandering streamwise velocity fields produced from [1]. (b) A Morlet wavelet with scale parameter $\sigma = 0.04\delta$ with a marked threshold level of three times the spatial RMS average of the wavelet coefficients. (c) For a given 'parent' $\hat{x}$-momentum structure of lengthscale $\lambda = 7\delta$, the distribution of 'child' structures that are contained within the parent hierarchy. (d) Contour levels corresponding to the coefficient-thresholded continuous wavelet transform of the velocity field, identifying a range of different physical scales of motion, in terms of the wavelet scales, from which the hierarchies were established.

Once the hierarchies were identified, the spatial phase and modulation relationships between 'parent' and 'child' members of each hierarchy were calculated using correlation analysis. However, unlike traditional scale modulation analysis, which involves filtering velocity signals to separate different scales of motion, after which the spatial relationships between scales are inferred [10], the statistical hierarchy approach outlined here naturally separates the scales and establishes their spatial relationships explicitly. The resulting scale-interactions were calculated between members of hierarchies using PIV measurements of a high Reynolds number boundary layer flow in a new, high speed water tunnel facility, and the ensemble averaged spatial scale-interaction relationships were compared with traditional filtering approaches.

A novel use of spatial wavelets and cluster-detection algorithms was shown to provide a new tool for the explicit identification of hierarchies of turbulent coherent structures and the study of scale interactions in wall-bounded flows.

ULTIMATE HEAT TRANSFER IN TURBULENT POISEUILLE FLOW BETWEEN PERMEABLE WALLS

Kenta Inada[1], Kentaro Tsugawa[1], Shingo Motoki *[1], Masaki Shimizu[1], and Genta Kawahara[1]
[1] Graduate School of Engineering Science, Osaka University, 1-3 Machikaneyama, Toyonaka, Osaka, Japan

Summary We study heat transfer in turbulent Poiseuille flow between permeable walls. The permeable wall model here assumes that the wall-normal velocity at the wall is proportional to the local pressure fluctuations. The temperature is treated as a passive scalar with a uniform heat generation and isothermal boundaries. As the bulk Reynolds number (or the permeability) increases, large-scale spanwise rolls appear, leading to turbulence promotion. Although the friction coefficient $C_f = \text{const.}$ is reached at high Reynolds number like a flow over rough walls, there is no flow separation near the permeable walls unlike rough walls. As a result, the similarity between momentum and heat transfer is maintained, and the Stanton number $St = \text{const.}$ is also achieved. The scaling implies the 'ultimate' state in which the heat flux is independent of the kinematic viscosity and the thermal diffusivity.

INTRODUCTION

The effect on the turbulent shear flow of wall surface properties is of great interest among many researchers in engineering and geophysics. In particular, flow over rough walls has been energetically investigated by experiments and numerical simulations. In turbulent flow, surface roughness leads to a significant increase in the flow resistance, and in the high-Reynolds-number region the friction factor becomes to be independent of the Reynolds number (i.e., independent of the kinematic viscosity), as seen in the so-called Moody diagram [1]. For smooth surfaces, the increase of skin-friction drag brings about the heat transfer enhancement because of the similarity between momentum and heat transfer [2]. For rough surfaces, however, the similarity breaks down since the increase of the flow resistance is attributed to the pressure drag due to the flow separation over the roughness elements [3, 4]. Thus, in terms of heat transfer enhancement, the introduction of surface roughness is not necessarily effective. The turbulent state in which the Stanton number is independent of the Reynolds number (i.e., the heat flux is independent of the viscosity and the thermal diffusivity) is related to the 'ultimate' state, which has been enthusiastically discussed in thermal convections [5]. However, it is still an open question whether or not the ultimate state can be achieved in convective turbulence even for rough surfaces [6, 7].

It is known that wall permeability remarkably increases the friction drag in turbulent plane Poiseuille flows [8, 9]. Although this is interpreted as due to the presence of large-scale spanwise rolls, originating from the Kelvin–Helmholtz-like instability, the Reynolds number dependence of the friction drag and heat transfer has not been clarified. In this study, we focus on momentum and heat transfer in a developed turbulent Poiseuille flow between parallel permeable walls.

FLOW CONFIGURATION

We conduct the direct numerical simulation (DNS) of turbulent forced convection in Poiseuille flow between two parallel permeable walls. The permeable walls are modeled assuming that the wall-normal velocity v at the walls (positioned at $y = \pm h$) is proportional to the local pressure fluctuations p', $v(y = \pm h) = \pm \beta p'/\rho$ (ρ is the mass density), and the no-slip condition is imposed on the walls (see [8]). The permeability coefficient β has the dimensions of an inverse velocity, and the flow between permeable walls is characterized by βu_b and the bulk mean Reynolds number $Re_b = 2hu_b/\nu$, where u_b is the bulk mean velocity and ν is the kinematic viscosity. The zero net mass flux through the wall is instantaneously ensured, and the blowing and suction are passively driven without an additional energy input. The temperature is treated as a passive scalar, and the advection-diffusion equation with a uniform heat generation and isothermal wall boundary conditions is solved. Periodic boundary conditions are employed in the streamwise (x-) and spanwise (z-) directions. The DNS is based on a Fourier–Chebyshev spectral method, and the time advancement is carried out with the implicit Euler scheme for the diffusion terms and the third order Runge–Kutta scheme for nonlinear terms, under a constant bulk mean velocity u_b and a constant bulk mean temperature θ_b.

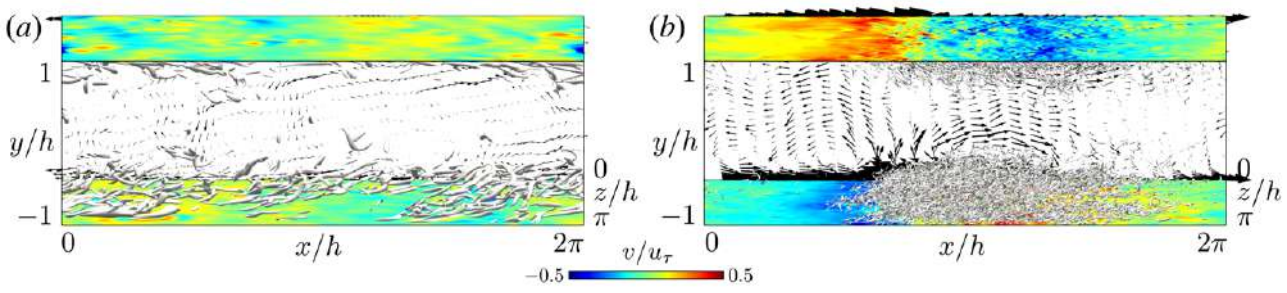

Figure 1: Instantaneous flow structures at (*a*) $Re_b = 8 \times 10^3$ and (*b*) $Re_b = 4 \times 10^4$ for $\beta u_b = 0.5$ and $Pr = 1$. The Gray objects show the vortex structures visualized by the isosurfaces of the positive second invariant of the velocity gradient tensor. The contours represent the wall-normal velocity v normalized by the friction velocity u_τ at the walls ($y = \pm h$). The vectors indicate the spanwise-averaged velocity fluctuations about the mean velocity, $(\langle u' \rangle_z, \langle v' \rangle_z)$.

*Corresponding author. E-mail: motoki@me.es.osaka-u.ac.jp

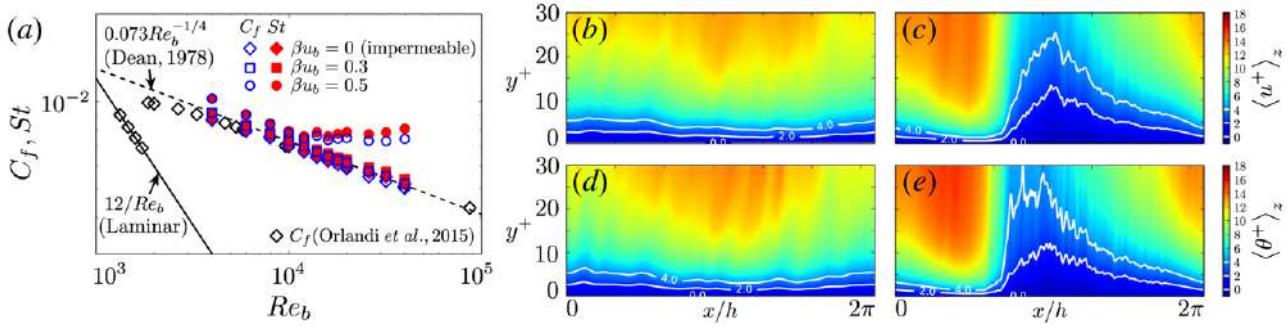

Figure 2: (*a*) Friction coefficient C_f and Stanton number St as a function of Re_b for $\beta u_b = 0, 0.3, 0.5$ and $Pr = 1$. The black open diamonds represent the DNS data for the impermeable plane Poiseuille flow [10]. The solid and dashed lines respectively indicate the laminar flow and the turbulent empirical correlation [11]. (*b-e*) Instantaneous spanwise-averaged streamwise velocity $\langle u^+ \rangle_z = \langle u/u_\tau \rangle_z$ and temperature $\langle \theta^+ \rangle_z = \langle \theta/\theta_\tau \rangle_z$. $y^+ = (y+1)/(\nu/u_\tau)$ is the distance from the wall normalized with the inner length scale. The white lines indicate the isolines of $0, 2, 4$.

RESULTS

In this paper, we present the results obtained in the domain $(L_x, L_y, L_z) = (2\pi h, 2h, \pi h)$ for the Prandtl number $Pr = 1$. Figure 1 shows the flow structures at $Re_b = 8 \times 10^3$ and 4×10^4 for $\beta u_b = 0.5$. At small Re_b (figure 1*a*), we see the turbulent structure similar to that in shear flows over impermeable walls, although it is accompanied by weak fluctuations of the wall-normal velocity v on the walls. In near-wall regions, quasi-streamwise vortices are distributed over the walls. At large Re_b (figure 1*b*), on the other hand, we can observe large-scale spanwise roll structures traveling downstream. The streamwise-traveling patterns in v on the walls are formatted, and small-scale vortex structures are localized in the blowing regions. The root-mean-square value $v_{\rm rms}(y = \pm h)$ is approximately 1% of u_b.

The friction coefficient $C_f = 2u_\tau^2/u_b^2$ and the Stanton number $St = 2u_\tau\theta_\tau/(u_b\theta_b)$ as a function of Re_b are shown in figure 2(*a*), where u_τ is the friction velocity and θ_τ is the friction temperature. At $Re_b \gtrsim 1.4 \times 10^4$ for $\beta u_b = 0.5$, we can observe $C_f = \text{const.}$ and $St = \text{const.}$, implying the ultimate turbulent state. In this range, St is maintained larger than C_f. For $\beta u_b = 0.3$, on the other hand, C_f and St are comparable to that in the impermeable cases even at $Re_b \approx 4 \times 10^4$, and they are almost the same due to the similarity between momentum and heat transfer. Although C_f and St gradually increase at any Re_b as the permeability βu_b increases, they have no effect on the scalings for small Re_b even at $\beta u_b = 0.5$. It is believed that the scalings $C_f = \text{const.}$ and $St = \text{const.}$ are attributed to the appearance of the large-scale spanwise rolls. Figures 2(*b-e*) show the spanwise-averaged streamwise velocity and temperature fields, $\langle u^+ \rangle_z = \langle u/u_\tau \rangle_z$ and $\langle \theta^+ \rangle_z = \langle \theta/\theta_\tau \rangle_z$, at $Re_b = 8 \times 10^3$ and 4×10^4 for $\beta u_b = 0.5$, corresponding to the instantaneous snapshots in figure 1. The white contour lines indicate $\langle u^+ \rangle_z = 0, 2, 4$ and $\langle \theta^+ \rangle_z = 0, 2, 4$, which exhibit the viscous and thermal diffusive sublayers. At $Re_b = 4 \times 10^4$ (figures 2*c,e*), significant fluctuations in both streamwise velocity and temperature fields can be observed in the near-wall region. However, there is no flow separation which causes an increase of pressure drag, and thus the similarity between momentum and heat transfer is maintained.

CONCLUSIONS

In turbulent Poiseuille flow between no-slip permeable walls, the scalings $C_f = \text{const.}$ and $St = \text{const.}$, implying the ultimate turbulent state, have been achieved. The wall permeability leads to large-scale spanwise roll structures which provide the significant promotion of turbulence mixing without flow separation.

ATTACHED EDDY MODEL REVISITED WITH A QUASILINEAR APPROXIMATION

Yongyun Hwang*[1] and Bruno Eckhardt[2]
[1] Department of Aeronautics, Imperial College London, London, UK
[2] Fachbereich Physik, Philipps-Universität Marburg, D-35032 Marburg, Germany

Summary Townsend's model of attached eddies for boundary layers is revisited within a quasilinear approximation. The velocity field is decomposed into a mean and fluctuations. While the mean is obtained from the nonlinear equations, the fluctuations are modelled by replacing the nonlinear self-interaction terms with an eddy-viscosity-based turbulent diffusion and stochastic forcing. The stochastic forcing is subsequently determined self-consistently by solving an optimisation problem which minimises the difference between the Reynolds shear stresses from the mean and fluctuation equations. When applied to turbulent channel flow in a range of friction Reynolds number up to $Re_\tau = 20,000$, the resulting turbulence intensity profile and energy spectra exhibit exactly the same qualitative behaviour as DNS data throughout the entire wall-normal location, while reproducing the early theoretical predictions of Townsend within a controlled approximation to the Navier-Stokes equations.

INTRODUCTION

There has been a growing body of evidence that wall-bounded turbulence is composed of self-similar energy-containing eddies throughout the entire logarithmic region (i.e. attached eddy hypothesis) [1, 2, 3]: for example, the logarithmic wall-normal dependence of turbulence intensities of wall-parallel velocity components [4], the existence of self-similar self-sustaining coherent structures [5], and the self-similar linear modes and exact coherent states of the Navier-Stokes equations [6, 7, 8, 9]. Despite the important progress made over the last decade, the above observations are primarily on the existence of the self-similar energy-containing eddies in the logarithmic region (i.e. attached eddies). Therefore the issue of how they would have to be exactly reconciled for the prediction of turbulence statistics such as mean, fluctuaions and spectra still remains unresolved. In fact, the series of the early models developed by Townsend, Perry and their coworkers [1, 2, 3] are exactly on this issue: the linear superposition of second-order statistical moments of the self-similar energy-containing motions constant Reynolds shear stress predicts the general behaviour of turbulence intensity in the logarithmic region. The objective of the present study is to reformulate this idea by employing a controlled approximation to the Navier-Stokes equations. In particular, we will utilise a quasilinear approximation to the equations in a way that it can be directly compatible to the original attached eddy model [1].

QUASILINEAR APPROXIMATION

We consider a pressure-driven turbulent flow over a infinitely long and wide plane channel, where the upper and lower walls are located at $y = 0$ and $y = 2h$, respectively (y is the wall-normal coordinate). For the purpose of applying a quasilinear approximation, the velocity is decomposed into a mean and fluctuations (i.e. Reynolds decomposition): $\mathbf{u} = \mathbf{U} + \mathbf{u}'$, where $\mathbf{U}$ is the time-averaged mean velocity and $\mathbf{u}'(= (u', v', w'))$ is the velocity fluctuation with u', v' and w' being the streamwise, wall-normal and spanwise components, respectively. The full nonlinear equation is considered for the mean streamwise velocity, whereas the following form of linearised equations are considered for fluctuating velocity:

$$\frac{\partial \mathbf{u}'}{\partial t} + (\mathbf{U}\cdot\nabla)\mathbf{u}' + (\mathbf{u}'\cdot\nabla)\mathbf{U} = -\frac{1}{\rho}\nabla p' + \nu\nabla^2\mathbf{u}' + \mathcal{N} \quad \text{with} \quad \mathcal{N} = \nabla\cdot(\nu_t\nabla\mathbf{u}') + \mathbf{f}', \tag{1}$$

where ρ is the fluid density, ν the kinematic viscosity, p' fluctuating pressure, and $\mathcal{N}$ a minimal model for the self-interacting nonlinear term in the original full Navier-Stokes equations. The model for $\mathcal{N}$ is composed of an eddy-viscosity-based turbulent diffusion (ν_t is the eddy viscosity from [6]) and unknown stochastic forcing. Here, the former is introduced to model the energy cascade and turbulent dissipation, whereas the latter is to drive non-trivial turbulent fluctuations through (1) especially given the linearly stable nature of the typical mean velocity in turbulent channel flow.

If $\mathbf{f}'$ is set to be unknown, the mean equation and the fluctuation equations (1) are not able to be solved – the number of unknown is greater than the number of available equations. Therefore, we start by assuming that the mean velocity is available from a model or from an experimental measurement. Once mean is assumed to be known, the related Reynolds shear stress can be obtained from the mean equation. Then, for the fluctuation dynamics to be consistent with the mean, the Reynolds shear stress from (1) must be identical to the one from the mean equation. This poses the following optimisation problem for the determination of $\mathbf{f}'$:

$$\min_{\mathbf{f}'} \left\| \overline{u'v'} - \langle u'v' \rangle \right\|^2 \quad \text{subject to} \quad \text{sufficiently smooth spectrum of } \mathbf{f}', \tag{2}$$

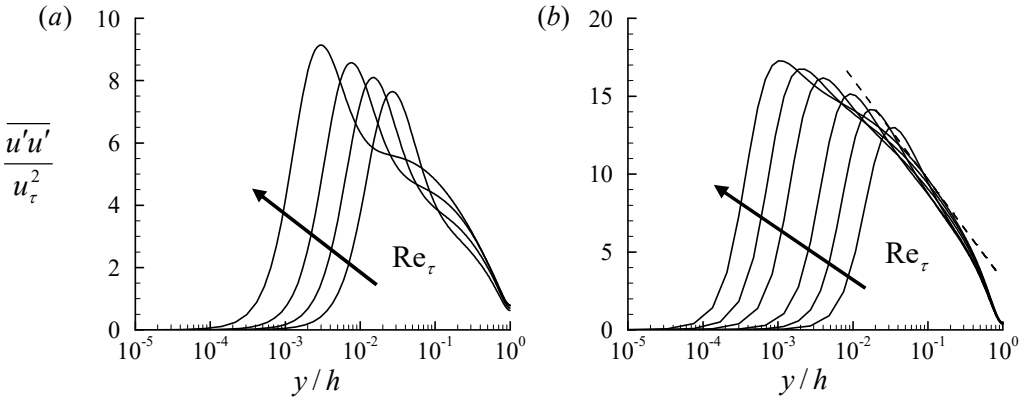

Figure 1: Streamwise turbulence intensity of (a) DNS at $Re_\tau = 543, 1001, 1995, 5186$ [10] and (b) QLA at $Re_\tau = 500, 1000, 2000, 5000, 10000, 20000$. In ($b$), the dashed line indicates the prediction of the original attached eddy model by Townsend. Here, Re_τ is the friction Reynolds number.

where $\overline{u'v'}$ are $\langle u'v' \rangle$ are the Reynolds shear stresses from the mean equation and the fluctuation equations (1), respectively, and $\|\cdot\|$ is an appropriate norm defined in the y-domain. Here, it should be mentioned that (1) admits the self-similar POD modes if the logarithmic mean velocity profile [6]. Given the linear nature of (1), this implies that the optimisation problem (2) can be solved by a linear superposition of such self-similar modes, the theoretical idea exactly the same as the one of Townsend [1]. In the final presentation, the full technical details on the solution procedure of (2) will be presented. From the solution to (2), $\mathbf{u}'$ can now be determined.

RESULTS AND DISCUSSION

Figure 1 compares streamwise turbulence intensity from direct numerical simulation (DNS) [10] with that from the present QLA in the outer-scaled wall-normal coordinate. It is found that the scaling behaviour of the streamwise turbulence intensity profiles of the QLA with Reynold number is strikingly similar to that of DNS at lower Reynolds numbers (up to $Re_\tau = 5186$). Furthermore, on increasing Reynolds number up to $Re_\tau = 20,000$, it becomes evident that the streamwise turbulence intensity gradually exhibits the logarithmic wall-normal dependence, as predicted by the classical attached eddy model of Townsend and Perry [1, 2]. It should be mentioned that this striking similarity to the DNS data also appears in the wall-normal and spanwise turbulence intensity profiles, while also exhibiting consistent behaviours with the classical predictions (not shown): in the logarithmic layer, the wall-normal turbulence intensity is obtained to be approximately constant and the streamwise one exhibits the logarithmic wall-normal dependence. Finally, spanwise wavenumber spectra for all the Reynolds stresses are also computed with QLA (not shown), and they also exhibit qualitatively identical behaviour to those from DNS.

CONCLUSIONS

In this work, we have presented a QLA for turbulent channel flow by formulating it in a way that it can be directly compatible to the attached eddy model of Townsend [1]. The reproduction of second-order turbulence statistics qualitatively identical to those of DNS evidently demonstrates the power of the original model of Townsend, while providing a new way to develop a predictive low-dimensional model for wall turbulence.

A UNIFIED, VIRTUAL-ORIGIN FRAMEWORK FOR THE DRAG-REDUCING EFFECT OF TEXTURED SURFACES

Joseph I. Ibrahim[1], Garazi Gómez-de-Segura[1], Daniel Chung[2], and Ricardo García-Mayoral * [1]
[1] Department of Engineering, University of Cambridge, Cambridge, UK
[2] Department of Mechanical Engineering, University of Melbourne, Melbourne, Australia

Summary Certain surfaces with texturing of small size can reduce drag by generating different virtual origins for the mean velocity profile and the turbulent fluctuations, traditionally characterised by the streamwise and spanwise slip lengths. We generalise this idea by conducting direct simulations with different virtual origins for all three velocity components, using Robin, slip-length-like boundary conditions. We find that, for small slip lengths, the virtual origin for turbulence is actually set by, and can be easily computed from, the wall-normal and spanwise slip lengths. This origin affects directly the near-wall quasi-streamwise vortices, while the origin perceived by the near-wall streaks, in contrast, plays essentially no role in setting that for turbulence. We show that, other than by the shift in origin, turbulence remains essentially smooth-wall-like. The typical modifications of turbulent quantities discussed in the literature for controlled flows can then be reduced to a mere offset effect.

VIRTUAL ORIGINS IN WALL TURBULENCE

Certain textured surfaces, such as riblets or superhydrophobic surfaces, can reduce turbulent skin-friction drag. Like many turbulent-flow control techniques, including active ones, they aim to reduce friction by manipulating the near-wall cycle. The general idea is to impede the flow in the streamwise direction less than the cross flow. Quasi-streamwise vortices are then 'pushed' away from the surface relative to the mean flow, reducing the local transport of streamwise momentum and thus the skin-friction drag. When the texture is small, the flow perceives it in a homogenised fashion and the direct effect is confined to the near-wall region, with the change in drag manifesting as a constant shift of the mean velocity profile above, ΔU^+. For riblets, [9] proposed that the streamwise flow experiences a 'virtual origin' deeper than that of the spanwise flow, and that the change in drag depends on the difference between the two, $\ell_u - \ell_w$, where ℓ_u and ℓ_w are typically measured from the riblet-tip plane. It was later proposed that, for $\ell_u^+, \ell_w^+ \lesssim 1$, where '+' indicates viscous scaling, the extra mean velocity far from the wall was $\Delta U^+ \propto \ell_u^+ - \ell_w^+$ [7, 8].

Superhydrophobic surfaces exploit the same mechanism, with the overlying flow effectively slipping over the entrapped gas pockets. The streamwise and spanwise velocities experience the surface through their respective slip lengths, analogous to ℓ_u^+ and ℓ_w^+. When the spanwise slip length becomes larger than a few wall units, however, the drag-increasing effect of ℓ_w^+ on ΔU^+ saturates [1]. This saturation can however be accounted for through an 'effective' spanwise depth, $\ell_{w,eff}^+$, empirically defined as $\ell_{w,eff}^+ \approx \ell_w^+/(1+\ell_w^+/5)$ [2, 6]. The saturation is caused by slip-only surfaces being impermeable, which limits the extent to which quasi-streamwise vortices can approach the surface. [4, 3] argued that, to fully describe the effect of such textured surfaces on the flow, the virtual origins for all three velocity components should be considered. When the depth for the virtual origin of the wall-normal velocity is set equal to that of the spanwise velocity, $\ell_v^+ = \ell_w^+$, no saturation in the effect of the spanwise slip was observed. For intermediate values $0 < \ell_v^+ \leq \ell_w^+$, the virtual origin for the wall-normal velocity would act as the impermeable, reference plane, and turbulence would experience a virtual origin, ℓ_T^+, such that $\ell_v^+ \leq \ell_T^+ \leq \ell_w^+$, yielding

$$\Delta U^+ = \ell_U^+ - \ell_T^+, \tag{1}$$

where $y^+ = -\ell_U^+$ is the virtual origin experienced by the mean flow, and that for turbulence would be given by

$$\ell_T^+ \approx \begin{cases} \ell_v^+ + \dfrac{\ell_w^+ - \ell_v^+}{1+(\ell_w^+ - \ell_v^+)/5} & \text{if } \ell_w^+ > \ell_v^+, \\ \ell_w^+ & \text{if } \ell_w^+ \leq \ell_v^+. \end{cases} \tag{2}$$

RESULTS FROM DIRECT NUMERICAL SIMULATIONS

To assess the validity of (1) and (2), we carry out direct simulations of turbulent channels with virtual origins for all three velocity components, implemented through Robin boundary conditions, $u = \ell_x \partial u/\partial y$, $v = \ell_y \partial v/\partial y$ and $w = \ell_z \partial w/\partial y$, as proposed in [5]. Here ℓ_x, ℓ_y and ℓ_z are the 'slip' lengths in the streamwise, wall-normal and spanwise directions, respectively. We conduct simulations for a range of combinations of ℓ_x^+, ℓ_y^+ and ℓ_z^+, with ℓ_u^+, ℓ_v^+ and ℓ_w^+ defined a priori by locating the heights for which the Robin conditions are satisfied in smooth-wall rms fluctuation curves. The depth ℓ_T^+ is measured a posteriori by fitting the resulting Reynolds-stress curve to smooth-wall data, and shows good agreement with the predictions from (2). Results are shown in figure 1. When the wall-normal coordinate is measured from the virtual origin for turbulence, $y^+ = -\ell_T^+$, and u_τ is defined from the total-stress curve also at $y^+ = -\ell_T^+$, the

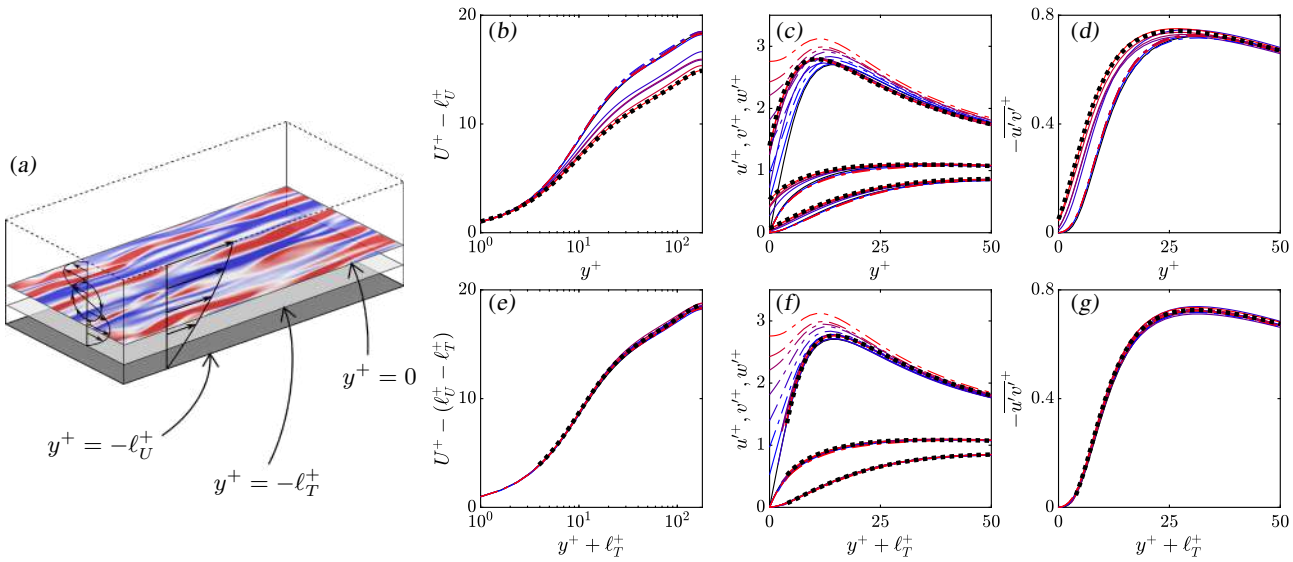

Figure 1: (*a*) Sketch illustrating the concept of virtual origins for turbulence, in light grey, and for the mean flow, in dark grey, below the reference plane $y^+ = 0$, where boundary conditions are numerically imposed, represented by isocontours of the streamwise fluctuating velocity. The cross-flow induced by quasi-streamwise vortices and the mean flow are represented with black lines. (*b-g*) Mean velocity, rms velocity fluctuations and Reynolds stress for simulations with slip and transpiration. Panels (*b-d*) portray results scaled with the conventional u_τ measured at $y^+ = 0$, while panels (*e-g*) portray results with y-origin at the origin for turbulence, $y^+ = -\ell_T^+$, and scaled with the u_τ value corresponding to that depth. Solid lines from blue to red, $(\ell_x^+, \ell_z^+, \ell_y^+) = (2,0,1.2), (2,2,1.2), (6,2,4.5), (4,4,1.2), (4,4,2.5), (4,6,1.5)$ and $(4,6,2)$; dash-dot lines from blue to red, $\ell_{x,f}^+ = 5, 10, 20, 50, 100$ and ∞ on the fluctuations and $\ell_{x,m}^+ = 0$ on the mean flow; black dotted line, $(\ell_{x,f}^+, \ell_z^+, \ell_y^+) = (4,6,2.2)$ on the fluctuations, but $\ell_{x,m}^+ = 10$ on the mean flow; solid black line, smooth-wall reference case.

cross-plane rms fluctuations and the Reynolds stress essentially collapse to smooth-wall data. The same is true for the mean velocity profile, save for a shift $\Delta U^+ = \ell_U^+ - \ell_T^+$, which is consistent with (1). This general collapse confirms that the near-wall dynamics remain smooth-wall-like, and that ℓ_T^+ captures the effect of the origin offset on turbulence.

The results also suggest that the virtual origin experienced by the mean flow is independent of that experienced by the streamwise fluctuations, and that the streamwise origin is relevant to ΔU^+ only through ℓ_U^+. One case in figure 1 has a larger slip length on the mean flow, $\ell_{x,m}^+ = 10$, than on the streamwise fluctuations, $\ell_{x,f}^+ = 4$. The resulting ΔU^+ is consistent with $\Delta U^+ = \ell_U^+ - \ell_T^+$, and $\ell_{x,m}$ has essentially no influence on the turbulence. To further test this, we run simulations with a slip length applied to the streamwise fluctuations only and no-slip on the mean flow. The results, also in figure 1, show that the peak value of the rms streamwise fluctuations exhibits a slight increase with increasing slip length, likely caused by the relaxation of the no-slip condition at $y = 0$, so that they effectively have an extended y-range over which to vanish. However, this has a negligible effect on the mean velocity profile, and ΔU^+ remains essentially zero.

EXTRACTING NONLINEAR DYNAMICS OF LOW-DIMENSIONALIZED FLOWS

Kai Fukami* [1], Takaaki Murata[1], and Koji Fukagata [1]
[1] Department of Mechanical Engineering, Keio University, Japan

Summary Sparse identification of nonlinear dynamics (SINDy) is performed to obtain a governing equation of low-dimensinalized fluid flows. The SINDy with adaptive Lasso is applied to a flow around a cylinder at $Re_D = 100$ as an example of high-dimensional unsteady flow problems. To handle the cylinder flow with SINDy whose coefficient matrix is not suitable for a combination of a large number of variables, a convolutional neural network-based autoencoder (CNN-AE) is considered so that a high-dimensional data can be mapped into low-dimensional latent space while keeping the information of high-dimensional dynamics. The temporal evolution of the high-dimensional flow can be represented successfully by using the CNN-SINDy based modeling. At last, we also introduce the application to a nine-shear turbulent flow equation as a future perspective of SINDy based modeling.

INTRODUCTION

With a recent trend of uses of fluid *big data*, machine learning methods have been emerged as one of the prominent tools to analyze and understand complex and chaotic fluid flow phenomena [1]. Although a vast kind of machine learning methods has been proposed, a sparse identification of nonlinear dynamics (SINDy)[2] has been attracting attention due to its interpretable sense as a form of equation. Thus far, the SINDy has been utilized to various applications, e.g., reduced order modeling with sensor-based measurement [3], and shown its great potential. Here, we focus on two concerns with the use of SINDy for fluid dynamics: 1. influence of regression method and their parameters, and 2. applicability to high-dimensional complex flows. For the first problem, let us consider a typical regression problem $\boldsymbol{C} = \boldsymbol{D}\boldsymbol{\beta}$, where $\boldsymbol{C}$ and $\boldsymbol{D}$ are the response variable and the explanatory variable. We usually aim to obtain a coefficient matrix $\boldsymbol{\beta}$ with the use of SINDy, but we have a lot of regression choices and need to select appropriate parameters so as to obtain a desired equation. It must be useful to have a guideline for selecting these parameters for fluid dynamicists, since the uses of SINDy have been started as introduced above. Regarding the second problem, because the coefficient matrix of SINDy is composed by a combination of considered variables, it is relatively tough to apply to high dimensional problems. Here, we consider four regression methods of SINDy and a convolutional neural network-based autoencoder (CNN-AE), in order to address these aforementioned issues. In this paper, we focus on the discussion for the CNN-SINDy modeling and its future perspective, although the preliminary test for searching parameters is skipped.

METHODS

Sparse identification of nonlinear dynamics (SINDy)

Sparse identification of nonlinear dynamics (SINDy)[2] can identify a governing ordinary differential equation from a data set of temporal discretized observation. Temporal evolution of the state of dynamics $\boldsymbol{s}(t)$ in a typical dynamical system can be often formulated as $\dot{\boldsymbol{s}} = \boldsymbol{f}(\boldsymbol{s}(t))$. For the SINDy formulation, we first prepare a temporal discretized observation of state $\boldsymbol{X} = [\boldsymbol{s}(t_1), \boldsymbol{s}(t_2), ..., \boldsymbol{s}(t_n)]^T$ and its time derivations $\dot{\boldsymbol{X}} = [\dot{\boldsymbol{s}}(t_1), \dot{\boldsymbol{s}}(t_2), ..., \dot{\boldsymbol{s}}(t_n)]^T$, where n is the number of covered temporal snapshots and $\boldsymbol{s}(t) = \{s_1(t), s_2(t), ..., s_k(t)\}$ with k variables. The basic concept of the SINDy is to represent this $\dot{\boldsymbol{X}}$ using a library matrix $\boldsymbol{\Theta}(\boldsymbol{X})$ composed by a combination of the considered variables of $\boldsymbol{s}(t)$ and a coefficient matrix $\boldsymbol{\Xi}$ such that $\dot{\boldsymbol{X}}(t) = \boldsymbol{\Theta}(\boldsymbol{X})\boldsymbol{\Xi}$. The details can be seen in Brunton *et al.*[2]. Mathematically speaking, the procedure to obtain the coefficient matrix $\boldsymbol{\Xi}$ can be formulated as

$$\boldsymbol{\Xi} = \mathrm{argmin}||\dot{\boldsymbol{X}} - \boldsymbol{\Theta}(\boldsymbol{X})\boldsymbol{\Xi}||^2. \tag{1}$$

In this study, we consider four regression methods, i.e., thresholded least square algorithm (TLSA)[2], least absolute shrinkage and selection operator (Lasso) [4], elastic net (Enet)[5], and adaptive Lasso (Alasso)[6], for the aforementioned minimization manner. Although more details are skipped due to space limitation, we also check the effect of sparsity constant α, which plays a role in tuning a sparseness of coefficient matrix, with all covered regressions. We have found in the preliminary test using Van der Pol ossilator that Alasso can provide the correct number of equation terms with a wide range of sparsity constant α. In this paper, we utilize the Alasso following our preliminary test.

Convolutional neural network-based autoencoder (CNN-AE)

To handle a high-dimensional unsteady flow with SINDy, we utilize an autoencoder [7] constructed by using a convolutional neural network[8], which is one of the unsupervised machine learning methods. For construction of the autoencoder, target data set which we want to reduce a dimension are prepared as the input and output $\boldsymbol{q}$. The autoencoder $\mathcal{F}$ has usually intermediate lower-dimensional latent space $\boldsymbol{r}$ than its input or output $\boldsymbol{q}$ so that we can map a high-dimensional input data into the low-dimensional space while keeping the feature of high-dimensional data if the model $\mathcal{F}$ is able to output the same data as the input successfully. Internal procedure of the CNN-AE can be mathematically formulated as

$$\boldsymbol{q} \approx \mathcal{F}(\boldsymbol{q}) = \mathcal{F}_e(\mathcal{F}_d(\boldsymbol{r})), \tag{2}$$

where $\mathcal{F}_e$ is an encoder, which can map a data $\boldsymbol{q}$ into a latent space $\boldsymbol{r}$, and $\mathcal{F}_d$ is a decoder which can recover to original dimension. In other words, the latent vector $\boldsymbol{r}$ can be regarded as a low-dimensional representation of $\boldsymbol{q}$. Because the decoder is employed to remap a latent vector to the high-dimensional original space, we can represent the temporal evolution of high-dimensional dynamics by following only that of the latent vector obtaind by SINDy.

MINI SYMPOSIA

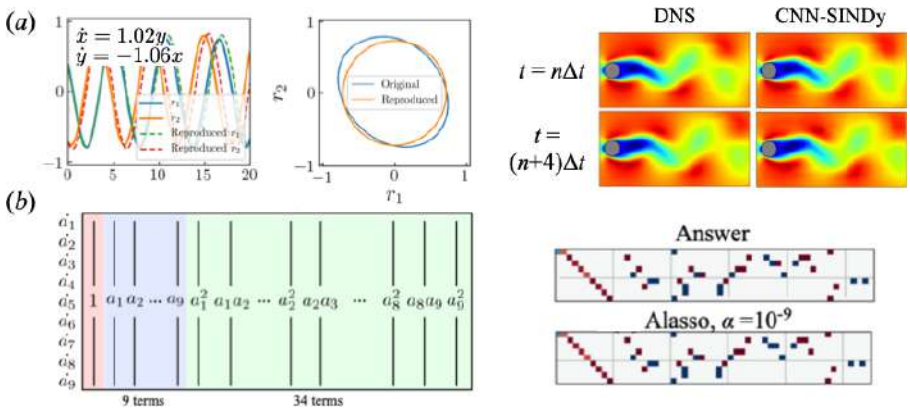

Figure 1: SINDy for (a) a cylinder wake with CNN-AE and (b) nine-shear turbulent flow equation.

RESULTS

As the example with high-dimensional data for the present modeling, a cylinder wake at $Re_D = 100$ is considered by numerically solving of a direct numerical simulation. The computational set up is the same as our previous study regarding the CNN-AE of unsteady flows[9]. The flow fields $\boldsymbol{q} = \{u, v\} \in \mathbb{R}^{384\times192\times2}$ are mapped into two dimensional latent space. We reported that the flow field can be mapped successfully thanks to nonlinear activation functions of the CNN-AE[9]. As introduced in methods, a temporal evolution of two latent values are followed by utilizing SINDy so that the high-dimensional dynamics can be also obtained with the present method. By using SINDy with Alasso, the sparse equation can be obtained, i.e., $\dot{x} = 1.02y$ and $\dot{y} = -1.06x$, and these are integrated successfully and stably, as presented in the time history and trajectory plots of figure $1(a)$. In addition, we see that the high-dimensional flow fields can be reconstructed well in time as shown in the right side of figure $1(a)$.

Through the cylinder wake example, we could demonstrate the great ability of the CNN-SINDy modeling. However, we also should care the remaining issue: applicability to turbulence. With the current autoencoder, it is tough to map complex turbulent flows into extremely low dimensional space, which is analogous to conventional linear theories[10]. Of course, with increasing a number of considerable variable, the size of coefficient matrix is also increased. Hence, our next suspicion here is whether SINDy can be applied if turbulence can be represented as low-dimensional manifolds. Here, let us consider a nine-shear flow equation[11] as the future perspective for SINDy modeling. In the nine-equation model, various statistics can be represented by using superposition of only nine Fourier modes $\boldsymbol{u}_j(\boldsymbol{x})$ and coefficients $a_j(t)$ such that $\boldsymbol{u}(\boldsymbol{x}, t) = \sum_{j=1}^{9} a_j(t)\boldsymbol{u}_j(\boldsymbol{x})$. The dynamics of coefficients is governed by the typical ordinary differential equation form $\dot{a} = f(a)$. We refer readers to Moehlis *et al.*[11] for details. Because the desired equation can be represented by 44 terms with a combination of up to 2nd order terms, we consider up to 2nd order terms of temporal coefficient to arrange a coefficient matrix as shown in figure $1(b)$. As shown in the right portion of figure $1(b)$, the dominant terms of the coefficient matrix can be caught perfectly by utilizing SINDy. It suggests that we may be able to present a machine-learning based reduced order modeling for turbulent flows with the interpretable sense as a form of equation, if well-designed model of mapping side can be constructed.

CONCLUSIONS

We performed SINDy to obtain governing equations of low-dimensionalized flow representations. Following our preliminary test not shown here, we used Alasso as the regression scheme for SINDy analysis. To handle a high-dimensional flow with SINDy, we also utilized a CNN-AE which can project a high-dimensional data into low-dimensional space. We found that the flow field can be reproduced successfully in time by utilizing the proposed model. At last, we further investigated the applicability of SINDy to turbulence using a nine-shear flow equation. The results implied that machine-learning based reduced order modeling for turbulent flows can be established with the interpretable sense as a form of equation, if a well-designed model on the mapping side can be constructed.

INTERMEDIATE SCALING FOR STREAMWISE VELOCITY IN WALL TURBULENCE

Sourabh S. Diwan* [1] and Jonathan F. Morrison[2]
[1] Department of Aerospace Engineering, Indian Institute of Science, Bangalore-560012, India.
[2] Department of Aeronautics, Imperial College London, London-SW7 2AZ, UK.

Summary Here, we propose an intermediate scaling for the streamwise velocity in turbulent pipe and boundary layer (TBL) flows. Using an intermediate length scale (akin to the meso-layer scaling) and an associated velocity scale, we show that the mean-velocity defect and variance profiles achieve a Reynolds-number (Re) similarity in the intermediate region for both pipe and TBL. This reveals a Reynolds-number invariant log region in wall turbulence, in terms of the intermediate variables. As a consequence, the classical log law is seen to emerge only at sufficiently large Re and the Townsend-Perry 'constant' shows a systematic Re-dependence. These findings could have important implications for "attached-eddy modelling", in terms of choosing the scaling and form of the 'attached' eddies. It is plausible that such eddies scale on the intermediate variables which are local to the inertial sublayer.

INTRODUCTION

The logarithmic ("log") variation of the streamwise mean velocity (U) and variance ($\overline{u^2}$) in the inertial sublayer are two of the celebrated results in wall turbulence (Eq. 1).

$$U^+ = \frac{1}{\kappa}\ln(y^+) + C, \qquad \frac{\overline{u^2}}{u_\tau^2} = B_1 - A_1 \ln\left(\frac{y}{\delta}\right), \tag{1}$$

where u_τ is the friction velocity, y is the wall-normal distance and $^+$ indicates scaling on wall variables. δ is the boundary-layer thickness for the turbulent boundary layer (TBL) and pipe radius for the pipe flow. κ and A_1 in Eq. (1) are the well-known von Kármán and Townsend-Perry [1] 'constants' respectively; C and B_1 are the additive 'constants'. The log law for $\overline{u^2}$ is a consequence of the attached eddy hypothesis proposed by Townsend. This idea was further extended by Perry and Chong [2] in the form an attached eddy "model", which predicted the log variation of the mean velocity and variance (Eq. 1) as dual conditions. The attached-eddy model continues to provide a useful physics-based framework for understanding and interpreting the statistics of the energy-containing motions in wall turbulence [3].

Within the framework of the attached-eddy hypothesis, κ and A_1 are believed to be universal constants [1]. However, there remain open, central questions regarding the Reynolds-number invariance and universality of κ and A_1. This is partly because it is not entirely clear if u_τ and δ are the appropriate velocity and length scales for the energy-containing motions in the inertial sublayer [4]. In this work, we examine the scaling behaviour of the streamwise mean velocity and variance in an intermediate region between the inner and outer layers in wall turbulence. We propose that the length scale appropriate for the intermediate region is $y_m^+ \propto \sqrt{Re_\tau}$ ($Re_\tau = u_\tau\delta/\nu$), which is the typical "mesolayer" scaling; the velocity scale is chosen to be the rms turbulence velocity at $y = y_m$. Using these scales, the mean velocity defect and variance in the intermediate region show a Reynolds-number similarity in both pipe and TBL flows. The consequences of this finding for the Re-number behaviour of κ and A_1, and the attached-eddy modelling are discussed.

SCALING FOR THE INTERMEDIATE REGION

Here we use the turbulent pipe-flow data obtained in Princeton Superpipe using NSTAP [5] for $Re_\tau = 1985 - 98190$. For the TBL, we use two data sets - one obtained in the HRTF experiments at Princeton University [6] ($Re_\tau = 4635 - 72526$; VHS) and the other obtained in the HRNBLWT experiments at Melbourne University [7] ($Re_\tau = 2353 - 15685$; MHM). The intermediate length scale is defined as $y_m^+ = 3.5\sqrt{Re_\tau}$ and the velocity scale $u_m = \sqrt{\overline{u^2}}(y = y_m)$ (see [4]). Fig. 1 (a) and (b) show the mean velocity defect ($U - U_m$) and variance profiles scaled on u_m and y_m for the pipe and TBL; here U_m is the mean velocity at $y = y_m$. It is evident from the figure that the mean velocity defect and variance show a Reynolds number similarity, to an excellent degree, in the intermediate region (i.e. around $y/y_m = 1$) for Re_τ varying over two decades [8]. Moreover, the data for the pipe and TBL show a good collapse indicating a plausible "universal" behaviour for the streamwise velocity in the intermediate region of wall turbulence.

Note that the region above $y/y_m = 1$ typically corresponds to the inertial sublayer where the log scaling is expected to hold [1]. This implies that there exists a Reynolds-number invariant log law, in terms of the intermediate variables, for both mean velocity and variance for $y/y_m > 1$ (Eq. 2).

$$\frac{U - U_m}{u_m} = \frac{1}{\kappa_m}\ln\left(\frac{y}{y_m}\right) + C_m, \qquad \frac{\overline{u^2}}{u_m^2} = B_1^m - A_1^m \ln\left(\frac{y}{y_m}\right). \tag{2}$$

The log-law constants in Eq. (2) can be obtained by fitting a straight line through the data points in the intermediate region (figure 1). This has been done for the pipe and TBL separately to compare the individual constants. For the pipe data, the

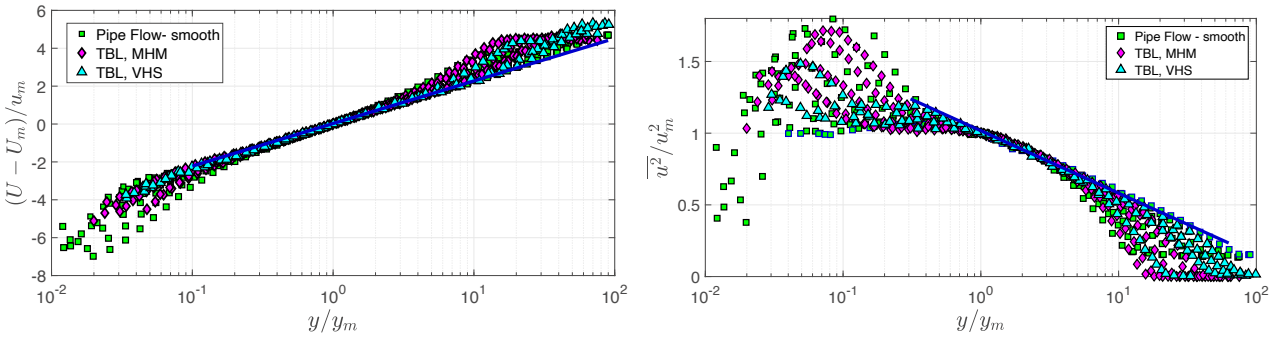

Figure 1: Profiles of (a) $U - U_m$ and (b) $\overline{u^2}$ scaled on y_m and u_m for the smooth-walled pipe [5] and TBL ([6],[7]) data. The extent of the log variation (indicated by a straight line) decreases with decrease in Reynolds number, for both mean velocity and variance.

extent of the log law is found to be $1.2 \leq y/y_m \leq 13$, whereas for the TBL it is $1.2 \leq y/y_m \leq 10$; the same interval is used for fitting the mean velocity and variance data for a given flow. Table 1 summarizes the numerical values of the constants in Eq. (2) obtained for the two flows. As can be seen from the table, the values for the log-law slopes, κ_m and A_1^m, are quite close to each other for the two flows, as expected from the good collapse among the data seen in figure 1. The averaged values of these constants are also included in table 1, which might represent, approximately, the plausible "universal" values for the constants. The straight lines shown in figures 1(a) and (b) represent the log fits to the mean velocity and variance data using the averaged values for the constants from table 1.

Table 1: Summary of the log-law constants for the pipe and TBL, along with averaged values for the two flows.

Case	κ_m	C_m	A_1^m	B_1^m
Turbulent pipe flow	1.034	0.0084	0.178	1.005
Turbulent boundary layer	1.015	0.044	0.200	1.028
Plausible "universal" values	1.025	0.0262	0.189	1.017

The log-law constants for the intermediate scaling (Eq. 2) can be readily related to the classical log-law constants (Eq. 1). The relations involve ratios u_m/u_τ and y_m/δ, which are functions of Re_τ [8]. We find that, for both pipe and TBL, κ has much higher values than can be associated with a log variation for $Re_\tau < 2 \times 10^4$, implying that a log law is untenable for lower Reynolds numbers [5]. For $Re_\tau > 2 \times 10^4$, κ falls in the range 0.4 ± 0.02 for the pipe and seems to asymptote to a value of 0.41 for the TBL. The Townsend-Perry 'constant' shows a systematic dependence on Reynolds number for both the flows, with $A_1 < 1$ for the smallest Re_τ, increasing to 1.24 for the highest Re_τ, consistent with [1].

The present findings have clear implications for the attached-eddy modelling. The work suggests that the energy containing eddies in the inertial sublayer, might scale better on u_m and y_m as compared to the classical scales, u_τ and δ. This is supported by the result that A_1 (Eq. 1) is a function of Re_τ, whereas A_m (Eq. 2) is Re-independent. Moreover, these eddies may not be physically attached to the wall [3], but rather, detached in some way. Some of these ideas need to be explored further in the context of the attached-eddy hypothesis. The choice of intermediate scales is being examined with reference to the kinetic energy balance around the outer peak [9].

CONCLUSIONS

We have shown that, using intermediate length and velocity scales, it is possible to achieve a Reynolds-number similarity in the intermediate region of wall turbulence. This implies existence of a Reynolds-number invariant logarithmic region, which seems to be "universal". As a consequence, the standard values of the Kármán 'constant' are realized only at sufficiently large Re_τ and that the Townsend-Perry 'constant' shows a systematic Re-dependence. The work can have important implications towards the attached-eddy modelling; more results on this will be presented during the talk.

SPATIAL ORGANIZATION OF WALL-COHERENT AND INCOHERENT STRUCTURES IN TURBULENT BOUNDARY LAYERS

Rahul Deshpande* [1], Jason P. Monty [1], and Ivan Marusic[1]
[1] Department of Mechanical Engineering, The University of Melbourne, Victoria 3010 Australia

Summary The study is aimed towards understanding the spatial organization of large coherent structures of the streamwise (u) velocity, in a zero pressure gradient turbulent boundary layer (ZPG TBL), by segregating the total flow into its sub-components: wall-coherent (WC) and incoherent (WI) structures. The decomposition is conducted by utilizing the spectral linear stochastic estimation (SLSE) technique [5]. Two datasets are considered, a low Reynolds number (Re_τ) DNS database of ZPG TBL [2], and a high Re_τ experimental database obtained via synchronous multi-point hotwire measurements of u. The instantaneous flow and mean statistics representative of the WC and WI motions are investigated for structure organization and scaling arguments, respectively. The eventual goal of this analysis is to propose a conceptual 3-D sketch of the large organized motions in TBL flow.

INTRODUCTION

Organized motions in canonical wall-bounded turbulent flows have been characterized into four principal elements [1], namely: near-wall streaks, hairpin vortices, large-scale motions (LSMs) and very-large-scale motions (VLSMs; superstructures or SS for external flows), with each of them being dominant at different wall-normal spacings. In the logarithmic (log) layer, the LSMs and VLSMs/SS constitute a majority portion of the Reynolds shear stress and kinetic energy [1]. The predominance of such large structures is evident in figure 1(a) which shows the instantaneous streamwise velocity (u) fluctuations in the wall-parallel (x-y) plane at the nominal start of the log-region ($z_o^+ \approx 2.6\sqrt{Re_\tau}$). The data are from the direct numerical simulation (DNS) of a ZPG TBL by Sillero et al. [2] at $Re_\tau \approx 2000$ (referred as $\mathcal{S}_1$ henceforth). Here, x, y and z refer to the streamwise, spanwise and wall-normal directions, respectively. Superscript '+' indicates normalization by viscous length (ν/U_τ) and velocity (U_τ) scales, while Re_τ refers to the friction Reynolds number calculated based on the boundary layer thickness, δ. The energetic predominance of the large structures is reflected via the premultiplied one-dimensional (1-D) streamwise and spanwise spectra of u shown in figure 1(b). Here, apart from the dataset $\mathcal{S}_1$, 1-D spectral estimates are also obtained from an experimental dataset of 2-D energy spectra for a $Re_\tau \approx$ 15,000 ZPG TBL (referred as $\mathcal{E}_1$ henceforth). These measurements were conducted in the High Reynolds Number Boundary Layer Wind Tunnel (HRNBLWT) at the University of Melbourne by following the same methodology as that of Chandran et al. [3]. In figure 1(b), the peaks at streamwise (λ_x) and spanwise (λ_y) wavelengths of 6δ and 0.7δ, respectively are observed for both the datasets and relate to the geometry and spatial organization of the δ-scaled SS [1].

The structures observed in the wall-parallel plane in figure 1(a) may be either wall-coherent (WC; i.e. they physically extend all the way down to the wall) or wall-incoherent (WI). The present study focuses on investigating these two sub-components of the ZPG TBL flow via instantaneous as well as statistical means. This is aligned with a recent upsurge in the interest towards understanding the WC motions, which have been found to be the principal candidates [4,5] for Townsend's 'attached' eddies. The study aims to revisit the spatial organization of large coherent structures, in the log-region of a ZPG TBL, after decomposing the total energy into WC and WI sub-components. Gaining new insights into the organization of WC and WI motions can help in clarifying several doubts/inconsistencies pertaining to the structural organization in the log-region, for example the meandering nature and formation of SS, etc.

ENERGY DECOMPOSITION USING SLSE

The decomposition is carried out by utilizing the scale-by-scale coupling between u-signals at two wall-normal locations, say z_o and z_r. Following Madhusudhanan et al. [6], the coupling is used to obtain a linear stochastic estimate (SLSE) of u at a given wall-normal location (z_o) based on measurement at another location (z_r). It is worth noting here that this approach enables estimation for only those scales that are coherent across z_o and z_r. The SLSE [5] essentially considers a scale-specific unconditional input to give a scale-specific conditional output following:

$$\widetilde{u}^E(z_o;\lambda_x,\lambda_y) = H_l(z_o,z_r;\lambda_x,\lambda_y)\widetilde{u}(z_r;\lambda_x,\lambda_y), \tag{1}$$

where $\tilde{u}(z_r;\lambda_x,\lambda_y) = \mathcal{F}[u(z_r)]$ is the 2-D Fourier transform of $u(z_r)$ in x and y. The superscript E represents the estimated quantity and H_l represents the scale-specific linear transfer kernel. The transfer kernel is computed from an ensemble of data following:

$$H_l(z_o,z_r;\lambda_x,\lambda_y) = \frac{\phi'_{uu}(z_o,z_r;\lambda_x,\lambda_y)}{\phi_{uu}(z_r;\lambda_x,\lambda_y)} = \mid H_l(z_o,z_r;\lambda_x,\lambda_y) \mid e^{i\psi(z_o,z_r;\lambda_x,\lambda_y)}, \tag{2}$$

with $\mid H_l \mid$ and ψ being the scale-specific gain and phase, respectively. To build the kernel we need ϕ'_{uu}, which is the 2-D cross-spectrum between $u(z_o)$ and $u(z_r)$, and $\phi_{uu}(z_r)$, which is the 2-D energy spectra at z_r. Both of these are available

*Corresponding author. E-mail: raadeshpande@gmail.com

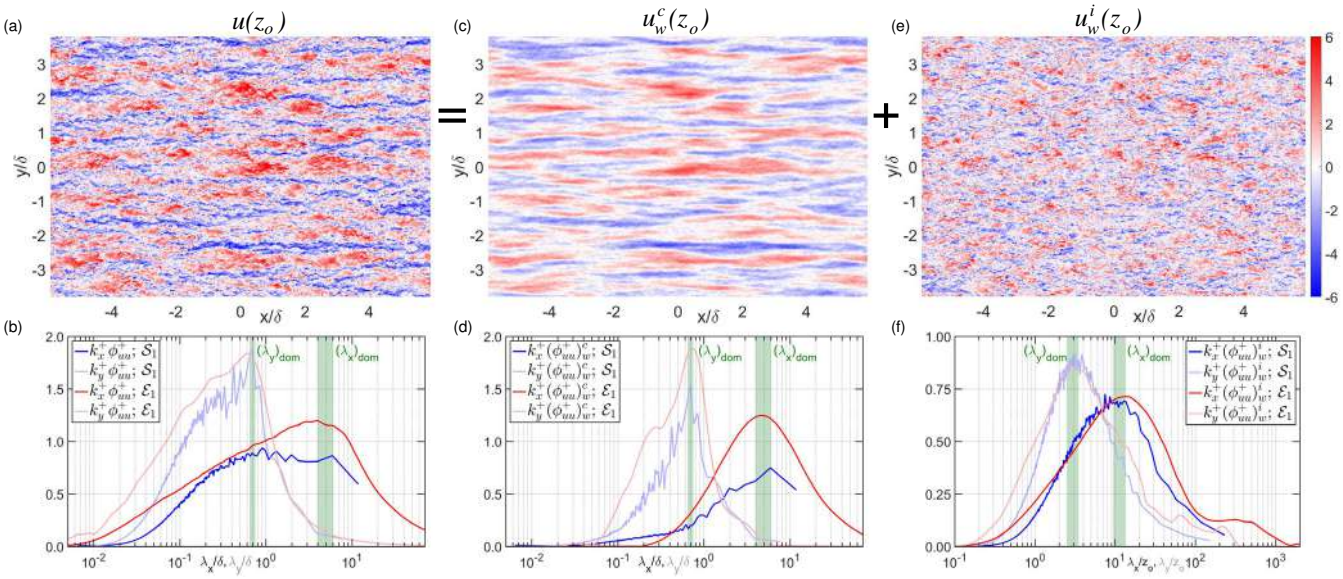

Figure 1: (a,c,e) The instantaneous streamwise velocity fluctuations from the $\mathcal{S}_1$ dataset at $z_o^+ \approx 2.6\sqrt{Re_\tau}$ with contributions from (a) all, (c) wall-coherent and (e) wall-incoherent structures. (b,d,f) Premultiplied streamwise (dark-shaded) and spanwise (light-shaded) energy spectra of the streamwise velocity component for $z_o^+ \approx 2.6\sqrt{Re_\tau}$ representing contributions from (b) all, (d) wall-coherent and (f) wall-incoherent structures. Data from $\mathcal{S}_1$ and $\mathcal{E}_1$ is plotted in blue and red, respectively while the green background is used to highlight the dominant streamwise and spanwise wavelengths.

for $z_o^+ \approx 2.6\sqrt{Re_\tau}$ and $z_r^+ \approx 15$ as part of the datasets $\mathcal{S}_1$ and $\mathcal{E}_1$. The linear stochastic estimate in the physical space, $u^E(z_o;x,y)$ can simply be obtained by inverse Fourier transforming the scale-specific estimate, $\widetilde{u}^E(z_o;\lambda_x,\lambda_y)$ obtained using equation 1. A stochastic estimate of the energy spectrum at z_o can be obtained from equation 1 following:

$$\phi_{uu}^E(z_o;\lambda_x,\lambda_y) = \mid H_l(z_o,z_r;\lambda_x,\lambda_y) \mid^2 \phi_{uu}(z_r;\lambda_x,\lambda_y). \tag{3}$$

Here, by considering z_r^+ at the wall (≈ 15), $u^E(z_o)$ and $\phi_{uu}^E(z_o)$ essentially represent the sub-components of $u(z_o)$ and $\phi_{uu}(z_o)$ that would include contributions from WC structures only. Accordingly, $u^E(z_o) \rightarrow u_w^c(z_o)$ and $\phi_{uu}^E(z_o) \rightarrow (\phi_{uu}(z_o))_w^c$ for z_r^+ near the wall. Following Baars and Marusic [5], the contributions from WI structures may be simply obtained by subtracting the WC contribution from the total, i.e. $u_w^i(z_o) = u(z_o) - u_w^c(z_o)$ and $(\phi_{uu}(z_o))_w^i = \phi_{uu}(z_o) - (\phi_{uu}(z_o))_w^c$. Availability of the instantaneous wall-parallel data at z_o^+ and z_r^+, as part of the dataset $\mathcal{S}_1$, allows estimation of u_w^c, u_w^i, $(\phi_{uu})_w^c$ and $(\phi_{uu})_w^i$ at z_o. On the other hand, only $(\phi_{uu})_w^c$ and $(\phi_{uu})_w^i$ can be computed from the high Re_τ $\mathcal{E}_1$ dataset. These estimates have been plotted in figure 1(c-f).

RESULTS

The decomposition of the full field (figure 1a) into WC (figure 1c) and WI (figure 1e) components leads to some noteworthy observations. In general, WC structures appear to be longer and wider compared to the WI motions. Further, the meandering behavior of the SS [1] is only seen in u_w^c, suggesting that the SS fall into the WC category. This is substantiated by the $(\phi_{uu})_w^c$ plots in figure 1(d), where both the streamwise and spanwise spectra peak at 6δ and 0.7δ, respectively unlike $(\phi_{uu})_w^i$. The peak in the spanwise spectra is consistent with the large-scale organization seen in u_w^c, wherein the low and high momentum fluctuations are arranged quasi-periodically (with period of the order of δ) along the spanwise direction. On the contrary, no such large-scale periodicity is discernible in u_w^i. Interestingly, the $(\phi_{uu})_w^i$ plots show that the dominant WI motions follow z_o-scaling, which is in contrast to the δ-scaling followed by the dominant WC motions. Future work would include investigating this behavior across the entire log-region, paving the way towards proposing a conceptual 3-D sketch of the large organized flow in the log-region.

ANALYTIC RESOLVENT ANALYSIS FOR WALL-BOUNDED FLOWS

Scott T. M. Dawson *[1] and Barbara Lopez-Doriga[1]
[1] Mechanical, Materials & Aerospace Engineering Department, Illinois Institute of Technology, Chicago, IL, USA

Summary This work presents an analytic approach for approximating the properties of the pseudospectra of linear operators related to wall-bounded turbulent shear flows, thus giving a means to predict the properties of energetically-dominant coherent structures at specific length- and time-scales. The method assumes that leading resolvent response modes (i.e. pseudoeigenmodes) of a given linear operator can be expressed as a sum of wavepackets with a given template shape, and then recasts the associated optimization problem as the minimization of a cost function over a low-dimensional space of parameters. In particular, we show how boundary conditions can be explicitly enforced within this framework through the use of "image" wavepackets on the opposite side of the boundary. This extends recent prior work that does not explicitly account for boundary conditions [1].

INTRODUCTION

While turbulent flows are highly nonlinear, evidence suggests that many of the underlying coherent features present in turbulent flows may be understood through linear mechanisms [2, 3]. In particular, shear-driven turbulent flows typically are associated with highly non-normal linearized operators, which can give rise to large transient growth and amplification of disturbances, even when the operator is asymptotically stable [7]. While the study of such operators can provide valuable insight into underlying mechanisms present in systems such as wall-bounded turbulence, the computational cost of such analysis is often a limiting factor. Indeed, it has been recently noted that "with current computational resources, [resolvent analysis of] fully inhomogeneous flows represent an unmet challenge" [5]. The present work provides an alternative pathway to such analysis motivated by wavepacket pseudomode theory [6, 4], which foregoes the need to form and decompose large discretized operators.

ANALYTIC RESOLVENT ANALYSIS

Analysis of linear amplification mechanisms for a dynamical system can be performed in the frequency domain using the resolvent formulation of the governing equations. Here, the Fourier-transformed (in time) state $\hat{\boldsymbol{x}}$ can be expressed as the result of applying the linear resolvent operator on $\hat{\boldsymbol{f}}$, which can represent nonlinearities and other unknown disturbances, through $\hat{\boldsymbol{x}} = (-i\omega\boldsymbol{I} + \boldsymbol{A})^{-1}\hat{\boldsymbol{f}}$. We are interested in finding the leading singular values and vectors in the singular value decomposition (SVD) of this resolvent operator. Under certain conditions, such modes are expected to resemble wavepackets that are local in both space and spatial frequency. Using this as motivation, rather than proceeding with numerical decomposition of the resolvent operator, we instead start with the assumption that the leading resolvent response mode (left singular vector) can be efficiently approximated by a small number of wavepackets of the form

$$\Psi(\boldsymbol{x}) = \sum_{j=1}^{r} c_j \exp\left(i\boldsymbol{k}_j^T(\boldsymbol{x}-\boldsymbol{x}_j) - (\boldsymbol{x}-\boldsymbol{x}_j)^T\boldsymbol{Q}_j(\boldsymbol{x}-\boldsymbol{x}_j)\right), \tag{1}$$

where $\boldsymbol{x}$ is the spatial coordinate.With this assumption, rather than computing the SVD numerically, we instead find the small number of coefficients that solve the minimization problem

$$\{\boldsymbol{c},\boldsymbol{k},\boldsymbol{Q},\boldsymbol{x}_0\} = \underset{\boldsymbol{c},\boldsymbol{k},\boldsymbol{Q},\boldsymbol{x}_0}{\operatorname{argmin}} \left\|(-i\omega\boldsymbol{I}+\boldsymbol{A})\,\Psi\right\|^2 := \underset{\boldsymbol{c},\boldsymbol{k},\boldsymbol{Q},\boldsymbol{x}_0}{\operatorname{argmin}} J(\boldsymbol{c},\boldsymbol{k},\boldsymbol{Q},\boldsymbol{x}_0;\omega), \tag{2}$$

where we analytically calculate the action of the linear operator on the template response mode shape. This was the approach taken in [1] for the case where $r = 1$, for systems with spatial homogeneity (and thus no localization) in the streamwise and spanwise directions. In this work, we consider the case with $r = 2$, which allows for the implementation of Dirichlet boundary conditions. For the purposes of exposition, here we focus on the simple operator $\boldsymbol{A} = -(iR)^{-1}D_{yy}+y$ in the vicinity of a boundary at $y = 0$, which is equivalent to the Squire operator with a linear mean velocity profile. Note in particular that this operator can be used in the understanding of the Orr mechanism in shear-driven turbulent flows. In order to satisfy the boundary conditions, we consider candidate response modes of the form

$$\Psi(y) = c\left\{\exp\left[ik_y(y-y_0) - q(y-y_0)^2\right] - \exp\left[-ik_y(y+y_0) - q(y+y_0)^2\right]\right\}. \tag{3}$$

For a specified frequency $\omega = \omega_r + i\omega_i$, we compute the cost function for this system to be

$$J(k_y,q,y_0;R,\omega) = \left[J_1 - qe^{\frac{k_y^2}{2q}+2qy_0^2}J_2 + J_3\right]\left(1 - 4k_yR^2e^{\frac{k_y^2}{2q}+2qy_0^2}\right)^{-1}, \tag{4}$$

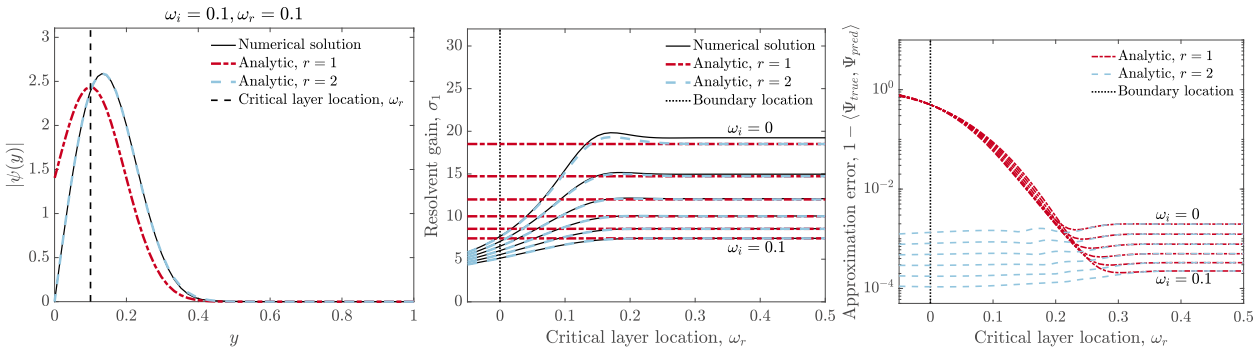
MINI SYMPOSIA



(a) (b) (c)

Figure 1: (a) Numerical and analytic mode shapes for a critical layer close to the wall at $\omega_r = 0.1$; (b) leading resolvent singular values; and (c) error between numerical and analytical modes for various complex frequencies. All results are for $R = 3000$, and compare analytic modes computed using a single wavepacket that does not account for boundary conditions ($r = 1$), and two wavepackets to ensure that boundary conditions can be satisfied ($r = 2$).

$$J_1 = 64q^6y_0^4 - 96q^5y_0^2 - 32q^4R\omega_i y_0^2 + 12q^4 + 16q^3Ry_0 + 4q^2R^2\omega_i^2 + 4q^2R^2y_c^2 + qR^2 - k_y^2R^2,$$
$$J_2 = \left(4q\left(3q^2 + 2q\left(3k_y^2 + R\omega_i\right) + k_y^4 + 2k_y^2R\omega_i + R^2\omega_i^2 + y_0^2 + y_c^2\right)\right) + 8qR(k_y - Ry_0y_c)\,\mathrm{erf}\left(\sqrt{2q}y_0\right) + R^2,$$
$$J_3 = 8q^3R\omega_i\,\mathrm{erfi}\left(\frac{k_y}{\sqrt{2q}}\right) + 4qk_yR^2y_c\,\mathrm{erfi}\left(\frac{k_y}{\sqrt{2q}}\right).$$

Figure 1 compares the performance of finding optimal mode shape parameters from this cost function to the mode computed from the numerical SVD, as well as to the analytic mode computed without enforcement of boundary conditions. We see using modes of the form given in equation 3 accurately captures both the shape and amplification of the numerically-computed leading resolvent mode even as the critical layer gets arbitrary close to the wall, which is not the case when only a single wavepacket is used.

CONCLUSION

The close agreement of the analytic and numerically-computed modes and singular values shows that the assumed form for the leading response mode shapes is valid. These results demonstrate the feasibility of extending this analytic analysis to more complex systems. Preliminary results suggest that this method can indeed extended to cases with multiple boundaries, multiple critical layers, and for the computation of suboptimal modes, though in some cases an exact closed-form expression for the cost function can be challenging to obtain. It is our goal to further extend this analysis towards systems where direct numerical computation of resolvent modes currently presents computational challenges (e.g. for cases with multiple directions of spatial inhomogeneity), particularly if needed for real-time modeling and control.

THE EFFECT OF SETTLING INERTIAL PARTICLES ON HOMOGENEOUS TURBULENCE

Filippo Coletti*[1,2], Roumaissa Hassaini*[1]
[1] Department of Aerospace Engineering & Mechanics, University of Minnesota, Minneapolis, MN, USA
[2] Department of Mechanical and Process Engineering, ETH Zurich, Switzerland

Summary We report novel measurements of the effect of microscopic heavy particles on the turbulence in which they are suspended. We use a unique apparatus that generate a large volume of homogeneous air turbulence, and use laser imaging to simultaneously track the particle motion and the air velocity fields from the integral to the Kolmogorov scales in both space and time. It is the first time this is achieved experimentally for particles in a Stokes number range that produces clustering and enhanced settling. We systematically vary the volume fraction from 10^{-6} to $5*10^{-5}$, and report clear trends for the particle settling velocity and clustering, as well as for the air turbulence statistics. With increasing concentration, clustering and settling velocity of the particles is enhanced, turbulence kinetic energy is augmented, the dissipation rate is reduced, and the scale-by-scale distribution of the energy is profoundly altered by the particles.

BACKGROUND

Particle Laden turbulence occurs in natural processes such as rain, snow and sand. These flows are difficult to characterize in nature and even at small volume fraction the particles can modify the turbulence. Is the turbulence increased or inhibited? And what processes are causing such modifications? Answering these questions is still challenging for the scientific community, both numerically and experimentally, given the wide range of parameters and spatio-temporal scales involved [1,2].

EXPERIMENT

In the present work, we shed some light on these questions by tackling the problem at the laboratory scale. Well controlled experiments have been used, where the only changing parameter is the particle volume fraction. The latter is increased from below 10^{-6}, where it is verified that the turbulence is not affected by the particles (one-way coupling), up to $5*10^{-5}$, where major influence of the particles on the fluid is expected (two-way coupling). The experiments have been carried out in a 5 m^3 chamber. Homogeneous air turbulence with quasi-zero mean flow is generated thanks to 2 planes of 128 each random jets [3]. Size-selected glass micro-spheres (50 micron in diameter) fall into the chamber through a 3-m long vertical chute. Multi-scale imaging is implemented using 2 synchronized high speed cameras resolving from the Kolmogorov scale up to the integral scale. Particle Image Velocimetry (PIV) and Particle Tracking Velocimetry (PTV) are used simultaneously to follow respectively the flow and the 50 um glass beads particles. The particle Stokes number (based on the Kolmogorov time scale) is St =3.5 and the Reynolds number based on the Taylor microscale is Re_λ =300. We will briefly present in the following some of the main results from the study, showing the effect of the increasing volume fraction on both the particle transport and the air turbulence.

PARTICLE TRANSPORT

We investigated the change of the rate of gravitational settling thanks to the reconstructed velocity field of the particles. It appears that the mean fall speed of the particles is enhanced when the particle concentration is increased as plotted in Fig.1a. For the highest volume fraction the mean vertical velocity reaches almost $2W_0$, W_0 being the expected terminal velocity measured in one-way coupled regimes. Similar trends have been reported numerically, but much weaker in magnitude [4].

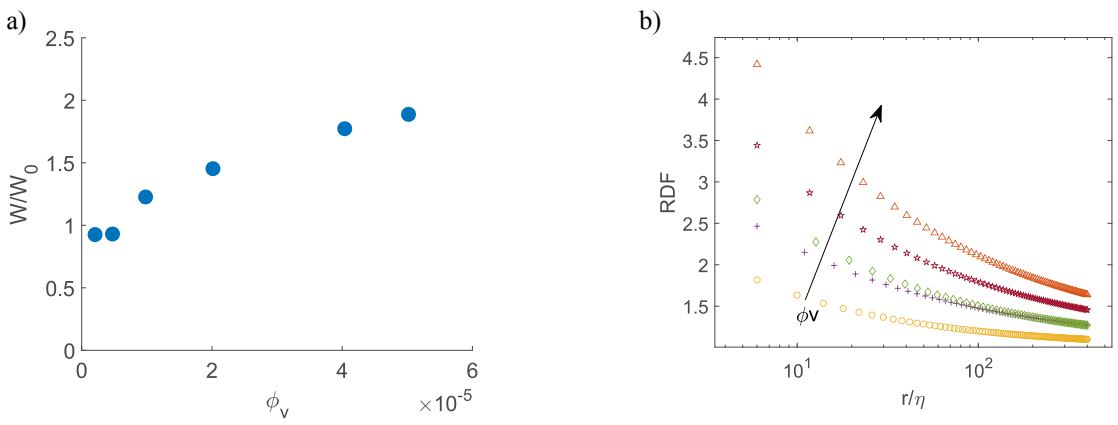

Figure 1. (a) Mean vertical velocity of the particles divided by W_0 versus the volume fraction. (b) RDFs of the particles in function of the scale r normalized by the Kolmogorov scale for different volume fractions.

*Corresponding author. E-mail: fcoletti@ethz.ch

At the present Stokes number, significant clustering of the particles is expected. To characterize such effect, Radial Distribution Functions (RDF) [5] are examined. As plotted in Fig1.b, the RDFs display significantly higher values as the volume fraction increases, which confirms an intensification of the clustering at all scales. Such effect, which we also confirm and explore via Voronoi tessellation (not shown), has never been documented experimentally before.

TURBULENCE MODIFICATION

The modification of the fluid by the particle-turbulence interaction is examined. The Turbulent Kinetic Energy (TKE) normalized by the unladen-case value is represented in fig2a, in function of the volume fraction, as retrieved from imaging at both small field of view (SFV) and large field of view (LFV). We observe a clear and major increase in the TKE. This turbulence augmentation is opposite to previous trends (turbulence modulation) observed in previous studies (e.g., Hwang & Eaton [6]) which considered much more inertial particles. We attribute the different behaviour to the important role of clustering and enhanced settling in the present regime.

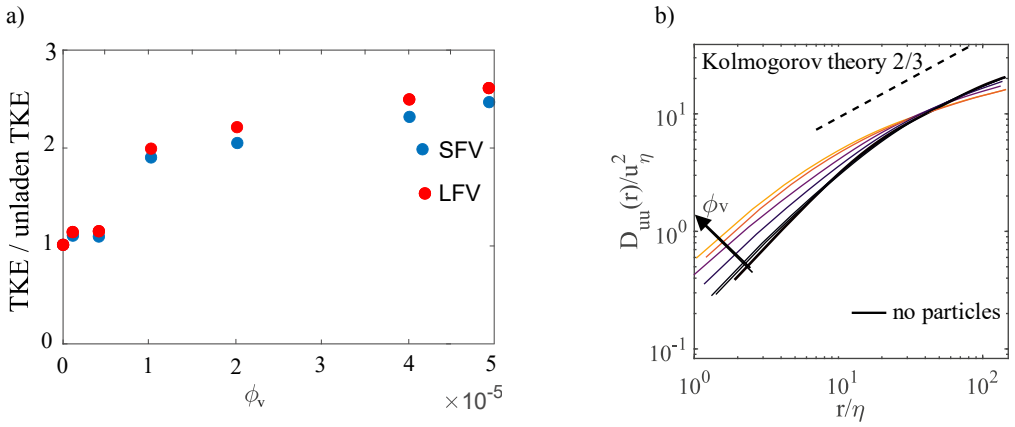

Figure 2. (a) Turbulent kinetic energy normalized by the unladen case in function of the volume fraction for the Small and Large Field of View. (b) Second-order velocity structure function versus normalized scale for the different volume fractions.

The energy distribution over the scales is of a great importance in turbulence. A quantity that can give us an insight to such distribution is the 2nd order velocity structure function, plotted in Fig 2b. As the volume fraction increases, we see a departure from the expected $r^{2/3}$ scaling predicted by Kolmogorov theory over the inertial scales. For significant loadings we have an excitement of the turbulence fluctuations at small scales whereas a modulation of these fluctuations is observed at larger scales. Such behaviour, termed pivoting, has been reported mainly numerically, and only sporadically experimentally [7,8]. The present systematic trend clarifies the picture and contributes to further our understanding of particle-turbulence interaction in the clustering regime.

LARGE-SCALE MODULATION OF AN EFFUSION FILM BY A TURBULENT BOUNDARY LAYER

Jeremy Basley *[1], Kevin Gouder[1], and Jonathan F. Morrison[1]
[1] Department of Aeronautics, Imperial College London, United Kingdom

Summary The evolution of a turbulent boundary layer injected with an effusion film is investigated for a range of film velocity over incoming velocity ratios, using Particle Image Velocimetry, visualisations, and hot-wire measurements. This work focuses on the momentum effects underlying the mixing of the effusion film. To that end, the geometry of a turbine blade is idealised in a large-scale facility, the upstream boundary layer is canonical and the effusion film is isothermal. The spectral content of the flow reveals that the effusion film first promotes near-wall turbulence until it separates above a critical velocity ratio and large-scale motions no longer penetrate the roughness sub-layer. Mixing is drastically altered by the injection of the film, as evidenced by amplitude modulation maps which feature intensified large-scale modulations of small-scale turbulence.

INTRODUCTION

In pursuit of higher efficiency in jet engines, the temperatures brought out in combustion chambers have to be maximised. As a result turbine blades located directly downstream of the combustion chamber endure harsh conditions, which must be alleviated by film or effusion cooling. Large velocity ratios are typically used to account for wide tolerances: typically VR $= U_f/U_\infty > 100\%$ up to 300%, where U_f and U_∞ are the characteristic velocities of the film and the incoming flow, respectively (see [1] for a review). This implies high flow rates are required for cooling, thus preventing further improvement of the engine's efficiency. A finer tuning of the film generation as well as minimised mixing must be achieved to maintain the integrity of the film and allow for lower velocity ratios to be used. This experimental study emulates the flow around a turbine blade using an idealised scaled-up configuration at low speed in order to get around the inherent constrains and challenges of internal flows in jet engines. This allows us to focus on the exchange mechanisms at play between the injected film and the incoming flow, and to concentrate on low velocity ratios (VR $< 40\%$).

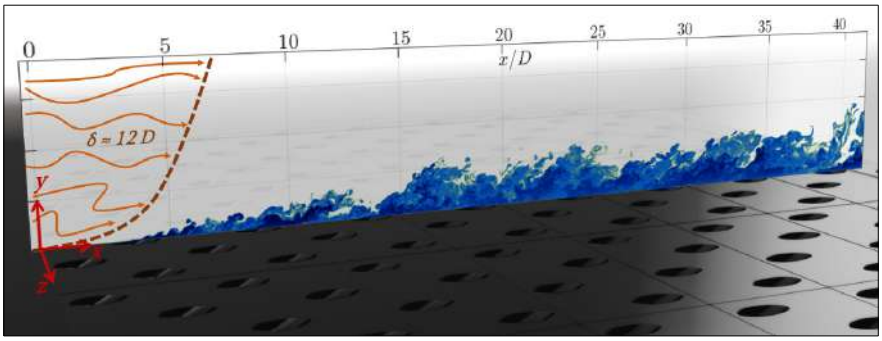

Figure 1: Illustration of the experimental set-up: rendered image of the effusion plate superimposed with a visualisation snapshot acquired in the plane aligned with the centre of effusion holes (for VR $= 26\%$).

EXPERIMENTS

The scaled-up effusion device consists of a plenum located directly underneath a thick plate with a staggered grid of inclined $D = 16$ mm diameter holes with a pitch of $5D$. This setup was placed in a self-similar turbulent boundary layer, tripped and developed over 15 m, yielding a Reynolds number between $2700 < u_\tau\delta/\nu < 4700$, with u_τ the friction velocity and $\delta \simeq 0.2$ m the boundary layer thickness upstream of the plate (Figure 1). Time-resolved planar PIV and visualisations were acquired in two streamwise wall-normal planes – one along the holes the other between two rows. A wide range of low velocity ratios were investigated, VR $< 40\%$ down to VR=0% whilst the holes remain open.

RESULTS & DISCUSSION

Power spectral densities were computed from stream-wise velocity fluctuations u. The spectral signature observed for VR=0% (Figure 2a) is consistent with high Reynolds number boundary layers [2]. It shows a scale separation between small-scale turbulence confined in the roughness sublayer – here generated by the perforated plate – and large-scale motions particularly intense in the log layer. Inserting the effusion film results in a broad-band increase of turbulence in the sub-layer, including large-scale motions (Figure 2b). Above a critical VR (around $15 - 20\%$) the separation of the film occurs and pushes away the large-scale motions outside the roughness sub-layer. This reduces the turbulent energy close to the wall but it generates a broad-band spike of large-scale fluctuations further around $y \approx 0.1\delta$ (Figure 2c).

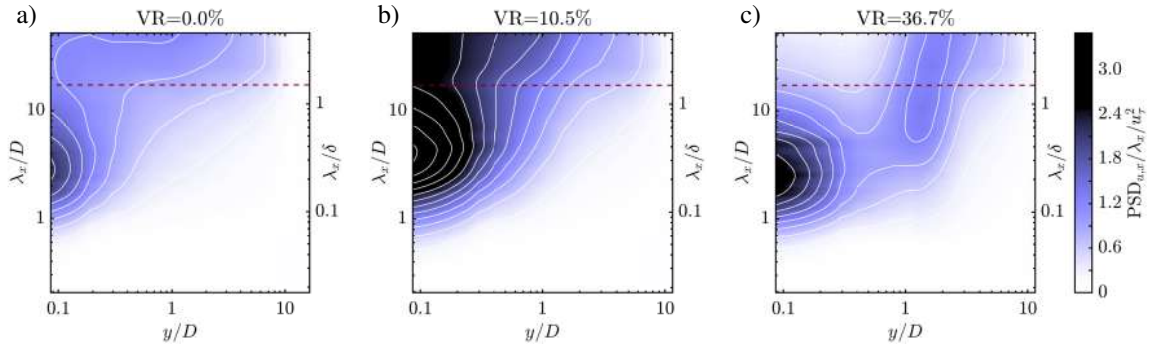

Figure 2: Pre-multiplied power spectral densities of stream-wise velocity $\mathrm{PSD}_{u,x}$ as a function of wavelength λ_x and wall distance y for three VR. Contour levels are shown every $0.3\,u_\tau^2$. The dashed lines mark the cut-off wavelength $\lambda_x = 1.5\delta$ used below.

The gap between small scales populating the roughness sub-layer and the large-scale motions allows for the decomposition of velocity fluctuations into $u = u_L + u_s$, where $u_L = u(\lambda_x > 1.5\delta)$ is the large-scale component obtained through stream-wise unbiased low-pass filtering, and u_s carries the remaining fluctuations at smaller scales. That decomposition has been used in numerous papers to quantify the amplitude modulation of small-scale turbulence by large-scale motions [3] via the coefficient AM, defined as the correlation between u_L and $(u_s^2)_L$, the large-scale envelope of small-scale fluctuations obtained by low-pass filtering u_s^2. Often restricted to temporal correlations of hot-wire measurements, AM has recently been extended to spatial correlations [4]. Here it is defined as

$$\mathrm{AM}(x_0, y_0, x, y) = \frac{\langle u_L(x_0, y_0) * (u_s^2)_L(x, y) \rangle}{\sigma_{u_L}(x_0, y_0)\, \sigma_{(u_s^2)_L}(x, y)},$$

where σ denotes a standard deviation. Contours of AM coefficient are shown in Figure 3. Inclined meandering large-scale motions modulate the amplitude of small scales in the roughness sub-layer, so that turbulence is intensified directly underneath at the front of these super-structures.

This mechanism which identifies inter-scale exchanges underlying the mixing within the boundary layer, is significantly altered by the presence of the effusion film. At low VR, modulations of small-scale turbulence are enhanced but remain confined near the wall. With increasing VR and the separation of the effusion film, large-scale motions no longer reach the inner layer. Instead the amplitude modulation occurs in the log layer at a much higher level. It is worth noting that such an evolution of AM is reminiscent of flat-plate boundary layers in adverse pressure gradients, which exhibit a similar separation of the inner sub-layer [5]. Further insight will be discussed in Milano, notably the extension of the large-scale modulation analysis to the concentration of injected fluid using synchronous velocity fields and visualisations.

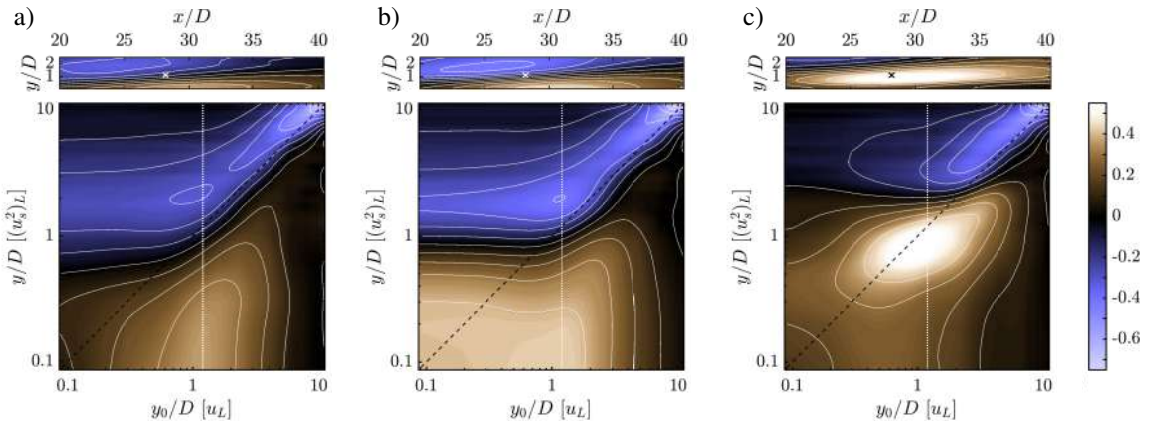

Figure 3: Amplitude modulation coefficient for (a) VR $= 0\%$, (b) VR $= 10\%$, and (c) VR $= 37\%$. (Top) single point correlation $\mathrm{AM}(x, y)$ at reference point $(x_0 = 28D, y_0 = 1.2D)$, and (bottom) two-point correlation profile $\mathrm{AM}(y_0, y)$ at $x_0 = 28D$. White dotted lines mark the intersections with top maps at $y_0 = 1.2D$ and black dashed diagonals mark the no-shift correlation ($y = y_0$).

CLOSED-LOOP CONTROL OF FORCED TURBULENT JETS

Igor A. Maia *[1], Peter Jordan[1], and André V. G. Cavalieri[2]
[1] Pprime Institute, CNRS, Université de Poitiers, ENSMA, Poitiers, France
[2] Divisão de Engenharia Aeronáutica, Instituto Tecnológico de Aeronáutica, São José dos Campos, Brazil

Summary We assess the possibility of performing closed-loop control of forced, turbulent jets through wave-cancellation. The study is motivated by the success of recent studies in applying wave-cancellation to control Tollmien-Schlichting waves in laminar boundary layers and Kelvin-Helmholtz instabilities in transitional mixing layers. Using a control law obtained through a system identification technique, here we demonstrate that wave-cancellation-based, closed-loop control is also possible in a fully turbulent jet.

INTRODUCTION

This work describes experiments involving closed-loop control of forced, turbulent jets. The strategy consists in eliminating disturbances through wave-cancellation. The technique assumes downstream propagation of disturbances to be linear and requires an estimation model capable of predicting their evolution in real-time. Wave-cancellation has been sucessfully applied in recent numerical studies to the control of Tollmien-Schlichting waves in laminar boundary layers [1], and Kelvin-Helmholtz instabilities in low-Reynolds-number, two-dimensional, transitional mixing-layers [2]. The results of these studies, which combine linear stability models and system identification, motivates the application of wave-cancellation to the control of disturbances in turbulent jets, which many recent studies have shown can be reasonably modelled using linear stability theory [3]. Kopiev et al. [4] have shown, in an open-loop configuration, that wave-cancellation of harmonic disturbances is possible. But wave-cancellation of stochastic disturbances in in a fully-turbulent jet, in a closed-loop configuration, has so far not been realised.

We tackle this issue experimentally. The goal of the forcing is to raise target axisymmetric disturbances above background turbulence levels, making them easier to control.

CONTROL STRATEGY

The control law design is based on that of Sasaki et al. [2] and Sasaki et al. [3]. We seek to eliminate a certain objective, z, which is given as a linear combination of sensor measurements, y, plus the actuation signal, u, which is itself dependent on the measurements. In the frequency-domain, this can be written as:

$$Z(\omega) = Y(\omega)H_{yz} + U(\omega)H_{uz}, \tag{1}$$

$$U(\omega) = K(\omega)\left(Y(\omega) + H_{uy}U(\omega)\right), \tag{2}$$

where Z, Y and U are the frequency-domain counterparts of z, y and u, H_{yz} and H_{uz} are the estimation and actuation transfer functions, respectively, and H_{uy} is a feedback transfer function. These are identified empirically, by computing the response of the jet to forcing and actuation separately. The control kernel, K is obtained by substituting Eq. 2 into Eq. 1, setting $Z = 0$ and solving for K. In the time domain, the control law is given by,

$$u(t) = \int_0^\infty k(\tau)y(t-\tau)\mathrm{d}\tau, \tag{3}$$

where k is the inverse Fourier transform of K.

The experiments were carried out in a jet with Mach and Reynolds numbers of $M = 0.05$ and $Re = 5 \times 10^4$, respectively, with the Reynolds number based on the jet diameter. The nozzle boundary layer was tripped at a distance of $2.5D$ (with D being the jet diameter) upstream of the exit plane, in order to ensure that the jet is turbulent.

Figure 1 shows a schematic of the experiment. The jet was forced at the nozzle lip by synthetic jets issuing from a 0.5 mm annular slot. The synthetic jets were generated by a system of eight loudspeakers acting in a synchronised manner so as to force axisymmetric wavepackets. The input measurements were provided by a ring of 6 microphones placed in the near pressure field of the jet at a streamwise distance of $0.3D$ from the nozzle exit. The actuators also consisted of synthetic jets generated by loudspeakers, and were placed at $1.4D$ downstream of the nozzle exit. The objective of the control law was to minimise the streamwise velocity fluctuations at the jet centerline, measured by a hot-wire placed at $2D$.

The jet was forced with band-limited stochastic signals in four different frequency bands: $0.3 \leqslant St \leqslant 0.45$, $0.3 \leqslant St \leqslant 0.65$, $0.3 \leqslant St \leqslant 0.85$ and $0.3 \leqslant St \leqslant 1$, where St is the Strouhal number, given by $St = fD/U_j$, with U_j being the jet exit velocity.

The closed-loop experiment is carried out using a LabVIEW software. The task of the sofwtare is to carry out the convolution given by Eq. 3 in real-time, using unsteady signals from the pressure measurements as input, y.

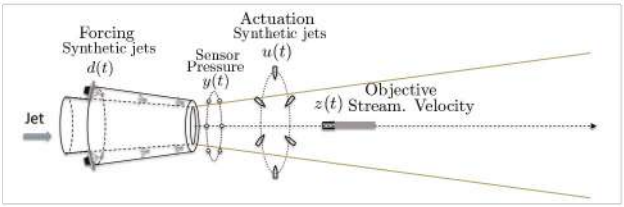

Figure 1: Schematic of closed-loop control experiment.

RESULTS

Linearity is a key feature for wave-cancellation. Here we use two-point coherence as a measure of the linearity of the system and a criterion for interpretation of the results. Control performance is dictated by two kinds of coherence: the coherence between sensor and objective, γ_{yz}, which we have found is a good proxy for the accuracy of the disturbance estimation; and the coherence between actuator and objective, γ_{uz}, found to be a good proxy for wavepacket generation.

Figure 2 shows streamwise velocity spectra of controlled and uncontrolled jets at the objective position. The spectra of the unforced jet is also shown for comparison. The coherences γ_{yz} and γ_{uz} associated with each control case are also shown. Two kinds of actuation were carried out: one whose gain was designed to reduce disturbance amplitude, named K_r and another designed to amplify disturbances, K_a, obtained by applying a π phase shift to K_r.

For the jet forced at the two narrowest frequency bands, control is effective in both reducing and amplifying the disturbances, thanks to the the high values of coherence. Reductions of up to 7dB can be observed in the frequency bands $0.3 \leqslant St \leqslant 0.45$ and $0.3 \leqslant St \leqslant 0.65$. At larger frequency bands, actuator performance is poor and nonlinear effects, reflected by the reduced coherence, γ_{uz}, degrade control authority.

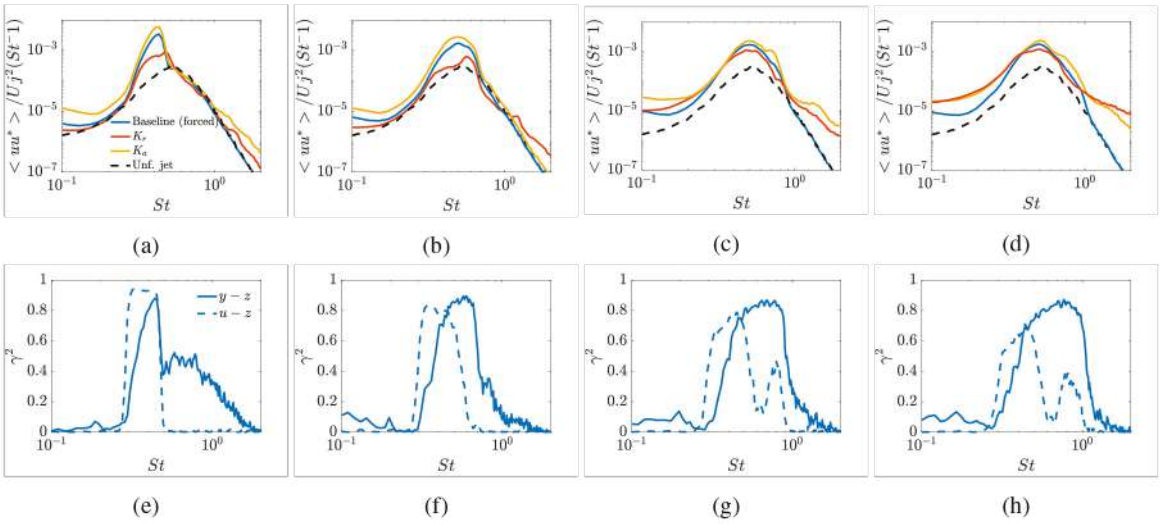

Figure 2: Streamwise velocity spectrum measured at the objective position of controlled an uncontrolled turbulent jets forced in the bands: (a) $0.3 \leqslant St \leqslant 0.45$; (b) $0.3 \leqslant St \leqslant 0.65$; (c) $0.3 \leqslant St \leqslant 0.85$; (d) $0.3 \leqslant St \leqslant 1$. Spectra of the unforced jet are also shown for comparison. The coherences corresponding to each case are shown on the bottom line.

CONCLUSIONS

We have shown that wave-cancellation is possible in a fully turbulent jet. This is the first time, to the best of our knowledge, that closed-loop control has been successfully applied to a turbulent jet. The performance of the control is shown to be largely underpinned by coherence between sensor and objective, on one hand, and actuator and objective on the other. These measures of coherence will thus be useful for the optimisation of actuation positioning.

A SIMPLE MODEL OF THE TURBULENT BOUNDARY LAYER BASED ON AN UNDERLYING BINARY FLOW STRUCTURE

Christopher M. White *[1], Alireza Ebadi1, Juan Carlos Cuevas Bautista[1], Greg Chini[1], and Joseph Klewicki[2]
[1] Department of Mechanical Engineering, University of New Hampshire, Durham, NH 03824, USA
[2] Department of Mechanical Engineering, University of Melbourne, Melbourne, Victoria, 3010, Australia

Summary Experimental and numerical studies over the past two decades reveal that as the Reynolds number becomes large the turbulent boundary layer is increasingly composed of large zones of uniform streamwise momentum segregated by narrow regions of high shear. Similarly, recent studies have shown that passive scalar fields in turbulent boundary layers also exhibit a binary spatial structure, namely, large uniform scalar zones separated by narrow regions of high gradient. Herein, a simple model of the turbulent boundary layer that exploits these essential binary elements of the boundary-layer structure is developed.

MODEL CONSTRUCTION

The present work focuses on recent studies in canonical smooth-wall flows, in which the momentum and passive scalar fields exhibit similar binary structures (extended regions of uniform quantity segregated by narrow regions of large gradient) [1, 2]. The target of the present work is to capture essential features of the momentum and scalar transport associated with this heterogeneous structure. This is achieved by employing a complementary set of theoretically educed and empirically observed findings to formulate a simple model for the streamwise velocity and passive scalar fluctuations in turbulent wall flows. In essence, this model leverages the physical space manifestation of scale separation between the extended regions of uniform quantity and narrow regions of large gradient. The model is informed specifically by analysis of the mean momentum equation and passive scalar transport equation.

Analysis of the mean momentum equation and mean passive scalar transport equation reveals the existence of a self-similar hierarchy of layers, on which the mean equation can be continuously rescaled into a single parameter-free form with all terms retaining leading-order significance [3, 4]. The width W^+ of each layer of the hierarchy, which is the characteristic length scale for the rescaling, is the average size of the turbulent motions responsible for the net flux towards the wall. The analysis shows that $W^+ = (-\frac{d^2U^+}{dy^{+2}})^{-\frac{1}{2}}$ and $W_\theta^+ = (-\frac{d^2\Theta^+}{dy^{+2}})^{-\frac{1}{2}}$ for the momentum and passive scalar fields, respectively. Here U is the mean streamwise velocity, y is the wall-normal direction, Θ is the mean scalar and a superscript $+$ denotes inner scaling.

In the present model a discrete version of the hierarchy layer structure is developed in which a region of uniform quantity and its adjacent region of large gradient are interpreted as one layer in the hierarchy. The model is constructed by first positioning a finite number of fissures (i.e. narrow regions of large gradient) across the boundary layer to create a master step-like profile. The wall-normal placement of the fissures are informed by analysis of the layer width profile W^+. In the inertial region of the boundary layer, this analysis is theoretically grounded while in the subinertial region it is primarily empirical. The master profile of velocity and passive scalar determined from the model are shown in figure 1 for a given Reynolds and Prandtl numbers. The fissures are then randomly displaced in the wall-normal direction following a minimal set of postulates, exchanging momentum and concentration as they move, to create instantaneous profiles of streamwise velocity and passive scalar concentration [5, 6]. This process is repeated to generate ensembles from which statistical moments are computed. The streamwise turbulent heat flux is computed by coupling the passive scalar model with the dynamical model.

RESULTS AND DISCUSSION

Figure 2 compares the statistical moments of the streamwise velocity and passive scalar computed from the model generated ensembles with the corresponding statistics extracted from channel flow DNS data [7, 8]. As evidenced by figure 2, the model is able to robustly predict the statistical moments of the streamwise velocity and passive scalar. Moreover, the streamwise turbulent heat flux is successfully reproduced by relating the motion of the thermal (passive scalar) fissures (TFs) to that of the vortical fissures (VFs), as determined by the model. The discrepancies in the near-wall region are attributable to the model restriction near the boundaries as described by [5]. Specifically, the fissures near the boundaries (wall and channel centerline) are fixed and not allowed to move (unlike other fissures). While allowing the near-boundary fissures to move improves the mean profile, it negatively impacts the higher statistical moments. In the absence of any analytical or physical justification, we did not attempt to tune the model parameters to produce more accurate results near the wall.

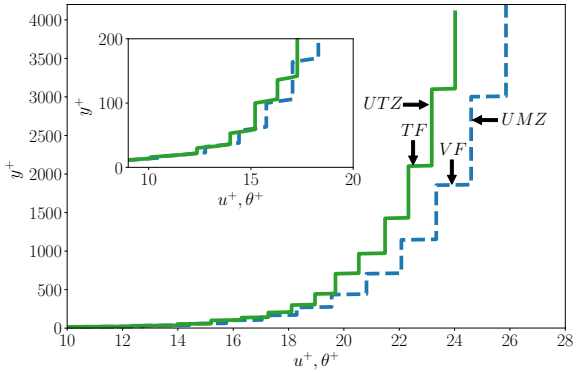

Figure 1: Discrete master temperature (solid lines) and velocity (dashed lines) profiles constructed from the model: uniform momentum zone (UMZ), uniform temperature zone (UTZ), vortical fissure (VF), thermal fissure (TF) at a friction Reynolds number $\delta^+ = 4088$ and Pr=1. Here the passive scalar is temperature. In the model, the VFs and TFs are randomly displaced to generate independent instantaneous profiles.

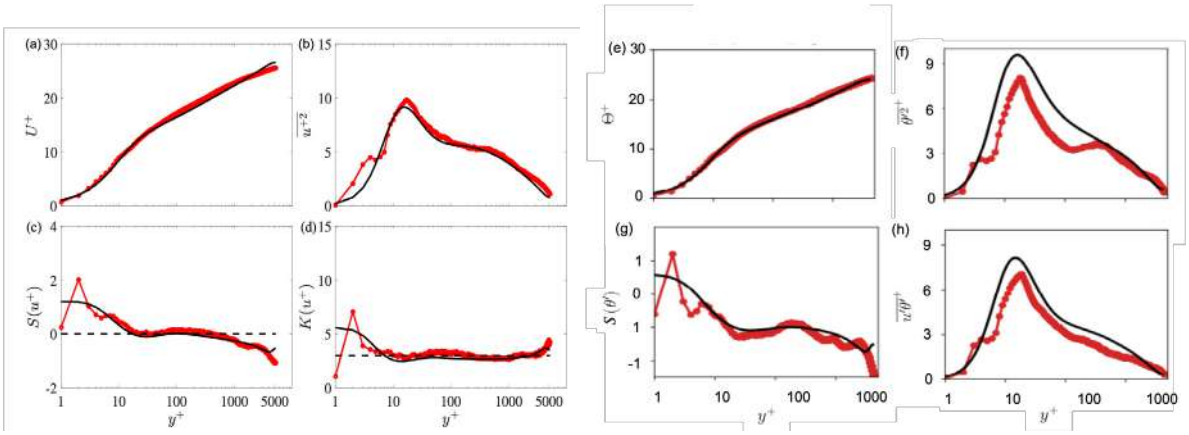

Figure 2: Statistical moments of the streamwise velocity and passive scalar (i.e. temperature) computed from the model. The profiles are (a) mean U^+, (b) variance $\overline{u'^{+2}}$, (c) skewness $S(u'^+)$ and kurtosis $K(u'^+)$ of the streamwise velocity u, (e) mean Θ^+, (f) variance $\overline{\theta'^{+2}}$, (g) skewness $S(\theta'^+)$ and (h) streamwise turbulent heat flux $\overline{u'\theta'}$ of temperature θ. The solid lines in (a – d) and (e – h) are computed from the DNS of [7] and [8], respectively.

CONCLUSIONS

A simple model to predict the statistical moments of the streamwise velocity and passive scalar in a turbulent boundary layer is developed. The formulation of the model begins with the analytical construction of master profiles that represent the most probable arrangement of the regions of large gradient (i.e. fissures). These master profiles are used in conjunction with a minimal set of postulated elements to randomly displace the fissures to generate realizations of the instantaneous streamwise velocity and passive scalar field, from which various statistics are computed. The model results are shown to agree remarkably well compared to statistics computed from DNS.

Summary Turbulent 2D thin shear layers of viscous incompressible fluid, namely boundary layer, mixing layer, free jet and channel flow were studied. To analyse the problem, an asymptotic method of multiple scales that is applied to the Navier-Stokes equations was used. Decomposition of the velocity as a sum of stationary and perturbation terms was introduced, which was applied instead of traditional summation of the mean-time value and fluctuation. A stationary flow inside the turbulent layer was identified using classical hypotheses. The basic flow was an entrainment of fluid from the external/core flow, which supplied the kinetic energy to the zone where turbulence was produced. The solution is applicable at the layer thickness scale and explains the 'turbulent viscosity' concept. The log-scale and Kolmogorov-scale regions do not influence this stationary solution in the main approximation.

MAIN ASSUMPTIONS

A stationary two-dimensional flow of a viscous incompressible fluid past a flat plate/in mixing layer/in jet/in channel of length L is considered; see Fig. 1. The characteristic time, size, and velocity of the incoming flow are equal to L/V_∞, L, V_∞, respectively. The pressure is introduced by the formula $\hat{p} = p_\infty + \rho V_\infty^2 p$, where ρ is the fluid density. All hydrodynamic functions, lengths and time are nondimensionalized via the traditional approach by using the specified flow parameters. The Reynolds number is introduced as $\mathrm{Re} = \rho V_\infty L/\mu$, which has a large value in this asymptotic study. In contrast to the external flow, the shear layer is assumed to be turbulent, considering the fluctuations of pressure and velocities relative to the sought-after basic profile of the streamwise flow velocity $u_0(x, y_1)$. The small dimensionless thickness of the turbulent shear layer has an order of magnitude of δ.

In this study, it is assumed that the amplitude of the perturbations is small in the main body of the shear layer; however, the squares of fluctuations (mean values of which are known as Reynolds stresses) should affect the basic flow. Estimates also must consider that, according to experiments by Schubauer & Klebanoff (1951) and Klebanoff (1955) and theory by Kolmogorov (1941), the main kinetic energy of fluctuations in the turbulent layer is contained in fast inviscid vortices whose characteristic dimensions on all axes are of the same order of magnitude and are comparable to the thickness of the layer δ; see Fig. 1. Such vortices belong to the 'inertial' range.

$$\left.\frac{\partial u'v'}{\partial y'} \sim u_0 \frac{\partial u_0}{\partial x};\quad x' \sim y' \sim z' \sim \delta\right\} \to v' \sim u' \sim w' \sim \delta^{1/2},\quad \delta \to 0$$

Based on the listed facts and assumptions, the asymptotic expansions of the solution in the main turbulent part of the shear layer should be sought at $\delta \to 0$, $\mathrm{Re} \to \infty$ in the form

$$u = u_0(x, y_1) + \delta^{1/2} u_1(x_1, y_1, z_1, t_1, x) + \delta u_2 + \ldots,\quad v = \delta^{1/2} v_1(x_1, y_1, z_1, t_1, x) + \delta v_2 + \ldots,\quad x - \text{slow variable}$$
$$w = \delta^{1/2} w_1(x_1, y_1, z_1, t_1, x) + \delta w_2 + \ldots,\ p = \delta^{1/2} p_1(x_1, y_1, z_1, t_1, x) + \delta p_2 + \ldots,\quad x_1 = \frac{x}{\delta}, y_1 = \frac{y}{\delta}, z_1 = \frac{z}{\delta}, t_1 = \frac{t}{\delta} - \text{fast variables} \qquad (1)$$

TECHNIQUES AND RESULTS

The analysis of the first and second approximations in (1) for the boundary layer/mixing layer [1]/free jet [2]/channel flow[3] is similar. However, unlike any laminar or averaged equations of motion for the main streamwise and vertical velocities in the shear layers, the main system in this analysis is the system of linear inviscid equations for perturbations of the vertical velocity v_1, pressure p_1 and main streamwise velocity u_0.

$$\nabla^2 p_1 + 2\frac{\partial u_0}{\partial y_1} \cdot \frac{\partial v_1}{\partial x_1} = 0,\quad \frac{\partial v_1}{\partial t_1} + u_0 \frac{\partial v_1}{\partial x_1} + \frac{\partial p_1}{\partial y_1} = 0 + O\left(\frac{1}{\mathrm{Re} \cdot \delta}\right) \qquad (2)$$

Fast perturbations dominate the stationary terms; however, a system of two equations (2) is not closed, thereby suggesting a solvability condition in next approximation. Furthermore, due to the linearity of the formulated problem, the solution for first-order perturbations, in the absence of a specified transverse flow, can be decomposed as a sum of slow two-dimensional stationary terms and fast three-dimensional non-stationary fluctuations:

laminar sublayer (on the Kolmogorov scale). This paper studies only the specified stationary velocities since it is possible to separate stationary and non-stationary problems in the first and second approximations. Due to linearity, the turbulence production zone and the Kolmogorov dissipation zone do not influence on the stationary solution in the main approximation.

It is possible to formulate the condition for the absence of secular terms (solvability condition) in the vertical velocity v_2, which results in a system of differential viscous equations for $v_{10}(x, y_1)$, $u_0(x, y_1)$, that depends on the vertical coordinate y_1:

$$\frac{1}{\mathrm{Re}\cdot\delta^{3/2}}\cdot v_{10}''' - v_{10}v_{10}'' + (v_{10}')^2 = 0, \qquad \frac{1}{\mathrm{Re}\cdot\delta^{3/2}}\cdot u_0'' - v_{10}\cdot u_0' + v_{10}'\cdot u_0 = 0 \tag{4}$$

System (4) admits the analytical solution for a mixing layer (see the comparison of this theory with the experiment, Fig.2), a 2D jet (Fig.3) and a turbulent boundary layer (Fig.4). The exact solution, which satisfies the impermeability condition on the wall, is the self-induced viscous stationary distributed entrainment of fluid into the turbulent boundary layer from the external flow. The parameter $Z_i = \mathrm{Re}\cdot\delta^{3/2}$ is excluded from equation (4.2) and $u_0(x, y_1)$ does not depend on Re: $v_{10} = -\dfrac{(-V_e(x))}{\mathrm{Re}\cdot\delta^{3/2}}\cdot(1-\exp(-Y))$, $u_0 = e^{-Y}\int_0^Y \exp(\eta - e^{-\eta})d\eta$, $Y = (-V_e)y_1$ $V_e(x) < 0$.

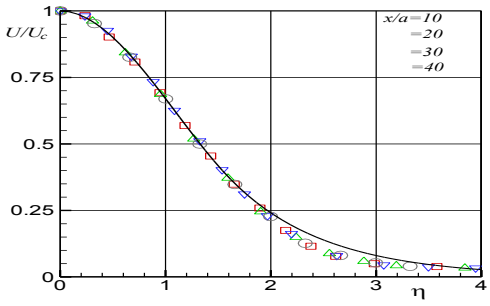

Figure 3. Jet: Miller & Comings 1957

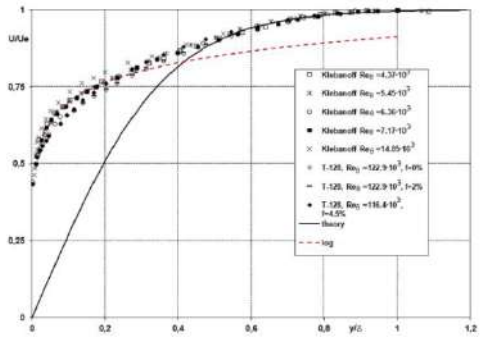

Figure 4. TBL: Klebanoff & Diehl 1952

CONCLUSIONS

Shear turbulent layers have a property of stationary entrainment, which defines the streamwise flow. The stationary flow (called secondary) is viscous throughout the entire thickness of the turbulent layer, which suggests a large-scale viscosity and substantiates the well-known physical concept of "turbulent viscosity". The self-induced entrainment of fluid into thin turbulent layer can be regarded as the mechanism of kinetic energy supply to the zone of production of turbulence, regardless of the type of production. The identified stationary solution does not depend on the turbulence production scale and the Kolmogorov scale in the main approximation.

TRANSIENT MODEL FOR EROSION MIXING PROCESS OF STRATIFIED LAYER CAUSED BY TURBULENT IMPINGING JET

Wooyoung Lee, Simon Song *[1], and Youngsoo Na, Jongtae Kim [2]
Department of Mechanical Convergence Engineering, Hanyang University, Seoul, Korea
Korea Atomic Energy Research Institute, Daejeon, Korea.

Summary The distribution and mixing of hydrogen gas in a containment building of a nuclear power plant in a severe accident can be characterized as the erosion mixing process of a stratified layer impinged by a turbulent jet. To predict the risk of a hydrogen explosion due to the erosion mixing, it is necessary to develop a transient model on the transient erosion mixing process over a long period of time. We experimentally and theoretically investigated the long-term erosion mixing process by the interaction between a stratified layer and a turbulent impinging jet. As a result, we proposed a transient model for predicting the interface displacement of the stratified layer and the mean axial velocity and half width of the jet. We found that the prediction results are in good agreement with experimental data when considering the density and pressure gradient of the stratified layer and the jet.

INTRODUCTION

An erosion mixing phenomenon of a stratified hydrogen layer by a vertically impinging jet is known to affect a safety of a containment building of a nuclear power plant under a severe accident. The hydrogen gas mixed with an air or a steam may cause combustion and explosion due to various ignition sources. To predict and prevent such a disaster, it is necessary to quantitatively analyze a detailed erosion mixing process over a long period of time because the mixing process determines thermo-hydraulic behaviours of the stratified hydrogen layer such as migration, mixing, heat transfer, and mass transfer. The transient behaviour of the interface of the stratified layer and the ambient gas is one of the important parameters for the quantitative evaluation of erosion mixing process. Nevertheless, most previous models on the erosion mixing have been developed to be valid for their initial state. We theoretically and experimentally investigated the erosion mixing process by interaction between a stratified layer and a turbulent impinging jet at a transient state. As a result, a theoretical model was developed for an interface displacement. The model prediction was validated against our own data in addition to other experimental data[1].

THEORETICAL BACKGROUND AND EXPERIMENTAL APPARATUS

We developed the theoretical model by applying the mass conservation law to the entrainment of the stratified layer into the impinging jet over a long elapsed time. According to the model, the interface displacement is affected by the elapsed time, ratio of the jet width to vessel size, and initial interfacial Froude number.

To validate the model, we performed experiments using a test facility for spray, aerosol, recombiner, and combustion (SPARC) built in Korea Atomic Energy Research Institute. The SPARC facility consisted of gas sampling pipes, a jet tube, and a helium injection tube contained in a cylindrical pressure vessel of 3.400 m in diameter, 9.532 m in height and 80 m^3 in volume. The erosion mixing was implemented by a vertical turbulent air jet onto a stratified helium layer formed at the upper part of the vessel. The helium concentration distribution in the vessel was measured at 13 vertical points along the vessel centreline by thermal conductivity analysis. The Reynolds number of experiments were 19,300 and 29,400 based on jet tube diameter, jet velocity at the tube exit.

RESULTS AND DISCUSSION

The interface displacement had a non-linear tendency with elapsed time where it increases rapidly at the initial state and then its growth rate decreases as time increases. In order to estimate its validity, the model proposed in this study was applied to the experimental data obtained under different conditions.[2] The prediction of the transient interface displacement by the theoretical model was in excellent agreement with the experimental data, demonstrating that the model would be useful for predicting the transient behaviors of an interface displacement of a stratified layer by an erosion mixing under various conditions as shown in Fig. 1a.
In addition, the mean axial velocity and width of the jet are modelled by considering a non-trivial density and pressure gradient in the stratified layer and jet unlike previous models. As a result, we found the prediction of current transient model are in good agreement with experimental data as shown in Fig. 1b.

Conditions	Transformed Previous Model	Current Model
Elapsed time	O (Transient)	
Density gradient of stratified layer	X	O
Pressure gradient of impinging jet	X	O

Figure 1. Comparison of model prediction and experimental data.

CONCLUSIONS

We studied erosion mixing behaviours of a stratified layer impinged by a turbulent jet over a long period of time to develop a transient model for the erosion mixing. A novel theoretical model has been developed to be valid for a long period of time and its prediction on the interface displacement and the mean axial velocity and width of jet is compared with experimental data obtained in SPARC and other facilities reported in literature. We found that the prediction was in good agreement with the experimental data when considering both density and pressure gradients in the stratified layer.

MODAL ANALYSIS IN CURVILINEAR COORDINATES

Aadhy Parthasarathy[1], Siddhi Suri[1], and Theresa Saxton-Fox *[1]
[1] Department of Aerospace Engineering, University of Illinois at Urbana-Champaign, Illinois, USA

Summary Modal analysis techniques have proven useful in understanding and modeling turbulent phenomena [1]. However, these techniques are more efficient in parallel flows where Fourier transforms can be taken along homogeneous directions. We suggest that quasi-1D methods can be applied to mildly non-canonical flows by using a curvilinear coordinate system. For a given base flow, we identify a curvilinear coordinate system that allows the Fourier-transformed equations of motion to be simplified into a quasi-1D system that can be efficiently analyzed.

When performing reduced-order modeling or stability analysis in parallel flows, significant order reduction is possible using Fourier-transforms along the homogeneous directions [4, 1]. But when one transitions to a non-parallel flow, these order reductions are lost, and one instead must do a global analysis [2], requiring more intensive computation. Particularly for weakly non-parallel flows, the exact solution of modes using 1D analysis techniques may be possible if one changes the coordinate system within which the equations are written. We aim to formulate local stability and resolvent analyses using curvilinear forms of the Navier-Stokes equations by iteratively solving for an appropriate coordinate system given a particular base flow. We seek a coordinate system within which a Fourier transform can be usefully performed.

We define the following transformation between Cartesian coordinates (x^i) and orthogonal curvilinear coordinates (Z^i) such that,

$$Z^i = Z^i(x^1, x^2, x^3), \tag{1}$$
$$x^i = x^i(Z^1, Z^2, Z^3). \tag{2}$$

In the curvilinear coordinate system, we write the Navier-Stokes equations as,

$$\begin{gathered}\frac{\partial U_k}{\partial t} + U^h \frac{\partial U_k}{\partial Z^h} + U_j \Gamma^j_{hk} U^h = -\frac{1}{\rho}\frac{\partial P}{\partial Z^k} + \nu\left[\nabla^2 U_k - 2g^{ij}\Gamma^h_{jk}\frac{\partial U_h}{\partial Z^i} + U_h \frac{\partial}{\partial Z^k}\left(\frac{1}{\sqrt{g}}\frac{\partial}{\partial Z^i}(\sqrt{g}g^{ih})\right)\right], \\ g^{kk}\left(\frac{\partial U_k}{\partial Z^k} - U_h \Gamma^h_{kk}\right) = 0\end{gathered} \tag{3}$$

where U_i and U^i are the covariant and contravariant components of velocity respectively, ρ is fluid density, P is the scalar pressure, ν is fluid kinematic viscosity, g^{ij} is the metric tensor, and Γ^i_{jk} are the Christoffel symbols of the second kind [3]. The metric tensor and Christoffel symbols are additional variables introduced to keep track of the changing length and direction of the basis vectors at every point in a curvilinear coordinate system, whereas the basis remains constant everywhere in Cartesian coordinates.

At this point, a choice of the specific curvilinear coordinate system has not been made. The coordinate transformation should be chosen such that, when the governing equations are cast in a form appropriate to perform stability analysis or resolvent analysis, it will allow taking a Fourier transform along at least one of the non-parallel flow directions. To identify the suitable constraints on such a coordinate system, we decompose the flow as $U_i = \bar{U}_i + u_i$ and expand the curvilinear Navier-Stokes equations in these terms. $\bar{U}_i$ is the base flow for stability analysis or mean flow for resolvent analysis, and u_i is the fluctuation about the base flow. In equation 4, we show the left hand side of the resulting equation in the Z^1 direction for a two-dimensional flow, without including the terms containing only the base flow for the sake of compactness. Terms that contain only the base flow can be directly computed.

$$\begin{aligned}&\frac{\partial u_1}{\partial t} + \left[\bar{U}_1\frac{\partial u_1}{\partial Z^1} + u_1\frac{\partial \bar{U}_1}{\partial Z^1} + u_1\frac{\partial u_1}{\partial Z^1}\right]\sqrt{\frac{g^{11}}{g_{11}}} + \left[\bar{U}_2\frac{\partial u_1}{\partial Z^2} + u_2\frac{\partial \bar{U}_1}{\partial Z^2} + u_2\frac{\partial u_1}{\partial Z^2}\right]\sqrt{\frac{g^{22}}{g_{22}}} \\ &- \left[{u_1}^2 + 2\bar{U}_2 u_1\right]\sqrt{\frac{g^{11}}{g_{11}}}\left(\frac{1}{h_1}\frac{\partial h_1}{\partial Z^1}\right) - \left[{u_2}^2 + 2\bar{U}_2 u_2\right]\sqrt{\frac{g^{22}}{g_{22}}}\left(\frac{1}{h_2}\frac{\partial h_2}{\partial Z^1}\right) \\ &- \left[\bar{U}_1 u_2 + u_1\bar{U}_2 + u_1 u_2\right]\left(\sqrt{\frac{g^{11}}{g_{11}}}\left(-\frac{h_1}{{h_2}^2}\frac{\partial h_1}{\partial Z^2}\right) + \sqrt{\frac{g^{22}}{g_{22}}}\left(\frac{h_1}{h_2}\frac{\partial h_1}{\partial Z^2}\right)\right)\end{aligned} \tag{4}$$

To efficiently represent the fluctuating velocity field using a Fourier transform in the Z^1 direction, $\bar{U}_1$ and $\bar{U}_2$ must not be functions of Z^1. For example, consider the Fourier transform of a term in equation 4,

*Corresponding author. Email: tsaxtonf@illinois.edu

$$\int_{-\infty}^{\infty} \bar{U}_1 \frac{\partial u_1}{\partial Z^1} \cdot e^{-ik_1 Z^1} dZ^1 = \begin{cases} \bar{U}_1(-ik_1)\hat{u}_1, & \text{if } \bar{U}_1 \text{ is constant in } Z^1, \\ \text{does not simplify}, & \text{if } \bar{U}_1 \text{ is a function of } Z^1, \end{cases} \tag{5}$$

where $\hat{u}_1 = \hat{u}_1(k_1, Z^2, Z^2)$ is the Fourier transform of u_1 in the Z^1 direction. When $\bar{U}_1$ is not a function of Z^1, the expression on the left hand side of equation 5 simplifies to an algebraic expression.

To identify the appropriate coordinate system $(Z^1, Z^2) = (T, B)$ in which $\bar{U}_T$ and $\bar{U}_N$ are constant along T, we use an iterative scheme. Given a simple, non-parallel base flow initially defined in (x, y) such that $\bar{U} = [\bar{U}_x \;\; \bar{U}_y]'$ (schematically illustrated in Fig.1), we approximate the appropriate coordinate system (T, N) by defining curves along which $\bar{U}_x$, $\bar{U}_y$ are constant. With the approximate (T, N), we compute the components of our velocity field in the new coordinate directions, $\bar{U}_T, \bar{U}_N$. We iterate between defining the coordinate system (T, N) based on the components of the velocity field $\bar{U}_T, \bar{U}_N$ and defining the components of the velocity field based upon the coordinate system (T, N) until the process converges to a consistent coordinate system.

We will test our algorithm by re-deriving Cartesian and cylindrical coordinate systems for input parallel and axisymmetric base flows. We will report on the coordinate system found, and / or on the constraints that prevent the identification of such coordinate systems. We will additionally look for and report any assumptions that could be used to approximately use such coordinate systems, enabling approximate use of local analysis for non-parallel flows.

EFFECT OF BI-MODAL EXCITATION PHASE ON A SHARP-EDGED IMPINGING JET

Basil Abdelmegied[1], and Ahmed Naguib *[1]
[1] Department of Mechanical Engineering, Michigan State University, East Lansing, USA

Summary In this study, we investigate the effect of bi-modal acoustic forcing on the flow structure of an impinging jet using flow visualization. The forcing scheme utilizes two frequencies: the fundamental instability frequency of the jet and its subharmonic. The focus of the work is to examine whether the phase angle between the two forced modes (the intermodal phase) has a significant effect on the vortical structure of the jet. Results reveal a striking outcome, whereby over a certain phase angle range, the initial development of the shear layer vortical structure is wake-like, leading to a significant growth in the shear layer and a corresponding reduction in the potential core.

INTRODUCTION

While there is a number of investigations utilizing bi-modal, two-frequency, axisymmetric forcing to control non-impinging jets [1-4], there is very little similar work done on the impinging counterpart. The two excitation frequencies employed in studies [2-4] are those of a fundamental instability (either the jet's preferred mode [2], or the initial shear-layer's instability [3-4]) and its subharmonic. [2] demonstrated that bi-modal forcing can lead to a more significant change in the jet flow than pure-harmonic excitation. [2-4] also showed that the phase angle difference between the fundamental and the subharmonic mode can have a substantial influence on the development of the vortical structures. For example, [4] demonstrated maximum enhancement of vortex pairing due to promoting subharmonic resonance [5] by having an optimum phase difference of $\pi/2$ *at the resonance streamwise location*. On the other hand, if the resulting phase difference at resonance is 0, pairing was suppressed. Overall, in comparison to single-frequency forcing, bi-modal forcing provides a larger number of degrees of freedom to affect the flow behaviour. In addition to the forcing level and frequency used in the former case, the latter approach presents opportunities for changing the jet behaviour through the phase difference and the amplitude ratio of the two modes. These opportunities remain largely unexplored for impinging jets. We found only one reference [6], which examined simultaneous excitation of an impinging jet using fundamental and subharmonic frequencies, where the authors employed both the first and the second subharmonic modes, each simultaneously with the fundamental mode. They found the first scenario to lead to enhancement of vortex pairing, and the second to promote amalgamation of three vortices. The authors did not undertake a systematic study of the intermodal phase influence. The present investigation is undertaken to study the effect of bi-modal acoustic forcing on an impinging jet with particular focus on the response of the jet flow structure to different values of the intermodal phase angle. Specifically, the forcing is defined as follows: $p'_a(t) = P_{a,f}\sin(2\pi f_0 t) + P_{a,s}\sin(2\pi f_0 t/2 + \phi)$; where, $p'_a(t)$ is the forcing acoustic pressure, $P_{a,f}$ and $P_{a,s}$ are the acoustic disturbance amplitude of the fundamental and subharmonic modes, respectively, f_0 is the fundamental mode frequency, and ϕ is the intermodal phase difference (where $0° \leq \phi \leq 180°$). In the present work, the overall root mean square of the disturbance $p'_{a,rms}$, the amplitude ratio $P_r = P_{a,s}/P_{a,f}$, and the fundamental frequency f_0 are maintained fixed while, ϕ is varied over its full range.

DESCRIPTION OF THE EXPERIMENTS

An axisymmetric air jet emerging from a sharp-edged opening is used in the present experiment. The jet diameter is $D = 12.7\ mm$ and the average jet exit velocity is $U_j = 5\ m/s$. The corresponding Reynolds number is $Re_D = 4{,}200$. A flat impingement wall is placed at a distance $H = 2D$ downstream of the sharp edge. To characterize the jet flow structure, flow visualization is utilized. This is accomplished by carefully seeding Polyethylene Glycol particles into two narrow slits on top and bottom of the plenum, upstream of the jet exit. Hot-wire measurements are used to check that the flow through the slits does not alter the main jet flow. The particles are illuminated using a laser sheet, and instantaneous images of the flow are captured using a CCD camera. The illuminated region spans the streamwise domain stretching between $0.5D$, downstream of the jet exit, to the impingement wall (as illustrated in the top left corner of Figure 1).

The fundamental forcing frequency is determined using spectra of the streamwise velocity close to the exit of the *unforced* jet, obtained from single-hot-wire measurements at the centre of the shear layer. The spectra exhibit a peak at a Strouhal number $St_D = f_0 D/U_j = 2.54$, which is utilized for the fundamental mode forcing. The amplitude ratio P_r is set to unity, and the overall sound pressure level is kept at $120\ dB$ (which corresponds to an acoustic velocity of approximately 1% of U_j). The intermodal phase ϕ is varied between 0° and 180° in steps of 15°. The characteristics of the forcing signal are verified using microphone measurements at $x/D = 0.75$.

RESULTS AND DISCUSSION

Figures 1a and 1b depict phase-averaged flow visualization images obtained at six phases of the subharmonic forcing cycle $\theta = 0°$ to 300° in steps of 60°. Each image is obtained from an average of 200 pictures captured by phase-locking triggering of the camera to the forcing signal, where $\theta = 0°$ corresponds to the start of the subharmonic cycle.

*Corresponding author. E-mail: naguib@egr.msu.edu.

Results for two intermodal phases are shown in Figure 1: $\phi = 0°$ and $\phi = 120°$. Other cases are not considered here due to space limitation. Comparing the two cases, the immediate impression is an apparent larger cross-stream spread of the seed particles towards both the centreline and the outside of the jet when $\phi = 120°$. This observation can be seen more easily by averaging the images over all cycle phases considered, leading to the images displayed in Figures 1c and 1d. The significant lateral spread of the jet when $\phi = 120°$, compared to $\phi = 0°$, is evident. Given that only the near-wall vortical fluid is seeded upstream of the jet exit, it is reasonable to interpret these observations as a significant influence of the bimodal phase on the spread rate of the jet shear layer and the development of the potential core.

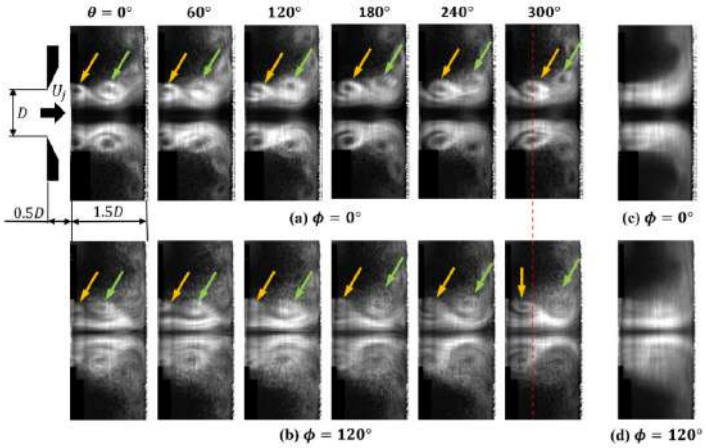

Figure 1. Comparison of the phase-averaged flow visualization images at six subharmonic-cycle phases for (a) $\phi = 0°$; (b) $\phi = 120°$. The corresponding cycle-averaged images are shown in (c) and (d) respectively.

Considering the evolution of the vortical structure in Figure 1, it takes approximately two subharmonic forcing cycles for a vortex to form and reach the impingement wall. In Figure 1, orange arrows are used to identify a single vortex ring as it evolves during the first cycle, and green arrows mark the vortex during the second cycle. Considering $\phi = 0°$ (Figure 1a), the organization, systematic evolution and coherence of the vortex ring due to forcing is evident. The vortex develops in the usual fashion for a shear layer, where the vortex consistently convects downstream from one image to the next as it grows in size. In comparison, for $\phi = 120°$, a notably different behaviour emerges, whereby during the first half of the first cycle ($\theta < 180°$), the vortex continues to roll-up (in the upper left corner of the flow) without translating significantly downstream. This behaviour is akin to vortex roll-up in the *wake* of a bluff body, in contrast to that expected in a jet's shear layer. Eventually, the vortex sheds and convects downstream. The surprising and fundamentally different initial vortex evolution is associated with other differences in the vortex characteristics. These include an apparently different vortex core size, vortex motion history (for example at $\theta = 300°$ in the first cycle, the vortex ring's streamwise position for $\phi = 120°$ lags behind that for $\phi = 0°$ by approximately $0.25D$; as may be visualized with the aid of the red broken line Figure 1), and larger vortex size at impingement (last image in the second forcing cycle).

CONCLUSIONS

Bi-modal excitation of a sharp-edged axisymmetric impinging jet at $Re_D = 4{,}200$ and jet-to-impingement-wall spacing of $2D$ revealed an intriguing effect of the intermodal phase angle on the jet vortical structure evolution. Specifically, the phase could alter the fundamental nature of the initial vortex evolution from being shear-layer to being wake like. This change is associated with differences in subsequent evolution and characteristics of the vortices, and the development of the jet shear-layer and potential core. Hot-wire and particle image velocimetery measurements will be carried out in future work to quantitatively characterize the observed change in the impinging jet behaviour.

Summary The present paper reports on the investigation of turbulent mixing for a model gas-turbine swirl burner (based on a design by TURBOMECA) under non-reacting flow conditions. Two different regimes of the model fuel (air with acetone) injection are compared. Namely, injection between vanes of the radial swirler to organize lean well-premixed combustion in a primary zone and supply of the model fuel from the swirler's ceneterbody as a central jet to organize a pilot flame. Stereoscopic PIV method, combined with tracer PLIF, is used to measure the velocity and concentration fields. A quantitative analysis of the impact of coherent flow structures on turbulent transport and mixing of the fuel is performed on the basis of POD of the PIV data and phase-averaging of the PLIF snapshots. Such data are important for development of efficient methods to supress unsteady combustion modes.

INTRODUCTION

Flame stabilization in combustion chambers of gas turbines is usually implemented by organizing flow swirl. A swirler in front of the combustion chamber produces rotating flow with a central recirculation zone, which ensures efficient flame ignition and combustion stability for a wide range of fuel and oxidizer flowrates, as well as a compact size of the combustion zone (Gupta et al. 1984, Weber and Dugue 1992). Meanwhile, turbulent flows with high swirl are usually featured by unsteady intensive velocity and pressure fluctuations, produced by large-scale vortex structures, including precessing vortex core. Since detailed measurements in full-scale combustion chambers of gas turbines are difficult and very expensive, the research on the fundamental aspects of the implementation of new technologies is carried out for laboratory-scale burners that adequately simulate important features of the operation of real devices with the possibility for detailed measurements of the physical and chemical processes. Since the use of contact measurement methods can lead to local perturbations of the flow and also significantly affect the conditions for the entire flame stabilization (Stricker 2002, Meier et al. 2004), optical methods have become widespread for studies of combustion processes.

In recent years, a number of studies have been published on the measurement of the instantaneous velocity fields in combustion chambers of gas turbines using particle image velocimetry (PIV), in order to study the effect of unsteady flow dynamics on flame stability and thermo-acoustic pulsations. To study the interaction of the velocity field with the flame front, the PIV method is applied simultaneously with planar laser-induced fluorescence (PLIF) (Stohr et al. 2009, Boxx et al. 2010). Such combination allows one to obtain the spatial distribution of velocity in a selected flow cross-section with a slice of the reaction zone. The analysis is often focused on the characteristics of coherent flow structures, which produce intensive velocity and pressure fluctuations, and on their relation with unsteady combustion modes. Proper orthogonal decomposition (POD) is used to extract the coherent structures and obtain phase-averaged shape of the reaction zone (e.g., Dulin et al. 2019). This information is important for development of efficient methods to control/alter unsteady mixing and combustion in swirl burners (Terhaar et al. 2014). However, non-intrusive experiments and quantitative analysis of the impact of the large-scale coherent structures on the fuel transport and mixing in combustion chambers are still scarce in the literature. The present study reports on such measurements for a model gas-turbine combustor by using a combined application of stereoscopic PIV and acetone PLIF.

EXPERIMENTAL SETUP

The experiments were performed for an optically accessible model gas-turbine swirl combustor at atmospheric pressure. The combustor consisted of a cylindrical plenum chamber, generic swirl nozzle (see Janus et al. 2007) and open combustion chamber with square observation windows (100x100 mm with the thickness of 4 mm) made of fused silica. 3D sketch of the swirl combustor and equipment used for the PIV/PLIF measurements are shown in Figure 1(a). The inset shows the design of the nozzle, which included a radial vane swirler and central pilot jet. The outlet diameter of the swirler nozzle was 37 mm. The swirl rate was approximately 0.7. The Reynolds number was Re = 30 000.

The model fuel could be supplied through the central jet or through holes between the vanes of the swirler. It was seeded by acetone vapour by bubbling the air flow through a heated tank with liquid acetone. The main air flow, supplied through the radial swirler, was seeded by TiO2 particles (with an average size of 0.5 um) by using a mechanical mixer. The flowrates were precisely controlled by mass flow meters (Bronkhorst High-Tech). Ratios of the volumetric flow rates of the main air and model fuel were chosen to simulate equivalence ratio 0.7 for the premixed mode. In the case of the pilot jet, the entire flow of the model fuel was injected through the central jet.

The PLIF system included a tunable pulsed dye laser (Sirah Precision Scan), pumped by a pulsed Nd:YAG laser (QuantaRay), was used to excite acetone fluorescence at approximately 283 nm (average energy of the pulses was 12 mJ).

*Corresponding author. E-mail: vmd@itp.nsc.ru.

Selection of the wavelength was conditioned by OH fluorescence experiments made at the same experimental setup. The laser beam was converted to a laser sheet by using a collimating optics and illuminated central plane of the flow. Intensity of the acetone fluorescence was captured by sCMOS camera (LaVision, 5 Mpix, 16 bit), connected to a UV-sensitive image intensifier (LaVision IRO). The image intensifier was equipped with a UV-lens and set of optical filters (with approximately 90% transmittance in the range 415–455 nm). The exposure time for each PLIF image was 200 ns. A set of images post-processing algorithms was used for subtraction of dark current and background intensity, correction for the laser-sheet intensity and spatial sensitivity of the sensor. To account for the non-uniformity of the laser fluence across the laser sheet and shot-to-shot variation of the pulses' energy, part (about 5%) of the laser beam was reflected by a fused silica plate into a calibration cuvette with a Rhodamine 6G solution. The spatial distribution of the fluorescence inside the cuvette was recorded by a CCD camera (ImperX Bobcat IGV-B4820, 16 Mpix, 12 bit).

The used stereoscopic PIV system included a pair of CCD cameras (ImperX Bobcat IGV-B2020, 4 Mpix, 8 bit) and double-head pulsed Nd:YAG laser (Quantel EverGreen 200, 6 ns pulses with 200 mJ at 532 nm). The cameras were equipped with lenses (Sigma 105 mm DG MACRO) and narrow-band optical filters, which transmitted light scattered by the tracer particles at 532 nm (± 5 nm). The laser beam was converted into a laser sheet by using a system of cylindrical and spherical lenses. Time separation between two PIV laser pulses was 20 μs. The PLIF images were captured almost in the middle of this interval. An in-house "ActualFlow" software was used to acquire and process the data.

SAMPLE RESULTS

Figure 1(b) shows the example of the instantaneous velocity and concentration snapshots. Large-scale vortex structures are highlighted by arrows. For the pilot jet mode, the flow mixing takes place in a highly unsteady manner with strong deflection of the central jet, since it flows against the central reverse flow. *The full paper will report on the Reynolds stresses and Reynolds fluxes distributions, their comparison with mean velocity and concentration gradients. The contribution of the coherent flow structures to the Reynolds stress and fluxes will be evaluated on the basis of the proper orthogonal decomposition.*

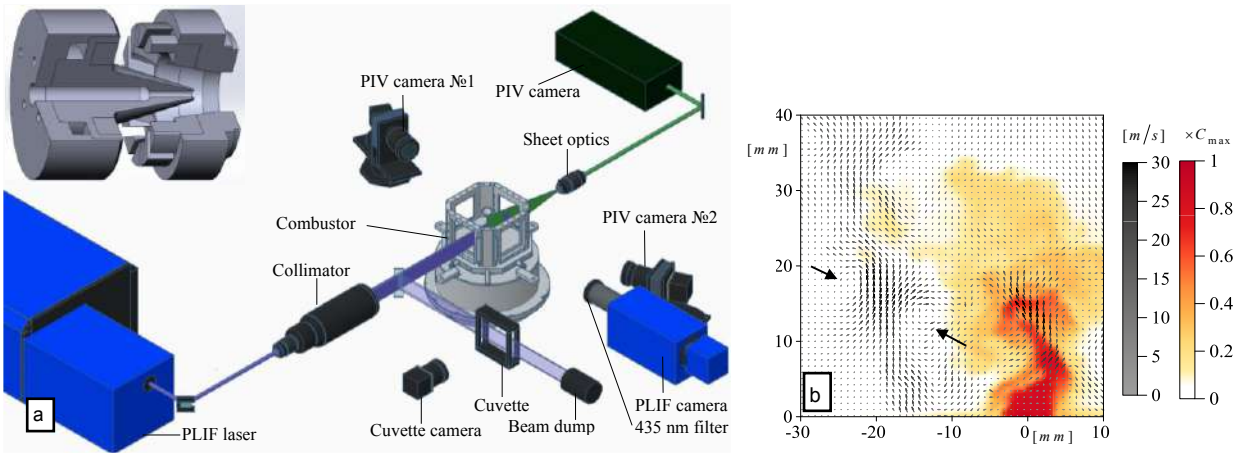

Figure 1. (a) Schematics of the PIV/PLIF setup and geometry of the swirler (inset). (b) Instantaneous velocity and (normalized) concentration fields for a piloted operation regime Large-scale vortex structure are indicated by arrows

Summary Spectral Proper Orthogonal Decomposition (SPOD) is a popular method of modal decomposition of flows due to its relationship with resolvent analysis, as a linear system forced with white noise should have SPOD modes identical to resolvent modes. SPOD may require long data sets due to the application of the Welch method, and a study of its convergence properties is lacking. Here, a linearized Ginzburg-Landau equation model with parameters set to mimic the dynamics of turbulent jets is considered. By computing SPOD modes of the white-noise forced equation, and comparing the result to the corresponding resolvent modes, convergence is studied. The error is shown to be related to the duration of blocks in the Welch method normalized by a convective time. Based on this finding, a method based on the convection velocity is proposed to further improve SPOD modes convergence. The proposed approach provides an order of magnitude improvement in convergence of the SPOD modes when compared to the classical method.

INTRODUCTION

Spectral Proper Orthogonal Decomposition (SPOD) method is a modal analysis, a Fourier space derivation of the homonym POD method, commonly used to identify coherent structures in data [1] as it provides an optimal orthonormal basis to represent coherent structures in space and time which contain most of the total data variance in the frequency domain, the method can be used to create a data-driven basis for the construction of reduced-order models from data. When applied to turbulent flows, the SPOD modes, and the associated eigenvalues, are related to the most energetic turbulent structures at each frequency for a chosen inner product norm.

The algorithm used to compute SPOD modes relies on the Welch method for spectral estimation. Therefore, the accuracy of computed gains λ and modes ψ is dependent on the appropriate choice of sampling parameters, number of flow snapshots/realizations N_t, time step between snapshots Δt, and estimations parameters, number of blocks N_b, snapshots per blocks N_{FFT}, overlapping between consecutive blocks O_{FFT} and windowing function. For a data set with given N_t and Δt (as in a given data set of experimental or numerical data), increasing N_b decreases N_{FFT} and *vice-versa*. Larger values of N_b penalizes frequency resolution and increases spectral leakage, whereas a larger value of N_{FFT} penalizes statistical convergence by reducing the number of averaging blocks. The proper compromise between these two types of error is often problem-dependent [2]. It is the purpose of this work to examine SPOD convergence in a model system, representative of fluid flows, and understand how SPOD errors scale as a function of sampling and estimation parameters.

METHODS

A model using the one dimensional linearized Ginzburg-Landau equation, $\frac{\partial q}{\partial t} = \left(-U\frac{\partial}{\partial x} + \mu(x) + \gamma\frac{\partial^2}{\partial x^2}\right)q + f$, where q and f are output response and input forcing respectively, is considered. When the system is forced with a spatially white forcing on a given frequency ω, the response SPOD modes, $\psi(x,\omega)$, are identical to the resolvent-analysis response modes, $\hat{u}(x,\omega)$ [2, 3]. We thus use such response mode, which is deterministic in nature, to quantify the SPOD estimation error of a the Ginzburg-Landau equation forced with a spatiotemporal-white forcing.

The parameters $\mu(x) = A(1 - x/10)$ and $\gamma = (1 - i)/10$ were set to mimic the system dynamics of jets [3]. Three distinct cases were investigated: $U = 10$ with $A = 0.6$, $U = 12$ with $A = 1$ and $U = 14$ with $A = 1.25$. Solutions were obtained using a Crank-Nicolson scheme for time marching, spatial discretization obtained using a grid spacing of $\Delta x = 0.1$ and a second-order non-centered finite difference scheme for $x \in [0, 30]$, having in total of $N_x = 300$ points. Because of the uniform grid, the inner-product matrix W is set to $I\Delta x$, where I is the identity matrix. Solutions were obtained for a time range of 500 time units and integration obtained using a time step of $\Delta t = 0.01$. A total of $N_t = 50000$ snapshots per case were generated. The N_{FFT} value is varied from 100 to 5000 in steps of 100, with $O_{FFT} = 75\%$ and number of blocks N_b set to comprise all N_t snapshots. This configuration ensures that all computations reach exactly the frequency $\omega = 2\pi$ rad/s in which SPOD and resolvent modes are compared. To reduce spectral leakage, an infinitely continuous windowing function [4] is applied on each block. The forcing is applied by setting the value at each grid point with a random complex number with uniformly distributed phase and amplitude at every timestep. To ensure that fluctuations are adequately resolved in frequency, we apply to the forcing signal a finite impulse response (FIR) low-pass filter of 30th order in time, with cut-off at 60% of the Nyquist frequency. The error ε between $\psi(x,\omega)$ and $\hat{u}(x,\omega)$ is calculated by $\varepsilon(\omega) = 1 - \frac{|\langle\psi,\hat{u}\rangle|}{||\psi||\,||\hat{u}||}$ with the operators $\langle .,. \rangle$ and $||.||$ being respectively the euclidean inner product and norm.

MINI SYMPOSIA

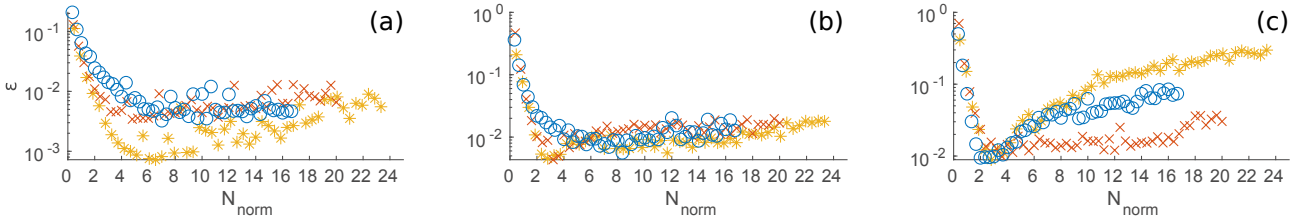

Figure 1: SPOD modes estimation error ε, at frequency $\omega = 2\pi$, plotted against the normalized window length $N_{norm} = N_{FFT}\Delta t/(x_{max}/U)$, with $x_{max} = 30$. The quantity x_{max}/U is the time taken to cross the entire domain based on the convection velocity. Legend: ($\circ$) $U = 10$, $A = 0.6$; ($\times$) $U = 12$, $A = 1$; ($*$) $U = 14$, $A = 1.25$ (a) Mode 1; (b) Mode 2; (c) Mode 3.

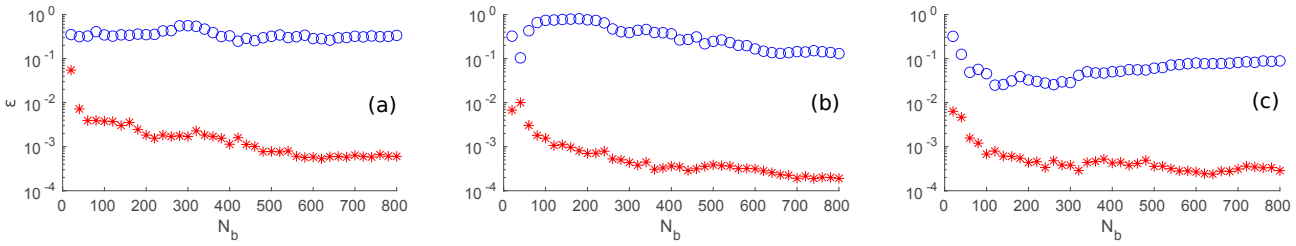

Figure 2: Estimation error ε of SPOD mode 1, at frequency $\omega = 2\pi$, plotted against number of blocks N_b using $N_{FFT} = 100$. Legend: ($\circ$) Non-shifted SPOD; ($*$) Shifted SPOD (a) $U = 10$, $A = 0.6$; (b) $U = 12$, $A = 1$; (c) $U = 14$, $A = 1.25$.

We anticipate that the error is related to the convection velocity U, which leads to a phase lag between lower and higher x with an apparent loss of coherence when the Welch method is applied with low N_{FFT} [5]. A proposed method to further reduce the total estimation error of the SPOD modes is to apply a temporal shift to the data as a function of the parameter U and position x. Considering a domain beginning at $x = 0$ and a matrix Q of realizations, with N_x rows and N_t columns, for each row i the columns are circularly shifted by $s_i = -\lfloor x_i/(U\ \Delta t)\rfloor$ positions. This maximises correlations and coherences between pairs of points, by application of the expected convection time as a delay to each spatial location. After application of the Welch method the i-th row of the resulting Fourier-transformed $\hat{Q}$ matrix, with N_x rows and N_b columns, is multiplied by $\exp(-j\omega s_i \Delta t)$ to correct the phase shift created by the temporal shift operation.

RESULTS

Using the total number of snapshots available, window size N_{FFT} and number of blocks N_b were varied and the estimation errors computed for the first 3 SPOD modes. The results shown in figure 1 indicate a relation between windows length, normalized by the domain size, and convection velocity U. For these cases, a normalized window size between 1 and 3 is a good compromise to achieve the best convergence across the first 3 SPOD modes. This provides a guideline for the selection of parameters for an accurate SPOD computation in convection-dominated flows.

In figure 2, we show that errors can be considerably reduced using applying a temporal shift, also based on the convection velocity U. Focusing on the window size considered, $N_{FFT} = 100$ (which corresponds to $N_{norm} < 0.5$ for all cases), errors obtained were significantly smaller, showing that convergence can be obtained using a fraction of the snapshots required by the classical method. The time shift method presented here is shown to provide a considerable reduction of the data needed for convergence of SPOD modes, which can be crucial for its application on datasets with short time lengths, as is typically the case in large experiments and simulations.

DISCOVERING LOCALIZED, MULTIDIMENSIONAL, AND MULTISCALE STRUCTURE WITH DATA-DRIVEN WAVELETS

Daniel Floryan[1], Alex Guo[1], and Michael D. Graham [1]
[1] Department of Chemical and Biological Engineering, University of Wisconsin–Madison, Madison, WI 53706 USA

Summary Turbulence consists of localized structures that coexist at multiple scales. We combine the energy optimality principle of proper orthogonal decomposition with the localization and multiscale properties of wavelets to develop a method that can rationally extract the structures of interest. We will present the results of applying this method to a handful of turbulence datasets.

MOTIVATION

Turbulent fluid flows consist of localized concentrations of vortex motion that are coherent in space and time, and coexist at a wide range of scales. A great challenge is to rationally identify and analyze the constituent structures from a flow field. The most popular method to do so is proper orthogonal decomposition (POD), which builds a data-driven orthogonal basis whose elements are optimally ordered by energy content [1]. The application of POD has yielded many structural and dynamical insights into turbulence, but POD basis elements tend not to be localized in space. In fact, in statistically homogeneous directions, POD basis elements are Fourier modes. For certain flows (e.g., turbulent shear flows), spatial localization is a key feature of the constituent structures, one that we would like to capture.

DATA-DRIVEN WAVELET DECOMPOSITION

To address the shortcoming of POD, we recently developed the data-driven wavelet decomposition (DDWD) [2]. DDWD combines POD with wavelet theory. Wavelets build orthogonal bases whose elements are spatially localized and multiscale, two key features of turbulent structures. However, wavelets traditionally are not constructed from data. We built the energy optimality principle of POD into wavelets in order to build orthogonal bases whose elements are spatially localized, multiscale, and derived from data: data-driven wavelets. To represent multidimensional data, a tensor-product generalization of the one-dimensional method can be used [3]. This method has been applied to a number of datasets, including homogeneous isotropic turbulence, wind tunnel data on pipe flow turbulence, and the Kuramoto-Sivashinsky and Swift-Hohenberg models for pattern formation. In particular, when applied to a dataset of homogeneous isotropic turbulence [4, 5], DDWD yields a hierarchy of localized self-similar structures in the inertial subrange, shown in Figure 1 [2].

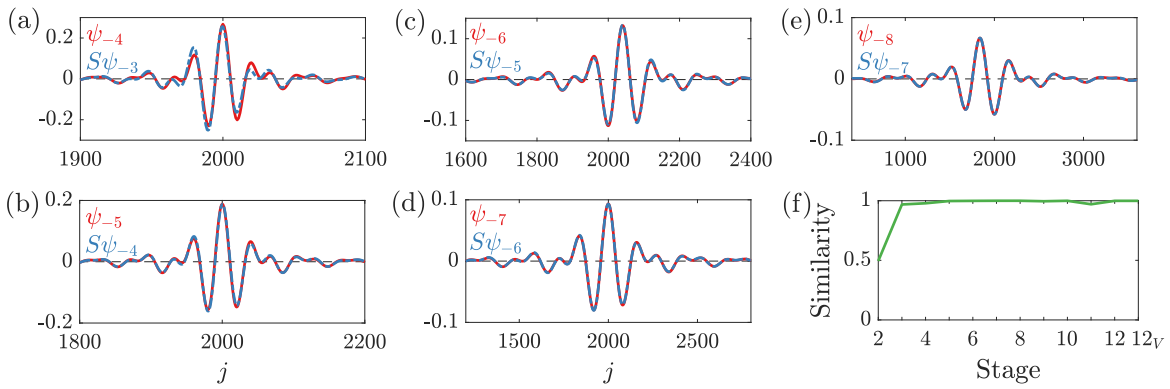

Figure 1: Data-driven wavelets computed from a dataset of homogeneous isotropic turbulence on a 4096^3 grid. Red curves show the computed wavelet at each stage, and blue curves show the wavelet from the previous stage dilated by a factor of 2.

GLOBAL STABILITY PROPERTIES OF THE CLIMATE: MELANCHOLIA STATES, INVARIANT MEASURES, AND PHASE TRANSITIONS

Valerio Lucarini[1,2,**]
[1] Department of Mathematics and Statistics, University of Reading, Reading, UK
[2] Centre for the Mathematics of Planet Earth, University of Reading, Reading, UK

Summary: In the current configuration, our planet is in a multistable regime - two asymptotic states can be realized. The warm state we experience in is in competition with the ice-covered snowball state. The bistability exists because of the positive ice-albedo feedback. Stochastically perturbing the parameter controlling the intensity of the incoming solar radiation the system perform transitions between the warm and the snowball state. The properties of the noise-induced escapes from the corresponding basins of attraction are studied in detail. We find the most probable paths for the transitions and show that the Melancholia states act as gateways. We also find evidence of a first order phase transition associated with the climate realized in the zero-noise limit.

For a wide range of values of the incoming solar radiation, the Earth has at least two competing attracting states, which correspond to different climates. The warm climate is similar to the present one; the snowball climate has global glaciation and conditions that can hardly support life forms. Paleoclimatic evidences indicate that in past our planet went through transitions between these two states. The main physical mechanism responsible for the multistability of the system is the ice-albedo feedback. In a previous work [1], we defined the Melancholia states unstable solutions that sit between the two climates. Such states live in the boundary between the two basins of attraction and are glaciated down to relatively low latitudes. Here, we study the global stability properties of the climate by introducing random perturbations as modulations to the intensity of the solar irradiance. We observe noise-induced transitions between the competing basins of attractions [2].

In the weak noise limit, large deviation laws can be used to express the invariant measure and the statistics of escape times. By empirically constructing the instantons, we prove that the Melancholia states are the gateways for the noise-induced transitions. An example is shown in Fig. (1). We also have that in the region of multistability, in the zero-noise limit, the measure is supported only on one of the competing attractors. For low (high) values of the solar irradiance, the limit measure is the snowball (warm) climate. The changeover between the two regimes corresponds to a first order phase transition in the system. Therefore, zero-noise limit and deterministic dynamics are not equivalent. What we propose seems of general relevance for the study of complex multistable systems. Finally, we propose a new method for constructing Melancholia states from direct numerical simulations, thus bypassing the need to use the edge-tracking algorithm [3].

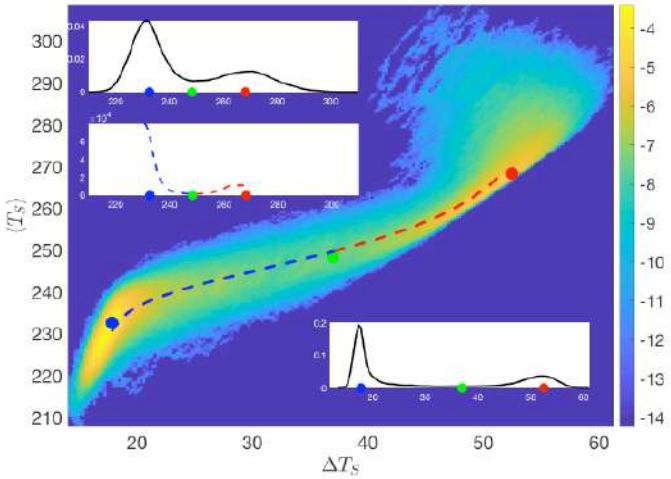

Figure 1. Main graph: invariant measure density in the projected phase space of equator-to-pole temperature difference (ΔT_S) vs globally averaged surface temperature ($\langle T_S \rangle$), with indication of the actual position of the warm attractor (red dot), snowball attractor (blue dot), Melancholia state (green dot) for standard conditions. The instantons are portrayed by the dashed lines.

SAMPLING EXTREME EVENTS AND PRECURSORS IN CLIMATE DYNAMICS USING MACHINE LEARNING AND RARE EVENT ALGORITHMS

Freddy Bouchet *[1], Corentin Herbert[1], Dario Lucente[1], and Francesco Ragone[1]
[1] Laboratoire de Physique, Ens de Lyon, Université Claude Bernard, Université de Lyon, CNRS, F-69342 Lyon, France

Summary Many key problems in climate dynamics require a huge computational effort. For instance, the study of extreme or rare events, the study of precursors of abrupt transitions to different climates, or the probabilistic prediction at the predictability margin, are three examples for which the computation of the relevant statistical quantities is impossible with reasonable computation resources, in comprehensive climate models. I will present several examples of new approaches we have developed, for instance using rare event algorithms and machine learning, for which we have solved these computational bottlenecks using concepts from statistical mechanics and dynamical systems.

The first application is the study of extreme heat waves using IPCC class climate models. For these models we have demonstrated a gain of several hundreds in the numerical cost for simulating extremely rare heat waves. We were able to compute return time plots for extreme heat waves with return times up to 10 000 years. Using the hundreds of simulated heat waves, we have exhibited global teleconnection pattern for extreme heat waves.

The second application is the computation of abrupt climate changes for Jupiter troposphere, and transitions to superrotating states for the Earth atmosphere dynamics.

The third application is a preliminary work on a simple model of El Nino to illustrate prediction at the predictability margin (prediction of interannual variability, beyond the Lyapunov time scale).

COMPUTING EXTREME HEAT WAVES USING RARE EVENT ALGORITHMS IN IPCC CLIMATE MODELS [3]

Studying extreme events and how they evolve in a changing climate is one of the most important current scientific challenges. Starting from complex climate models, a key difficulty is to be able to run long enough simulations to observe those extremely rare events. In physics, chemistry, and biology, rare event algorithms have recently been developed to compute probabilities of events that cannot be observed in direct numerical simulations. In this talk, we present such an algorithm, specifically designed for extreme heat or cold waves, based on statistical physics. This approach gives an improvement of more than two orders of magnitude in the sampling efficiency. We describe the dynamics of events that would not be observed otherwise. We show that European extreme heat waves are related to a global teleconnection pattern involving North America and Asia. This tool opens up a wide range of possible studies to quantitatively assess the impact of climate change. [3]

ABRUPT TRANSITIONS TO SUPERROTATION: WAVE-JET RESONANCE AND HADLEY CELL FEEDBACKS [1]

Strong eastward jets at the equator have been observed in many planetary atmospheres and simulated in numerical models of varying complexity. However, the nature of the transition from a conventional state of the general circulation, with easterlies or weak westerlies in the tropics, to such a superrotating state remains unclear. Is it abrupt or continuous? This question may have far-reaching consequences, as it may provide a mechanism for abrupt climate change in a planetary atmosphere, both through the loss of stability of the conventional circulation and through potential noise-induced transitions in the bistability range. We study two previously suggested feedbacks that may lead to bistability between a conventional and a superrotating state: the Hadley cell feedback and a wave–jet resonance feedback. We delineate the regime of applicability of these two mechanisms in a simple model of zonal acceleration budget at the equator. Then we show using numerical simulations of the axisymmetric primitive equations that the wave–jet resonance feedback indeed leads to robust bistability, while the bistability governed by the Hadley cell feedback, although observed in our numerical simulations, is much more fragile in a multilevel model. [1]

MACHINE LEARNING OF COMMITTOR FUNCTIONS FOR PREDICTING HIGH IMPACT CLIMATE EVENTS [2]

There is a growing interest in the climate community to improve the prediction of high impact climate events, for instance ENSO(El-Nino –Southern Oscillation) or extreme events, using a combination of model and observation data. In this talk we explain that, in a dynamical context, the relevant quantity for predicting a future event is a committor function. We explain the main mathematical properties of this probabilistic concept. We compute and discuss the committor

*Corresponding author. E-mail: freddy.bouchet@ens-lyon.fr

function of the Jin and Timmerman model of El-Nino. Our first conclusion is that one should generically distinguish between states with either intrinsic predictability or intrinsic unpredictability. This predictability concept is markedly different from the deterministic unpredictability arising because of chaotic dynamics and exponential sensibility to initial conditions. The second aim of this talk is to compare the inference of a committor function from data, either through a direct approach or through a machine learning approach using neural networks. We discuss the consequences of this study for future applications to more complex data sets. [2]

A BALANCED STATE CONSISTENT WITH PLANETARY-SCALE MOTION FOR QUASI-GEOSTROPHIC DYNAMICS

Summary The role of planetary-scale zonally-asymmetric thermal forcing on large-scale atmospheric dynamics is crucial for understanding low-frequency phenomena in the atmosphere. Despite its paramount importance, good theoretical foundation for the understanding is still lacking. Here we address this issue by providing a general framework for including planetary-scale thermal forcing in large-scale atmospheric dynamics studies. This is accomplished by identifying two distinct geostrophic motions of horizontal length scale L in terms of the external Rossby deformation length scale L_D: *i*) $L \sim \epsilon^0 L_D$ and *ii*) $L \sim \epsilon^{1/2} L_D$, where ϵ is the Rossby number. In addition, via multi-scale analysis, we show that the large-scale atmospheric dynamics can be described by mutual interaction between the two scales. The analysis results in planetary geostrophic equations with large-scale thermal forcing that provide the basic balanced states for processes such as the growth of synoptic waves. In the long-time limit, the continuous growth and decay of synoptic waves provides the convergence of horizontal heat and vorticity fluxes, which contributes to the energy flux balance in the planetary geostrophic scale with planetary-scale advection and thermal forcing.

