SIMULATION AND ANALYSIS OF VORTICAL FLOWS

Xiyun Lu*[1]
[1]Department of Modern Mechanics, University of Science and Technology of China, Hefei, Anhui 230026, China

Summary The fluid flows encountered in nature and technology come from the coexistence of three nonlinear fundamental processes, i.e. shearing process, compressing process, and thermal process, and their couplings both in the interior of the fluid flow and on boundaries. These processes are typically measured by vorticity, dilatation and entropy, respectively, and characterized by their respective localized but strong structures and interactions which can dominate the global flow performances. In this talk, I will attempt to introduce a general theoretical framework for multiple-process splitting and coupling and to apply it to examine the key flow structures and interactions based on our numerical simulations. I will demonstrate its applications to some typical flows covering the incompressible, transonic and supersonic flow regimes. The analysis in terms of the fundamental processes provides a physical insight into the understanding of the mechanisms underlying in these vortical flows.

FRAMEWORK FOR FUNDAMENTAL PROCESSES OF VORTICAL FLOWS

Any practical external or internal engineering vertical flow has a set of global performances as its design objectives, e.g. the lift and drag of a wing or the pressure ratio and efficiency of a compressor, as well as the stable operation ability of the flow. Contrary to the early-stage development of fluid dynamics focusing on structure-free potential flows, it has now been well recognized that all global performances are dominated by various local dynamic structures, such as boundary layers, free shear layers, vortices, turbulent coherent structures, shock waves and other nonlinear acoustic waves, as well as entropy waves [1-8]. The richness of local flow structures makes a big variety of complex flows in nature and technology.

Then, a fundamental fact on flow structures is: all of them are measured not by primary variables themselves (e.g., velocity, pressure, and entropy) but their spatial-temporal derivatives, e.g. vorticity, dilatation, pressure gradient, and entropy gradient. These derivatives appear in the local balances of mass, momentum, and energy, and thereby interact each other to produce various dynamic effects, for example the aerodynamic force.

In a multi-dimensional, viscous and compressible flow, the local structures as exemplified above come from three fundamental dynamic processes: the (transverse) shearing process, the (longitudinal) compressing process, and the thermal process. The first two processes are the fundamental bulk dynamic processes in fluid motion which are measured by the vorticity field and dilatation field, and their characteristic behaviors are governed by the Reynolds number and Mach number, respectively. These two fundamental process are inherently coupled both in the interior of the flow field via the nonlinear terms of the governing equations, and on flow boundary owing to the adherence condition. In addition, the thermal process is inevitably involved as long as the flow is compressible. It can be conveniently measured by the entropy field which is inherently coupled with both compressing and shearing processes. Therefore, we introduce a general theoretical framework for multiple-process splitting and coupling and further apply it to examine the key flow structures and interactions based on our numerical simulations below [3-7].

ANALYSIS OF THE FUNDAMENTAL PROCESSES BASED ON NUMERICAL SIMULATION

The forces exerted on a body moving through a fluid depend strongly on the local dynamic processes and structures generated by the body motion, such as flow separation, vortices, etc. A detailed and quantitative understanding of the effects of these processes and structures on the instantaneous overall force characteristics is of fundamental significance, and may improve our capabilities for flow analysis and control. We apply alternative unconventional force expressions to analyze numerical solutions of unsteady and viscous circular-cylinder flows [4,8]. The results confirm the exactness of the expressions and, more importantly, provide a unified understanding of the specific influence on the force of each individual flow structure at its different evolution stages.

The force of flapping plates is studied by vortex dynamic analysis [1,4]. Based on the dynamic analysis of the numerical results of viscous flow past three-dimensional flapping plates, it is found that the force is strongly dominated by the vortical structures close to the body. Further, the dynamics of the flapping plate is investigated in terms of viscous vortex-ring model. It is revealed that the model can reasonably reflect the essential properties of the ring-like vertical structure in the wake, and the energy of the plate transferred to the flow for the formation of each vortical structure possesses a certain relation. The results also provide the understanding of the dynamic mechanisms relevant to flapping locomotion [1,2].

*Corresponding author. E-mail: xlu@ustc.edu.cn

Numerical simulation and analysis of compressible vertical flows past cylinder and foil are also carried out to deal with the fundamental dynamic processes and the relevant flow behaviors [5-7]. Various fundamental mechanisms dictating the intricate flow phenomena, such as turbulent boundary layer characteristics, kinematics of coherent structures, flow separation and separated shear-layer instability, have been studied systematically. The local flow structures are reasonably captured using the instantaneous Generalized Lamb vector divergence and curl, and the underlying dynamical processes are clarified. The results provide physical insight into the understanding of the mechanisms relevant to compressible vortical flows.

Summary Buoyancy-driven convection plays a crucial role in turbulent mixing. It is well known that, for certain parameter ranges, background rotation may enhance the heat transfer in Rayleigh-Bénard convection turbulence, mainly due to the Ekman pumping near the boundary and the tall vortical structures in the bulk. Here we present our results on the vortical structures in rotating RB flows for a fixed Prandtl number $Pr = 4.38$ and different Rayleigh numbers Ra. We identify the optimal rotation rate which generate the highest heat transfer enhancement. We reveal that the vortical structures may take different forms at the optimal rotation rate. For low Ra, the vortical structures at the optimal rotation rate occupy the whole height of the domain, while for high Ra these structures cannot extend through the bulk. Therefore, different behaviors of the heat transfer enhancement are observed.

INTRODUCTION

Rayleigh-Bénard (RB) convection, which happens when a fluid layer is heated from below and cooled from above, has been extensively studied to improve our understanding of turbulent transport and mixing [1]. Meanwhile, since the seminal work of Rossby [2], it is well-known that background rotation may improve the heat transfer in certain parameter range due the Ekman pumping, namely, rising or falling plumes of hot or cold fluid are stretched into vertically aligned vortices that suck fluid out of the thermal boundary layers adjacent to the bottom and top plates. The Ekman pumping process depends strongly on the control parameters [3].

In this talk we study the rotating RB flow and focus on the heat transfer enhancement and corresponding vortical structures in the field. Consider a fluid layer bounded by two parallel plates, which are perpendicular to the direction of gravity and separated by a height H. The bottom plate has higher temperature than the top one. The whole domain rotates about an axis which is parallel to the direction of gravity. The control parameters include the Prandtl number $Pr = \nu/\kappa$, namely the ratio of viscosity to diffusivity, the Rayleigh number $Ra = \beta g \Delta H^3/\kappa\nu$ which measures the strength of thermal driving, and the Rossby number $Ro = \sqrt{\beta g \Delta/H}/(2\Omega)$ which indicates the relative strength of rotation, respectively. Here β is the thermal expansion coefficient, g the gravitational acceleration, Δ the temperature difference between two plates, and Ω the rotation rate, respectively.

MAIN RESULTS

We numerically solve the incompressible Navier-Stokes equation within the Oberbeck-Boussinesq approximation by using our finite-difference code [4]. The two plates are no-slip and with constant temperature. In the horizontal directions we use periodic conditions. For rotation we only include the Coriolis force in the governing equations. Throughout this study we fix Pr at 4.38 and considered two Rayleigh numbers $Ra = 10^8$ and 2.3×10^9. Then for each Ra we gradually increase the rotation rate, or equivalently $1/Ro$, from zero to sufficiently large values. A general trend as $1/Ro$ increasing is that the heat flux, first increases from the value of non-rotating case and then rapidly decreases, and the heat transfer enhancement is achieved only for intermediate rotation rates. We refer to the rotation rate with the highest heat flux as the optimal rotation rate.

We first show the vortical structures at the optimal rotation rate for each Ra in figure 1. Clearly, the structures have very different morphology for the two cases. For $Ra = 10^8$ the optimal rotation rate is $1/Ro = 5$, and the vortical structures extend the whole bulk and are almost in the vertical direction. For $Ra = 2.3 \times 10^9$ the optimal rotation rate is $1/Ro = 1.6$, and the corresponding vortical structures are much less pronounced and much shorter. Thus, at the optimal rotation rate, the vortical structures are much more coherent at $Ra = 10^8$ than that at $Ra = 2.3 \times 10^9$.

In order to quantify the above observation we characterize the coherence of the flow structures by calculating the following cross-correlation:

$$C(\delta z) = \frac{\langle w(x,y,\lambda_u) w(x,y,\lambda_u + \delta z)\rangle_{x,y}}{\langle (w(x,y,\lambda_u))^2\rangle_{x,y}}, \quad (1)$$

*Corresponding author. E-mail: yantao.yang@pku.edu.cn

where $\langle\cdot\rangle_{x,y}$ indicates the average in horizontal direction. As we are interested in the vertically aligned vortices, we calculate the correlation using the horizontal plane at the viscous boundary layer height ($z = \lambda_u$), where the base of the vortices forms, as reference. Figure 2a,b show the correlation C as a function of the distance from the viscous boundary layer δz for different rotation rates. For all cases the correlation C first increases from 1 for $\delta z = 0$ to some maximum value before it decreases below 1 further away from the boundary layer. The reason for the maximum is that the vertical velocities are higher at some distance above the viscous boundary layer height than at $z = \lambda_u$.

We take the δz value at which the maximum occurs as a measure for the height of the vertically aligned vortices and the magnitude C_m of the peak of $C(\delta z)$ as a measure of the coherence of the vortices. Figure 2c,d show that the variation of C_m with $1/Ro$ is similar for both Ra, which suggests that the flow coherence mainly depends on the rotation rate. However, the height of the plumes or vertically aligned vortices, which is indicated by δz_m, is very different for the low and the high Ra's. For the low Ra the height of the vertically aligned vortices is larger at smaller $1/Ro$ than that for the high Ra. For $Ra = 2.3 \times 10^9$ the height at which the vertical coherence is highest is similar for the non-rotating case and the optimal rotation rate. In contrast, the vertical coherence at the optimal rotation rate is significantly higher than that for the non-rotating case at $Ra = 10^8$.

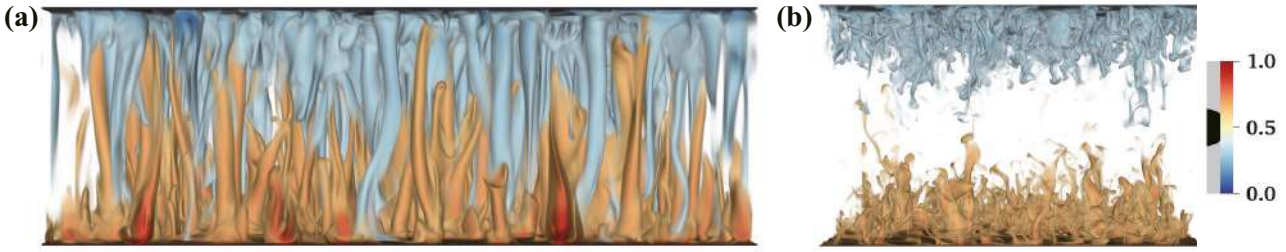

Figure 1: olume renderings of the temperature field at the optimal rotation rate for simulations with $Pr = 4.38$ at (a) $Ra = 10^8$ and (b) $Ra = 2.3 \times 10^9$. The colormap in both panels is identical. The figure shows that the flow structure at the optimal rotation rate is very different in the low and high Ra regime.

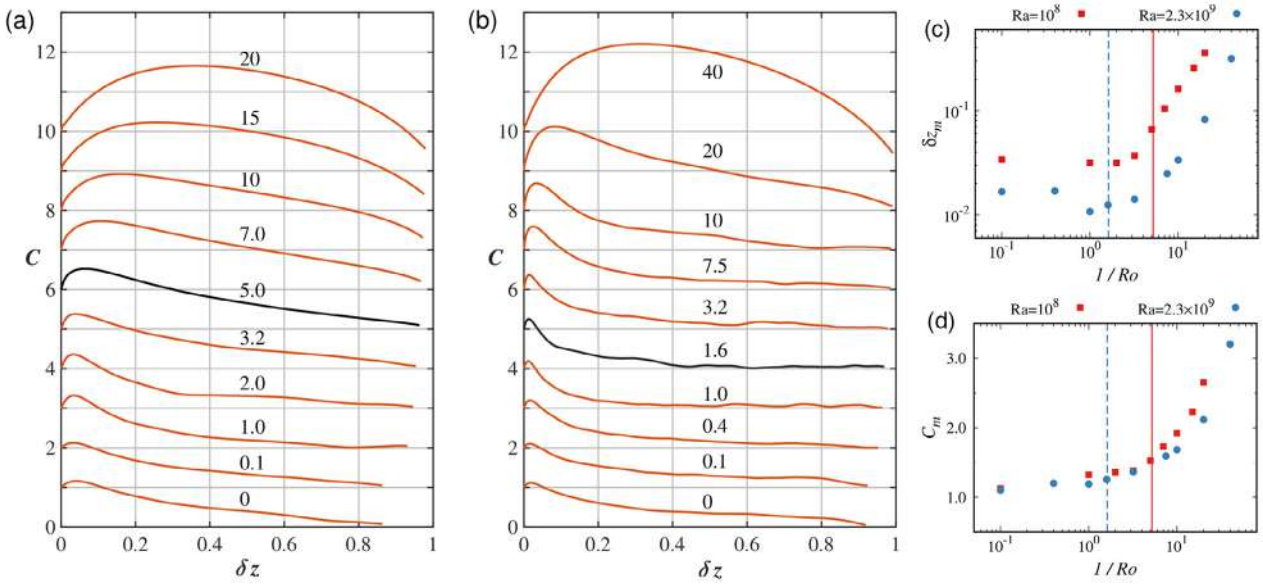

Figure 2: Correlation C as function of δz for different rotation rates in periodic domains in the (a) low ($Ra = 10^8$ and $Pr = 4.38$) and the (b) high Ra regime ($Ra = 2.3 \times 10^9$ and $Pr = 4.38$). The numbers indicate the value of $1/Ro$. The lines for each successive $1/Ro$ are shifted upward by 1 for visibility. The black line indicates the optimal inverse Rossby number. The (c) location δz_m and (d) magnitude C_m for the peak of the correlation function $C(\delta z)$ versus $1/Ro$ for $Pr = 4.38$ and two different Ra in periodic domains. The optimal rotation rate for $Ra = 10^8$ and $Ra = 2.3 \times 10^9$ is indicated by the solid and dashed line, respectively.

CHARACTERIZING THREE-DIMENSIONAL FEATURES OF VORTEX SURFACES IN FLOWS PAST A PLATE

Wenwen Tong[1] and Yue Yang[*1]
[1]State Key Laboratory for Turbulence and Complex Systems, College of Engineering, Peking University, Beijing 100871, China

Summary We extend the vortex-surface field (VSF), a Lagrangian-based structure identification method, to investigate vortex dynamics in flows past a plate simulated by the immersed boundary method. For the flow past an impulsively started translating plate, we quantitatively distinguish two types of vortical structures and refer them to as the leading edge vortex (LEV) and the tip vortex (TIV). We demonstrate that the lift generated from the LEV is suppressed by the finite growth of TIVs. In the wake region, we quantify the geometry of helical vortex lines in TIVs and the contribution of the helical vorticity component to the streamwise vortical impulse. Furthermore, we characterize the evolution of ring-like vortex lines and two series of inclined and distorted vortex rings in the wake of a flapping plate.

INTRODUCTION

The high lift and efficiency in unsteady flight relies on the generation of coherent vortical structures with strong three-dimensional features, e.g., the leading edge vortex (LEV) and tip vortex (TIV). The flow past a finite plate is a useful model for understanding the relationship between the vortical structures and forces and further improving flow control techniques. The interaction of LEV and TIV plays an important role in unsteady flight of finite wings, and the development of LEV can be suppressed by TIV [1]. In order to characterize the continuous evolution of vortical structures, Yang and Pullin [2] developed the vortex-surface field (VSF), whose isosurface is a vortex surface consisting of vortex lines. In the present study, we extend the VSF method to the flow past a finite plate. Then we characterize three-dimensional features of vortex surfaces in the flow evolution. In particular, we distinguish the LEV and TIV by introducing a mathematical definition of their boundary. Then we quantify the competition between LEV and TIV and the helical development of TIV tubes in the wakes.

NUMERICAL CONSTRUCTION OF VSFS

The immersed boundary method with the discrete stream function [3] is used to solve Navier-Stokes equations to get the velocity-vorticity field. The immersed boundary is represented by Lagrangian markers and the Lagrangian force is exerted on the immersed boundary to satisfy the no-slip condition. The calculation of VSFs is implemented as a post-processing step based on a times series of velocity-vorticity fields. We extend the VSF, which was only applied to flows with simple boundary conditions, to the immersed boundary condition which can have complex geometries. Since the plate is a vortex surface with all the vortex lines attached on its surface, thus we enforce the Dirichlet boundary condition for VSF on the plate by adding a source term to the VSF evolution equation. The two-time method [4] is used for calculating a Lagrangian-like temporal evolution of VSFs.

Using the numerical VSF solution, we characterize the temporal evolution of VSF isosurface for the flow past a translating plate (see Fig. 1). Based on the morphology of vortex surfaces and lines, we divide the VSF evolution into three-stages: (1) streamwise stretching of vortex lines on the plate; (2) rolling up of near-wall vortex surfaces; (3) formation of the hairpin-like vortex and helical vortex tubes.

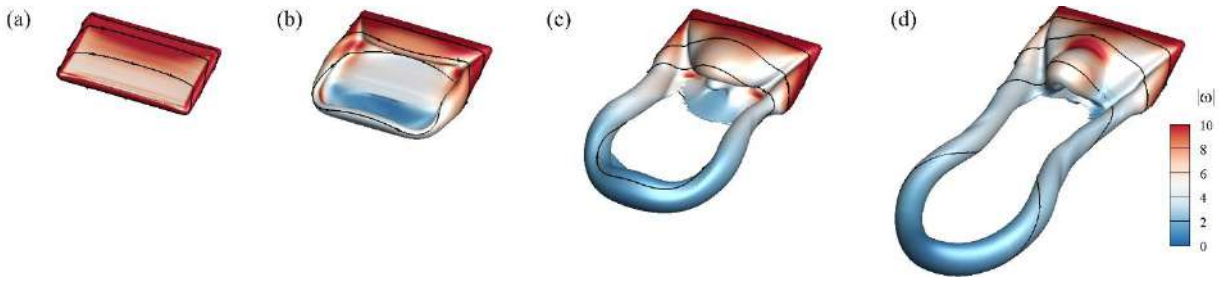

Figure 1. VSF isosurface color-coded by the vorticity magnitude at (a) $t = 0.1$, (b) $t = 1.0$, (c) $t = 3.0$, and (d) $t = 5.0$.

THREE-DIMENSIONAL FEATURES OF VORTEX SURFACES

The flow past a translating plate has two distinct three-dimensional features. Around the tip region, the LEV and TIV compete with each other. We distinguish LEV and TIV by mathematically defining the boundary of LEV based on $\omega_x = 0$ on the VSF isosurface in Fig. 2(a). Then we quantify the streamwise development of LEV and the competition between

*Corresponding author. E-mail: yyg@pku.edu.cn

LEV and TIV in Fig. 2(b), indicating that the LEV is suppressed by the finite growth of TIVs. In the wake region, the helical vortex lines evolve with time and form helical TIV tubes at a late time in Fig. 2(c). We apply a helical vortex model to characterize the development of the helical TIV, and we quantify that the helical vorticity component dominates the streamwise vortical impulse and further influences the drag force.

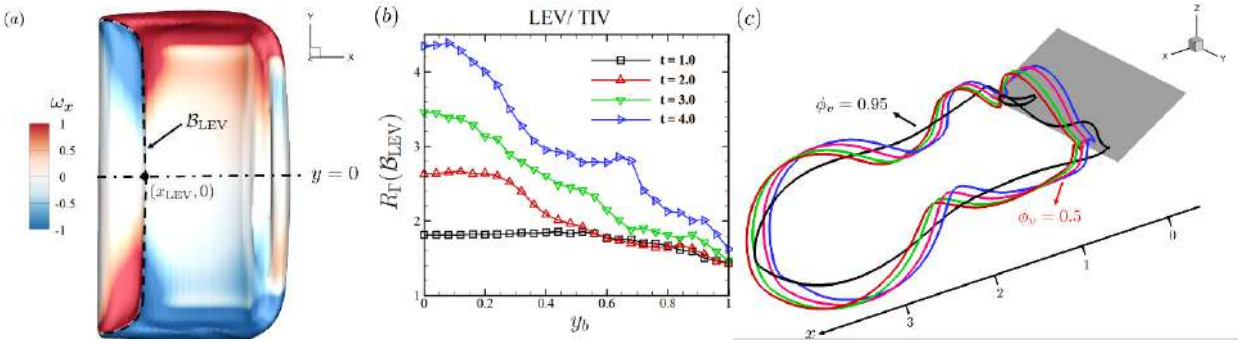

Figure 2. (a) The sketch of boundary of LEV at $t = 0.4$. (b) Relative intensity of LEV and TIV through the boundary of LEV. (c) Visualization of helical vortex lines on VSF isosurfaces at $t = 4.0$.

For the flow past a low-aspect-ratio flapping plate [5], the vortex surfaces with more complex geometry and topology are generated in the wake (see Fig. 3). Two ring-like vortical structures form in each flapping cycle T, and the wake is dominated by two series of distorted vortex rings. The shedding vortex surfaces roll up into vortex rings in further downstream, and generates jets with a pair of oblique rod-like structures. The vortical impulse is generated by inclined vortex rings, and it contributes to the thrust on the flapping plate.

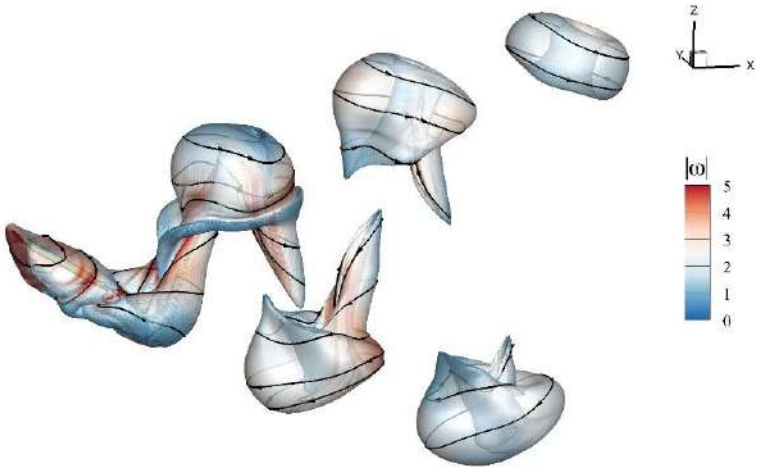

Figure 3. VSF isosurface at $t = 3T$ for the flow past a flapping plate.

CONCLUSIONS

We investigate the evolution of the VSF in the three-dimensional flow past a finite plate. The two-time VSF method is extended to the immersed boundary by adding a source term in the VSF evolution equation, and then the three-dimensional features of vortex surfaces can be characterized by numerical VSF solution. For the impulsively started translating plate, the VSF evolution can be roughly divided into three stages. We quantify the competition between the LEV and TIV, elucidating that the development of the LEV near tips is suppressed by the finite growth of the TIV. In the wake region, we quantify the helical development of TIV and demonstrate that the helical vorticity dominates the drag force. For the flow past a flapping plate, we characterize the evolution of ring-like vortex lines and two series of inclined and distorted vortex rings in the wake region.

EVOLUTION OF A VORTEX IN A STRATIFIED-ROTATING SHEAR FLOW

Iman Toghraei*[1] and Paul Billant[1]
[1]LadHyX, CNRS, Ecole Polytechnique, F-91128 Palaiseau CEDEX, France

Summary The dynamics of a vertical vortex subjected to an ambient shear flow has been studied numerically in a stratified-rotating fluid. Two distinct behavior have been observed depending on the Rossby number Ro, Froude number F_h and non-dimensional wavenumber K_z^* of the shear flow. When $K_z^* F_h \ll Ro$, the vortex is torn apart by the shear flow while in the opposite case, it resists to the shear flow and remains coherent. This result is explained thanks to the quasi-geostrophic scaling.

INTRODUCTION

Tropical cyclones such as the Hurricane Katrina (Figure 1) are the most deadliest vortices in nature. Their development can be prevented by the presence of a large ambient vertically sheared flow [2, 3]. This sensitivity to a shear flow has been reported to depend on the latitude [4]: cyclones at high latitudes (i.e. with higher Coriolis parameters) being less sensitive. In order to better understand these effects, we have investigated the dynamics of a single vortex in a sinusoidal shear flow as a function of the background rotation and the stratification.

Figure 1: Hurricane Katrina at peak intensity in the Gulf of Mexico [1]

NUMERICAL METHOD

The Navier-Stokes equations under the Boussinesq approximation has been simulated with a pseudo-spectral code (NS3D) in a rectangular box. The vortex is initially columnar with a Lamb-Oseen profile with vorticity $\omega_z = \Gamma/(\pi a_0^2)\exp(-r^2/a_0^2)$, where Γ is the circulation and a_0 the radius of the vortex. The shear flow has the profile $\boldsymbol{U} = U_s \sin(K_z z)\boldsymbol{e_x}$ where U_s is the shear flow amplitude and K_z is the vertical wavenumber (Figure 2). The height of the box l_z is set so as to simulate a single wavelength $K_z = 2\pi/l_z$ [5]. A buoyancy field is also associated to the shear flow due to the thermal wind balance.

The control parameters are the Rossby Ro, Froude F_h and Reynolds Re numbers, the rescaled vertical number K_z^* and shear flow amplitude:

$$Ro = \frac{\Gamma}{4\pi a_0^2 \Omega_b}, \quad F_h = \frac{\Gamma}{2\pi a_0^2 N}, \quad Re = \frac{\Gamma}{2\pi\nu}, \quad K_z^* = K_z a_0, \quad U_s^* = U_s \frac{2\pi a_0^2}{\Gamma}, \tag{1}$$

where Ω_b is the background rotation rate, N the Brunt-Väisälä frequency and ν the viscosity. The Schmidt number $Sc = \nu/\kappa$ is set to unity.

RESULTS

Figure 2 shows the evolution of the potential vorticity $\Pi = (\boldsymbol{w} + 2\Omega_b \boldsymbol{e_z}).\boldsymbol{\nabla} b_t$ in a strongly stratified fluid ($F_h = 0.5$) for weak rotation, $Ro = 5$, (top row) and strong rotation, $Ro = 1.67$, (bottom row). In the first case, the vortex is advected and completely torn apart by the shear flow. However, it's not only displaced in the direction of the shear flow but also in the perpendicular direction due to the self induction of the vortex. In contrast, when the rotation is higher $Ro = 1.67$, the vortex is not largely deformed by the shear flow but resists to it. Its bending deformation executes a rotation in the same direction as in the vortex core as reported previously [2]. Hence, the vortex displacement can be at some instant in the opposite direction of the shear flow.

The behaviour observed in several simulations for different parameters K_z^*, F_h and Ro are summarized in the parameter space $(K_z^* F_h, Ro)$ in figure 3. Typically the vortex resists to the shear flow (white circles) when $Ro \lessapprox K_z^* F_h$ and is torn apart otherwise (red circles). This result can be understand qualitatively by comparing the wavelength of the shear flow l_z to the quasi-geostrophic vertical length scale $a_0 F_h/Ro$. When $l_z \gg a_0 F_h/Ro$, i.e. $K_z^* F_h \ll Ro$, three-dimensional effects are weak and the vortex is not able to resist against the shear flow. On the other hand, when $Ro \ll K_z^* F_h$, three-dimensional effects are strong and keep the vortex coherent despite the effect of the shear flow.

The effects of the other parameters, (Re, U_s^*), the evolution of the minimum Richardson number as well as the evolution of the energy and enstrophy of the vortex have been also investigated.

*Corresponding author. E-mail: iman.toghraei@ladhyx.polytechnique.fr

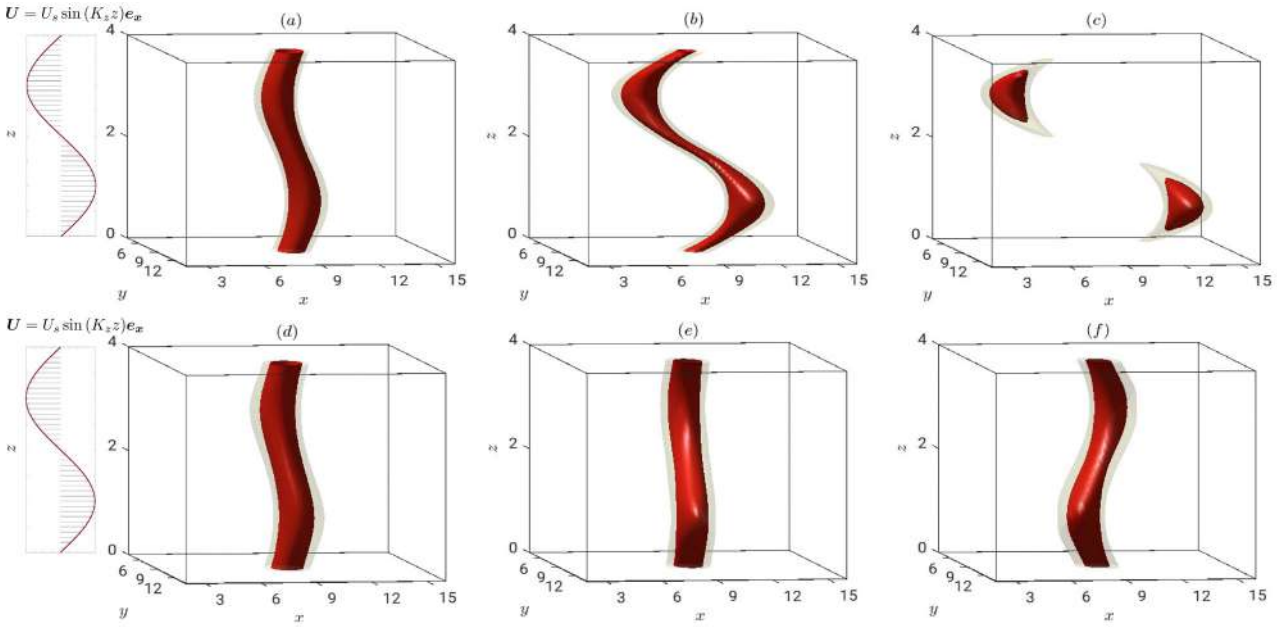

Figure 2: Evolution of the potential vorticity for $Re = 1000$, $K_z^* = \pi/2$, $F_h = 0.5$, $U_s^* = 0.2$ and $Ro = 5$ (top row) and $Ro = 1.67$ (bottom row) at $t = 5$ (a,d), $t = 20$ (b,e) and $t = 35$ (c,f)

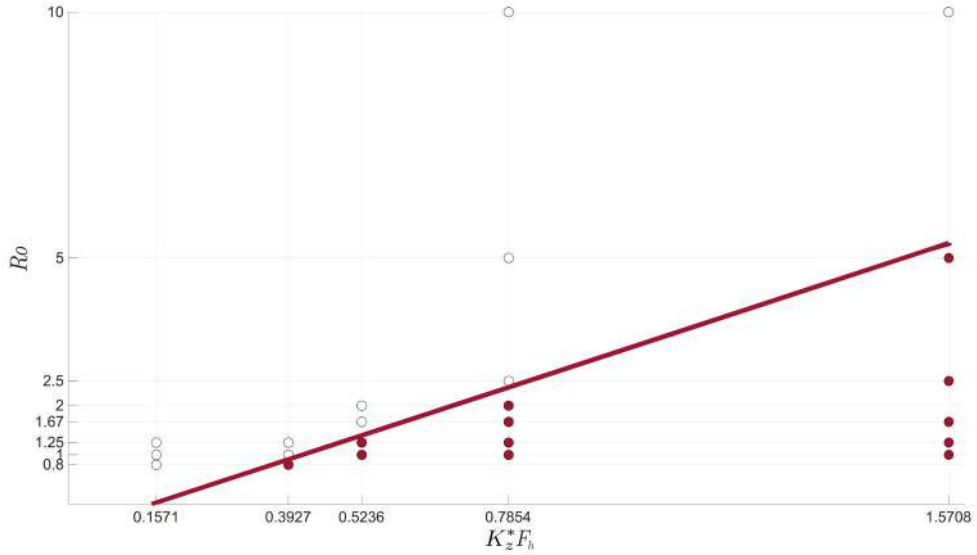

Figure 3: Summary of the simulations for $Re = 1000$ and $U_s^* = 0.2$ as a function of the rescaled wavenumber of the shear flow $K_z^* F_h$ and the Rossby number Ro. White circles indicate the simulations where the vortex is torn apart into two separated parts while the grey circles represent the simulations where the vortex remains coherent.

CONCLUSIONS

The evolution of a vortex in a stratified-rotating sinusoidal shear flow has been studied. Two different regimes have been identified. When three-dimensional effects are weak, the vortex is advected and torn apart by the shear flow. When three-dimensional effects are strong, the vortex resists the shear flow but it's bending deformation executes a rotation in the same direction as the vortex core.

ON THE STABILITY OF '2P' POINT VORTEX STREET EQUILIBRIA

Mark A. Stremler*
Department of Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA USA

Summary When a submerged bluff body oscillates transversely with respect to a uniform fluid flow at moderate Reynolds number, the wake structure that develops is most frequently of '2S' type or '2P' type. A useful reduced-order model of the wake consists of relative equilibrium configurations of $N = 2$ or $N = 4$ point vortices, respectively, in a singly-periodic strip. Th. von Kármán and others determined conditions for linear stability of '2S' point vortex streets with $N = 2$. We will discuss a linear stability analysis of '2P' point vortex street relative equilibria with $N = 4$.

BACKGROUND

Over a century ago [5, 6], von Kármán introduced his classic point vortex model of the flow pattern that appears frequently in the wake of a bluff body at moderate Reynolds number. This '2S' wake pattern (following the notation introduced in [11]) is formed when two single, counter-rotating vortices are shed alternately and periodically from a bluff body; an example is shown in Figure 1(a). The point vortex model of a general 2S street consists of two infinite parallel rows of oppositely-signed, periodically-spaced vortices or, equivalently, two oppositely-signed vortices in a singly-periodic domain of width h, as illustrated in Figure 1(b). The vortices move together as a relative equilibrium configuration for all values of the horizontal spacing a and vertical spacing b. The special case of the Bénard-Kármán vortex street corresponds to taking $a = h/2$, in which case the vortex motion is parallel to the rows.

A key aspect of von Kármán's analysis is the determination that the staggered configuration with $a = h/2$ is unstable to infinitesimal perturbations that preserve the energy and impulse of the system (to leading order) unless the vortex positions satisfy *von Kármán's criterion*, given by $\sinh(\pi b/h) = 1$, in which case the configuration is neutrally stable in the linearized analysis. The analysis has been extended to include obliquely translating 2S vortex street relative equilibria with $a \neq h/2$ [2, 7]. A linear stability analysis shows these configurations to be neutrally stable only when the vortex separations satisfy the *Dolaptschiew–Maue criterion*, $\sinh(\pi b/h) = \sin(\pi a/h)$; this criterion reduces to von Kármán's criterion when $a = h/2$.

It can be shown that instabilities with wavelength $2h$ are the most unstable [8]. Physically it can be argued that this is the most unstable mode because it is the mode of shortest extent that produces relative vortex motion. If this mode is not unstable to linear order, other modes of longer wavelength do not produce instability. Maue states [7]: "The proof is rather long and for a general understanding of the situation it is of secondary importance... The corresponding proof for the special case of von Kármán ... is indicated by Lamb."

'2P' POINT VORTEX STREET EQUILIBRIA

When a wake-producing body oscillates transversely with respect to the flow, more than two vortices may be generated per shedding cycle. The most common of these 'exotic' wakes is the '2P' wake [10], in which two pairs of vortices are shed per cycle; an example is shown in Figure 1(c). As a reduced-order model of the 2P-type wake, consider a system of $N = 4$ point vortices with positions $z_\alpha = x_\alpha + \mathrm{i}\, y_\alpha$ and circulations Γ_α in a singly-periodic strip of width L, as illustrated in Figure 1(d). In general, these vortices will move relative to one another, and there are sufficient degrees of freedom for the motion to be chaotic.

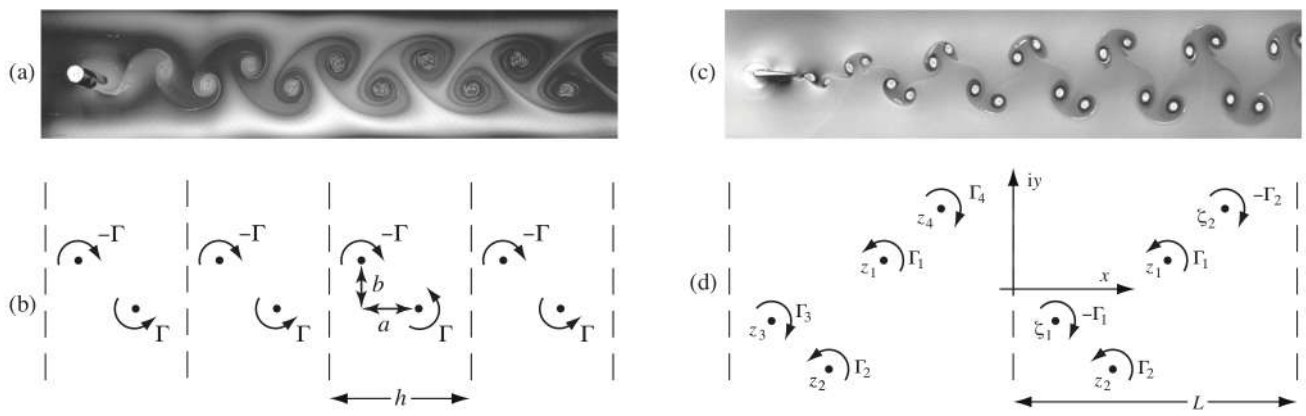

Figure 1: (a) 2S vortex wake behind a circular cylinder in a flowing soap film; photo by W. Yang (private communication). (b) A 2S point vortex street model. (c) 2P vortex wake behind a flapping foil in a flowing soap film, from [9]. (d) A 2P point vortex street model.

*E-mail: stremler@vt.edu.

Based on the shedding symmetries observed experimentally in 2P wakes, we assume that these $N = 4$ vortices are related via $\Gamma_3 = -\Gamma_1$ and $\Gamma_4 = -\Gamma_2$. As a further simplification, consider only those point vortex configurations that are moving in relative equilibrium, so that the inter-vortex spacing remains constant in time, analogous to the behavior of the classic 2S vortex streets. Finding these relative equilibrium configurations amounts to requiring that the translating velocity of each vortex be the same (complex) value V, giving the system of equations

$$V^* = \frac{1}{2Li} \sum_{\beta=1}^{N}{}' \Gamma_\beta \cot\left[\frac{\pi}{L}(z_\alpha - z_\beta)\right]. \tag{1}$$

Without any loss of generality, we assume $\Gamma_1, \Gamma_2 > 0$, and denote the locations of the negatively-signed vortices by $\zeta_1 \equiv z_3$ and $\zeta_2 \equiv z_4$. Under the vortex strength restriction $\Gamma_3 = -\Gamma_1, \Gamma_4 = -\Gamma_2$, the relative equilibrium configurations can be determined as a function of the parameters $\gamma = \Gamma_1/(\Gamma_1 + \Gamma_2)$, which is a dimensionless vortex strength, and

$$Z_0 = \tfrac{1}{2}(\Gamma_1 + \Gamma_2)\left[\gamma(z_1 - \zeta_1) + (1-\gamma)(z_2 - \zeta_2)\right], \tag{2}$$

which is proportional to the linear impulse for the vortex system. A few representative examples of relative equilibria for the special case $\mathrm{Im}(V) = 0$ are shown in Figure 2. Determination and characterization of exotic wake relative equilibria with $N = 4$ will be discussed.

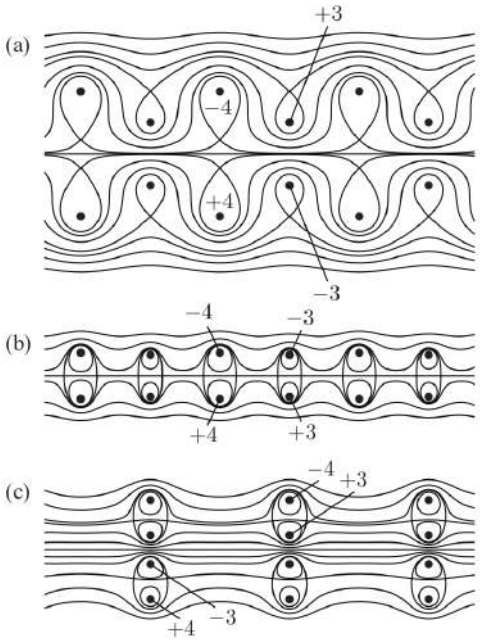

Figure 2: Example point vortex relative equilibria and representative streamlines in a co-moving frame for $N = 4$ and the parameters $\gamma = 3/7$ and $Z_0 = -1/2$. From [1].

STABILITY OF '2P' POINT VORTEX STREET EQUILIBRIA

The relevant stability analysis consists of (periodic, infinitesimal) perturbations in the (constant strength) point vortex locations from relative equilibrium states that preserve the energy and linear impulse of the system (to leading order). Based on the linear stability results for the 2S vortex streets, assume that the most unstable perturbations of the 2P vortex streets are those with the shortest wavelength that lead to relative vortex motion. For the 2P streets, superharmonic perturbations with wavelength L lead to relative motion, and thus it is these perturbations that form the basis of the linear stability analysis to be discussed.

Preserving the energy and linear impulse of the point vortex system under perturbation is a challenge that can be addressed in this case by adopting the 'Domm variables' [3] as used by Eckhardt & Aref [4] to analyze the motion of two vortex pairs in the plane, given here by Z_0 from (2), which is a constant of the motion, and

$$\hat{Z}_0 = \tfrac{1}{2}(z_1 + z_2 + \zeta_1 + \zeta_2), \quad Z_+ = \tfrac{1}{2}(z_1 - z_2 + \zeta_1 - \zeta_2), \quad Z_- = \tfrac{1}{2}(\Gamma_1 + \Gamma_2)\left[\gamma(z_1 - \zeta_1) - (1-\gamma)(z_2 - \zeta_2)\right]. \tag{3}$$

The vortex separations are independent of $\hat{Z}_0$, and as a result the system can be described by a Hamiltonian function $\mathcal{H}(Z_+, Z_-; Z_0)$ with equations of motion given by $\mathrm{d}Z_+^*/\mathrm{d}t = \mathrm{i}\,\partial\mathcal{H}/\partial Z_-$ and $\mathrm{d}Z_-^*/\mathrm{d}t = \mathrm{i}\,\partial\mathcal{H}/\partial Z_+$.

In the Domm system, the desired perturbations are achieved by holding Z_0 fixed while perturbing the Domm variables as $Z_+ + z_+$ and $Z_- + z_-$. Solutions of the resulting equations of motion for the (infinitesimal) perturbations z_+ and z_- show, to leading order, that there exist (neutrally) stable relative equilibrium configurations for the 2P vortex street, similar to the classic results for the von Kármán street. This linear stability analysis will be presented and discussed.

NUMERICAL INVESTIGATION OF THE STABILITY OF A LAMB-OSEEN VORTEX IN TWO-WAY COUPLED PARTICLE-LADEN FLOWS

Shuai Shuai[1] and M. Houssem Kasbaoui[1]
[1]School for Engineering of Matter, Transport and Energy, Arizona State University, Arizona, U.S.A

Summary This paper investigates the stability properties of the particle-laden Lamb-Oseen vortex. We conduct DNS simulation of the two-phase flow in the Eulerian-Lagrangian framework. Unlike the single-phase case where the Lamb-Oseen vortex is hydrodynamically stable to small perturbations, the presence of inertial particles leads to the emergence of an instability characterized by a concentration wave that expands radially from the core of the vortex. We examine how the interaction between inward fluid motion and outward particle ejection by the preferential concentration mechanism modifies the stability of the two-phase vortex.

INTRODUCTION

The swirling motion of a vortex is most often modeled using the Lamb-Oseen profile, a full solution to the Navier-Stokes equations. In a single-phase flow, a constant density Lamb-Oseen vortex is hydrodynamically stable [1]. This remarkable property explains why vortex tubes shed by an aircraft remain stable for long times.

When inertial particles are dispersed, the stability properties of the flow may be altered. Owing to the preferential concentration mechanism, inertial particles tend to accumulate in regions of low vorticity and high strain rate [2]. When dispersed in a vortex, such particles are ejected from the vortical core resulting in an outward momentum transport. The relative motion of particles and fluid leads to a configuration that could be subject to a Rayleigh-Taylor instability.

In this study, several 2D simulations are conducted to investigate the behavior and characteristics of the particle-laden Lamb-Oseen vortex flow. We show from numerical simulations that an instability exists when the full coupling between the two phases is considered. If the particle-feedback is neglected, the Lamb-Oseen vortex remains stable.

PHYSICAL MODEL

Vortex tubes can be represented using the Lamb-Oseen profile given by

$$\boldsymbol{u}_f(r,\theta) = \frac{\Gamma}{2\pi r}\left(1-\exp(-\frac{r^2}{r_c^2})\right)\boldsymbol{e}_\theta \tag{1}$$

where $\boldsymbol{e}_\theta$ represents the azimuthal direction, Γ is the vortex circulation and r_c is the vortex core radius. As demonstrated in [1], a two-dimensional Lamb-Oseen vortex is stable to small perturbations. However, little is known about the stability properties of the flow when inertial particles are present.

We explore the stability of the particle-laden Lamb-Oseen vortex with Eulerian-Lagrangian numerical simulations. In this framework, the governing equations for the fluid and the "i"-th Lagrangian particle are

$$\frac{\partial}{\partial t}\left(\rho_f(1-\phi)\right) + \nabla\cdot\left((1-\phi)\rho_f\boldsymbol{u}_f\right) = 0 \tag{2}$$

$$\frac{\partial}{\partial t}\left((1-\phi)\rho_f\boldsymbol{u}_f\right) + \nabla\cdot\left((1-\phi)\rho_f\boldsymbol{u}_f\boldsymbol{u}_f\right) = \nabla p + \mu_f\nabla^2\boldsymbol{u}_f + \boldsymbol{F}_p \tag{3}$$

$$\frac{d\boldsymbol{x}_p^i}{dt} = \boldsymbol{u}_p^i; \quad \frac{d\boldsymbol{u}_p^i}{dt} = f_D\frac{(\boldsymbol{u}_f-\boldsymbol{u}_p^i)}{\tau_p} \tag{4}$$

where ϕ is the particle volume fraction, $\boldsymbol{F}_p$ is the interphase momentum exchange term due to the force exerted by particles on fluid, f_D is the drag correction term. In the semi-dilute regime considered here, the remaining fluid-particle and particle-particle forces can be neglected.

The dynamics of Lamb-Oseen vortex in the semi-dilute regime are determined by 4 non-dimensional numbers. The Reynolds number based on the vortex circulation is defined as $\mathrm{Re}_\Gamma = \Gamma/2\pi\nu_f$ and determines the strength of the vortex swirl velocity. The Stokes number determines the particle inertia and is given by $\mathrm{St} = \rho_p\Gamma d_p^2/36\pi\mu_f r_c^2$. The coupling between the two phases is determined by the mass loading $M = \langle\phi\rangle\rho_p/\rho_f$, where $\langle\phi\rangle$ is the mean volume fraction. A measure of the discrete Lagrangian effects is given by the ratio of the vortex core radius and particle diameter. Simulations where the particle feedback force on the fluid is considered are identified as two-way coupling simulations, otherwise the simulations are labeled as one-way coupling. A summary of runs and parameters is given in Tab. 1. In all cases considered, $0.2 \leq \mathrm{St} \leq 1$ and $M = 1$ corresponding to significant particle inertia and strong interphase coupling. Effects due to the discrete nature of Lagrangian particles are negligible owing to a large ratio $r_c/d_p \simeq 625$. The Reynolds and Stokes numbers are varied by adjusting the vortex circulation.

Table 1: Non-dimensional parameters considered in this study.

	Case 1	Case 2	Case 3	Case 4
Re_Γ	1×10^3	1×10^3	3×10^3	5×10^3
M	1	1	1	1
St	0.2	0.2	0.6	1
r_c/d_p	625	625	625	625
Coupling type	One–way	Two–way	Two–way	Two–way

NUMERICAL SETUP

The simulations are conducted in a square domain of size $60r_c \times 60r_c$ with a grid of size 1536×1536. The computational domain is split in four quadrants where four anti-symmetrical vortices with randomly distributed Lagrangian particles are initialized. This approach allows the use of straightforward periodic boundary conditions while providing simultaneously 4 realizations of the flow. The governing equations are solved with the Eulerian-Lagrangian strategy in the flow solver NGA [3].

RESULTS AND CONCLUSION

The Eulerian-Lagrangian simulations point towards the existence of an instability that damps the core vorticity when two-way coupling is considered. Snapshots in Fig. 1 show how particles migrate outwards due to the swirling flow. In case 1 (one-way coupling), a sharp volume fraction front forms and the vortex structure is unchanged. In case 2 (two-way coupling), the volume fraction front is disrupted by azimuthal modes due to the formation of particle clusters and void bubbles. The interphase coupling leads to an outward dispersion of vorticity.

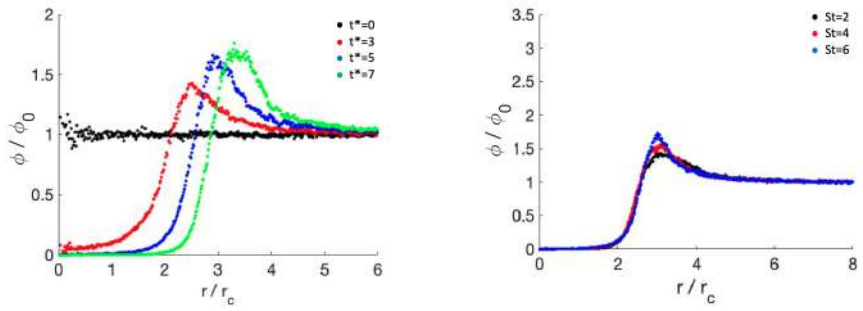
Figure 1: Particle volume fraction and vorticity magnitude at $t^* \approx 1$: (a,b): one-way coupling; (c,d): two-way coupling.



(2a) (2b)

Figure 2: Particle volume fraction profile: (a) case 2 at various non-dimensional times, (b) various St at $t^* = 5$.

Fig. 2a shows the radial evolution of the volume fraction front. Owing to the preferential concentration mechanism, particles are ejected from the vortex core leading to the outward transport of momentum and unstable coupling with the fluid. This process is controlled by a time scale $\tau_f = 2\pi r_c^2/(\Gamma \mathrm{St})$ as evidenced by the collapse of curves from all cases considered in Fig. 2b.

These preliminary simulations shed light on a novel instability that occurs in particle-laden vortex tubes. In future work, we will quantify the azimuthal mode that emerge and analyze the energy transfer between the two-phases.

OBSERVATIONS OF VORTEX INSTABILITIES IN THE WAKES OF COAXIAL ROTORS

Mehmet Fatih Konus, and Ömer Savas,*
Department of Mechanical Engineering, University of California, Berkeley, CA 94720-1740 USA

Summary The stability characteristics of helical vortex filaments are studied experimentally in a water tank in the wakes of a coaxial rotor model, of 26-cm diameter at rotor separations of 0.25-1 radius and speeds of 2-8 rps. The vortices from the lower rotor experience extreme distortions. At small separations, lower rotor filaments develop longwave vortex pairing instabilities while upper rotor filaments do not have sufficient space to develop mutual interactions. At a separation of half radius, hairpin vortices form beneath the lower rotor during the development of the longwave instability. Shortwave instabilities form quickly along the helical filaments at 2 & 4 rps cases whereas at 6 & 8 rps filaments develop them long after their formation simultaneously with the longwave instability mode where filaments develop large distortions beneath the lower rotor.

INTRODUCTION

Rotorcraft trail helical vortex filaments, generating an unsteady three-dimensional wake structure [1], which create a nonuniform inflow distribution over the rotor disk and continue to affect this distribution as they move downstream [2]. The characteristics of this inflow is greatly affected by the geometry of the wake and the behavior of the vortices below the rotor. Presence of second rotor introduces more complexities into the flow field. Interactions among the helical filaments of the same rotor and the different rotors as well as interactions of helical filaments from one rotor with the blades of the other rotor largely affect the stability and wake characteristics of coaxial rotor filaments. Even though the stability characteristics of two parallel vortex filaments are well studied [3], those of helices, however, have not been explored to same degree since the pioneering work Widnall [4]. Effect of coaxial rotor parameters, rotor spacing and rotor speed, on the stability and wake characteristics of the helical filaments is investigated through flow visualization and PIV measurements, an extension of the work on a single rotor by Ohanian *et al.* [5].

APPARATUS

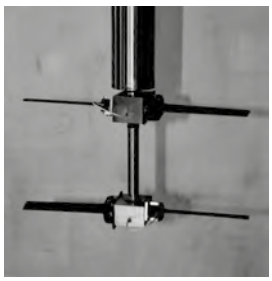

Figure 1: Coaxial rotors at separation $H/R = 1$.

Figure 1 shows the coaxial rotor model consisting of two $2R = 26$-cm diameter counter-rotating two-bladed rotors with a root cut-out of 3.2 cm, which are driven by a microstepper motor though a gearbox. The rotor separation H is set by using shaft extensions, H/R ranging from 0.25 to 1. The untapered blades, twisted 5°, are molded from carbon fiber reinforced plastic with length of $l = 9.5$ cm and chord of $c = 1.9$ cm, hence of solidity of $\sigma = 2cl/\pi R^2$ for a single rotor and $2\sigma = 0.136$ when in the coaxial configuration. The cores of the blade-tip vortices are rendered visible by injecting dye into the flow from the blade tips through tubes embedded in the blades. The collective angle is set to $\theta = 13.5°$. The experiments are done in a 1.2 m wide, 2.4 m long, and 1.2 m deep water tank.

GENERAL VORTEX WAKE CHARACTERISTICS

Figure 2 shows a sample flow at $H/R = 0.41$ and 6 rps. The first frame is an instantaneous picture of the wake where the filaments off the tips can be traced. The helices off the upper rotor maintain their helical form until the interact with lower rotor. The vortices off the lower rotor start out nearly helically, but soon, along with those off the upper rotor, undergo severe distortions. The second frame is the time average of the images over 25 revolutions of the rotors. The radius of the wake of the upper rotor contracts to about $0.75R$ by the time it reaches the lower rotor while the initial contraction of the wake of the lower rotor is to about $0.90R$. Further downstream, the combined wake expands and becomes diffuse due to the interaction of the vortex filaments. The third frame is the phase averaged image at the rotor phase corresponding to the first frame. The phase averaged vortex positions are indistinguishable from the instantaneous ones in the first frame, with almost no dispersion, which indicates a nearly deterministic behavior of the vortex interactions in these flows, the long wave instabilities in particular.

Figure 2: An instantaneous image, time averaged image and phase averaged image (25 samples) at $H/R = 0.41$ and 6 rps.

VORTEX INSTABILITIES

Longwave instabilities

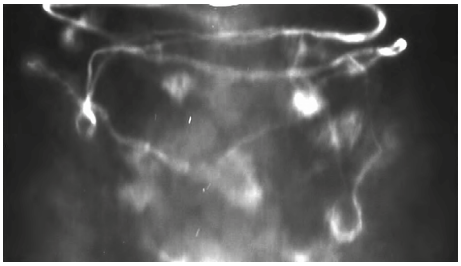

Figure 3: Two hairpins below the lower rotor. $H/R = 0.5$ at 8 rps.

In the longwave instability mode, which is also referred to as leapfrogging process, two adjacent vortices trailed from the blade tips of the lower rotor start to orbit around each other as they travel together in the streamwise direction. This is when these vortices start to develop unusual deformations as the turns of the trailing vortex leapfrog through the turns of the leading vortex. The contribution from the vortices trailed from the upper rotor affect the behavior of the lower vortices significantly, resulting in extreme deformation of the latter. The lower vortices get stretched in the streamwise direction and at certain rotor spacings they deform to into hairpin vortices, losing their orderly helical shapes. The most notable example of this kind of vortex structure formation is observed at rotor spacing of $H/R = 0.5$, an example of which is shown in Figure 3 where two hairpin vortices are visible on either side of the figure. Regardless of the rotor separation, the lower rotor continually operates in the wake of the upper rotor, resulting in mutual interactions between the vortices trailed from both rotor. Also, as the upper rotor filaments pass through the plane of the lower rotor, they interact with the lower rotor blades, which, in turn, cause them to become diffuse and make their subsequent trajectories hard to follow.

Shortwave instabilities

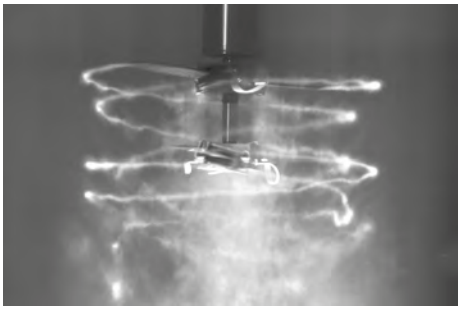

Figure 4: Shortwaves.$H/R = 0.5$ at 4 rps.

At rotor speeds of 2 & 4 rps, shortwave instabilities develop along all filaments. At 6 & 8 rps, however, filaments exhibit shortwave instability characteristics long after their generation and only locally, which become superimposed with the dominant longwave instability mode in the downstream locations of the wake (Figure 4). Figure 5 shows the shortwave instability wavelength λ/R against the vortex age ψ, which are extracted from flow images. The average wavelength in the wake of the upper rotor is $\lambda/R = 0.21 \mp .05$ and $0.25 \mp .08$ in the wake of the lower one. The wavelength data suggest that there is not a particular pattern for shortwave instability wavelengths at a particular rotor, rotor separation or speed, even though the average wavelengths along the upper rotor filaments is slightly lower than those along the lower rotor filaments. Although the wavelength data do not suggest a clear distinction between the upper and the lower rotor filaments, it is clear from the flow visualization images that the amplitude of the short waves along the lower rotor filaments grow in amplitude more rapidly than those along the upper rotor filaments.

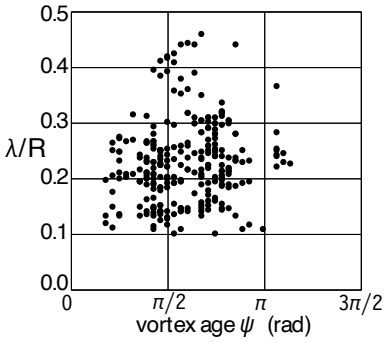

Figure 5: Consolidated shortwave instability wavelengths.

CONCLUSIONS

The tip vortices trailed from the lower rotor experience extreme distortions. At smaller rotor spacings $H/R < 0.5$, lower rotor filaments develop longwave vortex pairing instabilities along with extreme distortions. At $H/R = 1$, the upper rotor filaments develop longwave pairing instabilities similar to a single rotor, whereas those from lower rotor become unstable within first rotor revolution. At $H/R = 0.5$, hairpin vortices form beneath the lower rotor during the longwave instability mode developed by the lower rotor filaments. Similar deformations of the vortex filaments are observed at all rotor spacings. However, the clearest hairpin vortex structures are seen at the rotor spacing of $0.5R$. Regardless of the rotor spacing, shortwave instabilities formed along the helical filaments at 2 & 4 rps cases from their generation whereas at 6 & 8 rps filaments are only observed to develop these types of instabilities long after their formation and not as clearly as those observed in the wake of a single rotor [5], as they become superimposed with longwave instability mode.

TRANSIENT BEHAVIOR IN SPIN-UP OF THERMAL CONVECTION

Daisuke Noto*[1], Yuji Tasaka[1], Takatoshi Yanagisawa[2,1], Takehiro Miyagoshi[2], and Yuichi Murai[1]
[1]Laboratory for Flow Control, Hokkaido University, Sapporo, Japan
[2]Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Yokosuka, Japan

Summary Transient behavior in spinning-up of Rayleigh–Bénard convection (RBC) was experimentally investigated by giving an impulsive rotation to non-rotating RBC. For comprehensive understanding of the transient flow structures, the thermochromic liquid crystal particles were seeded into test water, and velocity and temperature fields were quantified. Thermal turbulent structures were blown away due to the impulsive rotation, and subsequently the concentric roll structures emerged from side walls to center of the fluid containers. Depending on the thermal and rotational force intensity, the roll structures were found to take two different states, spiral and ring structures. In both cases, the rolls collapsed into azimuthally aligned vortices along the roll boundaries. The size of the vortices emerged at the time is equivalent to that of the columnar vortices formed in equilibrium rotating RBC.

INTRODUCTION

Rotating thermal convection

Rayleigh–Bénard convection (RBC) in a rotating field has attracted many researchers in various research fields, e.g. fluid physics, geo-/astrophysics, and so on. Rotating RBC can be mainly characterized by two nondimensional parameters; Rayleigh number expresses the thermal force intensity as $Ra = g\beta\Delta T H^3/(\nu\kappa)$, where g, β, ΔT, H, ν, and κ are the gravity acceleration, the thermal expansion coefficient, the vertical temperature difference, the vertical gap between top and bottom plates, the kinematic viscosity, and the thermal diffusivity. Taylor number indicates the Coriolis force intensity as $Ta = (2\omega H^2/\nu)^2$, where ω is the angular velocity of the system. It is well known that the flow structure in rotating RBC is governed by columnar vortices with tall and narrow structures stretched into the rotational axis when both the thermal and rotational forces possess equivalent intensity to each other. Past studies have revealed flow morphologies, heat transfer characteristics and its scaling laws in detail at fully developed, i.e. equilibrium states of rotating RBC.

Transient states during spin-up of thermal convection

On the other hand, some researchers focused on the transient states appeared during spinning-up of thermal convection, not the equilibrium states. Boubnov and Golitsyn [1] reported formation of concentric convection rolls which aligned from center to wall inside a open cylindrical fluid container heated from the bottom. Vorobieff and Ecke [2] investigated quantitatively the flow structures during spinning-up of RBC (confined both top and bottom boundaries), and found that columnar vortices are formed by the Kelvin–Helmholtz (KH) instability. Zhong et al. [3] conducted a similar experiment in an open rectangle cavity only cooled by the air and reported the same transient phenomena; formation of concentric roll structures and columnar vortex formation due to KH instability. What they have in common is the formation of ring shaped convective roll structures regardless of the container geometry and the initiation order of convection or rotation. Although these experimental works explained these phenomena qualitatively and quantitatively in their intrinsic conditions, a comprehensive understanding of all the transient phenomena is still missing and valuable to be investigated.

EXPERIMENTAL INVESTIGATIONS ON SPIN-UP OF THERMAL CONVECTION

We conducted visualization experiments in two different radii cylinders with the same height (aspect ratio $\Gamma = 2.00$ and 4.75) confined with degassed water ($Pr \sim 7$). For visualization, thermochromic liquid crystal (TLC) particles were seeded into the test fluid, and a horizontal cross-section at the mid-height was illuminated by a white light sheet. TLC particles scatters specific coloration corresponding to the temperature, and its motion can be utilized for the velocity measurement. Two Rayleigh number $Ra = 2.0 \times 10^6$ and 1.0×10^7 with 5 different Taylor values $3.0 \times 10^6 \leq Ta \leq 2.0 \times 10^8$ are explored for both cylinders, and 20 parameters are compared in total. By giving an impulsive rotation to a fully developed non-rotating RBC at the specific Ra, transient states were observed until the equilibrium states of rotating RBC were realized.

Formation of concentric convective rolls

Soon after the initiation of the impulsive rotation, the thermal turbulent structures were blown away due to intense rotation, and concentric roll structures are formed as shown in Fig. 1(a) and (b). We found that two types of roll structures can be formed; spiral and ring, and they are easy to be distinguished to each other from the coloration of the visualized images. Types of roll structures of all the explored parameters are summarized in Fig. 1(c) as a regime diagram in Ra-Ta domain. The diagram clearly shows Ta and Γ dependence of the roll type, i.e. faster rotation and smaller cylinder tends to form ring-type rolls. Interestingly, two types of rolls can be roughly divided by the convective Rossby number at $Ro = \sqrt{Ra/(Pr\,Ta)} = 0.1$. Also, considering the fact that larger Γ was hard to form rings, the relatively stronger centrifugal force than the thermal force must have influenced the types of the roll formation.

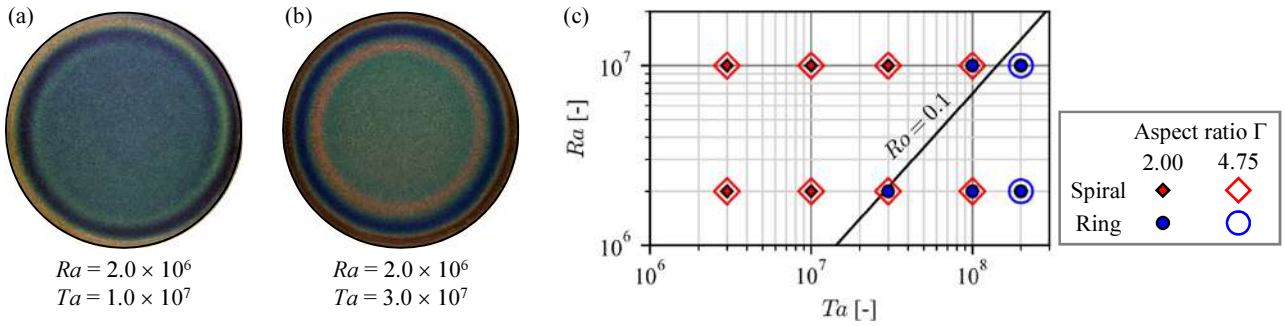

Figure 1: Two types of concentric roll structures visualized by TLC particles in the same cylinder ($\Gamma = 2.00$): (a) spiral ($Ra = 2.0 \times 10^6$, $Ta = 1.0 \times 10^7$) and (b) ring ($Ra = 2.0 \times 10^6$, $Ta = 3.0 \times 10^7$), and (c) a regime diagram for roll formation types of all the explored parameters in Ra-Ta domain.

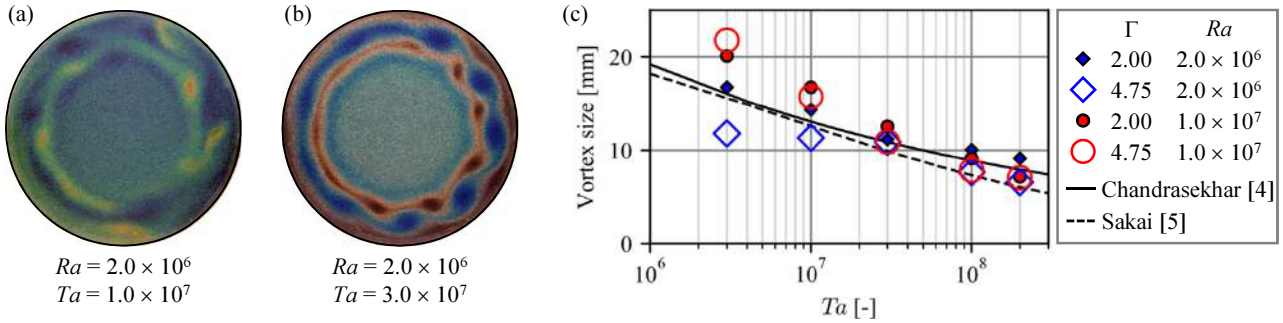

Figure 2: Formation of vortical structures along roll boundaries due to the KH instability ($\Gamma = 2.00$): (a) spiral ($Ra = 2.0 \times 10^6$, $Ta = 1.0 \times 10^7$) and (b) ring ($Ra = 2.0 \times 10^6$, $Ta = 3.0 \times 10^7$), and (c) horizontal size of vortical structures.

Emergence of azimuthally aligned vortices

After the formation of concentric roll structures, vortical structures emerged at roll boundaries as shown in Fig. 2(a) and (b). This is due to strong shear at the roll boundaries and KH instability is induced. The horizontal size of the vortices appeared at this moment is plotted in Fig. 2(c), which can be obtained using the tangential wavenumber and the radial positions of them. What should be pointed out here is that the horizontal vortex size during this transient state matches well with the cell size at the convection onset theoretically estimated by Chandrasekhar [4]. In addition, the columnar vortex size under the equilibrium state of rotating RBC estimated by Sakai [5] also shows good agreement with the present results. The columnar vortices under the equilibrium state are originated in the thermal plumes and their size are automatically determined to transport heat throughout the fluid container. And thus, the vortices formed by the KH instability and the columnar vortices in rotating RBC should have different formation mechanism.

CONCLUSIONS

Transient flow structures during spinning-up of Rayleigh–Bénard convection (RBC) were investigated experimentally. As former works showed previously, there are stepwise transitions from non-rotating RBC to rotating RBC; emergence of concentric roll structures and following formation of vortical structures. Two types of concentric roll structures were found: spiral and ring structures. Relatively weak centrifugal force to the thermal force tends to induce inperfection of ring roll formation. It is required to investigate the mechanism of spiral and ring roll formation more detail. Subsequently to the roll formation, azimuthally aligned vortical structures were formed along the roll boundaries due to the Kelvin–Helmholtz (KH) instability regardless of the type of the roll. The vortical structures possessed equivalent horizontal size to that of the columnar vortices formed under the equilibrium state of rotating RBC, even though the formation mechanism of them cannot be identical. The reason why the KH induced vortices and the columnar vortices possessed the same size is still an open issue and should be clarified.

VORTICAL STRUCTURE IN A HOMOGENEOUS ISOTROPIC TURBULENCE

Katsuyuki Nakayama[1]
[1]Department of Mechanical Engineering, Aichi Institute of Technology, Toyota, Japan

Summary Velocity structure of a vortex in a homogeneous isotropic turbulence is investigated including the vortical flow symmetry characteristic associated with the stability, pressure minimum and vortex stretching. The swirlity specifies the vortex center as its local maximum point, and the swirl plane and direction of the elliptic geometry of the vortical flow are given by the local geometry at the center. The statistical analysis shows that a vortex is not axisymmetric irrespective of the intensity of swirling. In the development of a vortex, its scale, vortical flow symmetry and pressure minimum codevelop. However, the vortex stretching component for the swirling is more intense in a weaker vortex. An intense vortex influences the turbulent flow more greatly, while the support of self-sustaining/reinforcing by the stretching become less.

INTRODUCTION

Vortices play important roles in a turbulent flow, and their dynamics change the turbulent features. The particular characteristics of vortices such as stability [1] or pressure minimum are derived from the velocity structure of the vortices. It has been shown that the statistical velocity structure of vortices in a homogeneous isotropic turbulence is similar to the Burgers vortex [2] that has axisymmetric velocity structure and can hold its structure as a steady state.

On the other hand, the several topological (geometrical) quantities have been defined in terms of the local flow given by the velocity gradient tensor $\nabla \boldsymbol{v}$, which enable to specify the precise flow geometry. The swirlity and sourcity specify the unidirectionality and intensity of the respective azimuthal and radial flows in a plane, i.e., swirl plane, and the vortical flow symmetry quantity identifies the skewness or elliptic shape of the vortical flow [3]. Specifically, it is noted that the vortical flow symmetry is an important quantity for pressure minimum characteristic and vortex stretching [4, 5]. These quantities have shown that, in the local geometry, vortices in the aforesaid turbulence are not axisymmetric [5].

The present study investigates the velocity structure of a vortex with a finite scale in a homogeneous isotropic turbulence with a low Reynolds number. In the statistical analysis, unifying the elliptic direction of vortical flow derives the precise vortical structure and characteristics. The analysis in different intensities of swirlity shows that vortical flow symmetry and scale of the vortex codevelop with the swirlity. On the other hand, effective vortex stretching to strengthen the swirling is more intense in the weak vortex. This is consistent with a vortex model of a vortex life in terms of the local flow where the more intense vortex has less benefit in the vortex stretching for swirling in this turbulence [5].

ANALYSIS AND DISCUSSION

Vortical structure is analyzed in a homogeneous isotropic decaying turbulence at the Taylor Reynolds number $Re_\lambda = 36$, where the pseudo-spectral method with the phase-shifting method is applied with the wavenumber $k < 121$ in the region $(2\pi)^3$ composed of 256^3 nodes [5]. The local maximum point of swirlity φ, as a center of a vortex, is identified using the spacial derivative and the Hessian (Hesse matrix) of φ at the node of the numerical analysis. The swirl plane Π is defined by the real and imaginary vectors of the complex conjugate eigenvectors of $\nabla \boldsymbol{v}$ [2].

Figures 1 and 2 show the velocity distributions $\boldsymbol{v}_{pl}$ of statistical intense and weak vortices in Π, respectively, where the velocity at the center is set to be zero. It is noted in all figures that x_1 and x_2 axes in Π are parallel to the complex conjugate eigenvectors of $\nabla \boldsymbol{v}$ [3-5]. φ at the center in the intense and weak vortices are approximately $\varphi_{ave} + \delta_\varphi$ and $\varphi_{ave} - \delta_\varphi$, respectively, where φ_{ave} and δ_φ denote the average and deviation of φ in vortical region ($0 < \varphi$), respectively. Their velocity distributions show that the scale of vortical flow depends on the intensity of swirling (φ). They also indicate that the vortical flows are not symmetric (axisymmetric) and exhibit skewed (elliptic) geometry. The decomposed azimuthal and radial flows in $\boldsymbol{v}_{pl}$, $\boldsymbol{v}_\theta$ and $\boldsymbol{v}_r$, clearly show that both $\boldsymbol{v}_\theta$ and $\boldsymbol{v}_r$ are not symmetric irrespective of the intensity of vortices. Specifically, although they are inflow (convergent) vortices, $\boldsymbol{v}_r$ has weak outflow in some directions (parallel to the eigenvector of $\boldsymbol{v}_r$ [3, 5]), which indicates that both vortices are difficult to have the efficient vortex stretching that strengthens both swirling and orthogonality of the vortical axis [5]. The vortical flow symmetry quantities c ($0 \le c < 1$) and sourcity σ at the center in the intense and weak vortices are $(c, \sigma) = (0.73, -7.8)$ and $(0.55, -3.1)$, respectively. It is noted that $c = 0$ and 1 indicate the shear and axisymmetric vortical flows, respectively.

Figures 3 and 4 show the contours of φ, pressure minimum ι_2, and vortex stretching component $\boldsymbol{nS\omega}$ in terms of swirling, in Π of the respective intense and weak vortices. ι_2 denotes the (negative) Hessian of the pressure in terms of flow kinematics (vortical flow) in Π [4], and is given by: $\iota_2 = (\varepsilon_R^2 - \varphi^2) + |(c - 1/c)\varepsilon_R|\varphi$ where ε_R denotes the average intensity of $\boldsymbol{v}_r$ that is equal to the real part of the complex conjugate eigenvalues of $\nabla \boldsymbol{v}$ [3] (note $\iota_2 < 0$ for pressure minimum feature). $\boldsymbol{nS\omega}$ denotes the inner product of the unit normal vector n_i of Π and vortex stretching vector $S_{ij}\omega_j$, where S_{ij} and ω_i ($i, j = 1,2,3$) denote the rate-of-strain tensor and vorticity vector, respectively. The weak vortex has approximately a quarter of φ in the intense vortex and slight pressure minimum feature, however, it has more intense vortex stretching effect for swirling, i.e., as twice as that in the intense vortex. This characteristic that more intense vortex has higher flow symmetry but less benefit of the stretching for swirling is similar to that in vortices in terms of the local geometry [5].

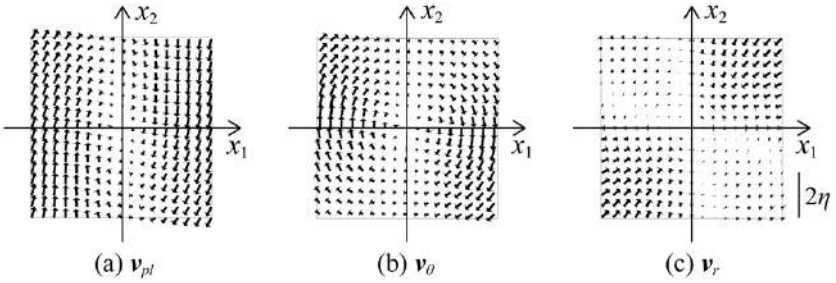

Figure 2. Velocity distribution of a weak vortex in Π. (a) $\boldsymbol{v}_{pl}$, and decomposed (b) $\boldsymbol{v}_{\theta}$ and (c) $\boldsymbol{v}_{r}$.

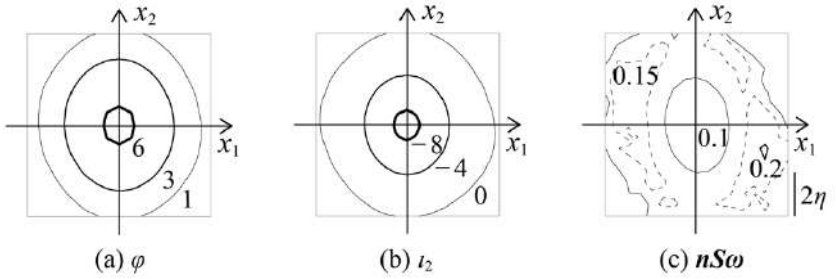

Figure 3. Distributions of (a) φ, (b) ι_2, and (c) $\boldsymbol{nS\omega}$ of an intense vortex in Π.

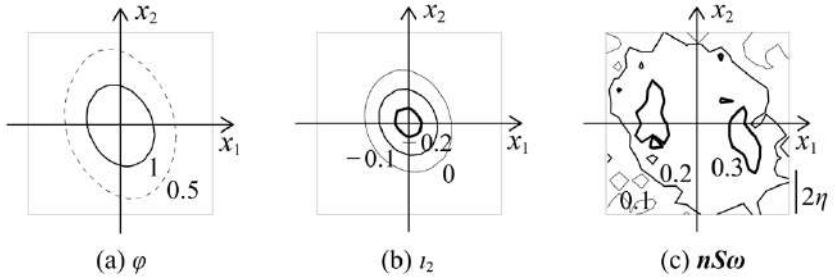

Figure 4. Distributions of (a) φ, (b) ι_2, and (c) $\boldsymbol{nS\omega}$ of a weak vortex in Π.

CONCLUSIONS

Vortices in a homogeneous isotropic turbulence is not axisymmetric and develop with both scale and vortical flow symmetry. An intense vortex has higher vortical flow symmetry and pressure minimum, however, the vortex stretching effect for swirling becomes less. A developed vortex that has a bigger scale and more intense swirlity and pressure minimum may influence greatly the turbulent flow, but decreases the support of self-sustaining/reinforcing function that may be associated with the limit of the growth.

FORMATION AND SCALING OF PRIMARY AND SECONDARY VORTICES

Guillaume de Guyon, Diego Francescangeli, and Karen Mulleners*
Institute of mechanical engineering,E cole polytechnique fédérale de Lausanne,Switzerland

Summary Vortices do not grow indefinitely. Depending on how they are generated, vortices reach different dimensional sizes and strengths, but their formation process is bounded by the same energetic constraint. The formation time of a primary vortex generated by accelerating objects from rest or impulsively ejecting fluid through holes has been studied extensively. The secondary vortices that form from the vorticity rejected by the primary vortex have received less attention. We present time-resolved experimental data of the formation process of primary and secondary vortices behind translating and rotating objects being uniformly accelerated from rest. We found a scaling law for the vortex circulation that predicts a constant limiting non-dimensional value for all acceleration and velocity values tested. Based on this scaling, the secondary vortices are 4 times weaker than the primary vortex.

INTRODUCTION

When a bluff body is accelerated from rest or a slug of fluid is impulsively ejected through an orifice or a nozzle in a quiescent fluid, a primary vortex is formed in the wake of the body or behind the orifice or nozzle exit. Due to the motion of the body or the slug of fluid with respect to the quiescent flow, vorticity is generated at the solid walls and accumulates in a shear layer that rolls up into a coherent vortex [1]. As the motion continues, this primary vortex grows in size and strength up to a certain limit at which it will no longer take up additional circulation and will pinch-off from the shear layer that feeds it. The dimensionless time at which the vortex pinch-off occurs is referred to as the vortex formation time or number. For various canonical flows with vortex shedding, a formation time of $T^* \approx 4$ can be observed, but the universal nature of vortex formation is not primarily tied to this magical number [2, 3]. It is the result of a more fundamental limiting physical process known as the Kelvin-Benjamin variational principle that states that vortex growth is governed by maximising the impulse-normalised energy. Any additional vorticity that is transported through the shear layer beyond the growth limit is rejected by the primary vortex and accumulates in a series of trailing secondary vortices. These secondary vortices are similar to each other in size and strength and they are generally substantially smaller and weaker than the primary vortex. The most prominent example is probable a completed vortex ring and its trailing jet generated by a piston cylinder [2].

The formation time scales of the primary vortices generated by accelerating a bluff body from rest or impulsively ejecting fluid by a piston cylinder have been studied extensively in the past [4, 5, 6]. The secondary vortices that form from the vorticity rejected by the primary vortex have received considerably less attention. If the vortex formation process is truly universal, it should also apply to the formation of the secondary vortices. To understand and characterise the differences in timing, strength, and size between primary and secondary vortices, we have experimentally studied the formation process of vortices behind a translating cone and around a rotating flat plate in water. In both cases, the objects were uniformly accelerated from rest up to a given constant translational or rotational velocity. The uniform acceleration, final translation or rotational speed, and the object geometries have been varied to investigate their influence on the timescales of the vortex formation process and on the circulation and size of the shed primary and secondary vortices. This information was extracted from time-resolved particle image velocity measurements around the objects.

RESULTS

Two exemplary snapshots of the vorticity field behind the translating cone and the rotating flat plate are presented in figure 1. The cone in figure 1(a) has been moving upwards from its starting position at $y/D = 0$ and has reached a constant velocity of $0.35\,\mathrm{m\,s^{-1}}$ above $y/D = 0.33$. An axisymmetric vortex ring is forming directly behind the cone with an aperture of $60°$ and base diameter $D = 61.5\,\mathrm{mm}$. The Reynolds number for this configuration is 2×10^4 based on the base diameter and the final constant translation velocity. The ridges of the positive and negative finite-time Lyapunov exponent (FTLE) are overlaid on the vorticity field and indicate the transport boundaries of the vortex. Only vorticity on the inside of the positive enveloping FTLE ridge will end up in the vortex, the rest will not be entrained and remains behind. The temporal evolution of the total circulation and the vortex circulation within the FTLE ridge is presented in figure 1(b). The total circulation in the flow field continues to increase while the cone is translating. The vortex circulation, normalised by the translation velocity and the base diameter, converges to a constant value of $\Gamma/(UD) \approx 2.2$ after a formation time $T^* = L/D \approx 3.5$ with L the vertical distance travelled before reaching a constant vortex circulation. The end of the vortex formation time corresponds exactly to the time at which the non-dimensional energy $E^* = E\sqrt{I\Gamma^3}$ drops below the critical value of 0.33 in accordance with the work of Gharib et al. [2]. Here, E, I, Γ are the vortex kinetic energy, impulse, and circulation.

The flat plate in figure 1(c) has been rotated $90°$ in clockwise direction from its initial vertical location at rest. At this time, the primary vortex has shed as well as three secondary vortices. The primary vortex is substantially larger in size and

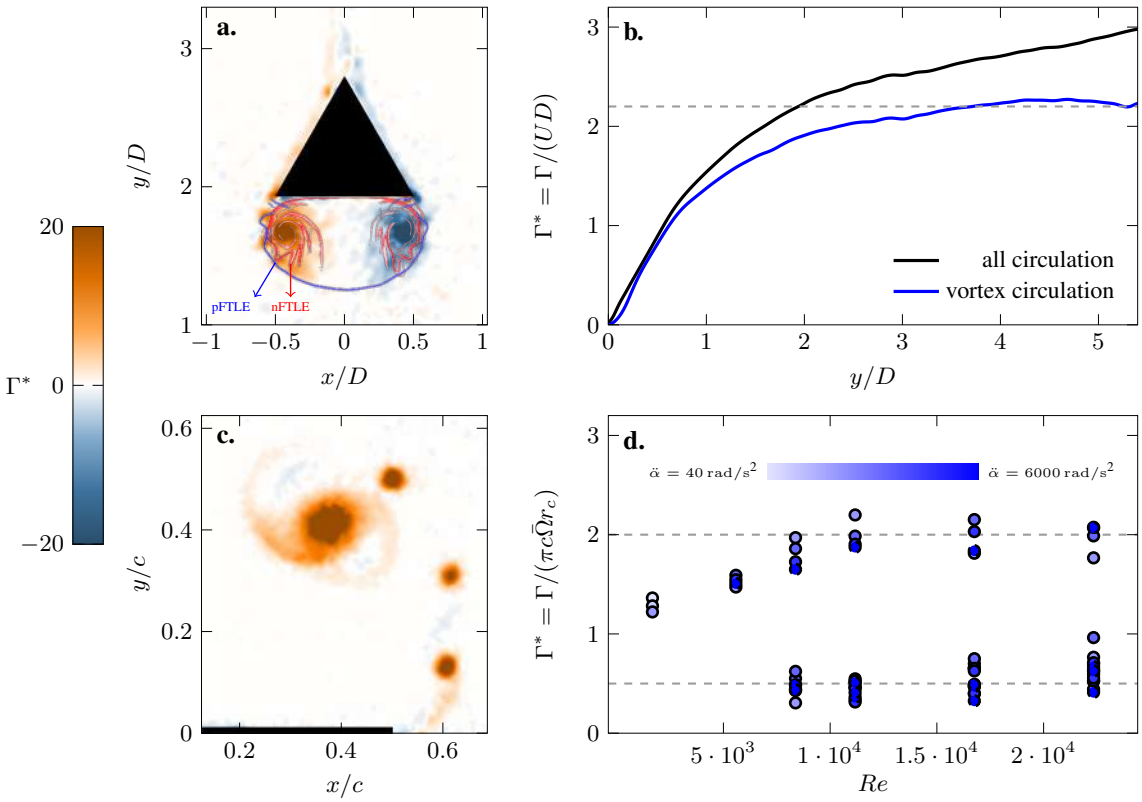

Figure 1: Snapshot of the vorticity fields generated by a translating cone (a.) and a rotating flat plate (b.) in a quiescent fluid. Temporal evolution of the circulation within the primary vortex and in the entire wake behind the translating cone (b.). Scaling of the circulation of the primary and secondary vortices created by the rotating flat plate for various rotation rates and acceleration values (d.).

strength that the secondary structures. A scaling of the vortex strength is proposed as $\Gamma^* = \Gamma/(\pi c\bar{\Omega} r_c)$, with c the width of the plate, $\bar{\Omega}$ the equivalent velocity inspired by Glezer [7], and r_c the size of the vortex core non-dimensionalised by the shear layer thickness. The normalised circulation values after a $90°$ rotation for the primary and secondary vortices for various rotational speeds and accelerations are presented in figure 1(d). The colours of the markers indicate the uniform acceleration value. The rotational speed is expressed through the Reynolds number based on the width and the tip speed of the plate. Two groups can be distinguished. The markers with values of non-dimensionalised circulation above 1 correspond to primary vortices and the other markers below correspond to the secondary vortices. Above $Re \approx 7 \times 10^3$, the primary vortices all have a non-dimensional circulation of $\Gamma^* \approx 2$ and for the secondary vortices $\Gamma^* \approx 0.5$. Below $Re \approx 7 \times 10^3$, the non-dimensional circulation of the primary vortex is lower that 2 and no secondary vortices are observed. For these lower Re conditions, the primary vortex has not reached its limiting size and strength yet after a rotation of $90°$ and will continue to take up vorticity when the motion continues.

OUTLOOK

Based on the analysis of the vortex formation processes behind the translating and rotation objects we derived a new kinematic argument for the closure of the primary vortex that will be presented as an alternative to the energetic argument based on the Kelvin-Benjamin principle. We will also present a model for the vortex growth behind the cone and discuss the vorticity leaking phenomenon that causes the vortex circulation to increase slower that the total circulation. The timing of the vortex shedding around the rotating flat plate has been analysed and core sizes of the primary and secondary vortices will be compared.

THEORETICAL PREDICTIONS FOR THE DRAG FORCE DUE TO EXOTIC WAKES

Emad Masroor*[1] and Mark A. Stremler [2]
[1]Engineering Mechanics Program, Virginia Tech, Blacksburg VA
[2]Department of Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg VA

Summary We present a generalized formulation of von Kármán's analysis of the drag on a bluff body with a vortex-street wake, allowing for the existence of exotic wakes with more than 2 vortices per period. This formulation recovers von Kármán's formula as a special case. We apply the method to exotic wakes by considering systems of N point vortices and their periodic images in relative equilibrium, allowing us to make quantitative comparisons of the drag due to exotic wakes with von Kármán's canonical drag formula.

INTRODUCTION

In 1911, von Kármán considered the drag (or thrust) on a two-dimensional body in uniform flow whose wake takes the form of what is now known as the Bénard - von Kármán vortex street: two rows of counter-rotating vortices [5]. Using the momentum flux through a contour surrounding the cylinder and cutting through the wake, and representing the wake as a series of point vortices in an ideal fluid, he developed the famous formula known by his name that relates the drag on a bluff body to the characteristics of its wake. In dimensionless form, this formula was given by [2] as

$$C_D = \frac{4}{\pi}\frac{L}{d}\frac{U_s^2}{U_\infty^2}\left[\coth^2\frac{\pi h}{L} + \left(\frac{U_\infty}{U_s} - 2\right)\frac{\pi h}{L}\coth\frac{\pi h}{L}\right], \tag{1}$$

where U_s is the self-induced velocity of the double row of vortices, U_∞ is the velocity of the free stream, L is the wavelength of the system, d is the length scale of the bluff body, e.g. the diameter of a cylinder, h is the transverse distance between the two rows, and C_D is the predicted coefficient of drag.

There is a wealth of recent work showing that the Bénard - von Kármán street is not the only arrangement of vortices that persists in the wakes of immersed bodies. The wakes of several moving and/or stationary bluff bodies are known to take on other, repeatable vortex patterns, which were first extensively classified by [8] according to the number and pairings of the vortices in each period of motion. Thus, the '2S' mode was assigned to wakes with two single vortices shed per period, the 'P+S' mode for a pair of vortices together with a single vortex per period, and the '2P' mode for two pairs of vortices per period. These modes are the most extensively documented ones, although more recent work has even found wakes with up to sixteen vortices per period [6]. Theoretical predictions for the forces exerted on a body whose wake takes these complicated forms, analogous to (1) for a Bénard - von Kármán street, are not currently available. Our work aims to fill this gap by generalizing (1) for more complicated vortex-street wakes.

The well-documented experimental observation of discrete, almost-spatially-periodic, temporally persistent vortical structures in bluff-body wakes, such as the 'P+S' and '2P' modes, is mirrored in ideal hydrodynamics by the existence of relative equilibrium solutions to the dynamical system comprised of $N = 3$ and 4 point vortices, respectively, in a singly-periodic vertical strip. The vortex trajectories associated with these equilibrium and near-equilibrium solutions have been shown [7] to approximate the behavior of real vortices in the wakes of bluff bodies reasonably well. Often, the time scale of relative motion of vortices (in a co-moving frame) is of approximately the same order as the convective time scale. Hence, many real vortex-street wakes can be fruitfully analyzed using equilibrium configurations of point vortices in a periodic strip, even when the vortices in the wake are exhibiting relative motion.

EXAMPLE: A PERIODIC VORTEX-STREET WAKE WITH N VORTICES PER PERIOD

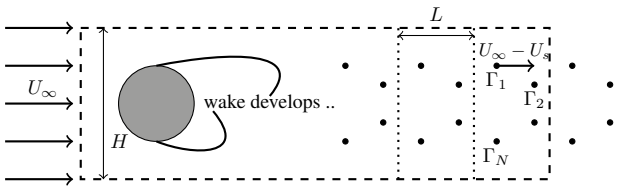

Figure 1: A periodic vortex-street wake with $N = 4$

We consider a wake that, in the well-developed region, can be approximated by a system of N point vortices (together with their periodic images to the left and right), as indicated in figure 1. The strengths $\mathbf{\Gamma} = (\Gamma_1, \Gamma_2, \ldots \Gamma_N)$ and locations in the complex plane $\mathbf{z} = (z_1, z_2, \ldots z_N)$ of the vortices are assumed to be such that the vortices are in *relative equilibrium*; these equilibria can be found using methods given by, e.g., [1]. The vortices tend to move to the left under their mutual induction at a speed U_s, but they are swept to the right with a velocity $U_\infty - U_s$ under the influence of the free stream.

We then write Newton's second law for the control volume defined by the dashed rectangle, supposing that the width H of the rectangle is made large enough that all disturbances die down at the horizontal boundaries; then, [3] gives the average drag force on the body as the sum of two terms,

$$F_D = \rho \oint y\zeta(\vec{v}\cdot\vec{n})\mathrm{d}s - \frac{1}{2}\rho\mathrm{Re}\int_{-H/2}^{+H/2}(u - iv)^2\mathrm{d}y = F_{D_1} + F_{D_2}, \tag{2}$$

*Corresponding author. E-mail: emad@vt.edu

where ζ is the vorticity, ρ is the fluid density, and $u - iv$ is the complex velocity induced by the system of vortices.

The first term, F_{D_1}, represents the flux of '$y \times \zeta$' out of the control volume, averaged over one period. For a system of point vortices, this is identical to the imaginary part of the linear impulse of the N vortices that leave the contour every period, i.e. the flux of $P = \sum_i^N \Gamma_i y_i$ averaged over one period.

The second term, F_{D_2}, requires the evaluation of the velocity induced by the point vortices at the right-side boundary of the control volume. Although the value of the velocity at any point will change with time, by Cauchy's residue theorem the integral in (2) will not change under certain symmetry conditions; thus, it is sufficient to calculate for any one instant the value of the integral in F_{D_2}.

These two terms can then be non-dimensionalized and added to give the expression for the coefficient of drag as

$$C_D = \frac{4}{\pi}\frac{L}{d}\frac{U_s^2}{U_\infty^2} \cdot f_1 \left[f_1 f_2 + \mathcal{P}\left(\frac{U_\infty}{U_s} - 1\right)\right], \tag{3}$$

where $\mathcal{P}$ is a non-dimensionalized form of P, and the non-dimensional quantities f_1 and f_2 are defined by the relations

$$U_s = \Gamma/(2L) \cdot f_1(\mathbf{z}, \mathbf{\Gamma}),$$
$$f_2(\mathbf{z}, \mathbf{\Gamma}) = \pi L/(\Gamma) \int (u - iv)^2 \mathrm{d}y.$$

Scalar Γ is the sum of the strengths of all vortices with positive circulations (or, equivalently, the sum of the strengths of all vortices with negative circulations). Thus f_1 expresses the relationship of $\mathbf{z}$ and $\mathbf{\Gamma}$ with U_s, and f_2 expresses the relationship of $\mathbf{z}$ and $\mathbf{\Gamma}$ with the integral in F_{D_2}.

Equation (3) is a generalized form of von Kármán's drag formula, and it can be applied to any spatially-periodic wake with the vortices in relative equilibrium by determining f_1, f_2, and $\mathcal{P}$ as a function of the vortices' positions and strengths. For the Bénard - von Kármán street, the three terms have straightforward closed forms: $f_1 = -\coth \mathcal{P}$, $f_2 = 1 - \mathcal{P}\tanh \mathcal{P}$ and $\mathcal{P} = -\pi h/L$. By substituting these expressions, we verify that (1) is indeed a special case of (3).

CONCLUSIONS

We use this method to give theoretical predictions for the drag force exerted on a body whose wake takes the often-observed 'P+S' or '2P' forms, using relative equilibrium configurations for $N = 3$ and 4 respectively. A representative example for a system of 4 vortices and their periodic images in relative equilibrium, representing a '2P' wake, is given in figure 2, where we show the predicted coefficient of drag as a function of Strouhal number $St \equiv f \cdot d/U_\infty$, with f the frequency of vortex shedding. The Strouhal number is itself an empirically-known, increasing function of the Reynolds number — as documented by, e.g. [9] — that varies between about 0.18 and 0.25 in the Reynolds number range $100 < Re < 1000$.

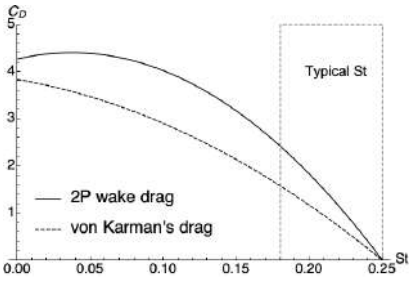

Figure 2: Predicted drag as a function of Strouhal number

It has long been known that abrupt changes in the mode of vortex shedding are related to changes in the forces experienced by the shedding body [4]. This work allows us to classify exotic wakes such as the '2P' and 'P+S' modes according to whether they lead to an increase or decrease in the drag force they cause on the body compared to the standard Bénard - von Kármán -type wake. Our model therefore suggests a theoretical basis for possible drag reduction or thrust-enhancement due to a 'switch' from one vortex-shedding mode to another.

VISUALIZATION OF MACROSCOPIC VORTEX RINGS IN SUPERFLUID ^{4}HE

Patrik Švančara and Marco La Mantia*
Faculty of Mathematics and Physics, Charles University, Prague, Czech Republic

Summary Macroscopic vortex rings are generated thermally in superfluid ^{4}He, by applying a brief heat pulse. The rings form above a circular tube and propagate upward with velocities of the order of 10 mm s^{-1}, resulting in Reynolds numbers up to 10^5. We visualize their cross-section, of size comparable with the 5-mm tube diameter, by capturing the ring-induced motions of small solid particles. We employ the latter to compute the Lagrangian pseudovorticity, which can be seen as a measure of the ring strength. We thus obtain information on the size, position and velocity of the vortex rings. We show that, in the range of investigated parameters, these rings behave as if they were turbulent vortex rings moving in classical viscous fluids, at least in the direction of ring propagation.

INTRODUCTION

The superfluid phase of liquid ^{4}He, which occurs at temperatures below 2.17 K, at the saturated vapour pressure, is often called He II and is characterized by unique properties, such as an extremely small kinematic viscosity, see, for example, [1] and references therein. Its turbulent flows are defined by the presence of quantized vortices, which are line singularities within the liquid, and quantum turbulence is the name usually given to the phenomenon originating from the mutual interaction between quantized vortex tangles and flows of superfluid ^{4}He.

We report here an experimental investigation on the motion of macroscopic vortex rings in a quiescent He II bath, following [2], where macroscopic means at scales larger than the mean distance between quantized vortices. The rings are thermally generated above a circular nozzle, after a short heat pulse, and have sizes of the order of the nozzle diameter, see figure 1(a). They are visualized by using relatively small solid particles, dispersed in the experimental volume and illuminated by a planar laser sheet. The particle time-dependent positions are collected by a digital camera and processed by using the Particle Tracking Velocimetry (PTV) technique, see, for example, [3] and references therein.