INTRODUCTION

The effects of zonally-varying thermodynamic or orographic forcing on large-scale atmospheric motions has been a main topic of investigation in atmospheric dynamics studies. This is because of the forcing's possible relationship to storm-tracks [1], large-scale atmospheric stationary waves [2] and low-frequency variability, such as the North Atlantic Oscillation [3] and Pacific North Atlantic mode [4]. However, despite this importance, adequate theoretical understanding is still lacking.

Zonally-*a*symmetric forcing poses a major challenge in dynamics studies. This is because obtaining a state in balance with an asymmetric thermal forcing is not trivial. For example, a radiative-convective equilibrium state with thermal wind balance does not automatically determine a basic balanced state for zonally-varying thermal forcing – as in the zonally-symmetric case. A possibility still exists for finding a statistically-stationary state with a zonally-asymmetric forcing. However, the connection between initial balanced state and subsequent growth of transient eddies is then lost.

Consider now the planetary scale, where the horizontal length-scale L_D is similar to the radius of Earth. The notion of planetary geostrophic motion has been introduced by [5] to explain the global thermocline structure of the ocean. Interestingly, the leading order PG equations are closed – i.e., it is not necessary to consider the next order to determine the leading order variables. In particular, the heat equation included in the leading order can take a global-scale thermodynamic forcing. Following this, planetary geostrophic motion for the large-scale atmosphere has been introduced by [6], wherein it is named 'geostrophic motion of type 2'. Significantly, in that study it is noted that large-scale flows would need to be forced to maintain the balance in the type 2 geostrophic motion. This suggests that the planetary geostrophic motion could serve in constructing a more physically realistic balanced state consistent with a zonally-asymmetric forcing. Indeed, in this paper we elucidate the relationship between planetary geostrophic (PG) and quasi-geostrophic (QG) motions and address how to deal with QG dynamics in the presence of planetary-scale zonally-asymmetric forcing.

TWO-SCALES IN LARGE-SCALE ATMOSPHERIC DYNAMICS

There are two different geostrophic motions in the large-scale atmosphere, which suggests that the large-scale atmospheric motions are shaped by the mutual interactions of the two scales. The two length-scales L and L_D for quasi-geostrophic and planetary geostrophic motion, respectively, have the ratio L/L_D whose order is $\epsilon^{1/2}$, where $\epsilon = U/(f_0 L_D)$. We will rely on this Rossby number for the planetary scale. The time-scale is chosen to be the advection time-scale. Hence, there are two time-scales $t \equiv L/U$ and $\tau \equiv L_D/U$, satisfying $\tau = \epsilon^{1/2} t$. A multi-scale analysis is applied to primitive equations based on the two scales with planetary-scale variables $\{X, Y, \tau\}$ and quasi-geostrophic scale variables $\{x, y, t\}$.

*Corresponding author. E-mail: woosok.moon@su.se

The leading equations in the multi-scale analysis are:

$$u_L = -\frac{\partial P_L}{\partial Y}, \quad v_L = \frac{\partial P_L}{\partial X}, \quad \rho_L = -\frac{1}{\rho_s}\frac{\partial}{\partial z}\left(\rho_s P_L\right) \tag{1a}$$

$$u_0 = -\frac{\partial P_0}{\partial y}, \quad v_0 = \frac{\partial P_0}{\partial x}, \quad \rho_0 = -\frac{1}{\rho_s}\frac{\partial}{\partial z}\left(\rho_s P_0\right) \tag{1b}$$

$$\frac{\partial w_L}{\partial z} + H w_L = \beta_L v_L \tag{1c}$$

$$\frac{\partial \Theta_L}{\partial \tau} + u_L\frac{\partial \Theta_L}{\partial X} + v_L\frac{\partial \Theta_L}{\partial Y} + w_L\left(\frac{\partial \Theta_L}{\partial z} + S\right) = -\left(\frac{\partial}{\partial t} + u_L\frac{\partial}{\partial x} + v_L\frac{\partial}{\partial y}\right)\Theta_0 - \frac{\partial}{\partial x}\left(u_0\Theta_0\right) - \frac{\partial}{\partial y}\left(v_0\Theta_0\right) - w_1\left(\frac{\partial \Theta_L}{\partial z} + S\right) + Q_L \tag{1d}$$

$$\frac{\partial}{\partial t}\nabla^2 P_0 + (u_L + u_0)\frac{\partial}{\partial x}\nabla^2 P_0 + (v_L + v_0)\frac{\partial}{\partial y}\nabla^2 P_0 + \beta v_0 = \left(\frac{\partial}{\partial z} + H\right) w_1\,, \tag{1e}$$

where the subscript 'L' refers to a planetary scale variable that depends only on X, Y, z and τ and the subscripts '0' and '1' represent quasi-geostrophic variables dependent on x, y, z and t. Note that the QG equations act as a short timescale forcing on the planetary scale. On the other hand, the PG motions provide a basic mean state satisfying the geostrophic and hydrostatic balance to the QG scale.

CONCLUSIONS

Large-scale atmospheric dynamics is controlled by processes of different scales and the interactions between them. Unravelling the interactions – and ultimately understanding the dynamics in full – requires a systematic approach. In this research, we have used an asymptotic approach to identify two separate scales in large-scale atmospheric dynamics and to understand the mutual interactions between them. Multi-scale analysis, in particular, is used in spatial and temporal domains to elucidate the interactions.

In this work, we have argued that the variation and structure of the large-scale atmospheric motion can be viewed in terms of the interaction of two geostrophic motions. One motion, the PG motion, can be interpreted as a balanced field directly forced by large-scale radiative-convective imbalance, as just noted; and, the other motion, aptly descried by the familiar QG vorticity equation, governs the lifecycle of synoptic waves that grow via the energy extracted from the balanced field.

Another significant perspective addressed through the multi-scale analysis is the construction of a statistically-stationary large-scale flow – i.e., PG motion forced by both the large-scale radiative imbalance and the QG eddies. Averaging the QG variables in time-domain shows the contribution of the QG motion to the slow time-evolution of the PG motion. The time-averaged horizontal heat flux convergence and vertically-integrated relative vorticity flux convergence act as forcing in the planetary heat equation. Then, the PG motion is balanced by the radiative imbalance and the heat and vorticity flux convergences.

THE ROLE OF WAVE BREAKING AND AIR-BUBBLES IN GLOBAL GAS TRANSFER

Luc Deike *[1,2]
[1] Department of Mechanical and Aerospace Engineering, Princeton University, Princeton, USA
[2] Princeton University, Mechanical and Aerospace engineering, Princeton, USA

Summary The transfer of gases at the ocean-atmosphere interface impacts weather and climate from local to global scales, with carbon dioxide (CO2) and oxygen key to marine ecosystems, and dimethylsulfide (DMS) affecting aerosols and atmospheric processes. Bubble mediated gas transfer by with breaking waves is a dominant term at high wind speed, but has remained poorly constrained, because of the wide range of scales involved, from wave statistics, to bubble dynamics. We present a multi-scale model that combines a statistical description of wave-breaking with a mechanistic model of air bubble entrainment by breaking coupled with a chemical model. This framework is validated against field measurements, and collapses all available CO2 and DMS gas transfer velocity data. We test implications of such sea-state dependent gas transfer model at regional and global scales for ocean and climate modeling.

INTRODUCTION

Physical processes at the ocean-atmosphere interface have a large effect on climate and weather by controlling the transfer of momentum and mass. Without wave breaking, transport between the ocean and the atmosphere is through slow conduction and molecular diffusion, while wave breaking is a transitional process from laminar to turbulent flow. When waves are breaking, the surface experiences dramatic changes, with sea spray ejection in the atmosphere and air entrainment into the ocean water. The complex dynamics and statistics of wave breaking in a particular ocean location depends mainly on the local wave state not the wind velocity, while current parameterizations for ocean-atmosphere interactions are based almost exclusively on the wind speed.

Ocean uptake accounts for approximatively 30% of the CO_2 released into the atmosphere. The gas transfer at the ocean-atmosphere interface is calculated from the gas concentrations in the air and water, expressed as a function of the gas solubility, α, and partial pressure in the water, p_w and in the air, p_a [1],

$$F = k_w \alpha (p_w - p_a), \tag{1}$$

where k_w is the gas transfer velocity which depends on the physicochemical properties (solubility and diffusivity D) of the gas and the atmospheric and oceanic conditions. State of the art ocean-atmosphere parameterizations for the transfer velocity, used in ocean and climate models [2], include a Schmidt number scaling (typically, $k_w \propto Sc^{-1/2}$, $Sc = \nu/D$, where ν is the kinematic viscosity) but depend solely on wind speed to account for turbulent and wave breaking induced transfers. Recent open ocean gas transfer velocity measurements of CO_2 and dimethyl sulfide (DMS) display very large scatter, when analyzed as a function of wind speed [2, 3, 4], exposing the failure of wind-speed parameterization at intermediate to high wind speeds that is associated with bubble-mediated gas transfer. Separating the contribution to the total flux into the bubble gas transfer and the diffusive transfer at an unbroken surface, bubble-mediated gas transfer had been introduced through the whitecap coverage [5], but was ultimately described by a function of the wind speed.

A SEA-STATE DEPENDENT GAS TRANSFER MODEL

We propose a general theoretical framework going consistently from the bubble scale to the final gas transfer velocity, elucidating its dependence on wind, wave parameters and physico-chemical parameters. Our approach accounts for the complex nature of wave breaking and air entrainment, a two-phase turbulent process, and the very large range of scales involved in the process, from wave statistics scales of order of km, O(1km), to wave breaking dynamics, O(1-10m), air entrainment, bubble generation and dissolution O(cm to μm), which is sketched on figure 1. We combine high fidelity direct numerical simulations, and laboratory measurement described in Deike et al 2016 [6], combined with the measured wave and wave breaking statistics top obtain a formulation for the volume flux of air entrained by breaking waves in the ocean, described in Deike et al 2017 [7]. The mass (gas) flux is then obtained by coupling the air flux formulation to a chemical gas transfer model [5], as presented in Deike and Melville 2018 [2], leading to a formulation for the bubble-mediated gas transfer due to breaking waves, taking into account processes at all scales. This theory is for the transfer of any gas and can be implemented in coupled wave-ocean-atmosphere and climate models, which should significantly reduce the uncertainties at moderate to high wind speeds.

The gas transfer velocity is first decomposed into the bubble and non-bubble components,

$$k_w = k_{nb} + k_b, \tag{2}$$

where the non-breaking gas transfer component, due to molecular diffusion enhanced by turbulence is given by $k_{nb} = A_{NB} u_* Sc^{-1/2}$ where $Sc = \nu/D$ is the Schmidt number, and A_{NB} a non-dimensional coefficient obtained from empirical

*Corresponding author. E-mail: ldeike@princeton.edu.

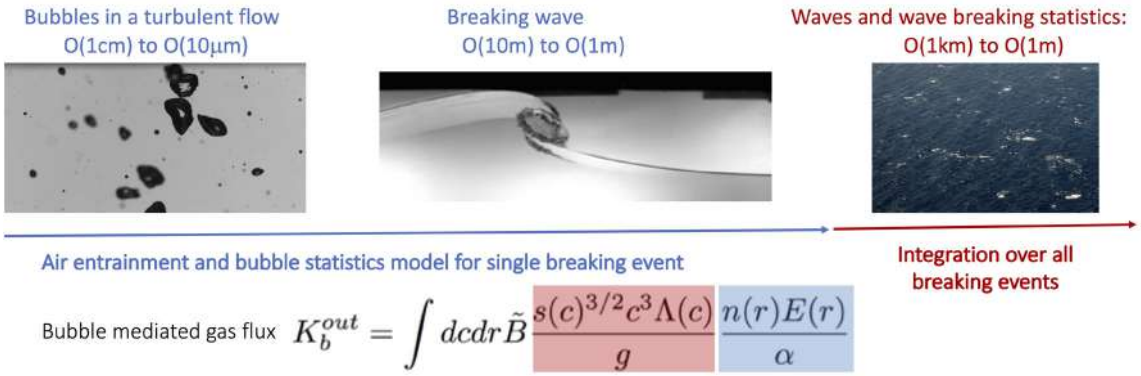

Figure 1: Sketch of the multi-scale modeling approach. The spectral model for the bubble mediated gas transfer depends on the size distribution of bubbles entrained by a breaking waves, determined from experiments and simulations. The gas transfer associated with these bubbles is estimated from a chemical diffusion model which accounts for the gas diffusivity, solubility and the bubble residence time. The gas transfer is then integrated over all the breaking wave statistics, itself related to the wave spectrum statistics and therefore the wind forcing conditions.

data on gas transfer at an unbroken interface [8]. The bubble mediated gas transfer k_b is given by a spectral formulation, integrating over the whole wave spectrum and the whole bubble size distribution [2],

$$k_b = \int dcdr\tilde{B}\frac{s(c)^{3/2}c^3\Lambda(c)}{g}\frac{n(r)E(r)}{\alpha}. \tag{3}$$

where $\Lambda(c)$ is the length of breaking crest distribution describing the breaking statistics as a function of wave speed c, $s(c)$ represents the slope spectrum, describing the saturation of the wave field and strength of air entrainment, g is gravity, $n(r)$ is the bubble size distribution (with r the bubble radius) under a breaking wave, α the gas solubility and $E(r)$ is the scale dependent efficiency transfer coefficient which depends on the bubble size, the gas solubility and diffusivity as well as the residence time of the bubble in the water. This model is validated against field measurements of the gas transfer velocity for CO_2 and DMS [4, 3] and very good agreement is observed [2].

We propose a simple parameterization for the cases of CO_2 and DMS, derived from the full equation, as a function of wind friction velocity u_* and wave height H_s, which capture the main wave effect, and solubility and diffusivity, that collapses all available data [2]. Such simple formulation can then be used to estimate globally the role of bubble mediated gas transfer, and evaluate the possible consequences on global modeling of biogeochemical cycle.

We use a global wave model, forced by realistic wind conditions to evaluate the global bubble contribution to air-sea gas exchange and identify the regions and seasons where such formulation could lead to improved accuracy when comparing to field measurements of gas transfer [9]. Finally, recent progress in wave modeling are now permitting to directly compute the breaking statistics [10], which will permit to investigate the role of the full wave complexity at high temporal and spatial resolution, capturing the wave field associated with storms with a high level of fidelity, and opening a pathway for more accurate models of ocean-atmosphere interaction, from gas transfer to spray generation, based on the present formulation.

TOWARDS A THEORY FOR THE OCEAN WAVE SPECTRUM

Anthony Bonfils *[1], Woosok Moon[1], Dhrubaditya Mitra[1], and John S. Wettlaufer[1,2,3]
[1] Nordic Institute for Theoretical Physics, Stockholm, Sweden
[2] Yale University, New Haven, USA
[3] Mathematical Institute, University of Oxford, UK

Summary The spectrum of surface gravity waves was measured in the sixties by Pierson and Moskowitz for a fully developed sea, however a theory explaining their observations has been lacking. The initial growth rate of waves is given by the linear theory of Miles which we compute using a new numerical scheme, solving the hydrodynamic Rayleigh equation for a general wind profile. Then, we compare it with analytical results obtained via the method of matched asymptotic expansions. However, there is a coupling between surface gravity waves and the turbulence of the wind that we believe plays an important role. Starting from the quasi-linear model of Janssen, we will consider the non-linear evolution of the ocean wave spectrum in a statistical mechanical framework, which might be useful for wave forecasting.

INSTABILITY OF A PARALLEL SHEAR FLOW OVER A FREE SURFACE

For centuries, scientists and sailors have been vexed by how the wind and the sea conspire to create the waves upon our oceans. Mathematically, the problem consists in calculating the spectrum of waves generated by a turbulent wind over a free surface. Phillips' theory [2] provides a good description of wave generation. Miles [3] proposed an instability mechanism for the growth of a mode traveling at the phase velocity c_0. His key assumption is that when the time scale of turbulent fluctuations is much smaller than the period of the wave, the wind profile $U(z)$ is logarithmic following the law of the wall (see figure 1). Since the density of air is much smaller than the density of water, their ratio $\epsilon = \frac{\rho_a}{\rho_w}$ is a natural small parameter. Thus, Miles could perturbatively solve the eigenvalue problem associated to the instability of a parallel shear flow over a free surface and calculate the initial growth rate:

$$\gamma = -\pi \epsilon c_0 \frac{U''(z_c)}{|U'(z_c)|} |\chi(z_c)|^2 \qquad \text{where} \qquad U(z_c) = c_0 \tag{1}$$

z_c is called the critical level and χ, the normalized perturbed vertical velocity, is solution of the Rayleigh equation

$$(U - c_0)(\chi'' - k^2\chi) - U''\chi = 0 \quad \text{with the boundary conditions} \quad \begin{cases} \chi(0) = 1 \\ \chi(z) \underset{+\infty}{\sim} e^{-kz} \end{cases} . \tag{2}$$

To compute γ, we developed a simple and efficient method for solving linear 2nd order boundary value problems with a regular singularity. Accuracy of the scheme has been checked by recovering the numerical results of Conte and Miles [4] for the dimensionless coefficient β (see its relation with γ in figure 2). We compare Miles' theory with four data sets of measurements of initial growth rates gathered by Plant [5]. It appears that the strength of wind-wave interaction, represented by the growth rate normalized by the frequency $\frac{\gamma}{f}$, is approximately proportional to the square of the wind forcing of waves $\frac{u_\star}{c_0}$. We study how this power law emrges from Miles' theory and show that it strongly depends on the wind parameter $\Omega = g z_0 \left(\frac{\kappa}{u_\star}\right)^2$. To do so, we solve equation (2) by asymptotic matching in the long and short wave approximations.

QUASI-LINEAR WIND-WAVE INTERACTION

Because the ocean wave spectrum $G(k,t)$ is continuous, each level above the surface can be seen as a critical one associated to a mode k of that spectrum. These critical layers interact in such a way that the wind profile gets modified. This can be seen as a analogous to wave turbulence. By a multiple-scale analysis, Janssen [6] established the following time evolution equation:

$$\frac{\partial U}{\partial t} = \frac{2\pi}{U^3(z,t)} \left|\chi_{k_c}(z,t)\right|^2 G(k_c,t) \frac{\partial^2 U}{\partial z^2} \quad \text{with } k_c(z,t) = \frac{1}{U(z,t)^2} \tag{3}$$

Miles' formula (1) still holds but the growth rate is now a function of time. Note that in the steady state, the wind profile should be linear. We numerically explore this model and extend our asymptotic methods, in order to understand the saturation of the waves.

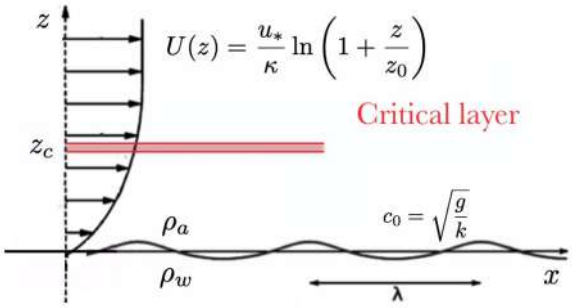

Figure 1: Schematic of a critical layer associated with a mode k that obeys the dispersion relation of surface gravity waves. In the law of the wall, κ is the von Karman constant, u_* the friction velocity and z_0 the roughness length.

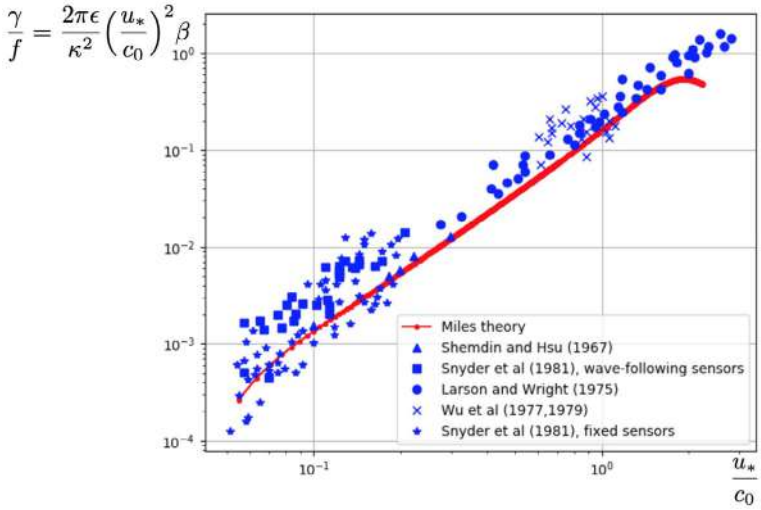

Figure 2: Comparison of Miles theory with experimental data. There is an approximate power law when β is a constant.

CONCLUSIONS

The small parameter ϵ introduces a scale separation in wind-wave generation. Whereas the evolution of gravity waves occurs on a short (fast) time scale, the energy transfer from the wind occurs on a long (slow) time scale. The feedback of growing surface waves on the wind profile occurs on an intermediate time scale. According to Miles' theory, waves can grow if the curvature of that profile is negative. Therefore, the vanishing of the curvature predicted by the model of Janssen will lead to the saturation of the waves, which is the first step in the transition towards a fully developed sea. It appears necessary to introduce stochastic methods in order to deal with the complexity of the non-linear interaction of waves through the wind in addition to the wave turbulence, which constitutes ongoing work.

HIGH-THROUGHPUT MEASUREMENT OF AN INDIVIDUAL'S RED BLOOD CELL SHEAR MODULUS DISTRIBUTION

Amir Saadat,[1] Diego A. Huyke,[2]† Diego I. Oyarzun,[2] Paulina V. Escobar,[4] Ingrid H. Øvreeide,[5] Eric S.G. Shaqfeh,[1,2,3] and Juan G. Santiago[2]
[1] Department of Chemical Engineering, [2] Department of Mechanical Engineering, [3] Institute of Computational and Mathematical Engineering Stanford University, Stanford, CA 94305, [4] Department of Mechanical Engineering, Pontificia Universidad Católica de Chile, 5 Department of Physics, Norwegian University of Science and Technology

Summary Red blood cell (RBC) deformability is critical in their flow through the microcirculation capillaries or the splenic sinusoids. To the best of our knowledge, this work is the first to measure the shear moduli of thousands of RBCs and is accomplished, thanks to a combined high-fidelity RBC numerical model and microfluidic system. There is no gold standard for shear modulus measurement using a microfluidic, high-throughput approach, which hampers the repeatability of microfluidic measurements across different labs. This work bridges this gap with figures of merit that are independent of operational and geometrical variables. Our results indicate excellent agreement with those measurements using "standard" optical tweezers or micropipette aspiration, however we take and analyze images of thousands of cells in several minutes.

INTRODUCTION

Deformability is a critical feature of red blood cells (RBCs) within their 100-120 day life-span through the blood circulation system, and it is a particularly important factor in their flow through the microcirculation capillaries or the splenic sinusoids. Deformability is affected by many pathological conditions and its alteration can impact the pathophysiology of many diseases. While primary reasons for altered deformability are hereditary, mutation, or parasite invasion, there are also many secondary biochemical pathways which influence RBC morphology, biochemistry, and biomechanics. As a result, RBC deformability is altered in many blood related diseases such as diabetes, sepsis, metabolic syndrome. For example, it was recently discovered that, even neurodegenerative diseases could be correlated to the deformability of RBCs due to the interrelation of neural activity and blood circulation.

Although the RBC structure is quite complex, the membrane is a few nanometers thick and therefore can be approximated with a 2D continuum sheet, defined by three main elastic moduli that describe its resistance to deformation; namely, the area dilatation, shear, and bending modulus (1, 2). The lipid bilayer as well as the spectrin network warrants an area inextensible sheet—the area expansion of the membrane is found to be negligible (3). In contrast, the ratio of bending to shear modulus of RBCs is very small which makes the bending resistance relatively inconsequential (2,4). As a result, RBC structure and deformability are largely governed by the membrane shear modulus.

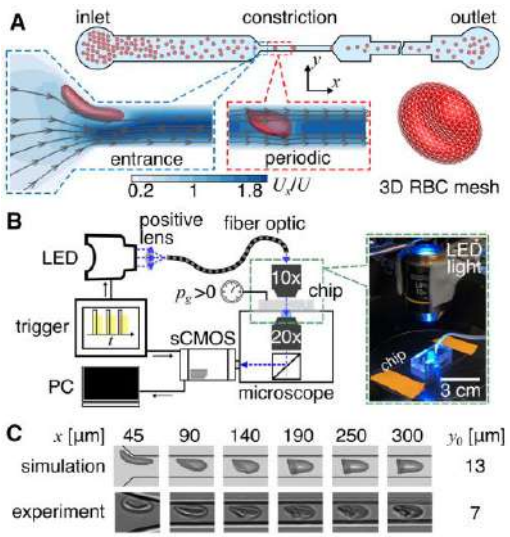

Figure 1. A schematic representation of our microfluidic chip design is shown in the top row of (A). Shown in the bottom row of (A) are the numerical simulation entrance and periodic domains and the mesh distribution over an individual RBC. In (B), a schematic and image of the experimental setup are shown. Panel (C) shows a qualitative comparison of simulation and experimental images of RBCs as they deform and approach a steady-state shape in a constriction with 7×7 μm2.

METHODS

Briefly, state-of-the-art methods to measure the shear modulus of RBCs are not high-throughput and, microfluidic platforms for high-throughput measurements of RBC mechanical properties have not yet enabled measurement of the shear modulus. These limitations challenge the development of diagnostic devices based on RBC shear modulus biomarkers. We demonstrate a high-throughput microfluidic platform, coupled with high-fidelity simulations to address this significant gap in technology. In contrast with existing technologies, this approach allows us to measure the shear modulus of individual RBCs and generate shear modulus distributions (for a given individual or multiple individuals) including measurements of thousands of cells in a few seconds of experimental data acquisition.

As shown in Figure 1A, immersed boundary simulations (5) were conducted near the entrance and in periodic channel domains to find the steady-state shape. We use the well-known Skalak model (55) for modelling the RBC membrane and we assume, as is usual, that these systems are largely surface incompressible. We then utilized the steady-state shapes to generate a surface for data interpretation relating the three important non-dimensional parameters: **the Taylor**

deformation (Ta) , the confinement (ϵ), and the capillary number (based on cell velocity) Ca_{cell}. Note the confinement is a geometric parameter that relates the square root of the projected area of the cell to the channel width, and is proportional to the surface to volume ratio of the RBC.

In conjunction with our high-fidelity simulations, we performed high-throughput experimental visualizations of RBCs under flow. The experimental setup consisted of a custom poly-dimethylsiloxane (PDMS) and glass microfluidic chip, as well as flow control and image acquisition instruments (Figure 1B). RBCs were imaged as they traveled through a $7\times7\times1000$ μm^3 constriction at velocities of 2-10 mm s^{-1} (Figure 1C). The experimentally measured, steady-state Taylor deformation of each RBC was compared to the aforementioned, computationally generated Taylor deformation versus confinement projection, and used to extract the nondimensional RBC capillary number.

RESULTS

From the simulations, we determined *Ta* at different values of ϵ and Ca_{cell} –the capillary number was selected in the range of 0.2-1.6 and the confinement levels were varied between 0.8-1.3. This parameter range is comparable to that which occurs physiologically in the microcirculation. We purposely selected values of ϵ and Ca_{cell} that guaranteed a static parachute shape. The values of *Ta* and ϵ were determined experimentally for every individual cell that is tracked in the microfluidic channels. One can then determine a unique Ca_{cell}, for specific values of *Ta* and ϵ. Then if one also measures the cell velocity, the modulus of the cell can be uniquely determined.

Figure 2 shows the shear modulus distribution for five different donors along with one sample that was "aged" for 5 weeks. We found that the distribution for each donor similarly follows a lognormal distribution. The mean shear moduli ranged from 16.6 to 27.2 μN/m. The standard deviations of shear moduli ranged from 8.6 to 20 μN/m. The results suggest that there are donor-to-donor differences in mean shear moduli as large as 10 μN/m. Moreover, the fresh blood distribution shows a mean shear modulus near 6.6 μN/m. After 5 weeks of storage, the mean shear modulus increases to 34 μN/m. The increase of the mean is expected due to the increase in the stiffness of the RBCs. All of our results are consistent with measurements made via micro-pipette aspiration or optical tweezers, except for the fact that we can make measurements of thousands of cells in minutes and thus determine distributions.

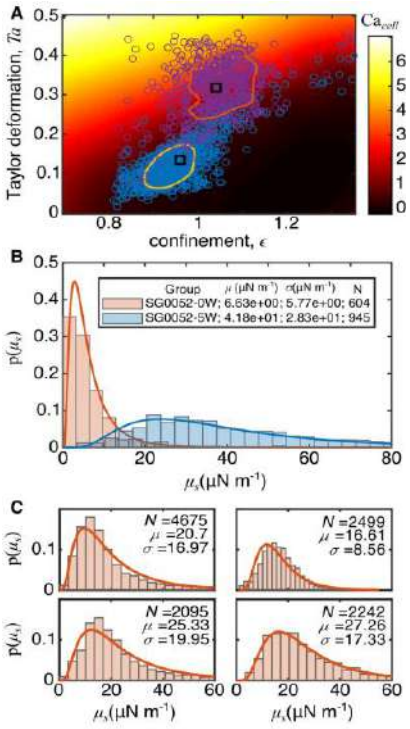

Figure 2. In (A) are shown experimentally Taylor deformation *Ta* versus confinement ϵ data for RBCs that were freshly withdrawn (purple, open circles) and 5-weeks stored in a 4°C fridge (blue, open circles). The solid lines enclose 50% of the experimental measurements. The scattered data is overlaid on the computationally generated *Ta* versus ϵ surface which results in a single capillary number of the cell Ca_{cell}. Panel (B) shows the shear modulus distributions corresponding to the same data set (fresh in orange and 5-weeks stored in blue). The shear modulus distributions (C) for four separate healthy donors was also found.

CONCLUSIONS

We have designed a high-throughput microfluidic platform for measuring the shear modulus and shear modulus distribution of an individual's blood sample. This was accomplished by fabricating microchannels with square cross-sections (7x7 μm^2) such that a steady-state parachute is formed after flow 300 μm downstream. We then determined the Taylor deformation parameter, *Ta*, using robust and automated single-cell tracking and shape quantification. Finally, we utilized our 3D computational method to construct a three-dimensional surface that is used to find the shear modulus and its distribution based on the experimentally measured values of *Ta*, confinement ratio, and cell velocity.

Summary The physics of blood flow in small vessel networks is dominated by the interactions between blood cells, plasma and blood vessel walls. This leads to strong couplings between the microvessel network architecture and the distribution of RBCs, which have been the object of a large amount of work. Most of them, however, consider complex microvascular architectures. Here, we present a series of experiments performed in both hexagonal and square periodic microfluidic networks, and gain physical insights on the results by comparison with discrete network models of RBC flow in the same configurations. We show that, despite the apparent simplicity of the geometries at hand, model predictions can differ significantly from experiments and are very sensitive to the network hierarchy, strongly suggesting that an improved description of blood flow at the local scale should be necessary.

INTRODUCTION

Microvascular networks are able to ensure adequate blood supply, feeding every cell in peripheral tissues with oxygen and nutrients under a wide range of physiologic conditions and varying metabolic needs. Their involvement in disease is also increasingly recognized [1, 2, 3]. Thus, since the very first observations of microvascular networks in small animals by Jean-Marie Poiseuille in the XVIIIth century, the blood microcirculation has been extensively studied. One of the most striking feature highlighted by the French physicist is the highly heterogeneous distribution of red blood cells (RBCs) throughout microvessel networks, with some vessels containing no blood cells and some others containing almost no plasma (suspending fluid) [4, 5, 6]. Because oxygen transported in the bloodstream is mainly stored within the RBCs, such heterogeneous distribution is likely to control the oxygenation of the surrounding tissue.

The physics of blood flow in these small vessel networks is dominated by the interactions between blood cells, plasma and blood vessel walls [7]. This leads to strong couplings between the microvessel network architecture and the distribution of RBCs. The emergence of such couplings has been the object of a large amount of work, from the scale of individual RBCs to the scale of the network (see [8] or [9] for recent reviews).

At network scale, in particular, a large variety of investigation tools, sometimes in combination, has been used, see, *e.g.*, [10, 11, 12, 13, 14, 15, 16, 17]: **a)** in vivo and in vitro experiments, **b)** network models where blood is described as an equivalent fluid with non-linear rheological properties, the RBCs being described by a volume fraction and their impact on larger scales being described by phenomenological descriptions, **c)** networks models coupled with simplified, discrete representations of the RBCs, as singular pressure drops, which are individually tracked, and **d)** more recently, direct numerical simulations resolving both the dynamics of the suspending fluid and of each individual RBC, as well as their large deformations, their interactions and the hydrodynamics of the suspending fluid.

Most of these works, however, consider complex microvascular architectures and vessel lengths and diameters distributed to match as closely as possible the *in vivo* distributions. This makes it difficult to isolate the contributions of local effects, such as cell partitioning at successive bifurcations [18], and large-scale couplings associated to the non-local nature of viscous flow in networks, even in the absence of any cell.

RED BLOOD CELL DISTRIBUTION IN SIMPLE PERIODIC NETWORKS

As far as we know, only the group of D. Obrist focused on simple generic model networks with channels of equal sizes and with periodic unit patterns [11, 17]. The first of these two works [11] was theoretical, based on the simplest possible Lagrangian network model of RBC flow, in order to reveal the underlying principles of RBC distribution at network scale, and considered square unit patterns, with 4-connectivity. One of their central theoretical result was the accumulation of RBCs in the network corners opposite to the inlet and outlet, *i.e.*, within the vessels exhibiting the smallest flow rates, as illustrated on Figure 1, left and middle pannels. This was a highly unexpected result.

In fact, previous *in vivo* experiments suggest that, on average, cell partitioning at individual bifurcations is highly biased toward the higher-flow pathway [18]. This results in strong spatial correlations between the volume fraction of RBCs (or hematocrit) and the flow velocity. In other words, vessels which exhibit higher flow velocities on average also exhibit higher hematocrits, which gives rise to the so-called tissue Fahraeus effect[1] [19].

Consistent with these previous works, the recent experimental results of Obrist's group [17], obtained with RBC suspensions flown through hexagonal, 3-connected, networks, display a preferential localization of the cells in the center of

*These authors have equally contributed to this work
†Corresponding author. E-mail: sylvie.lorthois@imft.fr

[1]The tissue Fahraeus effect denotes a reduction of the volume fraction of RBCs in the whole network by comparison to its discharge hematocrit (defined as the ratio between the RBC flow and the total flow). It is analogous to the the Fahraeus effect, *i.e.*, the reduction of the hematocrit within a single segment (tube hematocrit) by comparison to the discharge hematocrit, which results from the correlation between hematocrit and velocity within a single vessel cross-section [18].

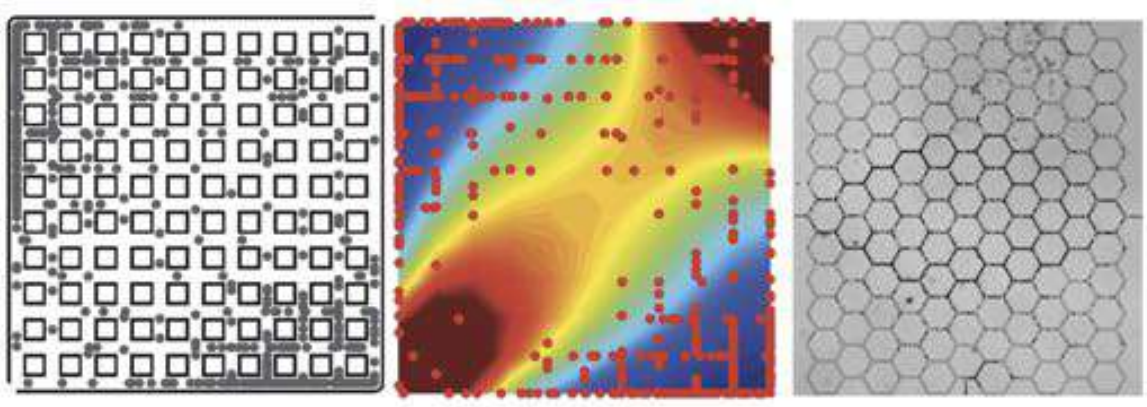

Figure 1: Spatial repartition of RBCs in a square microfluidic network with channels, as predicted by the discrete model with individually tracked RBCs proposed by [11]. Inflow is on the lower left corner and outflow is on the upper right corner. Channel radii are supposed sufficiently small for RBCs to flow in single line and follow the pathway of highest pressure drop at intersections. RBCs are displayed by dots in the figure panels. **Left**: Snapshot at 1.5 times the total network turnover time. **Middle**: Steady-state configuration. The colors indicate the average flow rate smeared out across the network (red, high velocities; blue, low velocities). The vessels are not shown. Reproduced with permission from [11]. **Right**: Human RBCs flowing from left to right in an hexagonal microfuidic network with channels of size $10\mu m$ x $10\mu m$ x $50\mu m$.

the network, whose channels have the highest velocities. By contrast, the network corners are almost devoid of RBCs. This raises several questions. For example, would the former theoretical prediction be supported by experiments performed in networks with square unit patterns? If yes, are there specific features of the studied configuration (*e.g.* channel diameters, connectivity) that sufficiently deviate from the subsequent experiments and typical *in vivo* conditions to explain the accumulation of RBCs in low flow vessels? What are the basic mechanisms and ingredients controlling the distribution of RBCs in simple generic networks with uniform vessel diameters?

To address these questions, we present a series of experiments performed in both hexagonal (*e.g.*, Figure 1, right panel) and square networks, and gain physical insights on the results by comparison with discrete network models of RBC flow in the same configurations. We show that despite the apparent simplicity of the geometries at hand, model predictions can differ significantly from experiments and are very sensitive to the network hierarchy, strongly suggesting that an improved description of blood flow at the local scale should be necessary.

MODELING THE COLLOIDAL HYDRODYNAMICS OF BIOLOGICAL CELL FUNCTION

Emma Gonzalez[1], Alp Sunol [1] Akshay Maheshwari[2], Drew Endy[2], and Roseanna N. Zia *[1]
[1] Department of Bioengineering, Stanford University, Stanford, California, U.S.A.
[2] Department of Chemical Engineering, Stanford University, Stanford, California, U.S.A.

Summary A physics-based computational model of a biological cell is presented, along with results from dynamic simulation of colloidal-scale biological processes. In a merging of biological modeling and physical modeling, biomolecules and their interactions are physically represented, individually and explicitly, in a representative voxel of translation molecules as well as a simple whole-cell confined model. With it, we show that an interplay between confinement, hydrodynamic interactions, Brownian motion, and interparticle forces qualitatively change particle dynamics. We find that colloidal-scale physics may be required to explain some life-essential biological processes in cells. The qualitative and quantitative influences of hydrodynamics, confinement and crowding, as well as the consequences of neglecting such influences, are discussed.

INTRODUCTION

Many mathematical representations of cellular behavior rely on abstractions that do not account for how macromolecules are organized and move within the crowded cell milieu. For example, linear algebra- and differential equation-based models typically do not represent individual biomolecules or their spatial position and motion. While atomistic modeling of biological cells is robust, structural biology modeling can evolve dynamics only over nanoseconds [figure 1(a)]. At the opposite end of the spectrum, systems biology abstracts space away entirely [figure 1(b)]. For many questions in biology these simpler models have been sufficient. However, a multitude of cellular processes occur between these two limits, at the colloidal scale [figure 1(c)]. I will discuss our progress in developing computational and theoretical tools to model biological processes in a simple model cell, by representing the cell as a spherically confined colloidal suspension, where biomolecules and their interactions are physically represented, individually and explicitly. By developing a more robust and physics-based model for how macromolecules interact within cells we can contribute to a more physically complete representation of living matter. A primary challenge in models of confined colloidal suspensions is the accurate and efficient representation of many-body hydrodynamic interactions, Brownian motion, and the enclosure itself. We have developed a "Cellular Stokesian dynamics" framework that accounts for spherically confined many-body hydrodynamic and lubrication interactions, Brownian motion, and active transport [2,3]. Utilizing this model, we study diffusion, hydrodynamic towing, confinement, and their impact on mRNA translation rates [3-5].

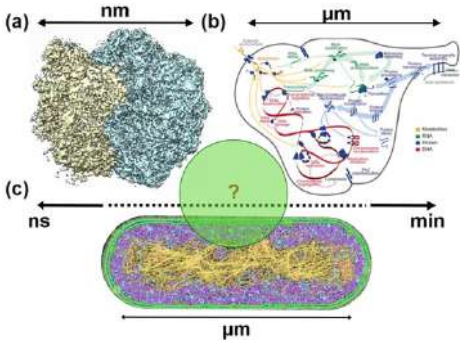

Figure 1 Presented work expands current range of modeling of biological cells. (a) Atomistic-scale modeling spans only nanoseconds. (b)Most whole-cell models are kinetics only with no spatial resolution. (c) Colloidal-scale processes are ubiquitous in cells, yet modeling them is emergent, partially owing to the difficulty in detailed representation of the relevant microscopic forces in low-Reynolds number flow. From [1].

METHOD OF SIMULATION

Our "Cellular Stokesian Dynamics" model [1] is utilized to represent a spherically confined colloidal suspension, fully modelling many-body hydrodynamic and lubrication interactions with an enclosing cavity and between particles. Brownian dynamics is also utilized to simulate a representative voxel of mRNA translation molecules. In both, the solvent is implicit. All biomolecules are represented as spheres of various sizes, relative to other biomolecules and relative to the enclosing cavity. The total packing fraction of solid to liquid of the model cell ranges from 50% to 5%; the degree of confinement ranges from a cavity 10 times to 400 times the size of the confined colloids. Hydrodynamic interactions are long-ranged and an infinitude of reflected interactions are fully accounted for by a novel set of mobility functions developed in our prior work [2]. We model coarse-grained interactions between proteins via a modified, continuous Kern-Frenkel model [6,7], which localizes attraction to an arbitrary number of patches on a protein's surface. Such a "patchy" model can capture the anisotropic nature of short-ranged attractions (e.g. hydrophobic interactions), as well as isotropic repulsions due to electrostatic interactions. Particle displacements, osmotic pressure, and reaction events are monitored throughout simulation, and utilized to compute self-diffusion and impact of entropic forces on relative transport rates during interactions between spheres representing translation molecules and other biomolecules.

INTERPLAY OF BROWNIAN MOTION, CONFINEMENT, POLYDISPERSITY, AND HYDRODYNAMICS

Study of particle volume fractions in the range between 0.05 and 0.40 reveals that confinement exerts a qualitative influence on particle dynamics, which in turn affects biomolecule association times in key biological cell processes. Confinement induces strong layered ordering [figure 3, left] and thus the mean-square displacement over all time scales depends on the position in the cavity [figure 3, center and right]. Additionally, at short times, the diffusivity is anisotropic,

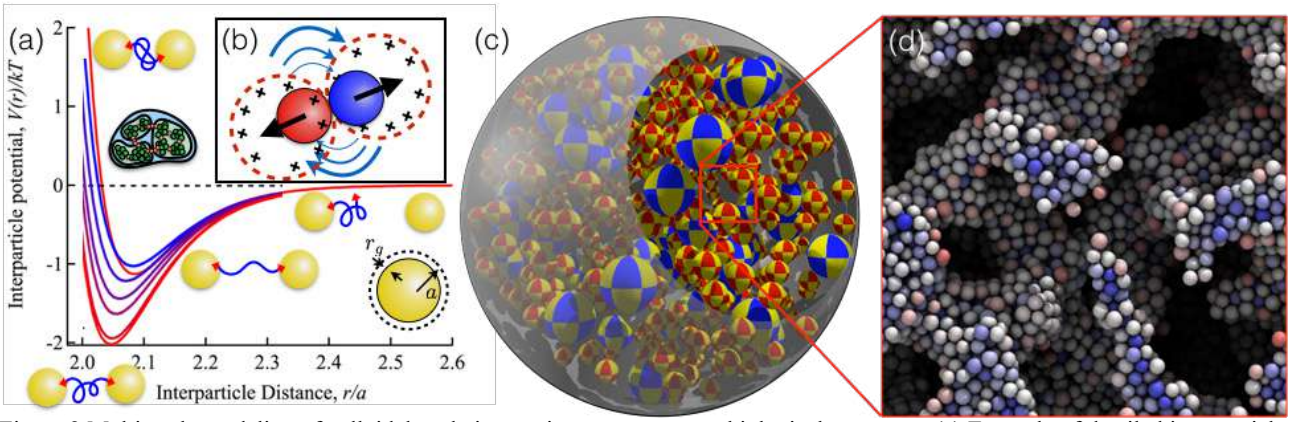

Figure 2 Multi-scale modeling of colloidal-scale interactions can represent biological processes. (a) Example of detailed interparticle potential. (b) Non-isotropic repulsive and attractive interactions of different ranges can be included in the model. (c) "Cellular Stokesian dynamics model of simple whole cell [1,2] includes many-body long-range reflected hydrodynamic interactions, lubrication interactions, Brownian motion, patchy interparticle attractions. (d) Colloidal gelation [8].

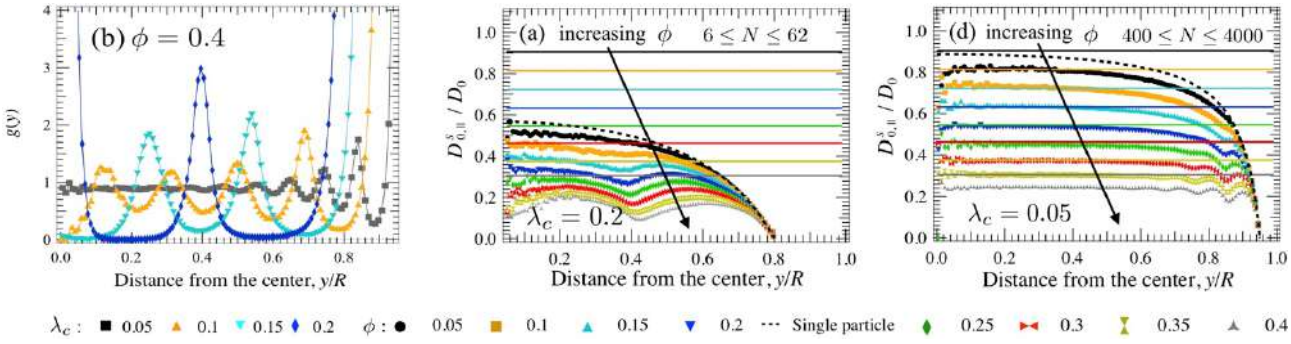
with diffusion along the cavity radius slower than diffusion tangential to the cavity wall, due to the anisotropy of hydrodynamic coupling and to confinement-induced spatial heterogeneity in particle concentration. The mean-square displacement is anisotropic at intermediate times as well and, surprisingly, exhibits super-diffusive and subdiffusive behaviours for motion along and perpendicular to the cavity radius respectively, depending on the suspension volume fraction and the particle-to-cavity size ratio. No long-time self-diffusive regime exists; instead, the mean-square displacement reaches a long-time plateau, a result of entropic restriction to a finite volume. In this long-time limit, the higher the volume fraction is, the longer the particles take to reach the long-time plateau, as cooperative rearrangements are required as the cavity becomes crowded.



CONCLUSIONS

The ordered dynamical heterogeneity seen in our dynamic simulations promotes self-organization of particles based on their size and self-mobility, which is of particular relevance in biophysical systems [3]. Subsequent studies of polydispersity [4] reveal an important interplay with confinement that explains our results regarding the role of Brownian motion and reactions in processes in prokaryotic cells [5].

DIURNAL VERTICAL MIGRATION OF *HETEROSIGMA AKASHIWO*

Li Zeng *[1], Tim Pedley[2], and Yu Yang[1]
[1] State Key Laboratory of Simulation and Regulation of Water Cycle in River Basin, China Institute of Water Resources and Hydropower Research, Beijing, China
[2] Department of Applied Mathematics and Theoretical Physics, University of Cambridge, Cambridge, UK

Summary Understanding the migration of *Heterosigma akashiwo* will make an important contribution to marine ecology. It is found that the fraction of helical and straight line motion modes changes greatly during the dark-light cycle. Cells' distribution exhibits three typical characteristics: stable accumulation at the top surface during the light period, the stable accumulation at both the bottom and upper surfaces during the dark period, and a non-equilibrium distribution during the transition between light and dark periods. The high concentration near the bottom is caused by downward swimming rather than sedimentation. It seems that cells' physiological rhythm rather than an asymmetrical mass distribution regulates the downward swimming. The Péclet number related to the vertical swimming velocity and translational diffusivity is found to vary with cells' vertical position.

INTRODUCTION

The migration of gyrotactic micro-organisms is quite significant for understanding many ecological phenomena in oceans. The type of gyrotactic micro-organism considered here is *Heterosigma akashiwo*, which is one typical species related to the harmful algal blooms occurring in coastal regions. Understanding the migration of *Heterosigma akashiwo* will make an important contribution to exploring the evolution of the marine ecosystem, especially the evolution of red tides. Regarding the migration of gyrotactic micro-organisms, there have been various theoretical, experimental, and computational investigations [1-7], with focus on swimming behaviours of individual swimmers, shear-triggered accumulation and trapping, bioconvection, etc. However, the diurnal migration of *Heterosigma akashiwo* is not well understood. Until now, the characteristics of swimming modes, detailed concentration distribution near the top and bottom surfaces, as well as the forces that drive the mean downward swimming during the whole dark-light cycle have been incompletely described. In this paper, therefore, we investigate the swimming modes of *Heterosigma akashiwo*, its concentration distribution, and the identification of potential factors to regulate the downward swimming during the dark-light cycle.

MATERIALS AND METHOD

Three groups of experiments were performed to investigate the diurnal vertical migration of *Heterosigma akashiwo*. The first experiment is to observe the migration in a confined micro-channel with height of 1 mm, width of 2.5 mm, and length of 50 mm. The objective is to explore the swimming modes and detailed concentration distribution near the wall during the whole dark-light period. The second experiment is to explore the diurnal vertical migration of *Heterosigma akashiwo* in one chamber with a height of 2 cm. The objective is to test whether similar behaviours still occur in the water body with larger spatial scale. The third experiment is to observe the distribution of *Heterosigma akashiwo* in the downward flow through a vertical tube. The objective is to explore whether the downward swimming in the dark period is caused by a change of relative positions of mass and buoyancy centers. The algal cells (GY-H24 *Heterosigma akashiwo* adopted in this work came from Zhoushan, Zhejiang, China, and were cultivated at the temperature of 25 $^{\circ}\mathrm{C}$ in a growth chamber with 12:12 light:dark photoperiod. The first experiment was carried out based on the MICRO-PIV system, and the second and third experiments were done based on the planar laser induced fluorescence (PLIF) technique.

RESULTS AND DISCUSSION

Experimental results showed that *Heterosigma akashiwo* can swim vertically upwards and downwards, on average, in still water. During the 1st hour (D1) to the 10th hour (D10) of the dark period, cells' downward swimming is stronger than their upward swimming, while, during the 3rd hour (L3) to the 11th hour (L11) of the light period, the upward swimming is dominant, as shown in figure 1. During the transition of dark to light or light to dark, there is no clear preference of swimming behaviour. The high concentration near the bottom wall is caused by cells' downward swimming rather than their sedimentation, since the mean swimming velocity of *Heterosigma akashiwo* in the dark period, approximately on the order of 100 $\mu\mathrm{m\ s}^{-1}$, is much greater than the sedimentation velocity, approximately 3 $\mu\mathrm{m\ s}^{-1}$.

Two typical swimming modes, helical motion and straight line motion, were observed during the dark-light cycle. The mean vertical swimming velocity of the straight line mode is approximately two times that of the helical mode. The fraction of swimming modes can change greatly during the dark-light cycle. It is found that the main swimming mode is straight line swimming in the dark period, while helical swimming dominates in the light period.

*Corresponding author. E-mail: lizeng@iwhr.com.

The accumulation of *Heterosigma akashiwo* near the top and bottom surfaces were also observed in the larger chamber with water depth of 3 cm, as shown in figure 2. The concentration distribution of *Heterosigma akashiwo* is not exponential, which means that the ratio of vertical swimming velocity and translational diffusivity near the wall is not constant. According to the balance of cells' flux contributed by the mean vertical swimming and translational diffusion in the vertical direction, the Péclet number based on the chamber depth, the mean swimming velocity and the translational diffusivity is found to vary with cells' vertical position. However, the separate variation of the mean swimming velocity and translational diffusivity is still not clear based on these data.

In general, bottom-heavy micro-organisms tend to swim upwards, while nose-heavy ones tend to swim downwards. It is well known that *Heterosigma akashiwo* is a bottom-heavy organism in still water during the light period [4], and their asymmetric mass distribution is beneficial in maintaining the upward swimming. Recent investigation has shown that a turbulent signal can trigger downward swimming by changing the relative position of the centers of mass and buoyancy [6]. The question arises as to whether downward swimming in still water is related to the change of relative position of the two centers? If it is, cells would swim towards the wall in the downward flow (with certain flow velocity) through a vertical tube during the dark period. However, our observation has shown that cells mainly accumulate in the central zone of the tube in the dark period as it did in the light period, which means that the downward swimming is not regulated by the asymmetrical mass distribution [1]. It appears that downward swimming is caused by the physiological rhythm of *Heterosigma akashiwo*.

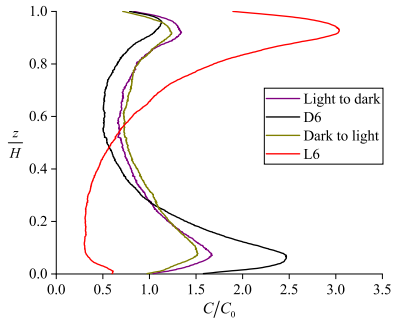

Figure 1: Variation of cells' concentration with z/H, where z is cells' vertical position, and H is the height of the confined micro-channel.

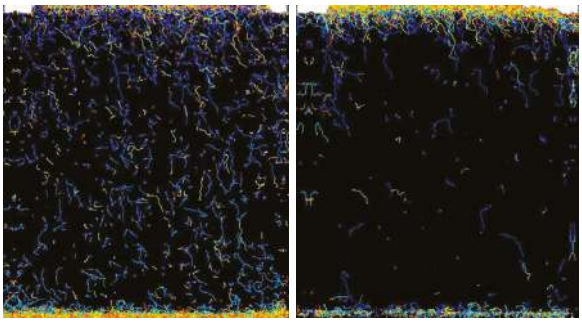

Figure 2: Instantaneous distribution of cells. Left figure corresponds to the dark period, and right figure corresponds to the light period

CONCLUSIONS

Distribution of *Heterosigma akashiwo* has distinct features in one dark-light cycle: stable accumulation on the top surface during the light period, and stable accumulation on both the bottom and top surfaces during the dark period. Detailed concentration structure of *Heterosigma akashiwo* has been identified for a time interval of 1 hour. The high concentration near the bottom is caused by cells' downward swimming rather than their sedimentation. It seems that the internal, physiological rhythm of *Heterosigma akashiwo* regulates the downward swimming. However, more evidence associated with both biology and fluid mechanics is required to further clarify this issue.

EMERGENCE OF METACHRONAL WAVES IN ARRAYS OF INSTABILITY-DRIVEN BEATING CILIA

Chenglei Wang*[1], Simon Gsell[1], Umberto D'Ortona[1], and Julien Favier[1]
[1] Aix-Marseille Univ., CNRS, Centrale Marseille, M2P2, Marseille, France

Summary This research explores hydrodynamic interactions among an array of naturally curved cilia driven by a tip-concentrated follower force, i.e., a constant-magnitude force acting on the cilium tip and always aligned with the tip direction, in low Reynolds number flows. This fluid-structure interaction (FSI) problem is solved using a numerical framework based on the immersed boundary lattice Boltzmann method (IBLBM) and the finite element method (FEM). Simulation results show that when the Reynolds number, force magnitude, cilia spacing and domain size are properly chosen, hydrodynamic interactions can successfully result in metachronal waves (MCWs).

INTRODUCTION

Cilia are micro-scale hair-like organelles protruding from the surfaces of many eukaryotic cells. They undergo various oscillatory motions driven by numerous internal dynein molecular motors for fluid transport. When clustering in large domains, they usually coordinate with their neighbors to produce metachronal waves (MCWs) instead of beating in either random or synchronous manners. This amazing phenomenon was hypothesized to result from hydrodynamic interactions, and has been extensively explored in literature through various fluid-structure interaction (FSI) models [1,2]. In most of the existing works, it is assumed that cilia are actuated by regulating dynein motors through geometric feedback control schemes, such as the curvature-based feedback control [2].

Recently, Bayly and Dutcher proposed that such regulation may not be required since dynein motors can supply sufficiently large axial stresses to trigger dynamic buckling instability and induce sustained oscillations [3]. A later study demonstrated that the instability-driven cilia exhibit realistic asymmetric beating patterns when taking into account that cilia are expected to be curved in equilibrium states in nature [4]. This immediately leads to interesting questions: How do the cilia hydrodynamically interact when they are driven by this new kind of actuation strategy? Can metachronal waves emerge in this configuration? If so, what are they like and how are they influenced by some key parameters, such as the Reynolds number, actuation strength, cilia spacing and domain size? This work aims to address these questions through systematic numerical investigations.

PROBLEM DESCRIPTION AND METHODOLOGY

In this study, an array of cilia (N_x and N_y in the x- and y-directions, respectively) is placed in an initially quiescent flow contained in a domain with length L, height H and width W, as shown in Figure 1. The cilium diameter is described by D, and the spacings between cilia in the x- and y-directions are referred to as d_x and d_y, respectively. The cilia are assumed to exhibit a circular shape characterized by the arc length L_c and arc angle θ at rest. Cilium bases ($s = 0$, where s the Lagrangian coordinate along the cilium) are perpendicularly clamped at the bottom, whereas cilium tips ($s = L_c$) are set free. The axial stresses along each cilium are simplified as a compressive follower force $\boldsymbol{F}_T$ which is tangentially applied at the cilium tip. As the cilium deforms, the force magnitude is kept constant and its direction remains tangential to the cilium tip.

In nature, cilia are slender bodies, since their diameters are much smaller than their lengths. Herein, the diameter-to-length ratios are set as 0.1 to satisfy this slender-body condition. To simplify the problem, cilia are modeled as elastic filaments without internal damping effects, and they are only allowed to undergo in-plane deformations. As such, the governing equation for the dynamics of each cilium can be written as

$$\rho_c A \frac{\partial^2 \boldsymbol{X}}{\partial t^2} - \frac{\partial}{\partial s}\left[EA\left(1 - \left|\frac{\partial \boldsymbol{X}}{\partial s}\right|^{-1}\right)\frac{\partial \boldsymbol{X}}{\partial s}\right] + \frac{\partial^2}{\partial s^2}\left(EI\frac{\partial^2 \boldsymbol{X}}{\partial s^2}\right) = \boldsymbol{F}_f \tag{1}$$

where ρ_c is the cilium density, A the cross-section area of the cilium ($A = \pi D^2/4$), E the Young's modulus, I the moment of inertia ($I = \pi D^4/64$), $\boldsymbol{X}$ the cilium position, and $\boldsymbol{F}_f$ the fluid loading acting on the cilium.

The dynamics of the incompressible flow can be described by the continuity and momentum equations as follows

$$\nabla \cdot \boldsymbol{v} = 0 \tag{2}$$

$$\rho_f \frac{\partial \boldsymbol{v}}{\partial t} + \rho_f \boldsymbol{v} \cdot \nabla \boldsymbol{v} = -\nabla p + \mu \nabla^2 \boldsymbol{v} + \boldsymbol{f}_e \tag{3}$$

where ∇ is the gradient operator, $\boldsymbol{v}$ the flow velocity, ρ_f the fluid density, p the pressure, μ the dynamic viscosity, and $\boldsymbol{f}_e$ the external force per unit volume.

MINI SYMPOSIA

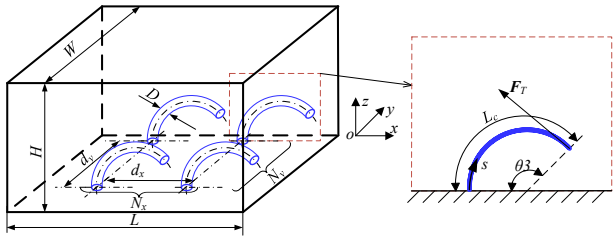

Figure 1: Schematic of an array of naturally-curved cilia located in the computational domain, where each cilium is actuated by a compressive follower force ($\boldsymbol{F}_T$) at its tip (not in scale). L, H and W are the length, height, width of the domain, respectively, L_c the cilium length, D the cilium diameter, d_x and d_y the x- and y-distances between two neighboring cilia, N_x and N_y the cilium numbers in the x- and y-directions, θ the cilium arc angle, and s the Lagrangian coordinate along the cilium.

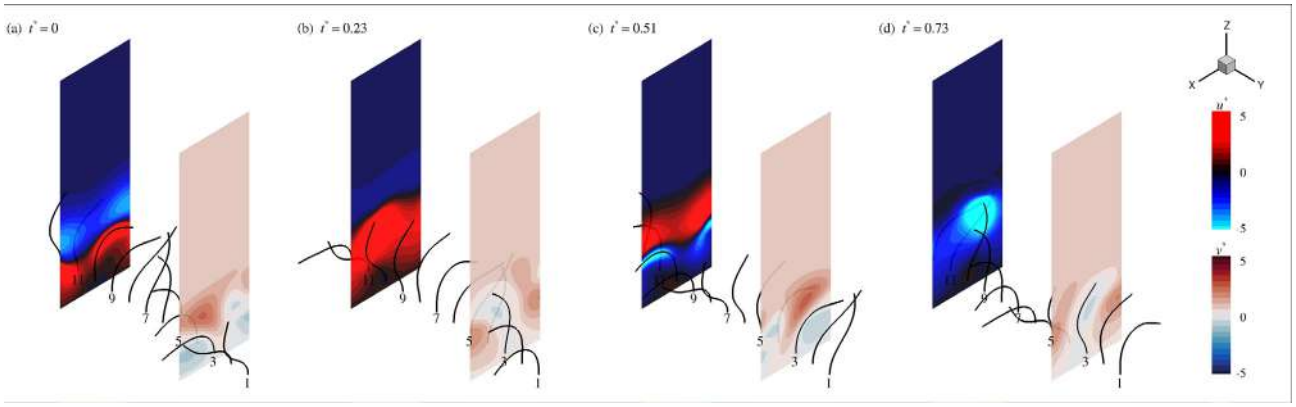

Figure 2: Snapshots of the cilia beating motion at instants $t^* = 0$ (a), 0.23 (b), 0.51 (c) and 0.73 (d), where $t^* = (t - t_r)\, EI/\mu L_c^4$ and t_r refers to the time for subfigure (a) in simulation. The four upper and lower contours display the dimensionless x- and y-velocities (u^* and v^*), respectively, where $u^* = u\mu L_c^3/EI$ and $v^* = v\mu L_c^3/EI$.

To study this FSI problem, the co-rotational finite element formulation is applied to solve structure dynamics. The multiple-relaxation-time (MRT) lattice Boltzmann method (LBM) is adopted as an alternative to simulate the three-dimensional fluid dynamics. To resolve the interplay between the flow and structure dynamics, the immersed boundary method (IBM) is incorporated so as to realize the no-slip boundary conditions on the structure surfaces as well as accurately evaluate the fluid loading.

RESULTS AND CONCLUSIONS

In this work, the collective behaviors of the one-and two-dimensional cilium arrays are explored over ranges of Reynolds number, force magnitude, cilium spacing and domain size. The simulation results reveal that all these parameters play important roles in the hydrodynamic interactions among cilia and the resulting collective behaviors. Particularly, various collective patterns, including metachronal waves, are observed. Herein, one representative case where a transverse metachronal wave emerges is briefly discussed for illustration.

In this case, a diaplectic row of cilia ($N_x = 1$ and $N_y = 12$) is evenly placed in the domain with the length $L = L_c$ and width $W = 3L_c$, corresponding to the x-distance $d_x = L_c$ and y-distance $d_y = L_c/4$, where L_c is the cilium length. The arc angle is set as $\theta = \pi/4$, and the magnitude of the follower force is $|\boldsymbol{F}_t| = 50EI/L_c^2$, where EI is the bending stiffness. The Reynolds number is $\mathrm{Re} = \rho_f EI/\mu^2 L_c^2 = 5$, where ρ_f is the fluid density and μ the dynamic viscosity. After a random initialization, a sustained wave formed by the 12 cilia with the wavelength of $3L_c$ emerges gradually, and it propagates along the positive-y direction, as shown in Figure 2. The x- and y-velocities of the flow fluctuate significantly around the cilia, whereas they remain relatively steady above the cilia, indicating that a more steady flow is generated in this region. Furthermore, the x- and y-velocities above the cilia are negative and positive, respectively, and they are nearly equal in magnitude. This implies that the global-flow-transport direction deflects from the ciliary beating direction by an angle of $\pi/4$, approximately.

LINGERING DYNAMICS OF MICROVASCULAR BLOOD FLOW IN SYRIAN HAMSTERS

C. Wagner[1], A. Kihm[1],*, S. Quint[1], M. W. Laschke[2], M. D. Menger[2]

Summary *The microvascular networks in the body of vertebrates consist of the smalle vessels, such as arterioles, venules, and capillaries. The flow of red blood cells (RBCs) through these networks ensures the gas exchange in the tissues, as well as the transport of nutrients towards the tissues. Any alterations in this blood flow may have severe implications on the health state. Since the vessels in these networks obey dimensions similar to the diameter of RBCs, dynamic effects on the cellular scale play a key role.*
We present a detailed analysis of the shape alteration of RBCs while passing bifurcations and confluences as well as so called lingering effects. These lingering events of cells at the apex of bifurcating vessels affects the temporal distribution of cell-free areas in the branches and may even cause a partial blockage in severe cases.

Motivation and goals

Red blood cells obey an inner network of spectrin fibers, being responsible for their biconcave shape at rest. Due to the flexibility of this spectrin network, RBCs are able to pass through constrictions much smaller than their size at rest. However, not only constrictions alter the shape of RBCs, but also the intricate structure of the vascular network itself with its merging and bifurcating vessels. The shape of RBCs undergoes a characteristic deformation when approaching the apex of a bifurcation or a confluence, respectively. Whereas this alteration of the shape is due to increasing or decreasing confinements depending on the geometry, cells may even linger around the apex of a bifurcation, as shown in fig. (1) [2].

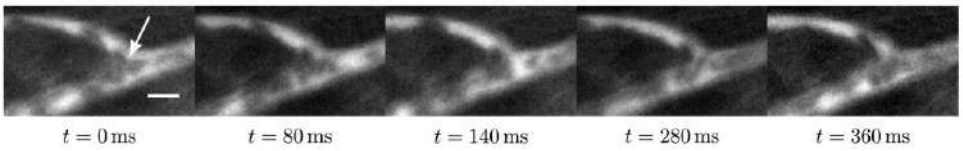

Figure 1. Time series of a lingering RBC at an arterial bifurcation for a time interval of 360 ms. At t=0 ms, an RBC is touching the apex of the bifurcation, marked by the arrow. The cell starts to deform and linger around this apex, leading to a partial blockage with decreased flow rate as can be seen in the upper branch of the daughter vessels for all subsequent images. Finally, the cell is detaching from the apex after 360 ms, exiting in the upper branch of the daughter vessels. Scale bar is 5 µm in width.

The steady progression in numerical modelling of RBCs even in complex networks has led to novel findings in the field of hemodynamics [2,3], especially concerning the impact and the dynamics of the lingering events. However, these results are yet unmatched by a detailed analysis of the lingering in experiments in vivo. To quantify this lingering effect in in-vivo experiments, we analyse branching vessels in the microvasculature of Syrian hamsters via intravital microscopy and the use of an implanted dorsal skinfold chamber (cf. Fig. (2)).

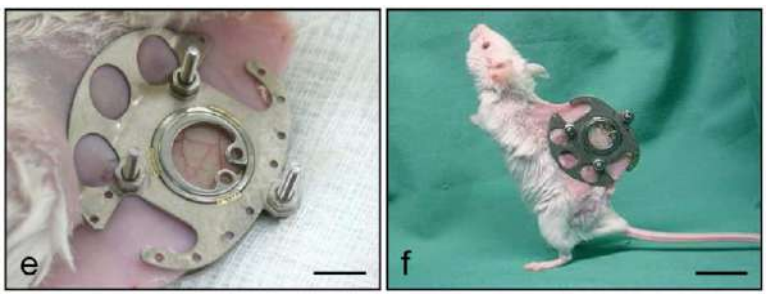

Figure 2. Stepwise preparation of a dorsal skinfold chamber in an anaesthetized balb/c mouse (e). Scale bar: 8 mm [1]. The animal tolerates the chamber well, as indicated by normal orientation behavior (f). Scale bar: 19 mm. After implantation, the blood vessels within the observation window can be investigated by means of intravital microscopy.

Using high-resolution objectives and high-speed cameras, the intravital microscopy provides insights into dynamic processes with single-cell resolution and is therefore perfectly suited to examine lingering in vivo.

Results and conclusions

The Hamster intravital images show various branching networks of vessels with different opening angles and diameter ratios. However, most of the observed topologies consist of only one or two bifurcations rather than multiple ones. Here we analyse as a typical example an area with 7 daughter branches in total (see fig. (3)).

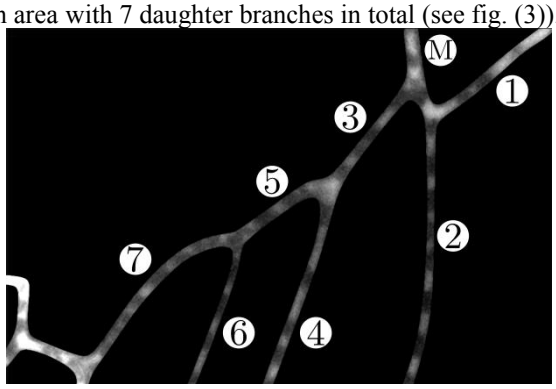

Figure 3. Branching arteriolar network. This geometry has been used for the detailed analysis shown in fig. 4. Blood flow is coming from the mother vessel (M) and exiting in all the other labelled branches. RBCs are black, in contrast to plasma or cell-free regions in white.

Using a self-written MATLAB image analysis script, we extract the temporal distribution of voids (cell-free regions) and RBCs in each branch. An exemplary time-signal of the measured intensities corresponding to these distributions is depicted in fig. (4). By normalising the void durations by the average passage time of a RBC, we are able to compare the void durations. We find that for distinctive pairs of branches, one vessel exhibits void durations of multiples of the RBCs passage time whereas the counterpart obeys rather short void durations. Interestingly, the lingering leads to substantially longer void durations in the branch of a bifurcation with the higher flow rate (branches #4,6). Several statistical measures will be presented that characterize the irregular flow dynamic of the network.

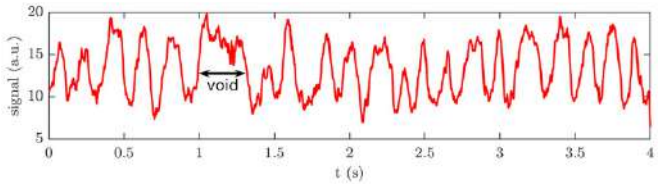

Figure 4. Intensity fluctuations along a line segment perpendicular to the vessel. Based on these findings, passage times of RBCs as well as temporal void lengths can be identified.

STABILITY OF A RED BLOOD CELL IN A NARROWRECTANGULAR MICROCHANNEL

Naoki Takeishi*[1], Hiroaki Ito[2], and Shigeo Wada[1]
[1] Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka, Japan
[2] Department of Physics Graduate School of Science, Chiba University, Chiba, Chiba, Japan

Summary The deformability of a red blood cell (RBC) highly affects the blood flow, both in large arteries and in the microcirculation, and hence it can be used to quantify the cell state. Despite numerous studies on the mechanical properties of RBCs much is still unknown about the relationship between deformability and the stable configuration of flowing cells in a confined rectangular channel. In this study, we numerically investigated the behavior of RBCs flowing at different $Capillary$ numbers (Ca) in a narrow rectangular microchannel that mimicked a microfluidic device. RBCs tend to exhibit asymmetrical shape for moderate Ca, while they show symmetrical shape for relatively low or high Ca. Since the slipper shape was only found at moderate Ca, measuring configurations of flowing cells will be helpful to quantify the cell state.

INTRODUCTION

It is well known that many blood-related diseases are associated with alterations in the geometry and membrane properties of red blood cells (RBCs) that result in reduced functionality [1]. Hence, cell deformability may be an important indicator of cell state, and might be used to diagnoses relevant blood diseases. Recent microfluidic techniques that are capable of high-throughput assay, and allows us to quantify the mechanical response of RBCs after spatial constriction in a confined microchannel [2]. Since the deformation of translating RBCs in the system is measured as projected two-dimensional configuration, a precise deformation especially in thickness direction of RBCs cannot be captured by means of the experimental observation. Along with the experimental study, recent computer simulation techniques have successfully been used to investigate aspects of cell dynamics [4, 5], where the RBC is modeled as a capsule than an inner fluid is enclosed by an elastic membrane. Since such numerical models allow us to investigate the effect of physical properties on cell behavior, the coupling of experimental and numerical approaches will be able to constitute a useful bioengineering strategy to quantify the cell state. The objective in this study, therefore, is to clarify the stable configuration of translating RBCs in a narrow rectangular microchannel. We numerically investigated the symmetry of the stable configuration of the deformed RBC for different Capillary number Ca, which is the ratio between the fluid viscous force and the membrane elastic force.

METHODS

We consider a cellular flow consisting of plasma and RBCs with radius a in a rectangular channel representing a microfluidic device with 10 μm $\times$ 3.5 μm along the wall-normal and span-wise directions, with a resolution of 16 fluid lattices per radius of RBC. The computational domain is shown in Fig.1(a) where the stream-wise length is set to be 50 μm. An RBC is modeled as a biconcave capsule, or a Newtonian fluid enclosed by a thin elastic membrane, with a major diameter 8 μm ($= 2a$), and maximum thickness 2 μm ($= a/2$). The membrane follows the Skalak constitutive law [3]. The flow was driven by a pressure gradient. Periodic boundary conditions were imposed on the inlet and outlet. To reproduce *in vivo* human RBC condition, the cytoplasmic viscosity was taken to be $\mu_1 = 6.0 \times 10^{-3}$ Pa·s, which is five times higher than the external fluid viscosity, $\mu_0 = 1.2 \times 10^{-3}$ Pa·s. Hence, the viscosity ratio λ ($= \mu_1/\mu_0$) was set to be 5. The problem was characterized by the capillary number $Ca = \mu_0 \dot{\gamma} a/G_s$, where G_s is the surface shear elastic modulus, and $\dot{\gamma}$ ($= U_m^\infty/H$) is the shear rate defined by the mean velocity of the external fluid without cell U_m^∞ and channel height H ($=$ 10 μm). The membrane was modeled as an isotropic and hyperelastic material that followed the Skalak constitutive law [3]. We used the lattice-Boltzmann method (LBM) coupled with the finite element method (FEM). These models were previously successfully applied to the analysis of cellular hydrodynamic interactions in channel flows [4]. More precise descriptions about numerical methods and model validations should be referred to our previous work [4, 5].

RESULTS & DISCUSSION

Figure 1(b) shows snapshots of a stable RBC configuration for different Ca at fully developed flow. The RBC demonstrated an almost unchanged (symmetrical) biconcave shape at small $Ca = 10^{-3}$, then shifted to an asymmetrical slipper shape as Ca increased. Such asymmetrical shape remains the same with twice the fluid mesh resolution [6]. Interestingly, similar asymmetrical shape can be also observed in the microfluidic device [6]. The RBCs finally attained a symmetrical parachute shape at further large Ca. To quantify the symmetry of the stable configuration of the deformed RBC, we propose a symmetry index ID_{sym}, which is defined by the volume ratio of two volumes that are divided by a plane parallel

*Corresponding author. E-mail: ntakeishi@me.es.osaka-u.ac.jp

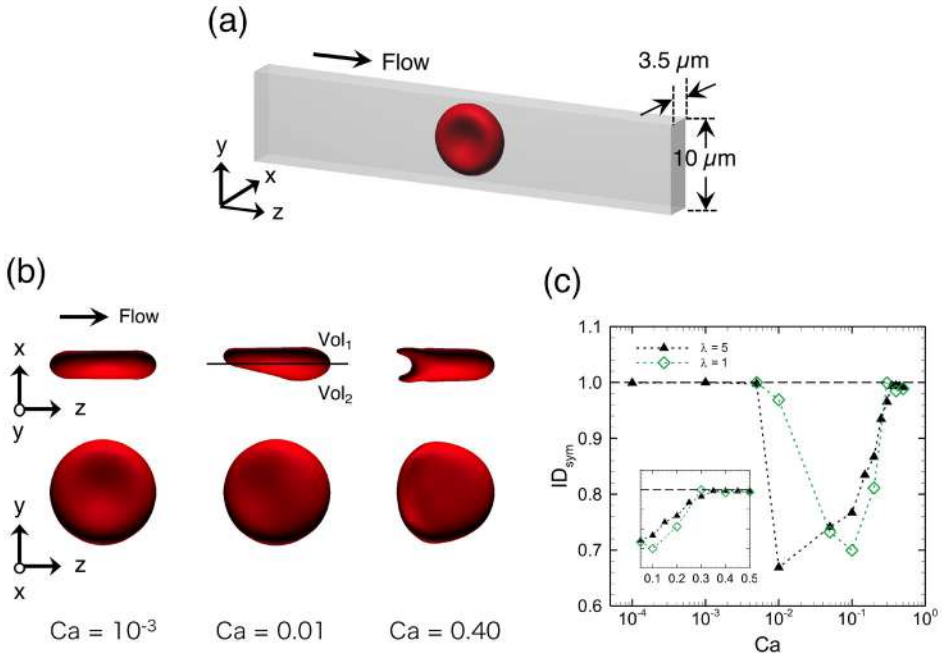

Figure 1: (a) Computational domain to reproduce a translating red blood cell (RBC) in the narrow rectangular microchannel. (b) Snapshots of a fully deformed RBC for different Ca at $\lambda = 5$, where the solid line denotes the center of the x-z-plane parallel to the flow direction, dividing the cell into the volume 1 (Vol_1) and volume 2 (Vol_2). (c) The symmetry index ID_{sym} as a function of Ca at $\lambda = 5$ (triangle) and 1 (diamond).

to the flow direction at the midline of the channel, as shown in Fig.1(b). Using volume 1 (Vol_1) and volume 2 (Vol_2), ID_{sym} is given as

$$ID_{sym} = \frac{MIN\,(Vol_1, Vol_2)}{MAX\,(Vol_1, Vol_2)}. \tag{1}$$

We show the results of ID_{sym} as functions of Ca in Fig.1(c). An asymmetrical parachute shape abruptly appeared for $Ca \geq 0.01$, but it gradually recovered and finally reached $ID_{sym} = 1$ for $Ca \geq 0.35$. These results suggest that there exists the following specific range of Ca that allows a RBC to deform into an asymmetrical slipper shape: $5 \times 10^{-3} < Ca < 0.35$. Figure 1(c) also showed that DI_{sym} was affected by λ. When λ decreased to unity (i.e., $\lambda = 1$), the membrane tended to assume a symmetrical shape even at relatively low $Ca = 0.01$. The most asymmetrical shape was found at at $\lambda = 5$, and the minimum $DI_{sym}|_{\lambda=1}$ shifted to larger $Ca \approx 0.1$ (Fig.1c). The value of DI_{sym} at $\lambda = 1$ started to recover beginning at $Ca = 0.1$, and finally almost reached ~ 1 at $Ca = 0.3$. Although we are not sure what perturbations are needed to destroy the stable symmetrical shape, identifying a stable mode of RBCs in a channel will be also helpful not only to understand the cell state but also to evaluate the blood rheology.

CONCLUSIONS

We numerically investigated the dynamics of translating RBCs in a narrow rectangular microchannel for different capillary numbers (Ca). Our numerical results showed that RBCs tend to exhibit asymmetrical shape for moderate Ca ($10^{-3} < Ca < 0.35$), while they show symmetrical shape for relatively low or high Ca ($Ca \leq 0.01$ or $0.35 \geq Ca$). The membrane deformation as a function of Ca remained the same even when the viscosity ratio λ decreased from physiological relevant value (λ = 5) to unity. If these shapes are found in diseased RBCs translating at specific velocities, the shapes will be an important indicator of cell state.

MINUET DANSE OF TWO CAPSULES IN SHEAR FLOW

Xu-Qu Hu[1,2], Dominique Barthes-Biesel[1], and Anne-Virginie Salsac*[1]
[1] Biomechanics and Bioengineering Laboratory (UMR CNRS 7338), Université de Technologie de Compiègne, Alliance Sorbonne Université, Compiègne, France

Summary We model the three-dimensional hydrodynamic interaction of a pair of spherical capsules freely suspended in a simple shear flow under Stokes flow conditions. The capsules are enclosed by a thin neo-Hookean elastic membrane and filled with a Newtonian liquid with the same density and viscosity as the suspending fluid. The motion and deformation of the capsules are modeled by means of a boundary integral technique coupled to a finite element method. Depending on their initial position and deformability, the two capsules may do a minuet danse: they oscillate about the flow gradient, get nearer to each other, finally interact strongly and separate. We identify the regions of space where simple crossing or minuet occur. This novel minuet motion leads to a significant capsule deformation (and potential damage), even when the interaction is initially weak.

INTRODUCTION

The hydrodynamics of pairwise interaction of deformable particles is a crucial topic for semi-dilute suspension rheology. The case of capsules (liquid drop enclosed by a thin elastic membrane) is complex because their motion and deformation result from non-linear fluid-structure interactions. Specifically, the capsules may be highly deformed as they cross each other, which may lead to potential damage of the membrane. This phenomenon is usually studied in a simple shear flow $\boldsymbol{v}^{\infty} = \{\dot{\gamma}\, x_2, 0, 0\}$ in a Cartesian reference frame centered on one capsule C_1, where $\dot{\gamma}$ is the shear rate. The center of the other capsule C_2 is initially positioned at $\boldsymbol{X}^{(0)} = \{X_1^{(0)}, X_2^{(0)}, X_3^{(0)}\}$. When the two capsules have their centres in the same shear plane ($X_3^{(0)} = 0$), C_2 is first displaced along the velocity gradient, 'jumps over' C_1 (*leap-frog motion*) and is shifted back towards the flow axis as it moves away (Figure 1a). The crossing leads to an irreversible trajectory shift along the x_2-direction. This phenomenon has been observed for initially spherical capsules (radius a) enclosed by a hyperelastic membrane [1, 2, 3, 4], for vesicles [5] and red blood cells [6]. The case of two capsules in different shear planes ($X_3^{(0)} \neq 0$) has been considered, since they are rarely in the same shear plane in practice: for a significant initial relative velocity ($|X_2^{(0)}| \geq 0.5a$), they do a sideways leapfrog motion [7, 5]. The objective of this paper is to investigate the three-dimensional motion of two capsules when their centroids are in or near the same x_1x_3-plane ($|X_2^{(0)}| < 0.2a$), a situation that has never been considered, but where close interaction and doublet formation may be expected to occur.

PROBLEM DESCRIPTION AND SOLUTION METHOD

We study the three-dimensional hydrodynamic interaction of a pair of identical, initially spherical capsules that are freely suspended in the simple shear flow $\boldsymbol{v}^{\infty}$ under Stokes flow conditions. The capsules are filled with a Newtonian liquid with the same density and viscosity μ as the suspending fluid. Their membranes are infinitely thin and satisfy the neo-Hookean constitutive law (surface shear modulus G_s), with negligible bending resistance. The relative flow strength is measured by the capillary number $Ca = \mu\dot{\gamma}a/G_s$. We concentrate on the case where the two capsule centres are initially located in two different shear planes ($X_1^{(0)} \neq 0, X_2^{(0)} = 0, X_3^{(0)} \neq 0$). The motion and deformation of the capsules are modeled by means of a boundary integral technique to compute the flow field, coupled to a finite element method to calculate the force exerted by the membranes on the fluids. We follow the motion and deformation of the capsules as they are convected towards each other after a sudden start of the shear flow.

MINUET DANSE VERSUS LEAPFROG

We first consider the situation where the two capsules are on the same streamline ($X_1^{(0)}/a = -8, X_2^{(0)} = 0, X_3^{(0)} = 0, Ca = 0.3$), in the shear plane where they remain under Stokes flow conditions. Although $X_2^{(0)} = 0$, the stresslet/rotlet disturbance created by C_1 displaces C_2 along the x_2-direction and thus convects it towards C_1. As shown in Figure 1a, the only way for C_2 to overpass C_1 is to 'leapfrog' over it in the x_1x_2-plane. Conversely, in the case $X_1^{(0)}/a = -2.6, X_2^{(0)} = 0, X_3^{(0)}/a = -2.6, Ca = 0.2$, capsule C_2 is located *off* the shear plane and can thus move freely in space. As shown in Figure 1b, C_2 catches up with C_1, interacts, overpasses C_1, reverses its motion and repeats the process twice before getting away: we call this process'minuet danse'. For successive close interactions (defined by $X_1 = 0$), the distance $|X_3|$ decreases (Figure 1b) and the capsule transient deformation increases (Figure 1c). The minuet danse may lead to damage

*Corresponding author. E-mail: anne-virginie.salsac@utc.fr.

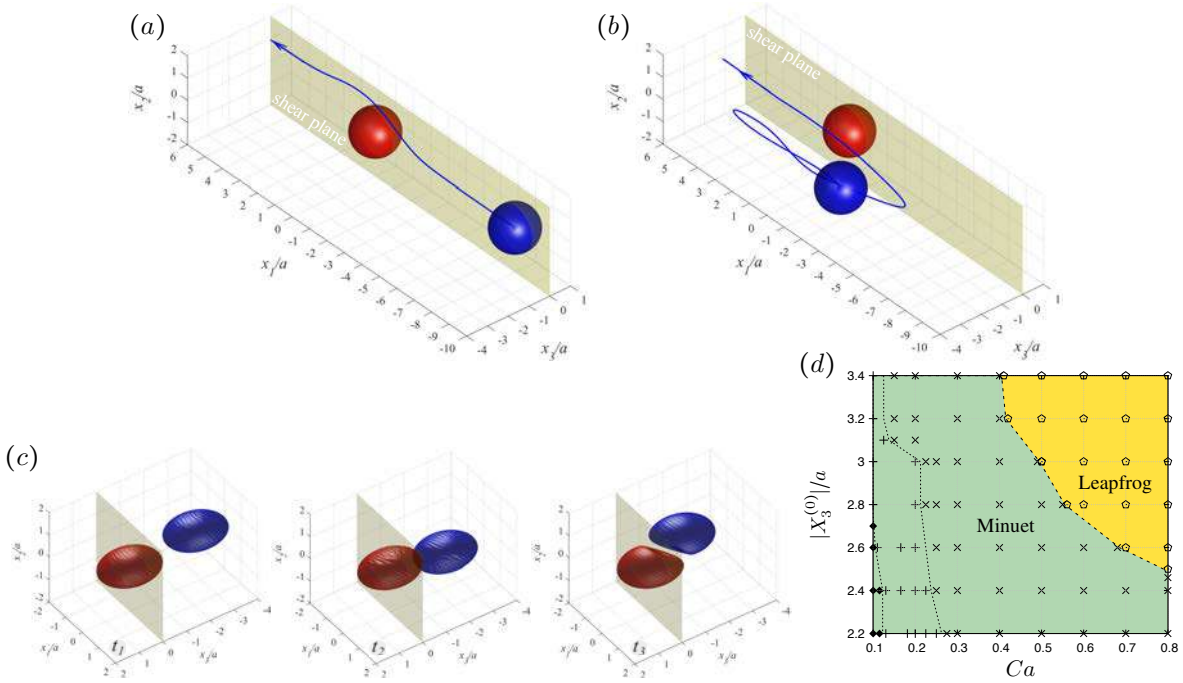

Figure 1: Trajectory of capsule C_2 (blue) in a reference frame centered on capsule C_1 (red). The two capsules are shown in their respective initial positions. (a) Leapfrog motion for $X_1^{(0)}/a = -8, X_2^{(0)} = 0, X_3^{(0)} = 0, Ca = 0.3$; (b) minuet danse with two reversions for $X_1^{(0)}/a = -2.6, X_2^{(0)} = 0, X_3^{(0)}/a = -2.6, Ca = 0.2$; (c) capsule profiles during close minuet interaction ($X_1 = 0$) at times t_1, t_2, t_3 in chronological order; (d) phase diagram showing the motion type as a function of position and deformability for $X_1^{(0)} = X_3^{(0)}$ and $X_2^{(0)} = 0$. The points represent the positions of C_2 at rest: × one oscillation, + two oscillations, ◆ three oscillations.

due to high transient deformation, whereas none was expected as the capsules were initially far apart (see the deformed profiles at the interaction time t_1 in Figure 1c). Depending on the capsule initial position and deformability, the minuet involves one, two or three reversals as shown in the phase diagram (Figure 1d). For non zero values of $|X_2^{(0)}|/a$ (less than 0.12), the boundary between leapfrog and minuet tends to occur for lower values of the distance $|X_3^{(0)}|$. This limited range of minuet motion explains why it had not been detected before. Note that if the capsules were pre-deformed to their steady profile in shear flow, they would take the same motion (leapfrog or minuet) as if they were initially spherical with only a small difference in the interaction times t_1, t_2, t_3. It follows that the minuet interaction is not restricted to the transient start of the flow of a suspension but is expected to occur steadily in a semi-dilute suspension under shear flow.

CONCLUSION

The situation that we have studied pertains to the pair interactions in a semi-dilute suspension of capsules. The novel aspect of our work is that we consider two capsules with their centres in (or near) the plane normal to the velocity gradient ($X_2^{(0)} \sim 0$). This configuration had never been studied before, because it entails long computations. The important results are (i) the pair can remain stable for a long time, while dancing a minuet, (ii) when they separate, the capsules can reverse direction, (iii) the less deformable the capsule, the more prone it is to do a minuet, (iv) this minuet dance progressively brings the capsules to closely interact and deform significantly: indeed, during the close interaction, the film thickness between the two capsules is of the order of $0.1a - 0.2a$. For small capsules, this may lead to physicochemical interaction.

Summary We perform boundary element simulations to describe the shape and stability of osmotically-deflated vesicles under a wide range of flows. The first half of this talk recaps vesicle dynamics in purely extensional flows, which are common in contractions, expansions, and/or suction flows. Above a critical flowrate, we find that find that moderately deflated vesicles undergo an asymmetric shape instability that is fundamentally different than droplet breakup. The physical origins of such shapes are discussed in detail and compared with microfluidic experiments. We will finish with simulations and experiments that describe vesicle shapes under general linear flows and large-amplitude oscillatory flows. The experiments will use a Stokes trap, a newly-developed technique that uses feedback control in a microfluidic device to trap particles under a given flow field for long periods of time.

OBJECTIVE

Vesicles are elastic and highly deformable sacs of fluid enclosed by a lipid bilayer. These entities are model systems to study physicochemical processes that occur in all cellular membranes. The shape and stability of vesicles are influenced by the type of flow, the elasticity of the membrane, as well the geometry of the flow channel. In turn, the shape of the vesicles influences their arrangement in the flow channel as well as the rheology of the medium. The conditions leading to vesicle fragmentation has been studied only in simple channel geometries and steady flows. A complete understanding of the physics of vesicle dynamics and stability under realistic non-equilibrium conditions is lacking, and achieving this knowledge will be invaluable for the manipulation of cells and vesicles in biomedical contexts. *The goal of this work is to use a combination of simulations, theories, and microfluidic experiments to investigate vesicle dynamics and stabilities under realistic flows (mixed- and time-dependent) and to understand how membrane elasticity confers stability.*

METHODOLOGY

Experiments: Vesicles are synthesized via electroformation, a technique where lipids on a conductive slide spontaneously swell upon addition of water and application of an AC electric field.[1,2] This procedure creates a polydisperse solution of unilamellar vesicles between 5-50 microns in size. To deflate the vesicles, an osmotic shock is applied through the addition of glucose, which is impermeable to the membrane. The lipids are a mixture of DOPC and a fluorescent dye for visualization (NBD-PC or rhodamine). Fig 1 shows snapshots of a osmotically-deflated DOPC vesicles at equilibrium. By visualizing the thermal fluctuations of the membrane, we can extract the membrane's bending modulus.[1,2]

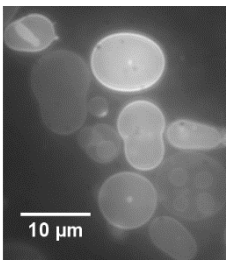

Fig 1: Osmotically deflated vesicles from electroformation[1]

The osmotically deflated vesicles are flowed into a Stokes trap,[1] a microfluidic cross-slot device with multiple inlet and outlet flows (Fig 2). By using an automated feedback loop on the inlet/outlet flowrates, one can generate a stagnation point in the device, as well as control the location, flow strength, and flow type of the stagnation point in real time. We use this device to hydrodynamically trap individual vesicles for up to a minute, and visualize their deformation over time. We use this information to understand what shapes the vesicles take in flow and identify shape instabilities that could lead to fragmentation.

Simulations: We model a vesicle as a droplet with a thin, elastic shell that represents the phospholipid bilayer. The elastic shell is area incompressible and has out-of-plane bending resistance. Thus, it is described by a Helfrich model with a bending modulus $\kappa \sim 5 - 50\ kT$. When placed under flow with a characteristic extension rate $\dot{\epsilon}$, there are several dimensionless groups that are important in describing the vesicle shape dynamics: (1) the viscosity ratio $\lambda = \mu_{in}/\mu_{out}$ between the fluid inside and outside the vesicle, (2) the reduced volume $\upsilon = 3\sqrt{4\pi}V/A^{3/2}$, where V and A are the volume and surface area of the vesicle, and (3) the bending capillary number $Ca = \mu_{out}\dot{\epsilon}a^3/\kappa$, which the ratio of viscous to bending forces on the surface, where $a = \sqrt{A/4\pi}$ is the vesicle's effective radius. The reduced volume tells the degree to which the vesicle is osmotically deflated. If the flow is time dependent and of mixed type (i.e., has vorticity + extension), there are additional dimensionless groups that describe the time scale of oscillation and the type of mixed flow.

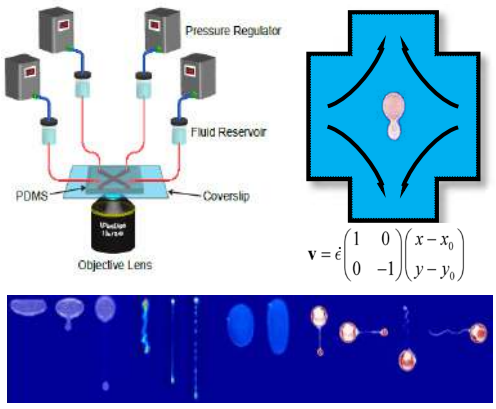

Fig 2: Top: schematic for Stokes trap. Bottom: pictures of vesicles stretched under planar extensional flow [1].

The simulations performed are based on the boundary integral formulation that has been used successfully to describe the flow physics of droplets, red blood cells, and vesicles. The technique uses

*Corresponding author. E-mail: vnarsim@purdue.edu

the fundamental solution to Stokes flow – the Green's function – to solve for the velocity on the vesicle surface due to the tension and bending forces. We discretize the vesicle surface into a triangular mesh and solve for the velocity field at each mesh point. Descriptions of the method are in references [3-5].

RESULTS

Fig 3 shows pictures of osmotically-deflated, DOPC vesicles under a planar extensional flow and corresponding simulation images. We have found that for moderately-deflated vesicles (reduced volume $0.60 < \nu < 0.75$), vesicles will stretch to an asymmetric dumbbell above a critical flowrate (i.e., critical bending capillary number). These shapes are fundamentally different than shapes observed during droplet breakup, and can be attributed to the incompressibility of the phospholipid bilayer. The physics of this shape transition can be shown to be a modified version of a classical Rayleigh-Plateau (i.e., capillary) instability,[3] with the following modifications: (a) the tension of the membrane is set by the flow, and (b) there is an additional bending resistance on the membrane.

When the vesicles are highly deflated and thread-like ($\nu < 0.60$), the vesicles stretch out symmetrically and sometimes form beads (i.e., 'pearls') in its central thread (Fig 4) [4]. These instabilities appear to be non-linear and hence depend on the initial conditions, especially in determining the number and size of beads formed. Again, we have been able to create phase diagrams that quantify these shape changes, and perform simulations to quantify the effects of different initial conditions [4].

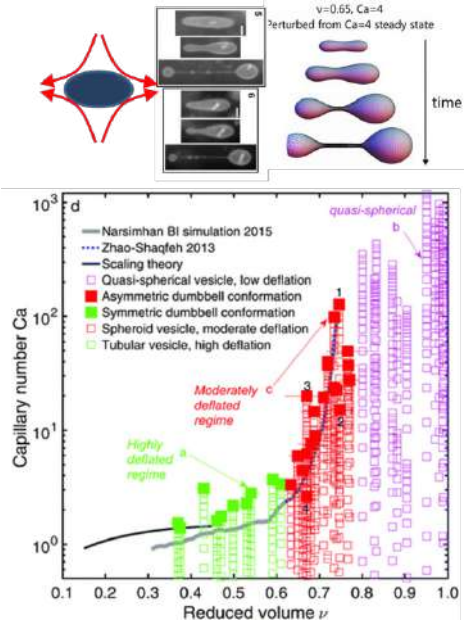

Fig 3: Top: Asymmetric dumbbell instability from experiments[2] and simulations[3]. Bottom: phase-diagram[1] of asymmetric and symmetric stretching modes under planar extensional flow.

Fig 4: Pearling instability and comparison to experiments [4] ($\nu = 0.38$, $Ca = 3.7$).

When the vesicle threads are stretched far from their initial shape and the flow is stopped, we can observe the vesicle relax to back to its original conformation. We observe two modes of relaxation – one associated with membrane tension and another associated with membrane bending. Interestingly, the volume of the vesicle appears to change after relaxation, which indicates that vesicles may undergo mechanoporation when subject to extreme strains. We are investigating the physics of this process in more detail.

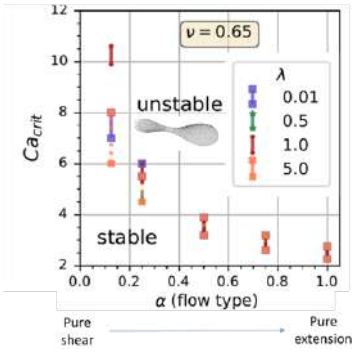

Fig 5: Onset of asymmetric instability vs. flow type for different viscosity ratios [5]

When vesicles are placed in a mixed linear flows (i.e., flows with vorticity and extension), we observe the asymmetric dumbbell instability depends greatly on the flow type [5]. Interestingly, vesicles do not appear to undergo shape instabilities under pure shear flow (Fig 5). This observation is vastly different than what is observed for droplets, which readily stretch and break up under shear. This phenomenon can be described using simple scaling/geometric arguments.[5]

Lastly, we will discuss some preliminary results for osmotically-deflated vesicles in time-dependent flows. We examine the deformation of giant, unilamellar vesicles under large amplitude, oscillatory extension (LAOE) to determine how their shapes evolve under time, and how these shapes play a role in non-linear rheology. We are in the process of developing phase diagrams that map different dynamical regimes for different flow rates and flow frequencies, for a wide range of reduced volumes. Interestingly, since vesicles experience compression during a half cycle of oscillatory flow, they can experience buckling (see Fig 6 for vesicle thread).

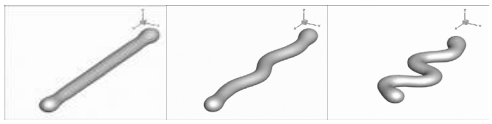

Fig 6: Vesicle thread buckling under planar compression from simulations

CONCLUSIONS

Vesicles and other cellular objects exhibit a rich set of dynamical behaviours under flow, due to the incompressibility of their phospholipid membrane and their non-spherical shapes when deflated. Observed shape instabilities include (a) asymmetric dumbbell stretching, (b) symmetric stretching, (c) pearling, and (d) wrinkling/buckling. We quantify the conditions under which many of these instabilities occur through simulation and microfluidic experiments, which hopefully will give better understanding on how to manipulate such biological objects under a wide range of contexts.

TRACKING THE SOURCE OF A PASSIVE SCALAR IN TURBULENCE

Rémi Monthiller *[1], Christophe Eloy[1], and Benjamin Favier[1]
[1] Aix Marseille Univ, CNRS, Centrale Marseille, IRPHE, Marseille, France

Summary How to find the source of an odour in a turbulent flow using only chemical cues? This problem is essential for the survival of plantkonic organisms since it affects feeding, mating and escaping predators. Darwinian selection has likely selected efficient solutions to solve this tracking problem, but the algorithms used by plankton are not yet known. In an attempt to reverse-engineer these algorithms, we have developed a 3D numerical environment, which allows us to simulate efficiently the advection-diffusion of a passive scalar together with the Lagrangian trajectories of active particles. To demonstrate the interest of this numerical environment, we address how sea slug larvae settle on coral reefs in response to chemical cues emitted by the coral [1].

CONTEXT: ODOUR TRACKING PROBLEMS

The survival of many organisms depend on their ability to locate targets (food, mate, predators) based on chemical cues [2]. Understanding this behaviour is needed to model ecosystems, but it also has applications to the conception of odour-tracking robots [3]. Copepods, that are millimetric crustaceans extremely abundant in fresh-water and marine environments, are model organisms to study this behaviour. Being blind, they use hydrodynamic and chemical sensing to detect preys, predator and mates [4]. To make the task even harder, copepods usually live in a turbulent flow. This flow not only stretches and stirs the chemical patches, but also induces a drift and a rotation of the copepods themselves. Yet, copepods have been very successful as species. Thus, they likely developed smart strategies to track odour in complex environments varying over space and time. However, these strategies and their fundamental properties are not fully understood.

APPROACH: DEVELOPMENT OF A VIRTUAL ENVIRONMENT

We have developed a 3D virtual environment to model the advection-diffusion of a passive scalar and the Lagrangian trajectories of active particles. The major challenge is to capture accurately the passive scalar field at each instant while remaining time-efficient. To address this challenge, we use kinematic simulations for the turbulent flow, the Diffusive Sheet Method (DSM) for the scalar field, and Jeffery's orbits for the active particles.

Our kinematic simulations aims to simulate homogeneous isotropic turbulence. It models the flow as a superposition of random Fourier modes varying in space and time over realisations [5]. These modes satisfy the incompressibility condition and their amplitude is chosen to match the Kolmogorov energy spectrum.

To track accurately the passive scalar in the turbulent flow, we use the Diffusive Sheet Method [6]. In turbulence, we expect the initial concentration to be stretched into an extremely thin convoluted sheet. This method is based on the Lagrangian tracking of this thin sheet with diffusion mainly occurring in the direction normal to its surface. Triangular surface elements are used to represent the advection and stretching of the sheet (Figure 1). To maintain an accurate resolution, triangulation is refined as the surface grows. Besides, the triangular elements whose concentration fall below a detection threshold are removed from the simulation, thus preventing the exponential blow-up of the number of triangular elements.

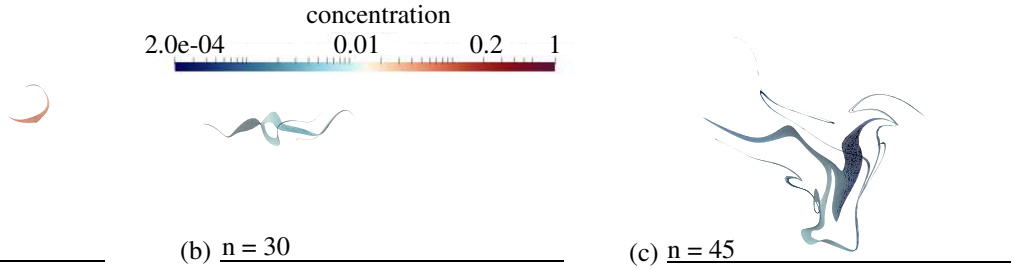

Figure 1: Illustration of the Diffusive Sheet Method [6] in a pseudo-turbulent flow. Initially a single triangular element is placed in the simulation box. The figure shows the advection and stretching of this initial distribution of passive scalar: (a) after 15 time steps, (b) after 30 time steps (c) after 45 time steps. The flow is simulated using kinematic simulation with 100 modes.

To complete this numerical environment, active particles are represented as ellipsoids smaller than the Kolmogorov length scale. Jeffery's orbits [7] are used to model how the flow affects the motion of the active particles. Thus, agents (1) drift with the local mean flow, (2) rotate with the vorticity, (3) rotate because of the strain components of the flow, and (4) actively swim in response to chemical sensing cues.

Using the previously described methods, the virtual environment is setup as an Open Source Library front-ended in Python. The complex and time-consuming algorithms are written in C++ to optimise performances.

EXAMPLE: SEA SLUG LARVAE SETTLING ON CORAL REEFS

Before simulating the behaviours of complex organisms such as copepods, we first focus on a simpler problem. We address how sea slug larvae settle on corals based on the sensing of chemicals produced by the corals and transported by a turbulent flow. Koehl et al. [1] proposed a simple individual-based behavioural model of this problem where individual larvae have an on/off behaviour: when no chemical cue is detected, individuals swim and when the concentration is above a certain threshold, they stop swimming and sink because of their negative buoyancy. Based on a simple 2D numerical model, they showed that this simple individual behaviour is sufficient to increase significantly the success rate of settling on the corals.

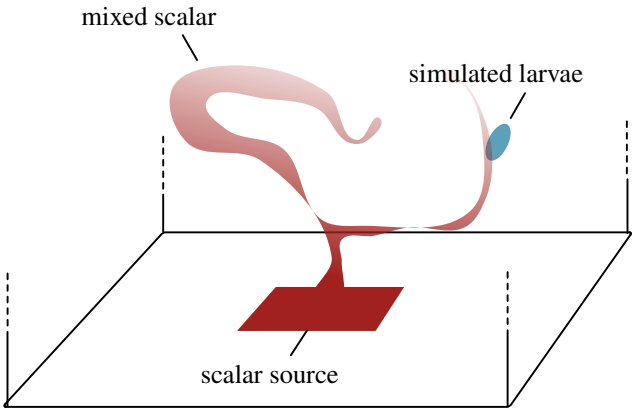

Figure 2: Illustration of the numerical setup in the example case.

We use our virtual environment to reproduce this specific tracking problem (Figure 2). Our aim is to assess the performance of the on/off behaviour and recover the results of Koehl et al. [1]. Besides, our model can be used to quantify the importance of the different parameters on the success rate (turbulence level, concentration threshold, swimming velocity, bottom-heaviness...) and thus inform us on how Darwinian evolution may have selected particular traits.

IN VITRO ANALYSIS OF TIME-DEPENDENT RED BLOOD CELL PHASE SEPARATION IN A COMPLEX MICROCHANNEL NETWORK

Alberto Mantegazza *[1], Francesco Clavica[1,2], and Dominik Obrist[1]
[1] ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Switzerland
[2] Integrated Actuators Laboratory, Ecole Polytechnique Fédérale de Lausanne, Neuchâtel, Switzerland

Summary In this study we provided quantitative data on red blood cell (RBC) partitioning in 21 divergent bifurcations embedded in a complex *in vitro* network. In the majority of bifurcations the branch receiving a higher blood fraction received an even higher RBC fraction (*classical partitioning*). However, in some bifurcations the low-flow branch received a higher RBC flow fraction (*reverse partitioning*). Moreover, we found that the phase separation is strongly time-dependent and some selected bifurcations oscillated between the two types of partitioning.

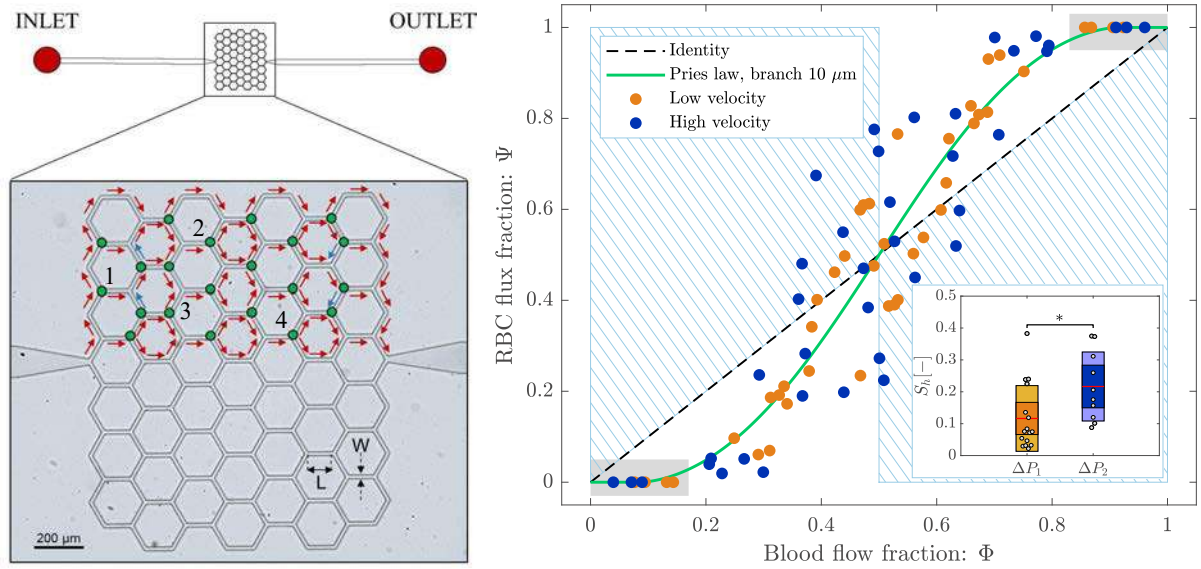
INTRODUCTION

The topology of microvascular networks is complex and characterized by multiple diverging and converging blood vessels and the red blood cell (RBC) partitioning (i.e. *phase separation*) at diverging bifurcations is non-uniform. In our recent study [1], the RBC phase separation was investigated in a microvascular network model featuring many sequential symmetric bifurcations (Figure 1(a)). The time-averaged results (Figure 1(b)) confirmed that in most diverging bifurcations the branch with the higher blood flow fraction Φ received an even higher RBC flux fraction Ψ (*classical partitioning*). However, in agreement with computational results [2], an inversion of the classical phase separation behaviour (*reverse partitioning*) was observed for diverging bifurcations with skewed hematocrit profiles in the parent vessel. The hematocrit profile skewness (inset of Figure 1(b)) and the reverse partitioning were enhanced for high flow velocities.

In this study, we examined in detail the origin of these time-averaged phase separation results by investigating how cell partitioning evolves in time at specific bifurcations in the network (time-dependent phase separation).

MATERIALS AND METHODS

The PDMS microdfluidic device was fabricated via soft-lithography and replica molding. It embedded a network with 49 hexagonal elements and 176 microchannels. All microchannels dimensions (width $W = 10\ \mu m$, height $H = 8\ \mu m$ and length $L = 85\ \mu m$, Figure 1(a)) were inspired by the typical length scales found *in vivo*.



(a) (b)

Figure 1: (a) Microscope image of the microchannel network. Red and blue arrows indicate the direction of blood and plasma flow, respectively. Green dots represent diverging bifurcations considered in this study. (b) Phase separation results for the low (orange) and high (blue) velocity experiments (adapted from [1]). The green line is the empirical low from Pries [3]. The inset shows that the skewness hematocrit index (S_h) is statistically significantly ($p = 0.014$) higher for the high velocity experiment.

The working fluid was a suspension of RBCs at feeding hematocrit $H_f = 10\%$ dispersed in a water-based buffer fluid. The final solution matched the density and viscosity of physiological blood. The flow was controlled by setting a pressure

*Corresponding author. E-mail: alberto.mantegazza@artorg.unibe.ch.

MINI SYMPOSIA

difference between the fluid level in the reservoir and the device outlet ($\Delta P_1 = 35.3\ mbar$ and $\Delta P_1 = 47.1\ mbar$, hereafter referred as *low velocity* and *high velocity* experiments, respectively).

Particle Tracking Velocimetry (PTV) was performed on the image sequences to compute RBC velocity ($U_{rbc}[mm/s]$) and tube hematocrit ($H_t[-]$) in each channel of the top half of the network. Similarly to Mantegazza *et al.*[1], the RBC flux and the total blood flow rate in a Region Of Interest (ROI, $width = W_{ROI}$, $heigth = H_{ROI}$) were computed as

$$Q_{rbc}(t) = U_{rbc}(t) \times H_t(t) \times W_{ROI} \times H_{ROI}, \tag{1}$$

$$Q_{blood}(t) = U_{rbc}(t) \times W_{ROI} \times H_{ROI}. \tag{2}$$

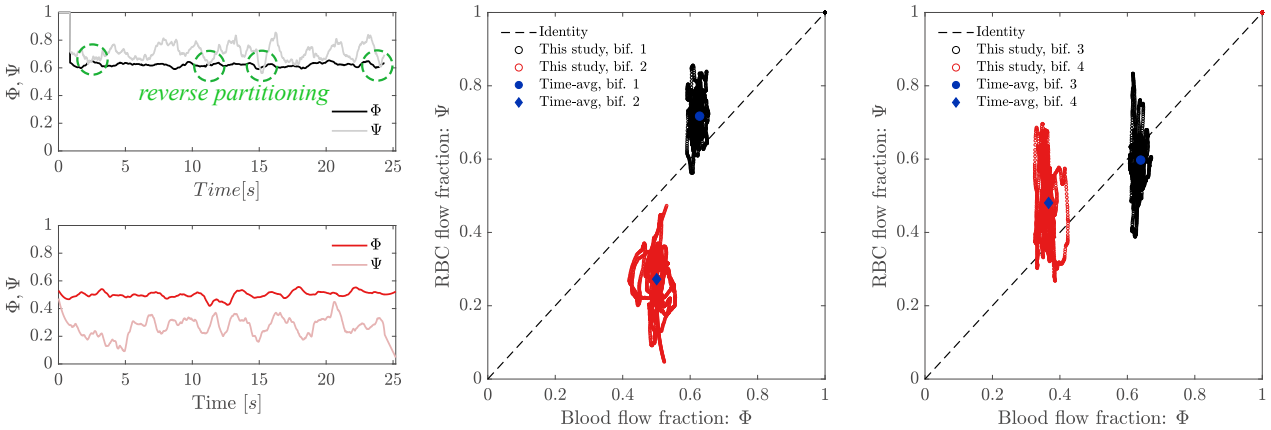
The fractional RBC flux ($\Psi^i(t)$) and the fractional blood flow ($\Phi^i(t)$) in the daughter branch i were given by

$$\Psi^i(t) = \frac{Q^i_{rbc}(t)}{Q^P_{rbc}(t)}, \quad \Phi^i(t) = \frac{Q^i_{blood}(t)}{Q^P_{blood}(t)}, \tag{3}$$

where $i = 1, 2$ denotes the daughter branch 1 and 2 of a generic bifurcation and P denotes the parent branch.

RESULTS AND DISCUSSION

We found that the RBC fluxes $\Psi^i(t)$ and blood flow rates $\Phi^i(t)$ are strongly time-dependent (Figure 2(a)). Even if the time-averaged phase separation is classical (Figure 2(b)) or reverse (Figure 2(c)), the time-dependent phase separation is not constant and it can switch between the two types of partitioning (data are scattered above and below the identity lines in Figure 2(b) and (c)). In agreement with the computational results of Balogh and Bagchi [2], we report that in a complex microchannel network a bifurcation could have a classical partitioning with intermittent episodes of reverse partitioning or vice versa. The origin of these fluctuations may be connected to the temporary difference of the daughter branch resistances due to the passage of individual RBCs.



(a) (b) (c)

Figure 2: Time-dependent phase separation (high velocity experiment). (a) Time sequence of $\Phi^i(t)$ (black and red) and $\Psi^i(t)$ (grey and pink) for bifurcations 1 and 2 (cf. Figure 1(a)) exhibiting a time-averaged classical partitioning. (b) $\Phi - \Psi$ diagram for the sequences shown in Figure 2(a). The classical partitioning occurs when $\Psi^i(t) > \Phi^i(t)$ for $\Phi^i(t) > 0.5$ (and vice versa). (c) $\Phi - \Psi$ diagram for bifurcations 3 and 4 (cf. Figure 1(a)) exhibiting a time-averaged reverse partitioning. The reverse partitioning occurs when $\Psi^i(t) < \Phi^i(t)$ for $\Phi^i(t) > 0.5$ (and vice versa). The solid circles indicate the time-averaged results (cf. Figure 1(b)) corresponding to the bifurcations 1,2,3 and 4 indicated in Figure 1(a).

CONCLUSIONS

For the first time we provided *in vitro* quantitative data on the time-averaged and time-dependent RBC partitioning in a complex network and we showed that both time-averaged classical and reverse partitioning contemporary occurred in the network and that selected bifurcations can cycle between the two types of partitioning over time.

DYNAMIC RESPONSE OF A FLAGELLATED ARTIFICIAL MICRO-SWIMMER ACTUATED BY ACOUSTIC POWER

Jinan Liu and Haihui Ruan *
Research Center for Fluid-Structure Interactions, Department of Mechanical Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong, China

Summary This work describes a theoretical study on a flagellated artificial micro-swimmer which consists of a rigid head and a flexible flagellum. We first clarified the dependence of head oscillation amplitude on acoustic pressure and frequency, and then employed the resistive force theory to relate the motility of a micro-swimmer and the dynamic response of the flagellum. The inertia and material damping were involved in the governing equation and the variable cross-section of a flagellum was also considered. We first validated the model by comparing the theoretical results with experimental results and then discussed the influences of several key nondimensional parameters and the results of optimization.

INTRODUCTION

The actuation and manipulation of micro-scaled robots have not been realized until the recent decade with the booming development of microfabrication. Among many potential applications, medical implementation could be the most significant impetus [1]. For example, it can be envisioned that a swarm of sperm-like micro-swimmers could be directed to the position of lesion under an external acoustic excitation, as shown in Figure 1(a).

However, the theoretical model of micro-swimmers is still lacking. Although acoustophoresis due to acoustic streaming has been well known, the particles that can be moved by sound is too small to carry medical functionalities. Recently, two new experiments on acoustic actuation have been reported in the open literature [2, 3]. These two works bring about an actuating mechanism different from the conventional acoustophoresis. It is observed that the dynamic response of the flagella of the artificial micro-swimmers described in these two works is similar to the wiggling of a biological flagellum [4], where the propulsive force can be determined based on the theories developed in the low-Reynolds-number regime [5]. In this regime, the resistive force theory (RFT) is widely adopted to explain the motion of microorganisms [6]. Therefore, the present study attempts to make clear the actuation mechanism of an acoustic wave that leads to the forward motion of a flagellum composed of a rigid head and a flexural tail. It should be noted that the inertia of the flagellum was not involved in most previous models of living microorganism based on RFT. Nevertheless, the foundation of the RFT is the Stokes equation, wherein only the inertia of fluid is neglected. In addition, the expression of the Reynolds number is related to the density of the fluid but irrelevant to that of a flagellum. Therefore, it is necessary to scrutinize the effect of inertia of a flagellum especially when the flagellum whips at a high frequency under external actuation. In order to make our model applicable in optimization an actual micro-swimmer design, we have further involved the effects of material damping and non-uniform flagellum cross-section in our analysis, which were not fully considered in previous theoretical works on flagellum propulsion.

MODELING AND RESULTS

Motion of the head

We denote the motion of the rigid head by the lateral displacement $u(t)$ and rotation $\theta(t)$. Under an acoustic actuation, it is intuitive to presume that both $u(t)$ and $\theta(t)$ should be periodic with the acoustic frequency f, that is $u(t) = u_0 \sin \omega t$ and $\theta(t) = \theta_0 \sin(\omega t + \varphi_h)$, where $\omega = 2\pi f$ is the angular frequency of the actuation, u_0 and θ_0 are the amplitude of the head oscillation. The phase angle difference between the translational and rotational motion is denoted by φ_h.

To understand the actuation mechanism, 3D finite element simulations for the head motion were carried out by using the software package COMSOL Multiphysics. Following Kaynak *et al*. [3], the head is assumed to be cone-shaped with two hemispherical ends, as depicted in Figure 1(b), where the white area is the head domain. It is featured by the radius r_1, r_2 ($r_1 > r_2$) of the end spheres and the distance d between their centers, and the line between the two centers is set to be the longitudinal axis of the head. The head is initially placed at the center of a box containing viscous fluids at room temperature. A transient sound pressure distribution is exhibited in Figure 1(b). In the simulation, the longitudinal motion of the head is constrained; the surface of the head is a sound hard wall; and a plane wave is incident from the lower boundary. The results confirm that the displacement and rotation of the head are both harmonic functions of time with frequencies identical to the acoustic frequency. The oscillating amplitude of the head is found proportional to the sound pressure p and the reciprocal of acoustic frequency $1/f$. The coefficients of proportionality can be extracted from the simulation results, which also tallies with the theoretical expectation of the case for an acoustic particle actuated by a plane wave [7]. These coefficients vary with the geometry of the head. It is found that the rotational motion strictly vanishes if a head is symmetric about a transverse plane (i.e., $r_1 = r_2$), but becomes nonnegligible for a droplet-like (i.e., $r_1 > r_2$) head. Noted that the phase angle difference φ_h is always 180° if the acoustic wave vector is normal to the longitudinal axis of the head. But it could slightly deviate from 180° if the incident wave is oblique.

Dynamic response of the flagellum

We assume that the head of a micro-swimmer whips the flagellum in the plane of acoustic wave propagation. The length of the flagellum is denoted by L and the cross-section is assumed to be a circle of area A. The flagellum is treated as a cantilever Euler-Bernoulli beam agitated by the motion of the clamped end (i.e., the head), resulting in the dynamic response $z(x, t)$, where z and x are the transverse displacement and the coordinate along the flagellum. The Young's modulus, flagellum density and the second moment of area are respectively denoted by E, ρ and I. The material of the micro-swimmer is assumed to be a Kelvin-Voigt viscoelastic material, and we denote η as the viscosity. Based on the RFT, the fluid force perpendicular to the flagellum $F_\perp$ and the force parallel to the flagellum $F_\parallel$ can be considered proportional to the local transverse velocity $\partial z/\partial t$ and longitudinal velocity, respectively. The drag coefficients are denoted by $c_\perp$ and $c_\parallel$, respectively. Then, the terminal velocity v_{prop} can be estimated from the equation: $F\cos\psi - F_\perp \sin\psi = F_{\text{head}} + \int_L c\, v_{\text{prop}}$, where ψ is the slope angle of the flagellum and the fluid force of the head F_{head} depends on the head dimension. The Galerkin method is employed to solve the governing equations.

Some non-dimensional parameters are introduced for discussion. The motility of the micro-swimmer V_{cs} is defined as $V_{cs} = c\,\bar{v}_{\text{prop}}/(Lf)$, where $\bar{v}_{\text{prop}}$ is the time-averaged terminal velocity and the factor c reflects the relative resistance between the head and the flagellum. $\gamma = \eta\omega/E$ denotes the material damping coefficient. $w_0 = u_0/L$ is the non-dimensional head amplitude. For the case of a uniform flagellum, we have introduced the following two non-dimensional parameters: $S_p = L\sqrt[4]{2\pi c_\perp f/(EI)}$ and $\omega_{ns} = \omega L^2\sqrt{\rho A/(EI)}$, which are named the sperm number [8] and the resonance index, respectively. The sperm number indicates the relative importance of external fluidic drag to the internal elastic stress on a flagellum. The resonance index can be used to illustrate the effect of resonance on the motility. For the case of the non-uniform flagellum cross-section, we assume that the diameter D of the flagellum reduces from the root to the tip, which is expressed as: $D(x) = D_0\left[1 - K_s(x/L)^\Lambda\right]$, where K_s and Λ are constants, and D_0 represents the largest diameter at the root.

Since the tapered flagellum has been adopted in Kaynak *et al.*'s micro-swimmer [3], we prescribe the parameters based on an estimate of their work. Specifically, in Figure 1(c), we set D_0 = 25 μm, L = 180 μm, E = 10 MPa, ρ = 1200 kg/m^3, γ = 5, f = 4600 Hz, K_s = 0.9 and Λ = 1 along with a spherical head with the radius of 25 μm. The fluid viscosity is set to be 1 Pa·s. The geometric meaning of K_s = 0.9 is illustrated in the top-left inset of Figure 1(c), where the diameter of the root is 10 times that of the tip. The curve shown in Figure 1(c) demonstrates a reasonable agreement with the experimental results in [3]. Correspondingly, the calculated wiggling profiles of the flagellum for u_0 = 12 μm are shown in the bottom-right inset of Figure 1(c). The obtained profiles also resemble the experimental results. Other numerical results indicate that a large K_s and small Λ would be better in achieving a high motility. To explicate the effect of resonance and material damping on V_{cs} of a uniform elastic flagellum, we also explored the variation of V_{cs} in terms of S_p and ω_{ns} upon a prescribed head actuation. The numerical results indicate that the most efficient way to achieve a high motility is to design the flagellum that achieves resonance. We found that the higher motility generally comes with the narrower frequency bandwidth, and a large S_p or a moderate material damping is beneficial to broaden the bandwidth at resonance. In non-resonance regimes, the high motility can be achieved in a range of S_p; and the effect of a moderate γ is to shift this range of sperm number to the lower side. Undoubtfully, excessive γ reduces the motility of the micro-swimmer.

Summary Several diseases are related to haemodynamics and require a better understanding of blood flow and related transport mechanisms. The presentation will give an overview of recent work towards reduced-order models informed by cell-based blood flow simulations in complex geometries, such as segments of the retina. The reduced-order models depend on the spatial distribution of red blood cells in microvascular segments and their development along the flow axis via cell-cell interactions and lift forces. In the future, these models could be used to simulate organ-level blood flow with significantly reduced computational cost, making these models more attractive for clinical applications.

INTRODUCTION

Every year, millions of people worldwide are affected by blood-related diseases, such as malaria, cancer or sickle cell anemia. Understanding disease pathways, the role of blood flow and the effect on haemodynamics and solute/particle transport is crucial for the development of diagnostic tests and informing treatment options. Since in-vivo blood flow experiments are challenging, there has been a recent increase in modelling of blood flow in disease [1]. Blood flow modelling becomes particularly challenging at the scale of arterioles and capillaries where the diameters of blood vessels and red blood cells (RBCs) are similar. In these cases, computationally expensive cell–based models are still required to uncover suspension flow effects and predict cell distribution and tissue oxygenation. Deformable RBCs are typically modelled as hyperelastic or viscoelastic capsule–vesicle hybrids that are fully coupled to the ambient fluid flow and capture the cell deformation and dynamics on the micron level [2]. In order to enable more quantitative predictions in larger blood vessel networks (e.g. on the organ level), more efficient reduced models are required.

NOVELTY AND RESULTS

There has been recent effort to better understand cellular blood flow in complex geometries [3]. A key challenge is the distribution of RBCs at diverging bifurcations where the flow ratio of RBCs is usually different from the suspension flow ratio [4, 5]. This well-known effect is caused by the existence of the cell-free layer.

However, existing models [6] do not consider the finite recovery length of the RBC distribution after a perturbation (e.g. via an upstream bifurcation or constriction) and the resulting bias of the RBC split at downstream bifurcations. This effect is illustrated in Fig. 1. If consecutive bifurcations are sufficiently close, which often is the case in solid tumours, the RBC split bias can accumulate, therefore potentially affecting the organ-level perfusion and oxygenation.

The presentation will show results obtained via the highly parallelised lattice-Boltzmann-based code HemeLB from a) consecutive bifurcations (see Fig. 1), b) bifurcations after a geometric perturbation and c) retinal networks (see Fig. 2). Based on these microscopic results, I will sketch the development of a reduced-order model that is able to predict RBC split based on few parameters, such as distance between bifurcations and asymmetry of the cell-free layer. In the future this model will be consolidated to enable organ-level perfusion and oxygenation without the need to run computationally expensive RBC-level simulations. Until then, microscopic RBC simulations are still necessary to uncover the physics and delicate flow details responsible for RBC distribution in complex geometries.

WICKING OF BIO-FLUIDS FOR PAPER BASED DIAGNOSTICS

Summary The field of paper-based biodiagnostics has received attention recently for its potential to create fast, cheap and portable medical devices. However, much of the design of these devices is based on trial and error due to a lack of understanding of the controlling processes. This includes wicking from a finite source such as a droplet and the effect of biological components such as cells and surface active proteins, forming a complex fluid. Here, the radial wicking of a blood droplet and its components is investigated on a paper substrate using high speed photography and numerical modelling. The dominant effect blood components have on wicking is identified to be an intensifying of porosimetry hysteresis. This is due to an increase in the advancing contact angle caused by protein adsorption onto cellulose fibers in paper.

INTRODUCTION

The radial wicking of a droplet on paper is a complex fluid dynamics scenario. Here, absorption of the droplet into the paper a finite time after deposition causes a decrease in spreading rate that can be identified by plotting the stain area against time on a log-log scale (Figure 1). The two stages are observed and are referred to as stage one, where the drop is still present above the paper and stage two, where the drop has been completely consumed. Before the transition, spreading is driven only by the infiltration of pores near the edge of the stain. After the transition the reservoir of fluid vanishes and any further stain growth is caused by the redistribution of fluid from the large pores to the unfilled small pores at the edge of the stain. This occurs due to the greater magnitude of capillary force causing a low pressure in small pores [3]. In addition to droplet absorption, the stain growth transition was also shown to depend on a hysteresis effect because of differences between filling and emptying porous networks [4]. This effect is only relevant in the second stage as before stage transition, no pores are emptying. The cause of this hysteresis is poorly understood and is likely to be material and fluid dependent. However, the most likely causes are liquid entrapment due to poor interconnectivity, contact angle hysteresis and fiber swelling.

The effect that blood components such as cells and proteins have on wicking in paper is poorly described and understood. However, droplets containing blood proteins were shown to create lower equilibrium stain sizes on paper and to have a higher advancing contact angles on cellulose than simple fluids [2]. The objective of this study is to identify the primary impact blood components have on the radial wicking process.

METHODS

Droplets of whole blood and plasma were placed on paper substrates and their stain growth was monitored with high speed photography. These are compared with results of simple water-ethanol and water-glycerol solutions [1] to separate the effect of biological components from changes in viscosity and surface tension. An axisymmetric numerical model based on Richard's equation was developed, incorporating effects of hysteresis by expressing contact angle as a function of the temporal gradient of local volume fraction.

RESULTS

Figure 1 shows the evolution of the measured stain area with time for 20 μL droplets of different fluids analysed on both a linear and log-log scale. The log-scale is shown because the time of stage transition is clearly identified on this scale, and the local gradient in each stage is equivalent to the power dependence of the relationship of stain growth with time. Results from non-biological fluids varying in viscosity and surface tension [1] show that first and second stage gradients are constants independent of physical fluid properties. However, results from biological fluids reveal the second stage log-scale gradient to vary significantly between fluids. This indicates that biological components are responsible for the reduction in the log-scale gradient in the second stage but do not affect it in the first stage.

The difference between first and second stage gradients was previously shown to be caused by hysteresis [1], and modelling results indicate that an intensified hysteresis effect results in a lower second stage power. Therefore, the observed decrease in the second stage log-scale gradient of biological fluids is likely to be caused by an intensification of the hysteresis effect. In this case, the intensification is due to the higher advancing contact angles for biological fluids on cellulose.

CONCLUSION

Understanding the radial wicking of biological fluids is important for the design of paper-based diagnostic devices. Previously two stages have been identified. These stages are defined by whether or not the droplet is still present above the paper. As the majority of stain growth occurs in the second stage, this regime deserves particular attention. Porosimetry hysteresis coupled with absorption of the droplet into the paper have been identified as the causes of the observed stain growth transition where the log-scale gradient of stain growth with time changes abruptly. Hysteresis effects are intensified in biological fluids due to protein adsorption, and therefore the second stage behavior of such fluids is unique. A Richard's equation continuum model was developed, incorporating the effects of hysteresis. This can be used to aid design of the next generation of fast, cheap and portable paper based diagnostic devices.

MODELLING OF THE DAMAGE OF A LIQUID-CORE CAPSULE UNDER SIMPLE SHEAR FLOWUNTIL INITIATION OF RUPTURE

Summary Capsules are composed of a droplet surrounded by a deformable membrane of small thickness. When capsules are subjected to an external flow, the viscous forces can damage the capsule membrane and lead to its breakup. To study capsule damage until initiation of rupture, we develop the first fluid-structure interaction (FSI) model of a capsule in flow taking into account the damage of the membrane. We apply the framework of continuum damage mechanics and model the membrane with an isotropic brittle damage model. The problem of the membrane is solved with the finite element method and the internal and external fluid problems are solved with the boundary integral method. We study the influence of the dimensionless parameter governing the FSI which is the capillary number, ratio of the fluid viscous forces to the membrane elastic forces, and determine the criteria needed to control rupture.

INTRODUCTION

Capsules composed of a droplet surrounded by a deformable wall are used in numerous industrial applications to protect and ensure the controlled delivery of an active agent. When capsules are in flow, the viscous forces from the external flow can damage the capsules, potentially until breakup. Damage corresponds to the formation of microdefects in the wall which modify the properties of the capsule locally and thus the exchanges between the inner and the outer fluids. As a domino effect, it can lead to rupture as the accumulation of the microdefects can initiate a crack that propagates over the wall. The protection/release of the encapsulated agent is thus conditioned by the control of the damage of the capsule.

There are numerous contributions on the study of the dynamics of capsules in flow [1]. Few of them have, however, studied the rupture of capsules: the approach has only been experimental (see e.g. [2, 3]). The damage phase in the rupture process has thus never been studied. We propose to enrich a fluid-structure interaction model by modelling damage at the macroscale using the framework of continuum damage mechanics (CDM) (see e.g. [4] for a recent review), that offers a systematic approach of rupture for structures. In this work, we incorporate, for the first time, a CDM model into a fluid-structure interaction framework and study the damage process of a capsule in flow until the initiation of rupture.

MODEL

We consider an initially spherical capsule of radius a. The wall is assumed to be of very small thickness and is modelled as a membrane of mid-plane S and surface shear modulus G_s. The capsule is immersed in a simple shear flow of shear rate $\dot{\gamma}$. The internal and external fluids are the same incompressible Newtonian fluids of dynamic viscosity μ. Considering a capsule of microscopic size, the gravitational and inertial effects are negligeable compared to the viscous and elastic effects. Hence the only dimensionless parameter that governs the fluid-structure interaction is the capillary number $Ca = \mu a\dot{\gamma}/G_s$ that compares the fluid viscous forces to the membrane elastic forces.

The flows are governed by the Stokes equations. The boundary integral method [5] gives an explicit expression of the velocity $\underline{v}$ of the fluids on S as a function of the jump of viscous stresses $[\![\underline{\underline{\sigma}}]\!] \cdot \underline{n}$ across the membrane:

$$\forall \underline{x} \in S, \quad \underline{v}(\underline{x}) = \underline{v}^{\infty}(\underline{x}) - \frac{1}{8\pi\mu} \int_S \underline{\underline{J}}(\underline{x}, \underline{y}) \cdot [\underline{\underline{\sigma}}] \cdot \underline{n}(\underline{y}) \, \mathrm{d}S_{\underline{y}} \,, \tag{1}$$

where $\underline{v}^{\infty}$ is the velocity of the unperturbed simple shear flow and $\underline{\underline{J}}$ is the second order Oseen-Burgers tensor.

The membrane is at equilibrium at any instant. Hence, the principle of virtual works gives a relation between the internal tension tensor $\underline{\underline{T}}$ of the membrane and the external load vector $\underline{q}$ on the membrane:

$$\text{for any virtual displacement } \hat{\underline{u}} \,, \quad \int_S \underline{\underline{T}} : \underline{\underline{\varepsilon}}(\hat{\underline{u}}) \, \mathrm{d}S \; = \int_S \hat{\underline{u}} \cdot \underline{q} \, \mathrm{d}S \,, \tag{2}$$

where $\underline{\underline{\varepsilon}}(\hat{\underline{u}})$ is the symmetric part of the surface gradient of $\hat{\underline{u}}$.

The motions of the fluids and the membrane are coupled by imposing, on the interface S, the continuity of the velocities and the stresses (the jump of viscous stress $[\![\underline{\underline{\sigma}}]\!] \cdot \underline{n}$ is equal to the external load $\underline{q}$).

The damage of the membrane is modelled in the standard framework of CDM. The damage variable d is chosen to be a scalar that ranges from 0 (sound material) to 1 (macrocrack initiation). The choices for the free energy and for the damage criterion are given in Table 1. The expression of the damage criterion f is chosen from a model developped by Marigo [6] for brittle damage where we introduce the two parameters Y_D and Y_C representing an initial damage threshold

*Corresponding author. E-mail: a.salsac@utc.fr.

Table 1: Damage model of the membrane. ϕ_{NH} is the free energy of a Neo-Hookean material.

Surface density of free energy	$\phi = (1-d)\phi_{NH}$
Damage criterion	$f = -\dfrac{\partial \phi}{\partial d} - (Y_D + Y_C d)$

and a hardening modulus, respectively. Following the standard framework, we derive the damage evolution law from the normality law and the consistency condition:

$$\begin{cases} f < 0 \implies \dot{d} = 0 \\ f = 0 \implies d = (-\dfrac{\partial \phi}{\partial d} - Y_D)/Y_C. \end{cases} \tag{3}$$

NUMERICAL METHOD

We perform a Lagrangian tracking of the membrane. At the begining of a given time step, the current configuration of the membrane is known. We begin by solving the solid problem (eqs. (2), (3)) with the finite element method. First, we solve the local problem of damage evolution (eq. (3)) at the integration points. Then, we solve the global problem of equilibrium (eq. (2)) to find the external load at the nodes. Then we solve the fluid problem by computing the velocity of the fluids at the nodes from eq. (1). Finally, following the method developed by Walter *et al.* [5], the velocity is integrated explicitly by using a second-order Runge-Kutta scheme to determine the position of the nodes for the next time step.

RESULTS

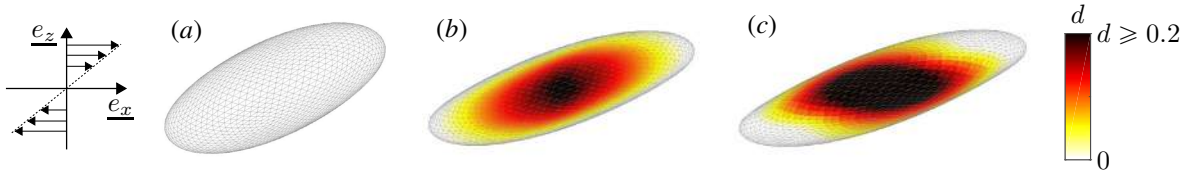

Figure 1: Damage of a capsule in simple shear flow observed, at steady state, in the shear plane ($\underline{e_x}$, $\underline{e_z}$) from the side, for (*a*) $Ca \leqslant Ca_c$ and (*b*) $Ca_c < Ca < Ca_\ell$, and (*c*) $Ca \geqslant Ca_\ell$ (shown at the instant of initiation of rupture, i.e. when $d = 1$ at the center of the capsule). Damage is symmetric with respect to the shear plane.

We have studied the damage process of a capsule as a function of the value of Ca for given values of the dimensionless damage parameters Y_D/G_s and Y_C/G_s. Damage occurs when Ca is larger than a critical value Ca_c and it leads to the initiation of rupture if Ca is larger than a limit value Ca_ℓ. When there is no damage ($Ca < Ca_c$), the motion of the capsule is known in the literature (see e.g. [5]): the capsule elongates in the flow strain direction, reaches a steady ellipsoidal shape and the membrane rotates around the vorticity axis (Figure 1a). When $Ca > Ca_c$, damage develops on the flanks of the capsule around the tip of the vorticity axis while the capsule elongates. If $Ca < Ca_\ell$, the capsule reaches a steady damaged state (Figure 1b), but when $Ca \geqslant Ca_\ell$, rupture is initiated when $d = 1$: it occurs at the tips of the vorticity axis (Figure 1c). The dimensionless damage parameters Y_D/G_s and Y_C/G_s influence the values of the thresholds Ca_c and Ca_ℓ and the intensity of damage.

In conclusion, the model proposed in this work enables to study the damage process and the criteria that control rupture of a capsule in flow.

HOW FLOW DETERMINES RED BLOOD CELL MOTION AND BLOOD PLATELET FORMATION

Stephan Gekle[1]
[1] Biofluid Simulation and Modeling, Theoretische Physik VI, Universit at Bayreuth, Germany

Summary We use Boundary-Integral and Lattice-Boltzmann simulations to study two biologically relevant examples of fluid-structure interaction: red blood cell motion through narrow capillaries and the biogenesis of blood platelets. In the first scenario, we discover a pronounced bistability: the final shape of the red blood cell is not only determined by external parameters such as flow speed or channel geometry, but also depends crucially on the initial position in quantitative agreement with microfluidic experiments by our collaboration partners. In the second scenario, we show how platelet production in the blood stream is strongly accelerated by hydrodynamic forces in agreement with recent experiments. We explain the acceleration mechanism by an elasto-hydrodynamic instability closely related to the classical Rayleigh-Plateau mechanism of a liquid jet.

A fascinating example of cell mechanics is the deformation of cells in blood flow. Here, we elucidate two examples where the cell-flow interaction is particularly relevant. The common link between both scenarios is that cell behavior is determined by the cell membrane which is passively elastic in the first and biologically active in the second case.

In the first case, we investigate red blood cells flowing through capillaries which assume a wide variety of different shapes owing to their high deformability. Predicting the realized shapes is a complex field as they are determined by the intricate interplay between the flow conditions and the membrane mechanics. We construct the shape phase diagram of a single red blood cell with a physiological viscosity ratio flowing in a microchannel. We use both experimental in-vitro measurements by our cooperation partners as well as 3D Bounday-Integral simulations to complement the respective other one. Numerically, we have easy control over the initial starting configuration and natural access to the full 3D shape. With this information we obtain the phase diagram as a function of initial position, starting shape and cell velocity. Experimentally, we measure the occurrence frequency of the different shapes as a function of the cell velocity to construct the experimental diagram which is in good agreement with the numerical observations. Two different major shapes are found, namely croissants and slippers as illustrated in figure 1. Notably, both shapes show coexistence at low (< 1 mm/s) and high velocities (> 3 mm/s) while in-between only croissants are stable. This pronounced bistability indicates that RBC shapes are not only determined by system parameters such as flow velocity or channel size, but also strongly depend on the initial conditions [1].

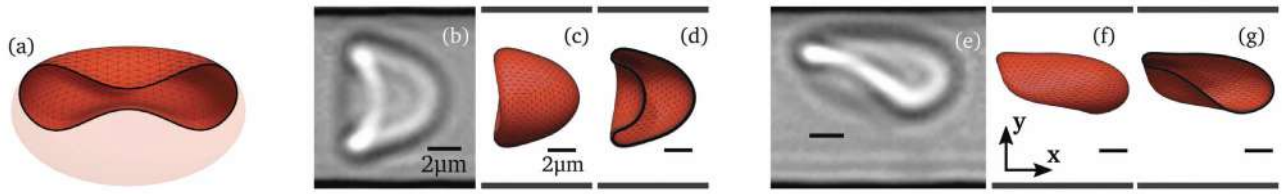

Figure 1: Typical RBC shapes from simulations and experiments. (a) The typical discocyte shape employed in some of the simulations as the starting shape. Half of it was made transparent for illustration purposes. Its horizontal diameter is $8\,\mu$m. (b) A typical croissant observed in the experiments when applying a pressure drop of $100\,$mbar (cell velocity $0.98(7)\,$mm/s). (c) A croissant with a velocity of $\approx 1.1\,$mm/s obtained from the numerical simulations. (d) The cross-section of the croissant from (c). (e) A slipper from the experiments at $500\,$mbar (cell velocity $5.16(11)\,$mm/s). (f) A typical slipper from the simulations with a cell velocity of $\approx 5.2\,$mm/s. (g) The cross-section of the slipper from (f). The black lines on the shapes from the simulations depict the mesh. The bottom and top black lines in all figures are the walls ($L_y \approx 12\,\mu$m apart), while the small black lines are scale bars of length $2\,\mu$m. The flow is in the positive x-direction (except in figure (a) where no flow exists).

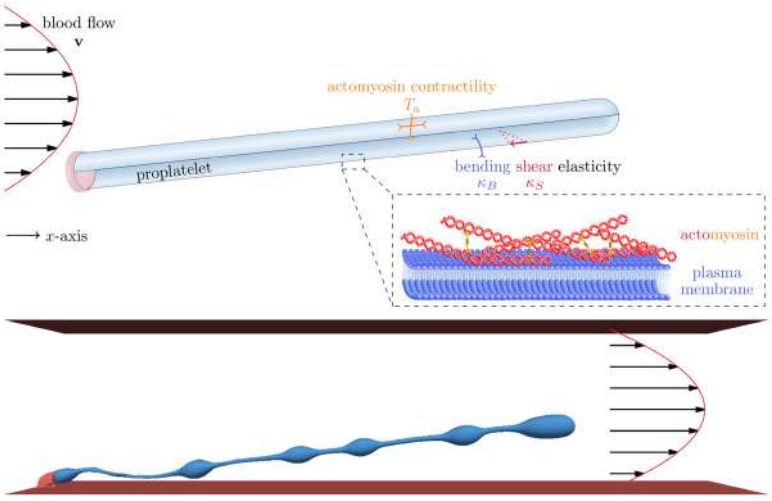

Figure 2: (a) Illustration of the simulation model for the proplatelet membrane. Plasma membrane and cortex (inlet) are treated together as elastic, active thin membrane. The membrane is endowed with bending κ_B and shear elasticity κ_S as well as actomyosin contractility T_a. We model the proplatelet as initially cylindrical membrane with one fixed end and one free end corresponding to the in-vivo situation. The proplatelet is subject to external blood flow. (b) A proplatelet forms periodic swellings in Poiseuille flow which rupture and lead to the release of platelets into the blood stream.

In the second case [2], we study blood platelets which are formed by fragmentation of long membrane protrusions (proplatelets) from bone marrow megakaryocytes in the blood flow. Using Lattice-Boltzmann/Immersed Boundary simulations we propose a biological Rayleigh-Plateau instability as the biophysical mechanism behind this fragmentation process. Our fully three-dimensional simulations, illustrated in figure 2 (a) highlight the crucial role of actomyosin contractility in the proplatelet cortex, which is required to trigger the instability, and illustrate how the wave length of the instability determines the size of the final platelets. The elasto-hydrodynamic origin of the fragmentation explains the strong acceleration of platelet formation in the presence of an external flow, which we observe in agreement with experiments [3] as illustrated in figure 2 (b). Our simulations then allow us to disentangle the influence of specific flow components: while a homogeneous flow leads to the strongest acceleration, shear flows can cause fusion events of two developing platelets leading to the release of larger structures which are observable as preplatelets in experiments. Together, our findings strongly point to a purely physical, rather than biochemical, regulation of platelet size and flow-accelerated platelet biogenesis.

CRAWLING IN A FLUID

Alexander Farutin*[1], Jocelyn Etienne[1], Chaouqi Misbah[1], and Pierre Recho[1]
[1] *Univ. Grenoble Alpes, CNRS, LIPhy, 38000 Grenoble, France*

Summary There is growing experimental evidence that amoeboid cells can swim in bulk fluid medium. In this study, we analyze theoretically a model of an almost-spherical cell suspended in a fluid. The models couples the cortex mechanics with the flow in the fluids inside and outside the cell. We show that a spherically symmetric cell can undergo a spontaneous symmetry breaking, which results in polarization and swimming of the cell. The swimming velocity of the cell is obtained as an explicit function of the main parameters governing the cortex mechanics. We show that the symmetry breaking can occur as a sub- or supercritical pitchfork bifurcation, depending on the cortex properties. For some parameters, a Hopf bifurcation is observed, which results in coupled oscillations of actin and myosin distributions in the cortex and oscillatory swimming of the cell.

INTRODUCTION

Motility on a cellular scale is ubiquitous in nature and plays an important role in many physiological processes. A notable class is amoeboid cells, which are characterized by strong deformation of the cell body during the locomotion. Experimentally, these cells are usually studied while crawling on a substrate, when adhesion is indispensable for propulsion. However, *in vivo* these cells usually move in a complex medium made of fluid environment and elastic obstacles, like, for example, during motion of a cell in a tissue. The requirement of adhesive contact during this motion was challenged experimentally[1]. There is now growing experimental evidence that amoeboid cells can propel themselves in bluk fluid environment[2, 3, 4]. Motivated by these experiments, we have analyzed theoretically the motion of a spherical cell in a fluid[5]. We find that the cells can swim, provided that the retrograde flow of their cortex can be transmitted to the outside fluid. Several such transmission mechanisms have been proposed in the literature: (1) by deformations of the cell[2], (2) by recirculation of the phospholipid membrane[3], and (3), more recently, by transmembrane proteins[4].

MODEL

The model has two main ingredients: (1) a gel of actin filaments which constitute the cell cortex and (2) myosin motors which cross-link the actin filaments and create pulling stresses inside the cortex. The cortex is modeled as a compressible two-dimensional fluid covering the inner surface of the cell. The mechanical stress in the cortex can then be related to the distributions of concentrations of actin and myosin according to the active gel model. This stress generates cortex force, which is balanced by the viscous stresses in the fluids inside and outside the cell. Solving the force balance equations allows us to express the velocity of the cortex as a function of the distributions of actin and myosin along the cell surface. This is done analytically by expanding all distributions in spherical harmonics. The evolution of actin and myosin concentrations is governed by advection-diffusion equations on the cell surface, where we also add a turn-over term to account for the polymerization and depolymerization of actin. The resulting equations are non-linear because of the advection term and have to be solved numerically in general case but we also analyze analytically the linear stability of the homogeneous solution and use perturbation approach close to the instability point. Initially, we make no assumptions about the symmetry of the cell but eventually dynamics tends to an axisymmetric solution in all explored cases. The 3 main parameters of the model are: myosin contractility, compressional stiffness of the actin gel and the turn-over rate of actin, where cortex viscosity, cell size, and diffusion coefficient of myosin motors are set to 1.

RESULTS

We show that the spherically symmetric solution becomes unstable for high enough contractility. The mode becoming unstable corresponds to the first harmonic of the concentration fields. This results in accumulation of actin and myosin at the rear part of the cell and their depletion at the front (Fig.1). A self-sustained flow of actin appears from cell front to back, which is balanced by actin polymerization at the front and depolymerization at the rear. This flow of actin results in flow of the fluid outside the cell, which leads to autonomous self-propulsion of the cell. An interesting observation is that the propulsion speed is independent of the viscosity of the outer fluid, provided it is much lower than the cortex viscosity. We show that the symmetry breaking instability occurs supercritically for high turn-over rate of actin but can also occur subcritically if the turn-over rate is low enough. A bistability is observed in the latter case, where the motile solution and the symmetric one are both stable for the same parameters. For even lower rate of actin turn-over the spherically symmetric solution becomes unstable via Hopf bifurcation. This instability results in coupled oscillation of the distributions of actin and myosin, where the high-concentration spots move from one end of the cell to the other periodically. The cell swims back and forth in this case.

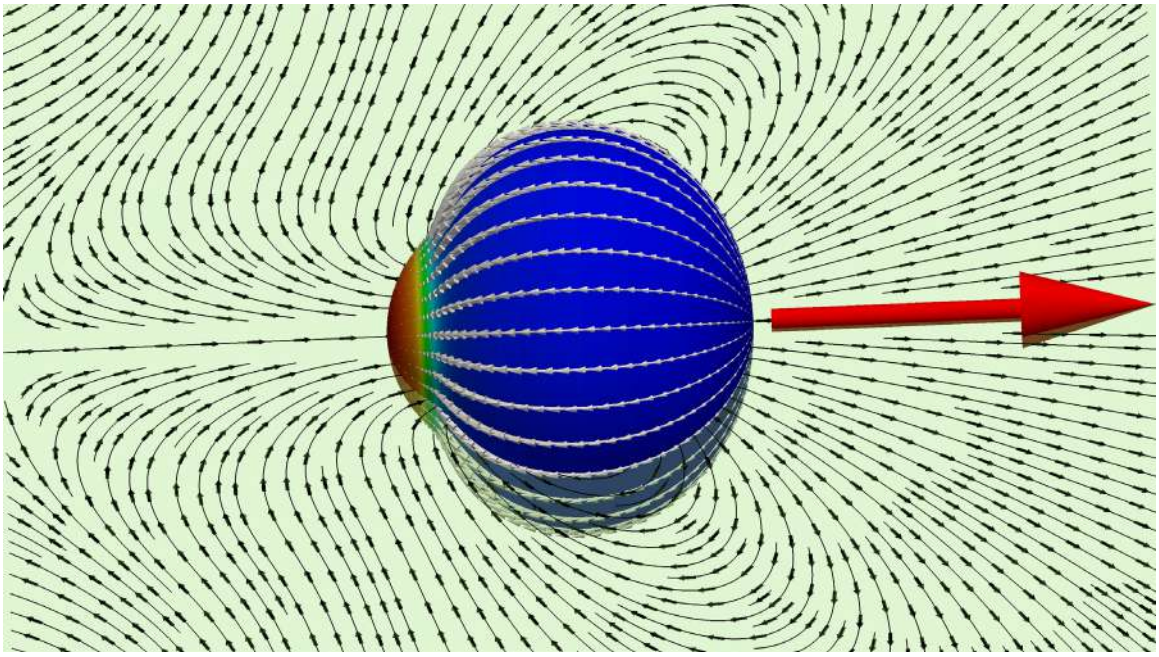

Figure 1: Flow lines around a swimming cell. Swimming direction is shown by a red arrow. Color code by actin distribution. Arrows on the cell surface show the retrograde flow.

Deformation of the cell is not a prerequisite of the motility in our model. Nevertheless, stresses in the cortex can lead to a non-spherical deformation of the cell. We have determined the shape of the cell that these stresses result in (Fig.1). Here we assume that the shape results from a balance of the cortex stresses, tension of the phospholipid membrane which encloses the cell, and a pressure surplus (due to osmosis) inside the cell. The resulting shapes are consistent with the shapes reported in earlier experiments.

More details can be found in [5].

A HYDRODYNAMIC MODEL FOR SPIROPLASMA MOTILITY

Christian Esparza-Lopez[1] and Eric Lauga [1]
[1] Department of Applied Mathematics and Theoretical Physics, University of Cambridge. Wilberforce Road, Cambridge CB3 0WA, UK

Summary *Spiroplasma* is a tiny helical bacterium that swims and performs chemotaxis in a non conventional way. Based on experimental observations [1] and following a previous numerical approach [2], in this study we develop a hydrodynamic model to describe *Spiroplasma* motility. We obtain expressions for the total linear and angular displacements per stroke of the cell body. Observing that the swimming gait corresponds to a run-reverse motion, we can define an effective swimming speed, v_s, which we use to calculate the energy dissipated in one stroke, $\dot{W}$, and to define a hydrodynamic efficiency, $e = \dot{W}_0/\dot{W}$, where $\dot{W}_0$ is the power spent by a straight filament moving at speed v_s. We show that the helical shape that maximises both, v_s and e, is a helix of pitch angle ϕ close to that of *Spiroplasma* $\phi \simeq 35°$, in agreement with previous simulations and experimental observations [1, 2].

INTRODUCTION

Spiroplasma is a helical-shaped bacterium with no flagella, that swims by progressively shifting the chirality of its body. The change in geometry gives rise to a wall domain, a kink, which propagates along the cell body (see Fig. 1). The chirality is then reverted in a similar fashion completing a swimming stroke. It has been observed that the change in chirality occurs in the absence of external stress, therefore the body bends with an angle $\theta = \pi - 2\phi \simeq 110°$, where $\phi \simeq 35°$ is the pitch angle of the helical body [2]. A chirality transformation with the stress free constrain allows for two kind of kinematic modes, the "crankshafting" and the "speedometer cable" mode [4]. In the former, one of the domains revolve around the other, while in the later, both domains spin around their axes. Simple scaling arguments for the energy dissipated on each mode suggest that the "speedometer cable" transformations are predominant, as seen in experiments [1, 2]. The whole deformation is non reversible in time, therefore swimming is achieved at low Reynolds number and the bacterium moves in the direction opposite to the kink pair propagation. The time between strokes appears to be exponentially distributed, with rate $\lambda_k \simeq 1\ \mathrm{s}^{-1}$. The time between a kink pair follows a normal distribution with mean $\tau_p \simeq 0.26$ s. The kink pair propagates at an average speed $v_0 \simeq 10\ \mu$m/s which is linearly related to the swimming velocity $v_s \simeq 3.3\ \mu$m/s [1]. The total arc length of *Spiroplasma* is $L \sim 10\ \mu$m and its helical radius is $R \sim 0.5\ \mu$m, so that it can be therefore considered as a slender body and resistive-force theory can be applied to describe its motion.

MATHEMATICAL MODEL

Following experimental observations, we model *Spiroplasma* as a deformable rod which performs the swimming stroke shown in Fig. 1. The force acting on the body per unit length can be obtained using resistive-force theory as follows [3]

$$\mathbf{f} = -\zeta_{\parallel}\mathbf{v}_{\parallel} - \zeta_{\perp}\mathbf{v}_{\perp}, \tag{1}$$

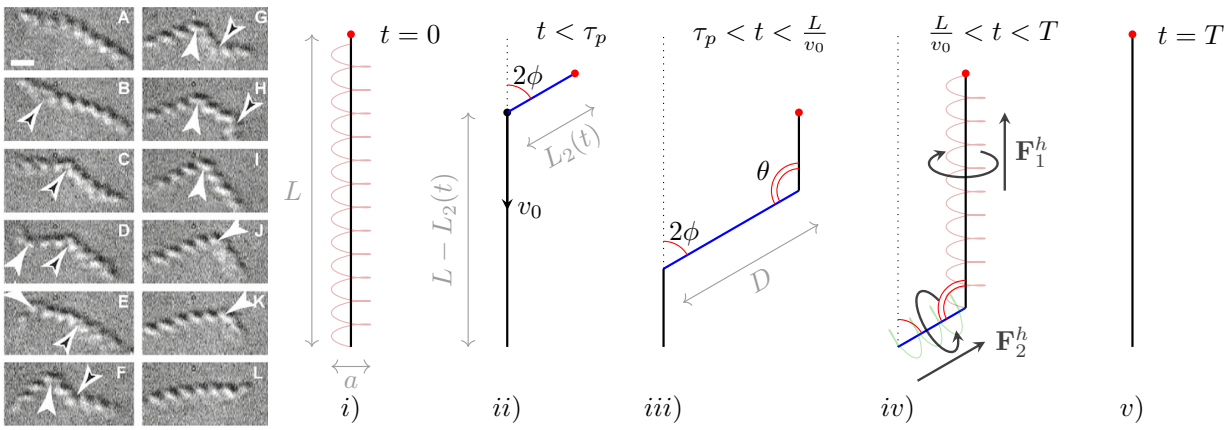

Figure 1: Spiroplasma swimming stroke (A-L) experiments [1] and (i-v) our model. (A,i): Initially the body has a right-handed helical shape. (B, C, ii): A kink appears at $t = 0$ and propagates from head (red circle) to tail along the body of length L at speed v_0. The deformed rod has two domains of size $L_2(t)$ and $L_1(t) = L - L_2(t)$. (D-H, iii): The second kink forms at $t = \tau_p$, the maximum distance between kinks is denoted by $D = v_0\tau_p$. (I-K, iv): The configuration is similar to that of ii), with reversed signs of the forces and torques acting on the body, the blue segment has left handed chirality and rotates clockwise, while the right handed segment rotates anticlockwise. The arrows represent the induced force. (L, v): The stroke finishes at $T = \tau_p + L/v_0$. The stroke is described in the frame of reference in which the tail is static.

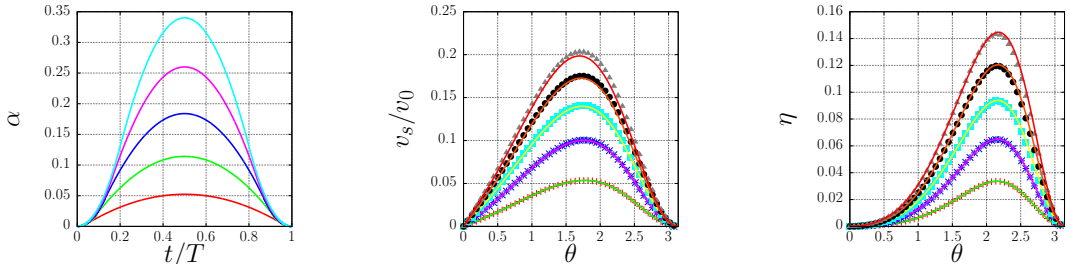

Figure 2: Angular displacement (left), swimming speed (center) and efficiency (right). Left panel shows that the body does not reorient after one cycle. The angle α is defined by $\cos\alpha \equiv \boldsymbol{\tau}(0)\cdot\boldsymbol{\tau}(t)$, where $\boldsymbol{\tau}(t)$ is the tangent vector to the "right-handed" domain. Center and right panels show a comparison between the full numerical solution and the asymptotic expansion of v_s and e at order d^2. The different curves in all panels correspond to increasing values of d (bottom to top) from 0.05 to 0.25 in steps of 0.05.

where $\zeta_{\parallel,\perp}$, $\mathbf{v}_{\parallel,\perp}$ are the parallel and perpendicular drag coefficients and swimming velocities respectively. The total force and torque acting on the body are given by $\mathbf{F} = \int \mathbf{f}\mathrm{d}s$ and $\mathbf{N} = \int \mathbf{x}\times\mathbf{f}\mathrm{d}s$, where $\mathbf{x}(s,t)$ is the position of a material point along the body at time t parametrised by the arc length s. We include the effects of helical geometry at a coarse-grained level by allowing the ratio of parallel to perpendicular drag coefficients, $\beta(\theta)$, to depend on the kink angle (or equivalently on the pitch angle ϕ) and by including external forces $\mathbf{F}_i^h$ (depicted in Fig. 1 iv), which account for the propulsion due to the rotation of the helical domains. We obtain the swimming velocity by considering the free swimming condition $\mathbf{F}+\mathbf{F}^h = \mathbf{0}$ and $\mathbf{N}+\mathbf{N}^h = 0$. The motion is symmetric under a half turn on the plane of motion and time reversal. Hence, by reversibility of Stokes flow, the body does not reorient at all after one cycle. This allows us to define an effective swimming speed as the ratio of the total linear displacement to the period of the stroke, that is

$$v_s^2 \equiv \frac{v_0^2}{(1+d)^2}\left(x_T^2+y_T^2\right), \tag{2}$$

where $d = v_0\tau_p/L$ is the ratio of the distance between kinks to the total length; x_T and y_T are the dimensionless components of the linear displacement $\mathbf{x}(t=T)/L$; and $T = L(1+d)/v_0$ is the period of the stroke. The energy dissipated in one stroke, $\dot{W}$, can be obtained by integrating the energy density, $\mathbf{f}\cdot\mathbf{v}$, along the body and over one period. We compare it to the energy dissipated by a straight filament moving at speed v_s, *i.e.* $\dot{W}_0 = \zeta\perp L v_s^2$. We finally define the hydrodynamic efficiency as

$$e \equiv \frac{\dot{W}_0}{\dot{W}} = \frac{T\zeta_\perp v_s^2}{\int_0^T\int_0^L \mathbf{f}(s,t)\cdot\mathbf{v}(s,t)\,\mathrm{d}s\,\mathrm{d}t}. \tag{3}$$

SUMMARY OF RESULTS

Despite the simplicity of the model, a full analytical solution seems impossible to obtain, due to the fact that the instantaneous swimming velocity $\mathbf{v}$ depends in a nonlinear way on β and θ. We can still make some progress by considering $d = D/L$ to be small. This assumption is supported by experiments, indeed according to Shaevitz et al. $v_0 \sim 10\ \mu$m/s, $\tau_p \sim 0.25\ s$ and $L \sim 10\ \mu$m hence $d \sim 1/4$ [1]. This approach is further justified by the fact that the numerical simulation shows that both v_s and e depend only weakly on d (see Fig. 2). We can therefore consider d small enough so that we can expand v_s and e in powers of d. Taking the first terms in the asymptotic expansion, it is found that the optimum kink angle lies between $\theta \simeq 100^\circ - 120^\circ$ which corresponds to a pitch angle of $\phi \simeq 30^\circ - 40^\circ$ in agreement with the experimental value $\phi \simeq 35^\circ$ [1].