Specifically, we observe the ring cross-section, appearing as a pair of counter-rotating vortices. In order to characterize the ring strength we employ the concept of Lagrangian pseudovorticity pv, which was introduced in [4] to account for the fact that the PTV technique does not give access to the classical Eulerian vorticity. We calculate the parameter on a square mesh and obtain relevant pv-maps, see an example in figure 1(b). As it is clear from the latter, the tool is adequate for the visualization of the generated vortex rings, which can be identified as regions of relatively large $|pv|$ values, and, consequently, it is possible to quantitatively track their motion.

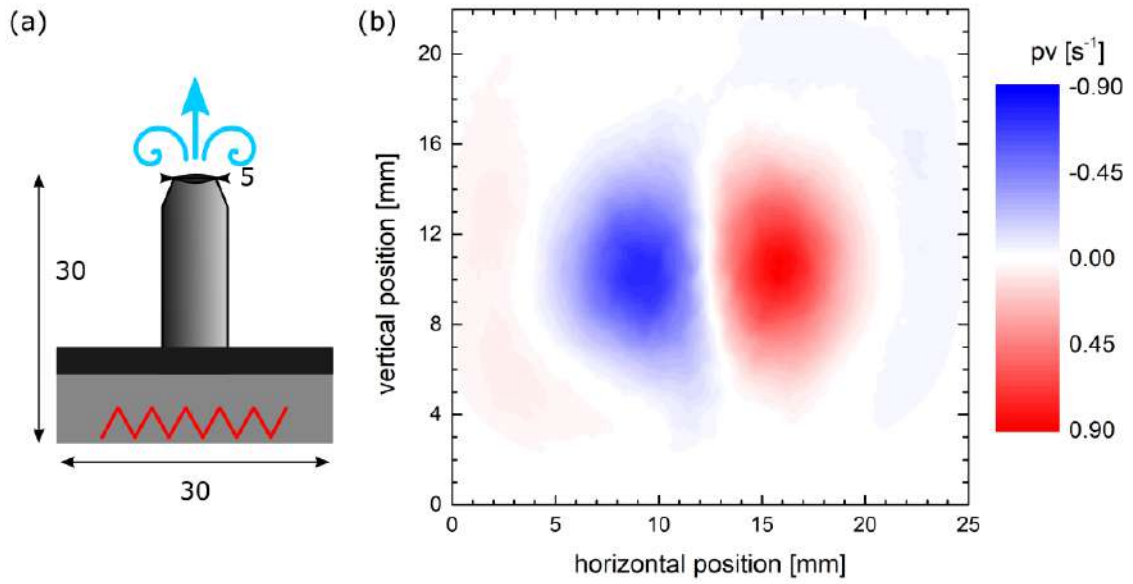

Figure 1: Panel (a) displays a scheme of the nozzle used for thermal generation of macroscopic vortex rings in He II; the red line indicates the planar resistive heater; dimensions are in millimeters. Panel (b) shows an example of pv-map; the cross-section of a macroscopic vortex ring, seen here as a pair of counter-rotating vortices, is well resolved; positive pv values indicate clockwise rotation; in this case the temperature was 1.50 K and a heat pulse of 278 mW cm^{-2} was applied for 500 ms, resulting in a Reynolds number of approximately 1.1×10^5; the displayed pv-map was obtained 1.1 s after the end of the heat pulse; the top of the nozzle matches the bottom of the field of view.

*Corresponding author. E-mail: lamantia@mbox.troja.mff.cuni.cz.

RESULTS

We experimentally investigate the early development of these macroscopic vortex rings, where early means at distances between 1 and 6 times the nozzle diameter. The rings were generated thermally, by applying a short heat pulse, at temperatures ranging from 1.28 to 1.95 K, and with heat fluxes between 35 and 450 mW cm^{-2}, resulting in Reynolds numbers of the order of 10^4, which indicates that they can be regarded as turbulent rings [5].

We observe that, as the distance from the nozzle and the time from the end of the heat pulse increase, the rings show the tendency to become larger and decrease their velocity, which is of the order of 10 mm s^{-1}. The outcome is consistent with the classical behaviour of vortex rings propagating in viscous fluids – see, e.g., [6, 7] – and reinforces therefore the view that, at sufficiently large scales, that is, at scales larger than the mean distance between quantized vortices, turbulent flows of superfluid ^{4}He may display distinctive classical-like features, as discussed, for example, in [8].

In order to further substantiate the claim we apply to our data the similarity theory developed in [9] for turbulent vortex rings, see also [10]. We find that the data obtained in He II closely follow the theory predictions in the direction of ring propagation. However, the agreement between the theory and the data is less satisfactory if one considers the self-similar ring evolution in the radial direction.

The outcome can be related to the fact that, in the range of investigated parameters, the experimentally obtained Lagrangian pseudovorticity does not appear to be suitable to capture the fine details of the ring structure, that is, the corresponding spatial distribution of the ring vorticity, while it seems adequate to resolve more general features, such as the ring position and propagation velocity.

In order to address the issue in a quantitative way we are currently processing existing numerical simulations of classical vortex rings propagating in a viscous fluid. Fluid particles are added to the obtained Eulerian flow fields and the corresponding pseudovorticity values are computed. Preliminary results show that, in order to get a closer agreement between the vorticity and pseudovorticity trends, one should likely employ a larger number of particles compared to that used in the present experiments.

CONCLUSIONS

We experimentally investigated the early development of macroscopic vortex rings, thermally generated in superfluid ^{4}He. The rings were identified and tracked by using the concept of Lagrangian pseudovorticity, recently introduced to quantify the strength of large vortical structures in the absence of Eulerian data [4]. We found that the ring features can be quantitatively assessed by using this method and can therefore be used to perform relevant comparisons.

Our aim was indeed to give a significant contribution to the active line of scientific enquiry focusing on the study of similarities and differences between classical and He II flows. We found that, in the range of investigated parameters, our rings behave as if they were turbulent vortex rings moving in a viscous fluid, at least in the direction of ring propagation. The claim is mainly based on the remarkable agreement between our experimental results and the similarity theory developed in [9] for turbulent vortex rings.

The results therefore reinforce the view that, at scales larger than the mean distance between quantized vortices, turbulent flows of superfluid ^{4}He may display distinctive classical-like features, regardless of the flow generation mechanism, as discussed, for example, in [8]. On the other hand, the reason why He II behaves in such a way is still largely unknown and further studies are needed to address the problem. Another research route, which is potentially not only relevant to quantum turbulence, could focus on clarifying the relation between the Lagrangian pseudovorticity and the Eulerian vorticity, which is yet to be quantitatively established.

DOUBLE-DIFFUSIVE INSTABILITIES IN ROTATING FLOWS: PSEUDO-HERMITICITY AND EXCEPTIONAL POINTS

Oleg N. Kirillov*[1]
[1]Northumbria University, Newcastle upon Tyne, United Kingdom

Summary The Prandtl number, i.e. the ratio of the fluid viscosity to a diffusivity parameter of other physical nature such as thermal diffusivity or ohmic dissipation, plays a decisive part for the onset of instabilities in hydrodynamic and magnetohydrodynamic flows. The studies of many particular cases suggest a significant difference in stability criteria obtained for the Prandtl number equal to 1 from those for the Prandtl number deviating from 1. We demonstrate this for a circular Couette flow with a radial temperature gradient and for a differentially rotating viscous flow of electrically conducting incompressible fluid subject to an external azimuthal magnetic field. Furthermore, in the latter case we find that the local dispersion relation is governed by a pseudo-Hermitian matrix both in the case when the magnetic Prandtl number, Pm, is $\mathrm{Pm}=1$ and in the case when $\mathrm{Pm}=-1$. This implies that the complete neutral stability surface contains three Whitney umbrella singular points and two mutually orthogonal intervals of self-intersection. At these singularities the double-diffusive system reduces to a marginally stable G-Hamiltonian system. The role of double complex eigenvalues (exceptional points) stemming from the singular points in exchange of stability between modes is demonstrated.

INSTABILITIES OF A CIRCULAR COUETTE FLOW WITH RADIAL TEMPERATURE GRADIENT

Circular Couette flow of a viscous Newtonian fluid between two coaxial differentially rotating cylinders is a canonical system for modelling instabilities leading to spatio-temporal patterns and transition to turbulence in many natural and industrial processes. Modern astrophysical applications require understanding of basic instability mechanisms in rotating flows with the Keplerian shear profile in accretion- and protoplanetary disks that are hydrodynamically stable according to the centrifugal Rayleigh criterion. Usually, these instabilities are a consequence of additional factors such as electrical conductivity of the fluid and the magnetic field of the central gravitating object. However, in the so-called dead-zones of protoplanetary disks that are characterized by high electrical resistivity due to very low ionization levels, some magnetohydrodynamic (MHD) instabilities become inefficient (e.g. the standard VelikhovChandrasekhar magnetorotational instability (MRI) in an axial magnetic field). Alternative mechanisms include MRIs caused by azimuthal or helical magnetic fields that work well also in the inductionless limit at a very low conductivity as well as pure hydrodynamic finite-amplitude nonlinear instabilities. Some recent studies indicated a possibility that Keplerian disks with strong mean radial temperature gradients can support the so-called Goldreich-Schubert-Fricke (GSF) instability, which is the instability of short-radial-wavelength inertial modes [1, 2, 3]

In [1] we applied the geometric optics stability analysis to circular Couette flow of a viscous Newtonian fluid with a temperature gradient in the absence of gravity, but retaining the term of the centrifugal buoyancy. We derived a system of characteristic equations that includes the transport equations for the lowest-order amplitude of the envelope of the localized perturbation and find a dispersion relation that takes into account the radial variation of the angular velocity and the temperature as well as the kinematic viscosity and the thermal diffusivity.

Using algebraic stability criteria for localization of the roots of polynomials in the left half of the complex plane, we obtained two stability conditions in compact and explicit form; one of them generalizes the Rayleigh discriminant for stationary axisymmetric instabilities to include viscosity effects, and the other provides a marginal stability curve in the parameter plane for oscillatory instabilities. In the case of a sole outer cylinder rotation, solid body rotation, and rotating flow with Keplerian shear we found a destabilizing effect of the inward temperature gradient that leads to oscillatory instability at small values of the Prandtl number ($\mathrm{Pr}<1$) and to stationary instability at $\mathrm{Pr}>1$ [1].

DOUBLE-DIFFUSIVE AZIMUTHAL MAGNETOROTATIONAL INSTABILITY

In [4, 5] we studied local instabilities of a differentially rotating viscous flow of electrically conducting incompressible fluid subject to an external azimuthal magnetic field. It was found that in the presence of the magnetic field the hydrodynamically stable flow can demonstrate non - axisymmetric azimuthal magnetorotational instability (AMRI) both in the diffusionless case and in the double-diffusive case with viscous and ohmic dissipation. It was shown in [4] that the dispersion relation for the double-diffusive AMRI is $p(\lambda):=\det(\mathbf{H}_0+\mathbf{H}_1-i^{-1}\mathbf{G}_1\lambda\mathbf{I})=0$, where $\mathbf{I}$ is the 4×4 identity matrix, $\mathbf{G}_1$ and $\mathbf{H}_0$ are Hermitian matrices and $\mathbf{H}_1$ is a complex non-Hermitian matrix of dissipative perturbations to a G-Hamiltonian (with a pseudo-Hermitian Hamiltonian) [6, 7] system of ideal MHD. Performing stability analysis based on the dispersion relation, we established that the threshold of the diffusionless AMRI via the Hamilton-Hopf bifurcation is a singular limit of the thresholds of the viscous and resistive AMRI corresponding to the dissipative Hopf bifurcation and manifests itself as the Whitney umbrella singular point. A smooth transition between the two types of instabilities is possible only if the magnetic Prandtl number is equal to unity, $\mathrm{Pm}=1$. At a fixed $\mathrm{Pm}\neq1$ the threshold of the double-diffusive AMRI is displaced by finite distance in the parameter space with respect to the diffusionless case even in the zero dissipation limit, see Fig. 1(left).

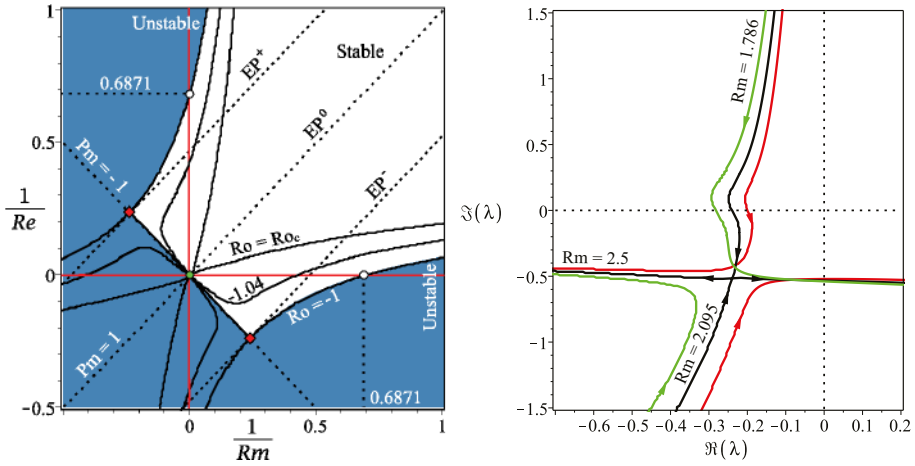

Figure 1: (Left) Contour plots of the neutral stability surface in the plane of inverse Reynolds numbers at (cuspidal curve) $\mathrm{Ro} = \mathrm{Ro}_c \approx -1.07855$, (filled area) $\mathrm{Ro} = -1$, and (intermediate curve) $\mathrm{Ro} = -1.04$. Two singular Whitney umbrella points (filled diamonds) exist at the intersection of the line $\mathrm{Pm} = -1$ and the neutral stability curve at $\mathrm{Ro} = -1$ and another one exists at the origin when $\mathrm{Ro} = \mathrm{Ro}_c$. From these singularities the lines $\mathrm{EP}^{\pm}, \mathrm{EP}^0$ of exceptional points are stemming that govern the transfer of modes shown in the right panel. (Right) For $\mathrm{Rb} = -1$, $\mathrm{S} = 1$, $n = \sqrt{2}$, and $\mathrm{Re} = 1000$ the movement of eigenvalues with decreasing Ro at various Rm chosen such that $\mathrm{Pm} < 1$. At $\mathrm{Rm} < 1000$ and up to $\mathrm{Rm} = \mathrm{Rm}_{\mathrm{EP}-} \approx 2.095$ it is the branch corresponding to perturbed imaginary eigenvalues with positive Krein sign that causes instability. When $\mathrm{Rm} = \mathrm{Rm}_{\mathrm{EP}-}$ two simple eigenvalues approach each other to merge exactly at $\mathrm{Ro} = -1$ into a double eigenvalue whose corresponding matrix is a Jordan block, $\lambda_{\mathrm{EP}-} \approx -i0.5086 - 0.2391$. At $\mathrm{Rm} < \mathrm{Rm}_{\mathrm{EP}-}$ the instability shifts to the branch of perturbed imaginary eigenvalues with negative Krein sign.

Let $\Omega(r)$ be the radial profile of the angular velocity of the fluid, $\mathrm{Ro} = \frac{r\partial_r\Omega}{2\Omega}$ the hydrodynamic Rossby number, $\mathrm{S} = \frac{\omega_{A_\phi}}{\Omega}$ the Alfvén angular velocity in the units of Ω, $\mathrm{Rb} = \frac{r\partial_r\omega_{A_\phi}}{2\omega_{A_\phi}}$ the magnetic Rossby number, Re the hydrodynamic Reynolds number, Rm the magnetic Reynolds number, and $\mathrm{Pm} = \mathrm{Rm}/\mathrm{Re}$ the magnetic Prandtl number.

Consider the following particular case: $\mathrm{Ro} = \mathrm{Rb} = -1$, $\mathrm{S} = 1$, and $\mathrm{Re} = -\mathrm{Rm}$ (that is $\mathrm{Pm} = -1$). Then, the dispersion relation for the double-diffusive AMRI takes the form $p(\lambda) := \det(\mathbf{H} - i^{-1}\mathbf{G}\lambda\mathbf{I}) = 0$, where $\mathbf{H}$ and $\mathbf{G}$ are Hermitian matrices

$$\mathbf{H} = \begin{pmatrix} n & 0 & \frac{i}{\mathrm{Rm}} - n & 0 \\ 0 & \alpha^2 n & -\frac{2\alpha}{n\mathrm{Rm}} & \frac{i\alpha^2}{\mathrm{Rm}} - n\alpha^2 \\ -\frac{i}{\mathrm{Rm}} - n & -\frac{2\alpha}{n\mathrm{Rm}} & n & 0 \\ 0 & -\frac{i\alpha^2}{\mathrm{Rm}} - n\alpha^2 & 0 & \alpha^2 n \end{pmatrix}, \quad \mathbf{G} = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & \frac{2i\alpha}{n} & \alpha^2 \\ 1 & -\frac{2i\alpha}{n} & 0 & 0 \\ 0 & \alpha^2 & 0 & 0 \end{pmatrix}$$

with $n = \frac{m}{\alpha}$ the modified azimuthal wavenumber and α the coefficient depending on wavenumbers of the perturbation. Hence, in the case of $\mathrm{Pm} = -1 < 0$ the dispersion relation is governed by a G-Hamiltonian system, which implies neutral stability on an interval in the plane of inverse Reynolds numbers, see Fig. 1(left). The loss of the neutral stability is accompanied by the Krein collision of two modes with the opposite Krein/action signs when the parameters correspond to singular Whitney umbrella points. The sets of parameters stemming form the singular points and corresponding to complex double eigenvalues determine transfer of stability between modes, see Fig. 1(right). This picture provides the detailed mechanism of the destabilization of the Chandrasekhar equipartition solution in the case when $\mathrm{Pm} \neq 1$ [4, 8, 9, 10].

NEW PERSPECTIVE ON MASS CONSERVATION LAW AND ROTATIONAL WAVES

Tsutomu Kambe*
Former Professor, University of Tokyo, Tokyo, Japan

Summary This is a new approach hinted by new finding of a general representation of rotational flows of an ideal compressible fluid satisfying Euler's equation of motion. In this representation, four independent fields are introduced. This fact is understood to predict existence of a new field interacting with the flow field. The action describing the interaction is, amazingly, analogous to that of Electromagnetism. The mass conservation law is closely associated with the symmetry of gauge invariance which the new field possesses inherently. Present combined system of fluid flow and gauge field enables excitation of *rotational* waves within shear flow field. An example is given for rotational waves superimposed on a streaky flow.

INTRODUCTION

Concerning the *mass* conservation law, a question may be raised whether it has been given *due* appreciation concerning its dynamical role. A symmetry implies a conservation law, and *vice versa* (*Noether's theorem* [2]). In the background of the mass conservation law, there exists the gauge symmetry [6, 7]. In fact, with respect to traditional formulations on the basis of action principle, a certain kind of weakness is recognized concerning the mass conservation condition. We approach this fundamental question from a quite unexpected direction by learning from the *Electrodynamic* theory (Landau & Lifshitz [3]). A general solution of rotational flow satisfying the Euler's equation of motion was given by Kambe [4] for an ideal compressible fluid. The action formulation that lead to this solution accords with the *gauge theory* of theoretical physics partly. The solution is regarded as an extended version of the Clebsch representation [1]. It is important to recognize that four independent fields are introduced in this new representation. This fact is understood to predict *existence* of a system of new fields governing those as a whole. Total action S of this system [4] was proposed to consist of two actions, S_{fl} for the fluid motion and S_{int} describing interaction. Thus we have $S = S_{fl} + S_{int}$:[1]

$$S_{fl} = \int_M \rho \left(\tfrac{1}{2} v^k v^k - \epsilon(\rho) \right) c_*^{-1} \mathrm{d}\Omega, \qquad S_{int} = -\int_M a_\nu j^\nu \, \mathrm{d}\Omega, \qquad \mathrm{d}\Omega = c_* \mathrm{d}t \, \mathrm{d}^3\boldsymbol{x}, \tag{1}$$

where $\boldsymbol{v} = (v^k)$ is the fluid velocity, $\epsilon(\rho)$ is the specific internal energy, ρ is the fluid density. It is assumed that $\partial\epsilon/\partial s = 0$ (where s denotes the specific entropy), because no entropy change occurs in the assumed uniform ideal (inviscid) fluid, and c_* is a parameter representing a phase velocity. For the expression of S_{int}, see the Appendix.

From an infinitesimal 4-vector $\mathrm{d}x^\nu = (c_*\mathrm{d}t, \mathrm{d}x^1, \mathrm{d}x^2, \mathrm{d}x^3)$ in the 4-dim space-time ($x^0 = c_* t$), one can form a current 4-vector $j^\nu = \rho \, \mathrm{d}x^\nu/\mathrm{d}t = (\rho c_*, \rho v^k)$. The four fields which were introduced in the solution (9) define a co-vector $a_\nu = (a_0, -a_1, -a_2, -a_3)$ in *component-wise*, with its vector counterpart being a^ν defined by $g^{\nu\lambda}a_\lambda = (a_0, a_1, a_2, a_3)$. Using a_ν, one-form $\mathcal{A}$ is defined by

$$\mathcal{A} = a_\nu \mathrm{d}x^\nu = g_{\nu\lambda}a^\lambda \mathrm{d}x^\nu = a_0\mathrm{d}x^0 - a_1\mathrm{d}x^1 - a_2\mathrm{d}x^2 - a_3\mathrm{d}x^3. \tag{2}$$

Then it is seen that the integrand $a_\nu j^\nu$ of S_{int} is a scalar quantity represented by the scalar product $g_{\nu\lambda}j^\nu a^\lambda$.

Consider a transformation $a_\nu \to a_\nu - \partial_\nu \Psi$ (a certain kind of *gauge* transformation; see below). Then the one-form $\mathcal{A}$ is transformed to $\mathcal{A} - \mathrm{d}\Psi$. The interaction action S_{int} is also transformed as

$$S_{int} \to -\int_M a_\nu j^\nu \, \mathrm{d}\Omega + \int_M (\partial_\nu j^\nu) \, \Psi \, \mathrm{d}\Omega - \int_M \partial_\nu (j^\nu \Psi) \, \mathrm{d}\Omega. \tag{3}$$

The last term drops out because it is transformed to surface integrals over ∂M surrounding the volume M of 4D spacetime. Then, the *gauge invariance* of S_{int} requires $\partial_\nu j^\nu = 0$ for arbitrary scalar function $\Psi(x^\nu)$:

$$\partial_\nu j^\nu = \partial_t \rho + \partial_k(\rho v^k) = 0, \tag{4}$$

where $\partial_\nu = (c_*^{-1}\partial_t, \partial_k)$. Thus the equation of mass conservation is required by the gauge invariance. Conversely, the mass conservation equation (4) assures the gauge invariance of S_{int}.

ACTION FORMULATION WITH TAKING ACCOUNT OF A BACKGROUND FIELD A_ν

Learning from the *electromagnetic* theory, it is proposed as hinted above that there exists a gauge field a_ν supporting the mass conservation law in the background. On the analogy with the electromagnetism [3] (EM in short), the present action formulation for fluid flows is represented by a three-component action S:

$$S = S_{fl} + S_{int} + S_F; \qquad S_F = -\frac{1}{4\mu} \int F_{\nu\lambda} F^{\nu\lambda} \, \mathrm{d}\Omega. \tag{5}$$

where μ and c_* are constant parameters. The first two actions are defined by (1): S_{fl} for the fluid motion and S_{int} for interaction. Each of the integrands of S_{fl} and S_{int} satisfies local gauge invariance with respect to both transformations

*Corresponding author. Email: kambe@ruby.dti.ne.jp *Home*: Meguro-ku, Tokyo, Japan 153-0043

[1] Latin indices $i, k, \cdots$ take the values $1, 2, 3$; while Greek indices $\lambda, \nu, \cdots$ take the values $0, 1, 2, 3$. Using the metric tensor $g_{\nu\lambda} = \mathrm{diag}(1, -1, -1, -1)$, a co-vector a_ν corresponding to a vector a^λ is given by $a_\nu = g_{\nu\lambda}a^\lambda = (a^0, -a^1, -a^2, -a^3)$.

of translation and rotation (note that mass element $\mathrm{d}m = \rho\,\mathrm{d}^3\boldsymbol{x}$ is invariant). Hence they are consistent with the gauge theory. The third action S_F should describe the new gauge field a_ν existing in the background of flow field.

Remembering the one-form $\mathcal{A}$ of (2) and taking its external differential d, we obtain the *field strength* two-form $\mathcal{F} = \mathrm{d}\mathcal{A} = \sum F_{\nu\lambda}\,\mathrm{d}x^\nu \wedge \mathrm{d}x^\lambda$, analogous to the EM case [5] where two EM-like fields are introduced by $\boldsymbol{e} = -\partial_t\boldsymbol{a} - \nabla\phi$ and $\boldsymbol{b} = \nabla\times\boldsymbol{a}$. Using the field strength tensor $F_{\nu\lambda}$, one can form a scalar by the scalar product $F_{\nu\lambda}F^{\nu\lambda}$. Thus the third action is defined *gauge-theoretically* by the form of S_F given in (5).

To find the *dynamical* equation of fluid motion by the principle of least action, we vary only the trajectory $\boldsymbol{x}_p(t,\boldsymbol{\alpha})$ of fluid particle $\boldsymbol{\alpha}$ with fixing both of the particle-label $\boldsymbol{\alpha}$ and the field strength $F_{\nu\lambda}$, finding

$$\partial_t\boldsymbol{v} + (\boldsymbol{v}\cdot\nabla)\boldsymbol{v} + \rho^{-1}\nabla p = \boldsymbol{f}, \qquad \boldsymbol{f} \equiv \boldsymbol{e} + \rho^{-1}\boldsymbol{j}\times\boldsymbol{b} \quad (\boldsymbol{j} = \rho\boldsymbol{v}). \tag{6}$$

On the other hand, to obtain the *field* equations, we assume the fluid motions (v^k and j^ν) given (fixed) and vary only the potentials a_ν (serving as the coordinates of the system). Thus we find a set of Maxwell-like equations [5]:

$$\nabla\cdot\boldsymbol{b} = 0, \qquad \partial_t\boldsymbol{b} + \nabla\times\boldsymbol{e} = 0, \qquad \nabla\cdot\boldsymbol{d} = \rho, \qquad -\partial_t\boldsymbol{d} + \nabla\times\boldsymbol{h} = \boldsymbol{j}, \tag{7}$$

where $\boldsymbol{d} = \epsilon\boldsymbol{e},\ \boldsymbol{h} = \mu^{-1}\boldsymbol{b}$ with $\epsilon = 1/(\mu c_*^2)$.

The greatest merit of the present formulation is that the four fields $(\boldsymbol{e},\ \boldsymbol{b}, \boldsymbol{d},\ \boldsymbol{h})$ are invariant with respect to the gauge transformation described at the paragraph above Eq.(3) and, in addition, the last two equations of (7) assure the mass conservation equation (4): $\partial_t\rho + \nabla\cdot\boldsymbol{j} = 0$ (with operating ∂_t and $\nabla\cdot$ respectively and summing up). Thus the mass conservation law is naturally connected with the symmetry of gauge invariance [6, 7]. This is consistent with the Noether's theorem mentioned in the beginning. It should be emphasized that there is no particular mathematical device (except the gauge invariance) assumed to derive the mass conservation.

Let us consider an application of the above formulation, showing an example of *rotational*-waves propagating through a shear flow along a straight channel or a pipe. The wave is characterized as *transversal*, compared with the acoustic wave studied extensively in the fluid mechanics which is *longitudinal*. There exist ample evidences of streamwise rotational-streaks and long meandering wavy-structures in streaky wall-turbulence.

Unperturbed state is a steady streaky flow with streamwise vorticity toward the x-axis. The unperturbed velocity is expressed as $\boldsymbol{U}_s(y,z)$ in the Cartesian frame with $(\nabla\times\boldsymbol{U}_s)_x \neq 0$. Fluid is assumed *incompressible*, for simplicity, with the uniform density ρ_0. The field vectors $\boldsymbol{e}$, $\boldsymbol{b}$ and $\boldsymbol{a}$ are governed by wave equations:

$$\nabla^2\boldsymbol{e} - c^{-2}\partial_t^2\boldsymbol{e} = \mu\,\partial_t\boldsymbol{j}', \qquad \nabla^2\boldsymbol{b} - c^{-2}\partial_t^2\boldsymbol{b} = -\mu\nabla\times\boldsymbol{j}', \qquad \nabla^2\boldsymbol{a} - c^{-2}\partial_t^2\boldsymbol{a} = -\mu\boldsymbol{j}', \tag{8a, b, c}$$

($c = c_*$ for simplicity), where $\boldsymbol{e} = -\partial_t\boldsymbol{a}$ and $\boldsymbol{b} = \nabla\times\boldsymbol{a}$ with $\phi = const$ owing to the incompressibility. These are wave equations with forcing terms derived from the current perturbation $\boldsymbol{j}' = \rho_0\boldsymbol{v}'$ with μ a coupling constant introduced in S_F. The waves propagate to the streamwise direction with frequency ω and wavenumber k: $\boldsymbol{e}, \boldsymbol{v}', \boldsymbol{b} \propto \exp[i(kx-\omega t)]$. Expressing the x-components of $\boldsymbol{e}$ and $\boldsymbol{v}'$ as $e_x = \tilde{e}(y,z)\exp[i(kx-\omega t)]$ and $v_x' = \tilde{u}(y,z)\exp[i(kx-\omega t)]$, we obtain a connecting relation for their amplitudes:

$$\tilde{u}(y,z) = (i/\mu\rho_0\omega)\,(\partial_y^2 + \partial_z^2)\tilde{e}(y,z) \qquad \text{from (8a)},$$

where the amplitudes $\tilde{u}$ and $\tilde{e}$ depend on cross-flow coordinates (y,z). The cross-flow modes of $\tilde{u}$ and $\tilde{e}$ are to be determined from (linear) analyses of the equation (6). There exist plenty of evidences of existence of cross-stream modes (not *irrotational*) in channel flows or pipe flows, both laminar and turbulent, to which this formulation may be applied.

Appendix: The interaction action S_{int}

The interaction part $S_{int} = -\int a_\nu j^\nu \mathrm{d}^3\boldsymbol{x}\,\mathrm{d}t$ was proposed originally by Kambe (2013) [4] as

$$S_{int} \equiv -\int_M \Big(\mathrm{D}_t\psi + \mathrm{D}_t\langle\boldsymbol{U},\ \boldsymbol{Z}\rangle\Big)\,\rho\,\mathrm{d}^3\boldsymbol{x}\,\mathrm{d}t, \quad = -\int_M \Big(a_\nu j^\nu + \partial_k Q^k\Big)\,\mathrm{d}^3\boldsymbol{x}\,\mathrm{d}t, \quad Q^k \equiv \rho Z^k\,(U_i v^i),$$
$$j^\nu = (\rho c_*, \rho\boldsymbol{v}), \quad a_0 = c_*^{-1}(\partial_t\psi + Z^k\partial_t U_k), \quad (-a_1, -a_2, -a_3) = \nabla\psi + \boldsymbol{Z}\times(\nabla\times\boldsymbol{U}), \tag{9}$$

Each of the three factors (ψ, $\langle\boldsymbol{U},\boldsymbol{Z}\rangle$ and D_t) in the definition of S_{int} satisfies local gauge invariance with respect to translation and rotation since first two are scalars and the operator D_t is gauge-invariant ([4], §5 (ii)). Hence it is consistent with the gauge theory.

VORTEX DYNAMICS ON A UNIT ROTATING SPHERE

Pankaj Jagad[1] and Ravi Samtaney *[1]
[1]Mechanical Engineering, Physical Science and Engineering Division, King Abdullah University of Science and Technology, Thuwal, SaudiArabia

Summary We study the effect of rotation on vortex dynamics on a unit sphere, for an incompressible and inviscid flow, using a Discrete Exterior Calculus (DEC) scheme. For a given initial vorticity distribution, we vary the rate of rotation of the sphere from zero (non-rotating case, corresponding to infinite Rossby number (Ro)) to 20 (corresponding to Ro = 0.025), and investigate the evolution with time. For the non-rotating case, the vortices evolve in to thin filaments due to so-called forward enstrophy cascade, and at late times much of these structures cascade beyond the smallest scale resolved in the simulation, and a quadrupolar vortical structure emerges. For finite Rossby number, rotation suppresses the forward cascade of enstrophy and the flow does not evolve in to a quadrupolar vortical structure at late times. Moreover, rotation aligns the vortices along the azimuthal direction.

INTRODUCTION

Incompressible, inviscid flow investigations on a unit sphere are usually performed to investigate atmospheric flows. These flows are characterized by two-dimensional (2D) turbulence wherein there is direct cascade of enstrophy to smaller scales and inverse cascade of energy to larger scales. In the investigations of such planetary atmospheric flows, it is important to include the effect of rotation of the planet. We investigate the effect of rotation on vortex dynamics on a unit sphere and investigate the direct cascade of enstrophy in 2D turbulence using a DEC method [1]. Exterior calculus deals with the calculus on differential geometries, hence differential forms, and provides an alternative to the vector calculus. DEC is numerical exterior calculus and deals with the discrete differential forms. A discreet differential form is an integral quantity on a mesh object, e.g., integral of a vector along a mesh edge $\int \mathbf{v} \cdot \mathbf{dl}$ represents a discrete 1-form. DEC retains at the discrete level many of the identities of its continues counter part. It is coordinate independent, therefore suitable for solving flows over curved surfaces. More details about DEC can be found in some of the representative references such as [2, 3].

EQUATIONS AND NUMERICAL METHOD

The governing Euler equations in rotating frame of reference and in DEC notations read

$$\left[\left(-\frac{1}{\Delta t}\right) I - \frac{1}{2}\left(W_V\right)^{n+1} *_0^{-1} \left[-d_0^T\right] *_1\right] \left(U^*\right)^{n+1} + *_1^{-1} d_1^T \left(P^d\right)^{n+1} = F, \tag{1}$$

with

$$F = \left(-\frac{1}{\Delta t}\right)\left(U^*\right)^n + \frac{1}{2}\left(W_V\right)^{n+1} *_0^{-1} d_b\left(V\right)^{n+1} + \frac{1}{2}\left(W_V\right)^n *_0^{-1} \left(\left[-d_0^T\right] *_1 \left(U^*\right)^n + d_b\left(V\right)^n\right) + \frac{1}{2}\left[\left(W_V\right)^{n+1} + \left(W_V\right)^n\right] *_0^{-1} f_{dual2}, \tag{2}$$

$$\left[d_1\right]\left(U^*\right)^{n+1} + \left[0\right]\left(P^d\right)^{n+1} = 0, \tag{3}$$

where U^* is the vector containing mass flux primal 1-form for all mesh primal edges, V is the vector containing the discrete primal velocity 1-forms for all mesh primal edges, and P^d is the vector containing discrete dynamic pressure 0-forms for all mesh dual vertices, Δt is the discrete time interval, d_0, $\left[-d_0^T\right]$, d_1^T are the discrete exterior derivative operators, $*_0^{-1}$, $*_1$, $*_1^{-1}$ are discrete Hodge star operators. The dual-2 form f_{dual2} corresponds to the Coriolis parameter $f = 2\Omega\cos\theta$, where Ω is the rate of rotation of the sphere, and θ is the colatitude. The details of the DEC discretization, the definition and expressions of the discrete operators as well as that of the matrix W_V and the operator d_b are available in [1]. The present discretization uses the energy-preserving time integration [4]. We employ a biharmonic viscosity as a means to filter and dissipate very high wavenumber content. The set of non-linear equations represented by equations (1) - (3) are solved using Picard's iterative method for the mass flux 1-form and dynamic pressure degrees of freedom.

RESULTS AND DISCUSSION

The time evolution of the vorticity field from a given initial vorticity distribution was studied for a non-rotating unit sphere as well as a rotating one at the rate of rotation (Ω) of 5, 10, and 20. The initial stream function distribution at the mesh primal nodes is computed as

$$\psi\left(\theta,\phi\right) = \sum_{l=4}^{10}\sum_{m=-l}^{l} \psi_{lm} Y_l^m\left(\theta,\phi\right), \tag{4}$$

where θ is the colatitude, ϕ is the longitude, Y_l^m is the spherical harmonic function of degree l and order m, and ψ_{lm} are the expansion coefficients with $\psi_{l-m} = (-1)^m \psi_{lm}^*$. Here ψ_{lm}^* is the complex conjugate of ψ_{lm}. The ψ_{lm} values as given in [5] were used. The initial mass flux 1-form for a primal edge was then computed as $u^* = d_0\psi$. The scalar (since, here, there is only one component of vorticity normal to the surface) vorticity distribution at the primal nodes was computed

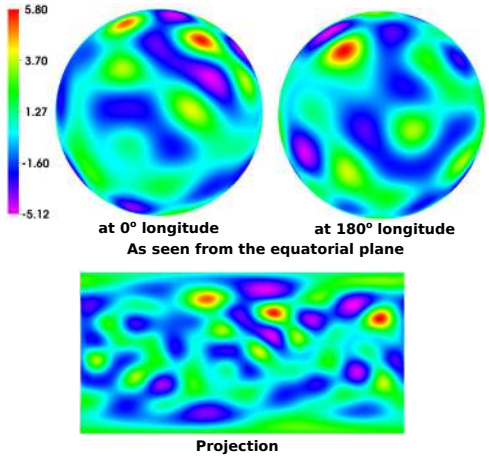

Figure 1: Initial vorticity distribution.

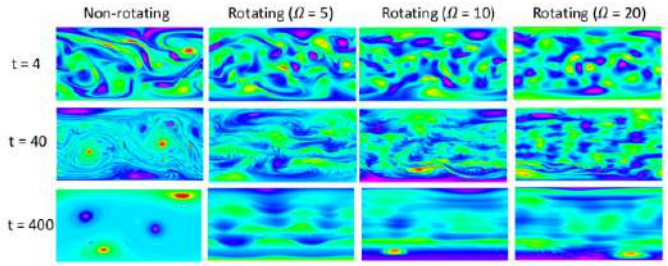

Figure 2: Vorticity distribution at later times.

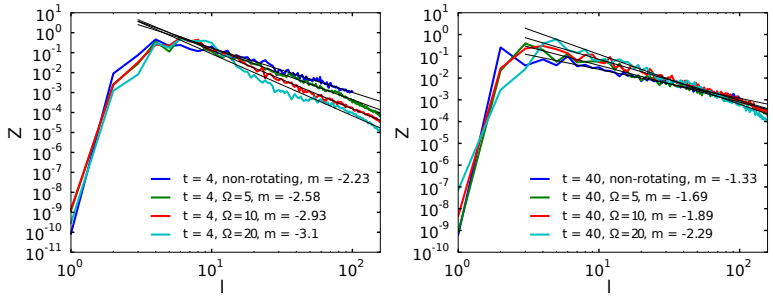

Figure 3: Vorticity power spectra.

from the relation $\omega = *_0^{-1}\left[-d_0^T\right] *_1 u^*$ for post-processing. Figure 1 shows the initial vorticity distribution. Figure 2 shows the vorticity distribution for different rates of rotation at later times. The plots show that for the non-rotating case, the vortices evolve in to thin filaments due to so-called forward enstrophy cascade by time $t = 40$, and at late times ($t = 400$) much of these structures cascades beyond the smallest scale resolved in the simulation and hence dissipate, and a quadrupolar vortical structure evolves. However, not much evolution in to the thin filaments is seen for the rotating cases, and at late times no quadrupolar vortical structure is formed. Thus, rotation suppresses the forward cascade of enstrophy. Moreover, alignment of vortices along the azimuthal direction is seen for the rotating cases. In order to quantify the effect of rotation, vorticity power spectra, vorticity probability density, probability density function (PDF) of aspect ratio (ratio of major to minor axis length of vortical structures), and that of the cosine of the angle between the major axis and the azimuthal direction (which is a measure of orientation of the vortical structures) are determined. Figure 3 shows vorticity power spectra. At $t = 4$, the slope of the spectrum is 2.23 for the non-rotating case for $10 \leq l \leq 100$. The slope increases with increasing Ω, and at $\Omega = 20$ it is 3.1, implying decrease of the enstrophy cascade to smaller scales with increasing Ω. Similarly at $t = 40$, the slope of the spectrum is 1.33 for the non-rotating case, and it increases with increasing Ω, showing suppression of the forward enstrophy cascade with increasing Ω. Moreover, for each Ω, the slope of the spectrum decreases from $t = 4$ to $t = 40$, showing forward cascade of enstrophy with time. The plots of vorticity probability density, and PDF of aspect ratio, not included here due to space limitation, also confirm the suppression of enstrophy cascade with rotation. The plots of PDF of cosine of the angle between the vortex major axis and the azimuthal direction, not included here due to space limitation, confirms that the rotation orients the vortices along the azimuthal direction.

CONCLUSIONS

We investigated the effect of rotation on the enstrophy cascade for a 2D turbulence on a unit sphere using a DEC scheme. Rotation suppresses the cascade and aligns the vortices along the azimuthal direction.

CROSSOVER FROM INTERACTION TO DRIVEN REGIMES IN QUANTUM VORTEX RECONNECTIONS

Luca Galantucci*[1], Andrew W. Baggaley[1], Nick G. Parker[1], and Carlo F. Barenghi[1]
[1]School of Mathematics, Statistics and Physics, Newcastle University, Newcastle upon Tyne, United Kingdom

Summary Reconnections of coherent filamentary structures play a key role in the dynamics of fluids, redistributing energy and helicity among the length scales, triggering dissipative effects and inducing fine-scale mixing. Unlike ordinary (classical) fluids where vorticity is a continuous field, in superfluid helium and in atomic Bose-Einstein condensates (BECs) vorticity takes the form of isolated quantised vortex lines, which are conceptually easier to study. New experimental techniques now allow visualisation of individual vortex reconnections in helium and condensates. It has long being suspected that reconnections obey universal laws, particularly a universal scaling with time of the minimum distance between vortices δ. Here we perform a comprehensive analysis of this scaling across a range of scenarios relevant to superfluid helium and trapped condensates, combining our own numerical simulations with the previous results in the literature. We reveal that the scaling exhibit two distinct fundamental regimes: a $\delta \sim t^{1/2}$ scaling arising from the mutual interaction of the reconnecting strands and a $\delta \sim t$ scaling when extrinsic factors drive the individual vortices.

Quantum vortex reconnections play a fundamental role in quantum fluid dynamics. In particular, reconnecting events redistribute energy and helicity amongst scales, trigger a turbulent energy cascade generating the same Kolmogorov spectrum of classical turbulence and, in the low-temperature limit, quantum vortex reconnections represent the ultimate mechanism for the dissipation of incompressible kinetic energy via acoustic emission.

In past studies, many authors have focused on the potential existence of a universal route to reconnections, which may take the form of a vortex ring cascade [4, 5], a particular rule for the reconnecting cusp angles [1, 9] or, more promising, a special scaling with time of the minimum distance $\delta(t)$ between the reconnecting vortex strands [6, 11, 7, 10, 2].

In the present work [3], we focus on the last property showing that $\delta(t)$ can obey *two* distinct scalings. In addition to the already observed $\delta \sim t^{1/2}$ scaling, we predict and observe a new linear $\delta \sim t$ behaviour [Fig. 1]. In our study we show how these two scalings arise from rigorous dimensional arguments and then demonstrate their existence in a vast campaign of numerical simulations performed with both the Gross-Pitaevskii (GP) model and the Vortex Filament (VF) method. Distinctive of our simulations are the larger initial distance compared to past numerical studies and the extension of the investigations to experimentally accessible trapped Bose-Einstein Condensates (BECs) (both box- and harmonically trapped), where vortex reconnections can now be studied with unprecedented resolution [8].

The numerical results obtained show that the $\delta(t)$ scaling is determined by the balance between the vortex mutual interaction (responsible for the $\delta \sim t^{1/2}$ scaling) and extrinsic factors (vortex curvature, density gradients, vortex images) driving the individual vortices towards reconnection (leading to the $\delta \sim t$ behaviour). The relevance of these two scalings arises from their observation in experimentally accessible condensates and in the two limiting, yet fundamental, cases of vortex reconnections in homogeneous systems, namely the reconnection of orthogonal vortices and the vortex ring - vortex line interaction.

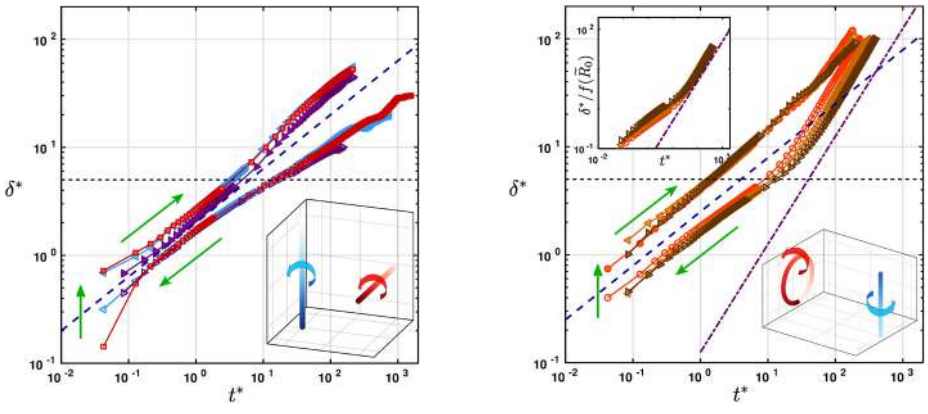

Figure 1: **GP simulations: homogeneous unbounded BECs.** Evolution of the rescaled minimum distance $\delta^* = \delta/\xi$ (with ξ being the healing length) between reconnecting vortices as a function of the rescaled temporal distance to reconnection $t^* = (t - t_r)/\tau$. Empty (filled) symbols correspond to pre (post) reconnection dynamics. **Left**: orthogonal vortices reconnection with rescaled initial distance δ_0^* equal to 10 (▷), 20 (◁) and 30 (□). **Right**: ring-line reconnection for constant initial distance $\delta_0^* = 100$ and vortex ring radii R_0^* equal to 5 (○), 7.5 (◁) and 10 (▷). In both sub figures: the horizontal dashed black line indicates the width of the vortex core ($\approx 5\,\xi$), the blue-dashed line shows the $t^{*1/2}$ scaling. Dot-dashed violet line in the right panel indicates the t^* scaling.

Summary A local deposition of a droplet of soluble surfactant solution on a water layer creates a surface tension difference along the air/water interphase. The resulting surface tension gradient sets the fluid in motion on each side of the water/air interphase. This effect is called the Marangoni effect. A continuous injection of the surfactant solution at the interphase leads to a quasi-steady Marangoni flow of finite size. The finite size results from the competition between the transport of surfactant molecules by the flow and their diffusion into the bulk water after their desorption from the interphase. The Marangoni stress at the fluid/fluid interphase creates a boundary layer which is advected outwards. When it reaches the edge of the Marangoni region, where the flow decelerates dramatically, the boundary layer winds up generating a stationary vorticity roll-up. In this study, we characterise the flow and the key parameters that play a role within its complex structure and its dynamic. To do so, we use surface flow visualisation and bulk water flow measurements with a 3D Particle Image Velocimetry technique. We propose a model that predicts the growth of the vorticity roll-up. Eventually, we discuss the destabilisation of the vorticity roll-up due to its interaction with a solid wall (bottom of the tank) and the free surface.

EXPERIMENTAL SETUP

We create a quasi-steady solutal Marangoni flow by injecting an aqueous solution of the surfactant Tetradecyltrimethylammonium bromide (TTAB) at a constant molar flow rate $0.2 < Q_\mathrm{a} < 2\ \mu\mathrm{mol}\cdot\mathrm{s}^{-1}$ at the surface of a water layer contained in a tank (Fig. 1.a.) in a fashion similar to refs [1, 2]. Since the surfactant solution is transparent, we visualise the flow by adding tracers, olive oil droplets, to the surfactant solution. These $50\ \mu\mathrm{m}$ droplets diffract light and make the flow visible (Fig. 1.b.). The Marangoni flow has been well characterised in refs. [1,2]. Indeed, the flow is axisymetric and oriented from the point of injection outwards up to a distance R_M with a velocity $U_\mathrm{s} \approx 0.1\ \mathrm{m}\cdot\mathrm{s}^{-1}$. At $r = R_\mathrm{M}$ the surface velocity decreases abruptly by more than one order of magnitude. This flow remains stationnary during several tens of minutes, until the concentration of surfactants in the water layer reaches the critical micellar concentration.

OBSERVATIONS

In this abstract, we present results corresponding to the study of the outer region of the Marangoni flow *i.e.* the region beyond R_M. Figure 1.b. shows several pairs of in-plane vortices emerging and growing from the Marangoni border outwards along the perimeter of the Marangoni border. These vortices are emitted periodically with a period t_w.

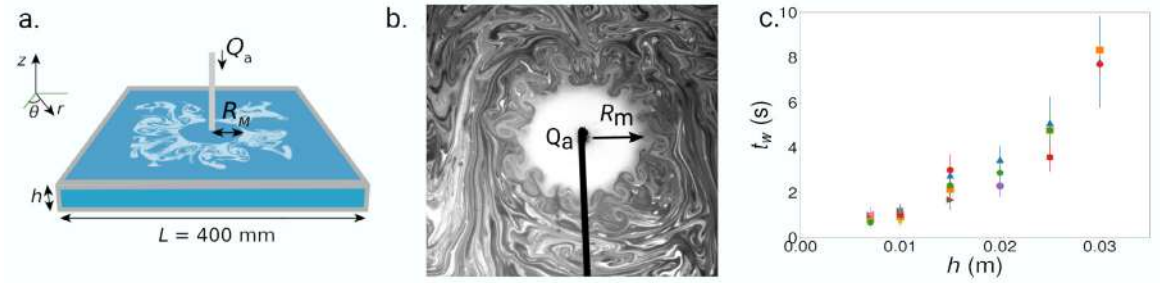

Figure 1: a) Sketch of the experimental setup. The surfactant solution is injected through the needle with a constant molar flow rate Q_a. Once the first drop of surfactant touches the free surface the Marangoni flow starts and reaches its maximum size R_M. We perform the experiments in a $400\ \mathrm{mm} \times 400\ \mathrm{mm} \times 40\ \mathrm{mm}$ tank. b) Top view of a continuous Marangoni flow created at constant flow rate $Q_\mathrm{a} = 1.8\ \mu\mathrm{mol}\cdot\mathrm{s}^{-1}$ and height of water $h = 15\ \mathrm{mm}$. Oil droplets accumulate at $r = R_\mathrm{M}$ allowing us to see the flow outside the Marangoni region. c) Whirl pair emission period t_w as a function of h for a range of flow rates.

Figure 1.c. shows that t_w depends mostly on the thickness of the water layer h. Other parameters such as Q_a have no influence. Tracers allow us to probe the surface part of the flow and Fig. 1.c. highlights the need to investigate flow in the bulk. To do so, we use a laser-scanning particle image velocimetry (LS-PIV) (Fig. 2.a.). that allows to reconstruct 3D maps of the velocity field. A moving mirror deviates the vertical laser sheet used to shine light on particles dispersed in the water layer in a periodic fashion at a 200 Hz rate. We record movies with a high-speed camera at a 5 kHz rate. Thus, we obtain PIV information for 25 planes in the volume of the layer at a rate of 20 fps.

VORITICITY ROLL-UP

Recirculation in the bulk of a liquid over which another liquid spreads is expected,[3, 4, 5, 6, 7]. Its existence is confirmed by LS-PIV measurements (Fig. 2.b). The boundary layer starts to roll-up near the interphase at time $t = t_0$ and then diffuses into the bulk towards the bottom of the tank. Growth occurs untill roll-up size is comparable to h, at which point the roll-up interacts with the bottom of the tank and destabilises. The duration of this process is similar to t_w (Fig 3.c.).

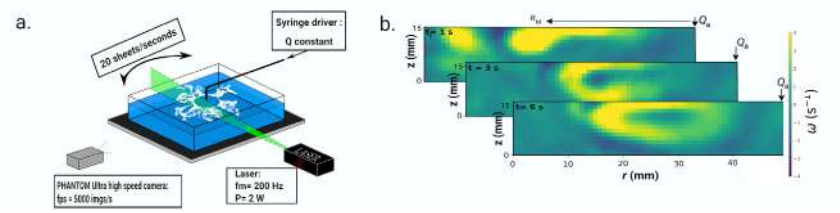

Figure 2: a) Sketch of LS-PIV. b) Vortex strength fields deduced from LS-PIV measurements in a single plane. $Q_\mathrm{a} = 0.5\ \mu\mathrm{mol} \cdot \mathrm{s}^{-1}$ at $h = 15$ mm. The boundary layer rolls up at $t_0 = 1$ s, near the interphase. At $t = 3$ s, the roll-up has diffused in the bulk towards the bottom of the tank. At $t = 6$ s it touches the bottom and start destabilising.

We can predict the growth of the vortex over time. We assume that the vorticity roll-up is fed by the output of the boundary layer located at R_M. Mass and angular momentum coming out of this layer are conserved and transferred to the roll-up. The vortex roll-up is characterized by its radius $r(t)$ and its angular velocity ω. Writing conservation laws for mass, momentum and angular momentum with azimuthal invariance, the time evolution of r obtains:

$$r(t) = \delta\sqrt{1 + \frac{ut}{\delta}}. \tag{1}$$

From Eq. 1, we can also deduce the time t_b that it takes to the vortex to reach the bottom *i.e.* $r(t_\mathrm{b}) = \frac{h}{2}$, it yields:

$$t_\mathrm{b} = \frac{\delta}{u}\left(\frac{h^2}{4\delta^2} - 1\right). \tag{2}$$

Equation 1 agrees well with the experimental results as long as the roll-u is free of interactions with the bottom wall of the tank (Fig. 3.b.). We also show that Eq. 2 predicts the correct scaling for t_w with h (Fig 3.c.). When the vorticity roll-up destabilises and interacts with the free surface it creates a second generation of vortices: the in-plane vortices.

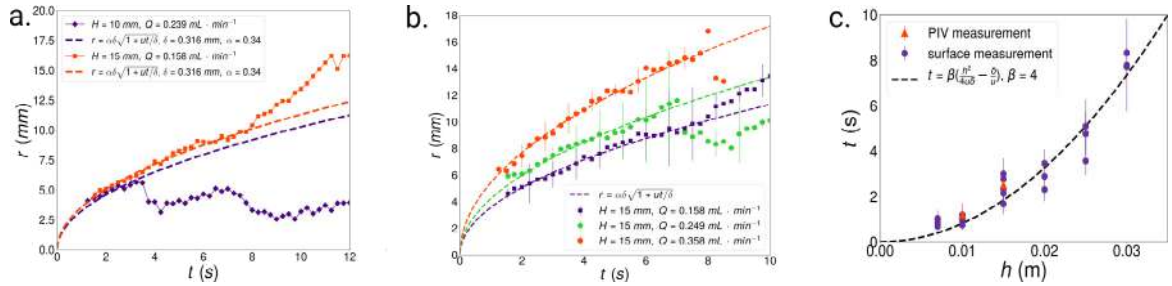

Figure 3: a) Growth of the voriticity roll-up as a function of time. The time of destabilisation increases with h. b) Thickness h is fixed and we increase Q_a. The vortex rolls up faster for higher Q_a but destabilises almost at the same instant t. c) Comparison between experimental emission times and Eq. 2 up to a prefactor.

CONCLUSION AND FUTURE WORK

We have the opportunity to study a soluto-capillary flow that generates beautiful in-plane vortices which are the consequence of the interaction between a vorticity roll-up and a free surface. This is shown by a simultaneous destabilisation of a 3D flow corresponding to a vorticity roll-up below the edge of the Marangoni flow. The future work will consist in studying the stability of the roll up in the frame of the Rayleigh criterion [8]. Therefore, I am looking forward to present and discuss our work at the International Congress of Theoretical and Applied Mechanics of 2020 in Milan.

COMPRESSIBILITY EFFECT ON VORTICITY PRODUCTION AND DARRIEUS-LANDAU INSTABILITY OF A PREMIXED FLAME FRONT

Yasuhide Fukumoto*[1] and Keigo Wada[2]
[1]Institute of Mathematics for Industry, Kyushu University, Fukuoka, Japan
[2]Center of Coevolutionary Research for Sustainable Communities, Kyushu University, Fukuoka, Japan

Summary The Darrieus-Landau instability (DLI) is a linear instability of a premixed flame front, for which the vorticity production plays an important role. We address the effect of compressibility on the DLI, based on a set of equations modeling a one-step overall reaction process of the Arrhenius type, which take account of the heat conduction and the diffusion of a deficient species as well as the viscosity. The method of the matched asymptotic expansions for analyzing the hierarchical thin structure of a flame front, the preheat zone and the reaction zone in it, is extended to second order in the Mach number Ma. The compressibility is shown to act to weaken the DLI. We focus on the Mach-number effect on the baroclinic vorticity production in a flame front of a reacting fluid.

INTRODUCTION

The Darrieus-Landau instability (DLI) is a linear instability of a planar flame front which is identified as a density discontinuous surface. The original analysis of the DLI concluded that a planar flame front is necessarily unstable with larger growth rate for disturbances of shorter wavelengths. This is not consistent with experimental observations, and stabilizing mechanisms have been pursued as exemplified by the Markstein effect of front curvature on the laminar flame speed [1]. The effect of weak compressibility has been considered for long wave disturbances, without entering into the reaction zone [2].

We address the effect of compressibility on the DLI, based on a set of equations modeling a one-step overall reaction process of the Arrhenius type, which takes account of the heat conduction and the diffusion of a deficient species as well as the viscosity. We pursue the large-activation-energy asymptotics under the assumption of large Zeldovich number β. The method of the matched asymptotic expansions [3] in the small parameter β^{-1}, which resolves the fine-scale structure inside a flame front, consisting of the preheat and the reaction zones, is extended to the square in the Mach number $Ma(\ll 1)$.

STABILIZING EFFECT OF COMPRESSIBILITY ON DLI

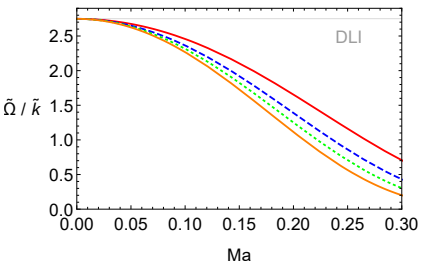

Figure 1: Ω divided by wavenumber k v.s. Mach number Ma. Prandtl number $P_r = 0$ (dot-dashed), 2/4 (dashed), 3/4 (dotted), and 4/4 (bold).

A detailed analysis of the reaction zone, a very thin layer sandwiched by the preheat zones, reveals remarkable effects of compressibility origin, a volumetric heat loss and a dramatic decrease in the laminar flame speed S_L. The spatial variation of pressure plays the role of heat source (sink) and naturally brings in the heat loss, temperature decrease at the edge of the reaction zone on the burned side.

This is seen from the heat-conduction equation, expressed in dimensionless form, as

$$R\left(\frac{\partial T}{\partial t}+(\boldsymbol{V}\cdot\nabla)T\right)=\delta\Delta T + \frac{\gamma-1}{\gamma}\left(\frac{\partial}{\partial t}+\boldsymbol{V}\cdot\nabla\right)P+qQ. \qquad (1)$$

Here R, $\boldsymbol{V}$, T, P and Q are respectively the density of mixture, the velocity field, the temperature, the pressure and the reaction rate of the Arrhenius type, with γ and q being the specific-heat ratio and the heat release, respectively. The dimensionless diffusion coefficient δ provides the scale factor of the preheat zone relative to the hydrodynamic one. The spatial variation of pressure plays the role of heat source (sink) and naturally brings in the heat loss, temperature decrease at the edge of the reaction zone on the burned side. It is noteworthy that the pressure terms couple (1) to the Navier-Stokes equation as opposed to the case of the low-Mach-number limit.

Associated with the heat loss is the decrease of the laminar flame speed S_L, through the burning rate eigenvalue problem [5]. The growth rate of the DLI is proportional to S_L, and therefore the decrease of S_L has a direct influence on stabilizing the DLI as shown in Figure 1. The growth rate Ω divided by the wavenumber k, is plotted as a function of Ma, for several values of the Prandtl number Pr. Figure 1 shows a dramatic decrease of the growth rate with Ma, even to close to zero. This trend is enhanced by viscosity (Pr).

VORTICITY PRODUCTION INSIDE A FLAME FRONT

The vorticity produced in a flame front, by the baroclinic effect, has a stabilizing effect on the DLI [5, 6]. The vorticity jump is affected by the pressure in the low-Mach-number limit [3]. With compressibility, the temperature and the mass flux take part in the vorticity production as illustrated in Figure 2. In the low-Mach-number limit, the normal component of the vorticity vector $\boldsymbol{\Omega}$, produced inside a flame front, is well known to be continuous at the leading order in δ. On the other hand, the tangential component of $\boldsymbol{\Omega}$ is discontinuous across a flame front. It is this component that has a stabilizing effect on the hydrodynamic instability [6]. The compressibility brings a novel effect of the temperature and the mass flux on the tangential jump of $\boldsymbol{\Omega}$ (Figure 2). We reveal that a viscous effect, of compressibility origin, plays a vital role for the suppression of DLI.

The vorticity jump across a flame front is derived from the following equation for the vorticity $\boldsymbol{\Omega}$.

$$\frac{\partial \boldsymbol{\Omega}}{\partial t} - \nabla \times (\boldsymbol{V} \times \boldsymbol{\Omega}) = \frac{1}{\gamma Ma^2} \frac{\nabla R \times \nabla P}{R^2} + \delta Pr \left(\frac{\Delta \boldsymbol{\Omega}}{R} - \frac{\nabla R \times \Delta \boldsymbol{V}}{R^2} - \frac{1}{3} \frac{(\nabla R) \times \nabla (\nabla \cdot \boldsymbol{V})}{R^2} \right). \tag{2}$$

Integrating (2) over the reaction and the preheat zones, we deduce the following jump condition for the tangential component of the vorticity vector.

$$\left[\!\left[\frac{M}{R} \boldsymbol{n} \times (\boldsymbol{\Omega} \times \boldsymbol{n}) \right]\!\right] = - \left[\!\left[\frac{1}{R} \right]\!\right] (\boldsymbol{n} \times \nabla) \left((1 + \gamma Ma^2) P_M + T - \frac{q^2}{2} \left(1 + \frac{4}{3} Pr \right) M \right), \tag{3}$$

where M and q are the mass flux and the non-dimensional heat release, and the double brackets means the difference of values between behind and ahead of a flame front on the hydrodynamic scale, for example, $[\![\phi]\!] = \phi_+ - \phi_-$ for a given function ϕ. The quantities on the right hand side of (3) are evaluated at the upstream unburned edge of a flame front. The pressure is expanded to square of the small Mach number ($Ma^2 \ll 1$) as

$$P = 1 + \gamma Ma^2 P_M; \quad P_M = P_{2M} + Ma^2 P_{4M}, \tag{4}$$

where P_{2M} was considered in the low-Mach-number limit [3] and P_{4M} is new, being tied with the velocity field of $O(Ma^2)$.

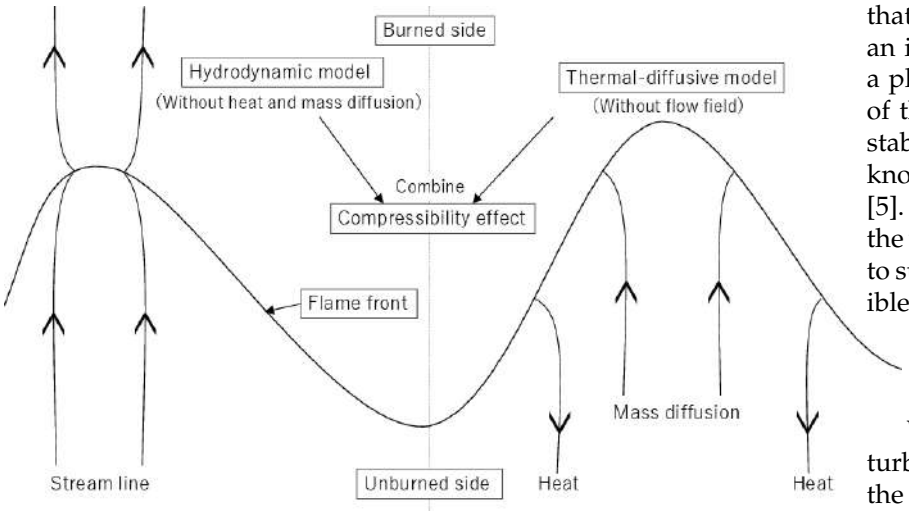

Figure 2: Compressibility combines two independent models.

The jump condition (3) suggests that the Prandtl number Pr plays an important role in the stability of a plane flame because the existence of the vorticity generically brings a stabilizing effect on the DLI as is known in zero-Mach-number limit [5]. We confirm that this is true and the viscous effect acts to weaken and to suppress the DLI in the compressible case as shown in Figure 1.

CONCLUSIONS

We show, by the singular perturbation method, the influences of the temperature and the mass flux on the vorticity production accompanied by the viscous effect. The higher-order term of the pressure in the Mach number is derived, with P_{4M} containing the Prandtl number. These results are obtained by combining the thermal-diffusive model with the hydrodynamic equation. The weakening and even the suppression of the DLI can occur in the coefficient of the linear, in wavenumber, terms in the growth rate.

GENERAL SOLUTIONS FOR CLOSELY SPACED CO-ROTATING HELICAL VORTICES

Andrés Castillo-Castellanos*[1], Eduardo Durán Venegas[1], and Stéphane Le Dizès[1]
[1]Aix Marseille Univ, CNRS, IRPHE, Marseille, France

Summary We extend the work of [2] and present solutions describing the interaction of helical pairs of closely spaced co-rotating vortices using a vortex filament approach. For these structures the helical symmetry is broken, but still display a form of spatial periodicity and are stationary in a rotating and translating frame. A low order approximation is proposed and compared against numerical results. Finally, we discuss how our results may be used to describe the far wake generated by a rotor.

CONTEXT

Rotating blades, such as the ones of a helicopter main rotor or those of a horizontal-axis wind turbine, generate concentrated vortices at their tips, which are transported downstream creating a helical geometry. These helical vortices are associated with several practical issues actively investigated. One concerns the interaction between a tip vortex and a following blade (Blade-Vortex Interaction, BVI), responsible in part for the accelerated wear in wind turbines and undesirable noise in helicopters during forward and descending flight [6]. One successful approach to mitigate BVI is to modify the flow structure by introducing a modified vane tip to split tip vortices in two [1].

Interactions between closely spaced co-rotating helical vortices are controlled by the separation distance d and core size a. If the ratio d/a is smaller than a threshold, vortices merge into a single entity (see, for instance [4]). This process can be accelerated by the development of short-wave instabilities [5]. For this work, we consider a is small enough to neglect the inner core structure and describe vortices as filaments [3, 2]. We also consider d/a is large enough prevent merging, but small enough for the vortices to twist around each other. For these vortices, we show there exist a unique moving frame where structure is steady, i.e. vortex elements are moving along the structure without distorting it. In this work, we present general solutions and characterize the tip vortex dynamics in this special configuration.

PROBLEM DESCRIPTION AND MAIN PARAMETERS

To identify the main parameters of our problem, consider a simple case of vortex interaction: a pair of equal vortices of circulation Γ which rotate around each other with constant angular velocity $\omega = \Gamma/(\pi d^2)$. If we impose an axial flow U_z, the vortices are passively transported streamwise creating a helical pattern. If we also introduce an eccentric rotation with angular velocity Ω, the resulting pattern describes a cycloidal curve defined by the distance between the axes of rotation R, the separation distance d and twist parameter $\beta \equiv 2\pi/\tilde{\theta}$ which compares the rotation of the vortex pair to the rotation around the eccentric axis (figure 1a). The ensemble is transported streamwise creating a helical pair with pitch $h = (\pi d^2 U_z)/\Gamma$ inscribed on top of a helix with pitch $H = U_z/\Omega$ (figure 1b).

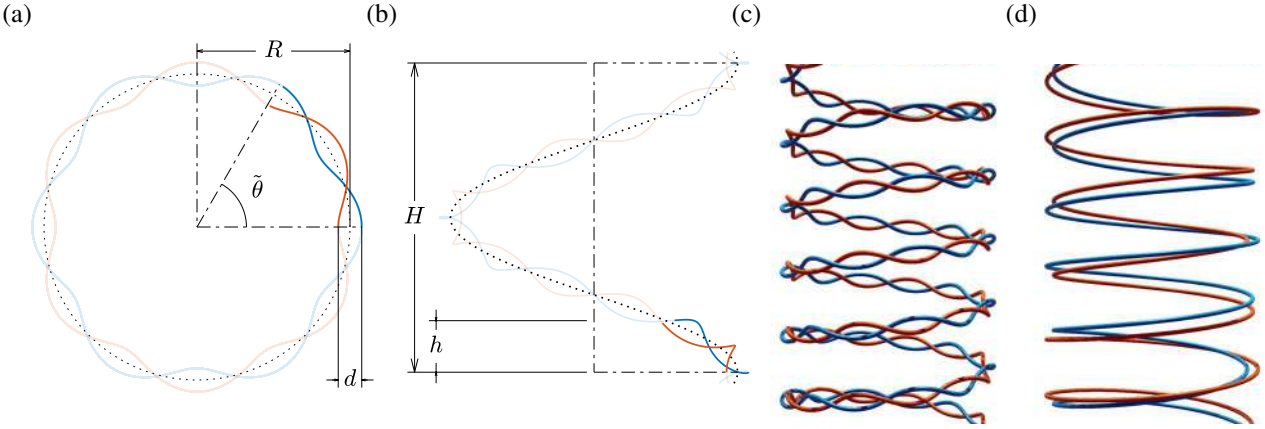

Figure 1: Representation of closely spaced helical pairs. (a) Top and (b) front view illustrate main parameters: radius R, separation distance d, pitch H, and $\beta = 2\pi/\tilde{\theta} = H/h$. Solutions describe a (c) braided pattern for $|\beta| > 1$, and (d) leapfrog pattern for $|\beta| < 1$.

From these parameters we identify the following dimensionless geometric parameters:

$$R^* = \frac{R}{d} \qquad H^* = \frac{H}{d} \qquad \varepsilon = \frac{a}{d} \qquad \beta = \frac{H}{h} \tag{1}$$

We consider $R^* = 9.5$, $\varepsilon = 0.2$, β between -8 and 8, and decrease H^* between 100 and a minimum value ranging between 3 and 6 depending on β. The resulting configuration may describe a braided pattern (figure 1c) or a leapfrog-type pattern where interior and exterior vortices trade places every $1/\beta$ turns (figure 1d).

DEFORMED SOLUTIONS

While the example above is based on (2-D) point vortices, we show that is indeed possible to obtain similar solutions which incorporate the complete 3-D vortex dynamics using the free-vortex method [3]. Different properties, such as radial deformation, frame velocity or induced flow, are provided from numerical simulations. Numerical results are compared with analytic expressions at zero- and first-order of approximation. In both cases, we assume the locally axial flow is decoupled from the axial vorticity dynamics. Zero-order expressions are deduced from (2-D) point vortex dynamics transported along the axial direction as in the example above. First-order corrections are introduced by considering the vortex pair to be transported along a direction locally tangent to a helix of radius R^* and pitch H^*. For this latter, a good qualitative and quantitative agreement is observed for values of H^* and β where mutual interaction is predominant (see, for instance frame velocities shown in figures 2a and 2b).

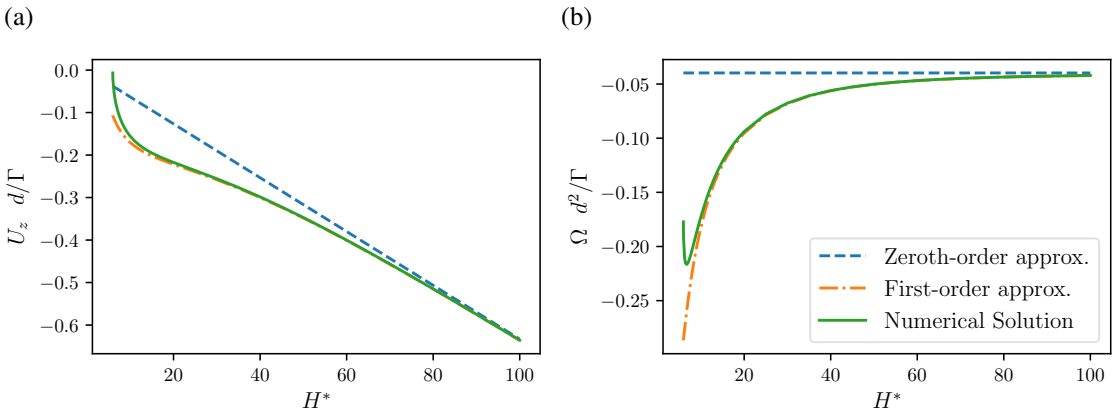

Figure 2: Dimensionless frame velocities for a closely spaced helical pair as function of H^* for $R^* = 9.5$, $\varepsilon = 0.2$, and $\beta = 8$. Numerical solutions are compared to expressions at zero- and first-order of approximation.

Finally, we discuss how these solutions may be used to represent the far wake generated by a rotor with a modified vane tip. If the flow was created by a rotor, the moving frame where each solution is stationary is necessarily attached to a rotor blade. By analyzing the direction of propagation of the vortices relative to that of the external wind, the general solutions are associated to a particular rotor flow regime.

TORRICELLI'S DISCHARGE LAW MODIFIED BY THE BATHTUB VORTEX

Aurore Caquas[1,2], Luc Pastur[1], Alain Genty[2]
[1]Institute of Mechanical Sciences and Industrial Applications, ENSTA Paris, Institut Polytechnique de Paris, France
[2]Den-Service de thermo-hydraulique et de mécanique des fluides (STMF), CEA, Université Paris-Saclay, F- 91191 Gif sur Yvette, France

Summary We study the discharge flow in presence of a bathtub vortex and compare it to the Torricelli's law $v = \sqrt{2gH}$, where v is the flow rate velocity, g the gravity constant and H the height of the water column [1]. The experimental set-up is composed of a cylindrical tank, a container and measuring devices, all embarked on a rotating platform. Mass measurements, particule image velocimetry (PIV) and ombroscopy give respectively access to the flow rate velocity, the vortex circulation and the shape deformation due to the vortex. Deviations to the Torricelli's law are observed only when the surface is deformed.

INTRODUCTION

The Torricelli's law [1,2] has been known now for over 300 years and predicts well the emptying speed of a tank whose orifice's size is very small in comparison to its own size [3]. Under this condition, the law only has to be corrected by a multiplicative constant $\alpha < 1$, owing to the *vena contracta* phenomenon and the singular pressure drop associated with it [4].

Vortex formation while emptying can appear in a simple bathtub but can also be present on much larger scales, as for example in the study of vortex flow in hydroelectric dams or in RNR-Na reactors. Yet, it is not clear how the vortex that commonly forms modify the discharge.

EXPERIMENTAL SETUP

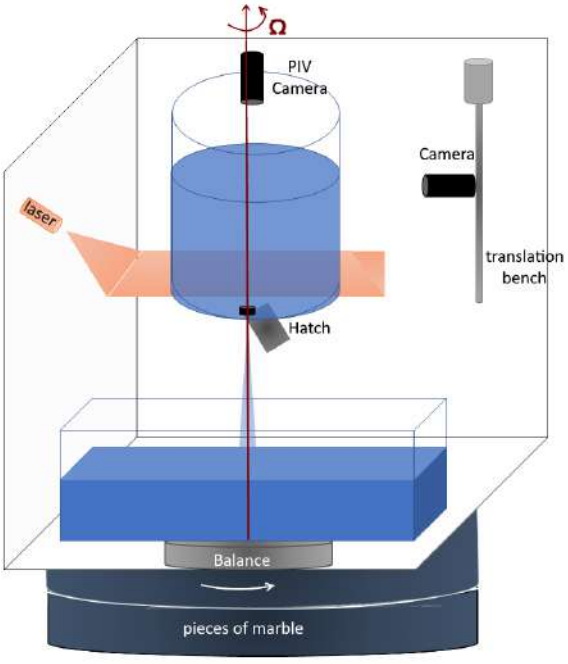

Figure 1. Experimental set-up (see text below).

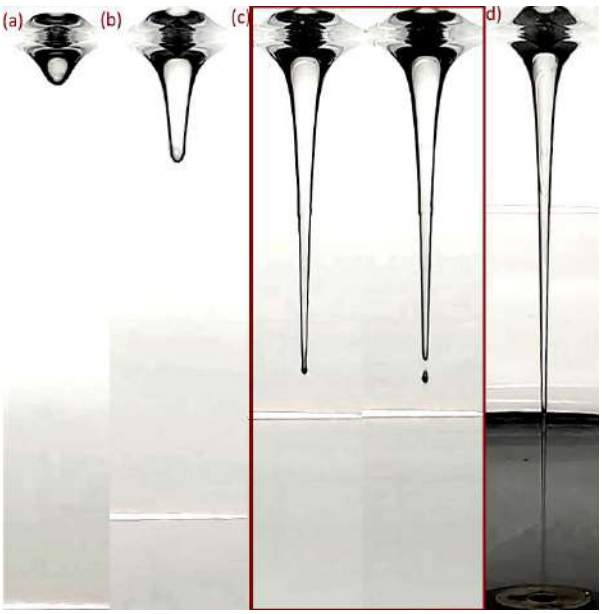

Figure 2. Pictures of the different states of the surface.

The plexiglas tank (fig.1) is a cylinder with radius $R = 300 \pm 1$ mm and height $L = 393$ cm, with a hole centred at the bottom. The diameter of the outlet section can be adjusted by means of cylindrical taps that clip into the hole. These taps have an internal diameter varying from 1 to 43 mm. The start of the draining process is controlled remotely by opening a watertight hatch under the tank. The tank is mounted on a rotating platform and is centered on the axis of rotation. The platform consists of two 20 cm thick cylindrical pieces of marble of diameter 1.5 m, piled up together and separated by a 1 mm thick film of pressurized air, which allows the upper part to rotate above the lower part without solid friction. The rotation speed can be continuously changed from 0 to 1 rad. s^{-1} (10 round. min^{-1}).

The cumulative loss of liquid in the tank is measured by a scale Ohaus Ranger 7000 with a precision of 0.5 g and a sampling frequency of 0.5 Hz. The balance is centered on the axis of the rotating frame, such that no inertial correction be required for the measurement of the weight. The height of water H is determined from the measurement of the mass loss M. The flowrate Q follows from the analytic derivative of $M(t)$ by using a Savitzky-Golay [5] polynomial interpolation of M over 20 points of measurement, yielding an estimated flow rate precision of about 0.03 L. min^{-1}.

The circulation Γ of the vortex is determined by averaging 3 to 10 successive velocity fields every 3 to 10 s, obtained by particle image velocimetry (PIV) with an acquisition frequency of 3 to 60 fps. The free surface shape is obtained by ombroscopy using a camera on a motorized translation bench. The translation bench is controlled in order to follow the interface and avoid parallax errors.

RESULTS

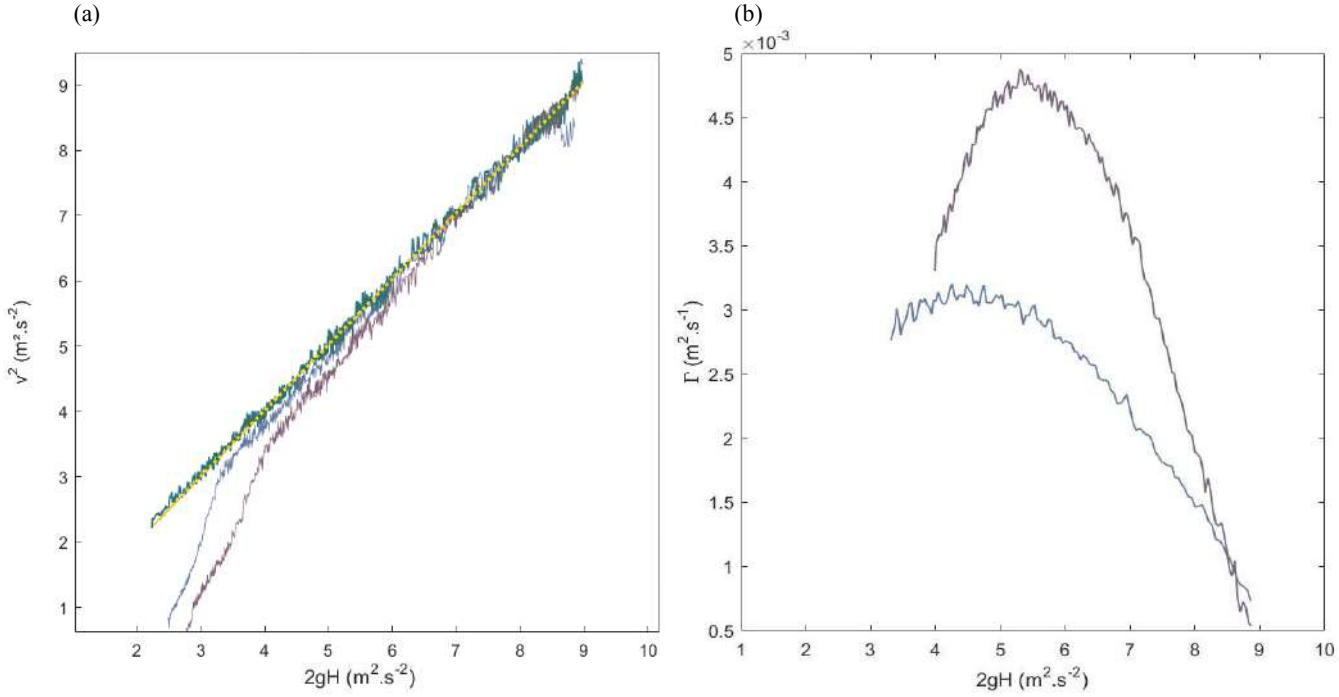

Figure 3 (a) Evolution of the velocity square as a function of $2gH$. The curve in green is the Torricelli's experimental case, the curve dashed in yellow is the theorical law. In grey, the tank rotation velocity is 1.03 round. s^{-1} and in burgundy 1.53 round. s^{-1}.
(b) Evolution of the circulation of the vortex as a function of $2gH$. In grey, the tank rotation velocity is 1.03 round. s^{-1} and in burgundy 1.53 round. s^{-1}.

At the beginning of the emptying, we have not measured any significant differences between the draining with a vortex and the Torricelli's case with water at rest before emptying (fig. 3.a.). In this first regime (3 $2gH > 7$), the free surface is not deformed, despite the presence of a vortex in the flow (fig. 3.b.). When the circulation of the vortex Γ increases and the fluid depth decreases, the free surface takes shape (fig. 2 a. and b.) and a deviation from the Torricelli's law is observed (see fig. 3.a for 4 $< 2gH < 7$). In this regime, the flow rate decreases. Then, bubbles are ripped off the tip of the gaseous core (fig. 2.c). Just after that, the tip quickly moves down to the drain section. As a result, the outlet section is reduced by the gaseous core, as shown in figure. 2.d and the emptying flow rate is further decreased (see fig. 3.a for 2 $2gH < 4$).

PERSPECTIVES

Surprisingly, the flow rate did not appear to be influenced by the presence of the vortex in itself but rather by the shape of the interface created by the vortex. This deformation depends on the vortex strength, the height of the water and the emptying flow rate. We are currently setting up a new experiment to confirm these initial results and refine them in a stationary regime. The new set-up will consist of a closed water circuit to keep the surface height constant.

NONLINEAR EVOLUTION OF VERTICALLY CONFINED INTERNAL GRAVITY WAVES IN NONUNIFORM STRATIFICATION

Bruce R. Sutherland*[1], Ton S. van den Bremer[2], Houssam Yassin[3], and Lois E. Baker[4]
[1]Departments of Physics and of Earth & Atmospheric Sciences, University of Alberta, Edmonton, Canada [2]Department of Engineering Science, University of Oxford, Oxford, England

Summary Because the density of the ocean increases with depth, internal gravity waves can propagate within it, moving under the influence of buoyancy forces. One mechanism for the generation of these waves is through the action of the tides periodically crossing submarine topography. Far from these sources, these "internal tides" are observed to propagate horizontally as vertically confined modes. It remains an open question as to how these internal tides ultimately break down - transferring energy from large scales to sufficiently small scales capable of mixing. Besides interacting with topography, currents and eddies, a well-studied mechanism for the spontaneous breakdown of internal gravity waves is through triadic resonant instabilities (with parametric subharmonic instability being a specific example). Although this readily occurs in uniform stratification, this work will show through theory and numerical simulations that in realistic (non-uniform) ocean stratification the dominant mechanism for energy transfer is through nonlinear self-interaction leading to the generation of mean flows and superharmonics.

THEORY

We restrict ourselves to the examination of two-dimensional, vertically confined Boussinesq internal waves, including the effects of background rotation, but neglecting diffusion and viscosity. The fully nonlinear equations may be combined to give a single equation for the evolution of the streamfunction, $\psi(x,z,t)$ [1]:

$$\underbrace{\left(\partial_{tt}(\partial_{xx}+\partial_{zz})+N^2\partial_{xx}+f^2\partial_{zz}\right)}_{\equiv\, L}\psi = \underbrace{\nabla\cdot\left[\partial_t(\zeta\vec{u})-\partial_x(b\vec{u})+f\partial_z(v\vec{u})\right]}_{\equiv\, \mathcal{N}}. \qquad (1)$$

Here $\vec{u}=(u,w)$ is the velocity velocity vector in the along-stream and vertical directions, ζ is the spanwise vorticity, and b is the buoyancy. The Coriolis parameter, f, is assumed to be constant, while the squared buoyancy frequency, $N^2(z)$, is an arbitrary function of height.

At leading order in amplitude, the right-hand side of (1) can be neglected and the resulting linear equation in $\psi_1 = A\hat{\psi}(z)e^{i\phi}$ (with $\phi\equiv kx-\omega t$) can be solved numerically to give the vertical structure function of the "parent mode" and its corresponding dispersion relation $\omega(k)$. From this result, the polarization relations give the corresponding leading-order expressions for u, v, w, ζ and b.

Our interest here is in the self-interaction of a mode-1 parent wave whereby products of the linear fields on the right-hand side of (1) acts as an order amplitude-squared forcing to the streamfunction, provided N^2 is non-constant. The products of the linear fields provide forcing both to superharmonics, with phase 2ϕ, and to a mean Eulerian flow (with zero phase).

Superharmonics

In the examination of superharmonics, the amplitude, A, of the parent mode can be taken as constant. Through use of Sturm-Liouville theory, the vertical structure of the forcing can be decomposed into vertical modes. Despite the complex vertical structure of the forcing, a straightforward analysis reveals that the most of forcing acts to excite a mode-1 disturbance. Furthermore, the natural frequency of the superharmonic mode is comparable to twice the frequency of the parent mode (which is the forcing frequency, 2ω). Consequently, the superharmonic is found to grow and decay periodically with a frequency determined by the difference of the forcing frequency and the natural frequency of the superharmonic [2]. If this difference is very small, the superharmonics can grow to amplitudes comparable with the parent wave, leading to possible irreversible extraction of energy from the parent mode through dynamics beyond weakly nonlinear theory. Such dynamics should be most significant close to the equator which is where, from the dispersion relation, the frequency has a near-linear dependence upon wavenumber.

Eulerian and Lagrangian Mean Flows

In order to determine the Eulerian flow induced by the parent mode, it is convenient to assume that the amplitude, A, is a slowly varying function of horizontal space and time. Then one can find corrections to the polarization relations that account for spatial variations in the amplitude envelope. This procedure was followed by van den Bremer et al [3] in the case of no background rotation. As with the study of superharmonics, with realistic ocean stratification it is found that the Eulerian mean flow induced by a mode-1 parent wave is predominantly mode-1 and these flows can be substantial

*E-mail: bruce.sutherland@ualberta.ca.

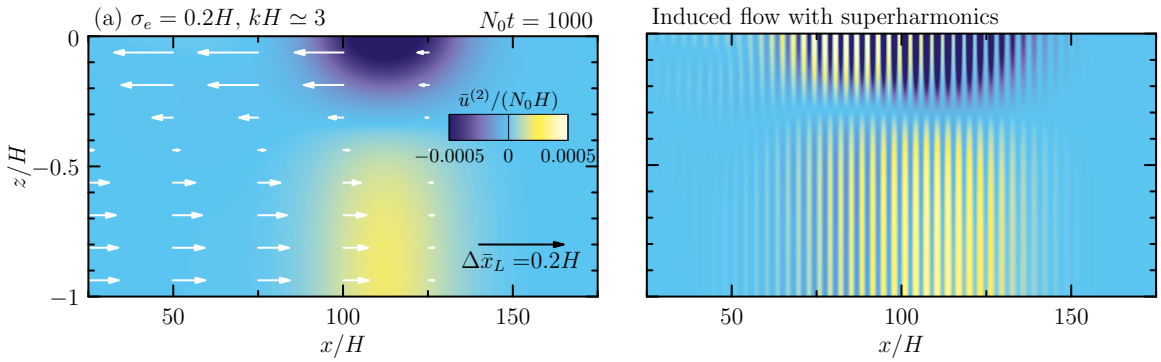

Figure 1: For numerical simulations with stratification decreasing exponentially with depth (with e-folding scale $\sigma_h = 0.2H$), snapshots from simulations: (a) Fourier-filtered horizontal flow at time $N_0 t = 1000$ and filtered parcel displacements, and (b) Horizontal flow with wave-packet removed to reveal the induced Eulerian flow superimposed with superharmonics. The Gaussian wave-packet has amplitude $a_0 = 0.01H$, $\sigma = 20H$ and $kH = 1$.

for a horizontally long parent wave. This has significant implications for the nonlinear evolution of the parent wave, which becomes Doppler shifted by the vertically varying horizontal currents associated with the induced Eulerian flow. Separately, the Stokes drift associated with the parent wave can be computed, but this is negligible compared with the induced Eulerian flow if the waves are long. Hence, for oceanic internal tides, the Lagrangian transport (the sum of the induced Eulerian flow and the Stokes drift [4]) is dominated by the Eulerian induced flow. Besides the interest in the influence upon the modulational stability of modulated internal modes, this study provides a step towards improved predictions for the transport of microplastics in the open ocean.

SIMULATION RESULTS

As an illustration of the theoretical predictions, Figure 1 shows a) the induced flow and b) superharmonics excited by a horizontally Gaussian small-amplitude internal wave packet with half-width 20 times the depth, H, of the domain. The background stratification is exponentially decreasing with depth having maximum buoyancy frequency N_0 at the surface and e-folding depth $\sigma_h = 0.2H$. This simulation was initialized with relatively short horizontal wavelength waves in the wave-packet such that $k = \pi/H$. In simulations with more representative oceanic values of $k \sim 0.2/H$, the induced Eulerian induced flow and superharmonic amplitudes are closer to that of the parent mode, leading to non-trivial nonlinear interactions between the disturbances.

CONCLUSIONS

This analysis presented here provides the starting point for a more thorough examination of the evolution and ultimate breakdown of the internal tides in the ocean. While there has been some observational [5, 6] and numerical [7] evidence for the occurrence of parametric subharmonic instability of low-mode internal tides, this is such a slow-growing process compared with self-interaction in non-uniform stratification [8] that its importance for the transfer to small scales of energy associated with internal tides is questionable. The relatively unexplored phenomenon of self-interacting internal modes in non-uniform stratification provides a fruitful ground in which to explore novel mechanisms for the breakdown of internal tides. Ongoing studies include examining the influence of the finite spanwise extent of the waves, their modulation by solar and lunar tidal forcing and their meridional propagation, accounting for changes in f with latitude.

ENERGY-FLUX VECTORS OF INERTIAL WAVES IN STRONGLY ROTATING TURBULENCE

Naoto Yokoyama *[1] and Masanori Takaoka[2]
[1]Department of Mechanical Science and Bioengineering, Osaka University, Toyonaka, Japan
[2]Department of Mechanical Engineering, Doshisha University, Kyotanabe, Japan

Summary The weak turbulence theory of inertial waves in strongly rotating turbulence tells us that the resonant interactions transfer energy to waves which have small scales perpendicular to the rotational axis without changing its scales parallel to the rotational axis. The energy flux determined at each wave number in the wave-number space is expected to reproduce that predicted by the weak turbulence theory. In this abstract, the energy-flux vector in anisotropic turbulence is proposed based on the net locality and the efficiency of the energy transfer. The energy-flux vector is confirmed to successfully reproduce the energy flux in the inertial-wave turbulence.

INTRODUCTION

In strongly rotating turbulence, anisotropy appears in a small wave-number range, where the inertial waves dominate and the weak turbulence theory can be applied. The weak turbulence theory predicts that the resonant interactions transfer energy to waves which have small scales perpendicular to the rotational axis without changing its scales parallel to the rotational axis. To quantitatively validate the prediction, it is indispensable to investigate the energy flux at each wave number.

In homogeneous isotropic turbulence, the quantitative feature of the flux for sufficiently large Reynolds numbers has been extensively examined. On the other hand, the flux in anisotropic turbulence still provokes a lot of debate, partially because the flux should be treated as a vector. In this abstract, the definition of the local energy-flux vectors in anisotropic turbulence is proposed. The vectors are compared with the prediction of the weak turbulence theory of the inertial waves in strongly rotating turbulence.

METHOD

In Navier-Stokes turbulence, the energy flux plays a key role in energy-cascading process, and is defined for a wave number in isotropic turbulence systems as

$$P(k) = -\int_0^k T(k')dk', \tag{1}$$

where the isotropic energy transfer $T(k)$ is obtained from $T_{\boldsymbol{k}} = \sum_{\boldsymbol{k}_1,\boldsymbol{k}_2} \mathcal{T}(\boldsymbol{u}_{\boldsymbol{k}};\boldsymbol{u}_{\boldsymbol{k}_1},\boldsymbol{u}_{\boldsymbol{k}_2})$ by integration of the triad-interaction function $\mathcal{T}(\boldsymbol{u}_{\boldsymbol{k}};\boldsymbol{u}_{\boldsymbol{k}_1},\boldsymbol{u}_{\boldsymbol{k}_2})$ over the solid angle of $\boldsymbol{k}$, and is assumed to be continuous as a function of $k = |\boldsymbol{k}|$. The triad-interaction function denotes the energy transfer from or to the wave number $\boldsymbol{k}$ via the triad $\boldsymbol{k} + \boldsymbol{k}_1 + \boldsymbol{k}_2 = \boldsymbol{0}$, and

$$\mathcal{T}(\boldsymbol{u}_{\boldsymbol{k}};\boldsymbol{u}_{\boldsymbol{k}_1},\boldsymbol{u}_{\boldsymbol{k}_2}) = -\frac{i}{4}\left\langle (\boldsymbol{k}_1\cdot\boldsymbol{u}_{\boldsymbol{k}_2})(\boldsymbol{u}_{\boldsymbol{k}}\cdot\boldsymbol{u}_{\boldsymbol{k}_1})\right\rangle \delta_{\boldsymbol{k}+\boldsymbol{k}_1+\boldsymbol{k}_2} + \text{c.c.} + (1\leftrightarrow 2), \tag{2}$$

where $(1 \leftrightarrow 2)$ respectively represent the terms with the suffices 1 and 2 interchanged in the preceding ones.

In this abstract, the rotational axis is denoted by z, and the isotropy in the x and y directions perpendicular to the rotational axis is assumed. Then, the energy transfers can be investigated in the $k_\perp$–$k_\parallel$ space, where $k_\perp = \sqrt{k_x^2 + k_y^2}$ and $k_\parallel = |k_z|$. The integrated energy fluxes perpendicular and parallel to the rotational axis

$$P_\perp(k_\perp) = -\int_0^{k_\perp} dk'_\perp \int_0^\infty dk'_\parallel T(k'_\perp,k'_\parallel), \qquad P_\parallel(k_\parallel) = -\int_0^\infty dk'_\perp \int_0^{k_\parallel} dk'_\parallel T(k'_\perp,k'_\parallel) \tag{3}$$

have been conventionally used, respectively. The anisotropic energy transfer $T(k_\perp,k_\parallel)$ is obtained from $T_{\boldsymbol{k}}$ by integration over the azimuthal angle of $\boldsymbol{k}_\perp$ and the sign of k_z. Because $P_\perp(k_\perp)$ and $P_\parallel(k_\parallel)$ are respectively obtained by integration of $k_\perp$ and $k_\parallel$, these integrated fluxes inevitably consist of contributions from all the turbulence regions, i.e., the weak-wave turbulence, the three-dimensional isotropic turbulence, and the dissipation. Thus, detailed local structures of the energy-cascading process in the wave-number space cannot be captured directly by the integrated energy fluxes.

To investigate the detailed local structure of the energy-cascading process, the energy flux is required to be a local geometric vector, because the energy flux can depend on the directions as well as the magnitudes of the wave numbers. Because of the energy cascade, the local energy conservation in the wave-number space

$$T_{\boldsymbol{k}} + \nabla_{\boldsymbol{k}}\cdot\boldsymbol{P}(\boldsymbol{k}) = 0 \tag{4}$$

*Corresponding author. E-mail: yokoyama@me.es.osaka-u.ac.jp

is assumed to hold as is implicitly assumed in the cascade theory of the isotropic turbulence. Here, $\boldsymbol{P}(\boldsymbol{k})$ is the energy-flux vector that quantifies the local energy flux. Unfortunately, $\boldsymbol{P}(\boldsymbol{k})$ cannot be determined uniquely yet because the degree of freedom of $\boldsymbol{P}(\boldsymbol{k})$ is approximately three times larger than the that of $T_{\boldsymbol{k}}$.

In this work, to uniquely determine the energy-flux vector in anisotropic turbulence, we employ the generalized (Moore-Penrose) inverse. The continuity equation of energy (4) is rewritten in a matrix form as $\mathsf{DP} = -\mathsf{T}$, where D is a fat matrix that corresponds to the divergence operator, and P and T respectively represent the generalized vectors consisting of all the wave-number components of $\boldsymbol{P}$ and T. Then, the vector P_* that has the minimal Euclidean norm among solution vectors is selected by using the generalized inverse matrix D^+ as

$$\mathsf{P}_* = -\mathsf{D}^+\mathsf{T} = \mathrm{argmin}\|\mathsf{P}\|_2, \quad \text{where } \mathsf{D}^+ = \mathsf{D}^T(\mathsf{D}\mathsf{D}^T)^{-1}. \tag{5}$$

The selection of the minimal-norm vector corresponds to the assumption that the energy transfer is "efficient". The minimal-norm solution P_* is irrotational. It results from the fact that the Moore-Penrose solution does not have the null-space component P_0 that satisfies $\mathsf{DP}_0 = 0$, and D corresponds to the divergence operator.

NUMERICAL RESULTS

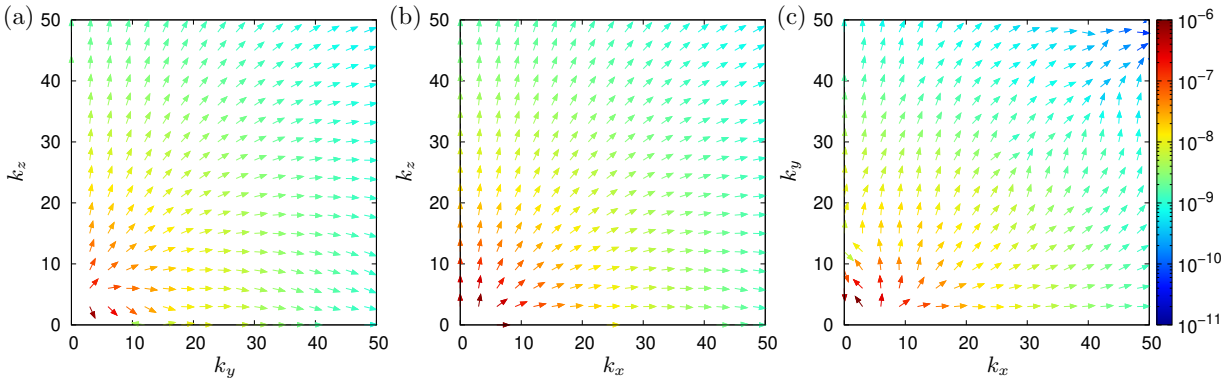

Figure 1: Energy fluxes on the planes of (a) $k_x = 0$, (b) $k_y = 0$ and (c) $k_z = 0$. The lengths of the energy-flux vectors are normalized, and the magnitudes of the vectors are expressed by color. Only the range $0 \le k_x, k_y, k_z \le 50$ is shown.

A direct numerical simulation of rotating turbulence is performed by using the pseudo-spectral method. The perpendicular wave numbers, k_x and k_y, are discretized with the spacing $\Delta k_x = \Delta k_y = 1$, while the parallel wave number k_z is discretized with $\Delta k_z = 1/4$. To obtain the statistically steady state, three-dimensional three-component random forces is added to the wavenumber mode in $k_\mathrm{f} - 1/2 \le |\boldsymbol{k}| < k_\mathrm{f} + 1/2$, where the forced wavenumber k_f is set to 4. The anisotropic energy-flux vectors are obtained from the energy transfer rate in the direct numerical simulation by using the Moore-Penrose inverse.

The energy-flux vectors on the planes of $k_x = 0$, $k_y = 0$ and $k_z = 0$ are drawn in Fig. 1. As the perpendicular wave numbers, k_y and k_x, become large, the energy-flux vectors become more parallel to the k_y and k_x axes in Figs. 1(a) and (b), respectively. It indicates that the energy is transferred to the wavenumbers having the same $k_\parallel$, and is consistent with the energy transfer due to the resonant interactions appearing in the weak turbulence theory of the inertial waves [1, 2, 3]. The alignment of the two-dimensional columnar vortex causes anisotropy on the $k_z = 0$ plane shown in Fig. 1(c), but this anisotropy should disappear if the large ensemble averaging were performed.

CONCLUSION

In this abstract, based on the net locality and the efficiency of the nonlinear energy transfer, the minimal-norm energy-flux vector obtained by using the generalised Moore-Penrose inverse is proposed to uniquely determine the energy-flux vector. It has been confirmed that the minimal-norm vector proposed here well reproduces the direction of the energy flux of the inertial-wave turbulence. In the presentation, the energy-flux vector will be shown to be consistent also with the prediction of the weak turbulence theory in stratified turbulence as well as the isotropy in the isotropic turbulence. In addition, the energy-flux vector is compared with the prediction of the critical balance in the buffer region between the weak turbulence and the strong turbulence.

AXISYMMETRIC INERTIA LATTRACTOR MODES IN A SPHERICAL SHELL AT LOW EKMAN NUMBERS

Lorenzo Valdettaro*[1] and Michel Rieutord[2,3]
[1]MOX - Department of Mathematics, Politecnico di Milano, Milano, Italy
[2]Université de Toulouse;UPS-OMP;IRAP;Toulouse,France
[3]CNRS; IRAP; 14, avenue Edouard Belin, F-31400 Toulouse, France

Summary We investigate the asymptotic properties when viscosity tends to zero of axisymmetric inertial attractor modes propagating in a spherical shell. These modes are made of thin shear layers adjacent to the periodic orbit traced by attractors of characteristics. We investigate them numerically using a pseudo-spectral linear eigenvalue solver of the linearized fluid dynamics equations. Using quadruple precision arithmetics we are able to extend the analysis done in [2] to those modes that are prone to round-off error. A simple quantization pattern emerges, although the quantum number is limited to a few values.

ATTRACTOR MODES IN A SPHERICAL SHELL

Attractor modes are eigenmodes associated with a specific attractor represented by a periodic orbit of characteristics. In a spherical shell these modes were first studied in [1] and their analytic form has been given by [2]. They are shaped by a fast oscillating wave whose typical wavelength scales like $\mathcal{O}(\mathrm{E}^{1/3})$ ($\mathrm{E} = \frac{\nu}{2\Omega R^2}$ is the Ekman number with ν the kinematic viscosity coefficient of the fluid and Ω the angular velocity, while R is the major radius of the spherical shell) trapped in a nearly gaussian envelope of characteristic width $\mathcal{O}(\mathrm{E}^{1/4})$. The wave packet remains at a distance $\mathcal{O}(E^{1/6})$ from the asymptotic attractor, which is reached at $\mathrm{E} = 0$. Numerical computations in [2] showed that a simple dispersion relation applies to eigenvalues of attractor modes. That dispersion relation was obtained using double precision arithmetics, by which only the first few damped eigenmodes are accessible, since it was shown that high order modes are very sensitive to round-off errors and cannot be properly computed using double precision.

In this presentation we make use of extended precision arithmetics. The range of the accessible eigenvalues increases and we find a simple governing law that extends the one found in [2], namely

$$\lambda_n = i\omega_0 - \sum_{k=0}^{\infty} \hat{\tau}_k \left(n + \frac{1}{2}\right)^k e^{i\phi_k} E^{\frac{1}{3}+\frac{k}{6}} \tag{1}$$

In this expression, ω_0 is the asymptotic frequency of the attractor, while $\hat{\tau}_k$ are positive real numbers that depend on the shape of the attractor. $n = 0, 1, \cdots$ is the quantum number that characterizes the mode.

We have found such families of eigenvalues in association with various attractors. Table 1 gives the parameters for six sets of such modes. In this table, we gathered the families of modes by pairs of families where we associated the attractor at ω_0 with the symmetric one at $\alpha_0 = \sqrt{1-\omega_0^2}$; in the table η is the shell aspect ratio, that is the ratio between radius of internal and external spheres.

We show in figure 1(a) the numerical evidence of formula (1) for the attractor 0.55537 at $\eta = 0.35$. We recall that double precision arithmetics is enough only for the first few damped eigenmodes (corresponding to $n \leq 3$ in formula (1)). Thus we make use of extended precision for all the computations.

We remark that as n increases the numerical resolution needs to be increased in order to resolve the eigenvector. This can be clearly seen on figure 1(a): the red eigenvalues (computed using resolution $L_{\max} = 800$ and $N_r = 300$, where $L_{\max}$ is the maximum of the index of Legendre polynomial expansion used in latitude and N_r is the number of radial Chebyshev nodes) are correct up to quantum number $n = 14$, but for $n \geq 15$ they are no more valid. Increasing the resolution to $L_{\max} = 1000$ and $N_r = 370$ we are able to obtain four more eigenvalues, and increasing further the resolution we can capture up to eigenmode $n = 19$. However, beyond $n = 19$, no matter the increase of resolution, we

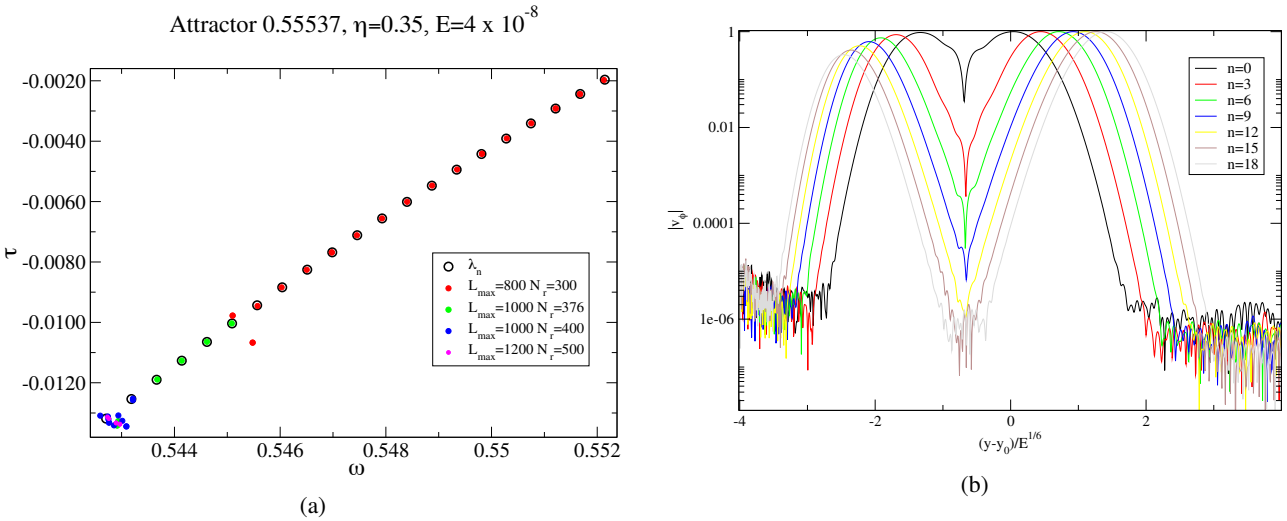
10^{-8}	16

Table 2: Maximum number of n for eigenvalues satisfying formula (1).



(a) (b)

Figure 1: (a) Eigenvalues at $E = 4 \times 10^{-8}$ for attractor 0.55537 at $\eta = 0.35$. Centers of black circles are given by the formula (1). (b) $|v_\phi|$ for some internal modes at $E = 4 \times 10^{-8}$.

obtain several dispersed eigenvalues that appear to be randomly positioned aroud the corresponding eigenvalue of formula (1). This can be seen in figure 1(a) for the eigenvalue corresponding to $n = 20$. This is reminiscent of the behaviour of eigenvalues that was obtained using double precision arithmetics and might suggest that round-off error affects extended precision computations for such eigenvalues. In table 2 we report such values: the total number of eigenvalues that are not affected by round-off error does not seem to increase when E decreases.

In figure 1(b) we plot the modulus of toroidal component of velocity v_ϕ in the direction normal to shear layer. It thus shows the envelope of the two shear layers adjacent to the attractor. We notice that increasing n the two adjacent rays become more and more separated, until for $n = 18$ (that is $n_{\max}$) they become separated by an interval where $|v_\phi|$ takes values of the order of the background noise. So for sufficiently small values of n the two adjacent rays interact and this might be the key to the dispersion relation. For large values of n instead this interaction is lost and the spectrum of eigenvalues changes shape. The way in which the spectrum is affected will be the subject of further study.

COMBINED NUMERICAL AND EXPERIMENTAL STUDY OF SPATIALLY EVOLVING WIND-WAVE FIELD

Santosh Kumar Singh[1] and Lev Shemer*[1]
[1]School of Mechanical Engineering, Tel-Aviv University, Tel-Aviv, Israel

Summary: The present study focuses on numerical simulations of waves evolving under steady wind forcing that is based on a new model that accounts for effects of nonlinearity, wind input and dissipation. The performance of the model and of the computational procedure is assessed by comparison of the numerical results with associated detailed measurements in a wind-wave tank.

INTRODUCTION

Different aspects of wind waves are of great interest for engineers, mathematicians and physicists due to the complexity of those waves and their importance for applications and basic science. Therefore, a substantial effort was made by the scientific community over the recent decades to accumulate extensive sets of reliable and accurate experimental data that will allow to study various aspects of the wind wave-problem. Despite advances in measurement techniques and instrumentation, the process of excitation of waves on the water surface and of their evolution and growth due to the action of wind is still far from being fully understood. Extensive reviews of the current state of the art on the subject were presented in [1], whereas the effects related to the limited fetch and duration are emphasized in [2].

MATERIALS AND METHODS

Experiments were conducted in the Tel-Aviv University wind-wave facility that has a 5 m long, 0.4 m wide and 0.5 m high test section. The facility is equipped with a closed-loop wind tunnel to generate waves at desired wind velocity; it is described in detail in [3]. Four capacitance type wave gauges made of 0.5 mm thick anodized tantalum wire were used simultaneously. The probes were placed on a bar with a spacing of 10 cm between the adjacent sensors, and supported by an instrument carriage. Each individual record lasted for 3600 s at the sampling rate of 300 Hz. Measurements were performed at eight carriage positions effectively covering the whole length of the test section. At each carriage location, measurements were performed for several mean wind speeds U ranging from 5.5 m/s to 11.5 m/s. The corresponding friction velocities u_* at the air-water interface for different values of U were measured in the present facility and reported in [4].

In order to carry out quantitative comparison of the experimental results with the theoretical predictions, the set of unidirectional discretized spatial Zakharov equations [5] that describes evolution of amplitude of each frequency harmonic in the spectrum with the distance x from inlet was used; the equation was modified to account for wind input and dissipation:

$$c_{g,j}\frac{\partial A_j(x)}{\partial x} = -i \sum_{\omega_j+\omega_l=\omega_m+\omega_n} V_{j,l,m,n} A_l^* A_m A_n e^{-i(k_j+k_l-k_m-k_n)x} + \beta_j A_j(x) - \alpha_j A_j(x) \qquad (1)$$

Here A_j is the complex wave amplitude, β_j and α_j are the wind input and viscous dissipation source terms, $c_{g,j} = d\omega/dk$ is the group velocity of the j^{th} spectral component and ω_j is the frequency related to its wave number k_j by the dispersion relation for gravity-capillary waves, $\omega^2 = gk(1+\gamma k^2/g)tanh(kd)$, where γ is the ratio of surface tension to water density and $d = 0.19$ m is the water depth. The measured at a short fetch $x_0 = 0.67$ m amplitude spectra were used to determine the initial conditions; for the relation between the measured initial amplitudes of the spectral harmonics $\hat{\eta}(\omega_j, x_0)$ and the corresponding initial complex amplitudes $A_j(x_0)$ see [5]. The nonlinear spatial evolution of the prescribed initial amplitude spectra was determined by solving numerically the discretized spatial Eq. (1) using 4th order Runge-Kutta numerical scheme.The wind input parameterization is adapted from [6, 7], however, it is applied here within the selected window:

$$\beta_j = \begin{cases} a_1\left(\frac{u_*}{c_{p,d}}\right)^2 f_d & \text{for } f_d - \Delta f < f_j < f_d + \Delta f \\ 0 & \text{otherwise} \end{cases} \qquad (2)$$

where a_1 is the wind input coefficient, f_d is the dominant frequency and $c_{p,d} = \omega_d/k_d$ is the phase velocity corresponding to the local dominant frequency. The size of the wind input window is defined as $\Delta f = f_d s_w$, where s_w is the coefficient related to spectral width which is calculated from the spectral moments. The wind input coefficient a_1 is chosen empirically to provide sufficient supply of energy by wind as determined in the experiments. In Eq. (1), α_j is the damping term of short waves that for the viscous damping at the water surface is $\alpha_j = -2\nu k^2$ [8], where ν is the molecular kinematic viscosity of water. To account for turbulence under wind waves, effective kinematic viscosity ν_{eff} is introduced instead of ν, with simulations performed for a range of effective viscosities $\nu \le \nu_{eff} \le 10\nu$. The value of the wind input coefficient a_1 is adjusted for ν_{eff} to retain energy growth compatible with the experimental result. The obtained simulation results suggested that the viscosity plays a significant role in frequency downshifting with fetch of young

*Corresponding author. E-mail: shemerl@tauex.tau.ac.il.

wind waves studied here and that the value of the effective kinematic viscosity ν_{eff} increases somewhat with increase in U up to $8\nu_{eff}$. In the present simulations the effective viscosity is taken as 0.08 cm^2/s for all the simulation runs.

RESULTS AND DISCUSSIONS

The wave amplitude and dominant frequency can be related to the fetch x and the friction velocity u_* of the wind using the dimensionless parameters based on the spectral moments m_j of the measured power spectrum $F(f)$ that are defined as $\int_{f_{min}}^{f_{max}} f^j F(f) df$ [9]. The dimensionless parameters are $\hat{m}_0^{1/2} = g m_0^{1/2}/u_*^2$, $\hat{f}_d = u_* f_d/g$ and $\hat{x} = gx/u_*^2$. The $\hat{m}_0^{1/2}$ and $\hat{f}_d$ may be written in terms of $\hat{x}$ as $\hat{m}_0^{1/2} = c_1 \hat{x}^{b_1}$ and $\hat{f}_d = c_2 \hat{x}^{-b_2}$, where c_1 and c_2 are the non-dimensional constants. Figs. 1 and 2 show that the experimental data fit a linear dependence in log-log coordinates and thus exhibit power-law behavior for two wind velocities. The characteristic wave amplitude $\hat{m}_0^{1/2}$ increases with the dimensionless fetch as $\hat{x}^{0.528}$ and $\hat{x}^{0.536}$ in experiments and simulations, respectively, while the corresponding decrease in dominant frequency $\hat{f}_d$ is $\hat{x}^{-0.33}$ and $\hat{x}^{-0.27}$, accordingly. These values of exponents are in a reasonable agreement with those obtained in numerous experiments and numerical simulations that vary in the ranges $0.35 < b_1 < 0.55$ and $0.23 < b_2 < 0.3$ [10]. The present results are in agreement with wind wave channel measurement at a comparable range of fetches $\hat{x}$ [9].

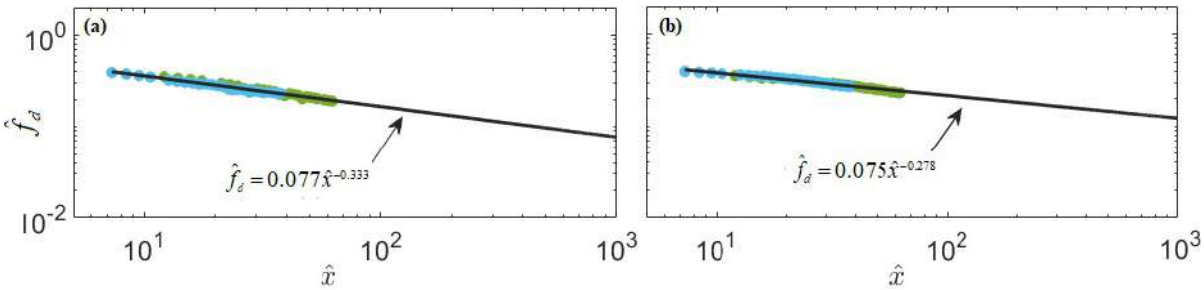

Figure 2. Dimensionless frequency down shifting the dimensionless fetch: (a) experiment and (b) simulation.

CONCLUSIONS

Results of numerical simulations of the spatial evolution of young waves under steady wind forcing are directly verified by comparison with measurements in a wind wave tank. A novel model to account for wind input is suggested. Good agreement between numerical simulations and measurements is obtained for the spatial evolution of global parameters such as dominant frequency downshifting and wave energy growth, as well as for the evolution along the tank of the wave spectra. It is shown that while nonlinearity plays an essential role in the peak frequency downshifting, the effect of dissipation and wind input on the spectral variation of young wind waves cannot be disregarded.

Summary An array of oceanographic instruments deployed in a cross-shore transect on the Senigallia shelf offshore Misa River Mouth captured persistent (≈ 2 days), low-frequency oscillations of sea level and cross-shore velocity, following the strong Bora event of Jan, 24-25th, 2014. Meteorological data and numerical modeling suggest that the oscillations character is consistent with transversal Adriatic seiching, likely forced by a combination of Bora gustiness and convection instability. This study highlights poorly-understood aspects of air-sea interaction processes associated with Bora events.

INTRODUCTION

Due to its basin shape and topography, the Adriatic may exhibit both longitudinal and transversal seiches. Longitudinal seiches are typically associated with intense winds out of SE, large frontal systems, or with cyclonic activity ([5]). The 22-hour fundamental mode typically dominates the sea-level power spectrum (e.g., [8]), and persists for days, losing energy through basin friction and radiation at the Strait of Otranto (e.g., [2]). Transversal seiches occur on smaller scales, most likely associated transversal forcing such as Bora events. Earlier studies (e.g., [11, 9]) identify periods 8.5, 5, 3.5 and 3 hours in sea level oscillations at Trieste and Venice. They are also less energetic, and due to their local structure, less studied and less understood (details of Bora events themselves have only recently been clarified; [6]).

Here, we investigate observations of 30-min oscillations of sea level and cross-shore velocity observed during a 2-day calm period following the strong Bora event of January 25, 2014.

OBSERVATIONS

The field experiment is described in detail in [1, 7]. The array of sensors (figure 1 a-b) captured on the Jan. 25th., 2014 a strong Bora event, which generated remarkably energetic waves (10-s peak period, 3-m significant height). Following the storm, pressure and velocity records show trans-infragravity (≈ 30 min) oscillations, with periods in the range of 20 to 120 min, with amplitudes in the order of 10-20 cm/s, associated with free-surface oscillations in the order of 2-10 cm (figure 1 c-i). The oscillations were exactly in phase across the entire 1.2-km array. The spectrum of the pressure and cross-shore velocity during this period shows well-defined, distinct peaks at frequencies ≈ 0.005, 0.01, 0.02, 0.03, 0.04, 0.05 min^{-1}, consistent with transversal seiches. The cross-shore velocity has two main peaks at 25 and 33 min, while the pressure spectrum exhibits additional peaks at 50 min and 100 min, a behavior consistent with the vicinity of an antinode. We investigate the generation mechanism using "conceptual", 2D numerical tests based on FUNWAVE-TVD Boussinesq model ([10]), and full 3D simulations covering the entire Adriatic using ROMS.

DISCUSSION

Similar oscillations have been observed in the wake of a cold-front passage at the Port of Rotterdam, the Netherlands, and identified as long-waves likely generated through a Proudman resonance mechanism, associated with strong wind-speed fluctuations and convection cells produced by an unstable atmospheric stratification over the North Sea [4]).

The Adriatic oscillations discussed here have a cross-shore standing-wave structure, discrete spectrum, and periods (harmonics of the fundamental ≈ 100 min) consistent with transversal Adriatic seiches. The generation mechanism is likely a combination of stress fluctuations in the Bora wind, and possibly convection cells associated with unstable atmospheric stratification in the wake of the Bora event. Bora wind develops as parallel narrow jets that exhibit significant instability (10-min oscillations between 15 and 25 m/s; [6]), possibly associated with N-S ocean circulation cells (e.g., [3]). Meteorological data supports this hypothesis. The weather forecast for Jan 25th, 2014 issued by the ESTOFEX (European Storm Forecast Experiment), called for a level 2 alert for the Adriatic sea area. Satellite ASCAT wind (figure 1 k) shows strong wind out of NW active till late evening of 25th Jan, 2014, while radar data shows convective cells developing to a convective line during the late Jan 24th and the early Jan 25th (figure 1 l). Like longitudinal seiches, once generated, transversal seiches would be expected to slowly dissipate due to basin friction, perhaps over several days, consistent with observations.

The study highlights aspects of the relation between Bora events and transversal seiches that are not well documented and poorly understood, but relevant in relation with other air-sea interaction processes that have a significant shoreline impact, such as wave activity, meteotsunamis, and flooding induced by storm surges.

ANALOG EXPERIMENT AND 1D MODEL OF THE QUASI-BIENNIAL OSCILLATION

Benoît Semin*[1,2], François Pétrélis[2], and Stephan Fauve[2]
[1]PMMH, CNRS ESPCI Sorbonne Université, Université de Paris, 7 quai saint-Bernard, 75005 Paris, France
[2]LPENS, Ecole Normale Supérieure, CNRS, Sorbonne Université, Université de Paris, 24 rue Lhomond, 75005 Paris, France

Summary The quasi-biennial oscillation (QBO) is the nearly periodic reversal of the large scale flow generated by internal waves in the equatorial stratosphere. Using a laboratory analog experiment and a 1D model, we study the instability that generates the QBO. We report the first quantitative measurements of the nonlinearly saturated velocity of the flow. We show both experimentally and using the 1D model that the bifurcation is either supercritical or subcritical depending on the dominant dissipative process.

INTRODUCTION

The quasi-biennial oscillation (QBO) is the periodic reversal of the wind in the lower equatorial stratosphere [1]. The period of the oscillation is 28 months on average, and is not linked to the year duration. This wind is known to be generated by atmospheric waves, in particular internal gravity waves.

We have set up an experiment which reproduces this phenomenon in the laboratory and solved a related 1D model.

EXPERIMENTAL SET-UP

A schematic view of the experimental set-up is shown in figure 1a. It has been described in detail in [4], and is inspired by previous works [2, 3]. The set-up is made of two transparent concentric vertical cylinders. The gap h between these two cylinders is filled with a linearly density-stratified solution of NaCl or $MgCl_2$ in water. The stratification is characterized by the Brunt–Väisälä frequency, $N = \sqrt{(g/\rho_0)\,\mathrm{d}\rho_0/\mathrm{d}z}$, where g is the acceleration of gravity, ρ_0 is the background density and z is the vertical axis.

Internal waves inside the fluid are forced using 16 silicone membranes which are in contact with the top of the fluid and move up and down in a sinusoidal manner. Two neighboring membranes are driven by motors in opposition of phase so that the forcing is a standing wave whose azimutal wavelength $\lambda_x = 200\,\mathrm{mm}$ is twice the curvilinear distance between 2 motors. We note M the amplitude of the motion of the membranes and $T_f = 15 - 17\,\mathrm{s}$ the forcing period.

The fluid velocity is measured using particle image velocimetry (PIV). The local velocity as a function of time is fitted with a sine function. The value of the mean flow, the amplitude and the phase of the wave are obtained from this fit.

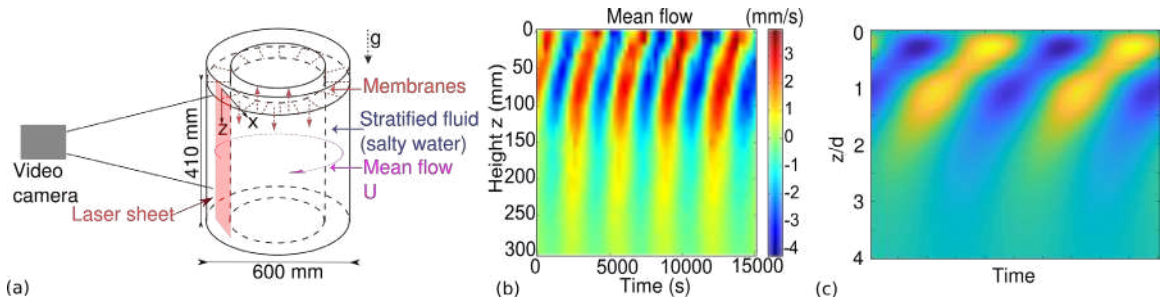

Figure 1: (a): schematic of the experimental set-up. (b): space-time diagram of the mean flow, forcing amplitude: $M = 13.5\,\mathrm{mm}$, forcing period $T_f = 17\,\mathrm{s}$, Brunt–Väisälä frequency, $N = 1.5\,\mathrm{Hz}$, observed mean flow period $T_{\mathrm{QBO}} = 3\,200\,\mathrm{s}$ (c) space-time diagram corresponding to the linearly unstable mode of the model.

MODEL

We have solved analytically the 1D model of Plumb and McEwan close to the QBO threshold. [2]. This model is an effective equation for the mean flow U, which takes into account the forcing by the waves and the dissipation of the mean flow. It is given in dimensionless form by:

$$\frac{\partial U}{\partial T} = -\frac{\partial D}{\partial \xi} + \Lambda_1 \frac{\partial^2 U}{\partial \xi^2} - \Lambda_2 U$$

where:

$$D(\xi) = \exp\left(-\int_0^\xi \frac{1}{(1-U)^4}\mathrm{d}\xi\right) - \exp\left(-\int_0^\xi \frac{1}{(1+U)^4}\mathrm{d}\xi\right)$$

*Corresponding author. E-mail: benoit.semin@espci.fr

traces back to the forcing of the mean flow by the waves. ν is the kinematic viscosity, γ is the wall friction, $F = \overline{u'\,v'}$ is the time average of the product of the vertical velocity associated to the wave (v') by the horizontal one (u'), $c = \omega/k_x$ is the horizontal phase velocity, $d = k_x c^4/(N^3\nu)$ is the vertical dissipation length, $\xi = z/d$ is the dimensionless height,u is the mean flow (which is horizontal), $U = u/c$ is the dimensionless mean flow, $\Lambda_1 = \nu c/(F(0)d)$ is the dimensionless friction corresponding to the bulk dissipation of the mean flow and $\Lambda_2 = \gamma cd/(F(0))$ the dimensionless friction corresponding to the dissipation in the boundary layer on the lateral walls. Time is made dimensionless using $cd/(F(0))$, which gives the order of magnitude of the mean flow period.

RESULTS

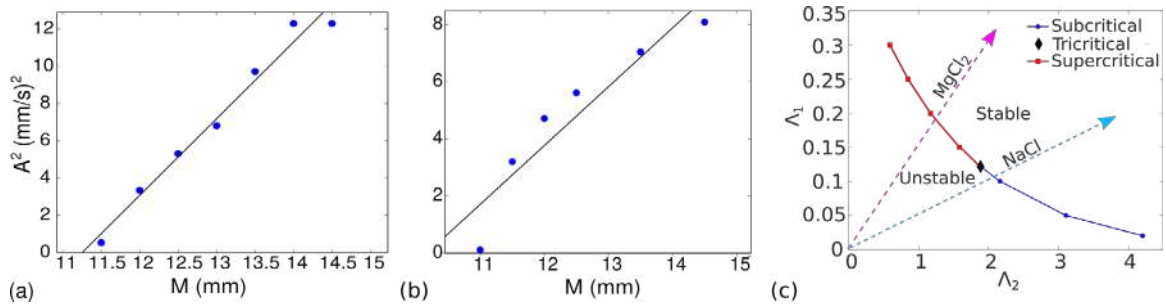

Figure 2: (a): Square of the amplitude of the mean flow as a function of the forcing amplitude M, for $N = 2.15\,\mathrm{Hz}$, i.e. with $MgCl_2$. The blue disc are the experimental measurements, the line is a linear fit (b): similar results for $N = 1.5\,\mathrm{Hz}$, i.e. with NaCl (c): stability diagram. Lines and points are theoretical results, the dashed lines indicate the possible values for the two different salts.

Below a forcing amplitude $M \sim 11\,\mathrm{mm}$, there is no mean flow generated by the waves in the experimental set-up. Above this threshold, there is a symmetry breaking and a mean flow is measured (see figure 1b). At a given height, this mean flow oscillates with a period which is much larger than the period of the waves. The observed pattern is in agreement with both the atmospheric observations [1] and the prediction of the model (figure 1c).

To investigate quantitatively the bifurcation, we decrease stepwise the amplitude of the forcing M. The amplitude of the mean flow A can then be measured for different values of M. The square of A as a function of M is displayed in figure 2a (for $MgCl_2$) and b (for NaCl). The experimental data are fitted with a linear function. The fit is good in figure 2a, indicating that the bifurcation is supercritical. This is not the case in figure 2b, showing that the bifurcation is subcritical in that case.

The effect of the salt is related to a change in the value of N, which modifies d and thus the ratio between Λ_1 and Λ_2. The 1D model predicts that the bifurcation may be supercritical or subcritical, depending on this ratio. The theoretical behavior agree well with the experimental one, without adjustable parameter (figure 2c).

CONCLUSION

We have characterized the bifurcation between a state with a mean flow and a state with no mean flow, in an experimental analog of the quasi-biennial oscillation. The measurements are in agreement with a 1D model. We found that the bifurcation is either supercritical or subcritical, depending on the dominant dissipation mechanism.

A perspective it to link this result with the atmospheric QBO, and to determine the nature of the bifurcation in general circulation models and in the atmosphere.

COASTAL WAVES IN A DEPTH-AVERAGED MODEL WITH AN ANISOTROPIC TURBULENCE AND A WEAKLY COMPRESSIBLE APPROACH

Gaël L. Richard*[1], Maria Kazakova[2], Benoit Fabrèges[3], and Arnaud Duran [3]
[1]Univ. Grenoble Alpes, INRAE, ETNA, 38000 Grenoble, France [2]Normandie Univ, INSA Rouen Normandie, LMI, 76000 Rouen, France

Summary We introduce two new approaches to model coastal waves and tsunamis. Firstly, averaging over the depth the LES equations enables to include explicitly in the model the anisotropic large-scale turbulence arising in breaking waves while the small-scale turbulence is modelled with a turbulent viscosity hypothesis. Secondly, a depth-averaged weakly compressible approach allows us to derive a fully hyperbolic model with dispersive properties, on a varying bottom. This enables to remove the time-consuming non-local step in the numerical schemes, which is due to the incompressible hypothesis, and to obtain a compressible extension to the Boussinesq-type models. The resulting depth-averaged model is used to perform efficient and accurate numerical simulations of shoaling and breaking waves in various situations. The numerical resolution shows also the decrease of the tsunami propagation speed due to compressibility.

INTRODUCTION

The Boussinesq-type models are one of the approaches for an efficient computation of waves propagation in nearshore areas. They are typically obtained by averaging over the fluid depth the equations of fluid mechanics. This procedure decreases the dimension of the system by one and incorporates the boundary equations at the bottom and at the free surface in the model equations, resulting in a reduced computational cost. The Serre-Green-Naghdi equations are a fully nonlinear variant where the waves amplitude is not supposed to be small with respect to the depth. They are more accurate than the Boussinesq equations in the final stages of coastal waves propagation. However all Boussinesq-type models are weakly dispersive because of the shallow water assumption i.e. the fluid depth is small compared to the wavelength. As a result, the deviation of the predicted linear dispersive properties to the Airy waves theory becomes significant if the depth increases. Another feature of the Boussinesq-type models is the existence of an elliptic or a non-local step in the numerical scheme of the equations. This is related to the presence of mixed space-time third-order derivatives in the equations. This step is highly time-consuming in the numerical resolution since a global system must be solved at each time step over the whole computational domain. Physically, this non-local effect is due to the incompressibility hypothesis which implies that the pressure variations propagate instantaneously at an infinite velocity. One of the goals of this work is to derive a depth-averaged model for coastal waves with a weakly compressible assumption to remove all non-local effects in order to reduce the computational time. Another goal is to obtain a compressible extension to the Boussinesq-type models to capture the reduced propagation speed of tsunamis due to compressibility [1].

To model breaking waves in the surf zone, dissipation effects must be added to the Boussinesq-type models. Some strategies have been proposed to achieve this result, in particular roller models, which involve many empirical parameters, or the switching approach, which is sensitive to mesh size and which can lead to numerical instabilities. Another approach is to model the turbulence with an eddy viscosity hypothesis. This is valid if the turbulence is not too far from isotropy and from an approximate balance between production and dissipation. Further, as for the roller and switching approaches, it is necessary to have a breaking criterion. In the case of the models with a turbulent viscosity, this criterion determines when the viscous terms are activated or deactivated. We propose to include the turbulence of breaking waves by averaging over the depth the Large-Eddy Simulation (LES) equations. The small-scale turbulence is modelled with an eddy-viscosity hypothesis but the anisotropic large-scale turbulence is explicitly resolved.

WEAKLY COMPRESSIBLE APPROACH

As for the Serre-Green-Naghdi model, the derivation uses the shallow water assumption and is fully nonlinear. The model is obtained with the assumption of a weak compressibility, using a low Mach number approximation. The pressure is divided into a hydrostatic part and a non-hydrostatic part. The variations of the depth-averaged density are due to the variations of the hydrostatic pressure caused by depth variations. An equation for the non-hydrostatic pressure is derived from the first law of thermodynamics with the assumption of a homentropic flow. A standard depth-averaging procedure gives the equations of the model for the fluid depth, the average horizontal velocity, the average vertical velocity and an average non-hydrostatic pressure. The model, even with a varying bottom, is hyperbolic. The solutions of the dispersive relation divide into a slow branch governing gravity waves and a rapid branch governing acoustic waves. The equations include the possibility of a mobile bottom, enabling the simulation of tsunamis generated by seabed vertical movements. If the compressibility is negligible, a pseudo-compressible approach using a much slower sound velocity than its physical value can be implemented. The model admits an exact conservation of energy, even on an arbitrary bathymetry. The linear dispersive properties are consistent with the linear theory of compressible fluids at the long-wave limit. The model can be extended to a hyperbolic system with improved dispersive properties.

BREAKING WAVES

To average over the depth the LES equations, the filtered horizontal velocity is decomposed as the sum of its depth-averaged value and of the deviation to this average velocity due to large-scale turbulence and shearing effects. These phenomena are taken into account in the depth-averaged equations by a symmetrical and anisotropic tensor, called enstrophy tensor, with the same dimension as the square of a vorticity. The small-scale turbulence, modelled with a turbulent-viscosity hypothesis, gives, after the depth-averaging procedure, viscous terms with the same structure as in a compressible fluid. The closure of the model is obtained by modelling the small-scale eddy viscosity and the turbulent dissipation. The breaking criterion is replaced with the virtual enstrophy concept. This quantity satisfies the same tensor equation as the physical enstrophy, except that its only influence on the system is to define the breaking threshold.

NUMERICAL SIMULATIONS

The numerical scheme is based on a splitting between a slow part treated explicitly and a fast part solved implicitly, but without any global linear system to solve. Numerical simulations are presented for a wide range of situations including coastal waves and tsunamis. The model is able to simulate with a very good accuracy the experiments of Beji & Battjes [2] with irregular waves propagating and breaking over a submerged bar (Figure 1a), or the propagation of a wave over a complex bathymetry, including a conical reef and a beach, with breaking, submersion of the island and run-up (simulation of the experiments of Swigler [3], Figure 1b). The simulations are able to calculate the delay of the arrival time of a tsunami in the far field due to compressibility (Figure 1c).

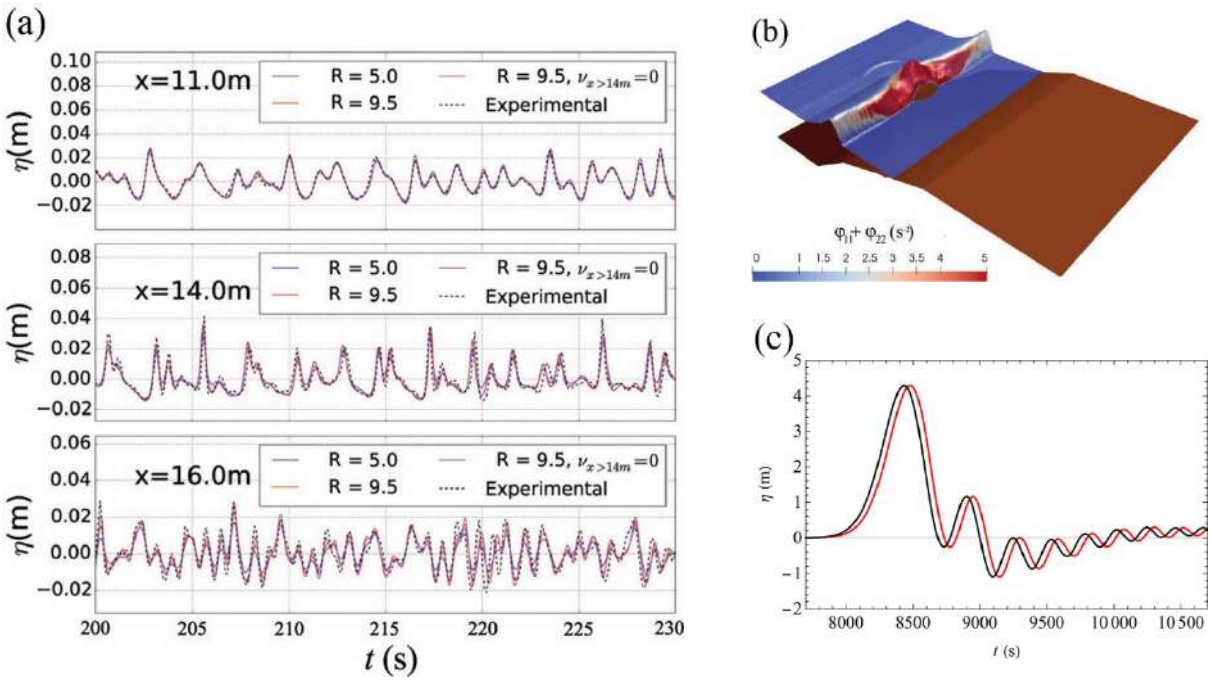

Figure 1 (a): Time evolution of the free surface before (top), above (middle) and after (bottom) a submerged bar in the case of irregular waves with comparison to the experiments of Beji & Battjes [2]. (b): A snapshot of the free surface for the simulation of the propagation of a wave on a complex bathymetry with a beach and a conical island. The red colour indicates the presence of large-scale turbulence (breaking wave). (c) Water elevation of a 1D-tsunami in the ocean after a propagation of 2000 km for the compressible case (red curve) and the incompressible case (black curve).

CONCLUSIONS

The depth-averaged LES approach enables to include explicitly the anisotropic large-scale turbulence in the model. These new approaches give efficient and accurate numerical simulations of shoaling and breaking coastal waves. The weakly compressible approach leads to a fully hyperbolic dispersive model on a varying bottom and can capture compressibility effects in a compressible Boussinesq-type model.

THE UNDULAR HYDRAULIC JUMP IN INVISCID AXISYMMETRIC FLOW

Dominik Murschenhofer*[1] and Wilhelm Schneider[1]
[1]Institute of Fluid Mechanics and Heat Transfer, TU Wien, Vienna, Austria

Summary Steady inviscid free-surface flow over a horizontal bottom is considered. The results of an asymptotic analysis for slightly supercritical upstream Froude numbers show that undular hydraulic jumps can exist if the flow is axisymmetric. Provided the origin of the jump is located at a very large radius, the free surface is described by the steady-state version of an extended Korteweg–de Vries (KdV) equation. A numerical solution of the extended KdV equation is shown in comparison with the corresponding one-dimensional flow approximation, indicating that the supercritical branch of the latter is prone to develop into an undular hydraulic jump.

INTRODUCTION AND PROBLEM DESCRIPTION

In hydraulics the transition from slightly supercritical to subcritical free-surface flow is characterized by a wavy surface known as the undular hydraulic jump. In *plane* flow, e.g. in open channels, the undular hydraulic jump is inherently associated with dissipation and cannot exist in inviscid flow [1]. In the present paper it is shown that in the case of *axisymmetric* flow the situation changes, and the governing equations of inviscid flow permit an undular hydraulic jump.

Steady inviscid axisymmetric free-surface flow over a horizontal bottom is considered. The basic equations are the continuity equation for incompressible flow and the Euler equations. Cylindrical coordinates are introduced, with r and z in radial and vertical direction, respectively. The free surface is defined by a streamline, and the ambient pressure is set to zero. The bottom is assumed to be impermeable for the liquid.

ASYMPTOTIC ANALYSIS AND HYDRAULIC APPROXIMATIONS

An asymptotic analysis of the governing equations for slightly supercritical upstream Froude numbers is performed, i.e. $(2/3)(\mathrm{Fr_r}-1)=\varepsilon\ll 1$, with the reference Froude number $\mathrm{Fr_r}:=Q/(r_\mathrm{r}\sqrt{gh_\mathrm{r}^3})$. Here Q, g and h denote, in this order, the constant discharge per unit azimuth angle, the acceleration due to gravity and the height of the free surface above the bottom. The subscript r refers to a reference state. A non-dimensional radius $R=\delta r/h_\mathrm{r}$ is introduced, with $\delta=3\varepsilon^{1/2}$ serving as a contraction parameter. The non-dimensional reference radius R_r is assumed to be very large such that R can be decomposed in $R=R_\mathrm{r}+\eta$ with $\mathrm{d}R=\mathrm{d}\eta$. In the present analysis R_r is chosen as $R_\mathrm{r}=\tilde{R}\varepsilon^{-5/2}$ with $\tilde{R}=\mathrm{const}=\mathrm{O}(1)$. The analysis for reference radii of other orders of magnitude, e.g. $\mathrm{O}(\varepsilon^{-2})$, is beyond the scope of the present paper and will be discussed elsewhere. Expanding all dependent variables in terms of powers of ε, e.g. $H(\eta)=h/h_\mathrm{r}=1+\varepsilon H_1(\eta)+\ldots$ for the non-dimensional height of the free surface, leads to a set of first-order equations that allow to express all unknowns in terms of the free-surface elevation H_1. The latter remains undetermined in the framework of the first-order equations. This requires an investigation of the second-order equations, leading to the solvability condition

$$H_1'''+H_1'(H_1-1)=\varepsilon^{1/2}/3\tilde{R}\,, \tag{1}$$

i.e. an ODE for $H_1(\eta)$. Equation (1) is a steady-state version of an extended Korteweg–de Vries (KdV) equation, with the constant term of order $\varepsilon^{1/2}$ on the right-hand side representing the extension due to axisymmetric flow. According to the present analysis, (1) can be expected to be uniformly valid.

The asymptotic analysis leads to the interesting result $U(\eta,Z)=u/u_\mathrm{r}=1+\varepsilon[c_1(Z)-H_1(\eta)]+\ldots$ for the non-dimensional radial velocity. The function of integration $c_1(Z)$ defines the velocity profile and can be chosen freely, as it does not affect the final result for H_1. If the reference velocity u_r is defined as the volumetric mean velocity, the integral of $c_1(Z)$ over the non-dimensional vertical coordinate $Z=z/h_\mathrm{r}$ has to vanish, i.e. $\int_0^1 c_1(Z)\mathrm{d}Z=0$.

For the purpose of comparison it is of interest to consider a one-dimensional flow approximation, known as the "hydraulic approximation". It is based on the equation of motion in radial direction with hydrostatic pressure distribution. Continuity is expressed as $urh=Q=\mathrm{const}$. Combining the continuity equation and the equation of motion gives

$$\frac{r}{r^*}=\frac{R}{R^*}=\frac{(2+\mathrm{Fr}^2)^{3/2}}{3\sqrt{3}\mathrm{Fr}}\,, \tag{2}$$

i.e. an implicit equation for the local Froude number, which is defined as $\mathrm{Fr}(r):=Q/(r\sqrt{gh^3})$. The asterisk refers to the critical state, where $\mathrm{Fr}=1$. Note that the relation (2) is "universal", as it is free of parameters describing the upstream state.

A near-critical version of the hydraulic approximation is obtained by expanding (2) for $|\mathrm{Fr}-1|\ll 1$. The result is

$$\mathrm{Fr}=1\pm\sqrt{3(R/R^*-1)/2}\,. \tag{3}$$

*Corresponding author. E-mail: dominik.murschenhofer@tuwien.ac.at.

Introducing the reference radius R_r instead of R^* in (3), using the relation $\mathrm{Fr}(\eta) = 1 + 3\varepsilon(1 - H_1)/2$ and expanding for $\varepsilon \ll 1$ gives

$$H_1 = 1 \mp \sqrt{1 + 2\varepsilon^{1/2}\eta/3\tilde{R}}\,. \tag{4}$$

The upper and lower signs in (3) and (4) correspond to the supercritical and subcritical branch, respectively. Both (3) and (4) are near-critical hydraulic approximations. They differ from each other due to the different reference states, i.e. $\mathrm{Fr} = 1$ at $R = R^*$ for (3) and $H_1 = 0$ at $\eta = 0$ for (4). It follows from (4) that the condition $H_1 = \mathrm{O}(1)$ for the validity of the asymptotic expansion is only satisfied if $\varepsilon^{1/2}\eta = \mathrm{O}(1)$. It may be of interest to observe that differentiating (4) with respect to η leads to an equation that is equal to (1) without the term H_1''', i.e. the extended KdV equation without the third-order term is equivalent to the near-critical hydraulic approximation.

RESULTS

In Fig. 1 a solution of the extended KdV equation (1) is shown in black. The red curve represents the solution of the hydraulic approximation, (2). In Fig. 1a) the sub- and supercritical branches of the near-critical hydraulic approximation according to (4) are shown as blue dotted and dashed lines, respectively. The initial conditions for the black curve are chosen such that initial value, initial slope and initial curvature are in accord with the *super*critical branch of (4) in the reference state, i.e. $\eta = 0$. Within a short distance from the reference radius the solution of (1) develops into a wavy solution oscillating around the *sub*critical branch of (4). Such a transition is a characteristic property of undular hydraulic jumps. In Fig. 1b) the radial coordinate is referred to the critical radius. The solution of the near-critical hydraulic approximation according to (3) is shown in green. In order to plot the solution of (1), the critical radius is determined from (2) using the parameter values of the reference state $\mathrm{Fr}_\mathrm{r} = 1.15$ and $R_\mathrm{r} = 2214$, corresponding to $\varepsilon = 0.1$ and $\tilde{R} = 0.7$. If, for instance, the discharge is chosen to be $Q = 10$ l/s, these parameters give the reference values $h_\mathrm{r} = 10.72$ mm, $r_\mathrm{r} = 2.50$ m, $u_\mathrm{r} = 0.37$ m/s, which appear reasonable for applications.

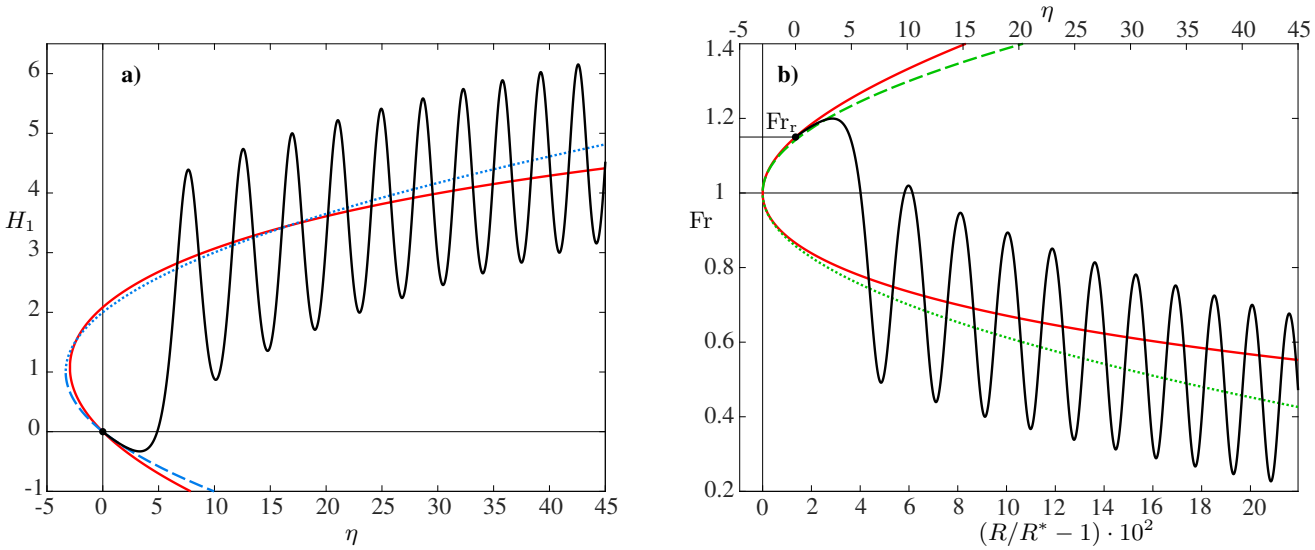

Figure 1: Results for an undular hydraulic jump in inviscid axisymmetric flow over a horizontal bottom; $\varepsilon = 0.1$, $\tilde{R} = 0.7$. a) Non-dimensional surface elevation, H_1. b) Local Froude number, Fr. Black: Numerical solution of (1) for $H_1(0) = 0$, $H_1'(0) = -0.15$, $H_1''(0) = 2.27 \cdot 10^{-2}$. Red: Full hydraulic approximation according to (2). Dotted and dashed: Sub- and supercritical branches, respectively, of the near-critical hydraulic approximation according to (3) in green, according to (4) in blue.

CONCLUSIONS

The present analysis demonstrates that – in contrast to inviscid plane flow – undular hydraulic jumps are possible in inviscid axisymmetric flow. The free-surface elevation is described by an extended steady-state version of the KdV equation. It turns out that the velocity profile can be chosen freely via a function of integration $c_1(Z)$, provided $c_1(Z) = \mathrm{O}(1)$. The velocity profile does not affect the final result for the surface elevation. The numerical solution of (1) shows that the supercritical branch of the hydraulic approximation is prone to develop into an undular hydraulic jump. The validity of the results is limited to non-dimensional distances from the reference radius up to $\eta = \mathrm{O}(\varepsilon^{-1/2})$.

ENERGY, BUBBLE AND DROPLET STATISTICS IN BREAKING OCEAN WAVES

Wouter Mostert[1], Stéphane Popinet [2], and Luc Deike [*1,3]
[1]Department of Mechanical and Aerospace Engineering, Princeton University, Princeton NJ, USA
[2]Institut Jean Le Rond d'Alembert, Sorbonne Université, Paris, France
[3]Princeton Environmental Institute, Princeton University, Princeton NJ, USA

Summary We present three-dimensional (3D) direct numerical simulation of breaking ocean waves at various Reynolds (Re) and Bond (Bo) numbers with resolved bubble and droplet size distributions and comprehensive budgets for kinetic, gravitational potential and dissipated energies. The budgets are compared with equivalent 2D simulations to determine the effect of dimensionality in the dissipation rate. At low Bo and Re, 2D and 3D energy budgets for the wave are similar, consistent with the literature. This breaks down at larger Bo with increasingly rapid transition to fully 3D flow. Bubble size distributions are well-resolved, including the Hinze scale r_H at small Bo, and we recover expected distributions of $r^{-10/3}$ for $r>r_H$ while extending somewhat to $r<r_H$. Numerical resolution of droplet size distributions remains challenging and well-resolved droplet ejection only occurs for larger Bo and Re.

BACKGROUND

Breaking ocean waves constitute a diverse and important means of mass, momentum and energy transfer between ocean and atmosphere which is incompletely understood in climate modelling [1]. First, the energy dissipation of breaking waves has been widely studied both experimentally [2] and numerically [3] for the purposes of incorporation into parameterization for regional of global scale wave modelling [4]. In particular, direct numerical simulation has been performed for two-dimensional waves based on the observation that, at small wavelengths, the measured dissipation rates correspond well to three-dimensional experimental counterparts [5]. This is explained by the delayed formation of three-dimensional structures in the breaking wave so that the most intense dissipation occurs during a time when the flow is mostly two-dimensional [5]. This hypothesis has not however been tested directly.

Second, bubble and droplet size distributions are important for understanding the mass transfer between sea and air. While experimental data exists for bubbles [6] and droplets [7], only bubbles have been resolved directly to a limited extent in a recent numerical study [3]. The Hinze scale, which sets the length scale at which bubble surface tension resists the deforming action of turbulent shear, has not been resolved and the bubble statistics below this scale remain elusive. Moreover, droplet size distributions are difficult to determine numerically because they proliferate only for large wavelengths, which are difficult to resolve satisfactorily in direct simulation, and the formation mechanisms occur at smaller length scale, probably of order tens of micrometres.

High-resolution direct numerical simulation (DNS) provides an avenue to investigate each issue. At low wavelengths, the sub-Hinze-scale bubble statistics can be more easily resolved, while at high wavelengths, both the dimensionality of energy dissipation and converged statistics for droplets can be more determined.

RESULTS

Methodology

We use the open-source package Basilisk [8] to perform DNS of the two-phase Navier-Stokes equations with surface tension and viscosity, using adaptive mesh refinement (AMR) to allow for high effective numerical resolutions of the flow field while retaining comparatively low computational costs. This allows us to resolve a wide range of length scales in the breaking wave, including the viscous sublayer and, for appropriate conditions, the Hinze scale in the bubble size distributions. The air-water interface is reconstructed and advected using a volume of fluid scheme with momentum conservation, so that bubbles and droplets are captured directly by the solver. We choose physical and numerical parameters to allow these bubbles and droplets to be fully resolved across a wide range of length scales.

We define the wave Bond number, $Bo = \Delta\rho g/(\gamma k^2)$, and wave Reynolds number, $Re = \sqrt{g\lambda^3}/\nu$, where $\Delta\rho$ is the density difference between the water and gas phases, g is gravitational acceleration, γ is surface tension, λ is the wavelength and k the wavenumber of the breaker, and ν is kinematic viscosity. Larger values of Bo and Re generally correspond with larger breaker wavelengths [9]. In this study we present breakers over a range $Bo = 200, 500, 1000$ and $Re = 40 \times 10^3, 100 \times 10^3$. The breaker is initialized by a high-slope third-order Stokes wave on a domain of a size λ, and the effective numerical cell size in the domain is set by $\Delta x = \lambda/2^L$, where $L = 9,10,11$.

Figure 1 shows a sample rendering of the evolution of the breaking wave, for the case Bo=1000, Re=100000. As the wave steepens nonlinearly, it overturns and breaks, generating a turbulent cloud underneath the surface, ingests air in the form of bubbles into the water, and ejects spray in the air.

Dimensionality of dissipation

The total dissipated energy in the domain of the breaking wave is given by the integral of the squared elements of the deformation tensor, $\dot{E} = 2\nu \int_v \sum_i \sum_j D_{ij}^2 dV$. Linearity of integration allows us to define $\dot{E}_{ij} = \int_V D_{ij}^2 dV$ without implicit summation such that $\dot{E} = 2\nu \sum_i \sum_j \dot{E}_{ij}$. In Cartesian coordinates where indices $i = 1,2,3$ correspond with

streamwise, spanwise and depthwise directions respectively, the dissipation constrained within the plane of the wave is given by the sum $\dot{E}_{in} = \sum_{i=1}^{2}\sum_{j=1}^{2} E_{ij}$, while the out-of-plane (essentially three-dimensional) contribution $\dot{E}_{out}$ is given by the sum of all other components. With these definitions we compare two-dimensional with three-dimensional simulations for the various Bo and Re tested here. By analysing the relative contributions of $\dot{E}_{in}$ and $\dot{E}_{out}$ to the total dissipation for various Re and Bo, we show that contrary to the understanding in the literature, the dissipation becomes properly three-dimensional at an early stage of the breaking process, so that numerical two-dimensional breakers cannot be effectively used to predict the real dissipation beyond the smallest wavelengths, approximately Bo<200. The transition to three-dimensional flow can be directly visualized by highlighting isosurfaces of the λ-2 criterion, featuring longitudinal filaments that form underneath the developing breaker. These filaments suggest the presence of a transverse instability which is probably mediated by surface tension and viscosity, and which constitutes an intermediate state between the initially two-dimensional flow and the terminal three-dimensional, turbulent flow.

Bubble size distributions below the Hinze scale

Figure 2 (left) shows the bubble size distributions for strong breaking waves and two Bond number. Above the Hinze scale, $r > r_H$, we recover $N(r) \sim r^{-10/3}$ in agreement with theory [10] and consistent with a previous study [3], but we emphasize in particular that the distribution also extends below the Hinze scale. Given that there is no known mechanism for bubbles to break up below the Hinze scale, it follows that the bubbles in that range can only be produced by the breakups of super-Hinze bubbles or direct entrainment of tiny bubbles at impact and can only be destroyed by rising to the water surface and bursting. The sub-Hinze distribution follows a slightly shallower power law. The super Hinze scale bubble size distribution appears independent of the Reynolds and Bond number, suggesting that only the size of the injected cavity and the strength of the wave impact control this range of bubble scale creation.

Droplet size distributions

We investigate droplet size distributions (Figure 2, right), averaged over the active breaking period, for various Bond and Reynolds numbers. Since the flow field in the air phase is not turbulent, and hence does not imply relevance to the Hinze scale, we consider the capillary length scale l_c as a relevant length scale. Depending on the Bond number, we can resolve droplets down to $0.14l_c$. We observe a sharp dependence in the total number of droplets being created as a function of Bond number, with very few droplets created at Bo=200. At higher Bond number, we observe a statistically meaningful distribution which follows two power laws, consistent with the observations of [7], although a theoretical argument to explain the approximate $N_d(r) \sim r^{-2.3}, r^{-5}$ dependences or the approximate transition at $r \sim l_c$ has not to our knowledge been developed.

To conclude, we present in this study high fidelity DNS of breaking waves at high Reynolds number, shedding light on the droplet and bubbles creation processes as well as the transition from a two-dimensional wave flow to a three-dimensional turbulent flow.

Figure 1. Snapshots of a breaking wave, Bo=1000, Re=100000.

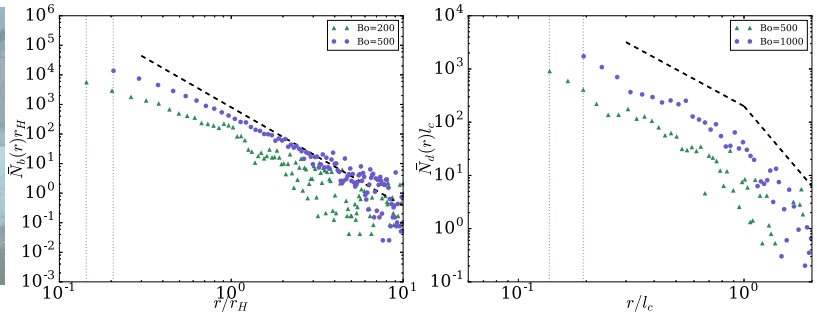

Figure 2. Bubble size distributions for Bo=200, 500; Re=40000,100000 (left) and droplet size distributions for Bo=500, 1000, Re=100000 (right) for various cases.

ON INSTABILITIES OF FINITE-AMPLITUDE INERTIA-GRAVITY WAVES

Michael V. Kurgansky*[1]
[1]A.M. Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russia

Summary The instability of monochromatic inertia-gravity waves (IGWs) of finite amplitude, propagating at small angles either to the vertical or horizontal, is studied. The corresponding angle serves as a small parameter in the problem, and instability is investigated using the Galerkin method. For IGWs that propagate at a small angle to the vertical, it is shown that stable density stratification is a stabilizing factor, and fluid rotation is destabilizing. The opposite is true for IGWs that propagate at a small angle to the horizontal. The previous analysis of the short wave instability of the internal gravity waves of finite amplitude that propagate at small angles to the vertical is generalised to the case of the IGW. As an auxiliary problem, the stability of a monochromatic inertial wave of finite amplitude in a fluid of uniform density is investigated in the same mathematical formulation.

INTRODUCTION

In geophysical fluid dynamics, the task of investigating the hydrodynamic instability of inertia-gravity waves (IGWs), which play an important role in the atmosphere and the ocean, is of interest. This is also closely related to the problem of generating and maintaining turbulence in these media. The instability of the IGW, both its wave packets and monochromatic waves of finite amplitude, has been studied repeatedly in the literature [1, 2]. The closest to the proposed study is, apparently, the work of Yau et al. [3], who, using Floquet's theory, investigated the three-dimensional instability of a monochromatic IGW of large amplitude. The proposed study is simpler in that we refuse to fully consider three-dimensionality and assume that fluid dynamic variables are independent on one of the horizontal co-ordinates, although the three velocity components remain nonzero. This 2½-dimensional formulation of the problem allows to fully utilizing the analogy between the effects of stratification and rotation and the resulting perfect mathematical symmetry of the problem. In this work, first, we set the objective of extending the previous analysis of instability of internal gravity waves [4] onto the case of monochromatic IGW of finite amplitude that propagates in the atmosphere at a small angle θ to the vertical when the buoyancy frequency N is much greater than the inertial frequency f. The second task is to use a small parameter in the problem, either θ, if an IGW propagates nearly vertically, or $\varpi = (\pi/2) - \theta$, if the IGW propagates nearly horizontally, for an asymptotic analysis of IGW instability at an arbitrary ratio of f and N. As an auxiliary problem, in the same 2½-dimensional formulation and for small angles θ and ϖ we study the stability of a monochromatic IW of finite amplitude in a fluid of uniform density.

RESULTS

We study the instability of a monochromatic IGW of finite amplitude with the phase velocity vector at an angle θ to the axis of rotation of the fluid, which coincides with the direction of acceleration of gravity, that is, with the vertical. The dependence of the fluid dynamic variables on one of the Cartesian horizontal co-ordinates is neglected and it is assumed that the three velocity components depend on two co-ordinates (x,z). In this 2½-dimensional formulation, the Boussinesq equations for a fluid heterogeneous in density and rotating at a constant angular velocity $f/2$ around the vertical axis z have the exact solution in the form of a monochromatic IGW of finite amplitude, with the frequency σ that satisfies the dispersion relation $\sigma^2 = N^2 \sin^2\theta + f^2 \cos^2\theta$. A linear stability of this exact solution is considered, the perturbation equations are taken in a non-dimensional form and transformed to the co-ordinate system, $X = x\cos\theta - z\sin\theta$, $Z = x\sin\theta + z\cos\theta - t$, co-moving with the IGW in the Z-direction.

A simpler case of an inertial wave (IW) that propagates in a neutrally stratified fluid is analysed. First, the case when an IW propagates vertically is considered. Following the Galerkin method with three basis functions, $\cos Z, \sin Z, 1$, and with the X-dependence as $\exp(\mathrm{i}\alpha X)$, a system of six differential equations with six unknowns is obtained. The wave is unstable only when $\alpha^2 < 2/\sqrt{3}$ and the instability, in the first place, develops with respect to long wave perturbations $\alpha^2 << 1$.

In IW applications to the deep ocean and the outer liquid core of the Earth, the second limiting case of $\theta \to \pi/2 -$ is of interest when the wave vector $\mathbf{k} = (k,q)$ is nearly perpendicular to the direction of fluid rotation and IWs have frequencies $\sigma << f$. Such a problem formulation is also relevant to laboratory experiments [5]. In this case, instability is of a short wave nature. In the middle of the instability interval, the increment of the growth of unstable disturbances is proportional to the square of the amplitude of the IW. A mathematically identical result is obtained, up to replacements $f \leftrightarrow N$, $k \leftrightarrow q$, for the instability of an internal gravity wave, which propagates at a small angle to the vertical [4].

*Corresponding author. E-mail: kurgansk@ifaran.ru.

We now take into account both the fluid rotation around the vertical axis and its stable density stratification and consider the problem of the hydrodynamic instability of IGWs. Specifically, we consider a case when f and N are comparable in magnitude. First, a limiting case when the IGW propagates at $\theta \ll 1$ is considered. Using the Galerkin method we obtain a system of nine equations with nine unknowns, which admits long-wave instability only if $Y < 1$, where $Y = N^2/f^2$. Density stratification is a stabilizing factor, but rotation, on the contrary, is destabilizing. For IGWs that propagate nearly horizontally, long-wave instability is possible only if $Y^{-1} < 1$, i.e., $N^2 > f^2$, and the fluid rotation is in this case a stabilizing factor, whereas the density stratification is destabilizing.

Interesting for applications to atmospheric dynamics is a case of approximate equality of the terms $N^2 \sin^2\theta$ and $f^2 \cos^2\theta$ in the dispersion relation for the IGW, when also $N^2 >> f^2$ and $\theta \ll 1$. Here, we ultimately arrive at the same characteristic equation as that for internal gravity waves. Thus, the conclusion about short-wave instability of internal gravity waves is generalized onto the range of such small θ that the effect of the Earth rotation in the IGW's dispersion relation is comparable in magnitude with the effect of atmospheric stable stratification.

To complement the analytical results a numerical stability analysis was performed at $\theta \ll 1$. We seek the solution with time dependence $\propto \exp(\lambda T)$ and use Maplesoft Maple 10 to calculate the roots of the ninth-order characteristic equation. The numerical results generally confirm the analytical prediction on the long-wave nature of instability that arises at $Y < 1$, if $Y = O(1)$. Very interesting is the appearance of a robust shortwave instability domain at $Y \ll 1$. This shows that the limit transition $Y \to 0$ should be investigated in more detail, since a pure IW that propagates vertically only exhibits long-wave instability. Therefore, we revisit the case of a pure IW, with $Y = 0$, and compare two options numerically: (i) $\theta = 0$ and (ii) $\theta = 10^{-2}, 10^{-1}$. In full compliance with the analytics, the numerical calculations reveal a long-wave nature of the instability of IWs at $\theta = 0$. However, they show at $\theta = 10^{-2}, 10^{-1}$ both long-wave and shortwave instability of IWs. It means that the limit transition $Y \to 0$ is regular, but the limit $\theta \to 0$ for the IW itself is singular, i.e. for small but finite θ-values a short-wave instability domain arises with the lower threshold wavenumber γ-value decreasing along with increase in θ in accordance with the law $\theta^{1/2}\gamma \cong const$

CONCLUSIONS

Attempts have been made to investigate, by applying simple analytical tools, the instability of monochromatic inertia-gravity waves (IGWs) of finite amplitude in two limiting cases when the IGW propagates either at a small angle θ to the vertical or at a small angle $\varpi = (\pi/2) - \theta$ to the horizontal. A particular methodically important case of instability of a pure inertial wave in a homogeneous fluid is also analysed in the same mathematical formulation.

In [4], the shortwave instability of an internal gravity wave was analysed for $\theta_0 \ll \theta \ll 1$, where $\theta_0 = \arctan(f/N)$. It is shown here that the same shortwave instability of IGWs is present for $\theta \sim \theta_0$, that is, when the Coriolis force is taken into account, if only $\theta_0 \ll 1$, as is the case in the atmosphere.

In the case of $f \sim N$ that matches with possible oceanic applications and also corresponds to conditions in intense vertical atmospheric vortices the situation changes radically. The instability of an IGW that propagates at $\theta \ll 1$ acquires a generally long wave nature. The condition $N < f$ must necessarily be met, that is, the stable density stratification is generally a stabilizing factor, and the general rotation of the fluid is destabilizing. The situation is reversed for IGWs that propagate at $\varpi \ll 1$, where inverse inequality $N > f$ must be maintained for long-wave instability.

The analytical results have been complemented with numerical calculations. In general, a fairly good agreement has been obtained with analyses. Interesting, is the appearance of short-wave instability at small θ and $N \ll f$, since a pure IW that propagates strictly vertically only experiences long wave instability. It is argued that the inclusion of an arbitrarily small turbulent viscous dissipation effectively dampens short-wave disturbances at indefinitely small but finite angles θ without noticeably affecting long-wave disturbances, which makes the limit transition $\theta \to 0$ regular.

DAMPED INTERFACIAL WAVE MECHANICS IN ORBITALLY SHAKEN CYLINDERS

Gerrit Maik Horstmann*[1], Sten Anders[1], Wietze Herreman[2], and Tom Weier[1]

Summary We present a new theoretical model describing damped gravity-capillary waves in orbitally shaken cylinders. Our model can account for both free-surface and two-layer interfacial waves and is therefore versatilely applicable to two different devices: to study interfacial wave instabilities in liquid metal batteries and to better predict mixing regimes in orbitally shaken bioreactors. We complement a potential model with viscous damping rates to incorporate energy dissipation. This approach allows us to calculate explicit formulas for the responding amplitudes and the phase shifts between wave and shaker, which are in good agreement with our experiments. As an unexpected result, the model predicts the formation of novel spiral wave patterns under the influence of strong damping. By employing a Background-Oriented Schlieren method we can experimentally verify their existence.

Introduction

The theoretical and experimental work presented in this talk originates from the growing interest in liquid metal batteries (LMB)s. LMBs are discussed today as one option for economic grid-scale energy storage, as required for the deployment of fluctuating renewable energies. These batteries incorporate stratified three-layer fluid systems consisting of two liquid metal electrodes separated by a thin molten salt electrolyte. Due to their completely liquid interior, LMBs are highly susceptible to various kinds of fluid dynamical instabilities [4]. Induced fluid flows can endanger the operational safety on the one hand, but they can also have beneficial effects such as increasing the mixing efficiency on the other hand. In particular, Lorentz force-driven interfacial wave instabilities, widely known from aluminum reduction cells (ARCs), have emerged as to be crucial for the operational safety of the batteries. They can arise from the interaction of external or self-induced magnetic fields with internal cell currents. Although such waves are destabilized by rotational Lorentz forces, parts of the evolving wave mechanics can be understood by entirely neglecting electrodynamics and applying classic irrotational wave theories. This was shown in the paper [1], where we have used a potential flow model to describe the wave coupling between the upper and lower interface. One of the most important unresolved questions in connection with these types of interface instabilities concerns the influence of mechanical dissipation. Dissipation effects are neglected in most theoretical models, as it is justified in large-scale aluminum reductions cells. But viscous damping is expected to have a strong influence on the instability onsets in lab-size LMBs. Similar as for the wave coupling mechanics, viscous damping mechanisms can be studied without considering the magnetohydrodynamic origin of the interfacial waves.

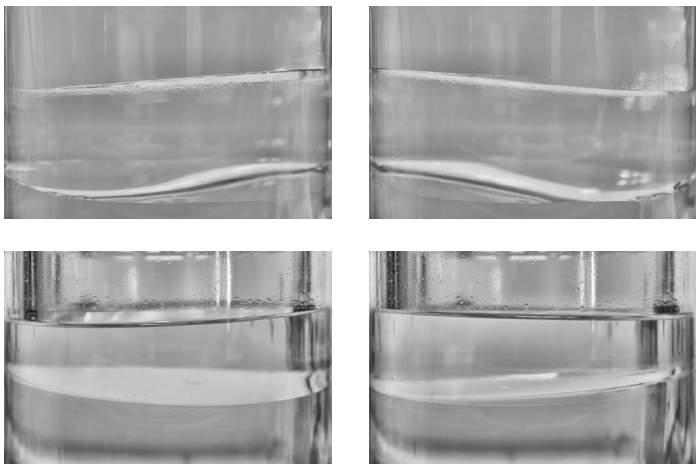

Figure 1: Symmetric (top) and antisymmetric (bottom) coupling modes shown for two different times in one period (left and right). The symmetric mode was realized by using a paraffin oil|silicon oil|water stratification, where the density differences at both interfaces are of similar magnitude. For the antisymmetric coupling we have employed an air|paraffin oil|silicon oil system, where the density differences are of different orders, see [2] for more details.

These two facts have inspired us to create a purely hydrodynamic analogy experiment, presented in [2]. The idea was to fill a cylindrical container with two or three inmiscible liquids and placing it on a shaking table prescribing circular translations. The resulting centripetal forces are known to excite approximately the same rotational gravity wave mode as it is commonly induced by magnetohydrodynamic instabilities closely beyond the linear instability onset. The experiment is therefore capable to imitate the resulting wave mechanics as they can arise due to Lorentz forces in LMBs.

*Corresponding author. E-mail: g.horstmann@hzdr.de

This is emphasized in Figure 1 showing the well-known symmetric (waves are in-phase) and antisymmetric (waves are phase-shifted by 180 °) coupling modes realized within different three-layer stratifications. The waves behave exactly as predicted in [1]: the symmetric mode is dominating when the density jumps at both interfaces are of similar magnitude, while the antisymmetric modes prevails when the density jumps are appreciably different.

Beside the coupling dynamics, we [2] have placed the main focus on measuring damped wave mechanics in two-layer systems. Since damping rates are usually very high for oil-water stratifications, measurements of exponential decay rates are difficult to achieve. Instead, it is advantageous to measure amplitude curves as a function of the shaking frequency. The peak amplitudes around the eigenfrequencies provide insights into the wave mode-dependent dissipation rates. However, we have noted that wave theories [5] for orbitally shaken cylinders entirely lack of any damping mechanism, such that the most interesting amplitudes close to resonance are not captured. Such inviscid approaches are insufficient to describe the measured highly-damped resonance curves presented in [2].

Theoretical model and experiments

Aiming to fill this gap, we have substantially extended the forced wave theory by [5]: the model is re-formulated for two-layer systems, expanded to account also for capillary forces and, most importantly, supplemented with viscous damping rates. Viscous damping rates for interfacial waves in upright circular cylinders have been recently derived by [3] using a perturbation method. The damping rates can account for dissipation arising in the Stokes boundary layers at the side wall, top and bottom walls as well as the interfacial layers above and below the interface. These damping rates provide many new insights into the nature of interfacial wave damping and fully explain the resonant wave amplitudes of the first wave mode measured in [2].

When restricting to the one-layer free-surface limit, our model can be exploited to better predict the wave dynamics in orbitally shaken bioreactors. We present explicit formulas for the phase shift between wave and shaker, which is known to considerably affect the mixing efficiency. Further, we can show that the often assumed linear scaling of the wave amplitudes with the Froude number for small excitation frequencies does not exist. The scaling only *appears* to be linear but results from different shifted resonance curves.

Finally, as an intriguing result, the model predicts the existence of linear spiral wave solutions, which arise due to a damping-induced symmetry breaking mechanism. Representative spiral wave patterns are shown in Figure 2 for the first four orbital wave modes. In contrast to the inviscid classical wave modes, the crests and troughs are connected to an one-armed spiral, which can be explained by the different mode-dependent phase shifts causing a twisting of the nodal cycles. By employing a Background-Oriented Schlieren method, we were recently able to experimentally verify the existence of these spiral wave patterns. We will present first measurements in this talk.

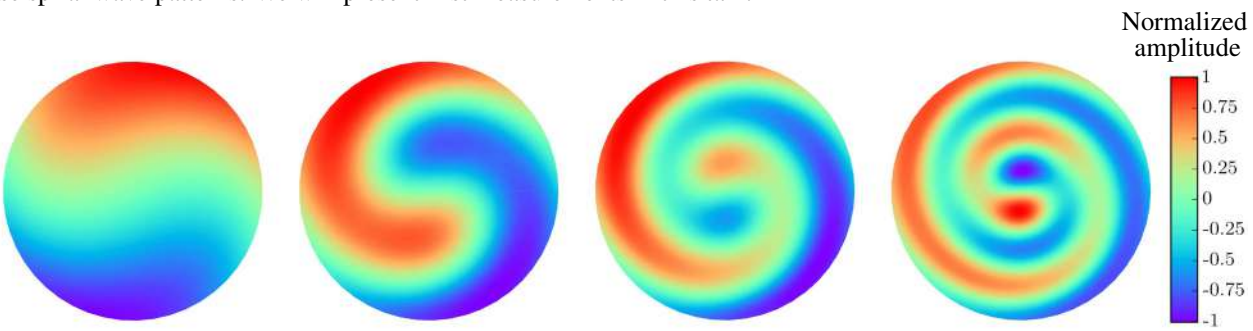

Figure 2: Normalized interface elevations of the first four orbital wave modes (compare with Figure 2 in [2]) under the influence of damping.

Conclusion

By complementing the forced wave theory by [5] with viscous damping rates, we have derived analytical formulas for wave amplitudes, phase shifts and fluid velocities of two- and one-layer gravity-capillary waves in orbitally shaken upright circular cylinders. The theory can explain the damped resonance curves presented by [2] and is helpful to get some new insights into interfacial wave dynamics in liquid metal batteries or to better predict mixing regimes in orbitally shaken bioreactors. As an surprising result, the model predicts the formation of novel spiral wave patterns we experimentally verify using a Background-Oriented Schlieren method.

RAPID TSUNAMI FORECASTS UTILISING THE EXTENDED GREEN'S LAW

Daniel Giles*[1], Audrey Gailler[2], and Frédéric Dias[1]
[1]School of Mathematics and Statistics, University College Dublin, Dublin, Ireland
[2]CEA, DAM, DIF, F-91297 Arpajon, France

Summary Tsunamis are rare but extremely destructive events. Owing to their speed of propagation, accurate and timely warnings are imperative in the mitigation of their damage. Tsunami Warning Centres are tasked with deciding the level of threat posed by an event and the areas at risk. These decisions are often based on regional forecasts of the maximum wave heights. Unfortunately, due to runtime constraints, high resolution localised forecasts are usually unfeasible. Transfer functions which generate localised wave heights from the regional forecasts by incorporating a site's response to an incoming tsunami have been developed. These functions are extensions of the classical Green's Law, which describes the evolution of long waves over varying bathymetry. The extended Green's Laws are shown here to be powerful tools which can provide extremely rapid and accurate localised tsunami forecasts.

INTRODUCTION

Tsunamis can travel at extremely high speeds in deep water, thus arrival times at the coastline are often on the $\mathcal{O}$(mins). Tsunami Warning Centres (TWC) are therefore under severe time constraints when deciding the level of warning and areas at risk from an event. To aid in this decision process, TWCs currently deploy a variety of tools which produce regional levels of warnings. One such tool is launching a faster than real time simulation (Fig 1). In order for these simulations to be completed in the required timeframe a coarse grid resolution must be used.

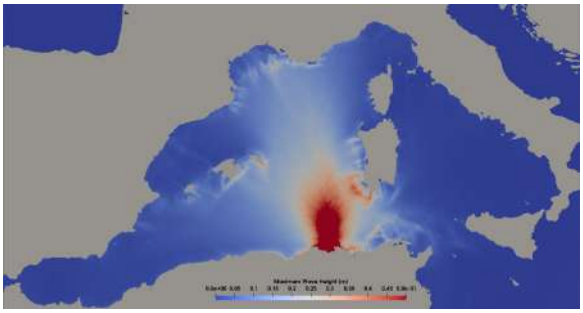

Figure 1: Faster than real time simulation of a tsunami event in the Mediterranean. Figure shows a regional maximum tsunami wave height forecast. Results obtained using Volna-OP2 [1] (4 hours of simulated time in 13s runtime on 2 GPUs)

The local bathymetry can have a large effect on the amplification or diminishment of an incoming wave. Thus, providing localised forecasts at strategic locations would help in the mitigation of damage. However, traditional high resolution simulations which can capture these localised effects are too costly to run from a TWCs perspective. Dealing with the run-up and amplification of long waves on beaches, shelves and shorelines has been extensively dealt with in the literature. However, these works mainly deal with the analytical solution of prescribed wave forms or experimentally derived relationships [2, 3, 4]. Green's Law (Eq. 1) is a classical result in this area of shallow ocean waves propagating over varying bathymetry.

$$\eta_2 = \eta_1 \left(\frac{h_1}{h_2}\right)^{\frac{1}{4}} \tag{1}$$

where η_2 and η_1 are the wave heights at a shallower and deeper point respectively, while h_2 and h_1 are the corresponding water depths at these points. The theory, however, neglects various physical phenomena, such as reflection and refraction which play an extremely important role in the amplification of shallow water waves. Recently, extended versions of Green's Law have been developed [5, 6], which aim to account for the localised effects on the tsunami amplification. These extended versions of Green's Law can capture local variability in tsunami wave height and allow for extremely rapid localised forecasts. Here is an extended version of Green's Law [5],

$$\eta_2 = \alpha\eta_1 \left(\frac{h_1}{h_2}\right)^{\frac{1}{4}} \tag{2}$$

where η_2, η_1, h_2 and h_1 are the same as above (Eq. 1), and α is defined as the local amplification factor. An empirically derived extended version of Green's Law [6] is given by,

$$\eta_2 = \eta_1 \left(1 + \beta\frac{h_E - h_2}{h_2}\right)\left(\frac{h_1}{h_2}\right)^{\frac{1}{4}} \tag{3}$$

*Corresponding author. E-mail: daniel.giles@ucdconnect.ie.

where again η_2, η_1, h_2 and h_1 are the same as above (Eq. 1) with h_E defined as a threshold depth and β is a local amplification factor.

Both versions of the Extended Green's Law incorporate site specific amplification parameters, defined as α and β in (Eq. 2) and (Eq. 3) respectively. The (Eq. 3) extension has been used to forecast maximum tsunami wave heights along the French Polynesia [7] and Mediterranean coastlines [8]. In these works a homogeneous site specific parameter was obtained for a whole site (harbour/bay area) via a 'trial and error' approach. A fully automated method which optimises for a heterogenous amplification parameter (i.e highlights variability within a site) has been developed here. A comparison between the two different formulations of the Extended Green's Law and between the two methods of calculating the site specific parameters has been made. Further, as these site specific parameters play a vital role in the accuracies of the localised forecasts, a robustness study of the values has also been carried out. The results below simply highlight the benefits of utilising the Extended Green's Law approach.

RESULTS

The high resolution sites studied here are located along the French mediterranean coastline. However, due to the lack of tsunami data for the Mediterranean area a collection of scaled historical events and hypothetical scenarios are simulated to capture a site's response to an incoming tsunami. The amplification parameters have been calculated within both formulations of the extended Green's Law (Eq. 2 and Eq. 3) using a fully automative method which optimises for the parameter via a gradient descent approach. A localised forecast is then compared to a computational expensive high resolution simulation (*ground truth*) of the same event. The localised forecasts can be run on a laptop for 5/6 sites within $\approx 30s$ and obtain a relative error of $\approx 10\%$ when compared to the *ground truth* (Fig 2). These results show the utility of this approach for providing extremely rapid localised forecasts.

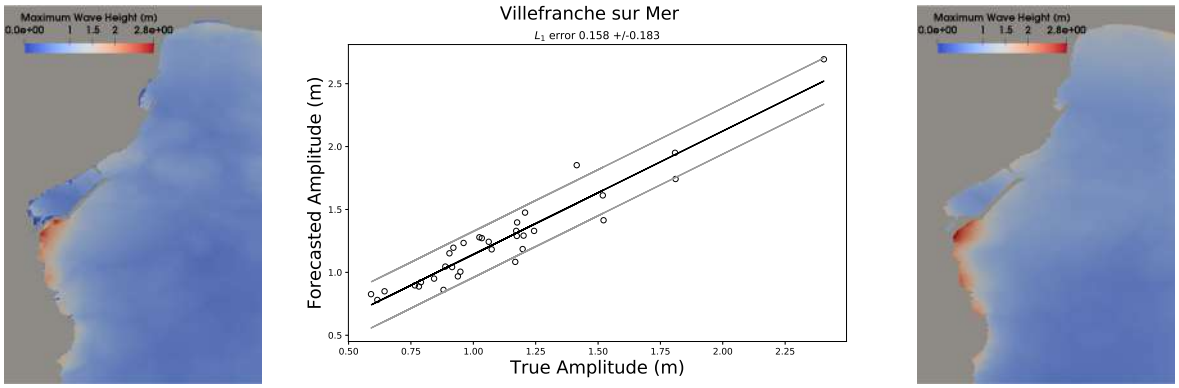

Figure 2: Comparison between the forecasted and true maximum wave heights along the Villefranche sur Mer coastline. Only results obtained with the Eq. 3 formulation of the Extended Green's Law are shown here. Left - Plot of the *ground truth* maximum wave heights. Middle - Comparison of the maximum wave heights at gauge points along the coastline. Right - Plot of the forecasted maximum wave heights. Please note that the forecast method doesn't predict wave heights on land, this explains some of the discrepancies between the left and right plots.

CONCLUSIONS

In the context of a TWC, providing localised maximum wave heights would help mitigate the risks of a tsunami event. One could provide localised forecasts for beaches, harbours or other strategic infrastructure located on the coast. The extended Green's Law approach has been shown to be a powerful tool in this context. The approach is extremely quick and provides an adequate level of accuracy. The various formulations and methods have been compared and a robustness study of the site specific amplification parameters has been carried out.

ASYMPTOTIC STRUCTURE OF ACOUSTIC WAVE SCATTERING BY FINITE-SCALE CYLINDRICAL VORTEX

Dmitry Gadzhiev*[1,2] and Alexander Gaifullin[1,2]
[1]Department of Aeromechanics and Flight Engineering, Moscow Institute of Physics and Technology, Dolgoprudny, Russia
[2]Central Aerohydrodynamic Institute, Zhukovsky, Russia

Summary The asymptotic solution to the two-dimensional problem of a plane sound wave scattering by an axisymmetric vortex with zero circulation at infinity is obtained for the case when the vortex effective radius L is much greater than the wavelength $2\pi/k$. The two well-known solutions for the non-zero circulation case [1] and [2], [3], [4], qualitatively different from each other, are included as separate limiting cases. There is a profound analogy between the patterns observed in the scattering problem and in problems of short-wavelength diffraction. The issue of sound scattering at small angles is resolved: the peak order of the scattered wave intensity is maintained within the elongated "wake" behind the vortex. The longitudinal size of the wake is the Fraunhofer distance kL^2.

OVERVIEW

Scattering of a plane monochromatic acoustic wave by a cylindrical vortex with a given distribution of circulation is a well-known problem in fluid mechanics and aeroacoustics studied since 1950s. In a two-dimensional scattering problem the scattered wave, a time-periodic addition to the superposition of the vortex and the incident wave, is expected to be an outgoing cylindrical wave with the amplitude fading as $1/\sqrt{r}$ at infinity. The common statement assumes that the vortex has non-zero circulation at infinity like the rectilinear point/Rankine/Lamb-Oseen vortex. There are two known solutions qualitatively different from each other. The first is singular on the line behind the vortex center [1]. The second is regular but maintains a non-decreasing amplitude at arbitrarily large distances [2], [3], [4], [5]; this seems to be confirmed by numerical solutions [6]; note that there is a prominent quantum mechanical problem illustrating the Aharonov-Bohm effect where the solution has the similar form [7]. The peculiar behaviour at small angles is related to the fact that sound interaction with the irrotational vortex is nonlocal because the vortex velocity field is decreasing at infinity slowly. As a consequence, the problem is ill-posed: there is no far field where the outgoing wave boundary condition can be imposed. This is naturally connected to infinitely large kinetic energy of the irrotational vortex, which can not exist in an unbounded fluid.

For a regularization, instead of the irrotational vortex with the constant circulation $\Gamma = \Gamma_*$ we take the vortex with the circulation distribution $\Gamma(r) = \Gamma_* (r/\delta)^2$ at $r \leq \delta$ and $\Gamma(r) = \Gamma_* e^{-\varepsilon^2 r^2}$ at $r > \delta$, which can be generated by the infinitely elongated hollow circular cylinder of radius δ rotating in a viscous fluid for a long time $1/(4\nu\varepsilon^2)$, where ν is kinematic viscosity. The similar idea appeared in [8]. We call such flow the *quasi-irrotational vortex*, as it is approximately irrotational when $\delta << r << \varepsilon^{-1}$ and exponentially weak at infinity (figure 1). This allows to model the problem of sound scattering by the irrotational vortex as the limiting case $\delta \to 0$, $\varepsilon \to 0$ of the well-posed boundary-value problem for the quasi-irrotational case.

SOLUTION

The flow obeys the two-dimensional Euler equations, the initial condition being the steady field of the quasi-irrotational vortex and the boundary condition at infinity being the field of the plane acoustic wave. We move to dimensional variables $k\vec{r} \to \vec{r}$, $\omega t \to t$, $\rho \to \rho_\infty \rho$, $\vec{v} \to c_\infty \vec{v}$, $p \to p_\infty p$. where $\vec{r}$ is the position vector, t is time, $\vec{k}$ and ω are the incident wave wavevector and frequency, ρ, $\vec{v}$, p are density, velocity and pressure, ρ_∞, c_∞, p_∞ are density, sound speed and pressure of the unperturbed fluid. We consider the vortex and the incident wave as independent perturbations of the

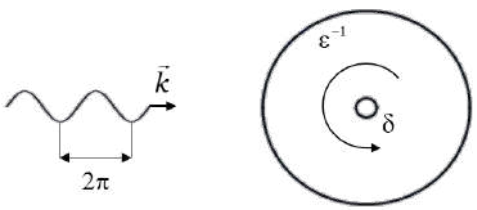

Figure 1: The problem statement in dimensionless variables. The wavelength is much smaller than the vortex outer scale and much larger than the inner one.

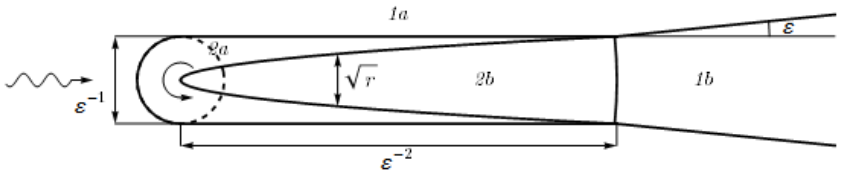

Figure 2: The asymptotic structure of the solution in the case $\varepsilon << 1$. The domain *1* is the far field where $|\rho_{11}| << 1$, with $|\rho_{11}| \sim 1/\sqrt{r}$ in the subdomain *1a* and $|\rho_{11}| \sim \varepsilon^{-1}/\sqrt{r}$ in the subdomain *1b*. The domain *2* is the near field where $|\rho_{11}| = O(1)$, with the sound intensity change much less than $O(1)$ in the subdomain *2a* and $O(1)$ in the subdomain *2b*. Inside the dashed circle, the solution is reduced to one obtained in [2], [3], [4], [5] for the case $\varepsilon = 0$.

homogeneous fluid, with the respective Mach numbers $M_0 = \Gamma_* k/2\pi c_\infty$ and M' assumed to be small. The solution for density perturbations is represented as

$$\rho = \sum_{i=0}^{\infty}\sum_{j=0}^{\infty} M_0^i (M' \mathrm{e}^{-\mathrm{i}t})^j \rho_{ij}(\vec{r};\varepsilon,\delta). \tag{1}$$

The scattered wave is a product of the wave-vortex interaction described in the main approximation by the term of the order $O(M_0 M')$, being much weaker than the vortex and the incident wave superposition. The solution satisfies the equation

$$\Delta\rho_{11} + \rho_{11} = -2i(\vec{k}\cdot\nabla)\left(\frac{(\vec{e}_z,\vec{r},\vec{k})}{r^2} e^{-\varepsilon^2 r^2} e^{i(\vec{k}\cdot\vec{r})}\right) \tag{2}$$

and the outgoing wave boundary condition at infinity, where $\vec{e}_z$ is the unit vector along the vortex axis. The solution for the case $\varepsilon > 0$ is unique and can be represented as convolution of the right-hand side of (2) with the Green's function $-\frac{i}{4}H_0^{(1)}(r)$ or using the Fourier transform method developed in [3], [4].

In the case $\varepsilon << 1$, the asymptotic structure of the scattered wave is profoundly analogous to the structure observed in the problem of the plane wave diffraction by a slit of the width ε^{-1} (figure 2). In the far field *1*, the solution is the outgoing cylindrical wave

$$\rho_{11} = \sqrt{\frac{\pi}{2r}} e^{ir - i\pi/4} \cos\theta \cot\frac{\theta}{2}\left(1 - e^{-\theta^2/4\varepsilon^2}\right), \tag{3}$$

peaking within the region *1b* with the order $\varepsilon^{-1}/\sqrt{r}$. In the near field *2*, the solution is the sophisticated wave with the amplitude $|\rho_{11}|$ maintaining the order $O(1)$. The near field includes the vortex region $r \sim \varepsilon^{-1}$ and the "wake" behind the vortex whose length is $O(\varepsilon^{-2})$. It can be divided into the parabolic zone $\theta \sim 1/\sqrt{r}$, where the maximum change of the sound intensity is reached; and the remaining zone *2a*, where the sound intensity change is small and only the phase shift is significant. At small scattering angles, the far field $r >> \varepsilon^{-2}$ corresponds to the Fraunhofer region while the near field $r \sim \varepsilon^{-2}$ to the Fresnel region. The detection of the characteristic scale extended far beyond the vortex is crucial for numerical/experimental modelling of the considered problem, as it imposes the lower limit on the computational/measurement domain size.

The solution for the formal limit $\varepsilon = 0$ confirms the fairness of the solution [2], [3], [4], [5] with reference to the irrotational vortex case: within the domain $r << \varepsilon^{-1}$ where the quasi-irrotational vortex is close to the irrotational one, the order of the scattering wave amplitude is constant. The singular solution [1] is equivalent to the far-field solution (3) at large angles; however, the far field is absent in the case of the irrotational vortex.

DAMPING OF SLOSHING WAVES BY CONTACT ANGLE HYSTERESIS

Benjamin Dollet*[1], Elise Lorenceau[1], and François Gallaire[2]
[1]Laboratoire Interdisciplinaire de Physique, CNRS and Université Grenoble Alpes, Grenoble, France
[2]Laboratory of Fluid Mechanics and Instabilities, EPFL, Lausanne,Switzerland

Summary The influence of wetting conditions on the damping of sloshing remains elusive, although it is been long shown to have a significant effect. We conducted controlled experiments on the simplest sloshing configuration, studying the oscillations of a liquid column in U-shaped tubes with different surface treatments. We show that the effect of wetting conditions is dramatic, and we propose a simple predictive model with contact angle hysteresis as the key ingredient explaining the additional friction at the contact line.

INTRODUCTION AND CONTEXT

Sloshing describes the oscillations of liquids in reservoirs [1, 2]. It is often detrimental and can lead e.g. to liquid spilling, or to destabilisation of spacecrafts, especially in its large-amplitude, nonlinear regimes. Therefore, understanding and optimising its damping is of primary importance for many spatial and terrestrial applications.
Existing theories of sloshing include viscous effects in the liquid bulk and along liquid/solid boundaries. However, already early studies have revealed that dissipation predicted as such underestimates experimental measurements of damping [3, 4], which also indicate a dependence on the solid material of the reservoir walls. Although this mismatch between theory and experiments has been qualitatively ascribed to interfacial effects such as contact line pinning, no satisfactory quantitative prediction of such effects is yet available.
We propose to bridge this gap, by leading controlled experiments of freely decaying liquid oscillations in the simple configuration of a U-shaped tube with controlled surface properties, and by proposing a model including contact angle hysteresis as the key ingredient for contact line friction.

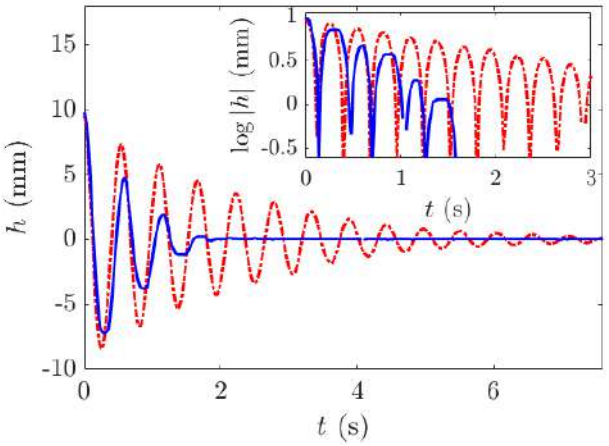

Figure 1: Plot of the height difference of one interface in a U-shaped tube with respect to its equilibrium height, as a function of time, for water in a hydrophobic tube (plain blue curve) and in a hydrophilic tube (dashed red curve). The length of the liquid column in the tube equals l = 10.6 cm. Inset: same data in semi-log. The dotted red line is a guide for the eyes.