CONCLUSIONS

In this work we develop a theoretical hydrodynamic model to describe the swimming of *Spiroplasma*. Our results show that the motility pattern corresponds to a run-reverse motion, as the body does not reorient after one stroke. Our theoretical model confirms that *Spiroplasma* optimises swimming efficiency at a maximum swimming speed.

MICROCIRCULATION OF RED BLOOD CELLS IN BIOMIMICKING SPLENIC SLITS

Anne Charrier [1], Alexis Moreau[1], Huije Lu[2], Emmanuèle Helfer[1], Zhangli Peng[2,3], and Annie Viallat*[1]

Summary Red blood cells (RBC) are responsible for distributing oxygen throughout the body. To pass through the smallest blood capillaries, RBCs must be highly deformable. To ensure this property, RBCs undergo the most stringent test by passing through the interendothelial slits of the spleen. This test which is believed to filter RBCs by retaining the stiff ones is also known to play an important role in many diseases such as malaria or sickle cell disease. However, the mechanisms that govern the cell dynamics through the slits are still unknown. We have developed the first device replicating the physiological dimensions of the splenic slits and allowing the observation of RBC dynamics by optical video microscopy. Trapping and deformation, reported for the first time in in vitro submicron fenestrations, definitely underline the importance of strong cell confinement and deformation.

INTRODUCTION

Although their apparent simple morphology, red blood cells (RBCs) are very deformable with well-adjusted rheological properties enabling their fast, efficient and resilient transport into the microcirculation. In the spleen, RBCs pass the most stringent physical fitness test of the blood circulation, consisting in squeezing through submicronic slits where they undergo extreme deformations. This test which is believed to filter RBCs by retaining the stiff ones is known to play an important role in many diseases such as malaria or sickle cell disease. However, the mechanisms that govern the cell dynamics through the slits are still unknown and this is due to the lack of experimental tools. To answer this question, we have developed the first microfluidic device containing slits with submicron width replicating the physiological dimensions of splenic slits[1] where the RBC dynamics can be observed through the slits and recorded by optical microscopy.

BIOMIMETIC SPLENIC SLITS

We report the dynamics of RBCs as a function of the relevant external parameters (slit dimensions, pressure drop) and cell morphologies. Trapping and deformation, reported for the first time in in vitro submicron fenestrations, definitely underline the importance of strong cell confinement and deformation. The specific behaviours observed here shed light on the alteration of the mechanical properties of RBCs in disease. In particular, we show original modes of deformation with the formation of tips at the cell front. Conjointly, our collaborator (Zhangli Peng's group, University of Illinois at Chicago) developed numerical simulations that recover both RBC transit times and shape deformation. The comparison of experiments and simulations leads to a deep insight of the mechanisms of RBC transit through the slits.

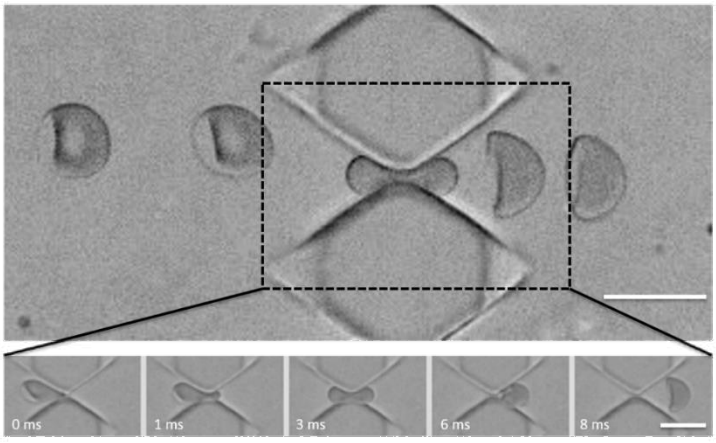

Figure 1. Superimposed images (top) and video sequences (bottom) of an RBC passing through slits of dimensions 0.67 x 1.9 x 4.7 μm^3. Scale bars: 10 µm. $\Delta P_{In/Out}$ = 10 mbar.

INFLUENCE OF RED BLOOD CELL DEFORMABILITY ON HEMODYNAMIC CHANGES IN PHYSIOLOGICALLY REALISTIC MICROVASCULAR NETWORKS

Prosenjit Bagchi[1], and Saman Ebrahimi
[1] Mechanical and Aerospace Engineering Department, Rutgers University, New Jersey, USA

Summary Microvascular networks are formed by capillary blood vessels and characterized by geometrically complex architecture of bifurcating, merging and winding vessels. Blood in such networks flows as a suspension of red blood cells (RBC) that are extremely deformable under healthy conditions. In many diseases, such as sickle cell disease, malaria, and diabetes mellitus, RBCs lose their deformability. Influence of the loss of deformability on hemodynamics at the scale of a microvascular network is poorly understood, and is the goal of this study. We use a 3D fluid-structure interaction model that accurately predicts deformation of every single RBC flowing through physiologically realistic microvascular networks. The model predicts that the loss of RBC deformability leads to a significant alteration to RBC distribution, and a significantly greater increase in vascular flow resistance in the vessels in the networks than isolated vessels. Physical mechanisms underlying these novel yet biologically important results are presented.

INTRODUCTION

Microvascular networks in human body are made of the smallest blood vessels, namely, capillaries, arterioles and venules. The architecture of a microvascular network is very complex and characterized by constantly bifurcating and merging vessels. The topology of networks can vary from organ to organ and also differ under healthy and disease conditions. Moreover, these vessels are not necessarily straight, and often highly winding. Blood in such small vessels behaves as a concentrated suspension primarily made of red blood cells (RBC) which are extremely deformable. Deformability of RBCs allows them to squeeze through the narrow capillaries with diameters less than their characteristic size.

Mathematical models of blood flow in such networks have treated the vessels as 1D straight segments neglecting the geometric complexity and details [1]. These models also do not consider the deformation and flow of individual red blood cell, and instead use empirical relations to prescribe blood viscosity and cell distribution at a vascular bifurcation. As such, these models cannot predict several hemodynamic processes and parameters that are of significant biological importance, such as formation of the plasma layer near the vessel wall, and wall shear stress gradient.

To overcome this limitation, we have developed a high-fidelity 3D, first-principle based, fluid--structure interaction model of blood flow in physiologically realistic microvascular networks [2]. The model retains the exact geometric details of the vasculature, e.g., 3D nature of the blood vessels and bifurcations, and vessel curvature. Deformation and flow of each individual red blood cell as they flow through the vessels are exactly simulated. The model does not assume any empirical viscosity law or bifurcation law; rather, these laws are predicted by the model. The model provides microscale details of hemodynamic quantities that are not readily available in experiments, and cannot be predicted by the traditional 1D network models, such as wall shear stress gradient and time-dependent red blood cell partitioning at bifurcations [3,4].

Of particular interest is the role of RBC deformability on network-scale hemodynamics. Many diseases, such as sickle cell disease, malaria and diabetes mellitus, are associated with a loss of RBC deformability. A detailed quantification of changes in network-scale hemodynamics under such conditions is lacking. Using the aforementioned high-fidelity model of RBC-resolved blood flow in capillary networks, here we provide the first-ever simulation results on the changes in network-scale blood flow under varying RBC deformability.

OVERVIEW OF MODEL

The numerical methodology is based on the framework of immersed boundary methods (IBM) for efficient fluid-structure interaction problems in conjunction with a 3D Finite Volume/Spectral fluid flow solver, and a Finite-Element solver for deforming interfaces. Two separate types of IBMs are employed to accommodate the wide variety of interfaces encountered in the cellular-scale blood flow, as follows. Blood cells are modelled as viscous drops surrounded by hyperelastic membranes with biconcave discoid resting shapes. The resistance of the cell membrane against shear deformation, bending and area dilation is modelled via appropriate constitutive relations. A Lagrangian mesh is fitted to the cell surface and is used to calculate the forces in the membrane due to deformation using the Finite Element Method. Cell deformation is coupled to the fluid flow, which is governed by the unsteady Stokes equations, via a continuous-forcing front tracking IBM. For rigid interfaces as defined by the walls of the blood vessels, and vascular bifurcations, a direct forcing sharp-interface ghost node IBM (GNIBM) is developed. With this, the no-slip boundary condition at the vascular wall is achieved by enforcing appropriate constraints on the fluid velocity at the Eulerian mesh nodes that are immediately outside the boundary (ghost nodes).

In silico microvascular networks are modelled from *in vivo* images and data using a standard CAD software, and maintaining the hierarchical structure and ordering as observed in physiological scenario (Fig. 1). The mesh defining the vessel surfaces is used in the context of the GNIBM to represent the nondeformable walls. Flow in the networks is driven by specifying inlet/outlet pressure or flow-rate boundary conditions corresponding to physiological values. The

present methodology is versatile, and can be used to simulate deformable cell motion in any capillary vessel networks, 3D or planar, of arbitrary complexity including cerebral, retinal and tumour microvasculature.

RESULTS

A visualization from one simulation is shown in Fig. 1a. The network geometry considered here covers a tissue area of about 450X300 μm^2. Generic characteristics of microvascular blood flow, such as heterogeneous distribution of blood cells and their highly deformed shapes including parachute/bullet/slipper shapes, are predicted by these simulations. Quantitative validations of hemodynamic parameters, such as vascular flow resistance and wall shear stress, against *in vivo* data were performed showing a good agreement.

We then simulate the flow of healthy and diseased RBCs through the networks to predict the influence of RBC deformability on network-scale hemodynamics. Diseased RBCs are modelled by increasing the cell membrane shear elastic modulus by a factor of ten. The most striking result is a significant redistribution of RBCs in the network upon their loss of deformability. This is shown in Fig. 1b where the percentage change in haematocrit in the vessels is shown. As can be seen here, while some vessels show as much as 30% increase in haematocrit, some show nearly similar range of decrease. Such altered distribution of blood cells has not been predicted before, and has significant biological implications in terms of oxygen delivery to tissues.

The physical mechanisms underlying such altered RBC distribution are identified, and attributed to the way RBCs are distributed to the daughter vessels as they flow through a bifurcation. We noted that the residence time of RBCs increased near the flow stagnation point at the bifurcations, a phenomenon we termed as 'lingering'. Because of this, a cell flowing through a bifurcation can either enter in to a daughter vessel which has a higher flow rate, or to the one that has a lower flow rate. The former is termed as the regular cell partitioning, while the latter as the reverse partitioning. We find that the reverse partitioning occurs less frequently, in a time-dependent sense, in presence of diseased RBCs than healthy RBCs, thereby resulting in the altered distribution of cells.

Fig 2c shows the changes in vascular flow resistance upon the loss of RBC deformability. A significant change is also noted here – while some vessels show a large increase in the flow resistance, some of them surprisingly show a drop in flow resistance. Also interesting to note is that when we simulate isolated vessels with diseased RBCs, the percentage increase in flow resistance is about 11—12% for vessels of 11—16 µm diameter. Thus the vessels in the networks impart additional resistance than isolated straight vessels in presence of diseased RBCs. The physical mechanism underlying such "excess" resistance is also the lingering event at bifurcations that causes large spikes in time-dependent flow resistance.

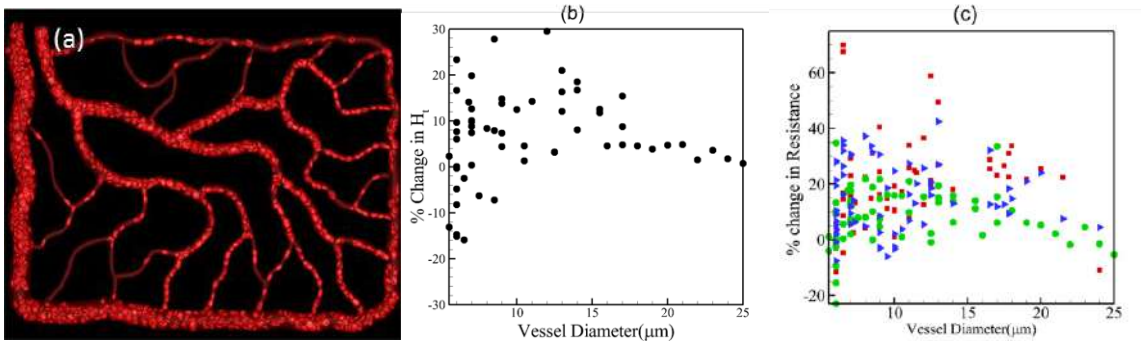

Figure 1. (a) An example fluid-structure interaction simulation of flow of many deformable blood cells through physiologically realistic microvascular networks. (b) Predicted change in haematocrit and (c) flow resistance due to loss of RBC deformability.

CONCLUSIONS

A high-fidelity, 3D fluid-structure interaction model is used to predict the changes in microvascular network-scale hemodynamics upon the loss of red blood cell deformability. The model accurately predicts the deformation of every single RBC flowing through physiologically realistic networks of capillary blood vessels comprising of multiple bifurcations and arbitrary vessel shapes. The simulations predict a significant alteration of RBC distribution upon loss of deformability; this result has biological implications in terms of oxygen delivery to tissues. Further, a significant increase in vascular resistance is also predicted for vessels in the networks, and is found to be higher than isolated vessels. The physical mechanisms underlying such changes are also identified.

VERTICAL MIGRATION OF MICROCYSTIS COLONIES

Yu Yang, Li Zeng *, and Yihong Wu
State Key Laboratory of Simulation and Regulation of Water Cycle in River Basin, China Institute of Water Resources and Hydropower Research, Beijing, China

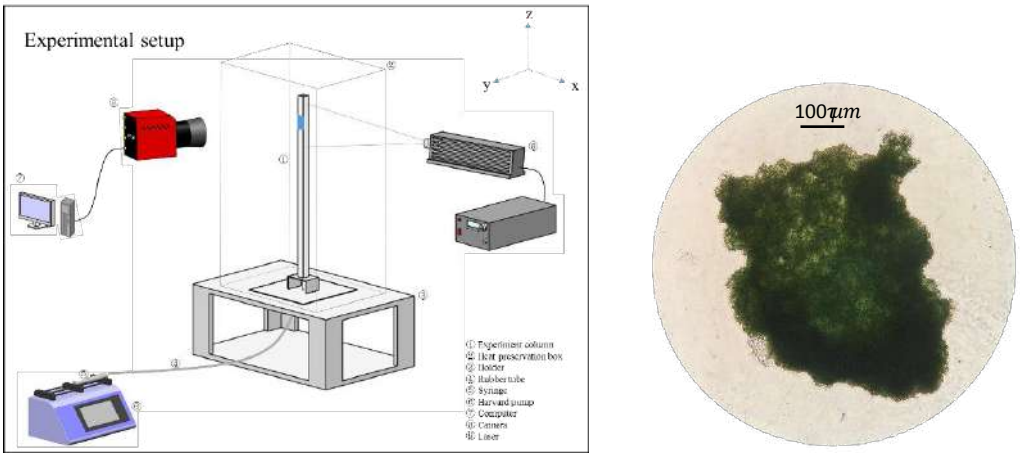
Summary Vertical migration of Microcystis colonies is significant for various ecological phenomena, especially for the harmful algal blooms. The trajectories of *Microcystis* colonies and the flow field around a *Microcystis* colony were measured by use of PLIF technique and PIV system. It is found that the migration direction of *Microcystis* colonies is subject to an Gaussian distribution. Two vortices are found to exist around *Microcystis* colonies, which differs from the flow pattern past a sphere at the same Reynolds number. An expression has been present to predict the vertical migration velocity of *Microcystis* colonies, based on Stokes' law.

INTRODUCTION

Blooms of *Microcystis*, occurring widespreadly in freshwaters, have received intensive concerns, due to its serious harms to aquatic ecosystem in terms of water quality deterioration, biodiversity reduction, massive death of fish, etc. [1]. Vertical migration of *Microcystis* colonies plays a significant role in blooms of *Mcirocystis*, in addition to nutrients, light, and temperature [2]. Regarding the vertical migration of *Microcystis* colonies, there have been various experimental and computational investigations, with focus on the velocity of vertical motion. Several empirical expressions have been presented to describe the relationship of migration velocity of *Microcystis* colonies and their size, based on the fields and laboratory observation [3-5]. However, these expressions are only valid for some specific conditions. Furthermore, hydrodynamic mechanisms of vertical migration of *Microcystis* are not been understood well. In this work, vertical migration of *Microcystis* colonies has been investigated, including the expression to calculate the vertical migration velocity and detailed flow structures around a *Microcystis* colony.

MATERIAL AND METHODS

The experimental system consists of a transparent test tube, an acrylic box, an imaging system, an injection system, and a planar laser device, as shown in Figure 1. The test tube (10mm×10mm×350mm, filled with BG-11 medium) was located in the acrylic box (100mm×100mm×400mm, filled with purified water) to prevent the convection due to the temperature difference of air and suspensions of *Microcystis* colonies. The 1.5 mm-thick pulse laser sheet was used to illuminate colonies in the centre-plane of the test tube. *Microcystis* (*aeruginosa,* FACHB1338), adopted in this work, came from the Freshwater Algae Culture Collection of the Institute of Hydrobiology, Wuhan, China, and was cultured in BG-11 medium at a temperature of 25℃ in a growth chamber of 12:12 light-dark cycle photoperiod. The trajectories of *Microcystis* colonies and flow fields around *Microcystis* colonies were measured by use of Planar Laser Induced Fluorescence (PLIF) technique and (Particle Image Velocimetry) PIV system.



(a) (b)

Figure 1. Experimental setup (a) and a *Microcystis* colony (b).

RESULTS AND DISCUSSION

Trajectories of *Microcystis* colonies in the test tube were measured, with the diameter ranging from 10μm to 1054.5μm. It was found that *Microcystis* colonies migrate upward vertically, on average, while each colony migrates upward with a stochastic angle against the vertical direction, due to the irregular morphology of *Microcystis* colonies, especially massive pore structures, as shown in figure 2 (a). Statistical analysis showed that the migration direction is subject to an Gaussian distribution, as shown in figure 2 (b).

The flow field around *Microcystis* colonies was measured based on PIV. The Reynolds number, based on the equivalent diameter of a *Microcystis* colony and the mean stable vertical migration velocity, is approximately 0.3, much less than 1. The flow structure surrounding the colony differs from that around a sphere with the same Reynolds nubmer. There are two obvious vortices for the former, as shown in figure 3, while no vortices will occur for the latter.

In this work, we presented one expression to predict the vertical migration velocity of *Microcystis* colonies, based on Stokes' law. Figure 4 presented the relationship of vertical migration velocity and diameter. It shows that the vertical migration velocity of *Microcystis* colonies increases with their diameter.The density-size relationship of *Microcystis* colonies has been given, as shown in figure. 5. It is shown that the density of *Microcystis* colonies is the exponential function of their size.

Figure 2. Trajectories and migration direction distribution of colonies.

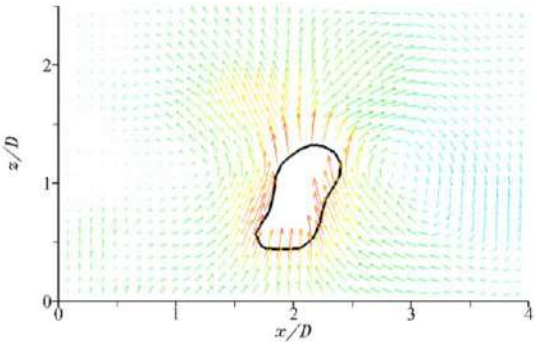

Figure 3. Flow field around a *Microcystis* colony

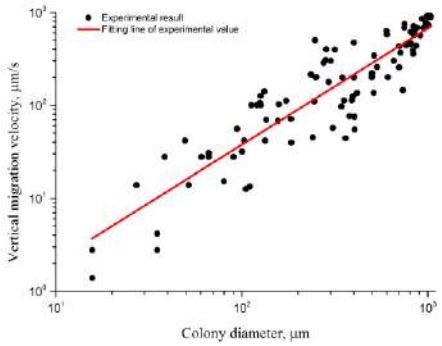

Figure 4. Variation of vertical migration velocity of *Microcystis* colonies with their diameter.

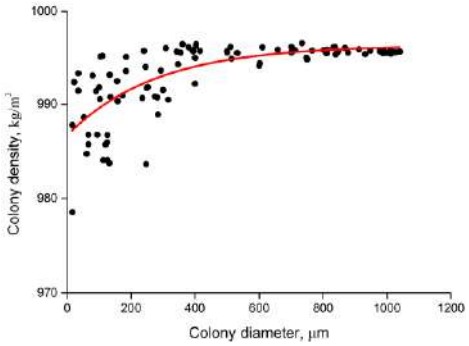

Figure 5. Variation of density of *Microcystis* colonies with their size.

CONCLUSIONS

The trajectories of *Microcystis* colonies and flow fields around them were measured by use of PLIF technique and PIV system. It is found that the migration direction of *Microcystis* colonies is subject to the exponential distribution. Two vortices are found to exist around one *Microcystis* colony, which differs from the flow pattern past a sphere with the same Reynolds number. An expression is presented to calculate the vertical migration velocity of *Microcystis* colonies, based on Stokes' law.

IN-SILICO CELL RHEOMETRY: MODELING OF ENDOTHELIAL CELLS UNDER STARTUP SHEAR CONDITIONS.

Konstantina Psaraki[1], Vlasis Mitsoulas[1], Yannis Dimakopoulos*[1], Stavros Pavlou[1], John Tsamopoulos[1]
[1] Laboratory of Fluid Mechanics and Rheology, Department of Chemical Engineering, University of Patras, Greece
Web: http://fluidslab.chemeng.upatras.gr/

Computational models of the endothelium, as well as experimental observations, can help in understanding the biomechanics of stress-induced cellular deformation, how mechanical stimuli are interpreted by endothelial cells, and important insights of disease progression. We present a new fluid-structure interaction model for the response of endothelial cell under startup shear conditions using an advanced Finite Element Method, while we introduce the poroelastic constitutive model for the rheological characterization of the cytoplasm. Since the mesh corresponds to the solid phase, forming a structure of solid net, we expect that the elasticity will differ from other works adopting hyperelastic models for the cell mechanics. We evaluate the rheological properties of the cell by implementing a benchmark compression experiment introduced by Caille et al.[1] and constructing force-deformation curves.

Introduction

Endothelial cells (ECs) form the basic barrier between blood vessels or capillaries and tissue, with the key function of controlling the flow of substances into and out of the underlying tissue ([2],[3]). Shear stress, which is the frictional force developed by blood stream above the endothelium, can elicit various responses with cell deformation, cytoskeletal rearrangement, and activation of signaling pathways, some of the principal ones [3]. Although the precise mechanisms of mechanical-chemical coupling in ECs exposed to shear-stress are not fully understood, the biochemical cascade for nitric oxide (NO) overproduction and calcium ions (Ca^{2+}) dynamics are linked to many harmful effects such as inflammations and induction of apoptosis [4]. This implies that we should deeply investigate the structural and chemical responses of endothelial cells under shear experiments and develop reduced biochemical models to provide accurate predictions with the minimum possible input.

Endothelial cells have mostly been modeled as “sacs” (cell wall) containing viscous fluids (cytoplasm) and a more viscous or even a solid nucleus ([1],[5-6],[10]). However, it is known that the nucleus is connected to the cell wall through numerous filaments that form a robust structure and act as the “skeleton” of the cell (cytoskeleton) [7-8]. Furthermore, the existence of a number of proteins throughout the cytoplasm, which are large biomolecules forming long chains of amino-acids, cannot confirm the Newtonian fluid notion [8]. In the present work, we implement a two-phase model for the characterization of the cytoplasm, which will consist of a viscous fluid (cytosol) flowing amongst the elastic solid structures (cytoskeleton) and thus constituting the “poroelastic” model. The other components of the cell, such as the nucleus, the cortex, the glycocalyx layer, the apical layer, and the cell wall, are modeled as elastic solids. A two-dimensional periodic model was developed for studying the dynamics described above and the kinematics of the surrounding blood plasma under startup flow conditions.

Nucleus minimum radius	6 μm	Tarbell et al.[10]
Endoplasmic Reticulum thickness	1 μm	Lewis et al.
Cell Wall Thickness	0.14 μm	Philips et al.[11]
Cell to cell distance	1 μm	Jean et al.[9]

Figure 1. Geometrical Features of our Endothelial Cell. Its nucleus, endoplasmic reticulum, cytoplasm and cell wall are being depicted.

Results

In order to evaluate the parameters of the endothelial-cell model, we make a similar setup as Caille et al. [1], incorporating in our cell model only the poroelastic cytoplasm and the solid nucleus between two microplates, one moving and one fixed and compressing it with a downward velocity $u = 2.0 \cdot 10^{-6} m/s$. We calculated the force acted upon the cell due to the compression and plotted it versus the deformation of the cell to get a stress-strain curve. By comparing the results to those of Caille et al. (2002) [1], we retrieve the Young moduli of the cytosol and the cytoskeleton that will correspond to the modulus of their defined hyperelastic cytoplasm. We also simulated the compression of an isolated nucleus to find its elasticity and viscosity.

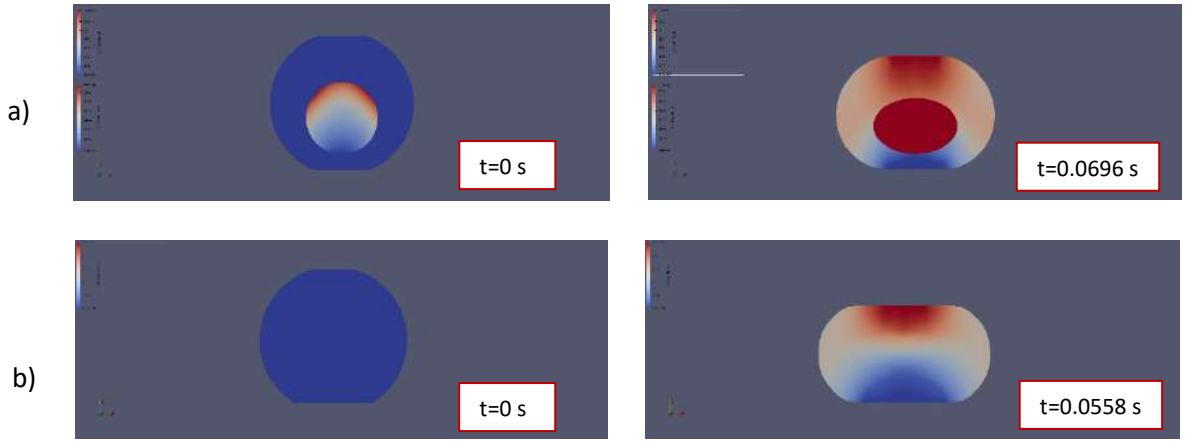

Figure 2 Compression of a round endothelial cell containing the solid nucleus ((a)). Compression of the solid nucleus ((b)) achieving a 27.6% deformation.

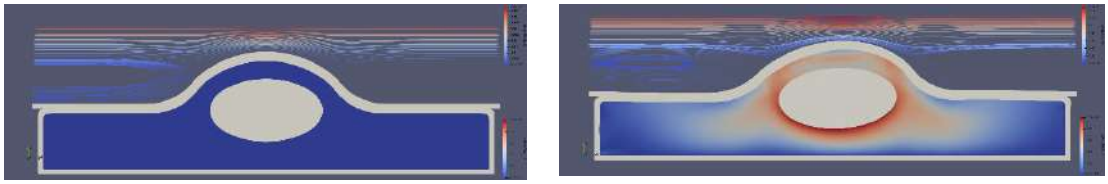
In our main analysis, we apply a constant shear velocity at the blood/plasma interface equal to $V_{x,CFL} = 53mm/s3$as a boundary condition. Under these conditions, our results indicate a significantly deformed endothelium, which in turn activates the biochemical cascade. These deformations are associated with tilting of the roundly extruded part of the endothelial cell towards the flow and even a slight movement and rotation of the nucleus.



(a) t = 0 s (b) t = 0.09992 s

Figure 3. Startup shear simulation due to bloodstream's velocity. Initial configuration including the cell wall, the glycocalyx layer, the endoplasmic reticulum, the nucleus and the cytoplasm (a). Final configuration depicting the deformation of the cell due to the flow (b).

Conclusions

A two-dimensional model was developed for studying the rheological behavior of the endothelium under startup flow conditions featuring a Fluid-Structure Interaction (FSI) algorithm along with a novel poroelastic model which incorporates the material properties of the cytoplasm. In Fig. 3 we observe that the blood's flow strongly affects not only the endothelial cell's structure but also leads to a slight rotation of the nuclear domain. The proposed model was then validated by a compression benchmark experiment as in Caille et al. [1] where the cell is introduced amongst two microplates, one moving downwards and one fixed. The simulation was conducted for both a round cell, consisting of the nucleus and the surrounding cytoplasm, and for an isolated round nucleus. The compressive stresses spread throughout the cell and nucleus, achieving a noteworthy nuclear deformation.

IN-SILICO RHEOMETRY OF GLYCOCALYX LAYER: INVESTIGATING THE EFFECT OF REAL PULSATILE PLASMA FLOW CONDITIONS AND MICROVESSEL DIASTOLE

Antonis Marousis[1], Vlasis Mitsoulas[1], Yannis Dimakopoulos *[1] and John Tsamopoulos[1]
[1] Labaratory of Fluid Mechanics and Rheology, Department of Chemical Engineering, University of Patras, Patras, Greece
Web: http://fluidslab.chemeng.upatras.gr/

The macromolecular layer covering the luminal surface of the vascular endothelium, known as the endothelial Glycocalyx layer (EGL), has a significant role in tissue hemostasis and mechanotransduction. In this study, we investigate the effect of the frequency of the pulsatile blood plasma flow as well as the capillary vasodilation-vasoconstriction on the behavior of the ESL. To this end, we perform 3D Fluid-Structure Interaction (FSI) simulations accounting for both blood plasma and endothelial glycocalyx (EG) body dynamics.

INTRODUCTION

The luminal surface of the vascular endothelium is covered by a network of membrane-bound proteoglycans and glycoproteins, forming the ESL. The ESL has been studied to a large extent over the years since it provides a vital role in vascular physiology and pathology [1], whereas its ability to control the capillary permeability may influence drug delivery processes [2]. However, the small scale of EG and its complex structure, especially in capillaries, makes it difficult for scientists to perform in vivo or in vitro experiments; hence most of the existing literature focuses on theoretical approaches. The blood plasma dynamics in ESL has been examined satisfactorily through hydrodynamic models, in which poroelastic walls have been considered [3]. Damiano & Stace [4] and Weinbaum et al. [5] attempted to evaluate the deformation and recovery time of EG after compression due to the passage of white blood cells, employing an electrohydrodynamic model and a mechano-electrochemical model, respectively. Accounting for the structure of EG, Squire et al. [6] identified that the glycocalyx fibers follow a quasi-periodic arrangement, findings which adapted by Weinbaum et al. [5] led to the development of an ideal periodic bush-structure model with hexagonal symmetry. More recently, Mitsoulas et al. [7] proceeded on a thorough analysis accounting for the mechanical and geometrical properties of EG through Fluid-Structure Interaction simulations (FSI).

In the present study, we investigate the effect of pulsatile blood flows with frequencies that do not correspond to normal heart rates on the ESL dynamical behavior. In addition, we account for a more realistic illustration of the capillary, in which the microvessel expands and contracts, and therefore the fiber-to-fiber distance variates with time. To address the problem, we consider the three-dimensional incompressible plasma flow perpendicular to the fibrous network, as shown in Fig. 1(a). Additionally, we adapt the minimal elementary domain of Mitsoulas et al. [7], see Fig. 1(b), which consists of two subdomains that correspond to fluid (blood plasma) and solid (EG fibers), respectively. The blood plasma has a Newtonian-fluid behavior, while the EG fibers are represented as hyperelastic solids. We solve the problem numerically using the Finite Element Method, while in order to account for the FSI solution, we implement the full monolithic coupling methodology with global unknowns. To better understand the dynamics of the coupled system, we evaluate the apparent permeability of ESL and dynamic characteristics such as the drag force and torque on a single fiber.

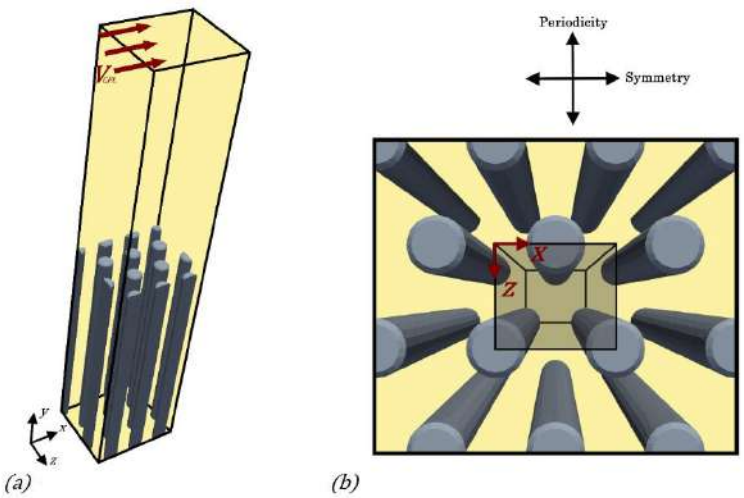

Figure 1. a) Side view of the 3D ESL periodical physical domain. b) Top view of the EG structure with unformed fibers. (The shaded area corresponds to the minimal elementary domain.)

RESULTS

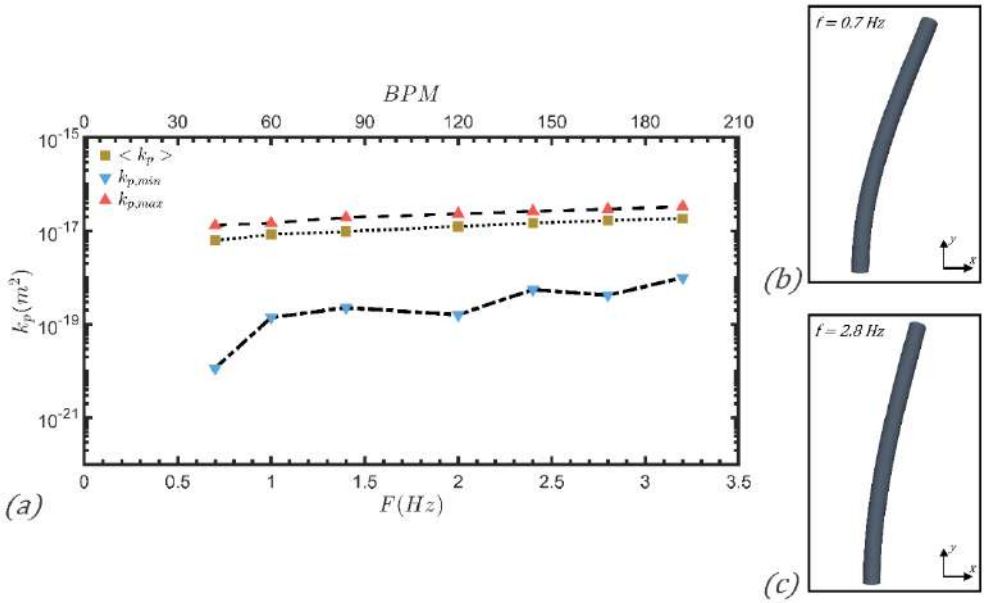

Figure 2. (a) Apparent permeability, k_p, as a function of frequency, F. The characters ■,▼, ▲ depict the mean, maximum and minimum value of k_p, respectively. (b),(c) Depiction of EG fiber in the fully deformed state for $f = 0.7Hz$ and $2.8Hz$, respectively.

We proceed with a parametric analysis concerning the frequency of the pulsatile plasma flow. In Fig. 2 (a), we present the evaluated minimum, maximum, and mean value of the apparent permeability of ESL, k_p, for various frequencies. Note that those results correspond to capillary diastole up to 15%. The minimum values of k_p correspond to the state when the EG fibers are fully deformed, and therefore the resistance to the flow is maximized. In conjunction, maximum k_p values arise when EG fibers are almost undeformed and flexible to move in the flow direction. By increasing the frequency, the maximum and minimum values of k_p become larger, with the latter exhibiting the largest increase. As shown in Fig. 2 (b), (c), which depicts the fully deformed state of the EG fiber for $f = 0.7$ and $2.8Hz$, the maximum deformation of the fiber is greater in the second case. In fact, in high frequencies, the rapid changes in the flow rate prevent the motion of EG fiber, which in turn causes smaller and time-limited deformations. As a result, it can be seen in Fig 2 (a) that the mean value of the transient apparent permeability is proportional to frequency.

CONCLUSIONS

In the present study, we examined the dynamical behavior of ESL through FSI simulations accounting for events that can take place in biological processes, such as variations in heart rate and capillary vasodilation-vasoconstriction. We found that the pulse frequency influences the behavior of EG, resulting in changes in the apparent permeability of ESL, more specifically, high-frequency pulsatile flows result in larger values of k_p.

NONLINEAR DYNAMICS FOR DESIGNING ANNULAR THERMOACOUSTIC SYSTEMS

Nicolas Noiray[1]*, Abel Faure-Beaulieu[1], Thomas Indlekofer[2], and James R. Dawson[2]
[1] Department of Mechanical and Process Engineering, ETH Zürich, Switzerland
[2] Department of Energy and Process Engineering, NTNU, Trondheim, Norway

Summary Annular combustors of modern aeroengines and gas turbines are subject to self-sustained azimuthal thermo-acoustic modes. These limit cycles are unwanted because the resulting intense acoustic field induces high-cycle fatigue of the combustor components. First, this paper presents a theoretical framework with a quaternion-based ansatz of the acoustic pressure for describing the slow-flow dynamics of the thermo-acoustic system. The associated variables define the state of an eigenmode, i.e. if it is purely standing or spinning, or a combination of standing and spinning waves, depending on the rotational and reflectional asymmetries of the annular system. Then, this framework is used to design interconnected nonlinear acoustic elements for controlling the thermo-acoustic dynamics.

One of the environmental challenges for civil aircraft transportation is the necessity to significantly reduce emissions of nitrogen oxides NO_x, which cause toxic pollution in the vicinity of airports and contributes to the formation of ozone in the high atmosphere. A technical solution for this problem is to burn lean fuel-air mixtures, which prevents near-stoichiometric hot-spots where NO_x are produced and reduces soot formation and unburned hydrocarbons. The problem is that the thermoacoustic stability is significantly reduced with these flames, because they are more sensitive to flow perturbations. In particular, they exhibit strong heat release rate response $\dot{Q}'$ to modulation of mixture composition or velocity field that result from the acoustic pressure field p'. Consequently, thermoacoustic instabilities, which are induced by the constructive coupling between the flames and the combustor acoustics, are more likely to occur. They yield high amplitude limit cycles which reduce the lifetime of the hot gas path parts because of the induced vibrations, or in the worst case destroy them during a sudden catastrophic event. In this context, numerous studies have been conducted about thermoacoustic instabilities in annular combustor geometries which are very common for land-based gas turbines and aeroengines, e.g. [1]. A fascinating aspect of thermoacoustic instabilities in annular combustion chambers is that they display pairs of azimuthal eigenmodes that yield standing or spinning thermoacoustic waves depending on the system symmetries as illustrated in Fig. 1.

In the present study, we propose a new low-order model of the thermoacoustic dynamics in annular combustors, which is used for designing interconnected nonlinear acoustic elements for controling the instabilities. In what follows, we briefly present the low-order model for idealized combustors exhibiting a mean low-Mach uniform swirling flow $\bar{\boldsymbol{u}} = U\mathbf{e}_\Theta + V\mathbf{e}_z$. A simple model with static nonlinearity is adopted for describing the heat release rate response to acoustic perturbations: $(\gamma-1)\dot{Q}' = \beta p' - \kappa p'^3$, where γ is the heat capacity ratio, and β and κ are real constants. It allows us to describe the phase space in the vicinity of supercritical Hopf bifurcations that are commonly encountered. This heat release rate model and a quaternion-based ansatz of the acoustic pressure are injected into the following acoustic wave equation

$$\left\{\frac{1}{c^2}\left(\frac{\partial^2}{\partial t^2} + 2\bar{\boldsymbol{u}}\cdot\nabla\frac{\partial}{\partial t}\right) - \nabla^2\right\} p' \;=\; \frac{\gamma-1}{c^2}\left(\frac{\partial \dot{Q}'}{\partial t} + \frac{U}{\mathcal{R}}\frac{\partial \dot{Q}'}{\partial \Theta}\right), \tag{1}$$

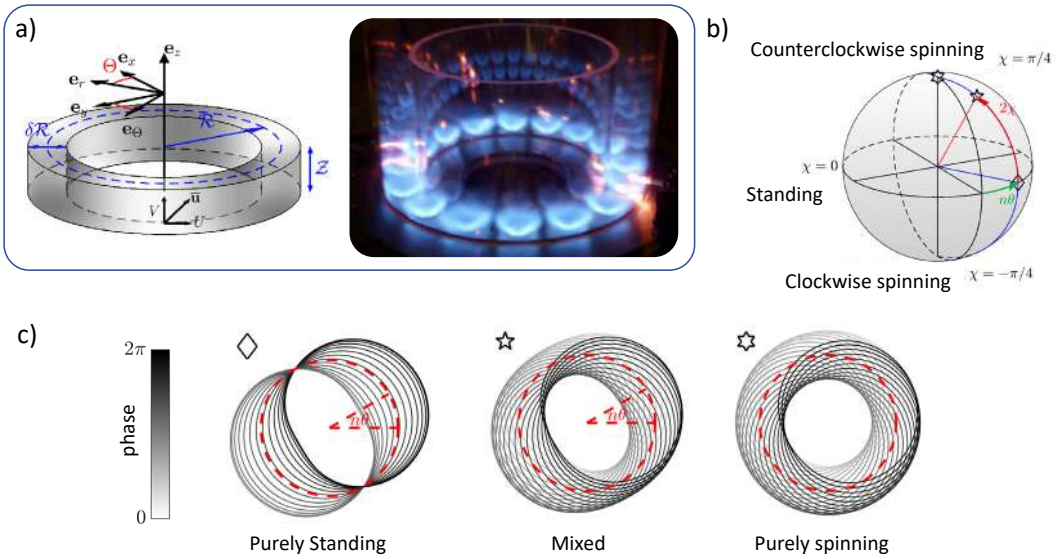

Figure (1) a) Sketch of an idealized annular combustor with coordinate system used in this work and picture of a lab-scale annular combustor [2]. b) Representation of the state of the thermoacoustic mode on the Bloch sphere, the markers correspond to the 3 cases displayed in c). c) Representation of the acoustic pressure in the chamber for 3 states of the first azimuthal mode: Standing mode with $\chi = 0$ and $\theta = \pi/6$, counterclockwise mixed mode with $\chi = \pi/6$ and $\theta = \pi/6$, and counterclockwise spinning mode with $\chi = \pi/4$.

*Corresponding author. E-mail: noirayn@ethz.ch

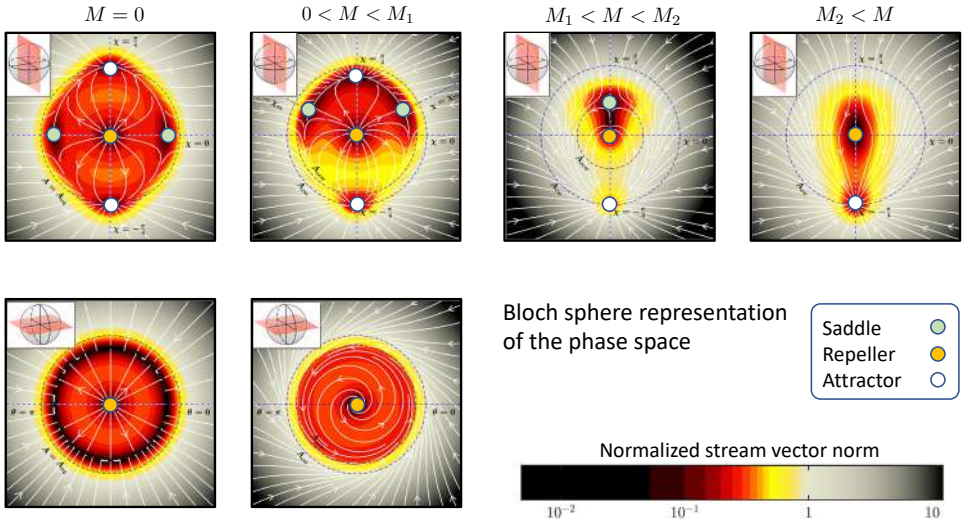

Figure (2) Streamlines describing the evolution of the phase space for a linearly-unstable azimuthal-thermoacoustic-mode, in the cases of a uniform distribution of the thermoacoustic feedback with and without uniform swirling mean flow. From left to right, the attractor landscape is modified when the Mach number $M = U/c$ of the azimuthal mean flow rises ($M = 0$, $M = 0.005$, $M = 0.02$ and $M = 0.1$). The other parameters are: $\beta = 160$ rad.s^{-1}, acoustic damping $\alpha = 155$ rad.s^{-1}, $\kappa = 0.5$ rad.s^{-1}Pa^{-2}, $\omega = 1167$ rad.s^{-1}.

where c is the speed of sound. The wave equation is then spatially and temporally averaged in order to obtain the system of differential equations, which governs the slow-flow phase-space variables [3]. In fact, the quaternion ansatz for the acoustic pressure $p' = \Re(\tilde{p})$ involves four real-valued variables that evolves slowly compared to the acoustic time scale $2\pi/\omega$. One has $\tilde{p}(\Theta, t) = A(t)\exp[i(\theta(t) - \Theta)]\exp[-k\chi(t)]\exp[j(\omega t + \varphi(t))]$, with i, j amd k the imaginary units of the quaternion algebra and with $(A, \theta, \chi, \varphi) \in \mathbb{R}^+\times]-\pi, \pi] \times [-\pi/4, \pi/4]\times]-\pi, \pi]$. The state of an azimuthal self-sustained thermoacoustic mode can then be graphically represented on a Bloch sphere with the first three slow-flow variables (A, θ and χ) taken as spherical coordinates as illustrated in Fig.1. Note that the temporal phase φ corresponding to slow drift of the fast oscillation frequency is not considered in this representation. The following dynamic system is then found for the slow-flow variables [3]:

$$\begin{cases} \dot{A} = \dfrac{1}{2}\Big(\beta\left[1 - M\sin(2\chi)\right] - \alpha\Big)A + \dfrac{3\kappa}{64}\Big(-5 - \cos(4\chi) + 4M\sin(2\chi)\Big)A^3, \\ \dot{\chi} = \dfrac{3\kappa}{64}A^2\Big(\sin(4\chi) + 6M\cos(2\chi)\Big) - \dfrac{M\beta}{2}\cos(2\chi), \\ \dot{\theta} = M\omega, \\ \dot{\varphi} = 0. \end{cases} \tag{2}$$

It allows us to describe the complex evolution of the phase space subject to explicit symmetry breaking associated to the presence of a mean swirling flow in the annular chamber (see Fig. 2). Indeed, the azimuthal Mach number $M = U/c$ breaks the symmetry between the two spinning waves. It is found that the counter-spinning modes have no longer the same frequency: $\omega(1 \pm M)$. Additionally, if the heat release occurs in a region where there is the uniform azimuthal mean flow, the spinning mode rotating against the swirl direction attracts the system with more strength than the co-rotating spinning mode. Beyond a critical azimuthal Mach number, a saddle-node bifurcation leads to a situation where the only attractor of the system is the spinning mode travelling against the mean swirl. Conversely, when the flames are not located in the convection zone, both counter-spinning modes are equally strong attractors (not presented in Eq. (2) nor in Fig. 2). The model predictions were recently confirmed experimentally [4], and this model can now be used to design interconnected nonlinear acoustic cavities for controlling the thermoacoustic instabilities in annular combustors. Indeed, taking advantage of these nonlinearities, unprecedented control will be achieved.

HARNESSING HYSTERESIS NONLINEARITIES IN MULTI-SCALE STRUCTURES

Walter Lacarbonara*
Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Roma, Italy

Summary Different kinds of multiscale hysteresis material and geometric nonlinearities can be advantageously harnessed for tailoring high performance material systems such as damping material layers, vibration absorbers or metamaterial systems embedding arrays of hysteretic resonators. Hysteresis is a memory-dependent material nonlinearity that can be exhibited as inter-wire friction in wire ropes, inter-crystal friction in shape memory materials (SMA), frictional sliding between polymer crystals or chains and carbon nanotubes (CNT) in nanocomposite materials. Previous works addressed SMA wire ropes hysteresis in nonlinear vibration absorbers and isolators as well as nanoscale frictional phenomena in nanocomposite CNT/polymer materials. The main focus here is on high-performance metamaterials featuring a periodic distribution of highly tunable damped oscillators with geometric and hysteresis nonlinearities. The nonlinear wavefrequencies and waveforms away from internal resonances obtained via a Lie series-based perturbation technique exhibit a high nonlinear tunability which is a key for advanced applications.

HYSTERESIS IN ABSORBERS AND NANOSTRUCTURED MATERIALS

Previous efforts addressed the high nonlinear tunability of a hysteretic vibration absorber [1] made of a constrained moving mass subject to the restoring forces of assemblies of steel and SMA wire ropes with different constraining mechanisms for the ropes. Such tunability is manifested in the rich nonlinear frequency response function ranging from softening

O107079

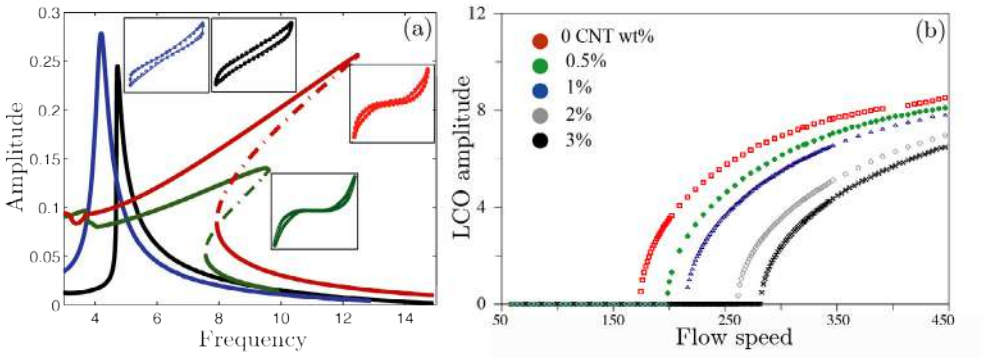

Figure 1: Two examples of high nonlinear dynamic tunability offered by (a) a vibration absorber with various hysteresis loops and frequency response functions, (b) supersonic flutter shift and LCO reduction vs. flow speed in a simply supported nanocomposite panel with different CNT weight fractions.

to hardening within the same multi-performance device (see Fig. 1a). Other applications dealt with isolators which combined the nonlinear hysteretic restoring forces of elastomers and SMA wires with the beneficial effects of a negative stiffness mechanism [2]. On a much different material scale, the frictional damping of carbonaceous nanofillers (here CNTs) [3, 4] dispersed in polymer hosting matrices was shown to lend itself to optimize high damping materials such as nanocomposite panels subject to supersonic flutter (see Fig. 1b). A multiple scales perturbation analysis proved that small CNT weight fractions can largely increase the flutter speed as well as control the limit cycle oscillation amplitude in the post-flutter range [3].

NONLINEAR WAVE PROPAGATION IN HYSTERETIC METAMATERIALS

A new hysteretic metamaterial is envisioned as an infinite one-dimensional periodic chain of stiff rings, each hosting a tunable *local resonator* with geometric and hysteresis nonlinearities [5].

The free propagation of nonlinear waves through such dissipative periodic lattice, by making use of the Floquet-Bloch theory for periodic structures, is governed by the following system of ODEs:

$$(1+\rho^2)\ddot{u}+\rho^2\ddot{w}+2l(\beta)u=0,\quad \rho^2\ddot{u}+\rho^2\ddot{w}+G(w,\dot{w})+F(w)=0 \tag{1}$$

where u and w denote the nondimensional displacement of the cell center of mass and of the resonator mass, respectively, $l(\beta):=(1-\cos\beta)/2)$ with β being the nondimensional wavenumber, (F,G) indicate the restoring forces in the springs and the hysteretic dashpot expressed as

$$F(w):=2w\left(\eta+(\mu-\eta)/\sqrt{1+w^2}\right),\quad G(w,\dot{w}):=\xi_1\dot{w}\left(1-\xi_2\exp(-\xi_3 w^2)\right) \tag{2}$$

*E-mail: walter.lacarbonara@uniroma1.it.

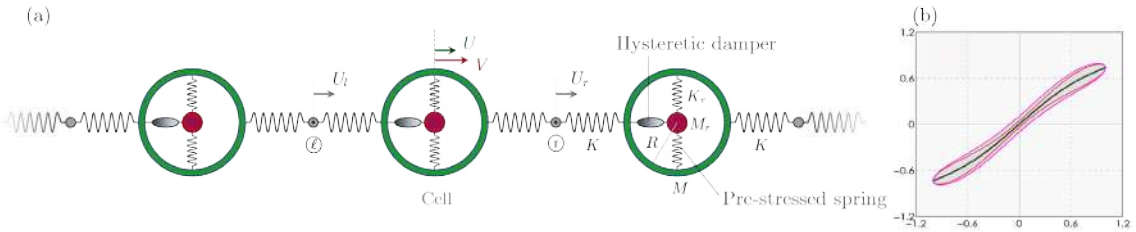

Figure 2: (a) 1D lattice of periodic cells (green) hosting nonlinear absorbers (red); (b) hysteresis loops of the cell response.

Moreover, ρ^2 is the mass ratio between the absorber and the ring, μ and η describe the nondimensional geometric and elastic stiffnesses of the secondary springs, and (ξ_1, ξ_2, ξ_3) are the coefficients regulating the hysteresis of the dampers. The third order Taylor series expansions of F and G yield $F(w) = 2\mu w - dw^3$ and $G(w, \dot{w}) = m\dot{w} + h\dot{w}w^2$ where $d := (\mu - \eta)$, $m := \xi_1(1 - \xi_2)$, $h := \xi_1\xi_2\xi_3$. Thus, d is the cubic stiffness coefficient (entailing a hardening nonlinearity if $d < 0$ or a softening nonlinearity if $d > 0$). On the other hand, while $m > 0$ is the linear damping coefficient, h scales the cubic part of the hysteresis damper force.

Equations (1) can be reduced to a first order form via a standard approach and then projected into the eigenvectors space. The four eigenvalues, for sufficiently small damping, are given by $\lambda_{1,2} = \alpha_1 \pm i\beta_1$, $\lambda_{3,4} = \alpha_2 \pm i\beta_2$, with $\alpha_{i,j}$ and $\beta_{i,j}$ both real. The Lie series operator approach to Hamiltonian perturbation theory is employed to yield the lowest order normal form in terms of time-dependent *action-angle* (I_j, ϕ_j)-variables (with $j = 1, 2$)

$$\dot{I}_j = 2I_j \left[M_{1,2}^{(j)} e^{2\alpha_1 t} I_1 + M_{3,4}^{(j)} e^{2\alpha_2 t} I_2 \right], \quad \dot{\phi}_j = \beta_j + \left[N_{1,2}^{(j)} e^{2\alpha_1 t} I_1 + N_{3,4}^{(j)} e^{2\alpha_2 t} I_2 \right] \tag{3}$$

which yield $\dot{\phi}_j = \beta_j + \left[N_{1,2}^{(j)} e^{2\alpha_1 t} I_1(0) + N_{3,4}^{(j)} e^{2\alpha_2 t} I_2(0) \right]$ on account of the fact that, to within leading order, $I_j(t) = I_j(0)$. The coefficients $N_{i,k}^{(j)}$ regulate the nonlinear frequency corrections of the acoustic $(j = 1)$ and optical $(j = 2)$ waves (see dispersion curves in Fig. 3a). The associated frequency corrections are softening (or hardening) depending on whether these coefficients are positive (or negative). Note that the coefficients depend on the mechanical parameters of the metamaterial, hence the waves can be largely tuned and made faster or slower on demand.

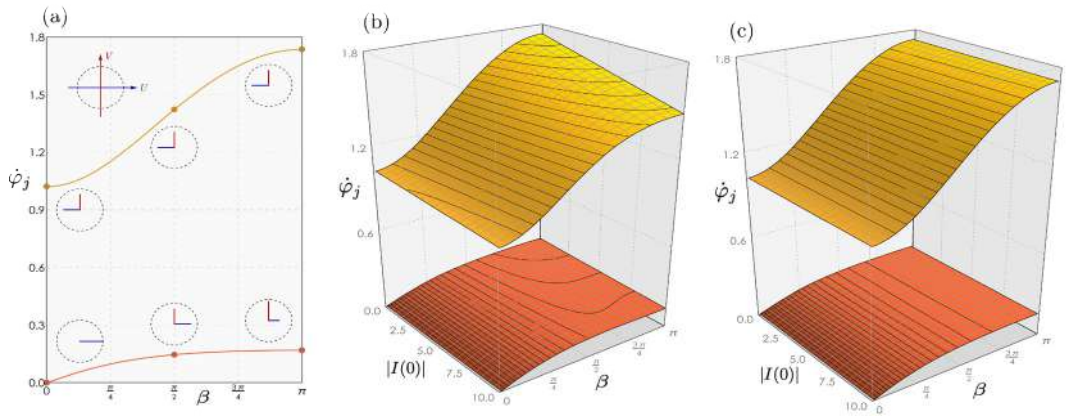

Figure 3: (a) Linear spectra for the acoustic and optical waves and snapshots of the nonlinear spectra with dissipation at different times: (b) $t = 0$ and (c) $t = 50$.

CONCLUSIONS

This paper discussed ways to harness multiscale hysteresis in multi-scale structures and metamaterials. The possibility of tailoring the metamaterial lattice properties to make the nonlinear waves faster or slower and of making these nonlinear effects more or less persistent over time depending on the hysteretic dissipation while allowing to fine tune the phases of the different waves is one of the key properties under investigation.

ON NONLINEAR VIBRATION ISOLATION VIA QUASI-ZERO STIFFNESS CHARACTERISTIC: BENEFITS AND CHALLENGES

Ivana Kovacic[1]
[1] Centre of Excellence for Vibro-Acoustic Systems and Signal Processing, Faculty of Technical Sciences, University of Novi Sad, Novi Sad, Serbia

Summary This work summarizes some of author's results achieved in the field of vibration isolation from the viewpoint of the beneficial use of geometric stiffness nonlinearity. The focus is on two models that contain springs which incline as they extend, introducing geometric stiffness nonlinearity into the equations of motion. The systems under consideration have either one or two degrees of freedom. In both of them, springs' characteristics are tuned to intentionally achieve a quasi-zero stiffness characteristic, and the beneficial regions of systems' parameters for vibration isolation are determined. It is also shown that these systems can exhibit certain nonlinear dynamic phenomena, including multiple bending of the backbone curves, different types of bifurcation and detached outer or inner parts of the frequency-response curves.

INTRODUCTION

Passive vibration isolation is one of the routes for mitigating undesirable vibration [1]. Last several decades and especially the very last one, have opened some new avenues for progress in this respect via intentional use of geometric stiffness nonlinearity [2, 3]. This work summarizes some of author's related results [4-10] achieved mainly jointly with her colleagues, primarily M.J. Brennan, Universidade Estadual Paulista, Ihla Solteria, Brasil [4-8] and also with G. Gatti, University of Calabria, Cosenza, Italy [7, 8]. The focus is on the utilization of geometric nonlinearity in two physical configurations that include springs that incline as they extend and can be optimised to result in quasi-zero stiffness: (i) Model 1 has one degree of freedom and contains three springs, while (ii) Model 2 has two degrees of freedom and comprises a linear oscillator and a nonlinear attachment consisting of four springs. Besides emphasizing the exploited beneficial effects of geometric stiffness nonlinearity, certain challenges and potential issues brough into bear by systems' nonlinear dynamics are pointed out as well.

MODEL 1

It is known that in a harmonically excited linear mass-spring system, the lower its natural frequency, the wider the isolation region and the more advantageous its application. This low natural frequency can be achieved by low static stiffness, which undesirably causes a large static deflection. This disadvantage can be overcome by adding additional springs that become oblique as the system oscillates (Figure 1a), introducing geometric nonlinearity into the equation of motion. Moreover, acting as a negative stiffness, such oblique springs can be adjusted to result in zero dynamic stiffness, i.e. the so-called quasi-zero stiffness (QZS). The QZS mechanism can produce a smaller stiffness at larger displacements about the static equilibrium position than the system with the linear springs [4] and can also yield certain improvements of the transmissibility properties [5, 10]. However, it is found analytically and confirmed numerically that such a nonlinear vibration isolator under an asymmetric excitation comprising a constant and harmonic excitation can exhibit bifurcations related to different shapes of their frequency-response curves (FRCs), where five different regions I-V can be distinguished (Figure 1b). They are characterized by different bending of the FRCs, different number of multiple solutions in certain frequency regions and multiple amplitude jumps [6]. The example of the FRCs corresponding to the regions II and III are presented in Figure 1c. This system can also exhibit period-doubling bifurcations and chaos [9], which need to be taken into consideration when making a choice of a suitable operating regime.

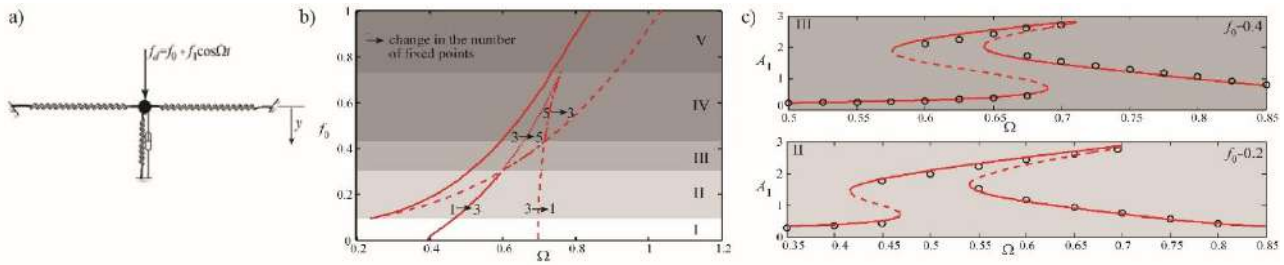

Figure 1. (a) Model 1 excited by a constant force f_0 and a time-varying force $f_1 \cos \Omega t$; (b) Saddle-node bifurcation set in the plane defined by the excitation frequency Ω and magnitude of the constant force f_0 (note that the set can be divided into five different regions labelled by I-V; (c) Typical shapes of the FRCs corresponding to the regions II and III (solid line – stable analytical results, dashed line – unstable analytical results, circles – numerical results).

Besides this physical configuration in which QZS is achieved via obliques springs, the presentation will also include the overview of other systems citing [4], but investigating the effects of QZS in the system whose design include magnets, X-shaped structures, cam-roller mechanisms, origami-inspired foldable cylinders, composite plates, etc. (Note that the number of citations of [4] is 224, source: SCOPUS, 3 Jan 2020, and the examples mentioned follow up [4]).

MODEL 2

Model 2 comprises a nonlinear oscillator attached and driven harmonically by an electro-dynamic shaker [7, 8]. The shaker is modelled as a linear oscillator and the nonlinear attachment consists of four springs (wires) [7], which incline as they extend (Figure 2a). The model is investigated in terms of the FRC of the relative non-dimensional displacement W, where the nonlinear attachment has a very small linear stiffness coefficient, which can be practically achieved by a very low tightening of the suspension springs during assembly of the mechanical rig, and this corresponds to a QZS configuration around the equilibrium position. It is found analytically and confirmed numerically that as a result of the change of the coefficient of pure cubic nonlinearity of the attachment, five different shapes of the FRCs can appear. Some of them are characterized by a two-part FRC, where a closed detached curve can appear outside or inside the main continuous resonance curve (Figure 2b). The latter is associated with a lower steady-state amplitude, and is, thus, desirable in practice. Experimental verifications of its existence are given in [11]. The presentation will include the overview of various methods (analytical, numerical and experimental) and the corresponding results completing the investigations of this system (Note that the number of citations of the related publications [7, 8] is 129, source: SCOPUS, 3 Jan 2020).

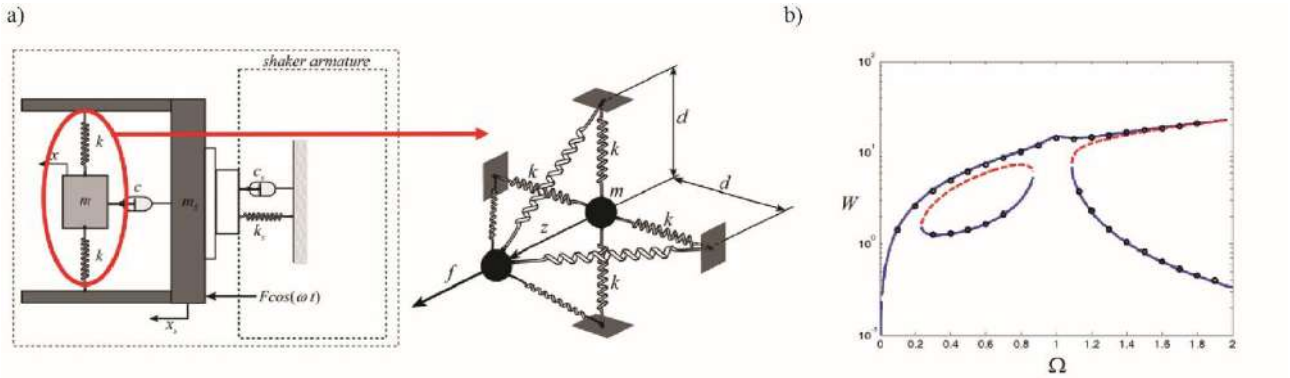

Figure 2. (a) Model 2 with the attachment comprising four springs; (b) One typical FRC with an inner detached part (solid line – stable analytical results, dashed line – unstable analytical results, circles – numerical results).

CONCLUSIONS

Two mechanical models comprising certain arrangements of springs whose deformations introduce geometric nonlinearities into the equation of motion have been presented. Certain characteristics of these springs can be adjusted to achieve a QZS configuration around the equilibrium position. The benefits of such configurations for nonlinear vibration isolation have been determined. In a system with one degree of freedom, these benefits involve widening the isolation region and achieving a smaller stiffness at larger displacements. In a system with two degrees of freedom, a detached part of the FRC appears inside the main continuous resonance curve, having a smaller steady-state amplitude than the co-existing stable solution at the same frequency. In both models, these beneficial effects are related to particular values of systems' parameters. It has also been demonstrated that variations of systems' parameters can lead to a diversity of nonlinear phenomena, which is a challenge to be taken care of in practical applications.

STABILITY AND STEERABILITY OF ROTARY STEERABLE SYSTEMS

Emmanuel Detournay *[1]
[1] Department of Civil, Environmental, and Geo- Engineering, University of Minnesota, USA

Summary Drilling geometrically complex boreholes in the subsurface has been made possible with the development of downhole tools that steer the bit. This paper outlines a model of borehole propagation that can be used to predict the bit trajectory and assess the conditions leading to abnormal situations, namely: the borehole tending to steer opposite to that intended with the steering tool; and a loss of directional stability leading to a limit cycle characterized by self-excited oscillations of the borehole attitude. Both the directional stability of the system and the counter-intuitive behaviors can be related to a key dimensionless group that can be interpreted as the ratio of a pseudo-stiffness characterizing the bit/rock interaction and the bending stiffness of the BHA.

INTRODUCTION

Drilling deep boreholes that weave complex trajectories in the subsurface has been made possible with the development of directional drilling, and in particular with the emergence of the *rotary steerable systems* (RSS) in the late 1990's. These servo-controlled downhole robots steer the bit by either applying a force on the borehole wall or by tilting the bit. Figure 1a sketches a typical rotary drilling structure, comprising a rig from which is suspended the *drillstring*. The rotary speed and the axial force (*hookload*) are imposed at the rig. The lower part of the drillstring is the *bottomhole assembly* (BHA), which is usually about one hundred meters long. It consists of heavier pipes and short elements of larger diameter, called *stabilizers*, which center the BHA in the borehole. The BHA or part of it is in compression in order to induce a sufficient *weight on bit*, the axial force transmitted to the bit at the lower extremity of the BHA. The RSS is located close to the bit. Such a semi-automated device works in association with sensors and downhole control units in order to steer the borehole. Considerations are restricted here to *push-the-bit* RSS, which apply a lateral force at a designated location on the BHA using a set of extensible pads that directly push on the borehole wall.

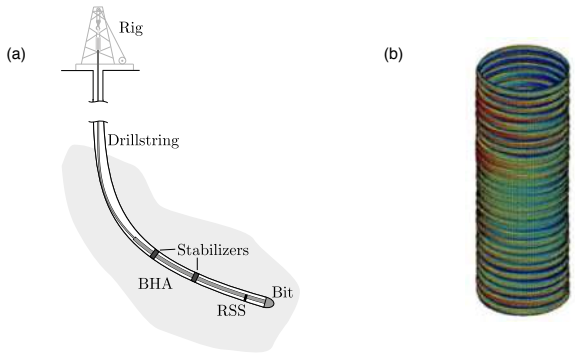

Figure 1: (a) Sketch of a drilling structure and (b) evidence of borehole spiraling from density log [8]

Study of this dynamical system is motivated by engineering issues, which include bit selection, designing the BHA to increase, maintain, or decrease the borehole inclination with or without the presence of a RSS [5], preventing borehole spiraling (Figure 1b) — an expression of self-excited limit cycle oscillations triggered by a directional instability of the drilling system and sustained by nonlinearities such as saturation of the bit tilt or intermittent contacts between the BHA and the borehole wall [4, 3], and devising an appropriate controller for the RSS to track a predefined well path [1, 2].

MATHEMATICAL MODEL

The borehole propagation model is constructed at the intermediate scale of the BHA, with boundary conditions capturing the processes at the two other scales [6, 7]. At the lower boundary, the bit is collapsed onto a point, with the details of the bit/rock interaction encapsulated into an interface law that relates the force and moment at the bit to penetration variables. At the upper boundary, the action of the drillstring is replaced by assumed known forces. All the dynamic and kinematic variables are averaged over many revolutions, implying that borehole propagation is a quasi-static process.

The directional propagation of the borehole depends on the force and moment at the bit; they are affected not only by the action of the RSS but also by the deformed configuration of the BHA, which is constrained by the stabilizers to espouse the existing borehole. The propagation of the borehole is thus governed by the interaction between a geometrical object, the wellbore, and a mechanical object, the drilling structure. The directional drilling model can be formulated by combining (i) a rate-independant *bit/rock interface law*, (ii) the *kinematic relationships* between the bit penetrations

*E-mail: detou001@umn.edu.

and the parameters characterizing the evolving geometry of the borehole, and (iii) the *beam model of the BHA* providing relationships linking the generalized forces at the bit to the geometry of the borehole and other external loads acting on the BHA. The equations governing the three elements of this model can be combined into two delay differential equations (DDEs), which represent the evolution equations for the borehole inclination and azimuth. The delays, corresponding to the positions of the stabilizers, capture the feedback of the borehole geometry on the transverse force applied at the bit.

Analysis of the propagation equations shows the existence of a critical dimensionless group $\eta\Pi = \eta W_a \ell_1^2/3EI$, which depends on several properties of the system: (i) lateral steering resistance η of the bit, a number that depends on the characteristics of the bit gauge; (ii) active weight on bit W_a, equal to the weight on bit reduced by the force transmitted by the wear surface of the bit; (iii) distance ℓ_1 between the first stabilizer and the bit; and (iv) bending stiffness EI of the BHA. Group $\eta\Pi$, typically of order $O(10^{-2} \sim 1)$, can be viewed as contrasting the resistance of the rock with the stiffness of the BHA, as the bit is tilted.

STABILITY AND STEERABILITY

The question of whether borehole spiraling occurs or not can be formulated as to whether a perturbation in the borehole trajectory is progressively amplified or dampened along the borehole, due to the geometric feedback embedded in the system, until a limit cycle is reached. A stability analysis of the governing DDEs indicates that there exists a critical value $\eta\Pi|_s$ of dimensionless group $\eta\Pi$, so that the system is unstable for $\eta\Pi < \eta\Pi|_s$, with the wavelength of the oscillations about equal to the distance between the bit and the first piece of equipment in contact with the wellbore — usually the first stabilizer. For a BHA with uniform mechanical properties, the bifurcation limit $\eta\Pi|_s$ depends essentially on the relative positions of the stabilisers. Although the BHA configuration can help make a system intrinsically more stable (*i.e.*, a system having a small $\eta\Pi|_s$), a system that is directionally stable initially may become unstable with increasing bit wear, higher rock strength, or reduced downhole weight on bit, all of which reduce the active weight.

The steerability of the drilling assembly also depends on $\eta\Pi$. Indeed, analysis of the DDEs indicate the existence of two particular values of that group, $\eta\Pi|_{\mathcal{V}}$, and $\eta\Pi|_{\mathcal{X}}$, that control the existence of different regimes of propagation. If $\eta\Pi = \eta\Pi|_{\mathcal{V}}$, the RSS is ineffective and the only possible solution is a vertical borehole; if $\eta\Pi = \eta\Pi|_{\mathcal{X}}$, gravity has no influence of the borehole trajectory. Thus $\eta\Pi|_{\mathcal{V}}$ characterizes the limit of steerability, as the borehole tends to steer opposite to that intended if $\eta\Pi \geq \eta\Pi|_{\mathcal{V}}$, while $\eta\Pi|_{\mathcal{X}}$ characterizes a holding tendency that marks, in the absence of a RSS, the transition between a dropping and a buiding assembly (respectively, negative and positive curvature of the trajectory).

The global response of the system to external loads is thus controlled predominantly by $\eta\Pi$ and the BHA configuration, on which the critical values depend. Noting that the steerability limit $\Pi|_{\mathcal{V}}$ is typically one order of magnitude larger than the stability limit $\eta\Pi|_s$, the directional drilling system should be designed in such a way that $\eta\Pi|_s < \eta\Pi < \eta\Pi|_{\mathcal{V}}$ so as to ensure both directional stability and steerability of the drilling assembly. Since $\eta\Pi$ is inversely proportional to D^4, with D the diameter of the BHA, small diameter BHAs are usually directionally stable, but could be prone to counter-intuitive drilling regimes. For large-diameter BHAs, the opposite is true: they are more at risk for directional instability, but less for a reversal of drilling regimes. The position of the first stabilizer is also influential as $\eta\Pi$ is proportional to ℓ_1^2.

CONCLUSIONS

The propagation of a borehole is governed by a set of delay differential equation in terms of the borehole inclination and azimuth, with the spatial delays corresponding to the position of the stabilizers on the BHA. Dimensionless group $\eta\Pi$, which measures the rock resistance against a tilt of the bit relative to the flexural rigidity of the BHA, is central to characterize the borehole trajectory. Indeed, the magnitude of $\eta\Pi$ relative to critical values that depend on the BHA configuration, defines different drilling regimes.

EMERGENT SUBHARMONIC ATTENUATION ZONES IN NONLINEAR LOCALLY RESONANT METAMATERIALS: NUMERICAL MODELING AND EXPERIMENTS

Valentina Zega*[1], Priscilla B. Silva[1], Marc G.D. Geers[1] and Varvara G. Kouznetsova [1]
[1] Eindhoven University of Technology P.O. Box 513, 5600 MB Eindhoven, The Netherlands

Summary Locally resonant metamaterials are attracting increasing interest from the scientific community because of their extraordinary properties, in particular the subwavelength size of their unit cell. Recently, we theoretically proved a new mechanism for wave mitigation and control that exploits the nonlinear behaviour (i.e. autoparametric resonance) of the resonant components of the unit cells of a locally resonant metamaterial. It consists in the nonlinear interaction between propagating and evanescent waves and leads to the opening of subharmonic attenuation zones. Here, we present the design of a new single-material nonlinear locally resonant metastructure able to exploit such principle and we provide, to the best of our knowledge, the first experimental evidence of the discovered phenomenon. A good agreement between experiments and numerical prediction is also shown.

INTRODUCTION

Acoustic metamaterials and phononic crystals provide new possibilities for acoustic wave control and manipulation, as e.g. overcoming the traditional limits in focusing, wave guiding, and subwavelength sound and vibration insulation [1]. Recently, the consideration of nonlinearity in these engineered materials has opened up new possibilities [2]. In particular, we have recently theoretically shown the existence of a new mechanism for wave mitigation and control that consists in a nonlinear interaction between propagating and evanescent waves in a nonlinear elastic locally resonant metamaterial due to autoparametric resonance and discovered the consequent appearance of a subharmonic attenuation zone in the transmission diagram [3]. In the previous work [3], a simple mass-spring chain was considered to physically unraveil the phenomenon. Here we design a single-material nonlinear locally resonant metastructure, and we experimentally demonstrate the emergence of the subharmonic attenuation zone in the transmission diagram induced by autoparametric resonance. To the best of our knowledge, this represents the first experimental evidence of emergent subharmonic attenuation zones in nonlinear locally resonant metastructures. Numerical and analytical models supported the design process of the resonant unit-cell and show good agreement with the experiments.

NUMERICAL MODELLING

The proposed locally resonant metastructure consists of a chain of 50 unit cells (2.2 cm x 6.9 cm x 5 mm) made by an external frame and an inner mass connected to the frame through two pre-deflected arch beams (Figure 1), providing the required nonlinear coupling between the matrix and the resonator. The simple geometry and the use of a single material allows to manufacture the prototype using standard production. In the present design of the unit cell, quadratic nonlinearities, responsible of the emergence of subharmonic bandgaps induced by autoparametric resonance, appear because of the pre-deflection breaking the symmetry in the resonator, while cubic terms are related to the effect of the axial load on a clamped-clamped beam for large displacements of the mass [4].

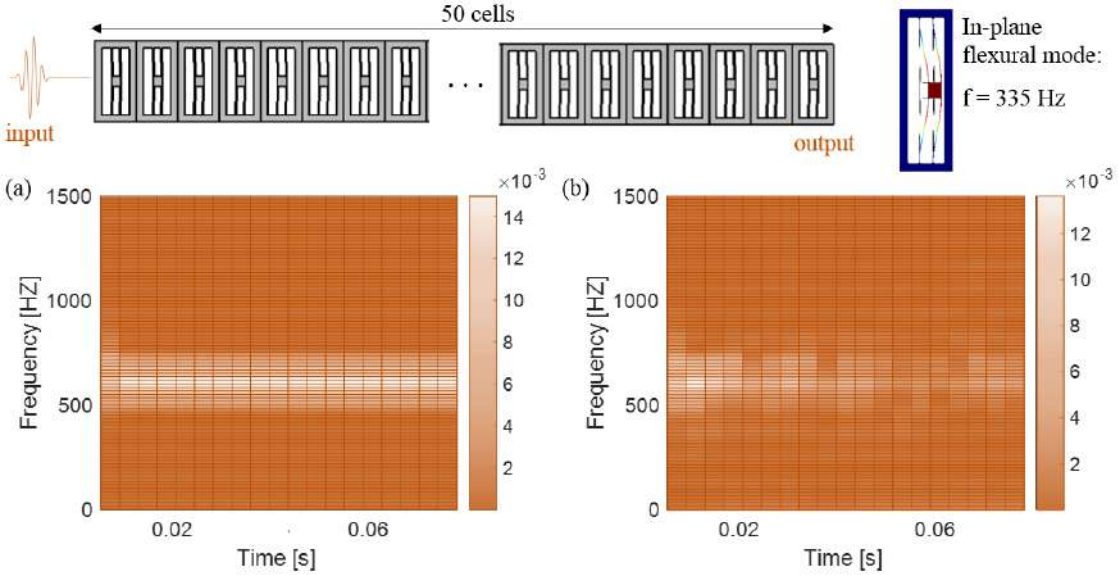

Figure 1. Nonlinear locally resonant metastructure and the first in-plane flexural mode of the unit cell. Spectrograms of the output signal computed at the right end of the chain in the (a) linear and (b) nonlinear regimes when a burst of 4 periods at around two times the natural frequency of the in-plane flexural mode of the resonator is applied as the input on the left side of the chain.

*Corresponding author. E-mail: zega.valentina@gmail.com.

As expected from the theory, the locally resonant metastructure shown in Figure 1 presents a bandgap in the longitudinal direction (only longitudinal waves are considered here for the sake of simplicity) around the natural frequency of the in-plane flexural mode of the inner resonator (f = 335 Hz from the modal analysis performed in COMSOLMultiphysics©). When an input signal at around two times the natural frequency of the inner resonator (700 Hz) is applied to the left side of the chain in the form of a prescribed 4-period burst displacement, on the right side of the chain full propagation (Figure 1a) is observed in the linear regime, while in the non-linear regime strong attenuation (Figure 1b) is obtained. Indeed, when the applied displacement is small, the autoparametric resonance does not activate and no attenuation outside of the bandgap frequency range is present. On the other hand, when the input displacement is sufficiently large to activate the nonlinear behaviour of the resonator, the autoparametric resonance induces the energy transfer mechanism between propagating and evanescent waves and a second attenuation zone emerges at two times the natural frequency of the resonator [3]. The numerical results reported in Figure 1 are obtained through 2D transient analyses in COMSOLMultiphysics© under the hypothesis of plane stress.

EXPERIMENTS

A prototype of the designed nonlinear locally resonant metastructure is fabricated from a single plate of AlMgSi1 alloy of 0.5cm thickness by electrical discharge machining (EDM). The employed experimental set-up is shown in Figure 2a: it consists of a shaker to apply the input displacements at the beginning of the chain, a laser vibrometer to detect the output displacements at the end of the chain and an acquisition board to transfer the signals to a computer for post-processing. The metastructure is suspended on wires to simulate free conditions on both top and bottom surfaces, as well as on one of the metastructure ends, thus avoiding any interaction with the table that could compromise the measurements.

The transmission diagram (20 $\log_{10}$ (output/input)) is measured in a wide range of frequencies for three different amplitudes of the input signal. When the amplitude input is small enough to not activate the nonlinear behavior of the resonator (red line in Figure 2b), the transmission diagram shows the expected linear behaviour with an attenuation in the proximity of the resonant frequency of the inner resonator and a full transmission at higher frequencies. When the input signal amplitude increases, a second attenuation zone emerges at two times the natural frequency of the inner resonator (blue and green lines in Figure 2b), as predicted by numerical analyses (Figure 1) and theoretical models [3].

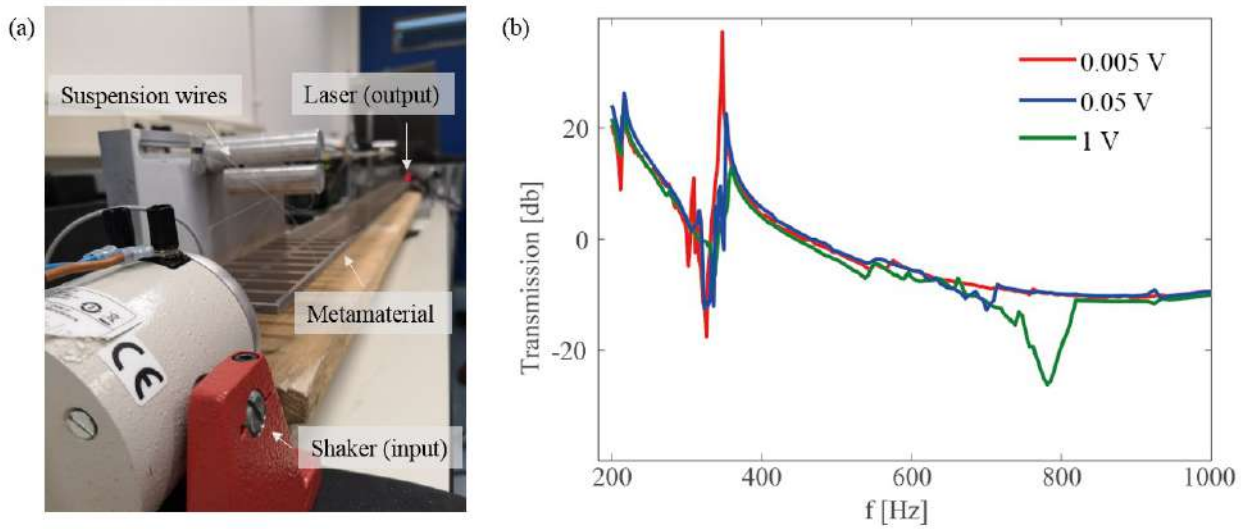

Figure 2. (a) Experimental set-up. (b) Transmission plot measured for different amplitudes of the input signal.

CONCLUSIONS

To the authors' knowledge, this work presents the first experimental evidence of the subharmonic attenuation zone induced by the autoparametric resonance energy exchange in a non-linear locally resonant metastructure. To this end, a new single-material nonlinear locally resonant metastructure has been designed and fabricated with standard processing techniques. Numerical simulations reveal an adequate agreement with experiments. This work exposes a new generation of nonlinear metastructures/metamaterials that can be employed in numerous potential applications.

BALLISTIC STUDY OF LONG ROD ERODING PROJECTILES AGAINST RHA AT OPTIMUM (L/D) RATIOS

Sana Zaki[1] and Dr Amir Mubasher [2]
[1] Department of Mechanical Engineering, SMME NUST, Islamabad
[2] Department of Mechanical Engineering, SMME NUST, Islamabad

Summary Long rod penetrators exhibit hydrodynamic behavior while striking against the target plates. Efforts of enhancing the target damage is the main purpose for upgrading the lethality of rounds. An experimental study is therefore devised controlling multiple variables like: change in penetrator length to penetration (P/L), optimizing length to diameter ratios (L/D) and material properties of TA rods. Every parameter has a unique contribution to the eroding pattern of projectiles which are later analyzed with numerical simulations in Abaqus. For optimization of parameters with the existing performance of rounds results from high speed camera are also accorded in the experimental study. It is found that the overall stability of eroding rod depends on smooth bore of heavy caliber gun, appropriate composition of charge bags (MCS and ACS), stable discarding of sabots and zero angle of attack while the long rod approaches to the target.

Introduction

Long rod kinetic energy rounds exhibit hydrodynamic behavior at their working velocities usually 1400-2000m/s. The eroding pattern of projectile into RHA at specified velocity, density and impact energy determines the damage done to Target. Several factors like increase in penetration to length (P/L), length to diameter (L/D) and material properties of penetrator are studied extensively and different combinations were subjected to test and trail to enhance the penetration. This hydrodynamic flow of Tungsten alloy penetrator in Target has been explained by various models, initially by the simplified Bernoulli equation [1] which is later on extended to modified equations by Tate [2,3,4] and Alekseevskii.

Analytical Tools

The perforation energy plays a vital role in achieving desired penetration of TA rod in RHA plate. Hence a projectile predictive model based on energy approaches is used [6]

$$E = kd^m t^n$$

Where,

$$m + n \approx 3$$

E: is the perforation energy
d: is the projectile diameter
t: is the plate thickness
k: is an empirically derived constant (as in figure 4)

MINI SYMPOSIA

Design Optimization

Case I: Change in Penetration with Penetrator Length (P/L)

The length of penetrator plays a vital role in ballistic study of long rod penetration.

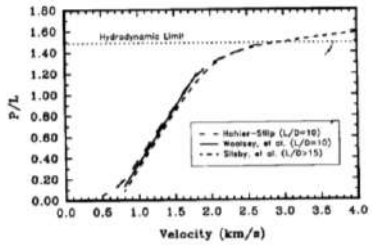

Fig 6. Hydrodynamic limit on penetration with change in (P/L) [9, 10, 11]

Case II: Change in Penetration with Length to Dia ratios (L/D)

In this study, the change in L/D has been examined both analytical and experimentally within $10 \leq L/D \leq 30$. Also there are certain analytical tools which verifies the depth of projectile in target plate. Lanz and Odermat [15] predicted an empirical formula that explicitly accounts the term L/D as shown in the below equation

$$\frac{d}{L} = \tau\left\{1 + \tau\frac{3.77}{L/D}\left[1 - tanh\left(\frac{L/D - 10}{6.89}\right)\right]\cdot\pi\left(\frac{\rho_t}{\rho_i}\right)^{0.745}\pi(\cos\theta)^{0.745}\cdot e^{-\frac{25.98}{\rho_t}V^2}\right\}$$

Case III: Change in Penetration with Penetrator Composition (W)

The overall functioning of kinetic energy rods are dependent on impact velocity, geometric parameters and material composition [16]. This process can be related with the below model

$$\sigma\tau = \varpi_s + \varpi_d \qquad \text{Eq (3.1)}$$

Experimental Results

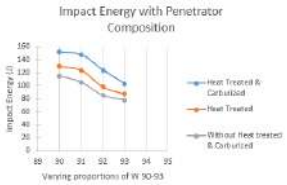

Graph 4. The change in penetration with increase in Impact Energy.

CONCLUSIONS

Long rod projectiles have multiple design variables that can increase target damage. In this study design optimization of 125mm APFSDS has been carried out and it is found that for a working range of L/D between 20-30 at ordnance impact velocity 1640m/s and impact energy 158J (W90-Ni-Cr-Fe) maximum penetration was achieved. It can also be concluded that at ordnance velocities the change of various variables like P/L and L/D is less significant than material composition related to its impact energy.

NONLINEAR DYNAMICS AND CONTROL OF AN AEROELASTIC AIRFOIL MODEL WITH RANDOM NOISY FLUCTUATIONS

Yong Xu *[1, 2], Qi Liu[1], and Jürgen Kurths[3]
[1] School of Mathematics and Statistics, Northwestern Polytechnical University, Xi'an 710072, China
[2] MIIT Key Laboratory of Dynamics and Control of Complex Systems, Northwestern Polytechnical University, Xi'an 710072, China
[3] Potsdam Institute for Climate Impact Research, Potsdam 14412, Germany

Summary Uncertain fluctuations widely exist in practice, such as turbulence, crosswind, pressure fluctuations, etc. It is of significance and meaning to explore complex random dynamics and control for a conceptual airfoil model. In this work, we study an airfoil model subject to various random excitations, including Gaussian noises and narrow-band noise as primary approximations to model external random fluctuations. Therein, viscoelasticity of the airfoil models are also included. Theoretical analysis is implemented by averaging technique or multiple-scales method, and its correctness is verified. We uncover that the airfoil models can show multiple-values responses and stochastic transitions due to the existing of nonlinearities and random fluctuations, and sliding mode control is employed to achieve the vibration suppression. Moreover, a fixed-interval smoothing of the airfoil model is also addressed. All the results indicate that our works may provide a valuable support for the structural design of aircrafts.

INTRODUCTION

During the past few decades, nonlinear aeroelastic dynamics of typical airoil models has attracted widespread attention, which have also been a hot topic in the aerospace field. For example, Lee et al. [1] studied nonlinear behaviors of airfoil models with three common structural nonlinearity, namely, cubic, free-play and hysteresis. However, most of the studies only focus on the case without random fluctuations, and influences of complex external random factors are not considered. In fact, many uncertain fluctuations always exist in real environments, such as atmospheric turbulence, pressure fluctuation, random wind loading, etc [2]. The aeroelastic airfoil models, as typical nonlinear systems, can exhibit several complex nonlinear dynamic behaviors under random fluctuations, such as random flutter, stochastic bifurcation and jumps, etc. Therefore, it is of significance to study the nonlinear dynamic behaviors of the airfoil models with complex random disturbances. In recent years, nonlinear dynamics of airfoil models subject to different uncertain disturbances have been reported. For instance, random flutter of two-dimensional airfoil model was investigated by means of a probabilistic and statistical methods [3, 4]. In addition, stochastic bifurcation and early warning of a typical airfoil section were studied through experimental and numerical approaches [5]. However, most of the works are based on numerical simulations or experiments, and rarely focus on a theoretical analysis. It should be noted that coupling of the random disturbances and the nonlinear factors brings great difficulties and challenges to the analysis in theory. Consequently, this work attempts to review some of our advances on nonlinear dynamics of typical airfoil models with varying random fluctuations, including Gaussian white noise, Gaussian colored noise and narrow-band noise. Meanwhile, we also study the fixed-interval smoothing problem of the airfoil models, and accurate state and parameter estimations are obtained.

RESULTS

As we know, a typical airfoil section can be simplified as a conceptual two-degrees-of-freedom model which oscillates in the plunge and pitch directions [1, 3, 4, 5, 6, 7, 8, 9], as shown in Fig. 1. The pitch angle α is positive if nose-up; the plunge deflection h is positive in the downward direction. L and M are the aerodynamic lift and moment acting on the airfoil respectively, U represents the flow velocity, and b is the half-chord length. EA is the elastic axis, and G is the center of gravity. The elastic axis is located at the distance ab from the mid-chord where a is a constant, and the center of gravity is situated at the distance $x_\alpha b$ from the elastic axis where x_α is the dimensionless distance. Both distances are positive when measured towards the trailing edge of the airfoil. The simplified model can be employed to reveal mechanisms of some practical behaviors. In recent years, we have studied nonlinear dynamics of the stochastic airfoil models for three different cases, including Gaussian white, Gaussian colored and narrow-band noisy fluctuations, from the analytical and numerical perspective. First, a Gaussian white noise is considered as a primary approximation to model the external random fluctuation, and then a stochastic airfoil model with harmonic excitation is presented based on the deterministic airfoil system [6]. Therein, we assume that the airfoil model is provided with slight coupling and nonlinearity. A perturbation technique together with a stochastic averaging method is employed to obtain the amplitude-frequency responses of the proposed random airfoil model, and numerical simulation results are implemented to test correctness of the obtained approximate analytical solutions. In fact, the Gaussian white noise is only regarded as an ideal model, which cannot well describe the complex external environmental disturbances in comparison with the colored noise with a nonzero correlation time. For this reason, we extend the previous work [6] to the case of Gaussian colored

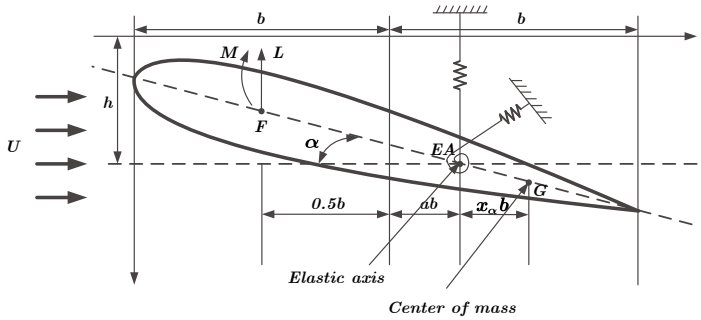

Figure 1: Structural model of a typical two-degrees-of-freedom airfoil section.

noise [7], and we find that intensity and correlation time of the colored noise excitations can all induce a stochastic jumps between high-amplitude and low-amplitude oscillations. The stochastic transitions between low-amplitude and high-amplitude oscillations are regarded as unwanted behaviors in aircraft flights, which can lead to fatigue and even damage of the airfoil structure. Hence, an effecitive sliding mode controller is designed for the proposed random airfoil model to achieve the stochasatic vibration suppression, and practical stability as a new concept is introduced to analyze stability of the controlled airfoil system. Furthermore, viscoelastic material propertis of the typical airfoil section are further explored [8, 9]. A fractional-order derivative is employed to describe the viscoelastic behavior of the airfoil material, and an averaging technique is applied to realize the theoretical analysis of the deterministic viscoelastic airfoil model [8]. Meanwhile, a fractional-order sliding mode control is implemented to study the vibration suppression of the introduced airfoil model. Besides, consider the effect of external random fluctuations, we further explore analytically the influences of random fluctuations as a narrow-band process on the airfoil model with viscoelastic terms [9]. Therein, the viscoelastic terms are characterized by a convolution integral over an exponentially decaying kernel function. The method of multiple scales are applied to obtain several approximate analytical solutions of the airfoil systems with random fluctuation and viscoelastic material property, including amplitude-frequency responses and steady-state moments. We uncover that the viscoelastic terms have a considerable influence on the system dynamical behaviors, which can simultaneously affect the structural damping and stiffness of the airfoil system. Similarly, stochastic jumps between high-amplitude and low-amplitude oscillations can be found due to narrow-band random fluctuations. In addition, a novel algorithm is introduced to explore the fixed-interval smoothing problem of the airfoil models from noisy measurement data. The results show that this algorithm can achieve accurate state and parameter estimations for the cases of Gaussian white or/and even more complex heavy-tailed measurement noises. Although both the airfoil models as mentioned above and the random noisy models are simplified, which are far from the engineering practice, we believe that these works can provide some valuable perspectives for the designers of the aircraft.

CONCLUSIONS AND FUTURE WORKS

In the present study, nonlinear dynamic behaviors of the airfoil models subject to Gaussian white, Gaussian colored and narrow-band noisy fluctuations are investigated theoretically by means of the stochastic averaging technique and the method of multiple scales method. The dynamic behaviors of the airfoil models will become more rich and complex due to the coupling effects of random and nonlinear factors. There are still several open problems worthing to further study as follows: **(1) More complex random excitation models must be considered.** Due to the synthesis of various environmental disturbances, several more complex cases such as Poisson noise, Lévy noise, etc., can be used to approximate the actual random fluctuations. **(2) Data-driven problems should be explored.** The present studies are based on the mathematical models established by physical mechanisms. However, with the rapid development of computer technology in recent years, data-driven problems and machine learning have caused widespread concern among scholars. Therefore, it is of more significance but difficulty to study the the airfoil models with complex random fluctuations from a data-driven perspective together with machine learning techniques, including response prediction, system identification, etc.

THE SIGNATURE OF NONLINEAR DYNAMIC SYSTEMSWITH DEGRADATION

Fabrizio Vestroni*[1] and Cristina Gatta[1]
[1]Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy

Summary The characterization of the dynamic behaviour of linear systems are exhaustively described by frequency response curves (*frcs*). For nonlinear systems, which are prone to depend on response amplitude, at least one *frc* for each excitation intensity is required to characterize the dynamic behaviour. Nonlinear systems, mainly dealt with in the literature are invariant with respect to the deformation history: as a consequence, *frcs*, obtained with increasing and decreasing frequency, coincide. On the contrary, for many real systems, which suffer from their past experience, the *frcs* do not coincide. The steady-state response of a masonry wall, which is characterized by degrading restoring force, is considered to analyse the effects of decay on the fundamental signature of systems, the behaviour of which is strongly affected by their deformation history.

INTRODUCTION

Frequency response curves (*frcs*) are comprehensive in representing the dynamic behaviour of linear systems. The response of nonlinear systems depends on the amplitude of deformations undergone. Hence, focusing on the steady state response to harmonic excitations, a *frc* obtained for each excitation intensity is necessary to describe the system dynamic characteristics. Even if there is a wide variety of restoring force relationships, the overcome on the *frc* shapes are only marginal, whereas are more evident on higher order features, such as unstable branches, wrinkles, detached *frc*. Thus, the different *frcs* can be grouped in two large families (Fig. 1), single valued curves or curves with limited ranges of multiple solutions.

This topic has been touched by a few authors, starting from the *frcs* as a first fundamental step to a more in-depth analysis of the dynamic response of a nonlinear system [1, 2]. However, focus was on systems with restoring force relationships irrespective of the history, whereas most nonlinear constitutive relationships are considerably dependent on the previous deformation experienced, especially in the case of material nonlinearities. In this study for these latter cases, the modifications of the frequency response curves are investigated, with a view to understanding the extent to which the original signature of the curves remains meaningful in representing the core of the system dynamics.

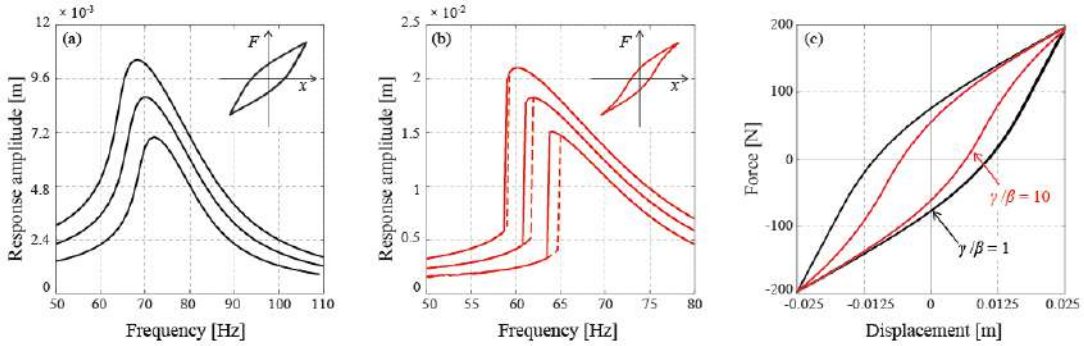

Figure 1. Single-valued (a) and multi-valued (b) *frcs* for fully ($\gamma/\beta = 1$) and reduced ($\gamma/\beta = 10$) hysteresis (c).

FREQUENCY RESPONSE CURVES OF A DEGRADING SYSTEM

The study addresses the dynamic behaviour of a slender masonry wall, restrained at the base. A non-local damage plastic model is proposed to analyse the behaviour of masonry structural elements [2]. The model, which adopts a macromechanical approach, captures strength and stiffness degradation with hysteretic dissipation characterizing the masonry response when it is subjected to a cyclic history beyond the elastic range. The stiffness recovery due to the crack closure, under cyclic loading conditions, is made possible by introducing, in the stress-strain constitutive law, two scalar damage variables, representing the damage in tension and compression, respectively. The cyclic response to an imposed displacement history is shown in Fig. 2a,b with the damage distribution, which is mainly concentrated at the base.

To validate the model, a real wall (Fig. 2c) has been realized and experimentally tested in the DISG Laboratory, Sapienza University. Shaking table tests were performed by imposing sinusoidal base accelerations with fixed frequency and increasing amplitudes. The numerical results are compared with the experimental outcomes which highlight that the wall response is strongly affected by the degrading mechanisms evolving in the panel, with a decrease of the wall natural frequency, due to the propagation of damage. It results that the model is able to capture the panel overall dynamic response, as both the actual resonance condition and the maximum reached displacement are satisfactorily matched.

*Corresponding author. E-mail: vestroni@uniroma1.it

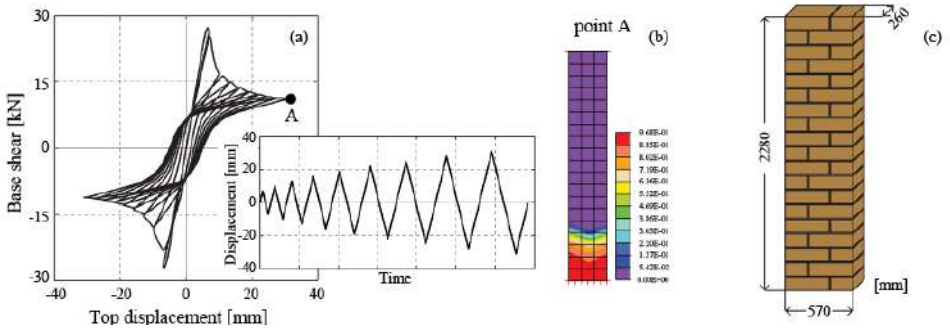

Figure 2. Cyclic load-displacement curve (a) and tensile damage distribution (b) for an example wall; experimentally tested wall (c).

The validated damage-plastic model has been used to numerically investigate the effect of mechanical properties evolution on the *frcs*, which are compared with those of a linear elastic system (Fig. 3). Horizontal harmonic base acceleration with slowly increasing (sweep 1) and decreasing (sweep 2) frequency, are applied at wall base, in the range [0.2 ÷1.5] of the initial frequency of the wall, for three acceleration intensities U/g = 0.04, 0.05, 0.06. For increasing excitation frequency (sweep 1), onset of damage leads to a decrease of wall natural frequency, while the forcing frequency increases. Thus, the wall suddenly leaves the resonance conditions, with a peak response attained at a frequency which slightly decreases with the increasing acceleration intensity, (Fig. 3a).

In the case of sweep 2, when the response curve leaves the elastic curve due to damage, the wall frequency decreases while the driving frequency also decreases and the response branch is bent on the left up to the resonance peak, just before falling down from the resonant to the non-resonant branch. A range of multiple solutions appears, which is clear by matching the curves obtained with sweep 1 and 2 (Fig. 3). This is consistent with the general results in [3]. For an assigned intensity, Fig. 3c shows the large difference between the two *frcs* for increasing and decreasing driving frequencies which is the impressive effect of the degrading properties of the wall. For this degrading system the multi-valuedness of the *frc* is not limited to a specific range, as occurs for the invariant restoring force relationships, but at any excitation frequency, the response oscillation amplitude is different as it depends on the history before reaching stationary oscillation.

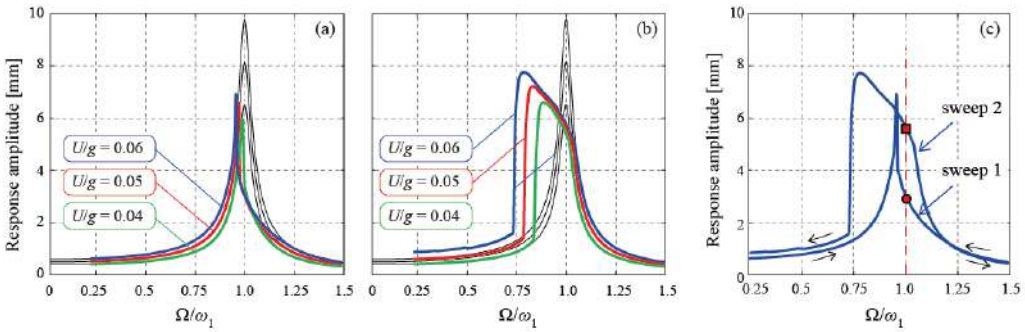

Figure 3. *Frcs* for sweep 1 (a) and sweep 2 (b): elastic response (black lines), damage-plastic response (green, red and blue lines corresponding to intensities U/g = 0.04, 0.05, 0.06, respectively); *frcs* for sweep 1 and 2 for U/g = 0.06 (c)

CONCLUSIONS

Frequency response curves are a fundamental tool to synthetically describe the dynamic response of a system. For invariant nonlinear systems *frcs* differ at different intensities, due to nonlinearity; however, for a given intensity only one curve describes the steady state response of the system, regardless of how an equilibrium point is reached. Here, the modification of this picture for a system characterised by mechanical properties which evolve with the deformation history, is given. Systems with degrading properties are common in the real world; explicit reference is made to a masonry wall for which a refined model has been validated by dynamic experiments on a shaking table. It is shown that the system is no longer represented by a unique *frc*, since any stable equilibrium point depends on the history followed to reach it.

DETERMINISTIC DETECTION OF ISOLATED PERIODIC SOLUTION BRANCHES

Jörg Wallaschek*, Torsten Heinze, and Lars Panning-von Scheidt
Institute of Dynamics and Vibration Research, Leibniz University Hannover, Hanover, Germany

Summary The present study explores the relevance and detection of isolated periodic solution branches commonly encountered in nonlinear dynamical system analysis. Attention is drawn to the development of an entirely deterministic computational scheme for uncovering separated solution branches of systems with hysteretic forces. Based on a harmonic balance approximation a specific frequency domain nonlinearity smoothing is proposed, facilitating the application of the global terrain method as a candidate for deterministic global solution methods. Finally, a homotopy continuation transfers the solutions of the smoothed system to the non-smooth case.

RELEVANCE OF ISOLATED PERIODIC SOLUTION BRANCHES

Isolated periodic solution branches are known to exist for a variety of systems covering nonlinearities or piecewise linearities such as hysteretic forces, mechanical impacts, suspended cable structures, atomic-force microscopy, feedback control systems with deadband, nonlinear energy sinks, or nonlinear tuned vibration absorbers. Simultaneous self- and external excitation often provoke the separation of solution branches from the main solution branch. Furthermore, the deep connection of internal resonances and backbone curves to nonlinear frequency-response curves is uncovered. Extensive literature overviews provide the historical context as well as insight into further computational methods for isola detection [1, 2].

The relevance of isolated periodic solution branches is subsequently demonstrated using the single-degree-of-freedom system with a shape-memory alloy nonlinearity shown in Fig. 1a. For information on the exact parameter values, the reader is referred to the literature [1]. The system is pre-stressed such that the oscillation encloses the center of the hysteresis loop. It is solved using the harmonic balance method constrained to the fundamental harmonic and a vanishing static displacement leading to an algebraic set of two equations for three unknowns: the Fourier coefficients of the motion related to the cosine and sine component as well as the vibration frequency.

The results of interest that are commonly investigated during the design process are the nonlinear frequency-response curves depicted in Fig. 1b. Here the variation of the curves w.r.t. the excitation amplitude is illustrated. For a specific parameter regime isolated periodic solution branches exist. The stability estimation is based on Hill's method [3] and verified using time simulation rendering the system bistable, cf. Fig. 1c. Unfortunately, this isolated resonance curve is easily missed by local path continuation tools; thus, the danger of considering an incomplete solution set during the design process should be kept in mind. Note that this type of solution curve separation is not related to self-excitation as known for friction-damped systems.

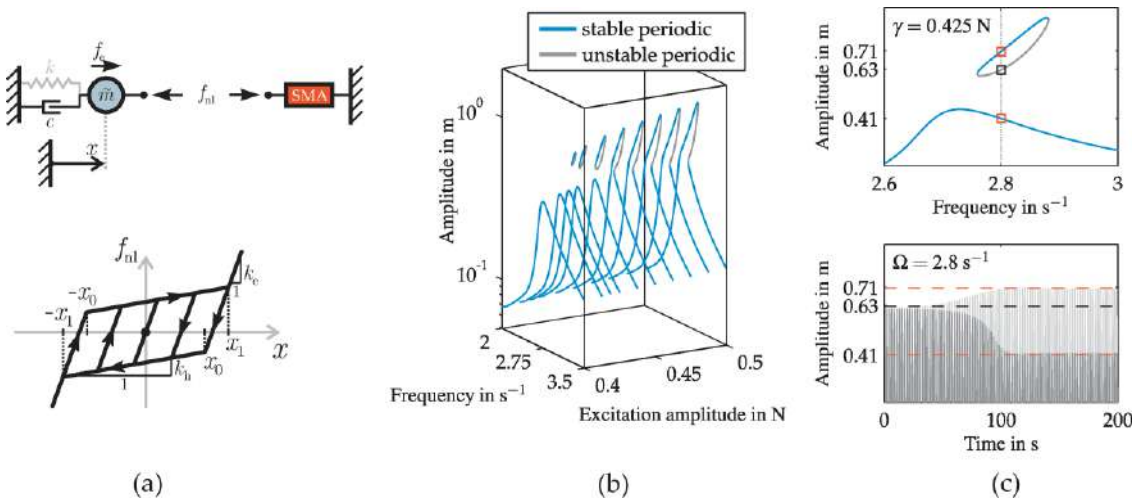

Figure 1. Periodic solutions of the single-degree-of-freedom shape-memory alloy model: (a) model definition and nonlinear force hysteresis, (b) merge of isola with main solution branch, (c) stability verification of harmonic balance solution using time integration [1].

ISOLA DETECTION METHODOLOGY

A global solution analysis for industrial purposes or possibly safety-relevant products should not compromise certainty in uncovering the complete set of solution branches. Therefore, the presented workflow relies solely on deterministic components to be given subsequently.

*Corresponding author. E-mail: joerg.wallaschek@ids.uni-hannover.de.

Nonlinearity smoothing

The employed global solution method requires C^2 continuous functions. The presence of the piecewise linearity of the hysteresis loop leads to deflections which are not continuously differentiable. Likewise, the harmonic balance approximation is not continuously differentiable as can be seen by plotting the squared norm of the harmonic balance residual, cf. Fig. 2a. The numerical treatment is performed using the alternating frequency/time domain method which relies on a time marching procedure to evaluate the nonlinear force law. In this study, we propose to modify the time marching procedure using a smoothed predictor-corrector scheme leading to a continuously differentiable nonlinear force term in the frequency domain, cf. Fig. 2b. Further details on the exact formulae and parameterization are provided in the literature [1].

Global terrain method

The set of unknowns is constrained by fixing the phase to yield distinct point solutions rather than branches. Since any isola covers a phase range of 360°, two points of each isola are within the set of solutions. As the nonlinearity is smoothed, the global terrain method can be applied [4]. It explores the squared norm of the residual in a structured way. In Fig. 2b the successful detection of all three solution points – one on the main branch and two on the isola – is shown. Note that only the relevant paths of the global terrain method connecting all three solution points are depicted. An extended variant with a specific search space scaling to overcome further discontinuity problems between solution points is presented in the literature [1].

Homotopy continuation

Finally, the found solution points of the smoothed residual function are transferred to the solution points of the non-smooth harmonic balance approximation using homotopy continuation. From these points, the entire isola can be computed using local path continuation. The feasibility of the homotopy continuation between two structurally equivalent functions – one smoothed and one non-smooth – is here presented for the shape-memory alloy system for the first time, cf. Fig. 2c.

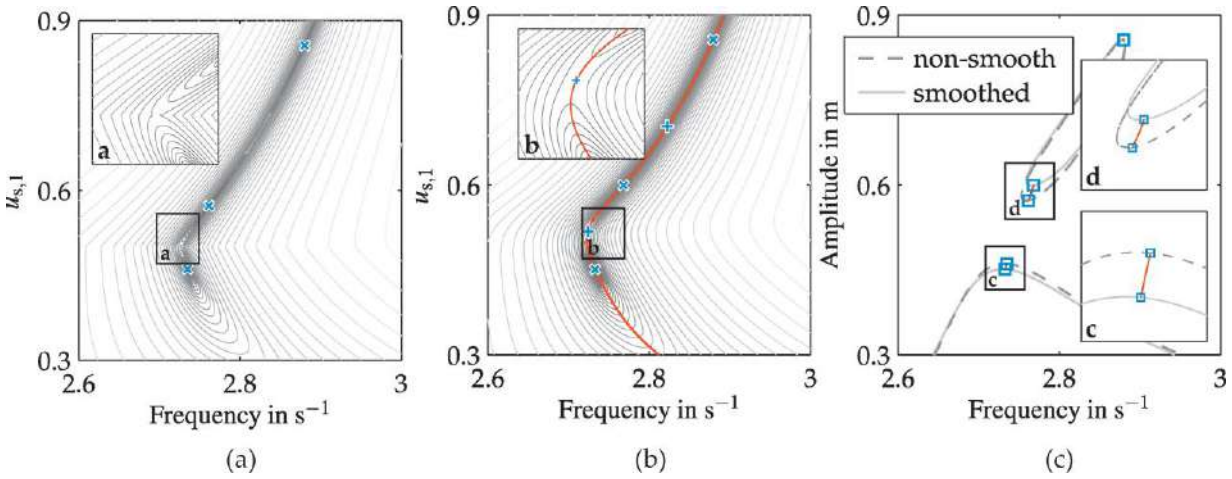

Figure 2. Deterministic detection of isola: (a) squared norm of non-smooth residual, (b) squared norm of smoothed residual and relevant subset of search paths of the global terrain method [1], (c) homotopy continuation between non-smooth and smoothed residual.

CONCLUSIONS

Within this study, the relevance of isolated solution branch detection was demonstrated. The proposed solution methodology enclosed a specific frequency domain nonlinearity smoothing within the harmonic balance method, a global solution method, and a homotopy continuation leading to the solutions of the non-smooth baseline system. A system with shape-memory alloy nonlinearity served as the test case for a successful application. The deterministic nature of the composing algorithms renders the overall detection methodology without the notion of uncertainty.

REDUCED-ORDER MODELS FOR INCLINED ELASTIC CABLES WITH ARBITRARY SAG UNDER SUPPORT EXCITATION

Guilherme Jorge Vernizzi *[1,2], Stefano Lenci[2], and Guilherme Rosa Franzini[1]
[1] Offshore Mechanics Laboratory - LMO, Escola Politécnica, University of São Paulo, Brazil
[2] Università Politecnica delle Marche, Ancona, Italy

Summary This paper focuses on the study of the vibrations of inclined elastic hanging cables not limited to the small sag condition, under the action of boundary imposed motion. The problem is investigated using reduced-order models, which is not made in previous literature for this specific excitation in the case of arbitrary sag. The reduced model is obtained by a Galerkin procedure and allows the evaluation of the effect of different interpolation functions for the response and for how the top motion influence is distributed along the structure. The obtained results so far show good agreement with finite element simulations.

INTRODUCTION

The use of hanging cables as structural solution can be found in different engineering applications. They are present in stayed and suspended bridges, transmission lines, offshore oil exploration, mooring systems, among other uses. These elements are under dynamic solicitation from different sources and can exhibit a rich dynamical behaviour. This work focuses on one of the possible sources, namely the imposed motion on one of the boundaries.

A detailed study made with the method of multiple scales (MMS) for this kind of problem is described in [1]. A horizontal taut string is considered with its axial inertia neglected, under the action of transversal and longitudinal motions of one of the boundaries. Good agreement is shown between the obtained analytical solutions and experimental results. In [2], an inclined taut string under support excitation is investigated with a reduced-order model (ROM) based on modal decomposition. An analytical solution is presented for the steady-state amplitude of motion for some mode combinations.

In [3], the wind loading is also considered together with the support motion excitation on an inclined cable with small sag, nearing a taut string. The axial dynamics is condensed by neglecting axial inertia and the resulting equation is discretized via a Galerkin procedure. The model is used to investigate the instabilities the cable can undergo. Finally, in [4], a horizontal hanging cable is considered, also with the axial inertia neglected. A ROM is obtained with a Galerkin procedure using both in-plane and out-of-plane modes. An analytical solution is obtained with the MMS, followed by a series of investigations on the dynamic responses of the structure.

In the present work a ROM is obtained and discussed for a planar inclined hanging cable with arbitrary sag. In this case the axial inertia cannot be neglected, with the modes of vibration being coupled in the axial and transversal directions. ROMs for this type of configurations, considering support motions as the source of excitation, are not found in the literature to the best of the authors' knowledge. The investigations are intended to be carried in the same fashion of [5] in order to discuss gains, advantages and problems concerning projections functions used in the construction of ROMs.

MATHEMATICAL MODEL

An elastic hanging cable in still fluid is herein considered, with axial stiffness EA, immersed weight γ_s and axial and transversal masses per unit length m and m_t respectively. Added mass can then be easily included in the model with the different mass values for each direction. The horizontal and vertical distances between the hanging supports are d and h respectively. The tension $T_e\,(s)$ and the angle with the horizontal direction $\theta\,(s)$ in the static configuration are considered to be known, with s being the arclength coordinate. Taking now u and v as the axial and transversal displacements with respect to the static configuration, the equations of motion obtained from balance laws for a cable element (see [6] for example) are given as:

$$T_e'\left(\cos\gamma-1\right)-T_e\left(\theta'+\gamma'\right)\sin\gamma+T_d'\cos\gamma-T_d\left(\theta'+\gamma'\right)\sin\gamma=m\ddot{u} \tag{1}$$

$$T_e'\sin\gamma-T_e\theta'+T_e\left(\theta'+\gamma'\right)\cos\gamma+T_d'\sin\gamma+T_d\left(\theta'+\gamma'\right)\cos\gamma-\frac{1}{2}\rho D\overline{C_D}\dot{v}\left|\dot{v}\right|=m_t\ddot{v} \tag{2}$$

The hydrodynamic nonlinear damping is considered using Morison's model for the drag force in the transversal direction, while drag in the axial direction is disregarded since it usually is much smaller. The solution for the static equilibrium, which depends on γ_s, is already considered in the equations. T_d stands for the dynamic tension variation, γ is the dynamic variation of θ, ρ is the specific mass of the surrounding fluid, $\overline{C_D}$ is the mean drag coefficient and D is the external diameter of the structure. Primes denote differentiation with respect to s while dots represent differentiation with respect to time. The static strain is considered small, allowing the approximation $\varepsilon=\varepsilon_s+\varepsilon_d$, with the subscripts denoting the static and dynamic parts. The expression for the dynamic tension becomes $T_d=EA\varepsilon_d$. The compatibility relations are obtained by differential geometry as $\sin\gamma=\left(u\theta'+v'\right)/\left(1+\varepsilon_d\right)$, $\cos\gamma=\left(1+u'-v'\theta'\right)/\left(1+\varepsilon_d\right)$ and $\varepsilon_d=\sqrt{1+2\left(u'-v\theta'+uv'\theta'-u'v\theta'+\left(u'^2+v'^2+\left(u\theta'\right)^2+\left(v\theta'\right)^2\right)/2\right)}-1$. The obtained model can be applied

*Corresponding author. E-mail: guilherme.jorge.lopes@usp.br.

to vibrations in air by simply adjusting the parameters of the model. The ROM is obtained using a Galerkin procedure after expanding the equations up to third order terms, with the displacements written as:

$$\{u, v\} = \left\{ \eta(t)\,\phi_s(s) + \sum_{k=1}^{n} A_k(t)\,\phi_k(s)\,,\, \eta(t)\,\psi_s(s) + \sum_{k=1}^{n} B_k(t)\,\psi_k(s) \right\} \tag{3}$$

ϕ_k and ψ_k being the shape functions of the vibration modes of the cable in the axial and transversal directions respectively. In turn, ϕ_s and ψ_s are the functions used to describe a instantaneous distribution of the displacement of magnitude $\eta(t)$ along the cable. The expressions of the ROMs are not shown due to the size of this extended abstract.

COMPARISON WITH FINITE ELEMENT SOLUTION

A simple example is considered here with a comparison in the amplitude of response of transversal motion with a solution obtained by the finite element method (FEM). The data herein adopted are $EA = 2314$MN, $m = 108$kg/m, $m_t = 141.24$kg/m, $\gamma_s = 727$N/m and structural diameter $D = 0.2032$m. The distances between supports are given as $d = 1500$m and $h = 1800$m. The cable is subjected to a horizontal component of tension valued $T_h = 680550$N, and a total length of $L = 2452$m. For this abstract, the hydrodynamic damping is disregarded. For the ROMs, the inextensible static solution is used, giving a relative difference of only 1% in the natural frequency of the first mode with respect to the FEM solution. Two ROMs are used, ROM (i) uses the displacement field of a unitary static displacement at the top for the functions ϕ_s and ψ_s, while ROM (ii) uses a linear interpolation between supports. A comparison is made in the amplitude of response under a support motion in resonance with the first mode of vibration, with a structural damping ratio of 2% for the first mode. The comparison for the modal shape and the amplitude response curve are shown in Fig. 1. The amplitudes of motion are made dimensionless with D and the amplitude is taken on the point at $s = 1508$m, which is the peak of transversal motion of the first mode. It is possible to see that the modal shape function is in good agreement,

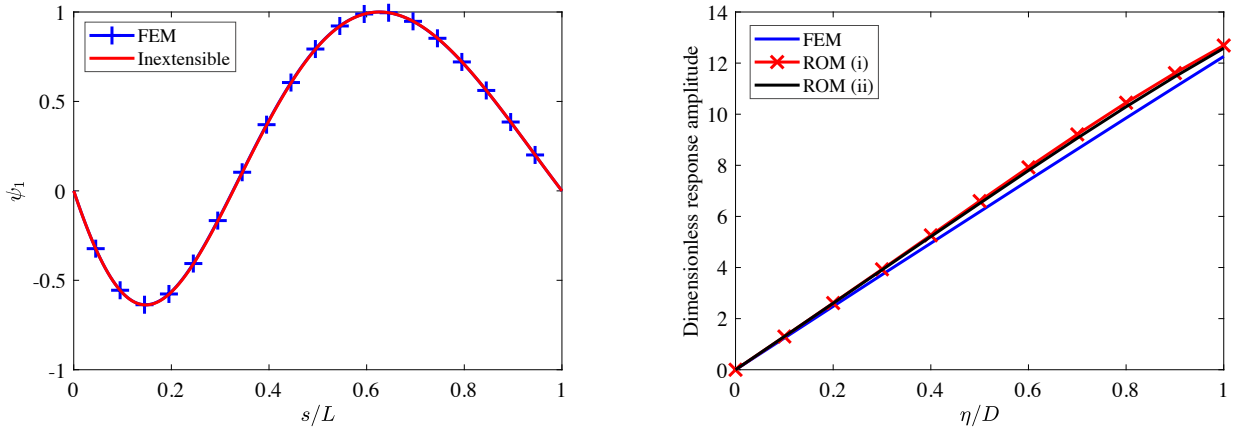

Figure 1: Left: Transversal shape function of the first mode for the FEM solution and the one using the inextensible static configuration. Right: Amplitude of response for the transversal displacement as a function of the excitation amplitude.

even with the use of the inextensible elastic configuration to calculate it. Also, it is possible to notice that, at least in the range shown, the use of a simple linear interpolation is able to give good quality results with respect to the FEM solution.

CONCLUSIONS

A reduced-order model (ROM) is developed using a Galerkin projection on the equations of motion of a hanging inclined cable. The projection contains a term for the contribution of the motion imposed to the boundary of the cable. The results show that the obtained model is in good agreement with finite element simulations. Further results and deeper investigations are intended for the conference, such as the use of more modes in the model, comparison of different ROMs for higher amplitudes of vibration and numerical tests with the effects of hydrodynamic damping.

THREE-DIMENSIONAL ROCKING MOTION OF FREE-STANDING BLOCKS

Péter L. Várkonyi [1], Tamás Ther[1], and Tamás Baranyai[1]
[1] Department of Mechanics, Materials, and Structures, Budapest University of Technology and Economics, Budapest, Hungary

Summary Historical stone and masonry structures undergo rocking motion under earthquake excitation. Impacts during rocking motion absorb energy and may result in remarkable earthquake resilience. Simple models of rocking use deterministic impact models and assume two-dimensional motion. Nevertheless in reality, individual trajectories of rocking motion are unpredictable due to extreme sensitivity of impacts to geometric imperfections. In addition, imperfections may induce three-dimensional motion even is the excitation is planar. We develop a non-deterministic impact model, which is applicable to arbitrary 3-dimensional motion. Model parameters are fitted to statistical results of physical experiments. Our model can be integrated into a simulation engine in order to evaluate how three dimensional motion and imperfections affect the earthquake resistance of rocking blocks.

ROCKING BLOCKS

Rocking is a form of motion of (quasi-) rigid, heavy objects in unilateral contact with a support surface in the proximity of a state of stable rest. An important feature of 'rocking' is that episodes of roll motion are from time to time interrupted by impacts. Slip motion may be present in rocking but friction is often assumed to be large enough to prevent slip. Impacts are usually assumed to be inelastic, which eliminates the possibility of liftoff.

The simplest and widely studied example of rocking is the planar, small-amplitude motion of a cuboid-shaped slender block on a flat plane, which undergoes an impact whenever the resting position is reached. Housner [1] was the first to propose a model for these impacts. He assumed that the impact impulse is transmitted through the corner of the block, and slip motion does not occur. Using these assumptions, he defined the *velocity reduction factor* as the ratio of post- and pre-impact angular velocities $r = \omega^+/\omega^-$ and showed that r takes identical values in each impact of a given block. His model can be combined with Newton's laws to simulate the motion of the rocking block, and also to predict if the block will overturn in response to a given excitation. (Fig. 1).

HOUSNER'S MODEL AND REALITY

Experimental works revealed that Housner's model is an inaccurate description of real impacts. Most importantly, the value of r strongly varies from experiment to experiment, moreover the value predicted by Housner has a strong tendency to underestimate the empirically measured velocity reduction factors [2]. As a consequence, Housner's model often predicts overly optimistic results about the earthquake resistance of rocking blocks. Many works proposed improved

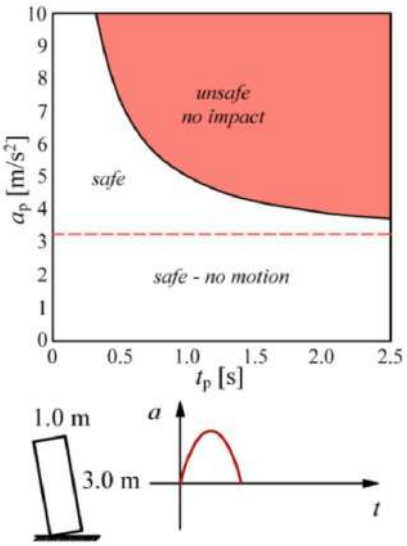

Figure 1: Overturning curve of a rocking block determined by numerical simulation using Housner's model. The horizontal acceleration of the ground is a half-sine pulse with peak acceleration a_p and duration t_p (bottom panel). If parameters fall into the shaded regions of the upper diagram, the block overturns, otherwise it stays upright.

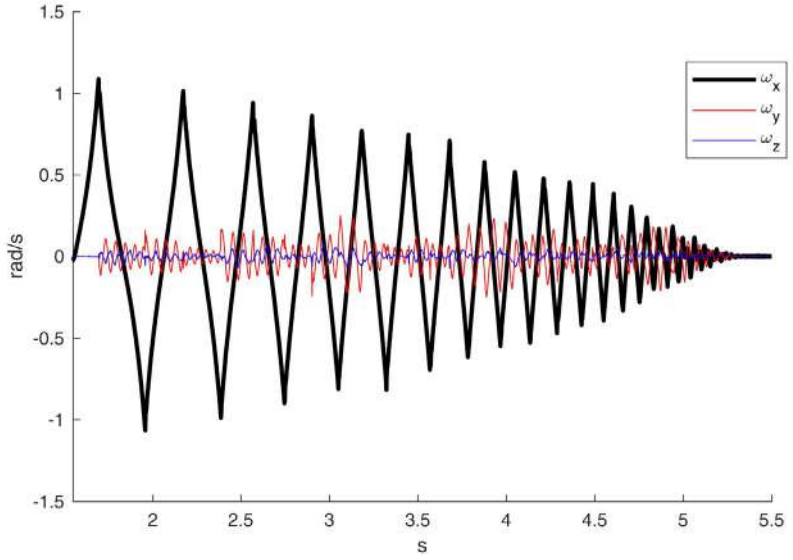

Figure 2: Angular velocitiy of a free-rocking stone block in a physical experiment (without excitation). The three curves show the components of the angular velocity in a coordinate frame with axes parallel to the edges to the block. Initially, the block rolls around an edge, and undergoes planar motion. Accordingly, $\omega_y = \omega_z = 0$. After the first impact, it undergoes three-dimensional motion, and all three components become non-zero

versions of the model that compensate for this tendency. Several authors have pointed out that the effect of geometric imperfections is responsible for the variability of r in experiments.

Sensitivity to imperfection is caused by the fact that in each impact, all points of the basal facet of the block reach the ground simultaneously. Contact forces can be transmitted to the block at any of these points during the (short) impact process and the net impulse resulting from these forces is not necessarily at the corner of the block. Indeed the whole process depends on small geometric imperfections of the base facet and of the underlying ground. In the limit of an ideally rigid block, an arbitrarily small imperfection may have finite effect.

THREE-DIMENSIONAL MOTION INDUCED BY IMPERFECTIONS

Imperfections may not only change the value of r, but they may also cause spontaneous symmetry breaking and the emergence of three-dimensional motion if the imperfections themselves are asymmetric. This is clearly visible in Fig. 2, which shows the angular velocity of a stone block measured in an experiment. Previous works did not study this effect and its consequences on earthquake resistence. Our aim is to fill this gap by developing an impact model and by integrating it into a numerical simulation engine.

DEVELOPMENT OF A NEW IMPACT MODEL

As first step we develop a parametrization of possible outcomes of the impacts as well as theoretical limits of the impact parameters dictated by physical laws (conservation of momentum, non-positive energy balance, etc.). Then, we measure probability distributions of the impact parameters two different ways including (i) physical experiments, and (ii) numerical simulations involving explicitly generated random imperfections. The parametrization and the measured distributions of impact parameters are combined into a non-deterministic impact model, which predicts post-impact angular velocities to be random values drawn from a certain probability distribution. We will later integrate the probabilistic impact model into a simulation engine, in order to perform systematic investigation of the behavior of blocks under earthquake excitation. Our ultimate goal is to produce (probabilistic) overturning curves (similar to Fig. 1), and to assess how the safety of blocks is affected by unpredictability and three-dimensional motion.

NONPARAMETRIC IDENTIFICATION OF A MICRO PORTAL FRAME WITH 2:1 INTERNAL RESONANCE

Rodrigo T. Rocha[1], Feras Alfosail[1,2], Mohammad I. Younis*[1], and Sami F. Masri[3]
[1] King Abdullah University of Science and Technology - KAUST, Thuwal, Saudi Arabia
[2] Consulting Services Department, Saudi Aramco, Dhahran 31311, Saudi Arabia
[3] Department of Civil Engineering, University of Southern California, LA, California, USA

Summary This work presents a nonparametric identification method applied on a nonlinear micro portal frame. The frame has two dominant modes of vibration, vertical and horizontal directions. These are directly related to the symmetric mode (second mode) and the anti-symmetric mode (first, sway mode). Due to its geometric nonlinearities, the structure exhibits 2:1 internal resonance, causing the appearance of the saturation phenomenon when excited at the highest resonance frequency. This work aims to model the dynamics of the micro portal frame at the saturation phenomenon using a nonparametric identification method, which is shown to be very efficient in capturing the characteristics of complex nonlinear systems.

INTRODUCTION

Nonlinearities are important as they arise in many systems from geometric, material and external excitations effects. Based on these effects, the response of nonlinear systems increases in complexity and can involve multi-modal response. In particular, portal frames have been shown to have a geometric nonlinearity due to the shortening caused by bending of its flexible elements. In some cases, this may set the system to a 2:1 internal resonance between the symmetric and anti-symmetric modes, which has very rich and complex nonlinear dynamics. When the second primary resonance is excited in resonance of the symmetric mode, a saturation phenomenon occurs [1-3]. Therefore, there is a considerable advantage to model these kinds of systems so that nonlinear phenomena can be widely explored. However, the more complex is the dynamics, the more daunting is the challenge of developing an accurate mathematical model.

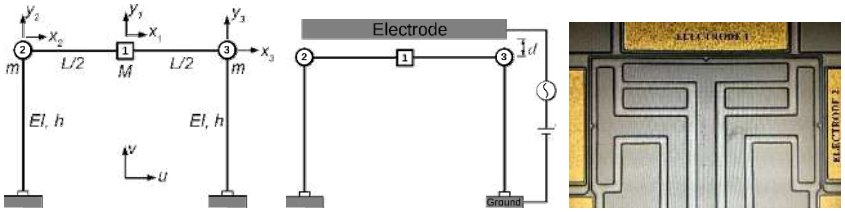
For this reason, identification techniques become increasingly important for formulating accurate models of complex nonlinear systems, generally classified into parametric and nonparametric. While parametric methods are used to obtain unknown parameters of a selected model class, the nonparametric methods can obtain a function from data measurements that can provide (partial) physical representations of a system [4-6], without prior knowledge of the system internal restoring forces or nonlinearities. This work aims to extend the application of the nonparametric identification technique demonstrated in [4] to identify the dynamic response of a micromachined nonlinear portal frame studied in [1,2] and through experiments.

MATHEMATICAL MODEL OF A PORTAL FRAME WITH 2:1 INTERNAL RESONANCE

The two-degrees-of-freedom 2-DOFs micro portal frame, shown in Fig. 1, is fabricated by the SOIMUMPs process of MEMSCAP [7]. It consists of a supported beam of length $L = 240\mu m$ attached to two columns with height $h = 133.1\mu m$ that are clamped in their bases. The beam and columns are considered as lumped masses, M and m, respectively. Their motions are described in two directions, vertical and horizontal. The coordinate u is related to the horizontal displacement of the mid-span of the beam, which is the anti-symmetric (sway) mode of vibration with natural frequency ω_1. The coordinate v is the vertical displacement of the mid-span of the beam, which is the symmetric mode with natural frequency ω_2. Geometric nonlinearity is introduced by considering the shortening due to bending of the columns and of the beam [1,2].

The microstructure is subjected to an electrostatic force through the electrode on top of the supported beam separated by a gap $d = 3.438\mu m$. The electrostatic force is considered as a harmonic cosine force $Q_{ext} = F\cos(\Omega t)$ in the mathematical model. The nodal displacements y and x are the vertical and horizontal motions for each lumped mass. Quadratic nonlinearities are included into the columns nodal displacements. Considering the generalized coordinates v and u as the motions of the mid-span of the supported beam, the dimensionless equations of motion of both horizontal and vertical motions are given, respectively, by

$$\begin{aligned} u'' + \omega_1^2 u + k_{31}u^3 + \mu_1 u' + \alpha_{11}uv + \alpha_{21}u^2u' + \alpha_{31}uu'^2 = 0 \\ v'' + \omega_2^2 v + k_{32}v^3 + \mu_2 v' + \alpha_{12}u^2 + \alpha_{22}v^2v' + \alpha_{32}vv'^2 + G = F\cos\Omega\tau \end{aligned} \quad (1)$$



(a) (b) (c)

Figure 1. (a) Lumped physical model, (b) experimental scheme; and (c) picture of the fabricated micro portal frame.

This 2DOFs portal frame was studied in [1,2], in which the existence of 2:1 internal resonance was demonstrated, where the second natural frequency is twice the first one, i.e., $\omega_2 \approx 2\omega_1 + \sigma_1$, where σ_1 is a detuning factor. When the second mode is excited in resonance ($\Omega \approx \omega_2 + \sigma_2$), where σ_2 is a detuning factor, saturation phenomenon occurs [1-3].

*Corresponding author. E-mail: mohammad.younis@kaust.edu.sa.

Using the parameters of Table 1, Fig. 2a is generated showing the frequency-response of the system when saturation phenomenon is active. In the interval ($1.932 \leq \Omega \leq 2.064$), the second mode gets saturated, exchanging vibration energy and, consequently, exciting the first mode. In this situation, the first mode has a bigger amplitude of vibration than the vertical motion. For an experimental qualitative confirmation, the fabricated device is subjected to a $V_{dc} \approx 40$V and $V_{ac} = 0.5$V. Using a laser Doppler vibrometer and a vacuum chamber with pressure of 40mTorr to avoid squeeze-film damping [8], the data measured is plotted in Fig. 2b. It is noted that 2:1 internal resonance is triggered, where the vertical motion saturated, exchanging energy to the horizontal motion of the structure, proving the existence of saturation phenomenon as predicted by the mathematical model.

NONPARAMETRIC IDENTIFICATION METHOD AND APPLICATION

The nonparametric identification technique utilizes the state variables of a system to be identified, expressing its characteristics in terms of orthogonal functions [4]. The main purpose of the procedure is to find a restoring force using Chebyshev polynomials, making it possible to obtain physical characteristics of the dynamical system to be identified. However, in this case, the subject is related to a system of two-degrees-of-freedom with 2:1 internal resonance, in which the complexity increases due to cross and coupling terms. The restoring force of each coordinate can be defined as

$$\begin{aligned} f_1(u,u',v,v') &= -u'' \\ f_2(u,u',v,v') &= F\cos(\Omega\tau) - v'' \end{aligned} \tag{2}$$

It is important to mention that the restoring forces do not depend only on two variables; they depend on the variables related to their own variables and the coupling related ones. Due to the dependence on four variables, the Chebyshev function is selected to be in the form

$$f_a(u,u',v,v') = \sum_{i=0}^{n}\sum_{j=0}^{m}\sum_{k=0}^{o}\sum_{l=0}^{p} C_{ijkl}T_i(u)T_j(u')T_k(v)T_l(v'); \qquad a = 1,2 \tag{3}$$

Then, assuming the data points provided from Eq. (2) and using the experimental data without prior knowledge of the system restoring forces or nonlinearities, the least-squares fit between them and Eq. (3) yields the true restoring force. However, the convergence of the coefficients depends directly on the coefficients n, m, o and p. To have such convergence, the values must be, at least, $n = 3$, $m = 2$, $o = 3$ and $p = 2$, resulting in the values of line 2 of Table 1.

CONCLUSIONS

This work presented the nonparametric identification of a 2DOFs micromachined nonlinear portal frame using data extraction from its mathematical model for the restoring force for data fitting. The method was efficient to identify both restoring forces with the nonlinear and coupling terms of the system without the need to assume a model class. For a future confirmation, we intend to utilize an error band of 5% for data fitting which increases the strength of the method.

EXTREME SENSITIVITY FOR DELAY PARAMETER IN BIFURCATIONS OF CONTROLLED CONTINUA

Gabor Stepan*[1] and Li Zhang [2]
[1] Department of Applied Mechanics, Budapest University of Technology and Economics, Budapest, Hungary
[2] State Key Laboratory of Mechanics and Control of Mechanical Structures, Nanjing University of Aeronautics and Astronautics, Nanjing, China

Summary The control of continuum bodies is a difficult task especially when the damping is low and many high-frequency vibration modes are involved in the relevant dynamics of the system. This study presents a beam model that describes extreme sensitivity with respect to the time delays that appear in the feedback loop. It is shown that in undamped cases, the slightest variation of the time delay results in the abrupt loss of exponential asymptotic stability. In the presence of small damping, the loss of stability occurs via Hopf bifurcations. It is shown that the frequencies of the emerging self-excited vibrations are also extremely sensitive for the change of the delay parameter. The results draw the attention for the difficulties in the design of these systems and they also explain why spatial discretization techniques do not converge to the limit case of controlled continuum bodies.

MOTIVATION

The appearance of the so-called squeal in public address systems is an annoying and difficult-to-predict phenomenon. When it occurs, a wide range of frequencies can be experienced, and these are often varying, some frequencies die, some others get stronger. The variation of the locations of the microphones and loudspeakers has an essential effect on the occurrence of the phenomenon in the same way as the variation of the amplification and the time delay in the control loop [1].

In this study, the simplest mechanical model and the corresponding governing equations are given, which describe the sensitivity of the system dynamics with respect to the delay parameters, including the sensitivity of the vibration frequencies of the emerging self-excited vibrations.

MECHANICAL MODEL

The simplest possible mechanical model of the public address system is presented in Fig. 1. A prismatic elastic beam of length l is considered with modulus of elasticity E and uniform density ρ. The longitudinal displacement $u(x,t)$ of the beam cross section is given at the spatial location x at the time instant t. The feedback loop is characterized by the amplification K that can be considered as a proportional gain, the nonlinearity of the system is represented by the saturation of the control action. The time delay τ is an unavoidable part of any control loop, although the value of this parameter is often assumed to be negligible. In the present analysis, this delay τ and the gain K take the roles of the bifurcation parameters.

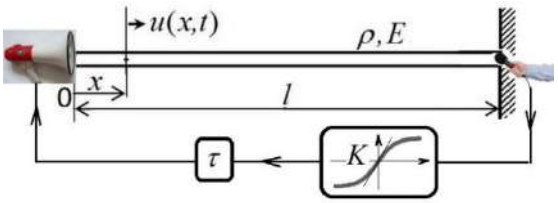

Figure 1. Simplified mechanical model of electroacoustic system

The governing equation of this system is the partial differential equation of the damped wave equation

$$\ddot{u}(x,t) - \eta c^2 \dot{u}''(x,t) - c^2 u''(x,t) = 0$$

where $c = \sqrt{E/\rho}$ is the speed of sound in the beam, and the parameter η characterizes the internal viscous damping in the beam. The corresponding two boundary conditions are of mixed typed and delayed:

$$u(l,t) = 0\,, \quad u'(0,t) = S \tanh\left(\frac{1}{S} K u'(l,t-\tau)\right)$$

where the saturation level of the actuation is set by the parameter S.

STABILITY AND BIFURCATIONS

In case of negligible damping $\eta = 0$, the stability analysis of the trivial solution can be carried out after the linearization of the second boundary condition: $u'(0,t) = K u'(l,t-\tau)$. The critical values of the time delay parameter are related to the time $T = l/c$ needed for the travelling wave to reach the end of the beam. By means of the general mathematical theorem of [2], one can prove that the system is exponentially unstable for any non-zero gain if the ratio τ/T is irrational.

Although from the continuous dependence of stability on parameters one might conclude that these systems are always unstable, this is not true in some infinite dimensional problems [3] like time delay systems. An analytical proof was given in [4] that there are thin exponentially stable parameter regions where the trivial solution is actually exponentially stable:

$$\tau/T = 4j-3, \quad 0 < K < \cos\left(\frac{2j-2}{4j-3}\pi\right) \quad \text{or} \quad \tau/T = 4j-1, \quad \cos\left(\frac{2j}{4j-1}\pi\right) < K < 0; \quad j = 1,2,\ldots.$$

These zero-measure stable regions become finite for positive damping $\eta > 0$. The stability boundaries are calculated with the help of computer algebra, and it is proved that there are Hopf bifurcations along the lobe structure of the stability boundaries. The corresponding stability chart is constructed in the plane of the delay and the gain parameters, but the fine fractal-like structure of the boundaries cannot be observed in Fig. 2 due to the limited resolution. It can be explored by zooming in numerically: the lobes intersect each other at several points resulting in double-Hopf bifurcations at the intersections.

FREQUENCIES OF SELF-EXCITED VIBRATIONS

The above described intricate stability properties are more apparent if the vibration frequencies of those self/excited vibrations are calculated, which appear at the Hopf bifurcations. These are presented in the panel below the stability chart of Fig. 2. Clearly, these frequencies are extremely sensitive even for the slight variation of the delay parameter. The frequencies belonging to certain lobes of the stability boundary jump from one mode to the other with varying delay, and at the double-Hopf points, quasi-periodic vibrations occur. Around the peaks/notches of the stability chart, three or even more vibration frequencies might be involved in the corresponding nonlinear vibrations.

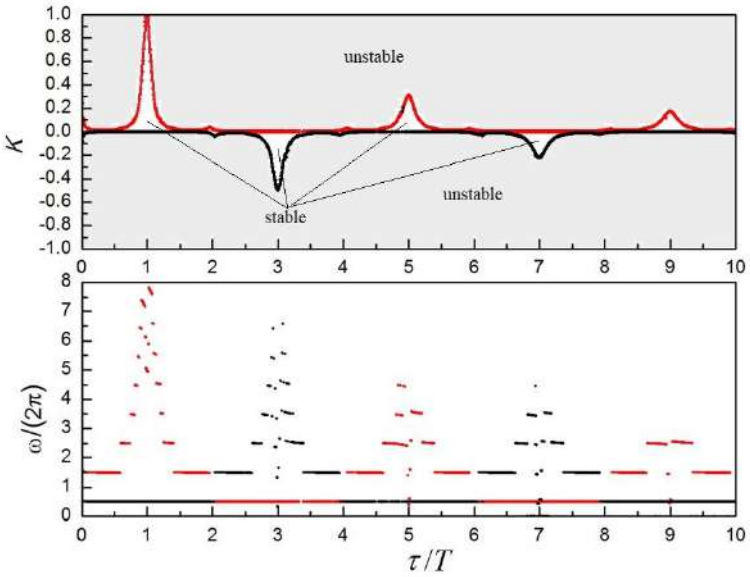

Figure 3. Vibration frequencies at the Hopf-type stability boundaries for damping parameter $\eta/T = 0.001$.

CONCLUSION

The mechanical model and its analysis draw the attention for the difficulties in the control design of systems involving continuum bodies. The results also explain why finite element techniques do not converge to the limit case of controlled continuum bodies. Similar phenomena are also observed in infinite dimensional problems [5]. The presence of time delay in continuum mechanical models result in infinite dimensional phase spaces with duplicate complexities.

STABILITY OF THE DRIVER-VEHICLE SYSTEM WITH THROTTLE CONTROL

Alois Steindl *[1], Johannes Edelmann[1], and Manfred Plöchl[1]
[1] Institute for Mechanics and Mechatronics, TU Wien, Vienna, Austria

Summary We investigate the stability of a controlled understeering vehicle along a steady-state cornering motion. To control the trajectory of the vehicle, the human driver is assumed to apply a constant front steering angle and a varying driving torque, which depends on the deviation of a point straight forward of the car at a fixed distance L_P from a reference circle. By varying the parameters of this feedback control we study the range of stable driving conditions and the system's dynamics after loss of stability.

VEHICLE MODEL

The basic two-wheel vehicle model with rear-wheel drive has been chosen to model the motion and stability properties of an automobile, Fig. 1. The state of the system is represented by the velocity of the vehicle v, the yaw rate $\dot{\psi}$, the vehicle side slip angle β, and the angular velocity of the driven rear wheel ω_R. The human driver (or a respective control system) applies a front steering angle δ_F and a drive torque M_R as input to the vehicle. The car's center of gravity lies on a height h above ground level. Thus, the equations of motion of the system read ([1])

$$m\dot{v}\cos\beta - m(\dot{\psi}+\dot{\beta})v\sin\beta = F_{xR} - F_{yF}\sin\delta_F, \qquad m\dot{v}\sin\beta + m(\dot{\psi}+\dot{\beta})v\cos\beta = F_{yR} + F_{yF}\cos\delta_F, \tag{1a}$$

$$I_\psi\ddot{\psi} = l_F F_{yF}\cos\delta_F - l_R F_{yR}, \qquad I_\omega\dot{\omega}_R = M_R - r_R F_{xR}, \tag{1b}$$

$$l_R F_{zR} - l_F F_{zF} = h(F_{xR} - F_{yF}\sin\delta_F), \tag{1c}$$

where $F_{zF} + F_{zR} = mg$. The tyre brush model [2] is applied to model the tyre characteristics, see Fig. 2, where the

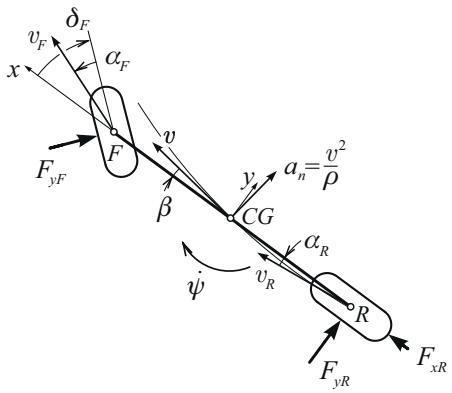

Figure 1: Two-wheel vehicle model.

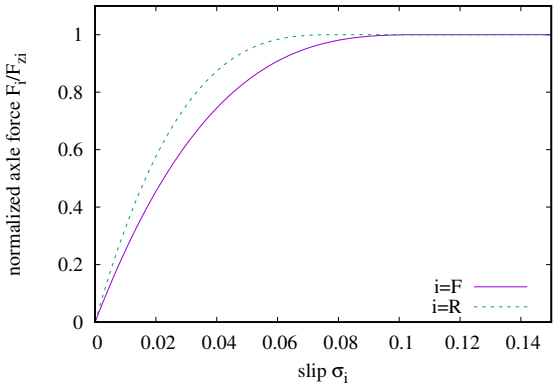

Figure 2: Normalized slip characteristics of front and rear simplified tyre/axle model at nominal loads.

mutual influence of the lateral and longitudinal force is considered.

Driver model

Our model for the driver assumes that during cornering the driver spots a point P straight ahead of the car at a distance L_P from the center of gravity, see Fig. 3. If the car drives along a circle with radius r_0 and center at the origin, the point P moves along a circle with radius r_{P0}. If the car leaves the circular path, the point P deviates from the circle and the driver adjusts the driving moment M_r accordingly. We apply the "simplified precision model" [3]

$$T_M\Delta\dot{M}_r(t) + \Delta M_r(t) = c_P\Delta r_P(t-\tau) + c_D\Delta\dot{r}_P(t-\tau), \tag{2}$$

with human reaction time τ and delay time T_M. For the preliminary results we use $\tau = T_M = 0$.

With $r_P = \sqrt{r^2 + 2L_P r\sin(\vartheta-\psi) + L_P^2}$ and $r_{P0} = \sqrt{r_0^2 + 2L_P r_0\sin\beta_0 + L_P^2}$, where r_0 and β_0 are the stationary values of (1), we obtain the first order approximation for the deviation

$$\Delta r_P \approx \frac{r_0 + L_P\sin\beta_0}{r_{P0}}\Delta r + \frac{L_P r_0\cos\beta_0}{r_{P0}}\Delta(\vartheta-\psi).$$

The position variables r and $\chi = \vartheta - \psi$ satisfy the differential equations

$$\dot{r} = v\sin(\chi-\beta), \qquad \dot{\chi} = \frac{v\cos(\chi-\beta)}{r} - \dot{\psi}. \tag{3}$$

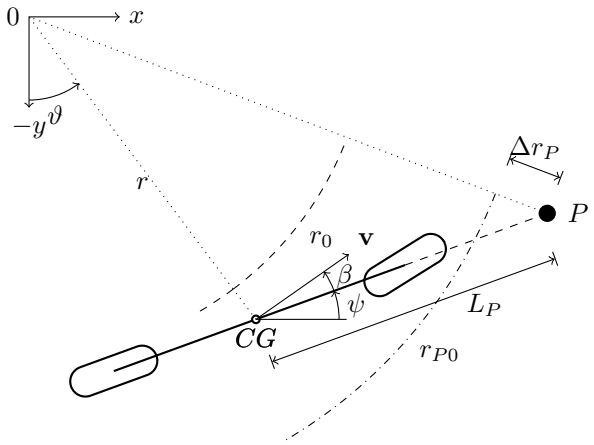

Figure 3: Geometric relations for the driver's preview model

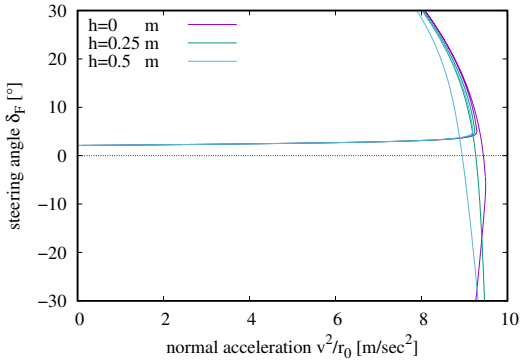

Figure 4: Handling diagram of the steady state vehicle model using $r_0 = 80\,\mathrm{m}$.

PRELIMINARY RESULTS

The handling diagram for the considered vehicle model is displayed in Fig. 4, which is computed for different heights h of the center of gravity and with constant curvature $r_0 = 80\,\mathrm{m}$. For normal accelerations $a_n = v^2/r_0 < 9\,\mathrm{m/sec^2}$ and small steering angles δ_F understeering behaviour ($\partial\delta_F/\partial a_n > 0$) is observed, In addition overdraw steering solutions and powerslide behaviour are visible. As expected, the regular steady state branch of the vehicle with fixed control parameters δ_F and M_r is throughout stable with one very small eigenvalue indicating singular perturbation behaviour.

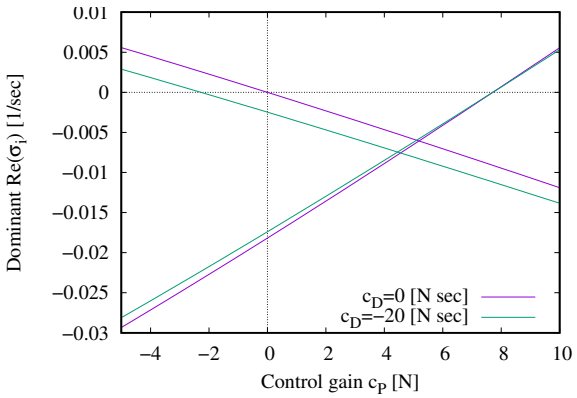

Figure 5: Evolution of the dominant eigenvalues for the linearized system (1–3) with $\tau = 0$, $T_M = 0$, $L_P = 20\mathrm{m}$, $h = 25\mathrm{cm}$, $r_0 = 80\mathrm{m}$ and $v_0 = 20\mathrm{m/s}$. For increasing control gains c_P the eigenvalues for the car position become stable, but the dominant eigenvalue becomes positive, leading to a strongly diverging system behaviour.

For the investigation of the driver's influence we choose the parameters corresponding to the steady state for $v_0 = 20\,\mathrm{m/sec}$. The variation of the real parts of the dominant eigenvalues can be seen in Fig. 5: For $(c_P, c_D) = (0, 0)$ a purely imaginary pair of eigenvalues occurs, because the car travels along a shifted circle, if it's initial position is perturbed. Increasing the gain c_P the purely imaginary eigenvalues become stable, but the weakly stable eigenvalue becomes unstable for sufficiently large values of c_P. For $c_D = -20\mathrm{N\,sec}$ the eigenvalues become a little bit more stable.

CONCLUSIONS

Adding to [4], our preliminary results indicate that carefully applied throttle control is able to stabilize the cornering motion of a vehicle and to track a desired curve. In the full paper a thorough analysis of the impact of several parameters of the simplified precision model will be given and a nonlinear stability analysis will be presented.

CHAOTIC SYNCHRONY OF PARAMETRIC PENDULUMS

Marek Balcerzak and Andrzej Stefanski
Division of Dynamics, Technical University of Lodz, Lodz, Poland

Summary We study the problem of complete synchronization of a pendulums' array attached to a common, externally forced structure. The presented analysis is focused on chaotic synchronization of the swinging, parametric pendulums. We propose a simplified criterion of synchronization for an arbitrary number of parametrically driven oscillators, which is based on the idea of a so-called *autonomous driver decomposition* and conditional Lyapunov exponents.

A pendulum is a classic example of a dynamical system, often used in mathematical and physical considerations. By means of pendulums one can model many engineering, technological systems and even dynamical processes from other branches of science. The antiphase correlation of oscillating two pendulum clocks was the first known case in history when the phenomenon of synchronization was observed and reported by Christian Huygens [1]. Over the three centuries after this fundamental report, plenty of studies on synchronized pendulums (also clocks, rotators etc.) have been published ([1–8] and references within). However, a vast majority of them concern systems of pendulums oscillating or rotating periodically. Recently, we have shown that introduction of an additional, intermediate structure between an external drive and a pair of pendulums causes their mutual coupling, which can lead to synchronization in a chaotic regime [9]. Here, this phenomenon is generalized for any number of pendulums. The novelty of the presented methodology consists in developing the *autonomous driver decomposition* [5] concept into a simple criterion of synchronization of any number of pendulums with a common parametric excitation. In general, the idea of this solution is based on separating a part of a dynamical system, which is treated as a master subsystem, and then duplicating the separated fragment. The duplicated part acts as a slave subsystem. Synchronous state between the master and the slave is stable if so-called conditional Lyapunov exponents, i.e. these connected with evolution of the slave subsystem, are negative.
In this Letter generalizes this phenomenon for any number of parametrically driven pendulums attached to the common structure and gives a criterion for its stability.

In this paper, a mechanical system of N+1 degrees of freedom, illustrated in Fig. 1, is analyzed. This structure is composed of a rigid beam of mass M_B and an array of N damped mathematical pendulums attached to it. The beam is harmonically driven (with an amplitude A and a frequency Ω) via a spring with stiffness K and externally damped (damping coefficient C). The pendulums have identical length l and it is assumed that for each of them the ratio between the damping coefficient c_i and its mass m_i (c_i/m_i ratio, i=1, 2, ..., N) is the same. As a result, taking $M = M_B + \sum_i^N m_i$ and $\omega = \sqrt{K/M}$ as the total mass and the reference frequency respectively, the following set of dimensionless equations describe the system:

$$\ddot{x} + \xi_y \dot{x} + x = q \sin \eta\tau - \sum_i^N \mu_i \left(\ddot{\phi}_i \sin\phi_i + \dot{\phi}_i^2 \cos\phi_i \right), \tag{1a}$$

$$\ddot{\phi}_i + (\ddot{x} + \gamma)\sin\phi_i + \xi\dot{\phi}_i = 0 \ , \tag{1b}$$

where x and ϕ_i are the dimensionless counterparts of the coordinates y, φ_i respectively (see Fig. 1), $\tau = \omega t$ is dimensionless time and $\mu_i = m_i/M$, $\xi_y = C/M\omega$, $\xi = c_i/m_i\omega l^2$, $q = A/l$, $\gamma = Mg/Kl$, $\eta = \Omega/\omega$ are dimensionless parameters. Consequently, in this representation, all the pendulums [Eq.(1b)] are identical even if they differ in masses or damping coefficients, as long as the ratio c_i/m_i is the same for each of them.

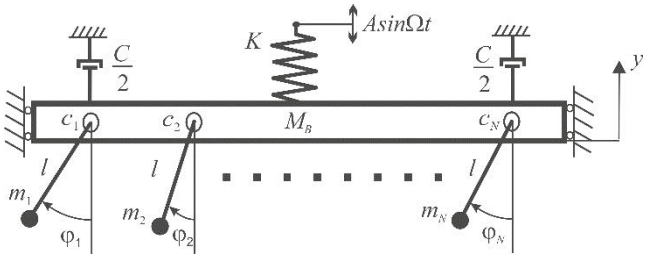

Figure 1.The analyzed system

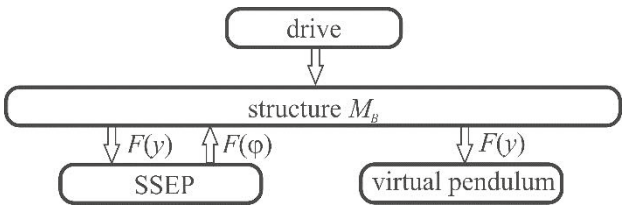

Figure 2.The scheme depicting the *autonomous driver decomposition* technique

The subject of our research is the phenomenon of complete synchronization (CS) of identical pendulums [Eq.(1b)]. In the synchronous regime ($\phi_i = \phi_j = \phi$), the array of pendulums (see Fig. 1) is reduced to a single, equivalent pendulum of the total mass $m = \sum_i^N m_i$ ($\mu = \sum_i^N \mu_i$) and the damping coefficient $c = \sum_i^N c_i$. Let it be called a *synchronous state equivalent pendulum* (SSEP). To rate the robustness of the synchrony, the *autonomous driver decomposition* technique [5] can be applied. The master subsystem is composed of the SSEP and the beam coupled mutually. On the other hand, "virtual pendulum" works as the slave subsystem. This pendulum plays the role of a synchronizability detector only and

does not affect the beam (see Fig. 2). Both pendulums are identical due to the same ratio $c/m = c_i/m_i$. If the CS between the SSEP and the virtual pendulum takes place, then the synchronous state of the pendulums' array reduced to the SSEP is stable. The condition for such stability is a negative value of the conditional Lyapunov exponents (CLE).

In Figs. 3(a)–3(c) bifurcation graphs generated for larger number of pendulums in the array (N=5, 10, 100), are presented. These pictures prove that synchronous state approach can be generalized for any number of parametrically driven pendulums. Independently of N, the synchronized chaotic swinging occurs in the same interval of the driving frequency ($0.941<\eta<0.966$), where the largest LE of the system is positive ($\lambda_1 > 0$) and the second LE, being the largest CLE, fulfills the condition $\lambda_2 = \lambda_C \le 0$. Increase of η over the threshold of negative λ_C (η >0.966) leads to synchrony loss, which is accompanied by the chaos–hyperchaos transition.

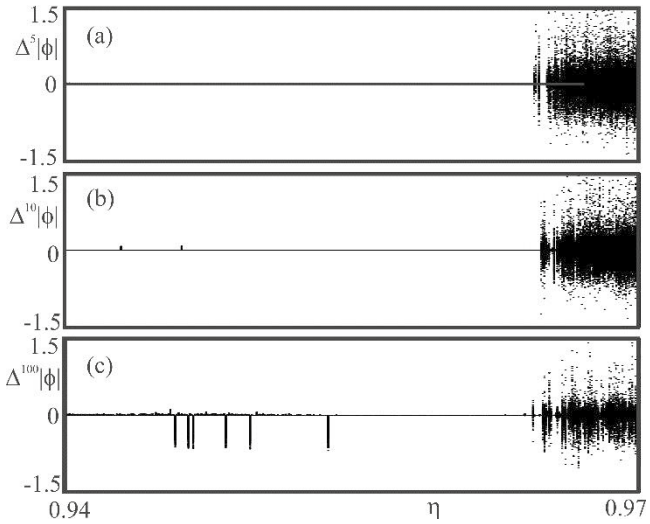

Figure 3. Bifurcation diagrams of the synchronization error $\Delta^N|\phi|$ versus driving frequency η: (a) N=5 – μ_i=0.1250, (b) N=10 – μ_i=0.0625, (c) N=100 – μ_i=0.00625.

In summary, the phenomenon of chaotic synchronization of dynamical systems under a common, parametric excitation has been demonstrated and its mechanism has been discussed. In this Letter, this phenomenon effect has been studied on the example of an array of pendulums attached to a driven structure. However, the same effect can occur, and the method of its detection can be applied, in other dynamical systems with an external (not only parametric) drive transmitted via a system component which is common for all receivers . In order to apply the presented method, an equivalent synchronous oscillator and its virtual replica, analogous to the SSEP and the virtual pendulum, respectively, should be modelled and used for detection of synchronization. Our research may shed a new light on the problem of controlling the dynamic behavior of parametric or externally driven oscillators. Introduction of an intermediate degree of freedom allows one to control the response of receivers even in the chaotic regime.