EXPERIMENTS

We studied the freely decaying oscillations of liquids in two U-shaped glass tubes, one which was rendered hydrophobic with a silanisation surface treatment, and one hydrophilic with a plasma treatment. We focused on two simple liquids: water and ethanol; we mention results only for water in this abstract. The two surface treatments induced very distinct wetting conditions. In the hydrophobic tube, water displays a large contact angle and a strong hysteresis between an advancing contact angle (θ_a = 93°) and a receding one (θ_r = 68°), the contact line being pinned in between these two angles [5]. In contrast, on the hydrophilic tube, perfect wetting was almost achieved.
The effect of wetting conditions on the damping of oscillations of these two liquids is striking: for water, the oscillations are much more quickly damped for water than for ethanol (Fig. 1). Moreover, the dynamics of damping is quite different: while the oscillations are exponentially damped in the hydrophilic tube, they decay faster in the hydrophobic tube, with a finite-time arrest, in marked contrast with the classical description of oscillations damped by viscous effects.
We studied the influence of the length l of the liquid column and of the initial amplitude h_0 (i.e. the initial height difference between the liquid/gas interfaces within the two arms of the tube) on the oscillations. This revealed another qualitative difference between the two surface treatments. For the hydrophilic tube, at given liquid column length, the

*Corresponding author. E-mail: benjamin.dollet@univ-grenoble-alpes.fr.

oscillations collapsed on a master curve once rescaled by the initial amplitude, as expected for linear damping. This was not the case for the hydrophobic tube, where larger damping was measured as the initial amplitude was decreased.
All these results suggested a nonlinear damping mechanism associated to contact line sliding, which we modelled as follows.

MODELLING AND COMPARISON WITH EXPERIMENTS

Since we observed that the contact line remains horizontal at all times, we proposed a simple dynamical model with a single degree of freedom: the difference h between the current height of one of the two contact lines and its equilibrium height. We included as physical effects: (i) the inertia of the liquid, (ii) gravity as the restoring force, (iii) a viscous term scaling linearly with the velocity $\dot{h}$, and (iv) contact line friction. The latter was modelled by projecting the forces acting at the contact line along the direction of motion, which naturally yields the contact angle hysteresis as a friction coefficient, with the same functional form as solid friction. These ingredients yield the following ODE for the dynamics of motion of the contact line, in dimensionless form:

$$\frac{d^2\bar{h}}{d\bar{t}^2} + \bar{h} = -\alpha\frac{d\bar{h}}{d\bar{t}} - \mu \times \text{sign}\left(\frac{d\bar{h}}{d\bar{t}}\right),$$

with $\bar{h} = h/h_0$ the height rescaled by the initial amplitude, $\bar{t} = \omega_0 t$ the time rescaled by the eigenfrequency $\omega_0 = \sqrt{2g/l}$ (with g = 9.8 m/s² the gravity acceleration), and two dimensionless dissipation parameters: α accounting for viscous dissipation, and $\mu = \gamma(\cos\theta_r - \cos\theta_a)/(\rho g a h_0)$ accounting for contact line friction (with γ the surface tension, ρ the density and a = 8.15 mm the tube radius).
The model was solved analytically by the multiple-scale method. The corresponding solution captured all qualitative trends found in experiments, notably the finite time of arrest of the oscillations, and the influence of the initial amplitude.
To go beyond this qualitative agreement, we fitted all our experiments by fixing the aforementioned prediction of the friction coefficient μ with the measured value of the contact angle hysteresis, and by treating the viscous prefactor α as a fitting parameter. We found a quantitative agreement with our experiments, confirming the relevance of our modelling.
However, the viscous parameter was found to be quite large. Complementary experiments revealed that its value was about 50% larger in the first phase of the experiments, where the contact line slides, than in a second phase where the contact line gets pinned while the interface is still oscillating and relaxes slowly. This suggests that dynamical contact angle effects should be accounted for. However, using the classical Cox-Voinov law quantifying this effect [6] did not fully explain the large difference of viscous damping between the sliding phase and the pinned phase. We discuss possible reasons for this discrepancy, which has been previously remarked in other studies on drop motion.

CONCLUSIONS AND OUTLOOK

We have confirmed that surface properties can drastically increase the damping of liquid oscillations, and shown that the key parameter to quantify this increase is the contact angle hysteresis.
This study was led in the simple configuration of a U-shaped tube, where the liquid oscillation can be described by a single degree of freedom, namely the height difference between the liquid/gas interfaces within the two arms of the tube.
An obvious perspective is the extension to reservoirs, for which we will present preliminary experiments. These show that not only do wetting conditions influence the total damping, but they also modify the very shape of the sloshing modes.
The eventual goal of this study is to provide an operational prediction of the extra dissipation present at the interfaces, which could be used for sloshing applications in aerospace and mechanical engineering; the main theoretical challenge is to extend our simple approach based on a single degree of freedom to the infinity of sloshing modes associated to a given tank shape.

DEFORMATIONS OF AN AIR-WATER FREE SURFACE BY HYDRODYNAMIC TURBULENCE.

Timothée Jamin[1,2], Eric Falcon[1], and Michael Berhanu*[1]
[1]MSC, CNRS, Université Paris Diderot, Université de Paris, France
[2]Univ Lyon, ENS de Lyon, Univ Claude Bernard, CNRS, Laboratoire de Physique, F-69342 Lyon, France

Summary The interaction between a turbulent flow and a deformable interface constitutes a difficult fundamental problem, which is seldom addressed. The free surface modifies the structure of the turbulence and the turbulent flow deforms in turn the free surface increasing its roughness. This situation typically occurs at the surface of rivers. Here, we investigate experimentally the deformation of an air-water free surface in response to a subsurface turbulent flow. Using randomly actuated jets, a turbulent flow with a small mean flow is produced in the water phase. The corresponding three-dimensional deformation of the free surface is measured by Fourier Transform Profilometry. The free-surface dynamics is interpreted as the combination of a passive response to the turbulence and of the propagation of excited waves.

Turbulence is ubiquitous in most of environmental flows of water like the sea currents, the rivers or the streams. We note in these examples the presence of a top free surface at the interface between the liquid and the atmosphere. The behavior of this deformable and renewable interface constitutes a very complex problem especially in presence of turbulence in the liquid phase. The free surface modifies the structure of the turbulence below and the turbulent flow deforms in turn the free surface and increases its roughness. Brocchini and Peregrine proposed a qualitative description of the turbulent dynamics of a free surface [1]. Its deformation results from the respective contributions of the pressure field, of the viscous stresses associated to the vorticity and of the propagation of surface waves, which corresponds to the natural response of the interface to perturbations. The roughness created by the turbulence in flow has tremendous consequences for the gas, heat and mass exchanges between the atmosphere and the water body. Facing the complexity of the dynamics of a turbulent free surface, a first step consists in understanding fundamentally the behavior of hydrodynamics turbulence at the vicinity of a free surface. To better distinguish the effect of the hydrodynamics turbulence on a free surface from the advection of perturbations by the mean current, we focus our study to the case of hydrodynamics turbulence dominated by the velocity fluctuations.

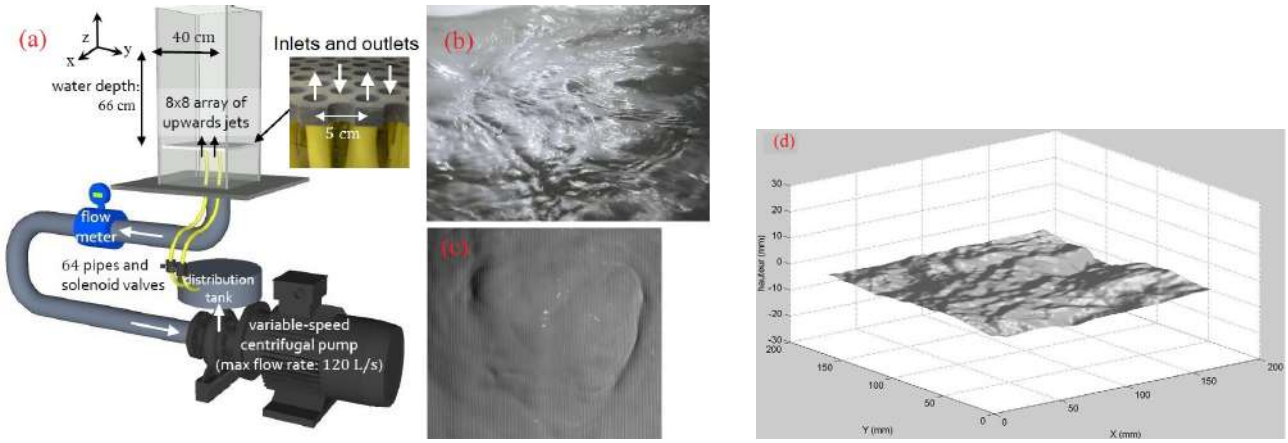

Figure 1: (a) Schematic of the experimental setup. (b) Photography of the free surface agitated by the turbulence. (c) Fringes projection in order to use the Fourier Transform Profilometry method. (d) Example of reconstruction of the deformed surface with this method.

Randomly actuated jets [2] is a convenient method to generate homogeneous and isotropic turbulence more efficiently than with oscillating grids. Our experimental setup [3, 4], consists in a tank of lateral dimensions 40×40 cm filled to a water depth of 66 cm (Fig. 1 (a)). The turbulent flow is produced by an array of 8×8 jets randomly actuated at the bottom and connected to a large pump with a controlled flow-rate. The intensity of the turbulence $\mathcal{U}_{rms}$ varies typically from 1 to 10 cm s^{-1} corresponding to a turbulent Reynolds number between 500 and 5000 and to an integral length L of order 5 cm. Using PIV measurements, we find the phenomenology of isotropic homogeneous turbulence in the bulk [4]. In contrast, the turbulence becomes anisotropic when approaching the free surface on a depth of order the integral length. Here, we investigate the deformations of the free surface $\eta(x, y, t)$ generated by the turbulence below. We observe a complex free surface dynamics (Fig. 1 (b)), with intermittent bumps of few centimeters similar to the "splats" described in the numerical simulations of Guo and Shen [5] accompanied with propagation of free surface waves and ripples. To measure $\eta(x, y, t)$, we use the Fourier Transform Profilometry method [6]. After adding a white pigment in the water, a fringe pattern is projected on the surface and imaged with a fast camera (Phantom V10) located above (Fig. 1 (c)). From the deformation of the fringe pattern, the free-surface dynamics is reconstructed with a good accuracy Fig. 1 (d).

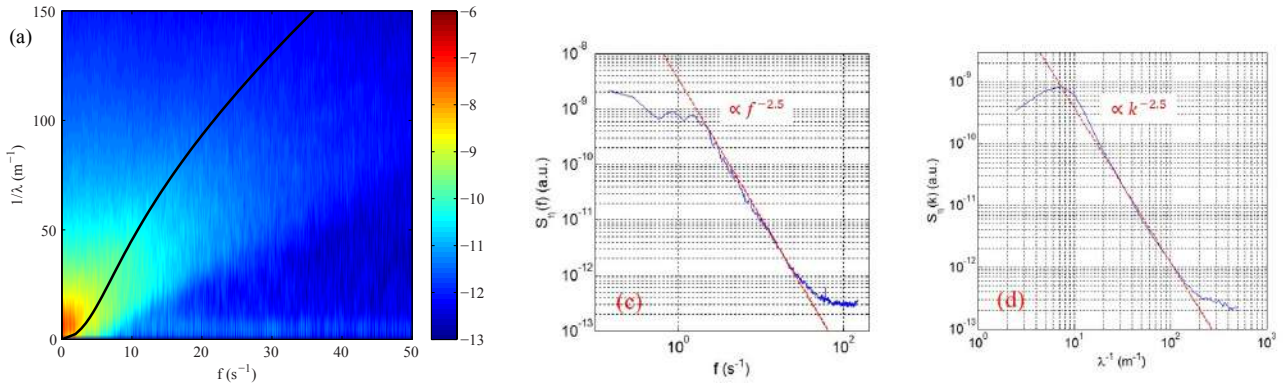

Figure 2: (a) Angular averaged, space-time spectrum of free surface deformation $S_\eta(f, 1/\lambda = k/(2\pi))$ for $\mathcal{U}_{rms} = 6.6$ cm/s. Colorscale log_{10} (arbitrary units). Black line, linear dispersion of surface waves. (b-c) Respectively, time and space spectrum S_η of free-surface fluctuations for $\mathcal{U}_{rms} = 10.5$ cm/s.

The root mean square amplitude of free-surface fluctuations σ_η increases nearly linearly with the turbulence intensity $\mathcal{U}_{rms}$, to reach about 2 mm for $\mathcal{U}_{rms} \approx 10$ cm s^{-1}, corresponding to a steepness $\langle|\nabla\eta|\rangle \approx 0.1$ and Froude number $Fr = \mathcal{U}_{rms}/\sqrt{2\,g\,L} \approx 0.1$. According to the qualitative analysis of free-surface deformations in presence of turbulence by Brocchini and Peregrine [1] and taking the integral length as the typical size of free-surface deformations, these measurements belong to the "wavy" domain, for which the interface is strongly distorted but does not break.

The free-surface dynamics is analyzed in the Fourier space by computing the spatio-temporal power spectrum $S_\eta(k_x, k_y, \omega)$. The angular averaged spectrum displays in Fig. 2 (a) more intensity at large scale and low frequency in a region not precisely defined but compatible with an advection cone of free-surface structures by the randomly fluctuating turbulent velocity field. However, for $S_\eta(k_x, k_y, \omega)$ plotted for a specific axis (not shown), we observe in addition presence of branches which are interpreted as dispersion relations of free-surface waves. Nevertheless, due to the Doppler effect these dispersion relations are broadened by the random advection of the flow and can be shifted if the surface mean flow is non exactly zero in the window of measurement. Due to their random advection, disentangling the waves from the deformation induced by turbulent pressure fluctuations constitutes a difficult task. Moreover, for sufficient turbulent intensity, time and space power spectra $S_\eta(f)$ and $S_\eta(k)$ both exhibit a well defined power law with a same exponent -2.5 in Fig. 2 (b-c), which argues that time dynamics result mainly from the turbulent sweeping of spatial fluctuations. Theoretically, the spectrum of pressure fluctuations for homogeneous isotropic turbulence follows in the inertial range a power law in $k^{-7/3} \approx k^{-2.33}$. The action of the turbulent pressure on the free surface may thus explain its dynamics. Following this idea and inspired by the recent work of Perrard et al.[7], we propose a simple model in Fourier space computing the linear response of the free surface submitted to turbulent fluctuations. The natural response of the free surface corresponds to the propagation of surface waves. However, in presence of sufficient wave dissipation due to viscosity and also here to the loss of correlation by the random advection, the free surface can show a significant response outside the wave linear dispersion relation. In these conditions, the model provides the correct order of magnitude of σ_η and predicts the linear relation with $\mathcal{U}_{rms}$. Using the hypothesis of random sweeping, the qualitative shape of the spectrum $S_\eta(k, f)$ shown in Fig. 2 (a) is recovered. Theoretical spectra $S_\eta(k)$ and $S_\eta(f)$ display also by construction power laws in $k^{-7/3}$ and $f^{-7/3}$.

Our measurements and the subsequent analysis demonstrate for the first time, that the fluctuations of an air-water interface subjected to a subsurface turbulent flow can be interpreted as the linear response of the surface to the turbulent pressure fluctuations. If the wave dissipation is not too important, surface waves are also excited. However, the random advection induces a strong widening of the experimental dispersion relations by Doppler effect. Using our experimental setup in the same range of parameters, we have also investigated the effect of turbulence on mechanically generated surface gravity waves in sinusoidal and random regimes. The dispersion relations are significantly broadened and the waves strongly attenuated due to the random advection by the turbulent flow.

WIND SUSTAINED VISCOUS SOLITONS

Marine Aulnette*[1], Marc Rabaud[1], and Frédéric Moisy[1]
[1] Université Paris-Saclay, CNRS, FAST, 91405, Orsay, France.

Summary We investigate the generation of wind waves at the surface of a highly viscous liquid. Contrarily to the classical low-viscosity case, we observe the intermittent formation of large localized structures that propagate rapidly downstream, which we call viscous solitons. These strongly nonlinear coherent structures propagate at a velocity given by the balance between the aerodynamic drag in the air and the viscous drag in the liquid. We propose here a model to describe their dynamics based on a subcritical bifurcation governed by the wind shear stress.

INTRODUCTION

When wind blows over water, small disorganized surface deformations, called wrinkles, first appear [1, 2]. These structures, elongated in the direction of the wind, are the random wakes generated by the turbulent pressure fluctuations traveling in the air flow. When the wind velocity is increased above a critical value, theses wrinkles evolve into nearly periodic waves propagating in the direction of the wind, with slowly increasing amplitude and wavelength.

This general picture remains unchanged for viscosity up to approximately 100 times the water viscosity. However, for more viscous liquids, the nature of the waves dramatically changes: the initial wave-packet becomes violently unstable and forms a large asymmetrical fluid bump pushed by the wind [3, 4]. While the energy of the disturbance is homogeneously distributed in the low-viscosity case, it is strongly focused in these large bumps at large viscosity. We call these nonlinear objects, first qualitatively described by Francis in 1954 [5], *viscous solitons*. They are illustrated in figure 1 for a liquid of kinematic viscosity ν_l =1000 mm^2 s^{-1} and wind velocity U_a = 9.6 m s^{-1}. They are typically 2 to 4 mm high, 4 cm in the propagation direction, and 5 to 10 cm in the transverse direction, with a steep rear facing the wind and a weaker slope at the front.

LIFE CYCLE OF VISCOUS SOLITONS

To characterize the viscous solitons, we set up an experiment consisting in a 1.5 m long tank filled with silicon oil of kinematic viscosity $\nu_l = 1000$ mm^2 s^{-1}, fitted to the bottom of a wind tunnel of rectangular cross-section. Wind is blown at velocity between 0 and 15 m/s, and the depth of the liquid tank h is varied from 20 to 150 mm. The surface deformation is measured by laser sheet profilometry, with a vertical resolution of 0.1 mm.

The life cycle of viscous solitons is characterized using spatio-temporal diagrams, as illustrated in figure 2. Above a critical wind velocity, of the order of 9 m/s, a small-amplitude wave packet of a few wavelengths is first formed at small fetch. This wave packet remains spatially confined but it is temporally unstable (figure 2 (a)): the wave amplitude slowly grows until one of its crests reaches a critical height and rapidly evolves into a viscous soliton. Once formed, the soliton accelerates, leaves the wave packet region, and travels along typically 30-50 cm with constant shape and a slightly decreasing velocity (figure 2 (b)). The initial wave packet disappears after the emission of a soliton, but it reforms after a

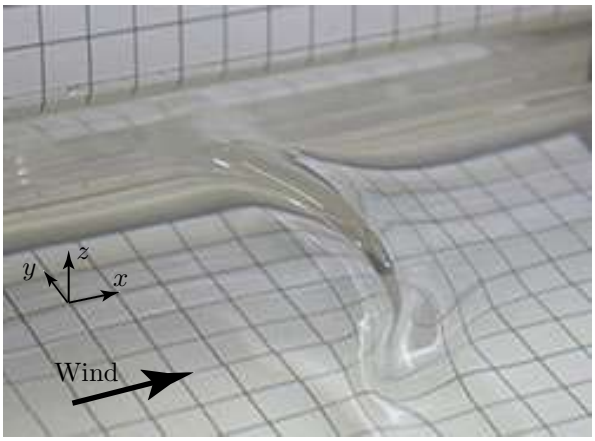

Figure 1: Viscous soliton propagating from left to right, generated by a wind velocity U_a = 9.6 m/s at the surface of silicon oil of kinematic viscosity $\nu_l = 1000$ mm^2 s^{-1}. The size of the grid pattern is 1.3 cm. From Ref. [4].

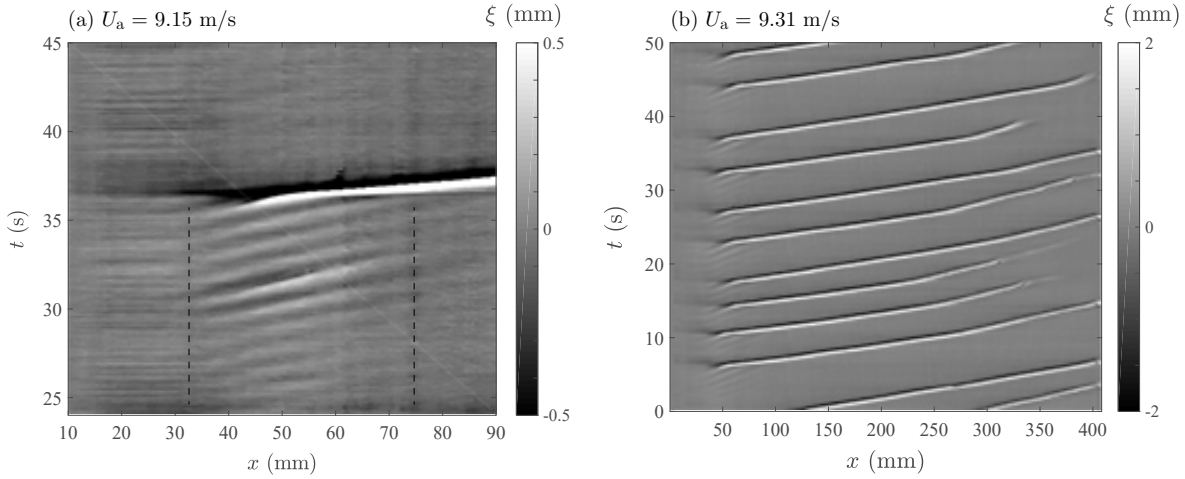

Figure 2: Spatiotemporal diagrams of the surface elevation $\xi(x,t)$ for a liquid depth $h = 35$ mm showing the emission, propagation and decay of viscous solitons. Figure (a) shows a zoom on the generation of a soliton from the instability of the initial wave packet for a wind velocity close to the onset ($U_a = 9.15$ m s^{-1}). Figure (b) shows the propagation and interaction of viscous solitons at larger velocity ($U_a = 9.31$ m s^{-1}): mature downstream solitons are slowed down because of the sheltering by newly created upstream solitons.

while and the process repeats. The waiting time between solitons is of order of 1 min close to the onset, but it decreases down to about 1 s at larger wind velocity.

The finite amplitude (about 2 mm) of the viscous solitons even close to the critical wind velocity suggests that they result from a subcritical instability. This is confirmed by additional experiments, in which solitons are excited for a wind slightly lower than the natural onset by using a small immersed wavemaker producing a finite-amplitude disturbance.

Systematic measurements of the soliton amplitude as a function of the downstream distance and wind velocity show that their dynamics is governed by the local wind shear stress: In the absence of mechanical forcing, viscous solitons spontaneously emerge from the initial wave packet that forms at small fetch, for a local shear stress above a first threshold $\tau_1 \simeq 0.25$ Pa. Solitons then escape from this initial wavepacket and propagate in the subcritical region over an appreciable distance, but because of the thickening of the turbulent boundary layer, the shear stress decreases with downstream distance and solitons disappear when the shear stress reaches a secondary threshold $\tau_2 \simeq 0.21$ Pa. The return to the base state is either natural, if the soliton is isolated and reaches the distance where the shear stress is below τ_2, or forced, when the air drag on the soliton is reduced by the nucleation of a new upstream soliton.

Viscous solitons provide a striking example of out-of-equilibrium coherent structures, resulting from a balance between external forcing and dissipation. These observations raise a number of questions: How their nontrivial asymmetric shape is selected by the liquid viscosity and surface tension? What governs the minimum viscosity to switch from the classical weakly non-linear wind-wave regime to the strongly non-linear soliton regime?

SUPERHARMONIC EXCITATION BY SELF-INTERACTION OF INTERNAL WAVE MODES IN NONUNIFORM STRATIFICATIONS

Dheeraj Varma*[1], Vamsi K. Chalamalla[2], and Manikandan Mathur[1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Madras, Chennai, India
[2]Department of Applied Mechanics, Indian Institute of Technology Delhi, New Delhi, India

Summary Superhamonic internal wave excitation due to self-interaction of internal wave modes in a nonuniform stratification is investigated using a combination of theoretical and numerical analysis. Weakly nonlinear theoretical framework is used to identify triadic resonance resulting from modal interactions of primary internal waves. Two dimensional numerical simulations are done using Stratified Ocean Model with Adaptive Refinement (SOMAR), and the spontaneous excitation of theoretically predicted superharmonic internal wave mode due to resonant/near-resonant interaction of an isolated primary mode is studied.

INTRODUCTION

In the recent past, generation of superharmonic waves due to nonlinear interactions has grabbed much attention. Theoretical studies (Varma *et al.* 2017, Wunsch 2017) and numerical simulations (Sutherland 2016) have investigated the generation of superharmonic waves due to modal interactions in nonuniform stratifications. This could be a potential mechanism by which tidally generated internal waves can transfer energy to smaller spatial and temporal scales. Most of the prior studies (see review papers by Staquet & Sommeria 2002 and Dauxois *et al.* 2018) have focused on the generation of subharmonic internal waves due to Parametric Subharmonic Instability (PSI). The relative importance of excitation of subharmonic and superharmonic waves is not well understood.

THEORETICAL FRAMEWORK

Weakly nonlinear constant-amplitude theory (Varma *et al.* 2017) predicts the superharmonic internal wave mode that would be excited due to resonant interaction of internal wave modes. The method of multiple scales is then used to quantify the spatial/temporal evolution of energy associated with each wave in the triad.

NUMERICAL SIMULATIONS

Numerical simulations are performed using SOMAR, which solves a set of conservation equations for momentum and buoyancy on a composite grid consisting of several levels. For details about the adaptive mesh capabilities of SOMAR, see Santilli & Scotti 2015. SOMAR uses second-order, central finite differences for the spatial discretization of viscous and diffusion terms, computed semi-implicitly for time advancement. Advection terms are computed using the finite volume Piecewise-Parabolic Method (PPM). The computational domain and the boundary conditions are shown in Figure 1(b).

RESULTS AND DISCUSSION

For the nonuniform stratification shown in Figure 1(a), we consider a case where a self-interacting mode-3 at $\omega_0/N_0 = 0.4466$ is in triadic resonance with mode-2 at the superharmonic frequency $2\omega_0$ as predicted by the constant-amplitude weakly nonlinear theory. In numerical simulations, mode-3 at the resonant frequency is continuously forced from the left end of the computational domain, and the wave field is filtered at the forcing frequency ω_0 and the superharmonic frequency $2\omega_0$ (shown in Figure 2(a) & 2(c)) after steady state is attained throughout the domain. The vertical mode shapes of the respective filtered velocity fields is shown in Figure 2(b) & 2(d), and the superharmonic wave has a mode-2 structure in corroboration with the theoretical prediction.

Furthermore, the spatial evolution of the modal amplitudes in the numerical simulations will be compared with the numerical solutions of the amplitude evolution equations obtained using the method of multiple scales. Numerical simulations are also performed at off-resonant frequencies to identify the range of primary wave frequencies (around the resonant frequency) over which spontaneous superharmonic wave excitation occurs.

NUMERICAL SIMULATION OF FLOW FIELD CAUSED BY UNDERWATER ULTRASONIC WAVE USING GLOBALLY CONSERVATIVE SCHEME

Masaya Orisaki*[1] and Takeo Kajishima[2]
[1]Department of Mechanical Engineering, Osaka University, Suita, Japan [2]Department of Mechanical Engineering, Osaka University, Suita, Japan

Summary We have developed the globally conservative scheme for analyzing acoustic and flow field in an adiabatic system. By using this scheme, the propagation and reflection of ultrasonic wave are properly simulated and we can maintain the conservation property of the mass of the entire computational domain. It enables the analyses of multiple phenomena involved in industrial applications of underwater ultrasonic wave such as waveform distortion, acoustic shock wave, acoustic streaming and interfacial phenomena. To elucidate the mechanism of the interfacial phenomena, underwater ultrasonic wave propagation considering the reflection at free surface and rigid wall is numerically investigated by using the proposed scheme. The results show that the interfacial deformation caused by underwater ultrasonic waves is mainly dominated by the acoustic streaming.

BACKGROUND

The interaction between ultrasonic wave and gas-liquid interface has attracted attention because of the applicability in industrial as well as medical techniques. Examples include ultrasonic atomization[1] for separation of solute from aqueous solutions. But the mechanism is not completely explained. For better understanding of the interfacial phenomena, the numerical investigation is expected together with experimental observations. To this end, it is necessary to organize the accurate methods to deal with nonlinear propagation and reflection of acoustic wave, interfacial deformation, and acoustic energy transfer at the interface. In other words, it is necessary to construct the computational scheme which maintains the conservation property of the entire system.

COMPUTATIONAL SCHEME

To simulate the phenomena we focus on, it is necessary to set moving boundaries such as sound source and water surface. We use fixed cartesian grid over the entire computational domain to capture the complex deformation of the water surface. Although a treatment of the sound source suitable for fixed cartesian grid has already been proposed[2], the conservation property of the entire computational domain is not enough due to using interpolation. To construct the treatment of the moving boundaries with excellent conservation property, we devised a new method to treat the sound source. To verify the conservation property of this method, we assume a situation in which plane acoustic waves are emitted from a oscillating plate to an adiabatic system consisting of an infinite rigid wall at $x = L_x$ as shown in Figure 1. In Figure 1, a and ω are an amplitude and an angular frequency of the oscillating plate.

We introduce the computational grids with equal interval Δ and time step Δt and denote the conservative quantity at $(x_i, y_j, t_n) = (i\Delta, j\Delta, n\Delta t)$ as $\boldsymbol{Q}^n_{i,j}$, as shown in Figure 2. $\boldsymbol{Q}^n_{l,j}(l = i, i+1, \cdots)$ and $\boldsymbol{Q}^{n+1}_{m,j}(m = i+1, i+2, \cdots)$ are computed by TVD (Total Variation Diminishing) and conservative scheme such as Chakravarthy-Osher scheme[3] .

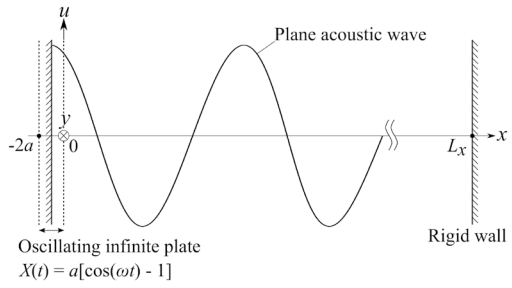

Figure 1: Set up for plane acoustic wave propagation simulation.

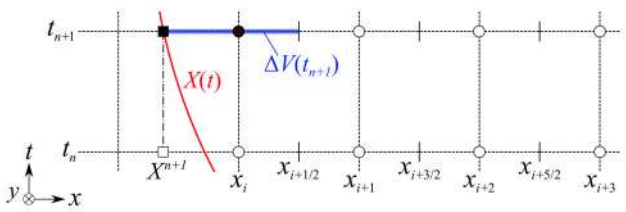

Figure 2: The mesh point near the oscillating infinite plate.

First, $\tilde{\boldsymbol{Q}}^{n+1}_{i,j}$ that is predict value of $\boldsymbol{Q}^{n+1}_{i,j}$ is determined by the moving boundary treatment[2] using interpolation and theory of characteristics. Next, to assume that the conservation error occurs in the computational cell containing the predict value, we can define a correction amount for the predict value of the density given by following equation.

$$\Delta\rho = \frac{M(t_0) - \tilde{M}(t_{n+1})}{\Delta V(t_{n+1})} \tag{1}$$

Where $M(t_0)$ is the initial total mass of the medium, $\tilde{M}(t_{n+1})$ is the total mass containing the predict value of the density, $\Delta V(t_{n+1})$ is the volume of the computational cell containing the predict value. $\tilde{\boldsymbol{Q}}^{n+1}_{i,j}$ is corrected as follows by $\Delta\rho$.

$$\boldsymbol{Q}^{n+1}_{i,j} = (\tilde{\rho}^{n+1}_{i,j} + w_{i,j}\Delta\rho)\left(\frac{\tilde{\boldsymbol{Q}}}{\tilde{\rho}}\right)^{n+1}_{i,j} \qquad \left[w_{i,j} = \frac{|\tilde{\rho}^{n+1}_{i,j} - \rho_0|}{N_y^{-1}\sum_{j=1}^{N_y}|\tilde{\rho}^{n+1}_{i,j} - \rho_0|}\right] \tag{2}$$

*Corresponding author. E-mail: orisaki@fluid.mech.eng.osaka-u.ac.jp

Where ρ_0 is the density in an initial undisturbed medium and $w_{i,j}$ is the weight function which is decided according to the magnitude of the density fluctuation (in the situation shown in Figure 1, $w_{i,j} = 1$).

We executed the numerical computation by using the existing method[2] and present method. The medium was an inviscid compressible fluid that can be described by Modified Tait EOS[4] and $\mathrm{Ma} = 0.01$ (Ma is acoustic Mach number), $L_x = 100\pi$, $\Delta = 2\pi/200$, and $\Delta t = 0.1\Delta$ were used for the computation. In both methods, waveform distortion and acoustic shock wave due to the nonlinear effect were properly simulated (Figure 3). The Figure 4 show the evaluation results of the conservation property of the mass and $\varepsilon_m = M(t_n) - M(t_0)$ in the Figure represent the error of the mass conservation of the entire computational domain. In the existing method, the error oscillates at an interval of the period of the acoustic waves, and the error accumulates over time. In the present method, the error was eliminated and ε_m was maintained at a small value ($\varepsilon_m \sim 10^{-14}$).

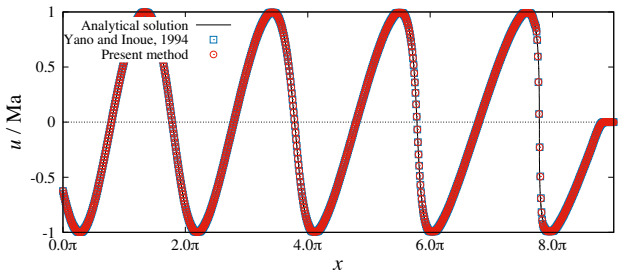

Figure 3: Velocity waveform at shock formation time.

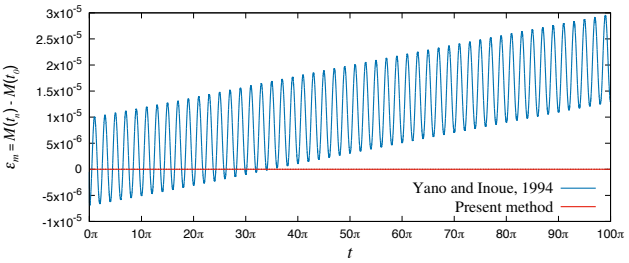

Figure 4: Conservation property of the mass.

RESULT AND CONCLUSION

To analyze the interfacial deformation that can be observed in advance of the ultrasonic atomization, we numerically simulated the situation in which underwater ultrasonic waves are emitted toward the free water surface from an ultrasonic oscillator set at the bottom of a cylindrical container (see Figure 4).The radius and acoustic Mach number of the ultrasonic oscillator are 2π and 0.005, respectively and the initial water level is $y = 8.5\pi$. The proposed method represented by eqs.(2) is applied to the simulation of the ultrasonic oscillator and the free water surface is simulated by height function method[5] using the interfacial velocity that satisfies mass conservation law. While the numerical computation was executed, the conservation property of the mass of the entire computational domain was being small value ($\varepsilon_m / M(t_0) \sim 10^{-8}[\%]$).

We successfully reproduced the water surface uplift above the sound source experimentally observed. It was elucidated that the acoustic streaming mainly dominates the interfacial deformation (see Figure 4). In addition, it was suggested that the remarkable acoustic streaming toward the water surface is caused by the increase in the nonlinear effect due to the reflection of ultrasonic waves.

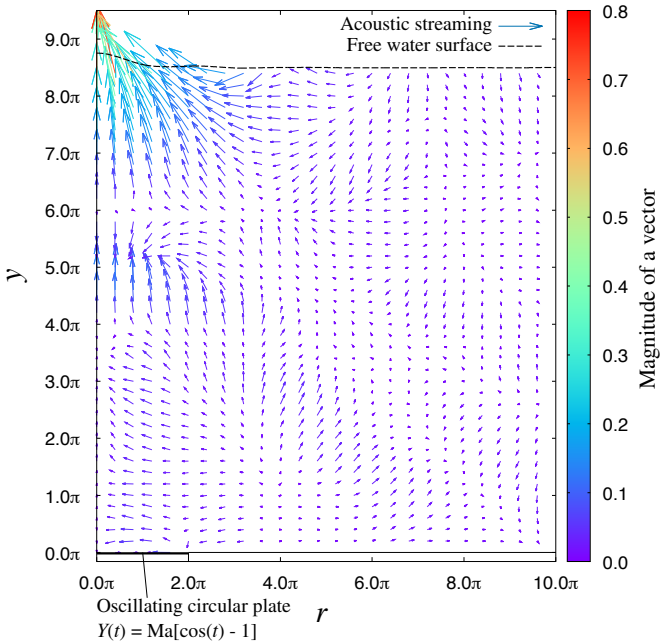

Figure 4: Acoustic streaming in the (r, y) plane at $t = 100\pi$.When the magnitude of the acoustic streaming is equal to Ma, the magnitude of the vector is equal to 1.0.

A SCHEME FOR INTERFACE ANALYSIS OF MAGNETIC FLLUID VALIDATED BY PHYSICAL LAWS

Yo Mizuta*[1]
[1]Department of Applied Physics, Hokkaido University, Sapporo, Japan

Summary For the stability or dynamic analysis in real time and in real space of the interface phenomena of magnetic fluids as the Rosensweig instability, quantities such as magnetic fields, stresses and fluid velocity on the interface are investigated numerically. The magnetic induction $\boldsymbol{b}$ is obtained efficiently by using the indirect boundary element method (IBEM). IBEM is used also for analyzing the fluid described by the velocity potential. The effect of nonlinear magnetization is incorporated in the magnetic stress difference T calculated from $\boldsymbol{b}$. Quantities on the interface in a two-layered system of fluid and vacuum domain under a homogeneous vertical magnetic field are shown. Though the magnetic stress or the gravity acts to grow or decay a raised interface for sure, actual behavior of the interface depends delicately on the change of the sum of interface stresses S.

INTERFACE ANALYSIS OF MAGNETIC FLUID

When we analyze the interface phenomena of incompressible, irrotational and inviscid magnetic fluid with all nonlinear effects but with no limitations on the interface profile, we use the following **equation for interface motion (EIM)** which is derived from Bernoulli's equation and the dynamic boundary condition on the interface [1]:

$$\rho\frac{\partial\varphi}{\partial t}+S=0,\quad S\equiv D+G+C+T+p_0, \tag{1}$$

where ρ, φ, D, G, C, p_0 are the fluid density, velocity potential, dynamic pressure, gravity potential, surface tension and atmospheric pressure, respectively. We omit hereafter D and p_0 in the sum of interface stresses S supposing slowly-moving interface and homogeneous atmospheric pressure.

The magnetic stress difference T representing the action from the magnetic field to the fluid is affected by the **nonlinear magnetization** [1], and determined as

$$T=-2\mu_0\left(Mb_Z\right)^2-\mu_0\frac{M_S}{\gamma}\ln\left(\frac{\sinh\gamma H}{\gamma H}\right),\quad H=\sqrt{h_X^2+h_Y^2+\left(\frac{b_Z}{\mu_1}\right)^2}, \tag{2}$$

where $M\equiv(1/\mu_0-1/\mu_1)/2$ with the permeability μ_J of the fluid (J=1) or the vacuum (J=0), and $\gamma\equiv 3\chi_0/M_S$ with the saturation magnetization M_S and the initial susceptibility χ_0.

The tangential magnetic field $h_{X,Y}$ and the normal magnetic induction b_Z are calculated from the magnetic potential ϕ and the normal magnetic induction b_Z. Through the Indirect Boundary Element Method (IBEM) [1], they are obtained rigorously as well as efficiently compared with the FEM, under arbitrary interface profiles and applied magnetic field distributions.

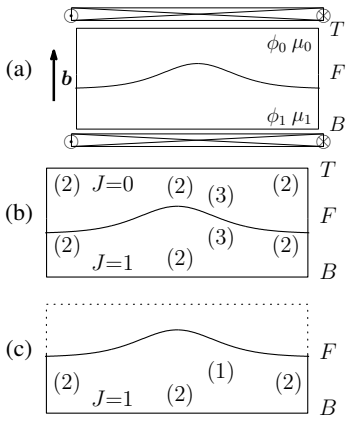

Figure 1: (a) Two-layered system under homogeneous vertical magnetic field. Boundary conditions for (b) magnetic analysis and (c) fluid analysis. (1), (2) or (3) denote boundaries where Dirichlet condition, Neumann condition or interface conditions are imposed, respectively.

TWO-LAYERED SYSTEM UNDER HOMOGENEOUS VERTICAL MAGNETIC FIELD

As shown in Fig. 1(a), a homogeneous vertical magnetic induction with the intensity $b_{\rm app}$ is applied on a two-layered system composed of fluid and vacuum domains with the same depth, and physical quantities are calculated on the axially-deformed solitary-wave-like interface F with the height $\zeta_{\rm pro}$ and the width $w_{\rm pro}$.

After [3], the magnetic fluid of gravity acceleration g=9.81 ms^{-2}, fluid density ρ=1.17 $\times10^3$ kgm^{-3}, capillary coefficient σ=3.09 $\times10^{-2}$ Nm^{-1}, saturation magnetization M_S=2.32 $\times10^4$ $\mathrm{A\,m}^{-1}$ and initial susceptibility χ_0=3.57 is supposed. From these values, critical parameter values where the interface linear wave becomes unstable are obtained as: wavenumber $k_{\rm C}=(\rho g/\sigma)^{1/2}$ =6.09 $\times10^2$ m^{-1}, wavelength $\lambda_{\rm C}=2\pi/k_{\rm C}$=1.03 $\times10^{-2}$ m. The intensity $b_{\rm app}$ changes between 15 mT and 25 mT. The height $\zeta_{\rm pro}$ is changed up to 3 mm, and its width $w_{\rm pro}$ is kept at $\lambda_{\rm C}$.

Boundary conditions to obtain ϕ and b_Z are shown in Fig. 1(b), where the known intensity $b_Z=b_{\rm app}$ is given on T and B, b_Z=0 on the side boundaries, and the interface conditions $\phi_1=\phi_2$ and $b_{Z1}+b_{Z2}=0$ are imposed on F. The magnetic induction vector $\boldsymbol{b}$ for the fluid domain (J=1) (Fig. 2(a),(b)) is obtained as $\boldsymbol{b}=\boldsymbol{b}_t+\boldsymbol{b}_n$ where $\boldsymbol{b}_t=\mu_J\nabla\phi_J\times\boldsymbol{t}_{ZJ}=b_{tx}\boldsymbol{x}+b_{tz}\boldsymbol{z}$ and $\boldsymbol{b}_n=b_{ZJ}\boldsymbol{t}_{ZJ}=b_{nx}\boldsymbol{x}+b_{nz}\boldsymbol{z}$ are the tangential magnetic induction vector, the normal magnetic induction vector and their components, respectively, where $\boldsymbol{t}_{ZJ}$ is the normal unit vector.

Once the magnetic analysis by the IBEM is established, incompressible, irrotational and inviscid fluid is readily analyzed by using the velocity potential φ which satisfies the Laplace equation $\nabla'\cdot(\nabla'\varphi')=0$. The law of conservation of volume is considered now. Figure 1(c) shows boundary conditions for the fluid analysis. On B and side boundaries, the normal fluid velocity v_n=0. On the free surface F, by contrast, the value of φ from the integration in time of the EIM (1) is given as the Dirichlet boundary condition, and the normal fluid velocity v_n is obtained which determines the interface elevation. To obtain v_n just after a short time Δt of the fluid initially at rest, we set here $-S\Delta t/\rho$ for φ. Figure 2(g) shows the fluid velocity $\boldsymbol{v}$ on the free surface, which is composed of the tangential fluid velocity $\boldsymbol{v}_t\equiv\nabla\varphi\times\boldsymbol{t}_Z$ and the normal fluid velocity $\boldsymbol{v}_n\equiv v_n\boldsymbol{t}_Z$.

*Corresponding author. E-mail: yomizuta@eng.hokudai.ac.jp.

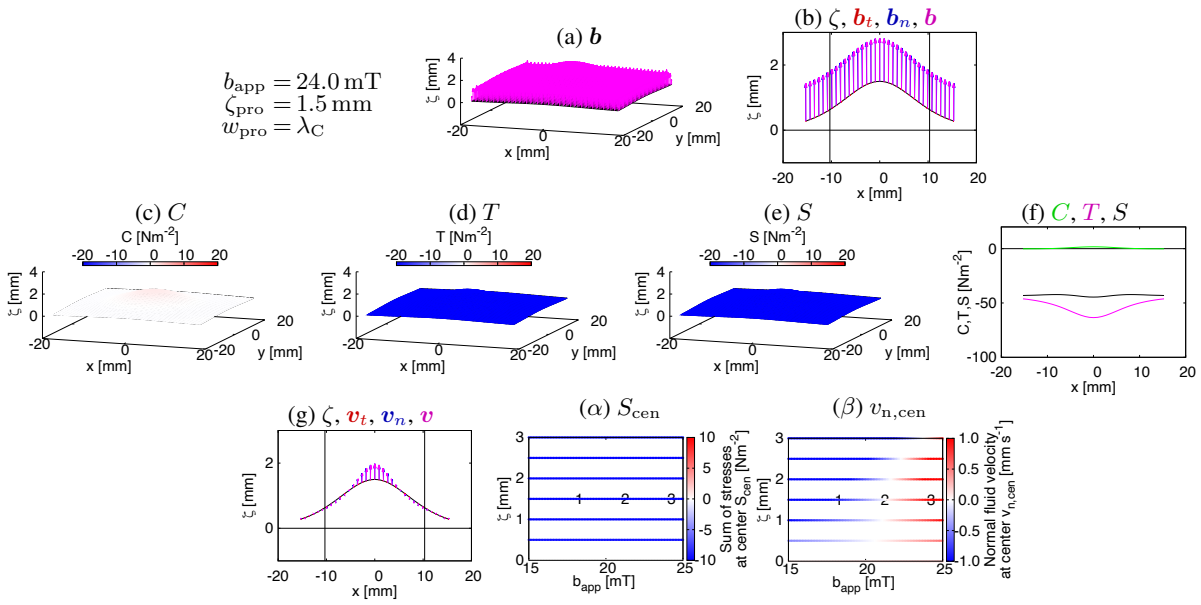

Figure 2: Distribution on the interface ((a),(c),(d),(e)) and within the cross section at y=0 ((b),(f),(g)) of (a),(b) tangential magnetic induction vector $\boldsymbol{b}_t$, normal magnetic induction vector $\boldsymbol{b}_n$, their composite $\boldsymbol{b}$, (c),(f) surface tension C, (d),(f) magnetic stress difference T, (e),(f) sum of interface stresses S including gravity potential G, and (g) tangential fluid velocity $\boldsymbol{v}_t$, normal fluid velocity $\boldsymbol{v}_n$ and their composite $\boldsymbol{v}$. (α) and (β) show dependence of sum of interface stresses S and normal fluid velocity v_n at the center of interface profile on intensity of applied magnetic induction $b_{\rm app}$ and height of interface profile $\zeta_{\rm pro}$.

Calculated quantities on the interface are shown in Fig. 2, and for visibility, their distribution within the cross section at y=0 in (b),(f),(g). The mean curvature H for the surface tension C=$-2\sigma H$ in (c),(f) is calculated through the differentiation in the interfacial direction of the function interpolating the interface profile. The magnetic stress difference T in (d),(f) is from (2), and the sum of interface stresses S in (e),(f) includes the gravity potential G. The correctness of these stresses are verified by the relation between interface stress and interface energy density (RELA) [2].

When the interface is flat, the same $b_{\rm app}$ as applied on T and B is expected to appear on F. Before F is deformed, it was confirmed that obtained ϕ and b_Z on F are continuous across the interface, and they are symmetric after rotated at a right angle due to the geometric configuration.

Figure 2(α),(β) show the value of the sum of interface stresses $S_{\rm cen}$ and the normal fluid velocity $v_{\rm n,cen}$ at the center of the interface profile, by changing $b_{\rm app}$ and $\zeta_{\rm pro}$. The results in (a)–(g) are those at the symbol 3.

DISCUSSION

When $\partial v_z/\partial t \simeq 0$, $\partial\zeta/\partial t \propto \partial\varphi/\partial t = -S/\rho$ holds, since $\varphi = \int_{-\infty}^{\zeta} {\rm d}z v_z$ with the interface elevation ζ and the vertical component of fluid velocity v_z. As Fig. 2(f) shows, under the present condition, T is always negative, positive G cancels it partly, and C is small compared with T and G in S. As the result, S changes gently in the central area, but is still negative. Then, the magnetic stress is expected to grow the interface against the gravity in all the range of $b_{\rm app}$ as shown in Fig. 2(α). In spite of this speculation, the interface decays ($v_n < 0$) in the range between 1 and 2 of Fig. 2(β), and larger $b_{\rm app}$ is needed to be $v_n > 0$ at 3 where v_n is positive in the limited central area as Fig. 2(g) shows.

In the case of 3, the curve of S in Fig. 2(f) is observed to change convex downward in the central area, in contrast to the case of 1 and 2 where convex upward in all area. This behavior of S directs the tangential fluid velocity toward the center, and generates the outward normal fluid velocity together with the conservation of volume. Though the preliminary speculation paid attention mainly on the sign of S, the change of S on the interface should be investigated carefully for discussing the behavior of the interface which is determined from C in addition to T on the basis of the magnetic analysis.

An amplitude equation $\partial A/\partial t = f(\varepsilon, A)$ with $\varepsilon = (B/B_0)^2 - 1$ is reconstructed and used for the nonlinear relaxation dynamics in the neighborhood of the Rosensweig instability [3, 4]. In the phase space spanned by the pattern amplitude A and magnetic induction B, the bifurcation curve is obtained from $f(\varepsilon, A)$=0, which is a stable (unstable) branch when $f(\varepsilon, A) < 0$ in the neighbor above (below) it. Also in Fig. 2(β), this branch is likely to be drawn by connecting the points with $v_{\rm n,cen}$=0 by the correspondence between A, B, $\partial A/\partial t$ and $\zeta_{\rm pro}$, $b_{\rm app}$, $v_{n,cen}$. However, it should be noted that this marginal curves is that for the initial fluid at rest at t=0, and the stable bifurcation curve is to be determined from the stationary v_n=0 at t=∞. After all, dynamic analysis from t=0 to t=∞ is needed considering the changes in $\zeta_{\rm pro}$, $w_{\rm pro}$ and S on the way.

TWO COUPLED NONLINEAR EVOLUTION EQUATIONS OF OBLIQUELY INTERACTING CAPILLARY GRAVITY WAVES OVER INFINITE DEPTH

Shibam Manna*[1], and A.K. Dhar [1]
[1]Department of Mathematics, Indian Institute of Engineering Science and Technology, Shibpur, India

Summary Two coupled nonlinear Schrodinger (CNLS) equations have been employed to discuss the modulational instability (Benjamin-Fier instability) due to unidirectional as well as bidirectional perturbations for two obliquely interacting capillary gravity waves over infinite depth of water under the circumstance of crossing sea states. Graphs and three-dimensional contour plots are demonstrating the fact that the rate of growth of instability G_r for two obliquely interacting wave trains is much elevated compared to the instance of modulation of one wave train. Therefore, freak waves may be created as a consequence of Benjamin-Fier instability. We have also examined a stabilising influence on modulational instability (MI) due to the effect of capillarity.

INTRODUCTION

Freak waves, first introduced by Draper [1], are exceptionally large amplitude waves, localised both in space and time which can be accompanied by deep holes that occur before and after the maximum crest. The devastating power of freak waves are liable for the destruction of numerous ships and lives [2], and resulting depreciation of offshore engineering structures have guided researchers to perform research works for acquiring sufficient information regarding the generation, formulation-mechanism, dynamics of amplification along with other relevant features of such waves. Freak waves may be formed due to both statistical and nonlinear effects, may exist both in shallow and deep water [3]. Employing Zakharov's integral equation, Onorato et al. [4] developed two CNLS equations for two nonlinearly interacting waves in deep water with two separate channels of spread. They presented an investigation of the instability growth rate for one dimensional two wave systems utilising those equations and observed that the growth rates rely on not just the wavelength of the perturbation and steepness of the primary waves yet in addition on the angle between the two wave frameworks. This outcome was then extended by Shukla et al. [3] for investigating the rate of growth of instability for bidirectional perturbations employing two CNLS equations as derived by Onorato et al. [4]. After investigating weakly nonlinear interaction of two wave systems spreading along with two separate directions in deep water, Laine-Pearson [5] inferred that the rate of growth of long-wave instability of two obliquely interacting waves is more significant than those due to resonant interaction of short-crested waves. Senapati et al. [6] determined two CNLS equations in the case of crossing sea states in the presence of uniform wind flow in deep water. All these analyses made by the aforesaid authors are for gravity waves. The present paper is an extension of Shukla et al. [3] to incorporate capillarity using multiple scale method unlike Onorato [4] and Shukla et al. [3]. Thus our paper deals with two CNLS equations for two capillary gravity wave packets in crossing sea states over infinite depth of water.

Evolution equations, Modulational instability:

Here two capillary gravity wave trains having carrier wave numbers $\boldsymbol{k}_1 = (k, l)$ and $\boldsymbol{k}_2 = (k, -l)$ respectively are propagating obliquely and making equal angle θ with the positive direction of x axis. Let $z = \eta(x, y, t)$ represents the equation of the undulating free surface at time t in perturbed state. The perturbed velocity potential $\phi(x, y, z, t)$ satisfies the Laplace equation. At the free surface, the kinematic boundary condition is, $\phi_z - \eta_t = \phi_x\eta_x + \phi_y\eta_y$ on $z = \eta$ (1)

The condition of continuity of pressure at the free surface is, $\phi_t + g\eta = -\frac{1}{2}(\nabla\phi)^2 + s\left[\frac{\eta_{xx}(1+\eta_y^2)+\eta_{yy}(1+\eta_x^2)-2\eta_{xy}\eta_x\eta_y}{(1+\eta_x^2+\eta_y^2)^{3/2}}\right]$, (2)

where $s = \frac{T}{\rho}$ represents the coefficient of surface tension and g is the gravitational acceleration, $\phi \to 0$ as $z \to -\infty$. To solve (1) and (2), we employ $P = P_{00} + \sum_{(m,n)\neq(0,0)}\left[P_{mn}e^{i(m\psi_+ + n\psi_-)} + P_{mn}^* e^{-i(m\psi_+ + n\psi_-)}\right]$, (3)

where $\psi_\pm = kx \pm ly - \omega t$ represent the phase functions of first and second wave trains respectively, P stands for ϕ, η. Here ϕ_{00}, ϕ_{mn} and ϕ_{mn}^* are slowly varying functions of $(x_1, y_1, t_1) = (\delta x, \delta y, \delta t)$ and z; η_{00}, η_{mn} and η_{mn}^* are functions of x_1, y_1, t_1 and $*$ denotes complex conjugate, δ is a small ordering parameter. The linear dispersion relation is $f(\omega, k, l) \equiv \omega^2 - gk_0 - sk_0^3 = 0$, $(k, l) = (k_0\cos\theta, l_0\sin\theta)$. Proceeding similarly as Senapati et al. [6], the evolution equation of the 1st wave train is: $i\frac{\partial\eta_{10}}{\partial t_1} + i\gamma_1\frac{\partial\eta_{10}}{\partial x_1} + i\gamma_2\frac{\partial\eta_{10}}{\partial y_1} + \gamma_3\frac{\partial^2\eta_{10}}{\partial x_1^2} + \gamma_4\frac{\partial^2\eta_{10}}{\partial y_1^2} + \gamma_5\frac{\partial^2\eta_{10}}{\partial x_1 y_1} = \Lambda_1\eta_{10}^2\eta_{10}^* + \Lambda_2\eta_{10}\eta_{01}\eta_{01}^*$ (4)

The coefficients of (4) are available in the Appendix. Similarly, for the 2nd wave train with carrier wave number $(k, -l)$ the evolution equation is: $i\frac{\partial\eta_{01}}{\partial t_1} + i\gamma_1\frac{\partial\eta_{01}}{\partial x_1} - i\gamma_2\frac{\partial\eta_{01}}{\partial y_1} + \gamma_3\frac{\partial^2\eta_{01}}{\partial x_1^2} + \gamma_4\frac{\partial^2\eta_{01}}{\partial y_1^2} - \gamma_5\frac{\partial^2\eta_{01}}{\partial x_1 y_1} = \Lambda_1\eta_{01}^2\eta_{01}^* + \Lambda_2\eta_{01}\eta_{10}\eta_{10}^*$ (5)

In the absence of capillarity (s = 0), the coefficients of equations (4) and (5) are in agreement with the corresponding coefficients of the equations made by Onorato et al. [4], as well as those of Senapati et al. [6] for $(U, r) = (0, 0)$. We choose the uniform wave train solutions of (4), (5) in the form $\eta_{10} = \alpha_0 e^{-it_1\Delta\omega_1} \equiv \eta_{10}^{(0)}$, $\eta_{01} = \beta_0 e^{-it_1\Delta\omega_2} \equiv \eta_{01}^{(0)}$, (6)

where α_0 and β_0 are real constants indicating the wave steepness of two wave trains and the nonlinear frequency shifts $\Delta\omega_1$ and $\Delta\omega_2$ satisfy the following relations: $\Delta\omega_1 = \Lambda_1\alpha_0^2 + \Lambda_2\beta_0^2$, $\Delta\omega_2 = \Lambda_2\alpha_0^2 + \Lambda_1\beta_0^2$ (7)

The nonlinear dispersion relation is $[(\Omega - Q_+)^2 - P_+(P_+ - 2\Lambda_1\alpha_0^2)][(\Omega - Q_-)^2 - P_-(P_- - 2\Lambda_1\beta_0^2)] = 4P_+P_-\Lambda_2^2\alpha_0^2\beta_0^2$, (8)

where $P_\pm = -(\lambda^2\gamma_3 + \mu^2\gamma_4 \pm \lambda\mu\gamma_5)$, $Q_\pm = (\lambda\gamma_1 \pm \mu\gamma_2)$ and equation (8) is in agreement with the equation (2) of Shukla et al. [3]. For $\mu = 0$, from (8) we get $(\Omega - \lambda\gamma_1)^2 = (\lambda^2\gamma_3)^2 + \lambda^2\gamma_3\Lambda_1(\alpha_0^2 + \beta_0^2) \mp \lambda^2\gamma_3\sqrt{(\Lambda_1(\alpha_0^2 - \beta_0^2))^2 + 4\Lambda_2^2\alpha_0^2\beta_0^2}$, (9)

*Corresponding author. E-mail: mannashibam31@gmail.com.

which is again an agreement with the equation (11) of Onorato et al. [4].

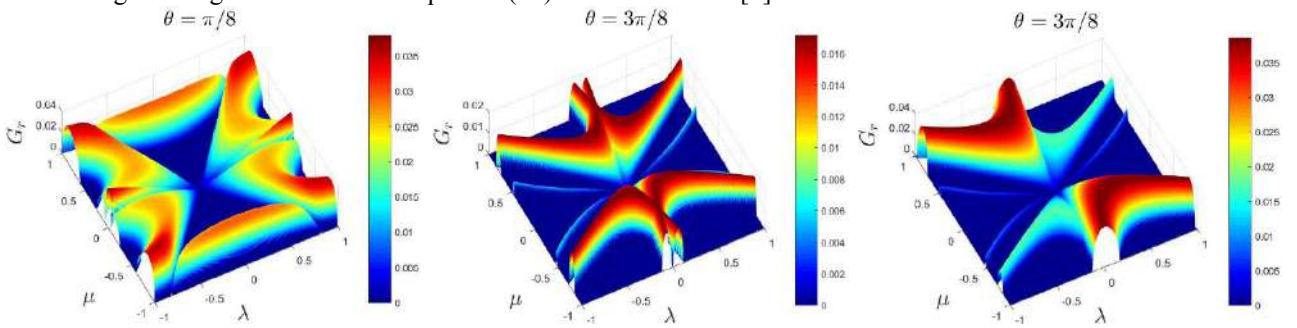

Fig-1: 3D Contour plot of $G_r = Im\Omega$ in (λ, μ) plane for $s = 0.035$, $\alpha_0 = \beta_0 = 0.15$(first two) and $\alpha_0 = 0.1, \beta_0 = 0.15$ (last one).

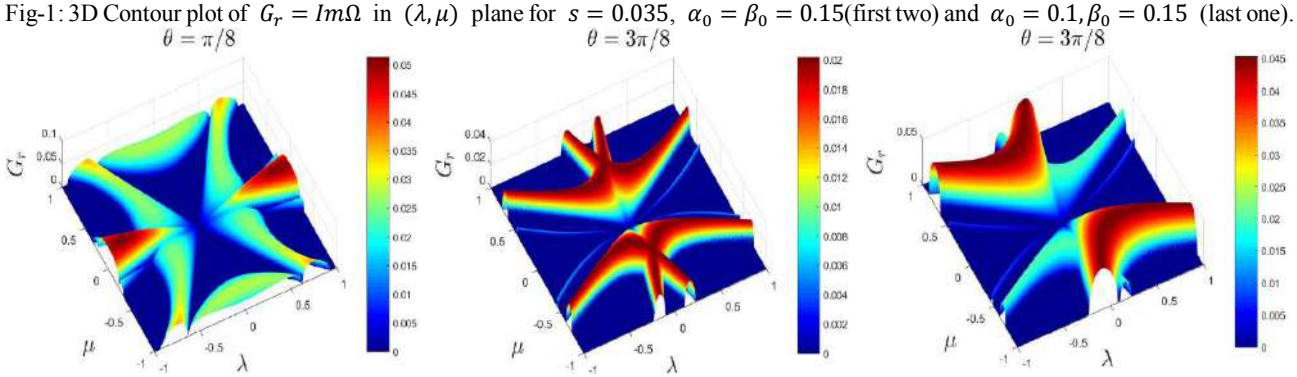

Fig-2: 3D Contour plot of $G_r = Im\Omega$ in (λ, μ) plane for $s = 0$, $\alpha_0 = \beta_0 = 0.15$ (first two) and $\alpha_0 = 0.1, \beta_0 = 0.15$ (last one).

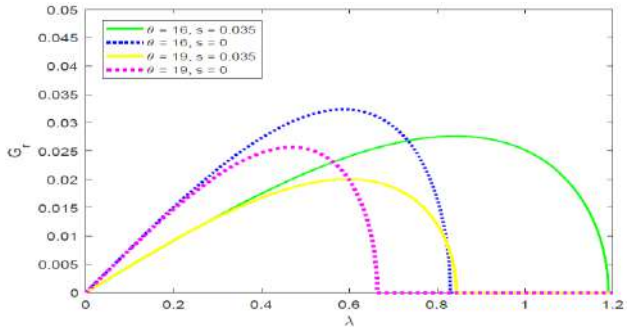

Fig-3: $G_r = Im\Omega$ as a function of λ, $\alpha_0 = 0.1, \beta_0 = 0.15$

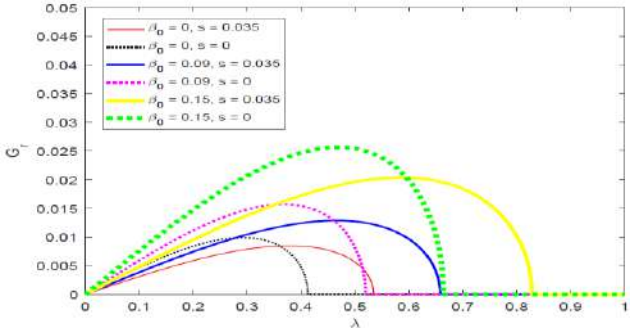

Fig-4: G_r as a function of λ, $\theta = 19°$ (…$s = 0$, __$s = 0.035$)

Fig-1, 2 exhibit that the effect of capillarity results in a decrease in the growth rate producing a stabilising influence. For $\theta = \frac{3\pi}{8}$ comparing Fig-1 with Fig-5 of Senapati et al. [6], we have inferred that due to capillarity G_r decreases. Further, the instability regions for $\alpha_0 = \beta_0$ are symmetric about $\lambda = 0$, $\mu = 0$ whereas for $\alpha_0 \neq \beta_0$ it is not so. Fig-3 exhibits that the capillarity effect produces a decrease in G_r up to a certain value of λ giving a stabilising influence and G_r increases as θ decreases. Finally, Fig-4 demonstrates that G_r increases with the increase of β_0 for a fixed value of θ.

CONCLUSIONS

Comparing Fig-1 with Fig-2, we conclude that the effect of capillarity produces a decrease in the growth rate of instability G_r. Figures 3 and 4 exhibits that G_r decreases due to the effect of capillarity up to a certain value of the wave-number λ and then G_r increases. Further, Fig-4 demonstrating the fact that G_r for two obliquely operating wave packets is much elevated than the instance of modulation of a single ($\beta_0 = 0$) wave packet [7]. Thus freak waves can be produced as a consequence of MI. Furthermore, G_r becomes higher as θ becomes smaller.

Appendix:

$$\gamma_1 = \frac{k(1+3s)}{2\omega}, \gamma_2 = \frac{l(1+3s)}{2\omega}, \gamma_3 = -\frac{k^2}{8\omega^3} + \frac{l^2+3s(l^2+2k^2)}{4\omega}, \gamma_4 = -\frac{l^2}{8\omega^3} + \frac{k^2+3s(l^2+2k^2)}{4\omega}, \gamma_5 = -\frac{kl}{4\omega^3} + \frac{(1+3s)kl}{2\omega}, \Lambda_1 = 2\omega + \frac{\omega(3\omega^2-3-12s)}{(2\omega^2-1-4s)} - \frac{s}{2\omega}\left\{3l^2k^2 - \frac{3}{2}(l^4+k^4)\right\}, \Lambda_2 = \frac{s}{2\omega}\{2l^2k^2 + 3(l^4+k^4)\} + \omega(3k^2-l^2) - \frac{\omega^3 l^2(k^2-l^2-2)}{2(1+4l^2s)} - \frac{\omega k(k^2+l^2-2k)^2}{k+4sk^2-2\omega^2}.$$

RADIATION-INDUCED INSTABILITY OF A MEMBRANE INTERACTING WITH A UNIFORMLY MOVING FREE SURFACE FLOW OF FINITE DEPTH

Joris Labarbe[1] and Oleg N. Kirillov[1]
[1]Northumbria University, NE1 8ST Newcastle upon Tyne, UK

Summary In a recent study [1], we investigate the motion of waves emitted due to flutter of an elastic membrane being at the bottom of a uniform horizontal potential flow of an inviscid and incompressible fluid of finite depth with free surface. The membrane is rigidly fixed at both extremities and placed at the center of a solid floor. The membrane has an infinite span in the direction perpendicular to the direction of the flow and a finite width along the flow axis. In the case where the length of the membrane is supposed infinite, we managed to derive a full dispersion relation that is valid for arbitrary depth of the fluid layer and find conditions for the flutter of the membrane due to emission of surface gravity waves. We describe this radiation-induced instability by means of the wave energy of the flow related to the concept of negative energy waves and study its relation to the anomalous Doppler effect. An extension to the case of a membrane with finite chord is also subject of a discussion in terms of stability, despite the more complex settings and analysis involved.

MEMBRANE FLUTTER DUE TO SURFACE GRAVITY WAVES EMISSION

Flutter of membranes is a classical subject for at least seven decades. Membranes submerged in a compressible gas flow and their flutter at supersonic speeds have been considered already in the works [2, 3]. Recent works on the membrane flutter are motivated by such diverse applications as stability of membrane roofs in civil engineering [4], flutter of traveling paper webs [5] and aerodynamics of sails and membrane wings of natural flyers [6, 7].

Surface gravity waves on a motionless fluid of finite depth is a classical subject as well, going back to the seminal studies of Russell and Kelvin [8]. Numerous generalizations are known taking into account, for instance, a uniform or a shear flow and surface tension [9], flexible bottom or a flexible plate resting on a free surface [10]. The latter setting has a straightforward motivation in dynamics of sea ice and a less obvious application in analogue gravity experiments [8].

Remarkably, another phenomenon that is being analysed from the analogue gravity perspective is super-radiance [8] and its particular form, discovered by Ginzburg and Frank [11], known as the anomalous Doppler effect (ADE) [12, 13]. In electrodynamics, the ADE manifests itself when an electrically neutral overall particle, endowed with an internal structure, becomes excited and emits a photon during its uniform but superluminal motion through a medium, even if it started the motion in its ground state; the energy source is the bulk motion of the particle [12].

Anomalous Doppler effect in hydrodynamics was demonstrated for a mechanical oscillator with one degree of freedom, moving parallel to the boundary between two incompressible fluids of different densities [14]. It was shown that the oscillator becomes excited due to radiation of internal gravity waves if it moves sufficiently fast. In [15] the ADE for such an oscillator was demonstrated due to radiation of surface gravity waves in a layer of an incompressible fluid.

Nemtsov [16] was the first who considered flutter of an elastic membrane being on the bottom of a uniform horizontal flow of an inviscid and incompressible fluid as an anomalous Doppler effect due to emission of long surface gravity waves. In the shallow water approximation, he investigated both the case of a membrane that spreads infinitely far in both horizontal directions and the case when the width of the membrane in the direction of the flow is finite whereas the span in the perpendicular direction is infinite. Nevertheless, the case of the flow of arbitrary depth has not been studied in [16] as well as no numerical computation supporting the asymptotical results has been performed. Another issue that has not been addressed in [16] is the relation of stability domains for the membrane of the finite width to that for the membrane of the infinite width.

Vedeneev studied flutter of an elastic plate of finite and infinite widths on the bottom of a uniform horizontal flow of a compressible gas occupying the upper semi-space. He performed analysis of the relation of stability conditions for the finite plate with that for the infinite plate using the method of global stability analysis by Kulikovskii [17, 18]. However, no connection has been made to the ADE and the concept of negative energy waves.

In the present work [1] we reconsider the setting of Nemtsov in order to address the finite height of the fluid layer as it is presented in FIG. 1. We managed in that setting to derive a full dispersion relation for the case of infinite membrane and find the flutter domains in the parameter space. Using perturbation of multiple roots of the dispersion relation, we analyze the character of the instability to determine the wave motion due to flutter of the membrane. We also investigate dependence of the flutter onset on the width of the membrane and we seek relations with the infinite membrane case by using a numerical model developped in [19] and new expressions for the pressure and the potential of the fluid derived in this work. Finally, we will explain the instabilities via the interaction of positive and negative energy waves by finding explicit formulations of kinetic and potential energy of the flow, and relate these results to the anomalous Doppler effect.

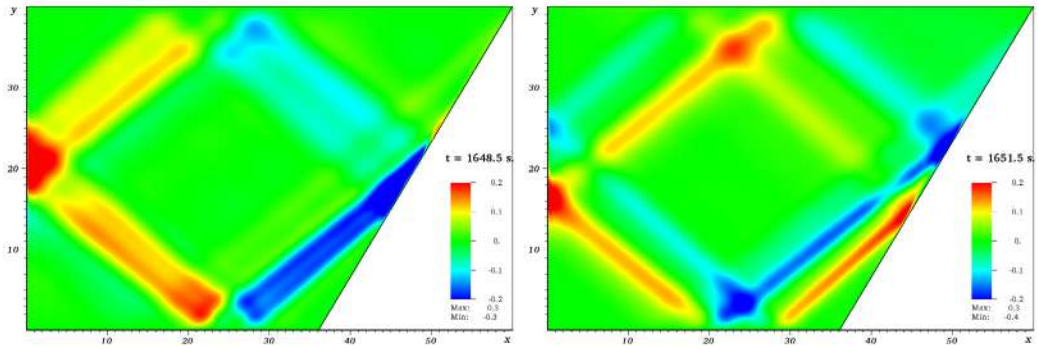
BIHARMONIC WAVE ATTRACTORS IN STRATIFIED OR ROTATING FLUIDS

Daniil Riazanov[1], Ilias Sibgatullin *[1,2], and Evgeny Ermanyuk[2]
[1]Ivannikov Institute for System Programming of the RAS, Moscow, Russia
[2]Shirshov Institute of Oceanology of the RAS, Moscow, Russia
[3]Lavrentyev Institute of Hydrodynamics of SB RAS, Novosibirsk, Russia

Summary Simultaneous appearance of different wave attractors in the same tank, which are formed due to external forcings with different frequencies are studied by direct numerical simulation. Structure of the flow for small amplitudes correspond to the linear theory only if the frequencies are not close to each other. For larger amplitudes the dependence of dynamical behaviour, transition to chaotic motion, level of kinetic energy and its pulsations on difference between the frequencies is discussed.

In stratified or rotating fluids accumulation of wave energy along closed paths or surfaces can occur due to peculiarities of dispersion relation of internal or inertial waves, which result in new rules of wave beam billiard in bounded domains. A necessary condition of formation of wave attractors is the presence of a surface inclined with respect to gravity direction or rotations axis. In oceanology and astrophysics it is quite a general situation, when there are several simultaneous tidal forcings from multiples sources, also there may be modifications of stratification or rotation rate affecting wave beams directions. This is why studies of flows with multiple external forcings with different frequencies are of considerable interest both for quite separated frequencies, and close frequencies. In this work we will conventionally call the flows with accumulation of wave energy and subject to two external periodic forcings by biharmonic attractors. In case of finite difference between the frequencies one can expect that there will be independent attractors, corresponding to different frequencies, because inside the domain the beams propagate linearly, and nonlinear effects occur only near the boundaries. In case of close frequencies the regime is less obvious since beating effect can change the regime, and the mean level of kinetic energy and its pulsations are quite different from monochromatic regime. Also viscosity effects, which define the width of the attractors, change the flow of closely interacting attractors. For unstable and turbulent flows the scenarios of transitions and spectra of final regimes are substantially different for monochromatic forcing, biharmonic forcing and slow change of external frequency.



Vertical component of velocity for small-amplitude biharmonic forcing (laminar mode) with frequencies different by 1/20 of the first frequency.

NUMERICAL INVESTIGATION OF WIND WAVE INTERATION

Jiarong Wu[1] and Luc Deike *[1,2]
[1]Department of Mechanical and Aerospace Engineering, Princeton, USA [2]High Meadows Environmental Institute, Princeton, USA

Summary In this study, we seek better physical understanding of surface wave interacting with a turbulent air flow by direct numerical simulations of the two phase Navier-Stokes equation with adaptive mesh refinement (AMR). A turbulent boundary layer flow interacts with a traveling wave train in a fully coupled manner, and we analyze the dynamics of the turbulent air and water flow, as well as the wave growth. We analyze the energy budget, in particular the wave growth rate, as well as the momentum budget, in particular the pressure and shear stress partition. We explore a wide range of controlling parameters in terms of wave age (ratio of wave speed over friction velocity) and wave slope.

INTRODUCTION

Wind wave interaction happens when wind blows across the water surface. The physics of this common but complex phenomenon is a long standing problem that attracts interests from both theoretical and practical point of view [1][2][3]. The complexity arises from the two-way coupling between turbulent air flow and gravity-capillary surface waves. As wind blows, it excites and amplifies waves and current through viscous shear stress and pressure forcing [4]; at the same time, the presence of a moving wavy boundary alters the turbulent boundary layer above significantly [5][6].

The momentum and energy transfer during this process provides valuable information for wave-resolved air-sea interaction modeling and has been the focus of many studies. However a detailed understanding of the small-scale dynamics including the coupling between the turbulent air and water flow through the waves is still incomplete. Indeed, it is very hard to obtain high resolution three dimensional experimental data near the moving water surface in field campaign and laboratory experiments to access the fluxes directly [6]. Numerical simulation presents an appealing alternative but the large range of scales involved has limited the ability to investigate the fully coupled two-phase flow problem. Direct numerical simulation (DNS) [5] and large eddy simulation (LES) [3] have been performed over the years, however, various degrees of simplifications were often made due to technical constraints and consideration of computational cost, typically resolving the waves with either the air or water turbulent layer, and use prescribed boundary conditions to represent the other side. Numerical simulation also enables investigation of the dynamics across a wider range of parameters, which is important because the dominant forcing mechanism can change under different flow conditions.

The present work leverages progress in adaptive mesh refinement algorithm for two-phase flows with the Basilisk framework to present simulations of the full coupling between idealized wave and the water and air turbulent boundary layer, without any prescribed boundary condition at the interface.

NUMERICAL SETUP

We solve the two phase Navier Stokes equation using volume of fluid (VOF) method to reconstruct the interface and with a momentum conserving AMR solver Basilisk[7] which has been extensively used and validated for complex multiphase flows [9]. Density and viscosity ratio between air and water ρ_a/ρ_w and μ_a/μ_w are kept constant using the realistic values across all simulations, while μ_w is varied to study Reynolds number effect. The problem can be described in terms of non-dimensional parameters: inverse wave age u_*/c, slope ak, friction Reynolds number Re_τ, and Bond number Bo defined as

$$Re_\tau = \frac{\rho_a u_* H}{\mu_a}, \; Bo = \frac{(\rho_w - \rho_a)g}{\sigma k^2} \tag{1}$$

u_*, c, H, a, k, g, σ are the friction velocity, wave phase speed, half channel height, initial amplitude, wave number, gravitational acceleration and surface tension respectively. We are restricted in the highest Re_τ we can reach because of the increasing resolution required to resolve the thinning viscous sub-layer. The numerical procedures are as follows:
Step 1: The air phase is initialized with a smooth wall turbulence profile and some random noise. The flow is driven by a constant bulk pressure gradient. The nominal air friction velocity u_* is related to the pressure gradient by

$$\rho_a u_*^2 = H \frac{\partial p}{\partial x} \tag{2}$$

The wavy boundary is initialized with a monochromatic Stokes wave of wave number k and amplitude a. The "wall" is kept stationary until the turbulence has reached a statistically stationary state.
Step 2: The water phase is initialized with solution based on third order Stokes wave orbital velocity [8] and released. The air and water phase evolve and interact without any prescribed kinematic or dynamic boundary conditions at the interface.

*Corresponding author. E-mail: ldeike@princeton.edu

We verify that the AMR grid is able to capture the turbulent boundary layer mean profile and statistics near the wall relatively well while keeping the total number of grids at a reasonable level. As shown in Figure 1, both the viscous linear profile and logarithmic profile are captured. The use of AMR and reasonably low resolution in the air layer will be used with higher resolution on the wave field to capture its development.

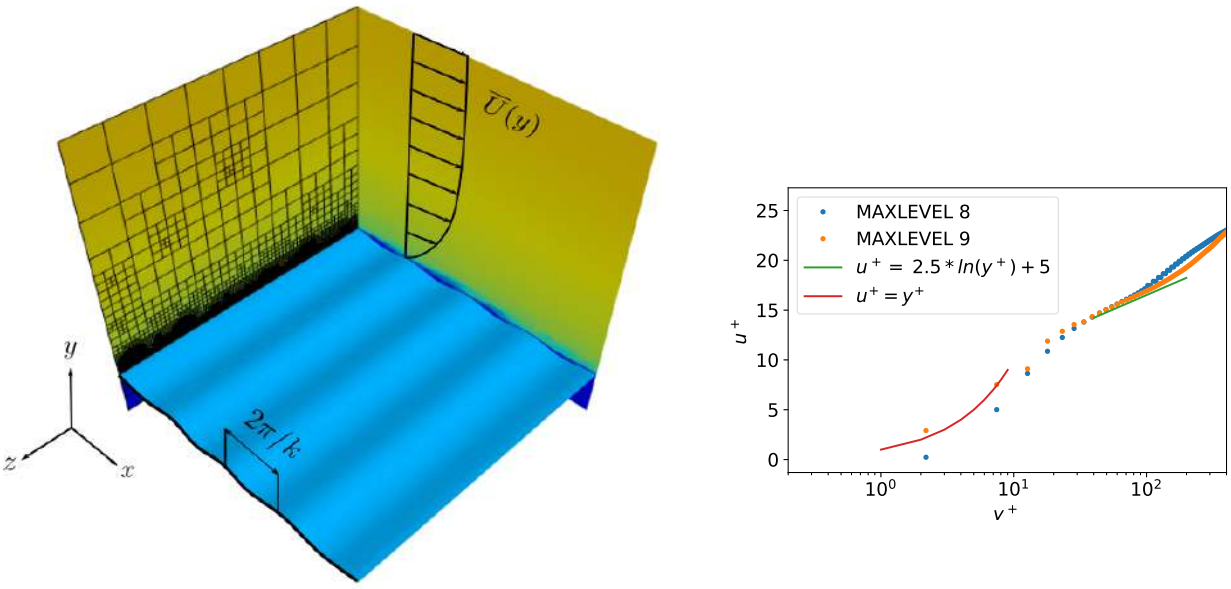

Figure 1: Left: numerical setup; right: reproduction of law of wall without the presence of waves. Refinement level convergence is verified. The friction Reynolds number Re_τ is 160.

RESULTS

The wave energy can be extracted from the mean square surface elevation and the non-dimensional growth rate $\overline{\beta}$ is computed as

$$E(t) = \rho_w g \langle \eta(t)^2 \rangle, \ \overline{\beta} = \frac{1}{\omega E(0)} \frac{dE}{dt} \tag{3}$$

We will discuss the scaling between $\overline{\beta}$ and the aforementioned parameters. From preliminary results at low initial amplitude, we recover the classic $\beta \propto (u_*/c)^2$, while observing threshold for wave growth that depends on the water viscosity. We observe and analyse the formation of a thin drift layer beneath the water surface.

DNS also provides us with detailed flow field data, therefore the momentum and energy partition between shear stress and pressure can be readily computed taking the value at the interface. Preliminary result confirms that most contribution to wave growth comes from pressure forcing. In addition, the time scale of wave growth is much bigger than the turbulence eddy turnover time, indicating that some of the averaging arguments are indeed applicable.

ON WAVES ARISING FROM DRY GRANULAR COLLAPSE INTO WATER

Wladimir SARLIN*[1], Cyprien MORIZE[1], Alban SAURET[2], and Philippe GONDRET[1]
[1]Université Paris-Saclay,CNRS,Laboratoire FAST,F-91405 Orsay,France
[2]University of California, Santa Barbara, Department of Mechanical Engineering, USA

Summary Tsunami-like waves can arise from significant geological events such as the collapse of a mountain flank or a volcano into a lake or an ocean. We reproduce here this situation at the laboratory scale. The landslide is modeled by the sudden release of a rectangular granular column, which then impacts a still water layer and generates a wave. Through experiments varying both the column dimensions and the initial water height, three regimes of nonlinear waves of different shapes are reported.

INTRODUCTION

Tsunamis generated by landslides, debris avalanches or rockslides are highly destructive phenomena, with several occurrences in the last decades. Caused by major geological events involving large volumes of debris such as mountain or volcano collapses, they may result in the generation of high amplitude water waves. A well-known example is the case of Lituya Bay (Alaska, USA) in 1958 [1], when a rockslide volume of $30.10^6 m^3$ fell into water and produced the largest wave runup recorded in history, destroying neighbouring coastal areas up to an altitude of 524 m.
To describe the wave generation accurately, the granular nature of the falling mass needs to be taken into account [2, 3]. In the present work, we investigate experimentally the collapse of granular columns into water. Various initial conditions for the column dimensions and the initial water depth are considered, which generate waves of different shapes.

EXPERIMENTAL SETUP

Waves induced by granular collapses are experimentally reproduced using a setup described in [4]. A rectangular granular column of initial height H_0 and width L_0 is located above a water layer of height h_0, on the left-hand side of a tank of length 2 m and transverse width 0.15 m [Fig. 1 (a)]. The water is colored with fluorescein in order to enhance the contrast between water, air, and grains. Lifting the vertical sliding gate quickly releases the granular column, which impacts the water free-surface and generates a wave, as presented in Fig. 1 (b)-(d) for different initial conditions. The time evolution of the collapse and the wave is recorded with a camera, and image processing allows to extract the water free-surface and the dry and wet granular profiles. For the granular material, glass beads of diameter 5 mm and density 2500 $kg.m^{-3}$ are used. For different column aspect ratios $a = H_0/L_0$, the water height is varied to investigate the wave generation process in a large range of global Froude number $\mathrm{Fr}_0 = \sqrt{H_0/h_0}$, between 0.5 and 4.4. This dimensionless number compares the typical vertical free fall velocity of the grains $\sqrt{gH_0}$ to the classical velocity of linear waves in shallow water $\sqrt{gh_0}$.

RESULTS

The following parameters are systematically extracted from the movies of the experiments : the maximum wave amplitude A_m, the corresponding wave mid-height width λ_m, and the maximum horizontal velocity v_f of the granular front at the interface $z = h_0$. Doing so, it is possible to estimate a local Froude number $\mathrm{Fr}_f = v_f/\sqrt{gh_0}$, which compares the typical velocity of the collapse to the water wave velocity [4].

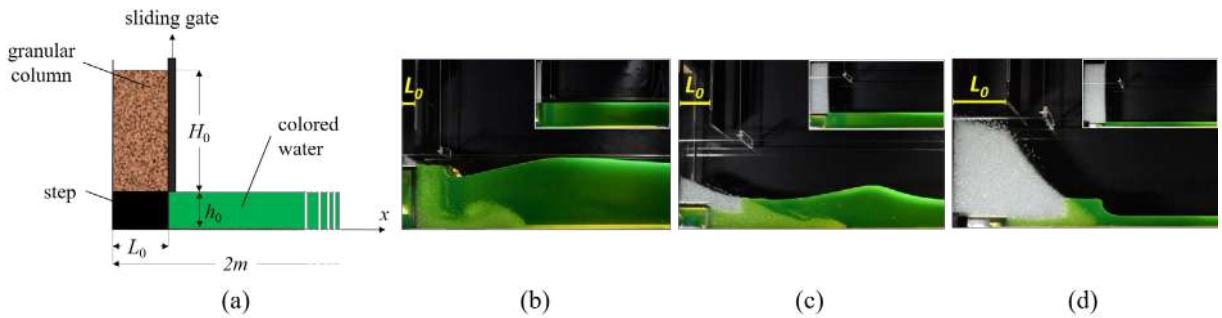

Figure 1: (a) Sketch of the experimental setup, and pictures of the different wave shapes observed for different initial conditions : (b) nonlinear transition wave ($H_0 = 39$ cm, $L_0 = 5$ cm, $h_0 = 25$ cm), (c) solitary wave ($H_0 = 29$ cm, $L_0 = 10$ cm, $h_0 = 9$ cm), and (d) hydraulic jump ($H_0 = 39$ cm, $L_0 = 14.5$ cm, $h_0 = 3$ cm). The inset of each figure shows the initial state of the experiment.

*Corresponding author. E-mail:wladimir.sarlin1@universite-paris-saclay.fr.

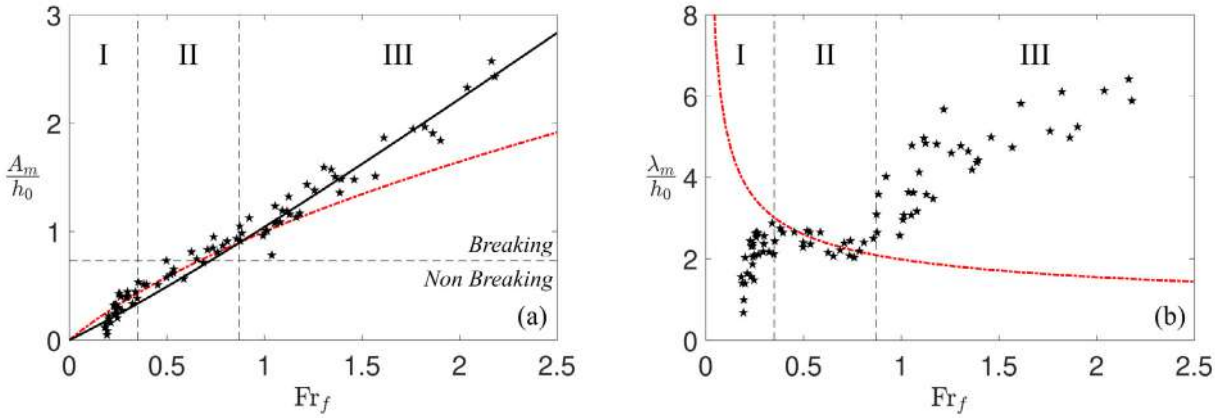

Figure 2: Evolution of (a) the relative amplitude A_m/h_0 and (b) the relative mid-height width λ_m/h_0 of the wave with the local Froude number Fr_f for all experiments (★), with predictions from Korteweg-de Vries solitary wave model (– – –), and from a hydraulic jump model (—); The two vertical dashed lines correspond to the transitions at $\mathrm{Fr}_f = 0.35$ between nonlinear transition waves (I) and solitary waves (II), and $\mathrm{Fr}_f = 0.87$ between solitary waves (II) and hydraulic jumps (III); The horizontal dashed line corresponds to the breaking criterion $A_m/h_0 = 0.73$.

For a given initial granular column, three distinct wave regimes are found when varying the initial water depth h_0, and thus the Froude numbers. For low values of the Froude numbers, a long primary wave followed by a weak dispersive wave train is observed (Fig. 1(b), for $\mathrm{Fr}_0 = 1.25$ and $\mathrm{Fr}_f = 0.19$), which corresponds to the nonlinear transition waves reported by [2] and [5]. At moderate Froude numbers, quasi-symmetrical solitary waves are observed (Fig. 1(c), for $\mathrm{Fr}_0 = 1.80$ and $\mathrm{Fr}_f = 0.52$), that can either break or not depending on the value of A_m/h_0 reached by the wave. Finally, for high Froude numbers, waves are close in shape to hydraulic jumps, breaking near the collapse region, due to the shock produced at the interface between grains and water (Fig. 1(d) for $\mathrm{Fr}_0 = 3.61$ and $\mathrm{Fr}_f = 1.86$).
Based on the local Froude number Fr_f, all data collapse onto a master curve for the relative wave amplitude A_m/h_0 [Fig. 2 (a)]. The first regime [I] observed for $\mathrm{Fr}_f \lesssim 0.35$, is very similar to the solution described by [6]. Waves are found to be highly unsteady, growing in amplitude until reaching a maximum, before flattening with a decreasing amplitude and a growing width. For $0.35 \lesssim \mathrm{Fr}_f \lesssim 0.87$ (regime [II]), waves are in good agreement with the Korteweg-de Vries theory (dash-dotted red curve in Fig. 2(a) and Fig. 2(b)), for both the amplitude and the mid-height width. Finally, for $\mathrm{Fr}_f \gtrsim 0.87$ (regime [III]), the hydraulic jump theory predicts well the maximum wave amplitude (solid black curve in Fig. 2(a)).

CONCLUSIONS

In this study, tsunami waves generated by a granular collapse display different shapes governed by a local Froude number Fr_f based on the horizontal velocity of the granular collapse at the water surface. For $\mathrm{Fr}_f \lesssim 0.35$, nonlinear transition waves are generated, whereas for $0.35 \lesssim \mathrm{Fr}_f \lesssim 0.87$, solitary waves are observed and well described by Korteweg-de Vries theory. Finally, for $\mathrm{Fr}_f \gtrsim 0.87$, hydraulic jumps arise in response to the strong shock at the interface. These experiments allow to characterize the hydrodynamics of landslide generated waves, for a range of initial conditions that cover most of the real cases observed in Nature [7].

TRANSFER BETWEEN WAVES AND EDDIES IN STRATIFIED OR ROTATING TURBULENCE

Henri Lam*[1], Alexandre Delache[1,2], and Fabien S Godeferd[1]
[1]Laboratoire de Mécanique des Fluides et d'Acoustique, Univ Lyon, École centrale de Lyon, INSA Lyon, Université Claude Bernard Lyon I, CNRS, France

Summary We propose to separate the waves and eddies in stratified and/or rotating turbulence by using an extended method exposed in Lam et al. (2020) [1]. This separation takes into account the spatial and temporal distortion due to the advecting flow, which modifies the dispersion relation of the waves through the sweeping effect. From this separation, we analyse the transfers and interactions that occur between eddies and waves. Furthermore, this permits the analysis of the detailed energy cascade and fluxes from the input scale to the dissipative ones.

INTRODUCTION

Internal gravity waves (IGW) in the case of stratified turbulence and inertial waves (IW) in the case of rotating turbulence are waves sharing some remarkable properties. They both satisfy a dispersion relation linking their angular frequency ω and the direction of the wavevector $\mathbf{k}$. For IGW $\omega_r = \pm N \cos\theta$ and for IW $\omega_r = \pm 2\Omega \sin\theta$, where N is the Brunt-Väisälä frequency, Ω is the rotation rate and θ is the angle made by the wavevector $\mathbf{k}$ against the horizontal plane. This was experimentally shown in experiments and in simuations of IW propagation [3, 4], likewise for IGW in stratified flows [2]. However, the frequency of the waves can be modified by the sweeping effect (similar to the Doppler shift). This corresponds to the advection of the waves by a large scale, slowly varying in time background flow. In stratified turbulence, this corresponds to the vertically shear horizontal flow (VSHF) composed of large velocity band invariant in the horizontal direction and in rotating turbulence to the geostrophic mode (GM) composed of two opposite vortices invariant in the z direction. In a rotating experiment [4], the geostropic mode is shown to be the main responsible of the modification of the frequency of the waves through the sweeping effect. A new 4D decomposition has been proposed [1] that takes into account the frequency of the waves ω and its wave vector $\mathbf{k}$ to make an estimation of the sweeping effect to separate the waves from the eddies. It requires the estimation of a uniform and constant in time advecting velocity $\mathbf{c}$ responsible of the sweeping effect. Using this estimation the waves are separated from the eddies because the waves are expected to satisfy the inequality $\omega_r - |\mathbf{c}\cdot\mathbf{k}| \leq \omega \leq \omega_r + |\mathbf{c}\cdot\mathbf{k}|$.

SEPARATION TECHNIQUE OF WAVES AND EDDIES

We propose a new separation technique for waves and eddies where the advecting velocity $\mathbf{c}(\mathbf{x},t)$ varies in time and space. This allows us to take into account the non-uniform and the slow variation in time of the expected advecting velocity. This algorithm requires two stages:

1. The advecting flow of the DNS is extracted to convect the response of a linear Navier-Stokes equation forced by a series of Dirac forces in time and space. The dispersion relation of the waves is modified by the advecting flow $\mathbf{c}(\mathbf{x},t)$. A filter $\zeta(\omega,\mathbf{k})$ is created which considers waves to be in areas of the (ω, $\mathbf{k}$) space with a high level of energy. On the contrary eddies are expected to be in areas of the (ω, $\mathbf{k}$) space with a low level of energy.

2. The filter $\zeta(\omega,\mathbf{k})$ is applied to the original DNS to separate the waves from the eddies.

The Navier-Stokes equation with the Boussinesq approximation are solved on a pseudo-spectral code with a three-dimensional 2π periodic domain size. The forcing is done on the kinetic part of the Navier-Stokes equation, it consists of a constant influx of energy P. From this algorithm the velocity vector $\mathbf{u}$ and buoyancy field b are separated in a wave (superscript w), an eddy (superscript e) part and a large scale flow like the VSHF or GM (superscript L). We obtain $\mathbf{u} = \mathbf{u}^w + \mathbf{u}^e + \mathbf{u}^L$ and $b = b^w + b^e + b^L$.

ENERGY BUDGET AND TRANSFER IN STRATIFIED TURBULENCE

We illustrate here the results of our wave-eddy decomposition only for IGW in stratified turbulence, but similar results are obtained for IW in rotating flows. In a statistically stationary flow, with constant injected power P, we have an equation of energy budget for waves and eddies on a large period T_0 . In stratified turbulence whithout considering the VSHF flow, it is:

*Corresponding author. E-mail: henri.lam@ec-lyon.fr

$$0 = \partial_t E^w = T^w_{ee} + T^w_{we} + \epsilon^w + P^w$$
$$0 = \partial_t E^e = T^e_{ww} + T^e_{ew} + \epsilon^e + P^e \quad (1)$$

where the total dissipation is $\epsilon^l = \frac{1}{T_0}\int_{T_0}\sum_k \frac{\nu k^2}{2}(|\mathbf{u}^l|^2 + \frac{|b^l|^2}{N^2})$, the total energy is $E^l = \frac{1}{T_0}\int_{T_0}\sum_k \frac{1}{2}(|\mathbf{u}^l|^2 + \frac{|b^l|^2}{N^2})$ and the total transfer is $T^l_{ij} = \frac{1}{T_0}\int_{T_0}\sum_k(\mathbf{u}^i \times \boldsymbol{\omega}^j)\mathbf{u}^l - \frac{(\mathbf{u}^i\cdot\nabla b^j)b^l}{N^2}$. T^l_{ij} means that i interacts with j to give or take energy to l (the subscripts or superscripts i, j, l stand for w or e). The input of energy P due to the forcing is separated in an eddy P^e and a wave P^w input of energy.

The energy budget can be represented by a Sankey diagram (see Figure 1) where the width of the bar is proportional to the flow rate. The injected power P on the left is dissipated by ϵ^w and ϵ^e on the right and subject to different interactions T^l_{ij} where the color indicates the origin of the flow (red=w, blue =e). The overall energy transfer is from the waves with the transfers T^w_{ee} and T^w_{we}, and to the eddies with the transfers T^e_{ew} and T^e_{ww}. By exploring different values of Froude and buoyancy Reynolds numbers, we show that the maximum of energy transfer from waves to eddies occurs when both are of similar magnitudes (at $\mathrm{Re}_b \sim 1$). Similar analyses will be presented for rotating flows.

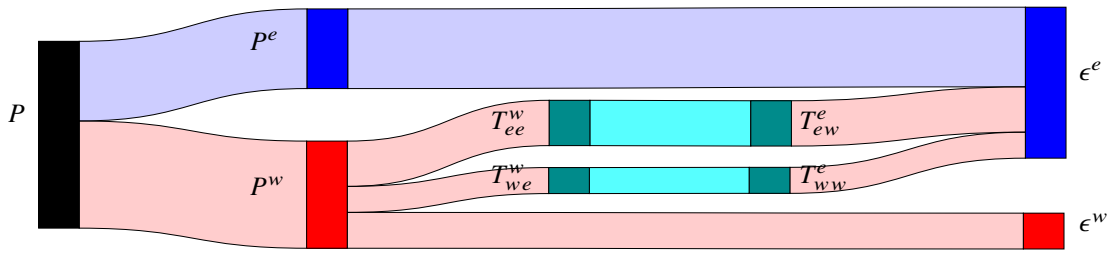

Figure 1: Energy budget for a DNS with buoyancy Reynolds number $\mathrm{Re}_b = 0.9$ and horizontal Froude number $\mathrm{Fr} = 0.015$.

It is hard to draw a clear pattern from the direct study of the fluxes of waves and eddies because they fluctuate a lot. Therefore, we decide to study these statistics through four values (see Figure 2):

- the total positive T^+ (resp. negative T^-) transfer, which correspond to the amount of energy given (resp. taken) from waves or eddies.
- the average scale of positive k^+ (resp. negative k^-) transfer T^+ (resp. T^-), which correspond to the scale at which on average the positive (resp. negative) transfer occurs.

For example, in Figure 2a, the strength of positive and negative transfer T^e_{ee} increases when the Froude number increases. It means that eddies interact more with each other when the flow is more turbulent. In Figure 2b, the transfer T^e_{ee} participates in a forward cascade (as $k^+ > k^-$), and we show that the forward cascade is stronger at high Froude number (when the flow is more turbulent). The same analysis can be done for the wave turbulence transfer T^w_{ww} and for all remaining transfers. Surprisingly, we observe that the wave-eddy interaction results in an inverse cascade for some Froude numbers.

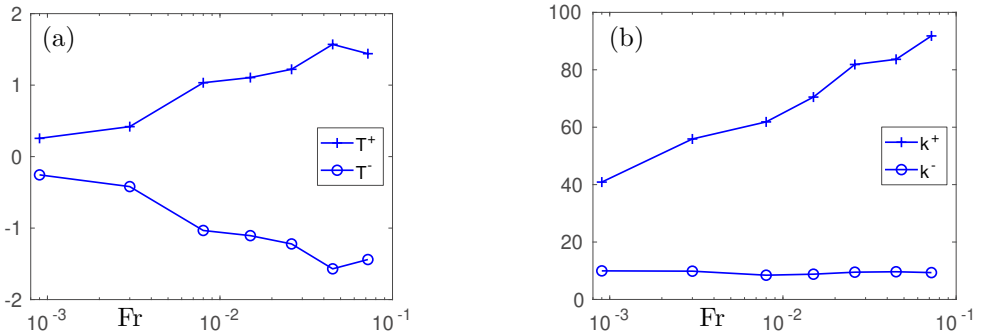

Figure 2: Statistics of the transfer T^e_{ee} for different Froude number. (a) Total positive $T^+$and negative transfer T^-. (b) Average scale of positive k^+ and negative k^- transfer.

INFLUENCE OF TEMPERATURE ON EHD CONDUCTION PUMPING

Pedro A. Vázquez*[1], M. Talmor[2], and J. Seyed-Yagoobi[2]
[1]Department of Applied Physics III, E.T.S.I, Universidad de Sevilla, Sevilla, Spain
[2]Multi-Scale Heat Transfer Laboratory, Department of Mechanical Engineering, Worcester Polytechnic Institute, Worcester, MA 01609, USA.

Summary The performance of EHD conduction pumps depends on the temperature of the liquid. Seemingly contradictory trends have been reported in experimental works in the literature. We will use an analysis of the working regimes of the EHD pumps used in those papers to explain this behavior.

ABSTRACT

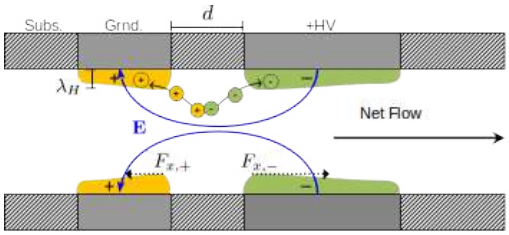

Figure 1: Illustration of the EHD conduction mechanism. The heterocharge layers locations are indicated in green and yellow. The corresponding polarity with respect to the electrodes is shown.

Electrohydrodynamic Conduction Pumping (EHDCP) of weakly conducting liquids is a very interesting practical application of Electrohydrodynamics (EHD) [2]. EHDCP pumps have no moving parts, are easy to miniaturize and to control. In previous works it has been shown that EHDCP works well for a wide range of pump sizes [4, 8, 7], even in absence of gravity [6]. This last feature makes these pumps especially suited for it use in satellites.

EHD flows are generated by electric forces acting on electric charges present in a liquid. In EHDCP systems the ions in the liquid are generated by dissociation of a weak electrolyte[1]. The application of an external electric field generates layers of net electric charge near each electrode, with opposite polarity. These are called heterocharge layers (see Figure 1). Their physical origin is the balance between electric drift and recombination of the ions in the liquid. The electric field acts upon these layers. If the layers have different sizes, the resulting effect is a net electric force that put the liquid into motion.

One of the main applications of EHDCP is the enhancement of heat exchange. Some contradictory results have been reported in the literature. Jeong et al.[3] observed that pressure generation and resultant mass flow rate decreased with increased temperature. However, Nourdanesh et al.[5] studied EHDCP of thin films of R-123 using flush electrodes and

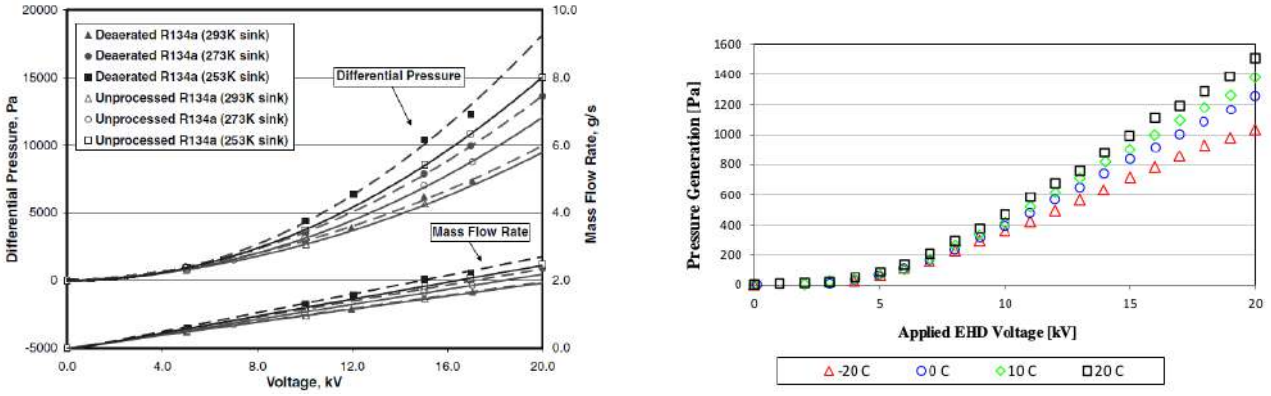

Figure 2: On the left, experimental results from Jeong et al.[3] showing increasing performance with decreasing temperature. On the right experimental results performed by Yang et al.[10] showing increasing performance with increasing temperature.

*E-mail: pvazquez@us.es

found that the generated flow rate increases with the working fluid temperature. Yang et al.[10] obtained similar results than Nourdanesh et al. with different liquids.

We will use the physical model presented in Vazquez et al.[9] to explain these seemingly contradictory results. The physical origin of this discrepancy lies in the different working regimes of these experiments. Two limit regimes can be describe in EHDCP: ohmic and saturation. The working regime can been characterized by two dimensional numbers: the conduction number C_0 and a new number β introduced in that paper. We will show the importance of this number β in the explanation of the different behaviors with temperature.

Summary We report the scientific background, the present construction status, and the prospects of the large-scale liquid sodium platform DRESDYN, which is devoted to experimental research into dynamo action and magnetically triggered flow instabilities.

INTRODUCTION

Magnetic fields are ubiquitous in the cosmos. They are being generated in planetary cores, stars, and entire galaxies by the homogeneous dynamo effect. Once produced, they can trigger instabilities in flows which would otherwise be hydrodynamically stable. The magnetorotational instability (MRI) figures most prominently here, since it can expedite dramatically the accretion process of central objects, such as protostars and black holes, from the accretion disks surrounding them. While widely considered as disjoint effects, self-excitation and magnetically triggered flow instabilities may well "conspire" in massively non-linear processes such as the MRI dynamo or the Tayler-Spruit dynamo.

Against the backdrop of a huge body of theoretical, numerical, observational investigations into cosmic dynamos and magnetically triggered flow instabilities, related experimental results are still scarce [1]. This has mainly to do with the significant technical effort needed to set-up flow experiments with high magnetic Reynolds numbers. The success of the pioneering liquid sodium experiments in Riga [2] and Karlsruhe [3] relied on careful optimizations of underlying paradigmatic models of single-scale and two-scale helical dynamos. The great accomplishments of the Cadarache experiment, in terms of showing field excursions and reversals [4], were achieved only when ferromagnetic propellers were used, which compromised the homogeneous character of this dynamo.

While the unanimous experimental proof of the standard version of MRI, with a purely axial magnetic field being applied, is still elusive, some related instabilities were successfully demonstrated in the liquid metal lab. This applies, in particular, to the helical [5] and the azimuthal [6] version of the MRI, as well as to the current-driven, kink-type Tayler instability (TI) [7]. Since these instabilities are governed by the Reynolds and the Hartmann number, they are much more easily realizable in liquid metal labs than standard MRI, whose onset depends on the magnetic Reynolds and the Lundquist number. As an interesting outcome of the numerical simulations dedicated to instabilities in liquid metals with their typical low magnetic Prandtl numbers, an intrinsic tendency for helicity oscillations was discovered and later exploited in a tidally synchronized Tayler-Spruit-type dynamo model [8], with possible ramifications for the solar dynamo.

THE PRECESSION DYNAMO EXPERIMENT

The most ambitious experiment in the framework of the *DREsden Sodium facility for DYNamo and thermohydraulic studies* (DRESDYN) is a large-scale liquid sodium experiment dedicated to the investigation of dynamo action in a precession-driven flow [9]. With diameter and height of the cylindrical vessel of 2 m each, and a planned rotation rate of 10 Hz, the experiment will attain a magnetic Reynolds number of 700. The turntable can rotate with up to 1 Hz. For maximum rotation and precession rates, the gyroscopic torque will reach values up to 8 MNm, which requires an extremely solid mechanical frame with a ground plate resting on 7 pillars reaching 22 meters into the bedrock. Figure 1 shows some impressions of the recent status of the experiment. First water experiments are planned for the end of 2020.

Besides the significant technical and safety related challenges of this experiment, some basic question about precession driven flows and their dynamo action are non-trivial as well. It has been known for some time that precession driven-flows in cylinders (and, very similarly, also in spheroids) undergo a (hysteretic) transition between a laminar regime and turbulent regime at a precession ratio (or Poincaré number) of around 0.1. Combining numerical simulations with experimental results from a 1:6 downscaled water experiment, this transition was shown to rely on the modified flow rotation profile just becoming Rayleigh-unstable, leading to the formation of a secondary Taylor vortex flow in a narrow window of the precession ratio. It is this Taylor vortex flow, together with the overall rotation and the basic forced m=1 Kelvin mode, which appears to be well suited for dynamo action. Present simulations with a kinematic dynamo code [10] point to a critical magnetic Reynolds number of around 430, which is safely below the technically reachable value of 700. Further detailed experimental and numerical investigations, including the flow structures at further nutation angles between 135° and 45° degrees, will refine the predictions for the large-scale experiment.

---

EXPERIMENTS ON MRI, TI, AND THEIR COMBINATIONS

The second largest experiment in the framework of DRESDYN is a versatile liquid sodium Taylor-Couette experiment for the study of various forms and combinations of MRI and TI. While its design parameters will allow for attaining standard MRI, there is much interesting physics to be studied in the region between the helical MRI and standard MRI, or between azimuthal MRI and TI, for that matter. It remains to be seen whether the recently discovered new form of helical MRI for flows with positive shear [11], which may be highly relevant for the near-equator regions of the solar tachocline, can also be investigated in this experiment.

CONCLUSIONS AND PROSPECTS

DRESDYN builds on the success of recent liquid metal experiments dedicated to dynamo action and magnetically triggered flow instabilities and tries to stretch the relevant parameters to the edge of technical manageability, thereby aiming, in particular, at the experimental demonstration of dynamo action in a truly homogeneous fluid, and at the transition from helical MRI to standard MRI. However, DRESDYN, with its entire sodium and safety infrastructure, is also a flexible platform for further installations, with a large Rayleigh-Bénard experiment under the influence of rotation and/or magnetic fields being one of the most obvious options.

HEAT TRANSFER IN LIQUID METAL DUCT FLOWS UNDER A STRONG UNIFORM MAGNETIC FIELD

Gregory J. Sheard
Department of Mechanical and Aerospace Engineering, Monash University, Melbourne, Australia

Summary Numerical simulation of fluid flow and heat transfer within ducts under a strong, uniform magnetic field is reported, motivated by the need for effective transport of heat from future magnetic confinement fusion reactors. The propensity of the flow to two-dimensionalise in the field direction permits employment of a computationally efficient quasi-two-dimensional model. Heat transfer is enhanced through the inclusion of physical obstacles within the duct designed to invoke convective heat transport. Electrically driven vortices are a promising alternative to physical obstacles, reducing duct pressure drop. Linear optimal growth analysis informs an active mechanism for increased heat transport behind a duct obstacle. Finally, three-dimensional quasi-static low magnetic Reynolds number simulations reveal the shift to quasi-two-dimensional dynamics with increasing Hartmann number.

INTRODUCTION

Hydrogen fusion powers our sun and stars throughout the universe, and has long stood as a tantalising cleaner and safer alternative to nuclear fission for terrestrial power generation. One technology being explored as an avenue towards viable fusion power generation is magnetic confinement, in which very strong magnets confine a hot plasma of the heavier hydrogen isotopes deuterium and tritium sufficiently to facilitate a fusion burn.

The ultimate goal is to harness the emitted heat to produce steam for electricity generation, which could be achieved using heat exchange principles involving coolant flow within ducts surrounding the reactor. Furthermore, the global scarcity of tritium necessitates its production as part of a viable reactor system. This can be achieved via a breeder reaction involving the bombardment of lithium with neutrons released from the fusion reaction (the helium-cooled lithium-lead, HCLL, breeding module to be trialled in the forthcoming ITER reactor is an example, in which a hot liquid lithium-lead alloy flows through ducts facing the plasma). The strong confining magnetic fields dampen and laminarise the flow, inhibiting heat transfer within ducts. This problem motivates the presented research, which seeks to investigate mechanisms for heat transfer enhancement within liquid-metal duct flows under strong magnetic fields.

METHODOLOGY

Given velocity and length scales U and L, this work assumes a small magnetic Reynolds number ($Re_m = UL/\eta$, where magnetic diffusivity $\eta = 1/\mu\sigma$, magnetic permeability is μ and electrical conductivity is σ), such that the magnetic field within the flow is approximately the surrounding uniform field $\boldsymbol{B}$. For a field acting orthogonal to two of the duct walls, Hartmann layers will form having thickness scaling with Ha^{-1}, where Hartmann number $Ha = aB\sqrt{\sigma/\rho\nu}$. Here a is the distance between the Hartmann walls, ρ the fluid density and ν its kinematic viscosity. Where it can be assumed that both the Hartmann number and interaction parameter (representing the ratio of electromagnetic to inertial forces) $N = \sigma B^2 a/\rho U$ are well in excess of unity, [1,2] demonstrate that outside of the Hartmann layers, these flows two-dimensionalise in the magnetic field direction. This permits the three-dimensional duct flow to be solved on a two-dimensional domain, with Hartmann layer friction captured via the addition of a linear braking term in the (two-dimensional) momentum equation. This will be referred to as the SM82 model hereafter. Heat transport is simulated via an advection-diffusion equation. The contributions of viscous dissipation and Joule heating are assumed to be insignificant and are neglected. Where $Ha \gg 1$ or $N \gg 1$ cannot be assumed, full three-dimensional direct numerical simulation using the quasi-static MHD approximation valid for low magnetic Reynolds numbers ($Re_m \ll 1$) is performed. This introduces the electric potential field ϕ.

Flows are predominantly computed using an in-house solver employing a nodal spectral element method on a conforming grid of high-order quadrilateral elements. Three-dimensional quasi-static MHD simulations employ a spectral element discretisation of across the duct cross-section and a periodic Fourier spectral discretisation in the flow direction. Time integration is via a third-order accurate backwards differentiation operator-splitting scheme [3].

RESULTS

To begin, flow in a duct under the SM82 model is computed, with a cold inflow and one hot duct side-wall. Various obstacles and duct widths (transverse to the field direction) are computed, and a range of Reynolds numbers and Hartmann numbers are considered. As reported in [4], a cylindrical obstacle with circular cross-section and axis aligned with the magnetic field is placed in ducts of several blockage ratios (β). Heat transfer was strongly dependent on Re, Ha and β, with the inception of vortex shedding producing a significant uplift in heat transfer (Nusselt number Nu), as demonstrated in Figure 1. This work was developed in [5], identifying an optimal gap between the obstacle and the hot duct wall. Following this, an obstacle of rectangular cross-section is considered [6], in which orientation angle and hot-wall gap ratio are optimised for further enhancement in heat transfer. A comparison between three representative obstacle shapes (circular, square and triangular) is conducted [7], where it is found that the triangular cross-section produces superior heat transfer enhancement.

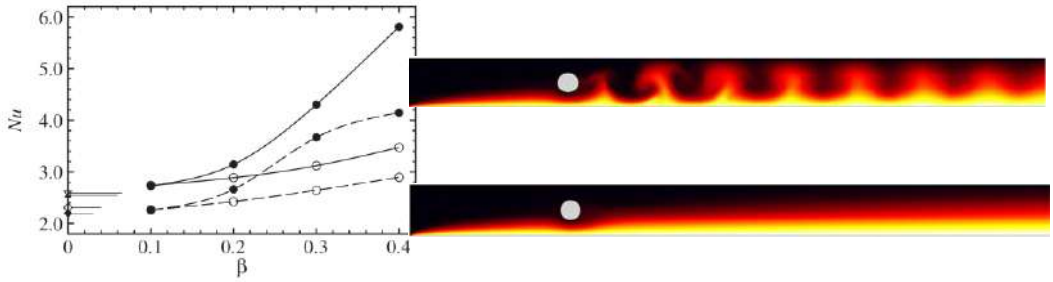

Figure 1. Nusselt number dependence on blockage ratio (β) at $Re = 2000$ (dashed lines) and $Re = 3000$ (solid lines). Inset contour plots of temperature (flow left to right) demonstrate that the uplift in heat transfer is due to mixing induced by vortex shedding convecting hot fluid into the core of the duct at low and high Ha.

An unusual property of these quasi-two-dimensional MHD flows is that electric current injected from an electrode embedded in one of the Hartmann walls spreads radially from the electrode over the Hartmann wall, driving rotation in a two-dimensional column of fluid across the core. An alternating current can then be tuned to produce a vortex street [8,9]. Electrically generated vortex streets are found to be effective for heat transfer enhancement, additionally avoiding the pressure drop penalty created by a physical obstacle. Given the prominent role of vortex shedding in enhancing heat transfer, and the increased suppression of vortex shedding at higher Ha, a linear transient growth analysis is used to better understand the optimal initial disturbances maximising kinetic energy growth over short time intervals [10,11]. A model for wake vortex decay is constructed, revealing conditions where viscous dissipation or Hartmann braking dominate [12].

The role of natural convection on the stability of SM82 duct flows is considered using a one-dimensional linear stability analysis [13]. Finally, an optimal growth analysis of three-dimensional quasi-static MHD duct flow [14] demonstrates the striking fidelity of the SM82 model at high Ha, and reveals the morphology from low-Ha hydrodynamic behaviour to high-Ha quasi-two-dimensional behaviour.

ACKNOWLEDGEMENTS

INTERACTIONS BETWEEN TWO BUBBLES RISING SIDE BY SIDE UNDER THE INFLUENCE OF MAGNETIC FIELD

Jie Zhang*[1] and Mingjiu Ni[2,1]
[1]State Key Laboratory for Strength and Vibration of Mechanical Structures, School of Aerospace, Xi'an Jiaotong University, Xi'an 710049, China
[2]School of Engineering Science, University of Chinese Academy of Sciences, Beijing, China

Summary A series of 3D numerical results are reported about the interactive behaviors between a pair of bubbles rising side by side in the liquid metal, and different magnetic fields are imposed to investigate the magnetohydrodynamics effects on the bubble interactions. It is observed that while a streamwise magnetic field always lead a bounced bubble pair to coalescence, however a horizontal magnetic field has an anisotropic effect on the bubble interaction depending on the direction of the field, particularly, a spanwise magnetic field has an non-monotonous influence on the bubble interaction while a transverse one always spur the two bubble to coalesce. A detailed investigation indicates different bubble interactions come from different vortex evolutions in magnetic fields.

INTRODUCTION AND NUMERICAL METHODS

In the metallurgical industry, external magnetic fields (MFs, hereafter) are one of the rare potential tools to control the motion of bubble plume which are used for metallurgical refining or smelting, objective to homogenize the physical and chemical properties of the liquid metal. Consequently, the combination of external MFs and gas bubble injections enables the liquid metal to produce an optimized environment for the final product quality. Nevertheless, the understanding of such bubbly flows under magnetohydrodynamics (MHD, hereafter) effect is far from satisfactory, and more seriously, how an external MF affect the interactions between the one bubble pair is unclear yet. Previously in ordinary fluids without MFs[1], our numerical results indicate that the increased shear inside the gap between the bubble pair will promote the strength of the double-threaded vortices, which would finally produce a lift force to cause the bubble pair to bounce. This finding, which confirms the importance of the vortex interactions during the bubble collisions, implies that the external MFs will have great influences on the bubble interactions because the vortex structures are known to be sensitive to the MF directions and strengths[2, 3].

Physically, the incompressible bubble flows under the influence of an external MF are governed by the combination of Navier-Stokes equations and the Maxwell equations, and a Lorentz force term is produced due to the coupling of the flow field and the magnetic field, given that $\boldsymbol{F}_l = \boldsymbol{J} \times \boldsymbol{B}$, where $\boldsymbol{J}$ denoting the induced current density and $\boldsymbol{B}$ being the external MF. Note that $\boldsymbol{J}$ is obtained from Ohm's law, given that $\boldsymbol{J} = \sigma_e(-\nabla\varphi + \boldsymbol{u} \times \boldsymbol{B})$ where σ_e being the electric conductivity and φ representinng the induced electric potential, φ is calculated by solving the electric potential Poisson equation due to the divergence-free condition of $\nabla \cdot \boldsymbol{J} = 0$. Typical dimensionless parameters are the Reynolds number (Re), the Weber number (We), the Gallilei number (Ga) and the Bond number (Bo), besides, a variant interaction number of $N_o = \sigma_e B^2 D/\rho u$ is used to characterize the strength of the MF, where D is the bubble diameter and $u = \sqrt{gD}$ is the characteristic velocity.

The numerical solver is as the same as that used in our previous study[1], that a volume-of-fluid approach is used for the interface tracking, and an adaptive mesh refinement (AMR) technique is used to capture the interface more accurately during the bubble motion. Note that besides a spatial resolution of $\Delta_i = D/60$ is set close to the bubble interface, additional local refinement is imposed in vicinity of the thin film between the bubble pair until a minimum mesh size of $\Delta_f = D/400$ is reached, and we will let the two bubbles coalesce numerically if the thickness of the film is thinner than this threshold. Two bubbles with a diameter of $D = 3mm$ are released freely at the bottom of the container which filled with liquid metal GaInSn, then the bubbles will rise under gravity that the shape deformation is permitted. With the help of this numerical tool, we will investigate the interactive behaviors between the bubble pairs when different magnetic fields are imposed externally, and more importantly, the role of the vorticity it plays in the interaction is studies in more details.

RESULTS

Firstly, the influences of the streamwise MF on the interactions between a pair of bubbles are presented, and the MF strength is varied within $N = 0$, $N_y = 0.09$, $N_y = 0.20$ and $N_y = 0.80$, while the corresponding rising trajectories of the bubble pair are presented in Fig. 1. In case of $N = 0$, the two bubbles bounce off at $H = 5.5$, however, if the magnetic field is as strong as $N \geq 0.09$, the two bubbles will coalesce instead of bounce, and clearly, the coalescence height is decreasing with intensified streamwise MFs. It means the streamwise MF weakens the collision between the two bubbles. As already verified previously[1], the bubble interaction is closely related to the vortex developments during bubble the approaching, and strong vortex interactions will produce greater lift force to make the bubble bounce off, otherwise the two bubbles will coalesce. Consequently, the vortex evolutions under the influence of streamwise MF are also studies, as plot in Fig. 2 whereas the dark and light contours denote $\omega_y = \pm 2.0$ repectively. It is clearly observed that streamwise MF tends to reduce the streamwise vortices, and thus the vortex interactions are significantly weakened that the bubble pair is coalesced instead of bouncing.

*Corresponding author. E-mail: j_zhang@xjtu.edu.cn

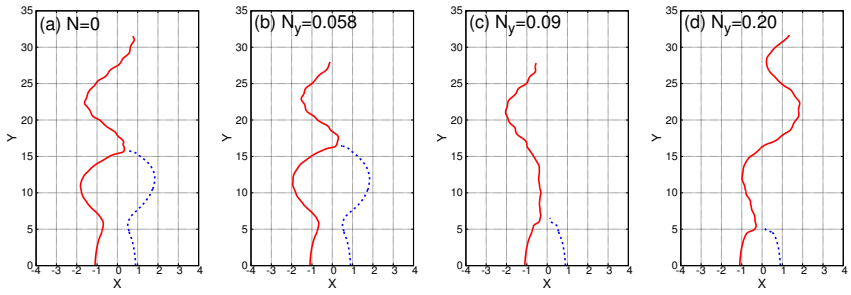

Figure 1: Rising paths of the bubble pairs exposed to different streamwise MFs, within a wide parameter spaces from $N = 0$ to $N_y = 0.80$. With an intensified streamwise MF, it is observed the interactions between the bubble pair to change from bounce to coalescence, indicating that the MF tends to weaken the interactive strengths.

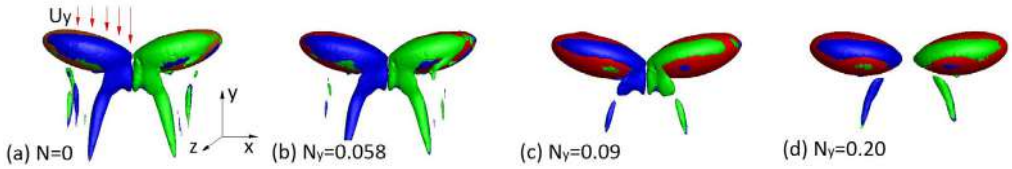

Figure 2: Streamwise vortices behind the bubble pairs at the "kissing" moment while the streamwise MF is varied between $N = 0$ and $N_y = 0.20$, and the iso-contours correspond to $\omega_y = \pm 1$. It is clear that the streamwise MF tends to weaken the double-threaded vortices behind the bubble pair, so that the bubble interaction is also diminished.

On the other hand, the influences of the spanwise (transverse) MF are also studies that the B-lines are parallel (perpendicular) to the line connecting the bubble centroid. The rising trajectories of the bubble pair indicate that the MHD effects are totaly different depending on the field direction, a weak-to-moderate spanwise MF makes the interaction between two bubbles change from bouncing to coalescence, however, a strong spanwise MF cause them to bounce or even repel again. In contrast, the transverse MF always spurs the two bubble to coalesce instead of repelling. After that, detailed investigations are carried out on the vortex evolutions during the bubble motion, and the mechanisms produing such anisotropic effects are detected. It implies developments of the vortices comply to the MHD theory[2, 3], which reveals the vorticity diffusion along the B-lines is enhanced so that a spanwise MF induces much stronger vortex interaction along the B-Lines, consequently, a strong spanwise MF causes the two bubbles to repel rather than coalescence. In contrast, the vortex interaction inside the gap between the two bubbles is nearly uninfluenced, so that the more spheroidal shape under transverse MF makes the bubble pair to coalesce.

TWIST EFFECTS ON THE EVOLUTION OF KNOTTED FLUX TUBES

Yue Yang*[1] and Shiying Xiong [1]
[1]State Key Laboratory for Turbulence and Complex Systems, College of Engineering, Peking University, Beijing 100871, China

Summary We develop a general method for constructing knotted flux tubes with the finite thickness, arbitrary shape and tunable twist. The helicity of the corresponding knotted field can be explicitly decomposed into the writhe, localized torsion and intrinsic twist. We construct several knotted magnetic flux tubes with various twisting degrees, and reveal twist effects on their evolution in resistive magneto-hydrodynamics flows using direct numerical simulation. The magnetic knot gradually shrinks to a tight stable state for large twist, whereas it splits at early times for small twist. The mechanism of the tube split is then elucidated using the phase portrait of the Lorentz force projected onto divergence-free space.

INTRODUCTION

Understanding the configuration and evolution of magnetic structures in magneto-hydrodynamics (MHD) flows is of fundamental importance for the device design and stability analysis in nuclear fusion and the corona dynamics in astrophysics. The knotted flux tube is a typical magnetic configuration with nontrivial topology and relatively simple geometry, so it is often used for investigating essential dynamics in MHD flows. For characterizing knotted fields, the helicity H is a topological measure of linking and knotting of field lines. In the present study, we extend the methods of Gold and Hoyle [1] and Xiong and Yang [2] to construct knotted flux tubes with the arbitrary shape and tunable twist. The constructed vector fields can be used as the initial magnetic field $\boldsymbol{b}$ in the direct numerical simulation (DNS) of MHD flows. In particular, we reveal the effects of the initial twist T_w of field lines on the evolution of trefoil flux tubes, and elucidate the mechanism of topological changes of magnetic fields in resistive MHD.

CONSTRUCTION OF COILED AND TWISTED FLUX TUBES

From the parametric equation of a given smooth and non-degenerate closed curve, we construct a vector field based on a curved cylindrical coordinate system along the curve. The vector has axial and azimuthal components. The axial component is determined by a given kernel function which decays with the radial distance from the curve. The azimuthal component is derived from our proposed constraints. We prove that this vector field is strictly divergence-free, so it can be used as the initial field of a magnetic tube whose central axis is prescribed by the curve. Within the framework of Chui and Moffatt [3], we derive the expression of H for the constructed vector field. This helicity can be explicitly decomposed into the writhe, localized torsion and intrinsic twist [4]. The sum of latter two components is referred to as the "twist" in this paper. Thus we can isolate the effect of each component in the investigation of helicity.

Corresponding to the theoretical construction, we extend the algorithm in Ref. [2] to construct knotted flux tubes with tunable twist in Cartesian coordinates (see Fig. 1). The relative numerical errors in the helicity calculation of trefoil flux tubes with a range of T_w from 0 to 32.48 are negligible on 512^3 unform grid points in a periodic box.

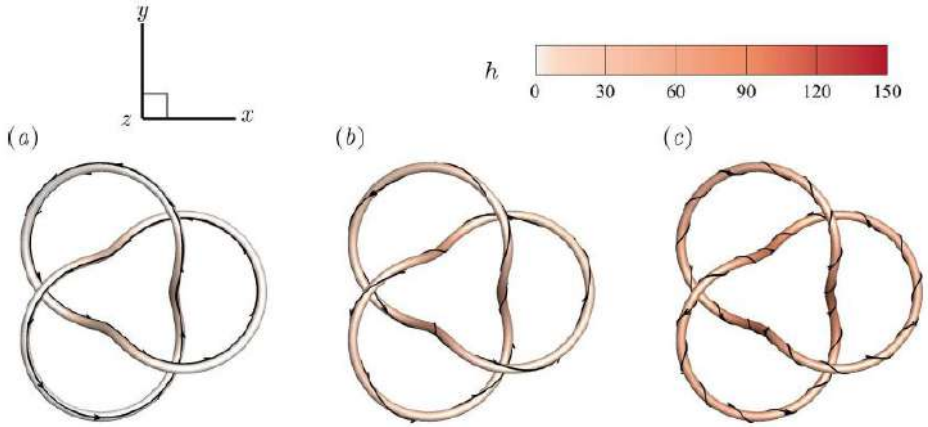

Figure 1. Initial knotted flux tubes with (a) $T_w = 0$, (b) $T_w = 12.48$, and (c) $T_w = 32.48$. The surfaces are color-coded by the helicity density h. Some field lines are integrated on the surfaces.

EVOLUTION OF KNOTTED FLUX TUBES

We use the constructed vector fields as initial magnetic inductions in DNS, and calculate the evolution of trefoil magnetic flux tubes with various T_w in resistive MHD flows. We find that T_w has an impact on the evolution of magnetic

*Corresponding author. E-mail: yyg@pku.edu.cn

knots (see Fig. 2). For large T_w, the magnetic knot gradually shrinks to a tight stable state, similar to the relaxation process in ideal MHD flows. For small T_w, the knotted flux tube splits and reconnects at early times, accompanied by the drastic release of the magnetic energy.

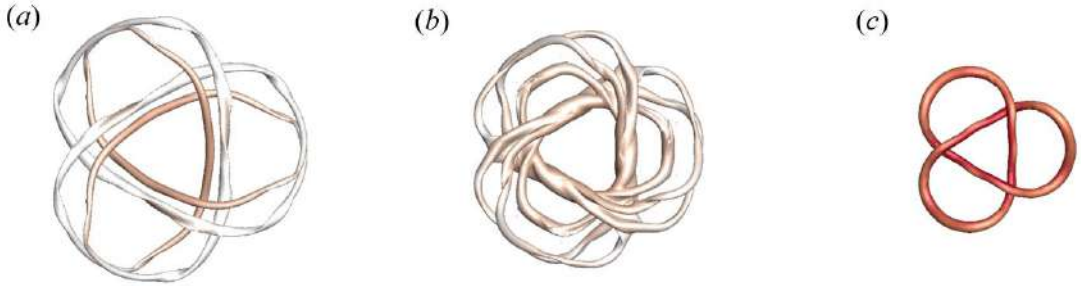

Figure 2. Isosurfaces of $|\boldsymbol{b}|$ in the temporal evolution of trefoil flux tubes with (a) $T_w = 0$, (b) $T_w = 12.48$, and (c) $T_w = 32.48$ at a late time $t = 0.1$. All the isosurfaces are color-coded by the helicity density

The effect of twist on the tube splitting is elucidated by the phase portrait of the Lorentz force $\boldsymbol{f}_p$ projected onto the divergence-free space. The initial counter-rotating $\boldsymbol{f}_p$ drives a bundle of field lines inside the flux tube into two for $T_w = 0$. With increasing T_w, an unstable spiral point of the projected force becomes a limit cycle via the Hopf bifurcation. The field lines inside the limit cycle form invariant tori, whereas the field lines outside the limit cycle become chaotic (see Fig. 3). The split of flux tubes and the chaotic rearrangement of field lines for low T_w lead to the rise of the magnetic dissipation rate.

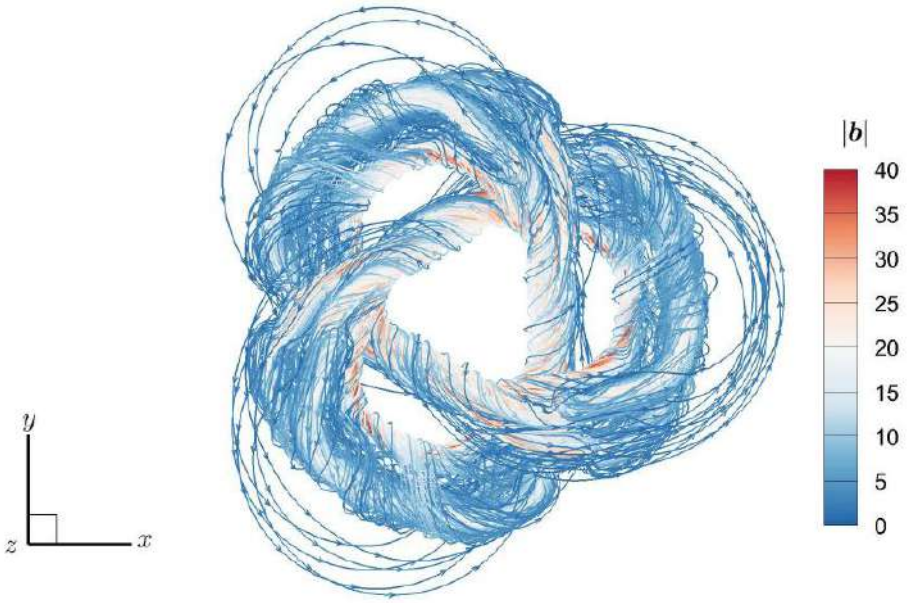

Figure 3. A chaotic field line color-coded by $|\boldsymbol{b}|$ for the magnetic knot with $T_w = 12.48$ at a late time $t = 0.04$ in the evolution.

CONCLUSIONS

We develop a novel method for constructing knotted flux tubes with the finite thickness, arbitrary shape and tunable twist. The central axis of the knotted tube is specified by a smooth and non-degenerated parametric equation, and the helicity of the corresponding knotted field can be explicitly decomposed into the writhe, localized torsion and intrinsic twist. We construct several knotted magnetic flux tubes with various T_w, and investigate the effect of twist on their evolution in resistive MHD flows using DNS. For large T_w, the magnetic knot gradually shrinks to a tight stable state, similar to the relaxation process in ideal MHD flows. For small T_w, the knotted flux tube splits at early times, accompanied by the rise of the magnetic dissipation rate. We find that the Hopf bifurcation of $\boldsymbol{f}_p$ from an unstable spiral point to a limit cycle occurs on the phase plane for finite T_w. In the evolution, field lines inside the limit cycle form invariant tori, whereas they become chaotic outside the limit cycle.

INTERPLAY OF SOLUTAL CONVECTION AND ELECTROMAGNETICALLY DRIVEN FLOWS IN LIQUID METAL BATTERY ELECTRODES

Tom Weier*[1], Steffen Landgraf[1], Michael Nimtz[1], Paolo Personnettaz[1], Norbert Weber[1], and Donald Sadoway[2]
[1]Helmholtz-Zentrum Dresden - Rossendorf, Bautzner Landstr. 400, 01328 Dresden, Germany
[2]Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA

Summary Mass transfer in the positive electrode is one of the main factors determining the efficiency of liquid metal batteries. While solutal convection is quite intense during charge, discharge rates are limited by diffusion into a stable density stratification. The resulting concentration polarization can be substantially reduced if electrodynamically driven flows are employed to stir the liquid alloy. This leads to marked improvements in battery performance.

INTRODUCTION

The quest for renewable energy sources entails an increasingly intermittent electricity supply due to the limited potentials of hydropower and biomass that leave basically wind and solar power as options for expanding generation capacity. Since transition grid updates can only partially account for balancing the resulting variations, large-scale stationary storage will gain importance in future energy landscapes dominated by volatile sources.

Given the massive storage capacity needs, its efficiency should be maximized, cost per unit storage should be minimized and storage devices have to be made from abundant and cheap materials. Batteries typically show high energy efficiencies compared to other options and can be flexibly sited, but they have a relatively high price per unit stored energy, are usually of complex construction and often depend on materials of limited availability. Today's battery technologies were, with the notable exception of redox-flow batteries, mainly designed for and driven by mobile applications. Those prioritize properties (energy density, power rating) that are less important for stationary storage. Thus, while particularly Li-ion technologies have shown enormous progress during recent years especially in terms of specific energy and energy specific price, battery technologies developed from the ground up to meet the needs of stationary storage have the potential to much better address the specifics of huge capacity installations.

Liquid metal batteries (LMBs) are a new technology for grid-scale energy storage, see [1] for a comprehensive review. They consist of all liquid cells that operate with liquid metals as electrodes and molten salts as electrolytes. The liquids separate into three stably stratified layers by virtue of density and mutual immiscibility (see the two upper left inserts in Fig. 1a). This conceptually very simple and self-assembling structure has the unique advantage to allow for an easy scale-up at the cell level: single-cell cross sections can potentially reach several square-meters. Such cell sizes enable highly favourable and otherwise unattainable ratios of active to construction material because of the cubic scaling (volume) of the former and the quadratic scaling (surface) of the latter. The total costs should therefore largely be determined by those of the active materials.

While mass transport in most modern battery systems is typically dominated by diffusion and migration in micrometer-scale liquid layers and solids, convection - with exception of the aforementioned redox-flow batteries - rarely plays a role. This is in stark contrast to LMBs were mediated by the fully liquid interior fluid flow can be driven by various mechanisms and has a strong influence on cell performance and operational safety [2]. Electric currents, magnetic fields, and heat and mass transfer are tightly coupled with the cells' electrochemistry. We will concentrate here on the influence of solutal convection in the positive electrode on the cycling behaviour of a cell and on the application of electromagnetically induced convection to improve mixing.

EXPERIMENTAL AND NUMERICAL RESULTS

In the absence of electromagnetic effects and without artificial stirring, natural convection remains as the only source of fluid motion. The bottom of the small cell shown in the top left insert of Fig. 1a is heated keeping the cells' core temperature at 460 °C. To prevent side-reactions the open cell is located in a glove box who's argon atmosphere is at room temperature [3]. The unstable temperature gradient thus created would drive convection. During charge transfer, however, mass transport competes with temperature driven convection. LMBs combine low density, alkaline or earth alkaline metals for the negative electrode (anode; Li in our case) with high density, post-transition metals or metalloids for the positive electrode (cathode; Bi in our case). Cathode metal densities are typically an order of magnitude larger than anode metal ones. In comparison, thermal expansion coefficients are quite small and due to the good thermal conductivity of metals temperature differences tend to be smoothed out quickly. Thus, compositional (i.e. solutal) gradients should dominate over thermal ones and constitute the primary cause or inhibitor of motion in the positive electrode [2].

In the discharged state, the positive electrode consists of a Li-Bi alloy. When charging the cell, low density Li is removed from the top of the positive electrode. This increases locally the density of the alloy and Li-depleted alloy starts to sink down in plumes. Rapidly, solutal convection drives a flow in the whole cathode and intensely mixes the remaining alloy. A snapshot of the concentration distribution and velocity vectors is shown in the lower left insert of Fig. 1a. In

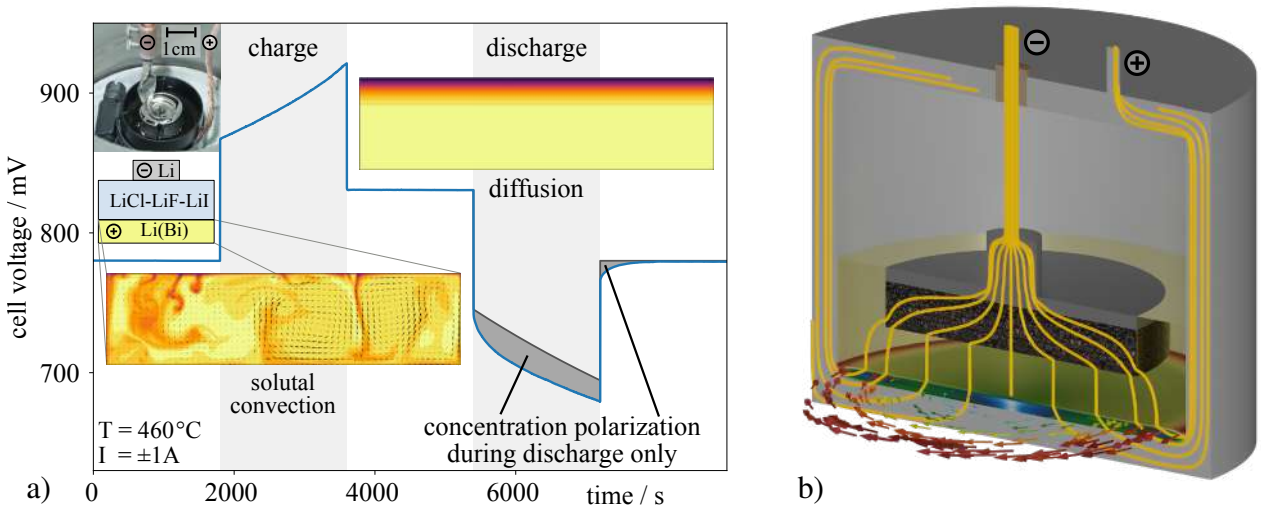

Figure 1: a: Cell voltage during a charge/discharge cycle with intermediate relaxation steps (blue curve) and Li concentration in a section of the positive electrode (insets). b: Exemplary full cell simulation in the presence of a vertical magnetic field with streamlines of the electric current (yellow) in the meridional plane, vectors of the flow velocity in a cross section of the positive electrode and Li concentration in the positive electrode (surface and meridional plane, red: high, blue: low).

thermal convection the analogous effect is sometimes termed 'self-stirring' [4].

LMBs can be understood as concentration cells whose open circuit voltage (OCV) is determined by the activity of the anode metal (Li) in the cathodic alloy (Li(in Bi)) directly at the interface with the electrolyte. During charge, the well mixed cathode guarantees the minimum Li concentration and thereby activity at the interface at every moment. In consequence, only the ohmic resistivity of the electrolyte generates an overvoltage. It results in a shift of the cell potential by a virtually constant value with respect to the OCV. When entering the relaxation step after switching off the charging-current, the cell voltage returns almost instantaneously to the OCV.

During discharge the situation is completely different. Low density Li is deposited on top of the high density cathodic alloy. The stratification is stable and inhibits mixing. The only remain transport mechanism is diffusion. In addition to the ohmic overvoltage, a diffusion overvoltage has now to be overcome that grows with time. After the end of discharge, the cell voltage relaxation happens gradually and with a time response that is again typical for diffusion phenomena.

Obviously, overvoltages diminish cell performance and should be reduced or ideally completely avoided. In addition, disproportionally high alkali or earth alkali metal concentrations in the cathodic alloy can lead to the formation of intermetallics. Depending on the materials combination used, those might be mostly harmless but could in other cases even seriously damage cell integrity. A remedy for these problems can be the application of Lorentz forces that would act as a source of momentum thereby offering a contactless way to stir the alloy. The cell current alone can generate electro-vortex flows. Their shape and magnitude depends on the design of the current collectors and of the feed line contacts. However, overcoming the stable solutal stratification is still a challenge. To improve mixing, addition of a vertical magnetic field component, i.e. by using loops in the feed lines, can be very effective. The resulting swirling flow driven by such a configuration in a numerical model of the 10 cm-diameter Li-Bi cell of Ning et al. [5] is shown in Fig. 1b. As can be inferred from the filled contours showing the Li concentration in the positive electrode, concentration differences do still exist, but regions of high concentration (red) are limited to the cathodes' rim. Mass transport overpotential during discharge can thereby decreased to a few millivolts.

CONCLUSIONS

Liquid metal batteries are a promising concept for large-scale stationary electricity storage. Fluid mechanics can provide valuable insights to optimize cell characteristics. Solutal convection in the positive electrode of an LMB is favorable during charge and enables fast charging. Without additional measures, diffusion overvoltages can arise during high-rate discharge, diminishing cell performance. Electromagnetic stirring is a proper means to improve mixing and to counteract diffusion limitation thereby increasing the cell's energetic efficiency.

AXISYMMETRIC VISCOUS MHD FLOW ABOUT A SOLID SPHERE TRANSLATING IN A CYLINDRICAL TUBE

Antoine Sellier*[1] and Selçuk Han Aydin[2]
[1]LadHyX, Ecole Polytechnique, 91128 Palaiseau cedex, France
[2]Department of Mathematics, Karadeniz Technical University, 61080 Trabzon, Turkey

Summary The quasi-steady Stokes MHD flow about a solid insulating sphere translating in a conducting quiescent liquid, bounded by a motionless insulating cylindrical tube and subject to of a uniform ambient magnetic field, is considered. The sphere center is located on the tube axis which is parallel to the magnetic field and the sphere velocity. The axisymmetric fluid velocity and pressure fields are numerically obtained by inverting a boundary-integral equation governing the stress exerted by the flow on the sphere surface, a truncated part of the tube and two far-enough tube cross sections. This key step appeals to two fundamental free-space axisymmetric Stokes MHD flows produced by distributing point forces on a circular ring and obtained elsewhere. For given tube and sphere, the MHD flow is found to deeply depend on the problem Hartmann number Ha based on the sphere radius.

We consider (see figure 1) the quasi-steady Stokes MHD flow about a solid insulating sphere, with radius a and surface S, translating at the velocity $U\mathbf{e}_z$ in a conducting and quiescent Newtonian liquid confined by a cylindrical motionless insulating tube Σ with radius R. The liquid is subject to a uniform steady magnetic field $B\mathbf{e}_z$ which is parallel with the tube axis of revolution to which the sphere center O belongs.

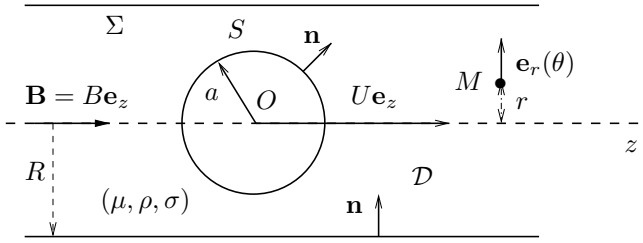

Figure 1: A solid insulating sphere translating, at the velocity $U\mathbf{e}_z$, parallel to a uniform magnetic field $\mathbf{B}$, in a conducting Newtonian liquid confined by a motionless cylindrical insulating tube. The sphere center O is located on the tube axis of revolution.

Assuming a low-Reynolds-number flow and sphere and liquid with equal uniform magnetic permeability ensures that the magnetic field is undisturbed by the sphere and thus equal to $B\mathbf{e}_z$ in the entire liquid domain $\mathcal{D}$. The flow, axisymmetric about the tube axis and without swirl, has velocity $\mathbf{u}(\mathbf{x}) = u_r(r,z)\mathbf{e}_r + u_z(r,z)\mathbf{e}_z$ and pressure $p(\mathbf{x}) = p(r,z)$ with (r,z,θ) the usual cylindrical coordinates and $\mathbf{x} = r\mathbf{e}_r + z\mathbf{e}_z$ (the unit local vector $\mathbf{e}_r(\theta)$ is shown in figure 1). Because both surfaces S and Σ are insulating and the magnetic field is uniform, there is no electric field in the liquid [1, 2, 3, 4]. Accordingly, the quasi-steady viscous flow $(\mathbf{u}, p)$ obeys the following MHD problem

$$\mu\nabla^2\mathbf{u} = \nabla p - \sigma B^2(\mathbf{u}\wedge\mathbf{e}_z)\wedge\mathbf{e}_z \text{ and } \nabla.\mathbf{u} = 0 \text{ in } \mathcal{D}\ , \tag{1}$$

$$\mathbf{u} = U\mathbf{e}_z \text{ on } S,\ \mathbf{u} = \mathbf{0} \text{ on } \Sigma,\ (\mathbf{u},p)\to(\mathbf{0},0) \text{ as } |\mathbf{x}|\to\infty \tag{2}$$

where $\sigma > 0$ and μ denote the uniform liquid conductivity and viscosity, respectively. The flow, with stress tensor $\boldsymbol{\sigma}$, exerts on the sphere surface S, where the unit normal pointing into the liquid is $\mathbf{n}$, the stress $\mathbf{f} = \boldsymbol{\sigma}\cdot\mathbf{n} = f_r(r,z)\mathbf{e}_r + f_z(r,z)\mathbf{e}_z$. Thus, the sphere experiences no torque about its center and a force $\mathbf{F}$, parallel to its translational velocity $U\mathbf{e}_z$, given by

$$\mathbf{F} = \int_S \mathbf{f}dS = [2\pi\int_{\mathcal{C}} f_z(P)r(P)dl(P)]\mathbf{e}_z = -6\pi\mu a\lambda U\mathbf{e}_z,\ \lambda = \lambda(R/a, \mathrm{Ha}). \tag{3}$$

In (3), the contour $\mathcal{C}$ is the half-circle trace of S in the $\theta = 0$ half plane and $\lambda > 0$ designates the so-called drag coefficient. Here, λ solely depends on the tube-sphere size ratio R/a and on the Hartmann number $\mathrm{Ha} = d/a$ which compares the Hartmann layer thickness $d = (\sqrt{\mu/\sigma})/|B|$ (see [5, 6, 7]) with the sphere radius a. Note that $\lambda = 1$ for $a/R = \mathrm{Ha} = 0$.

For a given truncation length $L > a$ the bounded liquid domain $\mathcal{D}_L$ is the set of points of $\mathcal{D}$ for which $|z| < L$. The trace of the boundary $\partial\mathcal{D}_L$ in the half $\theta = 0$ plane is the half-circle $\mathcal{C}$ plus a polyline $\mathcal{C}_L$ of obvious definition. Then, (1)-(2) is replaced with (1) in $\mathcal{D}_L$, $\mathbf{u} = U\mathbf{e}_z$ on S and $\mathbf{u} = \mathbf{0}$ on $\partial\mathcal{D}_L\setminus S$. The worked out procedure appeals, for each point $(\mathbf{x})(r,\theta,z)$ located in $\mathcal{D}_L$, to basic boundary integral representations of u_r, u_z and p. These key representations, derived as done in [4] for the unbounded liquid case, involve the stress $\mathbf{f}$ on $\mathcal{C}\cup\mathcal{C}_L$. More precisely,

$$u_\alpha(\mathbf{x}) = -\frac{1}{8\pi\mu}\sum_{\beta=r,z}\int_{\mathcal{C}\cup\mathcal{C}_L} G_{\alpha\beta}(M,P)f_\beta(P)r(P)dl(P) \text{ for } \alpha = r,z \text{ and } \mathbf{x} \text{ in } \mathcal{D}_L\cup S\cup\partial\mathcal{D}_L, \tag{4}$$

$$p(\mathbf{x}) = -\frac{1}{8\pi}\sum_{\beta=r,z}\int_{\mathcal{C}\cup\mathcal{C}_L} P_\beta(M,P)f_\beta(P)r(P)dl(P) \text{ for } \mathbf{x} \text{ in } \mathcal{D}_L \tag{5}$$

*Corresponding author. E-mail: sellier@ladhyx.polytechnique.fr

with $M(r,z)$ the point of the $\theta = 0$ half plane associated to $\mathbf{x}(r,z,\theta)$ and both Green quantities $G_{\alpha\beta}(M,P)$ and $P_\beta(M,P)$ analytically obtained in [8] in terms of $z - z(P), r, r(P)$ and the Hartmann layer thickness d [5]. Then, enforcing the boundary velocity conditions $\mathbf{u} = U\mathbf{e}_z$ on $\mathcal{C}$ and $\mathbf{u} = \mathbf{0}$ on $\mathcal{C}_L$ yields, using (4), coupled boundary-integral equations for the unknown stress components f_r and f_z on $\mathcal{C} \cup \mathcal{C}_L$. These integral equations are numerically inverted by a collocation method which resorts to quadratic curved boundary elements and N nodal points on $\mathcal{C} \cup \mathcal{C}_L$. Once the stress components f_r and f_z are gained both integral representations (4)-(5) are subsequently employed to efficiently compute the required flow (u_r, u_z, p) in the truncated liquid domain $\mathcal{D}_L$. For given $(R/a, \mathrm{Ha})$, the computed drag coefficient λ sensitivity to both N and the truncation length L is carefully investigated. The values of λ for vanishing Ha have also been convincingly compared with the predictions given in [9] for the pure Stokes flow (absence of magnetic field) case.

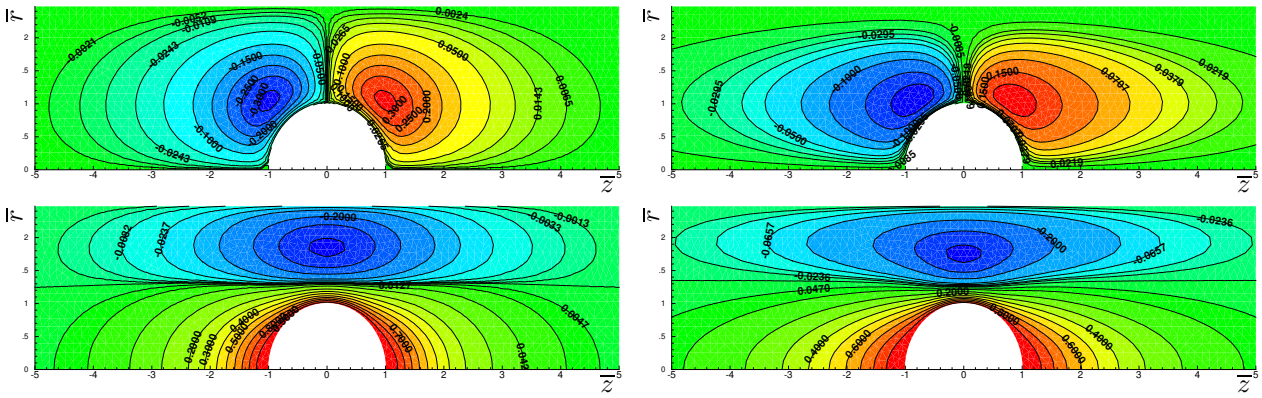

Figure 2: Isolevel curves of the normalized radial velocity u_r/U (top) and axial velocity u_r/U (bottom) for $\mathrm{Ha} = 1$ (left) and $\mathrm{Ha} = 5$ (right). Here $R/a = 2.5$. The selected number of nodal points N and truncation length are $N = 266$ and $L = 7.5a$.

Figure 2 provides for $R/a = 2.5$ and $\mathrm{Ha} = 1, 5$ the isolevel curves of the normalized radial and axial velocities $\overline{u}_r = u_r/U$ and $\overline{u}_z = u_z/U$ in the region $\overline{r} = r/a \leq 2.5$ and $\overline{z} = z/a$ in $[-5, 5]$. The radial component $\overline{u}_r$ vanishes on the sphere and on the tube, quickly decays away from the $(O, \mathbf{e}_z)$ tube axis and remains small especially outside two pockets close the sphere. As Ha increases the previous pockets extends upstream $(\overline{z} > 0)$ and downstream $(\overline{z} < 0)$. The normalized axial velocity $\overline{u}_z$ is positive nearly in a domain $\overline{r} \leq \overline{r}_c$ with $\overline{r}_c$ close to 1.3 and weakly sensitive to Ha. As expected, $\overline{u}_z$ takes the unit value on the sphere and vanishes on the tube. Moroever, its magnitude is less than unity in the entire liquid domain. As Ha increases the regions near the sphere where $\overline{u}_z$ exceeds 0.3 extend away both upstream and downstream the sphere close the $\overline{r} = 0$ axis. As also illustrated in figure 2, each velocity component is strongly sensitive to the value of the Hartmann number.

The drag coefficient values obtained for the flows considered in figure 2 are $\lambda = 3.67$ for $\mathrm{Ha} = 1$ and $\lambda = 5.03$ for $\mathrm{Ha} = 5$. Actually, λ is found to be nearly insensitive to $\mathrm{Ha} \leq 1$ for this size ratio $R/a = 2.5$ ([9] gives $\lambda = 3.60$ for $\mathrm{Ha} = 0$). Finally, our computations (not presented here) also reveal that, not surprisingly, λ increases as R/a decreases (confinement effect) for given Ha. For instance, for the unbounded liquid case addressed in [4] one gets $\lambda = 1$ for $\mathrm{Ha} = 0$, $\lambda = 1.18$ for $\mathrm{Ha} = 1$ and $\lambda = 2.35$ for $\mathrm{Ha} = 5$.

LARGE-SCALE MAGNETIC FIELD GENERATION BY WAVE INTERACTIONS IN HIGHLY CONDUCTING PLASMA

Krzysztof A. Mizerski*[1]
[1]Department of Magnetism, Institute of Geophysics, Polish Academy of Sciences, Warsaw, Poland

Summary It is well known that a field of random waves in a fluid of non-zero resistivity is capable of exciting a large-scale magnetic field through creation of an electromotive force (EMF) which leads to exponential growth of magnetic energy until the growing Lorentz force reacts back upon the wave field, leading to a saturated state. For highly conducting plasma it is generally found that kinematic fast-dynamos with finite growth rate in the limit of vanishing resistivity, have a pathological structure, non-differentiable wherever they are non-zero; the applicability of fast-dynamo theory to natural physical systems is then questionable. Here we relax the standard simplifying assumptions of stationarity of the background turbulence and introduce new fast-dynamo mechanisms, fully dynamic, that is incorporating the back reaction of the Lorentz force on the flow, for which the growing magnetic field remains smooth during the entire dynamo process. This results from a random superposition of waves, perturbed by the magnetic field. Particularly effective are the interactions of beating waves and nonlinear effects in the mean electromotive force. The MHD equations are renormalized to include the nonlinear effects of turbulent fluctuations on the means and the dynamics of the large-scale field is studied.

INTRODUCTION

The mean field theory (cf. Moffatt 1978) is most commonly used to describe large scale magnetic fields in natural systems. It is based on the following induction equation for magnetic field resulting from the Maxwell laws and the Ohms law and averaged over a statistical ensemble

$$\frac{\partial \langle \mathbf{B} \rangle}{\partial t} = \nabla \times (\langle \mathbf{u} \rangle \times \langle \mathbf{B} \rangle) + \nabla \times \langle \mathbf{u}' \times \mathbf{B}' \rangle + \eta \nabla^2 \mathbf{B}. \tag{1}$$

The ensemble average removes the quickly varying in space and time turbulent fluctuations in magnetic and velocity fields, $\mathbf{B}'$ and $\mathbf{u}'$, leaving the fields $\langle \mathbf{B} \rangle$ and $\langle \mathbf{u} \rangle$ which possess only slowly varying components. The averaged interactions of small scale fluctuations generate a large scale electromotive force (EMF) $\langle \mathbf{u}' \times \mathbf{B}' \rangle$, which is a physical foundation of the mechanism of generation of the large scale magnetic fields. In the isotropic case it takes the form

$$\mathcal{E} = \langle \mathbf{u}' \times \mathbf{B}' \rangle = \alpha \langle \mathbf{B} \rangle, \tag{2}$$

where the coefficient α dependent on the mean field $\langle \mathbf{B} \rangle$ due to the action of the Lorentz force in the flow momentum balance. The presence of the non-negligible Lorentz force is responsible for quenching of the mean EMF and leads to saturation of the large-scale field excited via dynamo action.

INTERACTIONS OF DISTINCT WAVES

The case of linear waves has been extensively studied (cf. Moffatt 1978), with particular attention directed to new mechanisms of the EMF generation based on interactions between distinct waves in Mizerski (2018a,b). The new mechanism results from interactions between fluctuations of the velocity and magnetic fields with the same wavelength but distinct frequencies; in other words, for linear waves, this corresponds to superposition of at least two different eigenmodes, i.e.

$$\mathbf{u}' = A_1 \mathbf{u}'^{(1)} + A_2 \mathbf{u}'^{(2)}, \qquad \mathbf{B}' = A_1 \mathbf{B}'^{(1)} + A_2 \mathbf{B}'^{(2)} \tag{3}$$

$$\begin{aligned} \mathcal{E} &= \frac{1}{2} \Re e \left(\mathbf{u}' \times \mathbf{B}'^{*} \right) \\ &= \frac{1}{2} \sqrt{\mu_0 \rho} \Re e \left[A_1 A_2^{*} \hat{\mathbf{u}}^{(1)} \times \hat{\mathbf{B}}^{(2)*} \mathrm{e}^{\mathrm{i}\Delta\omega t} + A_1^{*} A_2 \hat{\mathbf{u}}^{(2)} \times \hat{\mathbf{B}}^{(1)*} \mathrm{e}^{-\mathrm{i}\Delta\omega t} \right], \end{aligned} \tag{4}$$

where A_1 and A_2 are amplitudes of the eigenmodes and ω_1, ω_2 are the oscillation frequencies of each wave. Such an EMF oscillates on a timescale $1/\Delta\omega$, which can be much larger than that of the mean magnetic field growth and hence can lead to mean field dynamo. In the above $\Delta\omega = \omega_1 - \omega_2$ denotes the difference between the two eigenvalues associated with the two interacting eigenmodes.

Particularly effective are the interactions of beating waves (cf. Mizerski 2018b where waves forced at two disticnt but close frequencies were considered) and nonlinear effects in the mean electromotive force (cf. Mizerski 2018a). Figure 1 depicts an initial period of evolution of magnetic energy amplified by interactions between Lehnert (Magneto-Coriolis) waves; the inset clearly shows initial energy decay in the linear regime, thus demostrating the crucial role of the nonlinear effects from the Lorentz force. The importance of the new mechanism of the EMF generation results from the fact, that contrary to the standard mechanisms invoked in the literature it does not require the magnetic diffusivity to create a phase shift between the kinetic and magnetic components of the fluctuations; the wave interactions are effective at creation of the mean EMF even when the magnetic diffusivity is negligibly small. It follows, that the theory has the potential to be applied to dynamo generation of magnetic fields in the ionised gas of the early universe, for which the resistivity is extremely low (with characteristic diffusion times many orders of magnitude greater than the age of the entire universe); non-resistive dynamo mechanisms are strongly desirable in this context.

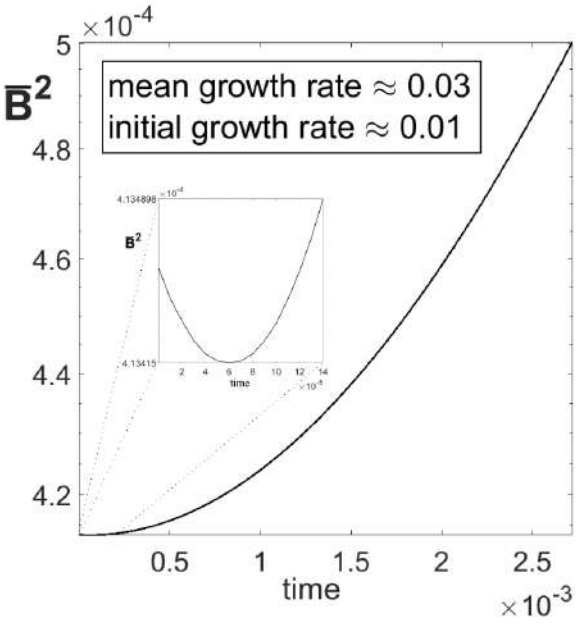

Figure 1: Initial period of growth of the spatially averaged energy of the mean magnetic field generated via interactions between Lehnert waves, in a periodic box; the waves are continuously generated at the top boundary. The inset shows in detail a very short initial stage of magnetic energy drop, before the nonlinear effects due to the Lorentz force (from Mizerski 2018a).

RENORMALIZATION

The theory if further developed by considering the nonlinear effects of waves via the renormalization-group approach, udertaken in a similar manner as in Yakhot and Orszag (1986) and Smith and Woodruff (1998). The assumption of isotropy of turbulence is put forward, but the turbulence remains non-stationary. The full MHD equations are renormalized in order to obtain an effective equation describing the evolution of the mean field, with the explicit form of the mean EMF. A particular dependence of the α coefficient on the large-scale field is obtained, which results from inclusion of the effect of the Lorentz force. In turn the full dynamics of the mean field and its saturation can be studied. The non-stationarity of turbulence turns out to be a crucial factor in the process of large-scale field generation in the limit of low generalized Rossby and Ekman numbers.

Summary The study addresses, both experimentally and numerically, flow instabilities in a heated vertical duct under a strong transversal magnetic field. Mercury is used as a model liquid metal. The experimental part has studied the temperature signals formed in a strong magnetic field and analyzed their statistical characteristics. The numerical simulations have reproduced the experimental conditions and provided an assessment of the emerging flow structures, determined the characteristic flow regimes. Also, symmetry properties of the system and their influence on the onset of unstable regimes have been studied. Based on the observed results, terminology to describe two different types of temperature fluctuations and associated flow instabilities has been proposed.

INTRODUCTION

This work is performed as a joint experimental-numerical study within a collaboration German-Russian research project, supported by DFG and RFBR. The experimental investigation of the liquid metal downward flow in a vertical duct under the influence of a transverse magnetic field has been performed by the joint group at MPEI and JHIT (Moscow). The geometry corresponds to a flat duct with the aspect ratio 3.5:1 (cross-section of 56×16mm and the length of about 1m), whereas the magnetic field B is applied along the long side of the duct and the heat flux – along the short side. Such configuration is close to the conditions in blanket modules of a tokamak-type thermonuclear reactor. Mercury has been used as a model liquid metal. The experiments have been conducted using an immersion probe with micro-thermocouple, moving inside the duct over a certain cross-section, which can, point by point, restore the profiles of the averaged and fluctuating temperature. It is known that the joint effect of electromagnetic and buoyancy forces may lead to the formation of secondary vortices on top of the main flow [1, 2], which causes fluctuation of temperature with high amplitude and low frequency. Particular attention has been paid to the role of wall heating, i.e. symmetric (two-sided) and non-symmetric (one-side) heating. It has been found that these two configurations of the applied thermal load generate instabilities, which, albeit retaining common features in their nature, are different in their spatio-temporal characteristics. Namely, two temperature signals have been found: quasi-harmonic temperature fluctuations observed at the symmetric heat load, whereas the non-symmetric heat load has led to the appearance of periodic temperature bursts [3]. However, since the velocity fields could not be measured with the necessary accuracy, yet there remained one open question – what are the specific flow structures, which may correspond to the temperature signals, obtained in the measurements [3].

RESULTS AND DISCUSSION

To answer the question above, we have performed a series of numerical simulations with our in-house finite-difference solver [4], aimed to mimic the experimental conditions at the maximum possible capacity. The simulations have been done in the essentially same duct, including the geometry settings and parameter space. Also, to mimic the real experimental conditions, we have implemented a virtual honeycomb installed at the duct inlet, which has also served the purpose of generating turbulent flow before entering the working "experimental" section, where heating and magnetic field are applied. The numerical resolution was 7200×512×128 points in the streamwise x-, spanwise y- and vertical z-directions, correspondingly.

Our numerical simulations have confirmed that the flow of liquid metal in a heated duct can develop at least two different families of instabilities under the transverse magnetic field. Symmetric and non-symmetric heating produces different patterns of fluctuating flow for the downward configuration, as shown in figure 1. We have found that secondary flows naturally develop and keep existing under magnetic field up to the maximum values of $Ha = 200$ accessible in the experiment (here the Hartman number and other parameters are calculated using duct`s half-height). The analysis of the numerical results, both velocity fields, and temperature signals, also fully reveals that symmetric heating of the duct produces quasi-harmonic fluctuations, while non-symmetric leads to quasi-periodic bursts observed at the same combination of parameters (Ra, Ha and Gr numbers) as in the experiment. Moreover, we have conducted a separate investigation on the effect of possible imperfections in the experimental setup, such as deflection from the vertical position and not truly symmetric heating at the two walls. The most interesting outcome here is that even a slight deviation from the ideal heating-symmetry, e.g., by about 5% between the left and right walls, is sufficient to trigger the instability at much lower values of Gr number. The flow patterns and the amplitude of temperature signals at such a slight non-symmetric heat load start to resemble those, identified at the purely one-side heating. At the same time, a 5% deflection from the vertical position did not affect the instability thresholds.

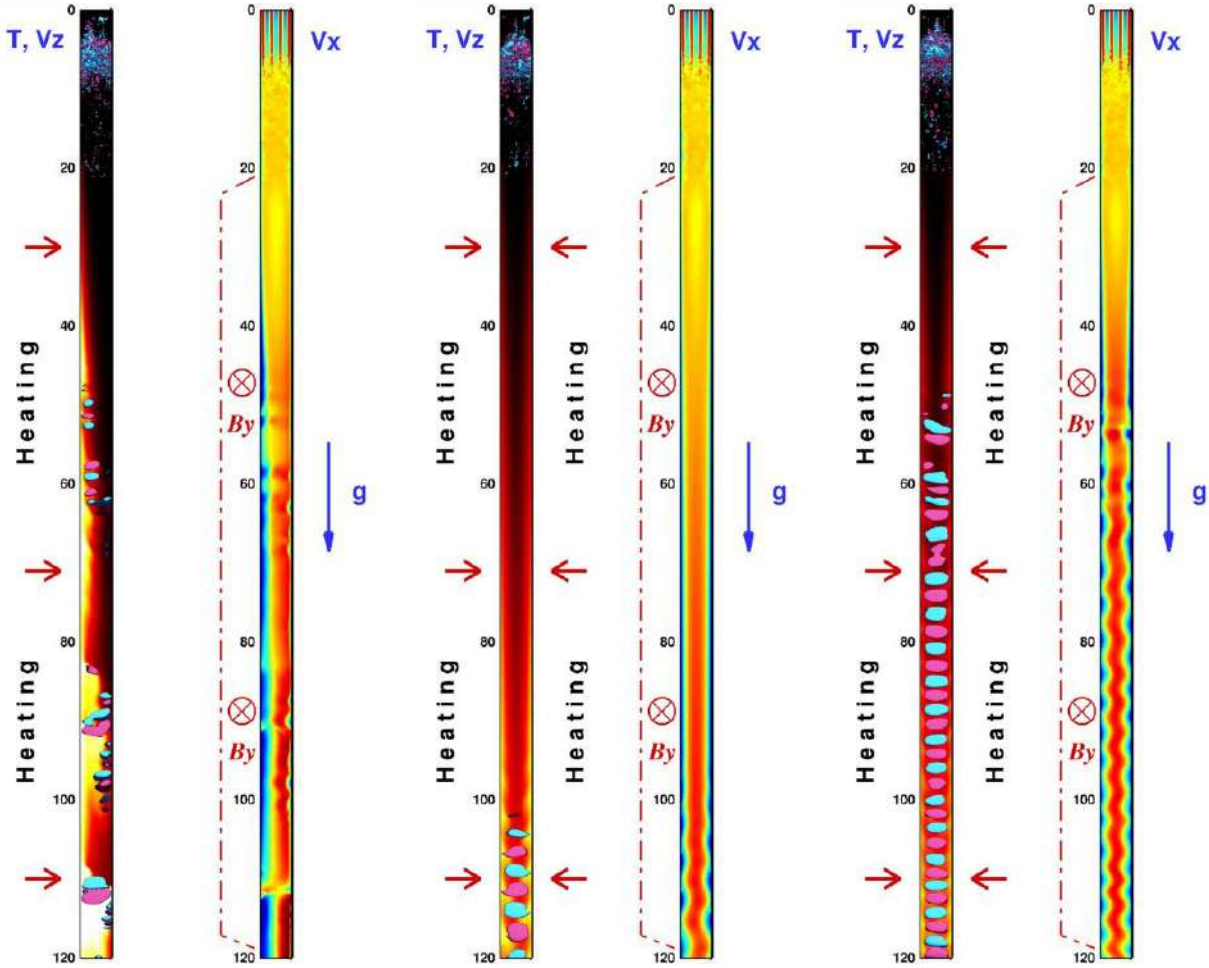

Figure 1. Downward flow in a vertical duct at Re = 5000 and Ha = 200 with (left) one-side heating at Gr = 1.6e6, and (middle and right) two-side heating at Gr = 2.5e6 and 5e6. The plots visualize flow structures in a (x; z)-cross-section of a fully developed state. On each plot, the left panel shows contours of the temperature field T and vertical velocity v_z (cyan and pink), the right panel shows contours of the streamwise velocity v_x.

CONCLUSIONS

The effect of the observed phenomena is actually two-fold. On the one hand, the observed regular 2D structures can produce additional flow mixing and significantly enhance heat transfer, possibly up to the levels observed at a fully developed turbulent state. On the other hand, however, the system appears extremely sensitive to the symmetry properties. Thus, these irregular bursts, observed for the cases of non-symmetric heating (and, to some extent, those with slight non-symmetry), can create unexpectedly high thermal loads or hot spots at the walls, which would pose potential problems for mechanical constructions. Furthermore, it turns out that non-symmetries in positioning are far less critical than those in heating. This may have direct implications for the construction and operation of fusion blankets. In the future work, we plan to address other non-symmetry factors (i.e. experimental or operating imperfections), such as inlet non-uniformity, offsets between both heaters, misalignment of the duct- and *B*-field-axis and finite conductivity of the walls. Finally, we will also provide a more detailed assessment of the observed flow structures and quantify their impact on the integral heat transfer properties.

VELOCITY-VORTICITY FORMULATION FOR THE MHD TAYLOR-COUETTE FLOW AND THE IMPORTANCE OF THE WIDE-GAP CORRECTION

Y. Velizhanina*, B. Knaepen*

The analysis of the stability of the hydrodynamic Taylor-Couette flow (i.e the flow contained between two concentric rotating cylinders) was first presented in the pioneering work of Taylor[1]. Taylor assumed axisymmetric perturbations but it was later observed experimentally and discussed theoretically that the most unstable modes become non-axisymmetric in case of sufficiently negative $\mu_\Omega = \Omega_{in}/\Omega_{out}$, where Ω_{in} and Ω_{out} denote respectively the rotation rates of the inner and outer cylinders (see e.g. Krueger et al.[2]). The stability of *the hydromagnetic Taylor-Couette flow* was also the subject of numerous studies, mainly in the context of finite magnetic Reynolds numbers and the magnetorotational instability[3]. Here we focus on the limit of small magnetic Reynolds numbers (inductionless limit). The stabilising effect of the uniform axial magnetic field in the axisymmetric case was first described by Chandrasekhar[4] and confirmed experimentally by Donnely & Ozima[5]. The importance of non-axismmetric modes was later concluded from the experiments by Donnelly & Caldwell[6] and investigated further in the framework of the narrow-gap approximation by Chen & Chang[7]. By performing an extensive parametric study these authors were able to separate two important regimes in which non-axisymmetric modes define the stability - first, for moderate values of Ha and negative values of μ_Ω and, second, for large Ha and arbitrary μ_Ω.

Here we present a novel formulation of the hydromagnetic Taylor-Couette flow stability equations based on the variables proposed by Burridge & Drazin[8] in the context of the hydrodynamic pipe flow. This compact system, valid for any gap ratio, is closed in terms of two equations for the wall-normal velocity and the wall-normal vorticity. We compare our numerical results with that of Krueger[2] for the hydrodynamic case and Roberts[9] for the MHD case and find a perfect agreement. The second part of this work concerns the accuracy of the narrow-gap approximation for negative values of μ_Ω where non-axisymmetric modes govern the instability (unfortunately, eventhough Roberts used a wide-gap formulation, the relevant set of parameters for this regime was not considered). For the hydrodynamic Taylor-Couette problem, the narow-gap approximation has proved its validity but it has been shown by Krueger[2] that its accuracy degrades significantly when $\mu_\Omega < 0$ and that the wide-gap correction becomes significant even for $R_{in}/R_{out} = 0.95$. Our results confirm that this observation is also valid in the magneto-hydromagnetic case and we show that the wide-gap correction significantly modifies the results reported by Chen & Chang[7].

MAGNETIC FIELD ASSISTED ELECTRODEPOSITION OF METAL ON CONICALLY SHAPED ELECTRODES

Mengyuan Huang*[1], Kerstin Eckert [1,2], Gerd Mutschke [1]
[1]Institute of Fluid Dynamics, Helmholtz-Zentrum Dresden-Rossendorf (HZDR), Dresden, Germany
[2]Institute of Process Engineering, Technische Universität Dresden, Dresden, Germany

Summary The electrodeposition of metal on conically shaped diamagnetic and ferromagnetic electrodes is studied under the influence of a vertical magnetic field. Analytical and numerical results show a beneficial influence of the magnetic field to enhance the cone growth, which can be attributed to the electrolyte flow forced by the Lorentz force and the magnetic gradient force. The influences of cone shape, cone size and distance between neighbouring cones are investigated in detail. The results deliver insights into the feasibility of magnetic field assisted electrodeposition towards nano-structured conical electrodes.

INTRODUCTION

Conical structures at length scales from micrometer to nanometer have numerous applications in areas including super-hydrophobic and electrocatalytic materials [1, 2]. Among the various methods of synthesizing micro- and nano-structured cones, magnetic-field assisted electrochemical deposition could be an important technology [3]. The magnetic forces, i.e. the Lorentz force and the magnetic gradient force, can generate an electrolyte flow that brings fresh electrolyte enriched with electroactive ions towards the cone tip, and thus enhances the local mass transfer [4]. It is therefore possible to support the cone growth during the electrodeposition process by properly adjusting the magnetic field imposed on the electrochemical cell.

For the purpose of separately investigating the influence of the magnetic forces, a homogeneous vertical magnetic field is applied to diamagnetic (Cu) and ferromagnetic (Fe) cathodes of conical shape. The magnetization of the Fe electrodes causes a strong magnetic gradient force near the cones, while for the Cu cones only the Lorentz force is acting. As the cathodes are placed at the bottom of the electrochemical cell, solutal buoyancy needs to be considered as well.

The numerical model consists of a coupled system of equations for mass transport of the ionic species involved, magnetic field, electric potential and electrolyte flow and was implemented in the finite element software COMSOL to study the electrolyte flow and mass transfer during the galvanostatic deposition process [5]. Early simulation results for the Cu case only and compared to experimental findings can be found in [6].

RESULTS AND DISCUSSIONS

Figure 1 shows the electrolyte flow near a Cu and a Fe cone (left) and its influence on the deposit thickness on the conical cathode (right) after 10 s deposition. For the Cu cone, the downward flow due to the Lorentz force is counteracted by the strong upward buoyant flow originating from the bottom of the cone. The magnetic gradient force in case of the Fe cone is creating an additional downward flow that is suppressing the undesirable buoyant flow at the upper part of the cone and therefore supporting the local mass transfer, which explains the enhancement of the deposit thickness on the Fe cone compared to the Cu cone.

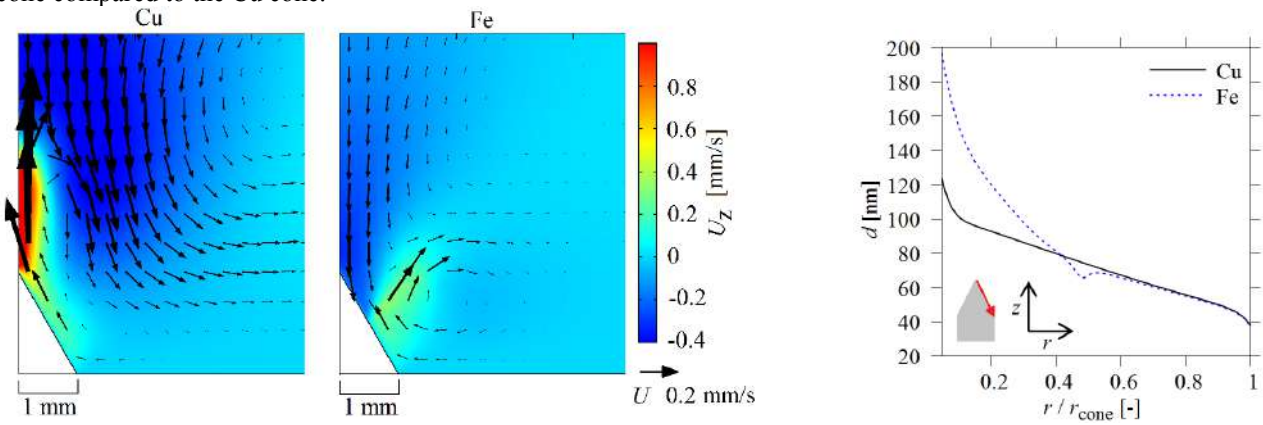

Figure 1. 2D axisymmetric simulation results for single Cu and Fe cones after 10 s deposition. Left: Color surface of the vertical velocity superimposed with the velocity vectors. Right: Deposit thickness on the cone surface. Horizontal axis normalized by the cone radius. The cone grows as the deposit thickness at the cone tip ($r/r_{\mathrm{cone}} = 0$) is higher than at the cone bottom ($r/r_{\mathrm{cone}} = 1$). 0.1 M $CuSO_4$ is used as electrolyte, the average cathode current density is 16 $\mathrm{mA/cm^2}$, the external magnetic field is 200 mT [5].

As the electrodeposition proceeds, the aspect ratio of the cone increases. In this regard, we studied sharp and flat cones to understand the supporting effects of the magnetic field at different stages of the evolution of cone growth. The sharpest

*Corresponding author. E-mail: m.huang@hzdr.de.

cone yields the strongest Lorentz force, which is related to the high current density arising from the geometrical inhomogeneity near the cone tip. For the Fe cones, the intermediate cone tip angle generates the highest magnetic field and the associated magnetic gradient force. These results indicate that in comparison to the Lorentz force, the magnetic gradient force exerts its largest influence at an earlier stage of the cone growth.

Damping effects from neighbouring cones were investigated by varying the distance between cones. While the primary azimuthal flow resulting from the Lorentz force is extending towards the neighbouring cones and is strongly damped when the cones get closer to each other, the meridional flow caused by the magnetic gradient force exists in a smaller region and is less affected by the neighbouring cones.

Scaling studies performed on cones with diameters ranging from 2 mm to 6 µm allow to draw conclusions on the magnetic field effects on the electrodeposition towards micro- and nano-cones. As the cone size shrinks, the geometrical inhomogeneity decreases, and the current density gets more uniformly distributed on the cone, which is making the cone growth more difficult. Furthermore, the flow forced by the magnetic field near smaller cones suffers from higher wall friction. On the other hand, this may partially be compensated by the larger magnetic gradients existing at smaller Fe cones, which is generating a beneficial downward flow also at a 6 µm Fe cone.

CONCLUSIONS AND OUTLOOK

Our work shows the superiority of the magnetic gradient force compared to the Lorentz force in terms of supporting cone growth for single cones of different shape and size, as well as for cone arrays [5]. Although it is more difficult to obtain conical structures when the distance between neighbouring cones decreases and when the cone size shrinks, a beneficial influence of the magnetic field can be stated in general. Future work will focus on optimization of the electrodeposition conditions for different metals and alloys by e.g. applying stronger magnetic fields and pulsed electrodeposition modes.

PARTICLE DISPERSION IN LIQUID METALS BY MAGNETIC SONICATION

Gunter Gerbeth*[1], Martins Sarma[1], and Ilmars Grants [2]

Summary Cavitation in liquid metals is supposed to provide conditions for the desired homogeneous dispersion of small particles, leading for metal matrix composites often to improved mechanical properties. A contactless magnetic field approach to induce cavitation in liquid metals is applied using a combination of AC and DC magnetic fields, which provide a strong oscillating pressure inside the molten sample. New results on the dispersion of a variety of particles in melts such as steel, iron and nickel will be given, including experiments in a high magnetic field laboratory.

INTRODUCTION

Acoustic cavitation by power ultrasound is widely used for the purpose of particle dispersion in room temperature liquids. There are also numerous experimental reports demonstrating that power ultrasound facilitates the dispersion of particles in a molten metal. So far, this technique has been applied for the production of metal matrix nano-composites (MMNC) of light metal alloys [1]. Being extremely violent on the micro-scale, the cavitation degrades also the vibrating surface transmitting the ultrasound into the liquid. A contactless technique for cavitation excitation is, therefore, desirable, in particular for high-melting liquid metals such as steel for which no ultrasonic transducers exist with a reasonable life-time in the melt. A contactless excitation of cavitation is possible by superposition of induction heating with a steady axial magnetic field. This combination creates an alternating radial magnetic body force in a cylinder [2]. The irrotational part of this force produces pressure oscillations. This contactless magnetic excitation of cavitation, which is furtheron called magnetic sonication, was first demonstrated in [3] using a steady magnetic field of up to 0.5 T. Here we report on experiments performed in much stronger steady magnetic fields up to 10 T, while using the same induction heater with an amplitude of up to 0.13 T.

THEORETICAL BACKGROUND

Consider an infinite liquid metal cylinder of radius a in a uniform magnetic field with a steady and an alternating component

$$\mathbf{B} = \left(B_z + b(r)e^{i\omega t}\right)\mathbf{e}_z. \tag{1}$$

The alternating component of the magnetic field induces an azimuthal current, which in combination with the static axial field creates an oscillating radial force. This force is curl-free and, therefore, is balanced by an oscillating pressure field. Suppose the frequency ω is high enough to cause a strong skin-effect ($\sigma\omega\mu_0 a^2 >> 1$, where σ and μ_0 are the electric conductivity and magnetic permeability of the metal, respectively), yet low enough to form a long acoustic wave with a wave length much larger than a. Additionally suppose that the alternating field component is much smaller than the steady one ($b_A << B_z$) where $b_A = |b(a)|$. Under these conditions the alternating magnetic pressure is uniform in the bulk and has the amplitude [3]

$$p = \frac{B_z b_A}{\mu_0}. \tag{2}$$

Acoustic cavitation is recurring non-linear growth and subsequent collapse of small bubbles due to the oscillating pressure in the liquid. In an ideal liquid, where transient voids are only created by thermodynamic fluctuations, the critical tension is comparable to the yield strength of metals. Such tension is out of reach for magnetic sonication. Thus, the observed beneficial effects of power ultrasound on particle dispersion in metal alloys depend on size and density of cavitation nuclei, which is largely unknown and uncontrolled. As bubbles start to cavitate, they emit their own sound containing characteristic sub-harmonics f_0/n, where f_0 is the drive frequency and n = 2,3… [3]. We use this property for the identification of cavitation inception, at least in the low-field case.

The melt flow and its stability during magnetic sonication was numerically analysed in [4]. The magnetic body force of the induction heater drives two symmetrical counter-rotating tori with inward-directed velocity in the midplane. An almost linear scaling with the driving force was observed for the maximum values of the velocity components in a strong steady field, until the flow becomes unstable at some specific control parameter combining both the alternating and steady magnetic field. As expected pronounced side-layers come up for increasing Hartmann number of the steady field. Regarding stability, a transition from the bulk instability mode with comparable low wave number to the side layer mode with larger wave number was observed. Besides steady forces driving a mean flow in the melt, there are force components oscillating with the ac field frequency. For increasing field strengths they may as well contribute to the mean flow by the steady streaming effect. Estimates for it will be presented.

EXPERIMENTAL SET-UP

A sketch of the experimental set-up in the low magnetic field (LMF) of up to B_z = 0.8 T is shown in Fig. 1. Experiments are made in an evacuated cell (p_0 < 400 Pa) consisting of the quartz tube 5 and water cooled copper caps 3. The cell is placed in a 82 mm wide vertical gap of an electromagnet. Water cooled copper screens 8 are used to protect the ferromagnetic pole shoes 9 from the induced currents. The refractory side support 6 accomodates vertical variations of the magnetic pressure. The electromagnet provides a magnetic flux density of up to 0.8 T in the experimental volume, and the maximum inductor current r.m.s value is I_{AC} = 1300 A that corresponds to b_A = 0.130 T. The AC frequency is f_0 = 14.7 kHz.

In order to reach a significant increase of the oscillating pressure amplitude, additional experiments in a high magnetic field (HMF) were conducted at the High Magnetic Field Laboratory of HZDR. The used magnet is 2290 mm long, has a 150 mm bore diameter and fields up to B_z = 19 T. The coils are immersed in liquid helium and the temperature is around 4 K. A use of the previous set-up was not possible, thus a modified melting cell was constructed. A multi-walled chamber using vacuum for thermal isolation was built. As the maximum field strength is located in the lower part of the bore, the induction coil was fed by 2200 mm long supply bars.

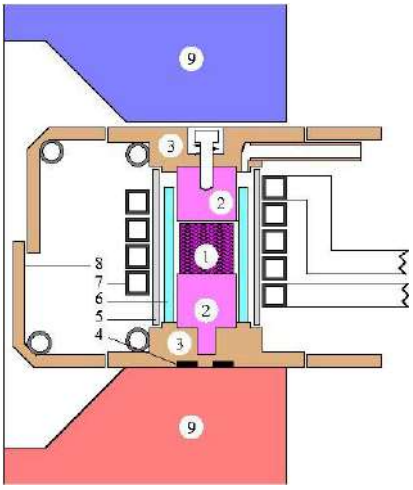

Figure 1: Scheme of the experimental set-up.

RESULTS

The onset of cavitation has been clearly observed in almost all liquid metals under consideration in the LMF experiments. Using piezoelectric sensors at the surface of the bottom cap allowed to display the sound spectrum, which for pressure oscillations above about 30 kPa showed sub-harmonics f_0/n characteristic for cavitation. In case of the HMF experiments this observation was not possible, as the induction coil with the long supply bars was forced to mechanical vibrations in the HMF, which superimposed and dominated the signals from the piezoelectric sensors. Thus, direct cavitation detection as in the LMF case was not possible here.

A multitude of samples have been processed with the high-temperature metals iron, nickel and steel using oxides (TiO_2, Y_2O_3, CeO_2), carbides (TiC, ZrC), nitrides (TiN) and borides (TiB_2, ZrB_2) as particles. For most of those cases the tendency that stronger pressure oscillations result in a better dispersion of the particles has been observed. An example is shown in Fig. 2 for TiB_2 particles (initial size 4 µm) in steel. Without a steady magnetic field large particle clusters are found throughout the matrix (a), whereas the application of an 8 T DC field prevents clustering and both large (empty arrows) and small (solid arrows) precipitates are found (b). More examples and details will be given in the presentation.

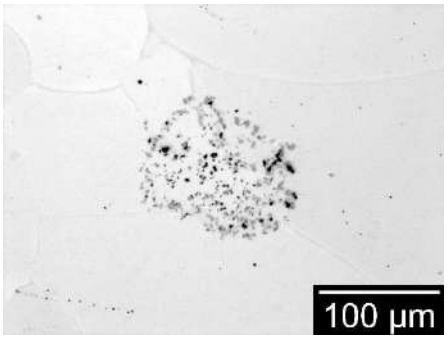

Fig. 2(a): TiB_2 particles in steel without DC field.

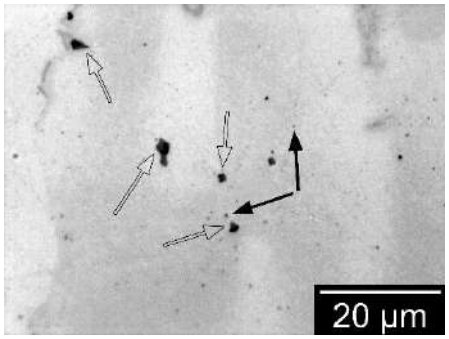

Fig. 2(b): TiB_2 particles in steel in an 8 T DC field.

CONCLUSIONS

Contactless magnetic sonication is capable of avoiding the agglomeration of particles in metal melts, as well as to break-up agglomerated particle clusters. Systematic experiments for a variety of particles in steel, iron and nickel showed this with the clear tendency that stronger pressure oscillations for increasing DC magnetic field improved the particle dispersion.

LINEAR STABILITY OF FERROFLUIDS IN DIFFERENT CONFIGURATIONS

Sarah Ferguson Briggs*[1] and Jonathan Mestel[1]
[1]Department of Mathematics, Imperial College, London, United Kingdom

Summary The linear stability of incompressible, isothermal ferrofluids is considered in different configurations. The stability of a column of ferrofluid, surrounded by another with a different magnetic susceptibility, centred on a current-carrying rigid wire that produces an azimuthal magnetic field, is determined. A ferrofluid with a continuous, spatially-dependent susceptibility, subject to a non-uniform field is considered in two configurations; a cylindrical and a planar geometry. Additionally, if the susceptibility varies slowly with space we prove a stability condition for a general configuration.

Ferrofluids are colloidal fluids, consisting of magnetic solids, such as magnetite, dissolved in a surfactant and carrier solution, usually water, kerosene or oils [1]. As a result, the liquid becomes magnetised in the presence of a magnetic field, and to prevent agglomeration, the nanoparticles are either electrically charged, or coated in a surfactant [2]. Technological and industrial applications of ferrofluids include dynamic sealing and heat dissipation, and there have been biomedical advances in their use in hyperthermia treatment and magnetic drug targeting [2]. For these various applications, ferrofluids will be in different domains subject to different magnetic fields. Thus, the theoretical investigation of a variety of configurations can be used in determining the strength and direction of a magnetic field necessary for a stable, real life system.

When a magnetic fluid is subject to a non-uniform magnetic field, the magnetic particles are attracted to a region of highest field intensity as a result of the magnetic dipoles rotating to align with the field, giving the minimal energy configuration [2]. We therefore investigate not only the interfacial stability of two ferrofluids with constant magnetic susceptibility, but also the stability of one ferrofluid with continuous susceptibility that varies spatially, subject to a non-uniform field.

FORMULATION

A ferrofluid (FF) obeys the magneto-static limit of Maxwell's equations, with free current density and Maxwell's displacement current deemed negligible. We assume the magnetisation is colinear with the magnetic field, $\mathbf{H}$. In the momentum equation the force density appears as

$$\mathbf{f} = \int_0^H H \boldsymbol{\nabla}_H \chi dH \tag{1}$$

but, assuming χ does not depend explicitly on H, (1) simplifies to

$$\boldsymbol{f} = \frac{1}{2} H^2 \boldsymbol{\nabla} \chi, \tag{2}$$

where χ is the magnetic susceptibility of the FF and $|\boldsymbol{H}| = H$ [1].

Additionally, when χ varies with space we impose

$$\frac{D\chi}{Dt} = 0,$$

such that χ is advected passively and diffusion processes occur on a large time scale.

CYLINDRICAL DOMAIN

The stability of a column of FF, with susceptibility $\chi = \chi_1$, centred on a rigid wire, surrounded by another FF, with susceptibility $\chi = \chi_2$, is investigated in a fully three-dimensional setting, shown in Figure 1. An electric current runs through the wire, generating an azimuthal magnetic field, $H \sim 1/r$. Since χ is constant, $\boldsymbol{f} = 0$ in the momentum equation, and the forcing acts as a magnetic stress at the interface of the fluids.

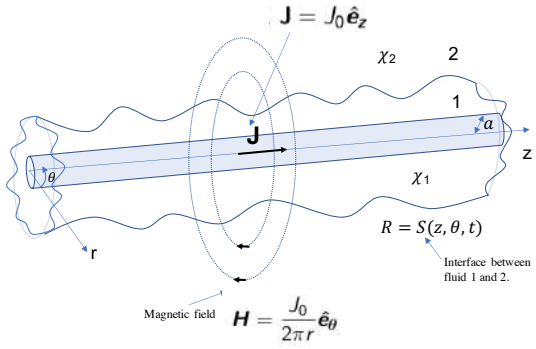

Figure 1: Schematic of the system.

*E-mail: sf218@ic.ac.uk

Results: When $\chi_1 > \chi_2$, it is unstable to axisymmetric perturbations only, and is stabilised by increasing the current in the wire. For $\chi_2 > \chi_1$, the system is unstable to both axisymmetric and non-axisymmetric modes, and increasing the current no longer stabilises the system.

When $\chi_2 > \chi_1$, the region of highest χ is not aligned with the region of highest field intensity, since $dH/dr < 0$, resulting in an unstable system. This motivates the investigation of an infinite column of FF centred around the wire, where $\chi = \chi_0(r)$, shown in Figure 2. For arbitrary Reynolds number, we consider axisymmetric perturbations and prove using variational methods that the system is unstable iff $d\chi_0/dr > 0$ at some point. In the inviscid limit the result holds for non-axisymmetric perturbations also.