This Letter has been supported by the Polish National Centre of Science (NCN) under project No. 2017/27/B/ST8/01619.

DESIGN OF A BASE-ISOLATED SINGLE-DEGREE-OF-FREEDOM SYSTEM WITH SYMMETRIC DEFORMABLE AND DISSIPATIVE CONSTRAINTS: A NUMERICAL STUDY

Giulia Stefani *[1], Maurizio De Angelis[1], and Ugo Andreaus[1]
[1] Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy

Summary During strong earthquakes, base-isolated structures are expected to undergo large displacements, due to the increase in flexibility introduced by the isolation system. Such displacements can be accommodated by ensuring an adequate seismic gap around the structures. The limitation of these displacements, through the positioning of obstacles, allows to prevent the possible damage of the isolators, to the price of an increase in acceleration. In absence of an adequate gap, the effects of the impact with adjacent structures, as acceleration spikes, can be mitigated reducing the impact stiffness, to the price of an increase in displacement. These two conflicting problems were numerically investigated in this paper considering a single-degree-of-freedom system. Suitable combinations of selected parameters, which allow to reach a compromise between conflicting objectives, were identified.

INTRODUCTION

Base-isolated structures, when subjected to severe earthquakes, are expected to experience large displacements relative to the ground, due to the increase in flexibility introduced by the isolation system itself. Such displacements, that can be accommodated by ensuring an adequate seismic gap around the structures, can damage or reduce the efficiency of the isolation system [1]. In absence of a sufficient gap, the large displacements can lead to pounding with adjacent moat walls or structures [2]. These impacts can damage the structure and produce acceleration spikes which can be detrimental for sensitive equipment housed in the structures [3]. Based on these considerations, two conflicting control problems arise [4]. The first one concerns the control of excessive displacements. This can be done by inserting obstacles which limit the motion of the structure, to the price of an increase in acceleration. The second problem concerns the control of excessive accelerations that arise as a consequence of the impact between the structure and a rigid obstacle. This can be done by reducing the contact stiffness [5], and consequently, accepting an increase in the relative displacement. Considering a numerical model of a base-isolated single-degree-of-freedom (SDOF) system, symmetrically constrained by two obstacles (bumpers) and subject to a harmonic base excitation, the aim of this paper is to investigate the influence of selected dimensionless parameters, namely stiffness ratio between bumper and damper and dimensionless gap between mass and bumpers, on the dynamic response of the system and to identify suitable combinations of these parameters in order to reach a compromise between displacements and accelerations control.

NUMERICAL MODEL AND RESULTS

The system consists of a base-isolated mass, symmetrically constrained by two bumpers, excited by a harmonic base acceleration (forward and backward sine sweep signal). Both the isolation damper and the bumpers are modeled by an elastic element and a linear viscous damper arranged in parallel. The system is described in terms of dimensionless

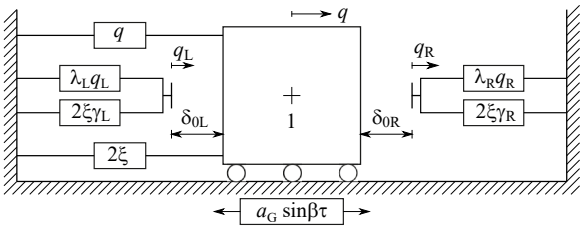

Figure 1: Numerical model of the SDOF system.

parameters, as shown in Figure 1, where q, q_j (j = R,L) are the dimensionless relative displacements, of the mass and of the Right and Left bumper respectively; β is the ratio between the circular frequency of the base excitation and the circular frequency of the isolated system; $a_G = 2\xi\sqrt{1-\xi^2}$ is the amplitude of the base acceleration; λ_j (j = R, L) is the ratio between the stiffness of the j-th bumper and that of the damper; γ_j (j = R, L) is the ratio between the damping coefficient of the j-th bumper and that of the damper; δ_{0j} (j = R, L) is the initial dimensionless gap, that is the initial distance between the mass and the j-th bumper. A value $\delta_{0j} = 0$ indicates that the bumpers are initially attached to the mass, a value $\delta_{0j} = 1$ indicates that the mass can only graze the bumpers without deforming them; if δ_{0j} takes values between 0 and 1, this indicates that the mass can beats and deforms the bumpers; the mass will be in the free flight condition for $\delta_{0j} > 1$.

*Corresponding author. E-mail: giulia.stefani@uniroma1.it.

The two control problems were studied assuming $\xi = 0.1$ and $\gamma_R = \gamma_L = \gamma = 5$ and investigating the influence of the stiffness ratio $\lambda_R = \lambda_L = \lambda$ and of the dimensionless gap δ_0 on the system response, represented in terms of maximum excursion of absolute acceleration η_a and relative displacement η_d of the mass in the forward sweep. This excursion was calculated as the difference between the maximum (positive) and the minimum (negative) values, evaluated at steady state resonance condition. Two different normalizations were adopted for the two problem. For the first problem (control of displacements) the normalization was made with respect to the free flight condition (η_{a0}, η_{d0}). For the second problem (control of accelerations) the normalization was made with respect to the case of rigid obstacle (η_{aR}, η_{dR}), conventionally assumed to occur for $\lambda = 100$. With reference to the first problem, from Figure 2(a), it can be observed that, compared to the free flight condition ($\eta_{a0} = \eta_{d0} = 1$), η_{d0} (blue lines) is always lower, while η_{a0} (red lines) is almost always greater, except for small values of both λ and δ_0. η_{a0} increases with increasing λ, while η_{d0} slightly decreases and remains almost constant for large values of λ. Furthermore, increasing δ_0 (increasing thickness of the lines), η_{a0} decreases while η_{d0} increases. The combination of small values of both λ and δ_0 appears to be a good choice which allows to realize a good compromise between reduction of displacement (primary objective) and limited increase in accelerations. With reference

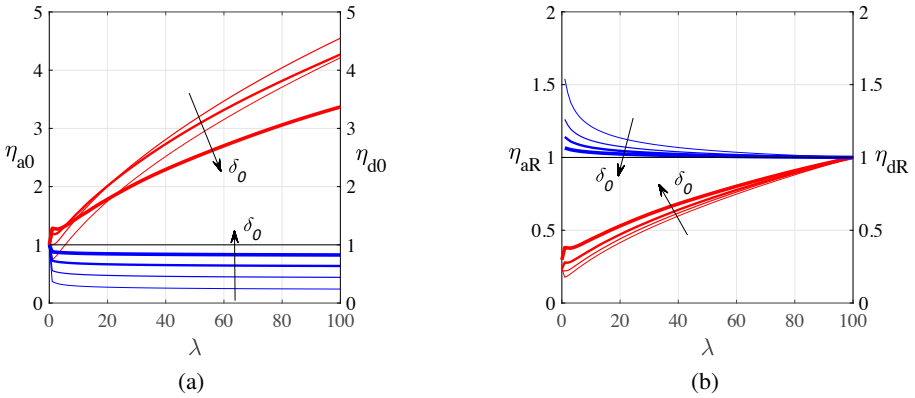

Figure 2: Maximum excursion of absolute acceleration (red lines) and relative displacement (blue lines) vs λ ($\xi = 0.1$, $\gamma = 5$): a) Problem 1; b) Problem 2.

to the second problem, from Figure 2(b), it can be observed that, compared to the rigid impact condition ($\eta_{aR} = \eta_{dR} = 1$), η_{aR} (red lines) is always lower, while η_{dR} (blue lines) is always greater. η_{aR} decreases with decreasing λ, while η_{dR} increases. Furthermore, increasing δ_0 (increasing thickness of the lines), η_{aR} slightly increases while η_{dR} decreases. The combination of small values of δ_0 and intermediate values of λ appears to be a good choice which allows to realize a good compromise between reduction of acceleration (primary objective) and limited increase in displacements.

CONCLUSIONS

In this paper a numerical study of the influence of selected dimensionless parameters on the dynamic response of a base-isolated SDOF system with symmetric deformable and dissipative constraints was performed. The response was represented in terms of maximum excursion of absolute acceleration and relative displacement of the mass. Two control problems, namely control of excessive displacements (Problem 1) and excessive accelerations (Problem 2) were considered, adopting two different normalizations. With reference to the Problem 1, it was observed that, compared to the free flight condition, the introduction of an obstacle allows to limit the displacement, with an increase in acceleration. However, by adopting small values of both dimensionless gap and stiffness ratio, it is possible to reach a good compromise between displacement reduction and not excessive acceleration increase. With reference to the Problem 2, it was observed that, compared to the case of impact with a very rigid obstacle (Problem 2), the interposition of a deformable obstacle allows to reduce the acceleration, to the price of an increase in displacement. However, by combining small values of dimensionless gap and intermediate values of stiffness ratio, it is possible to reach a good compromise between acceleration reduction and not excessive displacement increase.

MULTILEVEL DESIGN TOOLS FOR PARTICLE DAMPERS IN LIGHTWEIGHT MACHINES AND STRUCTURES

Robert Seifried * and Niklas Meyer
Institute of Mechanics and Ocean Engineering, Hamburg University of Technology, Hamburg, Germany

Summary Particle dampers are simple to manufacture damping devices. However, due to the complex nonlinear phenomena within the dampers, such as friction and impact, their efficient design and application is very challenging and nowadays mostly based on heuristic approaches. In this paper, a multilevel tool chain is presented to support a systematic investigation and design of particle dampers. Thereby various numerical models and experiments are used and coupled. The good agreement of the models and their efficiency for damper design are demonstrated on two application examples.

INTRODUCTION

In order to save resources, lightweight designs are becoming increasingly important these days. However, a smaller weight typically causes a decrease in stiffness and non-negligible vibration amplitudes. In recent years, the main focus of lightweight design techniques has been on increasing the stiffness of structures by design elements using shape or topology optimization. Damping is mostly not directly considered in these design strategies.
One type of promising damping devices to integrate in the lightweight designs are particle dampers. They are cheap and simply designed passive damping elements and can be seen as a derivative of single-mass impact dampers. Granular particles are embedded in a container attached to a vibrating structure. Due to structural vibrations, momentum is transferred to the granular material which interacts with each other. The mechanisms of energy dissipation are highly complex and involve impact and frictional phenomena. Due to these complex energy dissipation processes within the particle dampers, the dampers' efficiency depends on many design parameters such as material pairing, particle size, damper volume, and filling degree. Also, the working conditions, such as amplitude and frequency, have to be considered when designing appropriate dampers. While there have been already some very promising applications of particle dampers [1], the design process of such particle dampers is so far mostly heuristic and based on experimental trail-and-error strategies.
In this paper a systematic multilevel design methodology is presented, which is based on computational models as well as models derived from experiments. These models are not only useful for supporting the damper design and damper integration on the structure but also provide very useful insights into the processes, nonlinear effects and design parameters influencing the efficiency of the dampers.

MULTILEVEL MODELS FOR PARTICLE DAMPER DESIGN

For a meaningful understanding, and thus also for the design, of particle dampers investigations on different scales or levels are necessary using experiments and simulations, see Fig.1.
The first level is the single particle-particle and particle-wall interaction. Hereby, the energy dissipation in single impacts is of most interest. The energy dissipation is due to elasto-plastic or visco-plastic material behavior during impact. This energy loss is often described by the coefficient of restitution. Numerically these single impacts can be investigated in detail using finite element models of two impacting bodies [2]. Corresponding experimental investigations are performed for the impact of a sphere which is suspended by thin wires against a wall. Thus, the sphere can impact in a defined manner. The velocity of the impacting body is then measured by laser scanning vibrometer (LSV) PSV-500 from Polytec. By both methods the coefficient of restitution can be easily extracted for different impacting velocities.
The second level represents the investigation of an isolated particle damper and the determination of the energy dissipation for a given excitation frequency and amplitude. Hereby, dozens, hundreds or even several thousands of particles might be in one particle damper. Experimentally the testbed consists of a particle box with a free-free boundary condition that is excited by a controlled harmonic force via a shaker. The excitation force is controlled in such a way, that the frequency and acceleration magnitude of the box stays constant. With the used equipment this developed testbed allows the testing of a large frequency and acceleration range. Via the measured velocity of the box using the LSV and the measured force of the shaker, the complex power is determined [3]. By the complex power, the energy dissipation in one cycle and the loss factor can be calculated. Then characteristic diagrams are obtained, representing over acceleration and frequency the loss factor or energy dissipation, respectively. A similar setup is also used in the numerical model of the second level. Since simulations of dampers with many particles can be numerical burdensome finite element models are not useful here. Instead, a Discrete-Element-Model (DEM) is used. The spherical particles are rigid bodies and interact with each other and the particle box by continuous contact models. For the normal contact, these models are based on the contact law of Hertz and use modifications to introduce energy dissipation described by the coefficient of restitution obtained on the first level. Additionally, smoothed frictional forces are implemented. An efficient contact search algorithm based on the verlet list in combination with the link cell algorithm is used. For the time integration, a fifth order Gear predictor-corrector algorithm is applied. The damper model is excited by a harmonic motion using a rheonomic constraint. Then, from the reaction force and the acceleration of the damper the energy dissipation and loss factor can be determined again. Thus,

*Corresponding author. E-mail: robert.seifried@tuhh.de.

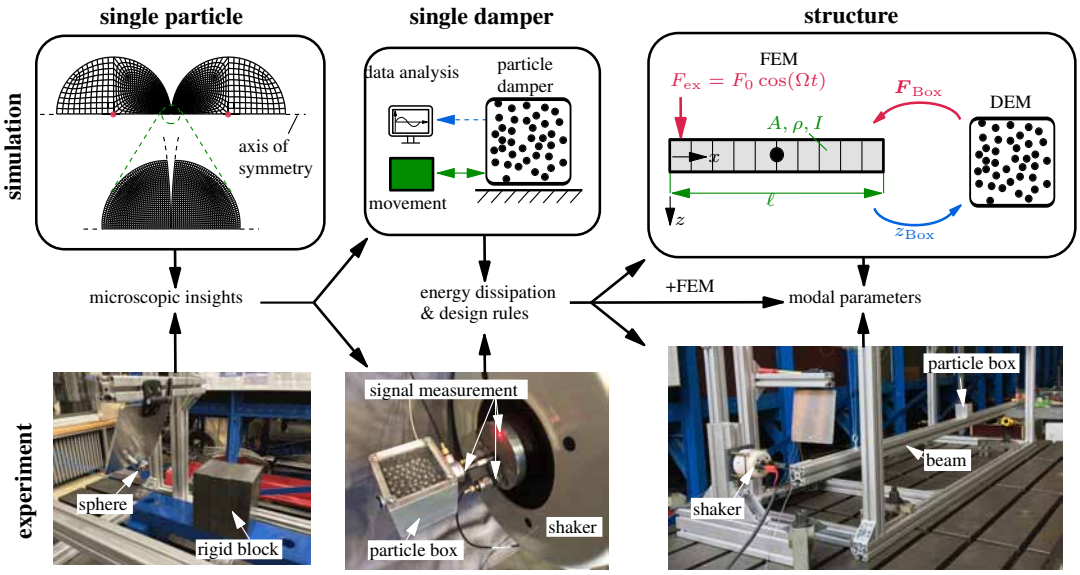

Figure 1: Tool chain for the analysis of particle dampers.

also by simulations characteristic diagrams for a given particle damper can be obtained. These diagrams can be stored and used on the third level for integration in a vibrating structure. Also, the characteristic diagrams and insights gained on the second level help to shorten the design phase for single particle dampers.
The third level represents the integration of one or several particle dampers in a vibrating structure or machine to evaluate their overall damping effect. Experimentally the testbed consists of a flexible structure supported by two soft cables, thus free-free boundary condition can be assumed. The structure is excited by a shaker and the excitation force is measured by a force sensor. The velocity profile of the structure is measured by the same LSV and analyzed with the software BK Connect providing the damping ratio. For the numerical investigations on the third level, two different approaches have been developed. In the first approach, the discrete element model from level two is coupled with a vibrating structure and simulated together. The flexible structure can be described e.g. by a continuous model, a reduced linear finite element model or a flexible multibody model. While this approach is very accurate and useful for verification purposes it is computationally very expensive, especially if a large frequency range should be investigated. Alternatively, the flexible structure can be coupled with the previously determined characteristic diagrams of the particle dampers. This coupling is easily implemented by a fixed point iteration and allows a fast simulation. Thus, different positioning and the application of several distributed dampers can be easily tested.
With models on these three levels, a holistic tool chain for the analysis of particle dampers is derived. This enables to design tailor made particle dampers at an early design stage of lightweight structures. On each level numerical models and experiments are available. On the one hand, in simulations many parameter variations can be computed yielding a good understanding of parameter sensitivities. On the other hand, the experiments are used once for the validation of the simulations. Also, from experiments one can get quickly a good impression of the behavior of some real possible particle combinations. Thus, numerical and experimental investigations should go hand in hand and on each level their results can be interchanged between experiments and simulations.

APPLICATION AND CONCLUSIONS

The efficiency of the developed multilevel tool chain is demonstrated using two applications. The first one is a simple beam-like structure where several distributed dampers are mounted. The second application example is a lightweight manipulator undergoing large working motion. This requires the modeling as flexible multibody system.
It is shown, that a very good qualitative agreement between the experiment and the numerical models are achieved on all three levels. Thus, the tool chain provides good and reliable insights to the complex mechanisms in particle dampers. For both systems different influence parameters on the damping behavior are analyzed, like the friction, particle radius, filling degree and material pairing. Finally, this allows optimized damper designs for either a certain defined excitation or a more broad excitation bandwidth.

Summary The paper presents modelling and experimental testing of non-linear degradation processes developing in two-phase ceramic matrix (CMCs) and metal matrix composites (MMCs) subjected to quasi-static and dynamic compressive loading. Modelling was performed by multiscale approach using both: (1) analytical and (2) numerical methods and selected Representative Volume Elements (RVE) based on SEM observations of composites. Both quasi-static and dynamic experimental tests were done applying standard MTS (100 kN) servo-hydraulic machine and Split Hopkinson Pressure Bar (SHPB) stand for impact tests with loading velocities 20 – 30 m/s. As a results we observed for CMCs in quasi-static loading failure mode by splitting of cylindrical samples, whereas for impact loading dynamic crushing process took place.

INTRODUCTION AND MOTIVATION

Quasi-static and dynamic degradation of semi-brittle ceramic matrix composites (CMCs) or metal matrix composites (MMCs) exhibit different mechanical response under uniaxial tension and uniaxial compression. In this paper we analysed cracking processes and failure under compression of two-phase CMC made of Al_2O_3 and ZrO_2 mixture and two-phase MMC built of WC grains and plastic Co matrix. The importance of these advanced composites results from their applications. The CMC is used as thermal barrier coatings (engines of aircrafts), whereas the MMC with addition nanoparticles is applied for modern cutting tools in different branches of engineering.

MULTISCALE MODELLING

Constitutive modelling of the analysed composites obeys description of: (1) elastic deformations of initially porous material, (2) limited plasticity and (3) cracks initiation and propagation. Description of polycrystalline composites with ceramic or metal matrixes behaviour at microscopic level is related to analysis of set of grains (RVE). The RVE is created with the help of SEM or μCT. In this paper we considered gradual degradation processes due to mechanical: quasi-static or dynamic loading. The basic elements of degradation are different defects growing inside polycrystal structure which includes: (1) dislocations or dislocation bands, (2) micro- and meso-cracks, kinked and wing cracks. To get macroscopic response of the material, one can calculate averaged values of stress and strain over the RVE with application of analytical approach or numerical one.

Analytical approach for quasi-static CMCs response

The constitutive equations for the considered CMC are the following:

$$\varepsilon_{ij} = S_{ijkl}(\sigma_{mn}, p, \omega^{(i)})\sigma_{kl}$$

where S_{ijkl} is the compliance tensor, ε_{ij} is the strain tensor, σ_{kl} is the stress tensor, p is the porosity parameter and $\omega^{(i)}$ are sets of parameters defining the presence of different kinds of defects "i" developing inside the material.

Cracks propagation mechanism is mainly along grain boundaries including defects kinking. It is strongly influenced by grain boundary porosity p_{gb}. Namely, any crack (straight or kinked one occupying grain boundaries) can propagate if the energy release rate G satisfies the following condition

$$G(\sigma_{ij}, \phi, p_{gb}) \geq \gamma_{gb}^{cr}(p_{gb}),$$

where ϕ describes orientation angle of cracks in RVE, γ_{gb}^{cr} is the critical value of the grain boundary surface energy.

Numerical approach for impact response of two-phase composites

Assessment of impact techniques is given in [1]. A basic model of MMCs is presented in [2]. The microstructures of Al_2O_3/ZrO_2 and WC/Co have different grain arrangement and their response is qualitatively different. In numerical models a low velocity impact of the two materials was investigated focusing attention on damage growth associated with microcracks and cracks initiation. We use finite element method (FEM) and meshless non-local peridynamics (PD), [3], Fig. 1. Further, the problems of binder modelling are different in both kinds of materials. In the WC/Co the binders are relatively thick and can be considered as elastic-plastic, while in the Al_2O_3/ZrO_2 the interfaces are thin and brittle. The

*Corresponding author. E-mail: sadowski.t@gmail.com or t.sadowski@pollub.pl.

grains in WC/Co are very hard, however, they are ductile as well [4]. The grains in Al_2O_3/ZrO_2 are both brittle. In the case of WC/Co the damage process develops rather along the binders, while in Al_2O_3/ZrO_2 the damage spread in both phases. A significant influence on crack initiation has initial voids, in particular in the CMC samples.

In case of WC/Co, the pulse duration was 10^{-7}s and the applied pressure level - 480 MPa. The proposed numerical model requires advanced FEM formulation including geometrical data and differet phenomena revealing inside of the RVE, like: (1) spatial distribution of the cermet constituents, (2) system of grain boundaries/binder interfaces modelled by interface elements, (3) rotation of brittle grains, (4) initiation and development of microcrakcs during loading process.

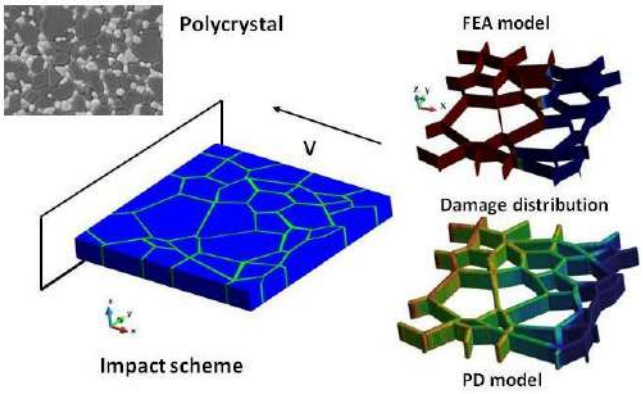

Figure 1. Numerical models in low velocity impact of CMC and MMC: FEM and PD.

RESULTS AND CONCLUSIONS

The obtained numerical results were compared with own experimental data for compression processes: under quasi-static loading using MTS (100 kN) and dynamic loading done with application of SHPB stand, Fig.2. The loading velocities were in the range 20 – 30 m/s.

Figure 2. Failure modes of CMC for: a) splitting in quasi-static loading (MTS) and 2) crushing during impact loading with SHPB.

Figure 2 presents qiute different failure modes for quasi-static loading and impact in case of CMC. We obtained splitting of specimens for quasi-static loading, wheras crushing took place during impact.

Similar phenomena were observed for the MMC. Its response due to pulse loading is significantly different in comparison to the quasi-static behaviour, i.e. the stress distributions and microcracking processes are quite different.

Comparison of the proposed models with experimental results lead to conclusion that theoretical models with good quality descrived non-linear behaviour of the two-phase composites under compression.

NON-LINEAR DYNAMICS OF COMPOSITE LAMINATES WITH CURVILINEAR FIBERS UNDER SUPERSONIC AIRFLOW

Hamed Akhavan and Pedro Ribeiro*
DEMec/INEGI, Faculdade de Engenharia, Universidade do Porto, Porto, Portugal

Summary This research examines non-linear dynamics of variable stiffness composite plates, composed of curvilinear fibres in a polymeric matrix, exposed to a supersonic airflow. A reduced-order model obtained by sequentially applying static condensation and truncating to a selected number of modes of vibration is applied. The inclusion of a large-enough number of modes in the latter technique is essential for observation of the, often overlooked, rich dynamics of plates under airflows. Different scenarios, including LCOs with one dominant harmonic, period-*n* LCOs, and chaotic oscillations, are found in this self-excitation problem. Symmetry breaking bifurcations may introduce unstable LCOs and the aperiodic oscillations are preceded by period doubling bifurcations. The bifurcations and the stability status are affected by the curvilinear fibre paths, a feature that can be used in design.

INTRODUCTION

The non-linear dynamic behaviour of composite plates with curvilinear fibres and under a supersonic airflow is investigated in this work. A composite plate with curvilinear fibres is a type of variable stiffness composite laminate (VSCL) [1]; it can be manufactured using automated fibre placement technology [2]. Curvilinear fibres allow designers to achieve a load distribution or vibration characteristics that are more adequate to specific demands. There are a few works on dynamics of VSCLs (see, e.g., [1], [3] and references therein), but only limited investigations (e.g., Refs. [4] and [5]) are dedicated to non-linear aerodynamics of VSCL. This work intends to explore the latter issue in more detail.

A VARIABLE STIFFNESS PLATE SUBJECTED TO A SUPERSONIC AIRFLOW

In this research, a rectangular plate, with length a and width b is studied. A Cartesian coordinate system (x,y,z) with the origin located at the geometric centre of the undeformed plate is employed in the following equations. The reference curvilinear fibre path changes linearly from T_0 at the left edge to T_1 at the right edge, being its angle defined as $\theta(x) = (T_1 - T_0)(x + a/2)/a + T_0$. In order to define the other fibre paths in the lamina, the reference fibre path shifts in the y-direction. A displacement field, based on a third-order shear deformation theory is introduced as

$$\begin{aligned} u(x,y,z,t) &= u^0(x,y,t) + z\theta_y^0(x,y,t) - cz^3\left(\frac{\partial w^0(x,y,t)}{\partial x} + \theta_y^0(x,y,t)\right), \\ v(x,y,z,t) &= v^0(x,y,t) - z\theta_x^0(x,y,t) - cz^3\left(\frac{\partial w^0(x,y,t)}{\partial y} - \theta_x^0(x,y,t)\right), \\ w(x,y,z,t) &= w^0(x,y,t), \end{aligned} \tag{1}$$

where u^0, v^0, w^0 are mid-plane displacements components and t represents time. Rotations of a normal segment around the x and the y axis are represented by θ_y^0 and θ_x^0, respectively. These components are discretized using a p-version finite element as

$$r(x,y,t) = \mathbf{N}^r(x,y)^T \mathbf{q}_r(t), \tag{2}$$

where r can be $u^0, v^0, w^0, \theta_y^0$ or θ_x^0, $\mathbf{N}^r$ are vectors of shape functions and $\mathbf{q}_r$ are vectors of generalized coordinates.

Supersonic airflow is considered on one (front) side of the plate, while constant undisturbed air pressure is set at the other (back) side. The pressure difference between the plate surfaces due to a highly unsteady airflow (in x-direction) is defined using linear Piston theory as

$$\Delta p(x,y,t) = -\frac{2q}{\sqrt{M^2-1}}\left(\frac{M^2-2}{M^2-1}\frac{1}{U_\infty}\frac{\partial w(x,y,t)}{\partial t} + \frac{\partial w(x,y,t)}{\partial x}\right), \tag{3}$$

with q representing the dynamic pressure, M the Mach number and U_∞ the freestream velocity.

The principle of virtual work, in conjunction with equation (2), leads to the full-order model equations of motion, representing the self-excited vibrations of a VSCL under supersonic airflow. These equations have the following form [5]

$$\mathbf{M}\ddot{\mathbf{q}}(t) + \mathbf{F}_{unsteady}\mathbf{q}(t) + \left(\mathbf{K} + \mathbf{K}_n(\mathbf{q}(t)) + \mathbf{F}_{steady}\right)\mathbf{q}(t) = \mathbf{0}. \tag{4}$$

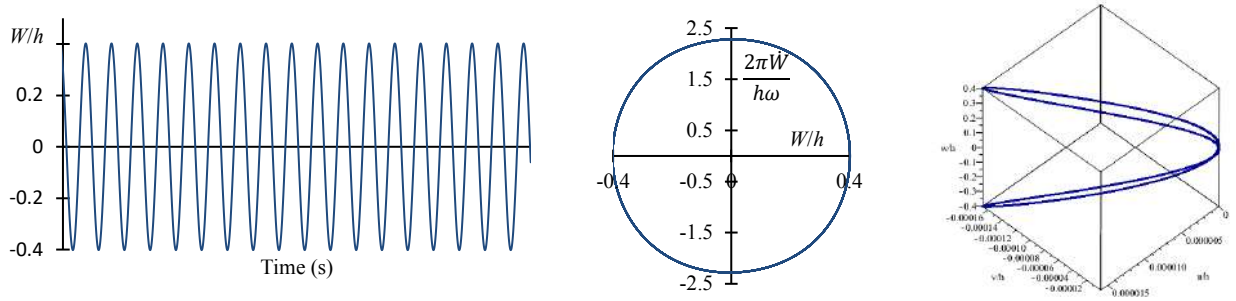
Matrices $\mathbf{M}$, $\mathbf{K}_\ell$ and $\mathbf{K}_{n\ell}(\mathbf{q}(t))$ are, respectively, the mass, linear and non-linear stiffness matrices [3]. Matrices $\mathbf{F}_{steady}$ and $\mathbf{F}_{unsteady}$ [5] are due to the interaction between the structure and the airflow. The order of the system of equations (4) is reduced first using static condensation, by neglecting membrane inertia, and then by transferring to a selected set of modal

*Corresponding author. E-mail: pmleal@fe.up.pt

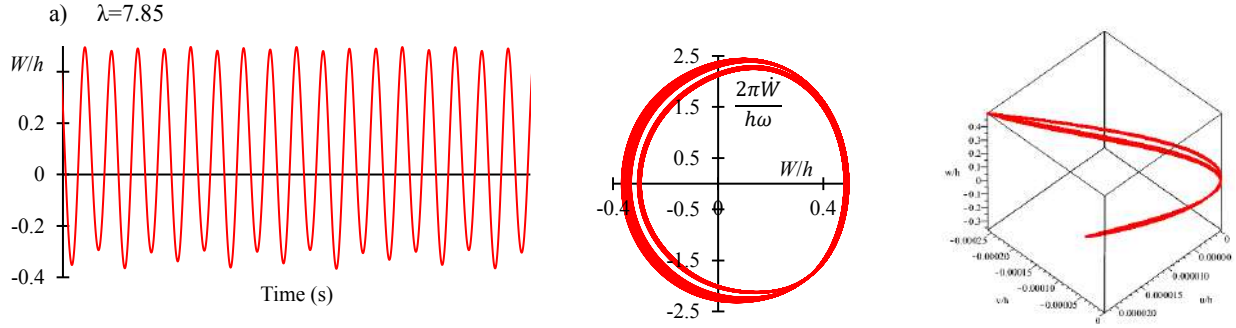
coordinates. It is important to note here that more modal coordinates are employed than what is common practice in aeroelastic analyses [4], a factor that is important for the detection of bifurcations, the stability analyses and the computation of aperiodic oscillations. The reduced-order model is solved using Newmark's method and a shooting method.

RESULTS

Time histories (deflection ratio versus time), phase-plane plots (non-dimensional velocity versus deflection ratio) and positions of a point (u/h, v/h, w/h) during oscillation – where h is thickness of the variable stiffness plate - are displayed in Figure 1, for two aerodynamic loads. In this variable stiffness plate, a Hopf bifurcation occurs at a critical flutter speed (linear regime) corresponding to a non-dimensional dynamic pressure λ equal to 7.22 ($\lambda=2qa^3/\left(D\sqrt{M^2-1}\right)$, D represents a plate bending stiffness). For $\lambda>7.22$, oscillations with magnitude bounded by the geometrical non-linearity arise. The results shown in the sub-figure (a) are calculated when $\lambda=7.85$ and correspond to a periodic oscillation (an LCO), while in the sub-figure (b) the aperiodic oscillation that occurs at $\lambda=7.954$ is displayed. A symmetry-breaking bifurcation occurs around $\lambda=7.86$ and the stable LCO (shown in sub-figure a) becomes unstable, while two new stable branches are born. The aperiodic oscillation shown in sub-figure (b) is found after additional bifurcations on one of the latter branches.



a) $\lambda=7.85$



b) $\lambda=7.954$

Figure 1. Time histories, phase-plane plots and positions of a point at plate during oscillation, at two aerodynamic loads.

CONCLUSIONS

This investigation demonstrated how a stable LCO passes through bifurcations, which lead to other stable and unstable LCOs, and even to aperiodic solutions. These bifurcations happened during non-linear flutter of variable stiffness plates and their appropriate detection required that the number of degrees of freedom in the mathematical model was not severely reduced. Curvilinear fibre paths in laminated composites can be varied in order to – to a certain extent - avoid the occurrence of flutter due to Hopf bifurcations or additional bifurcations at large vibration amplitudes. Although variable stiffness plates are the chief interest here, the reduced-order model of the type employed, with a large-enough number of degrees of freedom, is capable of finding rich non-linear dynamics in other plates subjected to airflows.

ACKNOWLEDGEMENT

This research is carried out in the framework of project Nº 030348, POCI-01-0145-FEDER-030348, "Laminated composite panels reinforced with carbon nanotubes and curvilinear carbon fibres for enhanced vibration and flutter characteristics", funded by FEDER, through *Programa Operacional Competitividade e Internacionalização* – COMPETE 2020, and by National Funds (PIDDAC), through FCT/MCTES.

NONLINEAR DYNAMICS OF PIEZOELECTRIC SCANNING MICROMIRRORS: MODELING AND EXPERIMENTAL VALIDATION

Andrea Opreni*[1], Nicolò Boni[2], Roberto Carminati[2], Massimiliano Merli[2], Gianluca Mendicino[2], and Attilio Frangi[1]

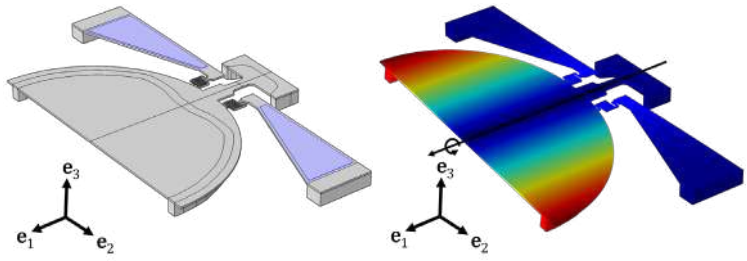
Summary Piezoelectric thin films have gained attention as key materials for the actuation of micro devices since they provide high drive forces, enhanced linearity, and improved reliability compared to electrostatic actuation. Here we address the simulation of piezo-micromirrors undergoing large rotations with reduced order models. We focus on obtaining a numerical estimate of the elastic energy term and of the piezo coupling coefficient starting from the Landau-Devonshire theory of ferroelectrics. The model is validated on a specific micromirror actuated with PZT patches.

INTRODUCTION

The development of optical Micro-Electro-Mechanical Systems (MEMS) is a direct result of market driven applications. Holographic lenses are becoming popular in the consumer industry, Head-Up-Displays are turning into a commodity of the automotive industry, and light manipulation is a requirement in most experimental scientific fields. Within the class of optical MEMS, scanning micromirrors provide excellent performance in terms of precision, compactness, and power consumption [1].
Piezoelectrically actuated micromirrors are subjected to both geometric and electromechanical nonlinearities. Concerning the latter, the theoretical work by Landau-Devonshire [2] shows that the strain experienced by piezoelectric materials upon the application of an external voltage is nonlinearly proportional to the polarization vector. Therefore, the linearized theory of ferroelectrics [3] holds for low values of applied voltages, hence it proves unreliable for modeling devices that require large drive voltages as scanning micromirrors.
In this work we develop a nonlinear piezoelectric model for the dynamic analysis of micromirrors actuated with Lead-Zirconate-Titanate (PZT) films. The model is validated on micromirrors with hardening behavior developed by STMicroelectronics. Preliminary results show a match between experimental data and the proposed model at oscillation amplitudes up to 21°.



(a) (b)

Figure 1: Tested micromirror geometry (a), and torsional mode of the device (b).

MODEL

According to the theory of ferroelectrics developed by Landau-Devonshire, the polarization vector $\boldsymbol{P}$ induces inelastic deformation of the elementary cell of the piezoelectric crystal due to spontaneous polarization below the Courie temperature. Considering linearized elasticity, the Cauchy stress $\boldsymbol{\sigma}$ can then be additively decomposed in elastic and inelastic terms as:

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\varepsilon}[\boldsymbol{u}] - \boldsymbol{\sigma}^{P}[\boldsymbol{P}] \quad \text{where} \quad \boldsymbol{\sigma}^{\varepsilon}[\boldsymbol{u}] := \mathcal{C} : \boldsymbol{\varepsilon}[\boldsymbol{u}], \quad \boldsymbol{\sigma}^{P}[\boldsymbol{P}] := \mathcal{C} : \boldsymbol{\varepsilon}^{P}[\boldsymbol{P}] \tag{1}$$

where $\boldsymbol{\varepsilon}$ is the infinitesimal strain tensor, $\boldsymbol{u}$ is the displacement, $\mathcal{C}$ is the fourth-order elasticity tensor, and the superscripts $(\cdot)^{\varepsilon}$ and $(\cdot)^{P}$ define elastic and inelastic quantities. Neglecting active forces, the weak form of the linear momentum conservation equation for piezoelectric MEMS subjected to finite transformations reads:

$$\int_{\Omega} \rho \ddot{\boldsymbol{u}} \cdot \boldsymbol{w} \, \mathrm{d}\Omega + \int_{\Omega} (\boldsymbol{\sigma}^{\varepsilon} - \boldsymbol{\sigma}^{P}) : \mathrm{d}[\boldsymbol{w}] \, \mathrm{d}\Omega = 0 \tag{2}$$

*Corresponding author. E-mail: andrea.opreni@polimi.it.

where ρ is the density, $\boldsymbol{w}$ is the virtual displacement, $\mathbf{d}$ is the rate of deformation tensor, and Ω is the material volume. Equation (2) is projected on the subspace of the generalized coordinate θ representative of the system nonlinear motion [4]. By adding a damping term proportional to the system velocity we obtain a one degree of freedom model of the form:

$$J\ddot{\theta} + J\frac{\omega_0}{Q}\dot{\theta} + f(\theta) = c_{nl}V_0\cos(\omega t) \tag{3}$$

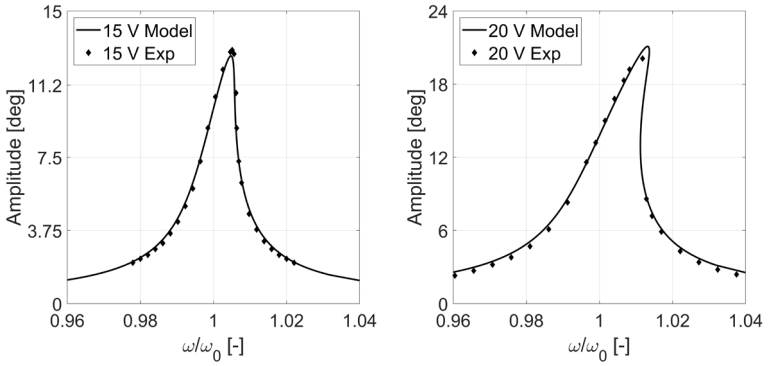
with J inertia, ω_0 resonance frequency of the mode of interest, Q quality factor estimated from experiments, $f(\theta)$ internal force vector evaluated with a nonlinear Finite Element model, V_0 drive voltage amplitude, ω excitation frequency, and c_{nl} piezoelectric coupling coefficient. If the piezoelectric patch is thin and deposited along the $\boldsymbol{e}_1\boldsymbol{e}_2$ plane, the electric field takes the form $\boldsymbol{E} = E\boldsymbol{e}_3$, thus if dielectric properties are isotropic $\boldsymbol{P} = P\boldsymbol{e}_3$. If we assume that the displacements of the piezoelectric material film are small, c_{nl} is then estimated by projecting the inelastic stresses on the mode of interest, and on the first cosine term of a Fourier basis:

$$c_{nl} = \frac{\omega}{\pi V_0}\int_0^T\int_{\Omega_P} P^2\Big[(\varepsilon_{11}[\boldsymbol{\phi}] + \varepsilon_{22}[\boldsymbol{\phi}])c_{31} + \varepsilon_{33}[\boldsymbol{\phi}]c_{33}\Big]\cos(\omega t)\,\mathrm{d}\Omega\,dt \tag{4}$$

where T is the period of the drive voltage, ε_{ij} are strain components, $\boldsymbol{\phi}$ is the linear mode basis, and c_{ij} are material constants.

NUMERICAL RESULTS AND EXPERIMENTAL VALIDATION

The proposed model was validated on micromirrors with hardening behavior developed by STMicroelectronics. The devices were made of monocrystalline silicon with (100) orientation actuated with PZT patches. The micromirrors geometry is reported in Figure 1a. The PZT patches are highlighted in light purple. The devices were actuated in their torsional mode. Its displacement field is reported in Figure 1b, highlighting that the PZT patches are subjected to small displacements. Preliminary results obtained for drive voltage amplitudes of 15 V and 20 V are reported in Figure 2. The charts show an excellent agreement between experimental data and proposed model.



(a) (b)

Figure 2: Comparison between model and experimental data for actuation voltage amplitudes V_0 of 15 V (a) and 20 V (b).

CONCLUSIONS

We have developed a novel technique for the analysis of the nonlinear dynamic behavior of structures actuated using thin films of piezoelectric material. The model is based on the theory of ferroelectrics and it allows simulating devices subjected to geometrical and electromechanical nonlinearities on the sole basis of the polarization history of the piezoelectric material.

A MODIFIED NON-LINEAR ENERGY SINK FOR PARAMETRIC-INSTABILITY CONTROL OF A SPRUNG CYLINDER

Carlos E.N. Mazzilli*[1], Breno A.P. Mendes [1] and Eduardo A.R. Ribeiro [1]
[1] Department of Structural and Geotechnical Engineering, Escola Politécnica da USP, São Paulo, Brazil

Summary: This paper addresses the vibration control of a rigid cylinder constrained by a spring and a linear dashpot. Parametric excitation is assumed to cause a harmonic variation of the spring stiffness about an average value. The case of principal parametric instability is considered and the vibration control is provided by a mass attached to a linear spring, able to slide along a guiding bar placed within the cylinder. The guide is free to rotate about the cylinder longitudinal axis, although damped by a linear rotational dashpot. The assemblage plays the role of a non-linear energy sink, since there exists no linear rotational stiffness associated to the controller. This non-linear vibration absorber introduces a modification with respect to a similar assemblage studied in the literature, because it accounts for a variable distance of the rotational mass with respect to the cylinder axis. Preliminary results show that the modified system overall performs as a better controller.

PROBLEM MOTIVATION

The classical tuned-mass dampers attached to the main structure have proved to be effective in vibration control for narrowband excitations [1]. Non-linear vibration absorbers, like the so-called non-linear energy sinks (NES), are an interesting alternative [2]. With a damper and a non-linearizable stiffness, a NES is effective for a non-preferable suppression frequency. Such devices have been used in passive vibration control of buildings [3] and structures subjected to flow-induced loading [4].

This paper addresses the classic problem of the parametric excitation of a rigid cylinder with viscous-elastic constraints, characterised by a harmonic variation of its support stiffness about an average value. It is common knowledge that when the excitation frequency is twice the structure's natural frequency, the trivial solution of the otherwise unforced cylinder equation of motion becomes unstable, a phenomenon called principal parametric instability. This scenario comes about, for instance, in offshore risers, when waves impose heave motions to the floating rig to which the riser is attached, causing an almost-periodic modulation in its geometric stiffness. The present study is inspired by this problem, yet in a very simplified way. In [5], parametric-instability control by means of a rotational non-linear vibration absorber in a similar model has already been discussed. Yet, the novelty here is that the rotating mass is attached to a linear spring and slides along a guiding bar mounted inside the cylinder cross section (see Fig. 1). The guide is free to rotate, although damped by a linear dashpot. Therefore, the mass distance to the cylinder axis is not fixed, as in [5], bringing about the interesting problem of the self-adjustment of the rotation radius that seems to play a key role in the controller's efficiency.

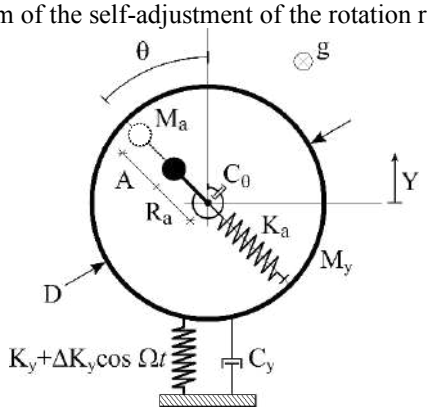

Figure 1. Cylinder with mounted NES.

$$y = \frac{Y}{D} \qquad a = \frac{A}{D} \qquad r = \frac{R_a}{D}$$

$$m = \frac{M_a}{M_y} \qquad \delta = \frac{\Delta K_y}{K_y} \qquad \tau = \omega_y t$$

$$\omega_y = \sqrt{\frac{K_y}{M_y + Ma}} \qquad n = \frac{\Omega}{\omega_y} \qquad \beta_1 = \frac{m}{(1+m)}$$

$$\beta_2 = \frac{C_y}{(M_y + M_a)\omega_y} \qquad \beta_3 = \frac{C_\theta}{3D^2 3M_a 3\omega_y} \qquad \beta_4 = \frac{K_a}{K_y}$$

Table 1. System variables and non-dimensional parameters.

MATHEMATICAL MODEL

The variables and non-dimensional system parameters are defined in Tab. 1, where Y is the cylinder displacement; A is the rotating mass radial displacement; D is the cylinder diameter; R_a is the NES radius for unstrained spring; M_y is the cylinder mass; M_a is the NES mass; K_y is the cylinder average stiffness; ΔK_y is the cylinder stiffness amplitude variation; K_a is the NES stiffness; ω_y is the cylinder reference natural frequency; Ω is the parametric-excitation frequency; C_y is the cylinder dashpot constant; C_θ is the NES rotational dashpot constant. It is worth mentioning that the NES unstrained spring length is assumed to be equal to the cylinder radius.

Hamilton's principle is used to obtain the set of non-linear differential equations that define the mathematical model:

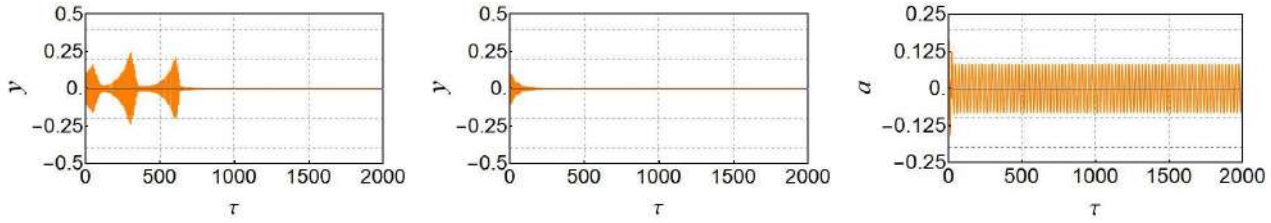
$$y'' + \beta_2 y' + (1 + \delta \sin n\tau)y + \{\beta_1[a'' - (r+a)\theta'^2]\}\cos\theta - \{\beta_1[(r+a)\theta'' + 2a'\theta']\}\sin\theta = 0 \quad (1)$$

$$(a+r)^2\theta'' + [2(r+a)a' + \beta_3]\theta' - (r+a)y''\sin\theta = 0 \quad (2)$$

$$a'' + \frac{\beta_4}{\beta_1}a - (r+a)\theta'^2 + y''\cos\theta = 0 \quad (3)$$

*Corresponding author. E-mail: cenmazzi@usp.br.

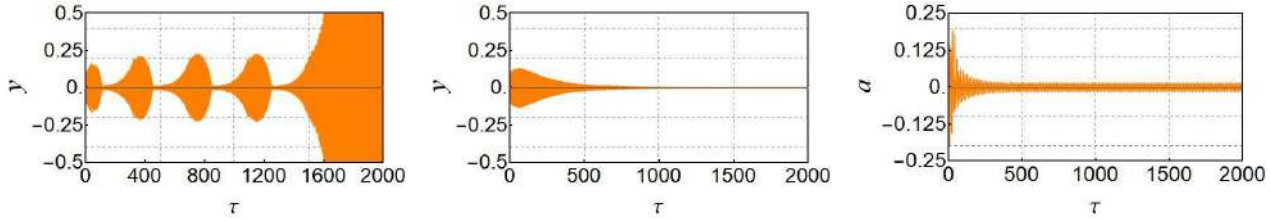
where $(\ )' = \frac{d}{d\tau}$. Numerical integration of the system equations was performed using *Mathematica*® in different scenarios, whose results are briefly commented in the following. Firstly, the case of an infinitely-rigid NES spring precisely retrieves results found in [5], which is a necessary validation step. Next, it is seen that the less stiff is the NES, the more efficient it is, in the sense that the time required for full cylinder vibration suppression is smaller (see Fig. 2).



(a) Rigid NES ($\beta_4 \to \infty$) (b) Flexible NES ($\beta_4 = 0.01$)

Figure 2. Time responses for $r = 0.25$, $m = 0.15$, $\xi_y = 0.01$, $\xi_\theta = 0.05$, $\delta = 0.10$ and $n = 2$.

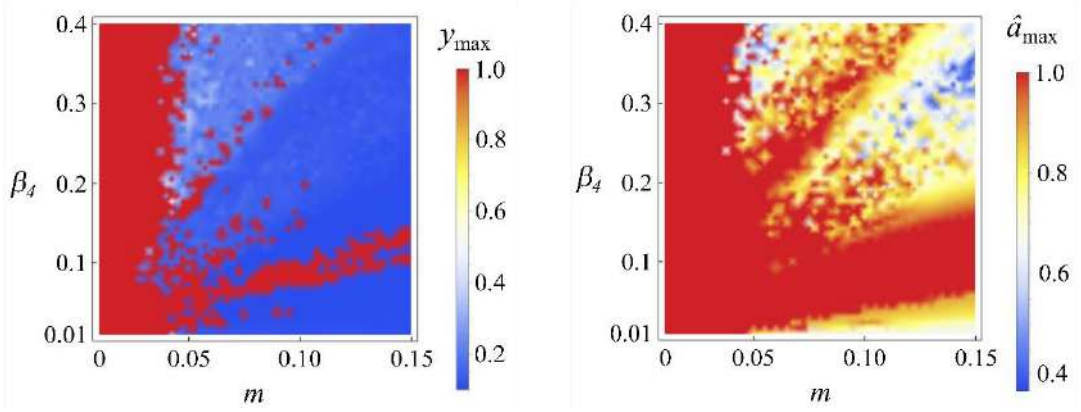
Even more evident is the NES' improved efficiency for the case depicted in Fig. 3, which shows that the infinitely-rigid NES is not able to control the parametric instability, whereas the one with a very low stiffness is.



(a) Rigid NES ($\beta_4 \to \infty$) (b) Flexible NES ($\beta_4 = 0.01$)

Figure 3. Time responses for $r = 0.25$, $m = 0.05$, $\xi_y = 0.01$, $\xi_\theta = 0.05$, $\delta = 0.10$ and $n = 2$.

Fig. 4(a) is a NES's efficiency chart, for different choices of stiffness and mass parameters. Overall, there is an increase in the zone of controlled vibrations (blue) with respect to the rigid NES studied in [5]. Nevertheless, it is noteworthy that a thin unstable-response tongue (red) appears for $0.05 \leq \beta_4 \leq 0.15$, where the rigid NES performs better. Fig. 4(b) depicts the rotating mass vibration amplitude. Of course, meaningful maximum free-course sliding amplitudes $\hat{a}_{\max}$ should be smaller than one, where $\hat{a} = a/\left(\frac{1}{2} - r\right)$.



(a) $y_{\max}$ (b) $\hat{a}_{\max}$

Figure 4. NES efficiency chart for $\xi_y = 0.01$, $\xi_\theta = 0.05$, $\delta = 0.10$, $n = 2$ and $r = 0.25$.

CONCLUSIONS

Although this is still a work in progress, due to the high control-parameter-space dimension, it can already be seen that the optimization of the proposed modified rotating NES leads to a more efficient vibration controller.

DESIGN OF STABILITY PRESERVING SIMULATION METHODS FOR THE PREDICTION OF ROCKFALL

Remco I. Leine *[1], Giuseppe Capobianco[1], Perry Bartelt[2], and Guang Lu[2]
[1] Institute for Nonlinear Mechanics, University of Stuttgart, Germany
[2] WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland

Summary The stability properties of a freely rotating rigid body are governed by the intermediate axis theorem, i.e. rotation around the major and minor principal axes is stable whereas and rotation around the intermediate axis is unstable. The stability of the principal axes is of importance for the prediction of rockfall. Current numerical schemes for 3D rockfall simulation, however, are not able to correctly represent these stability properties. In this paper we give a proof using Lyapunov functions of an extended intermediate axis theorem, which not only involves the angular momentum equations but also the orientation of the body. Inspired by the stability proof, we present a novel scheme which respects the stability properties of a freely rotating body and which can be incorporated in numerical schemes for the simulation of rigid bodies with frictional unilateral constraints.

INTRODUCTION

A full 3D simulation technique for rockfall dynamics, taking rock shape into account and using the state-of-the-art methods of multibody dynamics and nonsmooth contact dynamics, has been developed in [2]. The rockfall simulation technique is based on the nonsmooth contact dynamics method with hard contact laws. The rock is modeled as an arbitrary convex polyhedron and the terrain model is based on a high resolution digital elevation model. The developed numerical methods have been implemented in the code RAMMS:rockfall (Figure 1), which is being actively used in the natural hazards research community, and is to date the only 3D code which takes rockshape into account [1].

Field observations of natural rockfall events as well as high precision measurements with instrumented experimental rocks have shown that platy disc-shaped rocks have the tendency to roll and bump down the slope around their major principal axis. Simulations with the present implementation of RAMMS:rockfall, however, fail to represent the observed rolling phenomenon.

The intermediate axis theorem is a result of the Euler equations

$$\boldsymbol{\Theta}\dot{\boldsymbol{\omega}} + \boldsymbol{\omega} \times (\boldsymbol{\Theta}\boldsymbol{\omega}) = \mathbf{0}.$$

describing the movement of a rigid body with three distinct principal moments of inertia. The theorem describes the following effect: rotation of a rigid body around its minor and major principal axes is stable, while rotation around its intermediate principal axis is unstable. The classical intermediate axis theorem, however, only involves the Euler equations for the three components of the angular velocity. In this paper, we describe the dynamics of a freely rotating body in state-space form using as states the three angular velocity components $\boldsymbol{\omega}$ and an arbitrary parametrization of the orientation of the body with respect to the inertial frame, (i.e. the transformatiojn matrix $\boldsymbol{A}_{IK}$). Using the method

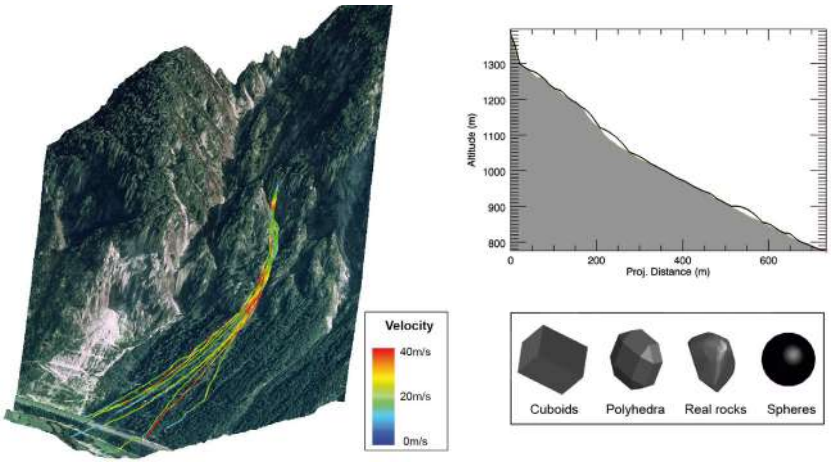

Figure 1: Graphical user interface of the RAMMS rockfall module.

of Lyapunov functions we rigorously prove an extended version of the intermediate axis theorem which considers the stability of the motion in the full state-space $(\boldsymbol{A}_{IK}, \boldsymbol{\omega})$.

In this paper we will show that the present scheme, which is fully explicit during flight phases of the rock, does not respect the intermediate axis theorem. Furthermore, we will present an implicit scheme which correctly describes the stability properties of a freely rotating body.

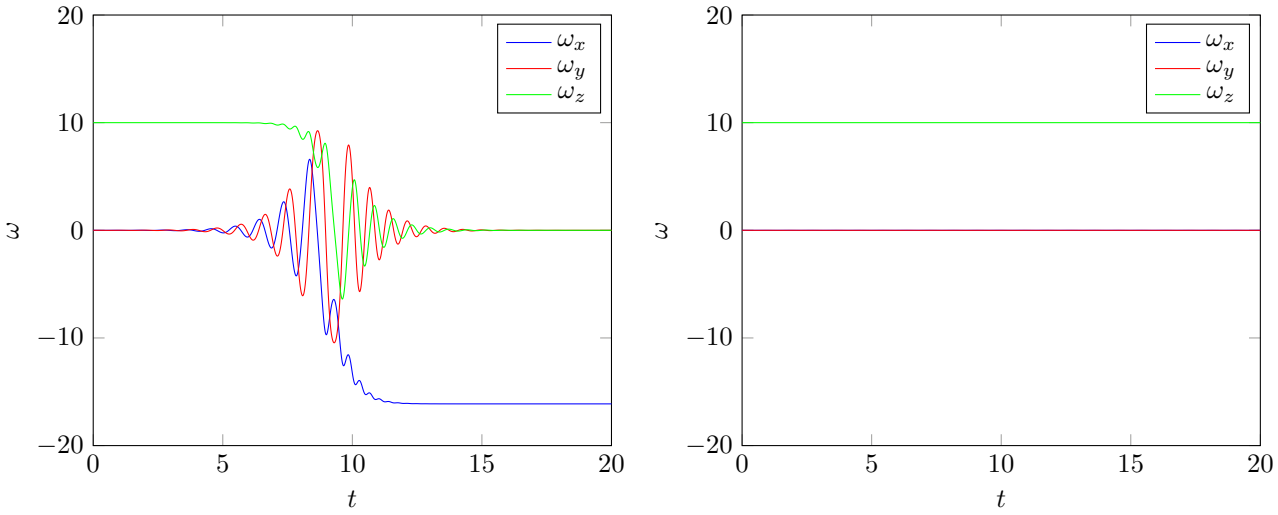

Figure 2: Angular velocities: left the explicit scheme, right the implicit scheme

A STABILITY PRESERVING IMPLICIT SCHEME

The alternative scheme for rockfall simulation is implicit and preserves the stability properties of the principal axes of rotation in accordance with the intermediate axis theorem. The implicit scheme consists of two parts:

1. as update rule for the angular velocity, we use the implicit scheme proposed by [3] which preserves the kinetic energy as well as the magnitude of the spin (i.e. the angular momentum with respect to the center of mass),

2. for update of the orientation parametrization, we propose a novel scheme which preserves the direction of the spin.

The stability properties of the implicit scheme are proven using the Lyapunov function which has been derived to prove the extended intermediate axis theorem.

NUMERICAL RESULTS

We compare the explicit and the implicit scheme on a numerical example by considering a cuboid with principal moments of inertia such that $A < B < C$. Rotation in the neighborhood of stationary rotation $\boldsymbol{\omega}_\star = \Omega \boldsymbol{e}_3$ around the major principal axis $\boldsymbol{e}_3$ is considered. We simulate 20 s using a time-step of $\Delta t = 0.01$ s using the explicit and implicit scheme. The results of both schemes are shown in Figure 2. The body initially rotates in the vicinity of the major principal axis with angular velocity $\omega_z = \Omega = 10$ rad/s, which is stable as follows from the extended intermediate axis theorem. However, in the numerical solution of the explicit scheme, the body deviates from stationary rotation around the major principal axis (approximately at $t = 10$ s) and tends to stable rotation around the minor principal axis with angular speed $\omega_x = -\sqrt{C/A}\Omega$. If a smaller time-step is taken in the explicit scheme, then the change of axis will be slower and will take place at a later point in time. The solution of the implicit scheme remains very close to the major principal axis, both in angular velocity and in orientation and is therefore much more accurate.

CONCLUSIONS

In this paper an extended intermediate axis theorem has been proven using Lyapunov functions. Using the same Lyapunov functions, we have given a rigorous proof that the implicit scheme presented in [3] respects the extended intermediate axis theorem. The computational cost per time-step is larger for the implicit scheme than the explicit scheme, as Newton iterations are needed to solve the implicit equations. However, numerical simulations show that the implicit scheme is far more accurate as it respects both the energy conservation and the invariance of the spin. The implicit scheme therefore allows to take larger time-steps without excessive error, making it a suitable scheme for rockfall simulation.

TOWARDS NEW DYNAMICAL FUNCTIONALITIES WITH EXTREME PARAMETRIC OSCILLATORS

Alvaro Anzoleaga Grandi[1], Suzie Protière[1], and Arnaud Lazarus *[1]
[1] Institut Jean Le Rond d'Alembert, CNRS UMR7190, Sorbonne Université Paris, France

Summary Parametric instabilities can arise when the mechanical state of a structure is periodically modulated in time. It is often seen as a phenomenon to avoid for example with parametric rolling in ships but it can also be exploited, e.g. with parametric amplifiers in MEMS. One limitation in fully exploiting those dynamical instabilities is that inherent friction forces rapidly cancel sub harmonic parametric resonances. To overcome this drawback, we propose to extremely modulate the mechanical state of the system in order to enhance parametric instabilities. This original concept of "extreme" parametric oscillator is illustrated here through the numerical and experimental implementation of an electromagnetic pendulum. We find that it is possible to greatly enhance and control the number of sub harmonic instability regions which open the way for new promising design in structural dynamics.

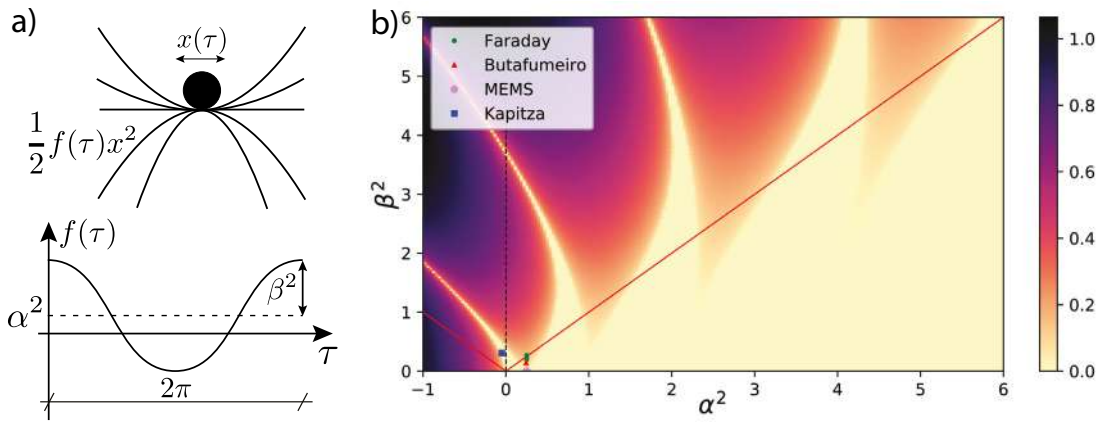

Figure 1: Linear stability analysis of parametric systems. a) A linear time-periodic system is an oscillator whose potential energy is periodically varied (here the modulation function is harmonic in time). b) Stability diagram of the parametric oscillator in the modulation parameters space α^2 and β^2. Darker regions are the so-called Mathieu's instability tongues. Parametric oscillators are usually used in a very restricted region of the modulation space as shown by the points around $\alpha^2 = \beta^2 = 0$.

Nowadays, from the use of buckling for folding [1] to the exploitation of fluttering piezoelectric flags for energy harvesting [2], instabilities eventually occurring in slender elastic structures are often seen as an opportunity to seize rather than a failure to avoid. Parametric instabilities, found in many engineering and physics problems [3, 4, 5], can be ultimately explained by the periodic modulation in time of the local potential energy of a dynamical system and described by archetypal instability tongues in the modulation parameters space (see Fig.1). Although this dynamical instability should theoretically offer a great freedom to design elaborate dynamical functionalities, it turns out practical parametric oscillators are often used at relatively low amplitude of modulations, because the modulation parameter is often a geometrical or mechanical parameters that is too cumbersome to effectively vary. Here, based on simple energetic concepts, we propose a first experimental proof of concept of an extreme parametric oscillator, a dynamical system whose potential energy can be easily and freely varied in time. In these type of systems, parametric instabilities are enhanced, even in the presence of frictional forces, and can be tailored to design interesting functionalities.

The proof of concept under study is the electromagnetic pendulum shown in Fig.2a). The experiment consists of a metallic pendulum that is symmetrically placed between two attracting electromagnets. When the electromagnets are OFF, the system is a simple pendulum, oscillating in the plane, that can be modeled by a mass in a harmonic potential well as shown in Fig.2b). When the electromagnets are ON, at a given input electrical current I, the energy landscape is varied (see Fig.2b)). When quasi-statically increasing the control parameter I, the natural frequency of the electromagnetic oscillator is decreasing (as is the local curvature of the potential), up to a particular value, $I = I_{max}$, where the metallic mass is no more naturally oscillating, but diverging (potential with a negative curvature), on the right or left electromagnet, depending on the imperfections in our system. This mechanical system is therefore an ideal candidate for what we coined an extreme parametric oscillator, because with a single parameter I, we are easily and drastically changing the state of our system, eventually from an oscillating to a diverging state. In classical parametric oscillators [3, 4, 5], this extreme modulation is hardly reachable because the geometrical of mechanical modulation parameters that come into play (length, gravity, height of the waves, etc...) are not easily varied on such scales.

*Corresponding author. E-mail: arnaud.lazarus@sorbonne-universite.fr

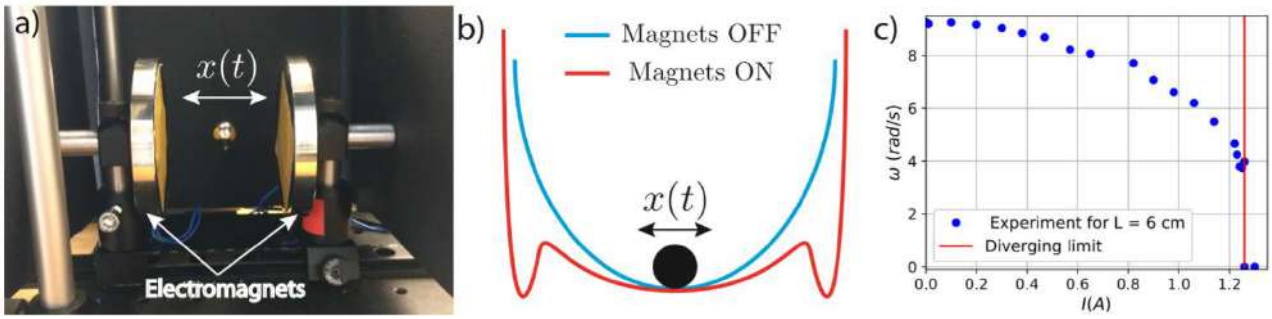

Figure 2: The electromagnetic parametric oscillator under study. a) A pendulum with a metallic mass is symmetrically placed between two identical attracting electromagnets that are periodically turned ON (red energy states in b)) and OFF (blue energy states in b)). b) Simplified "Particle in a time-varying potential well" model. c) Evolution of the natural frequency of the pendulum for various value of the electrical current I in the two electromagnets. Below $I < I_{max}$, the pendulum is naturally oscillating if perturbed. Eventually, for I close to the diverging limit I_{max} , the natural frequency goes down. Above I_{max} the mass is no more oscillating but diverging.

A parametric system is simply obtained by periodically turning the electromagnets ON or OFF in a square wave fashion as illustrated by the inset of Fig.3. The linear stability of such a system is supposed to be governed by the so called Meissner equation [6] that is a linear Ordinary Differential Equation with a piece-wise constant coefficient. Fig.3 shows the experimental stability charts of the electromagnetic pendulum represented in the Meissner modulation parameters space. The blue triangles indicate that the pendulum is dynamically stable, i.e. that the pendulum may be slightly vibrating but stay close to the trivial vertical state, in the middle of the electromagnetic box. The crosses indicate the modulation parameters for which the mass was parametrically unstable, i.e. dynamically impacting the electromagnets. The inset on the right side of Fig.3 representing Meissner's instability tongues in dark color shows that our experimental results are well predicted, at least for the two first parametric instability regions. But even more interesting is the main instability diagram of Fig.3: our dynamical system is able to trigger an unprecedented number of sub-harmonic parametric instability regions (here up to the 58^{th} regions when the current record demonstrated in a microelectromechanical device was found to be 28^{th} [5], thanks to ultra low damping). This ability to fully exploit the extended stability chart of parametric instabilities will be discussed for eventual new functionalities.

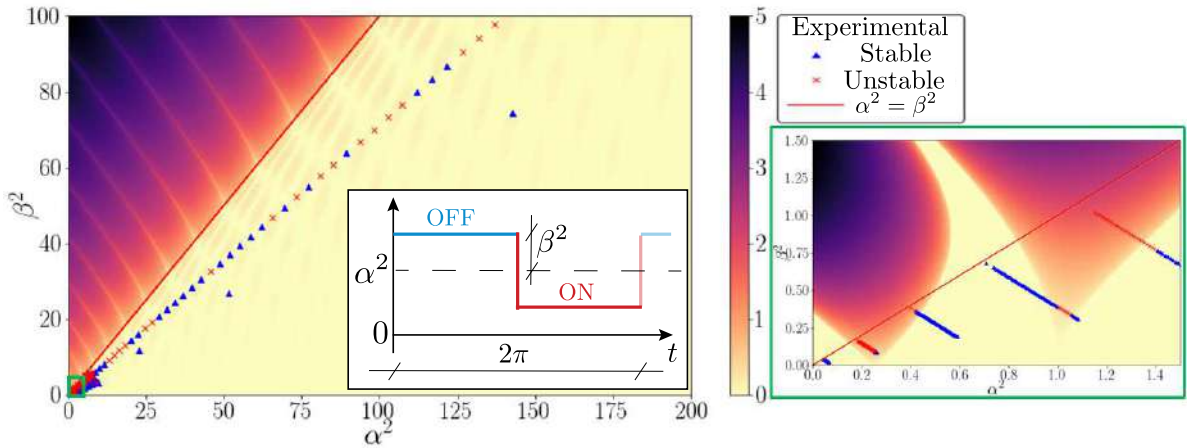

Figure 3: Extended stability chart showing the dynamical stability of the Meissner parametric system. Darker regions represent instability tongues. The blue triangles correspond to the experimental stable states and the red crosses correspond to the unstable ones. The red curve ($\alpha^2 = \beta^2$) represents the limit between systems that are naturally stable and systems naturally unstable (over the limit).

MODAL SUBSTRUCTURING USING NONLINEAR NORMAL MODES

Francesco Latini *[1], Jacopo Brunetti[2], Walter D'Ambrogio[2], and Annalisa Fregolent[1]
[1] Dipartimento di Ingegneria Meccanica e Aerospaziale, Università di Roma La Sapienza, Roma, Italy
[2] Dipartimento di Ingegneria Industriale e dell'Informazione e di Economia, Università dell'Aquila, L'Aquila, Italy

Summary Mechanical systems usually consist of many components connected together. The objective of this work is to define a coupling procedure based on Dynamic Substructuring to deal with coupled substructures jointed through nonlinear connections. It can happen that the nonlinearity at the connection is dominant with respect to those of the uncoupled components. Thus, it is possible to consider the latter as linear and account for the nonlinear effects of the connection. The connecting elements are thus considered as additional substructures included in the substructuring process. This is performed by setting the coupling procedure in the modal domain, considering the Linear Normal Modes (LNMs) for the linear substructures and the Nonlinear Normal Modes (NNMs) for the nonlinear connecting elements. The proposed method is used to couple two linear beams, connected through two cubic springs.

INTRODUCTION

Mechanical systems are in general made up of multiple components connected one to each other, thus each one affects the behaviour of the whole assembly. However, in many cases the connections themselves can have non negligible effects on the system's dynamics. The use of Finite Element Method (FEM) allows to get very accurate information regarding the system's behaviour, but the computational burden can largely increase if complex structures are under investigation. The need of reliable results in lesser time has led over the years to the development of other techniques, suitable to analize many situations. Among the others, Dynamic Substructuring [1, 2] has shown to be one of the most efficient in terms of computational time and accuracy of the achieved results. They have been first used to deal with linear systems [3], but some modifications have been made to account also for nonlinear phenomena. Although all the structures present nonlinearities, in some cases the nonlinear effects due to the connection are the most relevant. In such cases, the subsystems can be considered as linear, while the connection can be accounted in an additional nonlinear substructure to be included in the coupling process. This work aims at the definition of a substructuring-based procedure able to account for the nonlinear effects due to the connecting elements. Their nonlinear behaviour can be evaluated by computating their Nonlinear Normal Modes (NNM). They were first studied by Rosenberg [4] and later by Kerschen [5], who gave the definition for a nonlinear normal mode as the periodic response of a conservative nonlinear system which is characterized by energy dependent frequency and amplitude distribution. The coupling technique used here is based on the one proposed by Kuether and Allen [6], who managed to couple two nonlinear beams at their common interface. The procedure is performed in the modal domain, considering the Linear Normal Modes for the linear substructures and the Nonlinear Normal Modes for the substructures representing the nonlinear connecting elements. The NNMs of the coupled system achieved from the coupling can then be compared to the ones obtained by applying the Harmonic Balance (HB) [7] on the final assembly. This procedure was first applied to lumped parameter systems [8], providing very satisfactory results. The objective of this work is to evaluate the effectiveness of the method when linear continuous substructures connected through nonlinear springs are analyzed.

MODEL AND RESULTS

The model is composed of two linear beams coupled through two nonlinear cubic springs, as shown in Fig. 1. The parameters used for the analysis are listed in Table 1, where L is the length of the beams, t represents their thickness, w their width and n stands for the number of nodes considered for each beam. Fig. 2(a) shows the comparison between

L_A	w_A	t_A	L_B	w_b	t_B		ρ	E	n_A	n_B	k_l	k_{nl}
1000	10	2	1000	10	4	mm	7800 kg/m^3	205e9 Pa	21	21	1000 N/m	5e6 N/m^3

Table 1: Values of the physical and geometrical parameters of the model.

the first five NNMs obtained using the coupling procedure and the ones achieved applying the HB method. There is great correspondence between the curves, with an average error that is around 0.4% and being the maximum error below 0.7%, as shown in Fig. 2(b). Although it is not possible to retrace the presence of internal resonances, this is still a great result, because the main backbone of each NNM is reconstructed. Thus the method can be considered as reliable to investigate the dynamics of distributed parameter systems coupled with connecting elements, when the main behaviour of the structure needs to be analyzed.

(b) Percentage Error.

Figure 2: Comparison between the NNMs obtained from the coupling procedure and Harmonic Balance

CONCLUSIONS

The coupling procedure presented here represents an alternative and fastmethod to analyze complex coupled structures in which the nonlinearities are only due to the presence of nonlinear connecting elements. The novelty of the approach is to consider the connections themselves as nonlinear substructures to be included in the coupling procedure. It is made possible by computing their NNMs to be used in the modal substructuring process. Further studies will be performed to evaluate the effects of modal truncation and see how the cut-off frequency affects the accuracy of the results.

DYNAMICS OF ROTATING COMPOSITE BEAM WITH NONLINEAR PIEZO-LAYERS

Jarosław Latalski *[1] and JerzyWarminski[1]
[1] Department of Applied Mechanics, Lublin University of Technology, Lublin, Poland

Summary The dynamics of a rotor consisting of a rigid hub with attached thin-walled active composite blade is presented. It's posed the beam is made of an orthotropic laminate with an embedded additional layer of piezoelectric material. When modelling the structural behaviour of the piezoceramics the higher order constitutive relations with respect to electric field have been adopted to properly capture the electromechanical properties of the transducer. Using the Hamilton's principle and next the Galerkin's method a system of mutually coupled nonlinear ordinary differential governing equations has been derived. A series of numerical simulations has been run to investigate the natural vibrations of the structure; next the forced vibrations excited by hub driving torque have been examined.

INTRODUCTION

The science of active structures, which is concerned with the interaction of electric/electromagnetic fields and elastic deformation of structures, has developed rapidly in the recent years. Typical applications of multifunctional designs range from civil structures, marine systems and MEMS to aerospace and aeronautics systems [1, 2]. Representative examples of active aerospace designs might be active rotors offering e.g. control of flutter and enhanced handling and maintenance. The topic of rotating smart composite beams is investigated worldwide by numerous research groups. Authors of the present submission contributed to this area presenting the mathematical model of the coupled behaviour of a laminate structure with an embedded active layer made of piezoceramics [3, 4].

STRUCTURAL MODEL AND PROBLEM FORMULATION

Let's consider an elastic single cell thin-walled beam with box shaped cross-section. The beam is clamped to the rigid hub rotating about fixed vertical axis CZ_0 – see Figure 1(a) driven by the external torque $T_{\mathrm{ext},z}$. The considered beam is made of unidirectional (UD) fibre reinforced composite material with additional structural layers of transversely isotropic piezoceramic material embedded onto opposite beam faces – Figure 1(b).

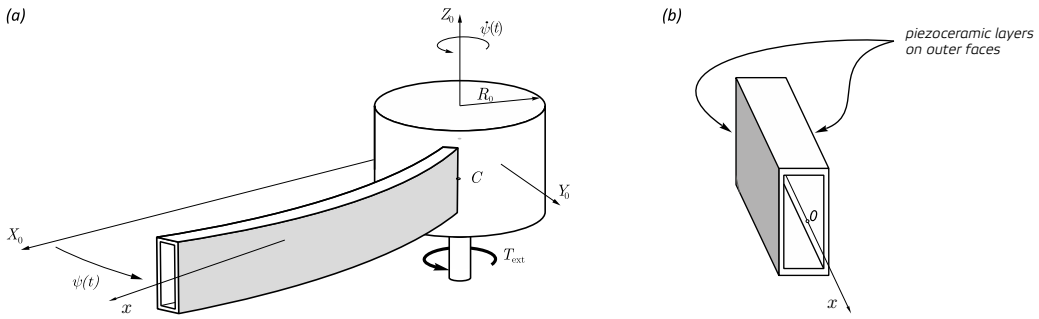

Figure 1: Model of the rotating hub—piezoelectric composite beam structure (a); placement of active material layers on the beam faces (b).

The mechanical equations of motion of the rotating hub/beam and a supplementary electric domain equation are derived according to the extended Hamilton's principle of the least action. In the presented research the higher-order constitutive relations of the piezoceramic material are postulated to extend the generality of the formulation and properly model the actual characteristics of active layers [4, 5]

$$\boldsymbol{\sigma} = \mathbf{C}\boldsymbol{\varepsilon} - \mathbf{e}\mathbf{E} - \hat{\mathbf{b}}\,\mathrm{sgn}(E_3)\mathbf{E}^2 \qquad \mathbf{D} = \mathbf{e}\boldsymbol{\varepsilon} + \boldsymbol{\xi}\mathbf{E} + \boldsymbol{\chi}\mathrm{sgn}(E_3)\mathbf{E}^2 \tag{1}$$

In the above relations—comparing to the classical linear ones—new terms are added where $\hat{\mathbf{b}}$ represents effective electrostrictive constants tensor and $\boldsymbol{\chi}$ is third order electric susceptibility tensor.

The system of coupled electromechanical partial differential governing equations is derived through standard variational calculus steps followed by adopting the derived orthogonality condition for complex bending-shear-torsional deformation of the beam. After transformation to the ordinary differential form and dimensionless notation one reads

$$\begin{gathered}\ddot{q} + \alpha_{12}\ddot{\psi} + \varsigma_1\dot{q} + \left(\alpha_{11} + \alpha_{13}\dot{\psi}^2\right)q + \alpha_{14}\dot{\psi}\dot{q}q + \alpha_{15}\mathrm{sgn}(q)q^2 = 0 \\ \left(1 + \widehat{J}_{\mathrm{h}} + \alpha_{h2}q\right)\ddot{\psi} + \alpha_{\mathrm{h}1}\ddot{q} + \varsigma_{\mathrm{h}}\dot{\psi} + \alpha_{\mathrm{h}3}\dot{q}\dot{\psi} = \mu_0 + \rho\sin\omega\tau\end{gathered} \tag{2}$$

*Corresponding author. E-mail: j.latalski@pollub.pl.

where the generalized coordinate q involves all three beam mechanical variables (flexural displacement, cross-section rotation and twist angle) and electrical one with different relative importance dependent on mode order and composite reinforcing fiber orientation. Symbol $\widehat{J}_{\mathrm{h}}$ stays for the relative mass moment of inertia and the driving torque is represented as a sum of a constant component μ_0 and a harmonic one with amplitude and frequency denoted by ρ and ω, respectively.

NUMERICAL RESULTS

A series of numerical simulation tests were performed to examine the dynamic performance of the system and to study the importance of nonlinear terms present in the piezoceramic material constitutive relations Eq. (1). Resonance curves around first natural frequency of the considered structure were plotted – see Figure 2 (a) and (b) for the beam and hub subsystem, respectively. The analysis was performed for different magnitudes of the dimensionless torque excitation amplitude ρ ranging from 0.001 up-to 0.01. Both resonance curves are bent to the left denoting a significant softening effect with stable and unstable regions highlighted by customary solid and dashed lines.

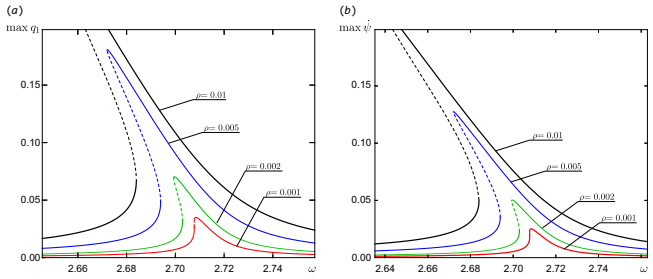

Figure 2: Resonance curves for the beam (a) and the hub (b) sub-systems around the first natural frequency with respect to excitation amplitude ρ. The solid (dashed) curves represent stable (unstable) solutions.

To confirm the results given in the above response diagrams time series plots were prepared — Figure 3. The envelopes of transient and steady state responses were shown with grey and blue colours corresponding to nonlinear and simplified (linear) piezoelectric effect, respectively. The results were obtained for the excitation amplitude $\rho = 0.01$ and frequency $\omega = 2.68$ for initial conditions matching lower branches of frequency response curves (Figure 2).

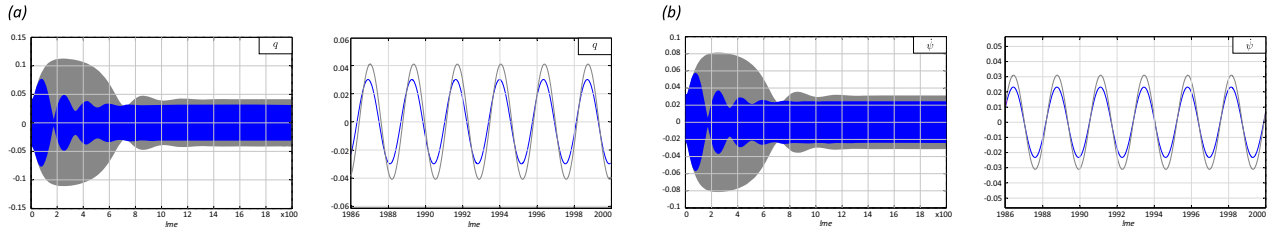

Figure 3: Envelopes of linear and nonlinear transient and steady state responses of the beam (a) and the hub (b) for excitation frequency $\omega = 2.68$ and amplitude $\rho = 0.01$; initial conditions: $q|_{\tau=0} = 0.04$, $\dot{q}|_{\tau=0} = 0$, $\Omega|_{\tau=0} = 0.005$. Colour code: gray – nonlinear piezoelectric effect, blue – linear piezoelectric effect.

FINAL REMARKS

The proposed mathematical model of the active rotor takes into account the nonlinear constitutive relations of the piezoceramic material beam layers. The performed numerical studies revealed the non-linear softening type frequency response of the system if driven by the torque applied to the hub. The important observation is the nonlinear features of the characteristics were present both for the beam and for the hub as well. Moreover, a significant difference in transient state was revealed when comparing nonlinear and linearized active beam response time series plots.

NONLINEAR FLEXURAL-FLEXURAL INTERACTIONS OF THE EXTENSIBLE SIMPLY SUPPORTED BEAM WITH AN AXIAL SPRING

Lukasz Kloda *[1,2], Stefano Lenci[2], and Jerzy Warminski[1]
[1] Department of Applied Mechanics, Lublin University of Technology, Lublin, Poland
[2] Department of Civil and Buildings Engineering and Architecture, Polytechnic University of Marche, Ancona, Italy

Summary In this paper large amplitude vibrations of the planar beam-spring system are studied. The model has linear behaviour of the material, inertia forces, linear viscous damping and nonlinear geometric deformations, and is subjected to an external excitation. The main goal is to investigate the first and second bending modes interactions which occurs not so close to primary (linear) resonance. Selected numerical results are compared with experimental tests and then the numerical analysis is extended beyond the experimental results.

INTRODUCTION

Structural systems based on simply supported beams are common in engineering applications. The study of the dynamic response of those structures is of great importance in stability and control analysis, and can have different behaviours. For instance the simply supported beam (when inertia terms are properly considered) has softening nature while the same structure with axially restrained ends has a hardening behaviour [1]. The boundary conditions at the beam's end can be controlled by an axial spring whose stiffness could be increased from 0 to ∞. Then, the system response changes continously his nature from softening to hardening phenomenon for the parametrically excited system [2] as well as the externally excited case [3]. The aim of this paper is to study the case of the primary resonance, when interaction between the first and the second bending modes occur for large amplitude oscillations. For this purpose a laboratory setup is built and based on experimental tests a numerical model is developed and used to match the experimental results

RESEARCH OBJECT

The beam-spring system consists of an initially straight beam mounted at the hinge (left) and the sliding support with axial compression spring (right), see Fig. 1a. The holder is screwed to a slip table, which enables tabletop periodic movement in the beam's flexible plane. The spring and beam can be replaced in order to vary the stiffnesses $EA(L)^{-1}/k_s$ which is a dimensionless parameter and correlate parameters of the beam-spring structure. The beam's dimensions are $L\times b\times h = 450\times 20\times 4.75$ mm, the hinge has mass moment of inertia $I_0 = 1.0928\times 10^{-5}$ kgm^2 and movable tip elements are reduced to mass moment of inertia $I_t = 7.556\times 10^{-6}$ kgm^2 together with concentrated tip mass $M_t = 0.155$ kg.

The prototype is modeled in ABAQUS_CAE© software by 100 equal-length linear beam elements $B21$ type placed in XZ plane (Fig. 1b). Boundary conditions are written $U(Z=0) = U(Z=L) = W(Z=0) = 0$, the axial spring is tied to node 101, and inertia elements are assigned to the beam nodes 1 and 101. Simulations are run in time domain, where frequencies of external excitation $\xi \sin \Omega T$ are gradually changed by sweep forward and backward to follow stable path solutions. The completed simulation is post-processed from the time domain to the domain of the excitation frequency and associated steady state motion amplitude $U_{max}(\xi, \Omega)$.

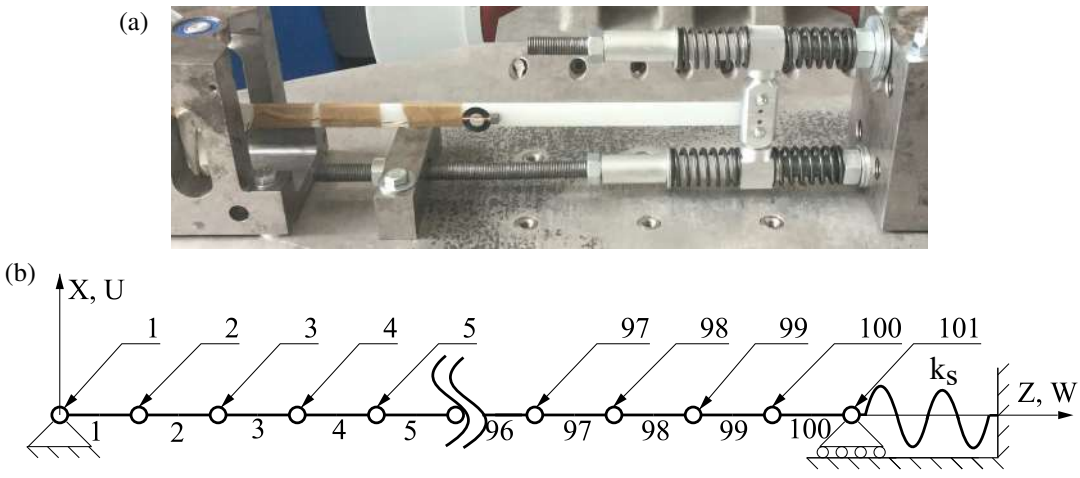

Figure 1: The hinged-simply supported beam with an axial spring: front view of experimental setup (a) and top view of finite element model (b).

*Corresponding author. E-mail: l.kloda@pollub.pl.

RESULTS AND CONCLUSIONS

Findings of the experimental and numerical investigations show a very good agreement for small amplitude of kinematic excitation $\xi = 1.0$ mm as well as large one $\xi = 2.5$ mm (Fig. 2a). Tests on Plexiglas beam with spring stiffness $k_s = 29254$ N/m $(EA(L)^{-1}/k_s = 0.042)$ present hardening nature with hysteresis and expose the interaction between the first and second bending modes (Fig. 2b), despite the fact that the second mode is not directly excited. It means that superharmonic resonance 1 to 3 between these modes occurs through nonlinearities and inertia terms, see Fig. 2c.

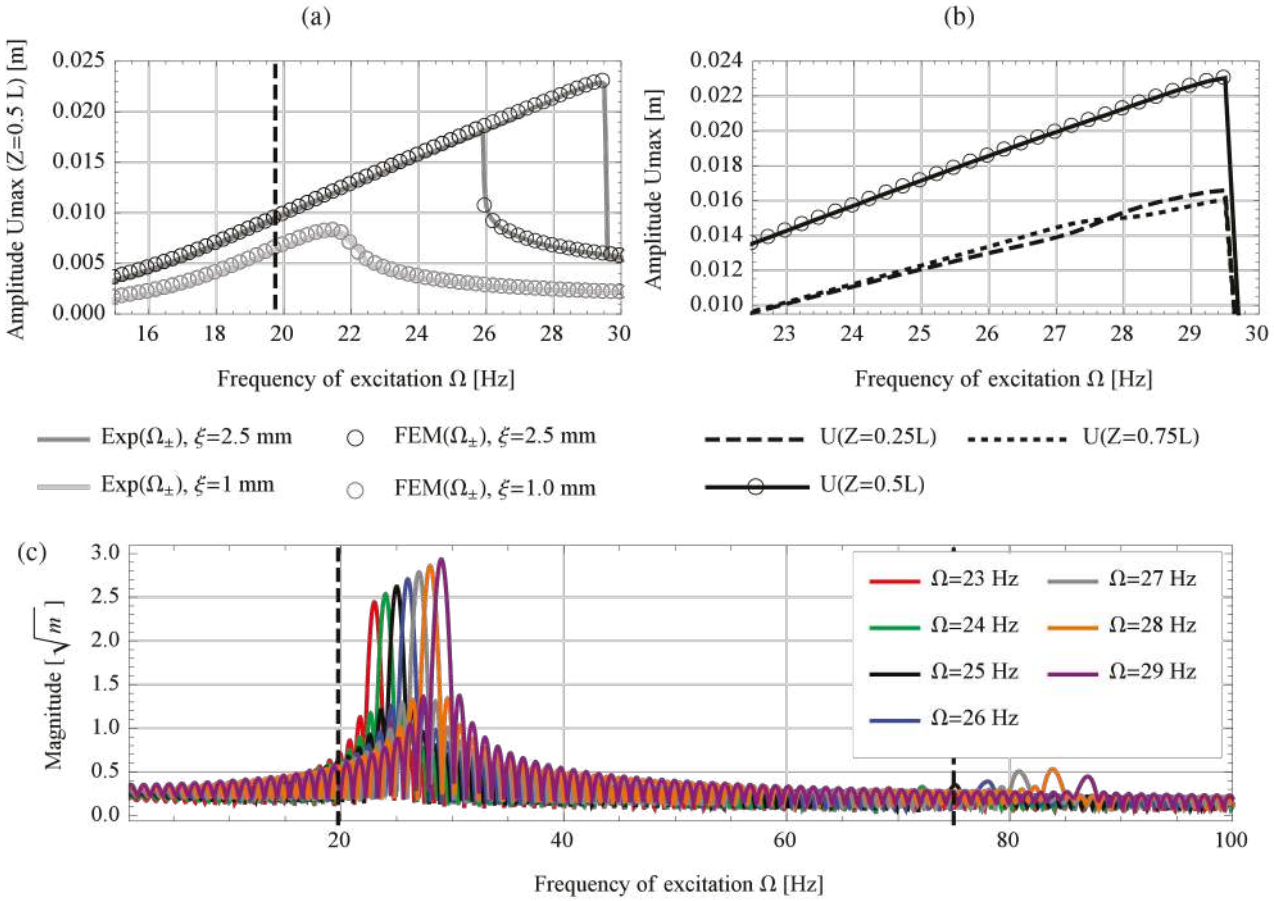

Figure 2: Frequency response curves for the beam: experiment vs finite element method (a), numerical simulations with modes interactions (b) and corresponding FFT analysis for node 26 (c). Black dashed vertical lines represent the natural frequencies.

In the future tests both flexural modes will be excited directly e.g. by concentrated force applied at $Z = 0.25L$ or periodic angular rotation of the hinge. In the proposed case presence of an additional stable solution is expected, different than in [4] where the response is significantly changed, rather as an imposition of a secondary resonance on a primary one with two solution hysteresies - wide and narrow [5].

Summary An overview of the new derived nonlinear differential equations and phase trajectory equations of the body's rolling along curvilinear stationary and rotating curvilinear line - trajectories, as examples of rolling pendulums with one degree of freedom is done An appropriate system of coupled nonlinear differential equations for a homogeneous heavy ball rolling on an arbitrary surface with all elements of geometry, kinematics and rolling dynamics was performed. A generalization is given for the example of rolling a ball along the coordinate surfaces of functional nonlinear coordinate systems of curvilinear orthogonal coordinates, using the base vectors of the tangent space of the vector of the position of the contact point of the ball in rolling with the coordinate surface at which it rolls.
Based on Petrovic's theory Elements of Mathematical Phenomenology and Phenomenological Mapping, the theory of collisions between rolling bodies through geometry, kinematics and dynamics of impact and collision of balls in rolling is formulated, and examples of the dynamics of vibro-impact systems containing rolling balls are given.

ROLLING PENDULUMS ALONG STATIONARY OR ROTATE CURVILINEAR TRACES

1* We observe an axially symmetric body with one central plane of symmetry that is governed by the axis of symmetry of the body, Figure 1.a*. Let's propose that curvilinear trace of rolling is a curvilinear line defined by $y=f(x)$ in vertical coordinate plane $P(x, y=f(x))$. The rolling body, without slipping, has a degree of freedom movement along the curvilinear path, determined by generalized coordinate x . Nonlinear differential equation of dynamics of a rolling, heavy axial symmetric, with on a plane of symmetry, body along general curvilinear trace in vertical plane, is derived in the form: $\ddot{x}+\frac{1}{2}\dot{x}^2\frac{F'(x,r)}{F(x,r)}+\frac{g}{\kappa}\frac{f_C'(x,r)}{F(x,r)}=0$, (1) where coefficient of rolling $\kappa=\frac{\mathbf{J}_P}{Mr^2}=\frac{\mathbf{i}_P^2}{r^2}=\frac{\mathbf{i}_C^2}{r^2}+1=\kappa$. The first integral of the previous differential equation is equation of phase trajectory. A qualitative analysis of content of set of singular points, depending of the forms of curvilinear trace of rolling body is presented.

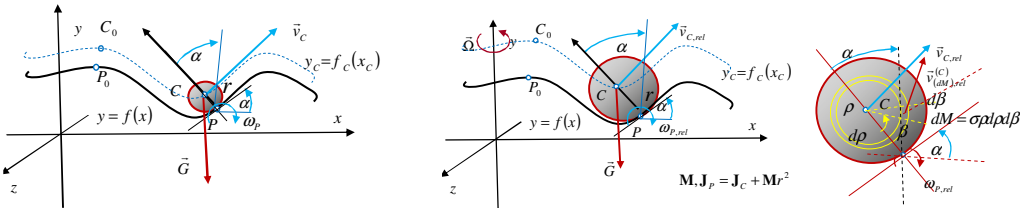

Figure 1. a* Geometric parameters of rolling of a rigid body along the curvilinear trace in a vertical plane; b* and **c*** Geometric parameters of rolling of heavy rigid thin discs on a rotating curvilinear trace in a vertical plane around a vertical axis

2* Nonlinear differential equation of rolling motion of a heavy thin rigid disk, without slipping with radius r, along rotate the curvilinear trace of the form $y=f(x)$, around vertical axis with constant angular velocity Ω, (see Fig.1.b* and c*), is: $\ddot{x}+\frac{1}{2}\dot{x}^2\frac{F'(x,r)}{F(x,r)}-\frac{r^2}{2}\Omega^2\frac{\mathbf{J}_z'(x,M,r)}{\mathbf{J}_P F(x,r)}+\frac{g}{\kappa}\frac{f'(x)}{F(x,r)}=0$, (2) . The first integral of the differential equation is phase trajectory equation and in the following form:

$$[\dot{x}(x)]^2=e^{-\int\frac{1}{F(x,r)}\frac{\partial F(x,r)}{\partial x}dx}\left[\Omega^2\int\left\langle\frac{r^2\mathbf{J}_z'(x,M,r)}{\mathbf{J}_P F(x,r)}\right\rangle e^{\int\frac{1}{F(x,r)}\frac{\partial F(x,r)}{\partial x}dx}dv-\frac{2g}{\kappa}\int\left\langle\frac{f'(x)}{F(x,r)}\right\rangle e^{\int\frac{1}{F(x,r)}\frac{\partial F(x,r)}{\partial x}dx}dv+C\right] \quad (3)$$

A Theorem is formulated. A qualitative analysis of stability of singular points and relative equilibrium positions on trace of rolling body is presented. Particular examples are presented in References [1-5].

ROLLING A HEAVY BALL OVER THE CURVE COORDINATE SURFACES OF ORTHOGONAL CURVILINEAR COORDINATE SYSTEMS

Suppose, we look at the coordinate surface of the functional nonlinear coordinate system, orthogonal curvilinear coordinate lines q^1, q^2 and q^3, with corresponding basic vectors $\vec{g}_i(q)$, $i=1,2,3$ each tangent to one of these coordinate line at considered point $P(q^1,q^2,q^3)$, see Fiig. 2.a*.. This coordinate surface is defined by two coordinate

*Corresponding author. E-mail: **khedrih@sbb.rs**, katicah@mi.sanu.ac.rs

lines q^1 and q^2 for $q^3 = const$, at considered point $P(q^1, q^2, q^3 = const)$, or by two basic vectors $\vec{g}_1(q)$ and $\vec{g}_2(q)$, in the tangent plane to the surface and third $\vec{g}_3(q)$ orthogonal to the tangent plane of the surface in corresponding point $P(q^1, q^2, q^3 = const)$. These coordinate lines q^1 and q^2 for $q^3 = const$ lie in that surface, that is, determine the shape of that surface. Suppose that a heavy rigid ball rolls over this coordinate surface. We denote with P point of the contact between ball's spherical surface and corresponding coordinate surface over which ball is in rolling. Assuming that there is no proper self-rotation, but only rolling, without slipping, then expression of the kinetic energy $\mathbf{E}_k$ is equal to: $\mathbf{E}_k = \frac{1}{2}\mathbf{J}_P\omega_P^2 = \frac{1}{2r^2}\mathbf{J}_P\left\langle g_{11}(\dot{q}^1)^2 + g_{22}(\dot{q}^2)^2\right\rangle + \frac{1}{2}\mathbf{J}_P\frac{g_{33}}{(|\vec{g}_3|)^2}\left(\dot{q}^1\frac{\partial|\vec{g}_3|}{\partial q^1} + \dot{q}^2\frac{\partial|\vec{g}_3|}{\partial q^2}\right)^2$, (4). As we adopted the generalized coordinates q^1 and q^2, by which we expressed kinetic $\mathbf{E}_k$ and potential $\mathbf{E}_p$ energy, now using the Lagrange differential equations of the second kind for independent generalized coordinates q^1 and q^2, we write two coupled nonlinear differential equations of rolling heavy ball over the coordinate surface.

COLLISION THEORY AMD DYNAMICS OF VIBRO-IMPACT SYSTEMS

Based on Petrovic's theory Elements of Mathematical Phenomenology and Phenomenological Mapping, the theory of collisions between rolling bodies through geometry, kinematics and dynamics of impact and collision of balls in rolling is formulated, and examples of the dynamics of vibro-impact systems containing rolling balls are given [2-5].

CONCLUSIONS

The corresponding systems of nonlinear differential equations of rolling the heavy ball along the coordinate surfaces of several functional nonlinear coordinate systems, including the spherical coordinate system, (Fig. b* and c*) is done. It has been proved that rolling the ball along a curved line is a system with one degree of freedom, and rolling the ball over the surface is a system with two degrees of freedom. Some examples of the vibro-impact dynamics are investigated.

NONSTATIONARY RESPONSES OF MDOF NONLINEAR SYSTEMS UNDER RANDOM EXCITATIONS

Siu-Siu Guo *[1] and Qingxuan Shi[2]
[1] School of Civil Engineering,Institute of Mechanics and Technology, Xi'an University of Architecture and Technology, Xi'an, China
[2] School of Civil Engineering, Xi'an University of Architecture and Technology, Shaanxi, China

Summary The key to dynamical response analysis of MDOF structure under random excitation is generally to solve corresponding high-dimensional FP equation, which has been a great challenge for many years. A novel technique is developed for determining nonstationary solution of the FP equation. Specifically, the FP equation is reduced to a lower dimensional one through the state-space-split (SSS) technique. Then exponential-polynomial closure (EPC) method is applied to solve it. Monte carlo simulation (MCS) is conducted to verify the proposed solution procedure. A ten-degree-of-freedom nonlinear system under random excitations are studied to validate the effectiveness of the proposed procedure. It is found that obtained results agree well with the simulated ones. Moreover, computation time taken by the proposed procedure is only a smaller fraction of the one taken by the simulated method.

INTRODUCTION

Many systems are often modelled as multi-degree-of-freedom (MDOF) systems. They are generally subjected to stochastic loads, such as earthquake, wind or sea waves. Under these excitations, many systems experience inelastic deformation and exhibit nonlinearity. In the presence of the coupling of nonlinearity and randomness, stochastic response analysis becomes extremely difficult, especially for MDOF systems [1].

On the premise of Markov process, the response PDF is governed by Fokker-Planck (FP) equation. For a dynamical systems of dimension $2n$, corresponding FP equation is with $2n$ spatial dimensions and one time dimension. In this sense, MDOF systems results in high-dimensional FP equation. The FP equation has been explored for more than fifty years. Nonetheless, great challenges still exist for high-dimensional or multi-degree-of-freedom (MDOF) nonlinear stochastic systems.

In this paper, the SSS-EPC method is further improved to consider the time effect and makes nonstationary solutions of high dimensional FPK equations available. In this regard, random response analysis of MDOF nonlinear system becomes possible. The paper is organized as follows: the SSS technique is adopted to reduce the initial high dimensional FP equation to the interested lower one. Then the EPC method is employed to solve the treated one. Meanwhile, MCS is conducted to verify the proposed solution procedure. Finally, a ten-degree-of-freedom MDOF nonlinear system under external excitation is investigated to prove and validate the effectiveness of the proposed procedure.

SOLUTION PROCEDURE

MDOF system under random excitations are described in Ito's form as follows

$$\frac{d}{dt}X_i = f_i(\mathbf{X},t) + g_{ij}(\mathbf{X},t)W_j(t) \quad i = 1,2,...,n_x, j = 1,2,...,m \tag{1}$$

where X_i are components of the state vector $\mathbf{X}$; functions $f_i(\mathbf{X},t)$ and $g_{ij}(\mathbf{X},t)$ are generally nonlinear functions with deterministic forms. For the sake of simplifying the analysis, random normal excitations $W_j(t)$ are assumed to be independent of each other. They are characterized with power spectral densities

$$E[W_i(t)W_j(t+\tau)] = S_{ij}\delta(\tau), \quad i,j = 1,2,...m. \tag{2}$$

where $\delta(\cdot)$ is Dirac function, S_{ij} are constants.

Due to white noise excitations, the state vector is Markovian. As a result, the PDF $p(\mathbf{x},t)$ of the state vector is governed by the high-dimensional FP equation. With state space split technique, the whole state space $R_{\mathbf{X}}$ is divided into two parts $R_{\mathbf{X}_1}$ and $R_{\mathbf{X}_2}$. The first part $R_{\mathbf{X}_1}$ is related to interested state space $\mathbf{X}_1$, the other part $R_{\mathbf{X}_2}$ is the left space $\mathbf{X}_2$. Accordingly, the coefficients of the FP equation are divided into functions of only the interested state variables $\mathbf{x}_1$ characterized by PDF $p(\mathbf{x}_1,t)$ and functions with other state variables $(\mathbf{x}_1,\mathbf{x}_k)$ characterized by joint PDF $p_k(\mathbf{x}_1,\mathbf{x}_k,t)$. After a series of treatment, the high dimensional FP equation is finally reduced to a lower dimensional function of only few interested states [2]. With equivalent linearization technique, the lower dimensional FP function is further simplified as an approximated one.

With regard to the reduced approximated lower dimensional FP equation, traditional approximate methods becomes available. Herein the EPC method is utilized to solve nonstationary solutions of the treated FP equation [3].

On the other hand, since there is no exact solution to the high dimensional FP equation, MCS method with an sample size of 10^6 is conducted to verify the efficiency of the proposed solution procedure.

Figure 2: Log(PDF) of displacement x_{10} at different time instants

NUMERICAL EXAMPLES AND RESULTS DISCUSSIONS

Considering the following 10-degree-of-freedom nonlinear system under external excitation

$$\ddot{\mathbf{X}} + \mathbf{C}\dot{\mathbf{X}} + \mathbf{K}\mathbf{X} + \mathbf{H}(\mathbf{X};t) = f(t)\mathbf{I}W(t), \tag{3}$$

where $\mathbf{X}(t) = \{X_1, X_2, ...X_{10}\}$; $H(\mathbf{X};t) = \{X_1^3, X_2^3, ..., X_{10}^3\}$, $\mathbf{I} = \{1, 1, ..., 1\}^T$, $f(t)$ is of Amin and Ang type modulating function, $W(t)$ is Gaussian white noise process with power spectral density $E[W(t)W(t+\tau)] = 0.1\delta(\tau)$.

The results are shown in Figure 1 and Figure 2. By comparison, it is found that approximate solutions close to the simulated ones at different time instants.

Most importantly, it should be noticed that the computational time of the proposed procedure taken is greatly less than the one of the MCS method. For example, the time spent for the PDF results at time instants $t = 7s$ is about two seconds, while it is up to about half an hour for the MCS method.

CONCLUSIONS

In this paper, MDOF nonlinear systems under nonstationary random excitations are analyzed via high dimensional FP equation. It is solved by the generalized SSS-EPC method in a computationally efficient manner. Comparison with pertinent MCS results have demonstrated a relatively high accuracy degree of the proposed solution. Moreover, obtained results can be further utilized to conduct reliability analysis of engineering structures.

A COMBINED LOCAL AND GLOBAL BIFURCATION APPROACH FOR NONLINEAR DYNAMICS BASED DESIGN OF A SELF-EXCITED INERTIA WHEEL PENDULUM

A. Zelman, S. Tsulker, R. Manikandan, A. Wolf and O. Gottlieb
Department of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary: We consider a combined local and global bifurcation approach for nonlinear dynamics based design of a self-excited inertia wheel pendulum. The dynamical system can exhibit coexisting equilibria and periodic limit cycle oscillations culminating with possible nonstationary rotations which are an outcome of the implemented nonlinear feedback scheme. While a linear analysis is sufficient to for local stability of equilibria, an asymptotic analysis is required to determine if the Hopf threshold of periodic limit cycle oscillations is supercritical or subcritical and a global Melnikov approach is employed to obtain an estimate for the onset of transverse homoclinic rotations. We demonstrate our combined bifurcation approach via numerical integration and a desktop experiment.

INTRODUCTION

Self-excitation of restrained and freely oscillating rigid bodies are encountered in a variety of engineering applications including friction induced vibration, aeroelastic limit cycle oscillations and fluid-structure interaction. Stabilization of limit cycle oscillations has been proposed by several approaches including boundary feed forward control of a multi-tethered lighter-than-air sphere [1] and digital delayed feedback control of an aero-pendulum [2].While both translating internal attachments and internal rotating rigid-bodies have been shown to reduce the magnitude of oscillations of primary structures undergoing vortex-induced vibration, this reduction was documented for a specific set of control parameters (such as effective linear structural damping) and has been shown to lead to violent and non-stationary behaviour [3]. Of particular importance is the capability of an inertia wheel (or reaction wheel) with nonlinear feedback to obtain stable and robust limit-cycle oscillations in underactuated dynamical systems [4]. Thus, we consider here a planar pendulum augmented with a rotating inertia wheel (see Fig.1-left) where the unperturbed Hamiltonian system can be shown to exhibit a heteroclinic pitch phase plane with linear feedback (see Fig.1-middle) and a combined homoclinic and heteroclinic phase plane (see Fig.1-right) with nonlinear saturation [5].

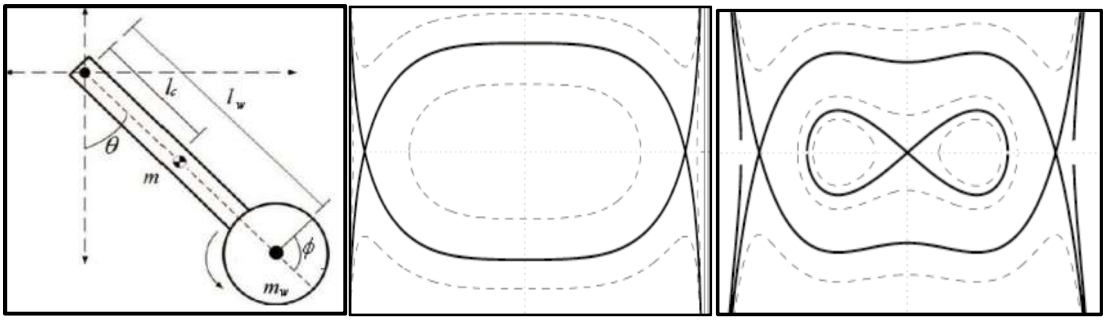

Figure 1. Inertia wheel pendulum coordinate system (left), heteroclinic (middle) and homoclinic (right) unperturbed Hamiltonian pitch phase planes with linear and nonlinear saturation based feedback respectively.

RESULTS

We summarize the local behaviour of the inertia wheel pendulum for the case of linear feedback with bifurcation diagrams for two sets of gains that enable a supercritical bifurcation about the zero equilibrium (Fig.2-left) and a subcritical bifurcation about the upright position (Fig.2-middle) respectively.

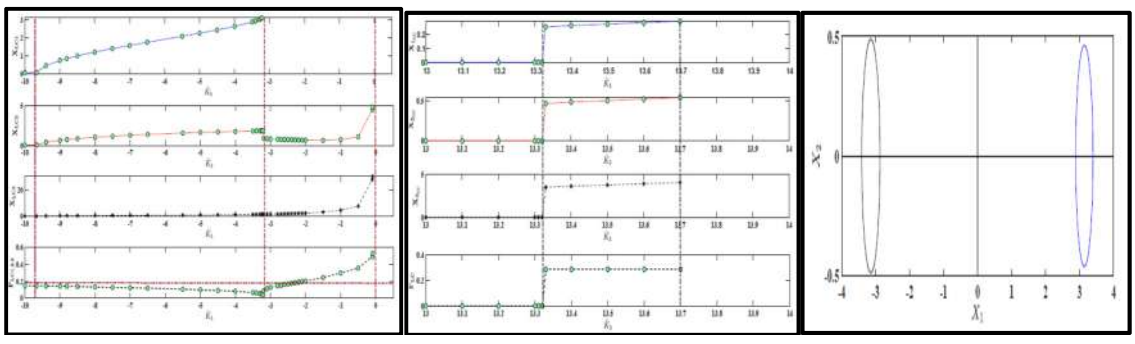

Figure 2. Supercritical (left) and subcritical (middle) bifurcation diagrams of stabilized inertia wheel dynamics as a function of wheel velocity gain and pitch phase plane (right) a pair of periodic limit cycles about the unstable upright position.

Numerical integration of the inertia wheel system with a gain set in the subcritical range reveals the anticipated pair of limit cycles about the upright position (Fig. 2-left). We employ a Melnikov based analysis [6] on a reduced third-order system obtained for a configuration with a cyclic coordinate for the inertia wheel position. The obtained threshold yields a bound on the gains required for periodic oscillations. The limitations of this approach consist of weakly nonlinear damping mechanisms for both pendulum and wheel friction bearings, and a sufficiently small gain for the pendulum angular velocity.

An investigation of the inertia wheel pendulum with nonlinear saturation feedback yields the addition of a pair of equilibria between the zero and upright positions. We make use of the local criteria to design a desktop experiment (Fig.3-left) where system parameters are obtained from a set of controlled free vibration decay experiments [7]. The latter reveal that a nonlinear dry friction Coulomb model is required to describe the system bearings. The estimated parameter set is incorporated into the model to yield a candidate set of gains for limit cycle oscillations about the upright position. We note that the nonstationary results portrayed in Fig.3 are possibly due to the implemented Arduino controller (not shown) which controls the speed of the motor driving the inertia wheel. The nonstationary time histories of the pendulum angle and velocity (Fig.3-middle) are sampled every positive zero-crossing of inertia wheel velocity to yield a wide spread Poincare' map (Fig.3-right).

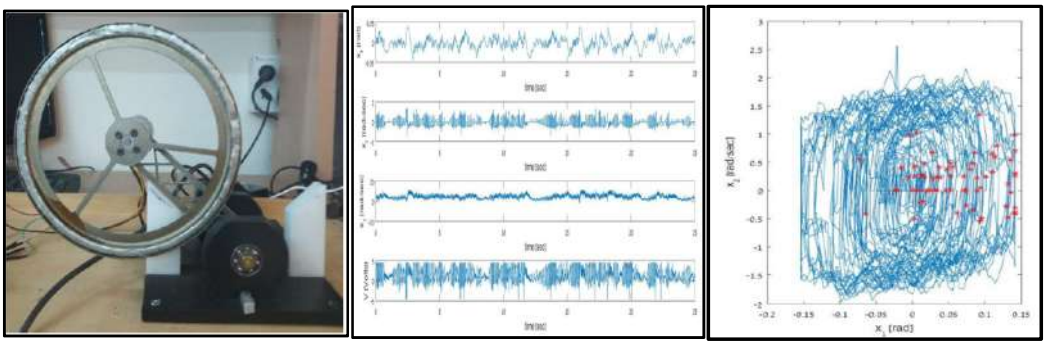

Figure 3. Inertia wheel experimental setup (left), nonstationary response (middle) and pitch phase plane overlaid with a Poincare' map (right).

CLOSING REMARKS

We consider a combined local and global bifurcation approach for nonlinear dynamics based design of a self-excited inertia wheel pendulum. The dynamical system can exhibit coexisting equilibria and periodic limit cycle oscillations culminating with possible nonstationary rotations which are an outcome of the implemented nonlinear feedback scheme. While a linear analysis is sufficient to for local stability of equilibria, an asymptotic analysis is required to determine if the Hopf threshold of periodic limit cycle oscillations is supercritical or subcritical and a global Melnikov approach is employed to obtain an estimate for the onset of transverse homoclinic rotations. We demonstrate our combined bifurcation approach via numerical integration and a desktop experiment. This combined approach implemented on a reduced third-order dynamical system can serve as a basis for comparison of different control strategies that exhibit a similar heteroclinic or homoclinic bifurcation structure.

NONLINEAR DYNAMIC OPTIMIZATION OF HYSTERETIC NANOSTRUCTURED BEAMS

Giovanni Formica *[1] and Walter Lacarbonara[2]
[1] Department of Architecture, Roma Tre University, Rome, Italy
[2] Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy

Summary The nonlinear dynamic response of carbon nanotube (CNT)/polymer nanostructured hysteretic beams is investigated with the aim of achieving optimal nonlinear material designs in terms of maximum multistability bandwidth. Leveraging on multistability is indeed regarded nowadays as an additional functionality for smart multifunctional structures in a variety of engineering applications, with the potential of promoting a growing aerodynamic morphing demand.
Optimal solutions are found employing asymptotically obtained Frequency Response Curves (FRC) over a certain range of excitation frequencies, by varying the meaningful nanostructured beams parameters, such as the CNT/polymer interfacial shear strength, the CNT volume fraction, direction and agglomeration, the CNT functionalization through the cross-section thickness.
Both accuracy and efficiency are attained through a nonlinear hysteretic beam model, obtained by reduction of a 3D mesoscopic theory, subsequently treated via the method of multiple scales to yield the asymptotic dynamic response.
The richness of the optimal solutions is induced by the unusual and unique combination of material and geometric nonlinearities, the former associated with the interfacial frictional sliding that yields hysteresis, the latter with stretching nonlinearities of the beam itself.

NONLINEAR NANOCOMPOSITE BEAM MODELS

The nonlinear 3D nanocomposite constitutive model capable of capturing the hysteretic nanostructural stick-slip behavior between the CNTs and the hosting polymer matrix, proposed and validated in previous works (see, e.g., [1, 2]), was reduced to accommodate the Saint-Venant plane bending kinematic state parametrized by the elongation of the centerline and the bending curvature. Following [3], where only the case of perfectly aligned CNTs was considered, the tension-elongation and moment-curvature relationships are obtained for generic CNT orientations according to an unusual derivation by which the tangent conditions in the CNT/polymer stick phase at the origin and past the onset of CNT slip are derived. The transition between these two states (namely, elastic and post-elastic phases) are assumed to be regulated by a hysteresis operator that mimics the Bouc-Wen model. Such approach yields the following moment-curvature relationship (M–κ):

$$M = \overline{EJ}^{(\mathrm{e})}[\delta\kappa + (1-\delta)\,\chi] \tag{1}$$

where $\delta := \frac{\overline{EJ}^{(\mathrm{p})}}{\overline{EJ}^{(\mathrm{e})}}$ is the ratio between the post-slip bending stiffness and the elastic bending stiffness, respectively, and χ is the hysteretic contribution to the bending curvature given in rate form by:

$$\dot{\chi} = \left[1 - \left(\bar{\beta} + \bar{\gamma}\,\mathrm{sign}(\chi\dot{\kappa})\right)|\chi|^n\right]\dot{\kappa} \tag{2}$$

with $(\bar{\beta}, \bar{\gamma}) = (\beta, \gamma)/\kappa_y^n$, where $\kappa_y = \frac{M^{(\mathrm{o})}}{(1-\delta)\overline{EJ}^{(\mathrm{e})}}$, while (β, γ, n) are the well-known Bouc-Wen parameters, and $M^{(\mathrm{o})}$ is the limit moment depending on the CNT/polymer interfacial shear strength $S^{(\mathrm{o})}$.

The mechanical beam parameters here introduced depend on Young's moduli and Poisson's ratios of the two material phases $\{E^{(i)}, \nu^{(i)}\}$ $(i = 1, 2)$, namely the CNTs and the polymer, and on the phase volume fraction ϕ, according to the "Equivalent Inclusion–Average Stress" approach [4, 5]. Such approach, in the average sense proposed by the Mori–Tanaka method, combines the equivalent stress-strain response of the CNTs treated as an inclusion, embedded in an hosting matrix phase (here the polymer), with the Eshelby theory of equivalent inclusion (see, for instance, [6]). Additionally, following [7], in the 3D continuum constitutive response (in whose setting the beam material response is derived) we introduce the effects of CNTs orientation (random or aligned along a preferential direction), and shape, geometry and variability of the CNTs length within the same nanocomposite.

Within such a theoretical framework, the considered mechanical parameters are condensed in the dependence of the bending stiffness coefficients on the above parameters. That is,

$$\left\{\overline{EJ}^{(\mathrm{e})}, \overline{EJ}^{(\mathrm{p})}\right\} = f\left(E^{(\mathrm{i})}, \nu^{(\mathrm{i})}, \boldsymbol{\varphi}, \bar{\phi}, \bar{A}\right) \tag{3}$$

where $\boldsymbol{\varphi}$ is the vector collecting the three Euler angles identifying the CNTs direction, $\bar{\phi}$ is the effective CNT volume fraction accounting for the CNT dispersion degree, and $\bar{A}$ is the CNT agglomerate area ratio.

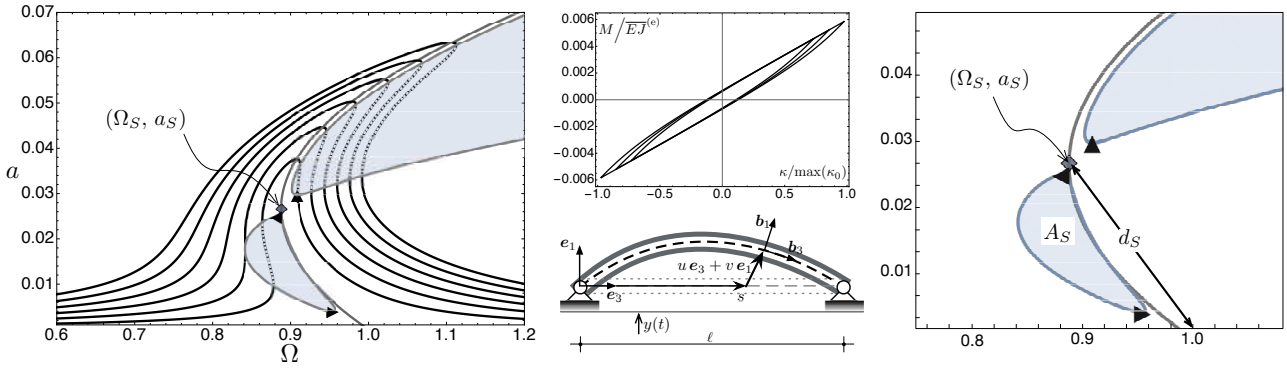

Figure 1: Typical FRC curve (on the left) showing deflection amplitude a vs. excitation-to-natural frequency ratio Ω of a simply supported beam (bottom center), and the moment-curvature hysteretic curves (top center). Within the regions bounded by the two grey lines, the softening or hardening responses are multi-valued and multi-stable (on the right, a zoom of the same FRC on the left).

OPTIMIZATION PROBLEM

The continuum beams incorporating hysteresis in the constitutive relationships are first discretized according to the approach proposed in [3]. To this end, the rate form of the moment-curvature relationship is integrated to yield a piece-wise closed-form representation for each of the four branches of the hysteresis cycles. The obtained piece-wise closed-form moment-curvature relationship is expanded in Taylor series and treated asymptotically in the context of the Galerkin discretization of the deflection field [3, 8, 9, 10, 11].

The ensuing piece-wise ODEs are then treated by the method of multiple scales to obtain the periodic responses to harmonic base excitations together with the frequency-response functions. In this way, the implicit form of the FRC, given in terms of deflection a and frequency ratio Ω, is obtained as:

$$\mathcal{G}(\Omega,\, a) = \mathcal{G}_1(a)\,\Omega^2 + \mathcal{G}_2(a)\,\Omega + \mathcal{G}_3(a) - \mathcal{G}_f(a)\,F^2 = 0. \tag{4}$$

where the coefficients $\mathcal{G}_k$ are explicitly given in terms of both mechanical and discretization parameters. The explicit form associated with (4) provides a simple explicit expression defining the backbone curves, determined as the loci of the peaks of the FRCs, *i.e.*, $\Omega = -\frac{\mathcal{G}_2(a)}{2\,\mathcal{G}_1(a)}$. Note that a qualitative switch of nonlinear behavior is observed in general nonlinear oscillators when the backbone curve exhibits a wiggle due to a change of bending so that the frequency response turns from hardening to softening or viceversa. The above transitions occur at threshold amplitudes where the local change of frequency with respect to the oscillation amplitude vanishes, that is, $\frac{d\Omega}{da} = 0$. This entails a linear response of the oscillator to within the sought order of approximation.

The interplay between the CNT/polymer nanostructural hysteretic nonlinearity and the geometric nonlinearity gives rise to rich and unexpected nonlinear behaviors with a remarkable tunability. By employing suitable fitness functions for maximum multistability bandwidth, such as the frequency bandwidth bounded by the switching point $(\Omega_S,\, a_S)$ and the linear frequency d_S, or the area enclosed by the instability regions A_S (see Figure 1 on the right), the optimization of the nansotructured beams is tackled thanks to the flexibility afforded by the asymptotic solution.

ANALYTICAL, NUMERICAL, AND EXPERIMENTAL INVESTIGATIONS OF A TUNED WEDGE DAMPER WITH SEGMENTED SMOOTH CONTACT SURFACES

Alexander Fidlin*[1], and Jimmy Aramendiz[1]
[1] Chair for Dynamics/Mechatronics, Karlsruhe Institute of Technology, Karlsruhe, Germany

Summary Diminishing detrimental vibrations directly influences the life span of machines and structures. Hence, vibration reduction alternatives have been intensively investigated, focusing either on vibration isolation, absorption or damping. This work proposes a damper, utilizing the last two vibration reduction mechanisms via dry friction and design of sliding contact surfaces. For low vibration amplitudes the damper acts as an absorber providing for almost perfect vibration annihilation, whereas for high vibrations it functions as a highly damped dissipation device. First, the minimal model of the damper is presented and simulated numerically, in order to gain a first insight into the system's dynamics. Then analytical investigations via averaging method are conducted in the vicinity of the resonance regimes. Finally, the numerical and analytical results are validated via experiments.

Vibration reduction has always been an essential aspect in the design of machines and structures [1]. Although, tuned mass dampers are a well-studied and broadly used, they do have their limitations. They can be tuned for an operating frequency; however additional resonance regimes are introduced into the system. Furthermore, in order to reach the operation frequency at least one structural resonance must be usually passed through. Alternatively, tuned mass damper parameters can be chosen in a broadband approach. In that case, however, the near-perfect vibration isolation at the tuned frequency is lost. An additional disadvantage of the common tuned mass damper is its lack of robustness. If the parameters of the tuned mass damper change due to wear or temperature, the tuning of the damper is lost and with it, the damper's effectiveness. The disadvantages of the tuned mass damper have forced engineers and researchers to investigate nonlinear dampers, in order to create robust, broadband, and effective solutions [2]. Friction based dampers have for years been an effective alternative in turbomachinery, railroad freight trucks, and civil engineering structures. In contrast to typical viscous dampers they do not require a complicated manufacturing or sealing and are robust with respect to environmental conditions. In general, friction based dampers with constant friction force are sensitive with respect to the excitation amplitude. However, this is circumvented by utilizing clamped contact surfaces with geometric variations. This alternative has been investigated in [3], in which a wedge damper was implemented to dampen the vibrations of a main structure.

Vibration reduction is mainly based on one of three mechanisms: vibration isolation, vibration absorption or vibration damping. This work proposes a nonlinear tuned wedge damper that utilizes the last two mechanisms. The damper is attached to a main system and improves the system's dynamics especially in the vicinity of the main system's structural resonance. Without loss of generality the main system is represented by a main spring c_1 and a main mass m_1. As an add-on solution the damper is attached to the main system, and is composed of an auxiliary mass m_2, an auxiliary spring c_2, two symmetrical contact surfaces and a third spring c_3, see Fig. 1(a). The third spring clamps the auxiliary mass between the symmetrical contact surfaces and has a small pre-stress displacement of $\Delta\ell$. The ratio of the contact forces between the auxiliary mass and the contact surfaces is described by the constant friction coefficient μ. Furthermore, the auxiliary mass is connected via the auxiliary spring and the contact surfaces to the main mass. The contact surfaces are mounted on the main mass in such a way that only horizontal forces are transmitted.

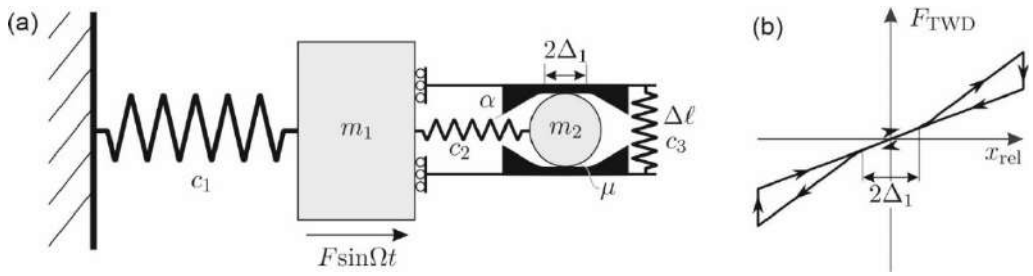

Figure 1: (a) The tuned wedge damper with segmented smooth contact surfaces. (b) The force characteristics of the damper

The novelty of this friction based tuned wedge damper lies in the design of the sliding contact surfaces. The surfaces are composed of five segments: a horizontal segment, two wedge segments, and two transition segments. The horizontal segment is parallel to the degrees of freedom and has the length $2\Delta_1$, whereas the wedge segments are rotated by the angle α with respect to the horizontal. The wedge segments are connected to the horizontal segment via the transition segments. Additionally, the transition segments are circular and are specifically chosen, in order to obtain a continuously differentiable contact area without impacts. Note that the friction coefficients for each section can be chosen separately. As mentioned above, the chosen design allows the damper to alternate between two vibration reduction mechanisms, vibration absorption and vibration damping. As long as the vibrations are sufficiently small the auxiliary mass oscillates within the Δ_1-range and, due to the proper choice of the pre-stress and friction coefficient, either minimal or no friction

MINI SYMPOSIA

affects the oscillations. Within this range, the damper operates as a vibration absorber and almost diminishing vibrations almost perfectly. If the relative vibration amplitude surpasses the Δ_1-threshold, the wedge and transition segments of the surfaces influence the damper's dynamics. This leads to a variable contact force and thus a variable friction force, which is proportional to the relative displacement between the masses. An exemplary damper force that acts on the main mass is depicted in Fig. 1(b). The damper force is composed of a dissipation free Δ_1-range and two outer dissipative sections.

The system's equations of motion are implemented and solved numerically. The discontinuities, which arise from the possible stick-slip-phases due to friction, are considered via event detection. For an appropriate choice of the system parameters (c_3<<1 & $\Delta\ell$=0), the numerical simulations give a first insight into the decoupling of vibration damping and vibration absorption, see Fig. 2(a). The outer wedge sections dampen vibrations with amplitudes larger than Δ_1, whereas vibrations with lower amplitudes remain completely undamped. The undamped vibrations are reduced via the absorption of the secondary spring and the absorber mass. A parameter study into the effect of the friction coefficient shows a reduction of the resonance peaks and an approximate invariance of the vibration absorption frequency for a large range of friction coefficient values. The system is effectively able to partially decouple the vibration reductions mechanisms as long as the vibration amplitude in the vicinity of the vibration absorption frequency are smaller than the displacement Δ_1. The angle α affects the effective stiffness and the effective damping outside of the Δ_1-range, whereas the length Δ_1 determines the change from vibration damping to vibration absorption. Variations of the pre-stress displacement $\Delta\ell$, show that this parameter determines if the system behaves predominantly as a one degree of freedom or a two degree of freedom system, similarly as in [3].

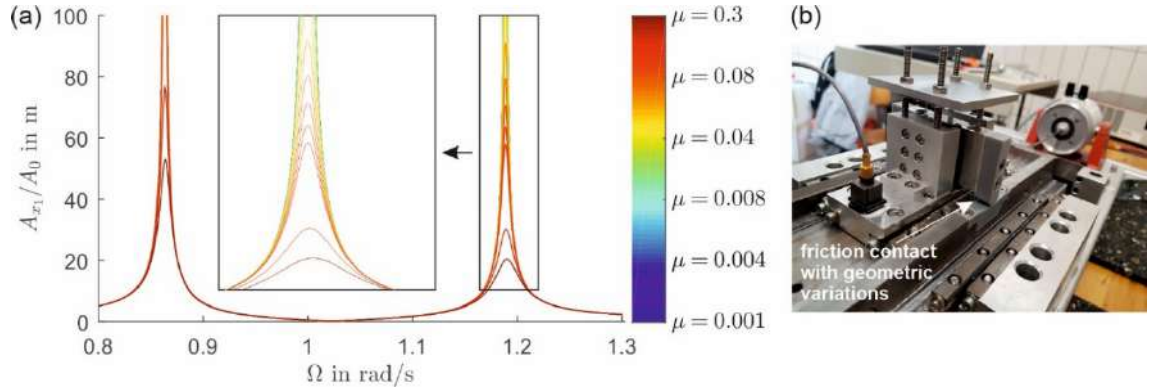

Figure 2: (a) Numerical investigation into the friction coefficient influence (b) Experimental setup of the tuned wedge damper

In order to obtain a deeper insight into the damper's dynamics it is investigated analytically. First, the equations of motion of the system are transformed into modal coordinates. Second, the coupled equations of motion are decoupled with the method proposed in [4]. Subsequently the resulting equations are analysed via averaging methods. The analytical solution concurs with the numeric results within the expected range of asymptotic methods.

The numerical and analytical results are validated via experiments with a setup described in [5]. The main structure is excited via a voice coil shaker that applies a sweep excitation with constant amplitude. Subsequently, the amplitude response functions of the system are derived for various excitations. The experimental results reflect qualitatively the numerical and analytical solutions and confirm the scalability of the effects with variating excitation amplitudes.

This work proposes a tuned wedge damper that decouples vibration damping and vibration absorption. It circumvents the disadvantages of the traditional tuned mass damper with regards to the sealing of the viscous component, robustness, and the trade-off between the damping and vibration absorption frequency. The proposed system is investigated numerically, analytically, and experimentally. These results give a first insight into the passive design of an effective damping device, and lay the foundation of a more complex implementation, e.g. in continuous or multibody systems.

MODELLING AND MITIGATION OF SLOSHING SYSTEMS USING PASSIVE ENERGY ABSORBERS

Maor Farid*[1], and Oleg Gendelman[2]
[1] Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA
[2] Faculty of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary This study treats oscillations of a liquid in partially filled vessel under horizontal harmonic ground excitation. When exposed to external disturbances, the liquid is divided into two portions: oscillating sloshing portion, and a-'static' non-sloshing portion, located at the bottom of the tank. Such excitation may lead to hydraulic impacts applied by the sloshing mass on the tank walls. Different equivalent mechanical models are suggested to mimic the liquid sloshing mass motion and essential dynamical regimes of the overall tank-liquid system, such as a series of pendula or mass-spring-dashpot systems which can impact the vessel walls. We use parameters of the equivalent mass-spring system for the well-explored case of cylindrical vessels. The hydraulic impacts are modelled by high-power potential function. Finite-Element (FE) method is used to determine and verify the model parameters and to identify dominant dynamical regimes, natural modes and frequencies. The tank failure modes and critical locations are identified. Mathematical relation is found between degrees-of-freedom (DOFs) motion and the mechanical stress applied in the tank critical section. This is the prior attempt to take under consideration large-amplitude nonlinear sloshing and tank structure elasticity effects for design, regulation definition and resistance analysis purposes. Both linear (tuned mass damper, TMD) and nonlinear (nonlinear energy sink, NES) passive energy absorbers (PEAs) contribution to the overall system mitigation is firstly examined. Dominant sloshing regimes, such as moderate amplitude, and vibro-impact (VI) violent sloshing are studied and described using reduced-order models and analytical methods.

INTRODUCTION

Partially filled liquid storage tanks of different shapes are used in many engineering fields, including vehicles, sea crafts, aircraft, for the storage of various, maybe hazardous, liquids. The term “sloshing” refers to oscillatory relative motion of the liquid with respect to the containing vessel. The liquid sloshing may be hazardous for the vessel safety, since dynamic loads related to the sloshing may have direct and rather strong calamitous effect on the vessel stability and robustness. So far, elaborated analytical studies are limited to small-amplitude sloshing in rectangular and cylindrical vessels. Thus, efficient numerical and analytic tools are desired for assessing the fluid loading on the structure and the coupling between their motions. While being most interesting and potentially hazardous, high-amplitude liquid sloshing in partially filled vessels still lacks complete analytic representation. The sloshing liquid has infinite number of degrees of freedom; boundary conditions on the free surface are nonlinear and time-dependent. It is noteworthy that the framework of the presented asymptotic analysis is not limited to specific tank shape. Any two dimensional tank shape with vertical walls in the free liquid surface zone can be treated. Moreover, we assume infinite roof height in order to eliminate both liquid spilling and interaction between the fluid and the tank roof.

REDUCED-ORDER MODEL DESCRIPTION

We introduce the equivalent mechanical model for liquid sloshing in cylindrical tank with the well explored TMD attached **[1]**. Parameters K and C are modal stiffness and damping of the vessel fundamental (1,1) beam-type mode, respectively. The tank is of radius R and height H and exposed to arbitrary external excitation of u_g.

The liquid static and dynamic portions heights and the combined tank-static liquid portion center of gravity height are denoted by h_0 and h_1, respectively. Parameters k_2 and k_3 represent the coupling stiffness associated with the TMD and NES, respectively. c_2 is the linear damping coefficient. The PEA installation height h_2 is determined by the designer. Masses $m_{\tan k}$ and m_0 are the tank shell mass and the liquid 'static' portion mass, respectively. The sloshing dynamics combines infinite number of sloshing modes with mass of m_n. However, as shown by Abramson **[2]**, the modal mass decreases rapidly with increasing mode number. Then, to reveal most important aspects of dynamics, one can take into account only the first sloshing mode and the static-like portion of the fluid in the mechanical equivalent model, as long as the excitation frequency is far from the natural frequencies of the higher modes. The normalized displacement coordinate of the sloshing mass m with respect to the tank axis is denoted by v. Impact takes place for the absolute value of v reaches unity. The liquid-structure interaction involves energy dissipation due to wave breaking and fluid viscosity, which exhibits VI behavior. Interaction between the sloshing mass and the tank walls is described by a strongly nonlinear power-form forces with high exponents potential and dissipation force functions **[3-5]**, fully-defined by empirical positive integers, which are going to be assessed both numerically and experimentally.

*Corresponding author. E-mail: faridm@mit.edu

Seismically-induced tank failure modes are explained extensively by Maekawa **[6]**. Based on the ROM, Von-Mises equivalent stresses were calculated in the tank critical point **P**.

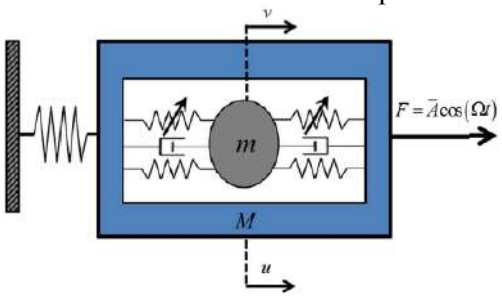

Figure1. System scheme-linear oscillator as the primary system and internal particle with both linear and cubic attachments. The displacements of the primary mass and the impacting mass are denoted as u and v, respectively

We separately apply both the well-known TMD and the cubic NES as vibration mitigation solutions. The following equations of motion are obtained for the overall tank-PEA system:

$$\begin{aligned}
&\ddot{u}+u+\varepsilon_1 v+Z\dot{u}+\varepsilon_1 Z\dot{v}-\varepsilon_2\left(1+\varepsilon_1\right)\beta_2^2 w-\varepsilon_2\kappa_2 w^3-2\varepsilon_2\beta_2\zeta_2\dot{w}=-\frac{\left(1+\varepsilon_1\right)^2}{R\Omega^2}u_{g,tt}\left(t\right)\\
&\ddot{v}+u+\left(\varepsilon_1+\left(1+\varepsilon_1\right)^2\beta_1^2\right)v+Z\dot{u}+\left(\varepsilon_1 Z+2\left(1+\varepsilon_1\right)\beta_1\zeta_1\right)\dot{v}-\varepsilon_2\left(1+\varepsilon_1\right)\beta_2^2 w-\varepsilon_2\kappa_2 w^3-2\varepsilon_2\beta_2\zeta_2\dot{w}+\left(1+\varepsilon_1\right)\kappa v^{4n+1}+\left(1+\varepsilon_1\right)\lambda\dot{v}v^{2n}=0\\
&\ddot{w}-u-\varepsilon_1\left(1+\left(1+\varepsilon_1\right)\beta_1^2\right)v+\left(1+\varepsilon_1\right)\left(1+\varepsilon_2\right)\beta_2^2 w+\left(1+\varepsilon_2\right)\kappa_2 w^3-Z\dot{u}-\varepsilon_1\left(Z+2\beta_1\zeta_1\right)v+2\left(1+\varepsilon_2\right)\beta_2\zeta_2 w-\varepsilon_1\kappa v^{4n+1}-\varepsilon_1\lambda v v^{2n}=0
\end{aligned}\tag{1}$$

While the TMD is examined, we take $\kappa_2=0$, when κ_2 is the parameter associated with the coupling between the NES and the tank structure, and in the same manner, when the NES is examined, we take $\beta_2=0$. The performances of both PEAs are evaluated with the help of two criteria; stress reduction and time of vibration decay. At this stage, the PEAs optimization is performed numerically; the TMD with mass about 10% of the total mass of the system allows up to 40% stress level reduction and 95% reduction of characteristic decay time in conditions of an optimal tuning.

CONCLUSIONS

ROM is used to describe main most hazardous dynamical regimes taking place in cylindrical tank subjected to horizontal ground excitation, and internal impact regime on particular. Additional TMD and NES vibration mitigation performances were primarily examined and exhibit promising results, in term of both decay time and stresses mitigation in the tank critical location.

TRANSIENT CHIMERA-LIKE STATES FOR FORCED OSCILLATORS

Dawid Dudkowski*[1], Jerzy Wojewoda[1], Krzysztof Czołczyński[1], and Tomasz Kapitaniak[1]
Division of Dynamics, Lodz University of Technology, Stefanowskiego 1/15, 90-924 Lodz, Poland

Summary We investigate the transient chimera-like states for the model of forced oscillators, realized in the form of physical double pendula hanged on an oscillating platform. We describe the dynamics of a single unit, uncovering different types of possible behaviors and discuss the properties of three such oscillators. Our results show, that the phenomenon of transient chimera-like states can arise and its lifetime is not straightforward, highly depending on possible uncertainties occurring in the system. The numerical study presented in this paper is confirmed by the experimental research, exhibiting that the described transient states have the same properties as the classical weak-chimeras and can be indistinguishable in real-world networks.

Chimera states occur widely in networks of identical oscillators as it has been shown in the recent extensive theoretical and experimental research. In such a state, different groups of oscillators can exhibit co-existing synchronous and irregular behaviors despite homogeneous coupling. Combining both coherent and incoherent types of responses, chimeras arise on the road to better understanding of the variety of phenomena occurring in nature. In our study we consider a star network, in which N identical peripheral end nodes are connected to the central hub node. The study is realized in the form of physical double pendula hanged on an oscillating platform, which have been shown in Fig. 1.

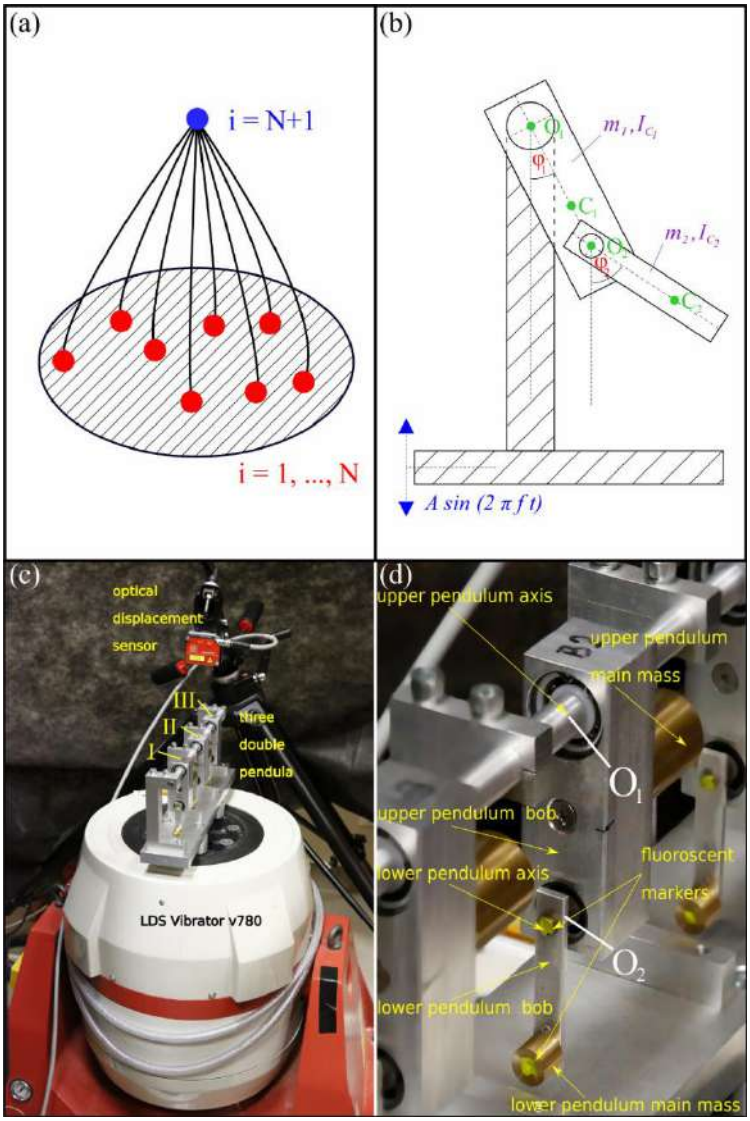

Fig. 1. In (a) a schematic model of a star network of N+1 nonlinear oscillator systems is shown, while in (b) a scheme of physical double pendulum used in the experimental research is presented. The experimental rig of three double pendula suspended on an oscillating platform and a zoom on a single double pendulum node are shown in (c) and (d), respectively.

*Corresponding author. E-mail: dawid.dudkowski@p.lodz.pl.

Each double pendulum shown in Figs. 1(b-c) consists of two elements, i.e., the larger pendulum (upper bob) which holds the smaller one (lower bob). The upper bob can rotate or oscillate around the axis O1 connected to the periodically oscillating platform and the lower bob can rotate or oscillate around the axis O2 as shown in Fig. 1(b) (both axis O1, O2 are perpendicular to the figure's plane). The upper and lower bobs have respectively masses m_1, m_2 [kg] and moments of inertia I_{C1}, I_{C2} [kgm^2] (around the perpendicular axes which crosses bob's mass centers C_1, C_2). The oscillations of the platform are described by the harmonic function $A\sin(2\pi ft)$, where A [m] and f [Hz] are respectively amplitude and frequency.

We describe the dynamics of a single unit, uncovering different types of possible behaviors and discuss the properties of three such oscillators. We find that if a single node exhibits transient chaotic behavior in the whole network, the pattern of transient chimera-like state, which persists for a significant amount of time, is created. Our results show, that the phenomenon of transient chimera-like states can arise and its lifetime is not straightforward, highly depending on possible uncertainties occurring in the system. The numerical study is confirmed by the experimental research, exhibiting that the described transient solutions can be observed in simple experiments with mechanical oscillators, which are controlled by elementary dynamical equations. Our finding suggests that transient chimera-like states have the same properties as the classical weak-chimeras and can be indistinguishable in real-world networks.

STRESSWAVES GENERATED DURING DYNAMIC FRACTURE OF A GLASS TUBE UNDER BENDING

Valentin van Gemmeren[1], Timothy Graf[1], and Jurg Dual *[1]
[1] Institute for Mechanical Systems, ETH Zurich, Zurich, Switzerland

Summary We experimentally induce dynamic fracture of a glass tube by focusing flexural waves. The resulting stress waves are modeled analytically by considering the diffraction of flexural waves at a partial crack. We observed the generation of both longitudinal and flexural waves during the dynamic fracture process. The crack rapidly traversed 85% of the cross section and then slowed down during the remainder of the cross section. Our work presents an experimental method for the generation of reproducible acoustic emissions and establishes a modeling approach.

INTRODUCTION

During fracture, stress waves are released that penetrate the surrounding bulk material. In the context of structural health monitoring, these stress waves are referred to as acoustic emissions and can provide valuable information about the presence, location, and size of cracks in a structure. Moreover, they are investigated in the context of fracture mechanics as they are a direct result of the failure mechanism. Among others, Schindler, Kinra, and Kolsky studied the stress waves released during fracture of glass rods under tension and four-point bending, and modeled their generation [1, 2, 3].

Recently, the authors have presented a method to produce precisely controlled dynamic fracture in a glass tube by focusing flexural waves [4]. Thereby, high loading rates were achieved and stress concentrations due to load transmission were avoided. In the present study, we investigate and model the acoustic emissions generated during the dynamic fracture due to flexural-wave focusing.

METHOD

Experimental setup

In the experiments, we induce dynamic fracture in a 1.5 m long glass tube with an outer diameter of 4 mm and a wall thickness of 0.5 mm. To induce fracture, a strong bending moment pulse with a duration of 100 ms is created in the middle of the beam through the constructive interference of two flexural-wave pulses propagating into opposing directions. The lateral deflection of the glass tube is measured on both sides of the fracture location with two laser Doppler vibrometers. The longitudinal motion of the tube is measured with laser Doppler vibrometer at the tip of the tube. Moreover, the fracture process is recorded with a high-speed camera at 252 kHz.

Modeling the generation of acoustic emissions

To model the generation of acoustic emissions, we compute the interaction of the two propagating flexural wave pulses with the gradual opening of a crack. We prescribe the crack depth with respect to time based on a piecewise linear function that was extracted from our experimental observations (see Figure 1). Further, we assume the crack surface to be traction-free and compute the resultant normal force, bending moment, and shear force of the transmitted and reflected wave pulses, respectively. We then simulate the propagation of the respective waves in the glass tube following Timoshenko beam theory for the flexural components [5], and cylindrical shell theory for the longitudinal components [6].

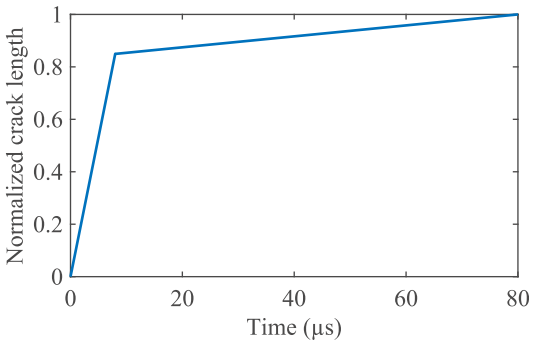

Figure 1: Model of the crack length with respect to time.

RESULTS AND DISCUSSION

Crack dynamics

With the help of the high-speed video recordings, we observed that the fracture process consists of two distinct stages. In the first stage that takes approximately 8 µs, the crack traverses 85% of the cross section with a relatively high velocity. In the second stage, the remainder of the cross section is traversed with at much lower speed. The fracture process in total takes about 80 µs (see Figure 1). In some instances when fracture does not occur directly at the focal point of the flexural waves, the crack turns slightly towards the axis of the tube.

*Corresponding author. E-mail: dual@imes.mavt.ethz.ch.

These observations agree to those of Kinra, Kolsky, and Schindler, who found the crack propagation under static bending to consist of a fast and a slow stage [2, 3]. In contrast, they observed the crack turning completely parallel to the axis of the tube and not traversing the remainder of the cross section at all. We attribute this difference in crack dynamics to our more load-controlled type of loading, compared to the displacement-controlled loading in three- and four-point-bending experiments.

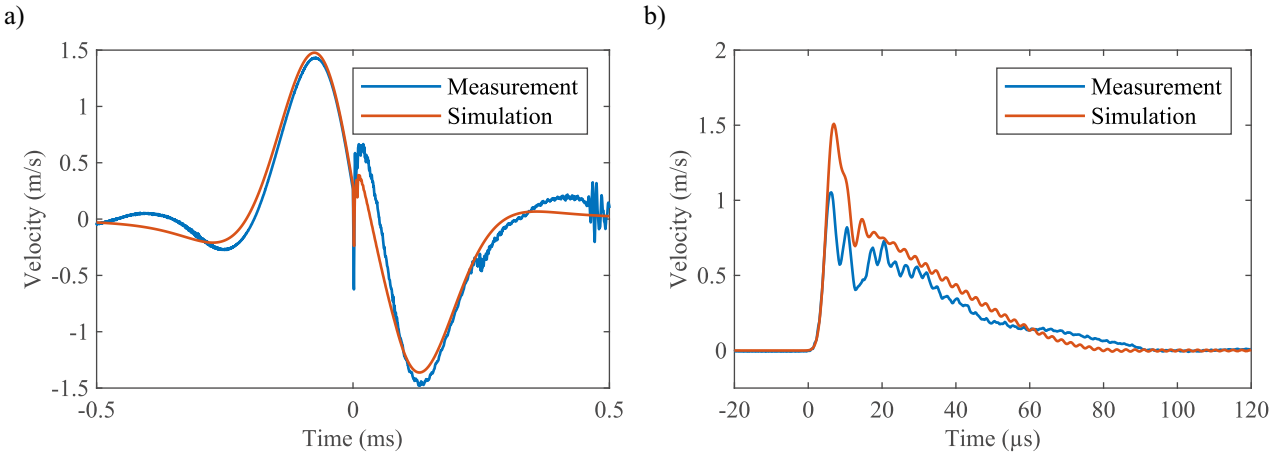

Figure 2: Measurement and simulation of the acoustic emissions generated during dynamic fracture under bending. (a) Flexural motion 10 mm next to the location of fracture. The sharp peak at 0 ms is generated during fracture. The sine-shaped motion before and after is mostly due to the flexural-wave focusing. (b) Longitudinal motion at the tip of the glass tube.

Acoustic emissions

Due to the asymmetry of the crack surface with respect to the axis of the tube, parts of the incident flexural waves are converted into longitudinal waves (see Figure 2b). The duration of the measured longitudinal wave pulse corresponds very well to the duration of the fracture process determined with the high-speed camera. The high-frequency ripples observed in measurement and simulation originate from the dispersion of the longitudinal waves in the tube. In the measurements of the lateral deflection of the glass tube, a sharp peak can be seen at the time instances where fracture occurs (see Figure 2a). This is due to the abrupt transition from wave transmission to wave reflection and is captured well by our simulation. However, the amplitude of the longitudinal wave pulse is overestimated by about 30%. We attribute this difference to our omission of modeling the stress waves ahead of the crack tip.

CONCLUSION

Our experiments show that the dynamic fracture of beams under bending can occur without the crack turning parallel to the beam, if the loading is load-controlled (produced by propagating flexural waves). The crack dynamics were approximated with a piecewise linear function and the normal and flexural components of the resulting acoustic emission were computed. This showed that the duration of the longitudinal pulse offers a good estimate of the duration of the fracture process. While our modeling already shows good results for the generated acoustic emissions, it would be interesting to further model the dynamic crack propagation to understand better the influence of different loading configurations. Our work provides an example of reproducible, experimental acoustic emissions that can be used to validate different modeling approaches.

A COMPUTATIONAL PLATFORM FOR CONSTRAINED DESIGN OPTIMIZATION OF DYNAMICAL SYSTEMS

Mingwu Li[1] and Harry Dankowicz *[1]
[1] Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, USA

Summary A recent update to the MATLAB-based continuation package COCO supports modular construction of algebraic, differential, and integral equality and inequality constraints that define feasible regions on manifolds characterizing solutions to dynamical systems along which optimization may be performed. The implementation also encodes the construction of the adjoint necessary conditions for candidate extrema of scalar-valued objective functions in terms of corresponding Lagrange multipliers. Use of a nonsmooth complementarity function and auxiliary relaxation parameters allows such points to be located using a method of successive continuation. This paper demonstrates the application of this functionality to inequality-constrained problems in design optimization along families of periodic orbits of nonlinear differential equations and the optimal control of an inverted pendulum.

MOTIVATING EXAMPLE

Periodic solutions of the harmonically excited linear oscillator governed by the differential equation

$$\ddot{x} + \dot{x} + kx = f\cos(t+\theta) \tag{1}$$

in terms of the stiffness k, excitation amplitude f, and phase shift θ are given by

$$x_{\rm per}(t) = f\frac{(k-1)\cos(t+\theta)+\sin(t+\theta)}{(k-1)^2+1}. \tag{2}$$

For fixed f, local extrema of $\dot{x}_{\rm per}(0)$ under variations in k and θ are obtained with $\dot{x}_{\rm per}(0) = (-1)^n f$ at $k=1$ and $\theta = n\pi$. A global minimum for $f \leq f_0$ is then obtained at $f = f_0$ with $\dot{x}_{\rm per}(0) = -f_0$. We may locate this extremum through a method of successive continuation applied to a suitably formulated constrained design optimization problem in terms of a nonsmooth complementarity function and auxiliary Lagrange multipliers and relaxation parameters. Specifically, as explained in [1] and [2], with independent variables x, $\dot{x}$, k, θ, and f, candidate minima are obtained from periodic solutions of (1) with period 2π that satisfy the Karush-Kuhn-Tucker (KKT) conditions

$$\ddot{\lambda} - \dot{\lambda} + k\lambda = 0,\ \lambda(2\pi) - \lambda(0) = 0,\ \dot{\lambda}(2\pi) - \dot{\lambda}(0) - k\eta_v = 0, \tag{3}$$

$$\int_0^{2\pi} \dot{\lambda}(t)x(t)\,{\rm d}t + k\eta_k = 0,\ \int_0^{2\pi} \dot{\lambda}(t)f\sin(t+\theta)\,{\rm d}t + k\eta_\theta = 0,\ \int_0^{2\pi} \dot{\lambda}(t)\cos(t+\theta)\,{\rm d}t - k(\eta_f+\sigma_f) = 0, \tag{4}$$

with $\eta_v = 1$, $\eta_k = \eta_\theta = \eta_f = 0$, and $\sigma_f(f-f_0) = 0$ on $\{\sigma_f \geq 0,\ f \leq f_0\}$. These imply that

$$\lambda(t) = e^{t/2}\frac{\sin\left(\frac{\sqrt{3}}{2}(2\pi - t)\right) + e^{-\pi}\sin\left(\frac{\sqrt{3}}{2}t\right)}{\sqrt{3}(\cosh\pi - \cos\sqrt{3}\pi)},\ k=1,\ \theta=0,\ \sigma_f = 1,\ f = f_0, \tag{5}$$

consistent with the prediction above.

By the linearity and homogeneity of the KKT conditions (3)-(4), we may arrive at this optimal solution from an initial solution guess with $\lambda(t) \equiv 0$, $\eta_v = \eta_k = \eta_\theta = \eta_f = \sigma_f = 0$ along an intersecting sequence of one-dimensional manifolds corresponding to periodic solutions $x(t)$ to (1) with period 2π and solutions to (3)-(4) coupled to the nonsmooth complementarity equality condition

$$\sqrt{\sigma_f^2 + (f-f_0)^2} - \sigma_f + f - f_0 - \kappa_f = 0 \tag{6}$$

in terms of the relaxation parameter κ_f. For example, for fixed θ, $f > 0$, $\eta_k = 0$, and $\kappa_f \geq 0$, continuation from the initial solution guess yields a one-dimensional manifold with $\lambda(t) \equiv 0$, $\eta_v = \eta_k = \eta_\theta = \eta_f = \sigma_f = 0$, and a local minimum $\dot{x}_{\rm per}(0) = -f(1-\cos\theta)/2$ at $k = 1 + \cot\theta + \csc\theta$. A second one-dimensional manifold of solutions runs through this point and intersects the point with $\eta_v = 1$, $\eta_\theta = f\sin\theta/2$, $\eta_f = (1-\cos\theta)/2$, $\sigma_f = 0$, and $k = 1 + \cot\theta + \csc\theta$. This point lies on a third one-dimensional manifold obtained by allowing θ to vary and instead fixing $\eta_v = 1$. This manifold intersects the point with $\eta_\theta = 0$, $\eta_f = 1$, $\sigma_f = 0$, $k = 1$, and $\theta = \pi$. Provided that $\kappa_f > 0$ initially, a fourth manifold obtained by allowing f to vary and instead fixing $\eta_\theta = 0$ also intersects the point with $\eta_f = 0$, $\sigma_f = 1$, $k = 1$, $\theta = \pi$, and $f = f_0 + \kappa_f(2+\kappa_f)/(2+2\kappa_f)$. We arrive at the global minimum with $\kappa_f = 0$ by continuation along a one-dimensional manifold obtained by allowing κ_f to vary and instead fixing $\eta_f = 0$. If, in contrast, $\kappa_f = 0$ initially, continuation along the fourth manifold terminates at the singularity of (6) at $\sigma_f = f - f_0 = 0$.

SOFTWARE IMPLEMENTATION

The methodology in the previous section generalizes to arbitrary problems of constrained design optimization along families of solutions to integro-differential boundary-value problems, e.g., periodic and quasiperiodic orbits of nonlinear dynamical systems, including with delay (cf. [3]). The construction of algebraic, differential, and integral constraints, as well as of $\mathbb{R}^n$-valued inequalities, follows a systematic modular paradigm. This is supported in the COCO software platform and leveraged in the construction of production-ready toolboxes for common classes of equality constraints, e.g., multi-segment boundary-value problems. Indeed, a release of COCO from November 2017 also provides support for the associated construction of the corresponding contributions to the adjoint necessary conditions for stationary points in the absence of inequality constraints. As documented extensively in the tutorials accompanying this release, the modular construction paradigm allows, for example, for locating points of locally maximal curvature along a solution manifold.

In an unreleased recent update to COCO, full support is provided for the construction of the KKT conditions for a design optimization problem with both equality *and inequality* constraints. For general multi-segment boundary-value problems, including periodic and quasiperiodic orbits, the adjoint contributions to the KKT conditions are automatically constructed from a predefined library. In lieu of the typical complementarity conditions, the implementation uses one nonsmooth complementarity equality condition of the form (6) for each inequality constraint.

Switching between different one-dimensional solution manifolds, whether at a branch point or as a result of a change in the variables that are free to vary, is a common operation in COCO. In particular, in the former case, COCO stores a candidate direction that lies in the plane spanned locally by the two branches and approximately orthogonal to the original branch. For general multi-segment boundary-value problems, the new COCO update automatically extracts the components of this candidate direction needed in the construction also of the adjoint KKT conditions.

EXAMPLES

A nontrivial example of constrained design optimization solved using COCO is shown in Fig. 1. Here, a control input is sought to minimize an integral objective functional $\mathcal{J}$ in terms of the angular displacement, angular velocity, and control input along trajectories of an inverted pendulum, subject to an integral inequality $\mathcal{I} \leq 0$ on the angular and horizontal displacements. The figure shows the values of $\mathcal{I}$ and $\mathcal{J}$ at the initial and final points of the successive continuation paradigm, as well as along each distinct one-dimensional solution manifold constructed during the solution process.

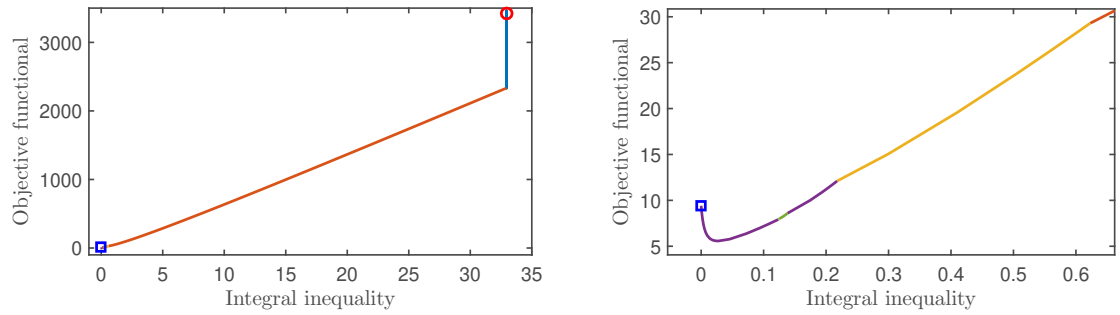

Figure 1: Projections of sequential continuation paths associated with a successive search for an optimal control input for an inverted pendulum. Feasible solutions correspond to nonpositive values of the integral inequality functional. The right panel shows a zoomed-in plot of the left panel around the located minimum (blue square). The initial point is denoted by the red dot in the left panel.

CONCLUSIONS

General-purpose support in the software package COCO for constrained design optimization with functional equality constraints and finite-dimensional inequality constraints is demonstrated using examples from nonlinear dynamical systems theory. While problem construction is straightforward, the specific application of the successive continuation paradigm is problem-dependent and nonunique. Importantly, as seen in both examples, the technique allows minima to be located with initial solution guesses also in the infeasible region.

[3] Universidade de São Paulo - USP, São Carlos, Brazil

Summary This work deals with a global sensitivity analysis in the nonlinear dynamics of a bistable piezo-magneto-elastic energy harvester. The objective is to evaluate the degree of influence of each input parameter variation, as well as their joint effect, on the system response. The global sensitivity analysis method used is the Sobol index, which is based on the idea of orthogonally decompose the total variance of the system response into a sum of conditional variances. The Monte Carlo-based analysis provides a detailed overview about the influence of the physical parameters on the energy recovering process in periodic and chaotic dynamic regimes.

INTRODUCTION

Piezoelectric energy harvesting technologies are considered a very appealing energy source to support low power electronic devices such as mobile phones or medical implants. Typically, it consists in an electromechanical system capable of capturing (mechanical) energy available for free in the environment and converting it into electrical potential. Several studies demonstrate that the introduction of nonlinearities in the system can optimize the electrical power harvested over a wide frequency range [1, 2, 3].

Global sensitivity analysis is a statistical tool that has been receiving great attention in the analysis of many engineering systems, providing a comprehensive approach on how an input variation can affect the underlying system response [4]. An application of these idea in the context of energy harvesting can be seen in the recent work of Aloui et al. [5]. The key point here is to evaluate the degree of influence of the input parameters, and their joint effect, on the system response. In the framework of nonlinear dynamical systems, is can be very useful tool to reveal the influence of each nonlinearity, especially because nonlinear systems, in general, present large sensitivity to variations on the input parameters.

In this work, a global sensitivity analysis based on Sobol' indices is conducted on a nonlinear dynamical system that emulates the behavior of a bistable piezoelectric energy harvester. This approach is based on the decomposition of the system output total variance in a summation of conditioned variances that quantifies the individual, and joint effect, of each model input variability on the system output power.

MATHEMATICAL BACKGROUND

The energy harvesting system studied is the piezo-magneto-elastic beam illustrated in Figure 1, proposed by Erturk et al. [2]. It consists of a cantilever ferromagnetic beam attached to a rigid base excited by a harmonic force, two magnets spaced from its free end causing bistable nonlinearity, and a piezoelectric transducer coupled to the structure with an electrical circuit.

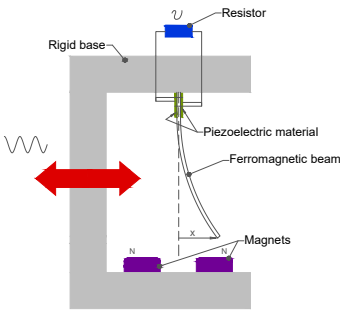

Figure 1: Schematic representation of the piezo-magneto-elastic energy harvesting system.

The electromechanical dynamical system evolves according to

$$\ddot{x} + 2\xi\,\dot{x} - 0.5x\,(1 - x^2) - \chi\,v = f\,\cos(\Omega t) \quad \text{and} \quad \dot{v} + \lambda\,v + \kappa\,\dot{x} = 0, \tag{1}$$

where x is the dimensionless tip displacement of the beam, Ω and f are the dimensionless frequency and amplitude of the harmonic force, respectively, ξ is a mechanical damping ratio, v is the dimensionless voltage, χ and κ are the mechanical

*Corresponding author. E-mail: americo@ime.uerj.br

and electrical piezoelectric coupling terms and λ is the reciprocal of the dimensionless time constant. The averaged output power delivered by this system is given by

$$P = \frac{1}{T}\int_{t_i}^{t_f} \lambda\, v(t)^2 \; dt, \tag{2}$$

being the main quantity of interest for the present study.

Now consider the mathematical model above in an abstract form $Y = \mathcal{M}(X)$, where X is a vector of k independent and uncertain parameters, and Y is a chosen scalar model output (quantity of interest). The Hoeffding-Sobol decomposition states that

$$Y = \mathcal{M}_0 + \sum_{i=1}^{k} \mathcal{M}_i(X_i) + \sum_{i<j}^{k} \mathcal{M}_{ij}(X_i, X_j) + \ldots + \mathcal{M}_{1,2,\ldots,k}(X_1, X_2, \ldots, X_k), \tag{3}$$

which is an orthogonal decomposition in terms of conditional expectations as defined by [4]. In this way, first-order Sobol' indices are defined as $S_i = Var[\mathcal{M}_i(X_i)]/Var[\mathcal{M}(X)]$, while the second-order Sobol' indices are $S_{ij} = Var[\mathcal{M}_{ij}(X_i, X_j)]/Var[\mathcal{M}(X)]$, etc. The total Sobol' indices are $S_{Ti} = 1 - S_{\sim i}$, by denoting $S_{\sim i}$ the sensitivity measure of all the variables excluding variable X_i.

NUMERICAL EXPERIMENTS

For all simulations reported here, the following dimensionless parameters used are: $\xi = 0.01$, $\chi = 0.05$, $\lambda = 0.05$, $\kappa = 0.5$ and $\Omega = 0.8$. Two set of values of f and initial conditions are considered, which produce two different dynamic behaviors: (i) $f = 0.083$ and $(x_0, \dot{x}_0, v_0) = (1, 1, 0)$ for periodic behavior; and (ii) $f = 0.115$ and $(x_0, \dot{x}_0, v_0) = (1, 0, 0)$ for chaotic behavior (see [3] for details). Sobol index analysis is performed based on the Monte Carlo (MC) method and the output parameter analyzed is the average power defined by Equation 2 by the interval $0 \leq t \leq 1000$. All parameters are considered independent with an uniform distribution centered in the nominal value with 20% of dispersion. Figure 2 show the first and second-order and total Sobol' indices for periodic (top) and chaotic (bottom) behaviors, considering the 5 most relevant second-order indices among the 15 possible.

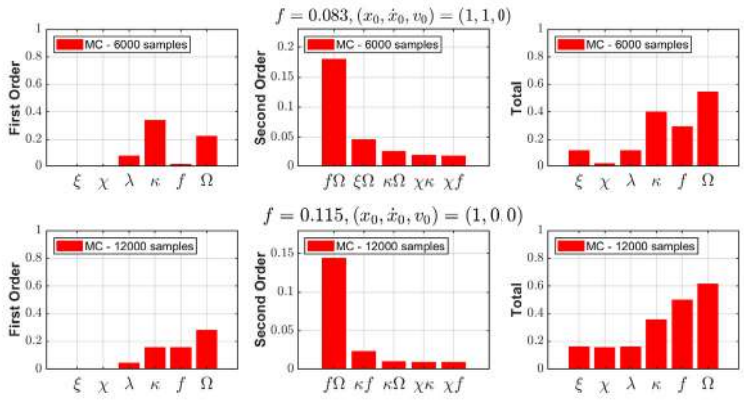

Figure 2: First, second-order and total Sobol' indices for the averaged output power, for periodic (top) and chaotic (bottom) behaviors.

Note that, for periodic regime, the piezoelectric coupling parameter κ, which controls the energy conversion, is the most influential parameter. Next, the excitation frequency Ω, the reciprocal time constant λ, for which the power is proportional, and finally the excitation amplitude f. Damping ratio and the mechanical piezoelectric coupling have negligible first-order influence, but the former has joint effect with κ. For chaotic behavior, an increase in the first-order influence of the mechanical parameters and f is observed, which may be explained by its high-sensitivity to variations.

FINAL REMARK

The global sensitivity analysis based on Sobol index is an adequate tool to describe the degree of influence of a nonlinear energy harvester parameters on amount of energy recovered for both, periodic and chaotic, dynamic regimes.

IMPACTS IN THE ROCKING OF MASONRY CIRCULAR ARCHES

Mario Como [1], Simona Coccia *[1], and Fabio Di Carlo [1]
[1] Department of Civil Engineering and Computer Science Engineering (DICII), University of Rome "Tor Vergata", via del Politecnico 1, 00133, Rome, Italy

Summary Analysis of the impacts occurring during the rocking of the masonry arch is the subject of the paper. Starting point is the study, in the context of the masonry Heyman's model, of the rocking motion of the arch along the two mechanisms u^- and u^+, having hinges mutually disposed at mirrored positions. Special attention is devoted to the instant in which the hinges of u^- become blocked: impacts and motion exchanges take place. A new impact model is proposed in the paper. The motion of the arch, just before and after impacts, is determined by application of the Principles of Conservation of linear and angular momentum. It is shown that the angular momentum of the arch evaluated around the hinges of the mechanism u^+ has to remain constant. The restitution factor is thus obtained.

Some recalls on the rocking of the column and of the masonry pier.

We consider some aspects of the alternate oscillations of the column based on a friction supporting plane π. Fig. 1a shows the column, rotating around the right corner O, just before colliding with π. At this instant all points of the base section, except the left corner O', touch without impact the plane π. The point O', on the other hand, that cannot cross the plane π, becomes instantaneously blocked. Impact occurs at O' and the impulse Pdt takes place (Fig. 1b). The column, continuing in its motion, rotates around the centre O' (Fig. 1c). Concluding, impact point matches the rotation centre of the succeeding motion. The case of the masonry pier is similar. The pier exhibits the typical diagonal cracks, testifying a past seismic event (Fig. 2 and Fig. 3). In this case, contacts occur along the diagonals except the base corners, that are at once rotation centres and impact points.

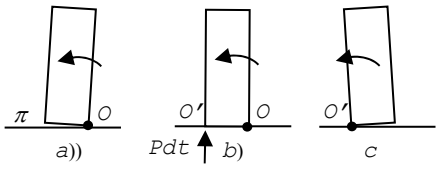

Fig. 1. The column.

Fig. 2. Diagonal cracks.

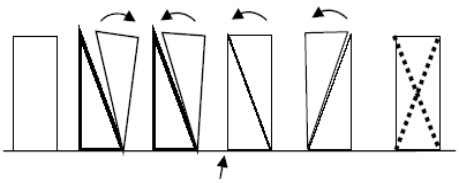

Fig. 3. The masonry pier.

The controversial position of impact points during the rocking of the masonry arch

The masonry arch, released from a defined configuration A, puts itself in motion along a single-degree-of-freedom mechanism u^-, the failure mechanism of the arch under a constant static distribution of horizontal forces. Fig. 4 shows the mechanism of the falling down arch. The arch continues its motion as far as the undeformed position is reached (Fig. 5). At this instant all hinges close and impacts take place. Just after the impacts, the arch continues to move still from the right to the left along the *reverse* mechanism u^+ that has a *mirrored hinges layout*, compared to u^- (Fig. 6). Tests made by DeJong et al. [1] confirm this assumption. Limit Analysis defines the positions of the hinges of mechanisms u^- and u^+ [2, 3]. The problem is the definition of the position of impact points.

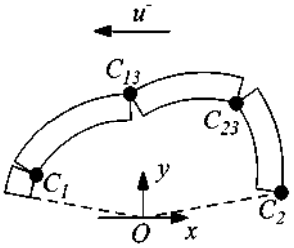

Fig. 4. The falling down motion.

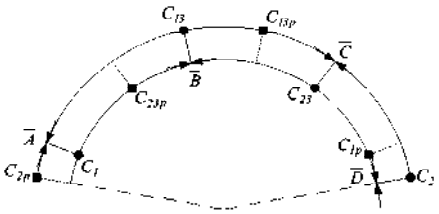

Fig. 5. The undeformed configuration.

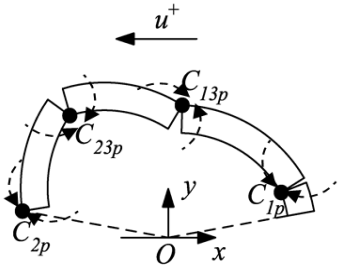

Fig. 6. The reverse mechanism.

In some studies, it is assumed that impacts occur at the same sections where the hinges of the first mechanism u^- are placed but on the opposite side [4]. This statement seems to come out from a questionable reading of what happens at the column base, above recalled. But the position of the impact point at O' in Fig. 1 does not derive from the fact that point O' of the base column is placed at the opposite side of the first centre O, but because O' is the rotation centre of the succeeding motion. Accordingly to the above assumption, we can distinguish, in all sections of the arch where the hinges C_1, C_2, C_{23} and C_{13} of the mechanism u^- are located but at the opposite sides, the assumed impact points $\bar{A}$, $\bar{B}$, $\bar{C}$ and $\bar{D}$. In Fig. 5 we can also see, marked with small squares, the hinges C_{1p}, C_{13p}, C_{23p} and C_{2p} of the succeeding mechanism u^+.

*Corresponding author. E-mail: coccia@ing.uniroma2.it

Concurrence of impacts points with the hinges of the succeeding mechanism u^+

Let us go back to Fig. 4 and let us consider the instant in which the hinges of the first mechanism u^- start to close. The facing sides of each hinge of u^- begin to go in contact. Consider, for instance, the left side of the arch. As soon as the hinge C_1 of the previous mechanism u^- closes, compressions transmit across the arch segment C_{13}-C_1, heading off to the left springer, while the hinges C_{2p} and C_{23p} take shape. Pushed by inertial forces the segment C_{2p}-C_{23p} starts to rotate counterclockwise around C_{2p}, so that the springing section of this segment at C_{2p} attempts to go across the rigid base plane of the left spring of the arch. The lower section of the segment C_{2p}-C_{23p} becomes suddenly blocked at C_{2p} and impact occurs at this point. The same stands for all facing sides of the other hinge sections of the segments C_{23p}-C_{13p} and C_{13p}-C_{1p}. Therefore, impacts occur at points C_{2p}, C_{23p}, C_{13p} and C_{1p} (Fig. 6). We conclude that in the masonry arch, such as in the column and in the masonry pier, impact points match the hinges of the succeeding mechanism u^+.

The new impact model

The velocity of all rigid segments in which the arch is subdivided just after the impact can be determined by applying the Principles of Impulse and of the Angular Momentum. As shown in Fig. 7, impulsive forces at internal post-impact hinges balance each other. Impulsive forces at external post-impact hinges, named F_1dt and F_2dt, and the rotational velocity immediately after the impact are unknown. A system of five equations is then required for a proper definition of the energy dissipation model. We can write two equations expressing the balance of the linear momentum of the entire arch along x and y directions and a third equation expressing the balance of the moment of momentum around the point O.

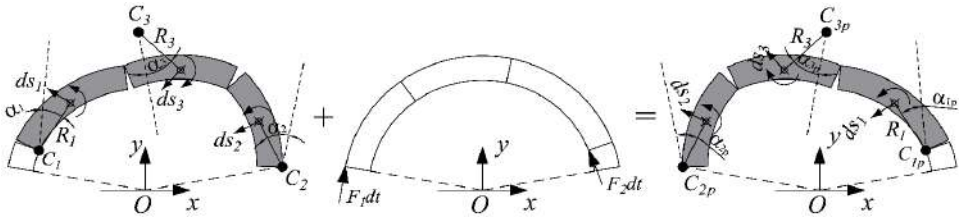

Fig. 7. Application of the Principle of Impulse to the whole system.

Let us go now to the fourth and fifth equations, referring to the conservation of the Angular Momentum around the points C_{23p} and C_{13p} as of the portions of the arch located *at the left* of the post-impact internal hinge C_{23p} (Fig. 8), as of the portion of the arch located at the right of the post-impact internal hinge C_{13p} (Fig. 9). The rotational equilibrium is written just around points C_{23p} and C_{13p} to eliminate the contribution of the unknown internal impulsive forces.

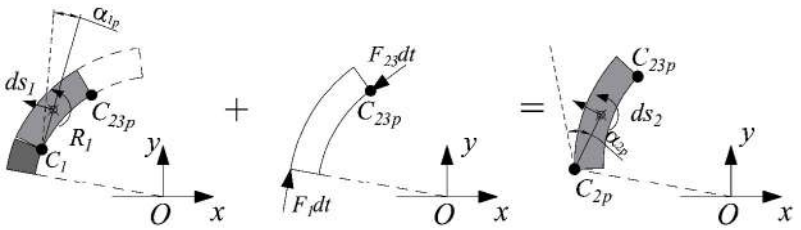

Fig. 8. Angular Momentum Principle on the portion of the arch located to the left of C_{23p}.

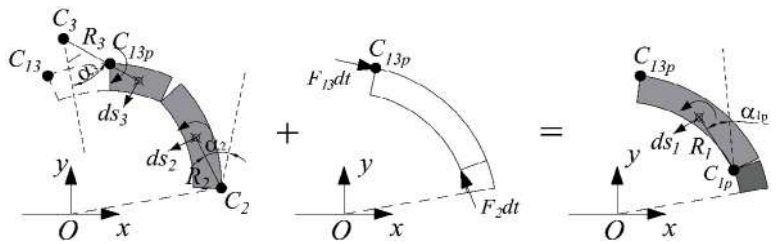

Fig. 9. Angular Momentum Principle on the portion of the arch located to the right of C_{13p}.

Numerical investigation is made to evaluate the corresponding restitution factor.

AGING AND SINGULAR PROBLEMS IN THERMO-VISCOELASTICITY AND MAGNETO-VISCOELASTICITY

Sandra Carillo *[1,2] and Claudio Giorgi[3]
[1] Dipartimento di Scienze di Base e Applicate per l'Ingegneria, Università di Roma LA SAPIENZA ,Rome, Italy
[2] I.N.F.N. - Sezione Roma1, Gr. IV - Mathematical Methods in NonLinear Physics, Rome, Italy
[3] Department DICATAM, Brescia, Italy

Summary The model of viscoelastic body is considered aiming to describe a wider variety of phenomenological situations. Accordingly, different concurring effects are coupled with viscoelasticity to take into account the combined mechanical response to different effects. Specifically, the classical model of viscoelasticity, is generalised to describe new magnetically sensible materials coupling the viscoelasticity with a magnetisation equation. Key property of the viscoelastic behaviour is the relaxation function G. The *classical* regularity assumptions are the framework to start with. A further generalisation consists in the introduction in the model of thermal effects. Indeed, a realistic description of the mechanical response of a material in most cases cannot disregard thermal effects further to mechanical and magnetic ones. In this framework, magneto-viscoelastic materials, for instance gels in which micro-particles magnetically sensible are inserted and thermo-magneto-viscoelastic ones, i.e. the same gels when also the thermal effects are taken into account, are considered. In such cases, the mechanical behaviour of the material, respectively, is influenced also by by an external magnetic field or also by the temperature.

INTRODUCTION

The mechanical response of a body termed *magneto-viscoelastic* is modelled via integro-differential equations in which the integral terms take into account the *deformation history* of the material. Specifically, a body is termed viscoelastic when its stress depends not only on the present status but also on its deformation history. It is termed thermo-viscoelastic if in addition its stress and thermal power depend on the temperature history. The kernels of the integral terms characterise the viscoelastic material to study: the relaxation functions $\mathbf{G}$ and c rule the dependence on the deformation and temperature histories, respectively. The combination of the viscoelastic behaviour with thermal or magnetic effects is introduced and scrutinised.

Viscoelastic body

The quantities suitable to describe the problem are: the *strain tensor*, denoted as $\mathbf{E} = \mathbf{E}(t)$, the *stress tensor* $\mathbf{T} = \mathbf{T}(t)$ the *relaxation modulus* $\mathbf{G} = \mathbf{G}(t)$, whose initial value is denoted as $\mathbf{G}_0 := \mathbf{G}(0)$.

The body is assumed to be homogeneous and isotropic so that the dependence on the spatial variable can be omitted when the viscoelastic behaviour of the body is described. Conversely, the dependence on time is not only through the present time, but also on the past (deformation) *history* of the material. The surrounding environment is assumed to be *passive*, that is, it is not affected by the presence of the viscoelastic body.

The quantities which describe the mechanical status of the viscoelastic body are related via *constitutive assumptions* which guaranty, the physical meaningfulness of the model [1]:

$$\mathbf{T}(t) = \int_0^\infty \mathbf{G}(\tau)\,\dot{\mathbf{E}}(t-\tau)\,d\tau \iff \mathbf{T}(t) = \mathbf{G}_0\mathbf{E}(t) + \int_0^\infty \dot{\mathbf{G}}(\tau)\ ,\ \mathbf{G}(t) = \mathbf{G}_0 + \int_0^t \dot{\mathbf{G}}(s)\,ds \tag{1}$$

where $\mathbf{E}^t(\tau) := \mathbf{E}(t-\tau)$ denotes the *strain past history*. In addition, $\mathbf{G}$ enjoys the *fading memory property*, that is

$$\forall \varepsilon > 0\, \exists\, \tilde{a} = a(\varepsilon, E^t) \in \mathbb{R}^+ s.t.\ \forall a > \tilde{a}, \left| \int_0^\infty \dot{\mathbf{G}}(s+a)\mathbf{E}^t(s)\,ds \right| < \varepsilon \tag{2}$$

The classical one-dimensional evolution problem reads

$$u_{tt} = G(0)u_{xx} + \int_0^t \dot{G}(t-\tau)u_{xx}(\tau)d\tau + f\ ,\ \text{i.b.c}: u(\cdot,0) = u_0,\ u_t(\cdot,0) = u_1 \text{ in } \Omega\,;\ u = 0 \text{ on } \Sigma = \partial\Omega \times (0,T) \tag{3}$$

wherein u denotes displacement and f external force which includes the history of the material. The classical assumptions the relaxation modulus satisfies are:

$$\dot{G} \in L^1(\mathbb{R}^+)\ ,\ G(t) = G_0 + \int_0^t \dot{G}(s)\,ds\ ,\ G(\infty) = \lim_{t\to\infty} G(t). \tag{4}$$

When, as commonly assumed, $G \in C^2(\mathbb{R}^+)$, then $\quad G(t) > 0, \qquad \dot{G}(t) \le 0, \qquad \ddot{G}(t) \ge 0, \qquad t \in (0,\infty).$ (5)

Under these assumptions, the problem (3) admits a unique solution as proved by Dafermos [2].

MAGNETO-VISCOELASTIC PROBLEM

The magneto-viscoelastic problem which models the behaviour of a viscoelastic body subject also to an external magnetic field, in the 1-dimensional case [3, 4], it is modelled by the nonlinear system

$$\begin{cases} u_{tt} - G(0)u_{xx} - \displaystyle\int_0^t G'(t-\tau)u_{xx}(\tau)d\tau - \frac{\lambda}{2}(\Lambda(\mathbf{m})\cdot\mathbf{m})_x = f\,, \\ \\ \mathbf{m}_t + \mathbf{m}\dfrac{|\mathbf{m}|^2-1}{\varepsilon} + \lambda\Lambda(\mathbf{m})u_x - \mathbf{m}_{xx} = 0\,, \end{cases} \quad \text{in } \Omega\times(0,T) \tag{6}$$

where $\Omega = (0,1)$ and $\mathbf{m} = (0, m_1, m_2)$, denotes the magnetization vector, orthogonal to the conductor, since $\mathbf{u} \equiv (u,0,0)$, when both quantities are written in $\mathbb{R}^3$. In addition, Λ is a linear operator defined by $\Lambda(\mathbf{m}) = (0, m_2, m_1)$, the scalar function u is the displacement in the direction of the conductor itself, here identified with the $x-$axis and λ is a positive parameter. In addition, the term f represents an external force which also includes the deformation history up to $t = 0$. Letting $\boldsymbol{\nu}$ be the outer unit normal at $\partial\Omega$, initial and boundary conditions are given as follows

$$u(\cdot,0) = u_0 = 0,\;\; \mathbf{m}(\cdot,0) = \mathbf{m}_0,\quad |\mathbf{m}_0| = 1 \quad \text{in } \Omega\,,\;\;,\;\; u = 0,\qquad \frac{\partial\mathbf{m}}{\partial\boldsymbol{\nu}} = 0 \qquad \text{on} \quad \Sigma = \partial\Omega\times(0,T)\,, \tag{7}$$

Under the assumptions $G(t) \in C^2(0,T)$, $u_0 \in H_0^1(\Omega)$, $u_1 \in L^2(\Omega)$, $\mathbf{m}_0 \in H^1(\Omega)$ and $f \in L^2(\Omega\times(0,T))$, the existence and uniqueness of the solution to the problem given by (6)-(7), is proved in [3]. The corresponding 3-dimensional problem is studied in [5].

MAGNETO-THERMO-VISCOELASTIC PROBLEM

Borrowing the arguments presented in [6], in a thermoelastic solid the stress–strain relation is given by

$$\mathbf{T}(t) = \mathbf{G}_0[\mathbf{E}(t) - \mathbf{E}^{\theta}(t)] + \int_0^{\infty} \dot{\mathbf{G}}(\tau)\,\mathbf{E}^t(\tau)\,d\tau$$

where $\mathbf{E}^{\theta}(t)$ is the *thermal strain*, whereas the *relative temperature* θ is ruled by the heat balance equation

$$c\,\dot{\theta}(t) + \int_0^{\infty} \gamma(\tau)\,\dot{\theta}\,(t-\tau)\,d\tau = \mathbf{B}\cdot\dot{\mathbf{E}}(t) - \nabla\cdot\mathbf{q}(t) + r(t).$$

In the isotropic Fourier case, $\mathbf{E}^{\theta}(t) = \alpha\,\theta(t)\,\mathbf{I}$ and the heat flux vector is given by $\mathbf{q} = -k\nabla\theta$. Then, the corresponding magneto-thermo-viscoelastic problem reads

$$\begin{cases} u_{tt} - G_0[u_{xx} - \alpha\theta_x] - \displaystyle\int_0^t G'(t-\tau)u_{xx}(\tau)d\tau - \frac{\lambda}{2}(\Lambda(\mathbf{m})\cdot\mathbf{m})_x = f\,, \\ c\,\theta_t + \gamma_0\theta + \displaystyle\int_0^t \dot{\gamma}(\tau)\,\theta\,(t-\tau)\,d\tau = \beta\,u_{xt} + k\,\theta_{xx} + g \\ \mathbf{m}_t + \dfrac{\mathbf{m}}{\varepsilon}(|\mathbf{m}|^2-1) + \lambda\Lambda(\mathbf{m})u_x - \mathbf{m}_{xx} = 0\,, \end{cases} \quad \text{in } \Omega\times(0,T) \tag{8}$$

where the term g includes the heat source r and the temperature history up to $t = 0$. System (8) is studied assigning *natural* initial and boundary conditions.

CONCLUSIONS AND PERSPECTIVES

The presented model systems are studied under the classical assumptions (4)-(5). Further generalisations to describe also the behaviour of new materials such as in [7], can be introduced when *singular kernel* problems are considered as in [9, 8]. Indeed, as discussed in [10], the classical assumptions are not suitable to describe many cases of interest in real materials, such as for instance, anti-seismic ones, or when damage effects are introduced to take into account the natural *aging* of materials.

ROBUST TRACKING OF PERIODIC SOLUTIONS IN EXPERIMENTS WITH CONTROL-BASED CONTINUATION

Sandor Beregi *[1], David A. W. Barton[1], Djamel Rezgui[1], and Simon A. Neild[1]
[1] Faculty of Engineering, University of Bristol, United Kingdom

Summary Characterising the dynamics of noise-polluted experimental systems can be often strenuous as measurement noise may conceal certain features of the deterministic system dynamics. In this study, we perform robust continuation of the steady-state periodic solutions of a nonlinear oscillator under noise-load. The periodic solutions of the system are traced by employing control-based continuation (CBC) while the experiment is contaminated with different levels of physical noise. The performance of the algorithm is then assessed with the help of parameter identification in the model of a Duffing-type oscillator, based on the acquired measurement data. By comparing the results to open-loop parameter sweeps, we demonstrate that CBC is more robust to random perturbations and, as a result, it can reveal the finer details of the system dynamics in the presence of noise.

INTRODUCTION

Extracting information from noise-polluted experiments is often a challenge as persistent random perturbations may obscure the finer details of the underlying deterministic system. In our study, we analyse the steady-state periodic solutions of a physical nonlinear oscillator featuring a bistable response (a parameter region where three steady-state solutions, two stable and one unstable, coexist). In traditional open-loop measurements, only the stable solutions can be detected; the unstable solutions must be inferred indirectly. Moreover, measurement noise may result in the system 'jumping' between the domains of attractions of the coexisting stable solutions potentially leading to a loss of information even from a part of the stable solutions [1, 2].

In case of nonlinear mathematical models, the widely used techniques of numerical bifurcation analysis are able to identify the steady-state solutions (e.g. equilibria, periodic orbits, invariant tori) of deterministic systems regardless of their stability. The method of control-based continuation (CBC) adapts the ideas of bifurcation analysis to experiments making it possible to trace both stable and unstable periodic solutions of the experimental rig. The method can also be employed in the presence of noise [3]. Our aim is to assess whether CBC is more robust in extracting information from the underlying deterministic system in noise-polluted experiments than standard open-loop measurements.

EXPERIMENTAL STUDY OF A FORCED NONLINEAR OSCILLATOR

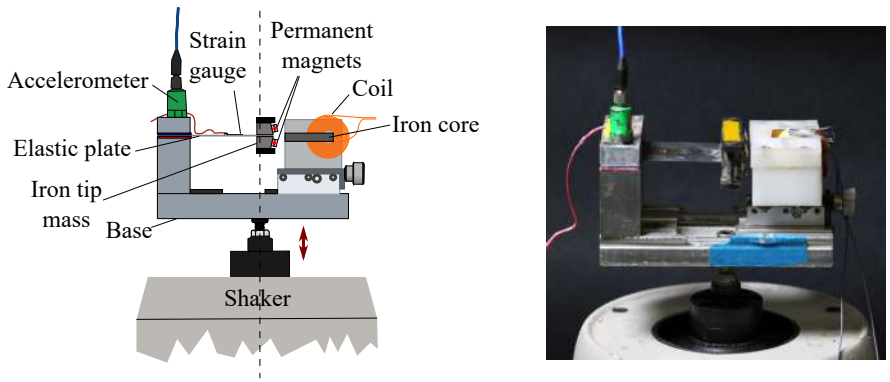

Figure 1: The nonlinear oscillator on the shaker providing forcing to the system. In the left panel, a schematic is presented while the experimental rig is shown in the right panel.

We studied the steady-state periodic solutions of the forced nonlinear oscillator (see Fig. 1) consisting of an elastic plate with an iron tip mass and permanent magnets and an electromagnetic coil. The device is designed such that the combination of the structural, inertial and electromagnetic forces result in a nonlinear restoring force while the experiment can be contaminated with physical noise by driving current through the coil.

We employ the technique of control-based continuation to trace the family of periodic solutions of the experimental rig for different forcing amplitudes at constant frequencies. Performing continuation in amplitude rather than frequency allows us to use a simplified version of the CBC algorithm [4]. Then we fit the model parameters of a Duffing-type oscillator to the acquired data considering odd order nonlinearities up to seventh order.

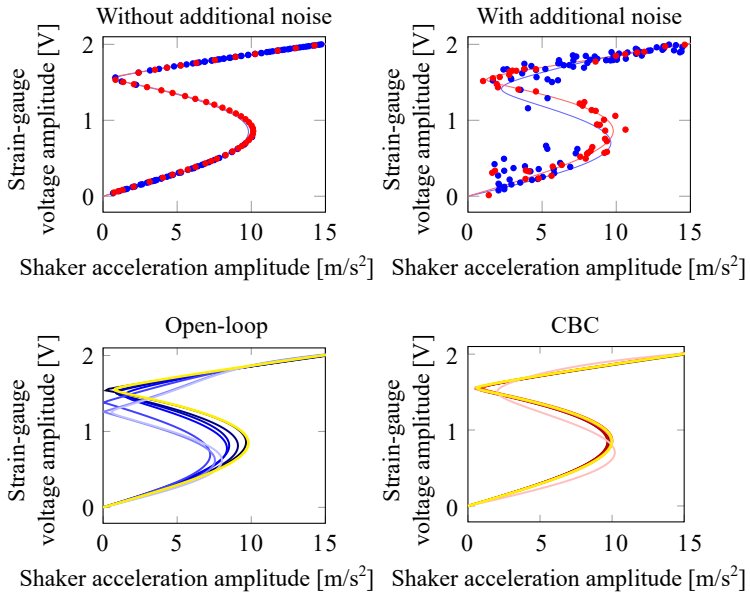

Figure 2: Top row: Amplitude response of the nonlinear oscillator at low and high noise-levels. The markers show the measurement data while the response of the fitted Duffing oscillator is indicated by the continuous lines. Bottom row: The amplitude-responses of the Duffing oscillator fitted to data acquired at different noise-levels. The response curves corresponding to measurements without noise added through the coil are highlighted in yellow. The blue markers and curves in each panel belong to parameter-sweeps while the red ones to CBC.

Robustness against noise

The parameter identification is used to characterise and quantify the resilience of the CBC algorithm against measurement noise (see Fig. 2). We traced the steady-state periodic solutions both using CBC and open-loop sweeps in the forcing amplitude while the experiment was physically polluted with different levels of additional noise through the coil. These tests indicate that while open-loop measurements can perform similarly at low noise levels as CBC, in the presence of a higher amount of noise the open-loop technique tends to fail to identify the location of the folds on the S-shaped response curve of the system whereas the deterministic response can be largely retained using CBC up to a noise level around 30 % of the largest vibration amplitude.

CONCLUSIONS

By performing experimental bifurcation analysis of a nonlinear oscillator, we demonstrated that CBC is capable to capture the underlying deterministic response even with a significant noise-load on the system. The steady-state response was captured both using CBC and standard open-loop parameter sweeps. By using the parameter-sweeps as benchmark, we established that CBC has the ability to extract finer details of the dynamics of the experimental rig than it was possible by open-loop approach. Thus, control-based continuation could be effectively used to investigate nonlinear systems experimentally where, beside the nonlinear effects, one has to deal with significant measurement noise.

Although our study focuses on forced vibrations, CBC can be generalised to study self-excited vibrations in autonomous systems such as in case of aeroelastic flutter [5]. In aeroelastic systems, the inherently unsteady airflow around oscillating aerofoils may results in a significant noise-load. Since the commonly used nonlinear mathematical models of these phenomena predict a complicated set of steady-state solutions [6] the robust experimental bifurcation analysis in aeroelastic systems may provide further novel results.

A SIMPLE, REDUCED COMPLEXITY METHOD OF LYAPUNOV EXPONENTS ESTIMATION FOR DISCONTINUOUS SYSTEMS

Marek Balcerzak*[1], Artur Dabrowski[1] and Andrzej Stefanski[1]
[1] Division of Dynamics, Lodz University of Technology, Lodz, Poland

Summary According to the state-of-art algorithms, finding the whole spectrum of *n* Lyapunov Exponents (LEs) requires to integrate *n* orthogonal perturbations of the system under consideration. In this paper authors show that application of the novel method reduces the number of integrated perturbations to *(n-1)*. This applies to smooth systems, as well as non-smooth or even discontinuous ones. Important assets of the new algorithm are simplicity and ease of implementation. Authors shortly present the novel method and explain why it enables to skip integration of the last perturbation. Then, it is shown how the new approach can be adopted to discontinuous systems. Finally, application of the algorithm for estimation of LEs spectrum of an impact oscillator is described. Authors hope that the novel method is going to facilitate research in the field of dynamical systems, including discontinuous ones.

THE METHOD

Consider a dynamical system described by an ODE and the corresponding linearized equation which defines evolution of an infinitesimal perturbation of the system:

$$\dot{\boldsymbol{x}} = \frac{d\boldsymbol{x}}{dt} = \boldsymbol{f}(\boldsymbol{x}, t), \qquad \dot{\boldsymbol{z}}^1 = \boldsymbol{f}(\boldsymbol{x} + \boldsymbol{z}^1, t) - \boldsymbol{f}(\boldsymbol{x}, t) = \boldsymbol{J}(\boldsymbol{x}, t)\boldsymbol{z}^1 \tag{1}$$

where $\boldsymbol{x} \in \mathbb{R}^n$ is a state vector, $\dot{\boldsymbol{x}} = d\boldsymbol{x}/dt$, n is the order of the system, t is the time, $\boldsymbol{f}(\boldsymbol{x}, t)\colon \mathbb{R}^n \times \mathbb{R} \to \mathbb{R}^n$ is a vector field, $\boldsymbol{z}^1(t)$ is an infinitesimal perturbation and $\boldsymbol{J}_{ij} = \partial f_i/\partial x_j$ is the Jacobian matrix of the vector field $\boldsymbol{f}$ with respect to the state vector $\boldsymbol{x}$. Lyapunov Exponents (LEs) are numbers that specify exponential rates in which infinitesimal perturbations of a dynamical system change their lengths [1]. Almost any perturbation in the phase space has a component along a direction of the largest Lyapunov Exponent (LLE). Consequently, the LLE specifies the rate of change of the length of disturbances in most directions of the phase space. Analogously, most perturbations orthogonal to the direction of the LLE change their lengths according to the second LE. Generally, norms of perturbations orthogonal to the directions of the first *i* LEs evolve according to the *(i+1)*-th LE.

In the paper [2] it has been shown that LEs can be estimated by calculating the following formula in each integration step:

$$\lambda_i^*(t) = \frac{\boldsymbol{z}^i(t) \cdot \frac{d\boldsymbol{z}^i}{dt}(t)}{|\boldsymbol{z}^i(t)|^2} \tag{2}$$

The average of all $\lambda_i^*(t)$ approaches the *i*-th LE. Please note that the value (2) is independent from the length of the perturbation vector $|\boldsymbol{z}^i(t)|$. The first perturbation $\boldsymbol{z}^1$ is computed directly from (1) and not modified. Other perturbations $\boldsymbol{z}^i$ need to be continually orthogonalized with respect to $\boldsymbol{z}^1, \ldots, \boldsymbol{z}^{(i-1)}$ [1]. Note that $\boldsymbol{z}^i$, due to orthogonalization, is restricted to a subspace of the dimension *(n+1-i)*. Therefore, the last perturbation $\boldsymbol{z}^n(t)$ is confined to a 1-dimensional subspace (a line) in the phase space, so its direction is known solely from orthogonalization with respect to $\boldsymbol{z}^1, \ldots, \boldsymbol{z}^{(n-1)}$. This fact, for the case n=3, is illustrated in Figure 1.

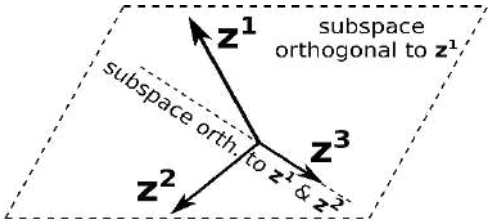

Figure 1. Perturbations and their subspaces for the case n=3. Direction of $\boldsymbol{z}^n$ is known solely due to orthogonalization.

As (2) is independent from perturbation's length, any vector in the subspace orthogonal to $\boldsymbol{z}^1, \ldots, \boldsymbol{z}^{(n-1)}$ (the line) can be used to calculate the last LE. Therefore, integration of the last perturbation is redundant.

If the system under consideration is discontinuous, the state and the perturbations may change instantaneously as the trajectory passes through a discontinuity. Assume that it is encountered at the times $t_1, \ldots, t_m$ and the transition

*Corresponding author. E-mail: marek.balcerzak.1@p.lodz.pl

rule, which defines transformation of perturbations at the discontinuity, can be presented in the form $\boldsymbol{z}^i(t_j+\epsilon) = \boldsymbol{T}[\boldsymbol{x}(t_j), t_j]\boldsymbol{z}^i(t_j-\epsilon)$ where $1 \le i \le n, 1 \le j \le m$ and ϵ is an arbitrarily small, positive number. The matrix $\boldsymbol{T}[\boldsymbol{x}(t_j), t_j]$ can be found using the method presented in the paper [3]. Then, the influence of the discontinuity on the values of LEs can be taken into account using the formula:

$$\lambda_i^{**}(t_j) = \lim_{\epsilon \to 0^+} \frac{1}{\Delta t} \ln \frac{\left|\boldsymbol{z}^i(t_i+\epsilon)\right|}{\left|\boldsymbol{z}^i(t_i-\epsilon)\right|} \tag{3}$$

where Δt is the integration step and $\boldsymbol{z}^i$ is orthogonalized with respect to the perturbations $\boldsymbol{z}^1, \ldots, \boldsymbol{z}^{i-1}$ both before and after passing through the discontinuity. It can be shown that in order to estimate the *i*-th LE in a system with discontinuity, one has to add the values (2) from each integration step, the values (3) computed during each transition through the discontinuity and divide the obtained sum by the number of integration steps.

NUMERICAL EXAMPLE

Consider the impact oscillator presented in Figure 2a. Its equations, in dimensionless form, are as follows:

$$\begin{gathered} \boldsymbol{x}' = \begin{bmatrix} x_1' \\ x_2' \end{bmatrix} = \boldsymbol{f}(\boldsymbol{x}, \tau) = \begin{bmatrix} x_2 \\ -x_1 - 2\beta x_2 + \cos(\eta\tau) \end{bmatrix}, x_1 < x_w \\ \lim_{\epsilon \to 0^+} \boldsymbol{x}(\tau_i + \epsilon) = \lim_{\epsilon \to 0^+} \boldsymbol{D}\boldsymbol{x}(\tau_i - \epsilon), \text{gdy } x_1(\tau_i) = x_w, \boldsymbol{D} = diag(1, -1) \end{gathered} \tag{4}$$

where $\boldsymbol{x} = [x_1, x_2]^T$ is the state vector and $\boldsymbol{x}'$ is its derivative with respect to the dimensionless time $\tau = t\sqrt{k/m}$, $\boldsymbol{f}$ is the vector field, $x_1 = kX/F$, $x_2 = \dot{X}\sqrt{mk}/F$, $\beta = c/(2\sqrt{mk})$, $\eta = \Omega\sqrt{m/k}$, $x_w = kX_w/F$, $\tau_i = t_i\sqrt{k/m}$ and $\boldsymbol{D}$ is the 2x2 diagonal matrix, which transforms the state vector $\boldsymbol{x}$ when a collision occurs (the position x_1 remains unchanged, whereas the sign of the velocity x_2 is reversed).

The presented method of LEs estimation has been applied for the system (4) with the following values of parameters: $\beta = 0.05, x_w = 2$. The non-dimensional forcing frequency η has been selected as a control parameter in the range $\eta \in [0.7, 0.76]$. The bifurcation diagram and LEs diagram are presented in Figure 2b. The LLE is marked with a solid line and the second LE with the dashed one.

a) b)

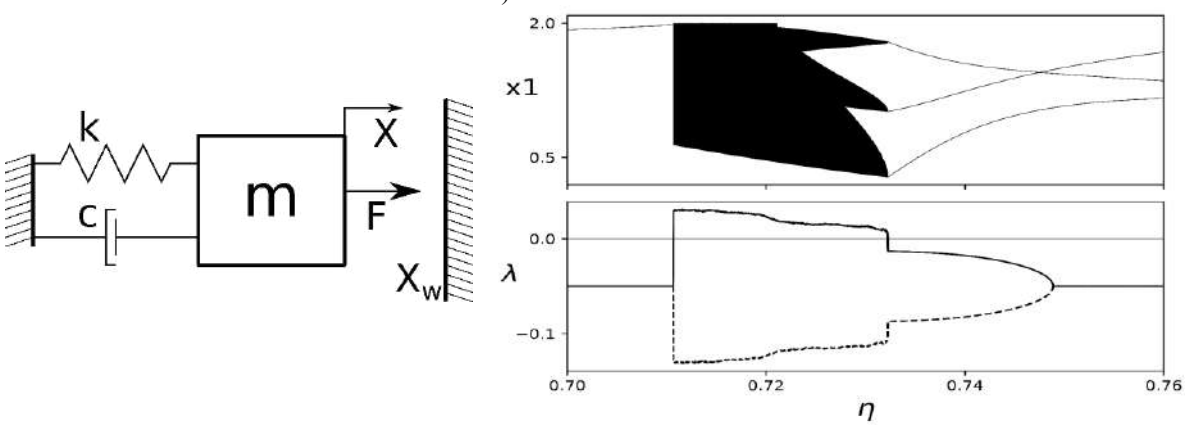

Figure 2. a) Scheme of the impact oscillator b) Bifurcation diagram and corresponding Lyapunov Exponents diagram

CONCLUSIONS

The presented results are in agreement with the publication [4]. Therefore, correctness of the presented method has been verified. Consequently, authors confirmed that it is possible to calculate the spectrum of n Lyapunov exponents of a non-smooth or discontinuous systems using only $n-1$ perturbations. It is expected that the presented method can simplify investigations of non-smooth dynamical systems and support research in this field.

MULTIPLE-SCALE ANALYSIS OF A GEOMETRICALLY EXACT BEAM MODEL

Enrico Babilio*[1], Stefano Lenci[2], and Elio Sacco[1]
[1] Department of Structures for Engineering and Architecture, University of Naples "Federico II", Naples, Italy
[2] Department of Civil and Building Engineering and Architecture, Polytechnic University of Marche, Ancona, Italy

Summary Slender and highly flexible structures are frequently used as members in systems designed to meet high to extreme performances. Hence cables, ropes, yarns, hoses and pipelines, which are essential parts of such structures, play a relevant role in practically every engineering field. However, in real operating conditions, beams and beam-like structures exhibit responses often too complicated for current modeling tools. In this respect there is a continuous need for reliable models. In this area, the present contribution considers a beam model equipped with non-standard constitutive laws and, in particular, it is aimed at deriving approximate solutions of the equations of motion via asymptotic multiple scale expansion.

BASICS ON THE BEAM MODEL

We consider a geometrically exact beam model deduced by stipulating a relation between one- and three-dimensional formulations for initially straight beams undergoing planar and twist-less deformed states. Using comma notation for derivatives, the equations of motion derived in [1], to which we refer for any further detail, are written as

$$m_0\,u_{,tt} - m_1(\theta_{,t}^2\sin\theta - \theta_{,tt}\cos\theta) + c_0\,u_{,t} + c_1\theta_{,t}\cos\theta = \left(N(1+u_{,x})\sqrt{2\varepsilon+1} - \frac{Tv_{,x}}{\sqrt{2\varepsilon+1}}\right)_{,x} + q_1\,, \tag{1}$$

$$m_0\,v_{,tt} - m_1(\theta_{,t}^2\cos\theta + \theta_{,tt}\sin\theta) + c_0\,v_{,t} - c_1\theta_{,t}\sin\theta = \left(Nv_{,x}\sqrt{2\varepsilon+1} + \frac{T(1+u_{,x})}{\sqrt{2\varepsilon+1}}\right)_{,x} + q_2\,, \tag{2}$$

$$m_1(u_{,tt}\cos\theta - v_{,tt}\sin\theta) + m_2\,\theta_{,tt} + c_1(u_{,t}\cos\theta - v_{,t}\sin\theta) + c_2\,\theta_{,t} = M_{,x} - T\sqrt{2\varepsilon+1} + q_3\,, \tag{3}$$

where $u(x,t)$ and $v(x,t)$ stand for the axial and transverse displacements of the beam axis, $\theta(x,t)$ is the cross-sectional rotation, $m_k(x)$ and $c_k(x)$, $k=0,1,2$ are mass and damping coefficients, $q_i(x)$, $i=1,2,3$ are external loads, $N(x,t)$, $T(x,t)$ and $M(x,t)$ are axial, transverse and bending generalized stresses given by

$$N = \frac{\sin^2\gamma}{\sqrt{2\varepsilon+1}}\,K_S + \frac{\varepsilon}{\sqrt{2\varepsilon+1}}\,K_0 + \cos\gamma\left(\frac{3\varepsilon+1}{2\varepsilon+1}\right)\kappa\,K_1 + \frac{1+2\cos^2\gamma}{2\sqrt{2\varepsilon+1}}\kappa^2\,K_2 + \frac{\cos\gamma}{2(2\varepsilon+1)}\kappa^3\,K_3\,, \tag{4}$$

$$T = \sqrt{2\varepsilon+1}\,\frac{\sin 2\gamma}{2}\,K_S - \varepsilon\sin\gamma\,\kappa\,K_1 - \sqrt{2\varepsilon+1}\,\frac{\sin 2\gamma}{2}\,\kappa^2\,K_2 - \frac{\sin\gamma}{2}\kappa^3\,K_3\,, \tag{5}$$

$$M = \varepsilon\sqrt{2\varepsilon+1}\,\cos\gamma\,K_1 + \left(\varepsilon + (2\varepsilon+1)\cos^2\gamma\right)\,\kappa\,K_2 + \frac{3}{2}\sqrt{2\varepsilon+1}\,\cos\gamma\,\kappa^2\,K_3 + \frac{1}{2}\,\kappa^3\,K_4\,, \tag{6}$$

where $K_j(x)$, $j=0,1,\ldots,4$ and $K_s(x)$ are stiffnesses and $\varepsilon(x,t)$, $\gamma(x,t)$ and $\kappa(x,t)$ are axial, shear angle and bending strains, related to displacements and rotations.

Since their introduction, Eqs. (1-3) have been analyzed in some depth [2, 3, 4] mainly through numerical investigations. On the contrary, the present paper, following [5], is focused on analytical developments, based on the method of multiple scales [6]. In particular, to draw frequency-response curves as those reported in Fig. 1, the exact partial differential Eqs. (1-3) are analyzed around frequencies corresponding to certain natural modes.

A SUMMARY ON THE MULTIPLE-SCALE ANALYSIS

On introducing a small book-keeping parameter ϵ, the unknowns and their m^{th} time derivatives in Eqs. (1-3) can be expanded, up to the order r, as

$$w_i(x,t) = \sum_{j=1}^{r}\epsilon^j W_{ij}(x;\tau_0,\tau_1,\cdots,\tau_r)\,, \qquad \frac{\partial^m w_i}{\partial t^m} = \prod_{k=1}^{m}\sum_{j=0}^{r}\epsilon^j\frac{\partial w_i}{\partial\tau_j}\,, \qquad i=1,2,3 \tag{7}$$

where w_i are dummy functions such that $u=w_1$, $v=w_2$, $\theta=w_3$, $\tau_0=t$ is a fast time scale, $\tau_1=\epsilon t,\cdots,\tau_r=\epsilon^r t$ are slow scales and W_{ij} are unknown functions to be determined. From these equations and further assuming that c_0 and K_3 are at most order ϵ^2; m_1, c_1, c_2, and K_1 are at most ϵ^3; the loads q_2, of order ϵ^3, and q_1 and q_3, of order ϵ^4, are periodic functions whose frequencies are close to natural frequencies ω_i, that is

$$q_i(t) = P_i\cos(\Omega_i t) = P_i\cos(\omega_i\tau_0 + \sigma_i\tau_2)\,, \quad i=1,2,3 \tag{8}$$

*Corresponding author. E-mail: enrico.babilio@unina.it

being σ_i detuning parameters small of order of ϵ^2, after some algebra, the set of linear differential equations

$$m_0\, W_{1j,\tau_0\tau_0} - K_0\, w_{1j,xx} = \mathcal{P}_{1j}\,, \tag{9}$$

$$m_0\, W_{ij,\tau_0\tau_0} + K_S^{-1}\,(m_0\, m_2\, W_{ij,\tau_0\tau_0} - (m_0\, K_2 + m_2\, K_S)\, W_{ij,xx})_{,\tau_0\tau_0} + K_2\, W_{ij,xxxx} = \mathcal{P}_{ij}\,, \qquad i = 2,3 \tag{10}$$

with the index j spanning from 1 to the order of expansion, can be derived. Equations (9-10), and the expansion of proper boundary conditions, can be managed in cascade, taking into account, at any step, suitable solvability conditions to avoid that the solution contains resonant terms.

As a sketch of results, we report in Fig. 1 some frequency-response curves for a beam, which is supported by immovable hinges at both ends. The curves are drawn as a function of the detuning parameter σ_2, appearing in the transversal load, for four different values of K_4, namely 0, 2.5×10^{-4}, 1.0×10^{-3}, and 3.0×10^{-3}. Because of boundary conditions, the curves are hardening. Further, we see that the higher is the value of K_4, the more the corresponding frequency-response curve is bent. The response remains still nonlinear for $K_4 = 0$, as it can be seen from Eqs. (4-6) and from Fig. 1.

The next steps of this study will be aimed at comparing the behavior of the model we are dealing with to others existing in the scientific literature [7, 8, 9], as well as to numerical results.

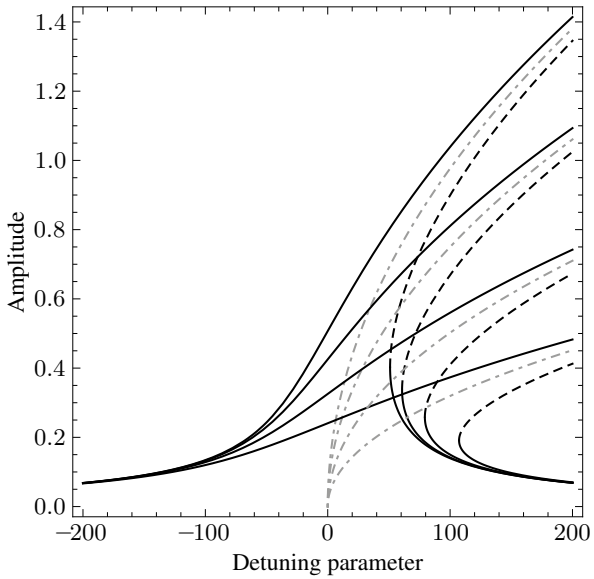

Figure 1: Stable (black solid lines) and unstable (black dashed lines) branches of frequency responses and backbone curves (gray dot-dashed lines) for four different values of the stiffness K_4, starting from 0 (corresponding to the less forward-bent curve) up to 3.0×10^{-3}.

CONCLUSIONS

The present contribution, which is part of an ongoing research focused on the analysis of a geometrically exact beam model with nonlinear constitutive relationships, reports about preliminary results from a multiple-scale analysis. The next steps, still in progress, will be focused on investigating the role played by parameters on the shape of frequency-response curves and comparing the present model with others and with results from numerical approaches available in the literature.

HYSTERETIC MODELS IN FERROELECTRICS

Claudio Giorgi[1] and Angelo Morro *[2]
[1] DICATAM, University of Brescia, Brescia, Italy
[2] DIBRIS, University of Genoa, Genoa, Italy

Summary The paper deals with hysteresis in ferroelectrics and develops a constitutive model which seems to be a basic reference also for other hysteretic phenomena. Neither hysteresis operators nor superpositions of a linear component to rate-type law are involved. Instead, the approach is based on constitutive equations where both the polarization and the electric field are simultaneously independent variables so that the constitutive functions depend on both of them. Thermodynamic requirements are derived and a class of models is shown to be allowed. It is a conceptual advantage of the class so established that the behaviour of the material is described in a consistent scheme of constitutive equations. For definiteness some hysteresis loops are shown to arise from the constitutive model.

THERMODYNAMIC REQUIREMENTS ON UNDEFORMABLE FERROELECTRICS

For simplicity we restrict attention to undeformable ferroelectric materials. Let $\mathbf{E}$ be the electric field, $\mathbf{P}$ the dielectric polarization, θ the absolute temperature, η the entropy density, ε the internal energy density (per unit volume). The dielectric material is assumed to be undeformable and non-conductor. The balance of energy is then taken in the form $\dot{\varepsilon} = \mathbf{E}\cdot\dot{\mathbf{P}} + r$, the superposed dot denoting the time derivative while r is the energy supply. Let $\Phi = \varepsilon - \theta\eta - \mathbf{E}\cdot\mathbf{P}$,called free enthalpy density or Gibbs free energy density. The second-law inequality is considered in the form

$$\dot{\Phi} + \eta\dot{\theta} + \mathbf{P}\cdot\dot{\mathbf{E}} \leq 0.$$

Let Φ, η be functions of $\mathbf{E}, \theta, \mathbf{P}, \dot{\mathbf{E}}, \dot{\mathbf{P}}$. It follows that Φ is independent of $\dot{\mathbf{E}}, \dot{\mathbf{P}}$ and that $\eta = -\partial_\theta\Phi$ while

$$-(\mathbf{P} + \partial_{\mathbf{E}}\Phi)\cdot\dot{\mathbf{E}} - \partial_{\mathbf{P}}\Phi\cdot\dot{\mathbf{P}} \geq 0.$$

Assume $\mathbf{P}$ and $\mathbf{E}$ are collinear and let P, E be the components in the common direction. The thermodynamic restriction becomes

$$(P + \partial_E\Phi)\dot{E} + \partial_P\Phi\,\dot{P} \leq 0.$$

As a consequence, along any closed curve in the $E-P$ plane, as the time t runs over $[0,T]$, we have

$$0 \geq \int_0^T \{(P + \partial_E\Phi)\dot{E} + \partial_P\Phi\,\dot{P}\}dt = \int_0^T \{P\dot{E} + \dot{\Phi}\}dt = \int_0^T P\,\dot{E}\,dt.$$

The requirement $0 \geq \int_0^T P\,\dot{E}\,dt = \oint P\,dE$ implies that the closed curve is run in the counterclockwise sense. Further, the thermodynamic requirement is made explicit by letting

$$(P + \partial_E\Phi)\cdot\dot{E} + \partial_P\phi\cdot\dot{P} = -\xi|\dot{E}|, \qquad \xi \geq 0.$$

MODELLING OF FERROELECTRICS

Look at time intervals where $\dot{E} \neq 0$. It follows

$$\frac{\dot{P}}{\dot{E}} = -\frac{P + \partial_E\Phi}{\partial_P\Phi} - \frac{\xi}{\partial_P\Phi}\mathrm{sgn}\dot{E}.$$

Except at stationary points we can write

$$\frac{dP}{dE} = \chi_1 + \chi_2\mathrm{sgn}\dot{E}, \qquad \chi_1 = -\frac{P + \partial_E\Phi}{\partial_P\Phi}, \quad \chi_2 = -\frac{\xi}{\partial_P\Phi},$$

χ_1, χ_2 being functions of P, E and θ. Paraelectric materials are viewed as those with $\chi_2 = 0$; hence χ_1 is the positive slope of the polarization curve, that is the differential susceptibility. We then require that $\chi_1 > 0$, $|\chi_2| \leq \chi_1$.

To determine χ_1 and χ_2 we start from a characteristic non-decreasing function $\mathcal{P}$ (anhysteretic function) such that $P = \mathcal{P}(E) \iff \chi_2 = 0$. As a consequence, once a free enthalpy function Φ is chosen, the anhysteretic curve is given by

$$\frac{dP}{dE} = -\frac{P + \partial_E\Phi}{\partial_P\Phi} = \chi_1 =: g(E) \geq 0.$$

*Corresponding author. E-mail: angelo.morro@unige.it

Owing to the counterclockwise property of ferroelectric cycles the function χ_2 is required to satisfy

$$\chi_2(E,P) >=< 0 \quad \Longleftrightarrow \quad P >=< \mathcal{P}(E).$$

For definiteness let $\Phi(P,E) = \mathcal{L}(P-\mathcal{G}(E)) + \mathcal{F}(E) - PE$ where $\mathcal{F}, \mathcal{G}, \mathcal{L}$ are undetermined functions. By definition

$$\chi_1 = \frac{\mathcal{L}'(P-\mathcal{G}(E))\mathcal{G}'(E) - \mathcal{F}'(E)}{\mathcal{L}'(P-\mathcal{G}(E)) - E}, \qquad \chi_2 = -\frac{\xi}{\mathcal{L}'(P-\mathcal{G}(E)) - E}.$$

Letting $\chi_1 = g(E)$ we find $\mathcal{G}' = g, \mathcal{F}' = Eg$. To determine $\mathcal{L}$ we require $\chi_2[P-\mathcal{P}(E)] \le 0$, whence, since $\xi \ge 0$,

$$\frac{P-\mathcal{P}(E)}{\mathcal{L}'(P-\mathcal{G}(E)) - E} \ge 0.$$

Hence we let

$$\mathcal{L}'(P-\mathcal{G}(E)) = \alpha[P-\mathcal{G}(E)], \mathcal{P}(E) = \mathcal{G}(E) + E/\alpha.$$

As an example,

$$\Phi(P,E) = (\alpha/2)(P-\mathcal{G}(E))^2 + \mathcal{F}(E) - PE,$$

$$\mathcal{G}(E) = \int_0^E g(y)dy, \qquad \mathcal{F}(E) = \int_0^E y\, g(y)dy,$$

$$\chi_1 = g(E), \quad \chi_2 = -\frac{\xi}{\alpha[P-\mathcal{P}(E)]}, \quad \mathcal{P}(E) = \int_0^E [g(y) + 1/\alpha]dy.$$

Consistent with the meaning of anhysteretic differential permittivity, we let $g(E) \to 0$ as $|E| \to \infty$. The model is complete once g and ξ are selected.

Since the hysteretic behaviour occurs below the Curie temperature, $\theta_{\mathcal{C}}$, we let

$$\xi = \gamma(E,P)h(\theta),$$

where $h(\theta) = \max\{0, 1-\theta/\theta_{\mathcal{C}}\}$ and hence $h \to 0$ as $\theta \to \theta_{\mathcal{C}}$ from below. Among the possible functions γ we select $\gamma(E,P) = \gamma_0 g(E)[P-\mathcal{P}(E)]^2, \qquad \gamma_0 > 0$, where $g(E) = \mathcal{P}'(E) - 1/\alpha$. Let $\gamma_h(\theta) = \gamma_0 h(\theta)$; it follows that

$$\frac{dP}{dE} = g(E)[1 - \tau_h(P-\mathcal{P}(E))\mathrm{sgn}\dot{E}], \qquad \tau_h = \gamma_h/\alpha > 0.$$

Some hysteresis cycles are shown.

CONCLUSIONS

The same approach seems to be applicable to ferromagnetism, thus improving previous models [1, 2]. A further investigation is in order to apply the present ideas to plasticity.

VIBRO-IMPACT SELF-PROPELLED CAPSULE IN MILLIMETRE-SCALE

Yang Liu*[1], Jiajia Zhang[1], Jiyuan Tian[1] Bingyong Guo[1], and Shyam Prasad [2]
[1] College of Engineering, Mathematics and Physical Sciences, University of Exeter, Exeter, UK
[2] Endoscopy Unit, Royal Devon and Exeter NHS Foundation Trust, Exeter, UK

Summary This work will study the prototype design of a vibro-impact self-propelled capsule endoscope for small-bowel diagnosis. Inspired by the nonlinear dynamics of nonsmooth dynamical systems [1], self-propulsion of a capsule endoscope can be achieved by employing an internal vibrational mass interacting with the main body of the capsule. In this work, we will show that the proposed concept has been implemented at the standard dimension of a market-leading capsule endoscope [2], which is 11 mm in diameter and 27 mm in length.

INTRODUCTION

Capsule endoscopy [3] has become established as the primary modality for examining the small intestinal mucosa. However, its reliance on peristalsis for passage through the intestine may cause variable locomotion speeds, which can result in incomplete visualisation of the mucosa and potentially missed pathology. Therefore, the current design is considered both time-consuming and burdensome for clinicians. Researchers have developed different propulsion methods for capsule endoscopy, and among many of them, the system driven by autogenous interactive forces using magnetic actuation [4] is a promising solution. In order to validate this concept, a millimetre-scale prototype of the capsule system will be presented in this paper.

THE PRINCIPLE, PROTOTYPE DESIGN AND EXPERIMENTAL SETUP

Physical model of the system and its prototype are presented in Fig. 1, where the rectilinear motion of the capsule is generated using a periodically driven permanent magnet (excited by external magnetic field) interacting with the capsule's main body as a hammer via the primary and the secondary constraints, in the presence of intestinal resistances. The external magnetic field is excited by a pulse-width modulation (PWM) signal, and the capsule can perform forward and backward progression by adjusting the amplitude, the frequency, and the duty cycle of the PWM signal.

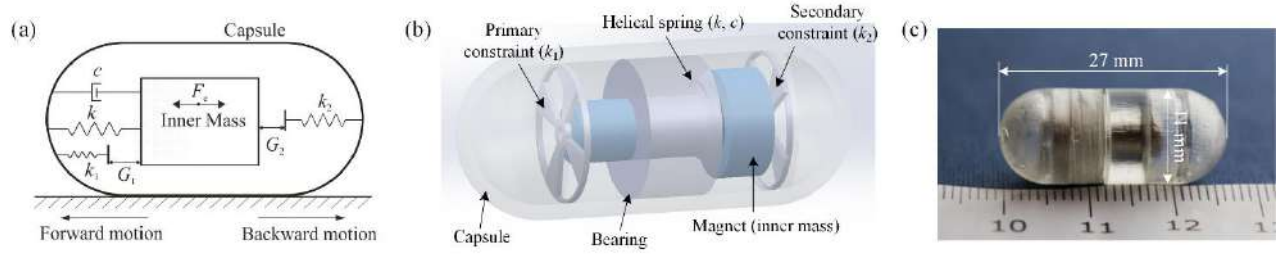

Figure 1. (a) Physical model, (b) conceptual design, and (c) 3D-printed prototype of the vibro-impact self-propelled capsule.

Schematics of the experimental setup and its photograph are shown in Fig. 2(a) and (b), respectively, where the coils are controlled by a drive circuit triggered by a pulse-width modulation (PWM) signal. A video camera was used to record the locomotion of the capsule, and the recorded video clip was analysed by using Tracker [5], a real-time tracking software for visualising the time histories of capsule's displacement as illustrated in Fig. 2(c) and (d).

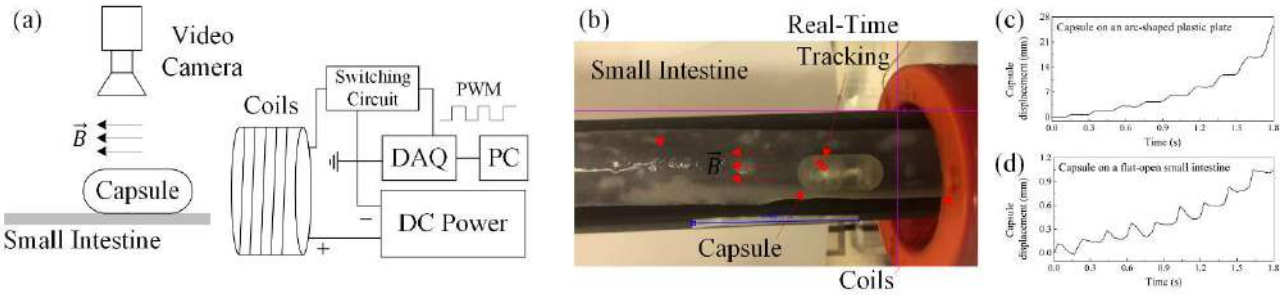

Figure 2. (a) Schematics and (b) photograph of the experimental setup. Time histories of capsule's displacement (c) on an arc-shaped plastic plate and (d) on a flat-open small intestine.

DYNAMIC IMPACT OF A CERAMIC SKELETON OF INTERPENETRATING PHASE COMPOSITES

Eligiusz Postek *[1], Tomasz Sadowski[2], Jarosław Bieniaś [2], Marek Boniecki[3]
[1] Institute of Fundamental Technological Research, Polish Academy of Science, Warsaw, Poland
[2] Department of Civil Engineering and Architecture, Lublin University of Technology, Lublin, Poland
[3] Institute of Electronic Materials Technology, Warsaw, Poland

Summary The paper presents modelling of a ceramic foam that works as skeleton of Interpenetrating Phase Composites (IPCs) before filling the preforms. The preforms are made of SiC or Al_2O_3. A dynamic analysis of an impact of such skeletons against rigid surface is performed. The results of the quasi-static analysis will serve as a reference to the dynamic analyses. The analysis of the IPCs skeleton is performed due to evaluation of the role of the skeleton in final product that is the filled IPCs.

INTRODUCTION AND MOTIVATION

Contemporary ceramic composites are used in many industries of strategic importance, such as the armaments industry, aviation, automotive [1] nuclear power [2] or space exploration, while in other areas they constitute the main source of technical progress [3]. In these applications, the material is often subjected to extreme loads, such as variable shock loads and high temperatures. In the presentation, we explore the degradation of an IPC skeleton.

In the last twenty years, the peridynamics that is a meshless non-local has been developed [4]. The method appears to be useful in analysis of brittle materials. The Metal-Ceramic composites are analysed in [5]. Metallic foams are analysed in [6].

NUMERICAL MODELLING

Problem statement

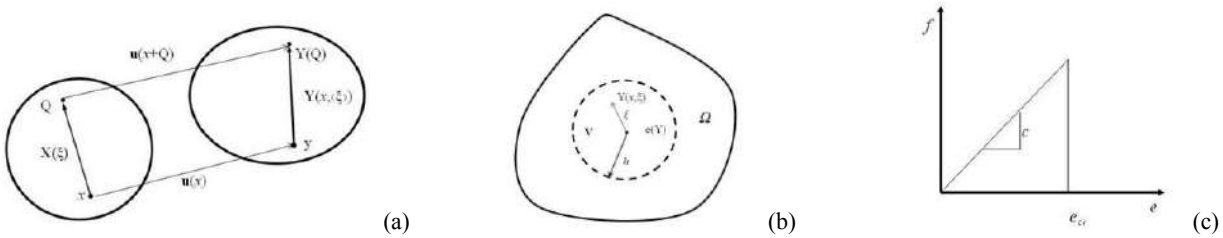

Figure 1. Peridynamics: state of deformation (a), integration over horizon (b), dependence of a force on stretch in a single bond (c).

When observing Fig. 1(a), x and Q are points in the undeformed body. It is a bond definition, $\xi = Q - x$. A reference state $\mathbf{X}$ is a function that acts on a bond, $\mathbf{X}(\xi)$. The deformation state depends on the new position of the coordinate x in the deformed configuration $y(x)$) as follows,$\mathbf{Y}(x, \xi) = y(x + \xi) - y(x)$. It yields $\mathbf{Y}(x, \xi) = y(Q) - y(x)$. The displacement state $U(x, \xi) = \boldsymbol{u}(x + \xi) - \boldsymbol{u}(\xi)$ yields $U(x, \xi) = \boldsymbol{u}(Q) - \boldsymbol{u}(x)$. Following Fig. 1(a), the scalar extension state $e(\boldsymbol{Y})$ is given as follows:

$$e(\mathbf{Y}) = |\mathbf{Y}| - |\mathbf{X}|$$

The scalar extension state is decomposed into its spherical e^i and deviatoric e^d parts:

$$e = e^i + e^d$$

The elastic force state $t(Y)$ is given in the form analogous to standard stress strain relation being the sum of the spherical and deviatoric parts as follows:

$$t(Y) = (3k\theta/m)\omega\underline{x} + \alpha\omega e^d$$

where k is the bulk modulus, θ is the dilatation, m is the weighted volume, ω is the influence function, $x = |\xi|$ is the basic scalar state, α is the coefficient related to the shear modulus $\alpha = (15\mu)/m$ where μ is the shear modulus.

The assumptions for the material failure model are as follows [7]. Bonds fail when their extension exceeds a critical value. Damage is caused by accumulation of broken bonds. Bonds failure is irreversible. A scheme for a single bond is shown in Fig 1(c) . The integration is over a domain V for all bonds. The dependence of force on its stretch in a bond is given in Fig. 1(b). It reads:

$$f = ce\zeta$$

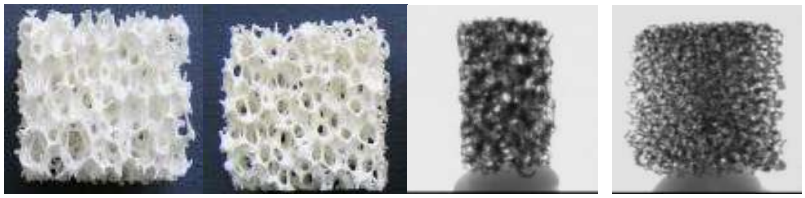
where c is a constant depending on bulk modulus k and radius of the horizon h, $c = (18k)/(\pi h^4)$. Function is history dependent (time t) and takes value 1 when bond stretch is lower than critical stretch ζ or 0 otherwise. The damage d is defined s follows:

$$d(x,t) = 1 - \int_V \zeta(x,t,\xi)dV \Big/ \int_V dV$$

where *d* varies between 0 for primordial material and 1 for fully damaged material.

Physical model

The AL_2O_3 preforms are shown in Fig. 2(a) and Fig 2(b). The performs are of large pores and small pores, respectively. To obtain a numerical model, the CT scans of the performs are performed. The scans are shown Fig. 2(c) and Fig. 2(b). Basing on the CT scans, the hexadral discretizations are obtained. The initial discretizations stands for a base of finite element an peridynamics numerical models.

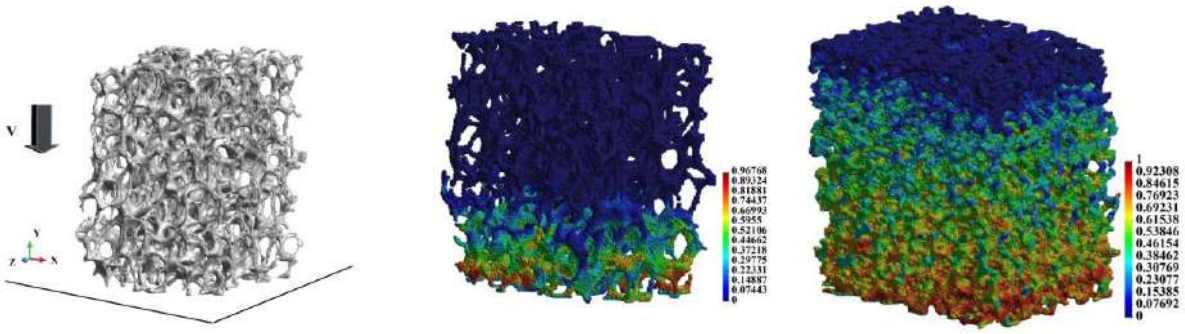


(a) (b) (c) (d)

Figure 2. Physical model: large pores sample (a), small pores sample (b), CT scan of large pores sample (c), CT scan of small pores sample.

Numerical model

The peridynamics models of the large and small pores samples are shown in Fig. 3. The impact scheme against the rigid surface is shown in Fig. 3(a). In this case, the impact velocity is 100 m/s. The damage development is shown in Fig. 3(b) and Fig 3(c) at time 9.5E-07 s. The difference in the range is clearly visible, the small pores sample is significantly more damaged than the large pores sample. The small pore sample is practically damaged in contrast to the large pores sample.



(a) (b) (c)

Figure 3. Damage distribution, impact velocity 100 m/s: a) impact scheme, b) large pores case, c) small pores case.

CONCLUSION AND FINAL REMARKS

We presented an application of peridynamics method for damage evaluation of the IPC skeleton. The damage development depends on porosity of the preforms strongly. It will be reflected in the final product as well. The calculations of the systems practically cannot be performed without application of High Performance Computing (HPC).

Summary Mode localization is explored in a weakly mechanically coupled system comprising of two doubly-clamped microbeams mechanically linked with a coupling beam close to the anchors. The phenomenon is explored among the lower and higher order modes of vibration. An eigenvalue analysis is performed under different side-electrodes bias scenarios. A forced vibration analysis is then carried out to study the response of the system under different perturbation scenarios.

INTRODUCTION

The phenomenon of mode localization [1] in micro and nanoelectromechanical systems (MEMS and NEMS) coupled structures has emerged as a promising technology toward developing highly sensitive micro and nano sensors [2]. Various investigations have been carried out to understand mode localization and associated eigenvalue curve veering (avoided-crossing) [3], and exploit them for different sensing applications [2, 4]. This work focuses on investigating the dynamic characteristics of a MEMS coupled system exhibiting localization and veering at the higher order modes. This work aims to reveal the rich dynamics of the coupled systems at higher order modes and their potential towards developing highly sensitive MEMS sensors [5].

MECHANICALLY COUPLED MEMS RESONATOR DESIGN

A mechanically coupled MEMS resonator, Fig. 1, is designed through coupling two identical doubly-clamped primary (input and output) microbeams connected by a third (coupling) secondary microbeam. All the beams are assumed uniform and of rectangular cross-sectional shapes. Each primary microbeam is actuated by an electrode of identical dimensions located underneath it.

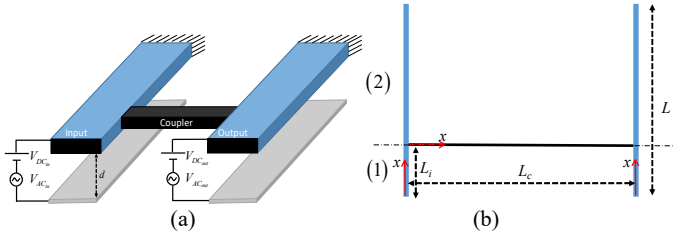

Figure 1. (a) 3D and (b) (2D) schematic of two doubly-clamped microbeams mechanically coupled through a third microbeam.

Table 1. Case Study

Parameter	Respective Value
Primary Microbeams Length L	600 μm
Primary Microbeams Width b	30 μm
Microbeams Thickness h	3 μm
Coupling Location	Vary
Coupling Microbeam Length L_c	300 μm
Coupling Microbeam Width b_c	10 μm
Electrodes Initial Gaps d	8 μm
Microbeams Young's Modulus E	169 GPa
Microbeams Mass Density ρ	2320 kg/m^3

FREE & FORCED VIBRATION ANALYSIS

First, the linear natural frequencies and mode shapes of the system consisting of two clamped-clamped microbeam (primary beams) coupled mechanically by a third microbeam (the coupler), Fig. 1, are computed. Then, the free vibration of the coupled resonator through solving both the eigenvalue problem with a linearized DC load electric forces only as well as the nonlinear dynamical responses of the resonator under DC and AC harmonic loads is investigated. Finally, we simulate the frequency-response curves of the mechanically coupled MEMS resonator when excited through its input microbeam by a DC load superimposed to an AC harmonic load of frequency near its lower and higher modes. In the dynamic analysis, long-time integration of the reduced-order model to obtain steady-state solutions needed to generate the frequency response curves of the coupled system is conducted.

SIMULATIONS & DISCUSSION

The variation of the eigenvalues (global natural frequencies of the system) considering different scenarios of the coupling location in order to capture the frequencies curve veering is first investigated. Figure 2 show the effect of varying the input microbeam static electrostatic load, assuming zero DC load on the output microbeam, on its lower: first/second (1/2) natural frequencies. Various coupling locations are chosen for different pair of modes for clear depiction of the mode localization phenomenon. One can clearly notice that the pairs of frequencies (1/2) do not intersect, their variation with the DC load simply showing two possible veering regimes near zero voltages, and then afterward at higher voltages that push up the lowest frequency due to the stretching effect toward the higher one. This portrayed veering phenomenon gets more and more distinctive as the coupling strength is further reduced to lower values among all lower and higher order modes. Coupling strength here is reduced as the coupling beam is moved closer to the anchor. It is observed that very weak coupling is required in order to notice these curve veering zones for higher-order modes, Figure 2.

Next, we explore the effect of the output microbeam electrode DC load $V_{DC,out}$ on the veering zones of the first/second frequencies pair, Figure 3. It is observed that through the DC bias of both input and output microbeams can be used as two independent tuning parameters that can shift the two veering zones upward or downward. The first veering zone

*Corresponding author. E-mail: mohammad.younis@kaust.edu.sa

(around small input beam DC load) whereas and the second veering zone (around higher input beam DC load) both show that the veering point frequency decreases with the increase of the output beam DC load.

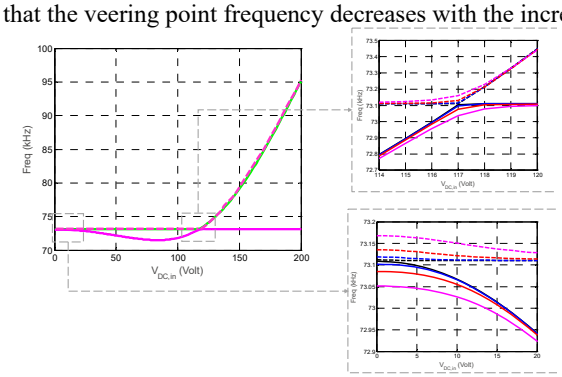

Figure 2. Variation of the first (continuous lines) and second (dashed lines) natural frequencies of the coupled resonator with $V_{DC,in}$ showing two veering zones and for: Black (L_c=20 μm), Blue (L_c =30 μm), Red (L_c =40 μm), and Magenta (L_c =50 μm).

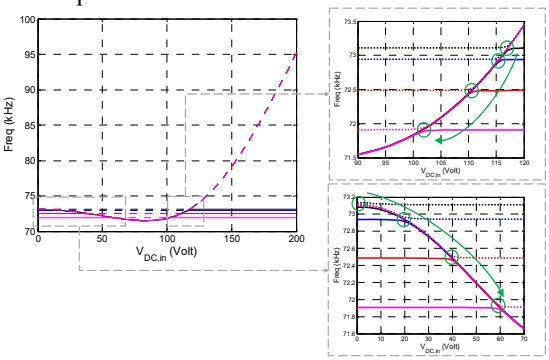

Figure 3. Variation of the first (continuous lines) and second (dashed lines) natural frequencies of the coupled resonator as varying the input bias voltage for L_c =40 μm and for: Black ($V_{DC,out}$ =0 Volt), Blue ($V_{DC,out}$ =20 Volt), Red ($V_{DC,out}$=40 Volt), and Magenta ($V_{DC,out}$ =60 Volt).

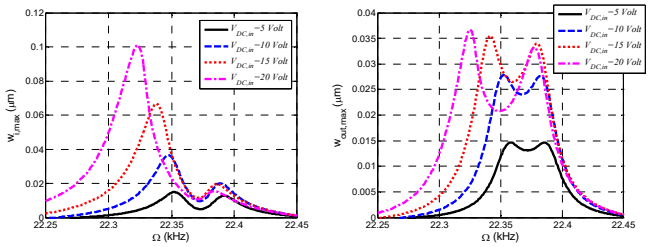
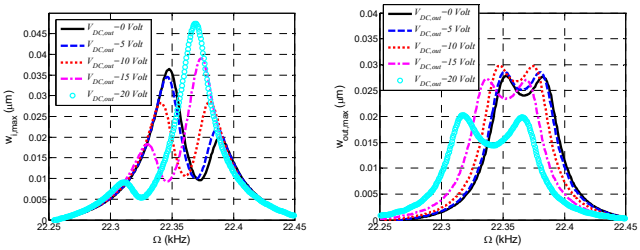
Next, we only consider the effect of the input beam DC bias. Figures 4a, and 4b show the steady-state dynamic frequency responses of the input beam and output beam, respectively, for different input beam DC load conditions as its AC input frequency is swept around the first and second global modes of the coupled resonator. It can be seen from Figure 4a that both pair of modes (1/2) show almost same amplitude for a small input DC load (at the first veering zone). Then as $V_{DC,in}$ is gradually increased, the modes start to exhibit localization. A stronger localization is observed in the first mode, where, more energy is confined into the input resonator, Figure 4a, which as a result vibrates with an amplitude much higher than the output beam. The localization becomes stronger for higher perturbation caused by high $V_{DC,in}$, Figure 4a. However, a slighter localization is observed in the second mode of vibration, where the energy is localized into the output resonator compared to the input resonator, Figure 4b. This is more evident for the case of $V_{DC,in}$ =20V in Figure 4.

Finally, we consider the case of direct excitation of the input beam (constant input DC load and varying AC input excitation frequency), and with perturbing the output beam overall stiffness through applying an output bias DC voltage, $V_{DC,out}$. Figures 5a shows that initially as the $V_{DC,out}$ is set to zero, the coupled system already exhibits localization due to the presence of $V_{DC,in}$. However, as $V_{DC,out}$ is increased, a similar localization behavior is observed, but now, the two modes swapped their roles, where second mode shows stronger localization compared to the first mode, Figure 5a (black).



(a) Input Microbeam (b) Output Microbeam

Figure 4. Simulated frequency response curves of the mechanically coupled resonators of the coupled resonator with the actuating frequency swept around the pair of modes (1/2) assuming coupling location at 50 μm and with various DC bias voltages of the input resonator. Assumed parameters are $V_{AC,in}$=0.05 Volt, $V_{DC,out}$=0 Volt, and Q=500.



(a) Input Microbeam (b) Output Microbeam

Figure 5. Simulated frequency response curves of the mechanically coupled resonators of the coupled resonator with the actuating frequency swept around the pair of modes (1/2) assuming coupling location at 50 μm and with various DC bias voltages of the output resonator. Assumed parameters are $V_{DC,in}$= 10 Volt, $V_{AC,in}$=0.05 Volt, and Q=500.

CONCLUSIONS

In this work, a basic research of the phenomenon of mode localization was examined theoretically for mechanically coupled microbeams based MEMS resonator at lower and higher modes. It was observed from the eigenvalue problem that by controlling the coupling strength and location and strength of perturbation, the veering zones and their respective localization characteristics (frequency and amplitude) can be altered. Furthermore, the forced vibration analysis using frequency response curves shows that in order to exploit the phenomenon of mode localization, the choice of the resonator under excitation and the coupling beam location is extremely important. Finally, findings of this study encourage experimental research into the performance parameters, like sensitivity and resolution, for utilizing mode localization at higher order modes for developing smart sensors.

A THIN STRIP MECHANISM WITH NEGATIVE TORSIONAL STIFFNESS AND VARIABLE COMPRESSIVE STIFFNESS

Jinyou Li[1], Kangjia Fu[2], Yongpeng Gu[1], and Zhihua Zhao *[1]
[1] School of Aerospace Engineering, Tsinghua University, Beijing, China
[2] National Innovation Institute of Defense Technology (AMS), Beijing, China

Summary Negative stiffness mechanisms have great potential in different fields, such as vibration isolation, energy absorption and mesh antenna unfolding. In this study, inspired by a toy, we developed a novel type of compliant mechanism composed of thin strips, possessing negative stiffness property under torsion [1], while its compressive stiffness along the Z direction also varies with the torsion angle. Demonstrated with examples, it was shown that the proposed mechanisms could be combined to realize unusual torque-angle or variable force-displacement relationships, which can be used in different applications.

INTRODUCTION

Negative stiffness mechanisms that have great potential in different fields can be achieved in an active or passive way, in which the active way requires sensors and sophisticated control systems, making it more challenging in terms of size, cost and reliability. As for passive way, although numerous compliant mechanisms have been implemented in literature, few of them are designed based on structural or topological optimization, and the obtained structure is usually complex. Undoubtedly, there remains a number of unknown simple structures that can generate negative stiffness, and proposing an original design strategy may open a new avenue for the future inventions.

In this study, inspired by a toy that can be considered as a compliant mechanism named as “happy twist”, whose structure is pictured in Fig.1(A), we developed a novel type of compliant mechanism composed of thin strips, possessing negative stiffness property under torsion, while its compressive stiffness also varies with the torsion angle. Unlike most previous designs, which utilize planar curve beams and/or mechanical buckling, the proposed design is based on spatial curved beams and involves no buckling at all.

PARAMETRIC ANALYSIS OF THE CONFIGURATION

Figure 1(B) sketches the proposed compliant mechanism, which is a rotational symmetric assembly composed of several identical flexible strips and two rigid discs, in which the bottom disc is fixed on the ground, and the top disc is allowed to rotate but not to translate along the global Z-axis. For simplicity, the illustrated mechanism has three strips pre-stressed into a semicircle shape. The geometry of the proposed mechanism is fully depicted by four parameters – the disc radius r, the radius of the strip centerline R, the width b, and the thickness t of the rectangular cross section.

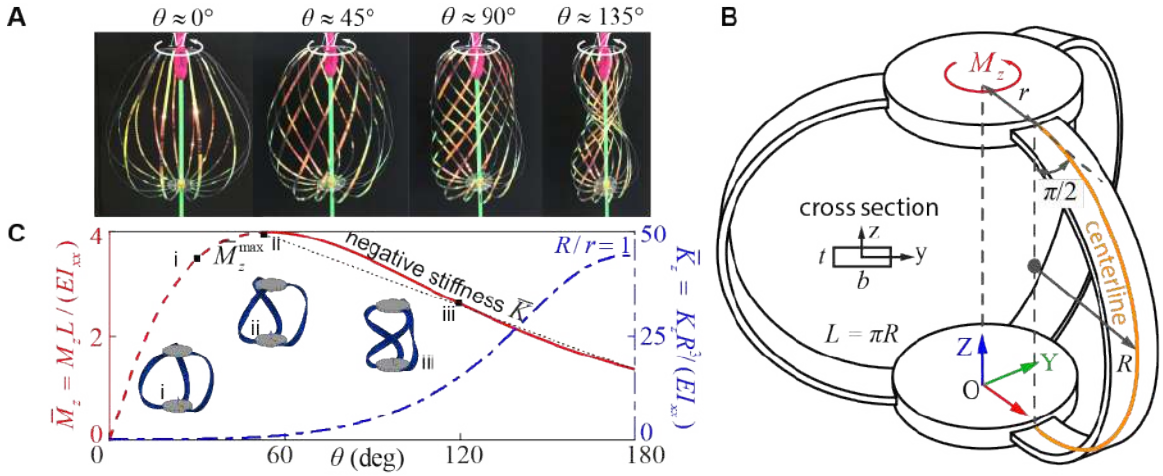

Figure 1: Compliant mechanism composed of thin strips.

To quantitatively describe the negative stiffness property, a numerical model was built based on our lab’s in-house code of flexible multibody dynamics [2]. Strips were uniformly meshed by geometrically-exact beam elements, whose deformations were shown in Fig. 1(C), and the torque $M_z(\theta)$ equaled the rotating reaction torque divided by the number of strips, the compressive stiffness $K_z(\theta)$ obtained the same way. The calculated $\bar{M}_z$ and $\bar{K}_z$ versus θ curve is plotted

*Corresponding author. E-mail: zhaozh@tsinghua.edu.cn

for $\theta \in [0, 180°]$, in which the nondimensionalized torque is defined as $\bar{M}_z \triangleq M_z L/EI_{xx}$, and the nondimensionalized axial stiffness is defined as $\bar{K}_z \triangleq K_z R^3/EI_{xx}$.

For a single strip of the designed mechanism, torque $M_z(\theta)$ and stiffness $K_z(\theta)$ are both functions of E, r, R, b and t, totally five mechanical and geometrical variables. The relationships between them and these parameters were analyzed through numerical simulations based on the well-known Buckingham π theory, whose results reveal that both relationships do not depend on t/r, weakly rely on b/t especially when $b/t > 10$, but vary significantly with different R/r. Thus, as an appropriate approximation, $\bar{M}_z(\theta)$ and $\bar{K}_z$ are sufficient to be considered as functions of R/r only. $\bar{K}_z$ varies in different trends with the value of R/r, which could be designed for different aims, and the negative stiffness of the torque from $\theta_{\max}$ to 180°, defined as $\bar{K}$, could be directly expressed as $\bar{K} = -0.409 - 1.658(R/r)^{-1.058}$.

SYNTHESIZED MECHANISMS FOR APPLICATION

Based on the proposed strip mechanism, unusual mechanisms could be constructed by combining it with other mechanisms in series or parallel. The mechanism shown in Fig. 2(A) is an example of the proposed strip mechanism in parallel with a helical spring. As shown in Fig. 2(B), the solid black line representing the total output of the elemental mechanism and the helical spring, gives a nearly constant torque within a certain range to produce a quasi-zero-stiffness mechanism, which has been frequently used in vibration isolation and energy absorption. Similarly, the mechanism in Fig. 2(C) is a series combination, which has lower positive stiffness but higher negative stiffness than the elemental mechanism alone, as shown in Fig. 2(D). As for the array mechanism in Fig. 2(G), its frame structures connecting the two-layer mechanisms can convert press into rotation, as shown in Fig.2(E)(F), so as to dynamically change compressive stiffness during the pressure process, which might be utilized to obtain gradient material to dynamically adjust the waveguide for acoustics.

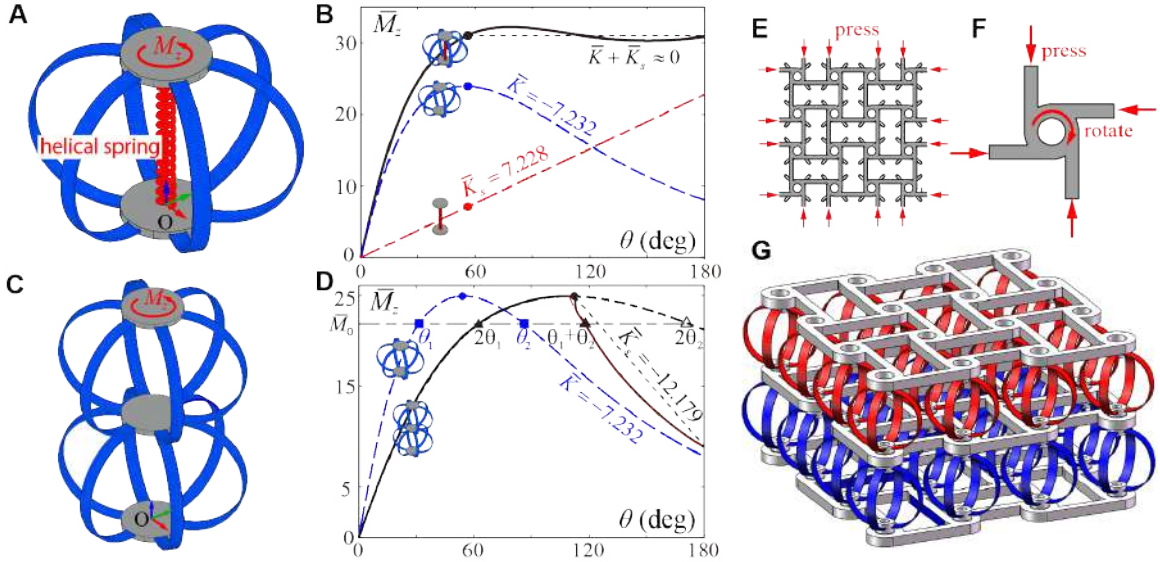

Figure 2: Synthesized mechanisms with unusual torque-angle relationships and adjustable compressive stiffness.

CONCLUSIONS

A novel type of compliant mechanism composed of thin strips was designed inspired by a toy named as “happy twist”. It generates negative torsional stiffness and variable compressive stiffness based on the spatial curved beams, which could be considered as a new path on designing mechanisms and might have application significance in different fields.

ANALYSIS OF COUPLED BENDING-TORSION VIBRATION OF A RUB-IMPACT ROTOR SYSTEMS WITH GEAR COUPLING

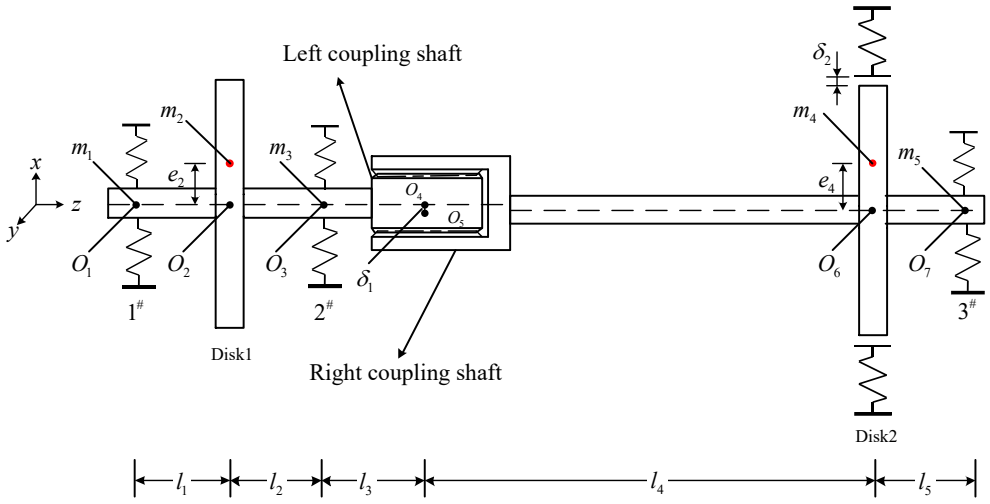
Yuanhang Hou [1 2 3], Shuqian Cao *[1 2 3]
[1] Department of Mechanics, Tianjin University, Tianjin 300354, China
[2] Tianjin Key Laboratory of Nonlinear Dynamics and Control, Tianjin 300354, China
[3] National Demonstration Center for Experimental Mechanics Education, Tianjin University, Tianjin 300354, China

Summary The gear coupling is an important connection structure for aero-engines. While transmitting torque, it can also compensate for the axis of the two rotors being parallel to each other or being at different angles. Tooth side clearance between gear coupling is a key assembly feature parameter that affects the quality of the gear teeth. Reasonable backlash value is very important to reduce the vibration of the engine and improve the reliability of the aero engine.

INTRODUCTION

With the mass imbalance of the rotor and the backlash of the gear coupling considered, the bending-torsional coupling vibration response of the rotor system under rub-impact is studied in this paper. Firstly, the motion equation of bending-torsional coupling is derived from the Lagrange method of rub-impacting rotor system Then its nonlinear vibration features, such as the frequency spectra, poincaré section，and rotor orbit is primarily analyzed based on numerical techniques.

THE ROTOR MODEL OF THE GEAR COUPLING IS CONSIDERED



In this paper, the dynamic model of rotor system with gear coupling is established by using Lagrange equation.

$$M\ddot{q} \quad C\dot{q} \quad Kq \quad G + F_u + F_r + M$$

Among them, M , C , K , and are generalized mass matrix, damping matrix and stiffness matrix respectively; F_r is the rubbing force vector, G is the generalized gravity vector and F_u is the unbalanced vector.The driving torque of the turbine and the load torque of the compressor are considered, and the two are considered to be equal and opposite in steady motion.Obviously, the coupling of centroid coordinates and torsional coordinates in the unbalanced vector results in the coupled vibration of bending and torsional.

In the modeling of the gear coupling, the tooth side clearance of that is taken into account, and the nonlinear relationship between torque and torsion angle is obtained as follows:

$$f(u) = \begin{cases} u + cl & u < -cl \\ 0 & -cl < u < cl \\ u - cl & u > cl \end{cases}$$

Among them,u,cl3are torsion angle and tooth side clearance of gear coupling.

MINI SYMPOSIA

CONCLUSIONS

The torsional stiffness of the system changes with the change of system load due to the existence of the tooth side clearance of the gear coupling, and the torsional vibration of the system has a rich frequency response at low speeds. As the speed increases, the influence of the tooth side clearance of the sleeve coupling on the vibration response of the system gradually decreases.

NONPLANAR NONLINEAR VIBRATIONS OF AN IMPERFECT ELECTRICALLY ACTUATED BEAM

Kaio César Borges Benedetti and Paulo Batista Gonçalves*
Department of Civil and Environmental Engineering, Pontifical Catholic University, PUC-Rio, Rio de Janeiro, 22451-900, Brazil

Summary The last decades have witnessed a growing interest in the nonlinear dynamics of microelectromechanical systems (MEMS), in particular microbeams. In the analysis of the latter structures it is usually assumed that the beam is perfect and displays a planar behavior. The aim of the present work is to study the nonlinear nonplanar vibration of a clamped-free imperfect microbeam subjected to electrostatic and electrodynamic actuation and evaluate how the flexural–flexural–torsional motions are affected by the imperfections and external load. To describe the nonlinear vibrations of the system, nonlinear integro-differential equations of motion, including geometric, inertial and load nonlinearities, are adopted. A detailed parametric analysis shows the influence of imperfections on the structural response.

INTRODUCTION

The analysis of MEMS and NEMS under electrostatic and electrodynamic forces is a promising research area, which has been active for a few years [1]. These devices have beam used in filtering, communications, mass/gas sensing, signal processing, energy harvesting and sensors/actuators applications. Among MEMS devices slender microcantilevers have beam applied successfully in many engineering fields. However, this is an inherently nonlinear problem where instability can have either negative or positive effects on the structural response. This work aims to investigate the nonlinear static response and nonlinear nonplanar vibrations of an imperfect microbeam under electrical actuation in the main resonance region.

FORMULATION AND RESULTS

In order to analyze the nonplanar vibrations of the cantilever beam, the formulation proposed by Crespo da Silva and Glynn [2] for an inextensible beam, considering both geometric and inertial nonlinearities, based on Bernoulli-Euler hypotheses, is adopted, enabling the analysis of different types of internal resonances [3]. The formulation is modified to include the effect of initial geometric imperfections. The beam is subjected to an electric force $V \equiv V_{dc} + V_{ac}(t)$ where V_{dc} is the electrostatic voltage induced by the potential difference between the beam and the electrode and $V_{ac}(t)$ is the electrodynamic harmonic force. The distributed force and torque, considering a beam with a rectangular cross-section, are obtained by applying the classical parallel plate capacitor formulation [4]. They are written in terms of the flexural and torsional displacements and imperfection magnitudes. The linear flexural and torsional vibration modes are used as interpolation functions and the Galerkin projection is applied to obtain a reduced order model composed of a set of nonlinear coupled ordinary differential equations in terms of the modal amplitudes. Although the beam dynamics can be linearized considering small displacement and rotations, the applied forces are inherently nonlinear. The electrostatically actuated beam nonlinear response and pull-in instability are significantly affected by imperfections in the form of the flexural and torsional vibration modes. Fig. 1(a) displays the nonlinear static response of the electrostatically actuated imperfect cantilever for selected values of the angular imperfection γ_0. Up to four stable and three unstable solutions are obtained. These solutions are only physically meaningful for static deflections $w_s < 0.4$ and torsional amplitudes $|\gamma_s| < 0.026$, with the system pull-in occurring for higher displacements. The bifurcation diagrams of the dynamically excited beam are obtained using a continuation arc-length method at different actuation voltage levels and imperfections and instability and the corresponding bifurcation type are identified by the use of Floquet theory. Fig. 1(b) shows the resonance curves of the imperfect beam under alternating current for selected values of the forcing magnitude λ with an imperfection in the form of the flexural mode. The resonant response displays a softening behavior. In the main resonance region (at $\Omega/\omega_w=1.0$), a saddle-node bifurcation occurs along the non-resonant branch and a period-doubling bifurcation occurs along the resonant branch, leading to jumps in the beam response. A similar bifurcation pattern occurs at $\Omega/\omega_w=0.5$. A detailed parametric analysis is conducted, in order to highlight the effect of each parameter on the resonant dynamics of the system. Since the shape and magnitude of the imperfections are not known a priori, the influence of their uncertainties on the beam response is also evaluated.

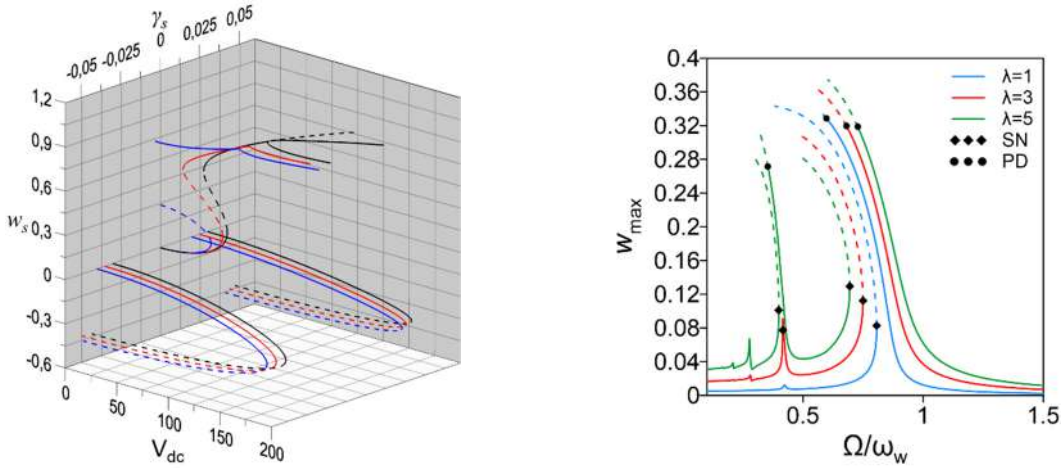

Figure 1. (a) Nonlinear static response of the electrostatically actuated imperfect cantilever (— perfect; — $\gamma_0 = 0.005$; — $\gamma_0 = 0.01$) ; (b) resonance curves of the imperfect beam under alternating current for selected values of the forcing magnitude λ with $V_{dc}=42, w_0=0.1, \gamma_0=0$ - SN: saddle-node bifurcation, PD: period-doubling bifurcation.

NONLINEAR VIBRATION RESPONSE AND BIFURCATION ANALYSIS OF FUNCTIONALLY GRADED MATERIAL PIEZOELECTRIC CYLINDRICAL SHELLS

Yunfei LIU *, Zhaoye QIN, and Fulei CHU
State Key Laboratory of Tribology, Department of Mechanical Engineering, Tsinghua University, Beijing. P.R. China

Summary The nonlinear forced vibrations of functionally graded material (FGM) piezoelectric cylindrical shells under multi-physics fields are studied. The FGM piezoelectric shells are subjected to electric-thermo-mechanical loads, and the porosity effect is considered here owing to the technical issues during the preparation of FGMs. An energy approach based on the Hamilton's principle is utilized to gain the nonlinear equations of motion. Afterwards, the Galerkin method is employed to transform the governing equations into multi-degree-of-freedom nonlinear ordinary differential equations, and subsequently the bifurcation analysis is conducted by using the pseudo-arclength continuation method. The effects of different parameters on the nonlinear dynamic response are investigated in this study.

INTRODUCTION

Piezoelectric materials, as a unique kind of smart materials, can generate electric fields due to mechanical deformation and also can cause mechanical deformations because of the electric fields' action. The inherent mechanical-electrical coupling effect of piezoelectric materials make them widely applied in engineering. Functionally graded piezoelectric materials (FGPMs) consist of two or more constituent phases with a continuous variation of material properties from one surface to another. As a consequence, FGPMs could solve the problems found in the traditional laminated composite materials such as matrix cracking, interlayer stress components jump, and interfacial debonding. Based on the above-mentioned advantages, a great deal of researchers studied the mechanical behavior of FGPM structures, while most studies only involve linear dynamics.

Investigation of the porosity effect, on the other hand, is limited in the literature. Owing to the technical issues during the preparation of FGMs, micro-voids or porosities usually occur within FGMs during the sintering preparation. The existence of micro-voids may change the structures' vibration frequency, reduce the mechanical strength, and even cause damage to the devices during operation. Therefore, in order to ensure the reliability of FGM structures, it is necessary to consider the porosity effect on vibration response at a design stage.

In practical engineering applications, the large amplitude vibration analysis is vital to assess the safety of structures, and several attempts have been made to obtain a solution for nonlinear vibration of structures [1–3]. It ought to be noted that, the nonlinear multiple internal resonance of piezoelectric materials, which may exhibit complex nonlinear dynamic responses, has not been studied in previous research.

Literature review shows that no study has been reported on nonlinear forced vibration and bifurcation analysis of FGM piezoelectric porous shells subjected to the electric-thermo-mechanical loads. Therefore, we focus on this novel issue and attempt to reveal the physics behind the numerical observations. The effects of different parameters on the nonlinear dynamic response are conducted in this study.

PROBLEM FORMULATION

Figure 1 presents a schematic diagram of FGM piezoelectric shells containing micro-voids. The material properties of the shells vary along the thickness direction, and the shells are subjected to electric-thermo-mechanical loads. It is assumed that micro-voids are dispersed evenly in the FGM structures here. The nonlinear governing equations are derived by using Donnell's nonlinear shallow-shell theory and Hamilton principle. Then, the system, a model involving forty-nine degrees of freedom, is discretized by the Galerkin method. Afterwards, the pseudo-arclength continuation method is employed to obtain numerical results.

Figure 3. Frequency-response curves versus external applied voltages (red line: driven mode; blue line: companion mode).

CONCLUSIONS

The results show that the external applied voltage, temperature change, external excitation, power-law exponent, and porosity volume fraction play important role on nonlinear vibration response and bifurcation analysis of the FGM piezoelectric cylindrical shells with micro-voids. The nonlinear multiple internal resonance exhibits complex dynamic behaviors, and the frequency-response curves with different parameters are obviously different. Branch Point cycle, Pitchfork, and Neimark–Sacker bifurcations of the forced vibration responses arising from internal resonances are detected, showing complex nonlinear dynamics.

OPTIMIZATION AND EVALUATION OF AM INFILL AND LATTICE STRUCTURES

Niels Aage[1], Morten Andersen[1], Jeroen Groen[1], Christian Rye Thomsen[2], Fengwen Wang[1], Yiqiang Wang[3], and Ole Sigmund *[1]
[1] Department of Mechanical Engineering, Technical University of Denmark, Lyngby, Denmark

Summary This paper discusses optimization and evaluation of Additively Manufactured structures with infill or composed of lattice structures from a mechanical perspective. Much work has been done analytically and numerically on identifying stiffness optimal open and closed-walled microstructures. Specifically, many different isotropic or cubic symmetric microstructures have been identified that achieve the theoretical optimum given by the Hashin-Strikhman bounds. However, much less work has been devoted to microstructures that are optimal for non-isotropic loadings or to microstructures that simultaneous to high stiffness also have high compressive yield strength. Here, we discuss these challenges seen from a topology optimization view point and with the aim of providing more insight into the appropriate choice of infill and lattice structures for Additive Manufacturing.

ABSTRACT

For weight saving and stabilization during manufacturing purposes, Additive Manufacturing (AM) often makes use of so-called infill material. Infill is more or less systematically repeated microstructure in the interior of an AM part. Often pre-processing software for AM allows control of the infill to a certain extent, but this is mostly limited to the choice between a few standard honeycomb types and the infill volume fraction. Mostly, however, infill is far from optimal with respect to stiffness or other physical properties and hence, much can be gained in terms of weight savings or even stiffness or strength improvements if the infill can be systematically optimized and manufactured.

On the other hand, the large geometrical freedom allowed by AM has spurred a surge in the use and manufacturing of lattice structures; either open – henceforth referred to as truss lattice structures (TLS) or closed – henceforth referred to as plate lattice structures (PLS). Lattice structures in different forms may have superior or even optimal elastic, thermal, optical, hydraulic or other physical properties if designed appropriately. In connection with AM, lattice structures may be used as structures themselves or as porous infill in structures meant to have smooth and closed external surfaces.

It has long been known that PLS provide the optimal stiffness to weight ratio [1, 2] and achieve the Hashin Strikhman bounds. Near-optimal, single-scale isotropic PLS with maximum Young's modulus have been identified in [3, 4] and a systematic study shows how optimized PLS are always stiffer (up to 200%) than their TLS counterparts for arbitrary loading cases [5].

Local stresses in AM parts are seldomly isotropic and uniform and hence using uniformly distributed isotropic infill or lattice structures is a waste of efforts which can be avoided if one uses locally adapted, anisotropic microstructures. 2D multiscale topology optimization studies making use of knowledge of optimal microstructures and efficient projection approaches [6, 7] show that stiffness can be improved by more than 50% by using locally adapted infill. This work has recently been extended to 3D [8]. Here, we will use this approach to investigate the differences in using isotropic vs. anisotropic and TLS vs. PLS when considering optimal stiffness design of AM parts.

Despite all the analytical and numerical work spent on identifying stiffness optimal isotropic and anisotropic microstructures, very few works have considered yield or compressive strength of these microstructures. In principle, stiffness optimal microstructures should also be (near)optimal with respect to yield strength. However, considering that infill and lattice structures often have low volume fractions, chances are high that local or global instability will happen before yield. In previous work we have topology optimized 2D microstructures for maximum buckling strength [9], where the stability criterion was established based on Floquet-Bloch wave theory and finite element analysis of the unit cell. Here, we extend this approach to 3D and extract simplified geometrical 3D microstructures with near optimal stiffness and significantly increased buckling strength. These microstructures are compared to commonly used TLS and PLS with regards to stiffness, strength and manufacturability and they are used as basic building blocks for 3D projections as discussed above.

Our study provides insight and tools for the systematic design of manufacturable AM parts with superior stiffness and strength properties.

IMMERSED BOUNDARY METHODS FOR SIMULATION IN ADDITIVE MANUFACTURING

Ernst Rank[1], Ferdinando Auricchio[2], Massimo Carraturo[2], John Jomo[2], Stefan Kollmannsberger[1], and Nina Korshunova[1], Alessandro Reali[2]
[1] *Chair for Computation in Engineering, Technical University of Munich, Germany*
[2] *Department of Civil Engineering and Architecture, University of Pavia, Italy*

Summary Immersed Boundary Methods have recently attracted much interest. In contrast to classical finite element methods they need only a very simple computational background grid instead of a boundary matching mesh. This advantage is particularly valuable in cases of complex geometry, where mesh generation is often one of the most time consuming working steps in a structural analysis, or in cases, where the geometry of a structure is significantly changing during a computation. Both situations frequently occur in problems of simulation of additive manufacturing. This presentation will begin with an introduction in immersed boundary methods and then show the opportunities of this approach for simulation of AM products and processes.

IMMERSED BOUNDARY METHODS

Immersed boundary methods are closely related to the finite element technique. Yet, they avoid meshing the domain of computation and instead embed an object in a larger, simply shaped domain, which is itself divided into a simple grid. The resulting 'elements' are non-conforming, i.e. cut by the boundary of the original domain. This seemingly simple modification of the original principle has many consequences. Several of the classical steps of FEM need to be redesigned, like the integration of element matrices, the definition of boundary conditions or the stabilization of equation systems. All these questions have been addressed with success during the last years in several variants of immersed boundary methods, like the Finite Cell Method (FCM, [1]), the CutFEM [2] or the cgFEM [3]. The FCM in particular, which is a high order immersed boundary method, can be directly connected to various types of geometric models without compromising computational efficiency or accuracy, yet with significant advantages over classical FEM. Furthermore, the capabilities of FCM have been extended by including the opportunity of local grid refinement as well as local increase of the approximation order of the shape functions.

The relief from the necessity of generating a boundary conforming mesh for a structure is particularly important for simulations in additive manufacturing, as will be shown in this contribution,. Two fields of application of the Finite Cell Method for AM technologies will be discussed in this presentation. The first addresses some problems from mesoscopic process simulation, the second virtual material characterization of complex porous structures obtained by additive manufacturing.

THE FINITE CELL METHOD FOR SIMULATION IN AM

Additive Manufacturing is adding material layer by layer to an already existing, evolving structure. Numerous process types have been developed over the past decades, and most of them involve multiple coupled physical phenomena. Thermo-mechanical and phase change problems are only mentioned as some of the most prominent ones. When FEM is used for a process simulation, the concept of 'element birth' is frequently used (e.g. [4]). Whenever a part of the structure is generated, one, several, or a full layer of elements is added to the structure and considered in the sequel of the coupled thermo-mechanical problem. In order to simplify the implementation of this transient process all 'unborn' elements are already generated before the start of the simulation, but activated only at the time of their 'birth'. One major disadvantage of this process is related to the multiscale nature of AM. The moving area of phase transition, being the computationally most demanding part of the domain is in general very small compared to the overall structure and requires a very fine mesh in order to achieve sufficient accuracy. Using FCM two remedies are available: The computational grid can be locally refined and unrefined, and only parts of finite cells can change their physical state during phase transition in the thermos-mechanical process. Both opportunities allow for a more precise and very efficient simulation of an AM process.

The second field of application of the Finite Cell Method addresses material characterization of additively manufactured products, whose mechanical properties highly depend on the AM process parameters. Slight changes in these parameters may lead, for example, to surface roughness, undesirable porosity or other microstructural defects. It is even more challenging to control parameters for AM *porous structures* in order to achieve a predefined nominal microstructure. Process-induced effects might deteriorate the mechanical properties of the final parts compared to conventionally manufactured ones. Therefore, the evaluation of the mechanical behaviour of AM components is one of the crucial tasks for defining their reliability and applicability. Yet, experimental mechanical testing of AM generated porous structures is limited by the high cost and time consumption, in particular, due to the need for a statistically significant number of

repetitions using the same type of specimens. Thus, the robust estimation of the mechanical characteristics of the final AM products through computational methods is a promising alternative. One important step in this *virtual material testing* is a precise structural simulation based on CT-scans of additively manufactured porous structures. When using finite element based techniques, an obvious challenge in this step is the generation of a finite element mesh for these complex structures. This crucial step can be avoided by using immersed boundary methods. We will show examples (see figure 1) of obtaining microscopic and macroscopic mechanical properties including homogenized elastic and elastoplastic parameters and compare them with experimentally obtained results.

Summary This lecture presents recent results on the fabrication, mechanical performance and failure mechanisms of nanoarchitected ceramic materials with plate- and shell-based topologies. We first discuss the beneficial size effects on strength presented by nanoarchitected materials and review fabrication approaches that can capitalize on these effects. Subsequently, we discuss the mechanical benefits of plate- and shell-based architectures, compared to the well-established truss-based lattices. Finally, we demonstrate ceramic nanoarchitected materials with exceptional specific strength and discuss their deformation behavior.

EXPLOITING NANOSCALE SIZE EFFECTS IN CERAMIC ARCHITECTED MATERIALS

Ceramics are ideal engineering materials, by virtue of their high theoretical strength, high stiffness, low density, chemical stability and resistance to very high temperatures. According to linear elastic fracture mechanics, the fracture strength of a material scales as $\sigma_f \sim K_{Ic}/\sqrt{a}$, with K_{Ic} the fracture toughness of the material and a the size of the largest crack contained in the sample. Unfortunately, in most ceramic materials cracks can propagate easily, resulting in very low fracture toughness ($K_{Ic} \sim 1-10\ MPa\sqrt{m}$), and consequently low fracture strength. This drawback dramatically limits the use of ceramic materials in structural applications. At the macroscale, the sample dimension, t, is many orders of magnitude larger than the the size of the largest crack, resulting in a very mild size effect (Weibull theory); but as the sample dimension is reduced to the order of the crack size, the scaling changes to $\sigma_f \sim K_{Ic}/\sqrt{t}$. This significant smaller-is-stronger size effect persists until the theoretical strength of the material, σ_{th}, is achieved, after which further reduction in sample size have no effect on the strength of the material. As $\sigma_{th} \sim E/10$, with E the Young's modulus of the material, nanoscale ceramic materials can potentially exhibit strengths of the order of 10 GPa. Additionally, as brittle fracture is delayed, these materials can exhibit significant amounts of plasticity, when loaded in compression, even at room temperature (Fig. 1). Unfortunately, strengths on the order of σ_{th} are typically limited to the nanometer scale, and ultra-strong monolithic ceramics are hence unachievable in macroscale components. Architected materials have the potential to bridge this scale gap, by allowing fabrication of effective materials at the macroscale, but with individual geometrical features below a_{cr} [1].

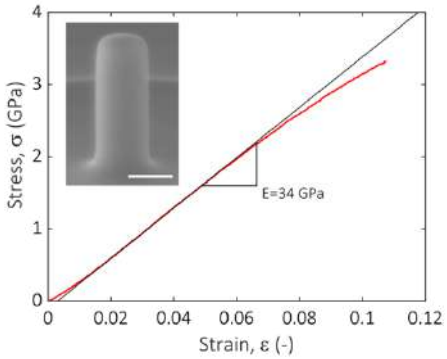

Figure 1. Compressive response of a pyrolytic carbon nanopillar (from [2]).

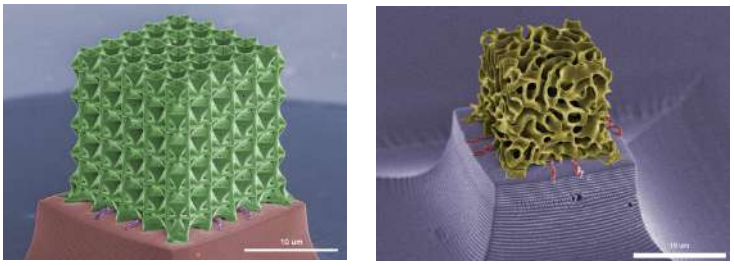

Figure 2. Carbon nanoarchitected materials with cube-octet plate and spinodal shell topologies.

THE MECHANICAL ADVANTAGE OF PLATE-BASED TOPOLOGIES

The vast majority of architected materials investigated over the past two decades have been truss lattices, by virtue of their relative ease of manufacturing and the simplicity in obtaining reasonably accurate analytical solutions for the mechanical and functional properties of interest. Over the past few year, remarkable progress in additive manufacturing technologies has opened the door to the investigation of more complex topologies. Two recent computational studies ([3], [4]) have predicted that closed-cell plate-based architected materials would be far superior to truss-lattices, with specific stiffness approaching the theoretical topological upper bound, while being virtually isotropic. Manufacturing challenges are very significant, though, as closed-cell topologies trap raw material, e.g. liquid monomer or powder, inside their cells. Here we demonstrate a fabrication process based on two-photon polymerization Direct Laser Writing followed by pyrolysis, resulting in closed-cell carbon plate-nanolattices. We demonstrate that these materials achieve the theoretical upper bounds in both stiffness *and* strength, and are the strongest cellular materials ever produced (Fig. 2). Details about their failure mechanisms are presented [5].

SHELL-BASED TOPOLOGIES DERIVED BY SPINODAL DECOMPOSITION

While we demonstrate that properly designed plate-based nanoarchitected materials achieve the theoretical upper bounds in both stiffness and strength, scalability for sample sizes beyond the micron-scale remains a challenge. This challenge may be overcome by adopting self-assembly techniques to generate shell-based topologies that approximate triply periodic minimal surfaces, with sample size at the macroscale, characteristic dimension at the micron scale and shell thickness at the nanometer scale. We computationally generate shell-based architected materials derived by spinodal decomposition of sacrificial constituents followed by postprocessing, and model their mechanical response. We show that these topologies are mechanically efficient while isotropic, and remarkably imperfection insensitive [6]. We fabricate nanoarchitected spinodal shell-based materials in carbon by two-photon polymerization direct laser writing of our computational designs, followed by pyrolysis [2]. While stochastic, these nanoarchitected materials are only slightly less efficient than the optimal plate-based materials discussed above (Fig. 2). When compressed beyond the elastic limit, these materials exhibit failure mechanisms that are strongly dependent on the wall thickness to unit cell size ratio: at small wall thicknesses, the crushing behaviour is progressive, with layer-by-layer fracture and significant energy absorption; at large wall thickness, the behaviour is catastrophic, with a single large crack destroying the entire sample at the same time. We explain this transition in terms of a competition between compressive and bending stresses in the shell sections. The implication is that, when properly designed, these architected materials can exhibit excellent energy absorption at low weight. Most importantly, these topologies are in principle amenable to scalable nanomanufacturing, when actual spinodal decomposition is used as a fabrication route. We will conclude with recent demonstrations of this approach [7].

ON THE THERMO-MECHANICS OF DISLOCATION FIELDS IN TRANSIENT HETEROGENEOUS TEMPERATURE FIELDS

Manas V. Upadhyay*[1]
[1] Laboratoire de Mécanique des Solides, C.N.R.S., Ecole Polytechnique, IP Paris, 91128 Palaiseau, France

Summary During a metal/alloy additive manufacturing process, a molten material undergoes rapid solidification in a few milliseconds. Following this, it undergoes multiple heating-cooling cycles, i.e. Solid-State Thermal Cycling (SSTC), at varying temperature rates and amplitudes for the remainder of the build time. Thus far, most research efforts have focused on studying microstructure formation during solidification. There have been no coherent experimental/modeling efforts dedicated to study microstructure evolution during SSTC. During a series of recent in-situ TEM SSTC experiments by the author and colleagues, it has been shown that significant microstructure evolution occurs during SSTC. Based on these results, a novel thermo-mechanical model for dislocation dynamics due to transient heterogeneous temperature fields is proposed. Advantages/implications of the model are discussed.

MOTIVATION AND AIM

During an Additive Manufacturing (AM) or 3D printing process, just after deposition, a liquid material rapidly solidifies and spends rest of the building time being subjected to Solid-State Thermal Cycling (SSTC), at varying temperature rates and amplitudes, an illustration is shown in Fig. 1. During initial stages of SSTC, temperature amplitudes higher than annealing points and temperature rates as high as $10^6 K/s$ can be encountered. Consequently, large transient temperature gradients are formed, which result in strong transient thermal stresses due to internal and/or external constraints. Such rapidly varying temperatures and thermal stresses can result in significant changes in the microstructure, including dislocation structure evolution via dislocation dynamics. During later stages of SSTC, a nearly steady-state heat conduction occurs at relatively high temperatures with respect to room temperature. Such relatively high temperatures along with internal stresses due to a metastable microstructure can also result in additional dislocation dynamics.

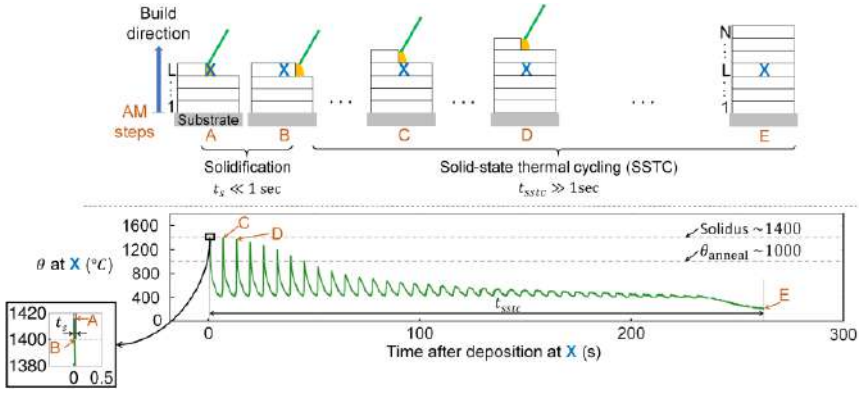

Figure 1: An illustration of temperature (θ) vs time (t) evolution at a material point X during additive manufacturing of a wall. t=0 corresponds to the moment the heat-matter interactions occur at X in a layer L<N, where N is the total number of layers.

Recently, a series of in-situ TEM SSTC experiments were performed on an AM 316L stainless steel by the author and colleagues (Dr. Lluis Yedra-Cardona, Dr. Eva Héripré) at the MSSMat Laboratory of CentraleSupélec. The experiments revealed significant changes to dislocation and precipitate structures (see Fig. 2). These results strongly motivate the need to better understand microstructural evolution during SSTC in order to have better control over the AM process. Here, the focus is on developing a model that allows studying dislocation dynamics due to SSTC during AM.

Most existing dislocation dynamics models, both discrete and continuous kind, are designed to study dislocation motion and interactions under isothermal and/or adiabatic conditions. Indeed, there exist couplings between heat conduction and phenomenological elastic-plastic theory as well as between heat conduction and dislocation mechanics theory. However, none of the existing dislocation dynamics models account for temperature change induced crystallographic dislocation driving forces. To that end, a thermo-mechanically rigorous model of evolving dislocation fields under transient heterogeneous temperature fields is proposed [1]. In essence, this model is a strong coupling between the Field Dislocation Mechanics (FDM) model [2], theory of quasi-dislocations [3] and the heat conduction problem.

THE T-FDM MODEL

We consider a body $\mathcal{B}$ with surface $\partial\mathcal{B}$ to be a thermodynamically closed system. We shall assume that the local temperature θ at any material point in $\mathcal{B}$ is always below the solidus. Let θ_0 be the reference temperature. Next, we assume that $\mathcal{B}$ is a simply connected body without voids or cracks. Furthermore, we assume that $\mathcal{B}$ is a single crystal. Let $\mathcal{B}$ contain an arbitrary distribution of continuously represented dislocations represented via an areal dislocation density field $\boldsymbol{\alpha}^p$. Furthermore, we account for an areal defect density $\boldsymbol{\alpha}^\theta$ associated with incompatible thermal strains. The governing field equations of the geometrically linear T-FDM model [1] are:

$$\boldsymbol{U} = \boldsymbol{\nabla u} = \boldsymbol{U}^e + \boldsymbol{U}^p + \boldsymbol{\varepsilon}^\theta \tag{1}$$
$$\boldsymbol{\varepsilon}^\theta = \boldsymbol{\gamma}(\theta - \theta_0) \tag{2}$$
$$\dot{\boldsymbol{\alpha}}^{p,\beta} = -\boldsymbol{\nabla} \times \left(\boldsymbol{\alpha}^{p,\beta} \times \boldsymbol{v}^{p,\beta}\right) + \boldsymbol{S}^{p,\beta} \quad \text{and} \quad \boldsymbol{\alpha}^p = -\boldsymbol{\nabla} \times \boldsymbol{U}^p = \textstyle\sum_\beta \boldsymbol{\alpha}^{p,\beta} \tag{3}$$
$$\dot{\boldsymbol{\alpha}}^\theta = -\boldsymbol{\gamma}\left[\boldsymbol{\nabla}\dot{\theta} \cdot \mathbf{X}\right] \quad \text{and} \quad \boldsymbol{\alpha}^\theta = -\boldsymbol{\nabla} \times \boldsymbol{\varepsilon}^\theta \tag{4}$$
$$\dot{\boldsymbol{\alpha}} = \dot{\boldsymbol{\alpha}}^\theta + \dot{\boldsymbol{\alpha}}^p \quad \text{and} \quad \boldsymbol{\alpha} = \boldsymbol{\nabla} \times \boldsymbol{U}^e \tag{5}$$
$$\boldsymbol{\sigma} = \boldsymbol{C} : \boldsymbol{\varepsilon}^e - \boldsymbol{\beta}(\theta - \theta_0) \tag{6}$$
$$\boldsymbol{q} = -\boldsymbol{K} \cdot \boldsymbol{\nabla}\theta \tag{7}$$
$$\boldsymbol{V}^\beta = \tfrac{1}{B^\beta}\left(\boldsymbol{\sigma} \cdot \boldsymbol{\alpha}^{p,\beta}\right) : \mathbf{X} = \tfrac{1}{B^\beta}\left(\boldsymbol{\sigma} \cdot \boldsymbol{b}^\beta\right) \times \boldsymbol{l}^\beta \quad \text{for} \quad \boldsymbol{\alpha}^{p,\beta} = \tfrac{1}{V}\left(\boldsymbol{b}^\beta \otimes \boldsymbol{l}^\beta\right) \tag{8}$$
$$\boldsymbol{\nabla} \cdot \boldsymbol{\sigma} + \rho \boldsymbol{f} = \rho \ddot{\boldsymbol{u}} \tag{9}$$
$$\rho c_v \dot{\theta} = \boldsymbol{\nabla} \cdot (\boldsymbol{K} \cdot \boldsymbol{\nabla}\theta) + \boldsymbol{\mathfrak{T}} : \dot{\boldsymbol{U}}^p - \theta \boldsymbol{\beta} : (\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^p) + \rho r \tag{10}$$

where $\boldsymbol{u}$: total displacement, $\boldsymbol{U}$: total distortion, $\boldsymbol{U}^{e/p}$: elastic/plastic distortion, $\boldsymbol{\varepsilon}^\theta$: thermal strain, $\boldsymbol{\gamma}$: thermal expansion coefficient matrix (assumed constant), $\boldsymbol{\alpha}$: Nye's dislocation density tensor, β: slip system, $\boldsymbol{\alpha}^{p,\beta}$: areal dislocation density, $\boldsymbol{b}^\beta$: Burgers vector, $\boldsymbol{l}^\beta$: dislocation line direction, V: volume over which dislocation density is averaged, $\boldsymbol{V}^\beta$: dislocation velocity, $\boldsymbol{S}^\beta$: dislocation source term, $\boldsymbol{\sigma}$: Cauchy stress, $\boldsymbol{C}$: elastic stiffness tensor, $\boldsymbol{\beta} = \boldsymbol{C} : \boldsymbol{\gamma}$: thermal moduli tensor, $\boldsymbol{q}$: heat flux vector, $\boldsymbol{K}$: heat conductivity matrix, B^β: dislocation drag term, $\boldsymbol{f}$: body force, ρ: material density, $\ddot{\boldsymbol{u}}$: acceleration, c_v: specific heat at constant volume, and ρr: heat loss term.

DISCUSSION AND CONCLUSIONS

In this work, a strong coupling between the FDM model, theory of quasi-dislocations and the heat conduction problem is developed to obtain the T-FDM model. The main motivation for developing this model is to study dislocation dynamics, interactions and structure evolution in crystalline solids experiencing transient heterogeneous temperature distributions such as those occurring due to SSTC during AM. Similar to most continuum models, the T-FDM model is based on the governing principles of rational thermodynamics: local thermodynamic equilibrium and Clausius-Kelvin-Planck formulation of the second law of thermodynamics. Since the T-FDM model is intended to be used to study dislocation dynamics under large temperature rates, it is crucial to verify that local thermodynamic equilibrium is always respected. Typically, the highest temperature rates occurring at a material point in a heat affected solid during an AM process are $\approx 10^6 K/s$, i.e. $10^{-6} K/picosecond$. Atomic fluctuations that accommodate thermal changes typically do so in timespans of $10^{-2} - 1 picoseconds$. Therefore, at the time scales at which temperature changes occur due to SSTC during AM, we can safely assume that they are instantaneously accommodated via atomic fluctuations. In other words, local thermal equilibrium is respected at any given instant in time. Furthermore, thermal stresses generated (if any) due to temperature gradients are also rapidly equilibrated resulting in mechanical equilibrium. If we assume that chemical equilibrium is also respected then the combined effect of these considerations is that for a system subjected to SSTC during AM, local thermodynamic equilibrium is respected at any given instant in time. The proposed model could be applied to study the dynamics of individual dislocations of any kind and/or their ensembles under any permissible combination of displacement, traction, temperature and heat flux boundary conditions.

Future work involves numerical implementation of the T-FDM model, extending it to a finite strain framework and up-scaling the model to the length scale of crystal plasticity approaches.

Summary We implemented a two-step methodology to estimate the residual stresses induced by the FDM manufacturing process in 3D printed composite parts. The first step consisted in an analytical thermo-viscoelastic homogenization procedure to derive the effective behavior of the filament. The second step consisted in a coupled thermomechanical structural analysis of the part. The homogenization procedure was assessed by comparing its predictions to full-field FFT-based computations. The structural analysis was assessed by comparing its predictions to experimental results.

FRAMEWORK

We are interested in the capabilities and performances of 3D printed parts made of thermoplastic matrix reinforced by short (≈100 μm) to intermediate (≈1 mm) glass fibers. Our aim is to estimate the residual stresses induced by cooling these parts from extrusion to room temperatures, which is a critical requirement to design these parts, in particular their filament's deposition trajectory. This estimation is challenging because of the complexity of the material (thermo-visco-elastic composite) and that of the FDM process itself (Fig. 1).

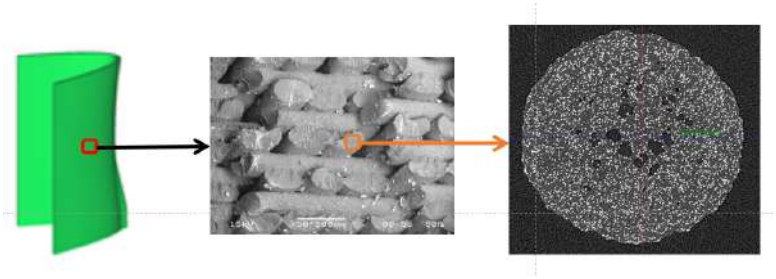

Figure 1: Three-scale configuration: printed part, fused filament structure and fiber-reinforced composite.

In the following, we provide some detail on each aspect of the methodology implemented.

HOMOGENIZATION OF REINFORCED POLYMER FILAMENTS

We estimated the FDM-induced residual stresses by using (i) a homogenization procedure to estimate the effective properties of the filament, and (ii) a coupled thermo-mechanical structural analysis. The homogenization procedure has two steps. The first step consisted in estimating the effective properties of the reinforced filament; the second step, in estimating the effective properties of the final 3D printed composite material.
The fibers of the filament were assumed to be elastic. Its matrix was assumed to be thermo-viscoelastic. Various mean-field methods were used to account for the fibers, and their predictions were compared with FFT-based full-field simulations. Finally, with these effective models at hand, the deflection and residual stresses in the whole part were estimated using an FEM code. Validation at the macroscale were then performed comparing FE simulations with experiments.

Thermo-viscoelastic modeling of the matrix The polymer matrix was assumed to be isotropic and its thermo-viscoelastic behavior to be described by an N-branch generalized Maxwell model, which is developed within the framework of generalized standard materials and characterized by the free energy $w(\boldsymbol{\varepsilon}, (\boldsymbol{\varepsilon}_v^i)_{i=1}^N, T)$ and the mechanical dissipation potential $\varphi((\dot{\boldsymbol{\varepsilon}}_v^i)_{i=1}^N, T)$, where $\boldsymbol{\varepsilon}$, $\boldsymbol{\varepsilon}_v^i$ are the strain and the viscous strain of branch i, respectively, and T is the temperature. For an N-branch model, these potentials can be written as

$$w(\boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}_v^i, T) = \sum_{i=1}^{N} \frac{1}{2}(\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}_v^i) : \boldsymbol{L}^i : (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}_v^i) + \sum_{i=1}^{N} (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}_v^i) : \boldsymbol{L}^i : \boldsymbol{\alpha}(T - T_0) + c_0 \left[(T - T_0) - T \ln \frac{T}{T_0} \right] - \eta_0 T + e_0,$$

*Corresponding author. E-mail: lahellec@lma.cnrs-mrs.fr

and

$$\varphi(\dot{\boldsymbol{\varepsilon}}_v^i, T) = \sum_{i=1}^{N} \frac{1}{2} \dot{\boldsymbol{\varepsilon}}_v^i : \boldsymbol{L}_v^i(T) : \dot{\boldsymbol{\varepsilon}}_v^i,$$

where $\boldsymbol{L}^i$ and $\boldsymbol{L}_v^i$ are the elasticity and viscosity tensors of branch i, respectively, $\boldsymbol{\alpha}$ is the thermal expansion tensor, c_0 is the heat capacity at constant stress, and η_0 and e_0 are the initial entropy and internal energy, respectively. The number of branches and the tensors $\boldsymbol{L}^i$ and $\boldsymbol{L}_v^i$ were found using DMA and creep experiments at different temperatures.

Upscaling FEM calculations were used to solve the macroscopic coupled mechanical and thermal equilibrium equations for the macroscopic stress, strain and temperature. At each integration point, these quantities are the average over a representative volume element of their microscopic counterparts, which solve the local mechanical and thermal equilibrium equations given by:

$$\mathrm{div}\boldsymbol{\sigma}(\boldsymbol{x}, t) = 0, \quad \boldsymbol{\sigma}(\boldsymbol{x}, t) = \frac{\partial w}{\partial \boldsymbol{\varepsilon}}(\boldsymbol{x}, \boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}_v^i, \overline{T}), \quad \frac{\partial w}{\partial \boldsymbol{\varepsilon}_v^i}(\boldsymbol{x}, \boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}_v^i, \overline{T}) + \frac{\partial \varphi}{\partial \dot{\boldsymbol{\varepsilon}}_v^i}(\boldsymbol{x}, \dot{\boldsymbol{\varepsilon}}_v^i, \overline{T}) = 0. \tag{1}$$

$$\mathrm{div}\boldsymbol{q}(\boldsymbol{x}, t) = 0, \quad \boldsymbol{q}(\boldsymbol{x}, t) = -\boldsymbol{k}(\boldsymbol{x}).\boldsymbol{\nabla} T(\boldsymbol{x}, t), \tag{2}$$

where $\boldsymbol{q}$ and $\boldsymbol{k}$ are the heat flux and conductivity tensor respectively. It should be noted that the microscopic mechanical and thermal equations (1) and (2) are uncoupled because of the following: i) Only the average macroscopic, $\overline{T}$, is considered in the mechanical formulation (1). ii) The dissipated energy is taken into account at the macroscale, which simplifies the heat equation as shown in (2). The thermo-mechanical coupling is then achieved at the macroscopic scale. Equations (1) and (2) are supplemented with appropriate boundary conditions to enforce that $\overline{\boldsymbol{\varepsilon}}$ and $\overline{T}$ are the respective averages of the local fields $\boldsymbol{\varepsilon}(\boldsymbol{x})$, solution of (1), and $T(\boldsymbol{x})$, solution of (2).

Mean-field models to account for the fibers We used mean-field methods to estimate the average of the thermo-mechanical fields that solve the local equations (1) and (2). The used mean-field methods handle the complexity of the composite material (non-alignment of the fibers, thermo-viscoelasticity of the matrix, etc.).
Mean-field methods aim at determining closed-form approximations of the mean fields in each phase using simplifying assumptions (usually valid for low to medium densities of inclusions) and analytical results coming from Eshelby's equivalent inclusion method. We used several models to estimate the effective elasticity tensor of the filament, $\boldsymbol{L}_{\text{eff}}$, including the Interaction direct derivative model [4], which is characterized by the following equation:

$$\boldsymbol{L}_{\text{eff}} = \boldsymbol{L}_{\text{M}} + \left(\boldsymbol{I} - c_{\text{F}} \int_S f(\boldsymbol{n}) \Delta \boldsymbol{L}_{\text{F,M}}(\boldsymbol{n}) : \boldsymbol{A}_{\text{F,M}}(\boldsymbol{n}) : \boldsymbol{P}_{\text{F}}^{\text{D}}(\boldsymbol{n}) dS \right)^{-1} : \left(c_{\text{F}} \int_S f(\boldsymbol{n}) \Delta \boldsymbol{L}_{\text{F,M}}(\boldsymbol{n}) : \boldsymbol{A}_{\text{F,M}}(\boldsymbol{n}) dS \right) \tag{3}$$

where S is the unit sphere, c_{F} is the fibers' volume fraction, $\boldsymbol{n}$ is the fibers' orientation, f is the orientation probability density function, $\boldsymbol{A}_{\text{F,M}}$ is the localization tensor accounting for the fibers' shapes and material contrast, defined as $\Delta \boldsymbol{L}_{\text{F,M}}(\boldsymbol{n}) = \boldsymbol{L}_{\text{F}}(\boldsymbol{n}) - \boldsymbol{L}_{\text{M}}$, and $\boldsymbol{P}_{\text{F}}^{\text{D}}$ is Hill's tensor accounting for the fibers' spatial distribution.
In the case of linear viscoelastic constituents, Laplace-Carson transform is classically used which allows defining a linear symbolic elastic composite in the Laplace domain (the so-called correspondence principle [3]). This method cannot be used directly because of the temperature dependence of the viscous moduli of the matrix. To overcome this difficulty, we used an incremental formulation [1] that allows the Laplace-Carson transform to be used, provided that the moduli change slowly with the temperature.

VALIDATION

The proposed mean-field model was assessed by comparing its predictions in terms of effective moduli to those of FFT-based full-field simulations on representative volume elements (RVE). The proposed macroscopic structural analysis was assessed by comparing its predictions in terms of warping with the warping that develops within 3D printed asymmetric plates (plates with two deposition orientations: $0°$ and $90°$).

Summary 3D printing offers a valuable opportunity to design and fabricate ad hoc composites with tailored properties for several applications. Dealing with metal matrix components can pave the way to define novel and enhanced materials that positively affect not only the final characteristics, which is the expected result, but also the processing variables in the manufacturing stage. In this regard, the modification of 3D printed copper specimens with just 0.1% w/w graphene oxide (GO) provided a clear evidence of the optimal nanofiller content referred to density improvement and superior processability and hardness. A feasibility study was carried out following two different routes to disperse GO into Cu matrix, including nanofiller deagglomeration in bidistilled water or not, before to process the composite powder by selective laser melting (SLM) technique. Several working conditions were considered, setting the laser power at 175 W as the best input parameter resulted from a preliminary screening assessment. Reflectance measurements, density evaluation, scanning electron microscopy, Raman spectroscopy, and mechanical characterization, through indentation tests, were carried out to characterize each stage of the 3D printing process from the composite powders to the final specimens.

INTRODUCTION

Most metals and alloys are unsuitable for additive manufacturing (AM), but the development of this technology can benefit the production of metal matrix composites to reproduce of metal matrix composites can benefit from this technology to reproduce samples of complex geometry with high details and proper functional features [1]. It is well-known that 3D printed components often include several defects, as high porosity, that negatively affect mechanical properties. In this regard, the addiction of nanofiller can likely ameliorate this feature.

The presented study aims to prepare GO–based metallic composites, using copper as a matrix. The excellent thermal conductivity makes this metal particularly interesting for industry, but it is difficult to print for his high reflectance, that plays a key-role in the production process [2]. The potential of GO as a filler can provide a relevant contribution to the final composite if an effective filler-matrix interaction is obtained, but it can be also regarded as a supportive means to modify the processing variables and thus tailoring the entire experimental protocol. The SLM was here assessed as an adequate technique to fabricate 3D printed Cu-GO composites with the aim to investigate different processing conditions [3]. Density measurements, Raman analysis and mechanical indentation were therefore performed to characterize the 3D printed composites in order to evaluate their properties and critically correlate the collected findings to the computed porosity.

MATERIALS AND METHOD

Materials

Graphene oxide (GO; powder, oxidation: 4-10%) was supplied by Sigma-Aldrich (Milan, Italy). Deionized water was supplied by Carlo Erba Reagenti (Milan, Italy). Cu powder (99.9% purity, 4.8 g/cm3 apparent density) was purchased from ECKA Granules (Germany).

Composite fabrication

The composite powder was obtained following two different routes: mechanical mixing for 12 h through a custom-made epicyclical gear system (Route A); filler was ultrasonically disagglomerated in deionized water for 30 min and then mixed to Cu powder, water was finally removed in an oven at 100°C for 24 h (Route B).

Composites were fabricated by means of the 3D printer MySint100 (Sisma, Italy), a powder bed system equipped with a 200 W laser, 1070 ± 10 nm wavelength, and 30 µm focus beam diameter. The melting process was carried out in inert environment with nitrogen over-pressure. Box-shaped specimens (7x7x10 mm^3) were built on platforms of AISI316, setting a laser power of 175 W, scan speed of 600 mm/s and hatch distance of 0.06 mm and 0.04 mm. These variables were selected after a preliminary screening process.

The reflectance values of the Cu-GO powder were analysed by means of the Ulbricht integration sphere, equipped with a led source of 15 mW power and 940 nm wavelength. The detector was a PIN photodiode at 940 ± 150 nm.

§Contributed equally to the work

The characterization of the 3D printed specimens was carried out by means of scanning electron microscopy (SEM; Philips XL30) to analyse the resulting morphology, Raman spectroscopy (InVia Raman microscope; Renishaw, UK) to investigate the GO distribution on the composite surface, and indentation tests (MTS Insight 5, USA) to assess the mechanical properties.

RESULTS AND DISCUSSION

The Cu-GO powder mechanically mixed was characterized by a reflectance value of 57.1%, while that obtained introducing the disagglomeration in an ultrasonic bath was 15.2%. The reflectance of the neat copper powder was 84.1%. These results confirmed that the addition of a carbon nanofiller can dramatically reduce the reflectance, even at very low concentration (0.1% w/w). It should be also noted that the possible formation of copper oxide might contribute to this result.

3D printed specimens were characterized by a quite large density distribution, which can be related to the energy density experienced by the powder during the fabrication process.

Surface morphology was analysed by SEM (Figure 1). Samples from Route A showed a rough surface, also revealing the presence of pores containing pristine copper powder. Instead, the Route B seemed to induce a slight modification of sample morphology, highlighting a more regular surface. This result can be related to the reflectance measurements since the composite powder prepared following the latter method seems to more efficiently interact with the laser source, thus inducing an enhanced melting of the powder.

Raman spectroscopy was carried out to evaluate the GO distribution within composites. A quite uniform filler distribution can be observed for all the investigated samples. Some quantitative indices were proposed, and the statistical analysis did not assess significant differences, confirming that the two experimental approaches led to a similar GO dispersion within the copper matrix.

Regarding the mechanical characterization, the indentation curves firstly showed a linear elastic region followed by a large plastic response with an almost constant slope up to the end of the test (Figure 2). Samples prepared following the Route B were characterized by a larger indentation force values in the plastic region compared to those from Route A. Generally, the mechanical response of a porous sample is related to the porosity degree of the structure, but in the present study, specimens with higher porosity showed better mechanical properties. This behaviour can be ascribed to the composite powder preparation: a preliminary filler deagglomeration in ultrasonic bath promoted an improved interaction with the copper powder, eliciting a competitive effect between the expected porosity weakness and the structural resistance. On the other hand, the GO mechanical dispersion failed to properly disagglomerate the as received nanofiller, leading to the presence of micro-aggregates as defects that added their negative role to the porosity level.

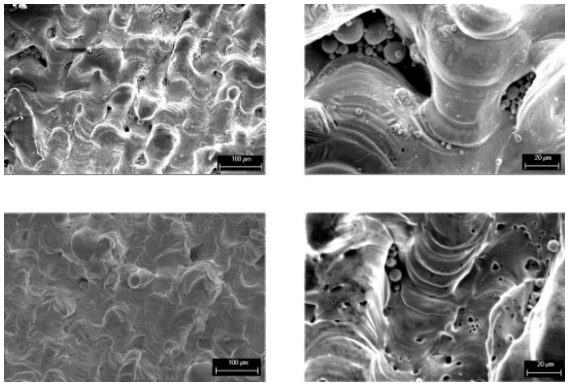

Figure 1. SEM micrographs of 3D printed composite samples fabricated following the Route A (upper panel) and the Route B (lower panel). Magnification: 200x (left column), 800x (right column)

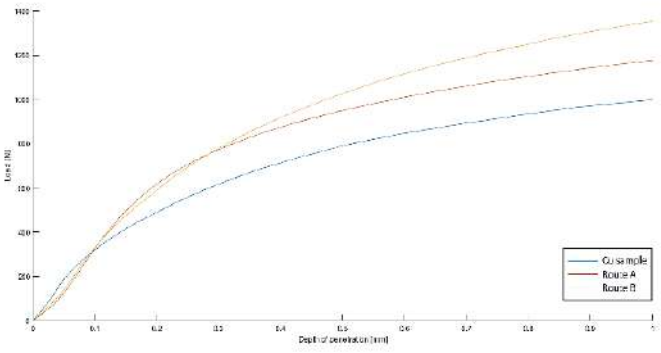

Figure 2. Representative indentation curves for 3D printed pure copper (blue), Route A (red) and Route B (yellow) specimens

CONCLUSION

3D printed metal matrix composites represent a valuable means to deal with components specifically designed to enhance required properties. CuGO composites, as an output of a SLM process, were here considered to evaluate the optimization of the fabrication protocol and the expected filler contribution. A mechanical reinforcement was measured for all the investigated composites when compared to pure copper specimens, the highest response being acquired from those specimens in which GO was disagglomerated by means of an ultrasonic bath. In order to counterbalance the negative effect related to the porosity degree, usually affecting 3D printed samples, the proposed approach could be an interesting option to be further exploited when specific structural properties are required.

Summary Acoustic forces are an attractive pathway to achieve directed assembly for multi-phase materials *via* additive processes. Programmatic integration of microstructure and structural features during deposition offers opportunities for optimizing printed component performance. Here, we demonstrate that acoustic fields can effectively assemble conductive particles into networks within polymer matrices, whose configuration is modulated prior to curing, to produce 2-D conductive, 1-D conductive, or insulating materials on-demand, all using the same precursor ink. Furthermore, patterning efficient percolated networks in this manner increases conductivity an order of magnitude over conventional dispersed-fiber composites with an order of magnitude lower particle loading, improving printability and allowing versatile orthogonal control of other properties.

The ability to control particle alignment across volume fraction ranges would create new opportunities to print composite materials with engineered anisotropic properties (mechanical, electrical, thermal, and optical) [1]. A promising approach for achieving top-down control over microstructure is to combine field-assisted assembly with direct deposition. While electrostatic or electromagnetic fields are suitable for a narrow range of ink compositions and particle types, acoustic fields are broadly applicable to a wide class of colloids, spanning a broad range of composition, particle shape, and size. We demonstrate acoustic-field-assisted assembly of two-phase aligned composites, such as silver-coated fibers in a flexible polymer matrix, using microfluidic print nozzles (Fig. 1A) coupled to inexpensive piezoelectric actuators. Mechanical and electrical characterization of the flexible composite materials demonstrate the orthogonal control of material properties, such as conductivity and rigidity (Fig. 1B-D), enabled by field-assisted patterning.

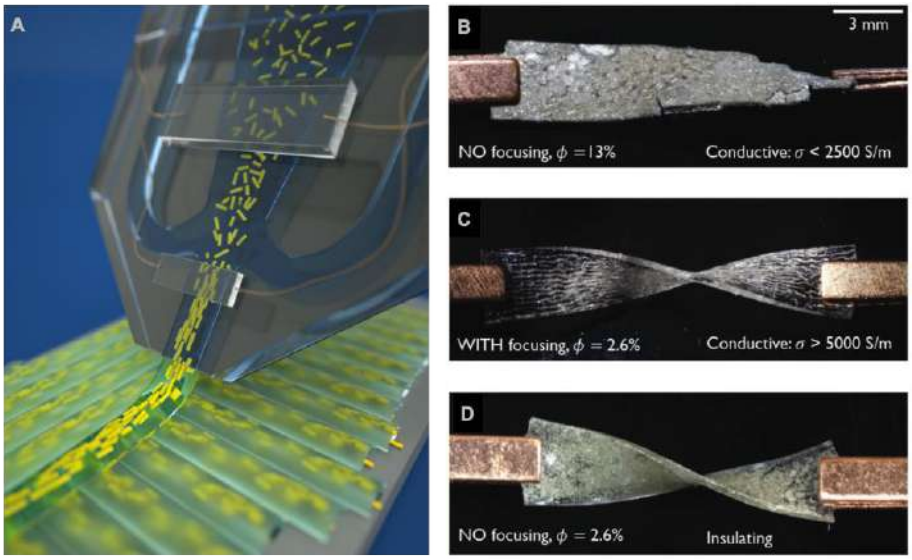

Figure 1: (A) Conceptual illustration of acoustic print nozzle. Piezoelectric actuation generates acoustic forces that align fibers during printing. (B-D) Photographs of silver-coated fiber elastomeric composites twisted to demonstrate gains in flexibility and conductivity via acoustic patterning. (B-D) Adapted with permission from [2].

Acoustic forces created by standing pressure waves are an attractive pathway to increasing the density and alignment of particles: they are active over large distances and relatively material agnostic (*i.e.*, they do not require specific surface functionalization, solution chemistries, or electromagnetic properties). In many applications, the particles are micron-sized or larger, such that the magnitude of easily achieved acoustic forces is much greater than those associated with fluid drag, implying that particles can be transported and assembled over relatively long distances on the order of seconds or less. These benefits create new opportunities to incorporate acoustic excitation in nozzles used for three-dimensional printing, to dramatically increase the density and alignment of particles relative to that of the 'ink'.

The acoustic nozzle schematic shown in Figure 1 illustrates the alignment of fibers in a viscoelastic matrix, which results from an applied acoustic force generated by piezoelectric elements mounted above the nozzle pathway. These nozzles are typically microfabricated in silicon or glass (150 µm deep) with a bonded glass capping layer according to the procedures in Ref. [3], with piezoelectric actuators bonded to the nozzle to generate standing waves in the channel.

Critically, acoustic focusing enables control of the microstructure of the deposited line by modulating acoustic excitation parameters, as demonstrated in Figure 1C for silver-coated fibers in a flexible polymer matrix. When the excitation frequency is tuned to induce focusing, fibers collapse to the acoustic nodes (tunable from 1 to N, frequency dependent). The patterned composite (Fig. 1C) exhibits conductivity at a particle volume fraction below the percolation threshold (Fig. 1C, unpatterned composite is insulating) due to structuring particles into percolated bundles rather than a

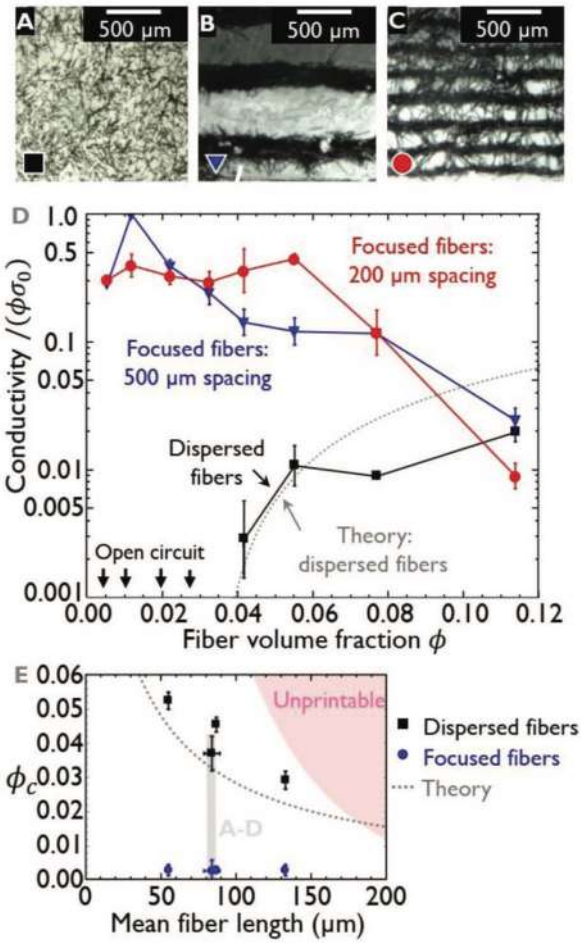

Figure 2: A) Image of a 0.5 vol% composite made without acoustic focusing. B) Images of 2.6 vol% composites made with acoustic focusing with 500 µm focused bundle spacing and C) 200 µm spacing. D) Electrical conductivity normalized by the conductivity of the fibers σ_0 and the volume fraction φ, which gives the volume fraction of fibers in the composite that contribute to the conductive network. Fiber alignment by shear flow, a factor especially apparent in the higher viscosity inks with high φ is expected to decrease conductivity below this model. E) The percolation threshold φ_c at which electrical behavior of composites transitions from insulating to conductive. Fiber alignment is expected to increase φ_c and high spread in the fiber length distribution is expected to decrease φ_c compared to the theoretical model shown here. [4] The "unprintable" region indicates approximately which volume fractions and fiber lengths clog the devices. Figure is adapted with permission from [2].

disconnected stochastic network. In order to achieve conductivity in the absence of patterning, a significantly higher particle loading volume is required (Fig. 1B), resulting in loss of mechanical flexibility.

Figure 2 illustrates the enhanced conductivity through acoustic focusing via assembly of carbon fibers dispersed in a UV-curable resin. The patterned composites in Figure 2B,C exhibit dramatically higher conductivity than Figure 2A as shown in Figure 2D. Below the percolation threshold for the dispersed-fiber composites φ_c, the patterned composites maintain high conductivity. Up to 97% of the fibers by volume contribute to the conductive network at φ = 1.2 vol% due to preferentially end-on-end stacking resulting from acoustic scattering forces [5]. At volume fractions up to 8%, the conductivity of the acoustically patterned composites is at least an order of magnitude higher than unpatterned, percolated composites from the same precursor ink. In contrast to the strong scaling in dispersed-fiber composites, conductivity in acoustically patterned composites is invariant from 1 to 10 vol%. This insensitivity to loading offers orthogonally control over material properties such as stiffness, strength, or thermal conductivity by tuning the filler loading.

The conductivity reported above is 1D, running parallel to the focused bundles of fibers, where bundles are insulated from each other. Control over conductivity in the perpendicular direction, however, is possible by tuning the applied pressure field. Modulating the focusing wavelength controls the bundle spacing, which in turn controls the number of fibers bridging between bundles: longer fibers are acoustically stable perpendicular to the focused bundles resulting in bridging. Controlling the focused line spacing modulates the electrical conductivity of the patterned composites between anisotropic or nearly isotropic. This response is suitable for on-the-fly modulation in a printing modality to allow programmable spatial control of electrical interconnects embedded in printed components.

These results are highly promising. Although the focus is on electrical conductivity, the approach described is extensible to other transport phenomena. As a relatively material agnostic technique for microstructural control, acoustic-focusing-assisted additive manufacturing greatly expands the library of printable multiphase inks. This technology demonstrates a novel approach to modulating material properties via microstructure control to pave the way for 3D printing components with embedded electrical circuits or other spatially modulated properties.

MICROSTRUCTURE CONTROL THROUGH DEPOSITION PATTERN OPTIMIZATION IN DIRECT METAL DEPOSITION

Vibhas Mishra, Can Ayas, Matthijs Langelaar, Fred van Keulen
Mechanical, Maritime and Materials Engineering, Delft University of Technology, Delft, The Netherlands

Summary Direct Metal Deposition provides a unique capability to deposit material along a wide variety of deposition patterns. Deposition patterns affect the thermal history experienced by the produced parts. The thermal history at a particular point determines its microstructure. This opens up the possibility to tailor the microstructure at specific locations, by optimizing the deposition patterns. In this contribution, each material point in a given design is associated with a time variable, indicating its printing time. The deposition pattern is given by the ascending sequence of the time variables. Based on this deposition pattern, thermal simulation is performed to evaluate the thermal history of the critical points in the structure. Microstructure is linked to this thermal history. Thus, we show that through deposition time field optimization, specific microstructures can be achieved.

INTRODUCTION

Direct Metal Deposition (DMD) shows potential to economically produce large-scale structures such as ship propellers and aircraft structures. In the Direct Metal Deposition (DMD) process, the metal is melted and deposited simultaneously on a substrate using a robotic arm while following predefined deposition patterns or order. A unique capability of DMD is that various deposition paths, planes and order can be chosen for given part layout. The thermal history experienced by the part during manufacturing depends on the choice of deposition pattern. Moreover, The local thermal history determines the microstructure evolution therein [1]. For a specific engineering material such as High-Strength Low-Alloy steel, the temperature range between 800°C - 500°C is particularly important, since the cooling rate in this interval determines the constituent phases at a specific location [1]. For example, high cooling rates (>100°C/s) result in the hard and brittle martensitic phase, whereas low cooling rates (~1°C/s) form the soft and ductile pearlite phase mixture and intermediate cooling rates lead to the bainite phase [1]. The deposition patterns can be modified to change the thermal history experienced by the printed part [2]. Therefore, it is possible to change the deposition pattern in such a way that a desired thermal history and henceforth a desired microstructure can be realized at a location of interest.

OBJECTIVE

In a structure, locations with stress concentrations should comprise favourable metallurgical phases and morphology in order to mitigate crack initiation and propagation. We propose to control cooling rates and temperature history at these locations through optimizing the deposition pattern. For example, consider a block with a cylindrical hole subjected to uniaxial tension, as shown in Figure 1. The maximum stress concentration occurs at the highlighted points (labelled as 1 and 2). If the block is manufactured by the DMD process, the microstructure at these high-stress locations could be controlled by choosing a suitable deposition pattern which in turn adapt the cooling rates at these locations.

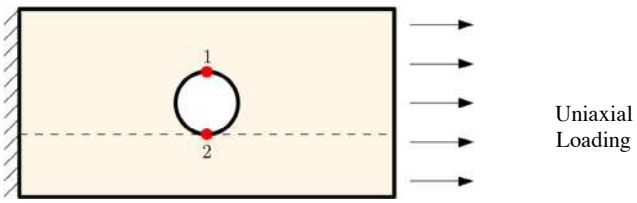

Figure 1 : Side view of a block with a cylindrical hole subjected to uniaxial loading. Highlighted points (1 and 2) in red are locations of stress concentration.

METHODOLOGY AND RESULTS

In order to achieve the objective, the structure will be discretized with Finite Elements (FE). At each FE a time variable is introduced which indicates when the associated material represented by the FE is printed; and the ascending order of the time variable represents the deposition pattern of the part. In order to maintain the continuity of the deposition pattern, continuity constraint proposed in [3] will be used. For every intermediate iteration during optimization, deposition patterns are obtained based on the time variable. The thermal history generated at the specific location through this deposition pattern can be evaluated by the element birth technique [4]. In the element birth technique, FEs are added sequentially in accordance with the time variable that represents the deposition pattern until the DMD process is completed.

Consider a solid block shown in Figure 2 which has been discretized with hexahedral elements. The block represents the lower region of the part shown in Figure 1 (region below the dashed line). Two basic raster strategies are shown in Figure 3. The corresponding thermal history generated at Point 2 of the block, as simulated for these two strategies, are shown in Figure 4. The graph shows temperature of Point 2 at every time step of transient simulation. Comparing the thermal profile obtained in the two basic strategies shows that the thermal history experienced by Point 2 is substantially different. Through optimization of the time field, the thermal history at points of interest can be modified such that desired

microstructures and material phases are obtained. The approach will be illustrated by several numerical examples. The optimized strategy to achieve a specific cooling rate at particular location in a structure will be presented.

Summary In this study, we developed an integrated multi-physics modeling framework for additive manufacturing to offer highly-accurate simulations of the metal powder melting-solidification process. In this framework, discrete element method is used for the powder delivery simulation, finite volume method is proposed to solving for the mass, momentum, and energy conservation equations for the multi-physics phenomena involving fluid flow, heat transfer, surface tension at powder scale, while an improved cellular automaton method is developed for the grain structure evolution during the solidification. We conducted numerical examples, of which the results are in good agreement with experimental data. It is demonstrated that the proposed modeling framework is a powerful approach to simulate the metal AM processes and to address the process-structure relationship.