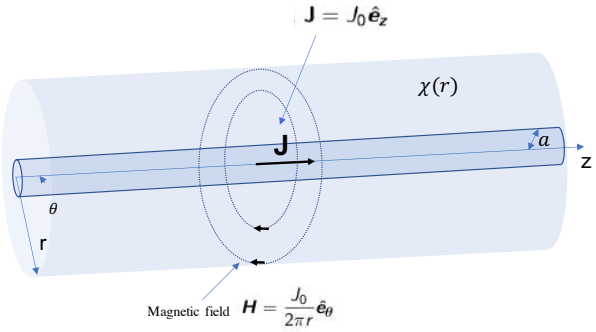

Figure 2: Schematic of the system

Importantly, applying a significantly strong axial field stabilises the system with $\chi = \chi_0(r)$ and when χ is piecewise-constant, irrespective of $\chi_2 > \chi_1$ or $\chi_1 > \chi_2$.

PLANAR DOMAIN

We now consider a FF between two walls, subject to a perpendicular field, $\boldsymbol{H} = H_0(z)\hat{\boldsymbol{e}}_{\boldsymbol{z}}$. For an equilibrium

$$\chi = \chi_0(z) = \frac{A}{H_0(z)} - 1,$$

where A is a constant such that $\chi_0 > 0$. It follows that $dH_0/d\chi_0 < 0$ and we prove the equilibrium is unstable.

Additionally, we prove applying a sufficiently large, rapidly rotating field stabilises the system.

GENERAL χ VARIATION

More generally, given a volume V of FF, where the equilibrium $\chi = \chi_0$, $H = H_0$, is such that χ_0 varies gradually with space and

$$\chi_0 \equiv \chi_0(H_0) \iff \boldsymbol{\nabla} \times \boldsymbol{f} = 0,$$

where $\boldsymbol{f}$ is given by (2). We prove the configuration is unstable iff $dH_0/d\chi_0 < 0$ somewhere in V.

CONCLUSIONS

(1) In the cylindrical, two fluid configuration, a sufficiently large current through the wire stabilises the system when $\chi_1 > \chi_2$, but not when $\chi_2 > \chi_1$. Applying a sufficiently large axial field will stabilise both.

(2) The equilibria considered in the cylindrical and planar geometries, when χ is space dependant, are unstable for $dH_0/d\chi_0 < 0$, and we prove this for a general configuration with $\chi = \chi_0$ varying slowly with space.

(3) For the cylindrical system an axial field will stabilise the system, and for the planar system a rapidly rotating field is needed.

STEADY CONVECTION OF DIELECTRIC FLUIDS IN MICROGRAVITY USING NON-UNIFORM AC ELECTRIC FIELDS

Alex Jawichian[1], Laurent Davoust*[1], and Samuel Siedel[1]
[1]Univ. Grenoble Alpes/Grenoble-INP/CNRS,SIMaP,EPMgroup,38402 Saint Martin d'Hères,France

Summary The role of an AC electric field on dielectric liquids confined in a differentially heated cavity is considered. In the purpose of sustaining steady TEHD flows, the electrode arrangement is modified, in contrast to the typical vertical planar case usually investigated in the literature, so as to create non-uniform electric fields. A numerical study is developed in order to investigate such a system in microgravity conditions. Our preliminary results show that a significant and steady perturbation of conductive heat transfers is possible via the use of non-intense and non-uniform electric fields. This suggests a significant improvement in heat transfer efficiency when electric fields are used. The results are compared to scaling laws for the Nusselt number.

INTRODUCTION

A finite volume of dielectric liquid, submitted to a temperature gradient in a closed cavity, experiences a change in its dielectric constant, ϵ_r, such that [1]:

$$\epsilon_r = \epsilon_{ref}(1 - \lambda(T - T_{ref})), \tag{1}$$

where λ is the thermo-dielectric coefficient, T is the temperature, and the ref subscript denotes a reference value. As a consequence, if a thermal gradient is applied upon a dielectric fluid together with an electric field, a joint contribution can be expected which gives rise to a convective motion of thermo-dielectrophoretic (T-DEP) origin [2]. This is all the more true as the dielectric relaxation frequency is always larger than the angular frequency of the applied voltage.

Since the dielectric liquid is considered to be confined, it is more relevant to write the vorticity equation (nondimensional). In microgravity, this writes as,

$$(\vec{u}.\vec{\nabla})\vec{\omega} = \mathrm{Pr}\nabla^2\omega + \mathrm{Pr.L}\,(\vec{E}.\vec{\nabla})\vec{E} \times \vec{\nabla}T, \tag{2}$$

with $\vec{\omega} = \vec{\omega}(0, 0, \omega_z)$ the vorticity, and $\vec{M}_{DEP} = \mathrm{Pr.L}(\vec{E}.\vec{\nabla})\vec{E} \times \vec{\nabla}T$, the DEP torque. The non-dimensional numbers are the Prandtl number, $\mathrm{Pr} = \nu\alpha^{-1}$ and the Roberts number, $\mathrm{L} = \frac{\epsilon_{ref}\epsilon_0\lambda\Delta T\Delta V^2}{\rho\nu\alpha}$. The symbols $\rho, \nu, \alpha, \epsilon_0$, and ΔV are respectively the density, the kinematic viscosity, the thermal diffusivity, the vacuum permittivity, and the voltage applied between the electrodes.

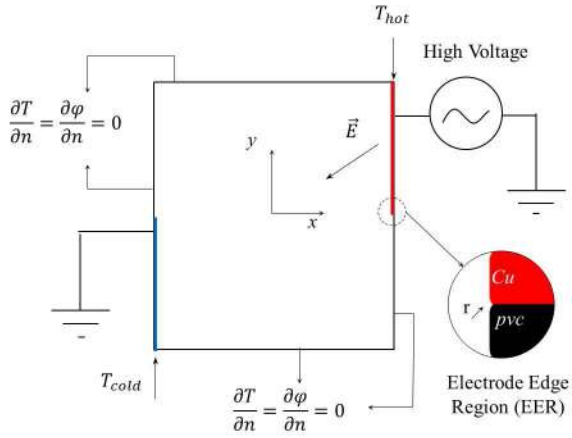

Figure 1: Half electrode pair, electrical, and thermal boundary conditions.

In the case of a differentially heated cavity, where the two isothermal vertical walls are also the electrodes, it can be noticed that in the perfectly conductive regime ($\vec{u} = \vec{0}$), the electric field, its gradient, and the temperature gradient are all aligned: the consequence is that the DEP torque drops to zero. In such a case, the fluid remains stagnant, and a linear temperature profile is established along the cavity [3]. In this communication, the aim is to investigate a new electrode arrangement that can steadily sustain a thermo-electrohydrodynamic (TEHD) flow based on a DEP torque at leading order.

In an attempt to deliver a significant effect of the DEP torque in (2), misaligned planar electrodes are placed along each vertical side wall (fig. 1). Thermally and electrically speaking, the walls in red and blue (pair of half electrodes) in fig. 1 are submitted to Dirichlet conditions, while the complementary part of the walls (in black) are submitted to Neumann conditions. The two half electrodes are not facing each other so that a non-uniform distribution of the electric field is achieved which depends on the electrode to wall lengths ratio, as well as on the curvature radius of the electrode edges (see EER in fig. 1).

*Corresponding author. E-mail: laurent.davoust@grenoble-inp.fr

RESULTS

Numerical simulations confirm that in microgravity conditions and for any value of the Roberts number, $L > 0$, the dielectric liquid is set in motion due to a steady contribution of the DEP torque.

In the presence of an electric field, the DEP force disturbs the stagnant conductive regime and leads to the generation of two counter-rotating vortices (fig. 2). The velocity scale, as well as the vorticity scale, grows with larger and larger electric Grashof numbers. The vortices are not symmetric, which is consistent with the asymmetry of the temperature and the electric potential distributions. Furthermore, the intensification of the angular momentum is present near the electrode edges due to the high intensity of the electric fields in these regions. The angular momentum is later diffused far within the volume under viscosity.

Concerning heat transfer enhancement, the averaged Nusselt number, defined as the ratio of the total heat flux to the conductive heat flux, is displayed in (fig. 2). Its significant increase demonstrates the capability of the DEP-induced convection to improve convective heat transfers. We also notice that for different Pr values, the Nusselt number scales as the Roberts number to the power one fourth $\mathrm{Nu} \sim \mathrm{L}^{0.25}$, while the Nusselt remains independent of the Prandtl number as predicted from the scaling analysis.

One also notices the presence of another regime that is established beyong a critical value of the Roberts number, $\mathrm{L_c} = 10^5$. In this regime, the Nusselt number scales as the Roberts number to the power of 0.15, $\mathrm{Nu} \sim \mathrm{L}^{0.15}$. This means that the heat transfer enhancement due to higher voltages becomes less significant. This can be explained by to the generation of a third vortex within the volume, that counteracts the previously existing counter rotating vortices (viscous damping).

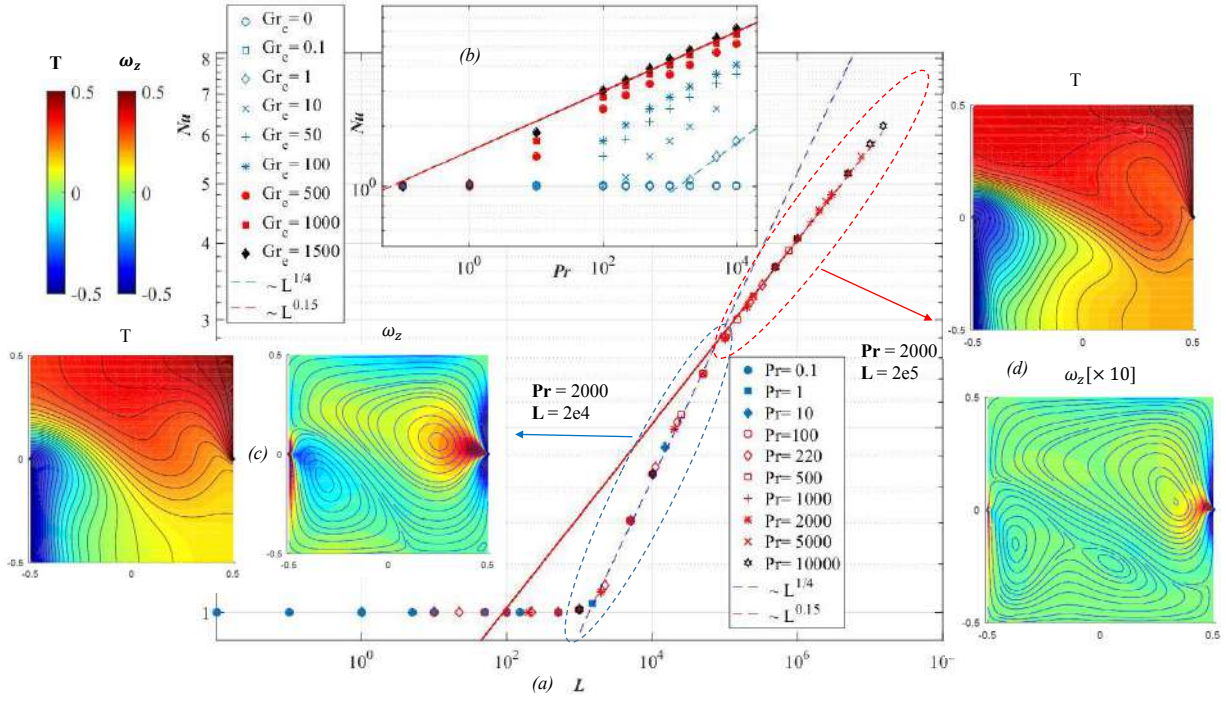

Figure 2: *(a)* Nusselt number as a function of the Roberts number for a range of Prandtl numbers, *(b)* Nusselt number as a function of the Prandtl number for a range of electric Grashof numbers, *(c)* Vorticity and Temperature fields for Pr=2000 and L=2e4, and *(d)* Vorticity and Temperature fields for Pr=2000 and L=2e5.

CONCLUSIONS

In microgravity conditions, it is demonstrated that the imposition of an AC electric field causes steady convective flows of dielectric liquids provided that a temperature gradient is made available, and that the electric field is not uniform. A steady DEP-induced convective flow is provided, which allows heat transfers to be enhanced within on-board systems, in microgravity conditions.

EHD ACTUATION OF A LIQUID-VAPOR INTERFACE ALONG A CAPILLARY ARRAY IN THE AC REGIME

Nicolas Cardin[1], Laurent Davoust*[1], Samuel Siedel[1], Stéphane Lips[2], and Jocelyn Bonjour[2]
[1]Univ. Grenoble Alpes, CNRS, Grenoble INP, SIMaP, F-38000 Grenoble, France
[2]Univ Lyon, CNRS, INSA-Lyon, Université Claude Bernard Lyon 1, CETHIL UMR5008, F-69621, Villeurbanne, France

Summary The present communication is devoted to the role of an AC electric field on the deformation of a meniscus confined inside a grooved capillary structure. In the presence of an electric field, an electric stress is seen to apply upon liquid-vapor interfaces. The normal component of the electric stress adds to the capillary stress and the gravity force, which leads to a modified pressure jump and therefore to the deformation of the interface. The latter is investigated experimentally thanks to chromatic confocal microscopy. In the presence of an AC electric field, a resonance phenomenon and a double frequency oscillation are observed, depending on the frequency of the electric actuation. A spectral analysis of the interfacial deformation as a function of the frequency is proposed making use of frequency sweep.

INTRODUCTION

This paper addresses the effect of an AC electric field on liquid ridges stretching along an array of U-shaped microgrooves. This study is motivated by the need to enhance the performance and the robustness of stratified two-phase systems such as heat pipes [1] for instance. In such systems, one main limitation is the capillary pumping of the liquid phase along the microgrooves. The capillary structure enables liquid pumping due to a pressure gradient which results from a non-uniform distribution of the interfacial curvature. When the capillary structure cannot provide a capillary pressure difference between the evaporator and the condenser high enough to overcome the pressure drop related to the back flow of the liquid phase, then the capillary limit is reached. This limit is widely encountered in industrial applications. One possible solution to increase the capillary limit is to impose externally an additional stress at the liquid-vapor interface. If an electric field is applied upon a stratified two-phase system, a normal electric stress arises at the interface as an adding contribution to the normal component of the momentum balance. This is expected to extend the capillary limit [2, 3]. A dielectric stress is found to arise at a liquid-vapour interface, which, together with the capillary force, is responsible for changing the pressure jump at the interface [4, 5, 6]. The experiments in the available literature performed with a EHD-enhanced capillary structure indicate an improvement of the thermal performances but neither the effect on the liquid distribution nor the distinctive effects of a DC regime versus a AC regime have been measured [7, 8, 9]. A numerical paper [10] were developed to investigate the effet of a DC electric field on two-phase thermohydraulics. In this paper, the ability of the electric field to change the shape of a meniscus is investigated by means of confocal microscopy. Resonance effects are observed when use is made of an AC field. A length scale selectivity is suspected depending on the frequency of the AC actuation.

GENERAL CONFIGURATION

In this study a sealed cavity is formed from two opposite plates. Because these plates are used as an electrode pair, a planar capacitor is thus obtained and is able to sustain a strong enough electric field. The top plate is flat and connected to a high voltage while the bottom plate is connected to ground. The bottom plate is characterized by a capillary structure made from a series of five squared (400 x 400 μm) grooves filled with HFE 7100, a dielectric fluid. This geometry, presented in Figure 1 is representative of a grooved heat pipe. Here, the length of the groove can be considered as infinite and the configuration is viewed as 2-D. Figure 1 represents the setup with a grooved aluminum plate at the bottom, separated from a glass plate at the top by a gasket seal made with PTFE. The glass plate is coated with an indium tin oxide (ITO) layer on its inner part and used as the high voltage electrode at the top of the cavity. The ITO layer is transparent and therefore allows for optical investigation of the liquid-vapor interface even when the electric field is applied. The ITO layer is connected to the high voltage owing to a very thin layer of copper inserted all around the cavity between the upper plate and the PTFE gasket. A spacing of 1.5 mm is ensured between top and bottom electrodes (Fig.1a). This volume is essentially filled by vapor while the liquid phase is essentially confined within the grooves.

When a voltage is applied between the electrodes in the studied configuration, the vapor and liquid phases behave like two superimposed electric capacitors due to their respective dielectric permittivities. This leads to a jump in the electric field at the fluid interface, as well as to a jump in the electric properties. The electric stress so generated at the interface has two components. Its normal component can actuate the liquid-vapor interface. It should be recalled that the normal electric stress is proportional to the square of the electric field $\tau_n \approx \varepsilon E^2$ (i.e. to the square of the applied voltage).

*Corresponding author. E-mail: laurent.davoust@simap.grenoble-inp.fr.

FREQUENCY SWEEP AND RESONANT FREQUENCIES

To study the effect of the electric stress on the interface, an oscillatory voltage with a time-dependent frequency is imposed between both electrodes (Fig.1b). The time-dependent elevation of the meniscus of the center of the microgroove is measured thanks to confocal microscopy (Fig.1c). A symmetry break-up on the signal delivered by the confocal microscope can be reported in the regime of low frequencies. Depending on the actuation frequency, the peak elevation of the interface can be observed. To analyse the frequency content of the signal, a time-dependent Fourier analysis is applied upon the elevation signal. A fundamental frequency, defined as the most energetic one, is found twice as much as the frequency of the actuation voltage. This is consistent because the oscillatory deformation of the interface is driven by the electric stress which is proportional to the square of the AC voltage. A sub-harmonic frequency, equal to the actuation frequency, is also found which suggests the presence of electric charge density in the liquid volume since the Coulombic force is proportional to the voltage applied. For a frequency large enough, the relaxation of the electrical charges makes possible the arising of multiple harmonic frequencies. This confirms that dielectric effects become prior. These frequencies correspond to the natural resonant modes of the liquid-vapor interface as confirmed from considerations on the dispersion relation. Because the viscous frequency is much smaller than most of the resonant frequencies, a decisive advantage of the AC approach over the DC approach is that it makes possible the local actuation of the liquid-vapor interface independently from the liquid reservoir located at the condenser of a heat pipe.

MAIN RESULTS

In this paper, the ability of an AC electric field to change the shape of a meniscus is investigated for the first time by means of confocal microscopy. The experimental bench consists in a slim closed configuration made with one grounded grooved plate at the bottom, facing a flat plate at the top (Figure 1a). The latter is submitted to a high voltage AC regime. The cavity is filled with HFE 7100 as a working fluid. Experimental results highlight the deformation of the liquid-vapor interface in presence of an electric field which is further compared to an in-house numerical method: a good agreement is found. The respective effects of DC vs AC regimes are also investigated: an electro-capillary hysteresis is observed when using a DC electric field whereas resonance effects are observed when use is made of a AC field. A length scale selectivity is suspected depending on the frequency of the AC actuation.

A THEORY OF DISSIPATIVE ALFVÉN WAVES IN A BOUNDED DOMAIN

Guillaume Bermudez*[1] and Alban Pothérat[2]
[1]Département de Physique, Ecole Normale Supérieure, Université PSL, 75005 Paris, France
[2]Center for Fluids and Complex Systems, University of Coventry, Priory Street, Coventry CV1, UK

Summary Magnetohydrodynamics (MHD) wave behaviour can occur under certain conditions due to the coupling between the velocity field of the fluid and the magnetic field; these waves are called Alfvén waves. Alfvén waves exist if their wavelength (proportional to the external magnetic field) is smaller than their dissipation lengthscale (due to viscosity and resistivity). Because the latter is usually very short, Alfvén are commonly assumed to be absent from small-scale laboratory experiments with liquid metals. Previous experimental works showed that this assumption breaks down for sufficiently high magnetic fields, prompting the question of the conditions in which these waves may be observed in laboratory scale experiments with liquid metals, especially when physical boundaries are present. In this paper, we set out to answer this question theoretically.

CONTEXT

Hannes Alfvén showed in 1942 [1], in what one can call a concise article, the existence of magnetohydrodynamic (MHD) waves in perfectly conducing and inviscid fluids due to the two-way coupling of the velocity and magnetic fields. Some later theoretical developments then showed that, under certain conditions, the waves can also be observed in resistive viscous fluids. Although quite challenging due to their high viscosity and resitivity, this fact has been experimentally confirmed throughout the XX$^{\text{th}}$ century [2–5]. These complex wave behaviours would be very promising subjects of research in the lab to model astrophysical phenomenon but are still limited by the highly dissipative tendency of liquid metals. However, most of the theoretical developments on Alfvén waves seem to be limited to open geometries when liquid metal experiments are bounded. Yet, the boundary conditions determine the growth of Alfvén waves, through the phenomenon of reflection *inter alia*.

MODEL AND RESULTS

In the present work, we derive a novel model describing the conditions to observe Alfvén waves in dissipative media. We study a compact geometry, bounded by two horizontal walls called Hartmann walls, and vertical lateral walls of arbitrary shape, allowing variable separation, which describes liquid metal experiments in tanks.

Let us consider a non-relativistic, quasi-neutral, incompressible conducing fluid and introduce its velocity field $\mathbf{v}$ and magnetic field $\mathbf{B}$. The fluid is governed by the full-MHD equations, which are a resourceful rewriting of Navier–Stokes equations and Maxwell equations, which, given our geometry, can be rewritten using alfvénic units as

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v}\cdot\boldsymbol{\nabla})\mathbf{v} = (\mathbf{B}\cdot\boldsymbol{\nabla})\mathbf{B} + \nu\boldsymbol{\nabla}^2\mathbf{v}, \qquad \boldsymbol{\nabla}\cdot\mathbf{v} = 0,$$
$$\frac{\partial \mathbf{B}}{\partial t} + (\mathbf{v}\cdot\boldsymbol{\nabla})\mathbf{B} = (\mathbf{B}\cdot\boldsymbol{\nabla})\mathbf{v} + \eta\boldsymbol{\nabla}^2\mathbf{B}, \qquad \boldsymbol{\nabla}\cdot\mathbf{B} = 0,$$

ν being the viscosity of the fluid, η the magnetic diffusivity of the fluid, the magnetic field being rescaled as the Alfvén speed.

The fluid, initially at rest, is submitted to an external stationary and homogeneous magnetic field $\mathbf{B}_0 = B_0\hat{\mathbf{e}}_z$ (generated by a magnet for instance) which breaks the symmetry of the system, introducing a preferential direction for Alfvén wave modes alongside its field lines z. As in a bounded geometry the reflection of Alfvén waves — which is nearly total [6] — is a crucial element determining the growth of wave modes, we separate the x, y normal boundaries on the side-walls on the one hand and the z tangential boundaries on the so-called Hartmann walls on the other hand.

To do so, we search for modal Alfvén z-propagating modes and we account for the side-walls boundary conditions expanding over the basis of the eigenmodes $\mathbf{v}_\alpha$ of the normal laplacian $\boldsymbol{\nabla}_\perp^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$ such that $(\boldsymbol{\nabla}_\perp^2 + \alpha^2)\mathbf{v}_\alpha = \mathbf{0}$, satisfying the side-walls boundary conditions. For these modes, the linearly perturbated full-MHD equations yields a complex (k, ω) dispersion relation, $\mathfrak{Re}\, k$ being the z-component of the wavevector, $\mathfrak{Im}\, k$ the corresponding growth rate and ω the frequency, depicted on Fig. 1 overleaf, which has two branches :

- a Hartmann mode k^+, an overdamped mode characterising the MHD boundary layer (red in Fig. 1) ;
- an Alfvén mode k^-, a wave-like mode propagating at the Alfvén speed (blue in Fig. 1).

The control parameters for that dispersion relation are the Prandtl number $\mathcal{P}m = \nu/\eta$ (ratio of kinematic and magnetic diffusivities), the Hartmann number $\mathcal{H}a = \dfrac{B_0\ell}{\sqrt{\eta\nu}}$ (acting as an nondimensional magnetic field) and the eigenvalue α.

Although damped, Alfvén waves can be observed if the damping length is significantly larger than the system size, and the latter is significantly larger than the wavelength which yields the condition that $|\mathfrak{Im}\, k^-| \ll 1/\ell \ll |\mathfrak{Re}\, k^-|$.

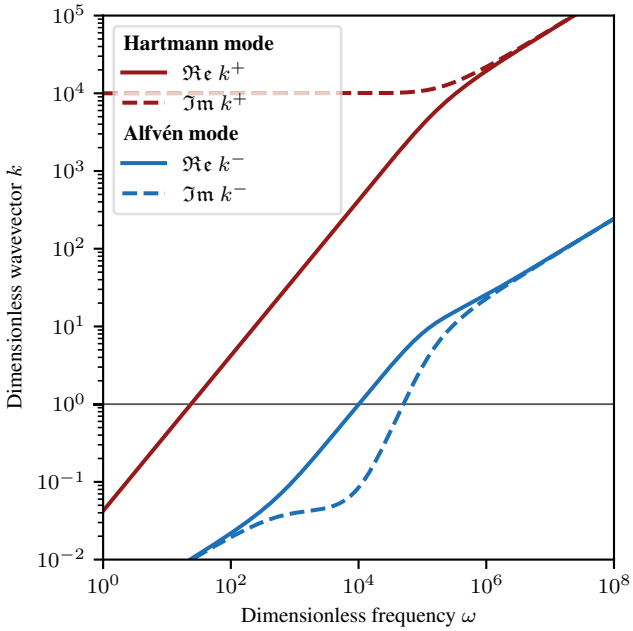

Figure 1: Plot of the dispersion of relation (k, ω) stemming from linearly perturbated full-MHD equations in a bounded geometry. Values of the influence parameters are taken for a typical galinstan experiment from *Alboussière et al.* [4] : $\mathcal{P}m = 10^{-6}$, $\mathcal{H}a = 10^4$, $\alpha = 1$.
The wavevector k has been made dimensionless with the z-characteristic length of the system ℓ and the frequency ω with the effective diffusion time $\ell^2/\sqrt{\eta\nu}$.

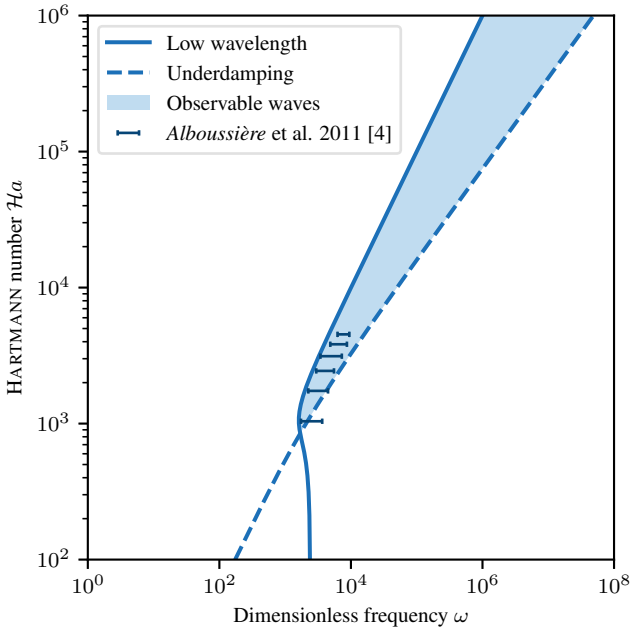

Figure 2: Plot of the region for which the alfvénic mode from the Fig. 1 are observed, compared with experimentally observed Alfvén waves from *Alboussière et al.* [4].
Values of the influence parameters are taken for a typical galinstan experiment [4] : $\mathcal{P}m = 10^{-6}$, $\alpha = 1$.
The frequency ω has been made dimensionless with the effective diffusion time $\ell^2/\sqrt{\eta\nu}$.

Such conditions restrain the observable frequencies to the region plotted in the Fig. 2 above. We have analytically proved that to observe Alfvén waves, the Hartmann number $\mathcal{H}a$ must be higher than a critical value

$$\mathcal{H}a > \mathcal{H}a_c = \alpha\sqrt{\mathcal{P}m^{-1} - 1} \qquad \text{for} \quad \mathcal{P}m \leqslant 1.$$

α can be understood as a geometrical factor. Noteworthily, this critical value is consistent with experimental observations as for a typical galinstan (GaInSn) experiment [4, 5] $\mathcal{H}a_c \simeq 3 \times 10^3$ in which $\alpha \simeq 1$ and $\mathcal{P}m \simeq 10^{-6}$. Indeed, our theoretical prediction matches the range of frequencies and Hartmann numbers where Alfvén waves were experimentally observed by *Alboussiere et al.* and others [4, 5], as it can be seen in the Fig. 2 above.

Finally, to account for the Hartmann walls and the associated no-slip, insulating z-boundary condition there, we decomposed our modes in its $\mathbf{B}_0$-normal and $\mathbf{B}_0$-tangential components to search for natural modes of the cavity. We proved that the tangential mode was forbidden in liquid metals for witch $\mathcal{P}m \ll 1$, which is consistent with the known fact that purely transversal Alfvén waves are actually an exact result of the full-MHD equations.

We showed that the reflection of Alfvén waves is a crucial element conditioning the growth of wave modes. Accounting for side wall boundary conditions, normal to the main magnetic field, allowed us to determine the critical Hartmann number $\mathcal{H}a_c$ to observe Alfvén waves, as well as their frequency range ; while Hartmann wall boundary conditions allowed us to demonstrate that the waves tangential to the main magnetic field are forbidden in such a geometry, both consistently with experimental results.

With this new approach, we expect to be able to identify Alfvén waves in the bulk of a class of wall-bounded MHD flows, from measurements at the walls only.

GENERATION AND REVERSAL OF HELICITY IN CONDUCTING FLUIDS

Wesley Agoua*[1], Wouter Bos[1], Alexandre Delache[1,2], Benjamin Favier[3], and Antoine Briard[4]

Summary This paper explains a mechanism for the generation of spatial mean helicity $h = \overline{\mathbf{u}\cdot\boldsymbol{\omega}}$ (with $\mathbf{u}$ the velocity and $\boldsymbol{\omega}$ the vorticity). In a conducting fluid with a vertical unstable stratification and imposed magnetic field, a correlation is established between helicity and spatial mean skew diffusion defined by $\mathbf{q} = \overline{\rho\boldsymbol{\omega}}$ with ρ the density. It is shown using numerical simulations that helicity is generated when the correlation length in the vertical direction becomes significantly larger than the horizontal one. The helicity saturates at a value dependent on the strength of the magnetic field, the mean temperature gradient and the Reynolds number.

STATE OF THE ART

A magnetic field has been protecting against stellar radiations our planet for more than three billions years . According to the laws of electromagnetism, it should have disappeared a few thousand years after the creation of the Earth if only diffusion is taken in account. The exact mechanism which maintains it is an open problem nowadays. However since a conference given by Larmor in 1919 [1] , the theory of the self-sustained dynamo is well accepted. The Earth's outer core is known to be a metallic liquid. Its movement creates an electric field which induces a magnetic field. Most of the proposed dynamical mechanisms which can generate and sustain a large scale field involve helical velocity fields [2]. The origin of this helicity is still a subject of debate [3],[4]. The present investigation focuses on one possible mechanism which can explain spontaneous and statistically homogeneous helicity generation.

UNSTABLE STRATIFICATION AND HELICITY GENERATION

The mechanism proposed in this paper uses the idea that the Earth's inner core is dynamically active, The temperature gradient between the core and the surface creates an unstable stratification. This vertical stratification is characterized by the parameter N defined by $N^2 = -\frac{g}{\overline{\rho}}\frac{\partial \rho}{\partial z}$. The mechanism we propose combines this vertical stratification with a vertical magnetic field leading to the generation of vertical helicity.

From the Navier-Stokes equations and the equation for the density fluctuations, two coupled equations are obtained for average quantities $h_3 = \overline{u_3\omega_3}$ and $q_3 = \overline{\rho\omega_3}$ where u_3, ω_3 and ρ are fluctuations of vertical velocity, vorticity, and density, respectively,

$$\begin{cases} \dfrac{\partial q_3}{\partial t} = N^2 h_3 + \nu\overline{\rho\partial_i^2\omega_3} + \kappa\overline{\omega_3\partial_j^2\rho} + \overline{\rho\omega_i\partial_i u_3} + F^{\omega L} \\ \dfrac{\partial h_3}{\partial t} = \dfrac{g}{\overline{\rho}}q_3 - \dfrac{1}{\rho}\overline{\omega_3\partial_3 p} + \nu\overline{\partial_i u_3\partial_i\omega_3} + F^{uL} \end{cases}$$

with F^{uL} and $F^{\omega L}$ terms associated with the Lorentz force.

In the absence of nonlinearity these equations will lead to an exponential increase of $\overline{u_3\omega_3}$ and $\overline{\rho\omega_3}$ with a growth rate determined by the parameter N.

NUMERICAL SIMULATIONS AND RESULTS

Numerical simulations are performed by using pseudo-spectral methods in a 2π-periodic square box. The fluid is forced with a normalized unstable vertical stratification with a parameter N. The fluid is characterized by its spatial average density $\overline{\rho}$ and viscosity ν. The magnetic field is characterized by the frequency $F = \frac{B^2}{\eta}$ with B the magnetic field strength and η the magnetic diffusivity.

*E-mail: wesley.agoua@ec-lyon.fr.

The first simulations without magnetic field show that the nonlinear damping terms are too strong to allow a generation of helicity in homogeneous stratified turbulence without walls or body forces. It can be shown analytically that these damping terms can be neglected in the case of a fluid which is invariant along the vertical axis, but it seems that the stratification alone is not sufficient to induce this invariance. Subsequently a static vertical magnetic field is therefore applied to the flows using the quasi-static approximation. As can be observed in figure 1 where are represented isosurfaces of helicity, the vertical invariance is enhanced, illustrated by the tube-shaped helicity isosurfaces.

Figure 1: Helicity isosurfaces without and with magnetic field in unstably stratified periodic box turbulence.

The invariance allows an initial exponential evolution of both helicity and skew diffusion with the parameter N as a growth rate, as predicted by the equations. After this linear evolution observed on figure 2, helicity keeps increasing up to a saturation value proportional to the magnetic frequency $\frac{B^2}{\eta}$ and the square root of N.

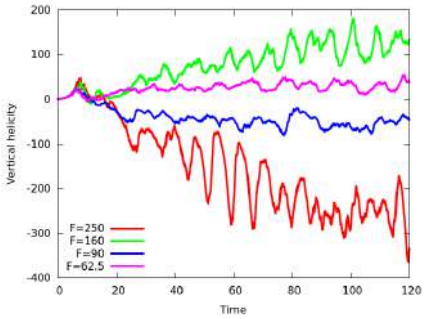

Figure 2: Helicity during the simulation for different values of the magnetic field.

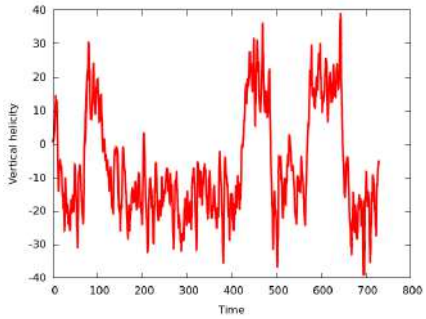

Figure 3: Reversals of the mean helicity are observed for certain parameters.

Another remarkable observation is that reversals of the helicity can be observed along time, (figure 3), more often when the flow is weakly invariant along the vertical axis. Instabilities of the tube-shaped structures for a relative weak magnetic field seem to be at the origin of this phenomenon.

CONCLUSIONS

Numerical simulations confirm the correlation between helicity and skew diffusion in the presence of a unstable stratification and a static magnetic field. The value of the helicity at saturation is determined by parameters characterizing the fluid and the forcing. We think that, possibly, this mechanism can constitute an interesting explanation for the generation of helicity in the outer core of the Earth.

NUMERICAL MODELLING OF ELECTRO-PULSING

D.E.A. van Odyck*[1]
[1]Tata Steel, R&D, IJmuiden, The Netherlands

Summary Inside a liquid melt one can use electromagnetic forces to manipulate (non-metallic) particles. Recently, experiments have shown promising results in redistributing non-metallic particles inside a liquid melt exposed to an AC current. It is believed that electromagnetophoresis is responsible for accelerating the particles. In this work the model is introduced that describes the liquid metal fluid flow and the particle motion under the influence of an applied current. The model is implemented in OpenFOAM 4.x [9] and some simulation results are presented.

INTRODUCTION

The distribution or removal of (non-metallic) particles in a liquid metal, can be of advantage in the processing of, for example, steel. A major issue in continuous casting is the presence of aluminium oxides. These particles can have a negative effect on process stability and final product quality. The removal or redistribution of these inclusions in such a way that they can not have a negative effect on the process or on the final product is still a topic of active research. A comprehensive overview of these methods is given in [1], [2].

In [3] experiments have been carried out using a rectangular container containing a liquid metal. Two opposing side walls were equipped with electrodes. A homogeneous mixture of liquid melt and small non-metallic particles (average diameter of $8[\mu m]$) was exposed to a pulsed electric current applied to the opposing electrodes. According to their article [3] the main reason for pulsing was to prevent Ohmic heating. The experiment showed a redistribution of particles away from the current density towards the meniscus and the bottom of the container. In their article [3] a free energy argument is used to explain the heterogeneous distribution of particles after electro pulsing. In this study it is proposed to use a more traditional approach, based on electromagnetophoresis [4], and see how well it approaches experimental data.

THEORY

In [4] it is argued that a particle with a different conductivity than the fluid will experience a net force ($\mathbf{F}_{EM}$) if the conducting fluid is exposed to a magnetic field ($\mathbf{B}$) and a current density ($\mathbf{J}$).

$$\mathbf{F}_{EM} = -E_L \mathbf{J} \times \mathbf{B} \ , \quad E_L = \frac{3}{2} V_p \frac{\sigma - \sigma_p}{2\sigma + \sigma_p} \tag{1}$$

where σ, σ_p, V_p are the fluid conductivity, particle conductivity and particle volume, respectively. Even if no external magnetic field is applied the current density alone generates an induced magnetic field that can contribute to the net force experienced by the particle. Particle motion is described by Newton's law:

$$m_p \frac{d\mathbf{u}_p}{dt} = \mathbf{F}_{EM} + \mathbf{F}_d + \mathbf{F}_g + \mathbf{F}_l \tag{2}$$

where $\mathbf{F}_d, \mathbf{F}_g, \mathbf{F}_l$ are the drag, gravity-buoyancy and lift force (detailed expressions for these forces can be found in [8]). According to Ampere's law, the applied current density induces a magnetic field. This magnetic field can be calculated using the so-called $\mathbf{A} - \phi$ formulation [6], where the vector potential ($\mathbf{A}$, $\mathbf{B} = \nabla \times \mathbf{A}$) and the electric potential (ϕ, $\mathbf{E} = -\nabla\phi$) are the unknown variables:

$$\begin{aligned} \tfrac{\partial \mathbf{A}}{\partial t} &= -\nabla\phi + \tfrac{1}{\sigma\mu_0}\Delta\mathbf{A} \\ \Delta\phi &= 0 \end{aligned} \tag{3}$$

where the current density follows from $\mathbf{J} = \frac{1}{\mu_0}\nabla \times \mathbf{B}$ and μ_0 is the vacuum magnetic permeability. The (incompressible) fluid flow is governed by the magnetohydrodynamic (MHD, [6]) equations:

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\frac{1}{\rho}\nabla p + \eta \Delta \mathbf{u} + \frac{1}{\rho}\mathbf{J} \times \mathbf{B} \text{ and } \nabla \cdot \mathbf{u} = 0 \tag{4}$$

where ρ, η are the fluid density and kinematic viscosity, respectively. Taking into account the size of the particles, small, the one-way coupled approach is assumed, meaning that the particles do not exert a force on the fluid. Only the fluid affects the particle trajectories.

*Corresponding author. E-mail: Daniel.van-odyck@tatasteeleurope.com

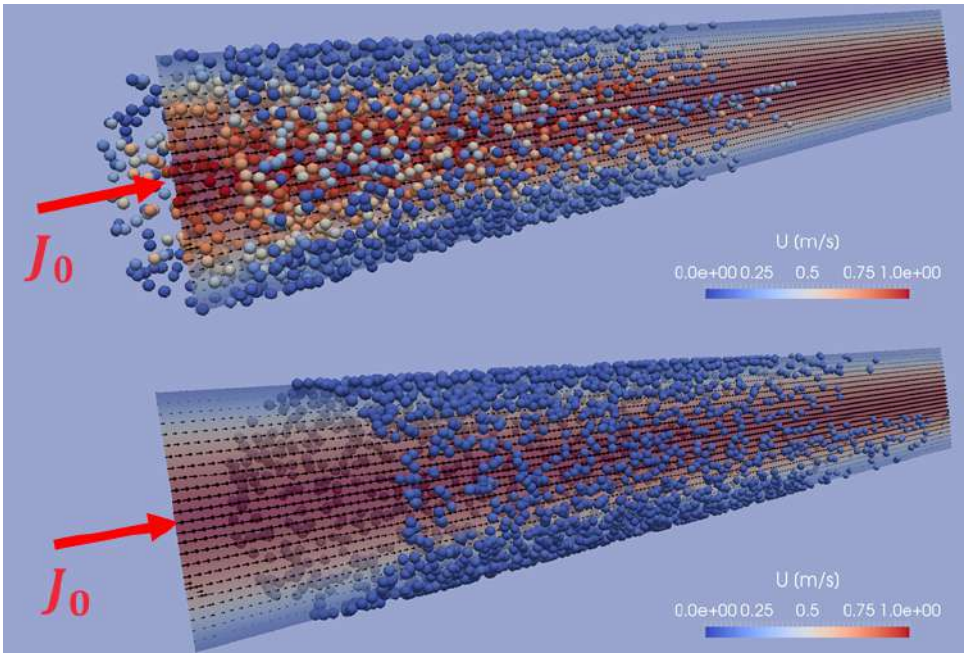

Figure 1: Fluid velocity indicated by arrows and colour scale. Particles indicated by spheres (not real size!) and their velocity is indicated by the colour scale. Top figure: Showing particle distribution during particle injection. Bottom figure: Showing particle distribution after particle injection stopped.

IMPLEMENTATION

The above described model was implemented in OpenFOAM 4.x and concerning the MHD implementation the methodology described in [7] was followed. As a first step, the flow inside an one meter long cylinder subject to a constant current density ($J = 7.13 \cdot 10^6\,[A/m^2]$) applied between the ends of the cylinder was considered. At the inlet of the cylinder a parabolic velocity profile is applied. Particles ($d_p = 70 \cdot 10^{-6}\,[m]$) are injected at random positions at the inlet. After a certain period injection of particles is stopped. Figure (1) shows particle positions at two different times (before and after stopping the injection of particles). It is clear that as time passes more and more particles are migrated towards the cylinder wall because of net Lorentz force ($\mathbf{F}_{EM}$) acting on the particles.

OUTLOOK

A new approach is presented to explain the particle separation between two electrodes as encounter in the work of Zhang [3]. It is based on MHD where the inclusions are modelled as particles subject to forces. During the presentation a more detailed comparison between the proposed model and the experimental results of Zhang [3] will be shown.

ELECTROROTATION OF A SPHERICAL CAPSULE IN AN APPLIED UNIFORM CONSTANT ELECTRIC FIELD

Alexander Tyatyushkin*[1]
[1]Institute of Mechanics, Moscow State University, Moscow, Russia

Summary The electrorotation of a capsule in an applied uniform constant electric field is theoretically investigated. The capsule is a rigid spherical shell inside of which a weakly electrically conducting polarizable liquid is contained and suspended in an infinite volume of another weakly electrically conducting polarizable liquid. The influence of the surface conductivity on the internal and external surfaces of the shell is taken into account. With use of the electrohydrodynamic approximation, Stokes approximation, and approximation of quasi-steady flow, the equations are obtained that determine the variation of the electric field and of the flow of the liquids inside and outside the shell. The angular velocity of the steady electrorotation is found.

INTRODUCTION

The study of the electrorotation of various objects attracts attention [1] both due to the fact that this is an interesting phenomenon from the point of view of fundamental science and due to its applications. Melcher and Taylor [2] investigated theoretically the electrorotation of a solid cylinder, Jones [2] investigated the electrorotation of a solid spherical particle. Turcu [4] studied the rotation of a rigid spherical particle in alternating electric fields. Turcu and Lucaciu [5] investigated the rotation a spherical object surrounded by a thin shell both in constant and in alternating electric field. He, Salipante, and Vlahovska [6] studied the electrorotation of a fluid drop.

In order the steady electrorotation occurs in a constant electric field, the solution with constant angular velocity should not only exist, but also be stable. For the electrorotation of a spherical particle, a rather simple situation takes place: if a solution with electrorotation exists, it is stable and the solution without electrortation is unstable; and if a solution with electrorotation does not exist, the solution without electrortation is stable. The situation may be more interesting for more complex objects.

The goal of the present work is to solve the problem about the electrorotation of a spherical capsule and to obtain the conditions of existence and stability for the solutions with electrorotation.

SETTING OF THE PROBLEM

Consider a spherical capsule containing an incompressible viscous weakly electrically conducting polarizable liquid and suspended in another incompressible viscous weakly electrically conducting polarizable liquid in an applied constant uniform electric field with the intensity $\vec{E}_{\mathrm{a}}$. The shell of the capsule is a rigid spherical layer with the external radius R_{e} and the internal radiusR_{i}. The liquids are regarded as sufficiently viscous so that the Stokes approximation is valid and their conductivities are regarded as sufficiently small so that the electrohydrodynamic approximation is valid. Let λ_{e}, λ_{l}, λ_{i} and ε_{e}, ε_{l}, ε_{i} be the conductivities and dielectric permittivities of the liquid outside the capsule, of its shell, and of the liquid inside it, accordingly, η_{e} and η_{i} be the viscosities of the of the liquids outside and inside the capsule, λ_{se} and λ_{si} be the surface conductivities of the external and internal surfaces of the shell of the capsule.

The system of equations for the electric field consists of the Maxwell's equations in the electrohydrodynamic approximations, the law of electric charge conservation, and the material relations. The system of equations for the flow inside and outside the capsule consists of the continuity equation and the Navier–Stokes equation in the Stokes approximation.

The boundary conditions for the electric field on the external and internal surfaces of the shell of the capsule include the continuity condition for the tangential component of the electric field intensity and the conditions for the jumps of the normal components of the electric induction and electric current density vectors. The boundary conditions for the flow on the surfaces of the shell include impenetrability and no-slip conditions and the continuity condition for the tangential component of the stress vector. The stress vector is the total stress tensor, which includes the electric stress tensor, contracted with the external unit normal vector to the surface. At infinity, the electric field intensity tends to the intensity of the applied electric field, $\vec{E}_{\mathrm{a}}$, and the velocity tends to zero. Besides, the electric field intensity and velocity should be bounded for all the values of the radius vector, $\vec{r}$, and time, t.

SOLUTION

The equations for the electric field and for the flow, boundary conditions at infinity, and conditions of boundedness, as well as the continuity condition for the tangential component of the electric field intensity and the impenetrability and

*Corresponding author. E-mail: tan@imec.msu.ru.

no-slip conditions for the velocity on the surfaces of the shell allow one to express the electric field intensity and the velocity of the liquids inside and outside the capsule in the form

$$\vec{E} = -\nabla\varphi, \quad \varphi = \begin{cases} -\vec{E}_{\rm a}\cdot\vec{r} + \vec{D}_{\rm e}\cdot\dfrac{\vec{r}}{r^3} + \vec{D}_{\rm i}\cdot\dfrac{\vec{r}}{r^3}, & r > R_{\rm e}, \\ -\vec{E}_{\rm a}\cdot\vec{r} + \vec{D}_{\rm e}\cdot\dfrac{\vec{r}}{R_{\rm e}^3} + \vec{D}_{\rm i}\cdot\dfrac{\vec{r}}{r^3}, & R_{\rm i} < r \leqslant R_{\rm e}, \\ -\vec{E}_{\rm a}\cdot\vec{r} + \vec{D}_{\rm e}\cdot\dfrac{\vec{r}}{R_{\rm e}^3} + \vec{D}_{\rm i}\cdot\dfrac{\vec{r}}{R_{\rm i}^3}, & r \leqslant R_{\rm i}, \end{cases} \qquad \vec{v} = \begin{cases} \dfrac{R_{\rm e}^3}{r^3}\vec{\Omega}\times\vec{r}, & r > R_{\rm e}, \\ \vec{\Omega}\times\vec{r}, & r \leqslant R_{\rm e}, \end{cases} \tag{1}$$

where the depending on the time parameters $\vec{D}_{\rm e}$ and $\vec{D}_{\rm i}$ and angular velocity of the electrorotation of the capsule $\vec{\Omega}$ are determined by the boundary conditions on the surfaces of the shell. Here, the origin of $\vec{r}$ is at the center of the capsule.

The equations for the variation in time of the parameters $\vec{D}_{\rm e}$ and $\vec{D}_{\rm i}$ follow from the conditions for the jumps of the normal components of the electric induction and electric current density vectors and have the form

$$-\frac{1}{4\pi}\frac{1}{R_{\rm e}^3}(\varepsilon_{\rm l}-\varepsilon_{\rm i})\left(\vec{D}_{\rm e}\times\vec{\Omega}+\frac{{\rm d}\vec{D}_{\rm e}}{{\rm d}t}\right)+\frac{1}{4\pi}\frac{1}{R_{\rm i}^3}(2\varepsilon_{\rm l}+\varepsilon_{\rm i})\left(\vec{D}_{\rm i}\times\vec{\Omega}+\frac{{\rm d}\vec{D}_{\rm i}}{{\rm d}t}\right)=\frac{1}{R_{\rm e}^3}\left(\lambda_{\rm l}-\lambda_{\rm i}-\frac{2\lambda_{\rm si}}{R_{\rm i}}\right)\vec{D}_{\rm e}$$
$$-\frac{1}{R_{\rm i}^3}\left(2\lambda_{\rm l}+\lambda_{\rm i}+\frac{2\lambda_{\rm si}}{R_{\rm i}}\right)\vec{D}_{\rm i}-\left(\lambda_{\rm l}-\lambda_{\rm i}-\frac{2\lambda_{\rm si}}{R_{\rm i}}\right)\vec{E}_{\rm a}-\frac{1}{4\pi}(\varepsilon_{\rm l}-\varepsilon_{\rm i})\,\vec{E}_{\rm a}\times\vec{\Omega}, \tag{2}$$

$$\frac{1}{4\pi}\frac{1}{R_{\rm e}^3}(2\varepsilon_{\rm e}+\varepsilon_{\rm l})\left(\vec{D}_{\rm e}\times\vec{\Omega}+\frac{{\rm d}\vec{D}_{\rm e}}{{\rm d}t}\right)+\frac{1}{4\pi}\frac{1}{R_{\rm e}^3}(2\varepsilon_{\rm e}-2\varepsilon_{\rm l})\left(\vec{D}_{\rm i}\times\vec{\Omega}+\frac{{\rm d}\vec{D}_{\rm i}}{{\rm d}t}\right)=-\frac{1}{R_{\rm e}^3}\left(2\lambda_{\rm e}+\lambda_{\rm l}+\frac{2\lambda_{\rm se}}{R_{\rm e}}\right)\vec{D}_{\rm e}$$
$$-\frac{1}{R_{\rm e}^3}\left(2\lambda_{\rm e}-2\lambda_{\rm l}+\frac{2\lambda_{\rm se}}{R_{\rm e}}\right)\vec{D}_{\rm i}-\left(\lambda_{\rm e}-\lambda_{\rm l}-\frac{2\lambda_{\rm se}}{R_{\rm e}}\right)\vec{E}_{\rm a}-\frac{1}{4\pi}(\varepsilon_{\rm e}-\varepsilon_{\rm l})\,\vec{E}_{\rm a}\times\vec{\Omega}. \tag{3}$$

The continuity condition for the tangential component of the stress vector on the surfaces of the shell yields

$$\vec{\Omega} = \frac{\varepsilon_{\rm e}}{8\pi\eta_{\rm e}R_{\rm e}^3}\vec{E}_{\rm a}\times\left(\vec{D}_{\rm e}+\vec{D}_{\rm i}\right). \tag{4}$$

Substituting the relation (4) into the equations (2) and (3), one obtains the system of ordinary differential equations that completely determines the variation of the parameters $\vec{D}_{\rm e}$ and $\vec{D}_{\rm i}$ if the values of these parameters at some initial instant are given. In particular, stationary solutions of this system of equations can found. With use of the relation (4), then the angular velocity of the steady electrorotation can be found.

The setting of the problem allows existence of both the solutions with electrorotation, for which $\Omega \neq 0$, and those without electrorotation, for which $\Omega = 0$. It follows from the relation (4), that the angular velocity is always normal to the applied electric field intensity vector. Due to the symmetry of the problem, it means that there exist an infinite set of the solutions with electrorotation that are determined by a unique value of the angular speed Ω.

The found formulas expressing the angular speed Ω, as well as the parameters $\vec{D}_{\rm e}$ and $\vec{D}_{\rm i}$ on the parameters of the problem $\vec{E}_{\rm a}$, $R_{\rm e}$, $R_{\rm i}$, $\lambda_{\rm e}$, $\lambda_{\rm l}$, $\lambda_{\rm i}$, $\varepsilon_{\rm e}$, $\varepsilon_{\rm l}$, $\varepsilon_{\rm i}$, $\eta_{\rm e}$, $\eta_{\rm i}$, $\lambda_{\rm se}$, and $\lambda_{\rm si}$ for the stationary solutions are not written down because they are too cumbersome for the present paper.

CONCLUSIONS

The investigation of the equations that determine Ω for the steady electrorotation allowed finding the conditions of existence and Melcher–Taylor's stability [2], based on the force moment balance, of the corresponding solutions. It is established that there always exists the only stationary solution with $\Omega = 0$ and that, depending on the parameters of the liquids and shell, the three cases can take place: 1) solutions with $\Omega \neq 0$ do not exist and the solution with $\Omega = 0$ is alwayes stable, 2) when $E_{\rm a} < E_{\rm c}$, solutions with $\Omega \neq 0$ do not exist and the solution with $\Omega = 0$ is stable, and when $E_{\rm a} > E_{\rm c}$, there exist stable solutions with $\Omega = \Omega_1 \neq 0$ and the solution with $\Omega = 0$ is unstable, 3) when $E_{\rm a} < E_{\rm c1}$, the solutions with $\Omega \neq 0$ do not exist and the solution with $\Omega = 0$ is stable, when $E_{\rm c1} < E_{\rm a} < E_{\rm c2}$, there exist unstable solutions with $\Omega = \Omega_2 \neq 0$ and stable solutions with $\Omega = \Omega_1 \neq 0$ ($\Omega_2 < \Omega_1$) and the solution with $\Omega = 0$ is stable, and when $E_{\rm a} > E_{\rm c2}$, there exist stable solutions with $\Omega = \Omega_1 \neq 0$ and the solution with $\Omega = 0$ is unstable. Here, $E_{\rm c}$, $E_{\rm c1}$, and $E_{\rm c2}$ are some critical values of the electric field intensity.

TRAJECTORIES OF CHARGED PARTICLES IN A TWO-STAGE ELECTROSTATIC PRECIPITATOR

Suantara Darma Gede, Chien-Lin Lai, and Wei-Hsin Tien*
Department of Mechanical Engineering, National Taiwan University of Science and Technology, Taipei, Taiwan

Summary The trajectories of charged particles under the influence of electric field and electrohydrodynamic (EHD) secondary flows were observed separately by Particle Image Velocimetry (PIV) and particle tracking velocimetry (PTV) for a two-stage electrostatic precipitator (ESP). The charging characteristics of the wire-plate charging zones were analysed, and the influence of the EHD secondary flow patterns were compared with the charged particle trajectories.

MOTIVATION

Particulate Matter (PM) has been confirmed to be serious health risks and the removal of PM has been the focus of many recent studies. C. Arden Pope III et al. [1] compiled a study about the effects of human inhaled aerosol, it can be related to effects and pathology of various organs when human inhaled aerosols. Günter Oberdörster et al. [2] showed that human inhaled particles deposited inside the body. Electrostatic Precipitator (ESP) is one of highly efficient and widely used particle collecting technologies for air purifier and industrial filtering system. Experimental studies related to ESP often adopt particle image velocimetry (PIV) to obtain velocity field information of the EHD secondary flow patterns [3-5]. Harmdi et al. [6] investigated various tracer particles used in PIV and showed that some of the tracer particles are not affected much by the electric field, while others may be affected significantly. This finding suggested that it is possible to use different tracers to reveal the EHD flow and the motion of the charged particles, which were the subject to be collected.

METHODS

A transparent acrylic is manufactured as a two-stage ESP model in the current study, as shown in Figure 1(a). The ESP model has dimension of length, width and height of 170 × 80 × 26 mm respectively and 5 mm thickness. In this setup there are 5 pin electrode has a diameter 0.8 mm used to corona discharge. The upper and lower collecting plates of the collection area are 60 × 50 mm, 70 × 50 mm respectively. The model is given two positive and grounded in the charging zone and the collecting zone through two high-voltage DC power supplies. As shown in Figure 1(b), the overall experimental setup includes transparent acrylic model, rectifier, fan, high-voltage power supply, pulsed laser, and high speed camera. Flow field was visualized by the laser light sheet shaped from a double-pulsed Nd-YAG laser, and the images were captured by a high-speed camera and sent to computers for post-processing. During the test, motion of charged particles were test with oil droplets generated by a hazer machine (HZ-350, Antari) and the processed by PTV, and the air flow patterns were measured with Al_2O_3 particles with PIV post-processing routine.

RESULTS AND CONCLUSIONS

This study successfully established a set of quantified flow field visualization settings to observe the particle flow of the two-stage electrostatic precipitator. In the charging zone when the voltage of corona discharge electrode increases, the particles move rapidly toward the excitation electrode due to increase ion wind speed. Electrohydrodynamics (EHD) formed between the corona discharge electrode and the back corona discharge. In the collection area of the electrostatic precipitator model, the movement trajectory will change with the flow velocity and the voltage of the collector plate. As the voltage of the corona discharge electrode increases, the number of charges the particles increases, make particle easier to pass through the collection area. The motion of charged particles has significantly deviation from the EHD influenced air flow.

QUASI-STATIC MAGNETO-HYDRODYNAMIC CONVECTION IN A CYLINDER

Anthony Rouquier*[1], Alban Potherat[1], and Chris C.T. Pringle[1]
[1]Fluid and Complex Systems Research Centre, Coventry University, United Kingdom

Summary We present a numerical study on the topic of magnetoconvection in a cylinder under the quasi-static magneto-hydrodynamic approximation using a spectral-element solver. The aim of this work is to obtain a better understanding of the convection process in planetary cores, in particular the formation of anticyclonic polar inside the tangent cylinder.

INTRODUCTION

The earth background rotation causes the convection of the Earth core to be divided in two zones due to the Taylor-Proudman constraint ; inside and outside of a theoretical cylinder aligned with the Earths rotation axis and touching the solid inner core, the tangent cylinder (TC). The convection process occurring inside this cylinder has garnered significant attention from the scientific community for decades [1]. In particular, the secular variation of the Earths magnetic field points to the existence of anticyclonic polar vortices in the Earths core [2, 3] Indeed, while Busse columns [4], generated outside the TC, are believed to be the main source of the magnetic field, they can not explain the Polar vortex and it's drift, nor the magnetic reversal. Non-magnetic experiments of the TC did not observe a polar vortex [5]. It implies that the addition of the magnetic field to the model is critical to its accuracy.

There are obstacles to accurately simulate the Earth inner core convective process. It is a complex problem with many governing parameters, and physical scales that can not be accurately numerically resolved with the current available processing power. There also are difficulties regarding the modelling the boundary conditions of the magnetic field. We consider the convection inside a cylinder under the quasi-static MHD approximation, thus circumventing the problems arising form the magnetic field boundary conditions. While less accurate than the geodynamo theory, this model should still yields insights regarding the convection in the inner core. The physical model may be expended upon in the future to obtain results closer to the actual physical process.

EQUATIONS FOR THE QUASI-STATIC MHD MODEL

The problem considered is the motion of an electrically conducting fluid in a closed cylinder with electrically insulated boundaries. An external homogeneous magnetic field $\mathbf{B_0}$ is imposed in the vertical direction, across the cylinder length.

In this work is used the quasi-static, low magnetic Reynolds number approximation. While the electric currents induced by the motion of the fluid in the magnetic field are non-negligible, the magnetic field induced by these electric currents can be neglected. Therefore the agglomerated magnetic field is indistinguishable from $\mathbf{B_0}$. It follows that solving the transport equation for the magnetic field is not necessary. We also work under the Boussinesq approximation, where all density differences are neglected with the exception the gravity-affected terms.

The scales used for non-dimensionalisation are the cylinder radius a, peak inlet velocity U_0, pressure ρU_0^2, time a/U_0, the temperature difference between the cylinder inlet and outlet ΔT, the field strength B_0 and electric potential aU_0B_0. The dimensionless system of equations describing our system can be written as:

$$\nabla \cdot \mathbf{u} = 0 \tag{1}$$

$$\frac{\partial \mathbf{u}}{\partial t} = -\nabla p - (\mathbf{u}\cdot\nabla)\mathbf{u} + Pr\nabla^2\mathbf{u} + RaPr\mathbf{e_y} + Ha^2Pr(\mathbf{j}\times\mathbf{e_y}) \tag{2}$$

$$\frac{\partial T}{\partial t} + (\mathbf{u}\cdot\nabla)T = \nabla^2 T\ , \tag{3}$$

$$\mathbf{j} = -\nabla\phi + \mathbf{u}\times\mathbf{e_y}\ , \tag{4}$$

where $\mathbf{u}$ is the fluid velocity, T its temperature, p the pressure, $\mathbf{j}$ the electric density vector and ϕ is the electric potential. , Ha the Hartmann number defined as $Ha = aB_0\sqrt{\sigma/\rho\nu}$. $Ra = g\alpha\Delta T a^3/\kappa\nu$ is the Rayleigh number and $Pr = \frac{\nu}{\kappa}$ the Prandtl number.

In the low magnetic Reynolds approximation, the current density is, for an electrically neutral fluid, solenoidal, such that $\nabla\cdot\mathbf{j} = 0$. Taking the divergence of Eq. 4 yields a Poisson equation:

$$\nabla^2\phi = \nabla\cdot(\mathbf{u}\times\mathbf{e_y})\ , \tag{5}$$

where ϕ is the electric potential. Eq. 5 can be solved to obtain ϕ and $\mathbf{j}$.

*Corresponding author. E-mail: ad4108@coventry.ac.uk.

The boundary conditions are Dirichlet-type conditions at the wall for the velocity :

$$\mathbf{u} = 0 \quad \text{at } r = 1 \,, \tag{6}$$

and Neumann-type boundary conditions for the electric potential, corresponding to electrically insulated horizontal and vertical side walls:

$$\frac{\partial \phi}{\partial r} = 0 \quad \text{at } r = 1 \,. \tag{7}$$

The temperature is fixed to T_1 at the inlet and T_0 at the inlet and lateral walls, with $\Delta T = T_1 - T_0$.

NUMERICAL MODEL

The system of equations (1)-(4) is solved using the spectral-element code Nektar++ [6]. The spectral-element approach is a formulation of the finite element method (FEM). the computational domain is divided into elements where the variables are projected within a polynomial basis within each element. Its specificity of the spectral-element method is that mesh refinement is mainly achieved by increasing the order of the polynomial of much higher order than the standard FEM. Moreover, the interpolation polynomials use GaussLobatto points for collocation points, ensuring spectral convergence as the order of the polynomials is increased. The spectral-element approach can then reach a higher degree of accuracy than other FEM while keeping more flexibility with regards to complex geometries than a spectral method. The time-stepping used is a second-order implicit-explicit (IMEX) method.

CONCLUSIONS

The code is still being developed as of now. In a first time will be conducted a linear analysis of the system is order to find steady states. Then branch tracing will be used from these states to obtain nonlinear solutions of the problem in function of the magnetic field and convection strength and how they compare to experimental data. Other questions of interest are whether the creation anticyclonic polar vortices occurs within the quasi-static MHD approximation and how the magnetic field affects the threshold for convective instability and the flow structures.

THE MECHANISM OF VORTEX INSTABILITY IN ELECTROMAGNETICALLY DRIVEN FLOW IN AN ANNULAR THIN LAYER OF ELECTROLYTE

John McCloughan[1] and Sergey A. Suslov[1]
[1]Department of Mathematics, Faculty of Science, Engineering and Technology, Swinburne University of Technology, Melbourne, Australia

Summary Experimental studies have shown that an azimuthal flow of a conducting fluid in an annular channel driven by a Lorentz force, quite unexpectedly, developed a robust vortex system appearing near the outer cylindrical wall. Our computations have demonstrated that such vortices arise on a background of a steady axisymmetric flow, which consists of two counter-rotating toroidal structures, and that the vortices are formed at the boundary between them. Our subsequent studies use linear stability analysis and disturbance energy balance considerations to pinpoint the physical nature of the instability that leads to the experimentally observed vortices. Specifically, we show that Rayleigh's inviscid centrifugal instability aided by radial shear in the boundary layer near the outer cylindrical wall is the mechanism responsible for vortex formation. While the background flow is driven by the Lorentz force, the electromagnetic effects have virtually no influence on its stability. Therefore, the vortices appear for purely hydrodynamic reasons.

PROBLEM FORMULATION AND GOVERNING EQUATIONS

Consider a layer of incompressible, viscous, weak electrolyte of thickness h, confined to an annular cavity formed by two vertical co-axial cylindrical electrodes of radius R_1 and R_2, $R_1 < R_2$. The bottom of the cavity is solid and non-conducting, while the top is a free surface. This system is placed above a permanent disk magnet that creates a predominantly vertical magnetic field. When an electric potential difference is applied between the electrodes the total current flows predominantly radially through the layer. The interaction between the applied vertical magnetic field $\mathbf{B}$ and the radial electric current $\mathbf{j}$ gives rise to a Lorentz force $\mathbf{F_L} = \mathbf{j} \times \mathbf{B}$ per unit volume which drives the flow circumferentially. Under the small magnetic Reynolds number approximation [1] the steady axisymmetric non-dimensional form of Poissons equation for the electric potential ϕ, and the momentum and continuity equations for an incompressible fluid written in cylindrical coordinates becomes

$$\frac{\partial^2\phi}{\partial z^2} + \epsilon^2\left(\frac{\partial^2\phi}{\partial r^2} + \frac{1}{r}\frac{\partial\phi}{\partial r}\right) = \epsilon^2 Ha^2\left[-B_r\frac{\partial u_\theta}{\partial z} + B_z\left(\frac{\partial u_\theta}{\partial r} + \frac{u_\theta}{r}\right)\right], \tag{1}$$

$$u_r\frac{\partial u_r}{\partial r} - \frac{u_\theta^2}{r} + u_z\frac{\partial u_r}{\partial z} = -\frac{1}{Fr^2}\frac{\partial p}{\partial r} + \frac{1}{\epsilon^2 Re}\left(j_\theta B_z - j_z B_\theta\right) + \frac{1}{Re}\left(\frac{\partial^2 u_r}{\partial r^2} + \frac{1}{r}\frac{\partial u_r}{\partial r} - \frac{u_r}{r^2} + \frac{1}{\epsilon^2}\frac{\partial^2 u_r}{\partial z^2}\right), \tag{2}$$

$$u_r\frac{\partial u_\theta}{\partial r} + \frac{u_r u_\theta}{r} + u_z\frac{\partial u_\theta}{\partial z} = \frac{1}{\epsilon^2 Re}\left(j_z B_r - j_r B_z\right) + \frac{1}{Re}\left(\frac{\partial^2 u_\theta}{\partial r^2} + \frac{1}{r}\frac{\partial u_\theta}{\partial r} - \frac{u_\theta}{r^2} + \frac{1}{\epsilon^2}\frac{\partial^2 u_\theta}{\partial z^2}\right), \tag{3}$$

$$u_r\frac{\partial u_z}{\partial r} + u_z\frac{\partial u_z}{\partial z} = -\frac{1}{Fr^2\epsilon^2}\frac{\partial p}{\partial z} + \frac{1}{\epsilon^2 Re}\left(j_r B_\theta - j_\theta B_r\right) + \frac{1}{Re}\left(\frac{\partial^2 u_z}{\partial r^2} + \frac{1}{r}\frac{\partial u_z}{\partial r} + \frac{1}{\epsilon^2}\frac{\partial^2 u_z}{\partial z^2}\right), \tag{4}$$

$$\frac{\partial u_r}{\partial r} + \frac{u_r}{r} + \frac{\partial u_z}{\partial z} = 0\,. \tag{5}$$

Here the aspect ratio of the electrolyte layer ϵ, the square of Hartmann number Ha^2 characterising electromagnetic effects, the square of Froude number Fr^2 describing the influence of gravity g on a free-surface flow and Reynolds number Re quantifying viscous effects are

$$\epsilon = \frac{h}{R_2 - R_1}, \quad Ha^2 = \frac{\sigma_e B_0^2 h^2}{4\mu}, \quad Fr^2 = \frac{2U_0^2}{gh}, \quad Re = \frac{\rho U_0 (R_2 - R_1)}{2\mu}, \tag{6}$$

where the velocity scale is defined as $U_0 = \left(\sigma_e \Delta\phi_0 B_0 h^2\right)/\left(2\mu(R_2 - R_1)\right)$. Upon the Introduction of a geometric parameter $\alpha = (R_2 + R_1)/(R_2 - R_1)$, the boundary conditions becomes

$$u_r = u_\theta = u_z = 0 \text{ at } z = -1 \text{ and at } r = \alpha \pm 1\,, \tag{7}$$

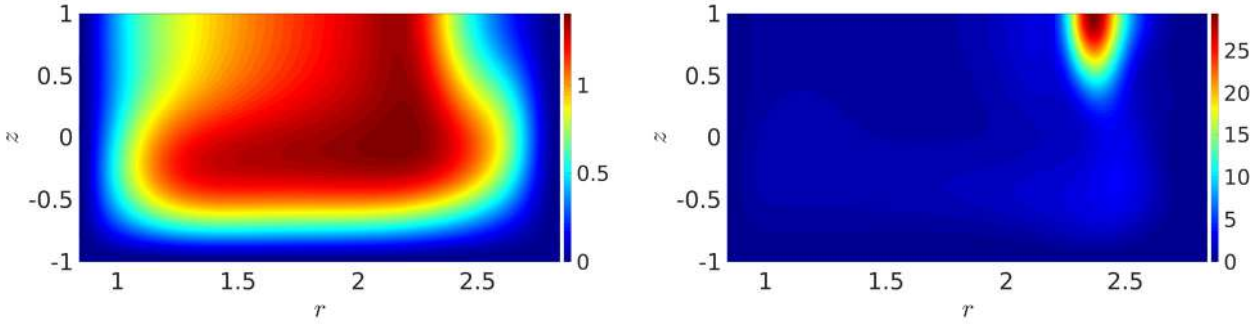
$$u_z = \frac{\partial u_r}{\partial z} = \frac{\partial u_\theta}{\partial z} = 0 \text{ at } z = 1\,. \tag{8}$$

$$\phi = 0 \text{ at } r = \alpha - 1 \text{ and } \phi = 1 \text{ at } r = \alpha + 1, \tag{9}$$

$$\frac{\partial\phi}{\partial z} = 0 \text{ at } z = -1 \text{ and } \frac{\partial\phi}{\partial z} = -\epsilon^2 Ha^2 u_\theta B_r \text{ at } z = 1\,. \tag{10}$$

BASIC FLOW

The governing equations (1)–(5) and (7)–(10) admit steady axisymmetric solutions referred to as basic flow below. As discussed in [3], when the radial current is applied the resulting Lorentz force drives circumferential flow. The centrifugal force is responsible for the creation of a radial flow component so that the overall flow becomes toroidal. This flow was called a Type 1 solution in [3]. If the Reynolds number is increased to a specific value Re_*, a second axisymmetric solution referred to as a Type 2 solution appears. For example, with fixed $\epsilon = 0.311$, $Ha = 4.59 \times 10^{-5}$ once the Reynolds



(a) (b)

Figure 1: Meridional distributions of kinetic energy $E_k = u_r^2 + u_\theta^2 + \epsilon^2 u_z^2$ for (a) basic flow and (b) linearised perturbations (arbitrary scale) for the Type 2 basic flow with $m = 2$ for $\epsilon = 0.331$, $Re = 799$, $Ha = 4.59 \times 10^{-5}$.

number reaches $Re_* = 799$ a Type 2 solution appears. The main feature of the Type 2 solution which distinguishes it from the Type 1 counterpart is the existence of a second counter rotating toroidal structure in the meridional plane near the free surface and the outer cylindrical wall. A stagnation point can be identified some distance from the outer cylindrical wall. It has been shown that for some fixed ϵ and Ha the Type 1 and Type 2 solutions can co-exist over a finite interval $Re_* < Re < Re_{**}$.

PERTURBATION ENERGY DISTRIBUTION RESULTS

We investigated the linear stability of the basic flow with respect to infinitesimal periodic perturbations written in the normal mode form

$$[\phi_1(r,z), u_{r,1}(r,z), u_{\theta,1}(r,z), u_{z,1}(r,z), p_1(r,z)]^T \exp(\sigma t + \mathrm{i}m\theta) + \text{c.c.}\,, \quad m = 0, 1, 2, \cdots, \tag{11}$$

where c.c. denotes complex conjugate terms, $\sigma = \sigma^R + \mathrm{i}\sigma^I$ is the complex temporal amplification rate and m is the azimuthal wavenumber. For thin layers of a weakly conducting electrolyte $\epsilon^2 Ha^2 \sim 10^{-7}$, then the perturbation of electric potential equations can be neglected without significant loss of accuracy. We found that only Type 2 basic flow can lead to formation of vortices experimentally observed on the free surface near the outer cylinder [2]. To obtain insight into the mechanisms driving this instability, the linearised perturbation equations corresponding to (2)–(4) were multiplied by the complex conjugate perturbation velocity components $(u_r^\star, u_\theta^\star, u_z^\star)$, respectively, then integrated (by parts where necessary) over the meridional cross section using the corresponding boundary conditions for velocities and the continuity equation to eliminate pressure and obtain an equation representing the conservation of mechanical energy in the system

$$\sigma^R \Sigma_k = \Sigma_{vis} + \Sigma_{Ha} + \Sigma_{cc} + \Sigma_{bf}. \tag{12}$$

where $\Sigma_X = \int_{-1}^{1}\int_{\alpha-1}^{\alpha+1} \Re\left(E_X\right)\, r dr dz$ and $\Re$ denotes real part. Each integral represents different physical characteristics and influences in the system. Only mechanisms corresponding to terms in the right-hand side of (12) that are positive can lead to instability. The term Σ_{vis} is the measure of viscous dissipation. It is negatively defined for all m. The term Σ_k is positively defined and represents the kinetic energy. Figure 1 compares the spatial fields of the basic flow ($E_{k,0}$, panel (a)) and perturbation ($E_{k,1}$, panel (b)) kinetic energies. The basic flow kinetic energy is distributed throughout the meridional cross section while the kinetic energy for the perturbations that lead to the vortices is strongly localised near the free surface and the outer cylindrical wall. We note that vortices are formed in the region where the basic flow is less energetic, and their occurence reduces the kinetic energy deficit there. The term Σ_{Ha} representing the electromagnetic effects is always negative and is several orders of magnitude smaller than any of the other terms. Therefore, it can be concluded that the Lorentz force, which drives the primary flow, makes a negligible contribution to the development of the instabilities. The effects of curvature and radial shear (including Rayleigh centrifugal destabilisation) are represented by Σ_{cc} while the energy exchange between the perturbations and the basic flow via non-radial shear is represented by Σ_{bf}. Both Σ_{cc} and Σ_{bf} are found to be positive and of same order of magnitude, and thus both contribute to the instability. Therefore we conclude that Rayleigh's inviscid centrifugal instability mechanism aided by radial shear in the boundary layer near the outer cylindrical wall is responsible for vortex formation while the electromagnetic effects remain negligible.

Summary The aim of this study is to investigate the practical ways to destabilize the interface between a Newtonian and a power-law fluid flowing in a microchannel under the effect of an electric field applied either normal or parallel to the flat interface. The interface can be practically destabilized by the electric number, the thickness and the viscosity ratios related to the applied voltage, flow rate ratio and the liquid type which can be changed easily in an experiment. Linear stability is conducted to determine the critical point where the interface starts to deflect.

INTRODUCTION

The stability analysis is important for the non-Newtonian fluids due to their applications in petroleum industries, packed bed reactors, etc. Moreover, lithographically-induced self-assembly (LISA) is a technique that uses a mechanical deformation to obtain patterns on the polymer substrate [1]. The linear stability of an interface separating a Newtonian and a power-law fluid has only been partially studied primarily by Khomami [2] in the absence of an electric field. The stability diagrams are obtained for various depth and viscosity ratios. Instead of the Newtonian fluids, additional unstable regions are obtained when the fluids are of power-law type. Sahu *et al.* [3] focused on the linear stability of the pressure-driven flow of two-layer flow where a Newtonian fluid overlays a Herschel-Bulkley fluid. The results show that higher shear-thinning tendency stabilizes the flow. Eldabe [4] studied the interfacial instability between two fluids undergoing a Couette flow and the interface is stressed by an electric field. The inertia affects the stability of the interface which can be considered in terms of the distribution of the vorticity.

PHYSICAL SYSTEM

The physical system consists of two fluids assumed to be immiscible, incompressible and leaky dielectric fluids undergoing a Poiseuille flow. The surface coupled model is employed thus, the electrical terms appear only at the interface conditions. The fluids are assumed to be leaky dielectric [5]. The physical system is depicted in Fig. 1 where a Newtonian fluid flows side by side with a non-Newtonian fluid and they share a common interface. The Newtonian fluid is indicated by $\star$ occupying the region $Z(x,t) < z < h^{\star}$ and the unstarred fluid is the non-Newtonian fluid occupying the region $-h < z < Z(x,t)$. The physical properties of the system are mainly the viscosity, the surface tension, the electrical permittivity and the electrical conductivity which are indicated by μ, γ, $\varepsilon\varepsilon_0$ and α, respectively. Here, ε_0 indicates the vacuum permittivity. To describe the rheological model of the non-Newtonian fluid, power-law model was chosen. An electric field is applied either parallel or normal to deflect the flat interface and at the critical voltage, it starts to deflect.

RESULTS

A linear stability analysis is conducted using Chebyshev spectral method in MATLAB. The perturbed governing equations, along with the boundary and the interface conditions are recast into an eigenvalue problem as $Au = \sigma Bu$. Here, σ is the eigenvalue indicating the inverse time constant of the given disturbance. The applied voltage for the parallel electric field is adjusted such that Eb for the normal electric field is equivalent to d^2Eb as described in [6] because of the ratio of the length scales. The results are presented in terms of dispersion curves, i.e. the growth rate, σ versus the wavenumber, k of the disturbance or in terms of neutral curves, e.g., critical wavenumber, k_c versus the electric number d^2Eb. It was shown that the electric number, Eb either stabilizes or destabilizes the system depending on the physical

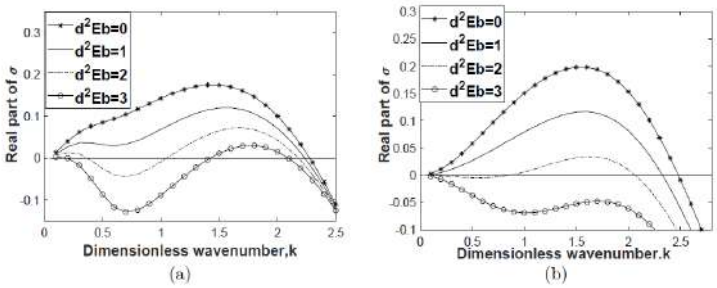

Figure 2: Stabilizing effect of the electric number (a) for the Newtonian/Shear-thinning and (b) for the Newtonian/Shear-thickening fluids

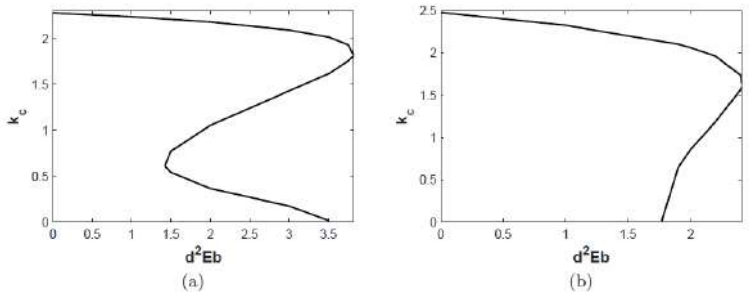

Figure 3: Critical wavenumbers for (a) for the Newtonian/Shear-thinning fluids and (b) for the Newtonian/Shear-thickening fluids

and the electrical properties similar to a system of two Newtonian fluids [6]. When the system is made unstable by the viscosity ratio in the absence of an electric field, e.g. $\lambda = 0.04$, the system can be stabilized by applying an electric field for the Newtonian/Shear-thinning fluids

CONCLUSIONS

In order to investigate the stability characteristics of the interface between a Newtonian and a power-law fluid, an eigenvalue problem is recasted to conduct the linear stability. The applied voltage to the system can stabilize or destabilize the interface depending on the electrical properties of the fluids similar to the Newtonian/Newtonian fluids system. The stable system can be destabilized by adjusting the applied voltage, namely the electric number.

INVESTIGATION OF DENSITY AND FLOW VELOCITY FIELDOF DBD PLASMA ACTUATOR IN QUIESCENT AIR USING BACKGROUNDORIENTED SCHLIEREN AND PARTICLE-IMAGE-VELOCIMETRYMETHOD

Yutaka Kaneko*[1], Kenta Emori [1], Takaaki Shimazaki [1], Yoshiyuki Tagawa [1], and Hiroyuki Nishida [1]
[1]Department of Mechanical Systems Engineering, Tokyo University of Agriculture and Technology, Tokyo, Japan

Summary DBD plasma actuator is an active flow control device which manipulates the flow utilizing the ionic wind and the Joule heating caused by atmospheric barrier discharge. In this study, we investigate the density and flow velocity field of DBD plasma actuator in the quiescent air using the BOS and PIV method, respectively. As a result, it is confirmed that a wall-surface jet (ionic wind) is induced along the device surface, and low-density field is also formed over the surface. The low-density field is due to the Joule heating at the electrode edge and convection of the heated air by the wall-surface jet. In addition, it is also clarified that both the displacement of the background image and flow velocity has the peak value at some distance from the electrode edge where the discharge occurs.

INTRODUCTION

Dielectric barrier discharge plasma actuator (DBDPA) is an active flow control device using dielectric barrier discharge [1,2]. It consists of two electrodes divided by an insulator; one electrode is insulated coted and the other is exposed to the air. Applying an AC high voltage between the electrodes as shown in Fig. 1, discharge appears, and plasma is generated. DBDPA has two kinds of mechanism manipulating the flow; one is the body force generation due to the momentum transfer between plasma particles and neutral particles (the electrohydrodynamic effect), and the other is the density disturbance caused from the Joule heating. The body force generation has been intensively studied by investigating the flow field (the ionic wind) induced by it. On the other hand, recently, quantitative investigation on the density field also started [3], however, it is not sufficient. It is important to understand the characteristics of not only the body force field but also the density field for further research and development of the DBDPA.

The objective of this study is to investigate the time-averaged density field induced by DBDPA together with the flow field. We adopt the Background Oriented Schlieren (BOS) technique to measure the density field. It is an optical flow visualization technique that enable quantitative and non-contact measurement of the density field [4]. The main advantage is its simple set up as shown in Fig. 2 using only a camera, a background image and a light source. The BOS technique is based on the displacement of the background image caused by the density (refractive index) gradient of the measurement object. The light ray from the background image is deflected by the density gradient, and the background image patterns are displaced. The displacement field can be obtained using an image correlation method and so on. Finally, we can quantitatively obtain the density field by numerical calculation based on the displacement field. Note that in this study, the discussion is made using the displacement field for simply discussing the BOS results. In addition to the BOS measurement, we measure the time-averaged flow field using the PIV method.

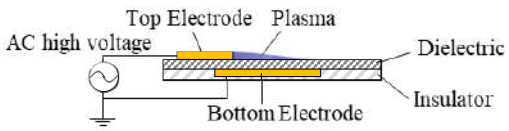

Figure 1. Schematic of the DBDPA.

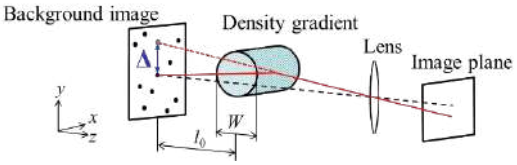

Figure 2. Principle of the BOS technique.

EXPERIMENTAL SETUP

Figure 3 shows the schematic of the DBDPA and the power supply system to drive the plasma actuator. The voltage waveforms from a function generator (Tektronix AFG2021) is amplified by the high voltage amplifier (Trek Model20/20C-HC) and applied to the actuator. The applied high voltage is measured by an oscilloscope (Teledyne Lecroy HDO4034) thorough a high-voltage prove (Tektronix PHV4002-3-Ro). We use the reference plasma actuator provided by the National Institute of Advanced Industrial Science and Technology (AIST). It consists of 0.4 mm thick silicone resin as a dielectric and 18 μm thick copper as two electrodes, and its span length is 100 mm. The applied voltage is 16 kV_{pp}, the frequency is 3 kHz, and the waveform is sinusoidal.

The BOS measurement system is shown in Fig. 4. A background image with random dot patterns, a white LED and a single-lens reflex camera (Nikon D3200) equipped with a single focus lens (Micro-Nikkor 105 mm f/2.8) is used. Imaging resolution and shutter speed is 0.017 mm/pixel and 1/100 s, respectively. Measurements are conducted for 40 times, and the time-averaged displacement field of the background image is calculated using the image correlation method based on the Fast Fourier Transform (FFT), which is often used for the PIV.

In addition, we obtain the time-averaged flow field from 250 instantaneous flow fields using the PIV method.

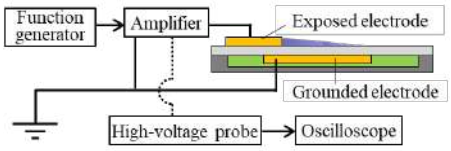

Figure 3. Schematic of the DBDPA and power supply system.

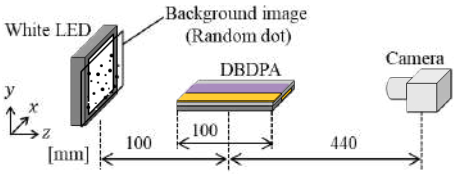

Figure 4. The BOS measurement system.

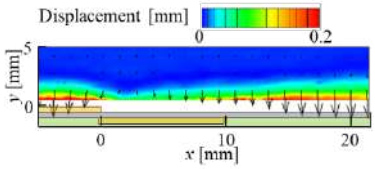
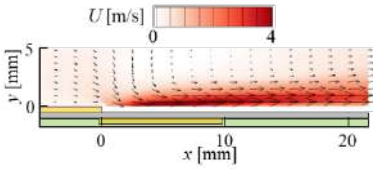
RESULT

Figure 5 shows (a) the time-averaged displacement field, (b) the time-averaged flow velocity field and (c) x-directional profiles of the displacement (y = 0.5 mm) and flow velocity field (y = 0.2 mm). In Fig.5 (c), the red and blue line indicates the horizontal velocity and displacement, respectively. First, focusing on the displacement field (Fig.5 (a)), it spreads over the dielectric and the exposed electrode surface and is vertically downward. It indicates that the density of the air near the actuator surface is lower than that of the ambient air. In addition, it has the peak value at some distance from the exposed electrode edge (Fig. 5 (c)). Next, focusing on the flow field (Fig. 5 (b)), the suction flow occurs at the exposed electrode edge, and the flow along the actuator surface is generated. The physical reason why such a displacement field was obtained is discussed using Fig. 6. Firstly, the Joule heating and the flow acceleration causes the density disturbance. When the plasma actuator is driven, the discharge occurs at the exposed electrode edge. In the discharge area, both the Joule heating and the acceleration due to the body force occur. The air flowing into the area is heated and the heated air is advected with expanding. As a result, it is considered that lower density area spreads over the dielectric surface, and the lowest density point is at some distance from the electrode edge. It is also considered that the expansion due to the acceleration of the flow is occurring at the same time. Next, focusing on the exposed electrode surface. From comparison with the flow field, there is no flow over the exposed electrode surface, however, the displacement appears. It is considered that the density of the air in this area becomes lower because of the Joule heating of the electrode caused by the current flowing into it.

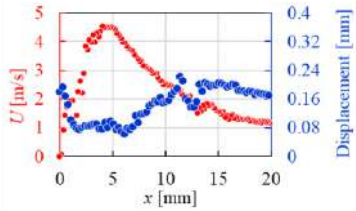
Second, as observed in Fig. 5 (c), the peak position of the displacement dose not corresponds to that of the horizontal velocity, and we can confirm that the displacement peak position is more downstream of horizontal velocity peak position.



(a) Displacement field.



(b) Flow velocity field.



(c) x-directional profiles of the displacement and flow field.

Figure 5. Time-averaged measurement results.

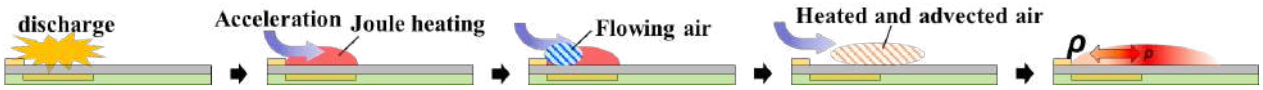


Figure 6. Mechanism of forming the density gradient field.

CONCLUSINOS

In this study, for discussing the density field induced by DBDPA together with the flow field, we adopt the BOS technique in addition to the PIV method and both measurements were conducted to obtain the time-averaged field. As a result, comparing the displacement field of the background image with the flow velocity field, it is confirmed that the BOS result is physically valid, and the peak position of the displacement is downstream of that of the horizontal velocity.

In the future works, for further investigation about the density field of the plasma actuator, we will calculate the density field from the displacement field and conduct the time-resolved measurements of the BOS and PIV. Moreover, we will investigate the effect of the applied voltage waveform on the density and flow field.

ELECTROMAGNETIC VIBRATIONS INFLUENCE ON DIRECTIONAL SOLIDIFICATION OF METALLIC ALLOYS AND COMPOSITES

Imants Kaldre *[1]
[1]University of Latvia, Institute of Physics, Jelgavas iela 3, Riga LV-1004

Summary Directional solidification is widely used to investigate how various parameters influence solidification structure of the metal materials. It is well known that main parameters influencing the grain structure of metallic alloys are solidification velocity and temperature gradient at the solidification interface. Liquid phase convection is also one of the important parameters which may affect solidification process. Electromagnetically created convection impact on the solidification has been studied and effect has been demonstrated. There are various electromagnetic effects. In this work we focus on the electromagnetically induced vibrations created by simultaneously applied AC and DC magnetic fields to study its impact on metallic alloy microstructure and admixed particle distribution.

INTRODUCTION

Solidification of metallic alloy is an extremely complicated multiphysical process where numerous physical processes take part and influence each other by different ways. Structure of the metal or alloy is also significantly affected by energy and solute transport in the liquid melt at the vicinity of the solidification interface during solidification process. In general, when regular cells are forming at relatively low rates, they grow perpendicular to the liquid-solid interface regardless of crystal orientation. When the growth rate is increased crystallography effects begin to exert an influence and the cell growth direction deviates toward the preferred crystallographic growth direction. Simultaneously the cross section of the cell generally begins to deviate from its previously circular geometry owing to the effects of crystallography. In this case it is called dendritic crystallization, which is the most common type of solidification of metallic alloys in practical metallurgy. Various kinds of dendrite morphologies are known today.

Evenly distributed dielectric particles in metal matrix can significantly improve some of metal properties, like mechanical strength, thermal properties and radiation absorption properties. Particles added to liquid metal tend to form agglomerates due to Van der Waals forces and electromagnetic separation between metal and particles or their ensembles. Dispersion of these agglomerates is a technical challenge which limits the production of these materials in larger quantities. Electromagnetically induced vibrations is one of the means how to disperse particles contactlessly. In previous works it has been shown that combined AC and DC magnetic fields can create sufficiently high pressure amplitude to disperse particles in some metals [1].

Electromagnetic effects on solidification of metal alloys and metal matrix composites has been widely studied. Various electromagnetic effects have different impact on the melt flow, solidification structure and impurity dispersion. Application of magnetic field can be additional mechanism to affect and create convection in the liquid melt and mushy zone of metallic alloy. DC magnetic field creates thermoelectromagnetic convection and melt flow perpendicular to magnetic field leading to anisotropic material structure [2]. Pulsed and DC electromagnetic interaction has been studied showing that electromagnetic vibrations is one of the methods to disperse particles and refine grain structure of the metallic alloys.

EXPERIMENTAL

Small scale experimental setup is designed and built to demonstrate the effect of combined AC and DC magnetic fields on the directionally solidified metallic alloys and metal matrix composites. AC magnetic field is created by high frequency inductor which also melts the sample. The samples are directionally solidified in a Bridgman setup at controlled growth velocities from 10 μm/s to 500 μm/s. Upper part of the sample is melted by the high frequency inductor around the crucible while bottom part is kept solid by water cooled copper ring. Inductor and water-cooled bottom ring are stationary while crucible is lowered by programmable stepper motor. Solidification front is located between heater and cooler at the same location, thus actual solidification velocity is assumed to be equal to the pulling velocity of the crucible. Various electromagnetic interaction parameters and solidification velocities are tested. Experiments are done using low temperature alloys Sn-Pb, Sn-Bi, but in future work with aluminium is foreseen. Numerical model is developed for interpretation of the results and calculation of the actual melt flow in the crucible. It is shown that applied AC and DC electromagnetic fields during directional solidification creates oscillating pressure and drives flow as well. Characteristic velocities of the flow is estimated from the numerical model and analytical estimations. Samples are analysed measuring grain structure and particle dispersion.

CONCLUSIONS

In this work it is demonstrated that applied electromagnetic interaction during directional solidification modifies the grain structure of the metallic alloy and its impact on the particle dispersion in metal matrix composite materials. It is confirmed that AC and DC electromagnetic interaction refines grain structure of the metallic alloys. Electromagnetic contactless technology seems to be promising solution for high temperature metals and aluminium alloys for particle dispersion. Electromagnetic interaction has similar effect that ultrasound. Ultrasound treatment is well known to be used for grain refinement and homogenization.

MODELING THE OSCILLATORY DYNAMICS OF GAS BUBBLES GROWING AT MICROELECTRODES

S. Sahil Hossain*[1], Aleksandr Bashkatov[1], Xuegeng Yang[1], Gerd Mutschke[1], and Kerstin Eckert[1,2]
[1]Institute of Fluid Dynamics, Helmholtz-Zentrum Dresden-Rossendorf, Bautzner Landstrasse 400, Dresden, 01328 Germany
[2]Institute of Process Engineering and Environmental Technology,Technische Universität Dresden,Dresden, 01062 Germany

Summary The working mechanism of the recently observed bubble oscillation on microelectrodes is explained [1]. The force balance includes contributions from a thermocapillary force and a Columb force on the charged bubble. Comparison between model predictions and experimental measurements is presented.

The literature on bubble evolution by water electrolysis dates back decades and over the time, one of the prominent phenomena that remain unresolved is the observation of bubble jump off and return to the electrode surface [3, 4]. Recently we also observed periodic bubble oscillations over Pt microelectrodes [1]. In this contribution, we explain the working mechanism of such phenomena alongwith a comparison of the model estimations with experimental observations.

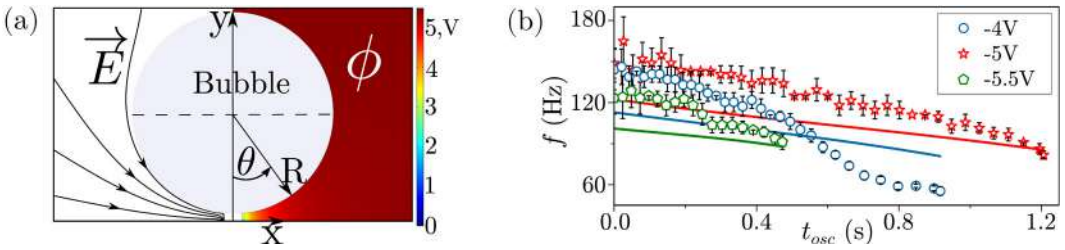

Figure 1: (a) Electric potential distribution and electric field lines in the electrolyte around the bubble, (b) Oscillation frequency estimates (solid line) compared with experimental measurements (open symbols). Reprinted from [1]

Figure 1(a) shows the numerically obtained potential distribution and the electric field lines in the electrolyte around the bubble. Due to the presence of adsorbed ions at the bubble-electrolyte interface, a vertically oriented electric force acts on the bubble. The magnitude of this force depends on the distance between the bubble and the microelectrode at the bottom, and on the surface charge density of the bubble interface. Equilibrium of Marangoni [2], electric and buyoancy forces at the moment of detachment provides an estimation of the interfacial charge density. The distance dependent electric force acts as a restoring force enabling bubble reattachement to the microelectrode. The oscillation frequencies are calculated by approximating the electric force as a linear spring. Figure 1(b) shows a good agreement between the experimentally measured and numerically predicted frequencies for different electrode potentials over the oscillation time.

This project is supported by German Space Agency (DLR) with funds provided by the Federal Ministry of Economics and Technology (BMWi) due to an enactment of the German Bundestag under grant no. DLR 50WM1758 (project MADAGAS).

CHARACTERISTICS OF DISCHARGE AND JET GENERATION OF PLASMA ACTUATOR UTILIZING DC AND AC DISCHARGES

Asami Hatamoto[1], Kumi Nakai [1], and Hiroyuki Nishida [*1]
[1]Department of Mechanical Systems Engineering, Tokyo University of Agriculture and Technology, Koganei, Japan

Summary Tri-electrode plasma actuator (TED-PA) is an active flow control device utilizing the ionic wind coming from atmospheric discharge. It consists of exposed a DC and AC high voltage electrode, dielectric plate and an covered ground electrode. For high flow controllability, the design optimization is needed to maximize the ionic wind from the DC electrode. In this report, we experimentally investigate the influence of AC discharge state on the DC discharge and DC ionic wind. For this purpose, the discharge photograph and flow velocity field is investigated. As a result, it is found that the DC discharge and ionic wind generation is enhanced by the AC barrier discharge. Increasing the AC frequency is effective for the enhancement.