INTRODUCTION

Metal Additive Manufacturing (AM) has found potential to revolutionize the global part manufacturing landscape in recent years because of its ability to realize rapid fabrication, precise geometric control, and flexibility to create or repair metal parts without the use of any die or mold [1]. Because the AM process involves many different physical phenomena taking place at a variety of temporal and spatial scales, however, it is challenging to optimize the AM process parameters to minimize final product defects such as surface roughness, void formation, heterogeneous grain structures, etc. via the costly trial-and-error experiments. To comprehensively understand the AM process and guide the process parameters optimization, in this work we presented a multi-physics modeling framework. In this framework, powder spreading and thermal-fluid flow models are applied to predict the thermal history and defect formation in the multi-track and multi-layer build with different processing conditions; the space- and time-varying temperature field of these simulations is passed to a cellular automaton-based microstructure model [2,3] to predict the grain structure during the solidification. Through this framework, we study the effects of various process parameters on the resulting thermal features, defects, and grain structures of the build. The simulation results (e.g., melt pool shape and size, cooling rate, and grain structures) are in good agreement with experimental results from literature [4], demonstrating the appealing potential of the proposed modeling framework, which can be used to manipulate the "driving forces" behind the complex physical phenomena to obtain AM fabricated parts with desired qualities.

MODELING FRAMEWORK

The proposed integrated modeling framework is shown in Fig.1, taking the powder bed fusion as an example. It consists of three models. Based on the discrete element method (DEM), a powder spreading model is applied for the fractional contact and collisions between metal powders and the rake over the substrate. The output of the powder spreading simulation is passed to the finite volume method (FVM) thermo-fluid flow model to conduct the powder-scale multi-physics simulation, including heat transfer, fluid flow within the melt pool, and surface tension, where the volume of fluid scheme is used for free surface modeling. Based on a one-way coupling algorithm, we feed the temperature profiles and voids information from FVM results to the cellular automaton (CA) method for the grain structure simulation. CA method simulates the evolution of the external envelope of each dendritic grain rather than the details of the dendrite arms with simplified models based on the physical nucleation and growth kinetic laws. To model the epitaxial grain growth in AM, an enriched nucleation model and a restart calculation scheme for the multi-scan and multi-layer fabrication process are developed.

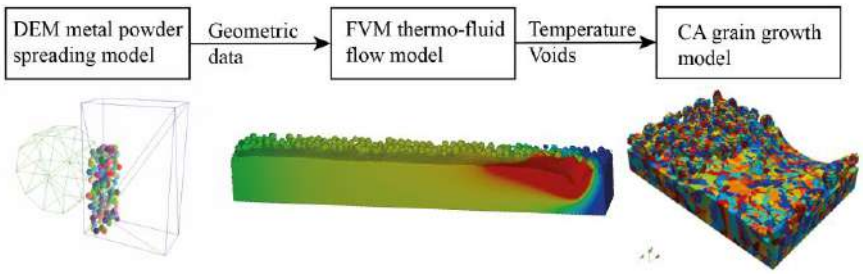

Figure 1 Integrated modeling framework for the process-structure relationship for additive manufacturing.

RESULTS AND DISCUSSION

Two sets of simulations are conducted to study the metal additive manufacturing with different process parameters. In the first set, we validated our modeling framework to the additive manufacturing benchmark (AM-Bench) experiments [4], AMB2018-02, by the National Institute of Standard Technology, USA. In AMB2018-02, melt pool geometry, cooling rates, surface topography, and grain structure in laser melted Inconel alloy IN625 bare plate were measured for three

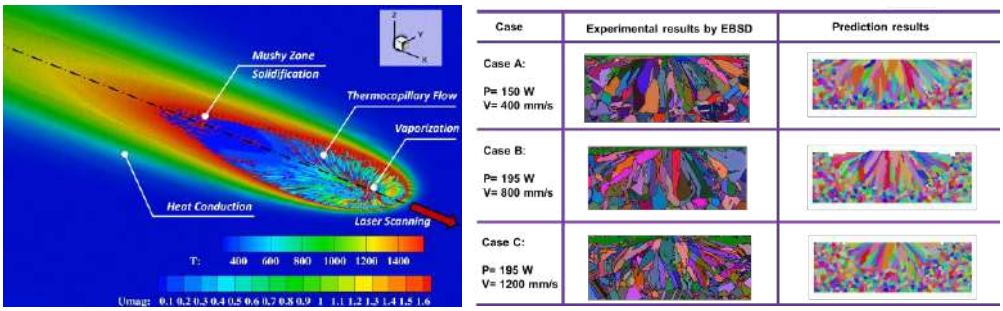
cases, which are Case A with laser power of 150 W and scan speed of 400 mm/s, Case B with 195 W and 800 mm/s, and Case C with 195 W and 1200 mm/s. The simulation results are compared with experimental data, as shown in Fig. 1 for the melt pool size and grain structure, Tale 2 for melt pool length and surface cooling rate, which demonstrate the performance of the modeling framework. In the second set, we conducted the simulations of the multiple-layer fabrication process in selective electron beam melting with different process parameters, i.e., electron beam power, layer thickness, and scan strategy, of which some results are shown in Fig. 3. It is revealed that the void formation between neighboring scans and layers due to the lack of fusion can be observed, and the surface roughness is related to the layer thickness with other process parameters given. Moreover, the obtained texture becomes stronger with the increase of deposited layers, and the completive grain growth is depicted by the thermal gradient distribution along the melt pool boundary, which leads to the complex grain structure, particularly within the overlap zone.



(a) (b)

Figure 2. Simulation results from the multi-physics modeling framework: (a) temperature distribution and streamlines within the melt pool for AMB-2018-02 Case B, (b) typical cross-sectional views of the grain structures for all 3 cases compared with the experimental results.

Table 1: Comparison of melt length and cooling rate between simulation results and experimental data

Case	Melt pool length (μm)			Surface cooling rate from 1563 K to 1273 K (K/s)		
	Experiment	Simulation	Difference	Experiment	Simulation	Difference
A	659±21	502	21%	$6.20\pm0.80\times10^5$	5.44×10^5	Match
B	782±21	772	Match	$9.35\pm1.43\times10^5$	7.59×10^5	19%
C	754±46	717	Match	$12.8\pm3.94\times10^5$	12.14×10^5	Match

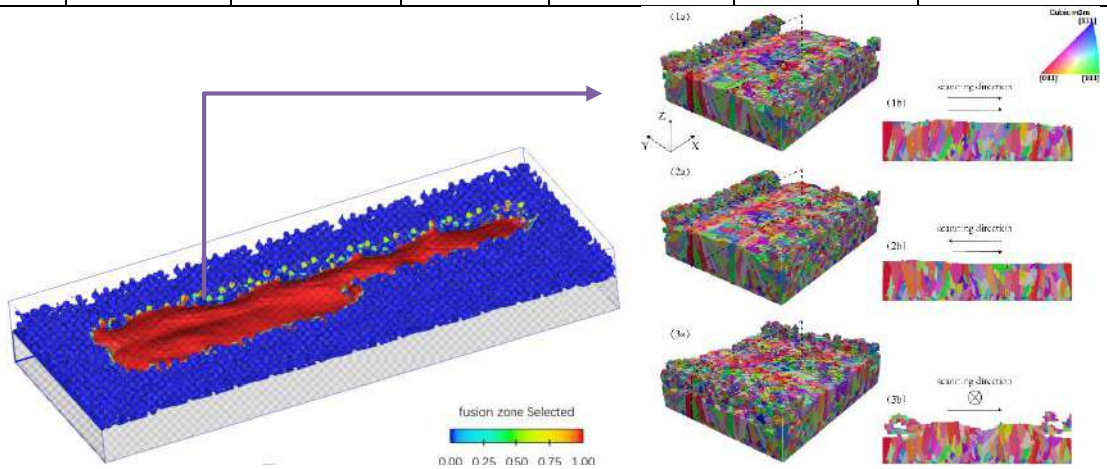


Figure 3. Simulation results with different scan strategies: (a) the 3D grain result and (b) cross-section view of (a) at the place marked by the dashed line. The scan strategies are Z-shaped, S-shaped and layer-wise rotation tracks for Case a, b, and c, respectively.

CONCLUSIONS

An integrated multi-physics modeling framework is developed for metal additive manufacturing (AM) processes. It is validated by the AMB2018-02 experimental results with three combinations of laser power and scan speed. Through this framework, the selective electron beam melting process is simulated at the powder-scale. The simulation results shed light on the effect of process parameters on the melt pool size, defect formation, and as-built grain structure. The modelling framework a powerful tool to guide the parameter optimization for AM.

Summary The present work investigates the mechanical response of additively manufactured (AM) Ti6Al4V lattice materials. The size and built-orientation dependency of the deformation and fatigue response of selective laser melted (SLM) Ti6Al4V has been analysed based on the observations from a set of miniature-specimen experiments. The gauge length and diameter of the specimens were 2mm and 200-500µm, respectively, and were built with AM orientations of 0°, 30°, 45°, 60°, and 90°. The generated deformation data were employed for underpinning an anisotropic elastic-plastic constitutive model with isotropic hardening. Implementation of the material model into a finite element model provided experimentally consistent predictions for the mechanical behaviour of macroscale lattice specimens.

INTRODUCTION

Additive manufacturing (AM) enables the fabrication of orthopaedic implants with lattice materials of tailored mechanical properties and enhanced bone ingrowth [1]. Furthermore, tuning the compliance of the lattice materials enables minimizing stress shielding, a typical drawback of current implants, thus improving mechanical biocompatibility [2]. Furthermore, the long-term mechanical integrity of AM lattice materials is an important requirement to consider for the design of orthopaedic implants. The objective of the present study is to characterise the deformation and fatigue response of the AM material at a size-scale similar to that of the struts in the lattice materials. The generated data can ultimately be exploited for the development of mechanical solutions for assessment of the deformation and fatigue of lattice-structured biomedical implants.

EXPERIMENTS

Miniature-specimen experiments

In order to rationalize the behaviour of AM lattices, investigations were performed on miniature-specimens representing the differently oriented struts of the lattices. A set of miniature tensile tests for selective laser melted (SLM) Ti6Al4V specimens with a nominal gauge length of 2mm and nominal gauge diameters of 200, 300, 400, and 500µm, built with AM orientations of 0°, 30°, 45°, 60°, and 90° were performed. The test setup and examples of the observed strain-force curves are presented in Fig. 1a and b. Similarly, miniature-specimens with different build orientations and diameters were used for a set of tension-tension fatigue experiments with R-ratio of 0.1, Fig. 1c. The fatigue endurance data display a large scatter, indicate negligible dependency to the built orientation for 200µm specimens, and show a slightly better fatigue performance for 500µm thick specimens. Micro computed tomography (µCT) was used to reconstruct the geometry of the miniature-specimens and quantify the extent of AM under/oversizing for consideration in post-processing of the experimental records (Fig. 1d).

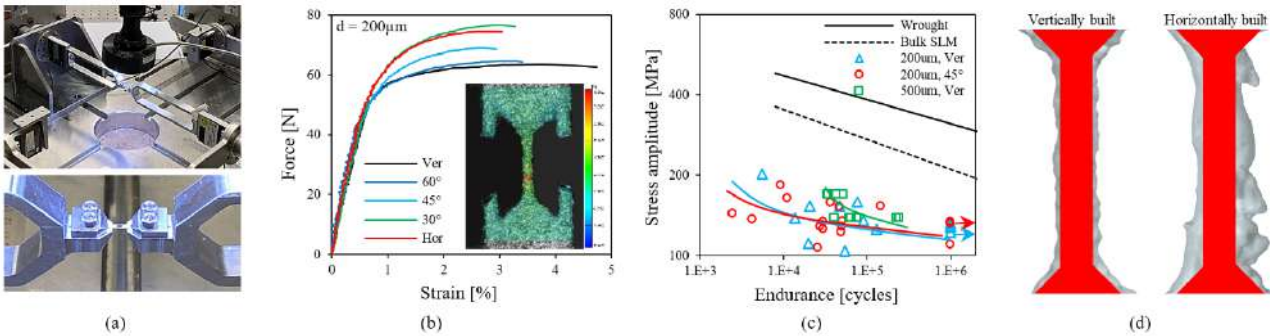

Fig. 1. a) Miniature-specimen testing setup equipped with digital image correlation (DIC) system for strain measurements, b) experimental strain-force curves for 200µm thick specimens with different AM orientations (inset: DIC analysis), c) fatigue endurance response of miniature-specimens compared with the reference lines for SLM and wrought Ti6Al4V, and d) comparison of the nominal and µCT reconstructed geometries for vertically and horizontally built miniature-specimens with diameter of 200µm.

Lattice-specimen experiments

A set of static tensile and tension-tension fatigue tests with R-ratios of 0.1 and -1.0 was conducted for the SLM Ti6Al4V lattices with tetrahedron cell topology and nominal porosity of 75% (Fig. 2). The observations from the fatigue experiments for the lattices indicated low fatigue to tensile strength ratios in the range of 0.04 - 0.05, as compared to

*Corresponding author. E-mail: ehsan.hosseini@empa.ch.

~ 0.3 and ~ 0.2 for wrought and bulk AM Ti6Al4V [3,4]. These observations highlight the need for further investigations on the fatigue response of AM lattices and careful use of such materials for cyclic loading applications. Similar to the miniature-specimens, µCT was employed to reconstruct the true geometry of the lattice specimens for consideration in subsequent finite element analyses (FEA).

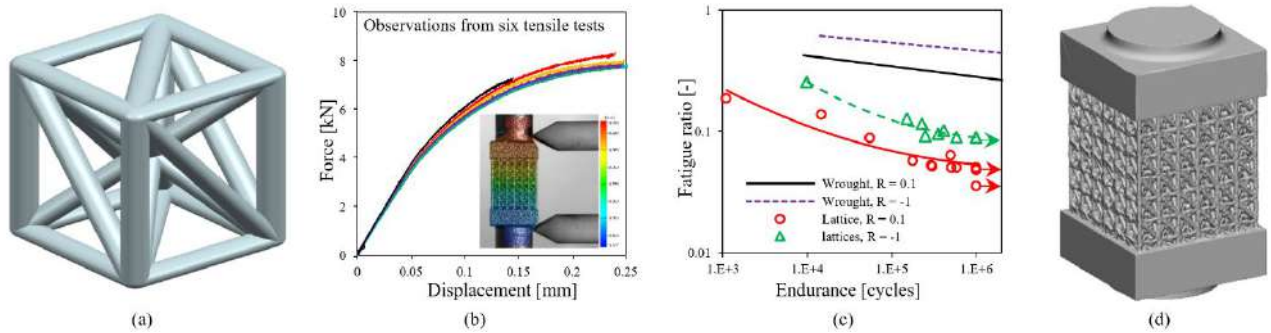

Fig 2. a) Tetrahedron cell topology, b) displacement-force curves for conducted tensile tests for SLM Ti6Al4V lattice specimens (inset: DIC analysis and side entry extensometer), c) fatigue endurance response of lattice specimens for R-ratios of 0.1 and -1.0 in comparison with reference lines for wrought Ti6Al4V, and d) an example for µCT reconstructed geometry of the examined lattice specimens.

CONSTITUTIVE MODEL DEVELOPMENT

The records from the miniature-specimen tensile experiments have been exploited for the development of an anisotropic material model for SLM Ti6Al4V. Due to the layer-by-layer manufacturing strategy, a transversely isotropic response is expected for SLM materials. This study, therefore, employed a transversely isotropic elastic-plastic model with isotropic hardening. An FE-based optimization strategy was utilised to derive the best set of model-parameters for representing the generated deformation data for miniature-specimens with different diameters and different built orientations. The designed FE model for the miniature-specimens used the µCT reconstructed geometries (e.g. Fig. 1d). The preliminary outcome of the optimization indicated a need for consideration of size effect in the material constitutive model and therefore the parameters of the proposed model were defined as a function of material-section thickness. Fig. 3a and b illustrate the representation of the developed constitutive model for different build orientations and section thicknesses, indicating a high stress level for the thicker and/or vertically built sections. The developed model was eventually used to describe the deformation response of the lattice specimens under tensile loading. As shown in Fig. 3c, the implementation of the constitutive model into FEA of the lattice specimens, based on the µCT reconstructed geometries (Fig. 2d), provided experimentally consistent predictions.

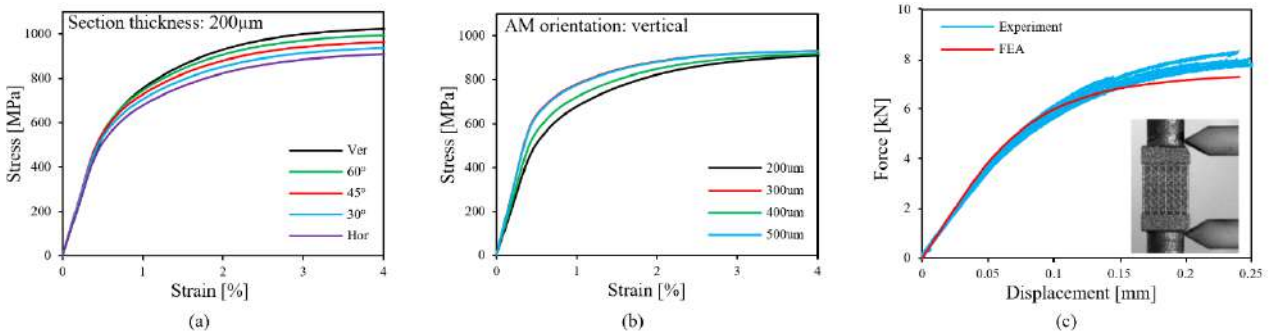

Fig 3. a) Model representation for the stress-strain response of SLM Ti6Al4V for a) different AM orientations and b) different section thicknesses. c) Comparison of experimental and model-predicted deformation response for the lattice specimens (inset: side entry extensometer for recording displacement).

CONCLUSIONS

Miniature-specimen experiments were employed to analyse the deformation and fatigue response of SLM Ti6Al4V at different AM build orientations and for specimens with different diameters. The observations were exploited for deriving a transversely isotropic elastic-plastic material constitutive model with isotropic hardening. The implementation of the developed material model into finite element models of the lattice specimens provided predictions consistent with the corresponding experiments.

PHASE-FIELD TOPOLOGY OPTIMIZATION FOR FUNCTIONALLY GRADED MATERIALS

Gianluca Alaimo1, Massimo Carraturo *[1], Alessandro Reali1, and Ferdinando Auricchio1
[1] Department of Civil Engineering and Architecture, University of Pavia, Pavia, Italy

Summary We present a numerical method to obtain topologically optimized functionally graded material (FGM) structures together with a possible pipeline to realize these kind of structural components using additive manufacturing (AM) technologies. In particular, we present a topology optimization routine based on phase-field approach FGM design together with a possible workflow to produce the resulting optimized components by means of different AM technologies.

INTRODUCTION

Functionally Graded Materials (FGMs) are characterized by a gradual spatial variation in composition and/or microstructure over the volume. Such a local variation allows to obtain global material properties in line with the functional requirements of the part. Accordingly, this class of materials introduces a radical shift from contour modeling to performance modeling since the performance-driven functionality is directly built into the material [1]. Additive manufacturing (AM) technologies drastically changed the approach to design, since the classical design for manufacturing is not required anymore and the designer can now focus on the function of the component itself. FGM design can be seen as a result of this change in the design perspective, where the component is optimized with respect to the specific application starting from its material microstructure. Nevertheless, even if recent AM technologies allow this possibility, the development of numerical methods suitable to generate FGM components is still an open issue for researchers. Moreover, implementations of automatized workflows from numerical results to final products are still an active field of research.

In the literature, we can find some numerical methods allowing to design FGM components. In particular, in [2] the mass of a structural component is minimized under stress constraints by means of the method of moving asymptotes, by optimally distributing the material density within a (fixed) initial domain. Our methodology has a similar objective, but additionally allows to obtain structures where also regions of voids can be accounted for, substantially introducing an additional degree of freedom within the design process.

FUNCTIONALLY GRADED MATERIAL TOPOLOGY OPTIMIZATION

FGMs are tightly connected with AM technologies since the high flexibility introduced into manufacturing processes allows to vary the material properties in an almost continuous fashion.

The presented topology optimization procedure aims at minimizing the compliance of FGM structures printed by means of AM processes, delivering component mechanical properties similar to periodic material structures, but employing less material. To this end, we exploit the possibility to obtain locally varying microstructures given by the most recent AM processes. Such a result is achieved by means of a phase-field topology optimization routine which is able to optimally distribute the material density parameter within the structure, allowing, at the same time, voids nucleations within the initial domain [3].

FROM SIMULATIONS TO 3D PRINTING

In order to convert the numerical results into printable data, we implemented the procedure described in Figure 1. The conversion procedure includes the following steps:

1. Choose the shape and the size of the microstructure cells;
2. Generate a Cartesian grid over the initial domain Ω with a constant size equal to the cell dimension;
3. Evaluate the average density value within each cell of Λ_ϕ and generate a cuboid (or any other geometric entity used to define the lattice cell) for each cell of Λ_χ;
4. By means of a simple boolean operation, subtracting Λ_χ to Λ_ϕ, we can obtain the final 3D virtual model ready to be printed.

The final structure is then printed and validated by means of experimental measurements [4]. Figure 2 shows the experimental setup for the three-point bending test.

CONCLUSIONS

In this work, we employ the phase-field method together with asymptotic homogenization for the analysis and the topological optimization of FGM structures, whereas an *in-house* developed code is used to convert the density map into a 3D virtual model suitable for AM processes. Experimental evidences show the higher mechanical properties of optimized FGM components compared to similar lattice structures of the same weight but uniform density.

A MICROMECHANICAL PHASE TRANSFORMATION MODEL FOR THE FINITE ELEMENT SIMULATION OF SELECTIVE LASER MELTING PROCESSES

Thorsten Bartel*[1], Isabelle Noll[1], and Andreas Menzel[1,2]
[1] Institute of Mechanics, Department of Mechanical Engineering, TU Dortmund, Dortmund, Germany
[2] Division of Solid Mechanics, Lund University, Lund, Sweden

Summary Additive manufacturing exhibits great potential for innovative industrial applications. The effect of the underlying process parameters on the properties of the final workpiece are, however, still rather vague. Thus, material and structural designs in order to obtain improved properties, in particular with respect to lifetime estimations, are rather based on empirical knowledge. This motivates the need for sophisticated material models and finite-element-based process simulations. In our contribution, the changes of state between the powder, molten, and re-solidified phase are modelled via a micromechanical phase transformation model based on energy minimisation. This model is embedded into a thermomechanically fully coupled FEM scheme for the simulation of selective laser melting processes. These simulations allow the prediction of, e.g., residual stresses and inherent strains.

THERMOMECHANICAL FRAMEWORK

The basic thermomechanical framework relies on a small-strain theory and the balance of linear momentum as well as the energy equation as global balance equations, viz.

$$\nabla_{\boldsymbol{x}} \cdot \boldsymbol{\sigma} + \boldsymbol{b} = \boldsymbol{0} \quad , \tag{1}$$

$$-\nabla_{\boldsymbol{x}} \cdot \boldsymbol{q} + r + \mathcal{D}_{\text{mech}} + \theta \, \frac{\partial}{\partial \theta} [\, \boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}} - \mathcal{D}_{\text{mech}} \,] - \widetilde{c} \, \dot{\theta} = 0 \quad . \tag{2}$$

In these relations, $\boldsymbol{\sigma} := \partial \overline{\psi} / \partial \boldsymbol{\varepsilon}$ denotes the stress tensor derived from an energy density (to be specified later), $\boldsymbol{b}$ are volume-distributed forces, $\boldsymbol{q}$ is the heat flux vector, r symbolises heat sources, $\mathcal{D}_{\text{mech}}$ is the mechanical dissipation, θ is the absolute temperature, $\widetilde{c}$ reflects the effective thermal conductivity which stems from the specific constitutive model and $\dot{\bullet}$ denotes the time derivative. These two equations are transferred to their respective weak forms and subsequently discretised with respect to the underlying degrees of freedom — displacements $\boldsymbol{u}$ and temperature θ — in a straight-forward manner. The finite element modelling of the additive manufacturing process, however, requires some non-conventional aspects which shall be addressed in the following.

CONSTITUTIVE FRAMEWORK

The material model follows a micromechanical approach, where each possible state of the material — i.e. powder, molten, and re-solidified — is considered as an independent phase of the material; cf. [1] and references cited therein. Accordingly, we first introduce material models for each individual phase in terms of phase energy densities, to be specific

$$\psi_{\bullet} := \tfrac{1}{2} \left[\boldsymbol{\varepsilon}_{\bullet} - \boldsymbol{\varepsilon}^{\text{in}}_{\bullet} \right] : \mathbf{E}_{\bullet} : \left[\boldsymbol{\varepsilon}_{\bullet} - \boldsymbol{\varepsilon}^{\text{in}}_{\bullet} \right] + \psi^{\text{cal}}_{\bullet} \quad \text{with} \quad \bullet \in \{\text{pow}, \text{mel}, \text{sol}\} \, . \tag{3}$$

Here, $\boldsymbol{\varepsilon}_{\bullet}$ denotes the total strains in each phase where "pow" represents the powder phase, "mel" the molten phase, and "sol" the re-solidified phase. Moreover, $\boldsymbol{\varepsilon}^{\text{in}}_{\bullet}$ are the respective inelastic strain contributions in each phase, $\mathbf{E}_{\bullet}$ denote the underlying fourth order elasticity tensors, and $\psi^{\text{cal}}_{\bullet}$ reflect the caloric energy contributions. These phase energy densities define the averaged energy density $\overline{\psi}$ of the possible phase mixture by applying the mixture rule

$$\overline{\psi} := \xi_{\text{pow}} \, \psi_{\text{pow}} + \xi_{\text{mel}} \, \psi_{\text{mel}} + \xi_{\text{sol}} \, \psi_{\text{sol}} \quad , \tag{4}$$

wherein $\xi_{\bullet}$ denote the volume fractions of the respective phase.

In contrast to models which make use of one global inelastic strain tensor only, which frequently is referred to as inherent strain tensor, the present approach considers distinct and inelastic strain contributions specific for each phase. While no inelastic strains are considered in the powder material, the inelastic strains in the molten phase are decomposed as

$$\boldsymbol{\varepsilon}^{\text{in}}_{\text{mel}} := \boldsymbol{\varepsilon}^{\text{vi}}_{\text{mel}} + \boldsymbol{\varepsilon}^{\text{tr}}_{\text{mel}} \quad , \tag{5}$$

incorporating a viscous strain contribution, $\boldsymbol{\varepsilon}^{\text{vi}}_{\text{mel}}$, and a transformation strain contribution, $\boldsymbol{\varepsilon}^{\text{tr}}_{\text{mel}}$. Moreover, the inelastic strains in the solid phase are introduced as

$$\boldsymbol{\varepsilon}^{\text{in}}_{\text{sol}} := \boldsymbol{\varepsilon}^{\text{pl}}_{\text{sol}} + \boldsymbol{\varepsilon}^{\text{tr}}_{\text{sol}} + \boldsymbol{\varepsilon}^{\text{th}}_{\text{sol}} \quad , \tag{6}$$

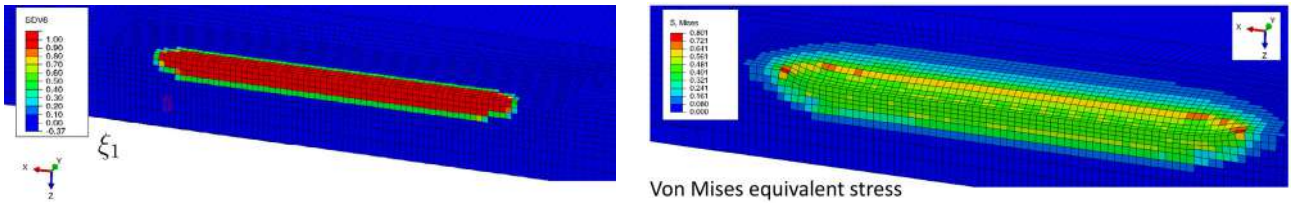

Figure 1: Selected results of the basic SLM process simulation after the addition of three layers. Left: Final distribution of the solid phase. The red parts symbolise purely solid regions with $\xi_{\text{sol}} = 1$, whereas blue regions illustrate the (still) powder material, and the apparent intermediate states (greenish colours) result from the interpolation algorithm used in Abaqus. Right: Illustration of the deformation and spatial distribution of the residual von-Mises equivalent stress.

which consist of a plastic part, $\varepsilon^{\text{pl}}_{\text{sol}}$, a transformation part, $\varepsilon^{\text{tr}}_{\text{sol}}$, and a thermal part, $\varepsilon^{\text{th}}_{\text{sol}}$. The transformation strains follow from the significant change in mass density, $\rho_\bullet$, and are defined as

$$\varepsilon^{\text{tr}}_{\text{mel}} := \frac{1}{3}\left[\frac{\rho_{\text{pow}}}{\rho_{\text{mel}}} - 1\right] \boldsymbol{I} \quad \text{and} \quad \varepsilon^{\text{tr}}_{\text{sol}} := \frac{1}{3}\left[\frac{\rho_{\text{pow}}}{\rho_{\text{sol}}} - 1\right] \boldsymbol{I} \quad , \tag{7}$$

wherein $\boldsymbol{I}$ denotes the second order identity tensor. The total strains $\boldsymbol{\varepsilon}_\bullet$ in each phase follow from the convexification of the multi-well potential defined in (4), which results in homogeneous stress states among the phases.

For the remaining internal state variables, namely ξ_{pow}, ξ_{mel}, ξ_{sol}, $\varepsilon^{\text{vi}}_{\text{mel}}$, and $\varepsilon^{\text{pl}}_{\text{sol}}$, thermodynamically consistent evolution equations are derived and solved at integration point level. The related inequality constrains, in particular the conservation of mass, are fulfilled and considered by so-called NCP functions (Nonlinear Complementarity Problem); see, e.g., [2] and references cited therein.

The heat conduction is modelled in terms of a Fourier-based formulation, i.e.

$$\boldsymbol{q} = -\,\widetilde{k}\,\nabla_{\boldsymbol{x}}\,\theta \quad \text{with} \quad \widetilde{k} := \left[\frac{V}{m}\left[\,\xi_{\text{pow}}\,\rho_{\text{pow}}\,k^{-1}_{\text{pow}} + \xi_{\text{mel}}\,\rho_{\text{mel}}\,k^{-1}_{\text{mel}} + \xi_{\text{sol}}\,\rho_{\text{sol}}\,k^{-1}_{\text{sol}}\,\right]\right]^{-1} \tag{8}$$

so that the averaged heat conduction coefficient $\widetilde{k}$ is obtained via homogenisation based on the respective heat conduction coefficients $k_\bullet$ of the individual phases. Moreover, the representation of the effective heat capacity results in

$$\widetilde{c} := -\,\theta\,\frac{\partial^2\overline{\psi}}{\partial\theta\,\partial\theta} = \frac{V}{m}\left[\,\xi_{\text{pow}}\,\rho_{\text{pow}}\,c_{\text{pow}} + \xi_{\text{mel}}\,\rho_{\text{mel}}\,c_{\text{mel}} + \xi_{\text{sol}}\,\rho_{\text{sol}}\,c_{\text{sol}}\,\right] \quad . \tag{9}$$

ALGORITHMIC IMPLEMENTATION

The material model addressed above is implemented into the Abaqus subroutine UMAT and UMATHT. An essential aspect of the subsequent Finite Element model is the modelling of the laser beam impact, in other words the specification of the heat source contribution r in (2). Here, we use a moving heat source according to [3] which can be incorporated into the Abaqus routine DFLUX.

FEM-BASED SIMULATION OF AN SLM PROCESS

The numerical example comprises a straight laser path and the addition of three powder layers to a solid base platform. This thermomechanically fully coupled simulation of a basic selective laser melting (SLM) process already provides important results, for example concerning the spatial distribution of the solid phase — which generally defines the geometry of the final workpiece — and the distribution and amplitudes of residual stresses after cooling, cf. Fig. 1.

It is remarked that the finite element simulations have been carried out by using an Updated Lagrange approach, where the configuration of the underlying system in the former time step is used as reference configuration for the current time step. This approach allows the use of a small strain theory with acceptable errors even though the occurring deformations, such as the change in width of the powder layer, is large.

Summary A sensitivity of the prediction of the melt pool shape and the temperature evolution with the thermo–physical properties in a high speed steel laser cladding process is investigated. The analysis is performed in the normal range of experimental errors in two finite element input data: the heat capacity and the thermal conductivity measurements. Significant effects for both a bulk and a thin–walled manufactured part are presented with their respective phenomena explanation. The process simulations with two and three dimensional finite element thermal models for each respective manufactured part shape consider a set of material parameters obtained from experimental data with both direct and inverse identification techniques. Microstructure prediction strongly depends on the pool size which is not only affected by the laser power but also by the variation of temperature dependent physical properties.

INTRODUCTION

Optimal cladding process parameters heavily rely on finite element (FE) simulations predicting melt pool size. However, the accuracy and the sensitivity of the FE results to the input thermo–physical material input properties are not often discussed, even if some validations are described. For instance, Chiumenti et al. [1] investigated the effect of preheating temperature on the thermal evolution and melt pool size. In the current work, a two (2D) and three dimension (3D) FE models are used to simulate the thermal evolution in both bulk and thin wall cladded samples, respectively. Previous studies conducted by Hashemi [2, 3] for high speed steel (HHS) bulk samples validate the substrate temperature and the melt pool size predictions. The thermal history accuracy is essential to explain the microstructure heterogeneity as shown by Jardin et al. [4]. The cladded samples studied hereafter are made by M4–HSS metal powder of 50 to 150 µm particle size. The bulk sample is composed by 36 layers with 27 parallel lines (tracks) each, giving a final parallelepiped shape of 40x40x27.5 mm. The targeted height per layer was 0.76 mm. The lines of the upper layers are printed with an offset to maintain contact with half of each of the two neighbouring lines of the lower layers. Temperature histories are measured by thermocouples located in the substrate at 10 mm from the sample in the direction of the lines and at 5 mm depth. The measured temperature level increases non–linearly with the number of the printed layers reaching a maximum global value. The temperature oscillations are correlated with the laser movements. Each oscillation observed in Fig. 1 (a) correspond to a layer deposit and the fourteen local maxima corresponds to the moment when the laser is closer to the thermocouple. More information about the cladding parameters applied to manufacture the thin wall and bulk samples are given in Table 1.

Table 1. Laser cladding process parameters selected for the samples manufacturing.

Sample	Laser beam speed (mm/s)	Laser power (W)	Preheating (°C)	Mass flow (mg/s)	Number of tracks per layer	Total number of layers
Bulk	6.67	1100	300	76	27	36
Thin wall	7.00	420	438	83	1	5

FE THERMAL MODEL FOR BULK AND THIN WALL LASER CLADDING PROCESSES

The FE code LAGAMINE developed at the University of Liège since 1985 is used to simulate both laser cladding processes (the bulk sample in 2D and the thin wall in 3D). The element birth technique is applied to model the addition of material within the processes. When a new layer is created and the laser beam moves, solid elements are activated with their respective surface elements for convection and radiation phenomena while the surface elements under this layer are deactivated. The bulk sample is modelled considering the vertical symmetry plane parallel to the laser movement during the tracks printing. The oscillations related to each track are consequently not captured by the 2D FE model. Considering the high temperature gradients, refinement of the mesh is performed in the cladding area to obtain accurate thermal history. Under the laser beam, the heat flux was applied through nodal input. At the surface, the energy balance equation is respected $k(\nabla T.n) = q_{laser} - h(T - T_0) - \varepsilon\sigma(T^4 - T_0^4)$, where k is the conductivity, n is the normal vector to the surface, ∇T is the temperature gradient, q_{laser} is the laser heat flux depending of the absorption factor (β) multiplied by the laser heat flux density distribution on the workpiece, h is the convection coefficient, σ is the Stefan–Boltzmann constant, ε is the emissivity coefficient and T_0 is the temperature of the environment. The temperature distribution for the cladded part is obtained from the three–dimensional heat conduction Eq. 1,

$$\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right) + Q_{int} = \rho c_p \frac{\partial T}{\partial t} \quad (1)$$

with $T(x,y,z,t)$ the transient temperature, Q_{int} the power per volume generated in the workpiece (phase transformation), ρc_p the heat capacity and t the time. More details regarding the model can be found in Tran et al. [5]. The parameters used in the reference boundary conditions for the two type of samples (Table 1) are inversely identified from experimental results shown in Figure 1 (a) and (d).

Table 1. Bulk and thin wall sample dataset inversely identified by correlating measurements and simulation results.

Sample	Convection (h) (W/m²K)	Emissivity (ε)	Absorption factor (β)
Bulk	230	1	0.067
Thin wall	10	0.8	0.44

ANALYSIS OF SIMULATION RESULTS AND CONCLUSIONS

Figure 1 (a) and (d) allows to validate the simulations of the cladding processes of bulk (bs) and thin wall (tw) samples. The range of variations for the sensitivity analysis is chosen within the accuracy of measurements associated with the experimental equipment used. The upper and lower bounds used hereafter are computed with the error variation of 3% for the specific heat, 7% for the thermal conductivity and 2% for the density. The numerical results presented in Figure 1 (b) and (e) show that a decrease of thermal inertia fraction produced by a lower heat capacity gives an increase in the temperature of the substrate of both samples. However, for the thin wall sample, the temperature is less sensitive to the increase of the ρc_p. This non–linear effect is explained by the low volume ratio between the clad and the substrate and by the relative high heat fraction related to the melting latent heat and the respective greater part of heat storage during superheating of the melt pool. The positive and negative variations of the conductivity shown in Figure 1 (c) and (f) yield quite symmetrical temperature differences compared to the curve associated with the reference conductivity value. However, an opposite behaviour appears between bulk and thin wall sample with the conductivity variations. The energy storage capacity within the melt pool has been found as the predominately driving feature of this behavior in the thin wall sample. Ongoing research validates this hypothesis and further details will be given in a future publication.

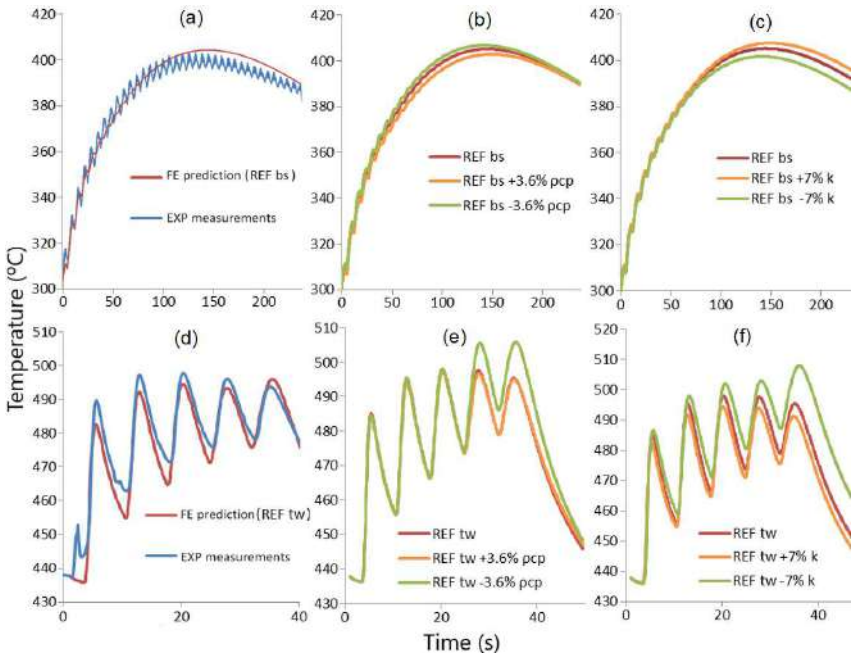

Figure 1. Experimental and predicted process thermal history at the local measurement points in the substrate of (a) bulk and (d) thin wall samples. Effect of the variations of ((b), (e)) heat capacity and ((c), (f)) conductivity on the computed temperature evolution.

COMPREHENSION OF DISTORTION IN METAL ADDITIVE MANUFACTURING BASED ON ASSUMPTION OF CONSTRAINING FORCE INDUCED DISTORTION

Deqiao XIE[1], Jianfeng ZHAO *[2], Lida SHEN[2], Zongjun TIAN[2] and Yingdong Song[1]
[1] College of Energy and Power Engineering, University of Aeronautics and Astronautics, Nanjing, China
[2] College of Mechanical and Electrical Engineering, University of Aeronautics and Astronautics, Nanjing, China

Summary Metal additive manufacturing has exhibited attractive prospect in aerospace, medical, and automobile industries. However, the distortion of metal part has been an obstacle in widespread application of metal additive manufacturing. We proposed an assumption of constraining force induced distortion (CFID) so as to quantificationally explain the distortion in metal additive manufacturing. The distortion can be regarded as a result of a constraining force acting on a certain structure. The constraining force derives from the inconsistent shrinkage during the additive manufacturing process. And its direction is determined by laser scanning routine. Based on the CFID, we are able to comprehend the distortion as a whole, as well as to effectively predict and decrease the distortion in metal additive manufacturing.

Introduction

As a promising technology, metal additive manufacturing has been used in fabricating an integrated, lightweight, and complex-shaped structure, which has potential application in aerospace, medical, and automobile industries. Much attention has been paid on the mechanism of distortion in additive manufacturing, especially for metal parts. Mercelis [1] and Kruth [2] explained the distortion of metal additive manufacturing based on the thermal gradient mechanism (TGM). The qualitative TGM model states that the laser heats up solid material, which tends to expand. After the laser leaves, the irradiated zone will be cool and tends to shrink. The captured distortion images with Digital Image Correlation (DIC) [3] and the recorded distortion curves with Laser Displacement Sensor (LDS) [4] verified the distortion behavior in heating and cooling process predicted by TGM. However, some phenomena cannot be interpreted well by TGM, such as the link between temperature and distortion.

Assumption of constraining force induced distortion

Figure 1(a) illustrates the laser converging on the substrate; this melted the substrate and the incoming powder, forming a molten pool. After the laser was removed, the molten pool cooled and solidified, forming a one-track deposition. The molten pool shrunk due to the temperature decline after the laser was removed. The deposited metal all underwent the same melting-cooling process in the single track LMD, so the deposited track was assumed to shrink uniformly. In Figure 1b, l_d represents half the length of the deposited track at a high temperature. Δl_d is half the shrinkage of the deposited track at low temperature if there was no constraint. Nevertheless, the substrate at room temperature showed a little shrinkage. As a result, a balanced distribution of deformation was generated between the deposited track and the substrate. The deposited track was stretched by the substrate, while the substrate was compressed by the deposited track. Thus, the half shrinkage of the deposited track Δl_d could be restricted to Δl_s due to the substrate constraint. The interaction force along the longitudinal direction between the deposited track and the substrate was assumed to be F_{ds}.

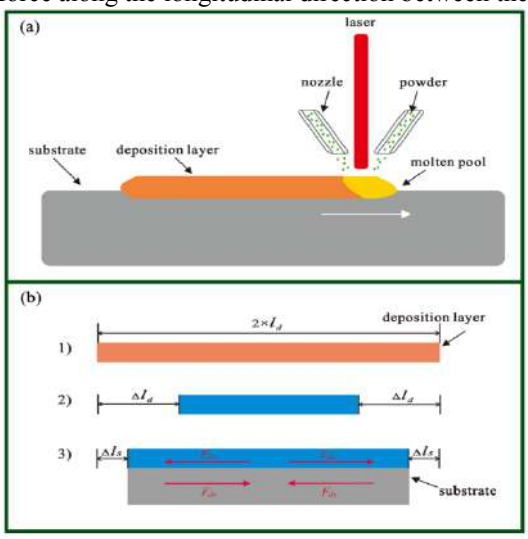

Fig. 1. Assumption of CFID.

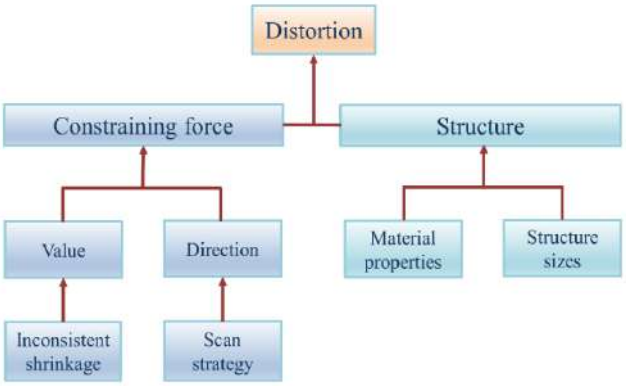

Fig. 2. Influencing factors of distortion.

Combined with melt-solidification process, the constraining force F_{ds} was expressed by Hooke's law as follows [5]:

$$F_{ds} = \frac{(\Delta l_d - \Delta l_d)}{l_d} \cdot E_d \cdot A_d = \frac{(\Delta l_d - \Delta l_d)}{\Delta l_d} \cdot \frac{\Delta l_d}{l_d} \cdot E_d \cdot A_d = k_{ds} \cdot \frac{\Delta l_d}{l_d} \cdot E_d \cdot A_d = k_{ds} \cdot (\alpha \cdot \Delta T + \beta_{pt}) \cdot E_d \cdot A_d$$

Distortion of thin-walled structure

Based on CFID, the longitudinal constraining force (LCF) in Fig. 3(b) is parallel to the longitudinal scan (LS) direction in Fig. 3(a), and the transverse constraining force (TCF) is also parallel to the transverse (TS). Fig. 4 shows that the side with LS was distorted. Besides, the side with TS was distortion-free. As a result, the assumption of CFID can be used to comprehend the distortion of thin-walled structure.

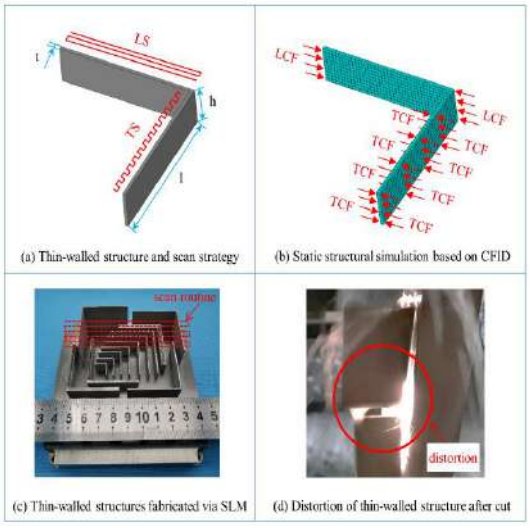

Fig. 3. Scan strategy of thin-walled structure via SLM.

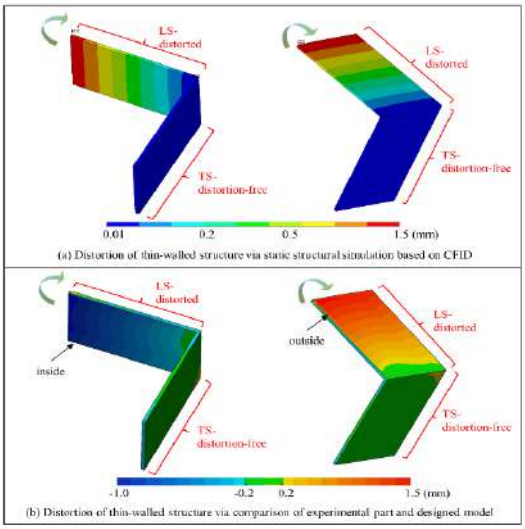

Fig. 4. Distortion of thin-walled structure.

Distortion of cantilever structure

Fig. 5 shows the assumed inconsistent shrinkage of cantilever structure based on CFID. It detailedly describes the evolution of inconsistent shrinkage. The experimental results validated the described inconsistent shrinkage, which impelled the distortion after the cantilever structure was cut from the substrate.

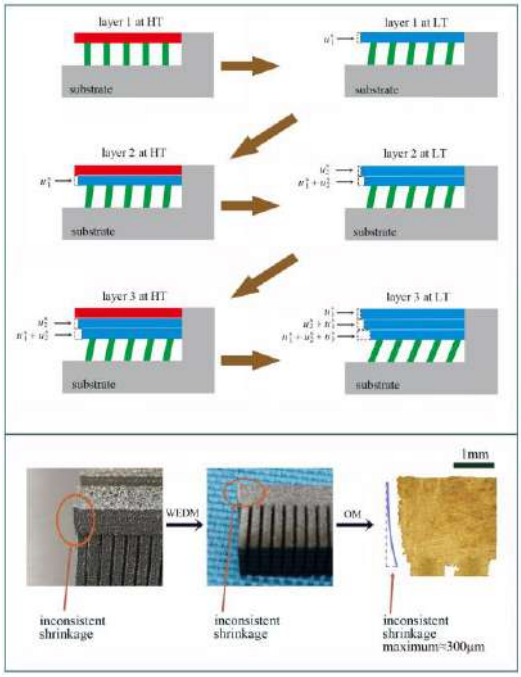

Fig. 5. Inconsistent shrinkage of cantilever structure.

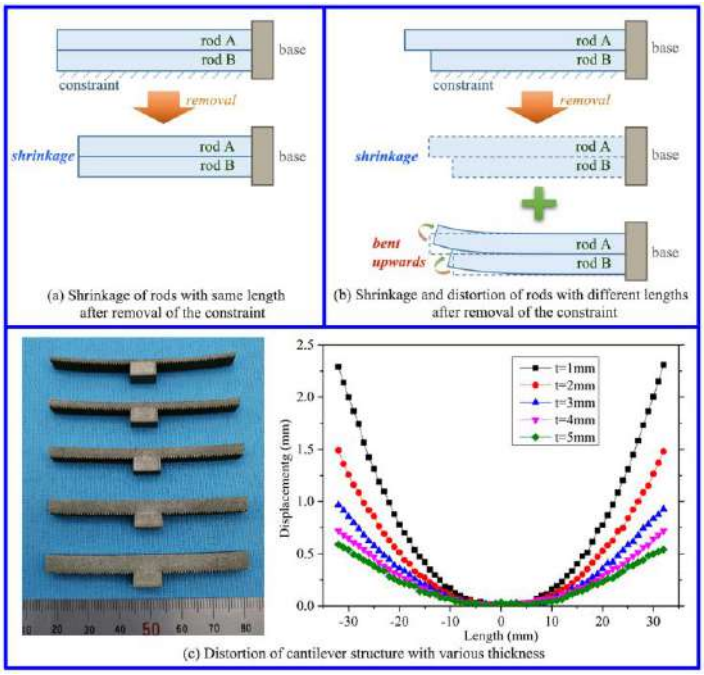

Fig. 6. Comprehension of distortion of cantilever structure.

Conclusions

We have proposed an assumption of Constraining Force-Induced Distortion (CFID) that offers a quantitative way to comprehend the distortion of additive manufacturing. The formula of constraining force pointed out the influencing factors of distortion as a whole. Based on the CFID, the distortion of typical structure, like thin-walled and cantilever structure, can be interpreted in detail.

MECHANICAL DESIGN IN ADDICTIVE MANUFACTURING: FROM 3D TO 4D PRINTING

Daining Fang*[1,2], Wei-Li Song [1], and Haosen Chen [1]
[1] Institute of Advanced Structure Technology, Beijing Institute of Technology, Beijing 100081, P. R. China
[2] State Key Laboratory for Turbulence and Complex Systems, College of Engineering, Peking University, Beijing, 100871, P. R. China.

Summary Development of addictive manufacturing technology has fundamentally exhibited great advantages, which provides an exclusive platform for manufacturing smart structures. Based on 3D printing added with additional dimension, either time or space, for manipulating shape, property or functions, in the present talk, I would initially analyse the key scientific issues in 4D printing technology as well as several examples based on our current studies for better understanding how 4D printing plays a significant role in designing and manufacturing smart structures and smart devices. The 4D printing technology is expected to open a novel strategy for substantially endowing the advanced structures with smartness and exceptionality.

Advanced manufacturing is one of the national strategies in China. Among the advanced manufacturing, addictive manufacturing technology holds the features of achieving complex arbitrary structures, typically in (1) integrating the materials and structures as well as (2) integrating design and manufacturing. Thus, these two features provide a new platform for mechanical structure design. There are three critical challenges in the addictive manufacturing. Challenge 1 is the mechanical design method and optimization theory toward addictive manufacturing. As is known, advantage extension upon layer-by-layer addictive manufacturing, while the appropriate mechanical design method is still incomplete. The second challenge is the mechanical modeling and simulation method for establishing relationship of "addictive manufacturing-design-performance prediction". It is a hot topic in structure design, process simulation and performance prediction separately, while integrating these three targets is still a great challenge. The third challenge is the advanced automatic equipment for developing addictive manufacturing via integrating design and manufacturing. For high-performance complicated structures in aerospace, addictive manufacturing equipment are required to develop for realizing the multi-yarn and pre-strengthening manipulation in promoting the effectiveness of the manufacturing. There are several critical factors in developing lightweight multi-functional materials and structures using addictive manufacturing, including design, equipment and manufacturing.

This presentation would focus on the mechanical design in the addictive manufacturing. In the mechanical design and manufacturing of 3D printing, there are three sections. In the first section, design methods for advanced 3D printed structures would be discussed on the design of zero expansion structures, chiral structures and auxetic structures. In the second section, design methods for shape retention in 3D printing would be included for alleviating two critical problems in the processing of addictive manufacturing. In the third section, design methods for property retention in 3D printing would be analysed to understand the microstructure regulating mechanism in the addictive manufacturing process.

Additionally, 4D printing technology would be systematically summarized. 4D printing uses an AM to create a 3D object with adding the dimension of shape change, property change or function variation over time and space. Initially, the background of 4D printing would be discussed. Subsequently, several demonstrations using 4D printing technology would be provided for better understanding the process. For example, swelling-driven 4D printed smart lattice structures could be established by the hetero-material printing based on the design lattice. Moreover, photo-polymerization-driven 4D printing would be realized via controlling the polymerization degree. Furthermore, active origami structures for reconfigurable antennas could be designed and constructed via multi-material printing and multi-stable origami design. In addition, stiff reconfigurable polygons for smart connecters could be assembled via two designed components. Also, precisely controllable smart chromatic films would be achieved via electrochemical manipulation.

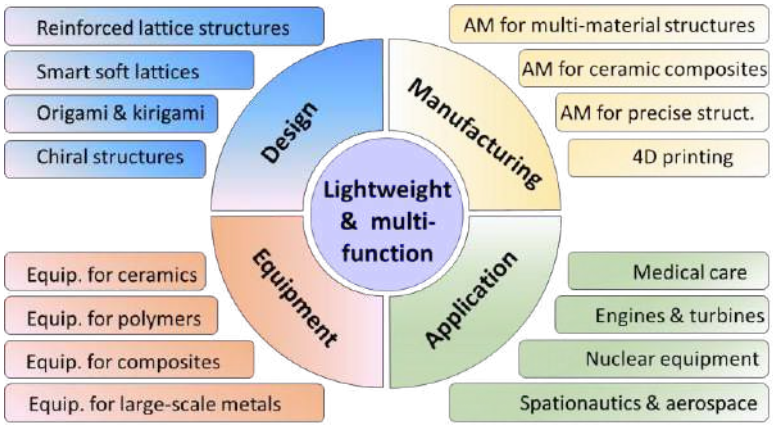

Figure 1. Schemes for illustrating the innovation R&D center for lightweight multi-functional structures

As shown in Figure 1, there is an innovation R&D center for lightweight multi-functional structures based on addictive manufacturing technology with range from design, manufacturing, equipment to applications. For a significant application

*Corresponding author. E-mail: fangdn@bit.edu.cn; fangdn@pku.edu.cn.

from addictive manufacturing technology, the very first all-printed metal satellite upon lattice structures was launched into the orbit. Such technology opens an era for designing & manufacturing key components for satellites using 3D lattice structures & addictive manufacturing, with great impacts on China's aerospace industry.

CONCLUSIONS

In conclusion, the core in the advanced manufacturing would be the mechanical design of structure unit cells for extending the concept of designing macrostructures, with expectation of breaking through the state-of-the-art of traditional materials and structures. With the assistant of mechanical design coupled with addictive manufacturing, various advanced structures with specific functions and applications would be expected to be achieved soon.

A THERMO-ELASTO-VISCOPLASTIC FINITE ELEMENT MODEL TO STUDY MICROSTRUCTURE EVOLUTION OF POLYCRYSTALS DUE TO INTRINSIC HEAT TREATMENT DURING METAL ADDITIVE MANUFACTURING

Nikhil Mohanan[1], Matthias Rambausek[1] and Manas Upadhyay*[1]
[1] Laboratoire de Mécanique des Solides, CNRS, Ecole Polytechnique, Institut Polytechnique de Paris, Route de Saclay, 91128 Palaiseau Cedex, France

Summary In this work, a strongly-coupled Thermo-Elasto-ViscoPlastic Finite Element (T-EVP-FE) crystal plasticity model is proposed. This model allows studying the elastic and plastic deformation of polycrystalline materials under the action of combined transient thermal and mechanical boundary conditions. These boundary conditions are obtained from a macroscale thermomechanical FE model that is used to simulate the building of AM samples. The simulated material is a 316L stainless steel. The role of single crystal elastic anisotropy and plastic heterogeneity on the intragranular and intergranular strains due to temperature/heat-flux boundary conditions is analysed and the key findings will be presented. Perspectives on comparison with experiments will also be presented.

MOTIVATION AND AIM

During an Additive Manufacturing (AM) or 3D printing process, just after deposition, a liquid material rapidly solidifies and spends rest of the building time being subjected to Solid-State Thermal Cycling (SSTC), at varying temperature rates and amplitudes, an illustration is shown in Fig. 1. During initial stages of SSTC, temperature amplitudes higher than annealing points and temperature rates as high as 10^6 K/s can be encountered. Consequently, large transient temperature gradients are formed, which result in strong transient thermal stresses due to internal and/or external constraints. Such rapidly varying temperatures and thermal stresses can result in significant changes in the microstructure, including dislocation structure evolution, recrystallization, phase transformation, etc. During later stages of SSTC, a nearly steady-state heat conduction occurs at relatively high temperatures with respect to room temperature. Such relatively high temperatures along with internal stresses due to a metastable microstructure can also result in dislocation recovery, grain growth, precipitation, etc.

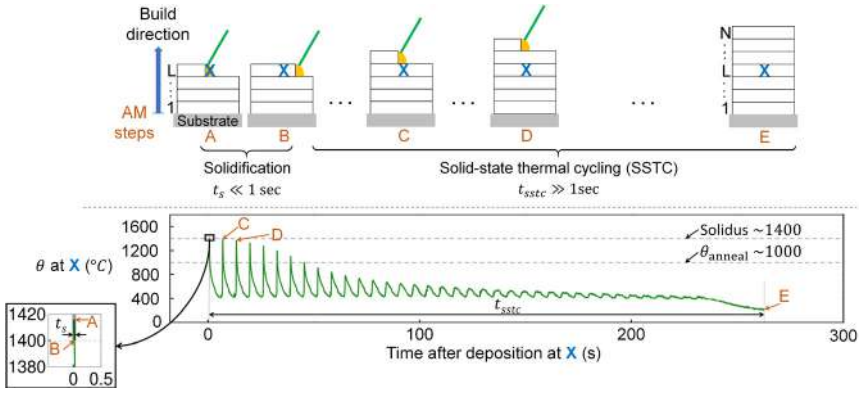

Figure 1: An illustration [1] of temperature (θ) vs time (t) evolution at a material point X during additive manufacturing of a wall. t=0 corresponds to the moment the heat-matter interactions occur at X in a layer L<N, where N is the total number of layers.

Currently, most research efforts in the field of modelling of microstructure evolution during metal AM are focused on understanding the microstructure formation during solidification. Thus far, very little efforts have been dedicated towards understanding the role of microstructure evolution due to SSTC during AM. In this work, we are interested in understanding what happens to the microstructure after it has solidified and until the end of the AM process, i.e. during the long period when it is subjected to SSTC.

Recently, Upadhyay [1] proposed the Thermal Field Dislocation Mechanics (T-FDM) model to study the dynamics of dislocations at the intragranular level under the action of transient temperature and heat flux boundary conditions. The focus of this work is at the polycrystalline level and our aim is to develop a crystal plasticity type modelling framework that captures the role of strong thermal gradients on the local and macroscopic elastic-plastic response of a material and that can be coupled/extended with other physics based-models, e.g. recrystallization/grain growth, to better capture microstructure evolution during SSTC.

To that end, we propose the Thermo-Elasto-ViscoPlastic Finite Element (T-EVP-FE) model to simulate the polycrystalline response due to SSTC during AM.

THE T-EVP-FE MODEL

We consider a body $\mathcal{B}$ with surface $\partial\mathcal{B}$ to be a thermodynamically closed system. We shall assume that the local temperature θ at any material point in $\mathcal{B}$ is always below the solidus. We assume that $\mathcal{B}$ is a simply connected body without voids or cracks. We also assume that $\mathcal{B}$ is a polycrystal with intergranular interfaces (grain boundaries) such that the total displacement ($\boldsymbol{u}$) is continuous everywhere. The main set of governing equations of the geometrically linear T-EVP-FE model are:

$$\boldsymbol{U} = \boldsymbol{\nabla u} = \boldsymbol{U}^e + \boldsymbol{U}^p + \boldsymbol{\varepsilon}^\theta \tag{1}$$

$$\boldsymbol{\varepsilon} = \boldsymbol{sym}\,(\boldsymbol{U}),\ \boldsymbol{\varepsilon}^e = \boldsymbol{sym}\,(\boldsymbol{U}^e),\ \boldsymbol{\varepsilon}^p = \boldsymbol{sym}\,(\boldsymbol{U}^p),\ \boldsymbol{\varepsilon}^\theta = \boldsymbol{\gamma}(\theta - \theta_0) \tag{2}$$

$$\dot{\boldsymbol{\varepsilon}}^p = \sum_s \boldsymbol{m}^s \left(\dot{\gamma}_0^s \left(\frac{\boldsymbol{m}^s : \boldsymbol{\sigma}}{\tau_{crss}} \right)^n \operatorname{sign}(\boldsymbol{m}^s : \boldsymbol{\sigma}) \right) \tag{3}$$

$$\boldsymbol{\sigma} = \boldsymbol{\mathcal{C}} : (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}^p) - \boldsymbol{\beta}(\theta - \theta_0) \tag{4}$$

$$\boldsymbol{q} = -\boldsymbol{K} \cdot \boldsymbol{\nabla}\theta \tag{5}$$

$$\boldsymbol{\nabla} \cdot \boldsymbol{\sigma} + \rho \boldsymbol{f} = \rho \ddot{\boldsymbol{u}} \tag{6}$$

$$\rho c_v \dot{\theta} = \boldsymbol{\nabla} \cdot (\boldsymbol{K} \cdot \boldsymbol{\nabla}\theta) + \boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}}^p - \theta \boldsymbol{\beta} : (\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^p) + \rho r \tag{7}$$

where bold font variables/symbols indicate vector/tensor (order ≥ 2) quantities, $\boldsymbol{U}$: total distortion, $\boldsymbol{\nabla}$: differential operator, $\boldsymbol{U}^{e/p}$: elastic/plastic distortion, $\boldsymbol{\varepsilon}^{e/p}$: elastic/plastic strain, $\boldsymbol{\varepsilon}^\theta$: thermal strain, $\boldsymbol{\gamma}$: thermal expansion coefficient matrix (assumed constant), θ_0: reference temperature s: slip system, $\boldsymbol{m}^s$: Schmid tensor, $\dot{\gamma}_0^s$: reference shear rate on a slip system s, τ_{crss}: critical resolved shear stress, n: power law exponent, $\boldsymbol{\sigma}$: Cauchy stress, $\boldsymbol{\mathcal{C}}$: elastic stiffness tensor, $\boldsymbol{\beta} = \boldsymbol{\mathcal{C}} : \boldsymbol{\gamma}$: thermal moduli tensor, $\boldsymbol{q}$: heat flux vector, $\boldsymbol{K}$: heat conductivity matrix, $\boldsymbol{f}$: body force, ρ: material density, $\ddot{\boldsymbol{u}}$: acceleration, c_v: specific heat at constant volume, ρ: density and ρr: heat loss term.

The model is implemented inside in the FEniCS [2] open-source software. The implementation is validated by comparing them with the predictions of a crystal plasticity fast Fourier transform model [3] under isothermal conditions and with analytical solutions for the heat transfer part. Next, the SSTC simulations using the T-EVP-FE model are driven using boundary conditions obtained from a macroscopic FE model that allows building AM structures. The results of these simulations will be presented. The role of single crystal elastic anisotropy and plastic heterogeneity on the intragranular and intergranular strains due to temperature/heat-flux boundary conditions is analyzed and the key findings will be presented. Finally, the different possibilities of comparison with experiments will be presented.

COMPUTATIONAL HOMOGENIZATION BASED ON THE MIXED TRANSFORMATION FIELD ANALYSIS: APPLICATION TO 3D-PRINTED MATERIALS

Elisabetta Monaldo *[1] and Sonia Marfia[1]
[1] Department of Engineering, Università degli Studi Roma Tre, Rome, Italy

Summary In this paper the Mixed Transformation Field Analysis, formulated for heterogeneous materials, is extended to the analysis of the mechanical behavior of the 3D-printed materials. In detail, a mixed-stress variational formulation of the elasto-plastic theory is considered. Under the assumption of periodic microstructure, a unit cell is identified and divided in subsets. In each subset, a self-equilibrated approximation of the stress and a constant plastic multiplier are assumed. The numerical results obtained are compared with some experimental evidence, available in literature, and with non-linear finite element (FE) analyses. The procedure allows to obtain effective results reducing the computing time usually associated to FE analyses.

INTRODUCTION

The 3D printing is a rapidly growing manufacturing technology that allows to make objects directly from a computer-aided design model. The ability to reproduce complex geometries, the rapid design-to-fabrication cycle times, the low maintenance costs and the lower amount of waste material generated are some of the advantages with respect to the conventional methods. Among the numerous methods, the fused deposition modelling is the most widely used. This technique, initially conceived as a process for making prototype, has found application as a manufacturing process for end-use parts. In order to be integrated as a part for serial production, the resulting 3D-printed components must possess the required mechanical properties. Several studies have shown that the process parameters, such as raster direction, layer thickness, and air gap, affect the mechanical properties of the resulting 3D-printed components by introducing anisotropy [1, 2]. Therefore, an open issue is the prediction of the 3D-printed parts behavior. Computational modelling techniques based on finite element (FE) method could be applied. Nevertheless, modelling the mechanical response of 3D printed structures taking into account the microstructural features by means of FE analyses requires a significant computational effort. Recently, in order to obtain efficient numerical homogenization procedures for heterogeneous materials characterized by plastic behavior, Reduced Order Models (ROM) heve been adopted [3]. Among ROM, the Mixed Transformation Field Analysis (MxTFA), based on a mixed stress variational approach considering an approximation of the inelastic strain based on a representation of the self-equilibrated stresses, results an effective approach as it reduces the number of macroscopic internal variables [4]. The aim of this paper is to determine the overall mechanical behavior of 3D-printed materials by means of the MxTFA. A numerical procedure is developed and verified with some numerical applications. The results obtained are compared with the experimental results available in literature and with FE-based reference solutions.

MATERIALS AND METHODS

The elasto-plastic homogenization problem is formulated in terms of the prescribed average strain and consists in finding the displacement field, the strain field, the inelastic strain field, and the stress field, which satisfy the compatibility, the constitutive and the equilibrium, with zero body forces, equations. In particular, the material is described as elasto-plastic and the classical Von Mises yield function is considered. Under the assumption of periodic microstructure, a unit cell (UC) composed by a printed fiber and voids is identified and divided into n non-overlapping subsets (see Fig. 1). The MxTFA defines an approximation of the stress and plastic multiplier over each subset. In detail, a self-equilibrated stress is considered introducing a constant, linear, or quadratic approximation and the plastic multiplier is assumed constant. Then, the inelastic strain approximation is derived through the flow rule. The MxTFA requires linear elastic pre-analyses, performed on a full discretization of the microscopic domain, in order to determine the localization operators necessary to recover the total strain in the typical point of the subset. The number of pre-analyses is related to the type of the selected stress approximation. The internal variables, i.e. the unknowns of the problem, are now the reduced stresses and the increment of the reduced plastic multipliers. They are obtained by enforcing the weak fulfilment of the compatibility equation and of the evolutive of the plastic multiplier over each subset. The evolutive of the reduced variables is solved employing a backward Euler algorithm with a return mapping technique. Finally, as usual in mixed stress formulations, the effective stress is evaluated directly from the reduced stress parameters defined in each subset that are obtained from the solution of the evolutive problem.

NUMERICAL APPLICATIONS

The effectiveness of the MxTFA-based homogenization procedure in the study of 3D-printed materials is verified by comparing numerical results with experimental results provided by [1] and with results recovered performing non-linear FE analyses. Since the problem is characterized by 3D displacement fields that do not vary along the fiber axis, the

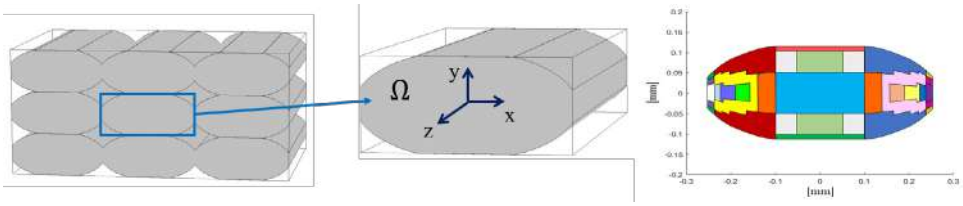

Figure 1: Periodic material, unit cell (UC), and subset discretization of the UC cross-section.

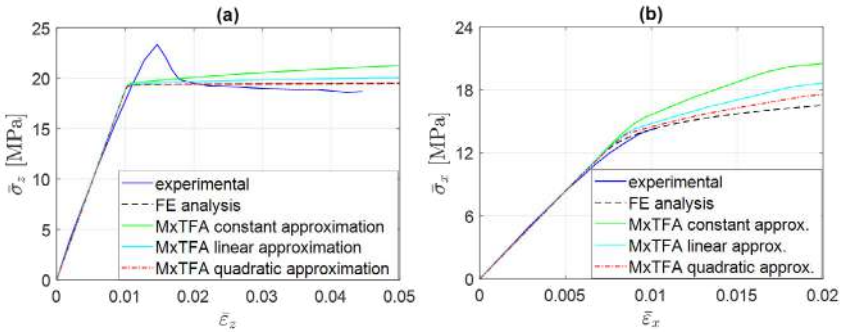

Figure 2: Macroscopic mechanical response of specimens with fiber orientation at $a = 0°$ (a) and $90°$ (b) subjected to tensile loading.

numerical analyses are performed on the UC cross section adopting a 3D-2D finite element with an enriched kinematic field. Both for the pre-analyses and for the micromechanical analysis, the UC is discretized with 2214 4-node 3D-2D quadrilateral finite elements and the homogenization procedure is realized considering a configuration with 22 subsets (see Fig. 1). The geometrical and mechanical parameters are chosen according to data provided by [1]. The mechanical response of specimens with unidirectional fiber orientation subjected to tensile loading is reproduced. In detail, denoting a the angle formed by the fiber axis with respect to the loading direction in a counter-clockwise rotation, specimens with $a = 0°$ and $90°$ are considered. Different analyses are carried out with constant, linear or quadratic stress approximation. Figure 2 shows the constitutive response of the equivalent homogenized materials together with the experimental response and with the FE solution. These results highlight that the MxTFA procedure is able to reproduce the both the elastic behavior and the plastic plateau of the material. Increasing the order of the stress approximation, the computed plastic response improves. Moreover, the MxTFA technique proves to be the most time-effective solution, drastically reducing the elapsed time in comparison to FE ones, also in the case with the highest order of stress approximation.

CONCLUSIONS

The Mixed Transformation Field (MxTFA) analysis is applied to compute the effective mechanical behavior of 3D-printed materials. The numerical applications have revealed the efficiency of the procedure and a good agreement with the reference results. Finally, the MxTFA analysis could represent an efficient tool for designing and prediction of the mechanical behavior of 3D-printed materials.

Summary Triaxial weaving is a craft technique commonly used to generate surfaces using tri-directional arrays of initially straight elastic strips. Traditional weaving uses discrete topological defects as building blocks for non-planar shaping. Taking an alternative point of departure, we introduce a novel approach for triaxial weaving that enables us to continuously span a variety of 3D shapes of the weave by tuning the natural in-plane curvature of the strips. We systematically explore the validity of our design strategy by quantifying the shape of experimental specimens with X-ray tomography in combination with continuum-based simulations. To demonstrate the potential of our design approach, we present a fullerene-like weave that is perfectly spherical, something that cannot be readily achieved using straight strips. Ellipsoidal and toroidal structures are also explored.

WEAVED STRUCTURES AS CURVED CRYSTALLOGRAPHIC SYSTEMS

Triaxial weaving (Fig. 1A) has long been loved by basket makers and artists seeking a combination of functional and aesthetically-pleasing structures. This ancient craft technique enables the generation of surfaces with tri-directional arrays of initially straight elastic strips. The design principles of traditional weaving are based on the observation that non-hexagonal topologies of strategically located unit cells impart out-of-plane shapes. In the realm of differential geometry, the weaving tradition is rooted in the concept of Euler characteristics through the Gauss-Bonnet theorem, with discrete topological defects being used as building blocks. The effect of topological charges in dictating the three-dimensional geometry of a surface is at the root of the morphology of many other curved crystallographic systems, as we have indicated in our previous work [1].

We take a unit-cell approach to revisit the study of traditional weaves using a combination of precision model experiments, computer simulations, and theory. As shown in the schematic diagram of Fig. 1B, each unit cell comprises n strips and n adjacent triangles. For simplicity, we focus on the case where the length, d, of all segments in the unit cell is uniform. The angle between two adjacent segment segments is α_i. In the first stage of the investigation, we start by considering strips that are straight in their rest (planar) configuration ($\kappa_g = 0$) and will then eventually relax this condition that possesses in-plane curvature ($\kappa_g \neq 0$) in their undeformed configuration, prior to weaving. For the particular case of $\kappa_g = 0$ and setting $\alpha_i = 2\pi/3$, the famous Gauss-Bonnet theorem states that the integrated Gaussian curvature of the unit cell is

$$\int \mathcal{K} \mathrm{d}A = \left(2 - \frac{n}{3}\right)\pi, \tag{1}$$

which is zero (planar weave) when $n = 6$ and can be varied in discrete steps of $\pi/3$ by modifying n. In Fig. 1C, we present: (top row) photographs of different instances of weaved unit cells for different values of n, (middle row) post-processed images obtained through X-ray micro computed tomography (μCT) including the computed Cosserat frame, and (bottom row) the corresponding simulated configurations using the finite element method (FEM). Excellent quantitative agreement is found between experiments and simulations. These topological defects are commonly used in traditional weaving to impart curvature on the structure (*e.g.,* at a corner), albeit with the drawback that curvature can only be injected discretely.

OBTAINING SMOOTH 3D WEAVES USING CURVED STRIPS

We now take an alternative point of departure toward circumnavigating the limitation mentioned above for traditional weaving, where the integrated Gaussian curvature of the structure can only be changed discretely by topological defects. We introduce a novel approach to triaxial weaving by considering strips that possess natural in-plane curvature. In other words, these curved strips relax the conditions on the zero geodesic curvature ($\kappa_g \neq 0$) and on the interior angles of the triangles ($\alpha_i \neq 2\pi/3$), such that the sum of their interior angles no longer adds up to π. Weaving with these curved strips allows for the integrated Gaussian curvature, $\int \mathcal{K} \mathrm{d}A$, to be varied continuously, as we detail next.

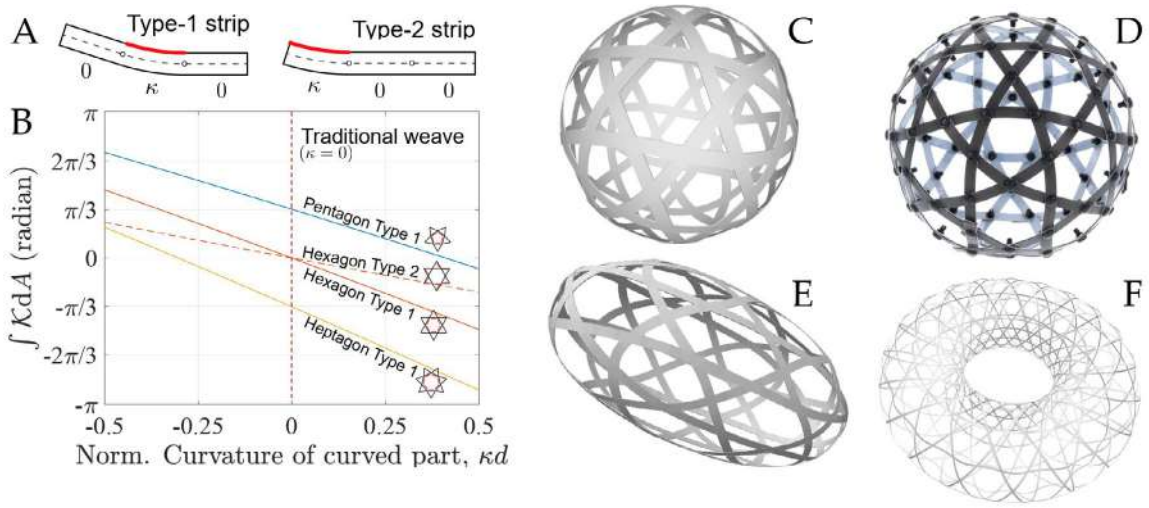

Figure 2: Weaving with curved strips. A. Our curved strips (in their rest configurations) can have either a constant curved portion in the center (Type-1) or at one of the extremities (Type-2). B. The integrated Gaussian curvature of unit cells with different topology can be varied continuously as a function of the normalized segment curvature, $\kappa^* = \kappa d$. C. Computational design of a spherical weave is achieved with strips with a sinusoidal geometry in their rest configuration. D. Photograph of corresponding experimental specimen. E and F. Our computational approach can yield design weaves with more complex geometries, such as ellipsoid and torus.

In Fig. 2A, we present schematics of the two types of curved strips that we consider in their rest (pre-weaved) configurations. These three-segment strips can either have a (constant) curved portion in their center (Type-1) or at one of their extremities (Type-2). We have systematically quantified the effect of the in-plane curvature, κ, in dictating the integrated Gaussian curvature of the unit cell, for different typologies. For convenience, we normalized the curvature of the curved segment as $\kappa^* = \kappa d$. The Gauss-Bonnet theorem yields the following prediction for the integrated Gaussian curvature:

$$\int_{\mathrm{n}} \mathcal{K}^I \mathrm{d}A = (2-n)\pi - n\kappa^* + n\left[\pi - \theta\left(\kappa^*\right)\right] \quad \text{and} \quad \int_{\mathrm{n}} \mathcal{K}^{II} \mathrm{d}A = (2-n)\pi + \frac{n\left[\pi - \theta\left(-\kappa^*\right)\right]}{2} + \frac{n\left[\pi - \phi\left(-\kappa^*\right)\right]}{2}, \quad (2)$$

for Type-1 and Type-2 strips, respectively, where θ and ϕ are the interior angles of the triangle adjacent to the curved part.

In Fig. 2B, we present predictions for $\int \mathcal{K} \mathrm{d}A$ as a function of κ^*, for Type-1 and Type-2 cells, with pentagonal, hexagonal, and heptagonal topologies. Importantly, we show that the curvature of the unit cell can be varied continuously by tuning the continuous variable κd, for each of these cases. For example, we can obtain a hexagonal unit cell with nonzero integrated curvature. We are in the process of validating these geometric predictions against experiments (using data obtained from X-ray tomography) and computer simulations. In our simulations, we use both FEM and the Discrete Elastic Rod (DER) method [3].

We have explored the geometric construction introduced above to design perfectly spherical fullerene-like weaves. Fig. 2C presents an optimized computed design with strips that, prior to weaving, have an in-plane sinusoidal geometry (*i.e.* they are not straight). Fig. 2D shows a photograph of the corresponding specimen realized experimentally, which deviates from a perfect sphere by at most 0.01% (standard deviation of the radial deflection from a sphere). Note that the resulting shape is strikingly smooth, despite the high-level of discreteness of the underlying unit cells. By contrast, following the classical topological approach of adding 12 pentagonal defects to a hexagonal weave using straight strips (as we did in the previous section), we would have obtained a far more faceted and non-smooth shape. We have leveraged our optimization-based computational approach to explore the weaving of more complex geometries. In Figs. 2E and F, we present examples for ellipsoidal and toroidal structures.

ON THE CONTINUUM MECHANICAL MODELLING OF BILAYER GRAPHENE

Paolo Podio-Guidugli[1]
[1] *Accademia Nazionale dei Lincei, Roma, Italy*

Summary A macroscopic model accounting for combined shearing, bending, and slipping, of bilayer graphene is proposed. The idea is to think of bilayer graphene as a single elastic surface equipped with a director, that is, a vector capable of changes in length and orientation.

EXTENDED SUMMARY

C-allotropic materials and structures – under all respects, we dare say, the 21st century materials and structures – have attracted a tremendous attention during the past few years for their amazing mechanical, electrical, and thermal conductivity properties. However, their potentialities are far from being exploited, for one reason out of many because their continuum mechanical modelling is still not completely satisfactory.

Our present study is an attempt to move a step toward building a continuum model for bilayer graphene. Our point of departure is offered by three recent papers.

The first is [1], where the stretching and bending behavior of a single-layer graphene sheet is given a continuum description in terms of a postulated quadratic representation for the corresponding elastic energies, whose constitutive moduli - one more than in classical linear elasticity - are given an atomistically-informed expression. The energy representations are partly justified on the basis of a delicate analysis developed in [2]; the atomistic information is deduced by building on the discrete model for graphene developed in [3, 4], in which atomic interactions are governed by a harmonic approximation of a 2nd-generation Brenner potential depending on bond lengths, bond angles, and two types of dihedral angles. In the second paper [5], the continuum limit of a harmonic approximation of such a Brenner potential is deduced and a description of bent graphene sheets is achieved, including an analytical expression of their Gaussian stiffness, a parameter ruling their rippling. In the third paper [6], the connection between microscopic and macroscopic description is established within the general framework of homogenization theory, confining attention to the small displacements approximation. The bending behavior of a graphene sheet is accounted for by determining the variational limit - in the sense of Gamma-convergence - of a sequence of discrete energy functionals under a topology that guarantees the convergence of minimizers.

At the macroscopic scale of continuum mechanics, we think of bilayer graphene as a single elastic bending-and-shearing resistant surface equipped with a *director*, that is, in the present case, a vector capable of changes in length (so as to account for interlayer distance changes) and orientation (so as to account for interlayer shearing and slipping). Equilibria of such a two-dimensional system would be ruled by a potential once again consistent with the Brenner potentials mentioned above and featuring also a contribution of van der Waals type. In this connection, we mention that the role of van der Waals interactions in keeping together multilayer graphene, molybdenum disulfide, and hexagonal boron nitride, structures when they are bent has been studied in [7]. In the context of the model we envisage, the slip-length parameter introduced in that study might be connected to the angle of the director to the surface's tangent plane; in this connection, we mention that slip-mediated bending is the subject of [8]. Finally, having a director field at our disposal might permit a juxtaposition with the predictions made in [9] about interlayer interactions in multilayer graphene structures with the use of a registry-dependent Kolmogorov-Crespi type [10] combining long-ranged van der Waals and short-ranged anisotropic electronic contributions.

NANO AND MICROSCALE ORIGAMI ENGINEERING: PRESENT AND FUTURE

Horacio Espinosa[1]*, Nicolas Alderete[1], Zhaowen Lin[1], Larissa Novelino,[2] Heming Wei[1], Glaucio Paulino,[2] and Sridhar Krishnaswamy[1]
[1] Theoretical and Applied Mechanics, Mechanical Engineering, Northwestern University, Evanston, USA
[2] Department of Civil Engineering, Georgia Tech, Atlanta, USA

Summary Origami structures have attracted considerable attention in recent years on account of their promise to yield deployable and tunable structures. Such properties are ideally suited for a variety of engineering applications from robotics to space exploration. Despite their potential, most efforts have been limited to macroscale demonstration. Therefore, research contributions for downscaling and expanding manufacturing capabilities are needed to achieve a broader spectrum of multifunctional capabilities stemming from morpho-functional transformations operating at micro and nanoscales. In this presentation, origami concepts combined with two-photon printing and *in situ* SEM mechanics analysis will be reported in the context of *microscale origami* exhibiting strong deformation anisotropy, auxeticity, and tunability of mechanical properties. Future research opportunities will be discussed.

INTRODUCTION

Origami, the ancient Japanese art form of paper (*Ori*) folding (*kami*) has established itself as a promising avenue for the design of deployable and highly tunable structures. Together with unusual mechanical properties, the stacking and space-filling capabilities of certain origami patterns make them formidable candidates for the design of architected metamaterials. Depending on the particulars of their geometry, these structures can give rise to a plethora of remarkable phenomena, including (but not limited to) mechanical anisotropy, shape recoverability, and multistability with high strength-to-density ratios. Notwithstanding, the complexities involved in their fabrication, regardless of lengthscale, still pose a substantial technical challenge and preclude the fruition of origami inspired engineering devices. At the macroscale, for example, the thermoset polymers used in additive manufacturing confer additional stiffness to the folds, which in turn requires the incorporation of a number of artifacts (e.g., flexible hinges) to attain the characteristic folding kinematics of origami. Likewise, often-complex geometric features present in origami designs and the requirement to accommodate multiple folding-unfolding cycles without structural damage, impose critical design constraints on both manufacturing and material selection. Unlike conventional metamaterials, the ability of origami principles to yield three-dimensional structures from planar forms (i.e., deployability) makes them especially attractive to applications where spatial economy is paramount (e.g., biomedicine, micro- and nanobotics, space exploration); a feature which also stresses the need to push origami engineering into the micro- and nanoscale realm. While translation of origami concepts into these scales presents inherent challenges pertaining to material handling, processing and metrology, their successful implementation opens the possibility of harnessing a wide range of phenomena inaccessible at the macroscale (e.g., size effects, quantum effects, photonics, phononics).

In an attempt to pave the way from macroscale to micro/nanoscale origami, we present results of two-photon polymerization 3D printing and *in situ* Scanning Electron Microscope (SEM) mechanical testing of micron-sized origami metamaterials resulting from the assembly of Miura-Ori tubes (Fig. 1a). The fabricated structures exhibit several unusual mechanical properties including anisotropic stiffness, configuration-dependent and reversible auxeticity, elastic mechanical instabilities and large degree recovery, a unique combination insofar absent from the portfolio of mechanical metamaterials. In this context, the potential of these Miura-Ori structures made of carbon allotropes will be theoretically explore.

MICROSCALE MIURA-ORI INSPIRED ORIGAMI METAMATERIALS

Two sets of origami metamaterials, with different dihedral angles, were investigated. The first set corresponds to a lattice comprised of Miura-Ori cells with folding angle ψ=55° (equivalent to 92.4% of the total extension of a Miura-Ori tube), and the second set corresponds to a folding angle ψ=40° (equivalent to 97.4% of the total extension of a Miura-Ori tube). Both configurations were fabricated via 3D direct laser writing (DLW), using a polymerization technique employing a two-photon liquid photoresist, tested with a nanomechanical platform inside an SEM, and analysed using Bloch theory and Finite Element Methods (FEM).

Stiffness Anisotropy and Elastic Instability

In situ SEM compression tests, with imposed oscillatory loading profiles, were performed along foldable directions of the origami structures to probe their stiffness as a function of compression level (Fig. 1b). The origami metamaterials exhibit pronounced stiffness anisotropy and tunability via compression along the X- and Y-directions (up to 200%). The relatively stable stiffness and the remarkable degree of recovery upon unloading and relaxation of these structures underscores their level of resilience (e.g., 93% recovery after 32% compression in the X-direction and 94% after 23% compression in Y-direction). The remaining direction of the origami structure, the stiff direction, was first approached via the Bloch Method in FEM to investigate potential elastic instabilities stemming from the restricted foldability and the

*Corresponding author. E-mail: espinosa@northwestern.edu

periodic arrangement of representative origami unit cells. Monotonic *in situ* SEM compression tests confirmed the predicted long wavelength critical load instability of the structure and revealed a subsequent cascading plastic collapse failure mode. Overall, the compression results along different directions point to a marked anisotropy and compression tunability, which makes these structures extremely appealing to load bearing, actuation, and sensing applications.

Poisson's Ratio Anisotropy and Reversible Auxeticity

The lateral expansion/contraction of the origami structures was measured for different combinations of compression/observation directions to uncover anisotropic behavior in Poisson's ratio. All directions presented marked anisotropic Poisson's ratio and marked auxeticity along certain directions (Fig. 1b). Moreover, origami structures with folding angle ψ=40° when tested along the X-direction revealed a switch in Poisson's ratio from positive to negative, constituting the first experimental observation of such phenomenon and unveiling the possibility of reversibly controlling the auxetic state of the metamaterial; a finding with profound potential implications in acoustic wave control.

FUTURE OF ORIGAMI ENGINEERING: THE ROLE OF C-ALLOTROPES

The future of origami engineering, as with most material and mechanical developments, lies undoubtedly at the micro and nanoscale. At the microscale, the micron-scale thickness of the origami panels, facilitated by manufacturing techniques like the one applied in our microscale origami structure, results in significantly reduced bending stiffnesses which enables folding without resorting to artificial hinges. At the nanoscale, folding of atomically thin sheets has been investigated in its capacity to perform programmed folding motions with or without the presence of external forces [1]. In this regard, the malleable nature of atomically thin graphene and its variants has made them forerunners in the pursuit of nanoscale origami and bottom-up techniques for engineering building blocks of more complex three-dimensional shapes and even nanoscale machines. Despite numerous computational studies on programmable graphene folding, experimental graphene origami remains elusive. Review of recent advances in graphene origami (Fig. 1c) and the prevailing technical challenges will be undertaken as the frontiers of origami engineering continues to be shaped.

Summary A long-standing challenge in material science and manufacture is to create porous materials that are simultaneously lightweight, strong, and resilient. Here we advanced a 3D microfabrication methodology to fabricate nanoarchitected pyrolytic carbon with lightweight densities ranging from 0.24 to 1.0 g/cm^3, GPa-level compressive strengths of 0.14 GPa to 1.90 GPa, and > 10% deformability before failure. The smallest characteristic length of the nanoarchitected carbons approaches the resolution limit of the available 3D additive manufacturing technologies, and their compressive strengths in this work approach the theoretical limits defined by the strengths of graphene and diamond.

INTRODUCTION

Porous, lightweight natural materials, such as bone, wood and diatoms, have been widely discovered and investigated. These natural materials have been shown to be both strong and resilient so that they are powerful in resisting high external loads and absorbing impact energy. Two design principles discovered in these natural materials lead to such excellent properties: (i) the flaw tolerance when the characteristic length scale of the material is below a critical value; and (ii) a hierarchical design which consists of multilevel architectures with dimensions ranging from macro- to nanoscale.

A long-standing challenge in material science and manufacture is to create porous materials that are simultaneously lightweight, strong, and resilient. Recent progresses in 3D microfabrication and additive manufacturing pave a promising way to achieve architected materials with delicate structural design and beneficial mechanical properties, like high specific stiffness and strength, good resilience/recoverability *et al*.

Here we achieved to fabricate nanoarchitected pyrolytic carbon with two prototype unit-cell geometries, octet- and iso-truss, and demonstrated a combination of their excellent properties with low density, high specific strength, imperfection insensitivity and good resilience.

RESULTS

We adopted a two-step method, using two-photon lithography (TPL) and pyrolysis in a vacuum at 900 °C, to fabricate two types of nanoarchitected carbon with octet- and iso-truss geometries, as shown in Figure 1. The octet architecture has cubic anisotropy and superior mechanical properties compared with other conventional porous architecture, including triangular, tetrahedral, or cubic trusses and stochastic foams. The iso architecture, based on the topological optimization, has been proven to be isotropic and possess the optimal stiffness compared with traditional truss topologies. After pyrolysis, each beam shrunk to 20-25% of its initial length dimension, and the final carbon trusses had unit-cell dimensions of ~2 μm, beam diameters ranging from 261 to 679 nm, and densities of 0.24 to 1.0 g/cm^3. The smallest diameter is much below the resolution limits of most available 3D lithographic technologies.

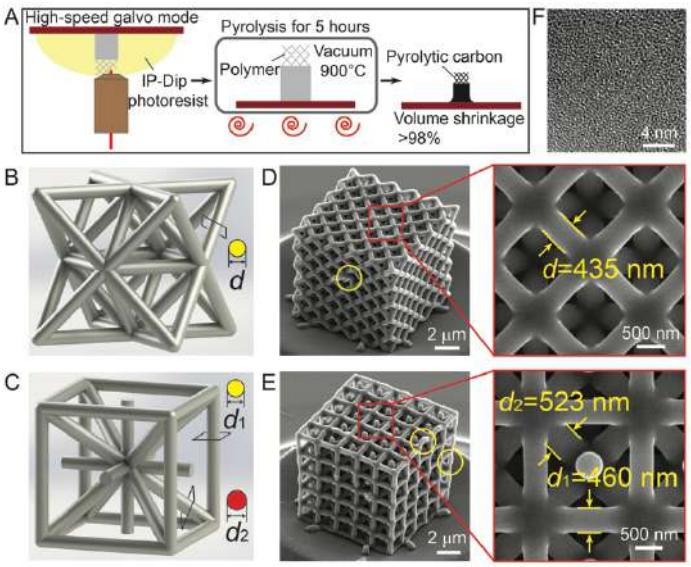

Figure 1. Fabrication and microstructural characterization of pyrolytic architected carbon of octet- and iso-truss.[1]

We performed uniaxial compressions on all pyrolytic architected carbon trusses. As the relative density ranged from 17% to 72%, Young's modulus of these carbon nanolattices increases from 2.28 GPa to 10.73 GPa, and the compressive strength increases from 0.14 GPa to 1.90 GPa. Elastic loading region persists up to an approximate 10-20% strain, then all pyrolytic carbon trusses are catastrophically failed via brittle fracture, which exceeds the value of reported carbon nano-/microlattices. The material property Ashby charts for Young's modulus and compressive strength versus density reveal that the moduli and strengths of these architected carbon are nearly one to two orders of magnitude greater compared with other micro-/nanolattices made up of vitreous carbon, alumina-polymer with comparable densities (Figure 2A).

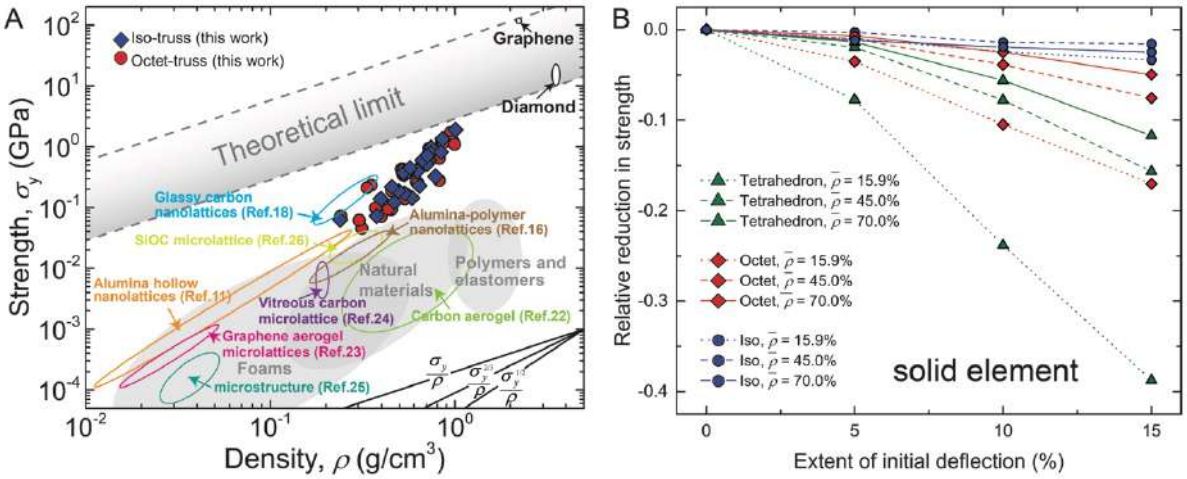

Figure 2. Ashby chart of compressive strength versus density and imperfection sensitivity of compressive strength in curvature of the structs.[1]

Besides, we observed some fabrication-induced defects in virtually all samples, including slight curvature of the struts, microvoids, and beam junction offsets or bulges. We performed finite-element (FE) simulations of the whole model to further investigate the influence of strut curvature imperfection on compressive strength. The FE simulation results show that for a given architecture, the nanolattices with higher densities experience smaller relative weakening associated with prebent imperfections; octet-truss and iso-truss unit cells for all densities are less susceptible to defects compared with tetrahedron-truss unit cells (Figure 2B).

CONCLUSIONS

We advanced a 3D microfabrication methodology to fabricate nanoarchitected pyrolytic carbon with lightweight densities below water density, GPa-level strengths, and larger than 10% deformability before failure. Departed from all existing work on micro/nanolattices reported before, the compressive strength of the nanoarchitected carbon in this work approaches the theoretical limits.

[4] School of Engineering Sciences, University of Chinese Academy of Sciences, Beijing 100049, China

Summary In this talk, we will summarize the current advances on the mechanics while interfacing graphene in applications of different methods, including (1) the interface during making large-area single-layer graphene with patches of single-crystalline graphene; (2) dimension scale-up to make three-dimensional graphene honeycomb; (3) the influence of 3D morphology on adhension.

5-7 ring mechanics and Grain boundaries in graphene

Like most crystalline materials, two-dimensional materials exhibit rich mechanical behavior which heavily depends on their crystalline orientations and the arrangement existing defects. Here we illustrate in detail how the strength and the fracture behavior are influenced by crystalline orientations in pristine graphene. We reveal the crack kinking behavior as well as the orientation dependence of apparent fracture resistances. In addition, we show how typical defects like pentagon-heptagon rings in GBs would influence the strength of polycrystalline graphene and the behind mechanical mechanisms accounting for the observed behavior.

3-D architectured C-honeycomb

Although graphene has been broadly explored due to their outstanding mechanical properties, there exist significant challenges in retaining such properties of basic building blocks when scaling them up to three-dimensional materials and structures for many technological applications. The realized mechanical and thermal properties of 3-D carbon materials, by staggering graphene sheets or vertically grown carbon nanotube arrays, are significantly lower than those of individual graphene sheets or individual CNTs.The huge gap in mechanical properties between the low-dimensional carbon allotropes and their 3-D derivatives originates from the dissimilar bonding characteristics between carbon atoms within graphene or CNTs and the architectured 3-D engineering materials: The intra-structure bonding is covalent in nature, while van der Waals bonding dominates between different layers/tubes or with other materials1. Such heterogeneous bonding leads to property inheritance that is a mission impossible. We demonstrate the feasibility of constructing stable 3-D architectured C-honeycomb with covalent bonding. The specific strength of C-honeycomb could be the best in structural carbon materials. Its specific thermal conductivity is also much better than most metal and high thermal conductivity semiconductors. Its strong anisotropic Poisson's effect may be utilized to design multi-functional structures with applications ranging from biomedical engineering to energy and environment systems.

The statistic nature of graphene-substrate interaction

Given the out-of-plane deformation is of soft nature (see the figure below), wrinkles are easy to form (as seen in Figure 1). Whether such rich 3D morphology influences the interaction between graphene and other substrate? Is it possible to manipulate wrinkling patterns for possible engineering applications? The adhesion of a soft membrane plays a central role for the functionality of many biological and engineering systems, from cell adhesion to advanced materials. We revealed that the adhesion of a membrane-buffered interface could be significantly modulated due to thermally induced surface corrugations in the membrane. Not expected from classical mechanics theories, an enhancement of the adhesion range and a linear variation of the adhesion strength could be observed as temperature rises, which facilitates long-range adhesion between soft membranes like graphene sheets and lipid-bilayers with a substrate. Such surprising findings may pave the way to understand temperature-sensitive kinetics in many biological systems where the interaction of cell membranes with extra-cellular environments is pivotal.

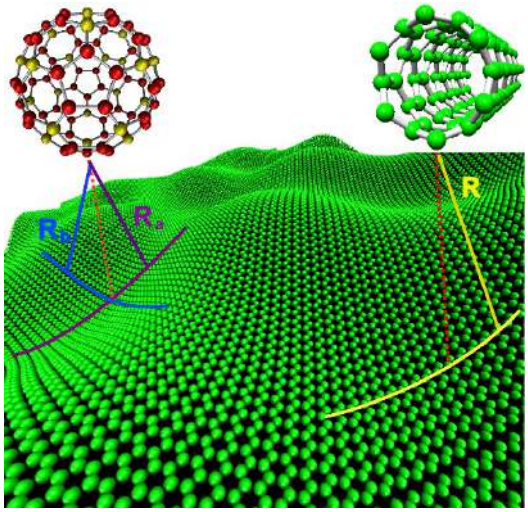

Figure 1. Illustration of the ultra-soft deformation in a graphene sheet and such a feature leads to the easy formation of fullerence and carbon nanotubes from graphene sheets. Such a process may involve the formation of defects in graphene which in turn alters the morphology and the deformation behavior of graphene.

CONCLUSIONS

High strength and ultra-low bending rigidity brings in uniqueness of graphene in contrast to other carbon allotropes. In this talk, we summarize the current advances on the mechanics while interfacing graphene in applications of different methods, including (1) the interface during making large-area single-layer graphene with patches of single-crystalline graphene, and how typical defects like pentagon-heptagon rings in grain boundaries would influence the strength of polycrystalline graphene; (2) during dimension scale-up to make three-dimensional graphene honeycomb using two-dimensional graphene, and what is the stable structure of those 3D carbon honeycomb and how is its mechanical properties; (3) given the out-of-plane deformation is of soft nature (see the figure below), wrinkles are easy to form. Whether such rich 3D morphology influences the interaction between graphene and other substrate.

ENHANCEMENT OF THE MECHANICAL PROPERTIES OF DIRECT-SPUN CARBON NANOTUBE MATS BY SUPERACID-ASSISTED DRAWING

Joe Stallard *, Wei Tan, Adam Boies, Norman Fleck.
Cambridge University Engineering Department, Trumpington St., Cambridge, CB2 1PZ, UK.

Summary: The mechanical behaviour of a direct-spun carbon nanotube mat is investigated upon fluid immersion. The elasto-plastic stress-strain response measured in air has significant orientation hardening and little in-plane anisotropy. Immersion in acetone, ethanol, toluene, NMP or chloroform reduces yield and failure strengths by up to 70%, without altering the ductility or shape of the stress-strain response. In contrast, chlorosulfonic acid immersion reduces tensile strength by almost 2 orders of magnitude, and increases ductility by over a factor of 5. Softening of the direct-spun mat upon chlorosulfonic acid infiltration is attributed to separation of bundled CNTs. Drawing in a chlorosulfonic acid solution followed by acid removal and drying increases the mat modulus by 2 orders of magnitude, and the tensile strength by a factor of 7, due to alignment of the nanotube bundle microstructure.

INTRODUCTION

Direct-spun carbon nanotube (CNT) mats and fibres are produced by drawing CNT aerogels from a floating catalyst chemical vapour deposition reactor [1]. The mat microstructure is a random interconnected network of CNT bundles, with a nodal connectivity of between 3 and 4. This microstructure deforms in a foam-like manner under macroscopic stress, with bending and shearing of CNT bundles, and so endows the mats with a typical tensile modulus of only a few GPa, much below that of CNT walls [2]. The modulus and strength of direct-spun mats and fibres are sensitive to the degree of alignment of the carbon nanotube bundle network [1]. Alignment may be enhanced through tensile drawing in the dry state, or whilst infiltrated with a polymer solution.

CNT-solvent solutions are also used to process nanotubes into mats and fibres. The van-der-Waals bonding between bundled CNTs prevents the formation of solutions in organic solvents, except at extremely dilute CNT volume fractions [3]. CNT dispersion is aided by sidewall modifications using oxidation or surfactants, yet relies upon sonication which reduces CNT length. CNTs separate when immersed in superacids, such as chlorosulfonic acid and oleum, forming a lyotropic mixture of isotropic and nematic liquid-crystalline phases [4]. Pultrusion of a CNT-superacid 'dope' into a bath of coagulating fluid creates an aligned CNT fibre, of modulus and strength up to 120 GPa and 1 GPa respectively [5]. Fibre properties vary with applied tension during coagulation, the choice of coagulating fluid, and CNT length.

The infiltration of organic solvents into direct-spun materials results in mechanical softening [6], yet the effect of superacid infiltration is hitherto unexplored, and forms the focus of this study. Herein, the stress-strain response of a typical direct-spun mat is measured in air, and whilst immersed in a range of organic solvents, chlorosulfonic acid, and solutions of chlorosulfonic acid and chloroform. Effects of immersion upon mechanical behaviour are discussed with relation to the mat microstructure. To increase alignment of the bundle microstructure, direct-spun mat samples are drawn whilst immersed in different fluids before fluid removal and drying; the enhancement in properties is then compared.

MECHANICAL PROPERTIES OF DIRECT-SPUN CNT MATS IN AIR AND UPON FLUID IMMERSION

The stress-strain response of direct-spun CNT mat samples (obtained from Tortech nanofibers Ltd.) were measured with a screw-driven tensile test machine at strain rate of $\dot{\epsilon} = 10^{-3}$ s^{-1} in air and whilst immersed in a range of liquids; the test setup is sketched in Figure 1(a). Load was applied with self-tightening wrapping grips; the strain state was measured optically by tracking the position of painted dots using a digital camera and image processing software.

Samples were submerged in acetone, toluene, NMP and chloroform for 3 hours before measurement of the stress-strain response whilst immersed; responses measured in air and in solvents are plotted in Figure 1(b). Whilst immersion in the solvents results in softening, the shape of the stress-strain response and ductility remain similar to that measured in air.

Now consider the influence of chlorosulfonic acid immersion upon the stress-strain response. After immersion in chlorosulfonic acid for a period of 5 minutes, the acid was drained and samples immersed in a solution of chlorosulfonic acid and chloroform; the volume fraction of acid f_{CSA} was varied between 0 (i.e. chloroform) and 1 (undiluted acid). Stress-strain responses measured whilst immersed in these solutions are plotted in Figure 1(c); the response measured when immersed in chloroform of Figure 1(b) is also included for comparison. The stress-strain response measured in chloroform after chlorosulfonic acid immersion is J-shaped with considerable hardening at nominal strains exceeding 0.4. Ductility rises and tensile strength reduces with increasing chlorosulfonic acid content.

EFFECT OF DRAWING UPON MECHANICAL PROPERTIES OF DIRECT-SPUN MATS

To increase their tensile modulus and strength, mat samples were drawn in air or whilst immersed in liquids as follows:

- **In air:** Samples were drawn to 80% of their nominal failure strength in air.
- **In chloroform:** Samples were drawn to 80% of their nominal failure strength in chloroform; the stress was maintained by application of a dead load whilst samples were dried in an oven at 70°C for one hour.

*Corresponding Author. E-mail: jcs202@cam.ac.uk

- **In chloroform and chlorosulfonic acid solutions:** Samples were immersed in chlorosulfonic acid for 5 minutes, then drawn in a solution of chlorosulfonic acid and chloroform of acid volume fraction $f_{CSA} = 1/64$ to a nominal stress of 10 MPa. The stress was maintained by application of a dead load whilst samples were rinsed in chloroform, acetone, and distilled water, and dried in an oven at 70°C for one hour, and 115°C for a further hour.

The stress-strain responses of drawn samples were then measured in air, with the same equipment and methods as described above. Results are plotted in Figure 2(a), alongside that of the original mat. The measured stress-strain behaviour of mats drawn in the presence of chlorosulfonic acid are elastic brittle. Images of the original and drawn mat microstructure in Figures 2(b) and (c) respectively reveal alignment of the bundle microstructure after drawing. The drawn sample modulus of approximately 55 GPa exceeds that of the original mat by two orders of magnitude. The stress-strain responses of mats measured after drawing in either air or chloroform absent acid are also above that of the original mat.

To establish the effects of fluid immersion in the absence of draw strain, samples were also immersed in identical fluids and dried for identical durations to those used to draw samples in the presence of chlorosulfonic acid, but without the application of any drawing strain. The mechanical properties of these samples were similar to those of the original direct-spun CNT mat. Thus, the enhancement in tensile strength and modulus is attributed to tensile drawing in the presence of chlorosulfonic acid, rather than to the influence of liquid infiltration and removal.

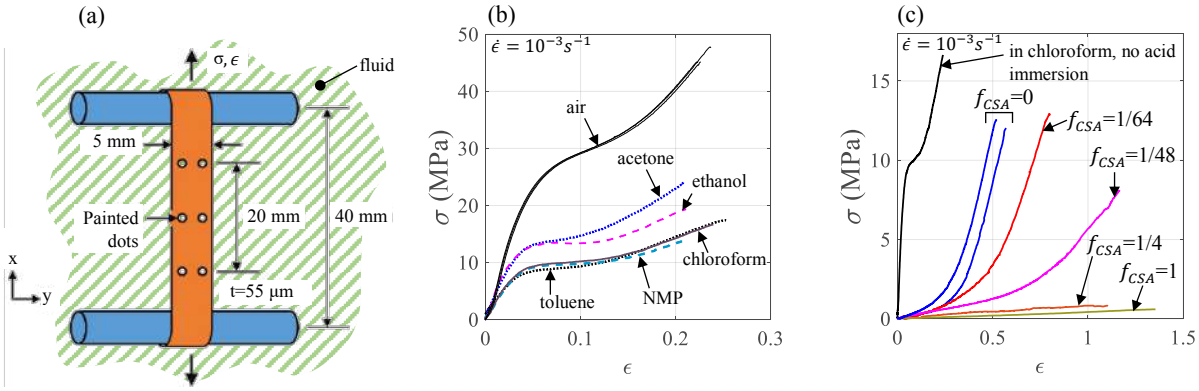

Figure 1: (a) Drawing response of immersed direct-spun mat samples. (b) The measured stress-strain response during drawing in air and organic solvents; (c) drawing response in solutions of chlorosulfonic acid and chloroform.

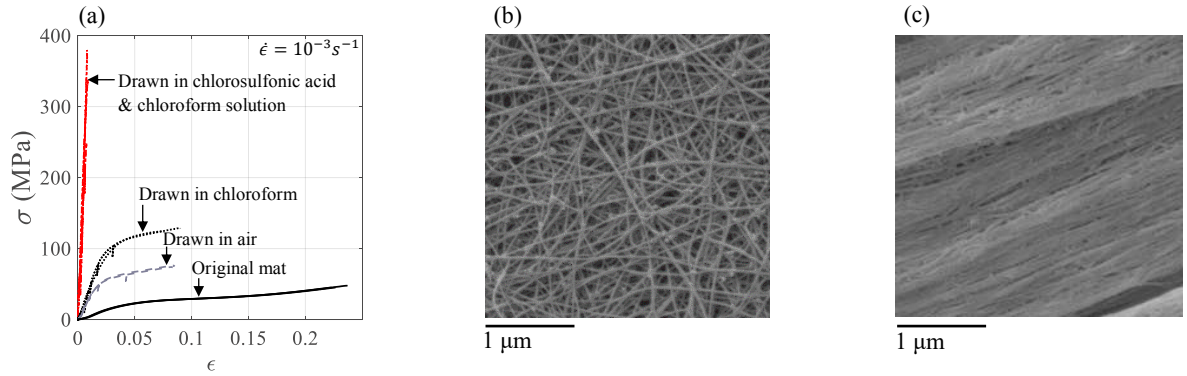

Figure 2: (a) Effect of drawing upon the stress-strain response of mat samples. (b) The CNT bundle microstructure of direct-spun mat in its original state; (c) the mat microstructure after drawing in a solution of chloroform and chlorosulfonic acid.

DISCUSSION & CONCLUSION

A network of tightly-packed CNT bundles forms the microstructure of direct-spun CNT mats. The reduction in tensile strength and increase in ductility measured upon chlorosulfonic acid immersion is attributed to the separation of bundled CNTs upon their exposure to chlorosulfonic acid, as described elsewhere in literature [4]. The influence of chlorosulfonic acid allows mat samples to be drawn to large strains, which facilitates microstructural alignment of the CNT bundle network. A drawing process was devised to enhance the mechanical properties of direct-spun CNT mat samples. Drawing in a chlorosulfonic acid solution increases the mat modulus by two orders of magnitude, and the tensile strength by up to a factor of 7. These enhancements are much above those obtained by drawing in air or in chloroform without acid.

OPTIMAL DESIGNS OF BIOLOGICAL NETWORKS: LUNGS AND ROOTS

Yeonsu Jung[1], Keunhwan Park[1], and Ho-Young Kim*[1]
[1] Department of Mechanical Engineering, Seoul National University, Seoul, Republic of Korea

Summary Airways in the lung and xylem of the root are network systems where both fluid transport and mass exchange with surrounding tissues occur simultaneously. Classical Murray's law, which explains the biological network design of cardiovascular systems and tree branches, is no longer valid in those systems involving mass exchange. Here we explore the design principles of the fluid-exchanging networks through the combination of theoretical and experimental approaches. This study not only elucidates the physical principles of general biological networks but also provides critical insights for artificial network systems.

INTRODUCTION

Natural creatures use various network systems to transport fluids within their bodies, which play essential roles in their metabolic activities. Those examples include cardiovascular system and lung airways in mammals, xylem, phloem and root networks in plants, and gills of fish. Because those networks have been evolved for millions of years to maximize their efficiency under constraints imposed by their surroundings, elucidating the physical principles behind their optimal structure can provide critical insights to enhance efficiency of artificial network systems. Here we consider two exemplary biological network systems, human lungs and plant roots.

BRANCHING RULES IN AIRWAYS OF HUMAN LUNG

The airway network of a human lung starts from conducting airways (from mouth to the 16th branching stage), which are connected to acinar airways surrounded by alveoli (from the 17th to 23rd branching stage) as shown in Fig. 1(a). The airway diameter gradually decreases through multiple branching, and the diameter reduction ratio in conducting and acinar airways is reported to be 0.79 and 0.94, respectively, as plotted in Fig. 1(b). The diameter reduction in the conducting airways, where no gas exchange with surrounding tissue occurs, was rationalized previously on the basis of classical Murray's law. Here, we mathematically show that the observed diameter reduction ratio in the acinar airway, where gas transfer between airway and alveoli arises, corresponds to the optimal value to maximize gas transfer rate per unit surface area under minimum cost for construction and maintenance of the organ [1].

ROOT LENGTH DISTRIBUTION OF PLANTS

Shaping a plant root into a structure optimized for water capture is increasingly important for the sustainability of agriculture in the era of global climate change. Although deep-reaching roots are favored by crop breeders and genetic engineers of plants, here we show that nature has apparently adopted a different strategy of shaping roots (see Fig 2a; roots are abundant over upper layers). We establish a mathematical model for optimal root length distribution by considering that plants seek maximal water uptake at the metabolic expenditure of root growth. Our theory finds a logarithmic decrease of root length density with depth to be most beneficial for efficient water uptake, which is supported by biological data as well as our experiments using root-mimicking network systems (see Fig 2b) [2].

FLUID FLOWS SHAPING MORPHOLOGY

Karen Alim [1,2]
[1]Department of Physics, Technical University of Munich, Munich, Germany
[2]Max Planck Institute for Dynamics and Self-Organization, Göttingen, Germany

Summary Fluid flows can propagate information on large scales an essential feature during the development of an organism. What are the principal mechanisms of how fluid flows induce, transmit and respond to biological signals and thus control morphology? The role of fluid flows is particularly prominent during the adaptation of transport networks. Here, the network-forming slime mould *Physarum polycephalum* emerged as a model. Investigating the pivotal role of fluid flows in this live transport network we find that flows are patterned in a peristaltic wave thereby optimising transport. In fact, flows are hijacked by signals to propagate throughout the network promoting their own transport by invoking a propagating front of increased flow. This simple feedback of flows on morphology is sufficient to explain complex dynamics of the living network like finding the shortest path through a maze.

Flow networks are a fundamental building block of life, whether as blood vasculature, bronchioles in the lungs, nephron in the kidneys, intestines, lymphatic system or as the brain passages of the spinal fluid. How network architecture is controlled by the interaction with the flows flowing through it is still unclear, despite the broad significance of the question and an interest that has lasted almost a hundred years [14, 13]. Our research wants to open up the possibility to control network function and performance by identifying the physical principles that control the adaptation of the network architecture.

The ideal model system that allows to quantify the dynamics of fluid flows and network architecture in parallel is the network-forming slime mold *Physarum polycephalum*. *Physarum* is the model organism of the plasmodial slime molds, which forms a two-dimensional, tubular network as a single gigantic cell [11, 16]. We have established *Physarum* as a model system for the role of fluid flows in living matter by perfecting cell culture in liquid solution and on agar plates and introducing quantitative analyses. The reduced complexity of *Physarum* to a flow network alone allows a unique interaction of observed, quantified dynamics based on light microscopy data and hypothesis development in theoretical models.

Characteristic for *Physarum* is the periodic shuttle flow of the cytoplasm enclosed by the tubes [9, 10], which extends over the entire network. Each individual tube consists of a gel-like outer layer interspersed with an actin cortex which encloses the cytoplasmic fluid [6]. The actin cortex radially contracts the tube about every 100 seconds and thus drives the rhythmic pendulum flow [5, 19, 18, 2]. The quantifiable dynamics of the tube diameters therefore provide information about the coordination of the flows as well as network architecture - a unique basis for deciphering the physical coupling of network architecture and flow.

We have shown that the contractions of the tubes in *Physarum* are organized along the entire network in a peristaltic wave, which also dynamically adapts its wavelength to the size of the network [2]. The important innovative step towards the spatio-temporal measurement of the contractions along the 0.5-2cm networks was to measure the dynamics of the individual tubes of about $100\mu m$ diameter by the amount of light transmitted through the tubes. The decisive factor is that the large dynamic range of the microscope camera allows a fine resolution of the transmitted light quantity and thus of the contraction state of a tube and is not limited in resolution by the number of image pixels. Furthermore, we have shown that the flows follow the Stokes flow equations [4] and are thus completely determined by the contractions of the tubes in the entire network [2]. This step opens up unprecedented access to physical parameters such as the relative local pressure of the cytoplasm, which cannot be measured experimentally but which now follows from the theoretical calculation of the flow based on observed contraction patterns. Core for this insight was the development of simultaneous live imaging of fluid flows and network morphology using fluorescent tracer particles, which allows to resolve the different size scales of network and single tube. For this purpose, $1\mu m$ fluorescent tracer beads in the *Physarum* liquid culture [17] are integrated into the liquid cytoplasm.

The observation of actin-cortex contractions coordinated over centimeters now raises the question how the contractions can be coordinated on such large scales. Our theoretical work shows that the flow-driven transport of messenger substances, which themselves couple to the dynamics of the actin cortex, enables such long-range coordination of contractions [8]. However, the confirmation that calcium as actin cortex regulator fulfills this function is still pending.

Physarum is known for its ability to solve complex problems like the problem of the traveling salesman [20, 7, 12] or to find the shortest way through a maze [15]. *Physarum* solves these problems by adapting its network architecture to stimuli in its environment. We investigate how this complex behavior is achieved by transporting, processing and storing signals by means of the flow in the network [1]. We have discovered that a food stimulus releases a signal molecule in the cytoplasm. This signalling molecule is spread by fluid flows, but at the same time amplifies the flow by locally increasing the contraction amplitude during the journey through the network [3]. Thus, the signal molecule initiates a feedback, which amplifies its own propagation. This mechanism explains the ability of *Physarum* to find the shortest path between food sources in the maze.

Summary Animal locomotion has the potential to expand the performance capabilities of robots by incorporating energy-efficient bioinpired designs. In addition, the robotic control of live animals enables further studies of entire organisms in more user-controlled, rigorous experiments for applications in animal-fluid interactions, robotics, and biology. This work presents a biohybrid jellyfish robot comprising a portable low-power microelectronic system embedded in live animals. Experiments in the laboratory to increase swimming frequency illustrate efficient enhanced swimming speeds of up to 2.8 times, dependent on bell kinematics that affect swimming hydrodynamics. This system was also deployed in the Atlantic Ocean to demonstrate the feasibility for future applications in ocean monitoring.

INTRODUCTION

A better of understanding of aquatic animal locomotion can potentially impact a wide range of fields, from addressing fundamental scientific questions about the ecology and evolution of basal organisms, to animal-fluid interactions [1], to applications in robotics and ocean monitoring [2-4]. In particular, *Aurelia aurita* (moon jellyfish) are a compelling model organism to study biological fluid dynamics and inspire more energy-efficient aquatic vehicles because of their low cost of transport (COT), the mass-specific metabolic energy expended to travel a unit distance [5]. The hydrodynamics and bell kinematics of natural *A. aurita* swimming have been well-characterized using flow visualization techniques such as particle image velocimetry (PIV) and image processing to track bell curvature. However, the application of embedded microelectronic systems to control their muscle contractions can further enable these tools to reveal fundamental biological and physical processes that cannot be understood by observation alone.

By directly inciting muscle contractions, robotic manipulation of jellyfish swimming enables systematic studies of how swimming frequency affects speeds, bell kinematics, and hydrodynamics. To do this, we incorporated a self-contained microelectronic system into live jellyfish to characterize the robotic control of jellyfish swimming in saltwater tanks in the laboratory, and field deployment of these biohybrid jellyfish robots in the Atlantic Ocean. Future applications could incorporate sensors and a closed-loop feedback mechanism to maneuver the biohybrid robot into targeted areas of the ocean to track temperature, pressure, etc. and collect data to monitor climate changes.

METHODS AND TECHNIQUES

Electrical stimulation using a square pulse wave, as illustrated in Fig. 1A, can reliably and robustly incite muscle contractions in live jellyfish [6]. A miniaturized system that encapsulates the microelectronic components in waterproof housing (Fig. 1B and C) enables free-swimming both in the laboratory [6] and *in situ*.

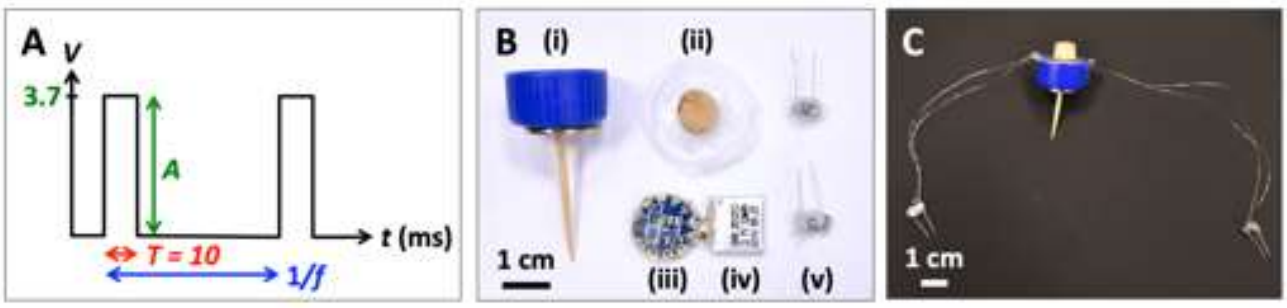

Figure 1. (A) Jellyfish muscle contractions can be externally controlled by using a square wave signal with an amplitude, A, of 3.7 V and pulse width, *T*, of 10 ms, set at frequencies, *f*, of 0.25, 0.38, 0.50, 0.62, 0.75, 0.88, and 1.00 Hz. (B) Components of a self-contained swim controller, which includes housing made from (i) a polypropylene cap with a wooden pin that embeds into the bell center, and (ii) a plastic film to waterproof the housing, both offset with stainless steel and cork weights to keep the device approximately neutrally buoyant. Microelectronics include (iii) a TinyLily mini-processor, (iv) lithium polymer battery, and (v) two platinum-tip electrodes with LEDs to visually indicate stimulation. (C) The fully assembled device, with the processor and battery encased in the housing. This figure is adapted from [1].

*Corresponding author. E-mail: nicolexu@stanford.edu

In the laboratory, free-swimming experiments were conducted using a self-contained two-electrode microelectronic system to demonstrate enhanced swimming speeds over a frequency range (0.25-1.00 Hz) in a 1.8-m vertical tank. Constrained experiments were also conducted to obtain oxygen consumption rates within this frequency range, to calculate COT values and determine whether enhanced propulsion was energy efficient or achieved at a metabolic cost to the animals. To track how bell kinematics and flow fields vary when the animals pulse at different frequencies, image processing techniques and 2D PIV were used in pinned animals, driven within this frequency range.

In the field, free-swimming experiments were conducted using the same self-contained two-electrode system to demonstrate the feasibility and robustness of the biohybrid robotic system as a proof of concept.

RESULTS: LOW-POWER BIOHYBRID ROBOTIC JELLYFISH CAN SWIM UP TO 2.8 TIMES FASTER

Fig. 2 illustrates the normalized swimming speeds (in body diameters s^{-1}) on the right ordinate axis over the swim controller frequency, from 0 Hz (inactive, swimming speed is due to the animals' natural pulses at 0.16 Hz) to 0.25 to 1.00 Hz (active swim control). The enhancement factor on the left ordinate axis is defined as the ratio of swimming speeds over the mean unstimulated swimming speeds (of $N = 6$ animals at 0 Hz). As shown, swimming speeds can be enhanced up to three times their natural animal counterparts, with a dependence on body morphology [6]. This trend has been similarly shown in a theoretical model, adapted from [7], to incorporate bell morphological parameters that mimic real animals. Enhancement factors increase as the aspect ratio of the bells increase (toward more prolate animals).

A noteworthy feature is the decrease in speeds when the animals are driven at higher frequencies, which is due to changes in the bell kinematics, in which the stimulation frequency increases beyond the limitation of natural jellyfish swimming (from biological constraints including contraction and relaxation stroke times). However, this difference in bell morphology has not been reported in literature. We will characterize the kinematics and fluid dynamics by using PIV to reveal how the bell kinematics change as a function of frequency.

Furthermore, this increase in swimming speeds does not create an undue metabolic cost on the animal and only comes at 10 mW of external power input to the microelectronics, which is 10 to 1000 times less external power per mass than existing aquatic robots in literature [6].

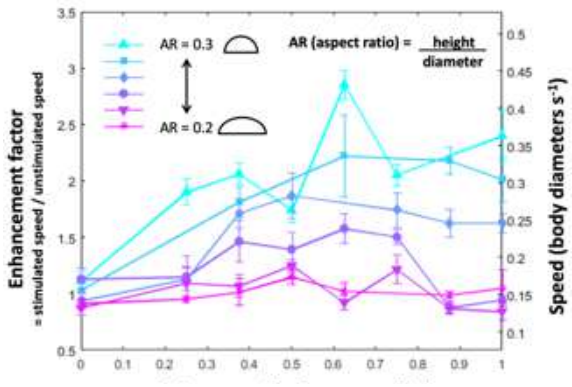

Figure 2. Enhancement factors and swimming speeds for jellyfish with external swim control from 0 to 1.00 Hz. Each animal ($N = 6$) is represented by a different color, with body geometry shown as an aspect ratio, or the bell height to diameter. Speed (in body diameters s^{-1}) is indicated on the righthand axis. Enhancement factor is defined as the speed scaled by the mean of the normalized 0 Hz speed for all 6 animals (in which the swim controller is embedded but inactive). This figure is adapted from [1].

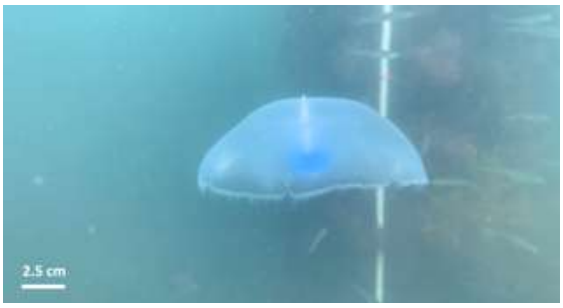

Figure 3. The biohybrid jellyfish robot was deployed in the Atlantic Ocean (at the Marine Biological Laboratory in Woods Hole, MA).

CONCLUSIONS

This biohybrid robotic jellyfish illustrates the capabilities of artificial control of aquatic animal locomotion. Enhanced propulsion has been demonstrated in laboratory conditions, and by successfully deploying this system in the Atlantic Ocean (Fig. 3), we demonstrate the robustness of this biohybrid system *in situ*. This suggests the potential for applications in sending biohybrid robots to collect data and monitor more sensitive areas of the ocean currently unexplored by other aquatic vehicles.

Summary The reliability of cardiovascular computational models depend on the accurate modeling of the hemodynamics, the realistic characterization of the tissues and the correct description of the fluid/structure interaction. The resulting multi-physics model thus requires an immense computational power and implies long time to get the results or to rely on external computational resources if multi–CPU processors are used (MPI acceleration). In the recent years, the graphics processing unit (GPU) has emerged as a popular platform for high performance computing and allows for considerable reductions of the time–to–solution. In order to develop a computational tool to support medical decision, our multi-physics solver [1] has been ported to GPU architectures using CUDA Fortran to tackle fast and accurate hemodynamics simulations of the human heart without resorting to large–scale supercomputers.

MOTIVATION

Each beat of the human heart is triggered by specialized pacemaker cells that generate rhythmical electrical impulses rapidly propagating through the heart, stimulating myocytes contraction and, in turn, pumping blood. The resulting hemodynamics yields shear stresses and pressure loads on the myocardium and on the valve leaflets, whose opening/closing ensures the correct flow direction across heart chambers. This highly sophisticated mechanism, however, can be affected by cardiovascular disorders (CVD) that reduce the pumping efficiency of the heart and can potentially yield life–threatening conditions. CVD are the main cause of death in developed countries and also one of the most relevant costs for health care systems (cost of 210 billion euro per year for the EU economy [2]). Computer simulations of the blood flow in the heart and arteries can be a precious tool to improve the predicting capabilities of diagnostics, to refine surgical techniques and test the performance of prosthetic devices. However, the reliability of cardiovascular simulations depends on the accurate modeling of the hemodynamics, the realistic characterization of the tissues and the correct description of the electro–fluid–structure interaction (FSEI).

THE MULTI–PHYSICS MODEL FOR THE LEFT–HEART

Our group has developed an innovative and versatile multi-physics model to simulate the left heart [1] In particular, the pulsatile and transitional character of the hemodynamics is obtained by solving directly the incompressible Navier–Stokes equations using a staggered finite differences method embedding various immersed boundary (IB) techniques to handle complex moving and deforming geometries. The structural mechanics is based on the Fedosov interaction potential method to account for the mechanical properties of the biological tissues, which are anisotropic and nonlinear [3]. The electrophysiology, responsible for the active potential propagation in the cardiac tissue triggering the active muscular tension, is incorporated by means of a bidomain model accounting for the different cellular models of the various portions of the heart [4]. All these models are three-way coupled with each other resulting into the FSEI as indicated in figure 1(a). The heart model is composed by realistic geometries of the left ventricle (figure 1b) and atrium whose active muscular contraction triggers a structural deformation of the endocardium that originates the hemodynamics, which, in turn, generates stresses on the surrounding cardiac tissue. The numerical framework also includes the bi-leaflet mitral valve, the three-leaflets aortic valve and the thoracic aorta, which are passive tissues experiencing continuous stretching and bending through the cardiac cycle. This computational framework is seen to provide realistic cardiovascular simulations both in terms of muscular activation, intraventricular hemodynamics and wall shear stresses. Figure 1(b) shows the instantaneous flow streamlines and the wall shear stress at the ventricle during the E-wave of the diastole, which is in qualitative and quantitative agreement with in-vivo and ex-vivo measurements [5].

In our model *the body kinematics comes as a result of the three-way FSEI* and a different cardiac configuration (e.g. cardiac output, heart rate, ventricle geometry, valve leaflets length and/or thickness) can be simply investigated by minimal modifications in the computational model [6]. The three-way FSEI makes the computational model predictive, thus opening the way to numerical experiments for virtually testing new prosthetic devices and surgical procedures.

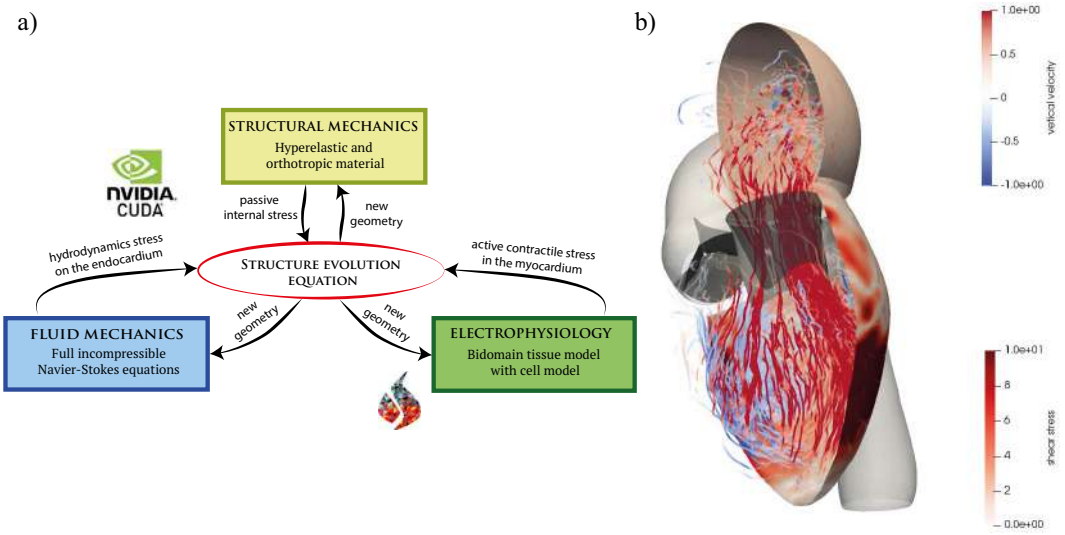

Figure 1: a) Sketch of the fluid–structure–electrophysiology (FSEI) coupling. b) Snapshot of streamlines coloured with the vertical velocity and wall shear stress on the tissue wet surface at the peak of the E–wave of the diastole.

PERFORMANCE BOTTLENECK OF THE MODEL

The fluid, structure and electrophysiology solvers are strongly interconnected and they may be solved simultaneously as a single large dynamical system through an iterative procedure (strong coupling) or sequentially where each model is used as input for the next one in a given order (loose coupling). Which of the two approaches is more efficient depends on the specific problem and its parameters. In the case the added mass phenomena or structures with reduced inertia do not play an important role the loose coupling is considerably faster than the strong one (computational time savings of the order of 50–70%). However, the time step size is physically limited by the elastic frequency of the stiff ventricle myocardium and a maximum time step of $2 \cdot 10^{-5}$ in nondimensional units (corresponding to $0.8\mu s$) is needed to ensure numerical stability. Such a small time step means that about *1 million time steps have to be run to integrate a single heart beat* and the computational model has to be highly optimized to resolve a heart beat within few hours in order to timely provide statistically converged results for clinical decision.

TOWARDS MEDICAL APPLICATION: GPU OPTIMIZATION

Efficient code parallelization and effective use of the computational resources are essential for clinical application where accurate and timely simulation results are needed. The current trends in high performance computing point towards GPU accelerators since this technology is well-suited to address problems where the same program can be executed on many data elements in parallel. Hence, the initial CPU code parallelized with MPI has been ported in CUDA Fortran with the extensive use of kernel loop directives (CUF kernels) in order to have a source code as close as possible to the original CPU version. The GPU accelerated multi-physics heart model shows good strong scaling characteristics, and the wall-clock time per step for the GPU version is in between one and two orders of magnitude smaller than for the CPU version of the code thus allowing for a timely solution of the intraventricular hemodynamics. Furthermore, since the main aim here is to provide an in silico tool to aid medical decisions we have tested the code not only on GPU clusters but also on a workstation mounting two Tesla V100 that could be easily installed in a hospital (on the contrary of a cluster). Due to the increased performance and efficient use of memory, the optimized GPU code on such workstation solves a single time step in 0.1 and 0.9 seconds on a 257^3 and 512^3 mesh, respectively thus reducing the time–to–solution of standard simulations to less than a day.

Summary Recent breakthroughs with *in vivo* measurement techniques reveal cerebrospinal fluid flow through a network of "perivascular spaces" (PVSs) in the brain. PVSs are annular tunnels around the brain's vasculature and part of the recently discovered glymphatic system, an important waste removal pathway implicated in Alzheimer's disease. We have made multiple important advancements in modeling PVS flow. We introduce an improved geometric model of PVSs which we: (i) use to argue that PVSs are optimally shaped to maximize CSF flow and (ii) use to perform direct numerical simulations of microscopic PVS flow. We develop a hydraulic network model to obtain estimates of CSF flow speed, Reynolds, and Péclet numbers throughout the PVS network. These predictions may be tested in the future as experimental methods advance, and meanwhile can guide hypotheses about the glymphatic system.

INTRODUCTION

The brain is bathed in cerebrospinal fluid (CSF), a fluid primarily composed of water which provides the brain with shock absorption and buoyancy. A growing body of experimental evidence [1] has demonstrated that CSF also flows through the brain to remove toxic metabolic waste, such as amyloid-β, and that disruption of this clearance mechanism can lead to neurodegenerative diseases such as Alzheimer's. This clearance pathway, often referred to as the "glymphatic system," includes CSF flow through perivascular spaces (PVSs), which are annular tunnels surrounding the vasculature in the brain (Figure 1a). Numerical simulations offer great potential for gaining novel insights into this waste clearance system, but such simulations are still in their infancy, and the models that have been developed have reached conflicting conclusions, even regarding the direction of CSF flow in PVSs (see the review [2]). A substantial obstacle to developing accurate numerical simulations is the scarcity of experiments which provide model parameterizations and measurements for validation. However, we have recently performed *in vivo* measurements of CSF flow through PVSs [3] which provide a foundation for substantial advancements in modeling this waste clearance system unique to the brain.

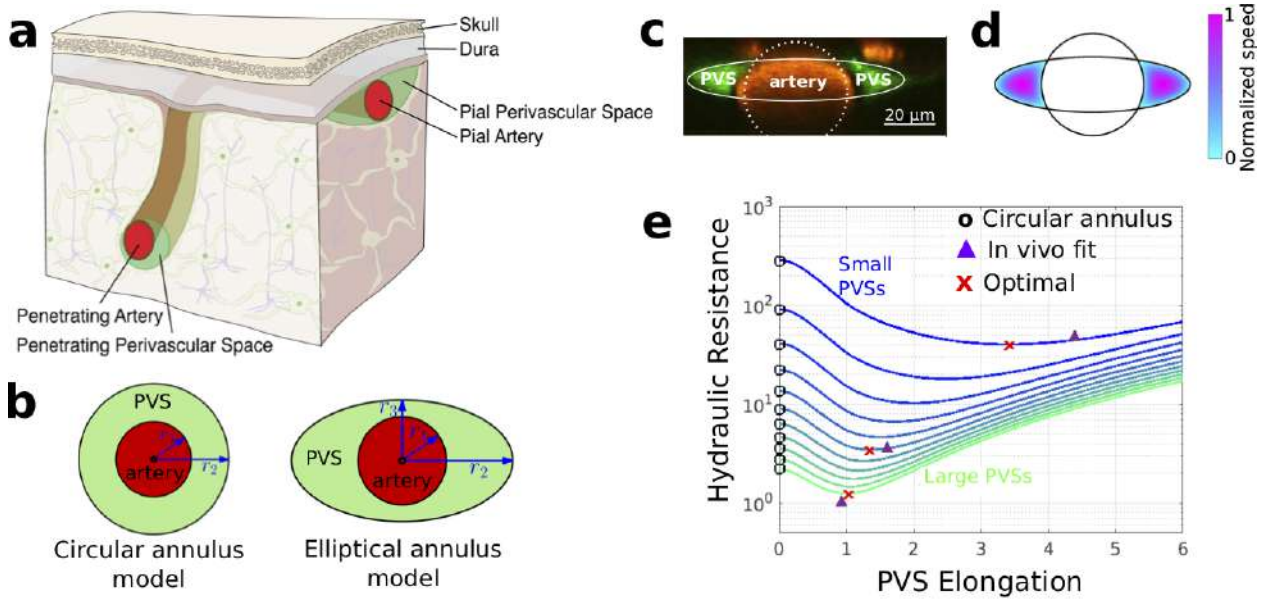

Figure 1: Improved modeling of perivascular spaces (PVSs) in the brain [4]. (a) A schematic illustrating PVSs as channels surrounding vasculature which contain flowing CSF. (b) All prior modeling studies have assumed the PVS has a circular annulus shape (left); we have introduced an elliptical annulus model (right). (c) An *in vivo* image of a PVS. (d) The speed profile computed for the optimal PVS shape which has the same cross-sectional area as the PVS shown in c. (e) Several curves of hydraulic resistance versus PVS elongation each with fixed PVS area. PVS shapes observed *in vivo* are nearly optimal, with hydraulic resistance much smaller than the circular annulus.

*Corresponding author. E-mail: j.tithof@rochester.edu.

IMPROVED MODELING OF PERIVASCULAR SPACES

All prior analytical and numerical models of CSF flow through PVSs have assumed that the PVS has a circular annulus shape (Figure 1b left). However, *in vivo* measurements [3] reveal that the outer boundaries of PVSs are often oblate and the arteries that form the inner boundary may be offset from the central axis (Figure 1c). Hence, we have proposed an improved model of the PVS which we refer to as the "elliptical annulus model" [4] (Figure 1b right). Using this model, we fit *in vivo* images of arteries and their PVSs to circles and ellipses, respectively, and then compute the velocity profile and hydraulic resistance for steady, laminar flow (Figure 1d). We find that for a fixed cross sectional area, the observed shapes of PVSs have hydraulic resistance that is lower than that of the circular annulus model by a factor ranging from 1.4 to 6.5. Furthermore, we find that the observed shapes of PVSs are very close to that of the optimal shape, defined as the shape which minimizes hydraulic resistance (minima of the curves in Figure 1e) and maximizes CSF flow. Our calculations demonstrate that the circular annulus assumed in all prior studies substantially overestimates the hydraulic resistance – and therefore underestimates the volume flow rate – in PVSs. We hypothesize that the nearly optimal shapes of PVSs may be a result of evolutionary optimization.

MICROSCOPIC AND MACROSCOPIC MODELS OF CSF TRANSPORT

The mechanism(s) driving CSF through PVSs is currently an open question. Although multiple hypotheses exist, most computational studies have pursued the hypothesis that flow is driven by arterial pulsations, a mechanism similar to peristalsis, which has the strongest experimental evidence [3]. We have performed direct numerical simulations (DNS) using finite element methods which capture the microscopic CSF transport due to arterial pulsations [5]. We employ the elliptical annulus model of the PVS, which is in contrast to all prior computational studies. We confirm that CSF is driven in the direction of the arterial pulse wave propagation (consistent with experimental observations [3]). We also find that an elliptical annulus gives rise to spanwise pressure gradients that drive azimuthal circulation (Figure 2a), an effect absent from prior simulations based on a circular annulus.

Since performing a DNS of the entire PVS network in the brain is not computationally feasible, we have developed a hydraulic network model (Figure 2b) based on the fluid flow analogue of Ohm's law: $dp/dz = Q\mathcal{R}$, where dp/dz is the pressure gradient along the streamwise direction, Q is the volume flow rate, and $\mathcal{R}$ is the hydraulic resistance. This model has been parameterized and validated using *in vivo* measurements and includes estimates of $\mathcal{R}$ based on realistic PVS shapes (Figure 1). Using this model, we obtain estimates of the pressure gradients, volume flow rates, flow speeds, Reynolds numbers, and Péclet numbers throughout the network. We also perform sensitivity analyses to set constraints on the potential volumetric flow rates deep within the brain, where high resolution experimental measurements are not yet feasible. Our results suggest the CSF flow through the brain's PVS network is strictly laminar and advection dominated for large molecules such as amyloid-β.

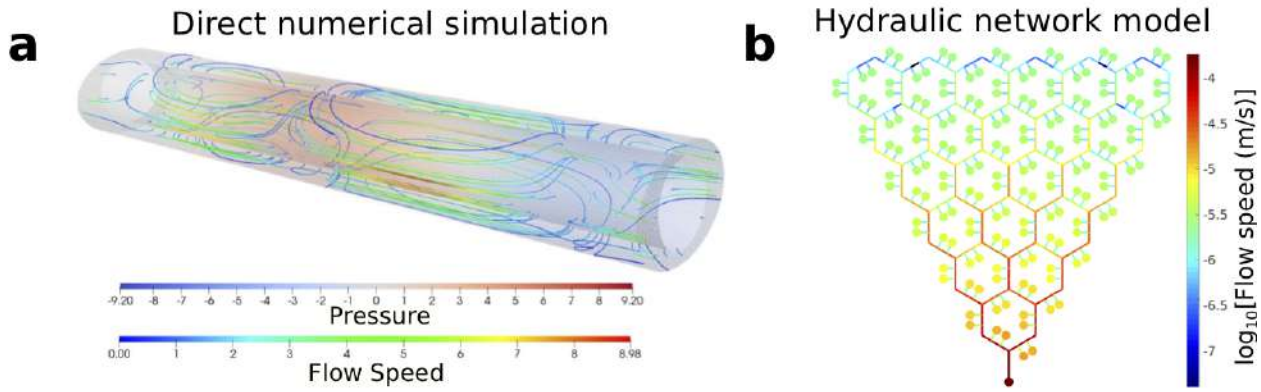

Figure 2: Microscopic and macroscopic simulations of CSF transport through PVSs. (a) Direct numerical simulation of arterial pulsation driven flow that captures microscopic CSF transport through a PVS. For an elliptical annulus, spanwise pressure gradients drive azimuthal circulation. (b) A hydraulic network model that captures the macroscopic CSF transport through the brain's PVS network. Each line or dot represents a pial or penetrating PVS (see Figure 1a), respectively, and the color coding indicates the flow speed. The hexagonal geometry is an idealized model of the vasculature at the surface of the brain [6].

SYNCHRONIZATION AND PROPULSION IN BUNDLES OF ROTATING HELICAL FILAMENTS

Maria Tătulea-Codrean[1] and Eric Lauga * [1]
[1]Department of Applied Mathematics and Theoretical Physics, University of Cambridge, Cambridge CB3 0WA, United Kingdom

Summary Multi-flagellated bacteria swim by rotating rigid helical filaments organised in bundles. The flagella within the bundle rotate in synchrony, and it has long been postulated that hydrodynamic interactions facilitate synchronization. Using a combined analytical (resistive-force theory) and computational approach (slender-body theory), we derive from first principles a dynamical system that explains the synchronization of two rotating helical filaments through hydrodynamic interactions. This is the first analytical model that accounts for the helical geometry of bacterial flagella, making a significant contribution to the mathematical understanding of a phenomenon revealed by computational studies more than a decade ago. We extend our analysis to self-propelling ensembles of N helical filaments and a spheroidal cell body, and we discover a novel and unexpected trade-off in propulsion.

INTRODUCTION

Bacterial motility is of fundamental interest to the scientific community, motivated not only by a desire to understand the oldest form of life on Earth, but also to draw inspiration from these resilient micro-organisms in order to design useful micro-robots capable of transporting cargo and navigating complex environments. Many species of bacteria propel themselves through viscous media by using an apparatus known as flagellum, which consists of a rigid helical filament actuated by a specialised rotary motor. In this work, we focus on bacteria that have multiple flagella and explore their environment using a strategy called "run-and-tumble" [1]. When a multi-flagellated bacterium starts to swim, the helical filaments are swept behind the cell body and rotate together in a coherent bundle, which leads to an interval of straight swimming called a "run". To change swimming direction, at least one motor must switch its sense of rotation, upon which the associated flagellum leaves the bundle and generates a torque on the cell body. The subsequent reorientation of the cell is called a "tumble". Recent advances in fluorescent microscopy have allowed the imaging of flagellar filaments whilst tracking swimming bacteria [2], allowing to probe open questions on the inner workings of a bundle of flagella and the reasons for having more than one flagellum. We address two aspects of this problem here: first the synchronization of helices within a bundle, and next the net propulsion they exert on the cell.

PROBLEM DEFINITION

We consider two parallel rigid filaments, with the same helical shape, rotating about their axes and separated by a distance d, as seen in Fig. 1(a). We model hydrodynamic interactions using Johnson's slender-body theory (SBT) with additional cross-helix interactions. The velocity of points along the centreline of helix k is expressed as

$$8\pi\mu\mathbf{u}_k(s) = \Lambda_k[\mathbf{f}_k](s) + \mathrm{K}_k[\mathbf{f}_k](s) + \sum_{l\neq k} \mathrm{J}_{kl}[\mathbf{f}_l](s), \tag{1}$$

where the functionals on the right-hand side represent integral expressions for the local (Λ_k) and non-local (K_k) part of SBT, and the interactions (J_{kl}) between helices [3, 4]. By using Legendre polynomials as an orthonormal basis for the force and velocity distributions along the filaments, Eq. (1) turns into an infinite linear system of equations which can be truncated and solved numerically. This numerical method is valid as long as the distance between the filaments $d \gg \epsilon$, the thickness of the filament. For distances $d \gg L$, the length of the filament, we further develop an asymptotic theory for calculating the interactions between the two filaments by hand. First, we calculate the single-helix resistance matrix, S_k, by integrating the force distribution along helix k, which we write as being proportional to the local velocity of the filament, according to resistive-force theory (RFT), i.e.

$$\mathbf{f}_k(s) = [c_\perp(\mathrm{I} - \mathbf{t}_k(s)\mathbf{t}_k(s)) + c_\parallel \mathbf{t}_k(s)\mathbf{t}_k(s)]\cdot[\mathbf{U}_k(s) - \mathbf{u}_\infty(\mathbf{r}_k(s))], \tag{2}$$

where $c_\perp$ and $c_\parallel$ are the local drag coefficients [5]. Once we know the behaviour of a single helix, we can calculate cross-helix interactions by noting that the leading-order flow induced by helix l at the position of helix k is a uniform flow coming from the far-field representation of helix l as a Stokeslet, which decays like the inverse of distance. Hence, the cross-interaction resistance matrix at order $\mathcal{O}(d^{-1})$ is

$$\mathrm{C}_{kl} = -\mathrm{S}_k^{1\leq j\leq 3}\cdot\left[\frac{\mathrm{I} + \hat{\mathbf{d}}_{kl}\hat{\mathbf{d}}_{kl}}{8\pi\mu|\mathbf{d}_{kl}|}\right]\cdot\mathrm{S}_l^{1\leq i\leq 3}, \tag{3}$$

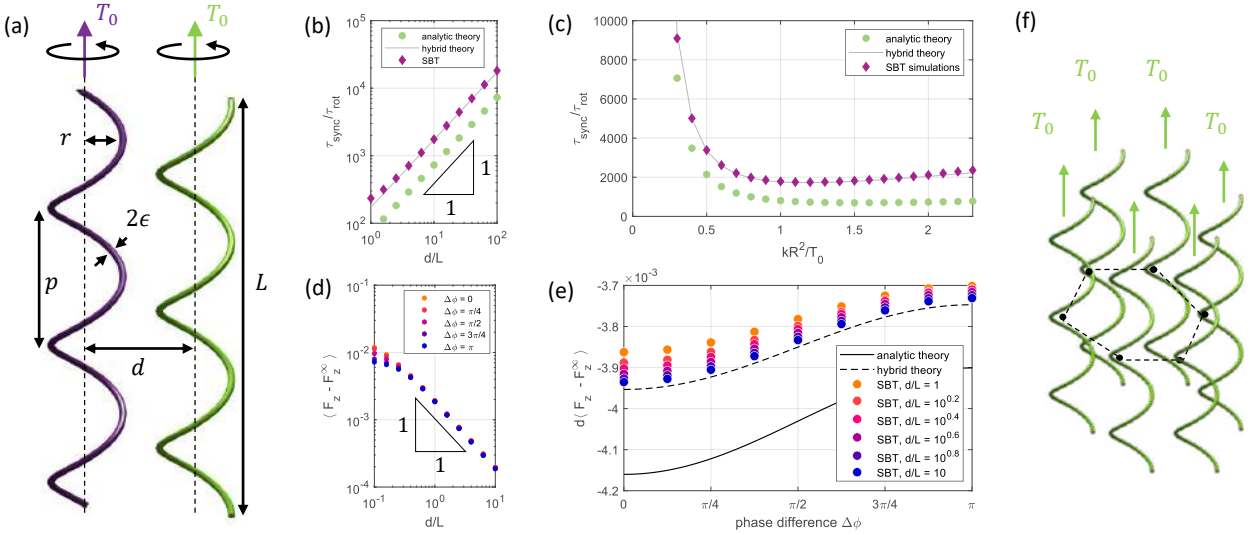

Figure 1: Synchronization and propulsion of rotating helical filaments. (a) Basic setup with two parallel rigid filaments of identical helical shape. (b) The time scale of synchronization increases linearly with the distance between the helices, and (c) achieves a minimum for intermediate values of the harmonic trap stiffness, k. (d) The deficit in propulsive force decreases with the inverse distance between the helices and (e) is largest when the helices are in phase. (f) Basic model for a bacterial flagellar bundle consisting of N rigid helical filaments in a regular polygonal arrangement.

where i and j indicate row and column numbers, and the vector $\mathbf{d}_{kl}$ is the separation between the two filaments. The matrices S_k and C_{kl} can be calculated by hand and, for simple cases, the full resistance matrix for the N-filament system can be inverted in order to find the linear and angular velocities of the filaments in terms of the forces and torques that are applied to them. This asymptotic theory, which we have further developed to include $\mathcal{O}(d^{-2})$ interactions, allows us to analyse the synchronization of a pair of identical parallel filaments through far-field hydrodynamic interactions.

RESULTS

Our analytical model for far-field interactions confirms the observation of previous computational studies [6, 7] that two rigid helical filaments driven by a constant torque cannot synchronize without some form of compliance – in our case, we consider the axes of the helical filaments being trapped in a harmonic potential. We derive a dynamical system for the phases and displacements of the two filaments, and we analyse this system analytically to determine the time scale of synchronization (Fig.1b,c) and the critical torque difference for which the filaments may still synchronize, at a non-zero phase difference which we determine. We also combine our far-field theory with SBT simulations to determine the loss in propulsive force on a rotating helical filament due to the presence of a second rotating helix at a distance d away from it (Fig.1d,e). We also consider a model of a bacterial flagellar bundle consisting of N helical filaments in a regular polygonal arrangement (Fig.1f). The challenge of extending our analytical framework to N filaments lies in the quadratic rise of computational time in our SBT simulations, and a greater complexity in the calculations we do by hand. Nevertheless, we succeed in quantifying the increase in synchronization speed with the number of flagella, and we discover a surprising phenomenon related to propulsion which has not been reported in the literature before.

CONCLUSIONS

Using an asymptotic calculation for the far-field hydrodynamic interactions between helical filaments, we develop the first analytical model that captures the synchronization of two rotating rigid helices in the presence of hydrodynamic interactions and elastic compliance. Our framework can easily be generalised to multiple body systems, which allows us to investigate synchronization and propulsion in realistic models of multi-flagellated bacteria. We complement our analytical theory with computations in order to compare the behaviour of such systems in the far vs. the near field.

Summary Nasal breathing difficulties are a common condition, and their treatment often requires surgery. Unfortunately, procedures are designed and carried out mostly based on the surgeon's experience; data supporting surgical choices are lacking. Computational Fluid Dynamics (CFD), by naturally accessesing functional properties of the human nose, improves the understanding of its flow field. However, a detailed flow prediction alone does not immediately lead to identifying the best surgical maneuver. We intend to leverage Machine Learning (ML) to bridge this gap and infer functional information from CFD data. The present study is preliminary and uses rather crude anatomical and computational models; however, its results demonstrate the potential of a ML model trained on CFD data.

INTRODUCTION

Nasal breathing difficulties (NBD) are a commonly encountered condition in the clinical practice of the Ear, Nose and Throat (ENT) doctors, causing huge societal cost. For example, the overall annual economic burden of chronic rhinosinusitis in the U.S. alone is estimated at 22 billion USD per year [1]. Though a variety of techniques is available to ENT surgeons, consensus is lacking on the surgical approach for a specific patient. As a consequence, up to 50% of the patients undergoing common surgical procedures, as for example septoplasty, report that symptoms did not improve [2].

During the last years, Computational Fluid Dynamics (CFD) has successfully tackled increasingly complex geometries; the anatomy of the human nasal cavity has become affordable, and CFD is nowadays a further item in the toolbox of the ENT surgeons (Fig.1a). We have designed a computational procedure, described e.g. in [3], that starts from a CT-scan of the patient, and reliably computes the (mean and instantaneous) flow field in the nose via Direct Numerical Simulation. Our ambitious long-term goal is the development of a robust tool to support ENT surgeons in discriminating pathologies from the normal, often large anatomical variations, and in selecting the best surgical approach.

However, it remains non-obvious how to translate the wealth of information contained in a CFD solution into a rational selection of the best surgery for each patient [4]. In this work we describe our preliminary evaluation of Machine Learning (ML) towards this goal. We assess the inference capabilities of ML algorithms by estimating geometrical measures using only fluid dynamics features. We notice that our goal differs from the majority of the research that applies ML to fluid mechanics, where the efforts are devoted to the improvement of flow modeling, optimization and control [5].

METHODOLOGY

The preliminary nature of the work calls for a simplification of the problem, in terms of both the anatomies and the physical modeling, while at the same time maintaining its key features. For the CFD simulations, we employ a standard $k-\omega$ SST RANS turbulence model (tuned with preliminary Large Eddy Simulations), and a Gaussian process [6] is used for inference. From the anatomical standpoint, an original parametric CAD model of the upper airways is developed (Fig.1b) which replicates the main features of a real nasal cavity, but without the paranasal sinuses. The parametric model is then modified to mimic some of the most common anatomical variations observed in the ENT practice: 4 corresponding to asymptomatic variations of healthy noses, and 3 to pathological conditions typically leading to severe symptoms (anterior hypertrophy of the inferior turbinate, hypertrophy of the whole inferior turbinate, and anterior hypertrophy of the middle turbinate). Combinations of these parameters lead to 200 unique anatomies, which are used to generate a CFD dataset with the associated task of predicting the severity of single pathology expressed in terms of one parameter.

Adopting ML models over CFD output is not straightforward, since every CFD analysis produces large amounts of data. Even the relatively coarse RANS simulations considered here run on about one million cells, and each cell carries at least 7 real values (three spatial coordinates, three components of velocity and pressure). Learning on such highly-dimensional feature space requires an enormous amount of annotated data. Thus, CFD simulations cannot be directly an input for ML, and more compact descriptors are required. We resort to feature engineering, by devising a small number of features designed by experts, i.e. CFD engineers and ENT doctors. Examples of features are: a polynomial fit of pressure along the nose (Fig.2 a); a histogram of total travel times of tracers released at 200 specified locations (Fig2 b); the flow variables averaged over 5 specific cross-sections of the domain and smaller portions of these (Fig.2 c). In the end, the number of features is 342, which is still very high considering the number of samples.

RESULTS AND CONCLUSIONS

Experiments performed by cross-validation over our dataset of 200 simulations, show that features extracted from CFD data can successfully infer the target measures of the CAD model. We performed feature selection to identify the most informative features, using both *Recursive Feature Elimination* and *Forward Feature Selection* by fitting *Extremely Randomized Trees* [7] as regression model. As an illustrative example, Fig.1c reports the results of a Gaussian Process trained on the most informative features for the anterior hypertrophy of the inferior turbinate, and shows that the mean square error of the prediction drops below 20%, when only 3 features are used. Remarkably, the *selected* features are often extracted from areas only indirectly affected by the geometrical modification, further indicating that CFD conveys important information. The most informative features are found to be the average flow values across the 5 slices.

CFD can have a large impact upon the ENT practice, as it provides functional *and* patient-specific information about the airflow in the human nose. In particular, our study indicates that features extracted from CFD data have the potential to identify pathologies even when accompanied by non-pathological variability. ML is thus a viable pathway to address those shortcomings that prevent CFD from being routinely deployed in clinical practice. The next step is to validate our study on more accurate CFD models (DNS), more realistic anatomies (CT scans of patients) and more realistic predictions (diagnosis of ENT specialists).

A SIMPLE MODEL FOR FISH LOCOMOTION: FROM KINEMATICS TO PROPRIOCEPTIVE DRIVING

J. Sánchez-Rodríguez*[1], C. Raufaste [1], and M. Argentina [1]
[1]Université Côte d'Azur, CNRS, Institut de Physique de Nice, 06100 Nice, France

Summary We have developed an elementary model of self propelled locomotion from which we compute the locomotion velocity as function of the swimmer kinematics. In our model, these kinematics are reduced to the tail amplitude and its beating frequency. The influence of parameters characterising the surrounding flow and physical features of the swimmer are also quantified. Our results are in good agreement with previous works [1, 2]. We hypothesize that the kinematic parameters might be selected by driving the tail motion with a proprioceptive feedback. The simplest feedback would be that the tail motion to be linearly dependant on the normal force felt by its body. In parallel to this theoretical approach, we have constructed a robotic compliant fish which is attached to a force sensor. Our theoretical model accurately predicts these experimental outputs.

INTRODUCTION

Fish across many species and scales cruise in a relatively narrow range of Strouhal numbers, around 0.3 [1, 3, 4]. This dimensionless parameter, $St = Af/U$, is a simple combination of the swimming velocity U, tail-beat amplitude A and frequency f. The self propelled locomotion is modelled by accounting for the fluid-structure interaction and neglecting the biological aspects. In that sense, numerous artificial systems have been studied in experiments and models such as flapping foils [2, 5, 6] or compliant robots [7, 8].

We first consider theoretically and numerically a simple model of aquatic locomotion to study the influence of various parameters on the Strouhal number. The second law of Newton is applied to a slender airfoil-shaped two-dimensional body. The tail undulates with a prescribed harmonic motion defined by an amplitude A and a frequency f. The thrust and drag forces are derived within the Theodorsen's approach [9, 10], which postulates a perfect fluid. In a second step, we test a feedback to control the swimming gait of a robotic fish, based on a proprioceptive loop: the normal force felt by the robot drives the tail motion. We theoretically figure out the range of parameters that triggers self propulsion.

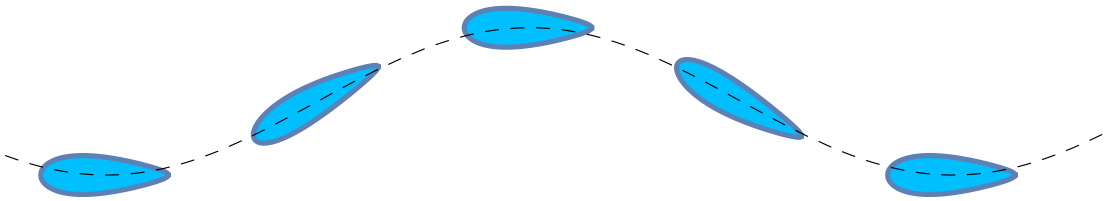

Figure 1: Orientation and trajectory of the swimming body predicted with the numerical simulation.

MODEL WITH KINEMATICS DRIVING

A simple model of aquatic locomotion is developed to analyze the effect of several parameters on the Strouhal numbers. These parameters are the tail-beat amplitude and frequency, the position of the center of mass in the swimmer body, the drag coefficient and the dimensionless added mass. We consider our swimmer to be a slender, airfoil-shaped, two-dimensional, rigid body performing a prescribed motion of amplitude A and frequency f in order to simulate the tail motion. Our theoretical approach assumes a two-dimensional, incompressible, irrotational and inviscid flow.

To assess the hydrodynamical forces acting on the swimmer, we follow the seminal paper of Theodorsen [9], and we take into account the pressure drag. The velocity potential of the flow is calculated with a conformal transformation, and the forces are written in the small amplitude regime. By balancing momentum, we deduce the equations describing the longitudinal and the transverse motion. The system is solved numerically, and we compute analytically solutions at the first orders in amplitude .

We show that the Strouhal number is strongly correlated with the drag coefficient c_d. With the values of c_d extracted from the literature, we forecast the Strouhal number belonging to the interval 0.1-0.3, in very good agreement with those measured on natural fish. The effect of the other parameters can be neglected up to the second order in amplitude and we obtain prediction for the phase delay between the heaving and pitching motions.

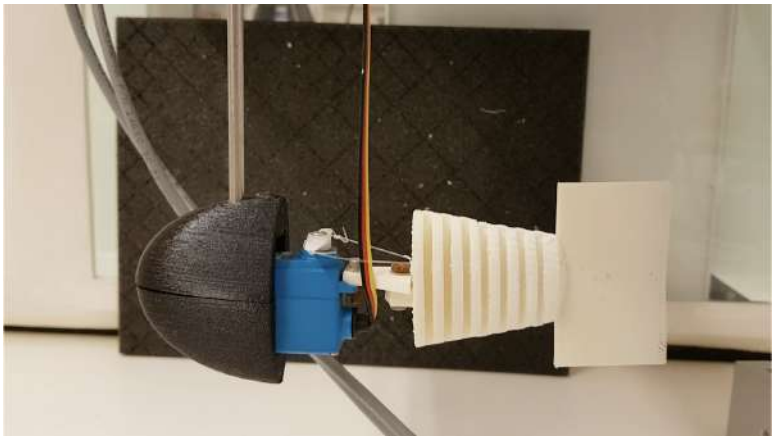

Figure 2: Picture of the compliant robotic fish.

MODEL WITH PROPRIOCEPTIVE DRIVING

We would like to take a step forward to understand which mechanism selects the parameter values. We postulate that swimming gait might be driven by a proprioceptive feedback, which would fix the amplitude and frequency. As a first guess, we assume that tail angle is proportional to the normal force felt by the swimmer. To explore this conjecture, we construct a robotic fish attached to a force sensor which detects both normal and longitudinal forces. We put this device in a water tunnel and we vary the value of the proportionality constant γ, which couples the normal force to the tail angle. For low values of γ, the system converges to a motionless phase, independently of the initial condition. For large γ, the robot oscillates periodically, and the undulation amplitude grows as γ increases, before to saturate to a constant value for larger values of the parameter. In between these two regimes, we experimentally predict the existence of a threshold in γ.

With our minimal model, we reproduce these results. Accurate modelling of the servo is essential to correctly mimic the tail movement observed in the experiments. The model presents excellent predictive properties: the threshold is accurately found, while the characteristics of the oscillation are perfectly captured, both numerically and theoretically.

NUMERICAL SIMULATION OF BLOOD FLOW IN THE THORACIC AORTA: STOCHASTIC SENSITIVITY ANALYSIS TO INLET VELOCITY SPATIAL DISTRIBUTION

Maria Nicole Antonuccio[1], Alessandro Mariotti[2], Simona Celi[1], and Maria Vittoria Salvetti *[2]
[1]BioCardioLab - Heart Hospital, Fondazione Toscana G. Monasterio, Massa, Italy
[2]Department of Civil and Industrial Engineering, University of Pisa, Pisa, Italy

Summary The effects of the spatial distribution of the inlet velocity in numerical simulations of the thoracic aorta are investigated. The velocity distribution is modeled through a truncated-cone shape, which well reproduces the in-vivo measured one in the systolic phase. The shape is changed by varying the ratio between the surfaces of the two bases. To carry out a systematic sensitivity analysis, a stochastic approach is adopted, in which the shape parameter is considered uncertain. This uncertainty is propagated through the numerical simulations and a continuous response of the output quantities of interest in the parameter space is obtained by means of generalized Polynomial chaos. The shape of the inlet velocity distribution has a significant influence on the velocity in the ascending aorta and hence on the wall shear stresses in this region, while the descending aorta is not affected.

INTRODUCTION

Blood flow and related stresses at the vessels walls play an important role in the initiation and progression of cardiovascular diseases such as in the case of ascending thoracic aortic aneurysms. Patient-specific in-vivo data can nowadays be obtained by 3D flow magnetic resonance (3D PC-MRI) imaging. However, MRI suffers of spatial and temporal resolution limitations and, thus, it is not able to provide quantitative flow indicators, such as wall shear stresses, with sufficient accuracy. A possible solution to obtain reliable and detailed information at a patient-specific level is to integrate in-vivo measurements with computational fluid dynamics (CFD), which can provide velocity, pressure and wall shear stresses with a resolution which is not presently attainable in experiments. On the other hand, different sources of uncertainties are present in CFD models, which might affect the accuracy of the results. Among others, a critical issue is given by inlet/outlet boundary conditions. In-vivo 3D PC-MRI data can be used to obtain indications on patient-specific boundary conditions for the simulations (see e.g. [4, 1]), reducing thus the uncertainty, as well as for comparison against numerical results, providing a cross validation.

The present work is part of a research activity towards the set-up and validation of a platform integrating in-vivo and in-vitro measurements with CFD simulations [2, 1]. We focus herein on the inlet conditions and, in particular, on the impact of the spatial distribution of velocity at the inlet on the blood flow and forces at the wall. The present analysis is motivated by previous studies in the literature [4, 3] and by the differences observed in the flow dynamics and wall shear stresses in simulations carried out by our group with plug flow at the inlet and with in-vivo measured inlet velocity respectively [5]. The inlet velocity profile is here analytically described by a truncated cone, which approximates reasonably well the measured velocity distribution in the systolic phase, which was observed in [5] to be the part of the cardiac cycle in which the flow variables were more sensitive to the inlet velocity distribution. The shape of the inlet velocity is then changed by varying the ratio between the surfaces of the two bases of the truncated cone, while the flow rate is always the same, equal to the in-vivo measured one. This analytic description of the inlet velocity distribution, together with a stochastic approach based on generalized Polynomial Chaos (gPC), allows the variability of the quantities of interest, i.e., velocity, pressure and wall shear stresses, with the shape of the inlet velocity profile to be systematically quantified.

COMPUTATIONAL SET-UP AND SENSITIVITY ANALYSIS

The considered aorta geometry and inlet flow rate are the same as in [1], obtained from MRI acquisitions performed on a healthy subject (28 years, male) with tricuspid aortic valve.

The open-source code *SimVascular* is used to carry out the hemodynamic simulations. The blood is considered as a Newtonian and incompressible fluid with density and kinematic viscosity. A finite-element method, including SUPG/PSPG stabilizing terms together with P1-P1 elements for both velocity and pressure, is used to discretize the governing equations. At the outflow boundaries, we use the 3-element Windkessel model [2]; on the arterial wall we impose a no-slip condition between the fluid and the wall and the effect of wall compliance is not taken into account in the simulations herein. As for the spatial distribution of the inlet velocity, the shape is assumed to be a truncated cone, which approximates rather well the measured inlet velocity distribution in the systolic phase (see Fig.1). The shape of the truncated cone depends on the ratio between the surfaces of the upper and the lower base, and thus the base area ratio $r = A_{top}/A_{base}$ is chosen as the uncertain parameter. It is varied in the range $r = [0.2 - 1]$, being $r = 1$ the plug flow condition. In order to obtain a continuous response surface of the quantities of interest with varying r, we use gPC, in which r is considered as a random variable with a given Probability Density Function (PDF) and the output quantities are obtained through a truncated orthogonal polynomial basis. We assume herein a uniform PDF of r on the given variation range because it is the least informative distribution with the highest variance in given intervals. The optimal polynomial

*Corresponding author. E-mail: maria.vittoria.salvetti@unipi.it

family for the gPC basis is thus given by Legendre polynomials. The polynomial expansion is truncated to third order and thus four quadrature points are needed to compute the coefficients of the expansion, which correspond to the following values of r: $0.256, 0.464, 0.736, 0.944$. Numerical simulations are carried out for these values of A_{top}/A_{base}. In all cases, the height of the truncated cone is calculated for each time instant in order to match the measured inlet flow rate.

RESULTS AND DISCUSSION

An example of the impact of the shape of the inlet velocity profile is given in Fig. 2(a−d), in which the distribution of wall shear stresses averaged over the cardiac cycle (TAWSS) is shown for the four deterministic simulations. By comparing Figs. 2(a−d) it is qualitatively evident that the TAWSS distribution in the ascending aorta and in the aortic arch changes with r, while it remains almost the same in the descending part. This observation is better summarized and quantified by the stochastic standard deviation of TAWSS obtained by means of gPC and reported in Fig. 2(e). This is a measure of the variability of TAWSS with r. The region of maximum variability of TAWSS indeed comprises the ascending aorta and the foremost part of the aortic arch.

The impact on the velocity field, pressure and flow rate waveforms at different sections has also been evaluated; it is not shown here for the sake of brevity, but it will be reported in the final paper. Possibly, in the final paper a similar analysis will be also shown by taking into account wall compliance.

Summary We present an image-based blood flow perfusion modeling of a whole organ vascular network for analyzing both its structural and functional properties. By using Light-Sheet Fluorescence Microscopy (LSFM) and adapted image post-treatment workflow, we could segment and reconstruct the entire micro-vascular network composed of 1.7 million vessels, inside a $\sim 25 \times 5 \times 1 = 125\text{mm}^3$ volume of the mouse fat pad. Vascular graph clustering network analysis revealed the structural and functional organization of meso-scale tissue as strongly connected communities of vessels. These communities share a distinct heterogeneous core region and a more homogeneous peripheral one, consistently with known biological functions of fat tissue. This work shows the existence of strongly connected functional vascular units in fat tissue.

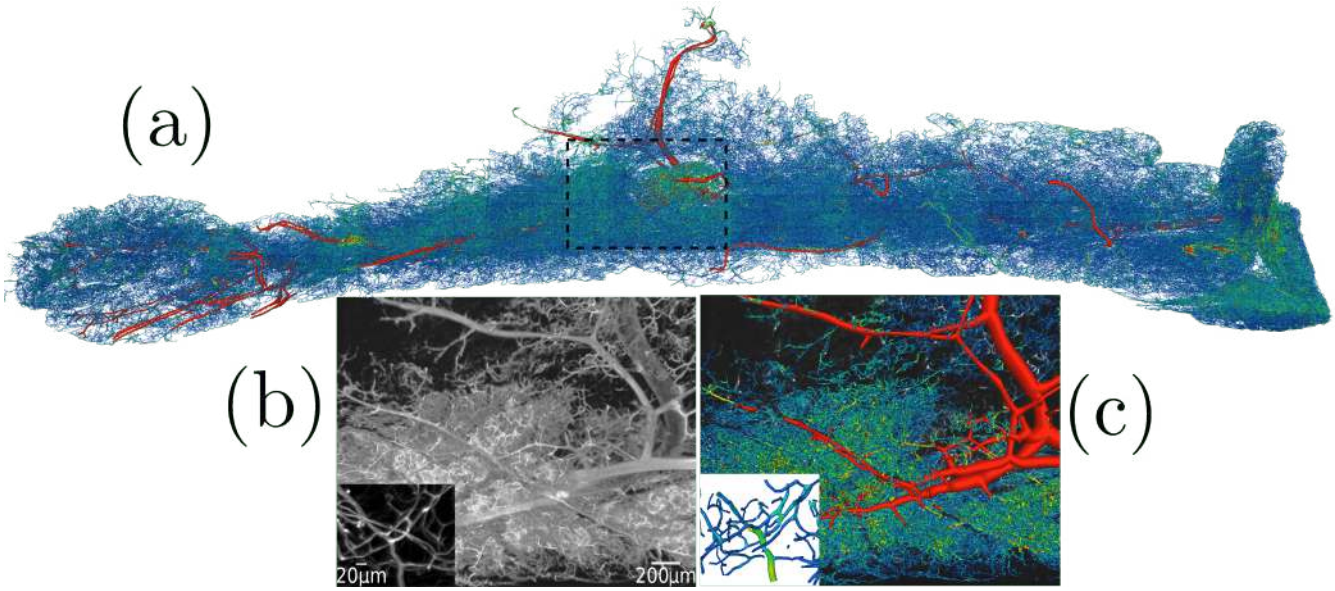

Figure 1: **All tissue vascular reconstruction** (**a**) The vascular network reconstructed from a $\sim 25 \times 5 \times 1 = 125\text{mm}^3$ volume of fat pad tissue based on image after various image post-processing. The vascular graph has $\sim 1.7.10^6$ edges and $\sim 1.2.10^6$ nodes. (**b**) Volume rendering of the maximal intensity projection of the original image of a small part of the tissue with another higher zoom level inside. (**c**) Corresponding reconstructed vascular graph highlighting the high resolution.

From LSFM imaging of mousse fat pad tissue, a complete reconstruction of the entire vascular network is performed, as illustrated in Fig. 1. Vascular perfusion is then computed over the entire network. Vascular graph clustering units are analyzed using graph clustering techniques with various graph weigths w_i, $i = 1, 4$ (see Fig. 2's legend for more details and [1]) so as to decipher the existence of functional units. The results are depicted in Fig. 2, showing the presence of strongly connected units. This work provides the proof of concept that in-silico all-tissue perfusion modeling can reveal new structural and functional exchanges between micro-regions in tissues, found from community clusters in the vascular graph.

Full lines are the linear regressions for each clustering weight w_i. w_0 no weight (slope $s = 0.61$); w_1 Euclidean distance ($s = 0.62$); w_2 curvilinear distance ($s = 0.66$); w_3 hydraulic resistance (Cf. S2) ($s = 0.25$); w_4: hydraulic conductance (Cf. S2) ($s = 0.28$). The gray curve is the result of Blinder et al. [1] with $s = 0.83$. Dashed lines delimit the boundaries of weak communities (therefore having strong connections between units) with slopes $s = 2/3$ and $s = 1$. Shaded areas are the standard errors associated with each regression.

AN INVISCID MODEL FOR SELF PROPELLED SWIMMING OF UNDULATING BODIES

Damiano Paniccia * [1], Giorgio Graziani [1], Claudio Lugni [2], and Renzo Piva [1]
[1] Department of Mechanical and Aerospace Engineering, University of Rome La Sapienza, Rome, Italy
[2] CNR-INM: Italian Research Council Institute of Marine Engineering, Rome, Italy

Summary A two-dimensional inviscid potential model with vorticity release has been developed in order to investigate the self propelled swimming of undulating bodies. The body is free to move not only in the forward and lateral directions, but it can also rotate around its center of mass, according to the forces and moments induced by the flowfield generated by its own prescribed undulation. The numerical model is based on an unsteady potential panel code for deformable airfoil. The vortex shedding process is modeled by an unsteady Kutta condition. The model is able to predict the full kinematics of the undulating airfoil by expressing forces and moments in terms of hydrodynamic impulse.

MATHEMATICAL AND NUMERICAL MODEL

In recent years, much progress has been obtained for the study of fish self-propulsion, starting from the mathematical models for elongated flexible body proposed by Lighthill [1] and Wu [2], up to the numerical solutions of Navier-Stokes equations for incompressible and viscous flow about a deformable body. In the present paper, however, we adopt a simplified model, which seems to be more appropriate for a wide analysis of the relevant parameters. In fact, we developed a coupling model able to combine the dynamic evolution of the deformable body with the two-dimensional inviscid flow simulation accounting for vorticity generation and release.

Following Kanso [3], who considered only the massless case in the frame of pure potential flow, we solved the body dynamics problem through hydrodynamic impulse conservation considering an appropriate wake model which rises the complexity of both the body motion and the flow solution due to their intrinsic coupling.

Body kinematics and flow solution

The force on the body can be obtained via the hydrodynamic impulse formulation, i.e.

$$\mathbf{F} = -\rho \frac{d}{dt}\left[\int_{S_b} \mathbf{x}\times\mathbf{n}\times\mathbf{u}\, dS + \int_V \mathbf{x}\times\omega\, dV\right] \tag{1}$$

where S_b and V are the body surface and the fluid volume around the body, while $\mathbf{u}$ is the velocity field, ω is the vorticity and $\mathbf{n}$ is the outward normal on S_b (into V). A similar relation could be obtained for the moment M. The expression for the force and moments can be combined with the dynamics equations

$$\mathbf{F} = \frac{d}{dt}\left(m\mathbf{u}_b\right), \quad \mathbf{M} = \frac{d}{dt}\left(I\boldsymbol{\Omega}\right) \tag{2}$$

where $\mathbf{u}_b$ and $\boldsymbol{\Omega}$ are the body linear and angular velocity, to eliminate the time-derivatives and obtain a simple linear system like $\mathbf{AX} = \mathbf{B}$. Here the unknown vector $\mathbf{X}$ contains the locomotion linear and angular velocity components and $\mathbf{B}$ is the forcing term related to the prescribed shape deformation.

Flow solutions, i.e. $\mathbf{u}$ and ω, are computed using an unsteady potential panel code consistently modified to allow for the solution about deformable airfoil representig a fish. The vortex shedding process is modeled by an unsteady Kutta condition, through a wake panel attached to the trailing edge which is concentrated into a point vortex and shed into the wake. The vortex shedding requires an iterative scheme, due to the non-linearity of the problem.

NUMERICAL RESULTS

Here we present a typical case of neutrally buoyant ($\rho = 1$) fish's self propelled swimming, represented as a NACA0012 foil deformed through the undulation of its centreline

$$h(s,t) = a_0 A(s)\sin\left[2\pi\left(\frac{L}{\lambda}s - ft\right)\right] \tag{3}$$

This relation is used for the carangiform swimming [4], where the amplitude law is $A(s) = 1 - 0.825(s-1) + 1.625(s^2-1)$, $\lambda = 1$, $a_0 = 0.1$ and the frequency $f = 0.5$. The curve coordinate along the centreline, s, ranges from 0 to 1.

Fig.1 shows the wake visualization of the self propelled airfoil after 5 oscillation periods. The reverse Von Karman vortex street is found in the wake, as evidence of the thrust experienced by the foil.

From the comparison shown in fig.2a between the swimming velocity obtained with the pure potential model (as in [3]) and the vortex shedding model, we can see that the presence of vorticity release compensates the high velocity

(a) (b)

Figure 2: (2a) Swimming speed obtained with pure potential and vortex shedding models - (2b) Horizontal U, lateral W and angular Ω velocity components. Constrained U is also shown in comparison.

oscillation predicted in the pure potential case. Moreover, the vortex shedding model reaches a steady state speed which is very close to the phase-velocity $\lambda f = 0.5$ of the traveling wave after a transient, while the pure potential model predicts a much lower velocity and reaches its steady state value since the beginning of the undulating motion.

Several studies about self-propelled swimming fish do not take care of lateral and angular kinematics of the airfoil, which is constrained to move along the horizontal direction only. Fig.2b shows the comparison between the obtained kinematics for a free swimmer and a constrained swimmer. The horizontal component of the swimming velocity U is about 35% higher when the airfoil is unconstrained. Therefore, forcing the airfoil to move along a fixed direction, or assuming that the fish's centre of mass is fixed to a point, leads to incorrect results both in terms of overall kinematics and energy and power consumption [5].

TURBULENT FLOW REDUCTION IN BILEAFLET MECHANICAL HEART VALVES

Hadi Zolfaghari[1], David Hasler[1], and Dominik Obrist * [1]
[1] ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Switzerland

Summary Bileaflet mechanical heart valves are successfully used for the replacement of stenotic aortic valves. Turbulent flow in the wake of these valves may be related to the formation of blood clots. Reduction of turbulent flow by natural laminar flow (NLF) is an established concept in aircraft design. It is our aim to apply this concept to heart valve design. Therefore, we study instability mechanisms leading to laminar-turbulent transition and discuss design optimization approaches to reduce turbulence.

BILEAFLET MECHANICAL HEART VALVES

The aortic valve is located between the left ventricle of the heart and the aorta. It opens during systole (contraction of the heart) and closes tightly during diastole (relaxation) to prevent blood from flowing back into the heart. At rest, the ejected blood stream reaches velocities of 1 to 2 m/s resulting in a Reynolds number of 3,000 to 6,000.

Aortic stenosis is a common disease of the aortic valve where the aortic valve does not fully open and creates a significant obstruction to the ejected blood stream [4]. In moderate to severe cases of aortic stenosis, the diseased valve is replaced by an aortic valve prosthesis. Especially in younger patients, mechanical heart valves are used because of their excellent durability. The most common design is the so-called bileaflet mechanical heart valve (BMHV) featuring two hinged valve leaflets which open and close during the heart beat (Figure 1a). However, it is known that unphysiological blood flow through BMHVs causes excessive viscous shear stresses which may lead to the formation of blood clots and blood trauma. For that reason, patients with BMHV are required to take life-long anti-coagulation medication which affects their quality of life. It is desirable to find ways to reduce the viscous shear stress levels in the flow past BMHVs and to obtain a more physiological blood flow.

Throughout systole, the flow past BMHVs is dominated by a turbulent wake. Next to its thrombogenic potential, turbulent blood flow may also be a factor in adverse aortic events (e.g. aortic dissection) because turbulent wall-shear stresses on the aortic wall may lead to endothelial damage. Moreover, turbulent viscous dissipation is a major contributor to the total pressure loss across the valve, which is one of the main performance parameters for artificial heart valves. In order to reduce turbulent shear levels, it is important to better understand the flow field past BMHVs and related instability mechanisms leading to laminar-turbulent transition. This allows to devise strategies to reduce turbulent flow as it has been successfully done in aircraft design by natural laminar flow (NLF).

METHODS

We investigate the flow past BMHVs by experimental and computational methods. For the experimental study, we use a pulsatile left heart flow loop and a tomographic particle image velocimetry (PIV) system as described in [1, 2]. It provides phase-averaged three-dimensional mean flow fields behind the BMHV. For the computational study, we perform direct numerical simulations (DNS) with a GPU-accelerated high-order Navier–Stokes solver [5]. The complex geometry of the BMHV is modeled by a sharp-interface immersed boundary method [3].

MEAN FLOW FIELD AND TURBULENT WAKE

Figure 1b shows the mean flow field past a BMHV at peak systole obtained with tomographic PIV [1]. The flow field comprises a complex configuration with multiple jets issuing from the three main orifices of the valve. As the jets widen in downstream direction, they reattach at the aortic wall about one valve diameter downstream of the valve orifice.

(a) (b) (c)

Figure 2: (a) DNS of the systolic flow past a BMHV with a turbulent wake (vortical structures visualized with the λ_2-criterion, $\lambda_2 = -0.1$). (b) Absolute instability between the leaflets leading to turbulent breakdown in the wake [6]. (c) Modified leaflet shape eliminating the primary instability [6].

Upstream of the reattachment points, there are two main regions of retrograde flow (recirculation) along the wall of the aorta.

The wakes and shear layers behind the two valve leaflets and between the forward and retrograde flow are unstable. This results in a strongly turbulent wake (Figure 2a). Although the flow in the sinus cavities (light blue regions in Figure 2a) is also unstable, it does not significantly contribute to the onset of turbulent flow behind the BMHV.

Quantitative analysis of the turbulent wake indicates high viscous shear stress levels beyond 10 Pa and turbulent viscous loss significantly contributing to the overall pressure loss across the valve. Furthermore, the analysis of velocity gradients along the aortic wall shows elevated levels of wall-shear stress as the turbulent wake attaches at the wall.

STRATEGIES FOR TURBULENT FLOW REDUCTION

Detailed analysis of the mechanisms leading to the turbulent wake indicates possible technical solutions for turbulence reduction, e.g. by shape optimization of the leaflet design. As it has been shown by Zolfaghari and Obrist [6], there exists an absolute instability close to the leading edge of the leaflets which leads to the breakdown of the Burgers vortex sheets in the wake of the two leaflets (Figure 2b). This primary instability can be suppressed by a slight modification of the leaflet shape (Figure 2c), i.e. by omitting the blunt leading edge of the leaflets which lead to an unstable impinging leading edge vortex (ILEV). This demonstrates the potential of design optimization for heart valve prostheses. Currently, a study on adjoint-based control of the ILEV instability is underway to identify optimal valve designs.

CONCLUSIONS

We have shown here that a detailed understanding of the flow past BMHVs can lead the way to better valve designs and less thrombogenicity. We have used modern experimental and computational tools to study the mean flow field and the turbulent wake of the valve. Tools of hydrodynamic stability theory were successfully applied to identify the origins of turbulent flow. Computational results suggest that NLF design concepts can be used to reduce turbulent flow past BMHVs.

BIASED RE-ORIENTATION IN CHEMOTAXIS OF PERITRICHOUS BACTERIA

Tonau Nakai *[1], Taishi Ando [1], and Tomonobu Goto [1]
[1] Department of Engineering, Tottori University, Tottori, Japan

Summary Chemotaxis of peritrichous bacteria is caused by the suppression of the switching of the rotation of the flagellar motors. We investigated whether the chemotactic behavior would appear in the turn angle during the tumbles. It is found that the turn angle depends on the concentration gradient of a chemoattractant that the cell sensed just before the tumble. The distribution of turn angle is biased toward smaller value when the cell swims up the gradient, whereas the distribution is almost uniform (random direction) when swimming down the gradient. Upwardly swimming cells make the turn angle smaller by loosening fewer flagellar filaments from the bundle during tumbles, resulting in accumulation around a chemoattractant. Our numerical simulation based on the biased random walk model has revealed that this bias in angular distribution clearly affects the cell's behavior around an attractant.

BACKGROUND

The mechanism of bacterial chemotaxis has been intensely studied for peritrichous bacteria that have multiple flagella. Cells swim by rotating their helical flagella with flagellar motors at the proximal ends of the flagella. When each motor rotates counterclockwise (CCW) being viewed from the flagellum to the motor, flagella form a bundle and the cell propels itself straight (run). When the rotational direction of the motor switches to clockwise (CW), the corresponding flagellum is released from the bundle and the swimming direction of the cell changes (tumble) [1]. If a cell senses that the concentration of an attractant has increased, the cell decreases the switching frequency from CCW to CW, which causes longer run in swimming up the concentration gradient than swimming down. The longer run duration toward the attractant source has been actually observed for *E. coli* [2] and *Salmonella typhimurium* [3] cells.

The aim of this study is to demonstrate that the turn angle distribution depends on the swimming direction (up or down the concentration gradient). Recently, Sourjik et al. have predicted that chemotactic behavior of peritrichous bacteria can be seen in the turn angles during tumbles [4]. An observational study regarding flagellar filaments of *E. coli* cells during tumble revealed that the turn angle becomes smaller when the fewer number of filaments are released during a tumble [5]. The number of flagella released during a tumble can become fewer when the switching from CCW to CW is suppressed due to sensing a chemoattractant.

METHODS

A strain of peritrichous bacteria, *Salmonella typhimurium* SJW1103 was used. Cells were cultured in 3 mL of LB medium overnight at 30°C. Then, 0.1 mL of the bacterial suspension was put into 3 mL of the motility buffer (pH 7.0, 10 mM KH_2PO_4, 0.1 mM EDTA, 10 mM sodium lactate) and incubated for 3 hours at 30°C. The solution was centrifuged for 1 minute at 10000 rpm. The supernatant liquid of 0.9 mL was removed and the buffer of the same volume was added. One molar of L-serine with 0.3% agar was aspirated into the glass capillary with the internal diameter of 1 μm. To observe a single cell for a long time, only a few cells were poured into the preparation with a microinjection. Cells accumulating around an attractant were observed by an inverted microscope.

RESULTS

Trajectory of the trapped cell around an attractant

Figure 1 (a) shows an example of a swimming trajectory. The cell stays within 100 μm from the source of attractant for 5 minutes. Whether the swimming movement shows chemotaxis or just a random walk can be determined by calculating the mean square displacement (MSD). As shown in Fig. 1 (b), MSDs of samples I-IV reach plateau in the time region of 10-100 s, indicating that each cell is attracted to the capillary tip. Without an attractant, the MSD should increase linearly with time.

Turn angle

Difference in the distribution of the turn angle between swimming up and down the gradient is investigated. The relationship between the turn angle θ and the posture angle ϕ just before the tumble with respect to the attractant source is described in the following. Figure 2(a) shows the definitions of θ and ϕ, and Fig. 2 (b) shows a plot of θ and ϕ for all the 268 tumbles of the single cell. The posture angle $\phi < 90°$ for "up" swimming and $\phi > 90°$ for "down". The turn angle θ is distributed uniformly when $\phi > 90°$, whereas the distribution of θ is biased to smaller angle when $\phi < 90°$. This indicates that cells approaching the attractant source have smaller turn angle than receding cells. As shown in Fig. 2(c), this bias is clearly visualized by plotting the cumulative probability of θ for up ($\phi < 90°$) and down ($\phi > 90°$). If θ is observed at an equal probability at any angle (random direction), the cumulative probability would correspond to a dashed straight line. The distribution "down" is almost random and "up" is above "down", indicating that the directional change during a tumble after swimming up the gradient tends to be smaller.

*Corresponding author. E-mail: nakai@tottori-u.ac.jp.

Biased random walk simulation

How this observed bias in the turn angle affects the degree of the accumulation is investigated by the numerical simulation. The authors have developed a mathematical model for bacterial chemotaxis based on the biased random walk [6]. The modeled cell changes the tumble frequency and the turn angle depending on its moving direction of the adjacent steps. One cell was placed at the origin, and the calculation was performed in a 3 dimensional space. Calculated MSD was compared with the observation. Although the calculated MSD is 5 times larger than the measured MSD, but the cell stays around the origin only with the biased distribution of turn angle.

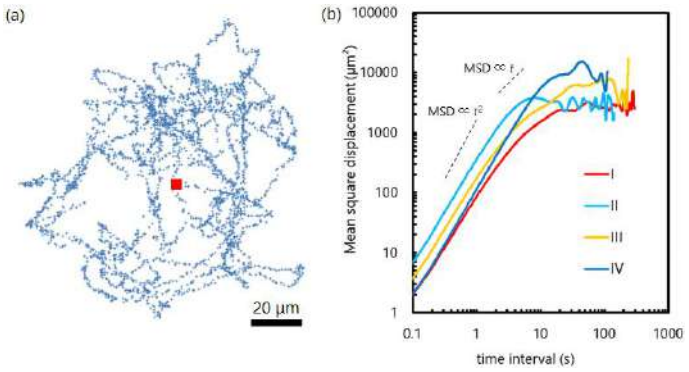

Figure 1. Single cell's behavior around the attractant source, (a) cell's trajectory, (b) mean square displacement of 4 cells.

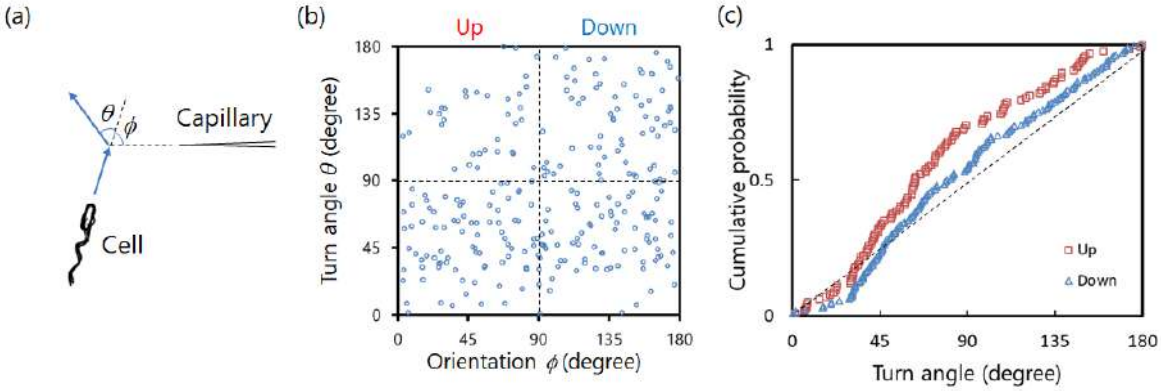

Figure 2. Turn angle distribution in a single cell, (a) definition of the turn angle θ and the orientation ϕ, (b) θ-ϕ plot, (c) cumulative probability of the turn angle.

CONCLUSIONS

We investigated the turn angle during the tumbles of peritrichous bacteria swimming in the concentration gradient of a chemoattractant. It is found that the turn angle depends on the concentration gradient that the cell sensed just before the tumble. The distribution of turn angle is biased toward smaller value when the cell swims up the concentration gradient, whereas the distribution of the angle is almost uniform (random direction) when swimming down the gradient. This behavior is reasonable because the nature of bacterial chemotaxis is changing the switching rate of flagellar motors according to the environment. Upwardly swimming cells make the turn angle smaller by loosening fewer flagellar filaments from the bundle during tumbles, resulting in accumulation toward higher concentration of the chemoattractant. How this observed bias in the turn angle affects the degree of the accumulation was investigated by the random walk simulation. In the concentration field where attractants diffuse concentrically from the point source, it was found that this angular distribution clearly affects the degree of accumulation of the cell.

MOTILITY AND AEROTAXIS IN SINORHIZOBIUM MELILOTI, A SOIL BACTERIUM

Julien Bouvard[1], Frédéric Moisy *[1], Carine Douarche[1], Nicolas Busset[2], Peter Mergaert[2], and Harold Auradou[1]
[1]Université Paris-Saclay, CNRS, FAST, 91405 Orsay, France
[2] Université Paris-Saclay, CEA, CNRS, Institute for Integrative Biology of the Cell (I2BC), 91198, Gif-sur-Yvette, France

Summary Aerotaxis is the ability of motile cells to move towards oxygen. Bacteria tracking and in-situ oxygen concentration measurements are used to characterize aerotaxis in *Sinorhizobium meliloti*, a motile nitrogen-fixing bacterium naturally present in the soil. Aerotaxis takes place in a sealed glass capillary closed at one end with an oxygen-permeable plug. Our results suggest that the oxygen dependence of the aerotactic velocity, $\propto \nabla c/c^2$, is stronger than the "logarithmic sensing" response ($\propto \nabla c/c$) found in other chemoattractants.

INTRODUCTION

Chemotaxis, the biased migration of a motile cell towards the source of a chemical gradient, is an ubiquitous phenomenon in nature. Yet, our understanding of the basic physical and hydrodynamical mechanisms behind chemotactic swimming in a liquid environment is still limited [1]. Among various chemoattractants, aerobic bacteria are sensitive to the oxygen content of the medium, a specific chemotaxis referred to as aerotaxis [2].

We are interested here in the aerotaxis of a motile nitrogen-fixing bacterium naturally present in the soil, *Sinorhizobium meliloti*, which forms a symbiotic association with some legume plants. Most experiments based on chemotactic/aerotactic assays for *S. meliloti* are qualitative, and do not provide quantitative information on its chemotactic response. A difficulty is to access simultaneously the dynamics of oxygen and bacterial concentrations.

Here oxygen concentration is measured using Ruthenium micelles, an oxygen-sensitive fluorescent dye encapsulated in phospholipid micelles to make it biologically inert [3]. We designed a simple experiment, shown in figure 1: a glass capillary, sealed at one end by a PDMS plug (which is permeable to oxygen) and at the other end by an oxygen-proof plug, is filled by a bacterial suspension mixed with Ruthenium micelles. Simultaneous measurements of oxygen concentration, bacteria concentration and bacteria swimming velocity are carried out to reconstruct the aerotactic response.

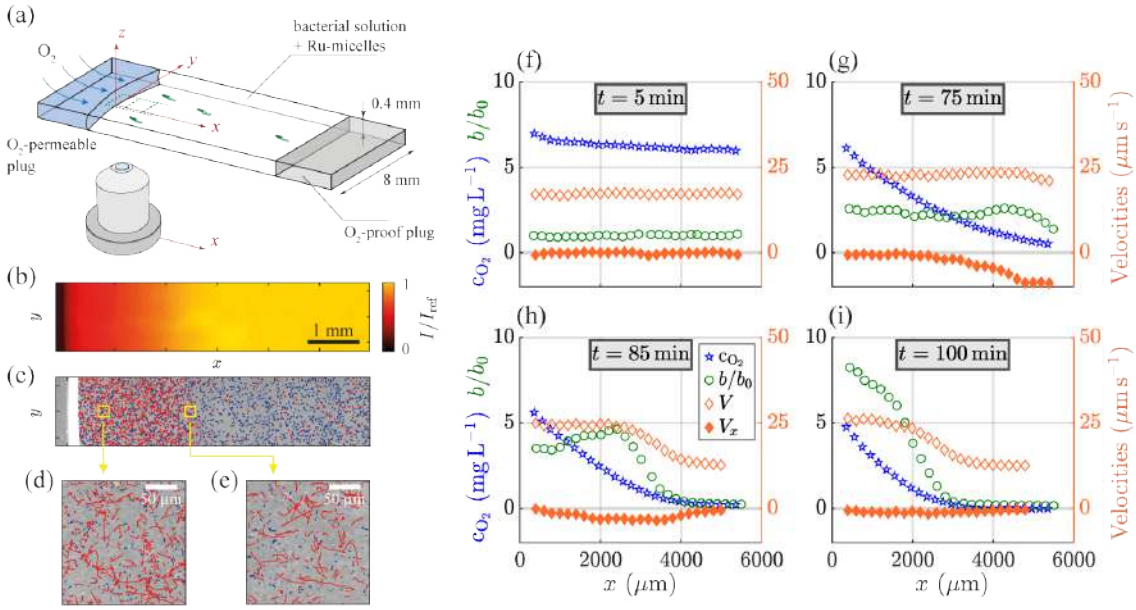

Figure 1: (a) Experimental setup: a glass chamber of rectangular section is filled with the bacterial suspension and Ruthenium micelles. One side of the capillary is sealed by pdms, permeable to oxygen, while the other side is sealed with an O_2-proof grease plug. (b) Fluorescence light intensity, mapping the oxygen concentration field (dark: high $[O_2]$). (c) Images of bacteria, superimposed to the bacteria tracks (non-motile and motile bacteria are in blue and red, respectively). (d), (e): Magnifications at two locations, showing the random and biased trajectories. (f), (g), (h) and (i): Variation of the local density of bacteria, oxygen concentration, magnitude of the swimming velocity of the bacteria and aerotactic velocity as function of the distance from the PDMS for four different times. The capillary is initially filled with an homogeneous suspension of bacteria at OD $= 0.05$.

*Corresponding author. E-mail: frederic.moisy@universite-paris-saclay.fr

RESULTS

Under usual conditions, a suspension of *S. meliloti* is composed of both non-motile and motile bacteria. Non-motile bacteria may be either attached to the substrate (on which they may form biofilms) or freely suspended in the liquid medium. We focus here on the motile population, swimming at a mean velocity of 20-25 $\mu\mathrm{m\,s^{-1}}$ and performing aerotaxis. Bacterial motion is observed using high-speed imaging under phase-contrast microscopy, and their trajectories are analysed by standard tracking methods using *ImageJ*.

Starting from an initial homogeneous concentration of bacteria and oxygen, oxygen consumption by the bacteria gradually produces an oxygen gradient near the oxygen-permeable PDMS plug, at $x = 0$. This oxygen gradient triggers the bacterial aerotaxis: Fig. 1 shows the propagation of a bacterial band escaping the low-oxygen region towards the oxygen source by swimming up the gradient. Reproducing this experiment with different initial concentrations yields the same qualitative result, on a time scale that depends on the initial bacterial concentration.

To infer the aerotactic response, we describe the bacterial concentration $b(x,t)$ using the standard one-dimensional Keller-Segel equation [4,5]:

$$\frac{\partial b}{\partial t} + \frac{\partial J_x}{\partial x} = 0, \qquad J_x = \chi(c) b \frac{\partial c}{\partial x} - \mu(c) \frac{\partial b}{\partial x}, \tag{1}$$

where c is the oxygen concentration, μ is the motility coefficient and χ the aerotactic sensivity coefficient. The averaged bacterial flux J_x has two contributions, aerotactic and diffusive. This equation assumes that the bacterial time response to changes in oxygen level is much faster than the dynamics of the propagating front, and that the mean run length is much smaller than the typical front width.

The flux in Eq. (1) is directly related to the averaged bacterial velocity V_x computed from the bacteria tracking through $J_x = bV_x$. This shows that the measured bacterial velocity V_x gives the aerotactic velocity $\chi(c)\partial c/\partial x$ only where b is uniform, *i.e.* at the location of the front or far from oxygen source, which severely limits the range of oxygen where $\chi(c)$ can be measured. Because of the large motility of *S. meliloti*, $\mu \simeq (8 \pm 2) \times 10^3\,\mu\mathrm{m^2\,s^{-1}}$, the diffusive flux represents a strong contribution to the total flux. Taking into account the diffusive flux term allows us to extend the range of oxygen concentration where the aerotactic sensivity coefficient $\chi(c)$ can be measured.

Our measurements show that the quantity $[V_x + (\mu/b)\partial b/\partial x]/(\partial c/\partial x)$ is indeed independant of x, t, and the initial bacterial concentration over a significant range of oxygen concentration, indicating that Equation (1) holds in the explored range of parameters. A power-law is found for the aerotactic sensitivity, $\chi(c) \propto 1/c^2$, over the whole range of oxygen concentration for which the cells are motile: between $0.3\,\mathrm{mg\,L^{-1}}$ (below which motility stops) and $5\,\mathrm{mg\,L^{-1}}$ (close to the saturation concentration). This scaling is compatible with the general form proposed by Lapidus and Schiller [6] and Rivero *et al.* [7], which applies when the dissociation constant of the considered chemoattractant (here oxygen) is much smaller than the ambiant attractant concentration.

Our results suggest that aerotaxis in *S. meliloti* is a very efficient process: the biased swimming towards oxygen is strongly enhanced in low-oxygen regions, with an oxygen dependence that exceeds the "logarithmic sensing" aerotactic response ($\chi \propto 1/c$) found in other species.

Summary Inspired by the precession of the Earth, a new bladeless mixer has been designed, which consists of a tilted and rotating cylinder. While increasing the rotation of the cylinder, the flow transitions from laminar to turbulent with a perfect agreement between experiments and theory. It creates a strong mixing which is as efficient as using a classical Rushton turbine, but with a shear 20 times smaller. This soft mixer is particularly interesting for bioreactors which require an efficient mixing of oxygen and carbon dioxide but where a strong shear can damage fragile cells. Preliminary results obtained for the growth of microalgae in such photobioreactors suggest that it can be a technological breakthrough in biotechnologies.

INTRODUCTION

In biotechnology, the large scale production of fragile cells is severely limited by the weak supply of oxygen obtained in large bioreactors. The flux of oxygen is usually increased through an enhanced mixing created by bubbling or rotating blades. However, both bubbles and moving blades generate a strong shear which drastically lowers the growth of fragile cells. The need for a soft mixer without blades is thus required in many biological applications.

LAMINAR-TURBULENT TRANSITION IN A ROTATING TILTED CYLINDER

We present here a new type of mixer, patented under the name soft mixer, which consists of a rotating cylindrical container with an axis tilted with respect to the vertical (see figure below). The free surface remains horizontal which forces inertial (Kelvin) modes of azimuthal wavenumber m=1. The height of fluid is chosen such that the amplitude of the modes diverge because the forcing is located at the node of the mode [1]. This generates large steady motions even for small tilt angles with an amplitude scaling as the square root of the Reynolds number (due to Ekman pumping saturation). This steady inertial mode can in turn destabilize via a triadic resonance as in precessing or elliptic vortices [2]. The instability exhibits two inertial modes with azimuthal wavenumbers m=5 and m=6 satisfying the resonance condition. The wavenumbers and the viscous threshold of the instability can be predicted analytically with no adjustable parameters and show an excellent agreement with the experiment.

*Corresponding author. E-mail: patrice.meunier@univ-amu.fr.

The mixing time of this flow has been measured experimentally by introducing a fluorescent dye and by measuring its variance as a function of time. In the absence of instability, the dye is simply advected without large stretching (see Fig. 2a). However, in the presence of the instability, the dye is stretched and folded in the whole cylinder in a few rotation periods. It clearly shows that the tilt of the cylinder accelerates the mixing efficiency because it creates a turbulent flow through the instability (see Fig. 2c). For sufficiently large tilt (above 1 degree), the mixing inside this soft mixer is as efficient as for a Rushton turbine. However, the shear is an order of magnitude smaller which is extremely interesting for biological applications.

A NEW GENERATION OF BIOREACTORS

A new type of bioreactor has been built based on the principle of the soft mixer. The rotating cylinder contains a nutritive liquid and is tilted with an angle of 3 degrees compared to the vertical (see Fig.3b). Shear sentitive microalgae (dinoflagellates Alexandrium, see Fig.3a) are introduced in the nutritive solution and grow with a duplication rate of about 2 to 3days to a very large concentration of about 20,000 cells/ml. This will allow to produce Saxitoxin which is naturally contained in the dinoflagellate. A large scale bioreactor of 150l is currently being tested for the production of these microalgae (see Fig. 3c).

Summary Flagella and cilia exist throughout the natural world, whether as appendages to help micro-organisms swim or to pump fluid near tissues in highly viscous environments. A wide variety of synchronisation behaviours has been observed, expanding the full range from perfectly in-phase synchrony to completely anti-phase motion. Here, we use an elastic filament model to study the emerging synchronisation behaviours of two base-driven microfilaments. We quantify the synchronisation states that arise as the torque driving their motion is varied. Four synchronisation states are found, two of which are stable and the others unstable. A bifurcation and stability analysis is carried out using the power-method and a bisection method, and reveals that these states are non-trivially connected through pitchfork and saddle-node bifurcations.

INTRODUCTION

Cilia and flagella are slender, microscopic filaments used by single-celled organisms for motility and the tissues of large organisms for fluid transport. One example is the biflagellate algae *Chlamydomonas*, which consists of a cell body with two flagella protruding from its anterior. The flagella are observed to have two stable synchronised states: the anti-phase, breast-stroke during forward swimming, and the in-phase, parallel beating. Parallel beating is observed when the cell experiences a sudden stimulus at its anterior end, and attempts to quickly move away from the source [1]. Experimental studies of flagellar synchrony on *Chlamydomonas* have shown that synchronous behaviour can arise purely through hydrodynamic interactions [2], but also an additional elastic coupling between the bases of the flagella, known as basal coupling, can have a large effect on the type of synchrony which arises [3].

While simple models that treat systems of flagella as coupled 'bead-spring' oscillators with prescribed driving forces have produced initial results of synchronised states [4], more recent models capture the flagellum shape and elasticity and use ideas such as geometric switching to change the direction of flagellar motion [5] and generating synchonized states. It was found that for the case of two nearby, independently driven filaments, both in-phase and anti-phase synchrony can occur, and, over a particular range of parameter values, the bistability of these states exists.

THE MODEL

We make use of the elastic filament model developed by Schoeller et al. [6], modelling the flagella as inextensible Kirchoff rods with bending modulus, B, length l, and cross-sectional radius, a. The force and moment balances that arise in the model are discretised into $N = 19$ segments. The hydrodynamic interactions between these segments are accounted for through the Rotne-Prager-Yamakawa (RPY) approximation [7] that incorporates the effects of a nearby no-slip surface.

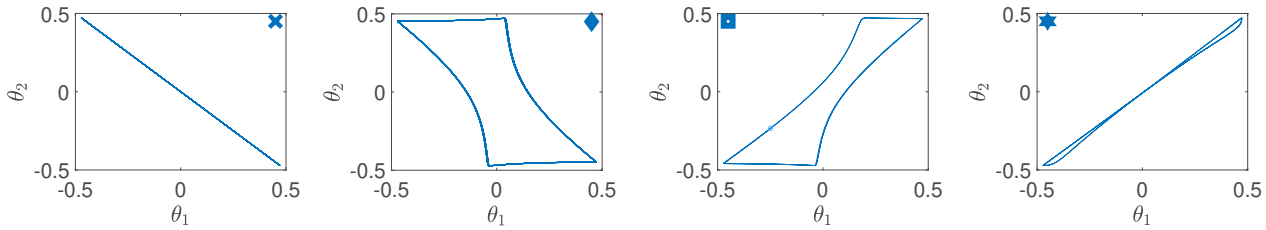

Figure 2: The phase diagrams plotting θ_1 versus θ_2 for the states indicated in Fig 1(a). The cases shown correspond to (a) the anti-phase synchrony, (b) the upper stable branch, (c) the intermediate unstable branch, and (d) the in-phase lower branch.

In our simulations, we consider two such flagella that are tethered to a planar surface a distance $b = l/2$ apart (see Fig. 1a). The filament $i = 1, 2$ is driven at its base by the torque $\tau_i = \alpha_i(t)M_b$, where M_b is the magnitude of the torque and $\alpha_i(t)$ controls the direction of the torque through a geometric switch. Specifically, the value of α_i transitions from 1 to -1 (or vice versa) when the filament base angle, θ_i, exceeds $\Theta = \pm 0.15\pi$ (see figure 1a).

To measure the synchrony of the system as it evolves, we compute the synchrony parameter,

$$Q = \frac{-1}{t_{end} - t_{start}} \int_{t_{start}}^{t_{end}} \alpha_1(t)\alpha_2(t)\mathrm{d}t. \tag{1}$$

If $Q = 1$, the filaments are perfectly anti-phase and if $Q = -1$ they are perfectly in-phase.

BIFURCATION ANALYSIS OF BISTABILITY

The recent work by Guo et al. [5] showed that there exists a region of bistability, by which the filaments can synchronise to two different stable states depending on the initial perturbation. In the present study, a total of four synchronisation states (including unstable ones) are computed, offering a complete description of the bistability. Figures 1 and 2 show a bifurcation diagram based on Q and M_b, and the phase diagram of each state depicted with $\theta_1(t)$ and $\theta_2(t)$, respectively. The upper-most branch is featured with the perfect anti-phase synchrony state (i.e. $Q = 1$; Fig. 2a), and becomes unstable through a supercritical pitchfork bifurcation near $M_b \simeq 7$. The intermediate stable state, emerged from this bifurcation, is continued with M_b, and reaches a turning point around $M_b \simeq 16$, at which it becomes unstable through a saddle-node bifurcation. Along the continued bifurcation curve, the phase diagram exhibits a continuous change (Figs. 2b and c). In particular, the two filaments are found not to be synchronised and their phase difference (i.e. $\theta_1 - \theta_2$) forms a limit cycle. Finally, the unstable intermediate state collides into the lower-most in-phase state at $M_b \simeq 5$ through a subcritical pitchfork bifurcation.

CONCLUSIONS

In this study, the bifurcation and stability of a system of two base-driven hydrodynamically interacting microfilaments have been fully described. These findings are particular important for biological systems such as swimming microorganisms. In particular, they underpin the statistical residence time of each state when the system is driven with stochastic noise. In this respect, characterising the stochastic dynamics of the system would be a natural step to pursue in the future.

CEREBROSPINAL FLUID MECHANICS IN THE BRAIN: EXPERIMENTS

Summary Fluid permeates the brain, not only providing buoyancy and cushioning, but also transporting neurotransmitters, wastes, and water as it passes around and through tissue. Waste removal is essential for avoiding diseases linked to its accumulation, like Alzheimer's. The glymphatic system is thought to drive fluid into brain tissue along spaces surrounding arteries, and we measure the velocity fields of such flows in live mice, finding evidence that flows are driven by the pulsing artery wall, as in peristalsis. We also show that high blood pressure alters the wave and weakens the flow. Water transport in an unhealthy brain can cause swelling that damages tissue, as in ischemic stroke. We present experimental studies of stroke in mice, including evidence that early swelling comes not from blood, as is canonical in medical education, but from cerebrospinal fluid surrounding the brain.

FLOW FOR WASTE REMOVAL: ARTERIAL PULSATION AND HYPERTENSION

The human brain makes up just 2% of body mass, but accounts for 25% of metabolic activity. Normal brain processes produce metabolic waste rapidly and in large quantities, and accumulation of waste products like amyloid-β and tau have been implicated in neurodegenerative disorders like Alzheimer's and Parkinson's diseases. Researchers have long been puzzled by the brain's apparent lack of lymph vessels, which sweep away cellular waste and excess fluid from most of the rest of the body. Recent identifications of lymph vessels in the periphery of the skull make the question more tantalizing: How is waste removed from the brain itself? Increasing evidence supports the hypothesis that waste is removed by cerebrospinal fluid (CSF) entering the brain along the perivascular spaces that surround arteries, then passing through brain tissue, a flow modulated by glial cells — dubbed the glymphatic system.

We present experimental studies of CSF flow in the brains of live mice. First, we focus on the perivascular spaces surrounding surface arteries, which we image with high spatial and temporal resolution (0.5 μm, 33 ms) using two-photon microscopy. Intravenous dye injections make arteries visible, and 1-μm polystyrene tracer particles infused into the cisterna magna track CSF flow, as shown in Fig. 1. We observe bulk flows that pulse in synchrony with the heart, proceeding on average in a direction parallel to the blood flow (not anti-parallel). The mean speed is 18.7 μm/s, so taking the width of the perivascular space as a characteristic length, we find the Reynolds number to be of order 10^{-3}: these flows are laminar. Using the diffusivity of amyloid-β, we find the Péclet number to be of order 10^2, so waste transport is dominated by advection here, though deep in the brain diffusion likely plays a larger role.

The fact that these flows pulse in synchrony with the heart is consistent with the existing hypothesis that CSF could be driven along perivascular spaces by a peristalsis-like mechanism as traveling mechanical waves deform the adjacent artery wall. If the hypothesis is true, then altering the traveling waves should change the resulting flow. To alter the

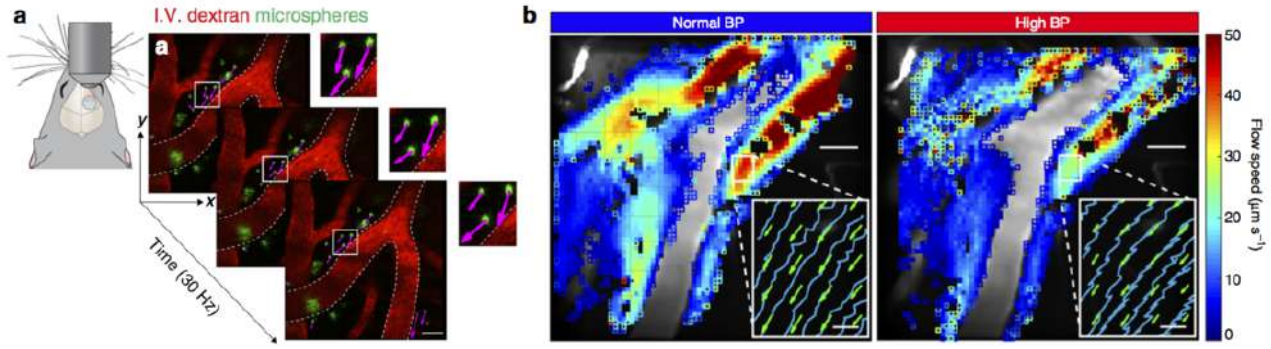

Figure 1: Flow of CSF in perivascular spaces for waste removal. Pale curves show measurements from separate animals; bold curves and shaded regions show mean and standard error of the mean. (d), Fluid flow in the perivascular space surrounding the middle cerebral artery speeds up substantially after the artery is occluded, and pulsatility is nearly lost. Later, the flow slows and again becomes more pulsatile. Scale bar is 40 μm. Insets show particle tracks demonstrating changes in pulsatility. Scale bar is 5 μm.

waves, we use the drug angiotensin-II to quickly and significantly increase blood pressure. Because the volume of the circulatory system is tightly regulated, increased blood pressure causes muscular artery walls to stiffen, preventing changes in diameter. We expected wave propagation to differ in stiffened tissue, and confirmed this with measurements. We also found that mean flow in perivascular spaces is significantly slower in the high-blood-pressure case (Fig. 1), that artery wall velocity oscillations closely match CSF velocity oscillations, and that transitory backflow in the high-blood-pressure case correlates with rapid artery contractions that do not occur when blood pressure is normal. These observations support the hypothesis that artery pulsation drives CSF flow in perivascular spaces. Interestingly, early-onset high blood pressure is a risk factor for Alzheimer's disease in humans. Our findings [1] suggest that reduced CSF flow might be the cause.

FLOW DURING STROKE: SPREADING DEPOLARIZATION AND SWELLING

Ischemic stroke occurs when a cranial artery becomes blocked, depriving part of the brain of oxygen, energy, and nutrients (Fig. 2). Within minutes, nearby neurons are no longer able to maintain healthy gradients of ion concentrations across their cell membranes, so a chemical reaction-diffusion wave propagates across the brain; the process is known as spreading depolarization. Afterward, the tissue experiences severe swelling, the primary cause of irreparable damage during stroke. The canonical view is that the fluid causing this swelling comes from blood, but we present experimental evidence that, at least in early stages, it comes from CSF.

We induce stroke by injecting a bead into the middle cerebral artery. Working with mice genetically engineered such that their brain tissue fluoresces during neural activity, we observe spreading depolarization directly via transcranial imaging. We simultaneously observe the motion of dye in the CSF, finding that soon after the spreading depolarization wave passes, CSF rushes through perivascular spaces and into brain tissue, much faster than in healthy conditions. Tracking particles in perivascular spaces at much higher magnification confirms the findings: though flow pulsation is significantly reduced after occlusion, mean flow speed increases dramatically, then eventually slows (Fig. 2). Moreover, high magnification shows that arteries constrict violently as the spreading depolarization wave passes. Constriction could cause the flows we observe if CSF rushes in to fill the spaces formerly occupied by arteries. To test that hypothesis, we constructed a fluid dynamical model, based on a realistic artery map, in which we prescribed a spreading depolarization wave and corresponding artery constrictions. The model produced inflow similar to what we observe. Our MRI measurements show that large reservoirs of CSF in the skull are simultaneously drained; they are the sources. The discovery that swelling during stroke [2] comes substantially from CSF instead of blood may open the door for new treatments and improved patient outcomes.

HOW INSECT WINGS AND PLANT LEAVES BLAST RAINDROPS

Sunghwan (Sunny) Jung *[1], Seungho Kim [1], Brian Wu [1], Ehsan Esmaili[1], and Jason J. Dombroskie [2]
[1] Department of Biological and Environmental Engineering, Cornell University, Ithaca, NY 14853, USA
[2] Department of Entomology, Cornell University, Ithaca, NY 14853, USA

Summary Many biological surfaces (e.g. bird feathers, insect wings, and plant leaves) are super-hydrophobic with physical morphology at different scales. However, it is not well understood how a raindrop impacts natural super-hydrophobic surfaces, and its significance of biological functions. In this present study, we found that a spreading drop at a high speed can generate wrinkled pattern (including shock-like waves) on a spreading liquid in the presence of surface morphology at the micro scale. Furthermore, the spreading drop is suddenly ruptured by growing holes followed by the shock waves, which leads to a decrease in contact time more than 50%. As a result, heat and momentum transfers are reduced by raindrops, which may lower the hypothermia risk of animals or less affect the stability of insect flights.

INTRODUCTION

In nature, many biological surfaces like bird feathers, insect wings, and plant leaves are super-hydrophobic with micro and nano structures [1, 2, 3]. Micro-structures cause a liquid-pinning behavior by allowing the liquid to penetrate into the gaps between the micro structures whereas nano structures hold air in between [4, 5]. The residence/contact time of a bouncing drop on superhydrophobic surfaces is predicted by balancing the inertia with capillarity [6, 7]. Hence, mass, momentum, and heat transfers strongly depend on its residence time of the drop on a substrate. There are a number of studies in terms of mass [8] and momentum transfers [9, 10, 11], but little attention has been paid to heat transfer aspects [12].

Drop impact on superhydrophobic structures is known to exhibit asymmetric spreading and retraction, a pancake-shaped rebouncing, finally leading to the rapid drop detachment with a significant decrease in the contact time. However, the role of micro-scale structures during drop impact was underestimated since most studies have focused on drop impacts at low speeds, quite lower than real raindrop impact speeds in natural events.

In this study, we will study how an impacting drop at high speeds can generate shock-like surface waves in the presence of surface morphology at the micro scale. The top air-liquid interface of the spreading liquid is perturbed due to the shock waves, and becomes vulnerable to film ruptures via hole nucleation. Finally, the holes grow in time and coalesce with each other. As a result, the contact time is reduced about 70%, and, correspondingly, the heat and momentum transfers of the impacting drop onto the substrate are reduced. Therefore, our findings may elucidate new functional benefits in terms of hypothermia risk, flight stability, spore dispersal of biological surfaces triggered by the micro-scale structures.

RESULTS

For details of the shock-like wave structure, we prepared two kinds of substrate with different wettability (contact angles). One substrate is a hydrophilic glass plate, and the other is a super-hydrophobic surface coated by hierarchical micro- and nano-structures using NeverWet coatings. On the smooth hydrophilic substrate, a drop merely spreads by forming a radially expanding rim as expected. No surface waves are observed. On the superhydrophobic glass, a drop spreads, retracts, and bounces at a low impact speed (fig. 1**b**), whereas a drop with a high impact speed exhibits shock-like surface waves and destructive break-up dynamics as in fig. 1**c**.

When a drop falls at a high speed, U, hundreds of shock-like surface waves were observed. Especially, these shock-like waves are formed only on top of micro-scale bumpy structures as in the second panel of fig. 1**c**. A drop spreads and then is suddenly ruptured, as holes are nucleated (see the third panel of fig. 1**c**). Eventually, the spreading drop breaks into smaller satellite droplets (the fifth panel) as the holes get bigger and coalesce. Therefore, we confirmed that, when a drop impacts hierarchical superhydrophobic surfaces with a high impact velocity, microscale bumpy structures interfere with the spreading drop to generate the numerous shock-like waves on the liquid-air interface and eventually break into smaller droplets.

CONCLUSIONS

In this talk, we showed that an impacting drop at high Weber numbers ($100 < \mathrm{We} < 1500$) generates interesting shock-like patterns and exhibits blasting fragmentation on hierarchical superhydrophobic surfaces. The shock-like waves are created only on topological bumps at the micro scale. Then, the interference of the shock-like waves triggers off hole nucleation and rupture, thereby breaking into small satellite droplets at earlier times. Such drop dynamics result in a decrease in the contact time up to 70%, which may indicate potential advantages of various biological surfaces to limit its heat transfer.

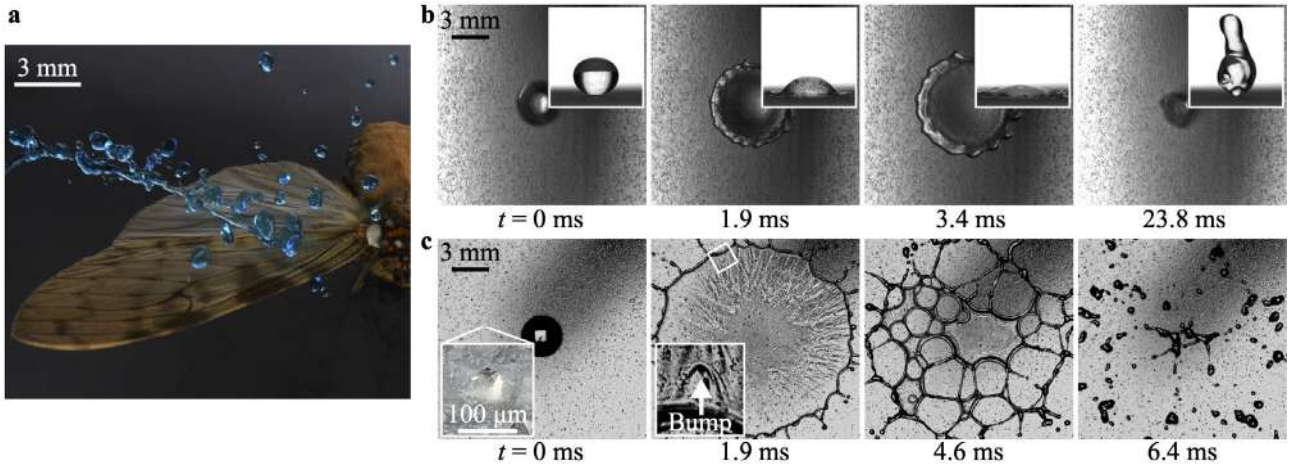

Figure 1: Dynamics of an impacting drop with 1.7 mm in radius on artificial surfaces. **a.** Drop impact on an insect wing at a high speed. **b.** Drop impact on a glass coated by hierarchical superhydrophobic structures at a low impact velocity, where [U, We] are [1.1 m/s, 60]. **c**. Drop impact on a glass coated by hierarchical superhydrophobic structures at a high impact velocity, where [U, We] are 3.8 m/s, 680], respectively. Insets in **b** represent the side-view image of drop impact achieved by a synchronized high-speed camera. Insets in **c** are magnified images of local area to clearly show the microbump, the shock-like wave on the microbump, and the nucleated hole followed by the shock-like wave, respectively. For low U, the impacting drop merely spreads, retracts, and rebounds, whereas, for high U, hundreds of shock-like waves are generated on the spreading drop, and then a number of holes are abruptly nucleated, which grow in time simultaneously (third panel). Finally, the contact time between the drop and the substrate gets shortened by breaking into smaller satellite droplets.

In nature, the exposure to cold rain can lower the body temperature of birds and destabilize flying insects [13]. The decrease in the drop-contact time and earlier fragmentation limit the heat and momentum transfer onto organisms. Our quantitative measurements and model predictions on various biological surfaces may unravel how birds lower hypothermia risks and how insects maintain flight stability as well as preserve regional heterothermy during rainfall. In addition, as an impacting drop is shattered into smaller satellite droplets, the droplets would spread plant pathogenic spores. It sheds light on a new spore dispersal mechanism based on satellite droplets besides recently discovered vortex-induced dispersal mechanism [8].

WAKE-MEDIATED INTERACTIONS BETWEEN SELF-PROPELLED TWO TANDEM FLEXIBLE FINS IN WALL EFFECTS

Young Dal Jeong[1], Jae Hwa Lee*[1] and Sung Goon Park[2]
[1] Department of Mechanical Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea
[2] Department of Mechanical and Automotive Engineering, Seoul National University of Science and Technology, Seoul, Korea

Summary It is known that self-propelled two tandem fins can take a hydrodynamic benefit. To analyze the wake–mediated interactions between two fins in wall effects, we perform a simulation for two tandem self-propelled flexible fins near a single wall (SW) or two-sided walls (TW). The vortex–vortex interaction near the wall for SW and TW greatly enhances a lateral flow, and synchronization of the strong lateral flow with a lateral motion of the follower reduces significantly the input power compared to that with no wall (NW). The follower for NW achieves large thrust using the interception mode to overcome a jet-like flow. However, the follower employs a mixed mode (i.e., combination of the interception mode and slalom mode) for SW and slalom mode for TW to maximize the benefit from the lateral flow since there is no need to generate a large thrust by the help of a negative horizontal flow.

INTRODUCTION

Collective motion is commonly observed in biological systems in nature (e.g., fish schooling and birds flocking). When the groups of active animals move in a fluid, each locomotion is influenced by the others through the wake–mediated interactions among them, and individuals in a schooling formation can take an energetic advantage in the light of hydrodynamics. Furthermore, flying/swimming organisms can take advantage of hydrodynamic benefits when they move near the wall. Although individual studies of self-propelled propulsors in a school (Zhu *et al*. 2014) and a single self-propelled propulsors in wall effects (Park *et al*. 2017), respectively, have performed, the hydrodynamic approach to the schooling behaviors under an influence of the walls have never been conducted simultaneously.

The objective of the present study is to examine the collective motion of self-propelled two tandem fins in wall effects. Introduction of the wall effects into dynamically moving fins in a school results in more complicated wake–mediated interactions between them than those without the wall effects (Zhu *et al*. 2014). To impose the wall effects on the wake–mediated interaction, two types of the walls are considered, i.e., one-sided single wall and two-sided walls on the bottom and top. Although one-sided single wall has been usually employed to examine the wall effects on the hydrodynamics of an isolated single fin thus far, the two-sided wall configuration has been also observed not only in the natural habitat of stream fish (e.g., rainbow trout) but also during the long distance migration of salmonid fish (e.g., Altantic salmon), when they swim near vertical structures such as stream margins, rock faces and large woody debris.

RESULTS & DISCUSSION

Figure 1 shows schematics of two self-propelled flexible fins in a tandem configuration with two coordinate systems, when the fins propel near a single one-sided wall (figure 1a) and between two-sided walls (figure 1b). The upstream and downstream fins are denominated as ‘leader’ and ‘follower’, respectively. Two fins are driven by harmonic plunging motions at the leading edge with a heaving amplitude (A_{head}) and flapping frequency (f) in the lateral direction, whereas the motion of the rest part is determined passively by the ambient fluid and nearby structures. In the horizontal direction, the fins are unconstrained, and thus they can move freely. The horizontal moving speed (i.e., cruising speed U_c) and the horizontal relative positions between the leader and follower (G_x) are determined spontaneously as a result of the interaction between the flexible fin and the ambient fluid. The lateral distance between the fin and the wall (d), which is important factor in determining the degree of wall effects, is prescribed using a mean lateral position of the leading edge when the fins are at the steady state. The fluid–flexible body interactions are modelled by solving the fluid and structure motion equations separately, and theses equations are coupled using an immersed boundary method (Huang *et al*. 2007).

Figure 2(a) shows schematics of the stable modes formed spontaneously for each case, i.e., interception mode for NW, mixed mode for SW and slalom mode for TW. $\boldsymbol{V_F}$=(u_{head}, v_{head}) and $\boldsymbol{V_T}$ denote the leading edge velocity and the vortex-induced velocity. In figure 2(a-i), the follower for NW takes the interception mode. The horizontal components of $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ at t^*/T=0 and 0.5 are opposite due to a jet-like flow generated by the leader, requiring a large thrust force for the follower. However, the lateral motion of the leading edge for the follower ($\boldsymbol{V_F}$) is in phase with the induced lateral flow by the leader ($\boldsymbol{V_T}$) in figure 2(a-i), and the synchronized flow in the lateral direction plays an important role as a ‘hydrodynamic puller’, leading to the reduction of the input power (Zhu *et al*. 2014). In figure 2(b-i), if the follower takes the slalom mode in the thrust wake as a stable spontaneous mode, both the horizontal and lateral components of $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ are opposite, leading to significant increase of the input power for thrust force of the follower.

In figure 2(a-ii), the follower for SW passes through the positive vortex, whereas it swims by slaloming beneath the negative vortex. Similar to the observation for NW, the horizontal component of $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ is opposite at t^*/T=0 and 0.5, while the lateral component of $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ is identical. However, the horizontal velocity during the upward motion is negative, because negatively induced horizontal velocity by the interaction between the main negative vortex and near-wall positive vortex (yellow arrow) is larger than the positively induced velocity by $\boldsymbol{V_T}$ at t^*/T=0. The horizontal velocity during the downward motion is positive due to the combined effects of the induced velocity by $\boldsymbol{V_T}$ and the induced velocity

*Corresponding author. E-mail: jhlee06@unist.ac.kr

between the main positive vortex and induced negative vortex near the wall (see t^*/T=0.5). In the lateral direction, the synchronized flows lead to the energy benefit for the follower. Particularly, the benefit from the lateral flow for the follower is strong during the upward motion (see the elliptic dashed line) under the significant influence of a vortex pair. As shown in figure 2(b-ii), if the follower passes through the negative vortex and swims through a region beneath the positive vortex as an another mixed mode, the horizontal and lateral directions of the velocity $\boldsymbol{V_F}$ are opposite to those of $\boldsymbol{V_T}$, leading to significant energy consumption of the follower over all flapping period. Given that the negative vortices are located above the trajectory of the follower due to the ascending motion of the vortex pair (figure 2a-ii) and the prescribed lateral movement of the follower near the wall (i.e., Eq. 4), an optimal trajectory of the follower for a maximum benefit from the lateral flow is achieved by passing through the positive vortices at the maximum lateral position.

In the slalom mode adopted by the follower for TW in figure 2(a-iii), the horizontal component generated by the positive and negative vortices has negligible effect on the follower at t^*/T=0 and 0.5 near the centerline. However, when the follower passes a region near the wall, it experiences strong negative horizontal flow created by the interaction between the main vortex and induced vortex near the wall (yellow arrow along the trajectory), reducing drag force acting on the follower. The identical lateral component of $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ always contributes to the hydrodynamic benefit. When the follower for TW takes the interception mode in the aligned vortex street instead of the slalom mode, a possible trajectory for the follower is shown in figure 2(b-iii). The follower at four instants (t^*/T=0.125, 0.375, 0.625 and 0.875) with $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ is denoted by the bold black lines. The lateral component of $\boldsymbol{V_F}$ coincides with that of $\boldsymbol{V_T}$ at t^*/T=0.375 and 0.875. However, the lateral components of $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ are opposite at t^*/T=0.125 and 0.625. In figure 2(a-iii), the slalom mode of the follower along the aligned vortex street maximizes the benefit from the lateral flow, and this trajectory gives rise to extra benefit by the negatively induced horizontal velocity component near the wall (yellow arrow).

In the conference, we will discuss the propulsive mechanism of the schooling fins in wall effects with two main questions: i) How the follower interacts with the vortex structures generated by the leader under an influence of the walls and ii) how the flow–mediated interactions improve (or deteriorate) the propulsive efficiency of the schooling fins near the walls. The underlying mechanism will be documented through the time evolution of the vorticity, horizontal and lateral velocities along the lateral line at the leading edge, temporal input power, averaged lateral velocity of the fin and averaged lateral flow acting on the fin. Furthermore, investigation of the pressure distribution will provide an intuitive understanding of the relation between the wake–mediated interactions and the propulsive performance of the fins.

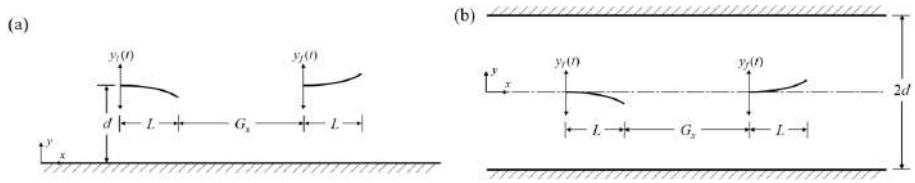

Figure 1. Schematic of two tandem flexible fins, when the fins propel (a) near the single wall and (b) between two parallel walls.

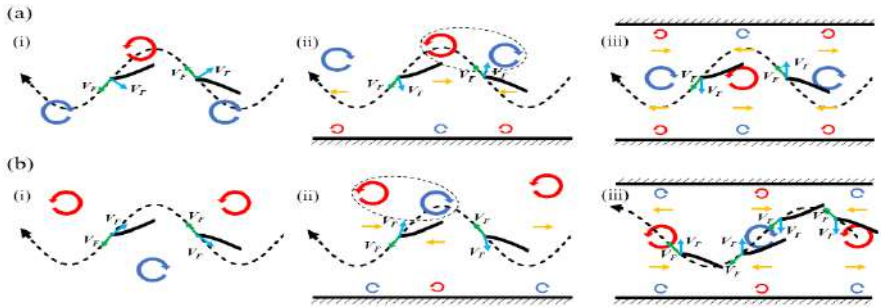

Figure 2. Schematics of (a) the stable spontaneous modes: (i) interception mode for NW, (ii) mixed mode for SW and (iii) slalom mode for TW. In (b), (i) slalom mode for NW, (ii) mixed mode for SW and (iii) interception mode for TW are shown as another stable modes for each case. $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ denote the leading-edge velocity for the follower and the vortex-induced velocity, respectively. In (ii) and (iii), upstream and downstream flows produced by main vortices (large circles) and induced vortices (small circles) near the wall are denoted by yellow arrows. In (a), (b-i) and (b-ii), bold black lines with $\boldsymbol{V_F}$ and $\boldsymbol{V_T}$ indicate the follower at t^*/T=0 and 0.5 (from right to the left). In (b-iii), bold black lines indicate the follower at t^*/T=0.125, 0.375, 0.625 and 0.875 (from right to the left). Bold dashed lines denote the trajectory of the leading edge for the follower. Red and blue circles with arrows indicate the positive and negative vortices, respectively. Elliptic dashed lines in (ii) indicate the vortex pairs.

UNDERLYING STABILITY MECHANISMS OF SEMI-AQUATIC SNAKES ON FREE SURFACE: A BIO-INSPIRED APPROACH

Johann Herault * [1], Jonathan Brossillon[1], Vincent Lebastard[1], Frédéric Boyer[1], and Seth M. LaGrange[2]
[1] IMT Atlantique, LS2N, UBL, 44307 Nantes, France
[2] University of Illinois/INHS, Champaign-Urbana, Illinois, USA

Summary At the crossroad of mechanics, robotics, and biology, we report an investigation aiming to understand the underlying mechanisms of stability of water snakes on a free surface. To address this complex problem, a new theoretical model is developed to seek quickly the equilibrium configurations (position and orientation) of a continuous slender body with finite deformations (torsion and bending) relative to the water surface. The non-linear description of the body geometry relies on the geometrically exact approach introduced by Simo [1], where the orientations of the sections are parametrized by a continuous field of rotation matrices belonging to a Lie group. Then, a command law is introduced to achieve a static positioning of a continuous body thanks to controlled body deformations. Finally, a new bio-inspired robot named NATRIX will be presented. To stabilize its posture, this robot has a new actuation mechanism based on a controlled rolling motion of each body segment in order to achieve static and dynamic positioning. These new results pave the way for the next generation of autonomous bio-inspired robots designed for maritime exploration in extreme conditions.

INTRODUCTION

Snakes are fascinating animals that have colonized a wide variety of ecological niches by adapting their limbless locomotion strategy to the physical constraints of the local environment. Among these species, semi-aquatic snakes living near rivers, such as the grass snake (Natrix natrix) or the cottonmouth snake, have developed extraordinary capacities to maneuver on water surface [2]. Indeed, snakes deform significantly their body to maintain stable postures on water, while their head remains above the surface. Field observations (Fig.1) show that their body deformations are complex compositions of relative lateral and dorso-ventral flexions combined with torsions bof the spine chord. Interestingly, their capacities decline when they become tired. Consequently, snakes actively control their posture to achieve an overall balance between gravity and buoyancy forces. Understanding and reproducing the performances of these animals could lead to new insight into biological evolution and to new applications in maritime engineering and naval robotic.

Indeed, bio-inspired naval robots are promising technologies, which display exceptional maneuverability and low impact on ecosystem [3]. Despite their great potential, their slender body becomes a handicap at free surface due to their small axial inertia. Unlike aquatic snakes, their performances are strongly degraded by their uncontrolled rolling motions. Hence, our bio-inspired approach aims to solve the problem of robot stability thanks to our animal model: the semi-aquatic snake.

Figure 1: Pictures of a Cottonmouth snake (Agkistrodon piscivorus) stabilizing and chilling on water. These photos were taken in Southern Illinois (USA) by Seth M. LaGrange.

In the talk, I will present the theoretical framework to tackle the problem of surface stability of a slender body. First, I will introduce a model describing the body as a continuous Cosserat rods thanks to the exact geometrical approach introduced by Simo [1]. Then, I will present a new command law allowing for the stabilization of the head configuration (position and orientation) thanks to controlled body deformations. Finally, I will show how our theoretical results could be used in bio-inspired robotics. I will introduce our new robot named NATRIX capable of stabilizing its body thanks to a new mechanisms of actuation.

FROM THE MATHEMATICAL MODEL...

To predict the stable configurations (position and rotation) of a snake relative to a flat sea surface, we have developed an efficient and fast tool, called STAB [4], computing the equilibrium configurations of a buoyant body undergoing large deformations. To take into account finite rotations, our approach relies on the exact geometrical approach introduced by

*Corresponding author. E-mail: johann.herault@imt-atlantique.fr

Simo [1] consisting in parametrizing the orientation of each body section thank to rotation matrices $\mathrm{R}(s)$ taking value in the Lie group $\mathrm{SO}(3)$, and its position vectors $\mathbf{p}(s)$. The body is thus modeled by a Cosserat beam, which is described as a continuous stack of elliptical rigid sections of infinitesimal thickness.

Our code computes the position $\mathbf{p}_0(s=0)$ and the orientation $\mathrm{R}_0(s=0)$ of the head as a function of the body shape, which is given by the configuration of each body section relative to the head. To approach our animal model, this body shape is defined from the deformation fields (bending+torsion) given by $\vec{\kappa}(s) = (\kappa_1, \kappa_2, \kappa_3)$, which is the natural parametrization of the muskulo-skeletal system. The stable configuration of the head is found via a new optimization algorithm respecting the geometry of the non-linear manifold $\mathrm{SO}(3)$. Furthermore, we have decomposed the deformation field into Tchebyshev polynomials to reduce the computing time and achieve real time computation for robotic applications. Our results are then compared to experimental data with a very good agreement [4](error $< 3\%$).

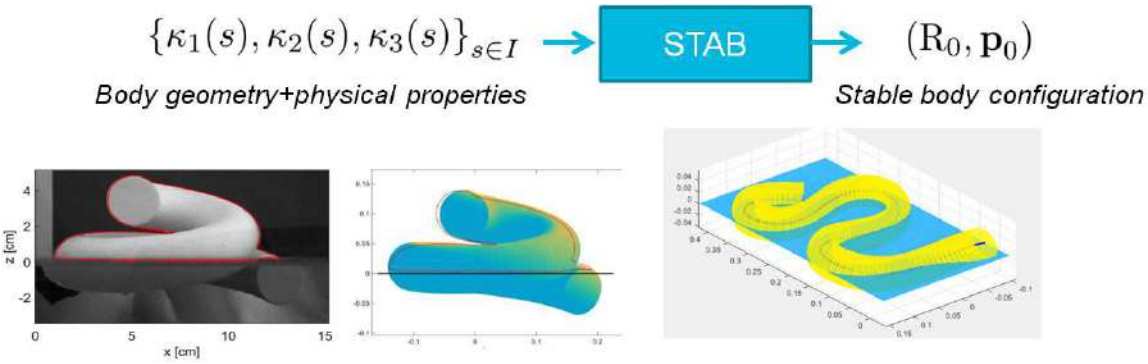

Figure 2: Top: principle of the code STAB. Bottom: experimental observation of a floating helical body (left), its numerical avatar (center) computed by STAB, and an illustration of stable configuration of a snake-like body.

From the code STAB, we are able to investigate the effect of the body deformations (bending and torsion) onto the stable configuration. This is the starting point of a control law imposing a desired configuration of the head $(\mathbf{p}_0, R_0)_{end}$ from an initial configuration $(\mathbf{p}_0, R_0)_{ini}$ thanks to a continuous evolution of the body deformation fields $\vec{\kappa}$. This complex inverse problem requires to find one body deformation among an ensemble of deformation fields $\{\vec{\kappa}\}$ corresponding to the same stable head configuration. Consequently, a new method is introduced to select the optimal deformation field for different criteria (minimal elastic energy, minimal time..etc) based on optimal control theory, paving the way for operational quasi-static positioning. Our results are then compared to observations of snakes to reveal the underlying strategy of these reptiles.

...TO THE BIO-INSPIRED ROBOT NATRIX

To translate these concepts into the physical world, we have developed a new serial robot with an innovative mechanical concept: a controlled and independent rolling motion for each segment. Previous bio-inspired robots have been designed to achieve anguilliform swimming, but they display poor stability. To achieve an active stability and an efficient swimming, our robot has a new degree of freedom so that each elliptical section can roll, independently and irrespectively of the net body orientation, to modify locally its immersed surface in order to control the buoyant effects. I will present the first tests of a three-links swimmer displaying 5 degrees of freedom (2 pivot joints, 3 rolling motion).

CONCLUSIONS

For the first time, we have investigated theoretically, numerically and experimentally the underlying stability mechanisms of semi-aquatic snakes on free surface. Our approach consists in developing new models of fluid-structure interaction, sufficiently concise to be exploited for maritime applications. By bringing together different disciplinary fields, our work aims to develop innovative and bio-inspired technological solutions to environmental issues.

RBC DYNAMICS UNDER SHEAR FLOW IN SICKLE CELL DISEASE. TOWARDS A MECHANICAL MARKER FOR MONITORING THE CLINICAL STATE OF PATIENTS

Summary Sickle Cell Disease (SCD), the most prevalent genetic disease in the world, is a haematological disorder in which red blood cell (RBC) rigidity is increased. This change results in problems of RBC circulation in narrow capillaries, leading to painful vaso-occlusive crises which are unpredictable and can be life-threatening. Here, we show that most RBCs from SCD patients have an impaired motion when submitted to a shear flow at low shear rate. We use this feature to propose a mechanical marker to follow the patient clinical state and to predict the very handicapping vaso-occlusive crises.

INTRODUCTION

The regimes of motion of red blood cells (RBCs) under shear flow have been extensively studied because they directly relate to the cell mechanical properties. In addition to tumbling and tank-treading motions, other regimes were recently discovered, such as swinging, flip-flopping, and rolling. Computational studies provide complex phase diagrams of motion that depend on λ, the ratio of RBC cytoplasm to external fluid viscosities, and on the capillary number Ca. Surprisingly, no experiments have been performed on RBCs from patients with sickle cell disease (SCD) which have altered mechanical properties, namely an increased rigidity due to mutated haemoglobin S that forms rigid fibers in the RBC [1].

RBC MOTION DYNAMICS UNDER FLOW

At very low shear rates, RBCs undergo tumbling-flipping motion and the orientation of their axis of symmetry with the flow direction, defined as the precession angle, is determined by the shear stress as a way to minimize energetically costly deformations [2]. The transition from tumbling to rolling undergone by RBCs as the shear rate is increased is a signature of their elasticity. At higher shear rates, the RBC enters in the tank-treading regime.
We show that the dynamics of RBCs under shear flow is modified in the SCD pathological condition. Though the tumbling - flip-flopping – rolling path observed by increasing the shear rate is not changed for SCD, the rolling-to-tank-treading threshold occurs at higher shear stress compared to healthy RBCs (Fig. 1).

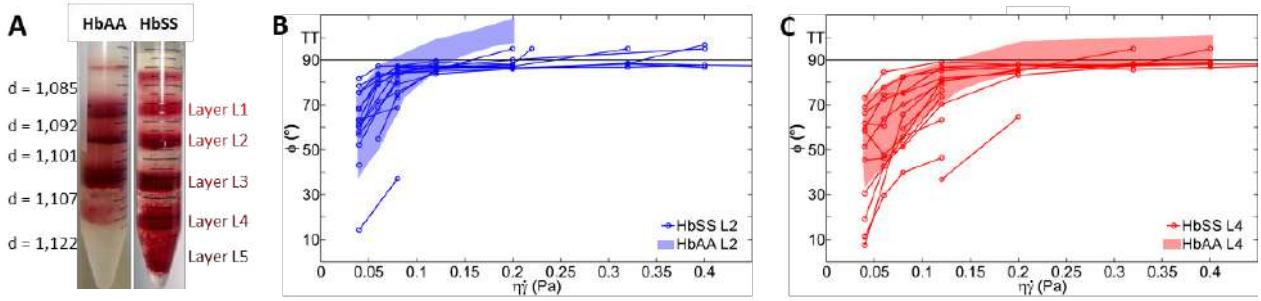

Figure 1. A) Density sorting of a healthy blood sample (HbAA) and of an SCD blood sample (HbSS). B-C) The evolution of the precession angle ϕ of RBCs with regards to the applied shear stress is shown for two density subpopulations of healthy and SCD blood samples.

A MECHANICAL PARAMETER OF SCD PATIENT STATE

Based on the above results we setup an experiment to measure the fraction of tank-treading RBCs, f_{TT}, in large cell populations from µL-size blood samples. As expected f_{TT} increases with increasing shear rate, moreover it is always

This work has been carried out thanks to the support of the A*MIDEX project (n° ANR-11-IDEX-0001-02) funded by the «Investissements d'Avenir» French Government program, managed by the French National Research Agency (ANR)

higher for healthy samples (Fig. 2). We show that f_{TT} depends on RBC density and state of hydration (internal water content), two parameters known to be critical in SCD. We thus propose f_{TT} as a mechanical marker of the average rigidity of blood samples that allows following the clinical state of SCD patients. We show that this marker is patient-dependent and is stable over time in the "out of crisis" period while it strongly varies during the course of a crisis. Our results pave the way to development for new inexpensive and easy-to-implement biological tests for monitoring the clinical status of SCD patients and for predicting the occurrence of disabling vaso-occlusive crises. Additionally, no treatment of SCD has been developed so far, due to the unpredictability of the vaso-occlusive events. Our assay can thus be used to test new pharmaceutical products as potential treatments.

CONTRACTILE ACTIVITY, FLOWS AND NETWORK RESHAPING OF GIANT UNICELLULAR *P. POLYCEPHALUM* CONFINED IN ANNULAR GEOMETRY

Valentin Busson and Marc Durand *
Matière et Systèmes Complexes (MSC), UMR 7057 CNRS & Université de Paris, Paris, France.

Summary Slime mould *Physarum Polycephalum* is a giant unicellular organism that develops a tubular network in which oscillatory flows are generated by the contraction of the membranous layer surrounding the veins. We report the first experimental observation of contractile activity, flows and network reshaping of *P. Polycephalum* confined in a ring geometry. We show that spatial confinement orients the contractile waves and and main flow direction, and affects the network hierarchization. Stable contractile phase patterns are identified.

INTRODUCTION

Like *E. Coli*, *C. Elegans* or *Drosophila*, *Physarum Polycephalum* is a model organism intensively studied by the scientific community [1]. In its vegetative phase, called plasmodium, this organism is made of thousands of undifferentiated cells fusing in a single, multinuclear cell, and can reach macroscopic sizes (dozens of cm^2). This organism then develops a tubular network in which oscillatory flows (with period $\sim$ 1 minute) are generated by the contraction of the membranous layer surrounding the "veins". Hence, *P. Polycephalum* is likely the simplest organism developing a vascular network. This transport network has a twofold role: first, it supplies diffusive flows which are too slow to efficiently transport oxygen, nutrients, or waste through the giant cell. Second, this allows efficient transporting of the body mass during the growing stage or displacement of the cell. Such transport requires from this organism, deprived from central nervous system, a local control of the sol-gel transition of the cytoplasm, and a synchronization of the contractile activity in the whole organism in order to generate a contractile wave traveling from one side of the cell to the other.

In spite of its apparent simplicity, the growth of *P. Polycephalum* network shares common features with the development of vascular systems in higher organisms, or with the mechanisms that take place in the irrigation of tumors. In particular, one can clearly identify two stages in the development of the plasmodium: a growing phase during which *P. Polycephalum* explores its environment covering all the plane with a very dense and ramified tubular network. Then a reorganizing phase during which network becomes hierarchical and less and less reticulated [2, 3], with some veins growing at the expense of others which disappear. From a physicist's perspective, the plasmodium is an active gel that is able, at short times, to generate and adapt contractile waves along the veins to generate peristaltic flows, and at long times to control actively its sol-gel transition to modify the network architecture.

The present study focuses in particular in the interplay between contractile activity, fluid flows, and shaping of the organism in a spatially confined environment. Spatial confinement will orient the contractile waves and flows, and prevent growth of migration of the organism.

CONFINEMENT IN RING GEOMETRY

We built transparent, annular, chambers with varying perimeter and gap width (see Fig. 1), allowing us to probe the effects of spatial confinement on contractile activity and network reshaping. Both temperature and humidity are controlled. During all experiments, the organism is deprived of food and isolated from any other stimulus. Contractile activity is

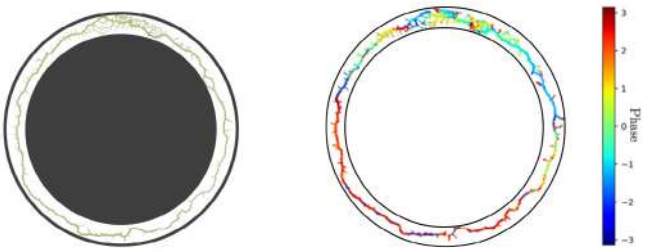

Figure 1: *P. Polycephalum* spatially confined in a ring chamber. Left: transmitted light imaging. Right: phase of the contraction wave.

recorded by transmitted light imaging. We then developed accurate image processing routines to extract properties from both the network architecture (vein lengths and widths, conductances) and contractile wave patterns (instantaneous phase, amplitude, wave-length, frequency, phase velocity). Additionally, from these measuring quantities we were also able to extract flow rates within the network.

RESULTS

Short timescales: contractile modes

Different stable wave patterns are observed [4], which can be categorized in two main families (see Fig. 2):

- Peristaltic modes: they correspond to contractile propagating waves, with phase that varies linearly along the ring (in one direction or in another). Its wavelength is L/n, where L is the ring perimeter and n a positive integer. These modes generate non-zero net flow.
- Amphistaltic modes: they result from two contra-propagative contractile waves emanating from a pacemaker whose location changes with time. These modes do not generate net flow and appear to be more stable.

Asymetric modes, resulting from superposition of the two modes above, are also observed.

Our experimental results are also compared with existing theories [5]. In our experiments, we did not detect any noticeable drop of the characteristic wavelength for larger ring perimeters.

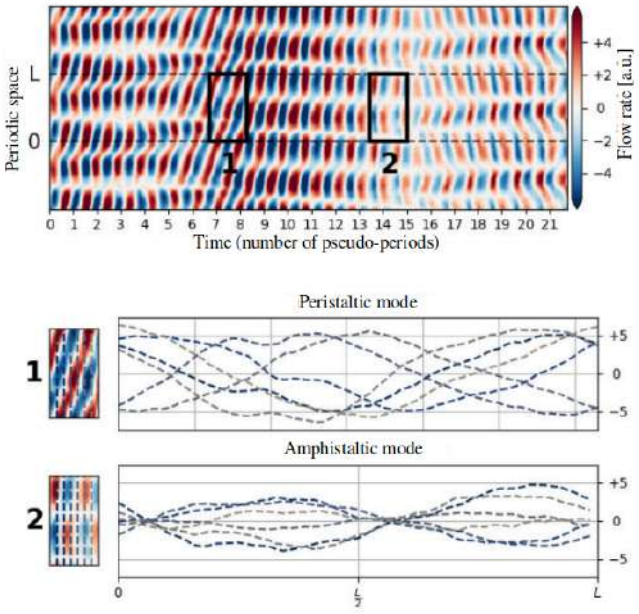

Figure 2: Top: Kymographs of flow rate around Physarum ring, where a transition from a peristaltic **(1)** to an amphistaltic **(2)** mode is observed. Bottom: for each mode, spatial variation of flow rate is plotted, for different times.

Long timescales: network hierarchization

On long timescales, network hierarchization is strongly affected by the confinement: veins at the middle of the ring and with orthoradial orientation expand, while peripheral veins shrink or disappear. Sometimes, the final network reduces to a single larger vein circling around the ring, as in Fig. 1. Most of the time however, small peripheral veins subsist, yielding a hierarchical, anisotropic network. We propose a simple model that reproduces these features, in which the evolution of a vein is related to the statistical flow going through it.

CONCLUSIONS

In summary, we report experimental observation of contractile activity, flows, and network reshaping of slime mould *P. Polycephalum* confined in an annular chamber. On short times, stable contractile modes are classified. On long times, we show that confinement strongly affects the network reshaping.

VARIATIONS OF OSCILLATING FLOW IN THE UPPER BRONCHIAL TREE

Katrin Bauer *[1], Thomas Janke [1], and Ruediger Schwarze[1]
[1] Institute of Mechanics and Fluid Dynamics, TU Bergakademie Freiberg, Germany

Summary There is still a lack of systematic analysis of the unsteady flow characteristics in the human airways. Thus, a realistic model of the human bronchial tree featuring the mouth throat region as well the bifurcating branches down to the 7th generation has been made from transparent silicone. By refractive index matching the oscillating flow inside the model geometry is visualized using Particle Image Velocimetry (PIV). Breathing parameters are varied from very low breathing activity up to breathing under heavy exercise. The results show that lower breathing velocities only lead to quantitative changes of the flow patterns during either in- or expiration. In contrast, at high breathing rates a remarkable qualitative change of the velocity profiles is observed during the expiration phase.

INTRODUCTION

Fundamental knowledge about flow characteristics in the human airways is crucial for the application of appropriate mechanical ventilation strategies as well as for efficient drug delivery within the lungs. Despite an increasing number of sophisticated flow investigations in the human bronchial tree, numerically as well as experimentally, systematic investigations aimed at understanding the flow physics in bifurcating airways, especially for higher Re, are rare and open questions remain. Banko et al.[1] investigated the three-dimensional, constant inspiratory flow at a realistic model of the upper bronchial tree for a typical breathing rate by means of Magnetic Resonance Velocimetry (MRV). At least for their specific model, representing a peak inflow situation, information about regional flow distortion and secondary flow strength could be given. The measurement technique of MRV was also carried out for investigating the inspiratory flow at a planar double bifurcation model for a large range of Reynolds numbers of Re = 100 - 5000 [3]. They could show that the secondary vortex intensity increases up to Re = 2000 and further decreases for larger Re. In 2018, Jalal et al. [2] extended their double bifurcation study by an oscillating flow at Re = 2000 and varying Womersley number Wo. At least for their parameter range they found stronger secondary flows for higher Wo during inhalation and weaker secondary flow during exhalation.

Recently, Janke et al. [4] presented PIV measurements at a realistic, patient specific upper airway (the SimInhale Benchmark Case) model for varying constant inflow conditions. Yet, unsteady flow measurements at such a realistic model have to the best of our knowledge not been done before and shall thus be presented here.

METHODS

The airway geometry represents the SimInhale Benchmark case [4, 5] which includes the mouth/throat passage and bifurcates down to the 7th generation (Fig. 1). For more information on model specifications see Lizal et al. [6]. This geometry has been 3D printed and surrounded by transparent silicone. After curing of the silicone, the model core has been dissolved in acetone and a transparent silicone block with the hollow lung geometry inside was received. The lung model was placed in a glass tank which is filled with a mixture of water and glycerin (mass ratio 42:58) in order to match the refractive index of the silicone. A linear motor generates an oscillatory motion of liquid through the model which mimics the appropriate breathing patterns. Flow similarity with breathing in air is maintained by considering Reynolds and Womersley similarity. The unsteady flow was measured phase averaged by planar PIV measurements at selected phase angles during the breathing cycle. The measurement plane was defined by a Nd:YAG Laser (Minilite) in the center of the main bifurcation. A total of 688 double images for each phase position were recorded by a PCO.1600 CCD camera. The recorded images were cross correlated by employing the software DaVis 8.4 from LaVision. The final window size was $16 \times 16\, px$ including $50\,\%$ overlap which corresponds to a spatial resolution of $0.5 \times 0.5\, mm^2$. Three different measurement settings were employed here with constant tidal volume of $500\, ml$ while the breathing frequency was varied. Thus, a low breathing situation (Re = 1100, Wo = 1.9), normal breathing (Re = 2200, Wo = 2.7) and breathing under exercise conditions (Re = 4400, Wo = 3.8) are compared here.

RESULTS AND DISCUSSION

Fig. 1 presents the color coded distribution of the averaged flow velocity. Shown are selected phase angles during the breathing cycle for low breathing (Re = 1100) and extensive breathing (Re = 4400) conditions. We refer here only to a change in Re since Janke et al. [7] have shown that a change in Wo in the same range as applied here has only neglectable influence on the flow.

During the inspiration phases, all breathing conditions are characterized by a strongly skewed velocity profile in the anatomical left main bronchus (right main branch in Fig. 1) and a large separation region.

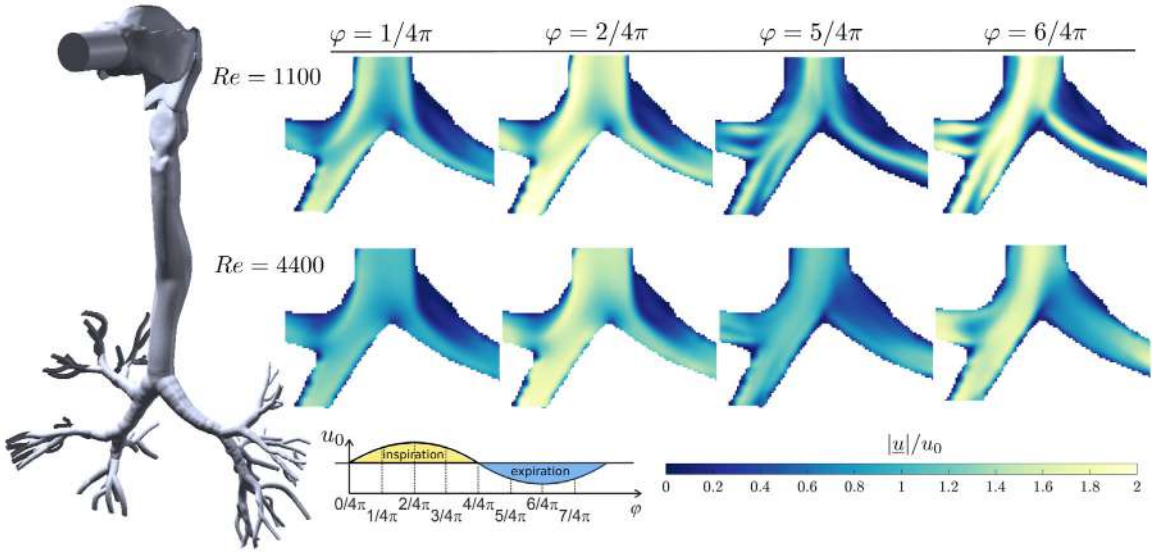

Figure 1: Lung geometry and velocity profiles at selected phase angles for low (Re = 1100) and normal breathing (Re = 4400) conditions.

Increasing Re from laminar to fully turbulent range only causes mild attenuation of the velocity profile skewness induced by turbulent fluctuations. Nevertheless, as reported by Jalal et al. [3], this turbulent diffusion already causes decreased secondary flow intensity. Considering the expiration, the streamwise flow has changed considerably. Besides a strong flow homogenisation, the location of high speed regions has changed, even from accelerated to peak expiration. Separation regions have completely vanished which suggests that secondary flows are not only strongly weakened but their location and structure has changed as well. 3D Particle Tracking Velocity (PTV) measurements at a generic lung model [7] in the range of Re = 250 - 2000 could already prove a displacement of helical flow structures during the expiration phase.

CONCLUSIONS

The results have shown that there occurs a change in flow structures during the expirational phase with increasing Re. This effect is universal for different lung geometries and will have a strong impact on flow distribution and particle transport. However, further 3D measurements are required to investigate the spatial development of helical structures, especially with regards to the secondary Dean structures in order to deduce transport pathways in more detail.

A NUMERICAL STUDY OF OXYGEN TRANSFER FROM BLOOD IN PERMEABLE MICROCIRCULATION TO SURROUNDING TISSUE IN THE PRESENCE OF A MAGNETIC FIELD.

Alana Sankar-Ramkarran*[1], Sreedhara Rao Gunakala [1], and Donna M. G. Comissiong [1]
[1] Department of Mathematics and Statistics, The University of the West Indies, St. Augustine, Trinidad & Tobago

Summary Oxygen transfer from microcirculation to tissue through permeable vessel walls was examined in the presence of an external magnetic field. We considered a two-layered blood flow consisting of a core region as a particle-fluid suspension and a peripheral cell-free plasma layer. In the blood, oxygen is transported by molecular diffusion and convection while in the tissue region it depended on both molecular diffusion and its metabolic consumption. A Finite Element Method was used to solve the governing equations which arose with a fixed-point iterative technique being applied when treating with the nonlinear terms. The effects of varying haematocrit, core region thickness, magnetic field strength and wall permeability on oxygen transfer were examined. These results were subsequently interpreted and explained in terms of the physical situations in which they arise.

BACKGROUND OF STUDY

Oxygen (O_2) plays a key role in cellular energetics. Both oxidation and other forms of energy production are dependent on there being a steady supply of oxygen to the cells. When air enters the body (through the mouth or nose) it goes to the lungs where oxygen is extracted. This oxygen is then carried by the bloodstream through the circulatory system to tissues where it is utilized. Thus, in order to fully understand the regulation of blood flow, the physical mechanisms of oxygen transport throughout the pathway must be investigated [1]. The Finite Element Method is a useful tool in studying such problems since it can easily handle the flow geometry and boundary conditions. This method was used to study the transport of oxygen in the systemic capillaries and surrounding tissues, but wall permeability was not considered [2]. The magnetohydrodynamic blood flow through microcirculation with permeable walls was examined where a two-layered flow was used but oxygen transfer was not examined [3]. This study examined how oxygen is transferred through permeable microcirculation to tissue which is then used to predict the role that factors such as varied haematocrit, core region thickness, magnetic field strength and wall permeability will have on this process.

MATHEMATICAL FORMULATION

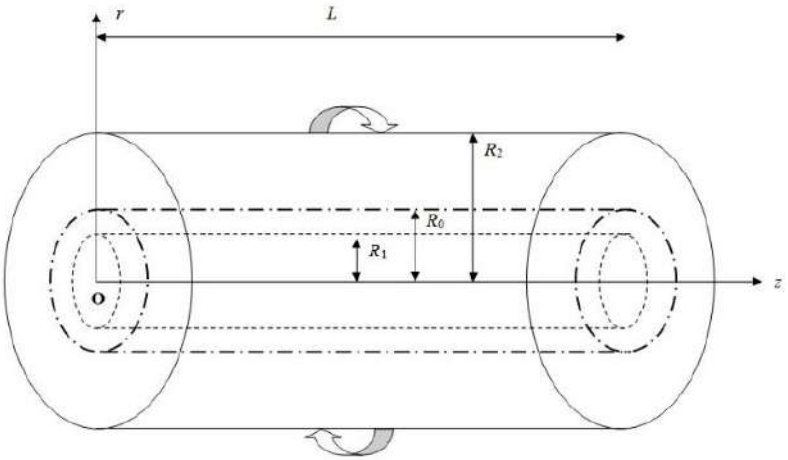

Figure 1. Geometry of the microcirculation in the presence of an external magnetic field.

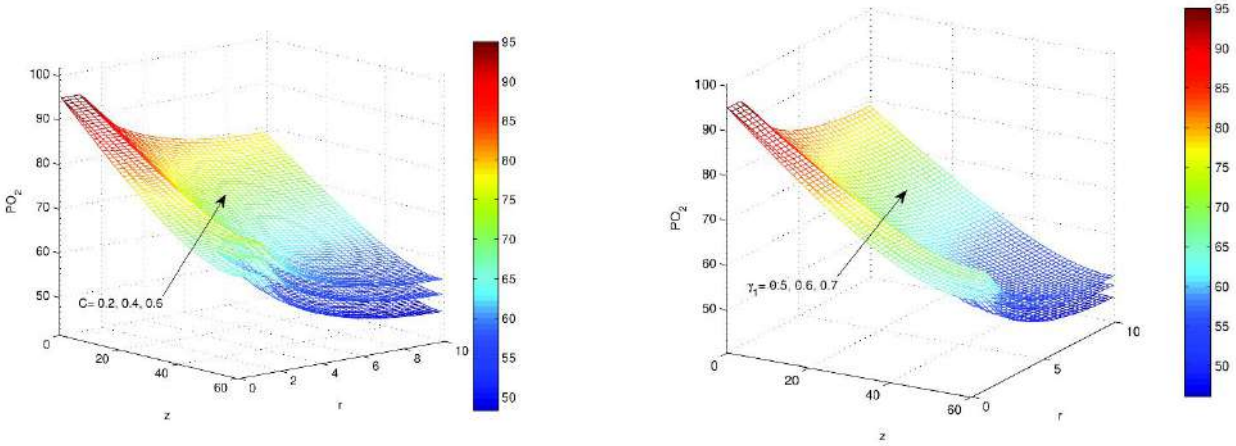
Consider the laminar, axisymmetric, steady and fully developed blood flow through permeable microcirculation in the presence of an external magnetic field surrounded by a tissue region. The blood vessel is assumed to be circular, uniform and of semi-infinite extent. Radius, entrance, end and special wall effects are neglected since the length of the vessel is assumed to be much greater than its radius. In the presence of the Lorentz's force, a macroscopic two-phase model was used in the core region of radius R_1 while a Newtonian fluid is suitable for the peripheral layer (R_0-R_1) [3]. In both regions, oxygen transfer occurs through molecular diffusion and convection with haemoglobin and oxygen being in chemical equilibrium inside the red blood cells. In the tissue region, the transport of oxygen is assumed to depend on molecular diffusion with the rate at which oxygen is consumed following zero-order chemical kinetics. Proposed equations were non-dimensionalized and appropriate interface and boundary conditions were included. The velocity solutions were found and the Galerkin finite element method was used to obtain the solution for the mass transfer in the blood vessel region. Matlab code was written to generate any size mesh using eight node serendipity elements and this mesh was utilized in this study. A grid independence test and code validation were conducted, then graphs were generated to observe the partial pressure of oxygen (PO_2) in all three regions.

*Corresponding author. E-mail: alana.sankar@sta.uwi.edu

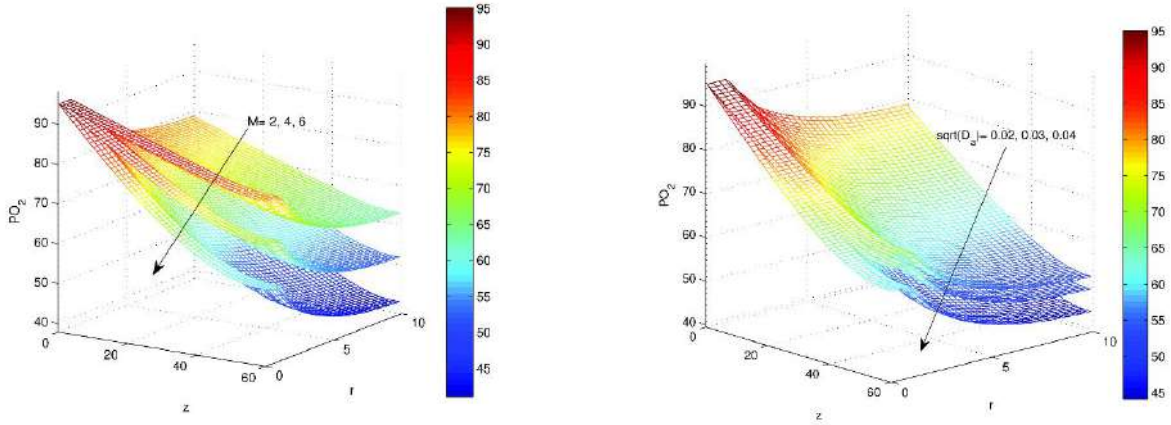
RESULTS

It was observed in Figure 2a that as hematocrit, C, increased, PO_2 was higher in all three regions. Thus, under conditions where the red blood cell count in the blood is lower than normal, for example in patients with plasma cell dyscrasias or Hb SS-sickle cell, there is less O_2 present which can be detrimental to the surrounding tissue which may become starved of O_2. Meanwhile, in patients with high hematocrit, for example those with polycythemia, there is a high O_2 concentration in the tissue which can lead to oxygen toxicity (hyperoxemia). This can result in twitching, dizziness, nausea, seizures and in severe cases can even be fatal. Another factor which increased O_2 is the thickness of the core region as shown in Figure 2b. An increased in the core region thickness corresponds to a thinning of the plasma layer. Hence as this peripheral layer thins, the oxygen content elevates in all regions.



Figures 2a, 2b. Increased PO_2 observed on increasing haematocrit and core region thickness.

During Magnetic Resonance Imaging (MRI) scans and in the treatment of chronic pain and non-healing or slowly healing ulcers, human are subjected to magnetic fields. From Figure 3a, increasing the Hartmann number (magnetic field intensity) resulted in a decline in PO_2, thus high intensity magnetic fields should be avoided. Furthermore, some drugs administered can alter vessel wall permeability [2]. Hence incorporating wall permeability in O_2 transfer is important. Figure 3b showcased a decrease in PO_2 in all three regions as the vessel walls became more permeable with an increasing Darcy number. Therefore, the effect of medication (such as ACE inhibitors, beta blockers, calcium-channel blockers, decongestants, antihistamines, sildenafil, nonsteroidal and anti-inflammatory drugs) should be closely monitored.



Figures 3a, 3b. Decreased PO_2 observed on increasing magnetic field strength and wall permeability.

CONCLUSION

In order to fully understand what occurs in microcirculation, it is important to examine how oxygen is transferred to tissues and what factors can affect this process. PO_2 increased on increasing haematocrit and core region thickness but decreased as the magnetic field strength and wall permeability were increased. Medical situations where these may arise were given and their effects discussed.

ORGANIZATION OF ACTIVE BACTERIAL SUSPENSION IN MICROFLUIDIC POISEUILLE FLOW

Axel Klein[1], Mathieu Jenny[1], Frédéric Jorand [2], and Nicolas Louvet*[1]
[1] Université de Lorraine, CNRS, LEMTA, F-54000 Nancy, France
[2] Université de Lorraine, CNRS, LCPME, F-54500 Nancy, France.

Summary We study the organization of a motile bacterial suspension under flow. Through pressure-driven flow microfluidic experiments and optical tracking techniques, we follow the Lagrangian trajectories of bacteria in a Poiseuille flow. From trajectories, we compute the bacteria orientations and concentration profiles as a function of the Peclet number, suspension concentration and walls confinement. Our first results highlight the strong influence of walls on the bacteria dynamics. Close to the wall, their orientations are isotropic as in the case of no applied flow.

INTRODUCTION

In their environment, wild type species of bacteria organize their motion as regular changes of direction to explore and harvest the environmental resources. To achieve its locomotion, the *Escherichia coli* (*E. coli*) bacterium regroups its flagella into a bundle and adopt a "Run & Tumble" swimming strategy. Under flow, bacteria are subject to hydrodynamic stresses that may cause changes in their swimming behaviour and thus lead to diversified transport properties [1]. We investigate experimentally the effect of flow strength and wall confinement on the organization of an active bacterial suspension.

MATERIALS AND METHODS

The wild type *E. coli* (ATCC9637) are suspended in motility medium (BMB) supplemented with 20 mM D-Glucose and 2:3 v/v Percoll. By computing the Mean Squared Displacement (MSD), from Lagrangian trajectories or using the Differential Dynamic Microscopy (DDM) technique, we measure bacteria swimming characteristics (i.e. the swim velocity V_b and the characteristic reorientation time t_b). In a fluid at rest and for a dilute suspension, V_b and t_b are, respectively, 12 µm/s and 1.5 s.

A pressure driven flow in microfluidic channel is used in order to manage the flow strength applied to the active suspension. The microfluidic device consists in a glass capillary connected to two syringes containing the bacterial suspension. The syringes are mounted on translating stages to adjust the height difference between the inlet and the outlet and thus impose the total pressure drop across the channel (Figure 1a). The channel has a rectangular cross section with high aspect ratio (width / height =10) which allows to discard effects due to lateral walls and consider a planar Poiseuille flow.

We use PIV and PTV techniques to measure fluid velocities and bacteria characteristics at different height in the channel (Figure 1b-c).

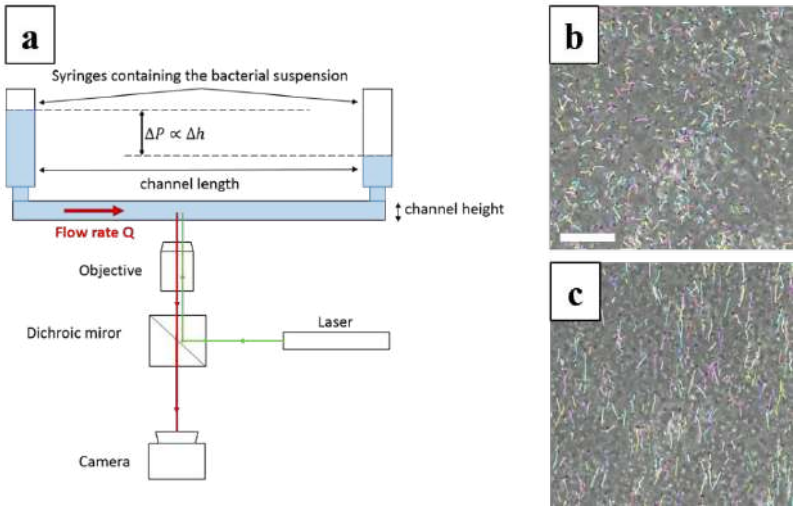

Figure 1: **a)** Experimental set-up used to track the bacteria behavior at various flow strength. **b) – c)** Bacteria trajectories close to the channel wall and at the mid channel height respectively. The pressure drop is 2 Pa corresponding to a maximum fluid velocity of 5 µm/s. The scale bar is 40 µm.

*Corresponding author. E-mail: nicolas.louvet@univ-lorraine.fr

FIRST RESULTS

From the bacteria trajectories measured by tracking technique, we compute the time and ensemble average of the bacteria orientation distribution. The results are plotted, Fig. 2, for two flow strengths at the wall and at the mid-height of the channel. We choose, as a reference, the case with no flow (black symbols) where the orientation is isotropic at both heights.

First results highlight the effect of the wall on the orientation distribution. In fact, in the near-wall region, the distribution of the bacteria swimming orientation is uniform meaning that a large part of bacteria swim upstream even at high flow strength (Fig.2 a-c). For the case (a) the Peclet number $Pe = \dot{\gamma}_w \cdot t_b$, with $\dot{\gamma}_w$ the wall shear rate, is close to 0.1 and the bacteria dynamic is not affected by the imposed flow. For larger Peclet numbers close to 1 (case (c)) we observe the same trend. In the middle of the channel bacteria are mostly oriented in the direction of the imposed flow (Fig.2 b-d). An increasing flow strength thus leads to a narrowing of the swimming orientation distribution. These results are in line with predicted Brownian simulations [2].

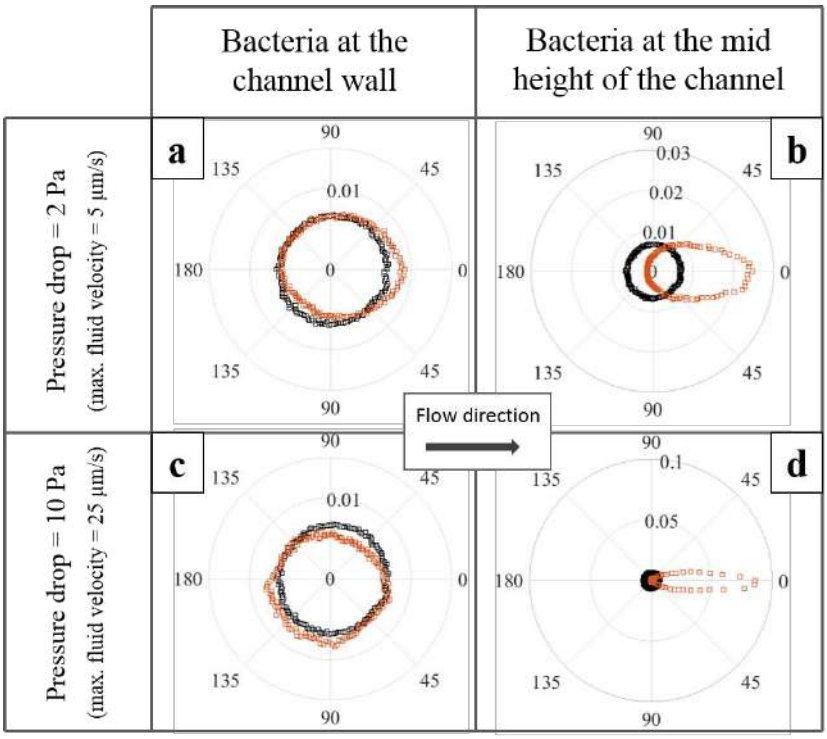

Figure 2: Polar representation of bacteria orientation under two flow strengths and two positions in the channel. The orange and black symbols are the cases with and without flow respectively. The bacteria concentration is 0.1 % vol.

CONCLUSION

We investigate the behaviour of motile bacteria under confinement at various flow strengths. We show that, in the near-wall region, upstream motions subsist, despite increasing Peclet number. However, in the mid-height of the channel, the flow strongly affects the bacterial behaviour and hinder upstream motions.

RECONSTRUCTION OF A CORONARY ARTERY FLOW FROM IVUS MEDICAL IMAGES

Raz Hechter*[1], and Alexander Yakhot[1]
[1] Department of Mechanical Engineering, Ben-Gurion University, Beer Sheva, Israel

Summary Vascular lesions are usually accompanied by changes in arterial stiffness, attenuation, morphology and flow field. The objective of this work is to develop and test a new tool for assimilating clinical imaging to aid in finding and assessing pathologies resulting from lesions. The proposed tool utilizes the Kriging method, originally developed for spatial interpolation, in time as well, in conjunction with proper orthogonal decomposition to eliminate noise. The method was tested on an intravascular ultrasound clinical clip and yielded a flow field, which enables further calculation of hemodynamic properties as well as border detection.

BACKGROUND

Vascular lesions are usually accompanied by changes in arterial stiffness, attenuation, morphology and flow field. There is a gap between comprehensive useful information for physicians and achievable data through clinical imaging and measurement. To resolve this gap, many studies based on computational fluid dynamics (CFD) have suggested the use of simulations as a tool that completes the picture by adding upon the measured data. Since it is not suitable for patient-specific analysis, it cannot be accepted by the clinical community as a diagnostic tool. The objective of this work is to develop and test a new tool for assimilating clinical imaging to aid in finding and assessing pathologies resulting from lesions.

METHOD

The proposed tool utilizes the Kriging method, originally developed for spatial interpolation, in time as well. In conjunction with the proper orthogonal decomposition (POD), the approach has been applied for reconstruction of arterial flow field from patient-specific intravascular ultrasound (IVUS) images. The Kriging interpolation fills-in the gaps in the data, while the proper orthogonal decomposition eliminates noise.

RESULTS

The method was tested on an intravascular ultrasound (IVUS) clinical clip consisting of 48 frames (~7 sec). Figure 1 show a selected frame from the IVUS clip along with its reconstructed form. The reconstructed velocity field is quite smooth; the coronary artery wall border (in blue) is recognized.

CONCLUSION

The proposed Kriging space-time interpolation method yields a flow field, which enables further calculation of hemodynamic properties as well as border detection.

STATISTICAL MODELLING OF CEREBRAL BLOOD FLOW AND TRANSPORT IN MICROVASCULAR NETWORKS

Florian Goirand *[1,2], Tanguy Le-Borgne[1], and Sylvie Lorthois[2]
[1] Geosciences Rennes, University Rennes 1, Rennes, France
[2] Toulouse Institute of Fluid Mechanics, UMR CNRS INPT UPS 5502, Toulouse, France

Summary Despite of the high dependency of brain cells function on the efficiency of blood transport throughout the micro-vasculature, only little is known about the physical processes that drive neural cell supply. Here, based on the statistical analysis of realistic blood flow computations in mouse brain micro-vascular networks, we develop a modular statistical framework allowing to integrate a growing number of flow and transport heterogeneities. In particular, this framework enables to capture the anomalous nature of the transport in brain micro-vascular networks. We further investigate the interplay between flow organization and vascular density decrease on the total amount of flow incoming in the network through random bond percolation.

GENERAL CONTEXT

The cerebral microvascular network and in particular its capillary bed is in charge of the local supply of vital chemical species (e.g. oxygen, nutrients) to brain cells and the removal of metabolic wastes (e.g. β-amyloid, τ-protein). Motivated by understanding the possible role of metabolic failure in diverse neurodegenerative disease, we analyse the organization of the blood flow at the microvascular level through various statistics from both Lagrangian and Eulerian point of views. The analysis is performed on the result of previous flow simulations performed in a 1 mm^3 of mouse cortex micro-vascular network ($\sim$ 14000 vessels) [1, 2] and provides key information to develop a statistical framework for blood flow and transport in such networks. On the other hand, a decrease of the cerebral blood flow associated to capillary vessel occlusions has been highlighted at early stage of Alzheimer disease [1]. Our numerical setup allowing a quantification of the consequences of network structure changes, we adapt classical percolation theory in dilute regime [3] aiming to predict the impact of such occlusions on global cerebral blood flow.

MAIN RESULTS

The Eulerian flow rate distribution shows two well-defined regimes: at high flow rates, the flow is ordered and reveals its dipolar nature induced by ponctual injection and pumping on the network. At low flow rates, the flow statistics are driven by the disordered organization of the network [4]. The analogy with dipole flows [5] and force distribution in random bead packs [6], akin to random aggregation theory, allows to derive analytical solutions for the Probability Density Functions (PDF) of flow in these two regimes.

From our analysis, we develop the first effective transport model based on micro-vascular structure and flow organization. Our transport model contains a deterministic part induced by the dipole structure and a stochastic component induced by the network disorder [7]. This approach allows to emphasize the ordering of the different transport properties on the observed statistics of travel times within the micro-vascular network. Comparison with simulated travel time distributions obtained by tracing the transport of passive particles through the network shows accurate predictions.

Furthermore, based on in vivo concentration measurements, we evaluate effective characteristic times of oxygen supply or β-amyloid removal. This evaluation indicates the importance of late time transport regime in the metabolic processes. In particular, this regime is characterized by a competition between the particle trajectory lengths and the heterogeneities of the velocity field as main drivers of the travel time variability within the micro-vascular network. Besides, this evaluation allows to identify critical transport times above which the metabolic processes might be significantly impacted (oxygen deprivation or accumulation of β-amyloid). We predict, in agreement with observations, that the weight of these critical regimes evolves non-linearly with cerebral blood flow decrease.

Eventually, we link massive variability of cerebral blood flow decrease induced by vessel occlusions to flow organization within a revisited dilute regime percolation theory. The latter allows to predict the non-linear evolution of the probability to experiment critically low global flow rates during the occlusion process.

DYNAMICS OF A SMALL PEPTIDE SIMULATED IN WATER MODELS WITH VARYING VISCOCITY

Agnieszka M. Słowicka[1], Gouri S. Jas [2], and Krzysztof Kuczera [3]
[1] Department of Biosystems and Soft Matter, IPPT PAN, Warsaw, Poland
[2] Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS, USA
[3] Department of Chemistry, University of Kansas, Lawrence, KS, USA

Summary The following paper concerns analysis of structure and dynamics of peptides in solution. We have studied the dipeptide N-acetyl-trypthophanamide (NATA) in water using molecular dynamics simulations, with solvent viscosity tuned by mass scaling. Increasing the viscosity of water had strong effects on the external and internal dynamics of NATA peptide. As expected, the rates of external peptide motions, describing overall translations and rotations, were inversely proportional to the effective solvent viscosity. Internal motions, representing conformational transitions, which may exhibited a more complicated pattern of change, will be studied in future work. Numerical results from molecular dynamics simulations were also compared with experimental measurements obtained by fluorescence anisotropy decay.

INTRODUCTION

The dynamics of small peptides have been considered numerically and experimentally [1-3]. The fundamental behavior of small peptides, like NATA, give us information about the internal and external dynamics of the basic biological protein systems immersed in the liquids with different viscosity. Interactions of biological particles with the solvent are manifested by a conformation changes of the molecule and its translation and reorientation in relation to the molecules of the solvent in which the particle is located [3]. The study of reorientation of the biological particles allows the recognition and isolation of the preferred behaviors of molecules in a contact with specific solvent. In this work, molecular simulations of peptide dynamics are compared with experimentally available measurements to verify the numerical results and microscopic effects that are difficult to investigate in the lab. The purpose of this analysis was to study the influence the solvent viscosity on the internal and external dynamics of the NATA peptide.

METHODS

Molecular dynamics (MD) simulations were used to study the behavior of NATA (see Fig.2) in a water-based liquid. Simulations of a single NATA molecule placed in water were performed using the GROMACS program with the OPLS/AA force field [4]. The TIP3P model was chosen for water modeling. Calculations of NATA peptide in a box of 1185 molecules of water were performed at the temperature T=300K using periodic boundary conditions in canonical ensemble (NVT) with the Nose–Hoover thermostat. To vary the viscosity of the liquid surrounding the peptide without changing the potential energy parameters, an artificial method of increasing the mass of the water molecule was used. With increasing the mass m in the molecular model, the viscosity of the modeled fluid increases proportionally to $m^{1/2}$. Numerical calculations were made for liquid models with viscosity $\eta = n \cdot \eta_0$, where n = 1,2,3,4,5 and η_0 is the basic viscosity of the the regular TIP3P model [7]. 200-nanosecond all-atom trajectories of NATA in water were generated with the five mass-scaled water models. The trajectories were analyzed by calculating peptide and solvent translational and rotational diffusion coefficients, as well as by following changes in internal structure like end-to-end distance and backbone and sidechain dihedral angles. Parameters calculated from the molecular dynamics simulations were compared with experimental measurements obtained for NATA in water [3].

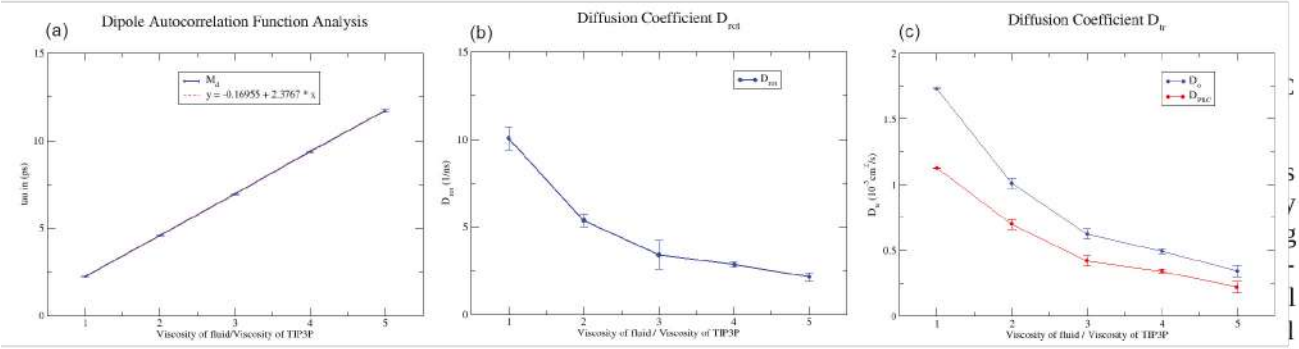
RESULTS

Numerical studies of the peptide dynamics were concentrated on determining how the change of viscosity of the solvent effects peptide behavior. Studying this phenomenon, first of all, the viscosity of the solutions surrounding the peptide were calculated. According to the fact, that the water viscosity is proportional to the rotational orientation time τ for dipoles [2], we determined the reorientation time τ from simulations for different models of solvent comparing the results with the assumed relative viscosity of the solution η . As is shown on the graph (see Figure 1a), the dependence between the reorientation times τ and modeled viscosity of solvent is linear and reproduce very well the expected hydrodynamical relation between these parameters.

Analyzing the external dynamics of NATA in different solutions, the translational D_{tr} and rotational D_{rot} diffusion coefficients of the peptide were calculated and presented in Figure 1b and 1c. Taking into account the hydrodynamic correction due to the difference between the Stokes friction in an infinite system and in a system under periodic boundary conditions (PBC), the parameters were recalculated with respect to the following forms:

$D_{rot} = D^r_{PBC} + \frac{k_b T}{6\eta V}$ (1) and $D_{tr} = D^t_{PBC} + \frac{k_b T \xi}{6\pi\eta L}$ (2), where D^r_{PBC} , D^t_{PBC} are the diffusion coefficients from PBC simulations (rotational and translational respectively), k_B- Boltzmann constant, T – temperature, ξ=2.837297, η -

TIP3P water viscosity, V – volume of the calculated box and L –length of the simulated cell [5,6]. In Figure 1c, the red line represents D^{t}_{PBC} values obtained from simulations and the blue line D_{tr} after correction for PBC effects, illustrating relatively large influence of the geometry of the simulation box on the global diffusion coefficient values.



dynamics of NATA by proportional increasing of characteristic relaxation times. MD results are consisted with results obtained experimentally.

The natural follow-up question is, how does the internal dynamics of the peptide react to the increasing of the solvent viscosity. The detailed analysis of this problem will be realized in future studies based on results obtained from structural clustering of peptide conformers and investigation of the kinetics of transitions between preferred conformers of NATA in water-based solutions with different viscosity (Figure 2).

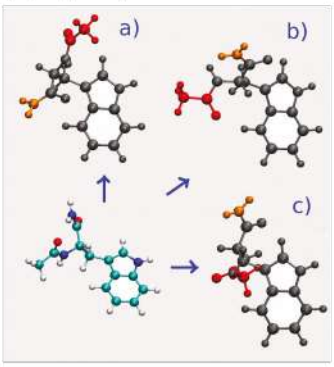


Figure 2. NATA molecule – typical conformations from MD simulation in TIP3P water (molecules of water not shown).

Summary As an application of reduced-order modeling in cardiovascular flow analyses, spectral proper orthogonal decomposition (SPOD) is applied to velocity data of the flow inside idealized and compliant models of an abdominal aortic aneurysm (AAA) at different expansion ratios. The idea is to construct low-dimensional models of AAA flow and to identify the most important low-dimensional features of the flow.

INTRODUCTION

An abdominal aortic aneurysm (AAA) is referred to as a localized dilation of the aortic wall in the abdomen. The disease severity, represented in clinical practice by the maximal diameter in the expanded area, is correlated with flow features within the aneurysm sac, which vary depending on the size. Therefore, AAA flow dynamics analysis can provide insights into its progression and possibly lower the risk of sudden rupture that can be fatal up to 81%. In this context, a promising approach to more effectively analyze the abundant and high-dimensional experimental and numerical data is to construct data-driven reduced-order models that can facilitate the identification of the coherent structures in AAA flow and the development of predictive tools for the growth and risk of rupture of AAAs. In modeling AAA or any cardiovascular flows, two standard techniques, proper orthogonal decomposition (POD) and dynamic mode decomposition (DMD), can be used to generate low-dimensional models with their associated pros and cons. POD can provide the most energetically optimal model but fails in an accurate description of the dynamics of the flow. On the other hand, DMD can more efficiently extract and reproduce the dynamics of the flow, its performance is undermined in cardiovascular applications because of the transient, aperiodic and chaotic nature [1]. The optimality of POD in maximizing the total variance and the superiority of DMD in expressing temporal correlation are merged into an alternative method, spectral proper orthogonal decomposition (SPOD). With SPOD, data is decorrelated to spectral and energetic content, meaning that the modes at each frequency can preserve both the temporal and spatial coherence. In this experimental study, SPOD specific features are used in order to gain a better fundamental knowledge of the flow in AAAs and to derive reduced order models of the flow.

METHODOLOGY

To replicate the flow experimentally inside the abdominal aortic aneurysm, an *in vitro* simulator is designed that consists of elastic and optically clear silicone replica of AAAs. The pulsatile flow circulation at 1.05 Hz (63 bpm) within the experimental setup is obtained using a positive-displacement gear pump coupled with a motor and controlled through a LabVIEW interface. A mixture of water and glycerol (40% v/v) is used as the working fluid with a measured density and dynamic viscosity of 1160 kg/m^3, 4.1 cP. The flow is pumped from a higher reservoir and reaches an anatomical model of the aorta by passing along a trileaflet bioprosthetic aortic valve. The flow branches off to the renal arteries and the abdominal aorta encased in an acrylic chamber filled with the same fluid mixture to minimize optical distortion. The infrarenal flow rate is 1 ± 0.18 L/min with systolic and diastolic pressures of 153/95 (±3) mmHg, and the mean Reynolds and Womersley numbers are 344 ± 7 and 13.2, respectively. The experiments are carried out for 4 cases including a model with a nominal aortic diameter (2 cm) and 3 models of aneurysms with ratio of maximal to nominal diameters (d_r) of 1.5, 2 and 2.5. The flow in the AAA was captured using 2D time-resolved particle image velocimetry measurements over one cardiac cycle (T=0.952 s). The flow was seeded with polyamide paricles and illuminated with a 1 mm thick laser sheet formed by a double-pulsed Nd:YLF laser. Using a high-speed camera, 500 double-frame images were acquired 900 μs apart at an acquisition rate of 525 Hz. Finally, the images are post-processed and the velocity field snapshots are obtained with a spatial resolution of 0.6 mm $\times$ 0.6 mm. The measurements are performed on the plane bisecting the abdominal aorta, namely, the sagittal plane where AAA clinical *in vivo* measurements are often being performed. For each investigated case, the velocity snapshots from an ensemble of realizations of the flow is used to construct the input data matrix for SPOD implementation where a single PIV dataset is regarded as one block. The algorithm starts by performing a discrete-Fourier transform (DFT) on each block separately decomposing its related flow data into spatial structures associated with specific frequencies. Then at each frequency, the cross-spectral density tensor is estimated and used as the kernel for the POD eignevalue problem, which results in SPOD modes with their corresponding energy contents. Details on SPOD background and algorithm can be found in [2].

RESULTS AND DISCUSSION

For each case and according to the number of realizations, decomposition yields a set of SPOD modes which are optimally ranked in terms of energy at each frequency. Considering the SPOD spectra (Figure1) and with POD intuition in mind, we see that for all the scenarios, there is a significant energetic difference between the first SPOD mode and the remaining modes (e.g., for the most dilated AAA, d_r=2.5, the energy fraction drops from 91.56% to 3.50% from the first to the second mode). Applying POD on the same velocity data will lead to a first mode that contains only 54% of the energy. So, the first mode is considered the leading mode to efficiently represent the flow at each frequency and

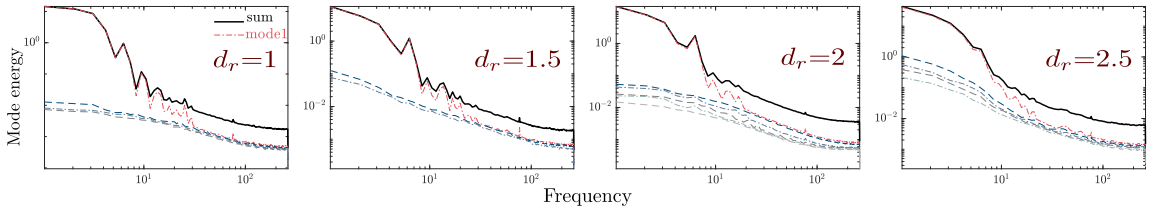

Figure 1: SPOD spectra for different AAA configurations as defined by the ratio of maximal to nominal diameters (d_r). Normal case d_r=1 and most severe case d_r=2.5.

identify the low-dimensional and essential features of the available flow field. To better illustrate this, the first SPOD mode at 5 primary harmonics (1.03-5.15) are visualized in Figure 2 for the most severe AAA, corresponding to d_r=2.5. SPOD is only applied to the fluctuating velocity components, and the temporal mean is subtracted. Since modes are mutually orthogonal on a spatiotemporal basis, we can say that the structures captured by a particular SPOD mode are temporally correlated with those extracted from the same mode at any other time within the flow field. This property of SPOD compared to POD where modes by definition cannot disclose any information on the flow history due to a lack of temporal correlation, makes it easier to interpret SPOD modes physically and correlate their shapes to the original flow field phenomena. Through qualitative visualization of the velocity snapshots, we can observe that the flow behavior, in this case, is characterized by the formation of an asymmetric vortex ring that travels downstream, pushing flow in its wake toward upstream. If we use the illustrated modes to reconstruct the initial velocity field, the structures extracted at the second harmonic (f=2.1) are reproducing the flow separation near the proximal neck followed by the retrograde flow of late deceleration and further propagation of the vortex, which can be noticed from the organization of the first SPOD mode streamlines at f=1.05. Therefore, this mode at six primary frequencies in the vicinity of the highest peak in the spectrum is used to illustrate the construction of a reduced-order model of the most complex aneurysmal flow being investigated in our study. Once the model is generated, by observing the instantaneous velocity, we can qualitatively say that the main features of the flow are well-reproduced. For further analysis and the significant contribution of the vortex ring to the flow dynamics in this AAA configuration, its presence and evolution over the entire cycle are quantified and compared to the original data in terms of vorticity. One snapshot of the vorticity field sampled from mid flow deceleration is plotted in Figure 2. We can notice that the strength of the vortex pair is very well-captured.

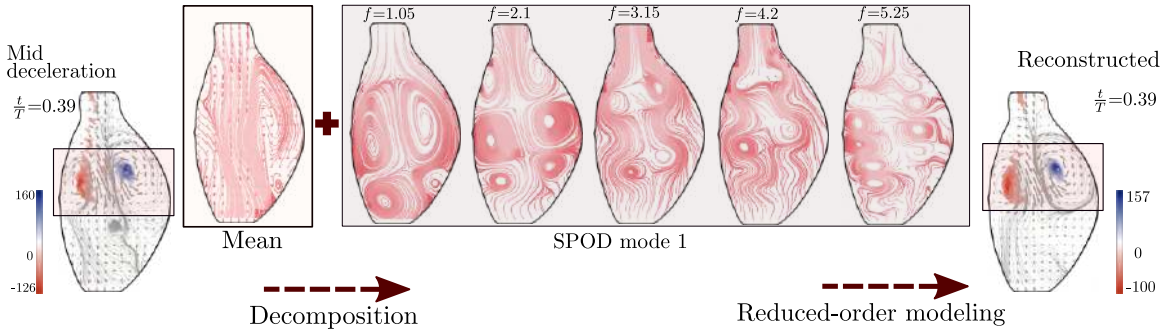

Figure 2: Decomposition and reconstruction of a low-dimensional model of the flow dynamics in a model of AAA with d_r=2.5.

Summary Carotid endarterectomy (CEA) is considered to be the golden standard to relieve stenosis conditions in both symptomatic and asymptomatic patients. Despite of numerous surgical techniques being developed in past few decades, superiority of one over another is still controversial. In this study, we present patient-specific results using computational fluid dynamics (CFD) to provide unbiased quantitative analysis of both primary closure (PC) and patch angiography (PA). Hemodynamic properties are calculated based on actual patient conditions to obtain values closer to the reality. As a result, pressure and flow rate match measurements and literature. WSS-related indicators show favorable outcomes for PC than PA, and PC technique may provide better postoperative consequences compared to PA.

INTRODUCTION

Carotid endarterectomy (CEA) has been the golden rule for treatment of moderate to severe carotid artery stenosis[1)]. Among various CEA techniques developed till date, two closing techniques are widely used, namely primary closure (PC) and patch angioplasty (PA). The superiority of these two techniques over one another is still undetermined and controversial while PA is preferred in clinical. This study aimed to compare the hemodynamic indicators of normal, PC, PA groups which influence atherosclerosis applying each patient's CTA image and Doppler Ultrasound data of common carotid artery (CCA). The total number of patients were 30, equally 10 people in each group. For clarifying the difference, 3D hemodynamic computational fluid dynamic (CFD) simulation was carried out. The hemodynamic indicators and flow parameter were quantified and compared. After that, the significance of the differences between groups was verified through a statistical method.

NUMERICAL METHOD

Unsteady hemodynamic simulations with patient-specific computational model were carried out for 30 carotid arteries using open - source CFD solver SimVascular[2)]. In all case, the modeling of 3D computational domain was conducted in same process. For virtual domains, a tetrahedral element mesh was generated. Also, prism layer using hexahedral mesh was adopted near vascular wall for measurement accuracy. Doppler ultrasound data were utilized to inlet boundary conditions. Due to inavailability of flow characteristic at arbitrary point, the outlet boundary conditions were assumed using windkessel lumped parameter model. Flowrates of internal carotid artery (ICA) and external carotid artery (ECA) were assumed to be 8 to 2 of CCA flowrate. For analyzing the results, 3 hemodynamic indicators which were time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI), relative residence time (RRT) were calculated. After that, 3 indicators were converted to LSA for TAWSS, OSA for OSI and RTA for RRT which means the area with threshold-over indicators, called 'atherosclerosis prone area[3)]'. The thresholds were calculated with data of all cases referring literature[4)].

RESULTS AND DISCUSSION

Figure 1. showed the atherosclerosis prone area of 3 representative case of normal (a-c), PC (d-f), PA (g-i) group. Due to geometrical characteristic of each patient groups, flow becomes turbulent near bulb and lateral side of ICA. This turbulent flow changes hemodynamic nature of carotid artery. Among the CEA techniques, PA causes the larger enlargement of bulb than others. Due to this sudden enlargement, PA has most intense disturbed flow and the widest atherosclerosis prone area (low in TAWSS, high in OSI, RRT) in 3 representative cases. In figure 2, showing data of all cases, the same trend which were seen in representative cases can be confirmed in 3 patient groups. Case of PA group has wide severe area while PC group has similar trend with normal group. Although the PA was preferred in clinical environment, PC techniques provided more favorable hemodynamic nature of carotid artery.

Summary In silico electro-mechanical model of heart is very important for better understanding of various diseases such as heart failure, cardiac arrhythmia, and cardiomyopathy. We have been developed a methodology for fluid-electro-mechanical model of heart tissue to provide mechanical response of the system. Some results for 3D biventricular heart model with constrains in septum zone are given. This model can give better understanding for real patient case for prediction of disease progression and development.

INTRODUCTION

It is very important to use detailed and complex model of heart electrical activity to understand disease progression as cardiomyopathy hypertrophic or dilated development. Muscles in the body are activated by electrical signals, transmitted from the nervous system to muscle cells, affecting the change of the cell membranes potentials. Additionally, calcium current and concentration inside the cell are main cause of generating active stress within muscle fibers. In electrophysiology, the goal is to determine the electrophysiological properties of all compartments and signal propagation characteristics within the body. For example, in heart electrophysiology, the fundamental advancements where achieved by designing the so called 'clamp' experiment [1] in order to determine characteristics of the membrane currents and constitutive relations for the conduction of currents. Following this break-through achievement, further important experiments were performed, with modifications and extension of the constitutive relations, e.g.[2-5]. Based on these experimental results, a large number of computational models related to electrical signal propagation within neural cells, along neural fibers-axons, and within extracellular space, have been introduced - in analytical and numerical (computational) form.

METHODS

Finite element model the patient parametric left ventricle has been modeling as fluid-structure interaction problem. The solid mechanics of the heart consist of two sources of stresses: the passive and active. The final stresses produced in the tissue are obtained adding the passive stresses and the active stresses. Passive stresses are a consequence of the structural properties of the cells and the connective tissues. We used model based on the recently available experimental investigation of Holzapfhel.

Boundary conditions for this model are: prescribed inlet velocity at mitral valve (right tube) and outlet aortic valve which was calculated as consequence of heart muscle contraction. As results we can see blood pressure and velocity distribution during whole heart cycle. Cardiac contractility is regulated by changes in intracellular Ca concentration. Normal function requires that Ca be sufficiently high in systole and low in diastole. Much of the Ca needed for contraction comes from the sarcoplasmic reticulum and is released by the process of calcium-induced calcium release.
Current flow through cell membrane contains ion currents of molecules such as sodium (Na^+), potassium (K) and calcium (Ca^{2+}), which are critically important for correct formulation of mathematical models for electrophysiology simulations. Additionally, calcium current and concentration inside the cell are main cause of generating active stress within muscle fibers.

RESULTS

Modelling such complex system is demanding in computational sense. In order to make computational models feasible for applications, we summarize our smeared methodology for modelling physical fields, so called composite smeared finite element (CSFE) for electrophysiology simulations [6]. In order to calculate calcium current and concentration within the cell, we coupled CSFE and OHara-Rudy (oRD) membrane model [7], a human ventricular action potential (AP) model formulated using undiseased human ventricular data which provide accurate ventricular myocyte electrophysiology and Ca^{2+} cycling validated over the entire range of physiological frequencies. Electrophysiology module is than coupled with muscle mechanics with widely used relation for heart muscle that connects calcium concentration and active stress along fibers [8].
Some of the results for coupled electro-mechanical simulation of 3D biventricular heart model with constrains in septum zone have been presented in the Figure 1. There is boundary conditions in the model (septum zone), fibers orientation from top viewpoint, fibers orientation from side viewpoint, displacements in coupled electro-mechanical model of biventricular heart for first cycle of electrical signal propagation.

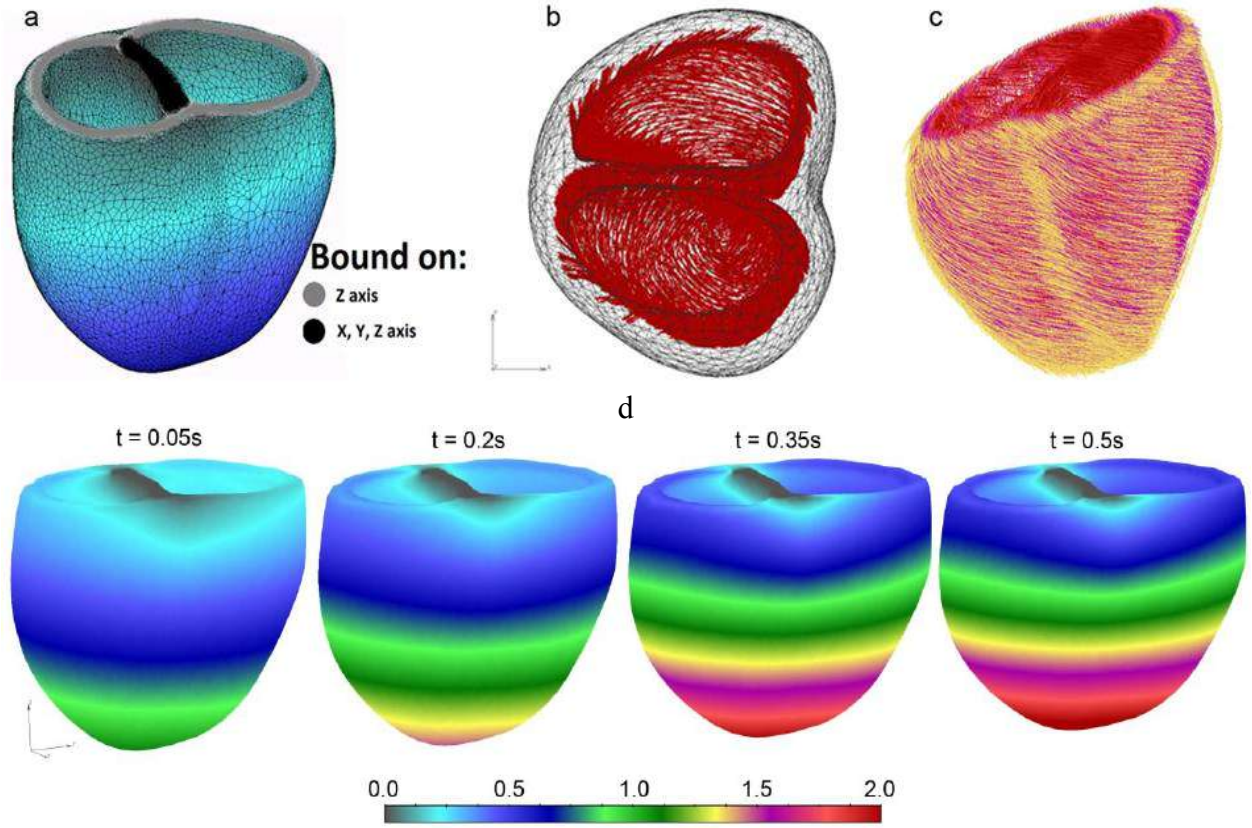

Figure 1. 3D biventricular heart model with constrains in the septum zone. a) Boundary conditions in the model (septum zone), b) Fibers orientation from top viewpoint; c) Fibers orientation from side viewpoint; d) Displacements in coupled electro-mechanical model of biventricular heart for first cycle of electrical signal propagation.

CONCLUSIONS

Coupled electro-mechanical model of heart failure, cardiac arrhythmia, and cardiomyopathy can give better insight in the everyday clinical practice. We presented our methodology for modelling physical fields, with composite smeared finite element (CSFE) for complex electrophysiology simulations. The prediction of disease development and progression is from crucial interest for a new patient specific medicine.

RECENT RESULTS ON DROPLET TRANSMISSION IN THE UPPER AIRWAY LEADING TO SARS-COV-2 INFECTION AND AN ESTIMATION OF THE INFECTIOUS DOSE

Saikat Basu *[1, 2]

[1] Department of Mechanical Engineering, South Dakota State University, Brookings, United States

[2] Department of Otolaryngology / Head and Neck Surgery, The University of North Carolina – School of Medicine, Chapel Hill, United States

Summary How human respiratory physiology and inhaled airflow dynamics proceed to impact transmission of SARS-CoV-2, leading to the initial infection, is still an open question. An answer can help determine the susceptibility of an individual on exposure to a COVID-2019 carrier and can also quantify the still-unknown *infectious dose* for the disease. Synergizing computational fluid mechanics enabled tracking of respiratory transport in medical imaging-based anatomic domains, with sputum assessment data from hospitalized COVID-19 patients and earlier measurements of ejecta size distribution during regular speech – this study shows that the regional deposition of virus-laden inhaled droplets at the initial nasopharyngeal infection site peaks for the droplet size range of 2.5 – 19 μ and reveals that the number of virions that can establish an infection can remarkably be in the order of hundreds.

INTRODUCTION

As is well-known by now (11/2020), transmission of respiratory infections such as COVID-19 occurs through carriage of pathogens via droplets of different sizes produced during sneezing, coughing, singing, normal speech, and even, breathing [1]. Owing to perceptional ambiguities, this study does not insist on any nomenclatural distinction between "droplets" and "aerosols", and refers to all expiratory liquid-base particulates as *droplets*.

For tracking what range of droplet sizes might be more potent for transmission of SARS-CoV-2 (causative agent for COVID-19) and to eventually induce infection, it is key that we identify the initial infection sites. At least two recent studies [2, 3] reveal a striking pattern of relatively high SARS-CoV-2 infectivity in ciliated epithelial cells along the nasal passage lining in the upper airway, moderate infectivity in cells lining the throat and bronchia, and relatively low infectivity in lung cells. Such viral tropism is governed by the abundance of angiotensin-converting enzyme 2 (ACE2), a single-pass type I membrane protein that is exploited by viral spike protein binding as a gateway for cellular entry. ACE2 is abundant on ciliated epithelial cells, but is relatively scarce on the surface of lower airway cells. These findings are however for *in vitro* samples; deposition of virus-laden droplets along the anterior nasal airway might not be as effective at launching an infection despite the presence of ciliated cells, since the mucus layer provides some protection against virus

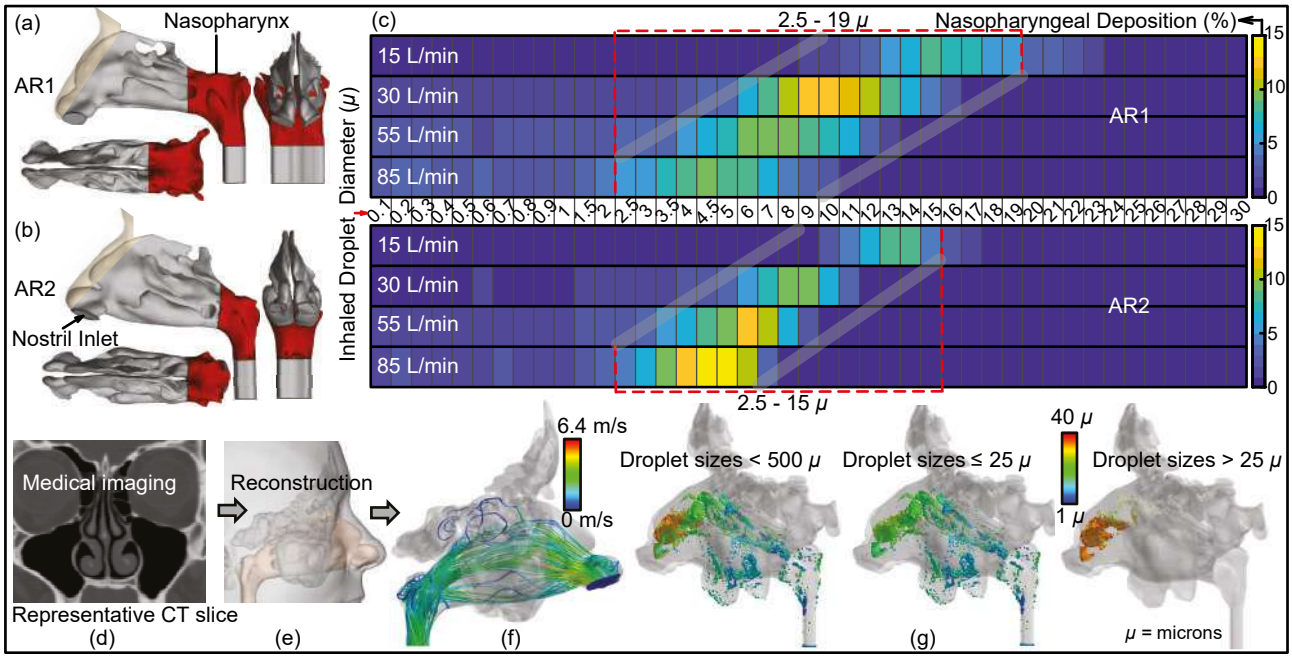

Figure 1: Panels (a)-(b) show sagittal, axial, and coronal views of the CT-based nasal domains, respectively in anatomic reconstruction 1 (AR1) and anatomic reconstruction 2 (AR2). Nasopharynx is marked in red. Panel (c) lays out the heat-maps for computational fluid dynamics (CFD) based inspiratory transmission, showing the percentage of inhaled droplets of each size undergoing nasopharyngeal deposition. Data for different breathing rates are arranged along separate rows. Tracked droplet sizes are along the horizontal axis (positioned between the two heat-maps). Nasopharyngeal landing peaks for droplets sized between 2.5 – 19 μ in AR1 and 2.5 – 15 μ in AR2. The patch bounded by the grey lines can be a definitive graphical technique to delineate the hazardous droplet sizes for various airborne transmissions. Panels (d)-(e) depict *in silico* geometry generation from medical grade scans. Panel (f) shows representative simulated streamlines during inhalation. Panel (g) characterizes intranasal regional deposition trends for sprayed droplets.

*Corresponding author. E-mail: Saikat.Basu@sdstate.edu; saikat_basu@med.unc.edu

invasion and infection. This points to the *nasopharynx* (region in the upper airway posterior to the septum and comprising the superior portion of the pharynx; see Fig. 1, Panels (a)-(b)) as the main *initial* infection site; it acts as the seeding zone for subsequent infection of the lower airway via aspiration of virus-laden nasopharyngeal fluid boluses. So at this point, a valid question to ask is: *what are the dominant inhaled droplet sizes that are making their way to the nasopharynx?*

METHODS

The study resconstructs two *in silico* anatomic geometries of the nasal airway from de-identified computed tomography (CT) scans. Use of the archived and anonymized medical records was approved with exempt status by the Institutional Review Board at the University of North Carolina. Test subjects include a 61 year-old female (subject for anatomic reconstruction 1, or AR1) and a 37 year-old female (subject for anatomic reconstruction 2, or AR2). The reconstructed geometries were meshed spatially into minute volume elements. Conforming with established mesh refinement-based protocols [4], each computational grid contained more than 4 million unstructured, graded tetrahedral elements.

Simulation of inhaled transport

Four different breathing rates were simulated, viz. 15, 30, 55, 85 L/min. The lower rate (i.e. 15 L/min) corresponds to comfortable resting breathing, and follows viscous-laminar steady-state flow physics. At higher flow rates commensurate with forceful breathing, shear layer separation from the tortuous cavity walls generates turbulence. For such flows, the study employs Large Eddy Simulations (LES), with Dynamic Kinetic Energy Subgrid-Scale Model for the small fluctuations. The numerical schemes implemented SIMPLEC pressure-velocity coupling and second-order upwind spatial discretization. On convergence of the airflow simulations, inhaled droplet dynamics were tracked (for each droplet size: 3015 droplets were tracked in AR1, 3000 in AR2) via Lagrangian-based discrete phase inert particle transport simulations.

RESULTS

Hazardous droplet sizes

Overall droplet size range of 2.5 – 19 μ registers the peak (see Fig. 1(c)) in terms of the percentage of droplets of each size that are deposited at the nasopharynx. The findings assume a post-dehydration density of 1.3 g/ml [5] for the respiratory droplets (expelled by the carrier and now being inhaled by the exposed individual). If there is little or no dehydration and as such the ejecta density remains at $\sim$1 g/ml, the hazardous size range for inhaled droplets revises to 3 – 20 μ; since the lighter droplets with lower Stokes numbers can now penetrate further into the intranasal airspace.

What could be COVID-19's infectious dose?

Infectious dose is a fundamental virological measure quantifying the number of virions that can go on to start an infection; the value of which is still not conclusively known for SARS-CoV-2, which is a single-stranded RNA virus. Sputum assessments [6] in hospitalized COVID-19 patients show an averaged viral load of 7×10^6 RNA copies/ml of oral fluid, with the peak load being 2.35×10^9 copies/ml. For the average load, probabilistic analysis shows that the chances for a dehydrated droplet of say 10-μ diameter to carry at least 1 virion is 13.6%. Subsequently, based on the new computations and the earlier reported range of droplet sizes emitted during normal speech [7], for a 5-minute exposure: the number of virions depositing at the susceptible individual's nasopharynx comes out to be 11.

To corollarily derive an *order-of-magnitude* estimate of the SARS-CoV-2 infectious dose, consider the March 2020 Skagit Valley Chorale superspreading incident, where a COVID-19 carrier infected 52 other individuals in a 61-member choir group, over an exposure time of 2.5 hours. The subjects were situated close to each other; which justifies ignoring the effect of spatial ventilation. Consequently, for an average RNA load, the number of virions depositing at a closely-positioned individual's nasopharynx in that duration approximates to $(11/5) \times 2.5 \times 60 \approx 330$. So, ~ 300 can be reckoned as a conservative upper estimate for the infective dose, the order agreeing with preliminary findings from other groups [8].

CONCLUSIONS

The quantitative estimate for the *still-elusive* infectious dose, together with this study's detection of the hazardous inhaled droplet sizes that target the infection-prone nasopharynx, can provide a key resource in COVID-19 mitigation.

WALL-ATTACHED STRUCTURES IN AN ADVERSE PRESSURE GRADIENT TBL

Hyung Jin Sung*[1]
[1] Department of Mechanical Engineering, KAIST, Daejeon 34141, Korea

Summary The three-dimensional clusters of the streamwise velocity fluctuations (u) in turbulent boundary layers (TBLs) are explored from the perspective of the attached-eddy model. We extract the u clusters from the direct numerical simulation data of TBLs subjected to adverse pressure gradient ($\beta = 1.43$). The identified structures are decomposed into attached self-similar, attached non-self-similar, detached self-similar and detached non-self-similar motions with respect to the minimum distance from the wall (y_{min}) and the height (l_y) based on Townsend's attached-eddy hypothesis. The attached structures ($y_{min} \approx 0$) are self-similar and universal in the logarithmic region. The tall attached structures with $l_y = O(\delta)$ are non-self-similar and extended beyond 6δ in the streamwise direction, reminiscent of very-large-scale motions or superstructures.

INTRODUCTION

Townsend (1976) deduced that the energy-containing motions in the logarithmic region of wall-bounded turbulent flows can be understood as a linear superposition of self-similar eddies that are attached to the wall. The sizes of each eddy are proportional to the distance from the wall (y). Townsend's attached-eddy hypothesis predicts the turbulence statistics of the logarithmic region in terms of such structures, i.e., the logarithmic variation in the wall-parallel components of the Reynolds stresses. A typical feature of turbulent boundary layers (TBLs) subjected to adverse pressure gradients (APGs) is the enhancement in the large-scale energy above the logarithmic region. A strong outer peak is observed in the streamwise Reynolds stress, which results from long-wavelength motions in the energy spectra. The large-scale motions (LSMs) with sizes of $O(\delta)$ in the logarithmic region, where δ is the 99% boundary layer thickness, influence the small-scale motions through amplitude modulation and their footprints extend into the near-wall region. Recently, Hwang & Sung (2018) reported that the wall-attached structures of the streamwise velocity fluctuations (u) are self-similar and contribute to the presence of the logarithmic layer in a zero pressure gradient (ZPG) TBL. Therefore, research is required into the application of Townsend's attached-eddy hypothesis to APG TBLs, particularly through analysis of the wall-attached u structures in order to predict the influence on the turbulence statistics of strengthened LSMs. Although many studies of the turbulence statistics of APG TBLs have been performed, sufficient attention has not been paid to wall-attached structures despite their importance.

RESULTS

Identification of wall-attached structures

The coherent structures of u are defined as groups of connected points of $u(\mathbf{x}, t) > \alpha u_{rms}(y)$ and $u(\mathbf{x}, t) < -\alpha u_{rms}(y)$ in instantaneous flow fields, where α is the threshold and u_{rms} is the root mean square of u as a function of y. The percolation diagram for the identified u clusters enables the choice of α (not shown here). The percolation theory describes the statistics of the contiguous nodes in a randomly distributed system. In the present study, we select $\alpha = 1.5$ based on the percolation transition. To detect each u cluster, we use the connectivity of neighboring six-orthogonal grids at a given node in Cartesian coordinates (Moisy & Jiménez 2004). Figure 1(a) shows the number of u clusters per unit wall-parallel area as a function of y_{min} and y_{max}, which are the minimum and maximum distances from the wall. The u structures are divided into two groups: those are observed at $y_{min}^+ \approx 0$ and $y_{min}^+ > 0$, i.e. the wall-attached and wall-detached structures, respectively. Figure 1(b) shows iso-surface of u in an instantaneous flow field of the APG TBL. Two insets show a sample of the attached and detached u structures, respectively. The length scales of an individual cluster are defined as the dimensions of the box circumscribing the object, i.e., l_x, l_y and l_z are its streamwise, wall-normal and spanwise lengths, respectively. The wall-normal height (l_y) of clusters is defined as $l_y = y_{max} - y_{min}$.

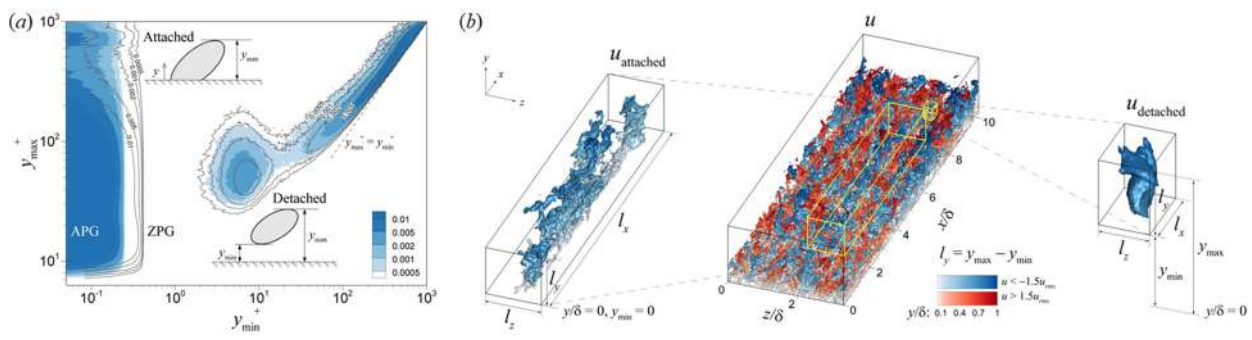

Figure 1. (a) The number of u clusters per unit wall-parallel area with respect to y_{min} and y_{max}. (b) 3D iso-surfaces of u in the APG TBL. Two insets show a sample of the attached and detached u structures, respectively.