INTRODUCTION

The Plasma Actuator is one of active flow control devices that induces a jet (ionic wind) using electrohydrodynamic force coming from atmospheric discharge. The Plasma Actuator has many advantages such as thin and light, no mechanical moving parts and excellent rapid controllability so it is expected to be applied to surface flow control of various fluid devices.[1] If the jet can be strengthened, the range of applications can be greatly expanded, and practical application can be accelerated. In order to obtain stronger jet, the Tri-Electrode Plasma Actuator (TED-PA) was proposed. The TED-PA is composed of three electrodes and a dielectric layer as shown in Fig. 1 (a). It induces a jet from both the AC and DC electrodes by applying high voltage to each electrode, and high performance is reported with a thrust of about 10.6 times and a thrust power ratio of about 6.0 times that of the conventional two-electrode plasma actuator.[2] The jet generation of the DC electrode contributes to the high performance of TED-PA, and therefore, for further high performance of TED-PA, it is necessary to optimize the design in order to maximize the DC jet.

The interaction between the AC and DC discharge has significant influence on the performance of TED-PA. Therefore, the objective of this study is to clarify the effect of the AC discharge state on the DC discharge and its jet generation. We investigate two types of plasma actuator; one is the TED-PA (Fig. 1 (a)), the other is the ACDC-PA which has the exposed AC and DC electrode but does not have the covered grounded electrode (Fig. 1 (b)). Depending on the presence or absence of the ground electrode, a dielectric barrier discharge and corona discharge occurs at the AC electrode of TED-PA and of ACDC-PA, respectively. In the experiments, the discharge photographs are taken to investigate the discharge condition, and in addition, flow velocity fields are obtained by the PIV (Particle-Image-Velocimetry) measurement.

(a) TED-PA configuration. (b) ACDC-PA configuration.

Figure 1. Schematic configurations of TED and ACDC plasma actuators.

EXPERIMENTAL SETTINGS

The discharge photographs are taken from the top of the actuator using a single-lens reflex camera (NIKON D3200) with a lens whose focal length is 105 mm. The imaging conditions are as following: the exposure time is 6 s, ISO is 100 and the F-number is 2.8. To quantitatively show the discharge intensity, the value obtained by dividing the brightness of the discharge at the DC electrode in the discharge photograph by the area of the discharge is defined as photo-emission strength around the DC electrode. Furthermore, a time-averaged velocity field is obtained from the 200 flow velocity field images obtained by the PIV method.

For plasma actuator, a copper tape with 0.05 mm thickness for the electrode, a PTFE with 2 mm thickness for the dielectric and a polyimide tape with 0.05 mm thickness and glass epoxy with 1 mm thickness for the Insulator is used, and the gap between the AC electrode and the DC electrode is 20 mm and spanwise length is 80 mm. The overlap between the ground electrode and the AC electrode is 1 mm, and the width of the ground electrode is 10 mm. The DC electrode and AC electrode (top electrode) are cut in a sawtooth shape in order to make the discharge uniform. The AC voltage amplitude is 10 kV_{pp}, the frequency is varied in the range from 0 to 8 kHz and the waveform is sinusoidal, and the DC voltage is 14 kV. Here, 'AC frequency of 0 kHz' indicates that the AC electrode is electrically grounded.

*Corresponding author. E-mail: hnishida@cc.tuat.ac.jp

EXPERIMENTAL RESULTS

Figures 3 (a) and (b) show discharge photographs of TED-PA and ACDC-PA when the AC frequency is 8 kHz. The discharge at the DC electrode is the same for both plasma actuators, which is a corona discharge, but the discharge at the AC electrode is different. In TED-PA, longer propagation of the discharge can be observed at the AC electrode. This indicates that a dielectric barrier discharge occurs between the AC electrode and the ground electrode. In ACDC-PA, many spot discharges are observed. This indicates the occurrence of corona discharge between the AC and DC electrodes.

Figure 4 shows the AC frequency characteristics of the photo-emission strength around the DC electrode. When the AC electrode is electrically grounded (0 kHz in Fig. 4), it can be seen that the photo-emission strength around the DC electrode of TED-PA and ACDC-PA does not change. Therefore, the presence of the lower ground electrode does not affect the DC discharge strength. In the case of TED-PA, the photo-emission strength decreases when the AC frequency is 1 kHz compared to the case that the AC electrode is electrically grounded. This is because the electric field strength around the DC electrode weakened due to the interaction among the DC and AC and ground potential of electrodes. On the other hand, in ACDC-PA, the photo-emission strength increases at 1 kHz. This is because the maximum potential gap between the DC and AC electrode increases, and it strengthen the discharge. Next, in TED-PA, the DC photo-emission strength increases as the AC frequency increases. This is because the barrier discharge at the AC electrode of TED-PA increases with the AC frequency. The electrons generated by the barrier discharge are supplied to the DC electrode, and the discharge at the DC electrode is enhanced. On the other hand, in ACDC-PA, as the AC frequency increases, the DC photo-emission strength decreases and becomes equal to the value for the case that the AC electrode is grounded. This is probably because the ion motion becomes to be not able to follow the high frequency change of electric field and the DC discharge strengthening by the AC high voltage is lost.

Figure 5 shows the AC frequency characteristics of the maximum flow velocity of the jet from the DC electrode obtained from the flow velocity fields. In TED-PA, the DC jet velocity firstly decreases and after that, increases with the AC frequency; this tendency is consistent with that of the photo-emission strength, and at 6 kHz it exceeds the value at the case that the AC electrode is grounded (0 kHz in Fig. 4). In contrast, in ACDC-PA, the value of the DC jet velocity does not change with AC frequency. Therefore, in order to maximize the DC jet, it is effective to generate the barrier discharge using the AC high voltage with high frequency. However, in the TED-PA of Fig. 5, the DC jet velocity decreases as the frequency increases from 6 kHz to 8 kHz. This is thought to be because the jet generated from the AC electrode became stronger as the barrier discharge at the AC electrode became stronger, and collided with the DC jet. This result indicates that there is a possibility that there is an optimum value between the DC voltage and the frequency of AC voltage.

(a) TED-PA. (b) ACDC-PA.

Figure 3. Discharge photographs of TED and ACDC plasma actuators.

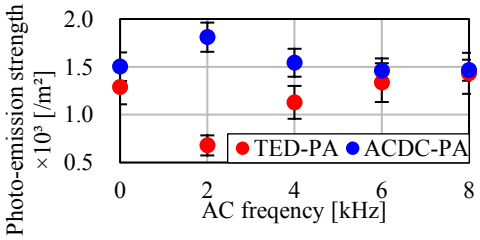

Figure 4. Photo-emission strength around the DC electrode.

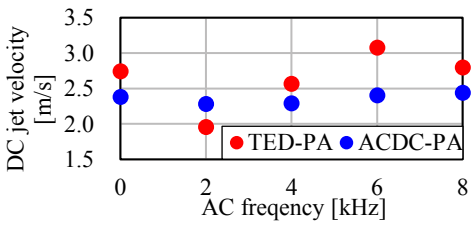

Figure 5. Maximum jet velocity of the DC jet.

CONCLUSIONS

To optimize the driving parameters of TED-PA, we investigated the influence of the AC discharge state on the discharge and jet generation at the DC electrode. From the discharge photographs and flow field measurement, we experimentally showed that it is effective to generate the barrier discharge by AC voltage with high-frequency. Note that, there is a possibility that there is an optimum value between the DC voltage and the frequency of AC voltage.

Summary: In this work we study metallic particles diving in a non-electrical conducting fluid under a harmonic magnetic fields with DNS method. Force, torque and Joule heating acting on the particles are calculated with an analytical model. Moreover, an experiment of magneto-convection in Rayleigh-Bénard cell is introduced. Both investigations are dedicated to the understand the hydrodynamic behaviour of a two phases corium with oxide and metal heated by an electromagnetic induction.

INTRODUCTION

In the frame of a hypothetic nuclear accident leading to the partial or the whole destruction of the nuclear fuel, the core could melt and create a high temperature mix named corium. If the mixture were to break through the vessel, it will spread out on a concrete apron and then triggered a reaction mentioned in the literature as Molten Core Concrete Interaction. This interaction result in a gradual concrete ablation intimately linked to the heat flux exchanged.

In order to understand this behavior, experiments using prototypical corium are performed at CEA Cadarache and using induction heating to simulate the residual heating power coming from the fission reaction within the corium in order to match with the reality, the volumetric power heating has concentrated exclusively in the oxide phase and not inside the metallic parts built-in the corium coming from the construction structure melted (cm-sized droplets and/or parietal layers according to the hydrodynamic regime).

The conductivity gap between the two phases raised several questions about the efficiency of the selected heating technology. Spherical droplets and magnetic field interaction may create a force, a torque and heating them up. Consequently, particles trajectory could be bias comparable to the reactor case, as the general hydrodynamic of the bath with the particles feedback on the flow.

NATURAL CONVECTION GENERATED BY INDUCTION HEATING OF PARTICLES

A 3D magneto-hydrodynamic direct numerical simulation investigates when the fluid carrier is neutral and only the metallic particles conduct electricity. An imposed changing magnetic field inside a box which decay exponentially from the bottom to the top of the vessel induced a magnetic levitation force and induction heating when conducting medium spans the changing field. By this means, the unconventional flow patterns shown up and two parameters, the density ratio between the two distinct phases and the concentration of particles may have helped to interpret the global dynamics.

Firstly, scattered particles reached a steady state at predicting position directly link to the balance between the electromagnetic and the gravity force and kickoff expected buoyant flow behavior.

Secondly, huge particles concentration results in heap stuck nearly the lower part of the domain supplying a main thermal plume.

Finally, the intermediate case involves the same conclusions seen previously when the concentration of particles is important. Nevertheless, droplets display high mobility and are ejected intermittently from the hearth following the plumes that they helped create. Picture above describes the last state sum up.

MAGNETO-CONVECTION EXPERIMENTATION

An experimental study of a magneto-hydrodynamic flow inside a cylindered vessel filled with a liquid metal under an AC magnetic field and bounded by a vertical temperature gradient is performed. Experimental setup explore a wide range of Rayleigh number based on the induction heating (up to 1.10^4-1.10^8) and Rm (up to 3) and investigate the average Nusselt number of the system.

An electrical and thermal insulated cylinder filled with a liquid metal corresponding to an unity aspect ratio (D/H=1) is manufactured in PEEK (PolyEtherEtherKetone) material in order to avoid electromagnetic power loose outside the fluid and heat loose from the wall. Two distinct flow circulation above a high thermal conducting ceramic (Silicon carbide) imposed a natural vertical thermal gradient ($T_{top}<T_{bottom}$) and sealed our system. Above a critical Rayleigh value, the fluid becomes unstable and it's referred as the Rayleigh-Bénard Instability. The fluid motion is made turbulent regarding the fluid properties, the temperature difference and the geometry length. Many researches have been made about this kind of instability to understand the behavior of the flow and our case is dedicated to study this configuration under the influence of an alternating magnetic field.

The natural convection container seats inside an inductor feed by an AC current supply power in order to induced a non-uniform, time dependent magnetic field within the conducting liquid metal. The frequency of the current flowing in the coil plays a significant role of the distribution in space of the eddy current estimate by the shield parameter (Rw). Playing on the frequency and the intensity of the current inside the coil, eddy current creates Joule heating with different intensity, spread in the whole volume or only distributed on the thin exterior surface of the conducting liquid. The fluid is also submitting to the Lorentz force and its action on the motion on the fluid require an extensive knowledge.

Velocity profile inside the vessel are recorded with UVP technology to catch the flow pattern in an opaque fluid. Several temperature sensors lead to the energy balance of the experiment and finally the average Nusselt number. Picture above describe all the test system.

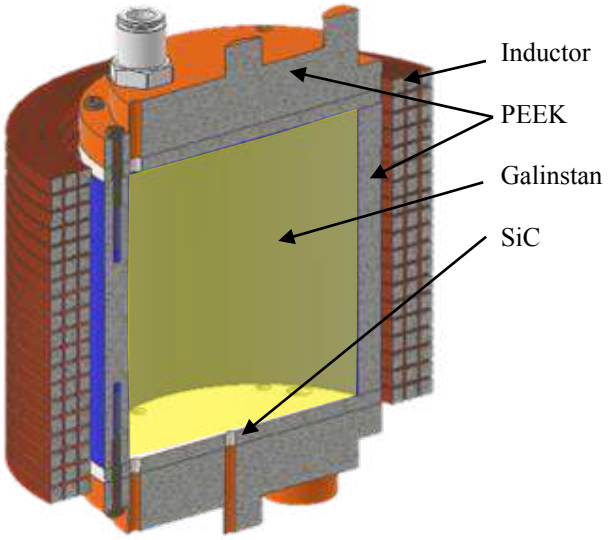

Figure 2 Natural convection cell surrounded by coil

CONCLUSION

In this work magneto-convection DNS of conducting particles in neutral fluid under a harmonic is presented. We find out three different patterns link to the density ratio between the fluid and the particles and the concentration of droplets. Finally, an experimental setup of magneto-convection in Rayleigh-Bénard of two phases with a AC magnetic field is presented.

A NEW EXPERIMENTAL FACILITY FOR IONIC PROPULSION STUDIES

Federico Sottovia[1], Samuele Fiorini*[1], Marco Belan[1], and Filippo Maggi[1]
[1]Dipartimento di Scienze e Tecnologie Aerospaziali, Politecnico di Milano, Milano, Italy

Summary In this work, an experimental setup for ionic propulsion studies is presented. The research aims to better understand the capabilities of a thruster that exploits corona discharge to produce propulsive force. Nowadays, electric propulsion in atmospheric conditions has been tested successfully for heavier-than-air aircrafts; whilst the theoretical principle is well understood at least for a standard corona discharge, the optimization of a thruster requires a wide range of configurations to be experimented and therefore a valid multipurpose experimental setup. For this reason, a test bench that can accommodate different electrodes arrays has been built, with adjustable electrode gaps and spacings. Induced flow can be characterized by means of velocity measurements from which thrust force can be obtained in order to compute the main performance parameters. Results obtained from a first measurement campaign are briefly presented. Using a vacuum vessel, experiments can also be performed with different pressure and gas compositions.

INTRODUCTION

Thrust generation by means of ions acceleration is a propulsion technique often used in space applications but much less studied for atmospheric ones. It allows to develop devices with a thrust per unit power much higher than thermochemical ones. However, this technology in atmospheric applications is used only in few cases, mainly limited by the weight of the high voltage generation system required for ions production and the low values of thrust per unit area achievable [1]. The main application fields are 1) atmospheric system for low orbit satellites, where rarefied gas is captured by a dynamic intake and electrostatically accelerated in order to generate enough thrust to maintain the orbit and 2) proper atmospheric flight system, created exploiting ionic wind produced by corona discharge between two high voltage electrodes.

A test aircraft model has been developed by a research team at MIT [2] showing the capability of sustained flight, having aboard the ionic propulsion system and the power source. The thrusters were designed with airfoil-shaped cathodes in order to optimize the produced force. Another remarkable result has been reached by Khomich and Rebrov [3], who realized a flying thruster with a wireless power source, verifying other possible configurations and applications of this technology.

Despite the knowledge about the underlying physical principle, the problem of increasing thrust efficiently by designing suitable electrodes geometry surely requires further investigations. Moreover, other important studies may arise by considering the use of ionic engines in environments with different gases. Hence, an adaptable setup to fit multiple configurations and environment conditions could help in starting new research lines.

To this purpose, it is presented a test bench that can accommodate arrays of anodes and cathodes with the possibility of varying the gap between opposite electrodes and the distance between similar electrodes. Intermediate electrodes between anodes and cathodes can also be included. The system has been conceived to allow multiple adjustable configurations, in order to explore a wide parameter space seeking for an optimal configuration for thrust generation. Moreover, the test bench can be inserted in a vacuum vessel where pressure and air composition can be controlled, extending the research field to different atmospheres.

A first measurement campaign has been carried out and calculated performances resulted in line with other state of the art devices. Table 1 presents two of the main parameters used during experiments as performance indicators, the thrust to power ratio $T/P = \Theta$ and the thrust to frontal area ratio $T/A = \Psi_A$, for one of the optimal configuration found during the tests and two other systems, the Aeroplane built at MIT [2] and the Ionocraft of Khomich and Rebrov [3].

Device	Θ $[N/kW]$	Ψ_A $[N/m^2]$
PoliMi EHD Thruster	5.62	3.22
Xu et al. EHD Aeroplane [2]	5.16	3.56
Khomich and Rebrov Ionocraft [3]	6.40	1.51

Table 1: Performance comparison between the setup used in the tests and some state of the art devices developed in the last two years. PoliMi data are obtained for a configuration with spacing $s = 30\ mm$ between similar electrodes and gap $g = 20\ mm$ between opposite electrodes.

EXPERIMENTAL SETUP

The experimental setup represented in Figure 1 includes a test bench made entirely of PMMA, which consists in a base of size 300×800 mm with rails screwed to it. The rails provide a sliding coupling with three bridges, each one with a frontal area of 200×355 mm. The vertical columns of each bridge serve as support for the electrodes. In the first

*Corresponding author. E-mail: samuele.fiorini@mail.polimi.it

presented configuration, ground electrodes are made of ABS coated with aluminium and shaped as NACA 0010 airfoils with 100 mm chord and 140 mm span. On both the lateral sides ABS clamps are mounted in order to lock the electrodes at the bridge columns at the desired height. In the same manner, clamps are used to hold tense 30μm diameter wires used as positive electrodes. The test bench is big enough to accommodate five anode-cathode couples or five groups of 3 electrodes, allowing a maximum vertical distance between adjacent electrodes of about 60 mm. Several supply units can be connected to the bench; in the present configuration, the supply voltage ranges up to 20 kV DC.

The test bench is designed to accommodate an almost arbitrary configuration of electrodes, and can be used to study the effect of gap distance on thrust generation or even the interaction between different electrode pairs. Velocity measurements downstream of the ground electrodes can be performed by means of a pitot probe made with a glass tube of diameter 1.2 mm connected to a high accuracy pressure transducer (an example of velocity profile is presented in Figure 2). The pitot can be accurately positioned along the vertical direction by means of a traversing system.

The bench can be entirely placed inside a vacuum vessel; in this case, velocity measurements are performed using a probe traversed inside the vessel thanks to a mechanical feedthrough. Suitable vacuum pumps are connected to the test chamber in order to reach the desired pressure for the experiments, continuously read by vacuum manometers. By means of injectors mounted on the walls, fresh gas can be introduced into the chamber. The desired atmosphere can be created by means of a multistage timer which drives the injectors, balancing their input mass flow with the output due to the main pumps. The same injectors can be used to change the mixture of gases present during the tests. Control over air composition and pressure guarantees a wide range of possible studies, allowing to investigate ionic propulsion in rarefied atmospheres made of different gases.

The system is completed by devices acquiring all the signals of interest, including the outputs of the pressure transducers and the electric quantities as supply voltages and electrodes currents.

NUMERICAL INVESTIGATION OF THE RICHTMYER-MESHKOV INSTABILITY IN MAGNETO- HYDRO-DYNAMICS

Sheng-Bo Zhang[1], Huan-Hao Zhang *[1], Wei-Tso Wu[2],Zhi-Hua Chen[1]
[1]Key Laboratory of Transient Physics, Nanjing University of Science & Technology, Nanjing, China
[2]School of Mechanical Engineering, Nanjing University of Science & Technology, Nanjing, China

Summary Based on the ideal compressible Magneto-hydro-dynamic (MHD) equations, the Richtmyer-Meshkov instability (RMI) caused by the incident plane shock wave impinging on the heavy gas density interface was numerically studied. The flow characteristics and wave patterns of hydrodynamic (HD, B = 0) and MHD (B = 10, 50, 100) situations are discussed, and verified by the corresponding experiments and numerical results. The suppression mechanism of transverse magnetic field on related interface instability is investigated. In addition, the evolution of the interface under the different transverse magnetic fields is quantitatively analysed.

1 INTRODUCTION

The RMI is produced in a wide range of natural and engineering problems, which include inertial confinement fusion (ICF) [1], supersonic combustion scramjet[2] and underwater explosive explosion[3]. It has the complex physical phenomena involved in the Richtmyer-Meshkov instability (RMI), such as flow stability, vortex, shock-vortex interaction and turbulence transition [3], a lot of attention has been paid on investigating RMI during the last decades. In the meanwhile, in the field of high-energy physics, most of the flowing matter is in a plasma state and is susceptible to the influence of magnetic fields. In recent years, controlling RMI by magnetic field has become a hot and difficult research point.

The effect of a magnetic field on the RMI was firstly analyzed by Samtaney [4] through numerical simulation in 2003 .Recent studies have shown that the growth of RMI can be inhibited from the presence of a magnetic field [3], but their references or data seem to be insufficient to prove this. Therefore, in this paper, we decided to conduct a deeper analysis of the basic mechanism of the transverse magnetic field suppressing RMI.

2 NUMERICAL METHOD AND PHYSICAL MODEL

2.1 Numerical Method

In order to simulate the evolution of the MHD RMI, the Navier-Stokes equations coupled with the Maxwell equations needs to be solved. In this paper, the Richtmyer-Meshkov instability (RMI) caused by the incident plane shock wave impinging on the heavy gas density interface with different transverse magnetic strengths was numerically studied using the ideal compressible Magneto-hydro-dynamic (MHD) equations. Magneto-hydro-dynamic (MHD) equations are solved by the CTU (corner transport upwind) + CT (constrained transport) algorithm which guarantees the divergence-free constraint on the magnetic field, i.e., $\nabla \cdot \mathbf{B} = 0$. Details of the algorithm can be found in Ref. [4].

2.2 Physical Model

As shown in Fig.1, the computational domain is set to [-0.02,0.06]×[0,0.01], and θ is the angle between the density interface and the y axis. Initially, the horizontal distance between the left vertex of the density interface and the left boundary is 0.02, and the plane incident shock wave is located on the left boundary, and then propagates from left to right from the initial position x = -0.02. The density ratio on both sides of the density interface $\eta = \rho_1 / \rho_2 = 3$, the shock Mach number M=2, and the density interface angle θ is 45°.

The upper and lower boundaries of the computational domain are set as reflected wall conditions, the right boundary is the outflow conditions, and a uniformly distributed Cartesian grid is used. After the grid independence test, the total number of grids are 10000×1250. To study the MHD RMI, we suppose the initial transverse magnetic field strength is B=0, 10 and 100. In addition, in order to make the gas affected by the magnetic field, plasma is selected.

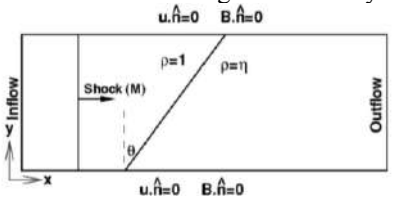

Fig.1 Schematic of computational model.

3 NUMERICAL RESULTS AND DISCUSSIONS

To verify the numerical method of RMI in the above numerical simulation HD, we numerically simulate the instantaneous flow structure of the flow field of the SF6 density interface ($\theta = 60°$), and compared with the corresponding experimental results of Liu [5], as shown in Fig 2. Obviously, the numerical result (down) is a good agreement with the experimental result [5] (up).

The flow characteristics and wave patterns of hydrodynamic (HD, B = 0) and MHD (B = 100) situations are verified by the corresponding numerical results of Samtaney[4], as shown in Fig. 3. The density field for the nonmagnetic RMI is shown in the top half part of the figure, while in the presence of a magnetic field is presented in the lower half. It is obvious that the flow characteristics, wave patterns, contact interface and vortex structures and the other shape density front for both nonmagnetic and magnetic RMI in our numerical results are in good agreement with Ref.

[5].In MHD, the density interface maintains a smooth interface, so the horizontal magnetic field significantly suppresses the RMI at the density interface.

Fig. 3 Comparison of the instantane flow structures of our numerical results with corresponding numerical results of Samtaney [4].

The suppression mechanism of the magnetic field on the interface instability is investigated, and found that the shock wave impinges on the interface, the magnetic field lines exhibit twist on the interface due to the RMI, which leads to the occurrence of the negative longitudinal magnetic field (B_y). The variation in the magnetic intensity on the interface causes the magnetic tension forming on the interface. Since the magnetic tension opposite to the direction of the vorticity generated by velocity shear, seen Fig. 4, the vorticity is attached to the Alfvén shock, and reduces the vortex deposition on the density interface. As show in Fig. 4(c), the strong magnetic field suppresses the later development of RMI more obviously. Therefore, the vorticity is transformed into two vortex sheets travelling away from the density interfaces, and the R-M instability is effectively suppressed.

4 CONCLUSIONS

Based on the ideal compressible MHD equations and CTU+CT algorithm, the Richtmyer-Meshkov instability (RMI) caused by the incident plane shock wave impinging on the heavy gas density interface was numerically studied. Our computational results are in good agreement with the relevant experimental [5] and numerical results [4]. It is found that the suppression mechanism of the magnetic field on the interface instability has two points. Firstly, the direction of the magnetic force is opposite to the direction of the vortex generated by the velocity shear, which suppresses KHI. Secondly, Vortex adheres to the Alfvén shock wave to reduce the deposition of eddy currents on the density interface.

EXPERIMENTAL INVESTIGATION OF THE TRANSITION TO TURBULENCE IN THE PLANE MAGNETOHYDRODYNAMIC (MHD) COUETTE FLOW

Brahim Moudjed[1] and Alban Pothérat *[1,2]
[1]Fluid and Complex Systems Research Centre, Coventry University, Priory Street, Coventry CV1 5FB, United Kingdom
[2]Laboratoire National des Champs Magn etiques Intenses-Grenoble, CNRS/UGA-UPS-INSA, France

Summary We present an experimental study of the plane MHD Couette flow where pressure and velocity fields are mapped by Particle Image Velocimetry in an electrically conducting electrolyte pervaded by the stray field of a superconducing magnet. We show how the magnetic fields affect the flow patterns compared to the classical Couette flow.

This study aims at characterising experimentally the influence of an externally applied static transversal magnetic field on the transition to turbulence in a plane Couette flow. Without magnetic field, the plane Couette flow is linearly stable for all Reynolds numbers but may be sensitive to finite amplitude perturbations, localised in time and in space: below a lower critical Reynolds number, estimated between 300 and 400 [2, 3, 4] disturbances decay in space and time. Above an upper critical Reynolds number of around 750 the disturbances invade the whole fluid domain and support turbulence. Between these two critical Reynolds numbers, turbulent spots coexist with the laminar flow. The upper and lower critical Reynolds numbers are expected to significantly change under the effect of the magnetic field so that a laminar flow may survive at significantly higher Reynolds numbers than without magnetic field. To investigate this question, a unique experiment was build. A 1600 mm long, 50 mm wide and 40 mm high rectangular glass tank is filled with sulphuric acid at 30 % mass, to ensure the highest conductivity (90 S/m) whilst retaining the necessary transparency for optical velocimetry techniques [1]. A mechanically-driven neoprene belt acts as the moving wall that entrains the fluid so as to generate a half-plane Couette flow between itself and the fixed bottom plate of the tank. The whole setup is placed in the stray-field of a superconducting solenoidal magnet, to apply a transversal continuous magnetic field in the flow of about 1T. A bespoke 2D Particle Image Velocimetry technique is used to map the velocity field and its fluctuations in the vertical and horizontal planes aligned with the streamwise direction.

The problem is controlled by two non-dimensional parameters, the Reynolds number, as in the non-MHD Couette flow, as well as the Stuart number N, that measures the ratio of Lorentz to inertial forces. We present results of the PIV measurement identifying the different regimes we encountered at $0 \leq N < 1$, and Re up to 10^4. We also show how the magnetic field affects the topology of the flow patterns in the intermediate regimes between the lower and upper critical Reynolds numbers.

CARTILAGE-ON-CHIP:A PHYSIOLOGICALLY INSPIRE DPLATFORM TO REPRODUCE ARTICULAR JOINT COMPRESSION AND SHEAR STRAIN

Carlo Alberto Paggi,[1,2]Bastien Venzac,[2]Jeroen Leijten,[1]Liliana Moreira Teixeira Leijten,[1]Marcel Karperien,[1]and Séverine Le Gac[2]
[1]Department of Developmental BioEngineering, TechMed Center, University of Twente, The Netherlands
[2]Applied Microfluidics for BioEngineering Research, MESA+ Institute for Nanotechnology & TechMed Center, University of Twente, The Netherlands

Summary. Here, we present a cartilage-on-chip platform comprising an innovative multi-modal actuation unit to subject chondrocyte-laden hydrogel to both compression and shear strain. The response of human chondrocytes to both healthy and pathophysiological mechanical stimulation is evaluated.

PURPOSE

Organ-on-chip models allow faithfully mimicking mechanical movements of tissues, as demonstrated for the lung or gut, yet using solely surface strain. However, other tissues such as articular cartilage require 3D multi-axial mechanical mimicry, which current microdevices are incapable of delivering. Moreover, as cartilage is an avascular structure that does not comprise nerves, stimuli received by the chondrocytes are essentially mechanical. Here, we report a versatile platform to exert complex mechanical stimulations on cell-laden hydrogels, in the view of creating a cartilage-on-a-chip model. This platform comprises three independently addressable actuation chambers, separated from a culture chamber by a thin vertical elastomeric membrane (Fig. 1). By applying specific pressure sequences in the three different actuation chambers, uniform compression and/or shear strain can be exerted on a cell-laden hydrogel in a controllable manner.

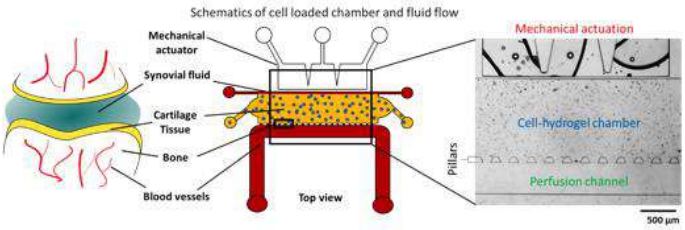

Figure 1: Schematic representation of the knee joint; Schematic and top view of the device comprising a mechanical actuation system, a cell-hydrogel chamber, a set of pillars and a perfusion channel

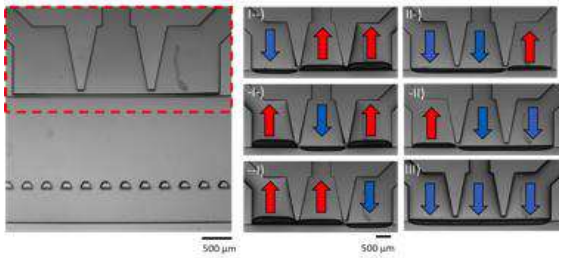

Figure 2: Top view of the system. Left: system at rest. Right: multimodal deformation of the membrane given by positive (blue arrow) and/or negative pressure (red arrow) applied to the individual chambers.

MATERIALS AND METHODS

The cartilage-on-a-chip platform was fabricated from an elastomeric material, polydimethylsiloxane (PDMS), using soft-lithography. The platform comprises three different sections as depicted in Fig. 1: a mechanical actuation unit comprising three individually addressable chambers; a cell-hydrogel section; and a perfusion channel, mimicking the blood circulation to provide nutrients to the cell-laden hydrogel. Compressive strain and shear strain were imposed on the hydrogel by deforming the thin membrane by applying positive and/or negative pressures to the three chambers (Fig. 2). Microbeads (15 µm) added to the hydrogel to evaluate its deformation upon mechanical stimulation and deflection of the elastomeric membrane. Human chondrocytes (hCHs) were cultured in an agarose hydrogel matrix using both proliferation and differentiation medium. The cell projected area was determined for seven different applied pressure amplitudes (100-700 mbar). Cell viability was evaluated using a live/dead assay and specific fluorescent stains, for different applied mechanical stimulation (0, 300, 700 mbar applied at 1 Hz for 1 h per day, starting from day 1). Glycosaminoglycan (GAG) production was assessed using Alcian blue staining, and nuclei were counter-stained with fast-red on histology cryosections after recovery of the 3D cellular constructs from the platform, after 15 days of culture and 14 days of mechanical stimulation at 1 Hz for 1 hour per day at 300 mbar.

RESULTS

Membrane deflection was quantified for various membrane heights and thicknesses, and PDMS formulations, as a function of the applied pressure. Applying higher pressures led to greater membrane deformation. Interestingly, switching pressures, from positive to negative, and vice versa, allowed different and complex membrane deformation patterns (Fig. 2). Hence, full control on the membrane deformation was achieved at the individual chamber level. Agarose deformation was next assessed (Fig. 3): the higher the pressure, the higher the strain. Importantly, both healthy (5-20%) and pathophysiological (>20%) strains could be applied in the vicinity of the membrane on the cell-laden agarose. Moreover,

combined compression and shear strain was obtained by single chamber stimulation. We further determined the projected cell surface area of primary chondrocytes upon increasing applied pressures. This projected surface area was found to decrease, and the closer a cell from the membrane, the larger its surface area decrease. Moreover, the cell surface area decrease correlated to the pressure imposed in the system (Fig. 4). Interestingly, hCHs cultured under hyper-physiological level of compression died after 3 days of stimulation while they maintained their viability under physiological stimulation.

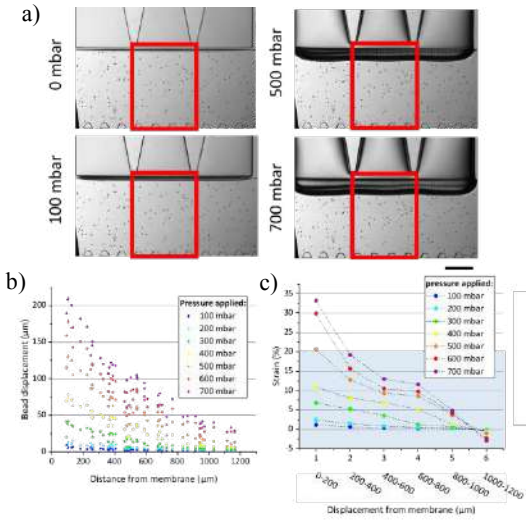

Figure 3: a) Top view of the system with agarose containing 15-µm beads at different pressures; b) Displacement of the microbeads at different pressures and positions in the hydrogel; c) Strain patterns in the hydrogel at different pressures.

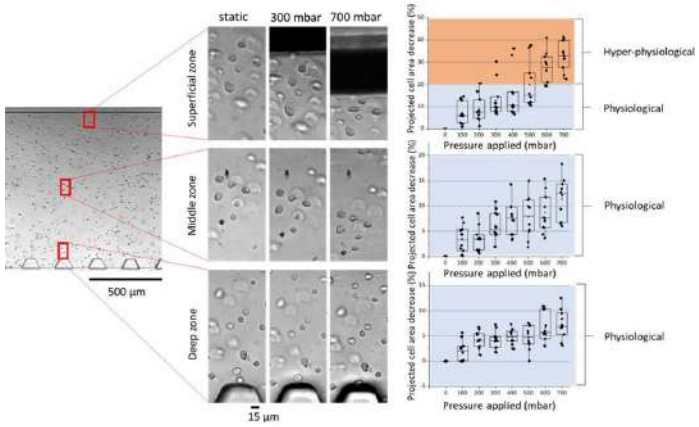

Figure 4: Top view of the middle of the culture chamber; Deformation of cells in different areas in the hydrogel in static conditions or during compression (300 and 700 mbar); Projected cell area deformation of 10 individual cells in the different areas. Light blue indicates physiological deformation; light orange hyper-physiological condition.

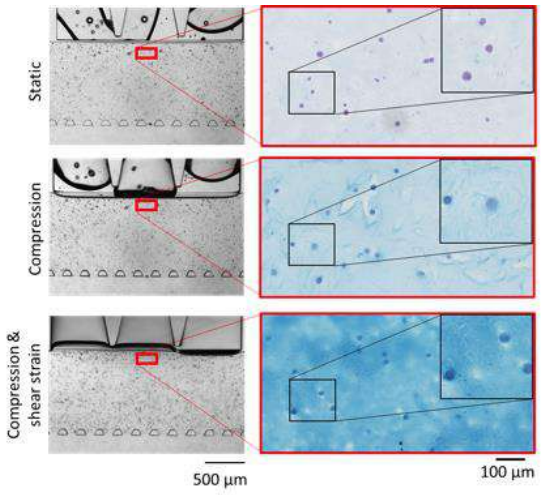

To further evaluate the effect of mechanical stimulation on the cells, hCHs were cultured under static or dynamic conditions, with only compression or a combination of compression and shear strain. Here, the GAG production levels, as analyzed through immunohistochemistry, were enhanced under mechanical stimulation, with formation of a pericellular matrix. Moreover, the combination of compression and shear strain further increased the GAGs production by the hCHs (Fig. 5).

Figure 5: Left, from top to bottom, transmitted image of the system in the three conditions; Right, histological sections after staining for GAGs (Alcian Blue) and cell nuclei (fast red). The ring around the cells corresponds to the pericellular matrix which appear after 15 days of culture (14 days of stimulation at 1 Hz for 1 h at 300 mbar).

To further evaluate the effect of mechanical stimulation on the cells, hCHs were cultured under static or dynamic conditions, with only compression or a combination of compression and shear strain. Here, the GAG production levels, as analyzed through immunohistochemistry, were enhanced under mechanical stimulation, with formation of a pericellular matrix. Moreover, the combination of compression and shear strain further increased the GAGs production by the hCHs (Fig. 5).

CONCLUSIONS

This novel microfluidic platform can be used to explore the impact of various mechanical stimuli on responses of individual cells. In specific, it allows mimicking the healthy and hyper-physiological ranges of stimulation of cartilage and can be used to impose multiple mechanical stimulation patterns on a 3D cellular construct. This platform will be further developed to study disease progression or to screen therapeutic agents. Our final goal is to extend this platform with units mimicking the synovium, ligament, bone and meniscus to engineer a full joint-on-chip.

A MECHANICAL MODEL FOR THE NON-LINEAR HEREDITARINESS OF LIGAMENTS AND TENDONS OF THE HUMAN KNEE

Emanuela Bologna[1], Luca Deseri[2], Kaushik Dayal[3], and Massimiliano Zingales*[1]
[1]Dipartimento di Ingegneria,Università di Palermo,Palermo,Italy.
[2]Dipartimento di Ingegneria Civile,Ambientale e Meccanica,Universitá di Trento,Trento,Italy.
[3]Department of Civil Engineering, Carneige-Mellon University, Pittsburgh, U.S.A.

Summary In this paper the authors introduce a non-linear model for fractional-order hereditariness for ligaments and tendons of the human knee that corresponds to experimental data. Creep and relaxation data on fibrous tissues have been obtained and fitted with logarithmic relations that corresponds to power-laws with non-linear dependence of the coefficients as well as of the order of time-evolution. The use of a proper non-linear transform allows to use Boltzmann superposition in the transformed variables yielding a fractional-order model for the non-linear material hereditariness if the stress/strain dependence of the evolution order is neglected. This approach is extended in the course of the present study resorting to a linear-time dependent mechanical system that corresponds, exactly to the provided time evolution of power-laws and that generalizes the case of stress/strain dependence in the order of the power-laws. Some numerical analysis has been provided to capture the effect of the proposed method with some experimental results in case of non-uniform time evolution of strain and stress.

INTRODUCTION

Material hereditariness is a challenging topic in the field of engineering and physical sciences since the very first observations on the long-term behavior of polymers, rubbers and concrete at the end of the XIX century. Indeed experimental campaigns conducted under long-standing loads (creep tests) and long-standing displacements (relaxation tests) shows that, besides an initial elastic displacement (strain in creep) or load (stress in relaxation) a time evolution of the initially measured strain/stress is clearly observed.

Mathematical modeling of materials time-dependence in terms of creep and relaxation has been intensively investigated since the beginning of the XX century [1, 2]. In such studies the use of Boltzmann superposition assumption yields constitutive equations involving convolution integrals among a kernel function that is material dependent and the material state variables [3]. The observation involving effect superposition corresponds to a linear behavior of the material such that linear hereditariness of engineering materials as wood, glass, bitumen has been extensively studied to account for long-standing loads. In this regard, the use of power-law Kernels to describe experimental material functions led several authors to introduce the fractional-order differ-integral operators to capture the material behavior in linear conditions [4]. Fractional-order constitutive equations have also been extended to three-axial conditions [5] and rheological equivalence has been also introduced [6]

The wide success of fractional-order calculus to deal with linear hereditariness is, however, not justified in the wider field of non-linear material hereditariness. Indeed, it is well-known since the very first long-standing experiments on rubbers and polymers [1, 2] that carbon-based materials undergoes large strains and a significative non-linear behavior is observed from experimental tests [7]. This latter observation has been also more evident in presence of fibrous biological tissues where no linear conditions may be observed even for small level of stress/strain [8].

In some recent papers the authors showed that in case of stress/strain independence of the order of power-laws in creep t^{β_c} and relaxation t^{β_r} by the level of stress or strain applied, a generalization of the well-known theory of quasi-linear hereditariness may be physically extended to fractional-order hereditariness and that a rheological model made by linear springs and linear dashpots fully justifies the assumption of quasi-linear hereditariness with power-law kernel.

In this paper the authors aim to introduce the use of fractional-order calculus to capture the experimental behavior of biological fibrous tissues of the human knee in presence of material non-linear behavior also in the order of the decay of creep $t^{\beta_c(\sigma)}$ and relaxation $t^{\beta_r(\varepsilon)}$ by means of the generalization of the mechanical model proposed. A complete physical and mathematical framework for the relations among creep and relaxation functions in presence of material non-linearities, contrasted with experimental data of a large experimental campaign have been provided by means of fractional-operators formalism.

EXPERIMENTAL CAMPAIGN ON HUMAN PATELLAR AND HAMSTRINGS

The experimental campaign has involved two kind of human tissue, namely patellar (P) and hamstring (H) tendons. The human tissues were obtained by a tissue bank (Lifelegacy Foundation, Arizona, USA) with the requirements that each ensemble of P and H were obtained by the same human knee to avoid donor variability. Biological specimens were stored at 80 $^\circ C$ and thawed in a 37$^\circ C$ water bath for 15 min prior to testing [9], then prepared for the test and finally each specimen was there cut approximately at the same length before clamping for the uniaxial test. commercial

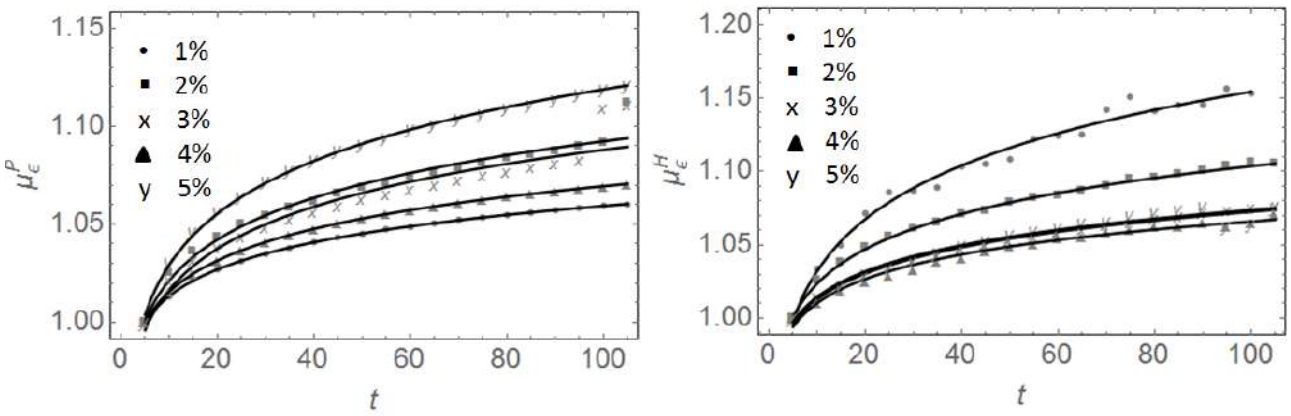

Figure 1: averaged creep functions for patellar and hamstring tendons

electromechanic system (Electroforce, Bose 3330) was used to test both the tendons' groups. We have used a specific protocol for the repeatability of the experimental campaign. Initially, the samples were preconditioned by cycling between 20 and 100 N, for twenty cycles at 0.25 Hz to remove any crimping in the tendon fibrils [**?**]; after preconditioning, we performed relaxation test with prescribed values of the strain level in the range $1-5\%$. We conducted the relaxation tests applying a linear ramp of displacement with speed 250 mm/s and after the hold fixed for 100s at the achievement of preselected value of strain, at the end of relaxation test resting the sample for 15 min in order to achieve the same length of the initial specimen measured at the end of the first phase. In last phase, the creep test obtained applying the same initial stress reached at the end of the relaxation test with a linear load ramp of 315 N/sec and holding the load 100s. During the test, the sample was continuously moistened with saline solution.

Data analysis

The experimental data in terms of the axial engineering strain $\varepsilon(\sigma,t)$ were averaged, for each level of applied stress. The averaged creep functions, namely $\mu_\varepsilon^{(P)}(\bar{\sigma}_i,t)$ and $\mu_\varepsilon^{(H)}(\bar{\sigma}_i,t)$ are reported in fig.(1), respectively. A more detailed representation of the averaged creep functions may be observed in a $log\mu_\varepsilon - logt$ plot reported in figs.(1,2) for the patellar and hamstring tendons, respectively. Data analysis reported in fig.(3,4) for the log-log plots reveals that good candidate to fit averaged values of creep functions $\mu_\varepsilon^{(P)}(\bar{\sigma}_i,t)$ and $\mu_\varepsilon^{(H)}(\bar{\sigma}_i,t)$ is the a linear model with equation:

$$\log \bar{\mu}_\varepsilon^{(j)}(\sigma,t) = \beta_j \log\left(\frac{t}{\tau_c^{(j)}}\right) + \alpha_j \log(\bar{\sigma}_j) \tag{1}$$

where $j = P, H$ denotes the specific tissue considered, $\tau_c^{(j)}$ and $\bar{\sigma}_j$ are respectively a characteristic time and the non-dimensional stress $\bar{\sigma}_j = \sigma_j E$ where E is the tangent elastic modulus obtained at the origin of a monotone test.

CONCLUSIONS

Direct inspection of the creep data shows that the order of evolution of the strain is very influenced by the level of stress applied in the experimental campaign. For this reason single-integral formulations can not be applied to capture the data. In this study the authors will discuss a proper mechanical model that corresponds, exactly, to the time evolution obtained by data analysis and that can be easily generalized to cases of time-variations of the applied stress and strain histories.

Summary *Mytilus edulis*, commonly referred to as blue mussels, is known for producing byssal threads, which allow them to adhere to rocks and each other in tidal zones. A byssal thread emerges from body tissue and ends with an adhesive plaque that is located at the other end of the thread and attaches to substrates. It is observed that the plaques are usually tiny, and their size does not vary much with different body sizes of mussels, which can cause different impact force in waves. With that said, it is not clear how these byssal plaques are designed for strong attachments. In this study, we combine mechanical testing with 3D printing and numerical modeling to investigate how the size of adhesive plaque affects the adhesion strength. We find that plaques with a diameter 3 to 5 times that of the byssal thread yields optimized strength upon detaching. Interestingly, plaque size larger than this will have a small marginal effect. Our results show that the architecture of byssal plaque is more important than simply increasing plaque size for bonding strength.

Mytilus edulis, commonly known as blue mussels, are known for their capability of hanging to rocky shores by using their bushy "beards", known as byssal threads. Such byssal threads attach to the rock surfaces and the shells of other mussels [1–3]. Each byssal thread has heterogeneous chemical composition and mechanics, making it simultaneously rigid and stretchy, similarly as a bungee cord, which helps to dissipate the repeatedly impact force caused by crashing waves. Both the schooling and the locomotion behaviors of mussels are ensured by the underwater adhesion of the byssal threads to substrates made of different materials, which is guaranteed by the adhesion of the byssal plaque at the far end of the thread, which is a thin film that connects the byssal thread to the rock surface (**Fig. 1A, B**) and it is composed of mussel foot proteins with high concentrations of L-3,4-dihydroxyphenylalanine, which has a strong affiliation with almost any type of material surfaces by forming either non-covalently bonding interactions or covalently bonding interaction to different substrates. Besides molecular mechanics, it is interesting how the entire byssal plaque contributes to the adhesion function. Similar to surface of gecko's toes, mussel byssal plaques are observed to have a clear branching structure, as shown in **Fig. 1C**, as the entire plaque is composed of micrometer fibers distributed in the radial directions that connect from the center of byssal thread to periphery on the substrate. It is intriguing to study how this tiny byssal plaque size (**Fig. 1D**) is beneficial for providing adhesion strength.

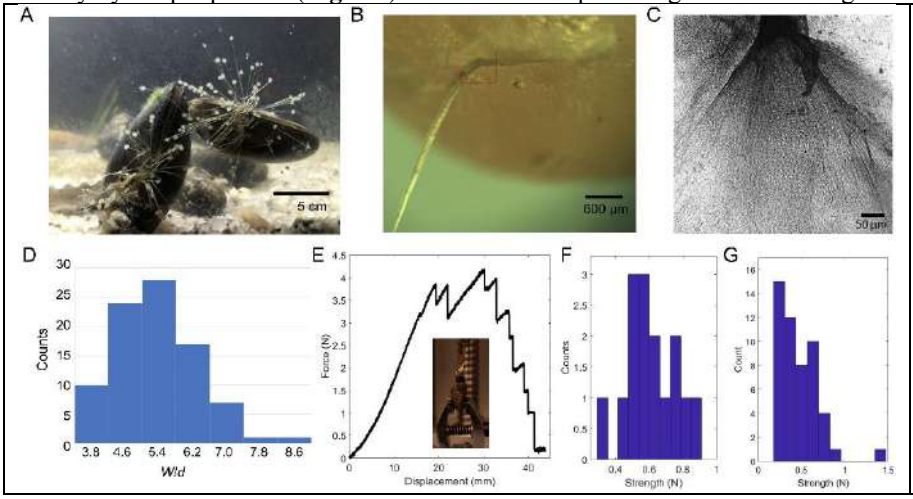

Figure 1. Image of mussels, the multiscale structure of byssal threads and their mechanics in the attachment. A. Snapshot of two mussels. Images of (B) optical microscope (C) laser confocal microscopy. D. measurements of the diameter of byssal plaque. E. A force-displacement curve of detaching a bundle of byssal threads. The histogram of the adhesion strength of detaching a single byssal thread from the rock surface (F) and from the mussel shell surface (G).

Using a mechanical test, we take measurements of the adhesion strength of byssus threads (inset of **Fig. 1E**) by fixing the substrate (rock and mussel shell), clamping their ends at the byssal gland and applying force by slowly moving the grips up with a constant speed. It is noted that the structure failure takes place by the individual detachment of plaques from the rock surface instead of catastrophic rupture, corresponding to each of the saw-tooth and causing significantly more energy dissipation than the area under the J curve. The peak force is 4.2 N as recorded, interestingly, the mean force of each thread (0.47 N) as obtained from detaching of this bundle agree with the strength of each individual byssal thread that is detached from the rock surface (0.61±0.16 N, **Fig. 1F**) and larger than the attachment strength to mussel shells (0.45±0.26 N, **Fig. 1G**). This agreement suggests the unique material composition of the byssal thread can synergistically integrate the strength of each plaque for mussel adhesion. Moreover, considering the area of each byssal plaque is merely 2.8 mm^2, the mean adhesion strength goes up to 215±56 KPa, which is almost one order of magnitude higher than the strength of these bioinspired glues [4–6]. We notice that although the mussel glue is strong, it will never be overused since the plaque size is only 3~6 times that of the byssal thread. (**Fig. 1D**) These

samples are taken from many mussels with their body size varies several tens of times. It seems the byssal thread and plaque of the mussel do not grow together with the mussel body. However, instead of varying the size of each plaque, the growth only affects the number of threads for attachment.

Design sketch of the printing model with parameters as thread diameter (d), plaque width (W), thread thickness (b) and plaque thickness (h). B. The tensile test of the failure process of the 3D printed model. C. Force-displacement curves obtained for mussel models with different W/d values. Featuring mechanical parameters are obtained from the curves including Young's modulus (E) as in D, the ultimate strength (σ_C) as in E and the energy dissipation (U) as in F. G. A summary of all the 3D printed experimental samples with different plaque width. FEM results of the distribution of normal stress within the soft material of the model W/d=1 (H) and W/d=6 (I) by subjecting to different deformations, where the concentrated stress and associated damage at the interface start from the middle and propagate to the two ends

To understand the size effect in mussel plaque, we design and make a series of 3D printed models, by scaling the natural observation up for 100 times, in order to test how the adhesion strength relates to the geometric design of the byssal plaque by using a multi-material 3D printer [7,8]. This model, as schematically shown in **Fig. 2A, G**, takes the 2D profile of a byssal thread near the attachment and is characterized by the diameter (d) and thickness (b) of the rod region that mimics the byssal thread and the width (W) and height (h) of the toe region that mimics the byssal plaque. The rubber-like material layer is defined by $W \times h \times b$ for simplicity and its existence can guarantee the rupture from this region, mimicking the failure of byssal plaque from the interface with substrates. We test the mechanical behavior of these samples with different plaque sizes. Interestingly, as the snapshots shown in **Fig. 2B**, not the entire middle region gets deformed once the structure is subjected to the loading force but the region near the middle of the rod gets more significantly deformed than the two edges. The failure always takes place from the middle of the interface and propagate toward the two ends.

CONCLUSIONS

We record the force-displacement curve as the testing result of models with different W/d ratio, as summarized in **Fig. 2C**. It shows that the larger toe width can increase the structure strength, as the peak of the force, but the effect is limited up to $3.5d$ and the effect becomes very small afterward. However, increasing W can lead to a longer tail region for more energy dissipation, which corresponds to the material failure within the rubber-like material phase by cracking from the center to the two edges. We repeat our test for 4 times for each of the samples and compute the average value and standard deviation of the modulus (E) strength (σ_C) and energy dissipation (U) before the total failure of the structures as shown in Figs. 2D, E, and F, respectively. These test results show a clear trend in common once subjected to tensile loading, as E, σ_C and U almost linearly increase with W/d up to 2 to 3 and thereafter their values trend to converge to a constant value except for U as the energy dissipation can still increase for W/d between 3.5 to 4.5 as the long tail region can grow with W, revealing that W/d from 3 to 5 yields the strong adhesion. Our finite element models (**Fig. 2H, I**) show that before the failure of the interface the stress and deformation largely happen at the middle region below the byssal thread but not the two sides outside this region, as the highest normal stress initiates from the middle point, suggesting the starting of the damage, and propagates toward the two ends. Together, our result shows that the mussel byssal plaque needs to be tiny, as a few times that of the thread for optimized strength.

MEDICAL IMAGE REGISTRATION AND INVERSE MODELING TO UNCOVER FETAL BRAIN FOLDING MECHANISMS

Johannes Weickenmeier*[1], Zhenling Wang[2], Yana Blinkouskaya[1], Blake T. Martin[2], and Krishna Garikipati[2]

INTRODUCTION

During fetal development, the human brain undergoes large topological changes and volumetric growth, roughly doubling in size every four weeks [1] and the gyrification index, a ratio related to the real brain surface area over the convex hull, increasing from 1 to 1.6 [2]. Such dramatic changes correspond to the brain changing from a nearly smooth surface to a highly folded structure, as shown in Fig. 1. The corresponding folding of the outer cortex- also known as gyrification- is driven by the migration of neurons from the ventricular zone towards the cortex. The accumulation of neurons in the cortex leads to primary folds that form consistently across all healthy brains during mid-gestation [3]. These neurons originate from the subventricular zone, where they differentiate, proliferate, and ultimately migrate outward to form the cortical layers. The signals driving migration pathways play a critical role in establishing the brain's functional network including the highly complex axon-based connectome [4]. The interconnections between neurons are responsible for the intricate communication between individual brain regions; yet, it remains poorly understood how this network forms, grows, and evolves throughout life.

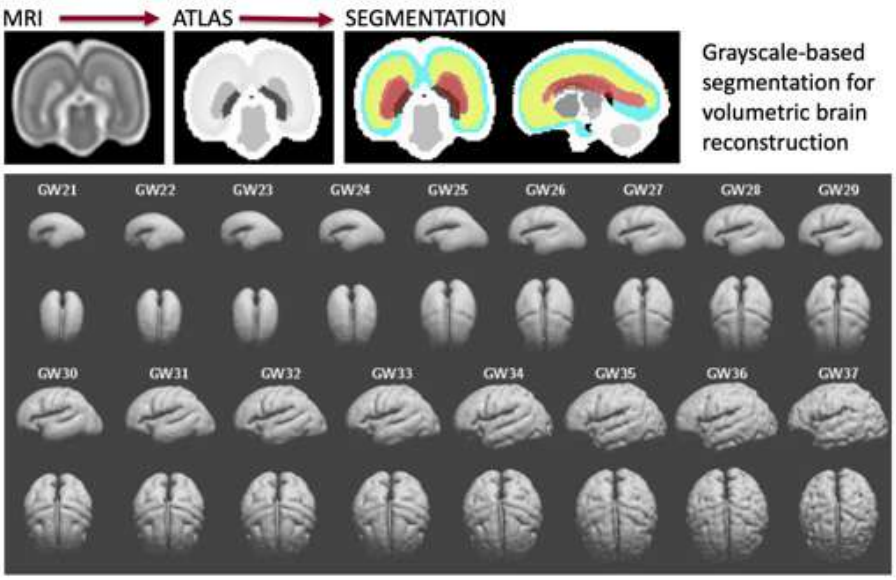

Figure 1: Fetal brain segmentation from medical images between gestational weeks 21 and 37. We differentiate between gray matter, white matter, and the ventricles. Brain volume reconstruction reveals overall growth, ventricular enlargement, and the emergence of primary folds at characteristic gestational timepoints. Based on our segmentations we then created tetrahedra-based finite element meshes for numerical simulations and our inverse problem.

In the present work, we uncover the role of mechanics in understanding the formation of primary folds during gestation. Our approach combines non-rigid image registration and inverse modeling. The former aims at extracting brain shape changes between two consecutive gestational weeks. The latter utilizes a continuum mechanics-based coupled multi-field model of cell migration and morphogenetic growth in order to derive a physics-based mechanism of brain folding.

METHODS AND RESULTS

We extract the spatio-temporal evolution of brain folding in a two-step approach. First, we determine brain shape changes between two consecutive gestational weeks from the longitudinal MRI dataset presented by Gholipour et al [5]. We apply a image registration technique developed by Pawar et al. that minimizes the pixel intensity difference between two medical images by non-rigidly deforming the slave image to coincide with the reference image [6]. The resulting registration mapping contains the deformation field of the brain between the two gestational weeks. As shown in Fig. 2, we are able to obtain physiologically meaningful displacement fields. We can identify the location and timepoint for the onset of primary folds and the overall cortical expansion due to volumetric growth.

*Corresponding author. E-mail: johannes.weickenmeier@stevens.edu.

We use our individual deformation fields as input to our inverse problem. Specifically, our formulation incorporates two fields, i.e. cell density c and deformation $\mathbf{u}$. We follow continuum mechanics theory and assume a hyperlastic behavior according to the Neo-Hookean material model. We prescribe brain growth via a multiplicative split of the deformation gradient, $\mathbf{F} = \text{grad}\,\varphi$, into an elastic and a growth part. We assume purely elastic response, with no viscous effects, while the growth part is coupled to the cell density such that volume increases proportional to cell density. We hypothesize that brain folding is driven by a cell density increase in the cortical layers leading to buckling due to volumetric expansion [7]. Our inverse model uses a gradient descent method to minimize the residual of the energy functional derived for our constitutive model. The registration-based deformation fields are inputs to the inverse model such that we obtain cell density distribution fields $\tilde{c}$ which reveal cell migration patterns during gestation.

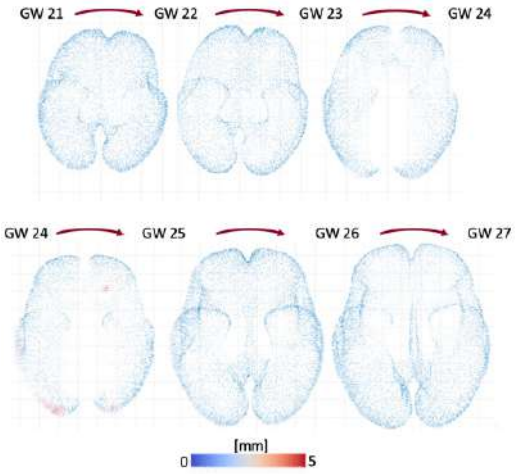

Figure 2: Non-rigid image registration provides brain deformation fields between consecutive gestational weeks. We capture brain deformation as a displacement vector field of our finite element meshes created from brain segmentation and interpolate nodal displacements in the registration maps from our registration tool.

DISCUSSION

Longitudinal MRI data inherently contains information on organ-level morphological changes; yet, reliable physics-driven tools for a quantification of these changes are mostly unavailable. Pawar et al.'s non-rigid framework was modified to deliver weekly brain deformations. Our method identifies the onset of primary folds and quantifies inhomogeneous cortical expansion patterns. The subsequent inverse problem then reveals cell density distributions at discrete gestational weeks that reproduce the displacement fields shown in Fig. 2. Based on our constitutive formulation and the inverse problem, we observe a variation in cell concentration changes between individual gestational weeks of up to $\pm 20\%$. That means, that some regions shrink while others expand producing very inhomogeneous brain volume change patterns which point towards the localization of folds. Fig. 3 shows the result from a forward problem using the initial conditions for for the concentration field based on the output of our inverse problem. It can be observed, that this yields a physiological brain deformation pattern including primary folds. Our method is not without limitations. As such, the solution of the inverse problem is non-unique, and is characterized by a strong dependence on the initial conditions.

CONCLUSIONS

Our work provides a mechanistic rationale for the origin of cortical folding and delivers a novel tool to study the physics behind brain network formation during early development. Our coupling of cell density and brain volume in a continuum framework accurately reproduces spatial folding patterns observed from longitudinal medical image data. Going forward, our approach will be utilized to explain the formation of the brain's complex axon network. Ultimately, we aim at understanding the physical origin of neurological disorders in order to develop novel diagnostic tools and medical interventions.

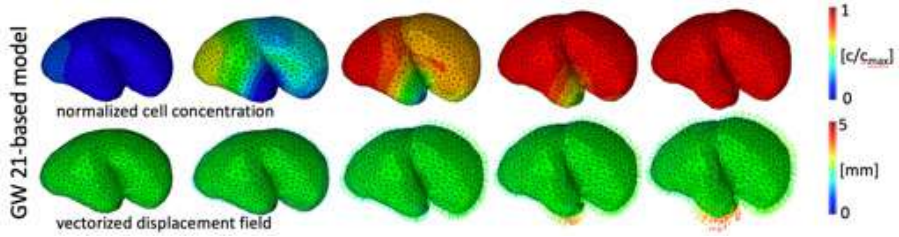

Figure 3: Non-rigid image registration provides brain deformation fields between consecutive gestational weeks. We capture brain deformation as a displacement vector field of our finite element meshes created from brain segmentation and interpolate nodal displacements in the registration maps from our registration tool.

THE MULTISCALE STIFFNESS OF HUMAN SKIN

Adam Wahlsten*[1], Alberto Stracuzzi[1], Ines Lüchtefeld[2], Alexander E. Ehret[1,3], and Edoardo Mazza[1,3]

Summary The mechanical properties of human skin determine tissue function, they change during wound healing, fibrosis, and aging, and regulate dermal cell behavior. Despite their importance, measuring these properties remains elusive with reported values of the Young's modulus ranging from below one kPa to tens of MPa. This contribution presents a thorough experimental and numerical study of skin stiffness across length scales. The stiffness at the cell-relevant microscale is found to be on the order of 1 kPa, in contrast to macroscopic uniaxial tension measurements on the adjacent tissue showing two orders of magnitude higher modulus. The results are rationalized using discrete and continuum modeling approaches, which highlight the influence of the heterogeneous microstructure of the skin and its nanoscale topography on the measured stiffness.

INTRODUCTION

The skin is the essential barrier that protects our internal organs from excessive damage due to mechanical loading, temperature changes, or irradiation, but also against pathogens and interstitial fluid loss. Its function derives from the layered structural assembly and the microstructural organization within the two main layers: the surface epithelium of differentiated keratinocytes, called the epidermis, and the collagen- and proteoglycan-rich dermis. The dermis is considered to be the load-bearing layer, where the interaction between the collagen fiber network, the proteoglycans, and the interstitial fluid results in a deformation behavior characterized by fiber alignment toward the loading direction and, as a consequence, strain-stiffening and large volume reduction under tensile loading [1]. The deformation mechanisms observed in these macroscopic experiments contribute to provide the skin with exceptional tear resistance and defect tolerance [2]. However, tests on the macroscale has consistently failed to predict the mechanical microenvironment of dermal cells, for which several orders of magnitude lower stiffness than on the macroscale has been reported [3]. Such a compliant cellular microenvironment has been shown in *in vitro* studies to promote physiological cell behavior, for example maintaining dermal fibroblast phenotype and gene expression profiles [4]. In general, measuring the stiffness of the skin remains challenging, as evidenced by reported Young's moduli ranging from 1 kPa [4] to tens of MPa [5], and an understanding of the differences, in particular between length scales, is lacking.

MATERIALS AND METHODS

Healthy skin biopsies from female donors undergoing surgery and providing signed informed consent are obtained and cut to yield samples for macroscopic uniaxial testing as previously described [1]. Adjacent tissue pieces are embedded in optimal cutting temperature compound and snap-frozen in liquid-nitrogen-cooled isopentane. Subsequently, through-thickness cryosections of 50 µm thickness are cut with a cryotome and collected on positively charged microscope slides. Atomic force microscope (AFM)-based indentation experiments are performed on skin sections hydrated in phosphate-buffered saline solution using a commercial AFM. The AFM is mounted on top of an inverted optical microscope, providing visual feedback to guide the cantilever over the skin cross-section and to clearly distinguish between epidermis and the papillary and reticular layers of the dermis (Fig. 1a). Each layer is independently probed using soft cantilevers (nominal spring constant 0.1 N m^{-1}) with a 6.1 µm diameter polystyrene colloidal particle attached to the cantilever tip. The local apparent modulus from each force–indentation curve is extracted by fitting the curve to the Hertzian contact solution for a rigid, spherical indenter and a flat, elastic half-space [6].

To rationalize the mechanical properties across length scales, a microstructural model of the human dermis is developed. The model consists of an assembly of discrete fiber elements, connected at cross-links to form a network, and coupled to a continuum representation of the surrounding non-fibrillar matrix [7]. Fibers are modeled as slender, nonlinear springs, with high stiffness in tension and low resistance to compression. Representative volume elements are generated for simulating macroscopic uniaxial tension experiments under affine-displacement boundary conditions, whereas microscale indentation is simulated by coupling fiber and continuum element nodes at the surface and modeling the interaction with a rigid sphere as hard, frictionless contact (Fig. 1d) [8].

RESULTS AND DISCUSSION

The extracted apparent moduli from AFM experiments (Fig. 1b) show a large heterogeneity (Fig. 1f), with values on the order of 1 kPa, consistent with a previous study [4]. The determined moduli from uniaxial tension tests are, however, roughly two orders of magnitude higher (Fig. 1c), in agreement with our previous data [1]. The differences observed between length scales can therefore not be attributed to natural variations between body locations or due to donor age, and additional tests on murine skin, following the same protocols, confirm the same order-of-magnitude discrepancy as observed for human skin.

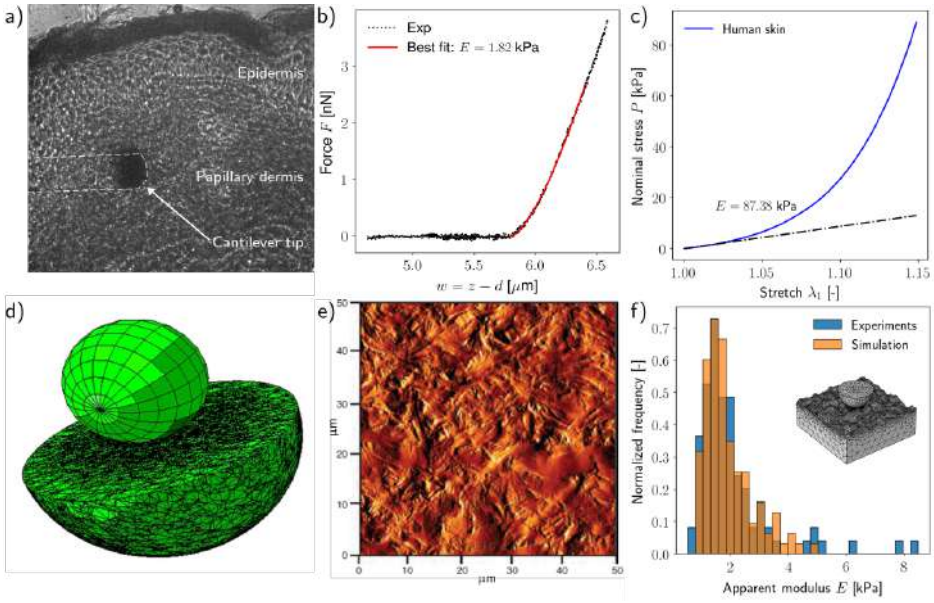

Figure 1: Multiscale measurements and modeling of skin stiffness. AFM indentation experiments were performed on through-thickness sections of human skin (a); a typical force–indentation curve is shown in (b). The macroscopic response in uniaxial tension is significantly stiffer (c). Indentation tests were simulated using a microstructure-based model of the human dermis (d). High-resolution AFM scan of a human skin cross-section showing topographical variations on the order of 1 µm (adapted from [4]). Incorporating realistic surface topographies reproduces the experimental results (f).

The AFM-based indentation experiments probe the local modulus on the length scale of 1 µm—of similar scale as the focal adhesions of a dermal fibroblast [9]—whereas the dimensions in macroscopic uniaxial tests are on the order of several millimeters. The collagen fibers in the papillary dermis form a network with fiber segment lengths of tens of micrometers [10], *i.e.* in between the length scales probed in the experiments. Our microstructural model shows that part of the stiffness difference originates from the network microstructure: the compliant response to indentation arises from the soft behavior of single, slender fibers and the non-fibrillar matrix, compared to a stiffer, collective response when homogenized. However, in disagreement with the AFM experiments, the microscale model predictions are stiffer and show only little variation between locations or the local network structure. These discrepancies can be rationalized in terms of significant variations in topography (Fig. 1e), which question the assumption of a locally flat surface in the analysis of AFM indentation data. Simulations of indentations on a rough surface, qualitatively similar to the measured topography, reproduce the experimental data of apparent moduli on the microscale (Fig. 1f).

CONCLUSIONS

An extensive experimental and numerical analysis of the scale-dependent stiffness of human skin was performed. The measured apparent moduli, differing by orders of magnitude depending on the length scale, were rationalized in terms of the heterogeneous microstructure of the dermis and the nanoscale topography. The analysis presented in this work provides a deeper understanding of skin mechanics across length scales, with implications for fundamental studies in cell mechanobiology and the design of tissue-equivalent materials.

Summary In soft collagenous tissues, resident cells use their focal adhesions to mechanically probe their environment. They also adapt to changes in osmotic pressure of the interstitial fluid. In fact, both mechanical and chemical cues affect cell processes and functionality. Due to the presence of negatively charged macromolecules interconnected with the collagen network, a mechanical load always induces an osmotic stress, and *vice versa*, causing an interplay which affects the macro- and micro-scales to different extents. We developed a hybrid discrete-continuum model to investigate the spatial heterogeneity of the mechanical stiffness and the chemical signal at the cellular length scale, and we show that the tissue chemoactive components play a key role in establishing the cell environment.

MECHANICAL CUES AND CHEMOACTIVE COMPONENTS

The mechanical characteristics of tissue extracellular matrix (ECM) strongly affect the behaviour of resident cells. In fact, cells use specific transmembrane proteins in so called focal adhesions (FAs) to anchor and effectively probe the ECM scaffold, whose mechanical properties may influence cells' behaviour, *e.g.* by controlling their direction of motion in durotaxis [1], or by inducing proliferation [2] or tumorigenesis [3].

In soft collagenous tissues, the extracellular environment is highly diverse. Resident cells live and move within the pore space shaped by the 3D network-like arrangement of collagen fibres. Moreover, long chains of proteoglycans (PGs) are tightly interwoven with the collagen network and carry negatively charged groups of glycosaminoglycans (GAGs), which regulate tissue hydration and influence the concentration of ions diffused in the interstitial liquid.

Due to the difficulty to assess experimentally the ECM mechanical contributions at a cellular length scale, recent studies recognized the need to analyse the cell environment using dedicated multi-scale numerical frameworks, which mainly focused on the representation of the fibre skeleton by using discrete network approaches, without considering the presence of mobile and fixed ions. These studies reveal that cells feel a strongly heterogeneous mechanical signal in terms of local stiffnesses at the FAs, both in 3D disordered fibre networks [4] and on 2D fibrous substrates [5]. However, the presence of dissolved chemical species not only constitutes an important cellular cue *per se*, but also in its interaction with the chemoactive components, *i.e.* PGs and GAGs. In fact, applied mechanical loads may change locally the concentration of fixed charges and the corresponding osmotic pressure, thus inducing fast redistributions of mobile ions and gradients of chemical potential which slowly drive the fluid in or out, over the tissue boundaries. The resulting chemomechanical coupling has been identified to be relevant also for soft biomembranes when subjected to physiological tensile deformation states [6]. In this particular case, upon stretching, the collagen network contracts, the tissue volume decreases as a consequence of water outflow, and the internal osmotic pressure increases, thus modulating the internal state of stress.

In this contribution, we analyse the effects on both the mechanical and chemical characteristics of the cell environment determined by the presence of chemoactive components within the ECM, by developing a hybrid discrete-continuum approach, representative of a real biological tissue, and probing it *in silico* at the cell length scale (~$10\mu m$).

A HYBRID DISCRETE-CONTINUUM MODEL

The proposed model is a combination of a discrete network of trilinear axial connectors [6], which model the collagen fibre ensemble, and biphasic continuum elements [7], which provide a lumped representation of water, PGs and other ECM components. Cubic RVEs are seeded with a specified density of crosslinks (Fig.1). These are then connected according to prescribed length and orientation distributions, and constitute the starting set of nodes to mesh the RVE domain with a Delaunay triangulation scheme (Fig.1). While crosslinks at the RVE vertices are always included, a subset of the remaining crosslinks is selected for the triangulation algorithm. Hence, the resulting mesh size is correlated with the definition of a length scale of interactions (LsI), which represents an average length of the entanglements between collagen fibres and PGs, allowing for parametric studies.

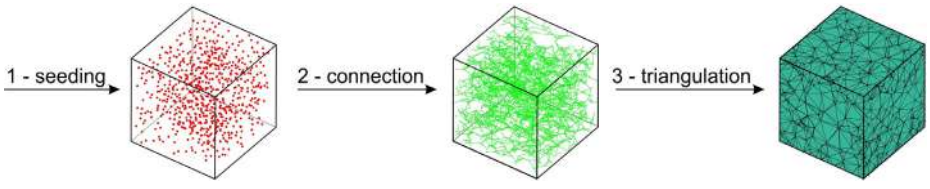

Figure 1: The three main steps of RVE generation.

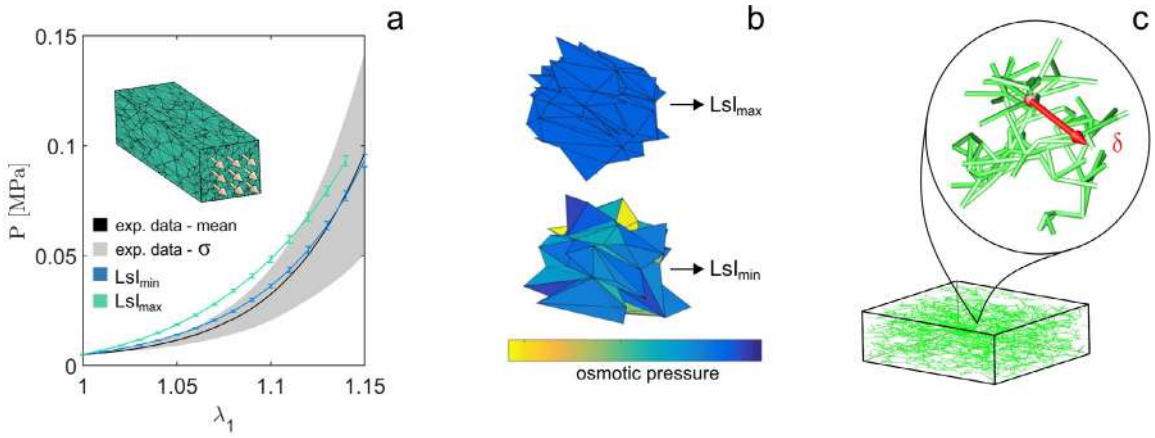

Figure 2: Macroscopic uniaxial response (a), osmotic pressure field of a subdomain of the RVE (b) and qualitative representation of a unit displacement of a crosslink for the determination of the local stiffness in a deformed RVE (c).

MULTI-SCALE NUMERICAL ANALYSES

In order to be representative of a biological tissue, most of the model parameters were derived from histological and morphological data of human dermis, and the macroscopic response of the RVE was then tuned according to uniaxial data of human skin [8]. The homogenised, macroscopic response showed good agreement with the experimental data, with minor dependence on the LsI (Fig.2a). In contrast to this, at cellular length scale, the chemical signal strongly depends on the LsI. In fact, the osmotic pressure passes from homogeneous to highly scattered when ranging from the highest to the lowest value of the LsI, respectively (Fig.2b). Further multi-scale simulations were performed to study the heterogeneity of the mechanical stiffness as perceived by resident cells. To this end, we applied a unit displacement to several random crosslinks (Fig.2c), and we extracted the local stiffness at the loaded points. While the general signature confirmed the broad spectrum of stiffnesses as found in previous studies [4], the resulting stiffness distributions revealed a marked dependence on the LsI. In addition to this large variability of the local mechanical stiffness, the calculations also show a long-range decay pattern for both forces and displacements over the crosslinks, especially if compared with corresponding homogeneous materials.

CONCLUSIONS

We present a hybrid discrete-continuum model which provides new insights on the mechanical and chemical signals experienced by cells in 3D collagenous tissues. In particular, the framework includes the osmotic contribution of the negatively charged PGs, thus providing access not only to the mechanical stimuli but also to the chemical signals and the way the latter influence cell mechanosensing.

QUANTIFYING MECHANICAL STRAIN IN STEM CELL DERIVED CARDIOMYOCYTES IN A CPVT DISEASE MODEL

Summary: Cardiovascular disease continues to be leading cause of death worldwide; of particular concern are diseases which can lead to sudden death, such as in patients with Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT). It is hypothesized that the amplitude of contractile strain can be utilized as a quantitative indicator of cardiomyocyte functionality and disease severity. Digital image correlation (DIC) allows for evaluation of strain across many cells acting in coordination by capturing displacement data throughout contraction events in collections of cardiomyocytes cultured *in vitro*. The technique is demonstrated using a disease model derived from a CPVT patient and a familial control, where we show statistically significant differences in maximum contractile strains between the disease and control conditions.

BACKGROUND

Cardiomyocytes are the contractile cell type of the heart and their coordinated contraction is required for proper pumping of blood throughout the body. Cardiovascular disease continues to be a leading cause of death worldwide motivating the need for models of cardiac function in both healthy and diseased states for both basic science and clinically translational research. Cardiomyocytes (CMs) derived from human induced pluripotent stem cells (hiPSCs) provide a source for developing *in vitro* cardiac models, however current *in vitro* analysis techniques provide only a portion of the necessary means to fully characterize functionality. Specifically, there is a need for additional techniques to quantify and understand the contractile behavior of CMs as the interact collectively with each other and their surroundings.

In these studies, a previously validated human stem-cell derived cardiomyocyte culture platform [1] was used. The platform is created by microcontact printing extracellular matrix (ECM) proteins onto a compliant polymeric substrate with physiologically relevant stiffness. This culture platform bridges the gap between single-cell and tissue studies, by allowing for measurement of contraction between multiple cells while including the structural detail of individual cells. Here we demonstrate the functionality of this platform and the application of digital image correlation (DIC) for analysis with a Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT) disease model. Full-field displacements were measured using high contrast images of sample regions containing CMs [2]. From displacement, principal strains were calculated. Of particular interest is the second principal strain, which in these experiments represents the contractile strain along the major axis of the cardiomyocyte and was used as the quantitative indicator of functionality and disease severity.

RESEARCH METHODS

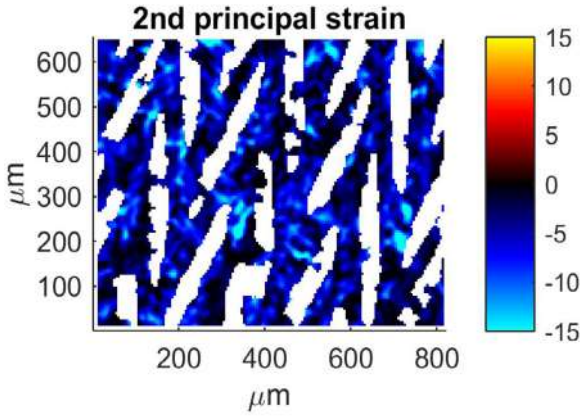

Figure 1: Full field contractile strain at peak contraction

The CPVT model was created using a patient-specific-derived iPSC line with RyR2-H2464D mutation and healthy control line from the patient's mother [3]. Cells were differentiated into cardiomyocytes using a modified version of the small molecule Wnt-agonist method [5], followed by a purification process to remove non-CM cell types.

CMs respond to substrate stiffness through focal adhesions, which enable connection between the cell's cytoskeleton and underlying ECM. Focal adhesions also play a role in formation and alignment of actin stress fibers and force transduction. Microcontact printing of ECM proteins was used to created patterned substrates on PDMS with a Young's modulus from 5-50 kPa, which spans the range of healthy to diseased myocardium [6]. The chevron pattern used was made up of narrow lanes connected by bridges. The lane width influences CM shape and sarcomere organization by providing defined

* Corresponding author. Email: astempien@wisc.edu

attachment regions, and the bridges increase connectivity which allows for synchronized contractions across a large array of CMs.

Videos of spontaneous contractions were captured using a Nikon Eclipse Ti microscope with a 10x objective and Nikon DS-QiMc camera at a capture rate of 11 frames per second and edited such that in the initial frame the CMs were in the relaxed state. Correlations between relaxed and subsequent frames during contraction of the cardiomyocytes were calculated for many spontaneous contractions and multiple biological replicates. The random high contrast pattern from the phase contrast of the cells is sufficient to allow tracking of displacements. The displacement fields in the horizontal and vertical directions for the entire pattern were calculated using the open source digital image correlation software, Fast Iterative Digital Image Correlation (FIDIC) [7] with input parameters of a target subset size of 32 pixels and subset spacing of 8 pixels. From the displacements, the strain tensor was calculated by taking the gradient of the displacement data. Principal strains and principal directions were then computed. Using the full field second principal strain (contractile strain), the average across all cells in the frame was taken and the maximum value over time, or peak strain, was used as the comparative measure between cell lines.

RESULTS

CPVT disease model experiments were performed using a range of PDMS substrate stiffnesses, and relative differences between patient and control varied based on stiffness. The maximum contractile strain of the patient line was 28% higher than the control line (p<.0001) when cultured on 30 kPa PDMS.

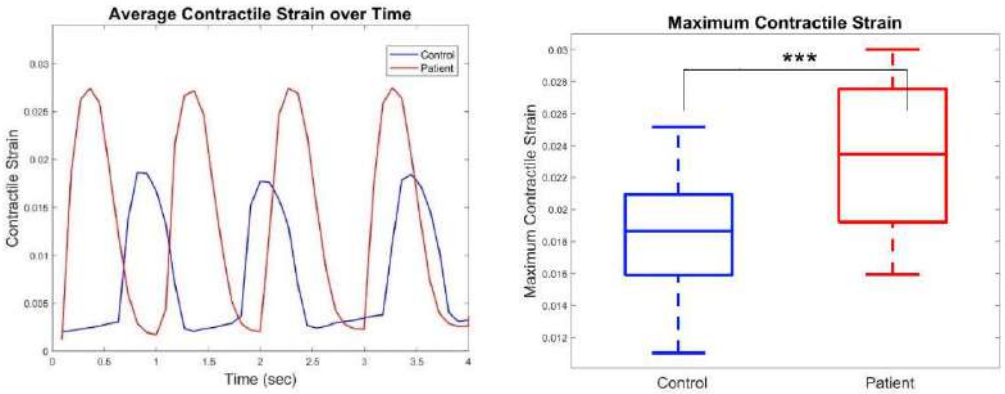

Figure 2: (A) Representative average contractile strains over time, and (B) maximum of average contractile strain over for CPVT cardiomyocytes cultured on 30 kPa PDMS. Patient data (n=19) is shown in red, and control (n=47) data is shown in blue. *** $p <$ .0001

CONCLUSION

DIC was used to investigate differences in mechanical function of human induced pluripotent stem cell derived cardiomyocytes cultured in a microcontact printed platform. A stem cell derived disease model for Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT) was compared to a familial healthy control line to assess differences in contractile function. Mechanical strain was quantified, and in particular second principal strain was used as a functional readout. Statistically significant differences in maximum contractile strains between the disease and control conditions were observed, demonstrating the utility of this approach in quantifying mechanical function as an indicator of disease severity.

THE VASCULAR ENDOTHELIAL GROWTH FACTOR RECEPTOR DYNAMICS DURING THE SPREADING OF ENDOTHELIAL CELLS:EXPERIMENTAL AND COMPUTATIONAL INVESTIGATIONS

Mattia Serpelloni*[1], Matteo Arricca[1], Elisabetta Grillo[2], Cosetta Ravelli[2], Stefania Mitola[2], and Alberto Salvadori[1]
[1]Department of Mechanical and Industrial Engineering (DIMI), University of Brescia, Brescia, 25123, Italy
[2]Department of Molecular and Translational Medicine (DMMT), University of Brescia, Brescia, 25123, Italy

Summary We propose a co-designed experimental and computational study of the Vascular Endothelial Growth Factor Receptors (VEGFR) dynamics during the spreading of Endothelial Cells (ECs), one of the key processes regulating tumor angiogenesis. The study combines evidence deduced from in vitro experiments on ECs plated on a substrate enriched of ligands with simulations of a predictive multi-physics model set up in the field of continuum thermodynamics. The work allows discerning the relevance of cell mechanics in tumor angiogenesis and realizing that predictive models could open unknown roads towards antiangiogenic strategies.

BIOLOGICAL BACKGROUND - MOTIVATIONS

A solid tumor, in order to survive and proliferate, exchanges nutrients and waste with the surroundings. The high metabolism of cancer cells leads to a rapid depletion of resources and simultaneously to a hypoxic state of the tissues nearby the tumor, compromising its survival. As a consequence, cancer cells release growth factors[1], specific proteins that act as signaling molecules. These immobilized factors, that are absorbed in the Extracellular Matrix (ECM), represent a persistent stimulus for the otherwise quiescent Endothelial Cells (ECs), eventually leading to tumor angiogenesis [1]. New blood vessels restore the exchange of nutrients and waste between cancer and the rest of the body and play a pivotal rule in metastasis of tumors, mostly at the very early stage.

At a molecular level, angiogenesis is triggered by the interaction between the growth factors and transmembrane proteins on the lipid membrane of ECs, called receptors[2]. Since the geometry of the membrane evolves in time, the mechanisms behind tumor angiogenesis are affected by the mechanical response of the ECs.

Vascular Endothelial Growth Factor Receptor-2 (VEGFR2) is one of the most relevant transmembrane proteins for tumor angiogenesis. Although the biochemical pathways that follow the activation of VEGFR2 are well established, investigations of the influence of cellular mechanics in angiogenic processes deserve further progresses.

The activation of VEGFR2 shall not be detached from the interaction between integrin (receptor) and fibronectin (ligand). This receptor-ligand interplay rules the continuous exchange of mechanical signals (mechanotransduction) between the ECM and bundles of actin that belong to the cytoskeleton, a dynamic network of proteins that organize themselves as a consequence of external stimuli and is responsible for the mechanical response of the ECs. An accurate description of the cytoskeleton evolution and of the receptor-ligand dynamics is thus pivotal in the modeling of tumor angiogenesis and is the goal of this work.

CO-DESIGNED EXPERIMENTS AND MODELS

Based on these premises, we developed a chemo-mechano-transport model to study the relocation and recruitment of VEGFR2 and integrin on the cell membrane during the spreading of an EC on a substrate enriched of VEGFA/Gremlin and fibronectin, which was concurrently experimentally investigated. The model accounts for the formation and reorganization of the cytoskeletal contractile machinery, in particular of the stress-fibers[3] (SFs).

The model formulation stems from three chemical reactions, two of which describe the ligand-receptor interactions that rule the mechano-transduction and the triggering of angiogenic stimuli, whereas the third describes the chemical interaction between the complex given by VEGFR2-VEGFA/Gremlin with integrin [2]. The affinity between the VEGFR2-Ligand complex and integrin makes the activation signal of the angiogenic stimulus more lasting and more robust.

Thermodynamically, the model can be seen as an instance of the framework presented in [3], in terms of Helmholtz free energies and constitutive relationships, enriched by models of the activation and reorganization of the cytoskeleton published in [4]. Coupling of the cytoskeleton evolution with the chemo-transport part of the model that accounts for the integrins diffusion and reaction, provides a description of the mechanotransduction apparatus in ECs.

*Corresponding author. E-mail: m.serpelloni002@unibs.it.

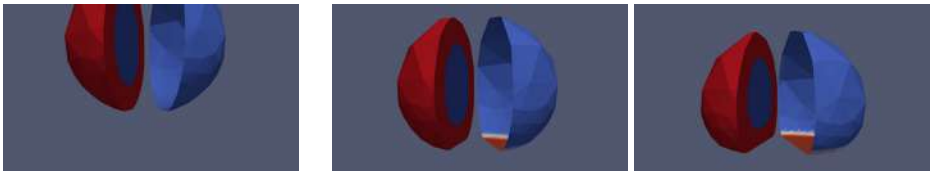
[1]Growth factors are also called ligands (e.g. the canonical ligand VEGFA or the non-canonical ligand Gremlin).

[2]Receptors are proteins that have an extra- and intra-cellular domain. This feature allows them to connect cells with their surroundings and makes the receptor-ligand interaction an optimal way for cell-ECM communication. For these reasons, several biological processes at the cellular level are modulated through the high degree of specificity of the chemical interaction between receptors and ligands.

[3]SFs are actin filaments connected to the ECM through integrins and focal adhesions. These actin bundles are among the entities responsible for contractile forces during EC adhesion on the substrate.

NUMERICAL SIMULATIONS

The governing equations have been rephrased in their weak form. Discretization and FEM numerical simulations are a further purpose of the present work. The implementation is carried out exploiting the high performance computing open source software library deal.ii (http://www.dealii.org). A picture of the evolution in time of the cell-substrate contact and spreading, as well as of VEGFR relocation and activation is shown in Fig. 1.



(a) (b) (c)

Figure 1: Time evolution of the cell-substrate contact dynamics. The cell is visually split in two halves: the left depicts the internal part of the EC (the nucleus in blue and the cytosol in red). The receptor relocation and the formation of the VEGFR2-Gremlin complex is shown on the right half.

The computational versus experimental time evolution of the concentrations of VEGFR2 and of its complex with Gremlin is shown in Fig. 2 [5], reprinted from a former publication [6] in which strong assumptions on cell mechanics were made. They have been removed in the present work. Modeling allowed finding a quantitative correlation between

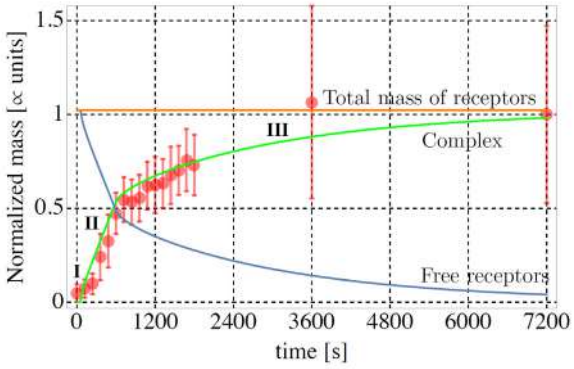


Figure 2: Evolution in time of the normalized concentrations of VEGFR2 and of its complex with Gremlin. The simulation outcomes are plot in continuous line, while the values of the experimental data are shown in dotted lines and error bars.

the phases of the recruitment of VEGFR2 (I, II, III in Fig. 2) and three distinct mechanisms: I) the cell-ligand contact, II) the chemo-mechanical evolution (until 600s) and III) the diffusive slow motion of the receptors.

CONCLUSIONS

Quantifying the influence of mechanical processes onto tumor angiogenesis can play a major role in the fight against cancer. For this sake, a mechanobiological study has been here proposed at a molecular level yet in a continuum mechanics framework. A mechano-chemo-transport model has been developed, capable of describing the relocation and recruitment of VEGFR2 and integrins on the lipid membrane during the mechanical spreading of an EC. The model describes the mechanical response of an EC during cell adhesion, accounting for the dynamic evolution of the cytoskeletal contractile machinery.

MULTISCALE SIMULATION OF THE LEFT VENTRICLE MECHANICS WITHIN THE CARDIOVASCULAR SYSTEM

Fedor Semin*[1,2], Albina Khabibullina[3], Anna Osepyan[3], and Andrey Tsaturyan[1]
[1]Institute of Mechanics, Lomonosov Moscow State University, Moscow,Russia
[2]Peoples'Friendship University of Russi a(RUDNUniversity),Moscow,Russia
[3]Department of Mathematics and Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary The paper presents a mathematical model of circulation with a detailed description of the left ventricle (LV) mechanics. The model was applied for simulations of heart-beats in normal and pathological conditions. In particular, it was demonstrated how the LV multiscale model allows one to simulate local and global changes in contractile or regulatory properties of the LV myocardium and examine numerically the influence of these changes on the macroscopic strains and stress of the LV walls, and the systemic and pulmonary haemodynamics. The results of the simulations of impaired myocardial contractility and the effects of some cardiomyopathic mutations in the regulatory proteins of cardiac muscle including the accompanying LV remodelling are presented.

INTRODUCTION

Modelling of the heart electromechanics is a very promising and fast-developing field of biomechanics. Electrical processes in LV myocardium were described in details in a number of papers. LV passive mechanics was also examined thoroughly. However, the implementation of active mechanics of cardiac muscles in the heart models is often quite simplistic although its detailed description is important for correct reproduction and numerical investigation of the effects of cell-level cardiac disorders on the heart performance.

Earlier, we developed a model of myocardium mechanics with active stress depending on the kinetics of the contractile and regulatory proteins in the cardiac muscle cells [1]. The kinetic model was set by a system of ordinary differential equations (ODEs) that makes it computationally suitable for 2D-3D simulations. The myocardium model was applied for the simulation of the LV pumping function in the cardiovascular system [2]. Here we present some results of the simulations of various cell-level myocardium dysfunctions examining their effects on the LV performance.

MODEL AND METHODS

Model of the cardiovascular system

The cardiovascular system (CVS) was described by a lumped parameter model in which the LV pressure P_{LV} and volume V_{LV} were specified from our multiscale model of the LV mechanics. The LV was approximated by an axisymmetric body with walls consisting of cardiac muscle. Myocardium was supposed to be an incompressible transversely isotropic solid material. The axes of the anisotropy were defined by the orientation of muscle fibres, which was specified by a rule-based algorithm: the fibres were aligned with helices (the helix axis is the axis of rotation for the LV approximation), and helical angle with the horizontal plane was linearly changed through the LV wall [3].

The LV stress is assumed to be the sum of an isotropic passive stress tensor specified by a strain-energy function, Lagrange multiplier (hydrostatic pressure) caused by incompressibility and the anisotropic stress tensor describing forces acting along the cardiac fibres. These forces were the passive nonlinear elastic tension of the giant muscle protein titin and the active force generated by the interaction of contractile proteins of cardiac muscle. The active stress was set by our kinetic model of cardiac muscle contraction and its regulation [1]. In brief, the model of cardiac muscle was specified by a system of ordinary differential kinetic equations for several states of contractile and regulatory proteins. The active tension was determined by the formation of so-called cross-bridges – the globular parts of one of the contractile proteins, myosin, bound to another contractile protein, actin. The number of cross-bridges was determined by the normalized concentration of the complexes of a regular protein, troponin, with the Ca^{2+} ions (CaTnC). The transition rates of the contractile properties depended only on one average micro-level strain of contractile proteins in a structural muscle unit, sarcomere. The transition rates of the regulatory proteins depended on the Ca^{2+} concentration, sarcomere length and some other variables providing so-called activation cooperativity.

The right ventricle and the atria of the heart were considered being viscoelastic reservoirs with time-depended stiffness and viscosity specified by ODEs. The other parts of the vascular bed including aorta, systemic and pulmonary arteries, systemic and pulmonary veins were described as elastic reservoirs with variable pressures and volumes and constant compliances. The final lumped parameter model was set by a system of ODEs for the pressures and volumes of the reservoirs and the flows between them.

The complete problem set for the heart contraction was specified by the following equations: equilibrium equations for the LV (inertial terms were neglected), incompressibility equations for the LV myocardium, the ODEs of the kinetic model of cardiac muscle, the ODEs of the lumped parameter model for the haemodynamics. The problem was solved by a finite element method (FEM) using small increments approach: at each time step, the equilibrium and incompressibility equations for the LV were linearized for small unknown increments of nodal displacements of a FEM mesh, pressures, caused by incompressibility, and LV blood pressure. The model implementation was described in details earlier [2].

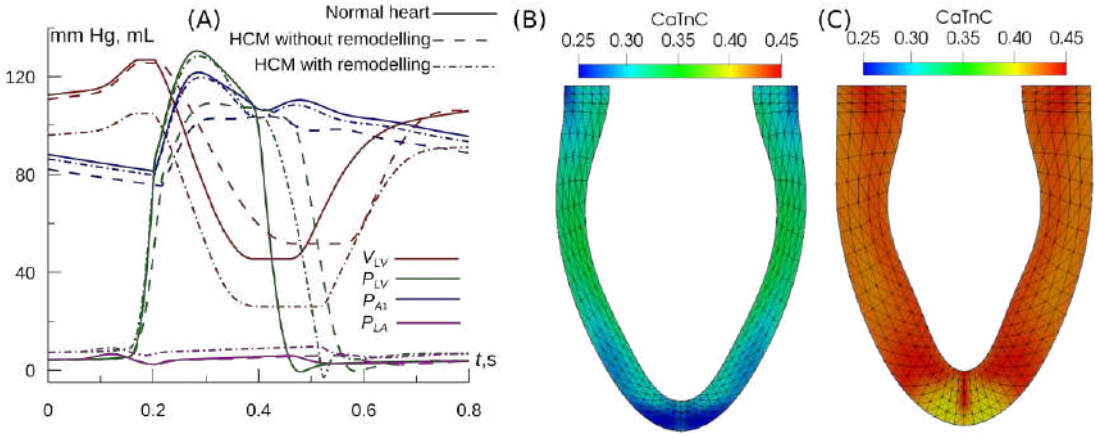

Figure 1: Simulated heart-beats with 'normal' and HCM LVs. (A) The LV, aortic and left atrial pressures (P_{LV}, P_{A1}, P_{LA}) and the LV volume (V_{LV}) for the simulation of a heart-beat with 'normal' LV myocardium (solid lines) and myocardium changed by a HCM mutation with either the 'normal' LV shape (dash lines) or with concentric hypertrophy (dash-dot lines). (B,C) The normalized concentration of Ca^{2+}-troponin complexes in the LV at the moment of the peak LV pressure in 'normal' (B) and hypertrophic (C) LVs.