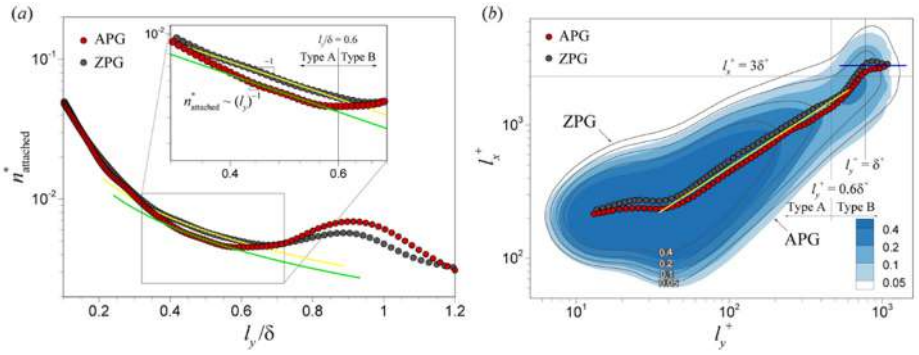
attached structures

e examine the population density ($n_{attached}^*$) of attached u structures with respect to l_y. Here, $n_{attached}^*$ is defined as mber of attached u structures ($n_{attached}$) per unit wall-parallel area with respect to l_y. Figure 2(a) shows the utions of $n_{attached}^*$. There is a region for which $n_{attached}^*$ is inversely proportional to l_y, reminiscent of the hierarchical -scale distribution of attached eddies (Perry & Chong 1982). Beyond the upper limit of the inverse power-law ($l_y/\delta > 0.6$), $n_{attached}^*$ increases and a peak is observed at $l_y/\delta = 0.92$ ($l_y^+ = 710$). This behavior indicates the relative ance of tall attached structures with size δ, which is equivalent to the weighting for the large scales to satisfy the ty-defect law and the presence of low-wavenumber peak in the energy spectra in the model (Perry *et al*. 1986). We compose wall-attached structures into two types based on the height of the attached u structures: i.e., type A ($100 < l_y^+ < 0.6\delta^+$) and type B ($l_y/\delta > 0.6$). Figure 2($b$) shows the joint PDFs of l_x and l_z of the wall-attached u structures with t to l_y. The mean l_x of the type A structures ($100 < l_y^+ < 0.6\delta^+$) scales with l_y, following the power law $l_x \sim l_y^{0.74}$ w solid line). Above $l_y^+ > 0.6\delta^+$, the mean l_x rapidly increases and exhibits a constant value $l_x^+ \approx 3.5\delta^+$ for $l_y^+ > \delta^+$ horizontal line), which indicates that very tall structures (i.e., type B) are non-self-similar ($O(3-6\delta)$).



2. (a) The variation in $n_{attached}^*$ with l_y/δ. The inset shows an enlarged view of the region $l_y/\delta = 0.32-0.72$. (b) Joint PDFs of l_x and l_y. Circles indicate mean lengths. The yellow line in (b) represents $l_x \sim l_y^{0.74}$.

CONCLUSIONS

coherent u clusters have been explored from the perspective of the attached-eddy model. We extract the u clusters by he connectivity of six-orthogonal neighbors in Cartesian coordinates without any assumptions from DNS datasets for $\beta = 1.43$) and ZPG ($\beta = 0$) TBLs with $Re_\tau \approx 800$. The identified structures can be decomposed into attached self-similar, ed non-self-similar, detached self-similar and detached non-self-similar structures with respect to y_{min} and l_y (figure 3). zes of the attached self-similar structures ($100 < l_y^+ < 0.6\delta^+$) scale with l_y, and their population density is inversely tional to l_y in the region $l_y/\delta = 0.4-0.58$. They contribute to the logarithmic variation in the streamwise Reynolds stress the presence of the k_z^{-1} region in the pre-multiplied energy spectra of u. The attached self-similar structures are universal otions in the logarithmic region that are not dependent on the pressure gradient. The attached non-self-similar structures 0.6) are responsible for the enhanced large scales in the outer region in the presence of the APG. Their streamwise sizes $3-6\delta$), and some of them extend over 6δ in the streamwise direction and penetrate deeply into the near-wall region, scent of very-large-scale motions. In addition, wall-detached structures are also decomposed into self-similar and non-nilar ones. We establish new insights into coherent structures in TBLs and the development of the attached-eddy model.

EFFECT OF THE PRESSURE GRADIENT ON NEAR-WALL TURBULENT FLOW AND ITS CONSEQUENCES FOR THE BOUNDARY LAYER AND FOR PERTURBED FLOW OVER UNEVEN TERRAIN

Paolo Luchini *[1]
[1] Department of Industrial Engineering, Università di Salerno, Fisciano, Italy

Summary Our recent results have shown that long-claimed discrepancies between different (Couette versus Poiseuille, or plane versus cylindrical) geometries can be resolved when the velocity profile is suitably interpreted as the superposition of a universal law of the wall common to all geometries and a pressure-gradient depending law of the wake, the latter having a different shape for parallel flow than the one introduced by Coles for the boundary layer. A surprising consequence of these results is that the effect of pressure gradient upon a turbulent velocity profile is opposite in sign to its effect upon a laminar velocity profile. This observation offers an explanation for a) failed past attempts to include the effect of pressure gradient in turbulence models of a boundary layer, and b) the peculiar long-wave behaviour of perturbed flow over uneven terrain.

LAW OF THE WALL AND LAW OF THE WAKE

Despite its widespread adoption in research and in teaching, the classical scaling theory of the logarithmic velocity profile based after Prandtl, von Kármán and Millikan on the distinction between a wall layer and a defect layer, and particularly its universality, has been challenged by multiple discrepancies between this theory and both experiments and numerical simulations. Serious doubts were issued in the literature about the precise form of this law, leading to the formulation of alternate theories and hindering ongoing efforts to measure von Kármán's constant κ. Even among scientists who accept the validity of the logarithmic law

$$u^+ = A \log z^+ + B \tag{1}$$

(where $u^+ = u/u_\tau$, $z^+ = z u_\tau/\nu$, and $u_\tau = \sqrt{\tau_{\text{wall}}/\rho}$), many have surmised that either the additive factor B [1] or both $A = \kappa^{-1}$ and B [2] are not universal and change from one geometry to another.

The formulation of this theory introduced by Coles [3] takes the form of a pair of matched asymptotic expansions (incidentally providing a framework for the inclusion of higher-order terms), the leading order of which describes the mean velocity profile through two functions of one variable, traditionally named law of the wall and law of the wake:

$$u^+ = f(z^+) + G(Z) \tag{2}$$

($Z = z/h = z^+/Re_\tau$ being the normal coordinate in outer units, with h denoting the half-height of the duct and $Re_\tau = u_\tau h/\nu$ the shear-based Reynolds number). Coles proposed that not only the law of the wall $f(z^+)$ but also the law of the wake $G(Z)$ have a universal form, and proposed for the latter an S-shaped curve similar to the mixing layer of a wake, whence its name. It should be noted that the universality of $f(z^+)$ is rooted in theory, whereas the universality of $G(Z)$ is (and was presented as) an empirical observation useful to simplify boundary-layer calculations.

The connection between (1) and (2) is in that the logarithmic law (1) appears as the asymptotic form of $f(z^+)$ for $z^+ \to \infty$; nevertheless it should be clear when trying to extract the log law from (2) that also the behaviour of $G(Z)$ for

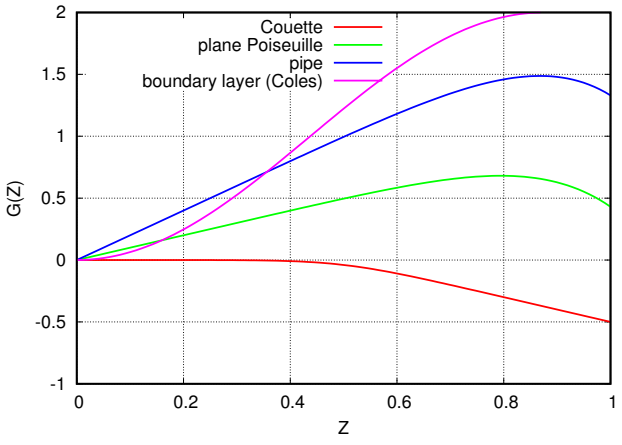

Figure 1: Wake functions of different geometries as extracted in [4].

*Corresponding author. E-mail: luchini@unisa.it.

$Z \to 0$ contributes to the velocity profile in the overlap layer $1 \ll z^+ \ll Re_\tau$. After devising an analytical method to separate $f(z^+)$ from $G(Z)$ by combining velocity profiles obtained in the same geometry at different Reynolds numbers [4], we could show that the law of the wall and the log law are indeed universal (with the same values of both κ and B) across plane Couette and Poiseuille flow and cylindrical pipe flow, but the law of the wake is different in each, and also different from the one determined by Coles for a boundary layer, in the way exhibited in figure 1 (taken from [5]).

In addition, the small-Z behaviour of $G(Z)$ is *linear* and proportional to the pressure gradient, as predicted in [6]:

$$u^+ = \underbrace{\kappa^{-1}\log(z^+) + B}_{f(z^+)} + \underbrace{A_1 g Z}_{G(Z)} \tag{3}$$

with $\kappa = 0.392$, $B = 4.48$, $A_1 = 1$, and $g = -p_x h/\tau_{\text{wall}}$ ($g = 0$ for Couette, 1 for plane Poiseuille, 2 for pipe flow).

THE OPPOSITE EFFECT OF PRESSURE GRADIENT IN LAMINAR AND IN TURBULENT FLOW

According to the above explanation, and also according to direct observation, the effect of pressure gradient pushes the velocity profile of turbulent plane Poiseuille flow upwards and *above* the velocity profile of turbulent plane Couette flow for the same wall shear stress (what you see when plotting both in wall units u^+ vs. z^+). This turbulent behaviour is strikingly opposite to laminar behaviour, where in wall units the velocity profile of Poiseuille flow is everywhere *below* Couette flow, as depicted in Figure 2 taken from [7] for an arbitrarily chosen Reynolds number $Re_\tau = 1000$.

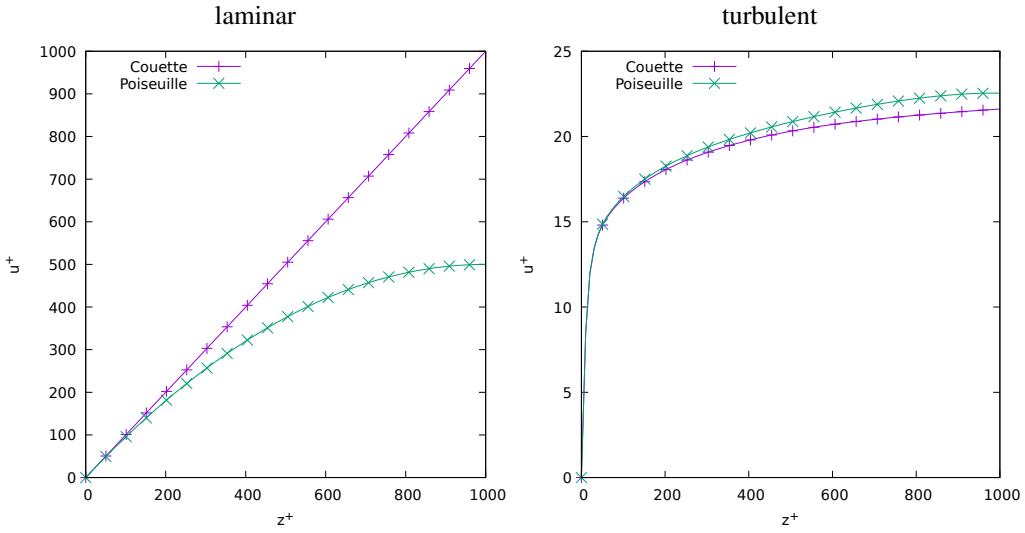

Figure 2: Couette and Poiseuille velocity profiles are oppositely situated in laminar and in turbulent flow.

This opposite effect explains why Johnstone *et al.* [8] found it inappropriate to model the action of pressure gradient upon the turbulent boundary layer as a change of the shear velocity from $u_\tau = \sqrt{\tau_{\text{wall}}/\rho}$ to $u_\tau = \sqrt{\tau(z)/\rho}$, which is in practice equivalent to adopting an eddy viscosity and predicts an effect of the pressure gradient of the same sign as laminar viscosity.

The phenomenon described in [7] is just as well consistent with the peculiar behaviour of perturbed flow over uneven terrain [9] in the large-wavelength regime, which again defeats description through an equivalent viscosity because the sign of the turbulent perturbation is opposite to laminar [10].

Summary The problem of identification and verification of the most important linear stability mechanisms of initial stages of laminar-turbulent transition in three-dimensional (3D) swept-wing boundary layers is discussed based on experimental and theoretical investigations performed, in particular, for real swept airfoil sections. Detailed analysis of all main boundary-layer stability characteristics with respect to the cross-flow (CF) instability modes and 3D Tollmien-Schlichting (TS) instability modes is carried out based on experimental data, as well as on computations within the framework of linear stability theories and the Parabolized Stability Equation (PSE) approach. The possibility of a very good agreement between all main measured and calculated stability characteristics is shown. Role of surface curvature and base-flow non-parallelism is discussed.

INTRODUCTION

Laminar-turbulent transition in 3D boundary-layer flows is of great scientific interest and significant importance for a wide range of technical applications. Its importance for aeronautical application has increased with the need for low-emission aircraft.

In general, there are several flow instability mechanisms which trigger transition in the swept-wing boundary layers, each having their own characteristics as well as sources of the disturbance excitation. The most significant of these instability mechanisms are: (*a*) the attachment-line instability, (*b*) the stationary and non-stationary cross-flow (CF) instability, (*c*) the Tollmien-Schlichting (TS) instability, and (*d*) the instability of separated shear layers that is important in presence of laminar separation zones.

The relative contribution of these modes to the transition process depends on the pressure gradient and the sweep angle. For instance, in case of a favorable, i.e., negative, streamwise pressure gradient (such as on the upper side of a long-laminar-run swept wing installed at a small positive or negative angle of attack) and a sufficiently large sweep angle, one may expect predominance of the stationary and/or traveling CF-instability modes inducing very specific transition scenarios. Meanwhile, in the case of nearly zero chordwise pressure gradients or weak adverse ones, the 3D TS-instability waves may prevail. Although the CF-mode instability of swept-wing boundary layers has been studied intensively for many years, the detailed qualitative agreement between all measured and calculated linear stability characteristics has not been obtained previously for real nonparallel boundary layers developing on curved surfaces of real swept airfoils. This is especially true for non-stationary CF-instability modes. For the 3D TS-instability characteristics of swept-wing boundary layers, the investigations are even rarer. This can be explained by the extreme complexity of accurate quantitative experimental investigations of these problems.

The present paper is devoted to description of the significant advancements in the described field achieved recently. These advancements are related to the CF- and TS-instability mechanisms.

EXPERIMENTAL AND THEORETICAL APPROACHES

The presentation starts with analysis of the problem and with description of recent steps directed towards its solution. In particular the present experimental approach is described. This approach is based on performing measurements in 3D boundary layers developing over a swept airfoil section equipped with specially designed contoured sidewalls helping to provide satisfaction of the sweep condition inherent for an infinite-span wing. In one of studies (called study '*A*'), an adverse chordwise pressure gradient was achieved at a negative angle of attack of the airfoil section. This gradient provided conditions favorable for predominance of the CF-instability mechanism. In another experiment (called study '*B*'), achieved at a positive angle of attack, the chordwise pressure gradient was very weak (close to zero one). The TS-instability mechanism was expected to be predominant in this case. The airfoil section was the same in the two studied cases, while the shapes of the sidewalls were different. The experiments were performed in Stockholm in the low-turbulence wind tunnel MTL of the Royal Institute of Technology (KTH).

All measurements were carried out at fully controlled disturbance conditions with excitation of either several oblique CF- or TS-modes of the frequency-spanwise-wavenumber spectrum or, alternatively, with excitation of spanwise-localized time-periodic wave trains of CF- or TS-instability modes. The excitation was carried out by specially designed disturbance sources representing either spanwise periodic or spanwise localized surface vibrators. The calculations consisted of two important steps: (*i*) the base-flow computations simulating the experimental conditions and (*ii*) the flow instability computations based on either locally-parallel linear stability theory or on the Parabolized Stability Equation (PSE) approach which took into account both the base-flow non-parallelism and the surface curvature. All main measurements were carried out by means of hot-wire anemometry, including two-component ones.

SOME IMPORTANT RESULTS

The experiments have shown that almost all stability characteristics of instability modes, dominated in the boundary layer in cases '*A*' and '*B*', are dramatically different from each other. In particular, this is observed for dependences of amplification rates of modes of the frequency-wavenumber spectrum on the wave propagation angle θ* (Figure 1). The same is true for the spanwise-wavenumber distributions of the instability-mode phase velocities C^*_x calculated in the direction of the potential flow velocity vector at the boundary-layer edge (Figure 2).

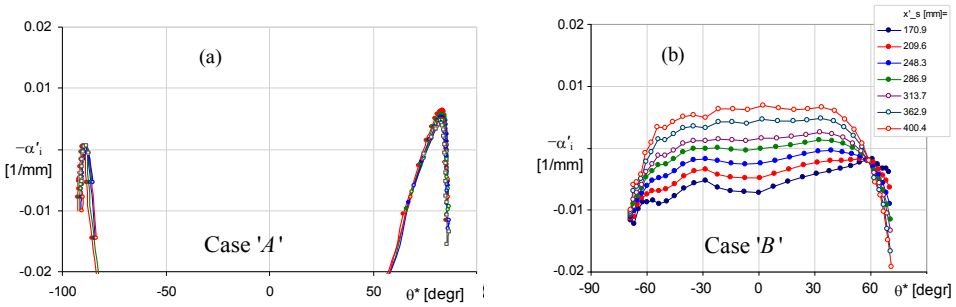

Figure 1. Radical difference of angular dependences of amplification rates of instability modes obtained in experiments '*A*' (*f* = 40 Hz, plot *a*) and '*B*' (*f* = 156 Hz, plot *b*).

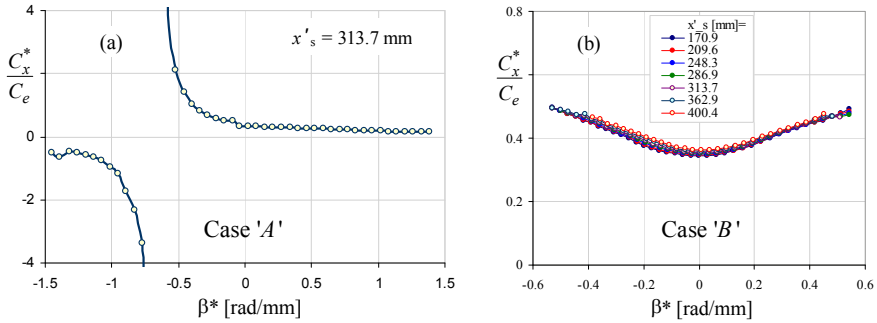

Figure 2. Radical difference of spanwise-wavenumber dependences of phase velocities of instability modes obtained in experiments '*A*' (*f* = 40 Hz, plot *a*) and '*B*' (*f* = 156 Hz, plot *b*).

Comparison of the measured and calculated stability characteristics has shown that in case '*A*' the CF-instability modes are predominant in the flow (see e.g. Figure 3), while in case '*B*' the TS-instability modes dominate.

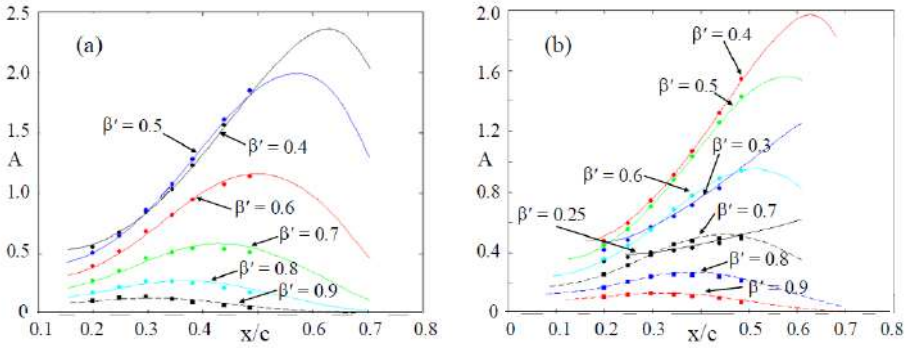

Figure 3. Comparison of measured amplification curves of boundary-layer disturbances, obtained in case '*A*' for frequencies *f* = 60 Hz (*a*) and 40 Hz (*b*), with those calculated for the CF-instability waves.

CONCLUSIONS

The present study resulted in clear identification of two types of the 3D boundary layer instability observed on a swept-wing model at two different angles of attack: (*i*) the CF-modes in case '*A*' and (*ii*) the TS-modes in case '*B*'. Their characteristics have been studied in detail and compared with each other. Very good agreement between all measured and calculated stability characteristics has been achieved, especially when the effects of the base-flow non-parallelism and the surface curvature were taken into account (in the framework of the PSE approach).

INTERACTIONS OF WING TIP VORTEX AND DBD PLASMA ACTUATOR INDUCED FLOWS AND THEIR EFFECT ON THE AERODYNAMIC CHARACTERISTICS

Kozo Fujii *[1], Takumi Abe[1], Takuto Ogawa[1] and Makoto Yamamoto[1]
[1] Faculty of Engineering, Tokyo University of Science, Tokyo Japan

Summary Large eddy simulations (LES) for the flows over a rectangular wing with and without flow control by a dielectric barrier discharge plasma actuator (DBD-PA) are conducted. The DBD-PA is installed near the leading edge and burst mode actuation is applied. Wing tip effect on the flow control authority of the DBD-PA is investigated and efficient electrode length is discussed. The effect is evaluated based on the aerodynamic characteristics of the wing and analysis of the flow structure behind them. The authority of DBD-PA for a two-dimensional airfoil is confirmed to be effective for the low-aspect-ratio wing with the tip especially at post-stall conditions. Effective length of the electrode turns out to be different for the angles of attack higher and below the stall due to the complex interaction of tip vortex, location of the electrode edge and two-dimensional vortices induced by DBD-PA.

Introductions

Control of flow separation over an airfoil has great interest as flow separation is a critical phenomenon for aircraft. DBD-PA which comprises two thin electrodes with a dielectric between them have been shown to be very effective for the control of flow separations over an airfoil [1]. DBD-PA is easily attached to the airfoil or wing surface as shown in Fig. 1. DBD-PA induces weak jet flows (with the maximum speed of a few meters/second in general) in a small region near the wing surface when high alternating current (AC) voltage is imposed. Better control of separated flows was shown when duty cycle is applied (called burst mode) due to the interaction of two-dimensional vortices induced by DBD-PA and separated shear layers. Both the experimental and computational analysis showed that DBD-PA is very effective for flow separation control at the Reynolds numbers of the order 10^4-10^5 [2-6], which is the range of small UAV or recent drone flight. DBD-PA was also shown to be effective for improving aerodynamic characteristics at lower angles of attack [5]. Interestingly, DBD-PA in the burst mode promote transition to turbulent flows at above the stall angle, but delay transition at below the stall angle if proper actuation is used. When applying DBD-PA for better control of aircraft motion, it is necessary to confirm our knowledge for two-dimensional airfoils is applicable since there occurs interaction of wing tip vortices with the induced flows by DBD-PA, which may influence to the aerodynamic characteristics of the wing. The effect of the electrode length and its edge should also be evaluated. The objective of the present study is to find out how flow control authority is influenced by the wing tip. Physical phenomenon behind it is also discussed for better design of DBD-PA.

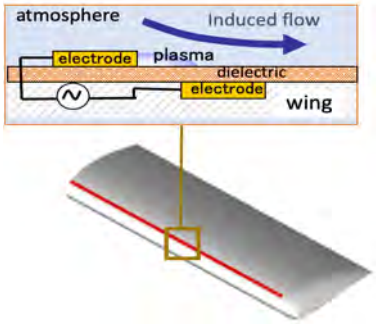

Fig.1 DBD-PA attached to a 3-D wing

Computational model and numerical approach

High fidelity implicit large eddy simulation (iLES) simulations for the flows over a rectangular wing having NACA0015 chordwise section of aspect ratio 2.0 with DBD-PA on and off are conducted under pre- and post-stall flow conditions. The Reynolds number is set to 63,000 ($c = 0.1$ [m] and $u_\infty = 10$ [m/s]), and the angles of attack are set to be 10, 12 and 14 degrees. Electrode of DBD-PA is attached from the root of the wing to 70%, 80%, 90% and 100% span location. An angle of attack of 14 degrees is the case above stall angle, 12 degrees just above stall, 10 degrees just below stall without DBD-PA. Three-dimensional compressible Navier-Stokes equations are solved with an iLES with a sixth-order compact differencing scheme for spatial discretization [2,3]. The body force terms of the DBDPA in the governing equations are those by the unsteady extension of the Suzen and Huang's model, which was validated in the previous studies [4,5]. The overset zonal method is adopted, and the total number of grid points is approximately 300 million. The former studies in the author's group showed the present grid system resolves a near-wall turbulence. The burst mode DBD-PA actuation with non-dimensional frequency of $F^+ = 6.0$ is used with the burst ratio BR to be 0.1. The DBD-PA is installed at 5% chord from the leading edge. Details of the numerical algorithm and the model of the DBD plasma actuator used here can be found in Ref. 6 and will be presented in the final manuscript.

Results and Discussions

Only the limited results are shown in this abstract. Figure 2 shows the spanwise lift-to-drag ratio (L/D) distributions for four different electrode length at angle of attack 14 degrees. Flow becomes totally separated without DBD-PA at this angle of attack. Remarkable increase of L/D is obtained for any case of DBD-PA/ON. If the electrode (therefore, DBD-PA induced flows) covers more than 80% of the span, L/D distributions do not show much difference. The L/D decreased

*Corresponding author. E-mail: fujii@rs.tus.ac.jp

toward the tip. There observed is strange reduction of L/D from 50% to 80% span region for the 70% span electrode. Figure 3 shows the top view of the flow structures over the upper surface of the wing at three different angles of attack for 90% span electrode. At α=14 degrees, two-dimensional spanwise vortices created by the DBD-PA promote turbulent transition and flow becomes attached except a small delay near the wing tip. Although not shown, surface Cp distributions and other information showed that DBD-PA recovers high suction peak near the leading edge by making the separation shear layer attached. Recovery of the suction peak increases the lift and early reattachment of the laminar separation bubble reduced the drag. Near the tip, effective angle of attack becomes lower due to the downwash of the tip vortex, and reattachment is delayed. This delay reduces the lift and increase the drag. This explains gradual decrease of L/D toward the tip, which is very different from what we expect from the typical elliptic lift loading of the square wing without PA. At α=12 and α=10 degrees, there appear two dimensional spanwise vortices in the inner part of the wing. Reference 6 showed that these stationary vortices are the key for drag reduction at angles of attack lower than the stall. At α=12 degrees which is slightly higher than the stall angle, inner part of the wing shows early transition similar to the result for α=14 degrees in Fig. 3(a). On the contrary, two-dimensional vortices stay downstream from 60% span to 90% span. Spanwise vortices covers much wider area at α=10 degrees shown in Fig. 3(c). This occurs because effective angle of attack becomes lower there by the downwash of the tip vortex. In Fig. 3(c), growth of disturbance seems to occur earlier near the tip and it gradually delayed from the tip toward the inner part of the wing. Edge of the electrode located at 90% span seems to be the reason for this region. Also, interaction with downwash of tip vortex would influence this phenomenon. Close-up view of the instantaneous flow structure of 70% span electrode is presented in Fig. 4 to explain the reason for the strange reduction of L/D from 50% to 80% span region in Fig. 2. Compared to 90% span electrode in Fig. 3(a), transition is delayed in this region. Longer laminar separation bubble exists in this region, which increase the drag in this region. Lift in this region decreases as a suction peak also reduces in this region. These explain strange reduction of L/D in this region in Fig. 2.

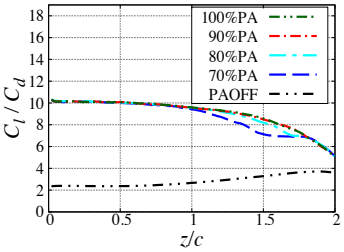

Fig.2 Spanwise *L/D* distributions for different electrode length. α= 14°

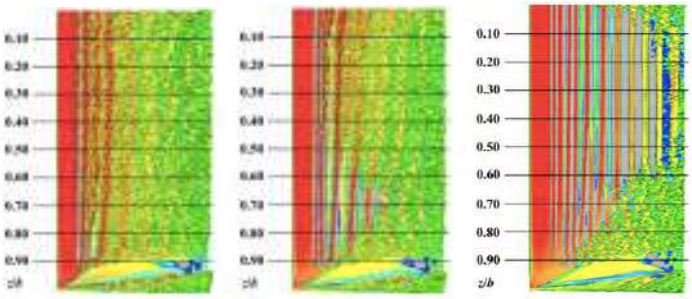

Fig.3 Instantaneous flow structures (Q-contours) at three angles of attack (90% span electrode)

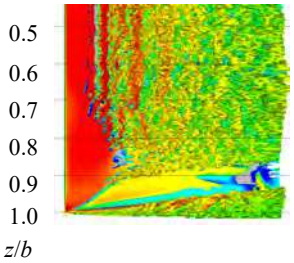

Fig.4 Close-up view of the flow structure at α=14° (70%span electrode)

Although not shown here due to the restriction of space, results for the angle of attack 10 degrees showed that DBD-PA is effective for increasing L/D at low angles of attack. Improvement of L/D for the wing remarkably reduced compared to that of two-dimensional airfoil (from L/D=22.0 to L/D=9.8) and the benefits of DBD-PA was not much. However, analysis of the flow structures indicated that reduction is mainly due to the interaction with wing tip and effect of electrode edge. Therefore, similar benefits should be obtained for a wing having larger aspect ratio.

Conclusion

Large eddy simulations (LES) for the flows over a rectangular wing with and without DBD-PA were conducted. Wing tip effect on the flow control authority of the DBD-PA was investigated and efficient electrode length was discussed. The authority of DBD-PA for two-dimensional airfoils was confirmed to be effective. Effective length of the electrode turned out to be different for angles of attack higher and below the stall due to the complex interaction of tip vortex, location of the electrode edge and two-dimensional vortices induced by DBD-PA.

Currently, additional simulations for a wing with large aspect ratio is underway. They will identify our speculative estimation for low angles of attack above to be confirmed. Also, snapshot POD and DMD analysis will be applied to the tip vortex flow field and flow region near the tip, which hopefully will separate the effect of tip vortex and the electrode edge. These will be included in the final manuscript with more precise discussion of the result shown in this abstract.

EXTENDED WALL-ATTACHED STRUCTURES IN A DRAG-REDUCED FLOW

Min Yoon[1] and Hyung Jin Sung *[1]
[1] Department of Mechanical Engineering, KAIST, Daejeon 34141, Korea

Summary We define extended wall-attached structures in the vicinity of the wall ($y^+ < 100$). The three-dimensional (3-D) coherent structures of streamwise velocity fluctuations (u) in a turbulent channel flow are explored in an effort to assess the extended wall-attached u structures for drag reduction near the Navier slip wall. The mean shear carried by short wall-attached u structures is significantly reduced by the streamwise Navier slip. The number of vortical structures circumscribing the wall-attached structures remain almost unchanged, whereas their strengths are attenuated. The conditional statistics are performed to examine the extended wall-attached structures near the wall. The extended wall-attached structures play a major role in the frictional drag reduction.

INTRODUCTION

Townsend (1976) presupposed that the main energy-containing motions in the logarithmic region are self-similar with respect to their height and attached to the wall. Townsend's attached-eddy hypothesis can predict turbulence statistics through randomly superimposed attached eddies, which is rigorously applied to inviscid flow near the wall for high-Reynolds-number turbulent flow. Perry & Chong (1982) extended Townsend's attached-eddy hypothesis into the model using a hierarchy of self-similar vortex eddies, of which the population density is inversely proportional to the height. Recently, Hwang & Sung (2018) extracted wall-attached structures from the direct numerical simulation (DNS) data of a turbulent boundary layer. They reported that wall-attached u structures contribute to the presence of the logarithmic layer with the inverse power-law distribution and are physically anchored to the wall. Here, u is the streamwise velocity fluctuations. The near-wall turbulence dominantly influenced by the viscosity is closely related to the skin-friction reduction in drag-reduced flows. Hence, it is critical to explore the extended wall-attached structures near the wall ($y < 100\nu/u_\tau$) to explore the mechanism of drag reduction, where ν and u_τ are the kinematic viscosity and the friction velocity, respectively.

RESULTS

Identification of wall-attached structures

In the present study, the DNS data for turbulent channel flows ($Re_\tau \approx 550$) with the Navier and no-slip boundary conditions (Yoon *et al*. 2016) are used. The 3-D u clusters can be defined as groups of connected points satisfying $u(\mathbf{x}, t) > \alpha u_{rms}(y)$ and $u(\mathbf{x}, t) < -\alpha u_{rms}(y)$ in instantaneous flow fields. Here, α is the threshold, which is selected from the percolation diagram. Figure 1(a) represents the percolation diagram for all the identified u clusters. To detect u clusters, we choose $\alpha = 1.6$. Based on this condition, each u cluster can be detected by using the connectivity of six-orthogonal grids at a given node in Cartesian coordinate. Figure 1(b) shows the population density (n^*) of all the identified u clusters as functions of y_{max} and y_{min}, which are the maximum and minimum distances from the wall, respectively. Two distinct groups are observed at $y_{min}^+ \approx 0$ and $y_{min}^+ > 0$, where we classify the former as wall-attached structures and the latter as wall-detached structures (Hwang & Sung 2018). The characteristic lengths of each object can be defined as the box sizes circumscribing that: l_x (streamwise), l_z (spanwise) and l_y (wall-normal; height).

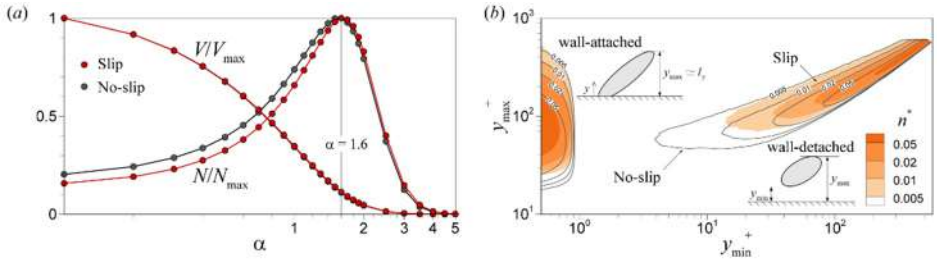

Figure 1. (a) The percolation diagram for the detected u clusters. Variations with α in the total volume (V) and total number (N) of clusters. (b) The number of u clusters per unit wall-parallel area (n^*) with respect to y_{min} and y_{max}.

Self-similarity of wall-attached structures

Figure 2(a) illustrates iso-surfaces of wall-attached structures ($u < 0$; blue, $u > 0$; red) and λ_{ci} clusters (yellow), where λ_{ci} is the swirling strength. For the slip, wall-attached structures are sparsely populated, but the numbers of the surrounding vortical structures per unit wall-attached structure remain unchanged. Figure 2(b,c) represents the joint probability density functions (PDFs) of l_x^+ and l_z^+ of wall-attached u structures with respect to l_y^+. The mean l_x^+ is proportional to l_y^+ with the power of 0.74 in the region of $l_y^+ > 100$, where the linear relationship $l_z \sim l_y$ is observed. As seen in the blue circles in figure 2(b,c), on the contrary, the mean l_x^+ and l_z^+ are not self-similar with l_y^+ in the region of $l_y^+ < 100$ and longer than

*Corresponding author. E-mail: hjsung@kaist.ac.kr

those of the no-slip, representing that the influence of the viscosity on wall-attached structures is dominant in the region of $l_y^+ < 100$ (i.e., $y^+ < 100$). The short wall-attached structures ($l_y^+ < 100$) are called the *extended* wall-attached structures in the present study.

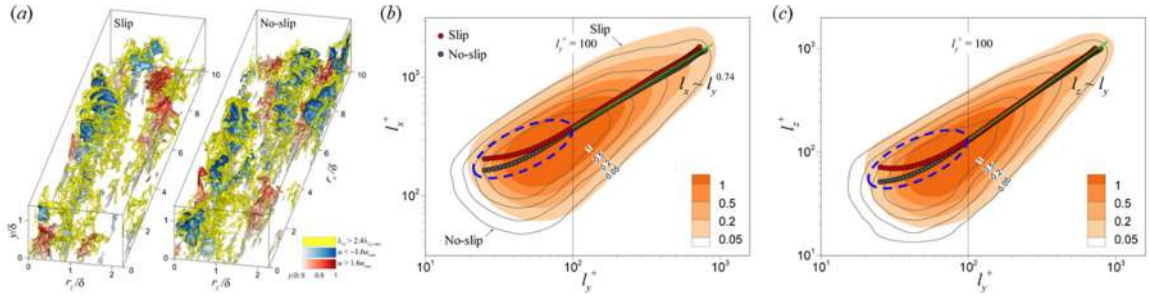

Figure 2. (*a*) 3-D iso-surfaces of λ_{ci} clusters (yellow) around wall-attached structures ($u < 0$; blue, $u > 0$; red) for the slip and no-slip cases. Joint PDFs of (*b*) l_x^+ and l_y^+ and of (*c*) l_z^+ and l_y^+ of wall-attached structures. Circles represent the mean lengths. The green line in (*a*) represents $l_x \sim l_y^{0.74}$ and in (*c*) $l_z^+ = l_y^+$.

Extended wall-attached structures

Figure 3(*a*) displays 3-D iso-surfaces of u carried by the wall-attached u structures in an instantaneous flow flied for the slip. All the wall-attached structures can be divided into the "extended" ($y^+ < 100$) and "self-similar" ($y^+ \geq 100$) (figures 2*b*,*c*). The 3-D iso-surfaces of u of the extended wall-attached structures ($u_{extended}$) below $y^+ = 100$ are illustrated in figure 3(*b*) for the slip and no-slip conditions. The streaks of negative $u_{extended}$ are more extended in the streamwise direction than those of positive $u_{extended}$, and the streamwise length of some structures are over 1δ. For the slip, empty spaces are observed more than those for the no-slip. Next, to examine the contribution of the extended wall-attached structures to the frictional drag, the skin friction (C_f) is decomposed into laminar ($C_{f,1}$) and turbulent ($C_{f,2}$) components using the FIK identity (Fukagata *et al*. 2002). C_f carried by the extended wall-attached structures ($C_{f,2a}$) can be examined through the conditional average. The tall wall-attached structures with the height of $l_y^+ \geq 450$ contribute half of $C_{f,2a}$. In particular, the skin-friction density of the extended wall-attached structures is over three times larger than the magnitude of total C_f over $l_y^+ = 30$.

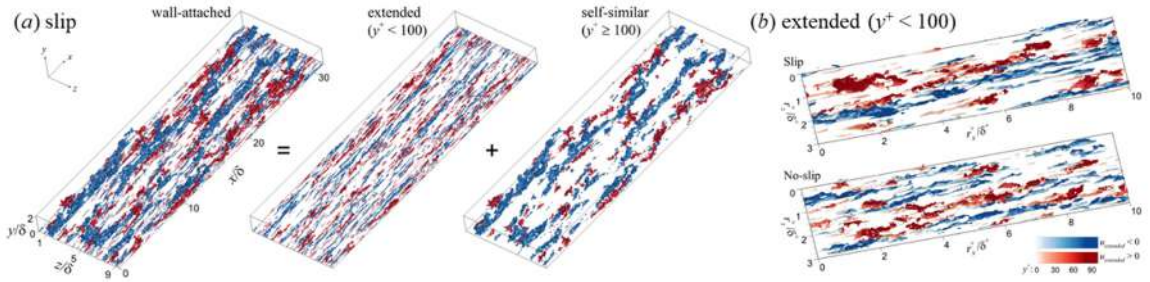

Figure 3. (*a*) 3-D iso-surfaces of wall-attached, extended ($y^+ < 100$) and self-similar ($y^+ \geq 100$) structures for the slip. (*b*) 3-D iso-surfaces of $u_{extended}$ at $y^+ < 100$ for the slip and no-slip cases.

CONCLUSION

We have examined structural features and statistics of extended wall-attached u structures and demonstrated the contributions to the frictional drag. We extract 3-D u clusters by using the connectivity of six-orthogonal neighbors in Cartesian coordinates from the DNS dataset for turbulent channel flows with the Navier slip wall ($Re_\tau = 470$) and no-slip wall ($Re_\tau = 577$) with the same Re_b. The skin-friction density of wall-attached u structures with the height of $l_y^+ = 100$ is approximately nine times of C_f. Moreover, the extended wall-attached u structures with the height above $l_y^+ = 100$ play a major role in the frictional drag reduction near the wall.

ANALYSIS OF INTERSCALE ENERGY TRANSFER IN A BOUNDARY LAYER UNDERGOING BYPASS TRANSITION

Hanxun Yao *[1], Jean-Paul Mollicone[2], and George Papadakis[1]

Summary The Karman-Howarth-Monin-Hill Equation (KHMH) is employed to study the interscale energy transfer in a transitioning boundary layer due to forcing from free-stream turbulence. We consider different streamwise locations that cover the laminar, transitional and turbulent regions. The scale energy flux is presented on the (r_3, Y) plane, where Y is the wall-normal distance and r_3 is the spanwise separation. The results demonstrate how the scale energy is transferred in the physical space (wall-normal direction) and in the scale space, including forward and reverse cascade, during transition.

KARMAN-HOWARTH-MONIN-HILL EQUATION

The Karman-Howarth equation was originally derived for the second-order structure function $\langle \delta q^2 \rangle$ for homogeneous, isotropic turbulent flow [1, 2]. The structure function, $\langle \delta q^2 \rangle = \langle \delta u_i^2 \rangle = \langle (u_i^+ - u_i^-)^2 \rangle$, is defined using the velocity fluctuations, u_i, at two points indicated by $+$ and $-$ in Fig. 1 (left panel), where $\vec{X}$ denotes the mid-point and $\vec{r}$ the separation between the points. $\langle \delta q^2 \rangle$ can be considered as the energy contained in a length scale (eddy) of size $|\vec{r}|$. Hill [3] extended the Karman-Howarth equation to a generalised form that does not assume homogeneity or isotropy. The equation takes the form [4]

$$\frac{\partial \langle \delta q^2 \rangle}{\partial t} + \frac{\partial \boldsymbol{\phi_{s}}_i}{\partial x_i} + \frac{\partial \boldsymbol{\phi_{r}}_i}{\partial r_i} = \mathcal{P} - \epsilon \tag{1}$$

where the vector $\boldsymbol{\phi_{s}}_i = (\phi_x, \phi_y, \phi_z) = \langle U_i^* \delta q^2 \rangle + \langle u_i^* \delta q^2 \rangle + \langle 2 \delta u_i \delta p \rangle - \nu \frac{1}{2} \frac{\partial \langle \delta q^2 \rangle}{\partial x_i}$ is the energy flux in physical space, and the vector $\boldsymbol{\phi_{r}}_i = (\phi_{r1}, \phi_{r2}, \phi_{r3}) = \langle \delta u_i \delta q^2 \rangle + \langle \delta U_i \delta q^2 \rangle - 2\nu \frac{\partial \langle \delta q^2 \rangle}{\partial r_i}$ is the flux in scale space; $\mathcal{P} = -2 \langle \delta u_i \delta u_j \rangle \frac{\partial \delta U_j}{\partial r_i} - \langle (u_i^+ + u_i^-) \delta u_j \rangle \frac{\partial \delta U_j}{\partial r_i}$ is the production term and $\epsilon = 4\nu \left(\langle \frac{\partial \delta u_j}{\partial x_i} \frac{\partial \delta u_j}{\partial x_i} \rangle + \frac{1}{4} \langle \frac{\partial \delta u_j}{\partial r_i} \frac{\partial \delta u_j}{\partial r_i} \rangle \right)$ is the dissipation term.

INDICATIVE RESULTS

The bypass transitional flow field is obtained through DNS; transition is triggered by homogeneous, isotropic free-stream turbulence at the inlet. All the terms of the KHMH equation are calculated at different streamwise locations, shown in Fig. 1 (right panel). Due to lack of space, we present results on the (r_3, Y) plane only and plot the flux vector (ϕ_{r3}, ϕ_y). The normal component of the 6-dimensional flux vector, which does not have a projection on the (r_3, Y) plane, contributes to the net production, as in [5]. We fix $r_1 = 0, r_2 = 0$ and performed spanwise and time averaging.

Turbulent region We first validate our results at the fully turbulent region. The streamwise location is indicated by the black dash line in Fig. 1 (right panel). The flux vector (ϕ_{r3}, ϕ_y) and contours of the net production are shown in Fig. 2 (right panel). The production peak is located at the buffer layer, at $y^+ \approx 16$ or $Y \approx 2L_0$, where $^+$ indicates wall units and L_0 is the Blasius similarity variable at the inlet of the domain. This peak is related to coherent structures near the wall, which contribute to the near-wall regeneration cycle [6]. It is interesting to observe the flux arrows; they originate from the peak of the net source and then point to two sinks, one towards the wall and the other towards small r_3 scales (indicating forward cascade of energy). This behaviour is similar to that observed in channel flow [5]. However, reverse energy cascade (red arrows pointing to larger r_3 scales) can be observed above the energy peak; the flux vector then bends to approach the Y axis ($r_3 = 0$). These so-called spiral-like curves are also found in low-Reynolds number, wall bounded turbulent flows [5].

Laminar region As shown in Fig. 2 (left), the flux in the laminar region (green dashed line in the right panel of figure 1), is similar to the flux in the turbulent region, however, its production peak appears at a higher wall-normal location and at larger spanwise scale. The peak in the laminar region represents the average spacing of the so-called Klebanoff modes [7], which have a spanwise length scale of the order of the boundary layer thickness. Scale energy flux originates from the net production peak then points to different directions, meaning that scale energy is transferred mainly to smaller but also to larger streak sizes. The largest flux appears at the same height as the peak ($y^+ \approx 25$) and points to smaller spanwise scales. The spiral curves found in the turbulent region can not be observed at this location.

Transitional region We calculated the fluxes of Eqn. (1) at seven different streamwise locations, marked as the pink dash lines in Fig. 1 (right panel). From Fig. (3), we can observe how this scale energy transfer evolves from laminar-like to turbulent-like shape. The peak of production moves towards the wall and to smaller r_3. Two dissipation regions are maintained throughout the transition. The boundary layer grows (as indicated by the horizontal dashed line in all

*E-mail: h.yao17@imperial.ac.uk

figures) and energy flows away from the wall and to the small spanwise scales at the height above the production peak ($20 < y^+ < 100$). This indicates that the equilibrium boundary layer is forming gradually during the transition process.

SUPPRESSION OF BOUNDARY-LAYER SEPARATION BY ELEVATED FREE-STREAM VORTICAL DISTURBANCES

Dongdong Xu[1] and XuesongWu *[1,2]
[1] Department of Mechanics, Tianjin University, Tianjin 300072, China
[2] Department of Mathematics, Imperial College London, London SW7 2AZ,UK

Summary In this paper, we investigate the excitation of streaks or Görtler vortices by low-frequency free-stream vortical disturbances (FSVD) in a boundary layer subject to an adverse pressure gradient, and show that vortical disturbances of rather moderate level eliminate the separation which would occur in the absence of FSVD.

INTRODUCTION

A steady boundary layer subject to an adverse pressure gradient usually separates. Experiments found that FSVD of moderate level can reduce the size of the separation bubble, and may even eliminate it [1, 2]. Direct numerical simulations (DNS) showed that streaks in the boundary layer induced by FSVD act to inhibit the separation [3]. However, in DNS the free-stream and inlet disturbances are represented by continuous spectra of the O-S/Squire operators, which are non-physical [4]. Xu, Liu & Wu (2019) [5] presented a theoretical description of how physically realistic FSVD generate streaks or Görtler vortices in a boundary layer that is subject to a pressure gradient but remains attached. That work is now adapted to the case of a strong adverse pressure that would cause separation, and we show that the separation is eliminated by FSVD of moderate intensity.

FORMULATION: INITIAL-BOUNDARY-VALUE PROBLEM

The flow of interest is an incompressible boundary layer that develops over a semi-infinite flat or concave wall. Free-stream turbulence is represented by vortical disturbances superimposed on the incoming stream with velocity U_∞. The flow is described in a curvilinear system $x\hat{\boldsymbol{i}} + y\hat{\boldsymbol{j}} + z\hat{\boldsymbol{k}}$, normalized by Λ, the spanwise integral scale of turbulence. The dimensionless time variable $t = U_\infty t^*/\Lambda$ is introduced. The Reynolds number and Görtler number are defined as

$$R_\Lambda = U_\infty \Lambda/\nu \gg 1, \quad G_\Lambda = R_\Lambda^2 \Lambda/r_0^* \sim O(1). \tag{1}$$

The turbulent Reynolds number is defined as $r_t = \epsilon R_\Lambda \sim O(1)$, where $\epsilon \ll 1$ is a measure of the disturbance intensity. FSVD are assumed to have low frequencies, or long wavelength of $O(\Lambda R_\Lambda)$.

Governing equations Streaks or Görtler vortices induced by FSVD are fully developed in the region corresponding to $\hat{x} \equiv x/R_\Lambda = O(1)$ and $y = O(1)$, where the velocity and pressure, (u^*, v^*, w^*) and p^*, can be written as

$$(u^*, v^*, w^*)/U_\infty = (u, R_\Lambda^{-1} v, R_\Lambda^{-1} w), \quad p^*/(\rho U_\infty^2) = R_\Lambda^{-1}(P_B + R_\Lambda^{-1} p), \tag{2}$$

where P_B is the steady mean pressure. The rescaled velocity $\mathbf{u} \equiv (u, v, w)$ and pressure p are governed by the nonlinear boundary region equations (NBRE) [6],

$$\nabla \cdot \mathbf{u} = 0, \quad \mathbf{u}_{\hat{\tau}} + (\mathbf{u} \cdot \nabla)\mathbf{u} + G_\Lambda u^2 \mathbf{j} = (-P_{B\hat{x}}, -p_y, -p_z) + (\partial_{yy}^2 + \partial_{zz}^2)\mathbf{u}, \tag{3}$$

where $\hat{\tau} = t/R_\Lambda$, and $\mathbf{j}$ is the unit vector in the wall-normal direction.

In the previous work [5], the total flow field is decomposed as a sum of the unperturbed base flow and FSVD induced perturbation. This decomposition becomes inappropriate in the presence of a strong adverse pressure gradient that induces separation because the solution for the former terminates at a Goldstein singularity. In order to avoid this dead end, the flow is decomposed instead as a sum of the steady spanwise-averaged and the unsteady or spanwise-varying components,

$$\{u, v, w, p\} = \{U_B(\hat{x}, y), V_B(\hat{x}, y), W_B(\hat{x}, y), P_B(\hat{x})\} + \{\hat{u}, \hat{v}, \hat{w}, \hat{p}\}\,(\hat{x}, \eta, z, \hat{\tau}). \tag{4}$$

Initial and boundary conditions The oncoming FSVD are distorted by the nonuniform invisicd mean flow. This must be analysed in the outer region corresponding to $x = O(R_\Lambda)$ and $1 \ll y \ll O(a^*/\Lambda)$, where the base flow $(U_B, V_B) \approx (U_e(\hat{x}), -U_e'(\hat{x})y)$, while the disturbance can be written as (Xu, Liu & Wu 2019)

$$\epsilon R_\Lambda \big[(\bar{u}_0, \bar{v}_0, 0, \bar{p}_0)(\hat{x}, \hat{y}, \hat{\tau}) + (\hat{u}_0, \hat{v}_0, \hat{w}_0, \epsilon\hat{p}_1)(\hat{x}, y, z, \hat{\tau}) + \ldots\big], \tag{5}$$

where the far field variable $\hat{y} = y/R_\Lambda$. The terms $\bar{u}_0$, $\bar{v}_0$ and $\bar{p}_0$ represent the two-dimensional part induced by the displacement effect. Substitution of (5) into the N-S equations shows that $\bar{v}_0$ appears in the governing equations of the three-dimensional component $(\hat{u}_0, \hat{v}_0, \hat{w}_0, \hat{p}_1)$, indicating that the latter is also influenced by the viscous displacement effect. The coupling with $\bar{v}_0$ can be removed by the generalized Prandtl transformation (Xu, Liu & Wu 2019),

$$\bar{y} = U_e(\hat{x})y - \hat{\delta}(\hat{x}, \hat{\tau}) \quad \text{with} \quad \hat{\delta}_{\hat{\tau}} + U_e\hat{\delta}_{\hat{x}} = U_e\bar{\delta}_{\hat{x}}(\hat{x}, \hat{\tau}), \tag{6}$$

*Corresponding author. E-mail: x.wu@ic.ac.uk

where $\bar{\delta}$ is the spanwise averaged displacement thickness. In terms of $\bar{y}$, the governing equations for $(\hat{v}_0, \hat{w}_0)$ read

$$U_e\hat{v}_{0\bar{y}} + \hat{w}_{0z} = 0, \quad \mathcal{L}_{\mathcal{N}}\begin{pmatrix}\hat{v}_0\\ \hat{w}_0\end{pmatrix} + \begin{pmatrix}-U_e'\hat{v}_0\\ \hat{w}_0\end{pmatrix} = -\begin{pmatrix}U_e\hat{p}_{1\bar{y}}\\ \hat{p}_{1z}\end{pmatrix}, \tag{7}$$

where $\mathcal{L}_{\mathcal{N}} = \partial_{\hat{\tau}} + U_e\partial_{\hat{x}} + r_t(U_e\hat{v}_0\partial_{\bar{y}} + \hat{w}_0\partial_z) - (U_e^2\partial_{\bar{y}}^2 + \partial_z^2)$. The solution to (7) is obtained and then rewritten in terms of y using (6) to provide the boundary condition for (3).

On the other hand, in the upstream limits of (7) and (3) the respective solutions are obtained to specify the appropriate initial condition (Xu, Liu & Wu 2019).

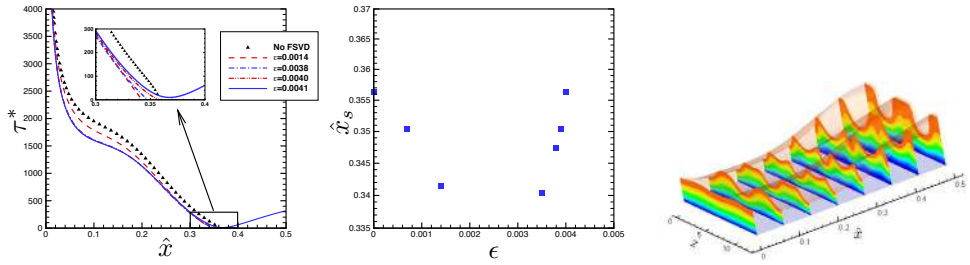

Figure 1: Flat-plate case ($G_\Lambda = 0$). Left: evolution of the minimum skin friction; middle: separation location $\hat{x}_s$ versus ϵ: right: nonlinear evolution of streaks ($\epsilon = 4.9 \times 10^{-3}$).

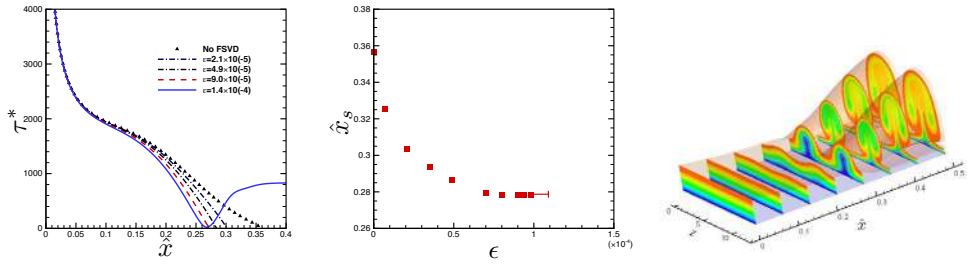

Figure 2: Concave-wall case ($G_\Lambda = 1501$). Left: evolution of the minimum skin friction; middle: separation location $\hat{x}_s$ versus ϵ: right: nonlinear evolution of Görtler vortices ($\epsilon = 1.4 \times 10^{-4}$).

MAIN RESULT: ELIMINATION OF SEPARATION

Calculations were performed for the slip velocity,

$$U_e(\hat{x}) = 1 + d\{\tanh^2[(\hat{x} - \hat{x}_0)\pi/L] - 1\} \text{ with } L = 0.5, \hat{x}_0 = 0.2, d = 0.112, \tag{8}$$

where d and L control the intensity and extent of the adverse pressure gradient respectively. Figure 1 shows the results for the flat-plate case. The boundary layer separates when the FSVD intensity $\epsilon = 0$ or small. As ϵ is increased, the separation first shifts upstream, but with further increase of ϵ, $\hat{x}_s$ increases and eventually approaches infinite when $\epsilon \approx 1.0 \times 10^{-3}$, which is critical intensity ϵ_c to eliminate the separation. The flow becomes attached when $\epsilon \geq \epsilon_c$. Figure 2 shows the results for the concave-wall case. As the FSVD level ϵ is increased, the separation moves upstream monotonically, and then no longer occurs when $\epsilon \geq \epsilon_c \approx 10^{-4}$. This critical intensity is much smaller than that in the flat-plate case, indicating that the centrifugal effect inhibits separation. Further results will be presented at the Congress.

UNSTEADY BOUNDARY-LAYER SEPARATION ON UPSTREAM MOVING WALL

A. I. Ruban *, A. Djehizian, and M. A. Kravtsova
Department of Mathematics, Imperial College London, UK

Summary This paper is concerned with unsteady boundary-layer separation during the stage when the separation point moves along the body surface in the downstream direction. Using the coordinate frame that moves with the separation point, one can reduce the problem to that of a steady flow separating from a wall moving parallel itself in the upstream direction. We assume the flow outside the boundary layer supersonic. First the problem is studied by means of numerical solution of the corresponding triple-deck equations, and then an analytical solution is given using asymptotic analysis. We found, surprisingly enough, that the separation takes place under the action of favourable pressure gradient that might be caused by an impinging Prandtl–Meyer expansion fan. We also found that the separation takes the form of what K. Stewartson termed 'collisional separation'.

PROBLEM FORMULATION

This is a long-standing fundamental problem of high-Reynolds-number flow theory, that attracted significan attention of various authors. The case of downstream moving wall was studied successfully by Vic. V. Sychev (see [1], [2]), with the supersonic version of his theory presented by Ruban *et al.* [3]. However, up to now, the separation on an upstream moving wall remained unresolved. This is, primarily, due to topological difficalties. It is well known that the boundary-layer separation on a motionless wall is identified by the condition of zero skin friction:

$$\left.\frac{\partial u}{\partial y}\right|_{y=0} = 0. \tag{1}$$

Here u is the longitudinal velocity component, and y is the coordinate measured perpendicular to the wall. In the case of downstream moving wall, the separation takes place at the point inside the boundary layer, where

$$u = \frac{\partial u}{\partial y} = 0. \tag{2}$$

In both cases, the velocity u is positive before the separation point. The conditions (1) and (2) identify the position where the flow reversal starts to form in the boundary layer. Contrary to that, for the upstream moving wall, a link between the flow reversal and boundary-layer separation does not exist. Indeed, even in unperturbed boundary layer on upstream moving wall there always exist a region near the wall where u is negative. Keeping this in mind we will identify the separation not by kinematic conditions, like by (1) and (2), but by the dynamic condition, namely, by the singularity in the solution of the governing equations.

To be specific, we consider, as an example, the boundary layer on the surface of a flat plate that is aligned with the oncoming supersonic flow. Our interest is in the incipience of the separation caused by an impinging shock or expansion wave. The later can be produced by an expansion ramp situated above the plate as shown in figure 1. It is convenient to perform the analysis in the coordinate frame that moves with the shock. In this frame the flow may be treated as steady.

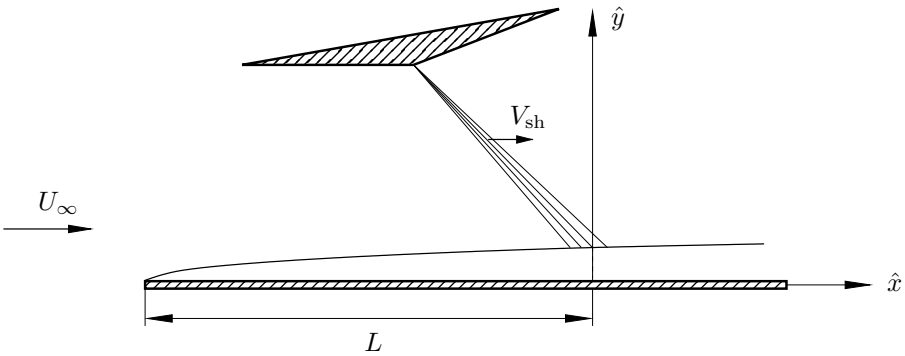

Figure 1: The flow layout.

NUMERICAL STUDY

We first assume that the shock speed $V_{\rm sh}$ is compatible with the triple-deck theory, that is $V_{\rm sh}/V_\infty = O(Re^{-1/8})$, where Re is the Reynolds number. The numerical solution of the triple-deck equations was conducted using the numerical technique described in Kravtsova *et al.* [4]. Both cases of impinging shock and expansion fan were analysed. We did not find any evidence of separation singularity in the case of the shock wave. So the main attention was payed to the boundary layer exposed to an expansion fan.

*Corresponding author. E-mail: a.ruban@imperial.ac.uk

An example of such calculations is displayed in figure 2. Here the wall speed is taken to be $U_w = V_{\rm sh}/V_\infty = -3.0$. We see two eddies forming in the flow; one lies downstream of the impinging expansion fan and the other upstream of the fan. The former was found to grows with U_w, while the latter becomes relatively smaller. This is the behaviour typical of 'collisional separation'.

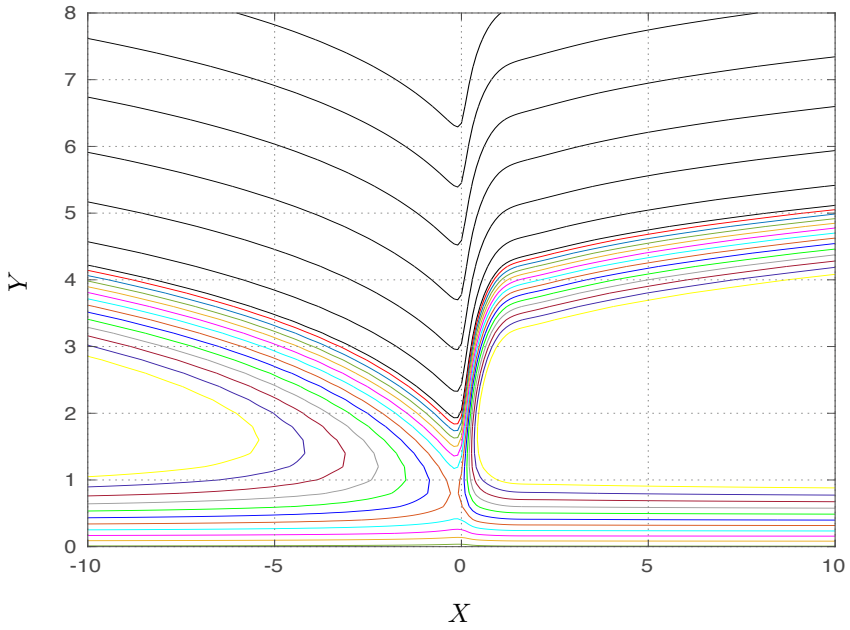

Figure 2: The streamline pattern in the boundary layer exposed to an impinging expansion fan.

THEORETICAL ANALYSIS

The theoretical analysis of the flow was conducted under the assumption that the impinging expansion fan speed satisfied the conditions $1 \ll V_{\rm sh}/V_\infty \ll Re^{-1/8}$. In this case the viscous lower tier of the triple-deck structure splits into the inviscid and viscous layers, and the pressure distribution along the interaction region can be found by analysing the interaction of the inviscid layer with the external supersonic flow. Still, to satisfy the no-slip condition on the body surface, one has to study the flow behaviour in the near-wall viscous later. This can be done analytically. We found that the solution in the viscous layer remains smooth in the case of impinging shock, but develops a singularity when the boundary layer is exposed to the expansion fan. A detailed analysis of the flow behaviour near the singularity shows that a new shorter region should be introduced in the vicinity of the separation point. An integro-differential equation for the pressure $P(X)$

$$\frac{1}{2} = \frac{d}{d\breve{X}}\left[2\int_{\breve{\Psi}_R}^{\breve{\Psi}_M} \frac{d\breve{\Psi}}{\sqrt{2\breve{\Psi} + e^{\chi(\breve{\Psi}+1)} - 2\breve{P}}}\right] + \frac{d\breve{P}}{d\breve{X}}\left[\int_{\breve{\Psi}_M}^{+\infty} \frac{d\breve{\Psi}}{\left[2\breve{\Psi} + e^{\chi(\breve{\Psi}+1)} - 2\breve{P}\right]^{3/2}} + \frac{1}{\sqrt{2\breve{\Psi}_M + e^{\chi(\breve{\Psi}_M+1)} - 2\breve{P}}}\right]$$

was deduced for this new region. Its solution shows that a collisional separation singularity forms in the flow at a finite position $\breve{X} = \breve{X}_0$ on the body surface, with the pressure behaving as

$$\breve{P} = \frac{\Lambda}{(\breve{X} - \breve{X}_0)^2} + \cdots \quad \text{as} \quad \breve{X} \to \breve{X}_0.$$

Conclusions

Thus we have established that (i) for the boundary layer to separate on an upstream moving wall, it should be exposed to a favourable pressure gradient, and (ii) the separation assumes the form of what was termed by K. Stewartson the 'collisional' separation.

VORTICAL STRUCTURES IN RELAMINARIZING BOUNDARY LAYERS

O. N. Ramesh*[1], Saurabh S. Patwardhan [2]
[1] Department of Aerospace Engineering, Indian Institute of Science, Bangalore, India
[2] Ansys India Pvt. Ltd, Pune, India

Summary In this work, we look at the evolution of vortical structures in relaminarizing turbulent boundary layers (TBL). A direct numerical simulation of relaminarizing TBL due to a favourable pressure gradient is carried out. Vortical structures are visualized using the λ_2 method proposed by Jeong and Hussain (1995). Two-point correlations of velocity and the near-wall streak structures are investigated. The weakened large-scale near-wall structures in a relaminarizing TBL progressively lean towards the wall. This is consistent with study of Dixit and Ramesh (2010) where a systematic decrease in the structure angle with FPG was observed. A new mechanism of stability of near-wall streaks in relaminarizing flows due to the kinematic action of wallward vertical velocity is proposed. A similar mechanism may also be operative during relaminarization due to strong suction.

NEAR-WALL COHERENT VORTEX STRUCTURES IN RELAMINARIZING FLOW

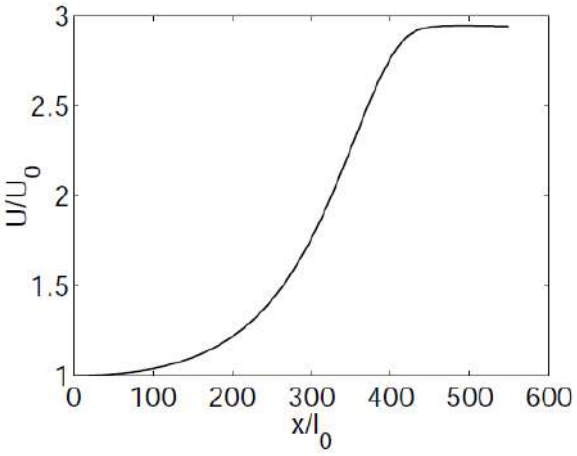

Figure 1 (a) Streamwise variation of U_∞

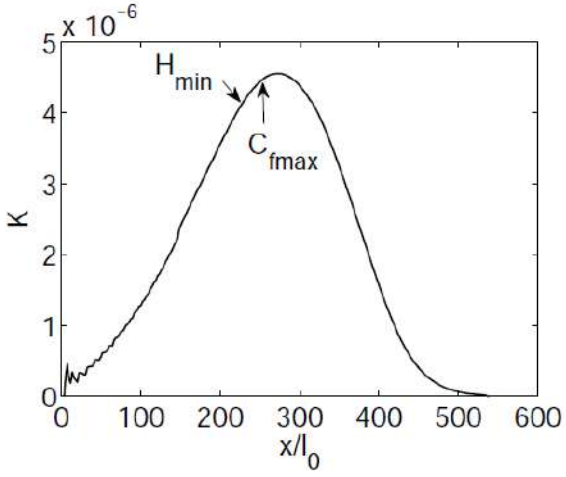

Figure 1 (b) Streamwise variation of K

In the present work, relaminarization of a zero pressure turbulent boundary layer at a Reynolds number of $\mathrm{Re}_\theta = 1000$ turbulent boundary layer, due to an imposed streamwise acceleration is investigated. This is a combined experimental and DNS study but presently only the computational results are presented. Details of the DNS study by a finite difference code and its validation by experiments will be discussed during the oral presentation and will not be presented here for brevity. Figure 1(a) shows the acceleration of the freestream velocity and the streamwise variation of the freestream acceleration parameter $K = \frac{\nu}{U_\infty^2}\frac{dU_\infty}{dx}$ is shown in figure 1(b). Studies in the literature (Narasimha and Sreenivasan 1973) have suggested the onset of relaminarization can be inferred to be either the location where the skin friction coefficient reaches a maximum or the shape factor reaches a minimum value. Both these locations are indicated in figure 1 (b) by arrows and they are seen to be very nearly the same; the relaminarization onset location can be taken to be $x/l_0 \approx 250$, where l_0 is a reference length scale. Figure 2 shows the visualisation of near-wall vortex structures in the initial turbulent region (fig. 2(a)) relaminarizing flow (fig. 2(b)) and the final retransition back to turbulence where streamwise acceleration (and K=0) (figure 2(c)). The vortex identification is based on the method proposed by Jeong & Hussain (1995). The value of λ_2 is -0.02 and is kept constant for the visualisation purpose at all locations. The vortex structures before the occurrence of relaminarization (fig. 2(a)) populate most of the boundary layer. The near-wall geometry is quasi-streamwise. As the pressure gradient increases, the vortices become fewer and the angle of inclination to the wall decreases (fig. 2(b)). This is expected as the favourable pressure gradient (FPG) stretches the streamwise vortex which increases the length of the vortex. After the pressure gradient is relaxed the flow retransitions. Figure 2(c) shows the retransitional structures which contain hairpin like vortices.

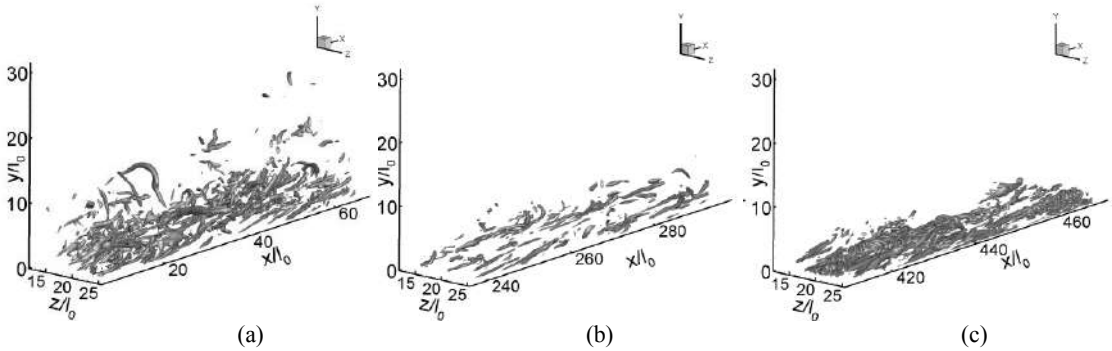

Figure 2. Near-wall vortex structures in relaminarizing flow

STREAK STABILISATION IN RELAMINARIZING BOUNDARY LAYER

The inner layer is known to play an important role in the process of relaminarization as it acts as a slip-boundary for the "Euler-like" outer region (Narasimha & Sreenivasan, 1973). Even though, the Reynolds shear stress is still relevant to the dynamics of the flow in the relaminarizing zone only in the inner layer, the turbulent intensity there decreases when scaled in inner as well as outer co-ordinates. We suggest that this occurs due to the stabilisation of lifted streaks in the near-wall region of the boundary layer. The decrease in the height of the crest along with the increased spanwise spacing of the streak results in a reduction of the streak flank angle. Figures 3(a) and 3(b) show a visualisation of the near-wall streaks in the relaminarizing flow. Figure 3(a) shows the streak view in the zone where the FPG is weak and figure 3(b) shows the streak view in the relaminarizing zone in the wall normal-spanwise plane (y–z plane). An important parameter which determines the stability of lifted streaks is the streak flank angle (Schoppa & Hussain, 2002). The streak flank angle is also a measure of wall-normal vorticity as $\omega_y = du/dz$. It was shown that larger the flank angle greater is the instability of the streak (Schoppa & Hussain, 2002). It is clear from the figures that the streak flank angle has decreased in the relaminarizing zone consistent with that expectation.

We believe the present study is crucial to understanding the near-wall structure of turbulent boundary layers – it is based on the expectation that one can understand the origin and cause of a structure better if we understand the condition under which such structures die out.

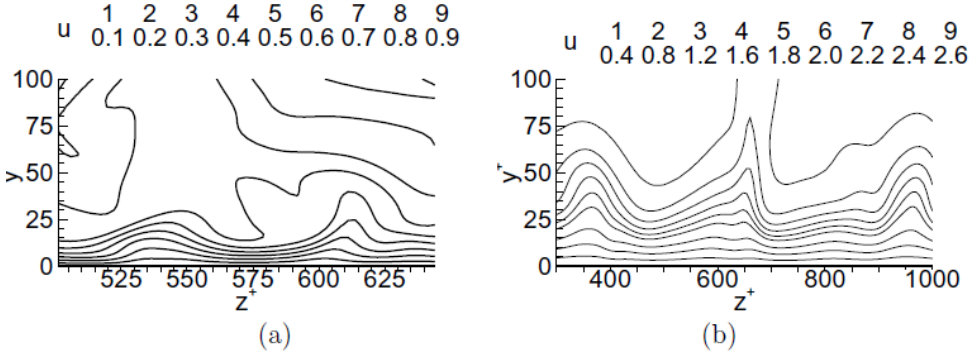

Figure 3. Near-wall streaks in relaminarizing flow

CONCLUSIONS

Near-wall vortex structures in relaminarizing flow become longer in the streamwise direction as the favourable pressure gradient increases. The angle made by the structures to the wall decreases. The structures become less populated in the near-wall region as relaminarization starts. Near-wall low speed streaks become longer and quieter. The spanwise spacing between the streaks also increases. A smaller flank angle of the lifted streaks in the relaminarizing zone results in the stability of these lifted streaks which in turn decreases the near-wall turbulent production. A decrease in turbulent production causes lower turbulent intensities. Strong wallward mean velocity appears to be the chief cause of the stability of lifted streaks. We believe that similar mechanism is prevalent in relaminarization caused due to intense wall suction.

Summary The influence of high-temperature effects on compressible wall-bounded turbulence is investigated by means of a direct numerical simulation of a hypersonic, chemically out-of-equilibrium, turbulent boundary layer. The analysis aims at assessing the effects of chemical reactions on turbulence, also by comparing the results with those of a frozen flow. We will present a detailed analysis of the turbulent statistics and near-wall dynamics; the validity of some classical scalings and Reynolds analogy will also be discussed.

The investigation of turbulent hypersonic flows is a major subject for a wide range of applications, including reentry vehicles, spatial tourism or trans-atmospheric flights. The high temperatures reached in these regimes can cause chemical reactions (with characteristic times similar to those of the fluid motion), giving rise to a nonequilibrium chemical state. Such high-temperature effects have a strong impact on aerodynamic performance and heat transfer rates, but may also affect transition and turbulence dynamics [1].
In this work, we investigate the influence of finite-rate chemistry on compressible wall-bounded turbulence. More specifically, we carry out the direct numerical simulation of a hypersonic, chemically out-of-equilibrium, turbulent boundary layer, encompassing the laminar-to-turbulent transition, triggered by means of a suction-and-blowing forcing at the wall. The analysis aims at assessing the effects of chemical reactions on turbulence, also by comparing the results with those of a frozen flow (i.e. a flow with chemical reaction times much longer than the flow scales).
Flows under investigation are governed by the compressible Navier–Stokes equations for multicomponent chemically-reacting gases. Concerning the chemical modeling, the five-species (N_2, O_2, NO, O, N) model of Park [2] is considered. Thermodynamic quantities are determined using the contributions of the translational, rotational and vibrational modes of each species, whereas transport properties are computed by means of Blottner's model and Eucken's formula [3]. Finally, mass diffusion pheomenon is modeled following Hirschfelder's approximation [4].
The simulations are carried out by means of an in-house CFD code. The code is equipped with high-order finite-difference schemes (tenth order for convective fluxes and fourth order for viscous ones) and selective standard filters, supplemented with the Localized Artificial Diffusivity (LAD) method for shock capturing [5]; this technique consists in adding artificial transport properties to the physical ones, in order to smooth out discontinuities and/or strong unresolved dynamic, thermal and mass gradients. The time integration is carried out by means of a low-storage, explicit third-order Runge–Kutta algorithm. The direct numerical simulation strategy has been preliminary validated against literature results for two single-species boundary layer configurations at $M_\infty = 6$ [6] and $M_\infty = 2.25$ [7], whereas the chemical non-equilibrium model has been assessed against the configurations described in [8], [9] and [10].
The proposed work is carried out in the free-stream conditions of [10], representing a reference state widely used for stability studies; specifically, M_∞=10, T_∞=350 K, p_∞=3596 Pa and $T_w \approx 5400$ K. A computational grid of $\approx 3.2 \times 10^8$ points is considered, which ensures a good spatial resolution in all directions, i.e. $\Delta x^+ = 3$, $\Delta y_w^+ = 0.6$ and $\Delta z^+ = 2$, being x, y and z the streamwise, wall-normal and spanwise directions respectively. An instantaneous visualization of the chemically out-of-equilibrium simulation is shown in figure 1; the oxygen mass fraction varies of one order of magnitude, from the wall (where the temperature is the highest and the oxygen is highly dissociated) to the edge of the boundary layer, where it reaches the free-stream conditions.
Some quantitative results are reported in figure 2. The trend of the skin friction coefficient $C_f = 2\tau_w/(\rho_e U_e^2)$ is shown in figure 2(a): finite-reate chemistry little affects the skin friction distribution in the laminar and fully turbulent regions. Significant discrepancies are observed in the transition region, albeit the qualitative trends are close-by. This result is mainly due to the varying mixture composition in the chemically-reacting case. The root mean square values of the temperature are shown in figure 2(b). The results for the chemically-reacting simulation present lower values of temperature fluctuations; this is due to the endothermic nature of the reactions, which subtract energy from the system. Figure 2(c) presents the root mean square values of the mass fractions, for the chemically-reacting simulation. The strongest chemical activity is concentrated at the wall, where the temperature is the highest; however, the peaks of the fluctuations are shifted away from the wall and their position corresponds to the largest temperature fluctuations. The curves are plotted with respect to $y^+ = y\rho_w u_\tau/\mu_w$, at $Re_\tau = 180$.
In the final study, we will present a detailed analysis of first- and second- order statistics and near-wall dynamics. The validity of classical Reynolds analogy will be assessed and a skin friction decomposition will also be discussed.

MANIPULATION OF WALL BOUNDED FLOWS WITH DENTICLES INSPIRED BY SHARK SKIN

Shane Nicholas*, Mohammed Omidyeganeh and Alfredo Pinelli
Department of Mechanical and Aeronautical Engineering, City, University of London. London, UK

Summary We have used Direct Numerical Simulation to analyse a pressure driven incompressible open channel turbulent flow bounded by a textured surface inspired by shark-skin-like denticles. The texture is obtained by combining a set of solid elements made out of a stem and a crown which are mounted uniformly on a solid wall. The resulting surface can be considered to be a realisation of an anisotropic porous wall allowing for differential wall-normal and wall-parallel permeability recently envisaged as a potential mean for skin friction drag reduction by a number of authors [1, 2]. The preliminary results show a non-trivial superposition of outer large-scale structures with others generated by the drag and the transpiration induced by the particular morphology of the canopy covering the wall.

INTRODUCTION

Viscous flows over surfaces covered with textured layers are ubiquitous in nature. In the last decades, many researches have dedicated their efforts in unveiling how these biological surfaces interact with fluid flows to deliver enhanced locomotion performances in terms of drag reduction and/or improved manoeuvrability. In particular, the great white shark capability of swimming at remarkable speed (almost 60 km/h) has motivated a number of experimental and numerical investigations focused on the eventual hydrodynamic advantages offered by the particular morphology of the skin of this large fish which is characterised by the presence of a dermal/tooth like structures acting as a permeable substrate. In particular, the whole skin is covered by denticle elements that can be modelled as the combination of three main geometrical features. A *stem* anchored to the impermeable surface of the skin holds on its tip a *crown* oriented in the streamwise direction (i.e. swimming direction). The crown also presents a series of *ridges* on its top. These striations of the crown have sparked the interest of many researches that inspired by these grooves have shown that the use of streamwise oriented roughness can effectively reduce the skin friction drag. In particular, the focus of the vast majority of the research has been focused on flat surfaces covered with riblets having a small protrusion height of few wall units ($y^+<15$) aligned in the streamwise direction of the flow that effectively act as an anisotropic roughness imposed on an impermeable wall. The experimental work of Berchert *et al.* [3], the theoretical analysis of Luchini et al. [4] and the numerical simulations of Choi *et al.* [5] are probably the most representative investigations striving to identify the physical mechanisms that promotes drag reduction and its breakdown for large values of the protrusion height. Indeed, the overall drag reduction produced by riblets is limited to a maximum of 10% with a non dimensionless riblet peak to peak spacing of about s^+=12-16. This maximum value of drag reduction attainable with a relatively simple streamwise oriented roughness is limited by the appearance of a linear instability that lead to the appearance of spanwise vorticity rollers also observed in other contexts when the value of the wall normal permeability is relaxed [6]. However, by assessing in detail the dermal structure of the skin of a smooth dogfish shark (*Mustelus canis*) using micro CT scans and gel-based surface profilometry methods, Ankhleyi *et al* [7] reported that the shark skin is fully covered with denticles that varied in size, shape, spacing, crown angle and presence/absence of ridges depending of the analysed portion of the body. However, while the presence of the stem and crown combination was a common characteristic that was observed throughout the whole shark skin, the ridges on the crowns were absent in its upstream portion of the body becoming a quite prominent feature in the rear part. This presence and absence of ridges led to the conjecture that the morphology of skin plays different hydrodynamic roles in different portions of the body, not only providing for a skin friction drag reduction mechanism. Recently, Bocanegra Evansa *et al* [8] conducted an experimental investigation looking at the possible role of the denticles on the control of boundary layer separation. Their observations confirmed that *ridgeless* denticles provide for a mitigation of the recirculation bubble in an adverse gradient turbulent boundary layer. On the other hand, Rosti *et al* [1] conducted numerical investigations on turbulent flows bounded by an anisotropic porous medium finding that the combination of vertical and in-plane permeability can potentially overcome the drag reduction limit of standard ribbletted surfaces. Similarly, more recently Gomez-de-Segura *et al* [2] conducted a stability analysis of turbulent flows over anisotropic porous walls, reporting that the formation of large spanwise roller which are due to a Kelvin Helmholtz like instability in standard ribbletted wall can be palliated enhancing the streamwise permeability as compared to the wall-normal one. The current study aims to explore the manipulation of turbulent wall bounded flows produced by the presence of denticles and the influence of their geometrical parameters on such manipulation in terms of either increase of local Reynolds stresses (i.e. separation control) or mitigation of skin friction drag.

PROBLEM FOMULATION

The current study has been carried out via a Direct Numerical Simulation approach using an in house developed incompressible Navier-Stokes Solver (SUSA). The governing equations are space discretised with a second order accurate, cell centred finite volume approach, while the time advancement is accomplished with a semi implicit, second order pressure correction scheme. The Poisson equation which enforces the continuity is solved directly with a fast solver exploiting FFTs in the periodic streamwise and spanwise directions. The MPI library is used in the framework of a domain

* Corresponding author. E-mail: shane.nicholas@city.ac.uk

decomposition approach to take advantage of parallel, memory distributed computer architectures. More information on the extensive validation campaign of the solver can be found in [10]. The denticles, which idealised model is shown at the bottom of figure 1, are modelled with the aid of a simplified Immersed Boundary method based on a Volume of Fluid (VOF) approach. In the current study, we have employed a denticle distribution of 32x16 in the streamwise and spanwise directions respectively, with an aligned arrangement which is reminiscent of the shark skin. Each denticle is fully resolved within the accuracy provided by the VOF formulation.

PRELIMINARY RESULTS

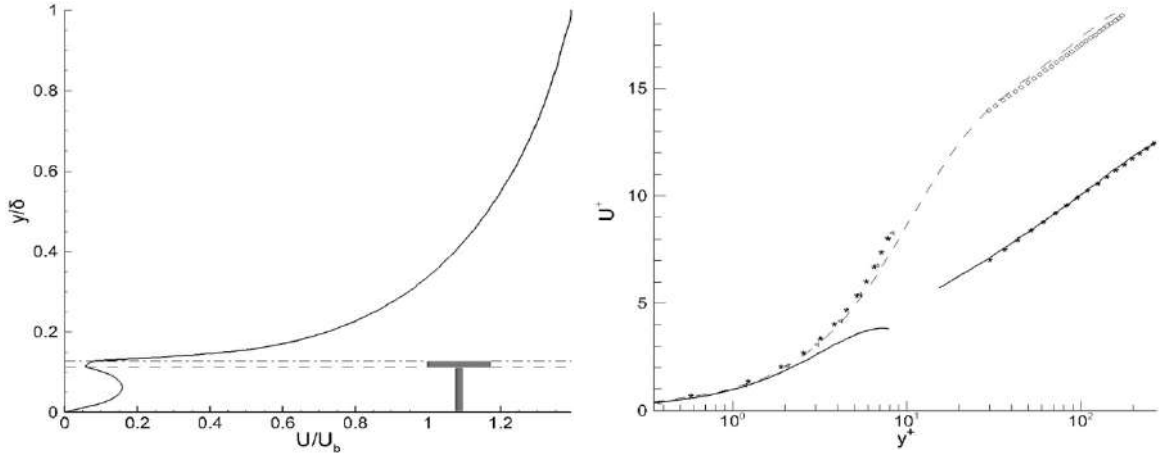

Figure 1. Mean velocity profile. On the left, the dashed line represent the position of the denticle crown. On the right, the dotted lines represent the logarithmic law whereas the dashed line represents, the canonical velocity profile of a channel flow at a nominal friction Reynolds number of $Re_\tau = 180$.

By inspecting the figure on the left showing the distribution of the mean velocity profile for denticles with spacing (s^+=13.6) distributed on the wall of an open channel with a nominal friction Reynolds number of $Re_\tau = 180$, it can be observed that there are three distinct flow regions, an outer layer which reminiscent of a canonical open channel turbulent flow, an inner shear layer that is formed underneath the denticle crown and a the wall layer in proximity of the zero velocity bottom surface. The outer flow continuously experiences an alternating boundary condition at the crown due to the transpiration that occurs by the voids between the adjacent denticles. The velocity profile formed in the inner layer bounded by the impermeable wall and the underside of the denticle crown is analogous to a parabolic function that characterises a laminar/transitional channel flow profile with a moving wall (i.e. a Poiseuille/Couette flow). Furthermore, the blocking effect of the denticle crown can clearly be evinced by the concavity of the inner profile. The overall shape of the mean profile resembles the one reported by Rosti *et al* [1] which could result in a drag reducing configuration. The figure on the right represents the mean velocity profile scaled by the inner and outer wall units. The outer flow was scaled by a friction velocity computed at the virtual origin. The latter can be interpreted as the location of the wall seen by the outer flow that can be deduced by inspection of the figure on the left side and can be explicitly determined to lay almost at the top of the denticle crown. The discontinuity of the profile is due to the second inner layer that is formed underneath the denticle crown with the complete modulation of the buffer layer dynamics.

CONCLUSIONS

To the authors knowledge the current investigation is the first attempt to produce a high-fidelity simulation of shark denticles from a viewpoint of a porous layer. Preliminary results have shed light on the various flow regimes. A complete discussion on the higher order statistics and pre-multiplied spectrum are presently ongoing and will be presented in the full paper. We would like to thank UKTC and EPSRC for providing computer time on Tier 2 CSD3, Cambridge.

EFFECTS OF TWIN BOUNDARY ORIENTATION ON PLASTICITY OF BICRYSTALLINE COPPER MICROPILLARS: A DISCRETE DISLOCATION DYNAMICS SIMULATION STUDY [1]

DeAn Wei[1], Haidong Fan[2], Michael Zaiser[3], Guozheng Kang[1], Qianhua Kan[1], Xu Zhang *[1]

[2] Department of Mechanics, Sichuan University, Chengdu, China
[3] Institute of Materials Simulation WW8, FAU University of Erlangen-Nuremberg, Fürth, Germany

Summary Twin boundaries (TBs) constitute a special type of symmetric grain boundary (GB). TBs influence plastic deformation in a complex manner. In the present work, we propose a model for dislocation-TB interactions in the framework of discrete dislocation dynamics (DDD) simulations, which we use to investigate the mechanical properties of bicrystalline copper micropillars containing a TB. We systematically investigate how the compressive response depends on the orientation of the TB with respect to the micropillar cross-section. The simulations show significant strengthening effects for TB orientation angles less than 45º, where the interaction between mixed dislocations and TBs plays an important role. For angles larger than 45º, the interaction between screw dislocations and TB dominates, leading to weak strengthening. At 45º, dislocations on the dominant slip systems glide parallel to the TB and no strengthening is observed.

COMPUTATION MODEL AND DISLOCATION-TB INTERACTION MODEL

The simulated samples are bicrystalline micropillars in a form of rectangular hexahedra of size $750 \times 750 \times 1500 nm^3$. The orientations of the matrix and twin are shown by Thompson tetrahedra in Figure 1(a). The TB has an angle θ with respect to the micropillar cross-section; it is rotated about the direction $\mathbf{A^IB^I}$ ($\mathbf{B^IIA^II}$) which is aligned with the specimen *X*-axis. Three typical dislocation-TB interaction mechanisms obtained from molecular dynamics simulations [2] were introduced in DDD frame work Paradis [3] as shown in Fig. 1(b-e).

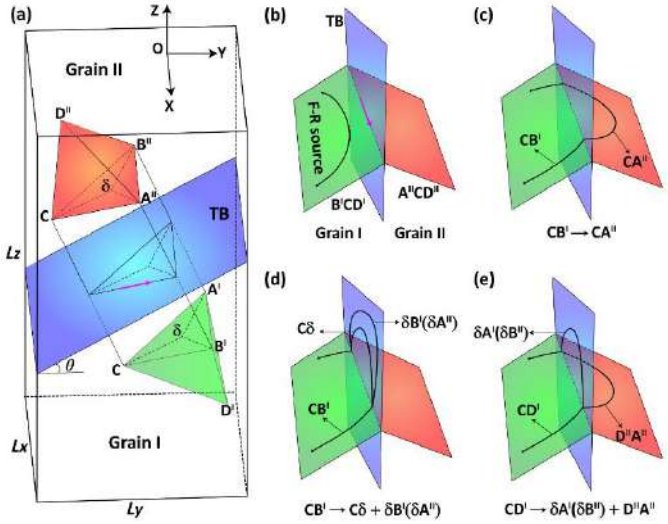

Figure 1. (a) A bicrystalline micropillar loaded along the Z-axis contains a TB. Schematic illustration of a dislocation approaching the TB. (c) Scenario 1: screw dislocation transmission through TB. (d) Scenario 2: screw dislocation absorption by TB. (e) Scenario 3: mixed dislocation penetration through TB.

MECHANICAL BEHAVIOURS

The overall stress-strain curves compiled in Fig 2(a) depends on TB angle. At angles from 0º to 15º, significant hardening is observed. As shown in Fig. 2(a), the yield stress is highest for θ= 0º. As the TB angle increases, the strength decreases and reaches a minimum at angles around 60º. Then the strength increases again as the orientation angle further increases. These findings, which are compiled in Fig. 2 (b), agree well with experimental results [4]. We can see that the yield stresses of the single crystals exhibit a similar trend as the bicrystal yield stress, which first decreases remarkably then increases. In addition, for orientation angles smaller than 45º the yield stress of the bicrystal is higher than that of the corresponding single crystals, indicating that the TB has a strengthening effect. For orientation angles larger than 45º, the bicrystals have comparable strength to the single crystals and their strength is intermediate between the two corresponding single-crystals, suggesting a weak hardening effect.

TB MICROSTRUCTURE EVOLUTIONS

Typical dislocation configurations are shown in Fig. 4. At $\theta = 0°$, mixed dislocations of multiple slip systems entangle

*Corresponding author. E-mail: xzhang@swjtu.edu.cn

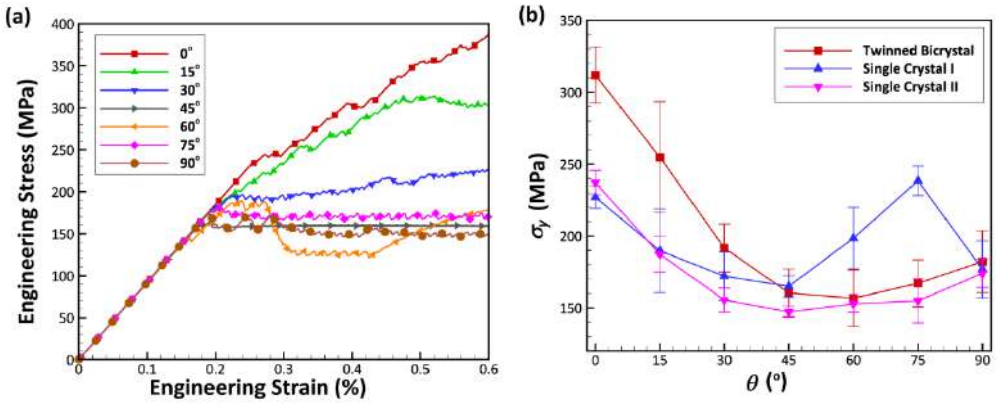

Figure 2. (a) Engineering stress-strain curves of bicrystals of various orientation angles. (b) Yield stresses of bicrystals and corresponding single crystals as a function of TB orientation.

as they pile up against the TB. At the orientation angle changed from15º to 45 º, the presence of the TB leads to a change in the deformation mechanism. Pilled-ups gradually disappears and free glide dislocations (slip parallel to TB) dominate plasticity. With a further increase of the orientation angle to 60º,), the $\mathbf{B^{II}C}$ dislocations then dissociate into two partial dislocations and glide on the TB, resulting in a high degree of twinning deformation and TB sliding. As the angle θ increases to 75° as shown in Fig. 4(f), screw dislocations $\mathbf{A^{II}C}$ and $\mathbf{B^{II}C}$ are activated and meet the TB, and the two phenomena – screw dislocation cross-slip and absorption by TB – can appear in the bicrystal at the same time. In the case of a 90º oriented TB, finally, all the active dislocations are screw dislocations. In this case, only dislocation transmission by cross-slips can be observed.

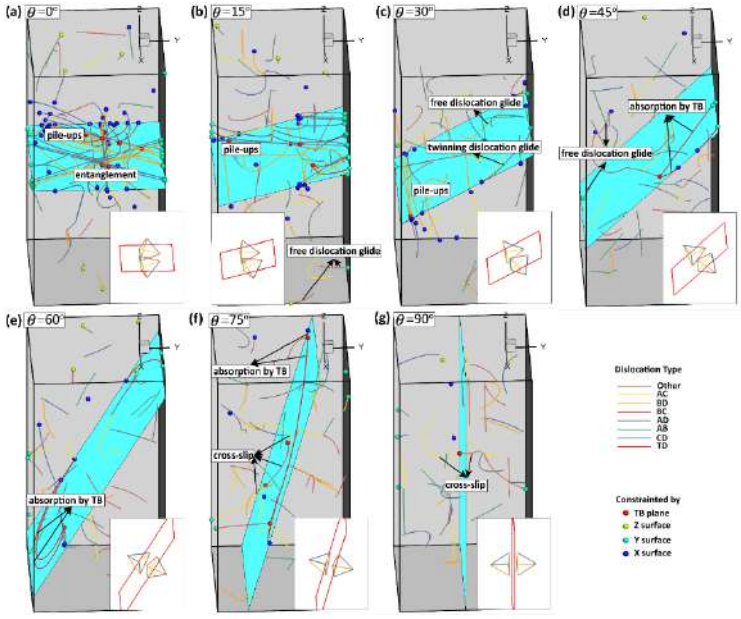

Figure 3 Typical dislocation configurations in the considered bicrystal micropillars at 0.6% total strain. (a) θ = 0º, (b) θ = 15º, (c) θ = 30º, (d) θ = 45º, (e) θ = 60º, (f) θ = 75º, (g) θ = 90º.

CONCLUSIONS

In this work, a dislocation-TB interaction model was introduced into DDD simulations to investigate the effect of TB orientation on the stress-strain response of axially loaded bicrystalline micropillars. The simulations show that the TB exhibits a strengthening effect, which however depends strongly on TB orientation. By changing the TB orientation with respect to the cross-section, the strengthening effect is found to be significant for angles less than 45º, but weak for angles larger than 45º. Especially at 90º, no strengthening effect is observed.

MARGINALLY SEPARATED BOUNDARY LAYER FLOWS: THE TRIPLE DECK STAGE

Dominik Kuzdas*[1] and Stefan Braun [1]
[1] TU Wien, Institute of Fluid Mechanics and Heat Transfer, Vienna, Austria

Summary High Reynolds number asymptotic theory is used to study laminar marginally separated boundary layer flows. From the asymptotic viewpoint, the bursting of a laminar separation bubble runs through various consecutive stages. The present work addresses triple deck equations governing the transient flow regime succeeding a finite time blow-up event in the solution of the fundamental equation of marginal separation theory. The numerical solutions of the corresponding Cauchy problem suggest the appearance of yet another finite-time blow-up, the associated break-down of the flow model and the formation of an Euler–Prandtl stage.

MOTIVATION

The transition from laminar to turbulent flow occurs in many engineering applications and still is not fully understood. In the present work we focus on the so-called 'by-pass' transition in localized boundary layer separation which typically may be observed in the flow past slender airfoils at small angles of attack or channel flows with suction. From a large Reynolds number point of view the bursting of a laminar separation bubble runs trough various consecutive stages. Each of them can be posed as a singular perturbation problem, Fig. 1.

The initial phase (i) is represented by a laminar wall-bounded shear layer on the verge of separation for which classical boundary layer theory ceases to provide an uniformly valid description. In the subsequent stage (ii) of so-called marginal separation viscous-inviscid interaction theory is capable of explaining the formation of closed, predominantly steady, reverse flow regions. However, the appearance of finite-time singularities in the numerical solution and the associated breakdown of the corresponding reduced model equations consequently leads to a spike formation stage (iii) which is governed by a fully nonlinear unsteady triple deck interaction. Although the Cauchy problem associated with this stage has been extensively studied in [1], a satisfactory numerical treatment of the suitably regularized problem is still lacking. In the present work we follow the achievements of [2] and [3] and aim for a reliable numerical solution of the triple deck stage (iii) to corroborate its terminal structure predicted by [1].

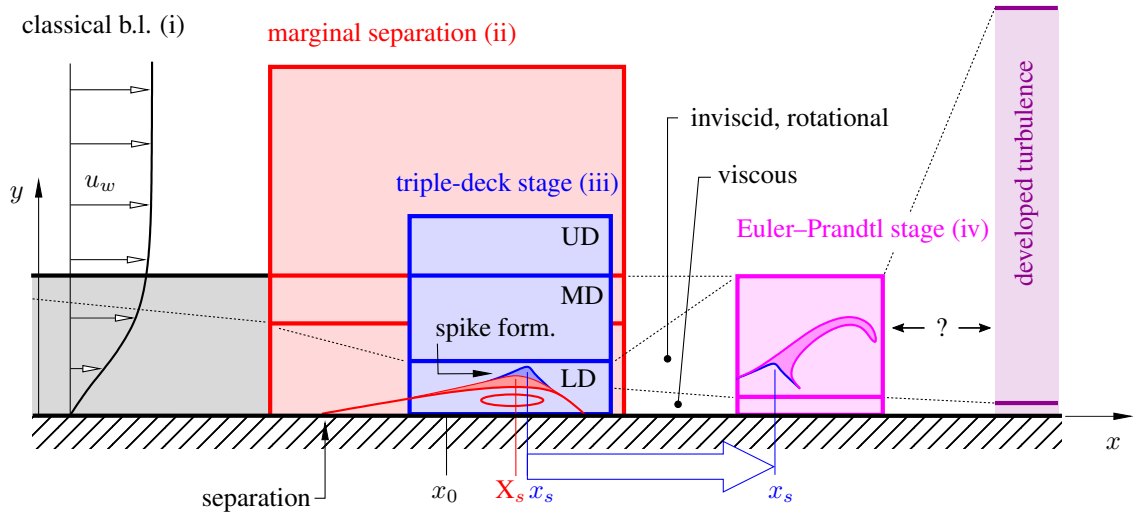

Figure 1: Asymptotic structure of the early stages of the laminar-turbulent transition process in laminar separation bubbles. Classical laminar boundary layer at the verge of separation (i), (black), composed of a viscous region (grey) and an inviscid outer flow (transparent). Consecutive interactive stages of marginal separation (ii) (red) and spike formation (iii) (blue), followed by self-induced vortex wind-up (magenta, shifted to the right for illustration) accompanied by finite-time blow-up events, here modelled up to the Euler–Prandtl (iv) stage. Continued bubble bursting finally leads to developed turbulent boundary layer flow (purple). Eventually a stage of fully developed turbulence may be reached.

SHORT OUTLINE

Based on the investigations regarding the finite time blow-up scenario of the marginal separation stage (ii) we want to address the consecutive triple deck stage (iii) numerically. For two-dimensional incompressible flows, the fundamental lower deck (LD) problem formulated in terms of the stream function $\psi(x,y,t)$, supplemented with the interaction law between the induced pressure $\mathcal{P}(x,t)$ and the displacement function $\mathcal{A}(x,t)$ from the upper deck (UD), reads

$$\frac{\partial^2\psi}{\partial y\partial t}+\frac{\partial\psi}{\partial y}\frac{\partial^2\psi}{\partial y\partial x}-\frac{\partial\psi}{\partial x}\frac{\partial^2\psi}{\partial y^2}=-\left(1+\frac{\partial\mathcal{P}}{\partial x}\right)+\frac{\partial^3\psi}{\partial y^3},\qquad \mathcal{P}=\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{\partial\mathcal{A}/\partial\xi}{x-\xi}\mathrm{d}\xi. \tag{1}$$

*Corresponding author. E-mail: dominik.kuzdas@tuwien.ac.at.

Here x, y and t denote the stream-wise, the wall-normal coordinates and the time with all quantities being nondimensionalized and suitably scaled, [3]. Equations (1) are subject to the no-slip boundary conditions $\psi = \partial\psi/\partial y = 0$ at the solid wall $y = 0$, the far-field conditions $\psi \sim (y+A)^3/A + \ldots$ as $y \to \infty$ and $\psi \to y^3/6, (A, P) \to 0$, as $|x| \to \infty$. The initial or equivalently matching condition ensures the connection to the self-similar blow-up structure of the preceding marginal separation stage,

$$\begin{aligned}
\psi &\sim |t|^{\frac{1}{3}} \left(\frac{\hat{Y}^3}{6} + |t|^{-\frac{7}{9}} \hat{A} \frac{\hat{Y}^2}{2} + |t|^{-\frac{14}{9}} \hat{\psi} \right), \\
\hat{\psi} &\sim \left(\hat{\psi}_2(\hat{X}, \hat{Y}) + \hat{A}_1^2 \frac{\hat{Y}}{2} \right) + |t|^{-\frac{4}{9}} \left(\hat{\psi}_{e1}(\hat{X}, \hat{Y}) + \hat{A}_1 \hat{e}_1 \hat{Y} \right) + |t|^{-\frac{7}{9}} \left(\hat{\psi}_3(\hat{X}, \hat{Y}) + \hat{A}_1 \hat{A}_2 \hat{Y} + \hat{A}_1 \frac{\partial \hat{\psi}_2}{\partial \hat{Y}} + \frac{\hat{A}_1^3}{6} \right), \\
[\hat{A}, \hat{P}] &\sim [\hat{A}_1, \hat{P}_1](\hat{X}) + |t|^{-\frac{4}{9}} [\hat{e}_1, \hat{p}_{e_1}](\hat{X}) + |t|^{-\frac{7}{9}} [\hat{A}_2, \hat{p}_2](\hat{X}) + |t|^{-1} [\hat{e}_2, \hat{p}_{e_2}] + \cdots
\end{aligned} \tag{2}$$

as $t \to -\infty$ with the similarity scalings $x = |t|^{4/9}\hat{X}$ and $y = |t|^{1/9}\hat{Y}$. The leading order term $\hat{Y}^3/6$ represents the separation profile of the classical boundary layer and the (unique) blow-up profiles $[\hat{A}_1, \hat{P}_1]$ as well as $[\hat{e}_1, \hat{p}_{e_1}]$, etc. form Hilbert pairs according to the second equation (1). Further, $\hat{\psi}_2$, $\hat{\psi}_3$,... etc. are uniquely determined, the eigenfunctions $\hat{e}_1$, $\hat{e}_2$ with arbitrary amplitudes carry the history of the flow and enable the embedding of the local into a global solution.

To solve the initial value problem (1) and (2) for the intrinsic unknowns ψ, $\mathcal{A}$ and $\mathcal{P}$ the infinite (half space) domain of the asymptotic description is mapped onto a bounded domain and discretized with Chebyshev spectral collocation methods, [4]. In order to capture the singular behavior of ψ as $y \to \infty$ and the similarity properties as $x \to \pm\infty$ we use the ansatz $\psi(x, y, t) = (bd)^3\{[\eta + \mathcal{A}/(b^7 d)]^3/6 + g\}$, $\mathcal{A} = b^{-6}A$, $\mathcal{P} = b^{-10}P$ and the scalings $x = b^4\xi$, $y = bd\eta$ where the auxiliary functions $b(t)$, $d(\xi)$ exhibit the properties $b \sim |t|^{1/9}$ as $t \to -\infty$, $b \sim O(1)$ if $t \sim O(1)$ and $d \sim |\xi|^{1/4}$ as $\xi \to \pm\infty$, $d \sim O(1)$ if $\xi \sim O(1)$.

Time derivatives are formulated analytically based on the matching condition (2) in the asymptotic regime $-t \gg 1$ and otherwise approximated by a backward third order accurate finite differencing scheme capable of adaptive time stepping on a mapped domain. Finally, the nonlinear system of equations is solved using a modified Powell hybrid method.

The results of the numerical investigation are most conveniently depicted in terms of the boundary layer characteristics, namely displacement thickness $\delta^* - \delta_0^*(x_0) \propto Re^{-1/14}\mathcal{A}(x,t) + \cdots$ and wall shear stress $\tau_w \sim Re^{-1/14}\partial^2\psi/\partial y^2\,|_{y=0}$, Fig. 2. Special emphasis is placed on a proper start based on (2), see insert of Fig. 2(a). Although the terminal blow-up structure of (1) forwarded by [1] is not fully confirmed yet, the growing amplitudes in Fig. 2(b) strongly suggest a finite-time blow-up in the numerical solution of the triple deck equations (1) which triggers the subsequent Euler–Prandtl stage (iv).

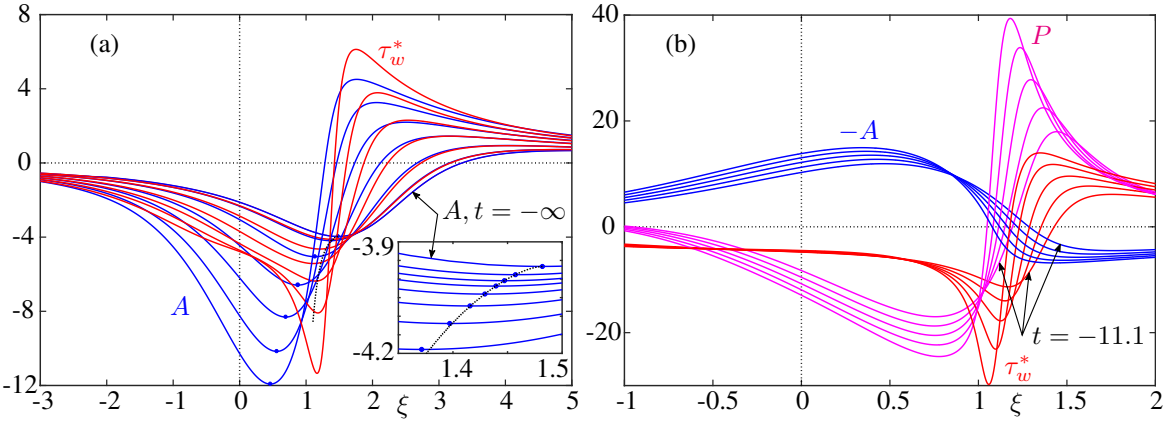

Figure 2: (a) Evolution of the displacement function $A(\xi, t)$ and the wall shear stress $\tau_w^*(\xi, t) = b^6\partial^2\psi/\partial y^2|_{y=0}$ for $t = -(\infty, 357, 58.2, 25.4, 17.0, 13.2, 11.1)$. Blue dots denote the minima of A according to (1) and the black dotted line the minimum of $\hat{A}$ in the limit as $t \to -\infty$, see eq. (2). Insert: Additional instants of time, $t = -(\infty, 6366, 3183, 2122, 1383, 889, 566, 357)$, confirm the connection to the preceding marginal separation stage. (b) Evolution of the induced pressure $P(\xi, t)$, $-A$ and τ_w^* for $t = -(11.1, 10.4, 9.75, 9.26, 8.83)$. The underlying polynomial approximation with the current resolution (n_ξ x $n_\eta \lesssim$ 230x115) fails to handle higher amplitudes for $t > -8.83$.

MECHANISMS OF COHERENT AND RANDOM CONTRIBUTIONS TO DISSIMILAR HEAT TRANSFER ENHANCEMENT INDUCED BY TRAVELING WAVE-LIKEWALL BLOWING SUCTION

Arjun J. Kaithakkal *[1], Yukinori Kametani[1], and Yosuke Hasegawa[1,2]
[1] Institute of Industrial Science, The University of Tokyo, Japan
[2] Division of Applied Mathematics, Brown University, USA

Summary A turbulent channel flow (TCF) subjected to a traveling wave-like wall blowing and suction is studied using direct numerical simulations (DNSs). The turbulence fluctuation in the controlled flow contains some organized contribution due to the coherent nature of the control input, and hence can be decomposed into coherent and random contributions. The roles of the two key factors generating the dissimilar heat transfer, namely the fluid pressure and viscosity, are revealed through the budget analyses of the coherent and random contributions to the dissimilarity.

BACKGROUND

Due to the similarity between heat and momentum transfer, the 'Reynolds analogy'[1] predicts that an increase in heat transfer will be followed by a corresponding increase in momentum transfer. However, even if the governing equations of momentum and passive scalar are similar, their respective dynamics were found to show non-negligible dissimilarity for the canonical flow configurations. Indeed, it has been shown that a downstream traveling wave of wall blowing and suction can achieve significant dissimilarity[2,3]. The resulting dissimilarity can be quantified using the analogy factor $A = 2St/C_f$, where St and C_f respectively represents the non-dimensional heat and momentum flux, and dissimilar heat transfer enhancement is defined as $A > 1$. In the present paper, the dissimilar heat transfer enhancement achieved in a TCF using a traveling wave-like wall blowing and suction is studied through the budget analysis.

Numerical setup and Methodology

A fully developed TCF is numerically solved by DNS with a pseudo-spectral method[2]. A constant flow rate is imposed at a bulk Reynolds number of $Re = 2293$ and Prandtl number $Pr = 1$. The sinusoidal traveling wave of wall blowing and suction is given as, $v_w = \phi \sin\{2\pi/\lambda_x(x - U_p t)\}$. Here, ϕ, λ_x, and U_p represents the amplitude, wavelength, and phase-speed of the traveling wave, whereas t denotes the time. The root-mean-square value of the control input is set to be 5% of the bulk mean velocity. The wave parameters $(\lambda_x, U_p) = (1.12, 0.30)$ were found to achieve the maximum value for the analogy factor[3], and hence considered in the present study.

Following the previous studies[2,3], the contributions of the coherent and random components to dissimilarity can be quantified using, $D \equiv 2St - C_f = 3\int_{-1}^{1} y\overline{\tilde{v}(\tilde{\theta} - \tilde{u})}dy + 3\int_{-1}^{1} y\overline{v''(\theta'' - u'')}dy$, where $\tilde{(.)}$ and $(.)''$ denote the coherent and random components of turbulent fluctuations, respectively. Now, the generation of the coherent and random contributions to dissimilarity can be understood by analyzing the budget of $\overline{\tilde{v}(\tilde{\theta} - \tilde{u})}$ and $\overline{v''(\theta'' - u'')}dy$ as given by (1) and (2).

$$0 = \underbrace{\overline{\tilde{v}^2}\frac{\partial(\bar{\theta} - \bar{u})}{\partial y}}_{\text{production } (P_C)} \underbrace{- \overline{\widetilde{u_j''v''}\frac{\partial(\tilde{\theta} - \tilde{u})}{\partial x_j}}}_{\text{coupling term-1}(P_{C1_C})} \underbrace{- \overline{\{\widetilde{u_j''(\theta'' - u'')}\}\frac{\partial \tilde{v}}{\partial x_j}}}_{\text{coupling term-2 } (P_{C2_C})} + \underbrace{\frac{\partial}{\partial y}\left[\overline{(\tilde{\theta} - \tilde{u})\widetilde{v''v''} + \tilde{v}\{\widetilde{v''(\theta'' - u'')}\} + \tilde{v}\tilde{v}(\tilde{\theta} - \tilde{u})}\right]}_{\text{turbulent diffusion } (T_{D_C})}$$
$$\underbrace{-\frac{1}{Re}\frac{\partial}{\partial y}\left[\overline{\frac{\partial \tilde{v}(\tilde{\theta} - \tilde{u})}{\partial y}}\right]}_{\text{viscous diffusion } (V_{D_C})} \underbrace{- \overline{\left\{-(\tilde{\theta} - \tilde{u})\frac{\partial \tilde{p}}{\partial y} + \tilde{v}\frac{\partial \tilde{p}}{\partial x}\right\}}}_{\text{pressure-velocity-temperature correlation } (\Pi_C)} \underbrace{+ \frac{2}{Re}\overline{\frac{\partial \tilde{v}}{\partial x_j}\frac{\partial(\tilde{\theta} - \tilde{u})}{\partial x_j}}}_{\text{dissipation } (\epsilon_C)}. \quad (1)$$

$$0 = \underbrace{\overline{v''^2}\frac{\partial(\bar{\theta} - \bar{u})}{\partial y}}_{\text{production } (P_R)} \underbrace{+ \overline{\widetilde{u_j''v''}\frac{\partial(\tilde{\theta} - \tilde{u})}{\partial x_j}}}_{\text{coupling term-1 } (P_{C1_R})} \underbrace{+ \overline{\widetilde{u_j''(\theta'' - u'')}\frac{\partial \tilde{v}}{\partial x_j}}}_{\text{coupling term-2 } (P_{C2_R})} + \underbrace{\frac{\partial}{\partial y}\left[\overline{\tilde{v}\{\widetilde{v''(\theta'' - u'')}\} + v''v''(\theta'' - u'')}\right]}_{\text{turbulent diffusion } (T_{D_R})}$$
$$\underbrace{+\frac{1}{Re}\frac{\partial}{\partial y}\left[\overline{\frac{\partial v''(\theta'' - u'')}{\partial y}}\right]}_{\text{viscous diffusion } (V_{D_R})} \underbrace{- \overline{\left\{-(\theta'' - u'')\frac{\partial p''}{\partial y} + v''\frac{\partial p''}{\partial x}\right\}}}_{\text{pressure-velocity-temperature correlation } (\Pi_R)} \underbrace{+ \frac{2}{Re}\overline{\frac{\partial v''}{\partial x_j}\frac{\partial(\theta'' - u'')}{\partial x_j}}}_{\text{dissipation } (\epsilon_R)}. \quad (2)$$

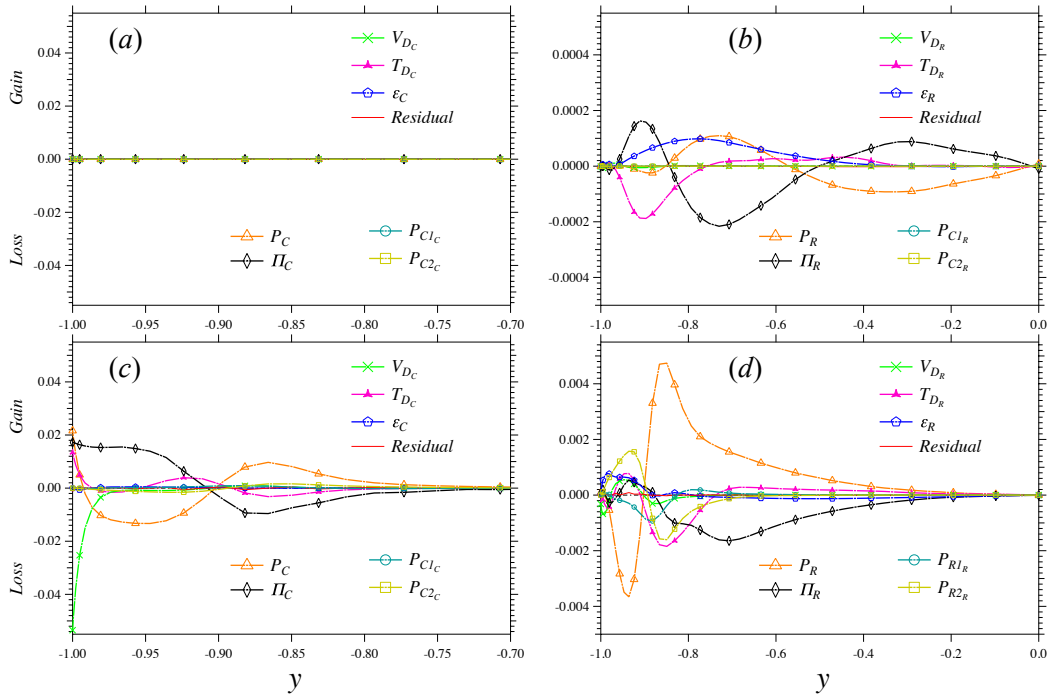

Figure 1: Terms in the budget equation for $-\overline{\tilde{v}(\tilde{\theta}-\tilde{u})}$ (a & c) and $-\overline{v''(\theta''-u'')}$ (b & d) for the uncontrolled (a & b) and controlled (c & d) channel flow.

RESULTS AND DISCUSSIONS

All the terms in the budget equation (1) and (2) are plotted in figure 1, for the uncontrolled and controlled channel flows (UCF and CF). The budget terms in the coherent contribution for the UCF and CF are respectively shown in figure 1(a) and 1(c). The absence of the coherent component in the UCF makes all the terms null as shown in figure 1(a). For the CF, on the other hand, the pressure fluctuation acts as the major factor causing dissimilarity in the coherent field. This can be confirmed from figure 1(c) by the dominant positive value of Π_C in the near-wall region where the coherent contribution becomes significant[3]. Π_C is balanced by P_C except in the near wall region. In the vicinity of the wall the positive contributions from Π_C, P_C, and T_{D_C} are balanced solely by the viscous diffusion term V_{D_C}, indicating the crucial role of viscosity in the dissimilar heat transfer process very close to the wall.

The plots of the budget terms in the random contribution to dissimilarity for the UCF and CF are respectively shown in figure 1(b) and 1(d). It is interesting to see that the budget of the random contribution to dissimilarity for the UCF is quite small, yet non-zero. This small contribution is caused by of the pressure fluctuation that affects only the dynamics of streamwise momentum. The vertical scale of figure 1(b) is one order of magnitude less than that of figure 1(d). Similarly, the range of the vertical axis in figure 1(d) is one order magnitude less than that of figure 1(c). It is worth noting, however, that the budget terms (production, diffusion, dissipation etc.) correspond to the 'fluxes' entering or leaving the system, and do not tell 'how much' remains in the system at an equilibrium state. Rather, the large budget terms (higher fluxes) of the coherent contribution in figure 1(c) should be interpreted as quick response of the coherent contribution, so that it can reach an equilibrium faster, while the random contribution is slower to reach an equilibrium (compare figure 1(c) and 1(d)). In figure 1(d), the term P_R represents a source term through the interaction of the mean component with the random component, and is found to be the most dominant term. Also, their positive and negative peaks agree well with those observed in the profile of the random contribution (not shown here). Since $\overline{v''^2}$ is always positive, the sign of is determined by the sign of $d(\bar{\theta}-\bar{u})/dy$. In fact it is found that the profile of $d(\bar{\theta}-\bar{u})/dy$ (not shown here) changes its sign between the respective peak locations.

In conclusion the analysis shows that the mechanism of the random contribution to dissimilarity depends on the indirect interaction between the coherent and random fields. This is in contrast to that of the coherent contribution to dissimilarity, where the correlation between velocity/temperature and pressure gradient, Π_C, is the dominant factor.

TOWARDS TURBULENT DRAG REDUCTION WITH PLASMA-BASED SPANWISE FORCING – A COMPARISON OF ACTUATION CONCEPTS

Marc T. Hehner[1], Jochen Kriegseis*[1], Nicolas Benard[2], Marios Kotsonis[3], Bettina Frohnapfel[1] and Davide Gatti[1]
[1] Institute of Fluid Mechanics (ISTM), Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

[3] Faculty of Aerospace Engineering, Delft University of Technology, Delft, The Netherlands

Summary Three distinct concepts of spanwise flow forcing using plasma actuators are synthesised, implemented and compared in terms of their respective advantages and limitations. The three concepts involve either temporal or spatial oscillation of the plasma forcing, ultimately aimed at turbulent drag reduction. All experimental characterization efforts of the respective concepts are discussed in reference to the ISTM duct-flow facility in order to provide the comparison in physical dimensions (as relevant for actuator development and operation) and furthermore in viscous units (as relevant for the control concept in a turbulent channel flow).

BACKGROUND

Across the board of external and internal flow scenarios, the skin-friction drag is one of the key factors to determine the energy expenditure required to perform respective engineering applications. Consequently, numerous research efforts addressed the successful reduction of this contribution of drag and thus achieved meaningful energy savings. Among the different techniques towards turbulent drag reduction [1], Streamwise Traveling Waves (StTW) of spanwise wall velocity have established as one successful approach [2]. StTWs impose a transverse fluid motion on the mean flow by periodic oscillation of the surface, as shown in figure 1 (a). Additionally, the oscillation is periodically modulated along the streamwise direction. The achievable amount of drag reduction can be visualized for particular conditions of Re_τ in a (oscillation-) frequency (f), -streamwise wavelength (λ_x) plane [3]. Experimental studies have shown that StTWs favourably interact with near-wall turbulence and attain great potential for turbulent drag reduction and net energy savings (see e.g. [4-7]). However, the so-far proposed devices mainly involve physical oscillation of the wall, achieved through various mechanical means. These yield high complexity and limited control ability. Resonant effects or mechanical inertia of physically oscillating walls bound the maximum oscillation frequency, thus limiting applicability to a narrow range of typically relatively low Re_τ.

Plasma actuators are a type of electrical flow-control device of less complex structure than their mechanical alternatives. They can be configured to mainly induce wall-parallel momentum in the vicinity of the surface, providing a promising alternative to pure in-plane wall movement. Finally, they are based on electrical rather than mechanical principles, thus having the potential for high-frequency operation. Pioneering efforts by Wilkinson [8] and Jukes *et al.* [9] have laid the necessary foundations for advanced concepts to accomplish plasma-based drag reduction. Recent experimental proof-of-concept studies by Hehner *et al.* [10, 11] and Benard *et al.* [12] demonstrated the feasibility of concepts to produce particular kinds of virtual StTWs by a spanwise forcing; see figures 1 (b) and (c), respectively.

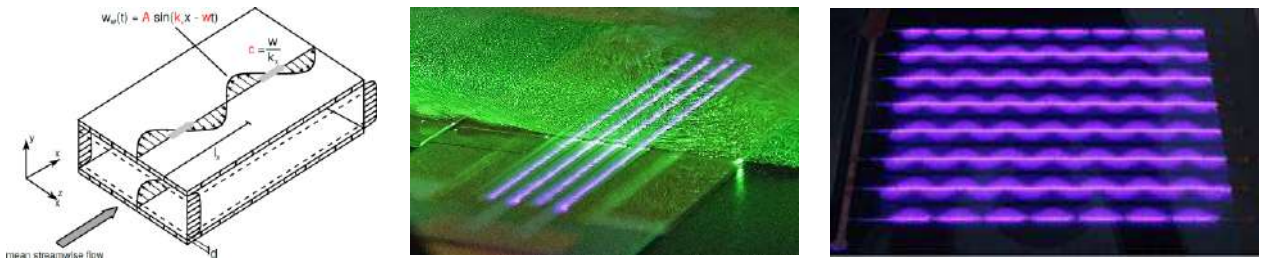

Figure 1: StTW of spanwise wall velocity. (a) Duct section and wall-velocity profile $w(x)$ of StTW. Reproduced from [6]. Spanwise forcing in (b) for virtual wall oscillation [10,11] and in (c) for (streamwise) standing waves [12] of virtual spanwise wall velocity.

OBJECTIVES

Due to the flexibility and large parameter space of plasma actuators, several concepts for efficient and effective StTW generation have been brought forward recently. The objective of the current work is to draw a comparison of the available actuation concepts for plasma actuators [10-12] through a well-documented common test case and elaborating advantages and disadvantages, relevant concept characteristics and Re_τ limitations. The drag-reduction map (f,λ_x-plane), presented by Gatti & Quadrio [6], spans two degrees of freedom for StTWs, which particularly lead to two special cases of (i) a purely temporal oscillation with $\lambda_x \rightarrow \infty$ and (ii) a standing wave in space without temporal oscillation, i.e. $f = 0$.

On the one hand this map provides a clear guideline for promising parameter combinations for successful flow control – on the other hand, however, this parameter space scales in viscous units, which closely relies on the considered test case

*Corresponding author E-mail: kriegseis@kit.edu

and, furthermore, requires a careful translation to physical dimensions, since the latter is the relevant parameter space for development, operation and control of either plasma-actuator concept. As such, the present contribution particularly elaborates the proper choice of control parameters from either perspective: flow requirements (in viscous units) and the actuator requirements (in physical units). This combined evaluation leads to a clear guideline for promising parameter combinations, which match the requirements from both perspectives. It is foreseen that all concepts are eventually applied, tested and evaluated in the ISTM duct-flow facility [6].

ACTUATION CONCEPTS FOR SPANWISE FORCING

Hehner *et al*. recently introduced two concepts for virtual wall oscillations with plasma actuators [10,11], both of which maintain a spanwise oscillatory forcing to virtually mimic wall oscillations. The so-called *burst* concept [10] individually operated various groups of electrodes in pulsed mode, where the duty-cycle (DC) and corresponding oscillation frequency f, and the force magnitude F can be adjusted precisely. The major drawback of the *burst* concept is the comparably fast material degradation of the dielectric due to continuous switch-on and -off events. The so-called *beat* concept is applied with the identical electrode array, but operated in a totally different way. In order to minimize the dielectric wear, the *beat* concept avoids any duty cycles, where all groups of electrodes receive a high-voltage signal at slightly different plasma frequencies, such that the resulting beat frequencies between the electrode groups lead to an effective duty-cycle frequency f. The advantage of a "mild" plasma operation comes with the price that the formerly independent control parameters of effective DC and forcing magnitude F are inherently coupled to the supplied high voltage for the beat concept. Benard et al. [12] introduced a plasma actuator that is capable of producing a virtually standing wave of spanwise velocity in the streamwise direction, as shown in figure 1 (c). This effectively *convective* oscillation concept works with steadily operated plasma discharges and only one group of high-voltage electrodes. In contrast to the electrical simplicity of this concept (at least in comparison with the *burst* and *beat* concepts), an accurately designed electrode shape along the main flow direction is of utmost importance for a successful operation of the *convective* concept. Particularly, the actuator design and operation have to match the optimal wavelength λ_x and forcing magnitude F for the respective Re_τ.

For the *burst* and *beat* concept the applicable Re_τ reaches an upper limit when the decreasing oscillation period cannot be compensated with an increase of the forcing magnitude. For the *convective* concept, Re_τ is limited by both a constructive and flow-characteristic confinement. The decreasing λ_x may lead to either too small geometric dimensions of the plasma actuator or to collapse of the induced standing wave. The main difference in the applicability of the three concepts is the adaptability of the control to the flow conditions. While for the standing wave the range of Re_τ at which drag reduction can be achieved is predetermined by the locked streamwise wavelength λ_x, the frequency of oscillation can be individually tuned for the *burst* and *beat* concept. Therefore, variable flow conditions can be considered for the latter applications, where a change of the oscillation frequency additionally requires an adjustment of the forcing amplitude.

Since all actuator concepts are scheduled to be evaluated in the channel-flow facility at ISTM [6], the actuator-parameter space will be converted into viscous units as apply for this wind tunnel, where skin friction is determined accurately via pressure-drop measurements. The test-section half height is $h = 12.6$ mm and the possible Reynolds number range is $200 < Re_\tau < 2500$.

The interplay of the influencing factors and control parameters will be comparatively discussed and evaluated along the drag-reduction map [3] as function of the possible Re_τ range of the ISTM test facility.

IMPROVED EQUILIBRIUM WALL STRESS MODEL FOR TURBULENT BOUNDARY LAYERS WITH ZERO PRESSURE GRADIENT

Kevin Griffin,* Lin Fu, and Parviz Moin
Center for Turbulence Research, Stanford University, Stanford, CA 94305, USA

Summary In practice, there are two inconsistencies encountered when applying the equilibrium wall model (EQWM) for wall-modeled large-eddy simulation (WMLES): 1) the assumption of a constant stress layer is often not satisfied, and 2) the matching location is often outside the log layer. Herein, we propose two improvements to the classical EQWM: a) we explicitly account for the dependence of total stress on the distance from the wall, and b) we propose a modified eddy viscosity model that is applicable for the wake region of the boundary layer. These improvements greatly enhance the predictive capability of the EQWM, even when the matching location is at the edge of the boundary layer. This flexibility renders the new model much more suitable for WMLES of flows over complex geometries.

INTRODUCTION

The classical form of the EQWM begins with the one-dimensional RANS equation (neglecting the pressure gradient and advection terms) as

$$\frac{d}{dy}\left((\nu_t+\nu)\frac{dU}{dy}\right)=\frac{d\tau/\rho}{dy}. \tag{1}$$

Invoking the constant stress layer assumption, the term on the right-hand side vanishes. This ODE is then solved for $U(y)$ between the wall, where the no-slip condition is applied, and a matching location, where the LES solution is provided. In general, moving the matching location further away from the wall decreases the LES resolution requirements but also increases the reliance on the RANS model. To close this equation for $U(y)$, Cabot and Moin (2000) [1] employed the algebraic eddy viscosity model

$$\nu_t=\ell_m u_\tau,\quad \ell_m=\kappa y D,\quad D=(1-\exp(-y^+/A^+))^2, \tag{2}$$

where the turbulence eddy viscosity scales linearly with y for large y^+. Consequently, when coupled with the constant stress layer assumption, it recovers the log law away from the wall. This is, however, only appropriate when this model is deployed with a matching location in the log region. Large errors are generated if the matching location is in the wake region, where the constant stress layer and linear eddy viscosity assumptions are not valid.

NEW MODEL

In this work, we develop a new model which accounts for a non-constant stress layer, and we introduce an eddy viscosity form that is accurate regardless of the matching location.

Total stress distribution

For the classical EQWM, the built-in assumption is that the variation of the total stress between the wall and the matching location is negligible if the matching location is in the log layer (e.g. $\mathcal{O}(200\delta_\nu)$). When the matching location is any significant fraction of the boundary layer thickness, the assumption is invalid and typically the total stress is a function of wall-normal distance. Chen et al. [2] propose a model for the dependence of the total stress on the wall-normal distance. This model, i.e.

$$\tau(y)=\tau_w\left(1-\left(\frac{y}{\delta}\right)^{3/2}\right), \tag{3}$$

has been verified for a large range of Reynolds numbers [2]. Fig. 1a indicates that the prediction of this model agrees well with the DNS data [6]. With this model, we account for the right-hand side of Eq. (1) explicitly, rather than neglecting it as in the classical model.

Modified eddy viscosity model

Maise and McDonald (1968) [5] observed that the mixing length behaves like κy in the log region but plateaus in the wake region to a nearly universal value of $C_{max}\approx 0.09\delta$. This observation is robust to changes in Mach number and even moderate adverse pressure gradients. We design a hyperbolic tangent function for a mixing length model since it is a simple function that obeys the aforementioned linear and constant asymptotes. We replace the classical mixing length model, $\ell_m=yD$, with a new model,

$$\ell_m=C_{max}\tanh(\kappa y/C_{max})D. \tag{4}$$

While Cabot and Moin (2012) [1] take u_τ as the velocity scale in the classical model (which is consistent with a constant stress layer assumption), we propose to use the velocity scale $\sqrt{\tau(y)/\rho}$ instead. Fig. 1b and 1c indicate that these new models for ℓ_m and ν_t agree much better with DNS than the classical model.

*Corresponding author. E-mail: kevinpg@stanford.edu.

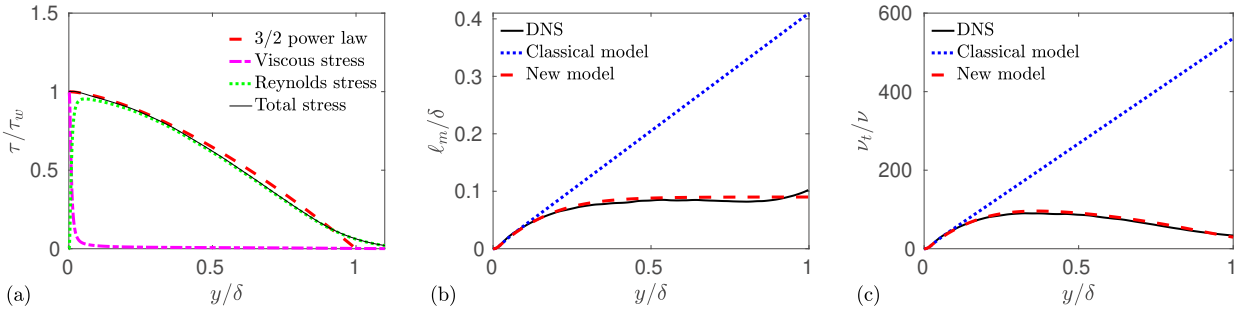

Figure 1: (a) The assumption of a constant total stress layer is not well motivated when the matching location $y_m/\delta > 0.2$. The new mixing length (a) and eddy viscosity (b) models agree well with DNS [6], unlike the classical models, which perform poorly in the outer layer ($Re_\theta = 4000$).

RESULTS

As shown in Fig. 2a, the new model correctly predicts the log law in the log region and also predicts the wake region well, whereas the classical model continues to predict a log law for all y. Fig. 2b with linear axes clearly shows the reduced prediction error in the outer layer from our new model. Fig. 2c shows that over a wide range of Re_θ from 300 (marginally turbulent) to 13000, the new model performs substantially better than the classical model.

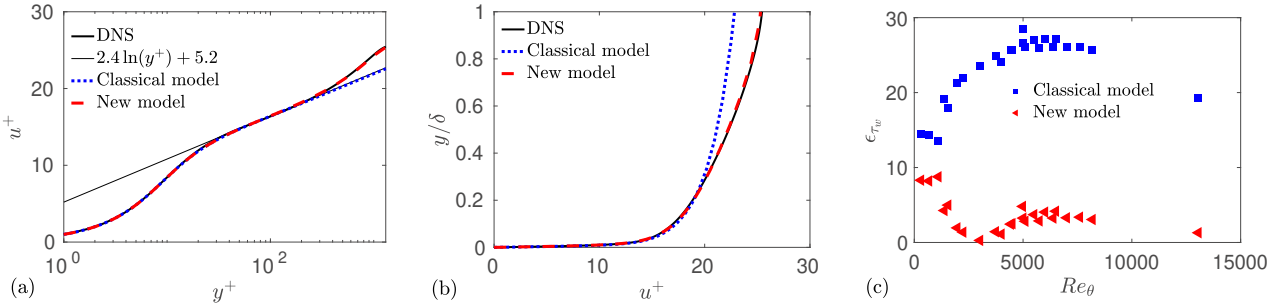

Figure 2: Velocity profiles for the new and the classical model on (a) semi-log and (b) linear scales show that the new model greatly improves the predicted mean velocity profile for the $Re_\theta = 4000$ case. (c) The percent error in wall shear stress, ϵ_{τ_w}, of the new model is much lower than that of the old model. Error is measured with respect to DNS, experiment, or WRLES [6, 4, 8, 3, 7].

CONCLUSIONS

We have improved the EQWM to accommodate a non-constant stress distribution and proposed a new eddy viscosity model for the wake region of turbulent boundary layers. These simple modifications greatly improve the predictive capability of the EQWM model and allow for setting the matching location for the model anywhere between the wall and the edge of the boundary layer. This flexibility in the choice of the matching location is essential for a robust deployment of the EQWM in complex geometries, since in such cases it is difficult and computationally expensive to guarantee that the matching location is in the log layer.

ANTOMY OF DETERMINISITIC TURBULENT SPOTS+

Kwing-So Choi*[1], Yaxing Wang[1], Mike Gaster[2], Chris Atkin&[2], Yury Kachanov[3] and Vladimir Borodulin[3]

Summary Experiments were carried out in a low-turbulence wind tunnel to study the initiation and development of deterministic flow structures in a laminar boundary layer over a flat plate under the excitation of broadband disturbances. Velocity measurements using a hot-wire probe revealed that the excited boundary layer developed well-organized events resembling turbulent spots. We found that these structures were highly reproducible until a very late stage of transition. Development of "deterministic" turbulent spots through a merger of low-speed structures is detailed here, which created a large delta-shaped lump accompanied by a thin positive velocity region near wall. Our investigation followed a recent experimental work on deterministic turbulence in order to study the anatomy of turbulent spots with a view to develop a strategy for controlling them for skin-friction drag reduction.

BACKGROUND

During the boundary layer transition, patches of turbulence, so-called turbulent spots can be observed as a part of the developing process leading to a fully developed turbulent boundary layer. Wygnanski et al [1] used electrical discharges to trigger a laminar boundary layer to generate turbulent spots for a detailed study of their structure. Gaster and Grant [2] used single-point impulses to excite a laminar boundary layer to create three-dimensional wave packets. Shaikh [3] used a sequence of broadband noise to excite the laminar boundary layer, where he found that the disturbance waves were modulated in a repeatable and deterministic manner. The subsequent generation of turbulent spots was similar to that observed in naturally excited situations. A similar wind tunnel investigation was performed by Borodulin and Kachanov [4] recently, who found that the boundary layer flow was deterministic until a very late transition stage where the turbulence statistics was similar to that of a fully developed turbulent boundary layer.

EXPERIMENTAL SETUP AND PROCEDURE

Experiments were carried out in a low turbulence wind tunnel at City, University of London. The wind tunnel test section had a dimension of 0.91 m (height) by 0.91 m (width) by 1.8 m (length), whose turbulence level was less than 0.005% for the frequency range of between 2 Hz and 2 kHz. The flat-plate test surface was made of aluminium cast tooling plate with a length of 1.5 m, which was vertically installed inside the test section. An excitation source consisted of 19 miniature speakers along the span. The cylindrical-shaped speakers of 12 mm in diameter, 9.5 mm high were embedded in the flat plate to excite the boundary layer through 19 small holes of 1 mm diameter. The excitation source was located at 325 mm from the leading edge, covering a span of 300 mm with a 15 mm interval. The wind tunnel speed was set at 18 m/s. The undisturbed baseline flow was set to zero-pressure gradient by adjusting the trailing edge flap and tab. The excitation signal was 400 ms long, which was repeated 20 times while the streamwise velocities were measured by a single hot-wire probe. The measurements were taken for a streamwise range from x = 350 mm to x = 1000 mm and over a spanwise range of z = ±60 mm across the whole boundary-layer thickness.

RESULTS AND DISCUSSIONS

The downstream change in the ensemble-averaged streamwise fluctuating velocity with a broad-band noise excitation from a point source is shown in Fig. 1. Here, the measurements were taken along the central line of the test plate between x = 330 mm and 700 mm. An early development of turbulent spots is seen only after 5 mm downstream of the excitation source, where a number of low-speed structures of approximately 1 mm high are seen at x = 330 mm. These are the precursor events to turbulence spots, which look like the heads of hairpin eddies. For example, five of such low-speed structures are seen at t = 110 ms at x = 330 (top figure), growing in size and strength as well as in number downstream. These low-speed structures will eventually "merge" together, creating a large delta-shaped lump accompanied by a thin positive fluctuating velocity region near wall, see the bottom figure at x = 500 mm. The contours of turbulent spots are highly reproducible in terms of their timing and duration as they are of relatively low frequency signal. This is in contrast to individual high-frequency spike signals (not shown here) within each turbulent spot, whose reproducibility is not very high. Therefore, the control strategy of "deterministic" turbulent spots must be developed based on the information of spot contour rather than individual low-speed hairpin structure within.

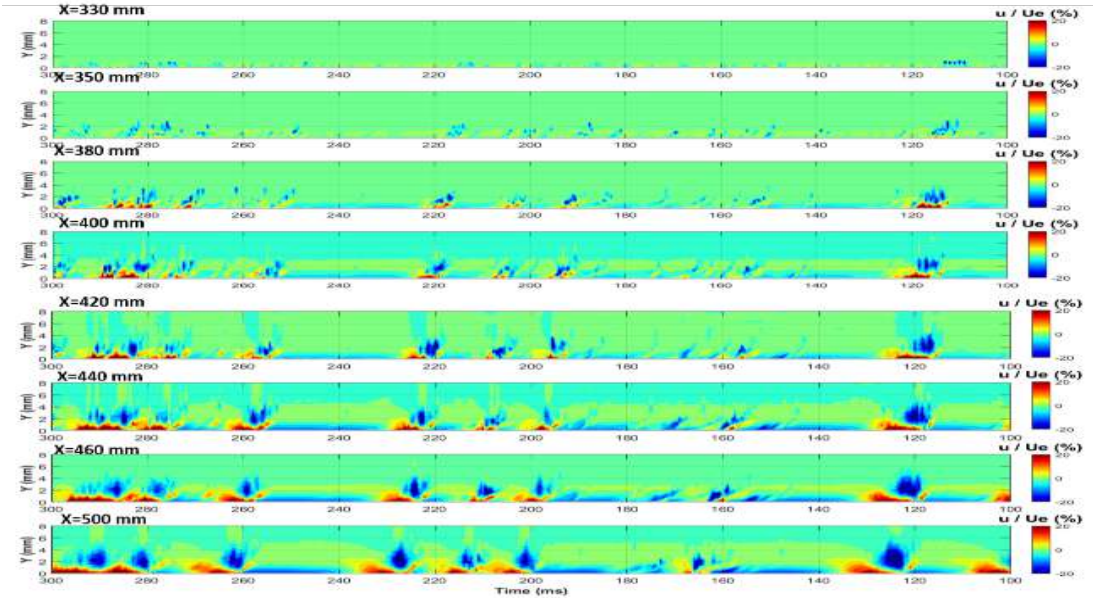

Figure 1. Contours of the streamwise velocity fluctuations, showing the downstream developments of boundary layer under a broadband excitation form a point source. The excitation source is at x = 325 mm from the leading edge.

Ensemble-averaged streamwise velocity contours of turbulent spots at x = 600 mm are given in Fig. 2 in t-z space. Here, the x-axis of the figure is represented by the negative time to show the spatial structure of turbulent spots from the temporal measurements. Here, we used Taylor's frozen flow hypothesis to convert time t to streamwise distance z using the measured convection velocity of turbulent spots. All turbulent spots are seen along the centreline (z = 0) of the flat-plate test surface. Turbulent spots are about 60 mm wide and 300 mm long at this streamwise location. Some turbulent spots are followed by another turbulent spot, while others are isolated. The number of turbulent spots does not seem to increase in the downstream, although the volume (length, width and height) of turbulent spots increased until they occupied all "empty" spaces. The turbulence level is high within the turbulent spots, increasing the intermittency downstream. At a wall-normal distance of y = 3.4 mm (bottom figure) only the wing-shape structure of negative velocity can be seen, suggesting that the leading edge of turbulent spots that is formed by the ejection of low-momentum fluid [5] is located further away from the wall. The wing-shaped structure is tallest at the centre (z = 0). At y = 1.0 mm (top figure), on the other hand, each wing of turbulent spots is followed by an oval-shaped high-velocity region. These high-velocity regions that are created by the downwash of high-momentum fluid [5] are always paired and are located closer to the wall. The coherent coefficient, a measure of the deterministic level of turbulence, across the span of turbulent spots is nearly constant.

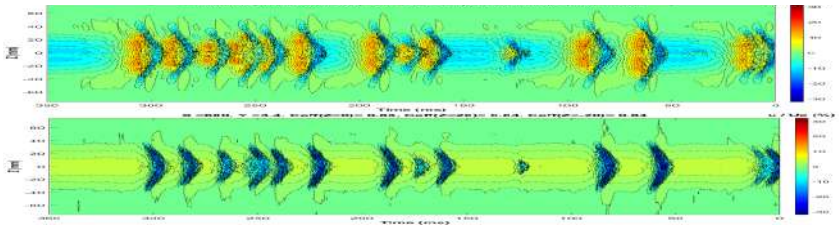

Figure 2: Contours of streamwise fluctuation velocity at x = 600 mm; y = 1.0 mm (top) and y = 3.4 mm (bottom).

CONCLUSIONS

Deterministic turbulent boundary layer was used to study the structure of turbulent spots in a low-turbulence wind tunnel. We were able to show that turbulent spots were initiated by hairpin-like structures that eventually merge to grow. They were highly reproducible, providing an opportunity for developing a control strategy for skin-friction drag reduction.

EXTENSION OF THE QSQH THEORY TO ALL VELOCITY COMPONENTS

Sergei Chernyshenko*
Department of Aeronautics, Imperial College London, London SW7 2AZ, UK

Summary An extension of the QSQH theory of the effect of large-scale structures on near-wall turbulence is proposed. It applies to all three components of the velocity and takes into account the fluctuations of the large-scale component of the wall friction. As an example of application, the dependence of the amplitude of fluctuations of the second moments of velocity on the Reynolds number is considered. The analysis explains why this dependence is particularly strong for the longitudinal and spanwise velocities. It also gives the shape of the increments of these two quantities with the Reynolds number as a function of the distance to the wall.

EXTENSION OF THE QSQH THEORY

According to the classical universality hypothesis, as the Reynolds number, Re, tends to infinity, the characteristics of the near-wall part of a turbulent boundary layer, if expressed in wall units, become independent of Re. It is now known that this hypothesis is not strictly accurate. The large-scale motions in the bulk of the boundary layer affect the near-wall flows [1]. This invalidates the classical universality hypothesis because the large-scale motions are Re-dependent in wall-units. The Quasi-Steady-Quasi-Homogeneous (QSQH) theory [2–4] describes the dominant features of the effect of large-scale motions. It has already been broadly confirmed, e.g. see [5–7]. The QSQH theory was originally formulated for the longitudinal velocity only, but recent comparisons [7] extend it to the spanwise and wall-normal velocity components, albeit without taking into account the fluctuations of the direction of large-scale wall friction. We will formulate the full extension of the QSQH theory and give an example of its application.

The QSQH theory presumes that any vector or scalar field can be represented as a sum of a large-scale and small-scale component. In particular, the wall friction $\boldsymbol{\tau}^*(t,x,z) = \boldsymbol{\tau}^*_L(t,x,z) + \boldsymbol{\tau}^*_L(t,x,z)$. We will use non-dimensional units based on the kinematic viscosity and the average large-scale friction velocity $\langle u^*_{\tau_L} \rangle = \langle \sqrt{|\boldsymbol{\tau}^*_L(t,x,z)|/\rho^*} \rangle$, where ρ^* is the density and the angular brackets denote averaging. Coordinate systems in figure 1 are related by the formulae $x_\theta = x\cos\theta - z\sin\theta$, $y_\theta = y$, $z_\theta = x\sin\theta + z\cos\theta$, $u = u_\theta\cos\theta + w_\theta\sin\theta$, $v = v_\theta$, and $w = -u_\theta\sin\theta + w_\theta\cos\theta$. The extended QSQH theory states that if $u_\theta(t,x_\theta,y_\theta,z_\theta,Re) = u_{\tau_L}\tilde{u}(\tilde{t},\tilde{x},\tilde{y},\tilde{z})$, $v_\theta(t,x_\theta,y_\theta,z_\theta,Re) = u_{\tau_L}\tilde{v}(\tilde{t},\tilde{x},\tilde{y},\tilde{z})$, $w_\theta(t,x_\theta,y_\theta,z_\theta,Re) = u_{\tau_L}\tilde{w}(\tilde{t},\tilde{x},\tilde{y},\tilde{z})$, and $\tilde{t} = tu^2_{\tau_L}$, $\tilde{x} = x_\theta u_{\tau_L}$, $\tilde{y} = y_\theta u_{\tau_L}$, $\tilde{z} = z_\theta u_{\tau_L}$, then the statistical properties of $\tilde{u}(\tilde{t},\tilde{x},\tilde{y},\tilde{z})$, $\tilde{v}(\tilde{t},\tilde{x},\tilde{y},\tilde{z})$, and $\tilde{w}(\tilde{t},\tilde{x},\tilde{y},\tilde{z})$ are independent of u_{τ_L}, θ, and Re. In general $u_{\tau_L} = u_{\tau_L}(\tilde{t},\tilde{x},\tilde{z})$ and $\theta = \theta(\tilde{t},\tilde{x},\tilde{z})$. If u_{τ_L} and θ were independent of time then u_{τ_L} would be equal to 1, the large-scale friction would be equal to the mean friction, our non-dimensional units would coincide with the wall units, and $\tilde{u},\tilde{v},\tilde{w}$ would be the velocity components in wall units. This highlights the physical meaning of the QSQH theory: the near-wall flow adjusts to the large-scale wall friction as if it were constant in time and homogeneous in space.

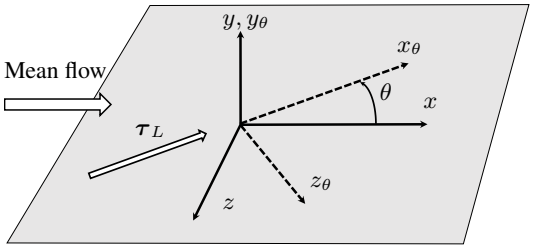

Figure 1: Coordinate x is in the mean flow direction, x_θ is in the direction of the large-scale component of the wall friction, y and y_θ are wall-normal, and z and z_θ are in the wall plane.

DEPENDENCE OF THE SECOND MOMENTS OF VELOCITY ON THE REYNOLDS NUMBER

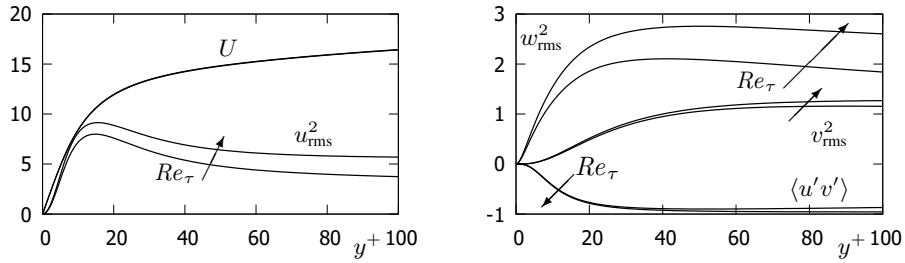

Figure 2: Data for plain channel at $Re_\tau = 950$ and 5200 from turbulence.oden.utexas.edu [8,9]. The curves for U overlap.

It is known that as Re changes, $u^2_{\rm rms} = \langle u'^2 \rangle$ and $w^2_{\rm rms} = \langle w'^2 \rangle$ vary much faster than $U(y) = \langle u \rangle$, $v^2_{\rm rms} = \langle v'^2 \rangle$, and $\langle u'v' \rangle$ (the primes denote fluctuations). But why is there such a difference? The very small variation of U with Re is explained in [3], and accounting for $\theta \neq 0$ adds little to it. We will concentrate on the second moments of velocity.

Applying the QSQH derivation technique described in [3] and assuming $\langle u'^2_{\tau_L} \rangle \ll 1$ and $\langle \theta^2 \rangle \ll 1$ gives the following expressions for the differences between the values at two Re:

$$\Delta u^2_{\rm rms} = \Delta\langle u'^2_{\tau_L} \rangle \left[\left(\frac{d\tilde{U}}{dy} \right)^2 + \frac{1}{2} \frac{d^2 y^2 \tilde{u}^2_{\rm rms}}{dy^2} \right] + \Delta\langle \theta^2 \rangle \left(\tilde{w}^2_{\rm rms} - \tilde{u}^2_{\rm rms} \right) + \ldots, \quad \Delta v^2_{\rm rms} = \frac{\Delta\langle u'^2_{\tau_L} \rangle}{2} \frac{d^2 y^2 \tilde{v}^2_{\rm rms}}{dy^2} + \ldots,$$

*Corresponding author. E-mail: s.chernyshenko@imperial.ac.uk.

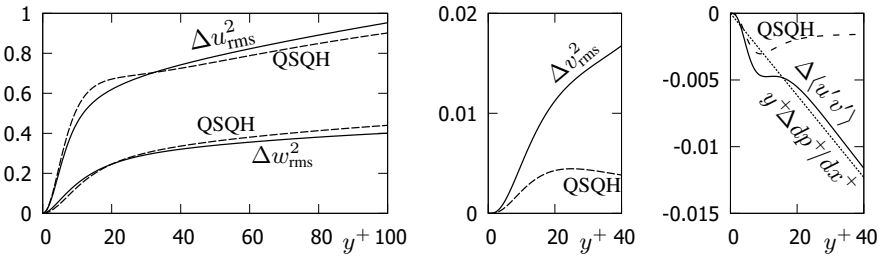

Figure 3: Increments of the second moments as Re_τ changes from 2000 to 5200: DNS ——, QSQH – – –, $y^+\Delta dp^+/dx^+$ ·····.

$$\Delta w^2_{\rm rms} = \frac{\Delta\langle u'^2_{\tau_L}\rangle}{2}\frac{d^2y^2\tilde{w}^2_{\rm rms}}{dy^2} + \Delta\langle\theta^2\rangle\left(\tilde{U}^2 + \tilde{u}^2_{\rm rms} - \tilde{w}^2_{\rm rms}\right) + \ldots, \quad \Delta\langle u'v'\rangle = \frac{\Delta\langle u'^2_{\tau_L}\rangle}{2}\frac{d^2y^2\tilde{\tau}_R}{dy^2} - \frac{1}{2}\langle\theta^2\rangle\tilde{\tau}_R + \ldots,$$

where $\tilde{U}(y) = \langle\tilde{u}\rangle$, $\tilde{u}^2_{\rm rms} = \langle\tilde{u}'^2\rangle$, $\tilde{v}^2_{\rm rms} = \langle\tilde{v}'^2\rangle$, $\tilde{w}^2_{\rm rms} = \langle\tilde{w}'^2\rangle$ and $\tilde{\tau}_R = \langle\tilde{u}'\tilde{v}'\rangle$. Since $\langle u'^2_{\tau_L}\rangle \ll 1$ and $\langle\theta^2\rangle \ll 1$, estimates can be done assuming that $\tilde{U} \approx U$, $\tilde{u}^2_{\rm rms} \approx u^2_{\rm rms}$, $\tilde{v}^2_{\rm rms} \approx v^2_{\rm rms}$, $\tilde{w}^2_{\rm rms} \approx w^2_{\rm rms}$, and $\tilde{\tau}_R \approx \langle u'v'\rangle$. The estimate shows that the terms with $\tilde{U}$ dominate. At $y^+ = 40$ for example, $(dy\tilde{U}/dy)^2 \approx 285$, while $u^2_{\rm rms} \approx 6$, and $U^2 \approx 203$, while $w^2_{\rm rms} \approx 2.4$. Dropping the much smaller terms gives that $\Delta u^2_{\rm rms} \approx \Delta\langle u'^2_{\tau_L}\rangle(dy\tilde{U}/dy)^2$, $\Delta w^2_{\rm rms} \approx \Delta\langle\theta^2\rangle\tilde{U}^2$, while $\Delta v^2_{\rm rms} \approx \Delta\langle u'v'\rangle \approx 0$. The physical mechanism of the term with $(dy\tilde{U}/dy)^2$ is the amplitude and wall-normal-scale modulation by the large-scale motions [2,3], while the term with $\tilde{U}^2$ is the effect of the fluctuations of the direction of the large-scale wall friction, which is introduced in the present work.

The precise values of $\langle u'^2_{\tau_L}\rangle$ and $\langle\theta^2\rangle$ and the statistics of the universal velocity depend on the definition of the large-scale filter. Assuming that a suitable filter exists one can adjust $\Delta\langle u'^2_{\tau_L}\rangle$ and $\Delta\langle\theta^2\rangle$ to fit $\Delta u^2_{\rm rms}$ and $\Delta w^2_{\rm rms}$. Taking $\Delta\langle\theta^2\rangle = 0.0016$ and $\Delta\langle u'^2_{\tau_L}\rangle = 0.0025$ for Re_τ changing from 2000 to 5200 gives the results shown in figure 3. The deviation of the QSQH predictions for $\Delta u^2_{\rm rms}$ and $\Delta w^2_{\rm rms}$ is not large and is of the same order of magnitude as reported in most cases in [3]. The QSQH predictions for $\Delta v^2_{\rm rms}$ and $\Delta\langle u'v'\rangle$ deviate considerably, by an order of magnitude, from the DNS results. This is because for these quantities the predicted QSQH effects are very small. The almost linear behaviour of $\Delta\langle u'v'\rangle$ for $y^+ > 20$ is suggestive. It is well-known that the dependence of the total shear stress on the distance to the channel wall is linear and in wall units is equal to $y^+dp^+/dx^+ = y^+/Re_\tau$, and that further away from the wall the Reynolds stress approaches the total stress. As Re_τ changes, so does the pressure gradient. The corresponding change in the total stress, equal to $\Delta y^+dp/dx = y^+(1/5200 - 1/2000)$, is shown with a dotted line in figure 2 and fits well the deviation between the QSQH prediction and DNS. Therefore, the deviation is due to the QSQH theory not taking into account the nonzero pressure gradient in a channel flow.

CONCLUSIONS

The proposed extension of the QSQH theory takes into account the fluctuations of the large-scale component of the wall friction. It describes the effect of large-scale motions on all three components of the velocity of near-wall turbulent flows. As an example of application, the extended theory explains the large sensitivity of the magnitudes $u_{\rm rms}$ and $w_{\rm rms}$ of the fluctuations of longitudinal and spanwise velocities to Reynolds number in comparison with the sensitivity of the mean velocity profile, the Reynolds stress, and the magnitude of the fluctuations of the wall-normal velocity. It is shown that the variation of $u_{\rm rms}$ with Re is largely caused by the variation of the amplitude and wall-normal-scale modulation by the outer, large-scale, Re-dependent motions, while the variation of $w_{\rm rms}$ is largely caused by the fluctuations of the direction of the large-scale, Re-dependent, component of the wall friction. The Re dependence of the other second moments is not dominated by these mechanisms because the mean universal wall-normal velocity is zero. In particular, the effect of the variation of the mean pressure gradient with Re is stronger than the QSQH mechanisms as far as the variation of the Reynolds stress with Re is concerned.

DRAG REDUCTION BY TRANSVERSAL SURFACE WAVES IN SWEPT FLAT PLATE FLOW

Marian Albers *[1] and Wolfgang Schröder[1,2]
[1] Institute of Aerodynamics, RWTH Aachen University, Wüllnerstrasse 5a, 52062 Aachen, Germany
[2] JARA Center for Simulation and Data Science, RWTH Aachen University, Seffenter Weg 23, 52074 Aachen, Germany

Summary Large-eddy simulations of the drag reduction technique of traveling transversal surface waves at varying sweep angle in turbulent boundary layer flow over a flat plate are conducted. The results show only a moderate effect on the overall drag reduction for small sweep angles and downstream traveling waves. For a partially upstream traveling wave the effect is more diverse with increased viscous drag reduction but also strong additional pressure drag.

INTRODUCTION

The improvement of the aerodynamic efficiency of aircraft is one of the key methods for substantially lowered global CO_2 emissions. Since the drag of slender bodies moving in a fluid is to a large extent determined by viscous forces at the body surface, which are mainly determined by turbulent boundary layer flows developing along the surface, there is considerable interest to decrease the friction and pressure drag through control measures. Active flow control techniques, i.e., techniques where energy is introduced into the system, have proven to be capable of significantly reducing the wall-shear stress in turbulent wall bounded flows. For instance, spanwise wall oscillations [1] or streamwise oscillations of spanwise wall velocity [2] can strongly decrease the wall friction with limited control input such that also net power savings are achieved. Another technique, spanwise traveling transversal surface waves, has similar effects on the turbulent flow field [3, 4] by indirectly creating oscillating spanwise shear close to the wall. Many techniques for active drag reduction have a preferential direction of the actuation, e.g., spanwise or streamwise. However, in real flows a perfect alignment is not always guaranteed. Therefore, we investigate the influence of small to moderate angles of the propagation direction for transversal surface waves.

SETUP

Large-eddy simulations (LES) of spanwise traveling transversal surface waves in swept flat plate turbulent boundary layer flow are considered. The flow is investigated for a momentum thickness based Reynolds number of $Re_\theta = 1000$ at x_0, i.e., the location where the control region is initialized. The physical domain is discretized by a time-dependent curvilinear structured grid. A grid resolution of at least $\Delta x^+ = 10.7$, $\Delta y^+|_{\text{wall}} \leq 1.05$ and $\Delta y^+|_{\text{bl-edge}} = 13.2$, and $\Delta z^+ = 4.3$ in the streamwise, wall-normal, and spanwise direction is used which ensures the accurate approximation of all relevant flow scales and also of the curved boundary surface. On the surface, a time- and space-dependent no-slip condition is used. The y-coordinate of the wall in the interval $0 \leq x \leq 150$ is described by the function

$$y^+|_{\text{wall}}(\tilde{z}^+, t^+) = g(x)A^+ \cos\left(\frac{2\pi}{\lambda^+}\tilde{z}^+ + \frac{2\pi}{T^+}t^+\right), \tag{1}$$

where $\tilde{z} = z - \sin\varphi(x - x_0)$ is the propagation direction of the traveling wave and φ is the sweep angle between the spanwise direction z and the propagation vector $\tilde{z}$. A smooth transition from the non-actuated to the actuated region and vice versa is enabled by the piecewise-defined function $g(x)$. The parameters of the wave motion are the wavelength $\lambda^+ = \lambda u_\tau/\nu = 3000$, period $T^+ = Tu_\tau^2/\nu = 50$, and amplitude $A^+ = Au_\tau/\nu = 70$. These values showed high drag reduction in a previous investigation [4]. Sweep angles of $\varphi \in [0°, 10°, 20°, 30°]$ are considered for partially downstream traveling waves and $\varphi = 30°$ for upstream traveling waves.

RESULTS

A first impression of the near-wall flow field for one of the actuated cases can be obtained from Fig. 1 where streamwise velocity streaks are depicted for upstream traveling waves with a sweep angle of $\varphi = 30°$. In comparison to the incoming flow, i.e., non-actuated turbulent boundary flow, the near-wall structures show a mean inclination to the streamwise direction. Furthermore, the streaks appear to be larger with less structures in the high-wavenumber end of the spectrum.

The impact of the sweep angle on the pressure and viscous drag is illustrated in Fig. 2. The first column, which represents the baseline case $\varphi = 0°$, shows a purely viscous drag reduction of about 25 percent. Since lines of equal phase of the wave motion are perfectly aligned with the streamwise direction no additional pressure drag contribution is obtained. This changes when the sweep angle has non-zero values. For the second, third, and fourth columns, which