Numerical experiments

Firstly, we simulated a heartbeat with model parameters corresponding to an average healthy human. Then we changed some cell-level parameters of the myocardium to investigate their effect on the heart performance. We simulated the regional decrease of myocardial contractility in the apical region of the LV (apical myocardial infarction) and a decrease of the maximal steady-state shortening velocity of the cardiac muscle, observed in some cases of cardiomyopathies. We also varied the cell-level parameters of calcium regulation of the muscle contraction reported for some mutations of a regulatory protein, tropomyosin, associated with the inherited hypertrophic and dilated cardiomyopathies. The remodelling accompanying the mutations – the LV wall thickening at the case of its concentric hypertrophy and an increase in the LV cavity volume at the case of its dilatation – was also accounted for.

RESULTS AND DISCUSSION

We showed previously, that resulting heamodynamic variables of the CVS and global and local strains of the LV in the case of the simulation of a 'healthy' heartbeat were in accordance with the data of medical observations [2]. The results of the numerical experiments reported here showed the decrease in the LV stroke volume upon apical infarction or the impairment of the force-velocity relationship for cardiac muscle. A decrease in the LV contractility estimated from the pressure-volume loops also took place. Figure 1 shows the results of the simulated effects of a mutation in a regulatory protein tropomyosin that causes hypertrophic cardiomyopathy (HCM). Despite an increase in Ca^{2+} sensitivity of troponin that results in an increase in the CaTnC concentration (Fig. 1B,C), the decreased maximal tension and length-dependence of Ca^{2+} activation, which are associated with the mutation [4], caused a significant decrease in aortic pressure, LV pressure and stroke volume (Fig. 1A). The remodelling compensated the impaired muscle contractility and regulation.

The model has certain limitations: we did not take into account the changes in passive properties of myocardium and redistribution of fibres orientation, which are often observed in animal and patients with cell-level myocardium disorders.

CONCLUSIONS

The model presented is able to reproduce the effects of such complex phenomena as apical myocardial infarction and cardiomyopathies caused by protein mutations due to the introduced model of myocardial mechanics. We believe that the model can be expanded for 3D patient-specific simulations of the heart.

The work was supported by grants No 18-31-00065 and No 17-00-00066 (a part of the complex project No 17-00-00071) of the Russian Foundation for Basic Research (RFBR).

ON THE ROLE OF INTERSTITIAL FLOW IN HUMAN SKIN BIOMECHANICS

David Sachs[1], Bettina Müller [1], Fanny Enz [1], Adam Wahlsten[1]and Edoardo Mazza [1,2]
[1]ETH Zurich, Institute for Mechanical Systems, Zurich, Switzerland
[2]EMPA, Swiss Federal Laboratories for Materials Science and Technology, Dubendorf, Switzerland

Summary Recent experimental observations of human skin's response to tensile loading revealed large volume changes associated with interstitial fluid flow. In this contribution, we show that a histologically motivated layered biphasic model is capable of rationalizing a wide range of in-vivo and ex-vivo experimental observations. The model allows to investigate the layer specific deformation mechanisms governing tissue response in in-plane tensile as well as out-of-plane suction experiments. The importance of fluid motion for the in-vivo dissipative response of human skin in cyclic suction experiments is examined, with special consideration to their application for diagnosis.

HISTOLOGICAL AND MECHANICAL FEATURES OF HUMAN SKIN

Medical applications increasingly benefit from mechanical analyses of human skin [e.g. 1, 2]. Skin is a multiphasic multi-layered soft tissue composed of a keratinocyte-rich epidermis, a collagen-based dermis and an adipocyte cell built hypodermis, as depicted in figure 1. Resulting from differences in collagen content and orientation, the dermis is further divided into a papillary and a reticular layer. Fine type III collagen fibres characterize the papillary layer, whereas thicker type I collagen fibre bundles are present in the reticular layer. Skin is a multiphasic material composed of a solid and a fluid component as well as distributed fixed charges. Extensive ex-vivo experimental characterization in our lab revealed specific features of its mechanical behaviour [3]. First, skin exhibits a strong volume reduction upon monotonic tensile loading, caused by ejection of interstitial fluid. Second, an out-of-plane deflection of the epidermal surface is visible in uniaxial experiments. Third, uniaxial relaxation experiments reveal a strong tension decay within short time. In-vivo suction experiments induce an equibiaxial stress state resulting in a reduction of thickness. Moreover, application of a constant suction pressure causes skin to creep. Further experimental investigation of skin response to suction experiments suggested motion of interstitial fluid as a key contribution to the observed behaviour [4]. Attempts to rationalize all characteristics with a single-layer biphasic model of skin did not succeed. We therefore hypothesize that subdivision of skin into an epidermal, papillary, and reticular layer is necessary.

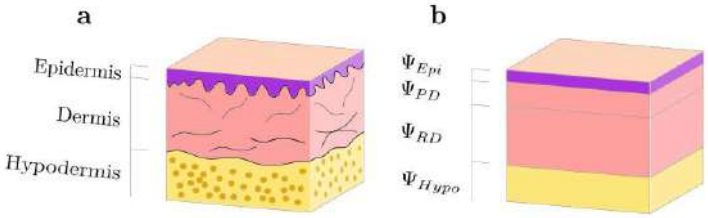

Figure 1. The biphasic mechanical model of human skin is motivated by experimental observations, the anatomy, and the histology of the tissue. We distinguish four layers: epidermis, papillary and reticular dermis, and hypodermis.

MODEL IMPLEMENTATION

A biphasic finite element model accounting for skin's layered structure was implemented in COMSOL [3]. The solid constituent was modelled with a Rubin-Bodner type strain energy function [5], with contributions from a compressible Neo-Hookean solid as well as elastic and dissipative fibre elements. The solid isotropic component represents the proteoglycan matrix (including fixed charges) and the fibres represent the contribution of the collagen network. The motions of the solid and fluid phases are coupled through the balance laws of a biphasic mixture [6], and the relative fluid motion is modelled using Darcy's law with a spatially isotropic deformation dependent permeability tensor. The osmotic pressure resulting from fixed charged groups attached to the solid matrix provides a contribution to the chemical potential, driving fluid flow [7].

RESULTS

The new multi-layered model rationalizes experimental results of in-vivo suction as well as ex-vivo uniaxial tensile experiments. Iterative optimization of the material model parameters yields a stiff and strongly anisotropic reticular dermis, a softer and less anisotropic papillary dermis, and a very soft and almost isotropic epidermis. Corresponding simulations show that for uniaxial tensile loading the reticular dermis is the main load-bearing layer of skin. In contrast, for suction experiments the influence of the upper layer increases for smaller probe openings. Furthermore, also the deformation state changes. For larger probe opening diameters an equibiaxial stress state dominates, whereas smaller probe openings cause a significant level of shear deformation. This results in a reduced dermal thickness for large probe openings and an increased thickness for small probe openings. Consequently, dissipative behaviour, i.e. creep and residual deformation after unloading, depends on the probe opening size. The layered model also quantitatively reproduces the

out-of-plane deflection in uniaxial tensile tests, as it is a direct result from the different mechanical properties in the dermal layers.

INFLUENCE OF INTERSTITIAL FLOW

Fluid mobility is essential for the response of each dermal layer to in-plane extension. It also determines the time scale of tension reduction in relaxation experiments. The model indicates that increased skin tension in-vivo generates conditions of increased hydrostatic and osmotic pressure, in particular in papillary and reticular dermis. The mechanical response to in-vivo suction experiments also depends strongly on the motion of the interstitial fluid. As depicted in figure 2(a) the maximum apex displacement increases with increasing permeability. The remaining apex displacement after one cycle, however, exhibits a non-monotonic relationship with the permeability. Both limiting cases of a very high and a very low permeability cause the residual apex displacement to vanish. This feature is enhanced for cyclic loading. As shown in figure 2(b), the residual apex displacement accumulates with each cycle, resulting in an overall creep-like behaviour. Analysis of extracellular fluid redistribution during suction experiments indicates that the dependence of the dissipative properties of skin on interstitial flow opens new possibilities for clinical applications. In fact, healthy skin, diseased skin as well as scars not only differ in their elastic but also in their dissipative properties, as results from their hindrance to interstitial fluid motion. Current investigations evaluate the possibility to characterize skin's viscoelasticity for an early diagnosis of fibrotic scar formation [7] or diseases (e.g. scleroderma [8]).

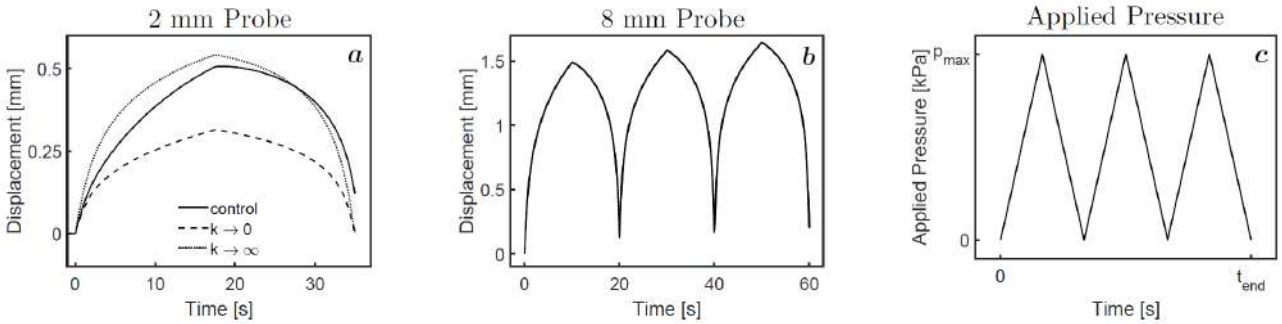

Figure 2. Suction response of human skin: Apex displacement for one cycle (a) and three consecutive cycles (b), the applied suction pressure is shown in (c).

CONCLUSIONS

The proposed multi-layered biphasic model of human skin contributes to a better understanding of the in-vivo as well as the ex-vivo response of human skin for various deformation modes. Thus, it represents a useful tool to investigate the clinical relevance of the assessment of specific mechanical properties of human skin. Future work will focus on the direct measurement of layer specific parameters including fixed charges density, permeability, hydration level, density and distribution of collagen fibres, as well as their variations in case of specific pathologies.

NUMERICAL SIMULATION OF A TWO COMPARTMENTAL FRACTIONAL MODEL IN PHARMACOKINETICS AND PARAMETERS ESTIMATION

Yanli Qiao[1], Huanying Xu[1], and Haitao Qi*[1]
[1]School of Mathematics and Statistics, Shandong University, Weihai 264209, PR China

Summary Compartmental model is the most widely used approach to study the pharmacokinetics characterization of drug. Recently, fractional calculus is introduced to describe the time course of drugs in human body which follow the anomalous diffusion mechanism. To consider the different fractional order transmission process, the two compartmental fractional model has been proposed and studied. And, it will be of great significance to find out a simple and efficient numerical method to solve the model and estimate model parameters. This work investigates two numerical methods of the two compartmental fractional model using finite difference schemes, which are based on the shifted Grünwald-Letnikov approximate formula and $L1$ formula, respectively. The hybrid Nelder-Mead simplex search and particle swarm optimization, denoted as NMSS-PSO, is provided to estimate the fractional model parameters. Comparison between the numerical solutions and the solutions obtained by the numerical inverse Laplace transform establishes the validity of the developed numerical algorithms. Then, the influence of the order of fractional derivative on the drug amount in human body is also presented and discussed. Finally, the two compartmental fractional model is applied to fit the amiodarone pharmacokinetics data based on the NMSS-PSO algorithms. This work will be of importance for the development of fractional pharmacokinetics.

INTRODUCTION

Fractional calculus, which introduces integrals and derivatives of fractional order, has almost the same history as classical calculus. However, only in recent decades, fractional calculus becomes popular because of its successful applications in different fields, such as physics, electrochemistry, bioengineering and pharmacology [1, 2, 3, 4]. Now it is well known that fractional kinetics offers an elegant description of anomalous kinetics owing to its memory effect and the non-local property. So it is natural to adopt the theory of fractional calculus to improve compartmental analysis when modeling the uptake, distribution and elimination of drug in human body [5].

Compartmental analysis originated from the study of radioactive tracers and was used to simplify complex physiological systems. Now, fractional compartmental models have been proved to be useful and successfully applied to describing the absorption of drug in a living biological system. But with the development of fractional calculus in pharmacokinetics and other fields, a new problem how to analytically and numerically solve the fractional compartmental model appeared naturally. Unlike the integer differential equations, fractional differential equations with the specified initial conditions are difficult and even impossible to find their analytical solutions. Therefore, it is essential to build efficient numerical algorithms to solve these corresponding problems. Dokoumetzidis et al. applied the numerical inverse Laplace transform (NILT) method to solve the system they proposed [6], but the direct numerical simulation of the two compartmental fractional model was not considered in their studies. Based on the fact, we propose two numerical methods of the two compartmental fractional model by using the shifted GL approximate formula and $L1$ formula respectively and compare the numerical solutions with the semi-analytical solution by the NILT method. And we also know particle swarm optimization (PSO) is a random global optimization technology moving towards the best goal and the Nelder-Mead simplex search (NMSS) algorithm remove the worst. So we used the NMSS-PSO method to improve the accuracy of the parameter estimation. This method is proposed by Liu et al. and has been proven the effectiveness for the fractional dynamical models [7, 8, 9].

TWO COMPARTMENT FRACTIONAL MODEL

A two compartment fractional model in pharmacokinetics will be considered shown schematically in Fig. 1. Compartment 1 corresponds to general circulation and well perfused tissue while compartment 2 represents the target tissue. The system can be represented mathematically as [6, 5]:

$$\begin{aligned}\frac{\mathrm{d}q_1(t)}{\mathrm{d}t} &= -k_{10}\ {}_0^C D_t^{1-\alpha_{10}} q_1(t) - k_{12}\ {}_0^C D_t^{1-\alpha_{12}} q_1(t) + k_{21}\ {}_0^C D_t^{1-\alpha_{21}} q_2(t) + u_1(t),\\ \frac{\mathrm{d}q_2(t)}{\mathrm{d}t} &= -k_{20}\ {}_0^C D_t^{1-\alpha_{20}} q_2(t) - k_{21}\ {}_0^C D_t^{1-\alpha_{21}} q_2(t) + k_{12}\ {}_0^C D_t^{1-\alpha_{12}} q_1(t) + u_2(t),\end{aligned} \tag{1}$$

where $0 < \alpha_{ij} \leq 1$ and $q_i(t)$ is the mass of drug in the compartment i. k_{ij} represents the rate of elimination, distribution and uptake from compartment i to compartment j and has a dimension of $[\mathrm{time}]^{-\alpha_{ij}}$. $u_i(t)$ is the infusion rate in compartment i, which has a dimension of $[\mathrm{mass/time}]$ and may be zero, constants or time dependent. Initial value for $q_1(t)$ and $q_2(t)$ can be considered $q_1(0) = d$, $q_2(0) = 0$, respectively. For this non-zero initial conditions, we can convert it to a zero initial value problem by variable substitution ($q_1^*(t) = q_1(t) - q_1(0)$) and then solve it numerically by means of the relationship of Caputo derivative and GL derivative.

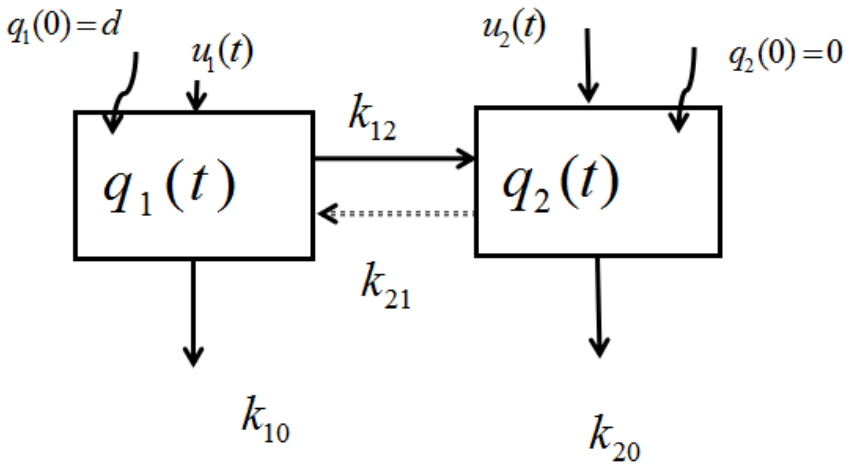

Figure 1: Schematic representation of a fractional two compartmental model. k_{ij} are constants that represent the rate of mass transfer from compartment i to compartment j , k_{i0} are elimination rates from compartment i and $u_i(t)$ denote infusion rates .

In this paper, we focus mainly on the following model including several processes of drug release in the body. One is the elimination from compartment 1, one is the distribution from compartment 1 to compartment 2 and the rest is the mass flux from compartment 2 to compartment 1. The first two processes are assumed to follow classic kinetics, while the last one is supposed to follow fractional kinetics. The system can be expressed in the following form

$$\begin{aligned} \frac{\mathrm{d}q_1(t)}{\mathrm{d}t} &= -(k_{12}+k_{10})\, q_1(t) + k_{21}\, {}_0^C D_t^{1-\alpha} q_2(t) + u_1(t), \\ \frac{\mathrm{d}q_2(t)}{\mathrm{d}t} &= k_{12}\, q_1(t) - k_{21}\, {}_0^C D_t^{1-\alpha} q_2(t), \end{aligned} \tag{2}$$

where $q_1(0) = d,\ q_2(0) = 0$ are initial conditions of the model. In this paper, we pay attention to the following two important cases of Eq. (2).

CONCLUSION

In this work, we consider the numerical simulation and parameters estimation of a two compartmental fractional model with different initial conditions, which consider the different transmission processes in pharmacokinetics. The finite difference algorithms based on the shifted GL approximate formula and the $L1$ formula of the Caputo derivative respectively are proposed. Meanwhile, we use the NMSS-PSO algorithm to achieve the parameters estimation and obtain the results we expected. Furthermore, we compare the numerical solutions with the semi-analytical solution and amiodarone data. The results indicate that two numerical methods are effective and available. And the influence of the order of fractional derivative on the drug amount in human body is also presented and discussed. The results show that the drug amounts of the compartment 1 resemble the power-law distribution and the amounts of compartment 2 fall more quickly with α increasing.

A MULTISCALE MICROSTRUCTURAL APPROACH OF CROSS-LINK INTERACTION IN THE HUMAN CORNEA

Anna Pandolfi*[1], Alessio Gizzi[2], and Marcello Vasta[3]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
[2]Department of Engineering, University of Rome Campus Bio-Medico, Rome, Italy
[3]Dipartimento INGEO, Universit Chieti-Pescara, Viale Pindaro 42, Pescara, Italy

Summary We propose a multiscale micromechanical model of the collagen reinforcement of the human cornea. We focus on the structural function of the collagen lamellae embedded in the stroma and construct a structure made of collagen fibrils and transversal chemical bonds (crosslinks). The specific design chosen for describing inter-crosslink and intra-crosslink bonds relies on the fact that the cornea's ability to carry loads depends on the density and strength of crosslinks that confer intrinsic transversal and shear stiffness to the lamellae. We conduct an extensive numerical analysis of the mechanical response under the action of the intraocular pressure of the system, varying multiple mechanical properties of the structure. Our approach shows that the weakening of transversal crosslinks is associated with a marked increase of the deformability of the system, typically observed in keratoconus corneas.

INTRODUCTION

Cornea Biomechanics & Keratoconus

The cornea, the external lens of the eyeball, sustains the intraocular pressure (IOP) exerted by the filling fluids. From a structural viewpoint, the cornea is a spherical shell made of many parallel layers reinforced with collagen fibrils to accomplish a load carrying function. The preservation of a stable spherical shape is due to the complex architecture of the collagen fibrils, embedded in a homogeneous matrix of proteoglycans and elastin, and of transversal chemical bonds that confer the necessary stiffness to the stucture. The central part of the cornea shows a typical fibril arrangement with nasal-temporal (NT) and superior-inferior (SI) patterns whereas a circumferential and radial organization is observed along the limbus, i.e. the outer part [1].

Keratoconus is a progressive disorder of the cornea that alters dramatically its shape [2]: irregular astigmatism, strong myopia and a marked loss of vision usually occur. Macroscopically, keratoconic corneas present a non-physiological conical shape, with abrupt changes of curvature, and degenerative and irreversible changes in the organization of the collagen architecture have been documented. Albeit the aetiology of keratoconus has not been clarified yet, the particular microstructure of the stroma in keratoconus suggests that a weakening of the chemical bonds (cross-link) appears between the collagen fibrils [3].

Object of study

We aim at developing a physically based model of keratoconus that can potentially account for its onset and progression. In particular, we propose a structural model of the stroma collagen microstructure in the human cornea. The model consists of a trusswork including the two sets of fibrils and the associated cross-links.

MICROMECHANICAL MODEL OF STROMAL COLLAGEN

The microstructural model of the collagen reinforcement was constructed from patient-specific cornea geometry and the trusswork was directly derived from the finite-element discretization [4, 5, 6, 7]. The micromechanical architecture of the collagen fibrils was also constructed on the basis of the well-known ex vivo X-ray data [1] disregarding the variability of such structures across the thickness. The model accounts for five sets of trusses. The first two sets (F1 and F2) describe the collagen fibrils. The two sets are separated by a small amount corresponding to the cornea thickness, and the chosen discretization allows one to define the topology of a hexahedron which is considered as the basic unit cell (see Fig. 1(a)). The third and fourth networks, parallel to F1 and F2, model the inter-fibril connections (inter-cross-links C1 and C2) that allow the fibrils to organize themselves in parallel sheets (lamellae). They are designed as trusses connecting the fibrils of the same network with non-parallel side links. The fifth network (C12) describes the intra-fibrils connections (intra-cross-links) between the two sets of fibrils. These trusses connect the fibrils of the anterior and the posterior lamellae along sub-diagonal directions to provide mechanical stability of the system. A coarse structure of the cornea is shown in Fig. 1(b) to understand the connections.

The fine structural model used in the static calculations, $\mathbf{KU} = \mathbf{F}$, is shown in Fig. 1(c). Here, $\mathbf{K}$ is the stiffness matrix, $\mathbf{U}$ the unknown displacement array and $\mathbf{F}$ is the external load array that collects the point loads with IOP. Adopting the linearized truss theory, we consider an equivalent rigidity parameter $D_i = E_i A_i$, with E_i the Young modulus and A_i the cross section area, such that the truss stiffness is $k_i = D_i/h_i$.

Numerical simulations are conducted with an in-house software developed specifically for this study. The trusswork includes 48 sub-parallel fibrils for each set, 5000 nodal points and 28 600 trusses.

(a) (b) (c)

Figure 1: (a) Detail of the cross-links between the fibrils of the same set (inter-link, green) and of two different sets (intra-link orange). (b) Coarse model of the assembled trusswork including all fibril and cross-link trusses. (c) Example of output of the numerical calculations. Colours map the displacement field, for the cases of keratoconus cornea.

RESULTS

The stiffness of trusses representative of the fibrils was estimated as an equivalent measure derived by homogenizing the contribution of the fibrils over a reference area. In particular, we estimated the equivalent rigidity of a fibril truss as $D_F = E_f A_f = 0.009N$. The stiffness of the trusses representative of the intermolecular covalent cross-links that connect fibrils of the same or different families was estimated on the basis of experimental data. The stiffness of the components of the trusswork was finally normalized with respect to the stiffness of the fibril truss, obtaining the values $D_{F1} = D_{F2} = 1, D_{C1} = D_{C2} = 0.8, D_{C12} = 0.5$.

With such a model we simulate the structural response of healthy and keratokonic corneas. In the case of a healthy cornea, we assign a uniform rigidity to all the elements of the same set. To model keratoconus, we make the assumption that the stiffness of both fibrils and cross-links reduces smoothly in the radial direction from the limbus, where it reaches its maximum value, to the centre of the conus, where it reaches its minimum value. To reach such a distribution, we consider three functional forms of material stiffness variation: linear, quadratic and cubic, respectively.

Numerical simulations show that the smooth reduction of stiffness of the components allows one to model the protrusion of keratoconus.

We further conducted an intense programme of factorial experiments considering the variation of the stiffness of each group of components of the network (fibrils F_1 and F_2, inter-cross-link C_1 and C_2, and intra-cross-link C_{12}). The study includes 28 764 analyses. Numerical results reveal that, as far as the conical shape is concerned, the most influential parameter is the stiffness of the intra-cross-link stiffness C_{12}. The reduction of the stiffness of the fibrils without a corresponding reduction of the intra-cross-link stiffness does not lead to a conical shape. Moreover, a reduction of the inter-cross-link stiffness does not lead to any significant modification of the spherical shape.

CONCLUSIONS AND PERSPECTIVES

This study achieved two goals: (i) to understand the importance of the explicit description of the cross-links in a microstructural model of the human cornea; (ii) to identify the components of the network whose failure is connected to the bulging and keratoconus. In the future, we will improve the purely microstructural model accounting for the actual causes (chemical, mechanical and inflammatory) that trigger the disease.

A BIOINSPIRED MECHANICAL MODEL OF THE ULTRASONIC CLICKS PRODUCED BY ERMINE MOTHS

Hernaldo Mendoza-Nava[1], Alberto Pirrera[1], Marc Holderied[2], and Rainer Groh *[1]
[1]Bristol Composites Institute (ACCIS), University of Bristol, Bristol, UK
[2]School of Biological Sciences, University of Bristol, Bristol, UK

Summary A recently discovered sound production system (Aeroelastic Tymbal) located at the base of the hindwings of ermine moths produces bursts of ultrasonic clicks. The sound is produced when a ridge area on the aeroelastic tymbal buckles. The resultant sound has similar characteristics to that produced by the tiger moth, which in a certain genus is capable of jamming a bat biosonar. The biomechanical function of the aeroelastic tymbal is idealised by a simplified one-dimensional compliant mechanism, and the stability of the structure is evaluated using the modified Riks method. The purpose of this research is to take inspiration from evolved biological structures found in insects, for the development of adaptive and well-behaved non-linear structures.

A tymbal organ, which is a well known sound production system found in cicadas [1], and also present in different moth species [1, 2], allows the production of sounds for social communication or defence purposes. A moth's tymbal organ consists of a cuticular membrane typically located at the tegula, thorax (muscular actuated tymbals) or wings (aeroelastic tymbal), and produces a high-frequency clicking sound when it buckles. Also, the tymbal's membrane can present a striated band on one side, leading to the production of bursts of ultrasonic clicks when buckled. It has previously been observed that ermine moths (*Yponomeuta*) continuously produce two sets of ultrasonic clicks while flying, and such sound production occurs during the rotational stages of the stroke cycle [3]. Furthermore, it is suggested that this species mimics the sound produced by toxic tiger moths; thus, warning their predators (bats) of potential danger. Experimental approaches such as the use of high-speed cameras have provided evidence on how a tymbal organ buckles [4]. However, far too little attention has been paid to the structural mechanics associated with such phenomena. An objective of this study is to investigate the aeroelastic tymbal actuation mechanism among ermine moths. The function is modelled using a one-dimensional compliant mechanism, analysed using the finite element method. This project provides an important opportunity to explore the feasibility of bio-inspired adaptive or morphing structures.

The aeroelastic tymbal is distinguished as a clear patch (due to the absence of scales) at the base of the hindwing (Figure 1A), located between the cubital (Cu) and postcubital (pCu) veins. A micro-computed tomography (micro-CT) shown in Figure 1B indicates the venation and parts of the aeroelastic tymbal. Individual ridges forming the striated band alongside the pCu vein are referred to as "microtymbals", the rest of the translucent patch is called the "window". Throughout the pCu axis, the membrane is folded through a steep angle, and this region is called the "wall". A set of micromanipulators on an ablated hindwing, and a bat detector (to detect ultrasound signals), allowed the identification of two conditions for the sound production. Folding and unfolding the crease along the pCu vein axis was found as the triggering mechanism. Both, the initial and buckled states are shown in Figure 1C, and the latter is characterised by the birefringence of the wing's membrane.

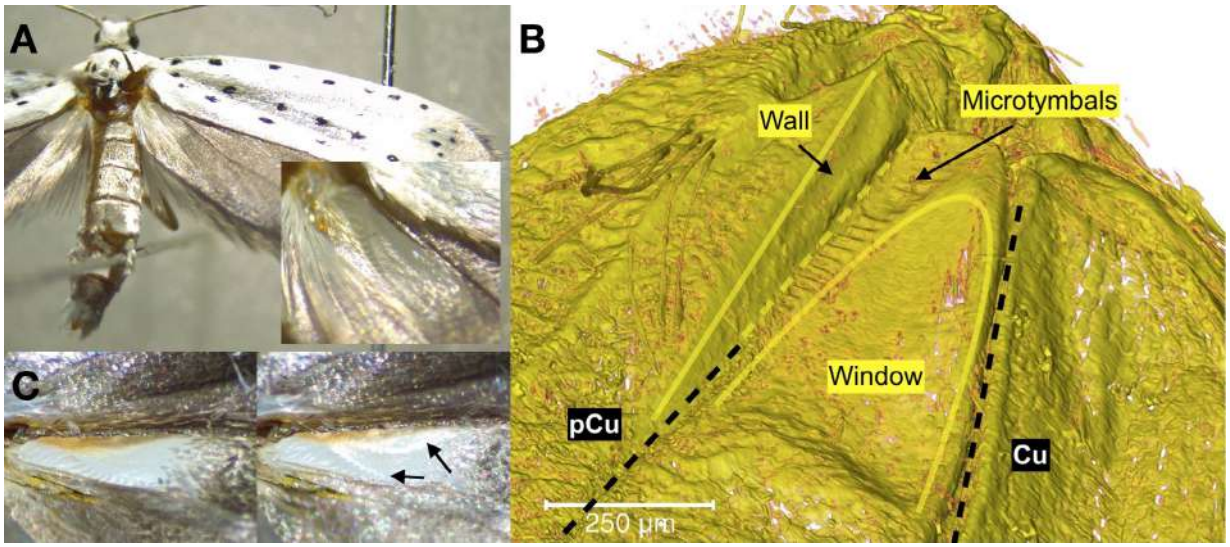

Figure 1: A. Ermine moth (*Y. malinellus*), with an enlarged image of the aeroelastic tymbal. B. Dorsal view of a micro-CT of the base of the hindwing (the yellow dotted line along the pCu indicates a folding region, also known as the claval furrow). C. Initial and buckled states of the aeroelastic tymbal (birefringance is indicated).

*Corresponding author. E-mail: rainer.groh@bristol.ac.uk.

From the micro-CT it can be observed that the tymbal is not a flat structure but a doubly curved membrane. The membrane's thickness was found to be less at the interface between the microtymbals and the window. Inspired from how the aeroelastic tymbal works, a simplified approach is undertaken. Taking a chordwise cross-section of the tymbal, the system can be represented by a curved compliant mechanism (Figure 2A). The stability response is then evaluated using the modified Riks method in the Abaqus commercial software package. Three design parameters (w_t/w_w: tymbal-to-window width ratio, t_t/t_{int}: tymbal-to-interface thickness ratio and the κ: tymbal's curvature), and the material properties (E: modulus of elasticity and v: Poisson's ratio) are considered, while the structure is simply actuated by a transverse force at the flexure hinge. Assuming the boundary condition (BC) at the Cu vein position is clamped and the BC at the pCu is simply-supported, the t_t/t_{int} ratio is the parameter driving the stability of the structure; which can be tuned to obtain a bistable or monostable behaviour. Assuming an even tymbal thickness, and a width ratio bounded to the tymbal-to-window dimensions, the tymbal response is characterised in terms of the thickness ratio. As a result, the Force-Displacement diagram in Figure 2B demonstrates that when a critical thickness value (t_{crit}) is achieved, the system behaves as a bistable structure.

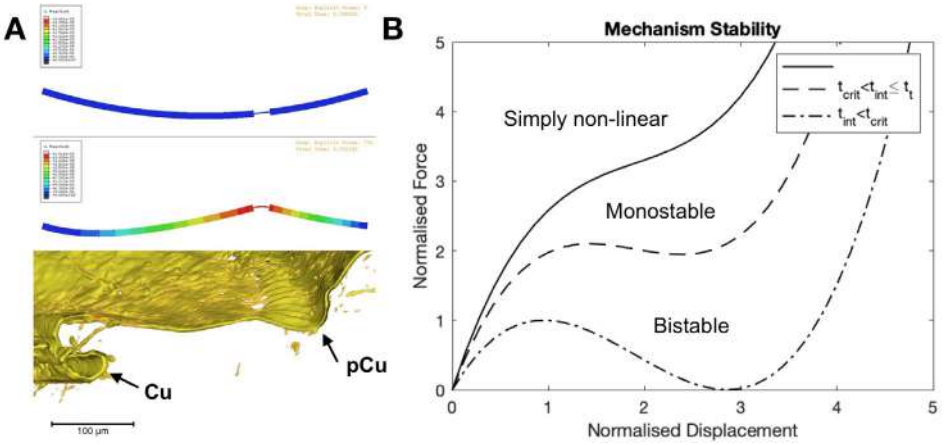

Figure 2: A. Compliant mechanism model taken from a cross-section of the aeroelastic tymbal. B. Force-displacement diagram of the stability behaviour of the compliant mechanism.

To gain insight into the acoustic response, a modal analysis is performed to obtain the fundamental frequency of the structure. This value can be tuned by modifying the elastic modulus to match the peak frequency obtained in acoustic recordings. The κ parameter determines the depth of the mechanism, controlling the maximum deflection attained from the initial to the secondary stable position. The transverse deflection of the structure is averaged and together with the resonant frequency, the sound pressure level can be calculated from a closed-form structural-acoustic model such as the baffled-piston [5], assuming the window as the sound radiator. However, this is only a representative result as the actual dynamic and acoustic response are influenced by the tymbal membrane's mass and the combined spanwise and chordwise constraints; added to the consideration that the baffled-piston model is a non conservative approach as it assumes an infinite baffle boundary.

CONCLUSIONS

The function of the aeroelastic tymbal was studied experimentally. Taking inspiration from this system, a curved compliant mechanism from a chordwise cross-section was designed. The stability, dynamics and acoustics of the one-dimensional structure were approached successfully to the extent of the assumptions. Further studies are undergoing on the design of a 2D shell structure to better address the function of the aeroelastic tymbal. This would improve the understading of the structural and acoustic response towards the design of larger scale adaptive structures.

FINITE ELEMENT ANALYSIS OF PERCUTANEOUS CORONARY INTERVENTION

Kiran Manjunatha*[1], Jan Frischkorn[2], and Stefanie Reese[1]
[1]Institute of Applied Mechanics, RWTH Aachen University, Aachen, Germany
[2]Volkswagen AG, Wolfsburg, Germany

Summary The aim of this work is to develop a computationally efficient simulation framework for percutaneous coronary intervention. In this regard, efficient finite element formulations to model filigree structures are investigated. Additionally, constitutive modeling of arterial wall is considered. Building upon the work presented here, models for plaque build up as well as vascular smooth muscle cell aggregation shall be arrived at.

INTRODUCTION

Constriction of the blood vessels in the heart arise due to plaque build up, which is a condition termed as atherosclerosis. Percutaneous coronary intervention (PCI) is a process of placing structures called stents within these constricted blood vessels to normalize the blood flow. The damage ensued in the vessel walls during PCI results in progressive narrowing of blood vessels due to an inflammatory response, the condition being termed in-stent restenosis. The overarching goal of this work is to setup a computationally efficient finite element framework to simulate PCI and thereby assist selection of stent materials and geometries, predict tissue damage during pre- and/or post-dilation and stent deployment, and finally arrive at optimal PCI conditions that reduce the risk of in-stent restenosis. Within the intended simulation framework, two important aspects are considered here: (a) Efficient modeling of stent deformation (b) Arterial wall and plaque mechanics.

EFFICIENT MODELING OF STENT DEFORMATION

Commercial stent configurations comprise of filigree constructions which render the three-dimensional finite element simulations of PCI computationally expensive due to the factors described in [1]. Additionally, the presence of multiple layers within the stent cross-sections (e.g. drug-eluting polymer layer, gold reinforce- ment layer for welds etc.) exacerbates the computational costs. The solid-beam finite element formulation (Q1STb) [1], serves as an efficient tool for simulating slender strut geometries of stents, while still inheriting the ease of handling contact interactions. However, the current focus will be on modeling drug-eluting stents, which possess a layer of drug-carrier vehicle on top of the metallic core of the struts. In this regard, to model the stent deployment mechanics, the solid-beam elements are to be used for the metallic core and the reduced integration hexahedrons (Q1SP), described in [2], shall be utilized for the drug-eluting polymeric layer. A critical section of a drug-eluting stent which repeats itself throughout the structure, is chosen for our investigations. Cross-section with just the metal core as well as that including the polymer layer are investigated under the boundary conditions shown below. Within the cross-section ($k-l-m-n$), the metal core is considered to be 0.8 mm wide and the polymer layer to be 0.08 mm thick. The sum of reaction forces at the point of application of displacement D is investigated and presented.
Abbreviations: NQT = number of quadrature points on the trasnverse plane at the center of beam axis, NEL = number of elements longitudinally along the radius, NET = number of elements across the thickness.

Table 1: Material parameters

Layer	Material model	E	ν	σ_y	H
Metal core	elasto-plasticity with linear isotropic hardening	200 GPa	0.3	370 MPa	7 GPa
Polymer	Neo-Hooke	1 GPa	0.49	-	-

It is observed that with just one element across both the layers, results comparable to those using fine discretizations of the strut with C3D8I and C3D8R elements (ABAQUS) are obtained.

ARTERIAL WALL AND PLAQUE MECHANICS

The arterial wall shall be simulated using a combination of the anisotropic hyperelastic models presented in [3] and [4], thereby considering dispersion of collagen fiber orientations as well as accurate incorporation of slight compressibility of soft tissues. The optical parameters required for the model shall be obtained from histological data via automated image processing techniques. The mechanical material parameters shall hence be fit to experimental data post fixation of optical parameters.

CONCLUSIONS

With minimal element count, stent structures are deemed to be characterized using the Q1STb and Q1SP elements. The arterial wall behaviour is highly sensitive to the collagen orientations and hence have to be accurately determined from histological data. Future work shall entail modeling of plaque growth modeling and vascular smooth muscle cell proliferetion.

Summary Resistance of porous scaffold to fluid flow within biological tissues causes a size- and rate-dependent material behavior known as poroelasticity. Indentation has been widely used to characterize the poroelasticity of soft materials and a variety of theoretical models have been well established for cases of small strain and modest force relaxation. However, when the force on the indenter at a fixed depth at long-time scale drops to below half of the initially peak force (*i.e.*, $F(0)/F(\infty) > 2$), the existing models are inapplicable for large relaxation. For such cases of large relaxation, we built upon the Biot theory and the Hertz contact theory to develop an indentation theory by considering fluid flow in biological tissues during both the indentation and relaxation periods of an indentation test. We performed indentation tests for representative biological tissues (e.g., porcine liver, spleen, kidney, skin, apple, and human cirrhosis liver), and demonstrated that the proposed theory is suitable for biological tissues exhibiting both small and large relaxations.

INTRODUCTION

Biological tissues are mostly porous materials, where their poroelastic properties are associated with physiological functions and many diseases. Characterizing poroelasticity can provide insight into a great variety of physiological functions, and has been applied to pathological study and disease diagnosis in clinic. Indentation combined with theoretical analysis is often used to characterize the poroelasticity of soft materials [1-3]. However, existing theoretical models are typically established by neglecting liquid transport as induced by deformation during indentation process, which may be not suitable when force relaxation is substantial. For example, recent studies have reported negative Poisson ratios in hydrogels [4] when the force relaxes to below half of the peak indentation force. Therefore, there is still an unmet need for a more effective indentation method by considering fluid-flow-induced deformation during the indentation process for biological tissues with large relaxation.

MATERIALS AND METHODS

Large relaxation indentation theory

We developed an indentation theory by considering fluid flow during both the indentation and relaxation processes by combining the Biot theory [5, 6] with the Hertz contact theory. We considered the asymmetrical, small strain, large displacement problem of indentation in a semi-infinite space (**Fig. 1A**), and obtained:

$$F(t)=\begin{cases} F_{Hertz}(u(t),R)\left(\dfrac{1}{1-Aexp\left(-\dfrac{t}{\tau_p}\right)}\right), -t_0 \le t \le 0 \\ F_{Hertz}(\delta_{max},R)\left(\dfrac{1}{1-A\,exp\left(-\dfrac{t}{\tau_p}\right)}\right), t>0 \end{cases}$$

where $A \approx \exp(-t_0/\tau_p)$ is a coefficient that quantifies the effect of solvent diffusion during indentation ($-t_0 \le t \le 0$) on subsequent force relaxation ($t > 0$), and F_{Hertz} is the force for a displacement δ_{max} predicted for linear elasticity

*Corresponding author. E-mail: tjlu@nuaa.edu.cn.

by the Hertz contact model, and τ_p is the poroelastic relaxation time-scale. The force required to indent a poroelastic material increases with indentation depth, but decreases with solvent flowing away from the compressed region. Thereafter, as the indenter is held isometrically, the force needed to hold the indenter at a fixed depth relaxes over time with continued solvent flow (**Fig. 1A**), which can be well predicted by our model (**Fig. 1B**).

Indentation testing

Indentation experiments were performed on a Bose ElectroForce 3220 (Bose Corporation, Framingham, MA). Before performing displacement control tests, the indenter tip was first adjusted to a position slightly above the surface, and then proceeded with indentation to a fixed depth δ at a speed of 0.5 mm/s. The indenter was held isometrically for a time interval sufficient to enable relaxation, and the applied force on the indenter was recorded in the real time. Through fitting the measured indentation relaxation curve with the proposed theoretical model, we characterized the poroelastic properties of several biological tissues, specifically the shear modulus, the Poisson ratio, and the diffusion coefficient. Specifically, we performed indentation tests for porcine liver, spleen, kidney, skin, apple and human cirrhosis liver tissues, respectively.

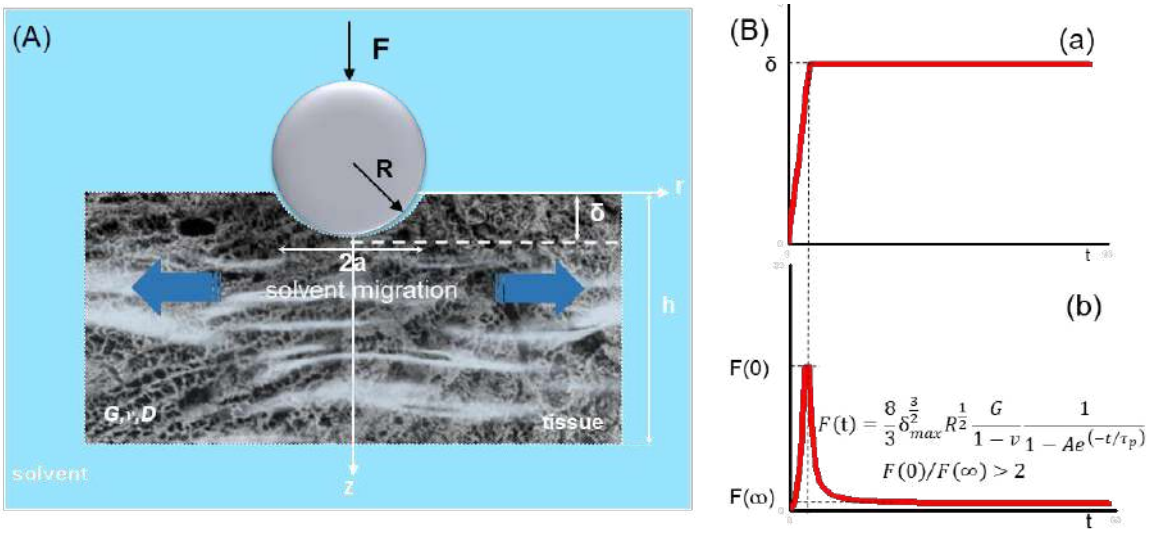

Figure 1. Indentation theory and test of biological tissue. (A) Asymmetrical problem of indentation in a semi-infinite space and cylindrical coordinates selected for theoretical modeling. The parameters G, ν and D are the Poisson ratio, shear modulus and diffusion coefficient of the biological tissue, respectively; a is the contact radius between the indenter and the tissue. (B) Force response of a poroelastic tissue in an indentation test. (a) The indenter is pressed into a liver tissue from zero to a fixed depth δ. (b) The solvent in tissue migrates, and the force on indenter in the indentation process is plotted as a function of time. $F(0)$, $F(\infty)$ are the maximal and minimum force on indenter during the relaxation process. δ_{max} is the maximal pressed displacement during the indentation. A is a modified coefficient, which reflects the liquid flow during the pressing process. $\tau_p = a^2/D$ is the poroelastic relaxation time-scale.

CONCLUSIONS

We proposed a method based on the modified spherical indentation model to characterize the poroelastic properties of biological tissues undergoing large relaxation by accounting for the effects of fluid flow in the tissue during loading. We demonstrated that this method is appropriate not only for biological tissues with small relaxation but also biological tissues with relaxation in large range ($1.6 < \frac{F(0)}{F(\infty)} < 3.9$). The modified theory provides substantially better estimates of Poisson ratio for cases of large relaxation in comparison with those estimated with existing models, while predicting diffusion coefficients and shear moduli on the order of existing results.

Summary In this work, we hypothesized that the high hydrostatic pressure of the tumor environment can contribute to cell metastasis, and therefore studied the balance between responses to hydrostatic pressure and adhesion. To elucidate the critical points in this balance, we developed and validated a theoretical model to describe the change of morphology and volume of adherent cells under hydrostatic pressure. Cell morphologies exhibited bistability under hydrostatic pressure in the physiological range for relatively low adhesion energy density. Importantly, we found a snap-through instability under small adhesion energy density and intermediate hydrostatic pressure. The snap-through instability of adhesive cells suggests a potential mechanism by which elevated pressure within a tumor can contribute to cancer metastasis.

INTRODUCTION

In many cancers, the progression from Stage I to Stages II and III involves cells spontaneously losing of adhesion from the bulk of a tumor and migrating to new tissues, a process known as metastasis. The balance between hydrostatic pressure and adhesions governs the morphology and volume of animal cells, which strongly influences various cell behaviors, such as cancer metastasis. To elucidate the critical points in this balance, we developed and validated a theoretical model to describe the change of morphology and volume of adherent cells under hydrostatic pressure.

MATERIALS AND METHODS

Theoretical model. The snap-through behavior related to the morphological and volume change of adherent cells under hydrostatic pressure (Fig. 1) can be predicted by

$$p_{out}^{*}=f(\theta_0)\left[\frac{(1+\cos\theta_0)^{\frac{1}{2}}}{[\Gamma^{*}+(1-\sigma_a^{*})(1-\cos\theta_0)]}+\pi_{out}^{*}\right]\left[1+\left(\frac{\Gamma^{*}}{1-\cos\theta_0}+\sigma_a^{*}\right)\right]^{3}(1+\cos\theta_0)^{-3/2} \quad (1)$$

where $f(\theta_0)=(8+9\cos\theta_0-\cos 3\theta_0)/12$.

Cell culture under hydrostatic pressure. Human lung cancer cells (CL1-5) were cultured on a culture dish at a density of 10,000 cells/cm^2. After incubation for 24 h, CL1-5 cells were loaded with hydrostatic pressure of 0, 1, 2, 4, or 8 kPa above atmospheric pressure for 8 hours, and interval sufficient for a steady state in height and volume to be reached.

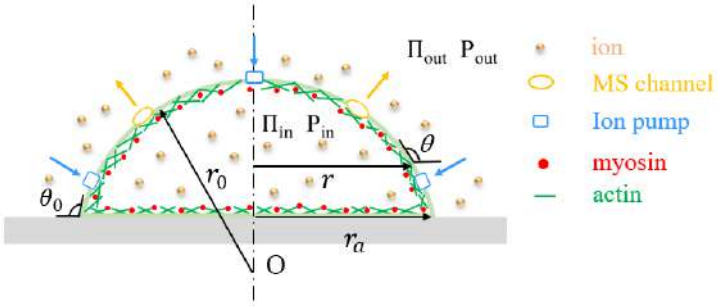

Figure 1 Schematic of the theoretical model:The adherent cell is enclosed by the actomyosin cortical layer and cell membrane

THEMATIC SESSION SM

RESULTS

The model predicted that the equilibrium contact angle decreases with the hydrostatic pressure, which may undergo a snap-through instability (Fig. 2). In this snap-through, cells suddenly jump up from the substratum in response to increasing hydrostatic pressure or down to the substratum in response to decreasing hydrostatic pressure. As the adhesion energy density decreases, this snap-through of contact angle is possible over a larger range of pressures.

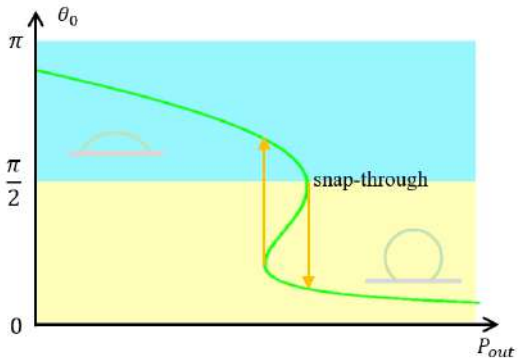

Figure 2 Snap-through instability of an adherent cell under hydrostatic

To further explore this instability phenomenon, we draw a phase diagram of normalized hydrostatic pressure and dimensionless adhesion energy density. This phase diagram revealed three different regions of cell adhesion, with a bistable region sandwiched between acute and obtuse contact angles.

DISCUSSION

We have many cures for many cancers, but, from the perspective of chemistry and genetics, nearly all cancers are different, and many remain untreatable. However, from the perspective of mechanobiology, a cure is possible. Death from cancer most often occurs not from a primary tumor, but from metastasis. From the mechanical view, metastasis could be interpreted as instability, where small changes of input lead to disastrous outcomes. Here, we demonstrate that how hydrostatic pressure could be the governing parameters inducing this instability. These findings provide new insights in controlling metastasis.

DETERMINING AND COMPARING THE TIMESCALES GOVERNING SINGLE CELL EVOLUTION

Alberto V. Ippolito*[1], Antonio DeSimone[2,3], Vikram S. Deshpande[1]
[1]Department of Engineering, Cambridge University, Cambridge CB2 1PZ, UK (ai318@cam.ac.uk)
[2]SISSA – International School for Advanced Studies, Trieste, Trieste, Italy

Summary The aim of this theoretical work is to compare the timescales of the evolution of a range of observables of single adherent cells and to elucidate and explain the physical phenomena that set the different evolution rates in single cells. We report the response of myofibroblasts adhering to micropatterned substrates with varying widths of fibronectin stripes. These investigations are performed with a novel computational model, an overdamped Langevin equation, derived from the homeostatic ensemble. The study demonstrates two distinct timescales governing cell expansion and elongation. Additionally, we predict that confinement severely changes the evolution rates of cell observables. Remarkably, our investigation reveals that these biological timescales are primarily driven by the landscape of the cell free-energy hypersurface.

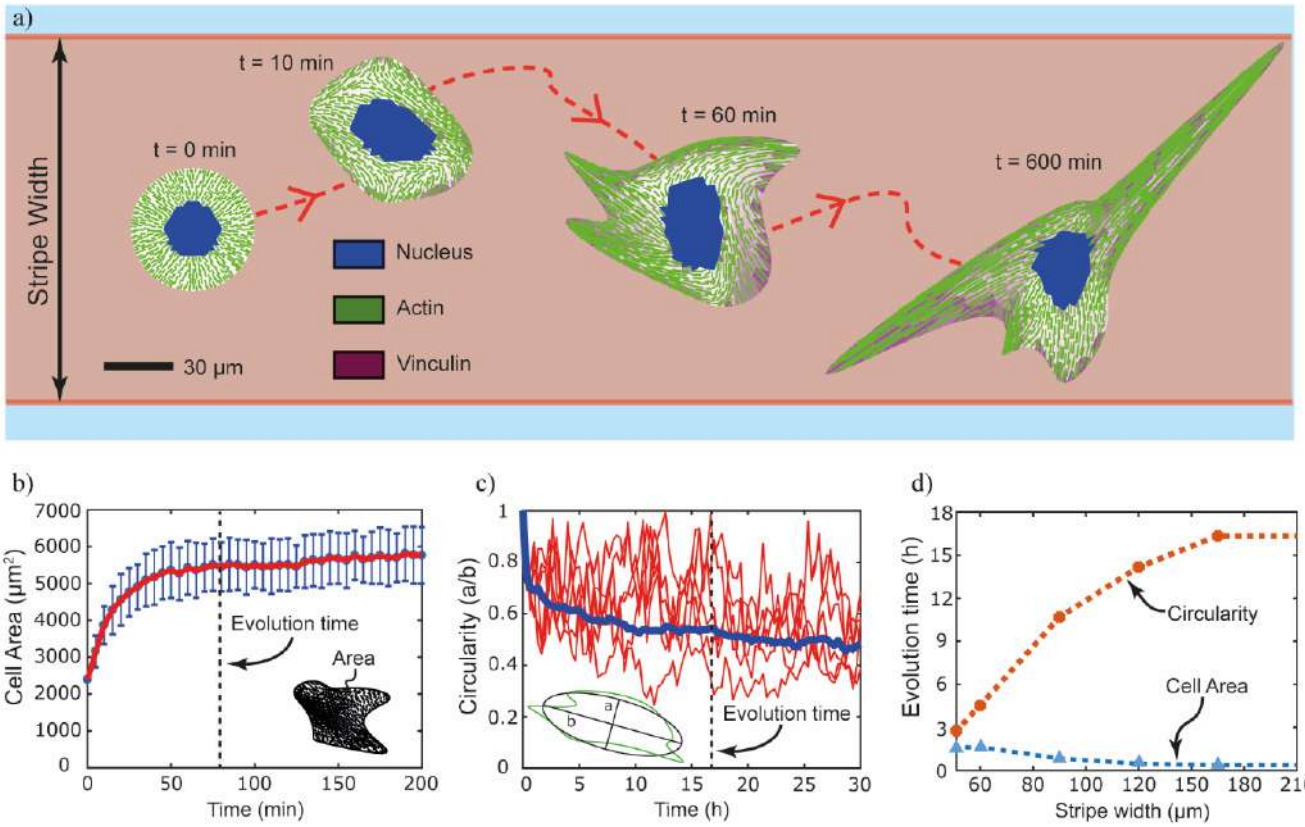

Fig. 1. Cell expansion and elongation on a patterned substrate. (a) Snapshot showing the temporal evolution of a fibroblast seeded from suspension on a fibronectin stripe of width 180 μm wide. In the early stages (t < 60 min), the cell expands and begins forming mature focal adhesions, as shown by the increase in vinculin density, but still does not form large protrusions. After several hours, the fibroblast becomes very elongated with large protrusions, several mature focal adhesions and long actin strands. **(b)** Temporal evolution of cell spread area on a wide adhesive stripe. The red line shows the average spread area measured from all simulations, while the variations over the $n = 100$ simulations are shown in blue. The evolution time of fibroblast area is taken to be 1.5 h. **(c)** Temporal evolution of cell circularity on a wide adhesive stripe. Blue line is the average behavior ($n = 100$) while each red line is the circularity variation for selected fibroblasts. The evolution time is 17 h. **(d)** The evolution times of cell area and circularity as a function of stripe width. As the stripe width reduces below 180 μm, the evolution time of the circularity decreases rapidly while the evolution time of the cell area increases slightly.

INTRODUCTION

Timescales and morphological transformations are critical in understanding living systems. For instance, during fetal development, the size and morphology of the embryo changes dramatically, also due to each organ forming and maturing at a different timescale. In fact, the brain forms at an earlier stage, but matures much later, than the fingers [1].

*Corresponding author. E-mail:ai318@cam.ac.uk

Since this very complex and fundamental process is characterized by vastly different timescales, it is sensible to think that the simpler evolutions of geometric observables of single cell spreading also may not occur concurrently. While the timescales of the evolution of some observables for single cells, such as expansion and elongation, have been reported in literature [2, 3] and are vastly different, the reason behind these timescale differences remains elusive. The aim of this theoretical work is to compare the timescales of the evolution of a range of observables of single adherent cells and to elucidate and explain the physical phenomena that set the different timescales in single cells. We report results for the response of single cells on substrates micropatterned with varying widths of fibronectin stripes.

METHODOLOGY

The evolution of single adherent cells on micropatterened fibronectin stripes is performed using a novel computational model: an overdamped Langevin equation derived from the homeostatic ensemble [4]. Briefly, the model describes the time evolution of the variables r_i, describing the shape of the cell, and is given by:

$$33333333333333333\dot{r}_i(t) = -\frac{1}{\gamma}\frac{\partial G}{\partial r_i} + \sqrt{\frac{2}{\zeta\gamma}}W(t), \tag{1}$$

where t is time, γ is the damping coefficient, G is the Gibbs free-energy of the configuration, $1/\zeta$ the homeostatic temperature [4] of the cell and $W(t)$ a Weiner process. The cell parameters are those of myofibroblasts [5], but the same study can be easily repeated for any cell type. A span-shot of the prediction of a simulated fibroblast in suspension seeded on a substrate patterned with a fibronectin stripe is shown in **Fig. 1a**.

RESULTS

- The simulations correctly demonstrate that, on an unpatterned substrate, cell area evolves with a much faster timescale than cell circularity, as shown in **Figs 1b and 1c** and also demonstrated in literature [2, 3] for fibroblasts.
- Our simulations suggest that confinement heavily influences the morphological evolution of single fibroblasts, see **Fig. 1d.** However, these changes only occur for stripe widths below 180 μm.
- Stripe widths smaller than 180 μm reduce the circularity evolution time, from 18h for 180 μm to about 3h for 60 μm, while only slightly increasing the evolution timescale of cell area; see **Fig. 1d.**

CONCLUSIONS

The study confirms that there are different timescales governing the evolution of single fibroblasts on a given substrate. The nature of the theoretical model used in this work, i.e. the overdamped Langevin equation based on the homeostatic ensemble [4], is such that the evolution of the cell is governed by energetic and entropic driving forces while maintaining a state of overall homeostasis. The analysis suggests that the evolution times of the morphological observables are dominated by the landscape of the of cell free-energy hypersurface. In particular, the gradients of the free-energy cause the fibroblast evolution path to choose a rapid initial cell spreading prior to the onset of cell elongation, i.e. a faster increase in cell area followed by a slower decrease in cell circularity. Confining the cell introduces barriers in the free-energy landscape which change the gradients of the free-energy, ultimately affecting the evolution path of the cell by enhancing the elongation rates while simultaneously reducing the rate of cell expansion.

PLANT CELL WALL GROWTH: FROM SOLID CONTINUUM MODEL TO MIXTURE THEORY MODEL

Ruoyu Huang*[1], Adib Becker[2] and Arthur Jones [2]
[1]Lightweight Manufacturing Centre (NMIS), Department of Design, Manufacturing and Engineering Management, University of Strathclyde, Glasgow, UK
[2]Department of Mechanical, Materials and Manufacturing Engineering, University of Nottingham, Nottingham, UK

Summary Plant cell wall growth has served as an interesting and important question inspiring, challenging and justifying different methodologies of growth modelling. In this work, a thorough study has been conducted to model the plant cell wall growth using both the single-phase solid continuum model and mixture theory model with fluid phase transporting through solid skeleton in typical direction taken into account. The present study not only established the integrative growth model to cover extensive features of cell wall growth in a consistent framework, but also deepen the understanding about the advantages and disadvantages of the different typical modelling methodologies.

INTRODUCTION

The very astonishing fact of growing plant cell is that the cell wall is living under high turgor pressure which may be up to five times higher than atmosphere (5 bars). The life of cell wall under pressure refers to a central question in plant developmental biology, i.e. whether and how mechanical forces serve as cues for cellular behavior and thereby regulate growth. (Hamant *et al*. 2008). For cells enclosed by a cell wall, growth is dependent on deposition of new wall materials driven by fluid transport coupled with turgor pressure to drive expansion of the cell in the longitudinal direction. Neither deposition of new wall materials nor turgor driven expansion is in itself sufficient to promote growth. Therefore, the well-known Lockart's equations stated that the growth of cell wall follows the rules in a parallel way as follows

$$r_g = \Phi(P - Y) \tag{1}$$

and

$$r_g = L_c \Delta\Psi \,, \tag{2}$$

where r_g is the (volumetric) growth strain rate which is either positive for $P > Y$ or zero for $P \le Y$, Φ is the extensibility of the cell wall, P is the turgor pressure and Y is the yield threshold, i.e. the minimum pressure required for growth, L_c is water conductance coefficient, and $\Delta\Psi$ is the water potential difference between protoplast and apoplast (Schopfer, 2006). The Lockart equations (1) and (2) indicates that the role of mechanics in cell wall growth can be subdivided into two intertwined parts: the role of stresses in the solid skeleton of cell wall and the role of fluid transport through the void space of cell wall.

Interestingly, it is noted that there are two key different methodologies to modelling growth, i.e. single-phase solid continuum model and mixture theory (see e.g. Taber (1995)). At the first glance, the mixture theory may naturally represent the aforementioned features of cell wall growth. However, it must need sufficient theoretical and numerical studies for understanding the advantages and disadvantages of the different typical modelling methodologies.

SINGLE PHASE CONTINUUM MODELLING

The typical single-phase continuum is proposed based on the decomposition of the total deformation gradient into two parts, i.e. the growth part and non-growth part. The growth part in principle is not subjected to geometric compatibility constraint which in finite strain theory can be represented by satisfying the vanishing condition of curvature tensor on a Riemannian manifold (so it is not the gradient of deformation). Thus, this part may be considered as the counterpart of plastic deformation gradient in plasticity theory. The growth part will follow a growth law which is mainly driven by stress, strain or energy with temperature effects. Unlike plasticity theory where the stress tensor plays a key role in the anisotropy of plastic deformation, most of the existing growth model has been focused on the anisotropy of materials, which did not reflect the bioscientists' hypothesis about anisotropic growth that there are the different growth mechanisms in the different directions. Our work presented the method to model the anisotropic growth by using the anisotropy of stress, which showed the good consistency with cell wall features where growth in wall thickness direction and wall longitudinal direction following the different laws as indicated in the Introduction. The non-growth part plays the role to piece together those incompatible local configurations of growth together for retaining the

*Corresponding author. E-mail: Ruoyu.huang@strath.ac.uk.

compatibility of the whole configuration. Based on this consideration, the finite strain fibre-reinforced viscoelasto-viscoplasticity-like growth models have been proposed to implement in Finite Element (FE) analysis is present work. Three components of the deformation of growing cell wall, i.e. elasticity, viscoelasticity, and viscoplasticity-like growth, are modelled within a consistent framework aiming to present an integrative growth model. The two key features of cell wall growth, i.e. turgor-driven creep and new material deposition, and the interplay between them are shown to be modelled by the typical concepts in solid continuum theory like yield function, flow rule, and hardening law.

MIXTURE MODEL

On the other hand, a cell wall growth model based on mixture theory has been established to be consistent with the Lockhart eqns. (1) and (2). To the authors' knowledge, it is the first time that the Lockhart eqns. (1) and (2) together are generalised to a 3D model. First, the kinematics and elasto-plastic decomposition are discussed. Secondly, governing equations including equilibrium equation, balance of mass, and inequality of entropy are presented. Thirdly, the elastic and inelastic responses of the mixture are proposed in a thermodynamics-consistent way and the crucial mechanisms of transport of new wall material in fluid are discussed. Numerical result of case studies with comparison with experimental data are shown to verify the model.

COMPARISON AND DISCUSSIONS

Above all, the present work demonstrated and verified that both single-phase continuum model and mixture theory model could cover the key features of the cell wall growth. However, for addressing the deposition of the new material on the surface of cell wall, the single component model of an open system may involve complicated higher order formulation which is not straightforward to implement in numerical study since the modified Cauchy stress and higher order derivative of displacement may cause the numerical difficulties for the convergence of solution. There are still some great challenges for the single component model to take into account mechanisms which in essence involves transport in a fluid. On the other hand, although it may describe the physical phenomena and underlying mechanisms in a more natural way, the general framework of growth modelling based on mixture theory itself still has some inherent open questions needed to be sorted out.

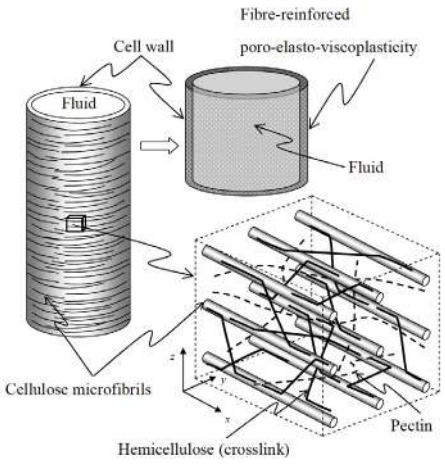

Figure 1. The hierarchy structure of cell wall.

CONCLUSIONS

By modelling the plant cell wall growth, the present work demonstrated and compared the effectiveness and limitations of the two key growth modelling methodologies: single-phase continuum model and mixture theory model. Both the key achievements and existing key challenges are discussed for inspiring the future work.

MORPHOELASTICITY OF LARGE BENDING DEFORMATIONS OF CELL SHEETS DURING DEVELOPMENT

Pierre A. Haas* and Raymond E. Goldstein†
Department of Applied Mathematics and Theoretical Physics, University of Cambridge, Cambridge, UK

Summary Deformations of cell sheets during morphogenesis are driven by developmental processes such as cell division and cell shape changes. In morphoelastic theories of development, these processes appear as variations of the intrinsic geometry of a thin elastic shell. However, morphogenesis often involves large bending deformations that are outside the formal range of validity of these shell theories. Here, by asymptotic expansion of three-dimensional incompressible morphoelasticity in the limit of a thin shell, we derive a shell theory for large intrinsic bending deformations and emphasise the elastic role of cell constriction. Taking the inversion of the green alga *Volvox* as a model developmental event, we reveal how the results of this model differ from those of a simpler shell theory which is not formally valid for large bending deformations.

BACKGROUND

During animal and plant development, cell division, cell shape changes, and related processes can drive deformations of cell sheets [1]. In elastic continuum theories of the development of the green alga *Volvox* [2, 3], tissue folding in *Drosophila* [4], or more general active surfaces [5], these driving processes appear as changes of the reference or intrinsic geometry of thin elastic shells. The elastic theories describing these shells have often been posited *ad hoc* in previous work, by replacing the elastic strains of classical shell theories [6] with measures of the difference of the intrinsic and deformed geometries of the shell. They therefore lack a formal derivation by asymptotic expansion of three-dimensional elasticity or *morphoelasticity* [7], the framework based on a multiplicative decomposition of the deformation gradient tensor into intrinsic and elastic deformations.

There is however one more serious limitation of these models: tissues in development undergo large bending deformations (Fig. 1) that are outside the formal range of validity of the thin shell theories underlying previous models. In particular, even if the ratio of the thickness of the cell sheet to its radius of curvature is small in the initial, undeformed state, the local value of this ratio may not be small in the deformed configuration. This is associated with cells contracting at one cell pole to splay and thereby bend the cell sheet (Fig. 1). Here, we derive a shell theory valid for these large bending deformations by asymptotic expansion of three-dimensional morphoelasticity.

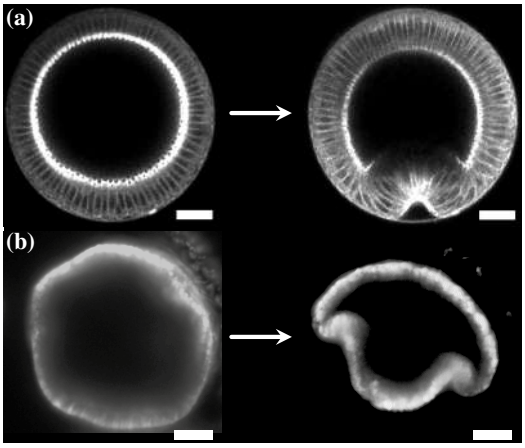

Figure 1: Large bending deformations during morphogenesis: even if the thickness of the cell sheet is small compared to the undeformed radius of curvature, it need not remain small compared to the local radius of curvature as the sheet deforms. (a) Cross section of ventral furrow formation in *Drosophila*, reproduced from Ref. [8]. (b) Midsagittal cross section of invagination in the spherical alga *Volvox globator*, reproduced from Ref. [3]. Scale bars: 20 µm.

ELASTIC MODEL

We consider an axisymmetric elastic shell of thickness h, made of an incompressible neo-Hookean material of elastic modulus E. (The restriction to axisymmetric shells avoids a bog of tensorial notation that arises in the general case.) The geometry of the undeformed shell is described by its arclength s and distance $r(s)$ from the axis of symmetry [Fig. 2(a)]. In the deformed configuration of the shell [Fig. 2(b)], arclength is $\tilde{s}(s)$, distance from the axis of symmetry is $\tilde{r}(s)$, and the tangent angle to the shell is $\tilde{\psi}(s)$. These quantities define the (meridional and circumferential) stretches and curvatures

$$f_s = \frac{\mathrm{d}\tilde{s}}{\mathrm{d}s}, \qquad f_\phi = \frac{\tilde{r}(s)}{r(s)}, \qquad \kappa_s = \frac{\mathrm{d}\tilde{\psi}}{\mathrm{d}\tilde{s}}, \qquad \kappa_\phi = \frac{\sin\tilde{\psi}(s)}{\tilde{r}(s)}.$$

The stretches relate the undeformed and deformed configurations of the shell. These stretches and curvatures differ in general from the intrinsic stretches f_s^0, f_ϕ^0 and intrinsic curvatures $\kappa_s^0, \kappa_\phi^0$ set by the underlying biological processes, such as cell shape changes. Deviations of the actual stretches and curvatures from their intrinsic values lead to elastic stresses.

We expand the three-dimensional elastic energy of the shell in its small thickness h. Large bending deformations are introduced by allowing $h\kappa_s^0$ to be an $O(1)$ quantity. After a long calculation, we find the leading-order expression for the elastic energy in the shell limit,

$$\mathcal{E} = \frac{\pi E}{6}\int \Big\{ h\left[\alpha_{ss}E_s^2 + (\alpha_{s\phi}+\alpha_{\phi s})E_sE_\phi + \alpha_{\phi\phi}E_\phi^2\right] + 2h^2\left[\beta_{ss}E_sK_s + \beta_{s\phi}E_sK_\phi + \beta_{\phi s}E_\phi K_s + \beta_{\phi\phi}E_\phi K_\phi\right] + h^3\left[\gamma_{ss}K_s^2 + (\gamma_{s\phi}+\gamma_{\phi s})K_sK_\phi + \gamma_{\phi\phi}K_\phi^2\right]\Big\}\,\mathrm{d}s, \qquad (*)$$

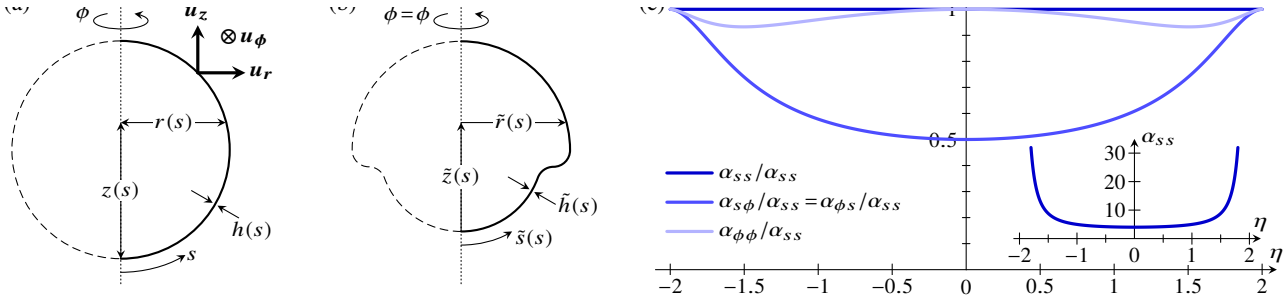

Figure 2: Elastic model: geometric setup and plot of some of the coefficient functions in Eq. (∗). (a) Undeformed geometry of an axisymmetric shell of thickness h, described by coordinates $r(s), z(s)$, where s is arclength, with respect to the basis $\{\boldsymbol{u_r}, \boldsymbol{u_\phi}, \boldsymbol{u_z}\}$ of cylindrical polars. (b) Deformed geometry of the shell: after a torsionless deformation, the shell has arclength $\tilde{s}$, and is described by coordinates $\tilde{r}(s), \tilde{z}(s)$ with respect to cylindrical polars. (c) Plot of the stretching coefficients $\alpha_{ss}, \alpha_{s\phi}, \alpha_{\phi s}, \alpha_{\phi\phi}$, scaled with α_{ss} to absorb the divergence as $\eta \to \pm 2$. Inset: unscaled plot of α_{ss} against η, showing divergence as $\eta \to \pm 2$.

wherein the shell strains and curvature strains are defined to be

$$E_s = \frac{f_s - f_s^0}{f_s^0}, \qquad E_\phi = \frac{f_\phi - f_\phi^0}{f_\phi^0}, \qquad K_s = \frac{f_s \kappa_s - f_s^0 \kappa_s^0}{\left(f_s^0\right)^2 f_\phi^0}, \qquad K_\phi = \frac{f_\phi \kappa_\phi - f_\phi^0 \kappa_\phi^0}{f_s^0 \left(f_\phi^0\right)^2},$$

and where the coefficients $\alpha_{ss}, \alpha_{s\phi} = \alpha_{\phi s}, \alpha_{\phi\phi}, \beta_{ss}, \beta_{s\phi}, \beta_{\phi s}, \beta_{\phi\phi}, \gamma_{ss}, \gamma_{s\phi} = \gamma_{\phi s}, \gamma_{\phi\phi}$ are functions of $\eta = h\kappa_s^0 / f_s^0 f_\phi^0$ only. We have obtained explicit expressions for these coefficients; the stretching coefficients $\alpha_{ss}, \alpha_{s\phi} = \alpha_{\phi s}, \alpha_{\phi\phi}$, for example, are plotted in Fig. 2(c). In the limit of small bending deformations, $\eta \to 0$, these coefficient functions limit to their well-known values from classical shell theories [6], $\alpha_{ss} = 2\alpha_{s\phi} = 2\alpha_{\phi s} = \alpha_{\phi\phi} = 1$, $\beta_{ss} = \beta_{s\phi} = \beta_{\phi s} = \beta_{\phi\phi} = 0$, $\gamma_{ss} = 2\gamma_{s_\phi} = 2\gamma_{\phi s} = \gamma_{\phi\phi} = 1/12$. For non-zero η, the values of the coefficients differ from their values in this small-bending limit. Hence the relative importance of the different deformation modes now depends on the amount of intrinsic bending. In particular, the coefficients diverge in the limit $\eta \to \pm 2$. This is the limit of constricted cells, i.e. wedge-shaped cells in which one surface of the cell sheet has contracted to a point. As the intrinsic configuration approaches this constricted limit somewhere, deviations from the intrinsic configuration become more and more expensive energetically there compared to other positions in the cell sheet.

EXAMPLE: *VOLVOX* INVERSION

The spherical embryos of the green alga *Volvox* turn themselves inside out during their development [2, 3]. At the start of this inversion [Fig. 1(a)], the cell sheet invaginates due to the formation of wedge-shaped cells near the equator, or, equivalently, a bend region of negative intrinsic curvature, $\kappa_s^0 < 0$, there, evolving quasi-statically. Fig. 3 shows shapes at two stages of invagination, respectively computed using Eq. (∗) and the classical theory (obtained from Eq. (∗) in the small bending limit $\eta \to 0$). The computed shapes differ the more the more constricted the cells in the bend region are (Fig. 3). Equivalently, model parameters inferred from strongly invaginated embryo shapes, as in Fig. 1(a), using the classical theory can be inaccurate.

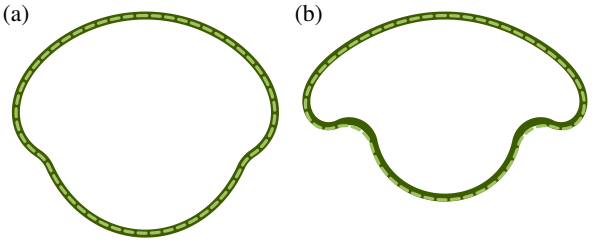

Figure 3: Invagination in *Volvox*. Midsagittal cross sections of computed shapes for (a) an early invagination stage, (b) a later stage in which the bend region near the equator is almost constricted ($\eta \approx -2$ there). Thick solid lines: Eq. (∗); dashed lines: classical model.

CONCLUSION

Here, we have derived, from first principles, an elastic shell theory for the large bending deformations that commonly arise in problems in morphogenesis (Fig. 1), illustrating the theory for invagination of a *Volvox* embryo. This example has in particular emphasised the elastic role of the geometric singularity of cell constriction.

SIMULATIONS OF BUBBLE GATING IN HYDROPHOBIC NANOPORES

Alberto Giacomello*[1] and Antonio Tinti[1]
[1]Department of Mechanical and Aerospace Engineering, Sapienza Università di Roma, Roma, Italy

Biological ion channels are the gates of cells which allow the exchange of ions and molecules across cellular membranes. The typical size of the interior of biological channels is of the nanometer or below, often characterized by hydrophobic residues. Molecular dynamics simulations have reported [1] that, in some ion channels, such confined conditions promote the formation of a nanoscale vapor cavity which is capable of blocking the flux of ions – giving rise to the so-called hydrophobic gating mechanism [2]. In addition, bubble formation in solid-state or hybrid nanopores may be detrimental in several bioengineering applications, such as DNA sequencing [3]. While molecular dynamics has proven an invaluable tool to connect the structure of biological channels with their function, an open challenge for simulations concerns the timescales that can be afforded on current architectures, still far from the biologically relevant ones, typically in the millisecond range. An analogous limitation applies to gating in synthetic channels.

In this talk, the state of the art in the understanding of gating in nanopores is discussed [4], with particular regard to molecular dynamics simulations combined with specialized rare-event methods capable of disclosing the long timescales of the thermally activated formation of vapor cavities (Figure 1) in hydrophobic nanopores immersed in water [5]. The mechanism and the kinetics of bubble formation are investigated in simple pore geometries, reproducing some salient features of biological ion channels but which are also relevant to synthetic nanochannels (Figure 2). The effect of extreme confinement on the phase behavior of water is assessed, revealing the contributions of size, geometry, and hydrophobicity in accelerating the formation of nanoscale bubbles. The relevance of these results for hydrophobic gating in biological ion channels is discussed together with more technology-oriented applications to porous materials with controlled wetting properties [6].

The considered models, in their simplicity, disclose the dependence of hydrophobic gating on the geometry, size, and hydrophobicity of the confinement. In addition, the presented methods allow to tackle the timescales of gating, opening the way to a direct comparison of simulations with experiments in electrophysiology and in the nanochannels literature. Overall the results are promising both for understanding some important biological phenomena, including the action of general anesthetics, and as quantitative tools useful in the design of nanoporous materials with controlled wettability for technological applications.

ACKNOWLEDGEMENT
This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 803213).

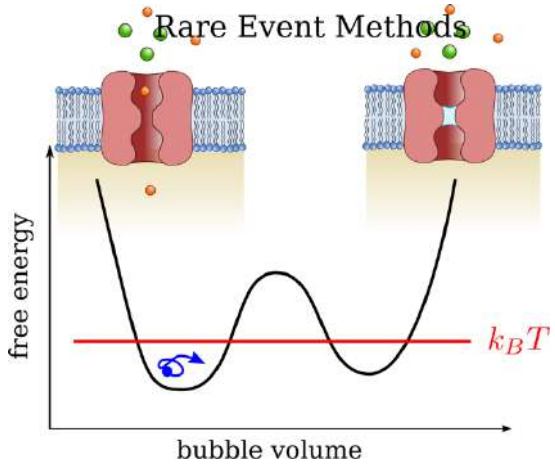

Figure 1. Illustration of the thermally activated formation of a nanoscale vapor cavity within a generic ion channel, giving rise to hydrophobic gating, in which the vapor cavity blocks ion currents. The free-energy profile shows that the bubble formation is a "rare event", i.e., it happens on timescales which are not amenable of brute force simulation.

SELECTION AND PARAMETER INFERENCE OF MYOCARDIAL CONSTITUTIVE LAWS: FROM EX VIVO TO IN VIVO

Hao Gao[1], Debao Gaun [1], and Xiaoyu Luo [1]
[1]School of Mathematics and Statistics, University of Glasgow

Summary Personalized cardiac modelling can provide unique insights on heart function both physiologically and pathologically. Choosing an appropriate constitutive law and inferring its parameters from limited experimental data, however, still remain a great challenge. In this study, we firstly analysed the descriptive and predictive capability of a general 14-parameter constitutive law developed for myocardial passive response using ex vivo data. We then reduced the general laws using Akaike information criterion (AIC) for different experimental studies by maintaining its mechanical integrity whilst achieving minimal computational cost. To model active stress, we introduced a structural tensor into the contraction model for describing dispersed myofibres. Finally we inferred those unknown constitutive parameters using routine clinical data with the constitutive law determined from ex vivo human data. Our results suggest that a combined ex/in vivo experimental and modelling approach is important in selecting an appropriate constitutive law for predictive biomechanical models.

INTRODUCTION

Constitutive laws that describe the mechanical responses of cardiac tissue under loading hold the key to the accurate modelling of biomechanical behaviours of the heart. Determining the constitutive laws and their parameters from limited experimental data, however, still remain a great challenge for the cardiac modelling community. It is even more challenging to infer those constitutive parameters for real patients with routinely available clinical data. There have been ample choices of phenomenological constitutive laws derived from experiments for describing myocardial responses, such as the strain-invariant based Holzapfel-Ogden 2009 model [1], denoted as HO2009. To model active contraction, a most widely used approach is the active stress formulation in which the total stress tensor is additively decomposed into a passive ($\boldsymbol{\sigma}^{\text{pass}}$) and active ($\boldsymbol{\sigma}^{\text{act}}$) parts. To date, only very limited studies included myofibre dispersion in active contraction for myocardium using the active stress formulation. Currently, there are no established approaches which can relate ex vivo calibrated parameters to in vivo myocardial behaviours, imposing a major difficulty for translational studies. In this study, we propose an initial attempt to address this issue from ex vivo to in vivo towards personalized modelling.

MYOCARDIAL CONSTITUTIVE LAW FROM EX VIVO DATA

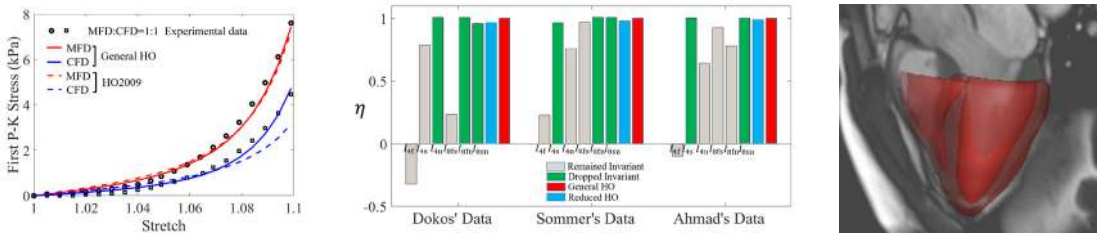
Three sets of experimental data were taken from ex vivo myocardial biomechanical studies: Dokos et al [4] investigating porcine myocardium; Sommer et al [5] investigating human myocardium; and, Ahmad et al [3] investigating neonatal porcine myocardium. To characterize the mechanical behaviours of myocardium, the general HO strain energy function [1] Ψ was considered here,

$$\Psi = \frac{a}{2b}\exp[b(I_1-3)] + \sum_{i=\text{f,s,n}} \frac{a_i}{2b_i}\{\exp[b_i(\max(I_{4i},1)-1)^2]-1\} + \sum_{ij=\text{fs,fn,sn}} \frac{a_{ij}}{2b_{ij}}[\exp(b_{ij}I_{8ij}^2)-1], \qquad (1)$$

where $a, b, a_i, b_i, a_{ij}, b_{ij}$ are the 14 material constants, $I_1 = \text{trace}(\mathbf{F}^T\mathbf{F})$, represents the overall squared stretch, $I_{4\text{f}}$, $I_{4\text{s}}$ and $I_{4\text{n}}$ are squared stretches along the myofibre direction ($\mathbf{f}$), sheet direction ($\mathbf{s}$) and sheet-normal ($\mathbf{n}$), respectively. $I_{8\text{fs}}$, $I_{8\text{fn}}$ and $I_{8\text{sn}}$ are invariants representing the coupling between two different directions. $\mathbf{F}$ is the deformation gradient. We first fitted the general HO model and HO2009 using all test data for each experimental study, and the unknown parameters were estimated using a non-linear least square minimization method. We found that the widely used simplified HO law (HO2009) failed to describe all experimental data, while the general HO model can fit all three experiments very well, as shown in Figure 1(a) for Sommer's data as an example. However, the general HO model has too many parameters, and determining unique values from limited experimental data be very challenging. To derive a simplified but competent strain energy function for a specific experiment, the Akaike information criterion (AIC) analysis was employed here to determine which term can be dropped in Eq.1. The importance of each strain invariant was ranked by the AIC value which was calculated by fitting the reduced constitutive law to experimental data without this strain invariant, the term with the least change (within 5%) was dropped. Figure 1 shows the associated AIC values of each strain invariant compared to the general HO model for the three experimental studies.

Experimental studies have shown that myofibres do not align perfectly along one direction at any location, but are dispersed [5]. We first adopted the structural tensor approach for calculating active stress by taking into account of myofibre dispersion following [6]. At any location, myofibre dispersion can be described as $\rho(\mathbf{M}) = \rho(\Theta,\Phi) = \rho_{\text{op}}(\Phi)\,\rho_{\text{in}}(\Theta)$, in which $\rho_{\text{op}}(\Phi)$ is the out-of-plane dispersion described by a π-periodic von Mises distribution, $\rho_{\text{in}}(\Theta)$ is the in-plane dispersion distribution. Φ and Θ are fibre angles in a Cartesian coordinate system ($\mathbf{e}_1$-$\mathbf{e}_2$-$\mathbf{e}_3$). The general structural tensor $\mathbb{H}$ can be defined over an unit sphere as $\mathbb{H} = \frac{1}{N}\int_0^{2\pi}\int_0^{\pi}\rho_{\text{op}}(\Phi)\,\rho_{\text{in}}(\Theta)\,\sin\Theta\mathbf{M}\otimes\mathbf{M}d\Theta d\Phi$, in which N is a normalization

[1]Corresponding author. E-mail: hao.gao@glasgow.ac.uk



(a) (b) (c)

Figure 1: (a) fitting HO2009 and the general HO model to Sommer's study [5], MFD: mean fibre direction, CFD: cross-fibre direction; (b) normalized AIC with respect to the AIC from the general HO model; (c) predicted end-systolic shape using optimal constitutive parameters superimposed in a MR cine image at end systole.

factor. Without loss of generality, considering the mean fibre direction at reference state $\mathbf{f}_0$ aligns to $\mathbf{e}_3$, the mean sheet direction ($\mathbf{s}_0$) along $\mathbf{e}_1$ and the mean sheet normal ($\mathbf{n}_0$) along $\mathbf{e_2}$, then we can define a structural tensor for describing the active stress $\hat{\mathbb{H}}_a = \mathbb{H}_{11} I_{4\mathrm{s}}^{-1} \mathbf{s}_0 \otimes \mathbf{s}_0 + \mathbb{H}_{22} I_{4\mathrm{n}}^{-1} \mathbf{n}_0 \otimes \mathbf{n}_0 + \mathbb{H}_{33} I_{4\mathrm{f}}^{-1} \mathbf{f}_0 \otimes \mathbf{f}_0$. Thus the dispersed active stress is

$$\boldsymbol{\sigma}^{\mathrm{act}} = T_a \mathbf{F} \hat{\mathbb{H}}_a \mathbf{F}^T = T_a \left(\mathbb{H}_{11} \hat{\mathbf{s}} \otimes \hat{\mathbf{s}} + \mathbb{H}_{22} \hat{\mathbf{n}} \otimes \hat{\mathbf{n}} + \mathbb{H}_{33} \hat{\mathbf{f}} \otimes \hat{\mathbf{f}} \right) \tag{2}$$

in which T_a is the active stress generated by myocytes, and usually described by a set of ODE functions. Because of the significant difficulty of in vivo myofibre acquisition, rule-based myofibre structures are still commonly used in cardiac mechanics modelling, even in personalized models. In this study, we simulated a bi-ventricular porcine heart using a rule-based generated fibre structure with dispersed active stress derived in Eq.2, based on a diffusion-tensor magnetic resonance imaging (DT-MRI) dataset, and then compared the pump functions with a similar bi-ventricle but using the DT-MRI fibres. Our results show that by incorporating fibre dispersion using a structural tensor $\hat{\mathbb{H}}^{\mathrm{a}}$ in active contraction, rule-based method can be a good approximation of realistic myofibre structures.

FROM EX VIVO TO IN VIVO

Currently, there is no consistent way on how to adjust parameters derived from ex vivo experiments to in vivo models. Published studies have suggested passive parameters estimated from ex vivo experiments can over-estimate the stiffness in vivo. Thus in many published studies, parameters of in vivo myocardium are scaled from ex vivo experiments to match in vivo measurements. For active contraction, most parameters are calibrated through single cell experiments, and usually, the isometric contractility (T_{max}) is inversely determined by matching the stroke volume or ejection fraction. In this work, a bi-ventricle model of a healthy volunteer at early diastole was developed from routine clinical MR cine images. The constitutive law for human myocardium and its parameters were determined in the previous section based on ex vivo human experimental data [5]. Two stages were designed to calibrate constitutive parameters for this healthy volunteer. In the first stage, a linearly ramped pressure was applied to the ventricular endocardial surfaces to passively fill the ventricle without active contraction, that is the diastolic filling phase. Passive parameters were then inversely determined through a multi-step optimization procedure by matching the volume and strains at end diastole [7], three sub-steps were involved including (1) scaling ex vivo parameters to match end-diastolic volumes as in [7]; (2) matching measured strains by optimizing a_{f} and b_{f} using a gradient-based method; (3) updating a and b to match end-diastolic volumes again. In the second stage, the myocardium contracted simultaneously after the simulation reaching end diastole with optimized passive parameters from the first stage, T_{max} was inversely determined by matching the measured ejection fraction. Figure 1 (c) shows the simulated end-diastolic shape of the bi-ventricle model, which agrees well with the MR cine image at end systole.

CONCLUSIONS

In this study, we applied the AIC analysis to the general HO model to derive a suitable passive constitutive law for a given set of ex vivo experimental data, and further introduced a structural tensor in active stress modelling based on fibre dispersion, and finally simulated a personalized bi-ventricular dynamics in vivo. Our results show that a combined experimental and modelling approach is important in selecting an appropriate constitutive law for predictive models.

MODELLING OF COMPLEX SIGNALS IN NERVES AND THE ANALYSIS OF COUPLING EFFECTS

Jüri Engelbrecht*, Kert Tamm, and Tanel Peets
Department of Cybernetics, Tallinn University of Technology, Tallinn, Estonia

Summary. In this talk a mathematical model which describes jointly electrical, mechanical, and thermal signals in axons is proposed and analysed. The model is based on the analysis of experimental results. The governing equations of single effects are united into a system with coupling forces. As a result, the numerical simulation demonstrates that an ensemble of waves will emerge following the predictions of experiments. The properties of this ensemble are analysed in detail.

INTRODUCTION

Recent studies have revealed the complex structure of nerve signals in axons. There is the experimental evidence that the propagation of an electrical signal (an action potential) is accompanied by mechanical and thermal effects. This calls for analysis at the interface of physiology, mechanics and mathematics taking into account the structure of an axon and possible processes in them. A nerve is actually a cylindrical tube with the wall made of lipid molecules (a biomembrane) inside of which is the axoplasmic (intracellular) fluid. The biomembrane has ion channels through which the ions can pass from the intracellular fluid to the extracellular fluid and vice versa. Experiments have demonstrated beside the action potential (AP) the existence of longitudinal (LW) and transverse (TW) displacements of the biomembrane, the pressure wave (PW) in the axoplasm and the temperature changes (Θ) accompanying the propagation of an AP. It is a challenge to build up a mathematical model able to describe all these effects as an ensemble. In this paper, such a model for unmyelinated axon is presented and analysed. This phenomenological model is based on the analysis of experimentally measured mechanisms of interactions between the single components of the ensemble which permit to propose hypotheses for building up the mathematical description of the whole process.

MODELLING

Based on classical understandings of axon physiology [1] the following basic assumptions are made: (i) electrical signals are the carriers of information and trigger all the other processes; (ii) the axoplasm can be modelled as a fluid where a pressure wave is generated due to the electrical signal [2]; (iii) the biomembrane is able to deform (stretch, bending) under mechanical impact [3]; (iv) the ion channels in biomembranes can be opened and closed under the influence of electrical signals as well as of the mechanical input. Such a description needs the existence of interaction forces between the single components. Three physical mechanisms responsible for coupling are:
(i) electric-biomembrane interaction resulting in a mechanical response (LW, variable U);
(ii) electric-fluid (axoplasm) interaction resulting in a mechanical response (PW, variable $\bar{P}$);
(iii) electric-fluid (axoplasm) interaction resulting in a thermal response (Θ).

The following hypotheses are made: (i) all mechanical waves in the axoplasm and the surrounding biomembrane together with the heat production are generated due to changes in electrical signals (AP or ion currents) that dictate the functional shape of coupling forces [5]; (ii) the formalism of internal variables is used for describing the exo- and endothermic processes of heat production [6]. In addition, not only the influence of an AP to other effects but also possible feedback is taken into account. The possible mechanisms of coupling are described by space or time derivatives of variables governing the AP (amplitude Z), the LW (amplitude U), PW (amplitude $\bar{P}$), temperature Θ. The transverse displacement of the biomembrane W is taken proportional to the gradient of U like in the theory or rods.

A block-scheme of modelling is shown in Fig. 1 (left).

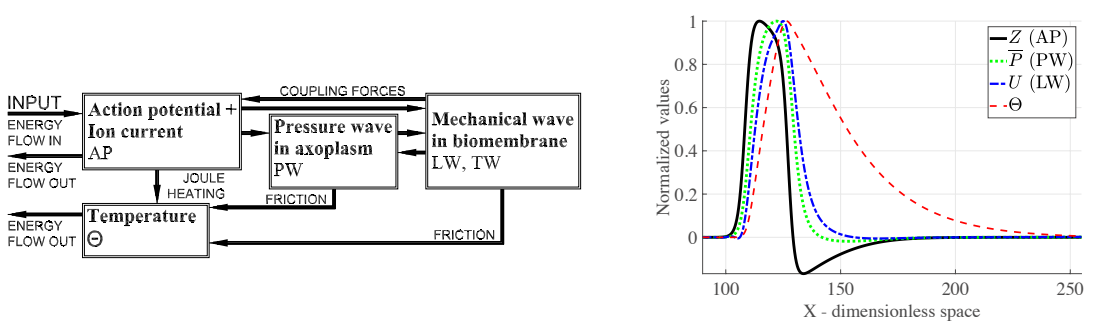

Figure 1. Block diagram of the model (left) and solutions of the dimensionless model equations (right).

* Corresponding author. E-mail: je@ioc.ee.

The governing equations in the dimensionless form are as follows. In the first approximation, the AP is modelled by the FitzHugh-Nagumo model [7]

$$Z_T = Z\big(Z - (a_1 + b_1)\big)(1 - Z) - J + DZ_{XX},$$
$$J_T = \varepsilon(-J + (a_2 + b_2)Z),$$

where Z is the voltage, J is an ion current, a_i, b_i, D and ε are constants. Indices T and X here and further indicate differentiation with respect to time and space, respectively.

Pressure wave (PW) in the axoplasm is governed by the 1D wave model with added viscosity term

$$\bar{P}_{TT} = c_f^2 \bar{P}_{XX} - \mu \bar{P}_T + F_1(Z, J),$$

where $\bar{P}$ is pressure, c_f – the velocity, μ – the viscosity constant and $F_1(Z)$ is a force from the AP.

The longitudinal wave (LW) in biomembrane is governed by the improved Heimburg-Jackson model [3,4]

$$U_{TT} = [(c_0^2 + PU + QU^2)U_X]_X - H_1 U_{XXXX} + H_2 U_{XXTT} + F_2(J, Z),$$

where $U = \Delta\rho_A/\rho_A$, ρ_A is the density, velocity c_0 corresponds to the unperturbed state, P, Q, H_1, H_2 are constants and $F_2(J, Z)$ is the force from the AP. Transverse wave (TW) in biomembrane, which is actually measured in experiments, can be modelled like in the theory of rods [4]

$$W = \kappa U_X,$$

where κ is a coefficient.

Temperature Θ is governed by the modified diffusion equation

$$\Theta_T = \alpha \Theta_{xx} + F_3(Z, J, U, \bar{P}),$$

where α is a coefficient and $F_3(Z, J, U, \bar{P})$ is the force from the AP, LW and PW.

The functional shapes of contact forces are proposed on the basis of several experimental studies taking into account the hypotheses introduced above. The specific mechanisms of coupling and feedback will be discussed in the talk. The heat transfer responsible for changes in temperature Θ is analyzed by introducing several possible physical mechanisms including the process with the internal variables [8]. Such an approach allows distinguishing, if needed, the role of various ion currents when replacing the FitzHugh-Nagumo model [7] with the Hodgkin-Huxley model [6].

The model equations presented above are solved in their dimensionless form by making use of the Fourier transform based pseudospectral method [4]. An example of an ensemble of waves is shown in Fig. 1 (right).

CONCLUSIONS

The model described above is actually the first attempt in order to couple all the measurable effects of the signal propagation in nerves (axons) into a system. This is an interdisciplinary approach at the interface of physiology, physics and mathematics. Clearly the signal propagation in nerves is a complex electro-mechano-thermo-physiological process spiced with molecular effects (opening and closing the ion channels) resulting in emergence of an ensemble of waves. Like demonstrated in various experiments, the components of the ensemble have synchronized velocities. The proposed mathematical model is robust following the trends in systems biology and also in the theory of complex systems. It permits easily modifications by taking more physiological effects into account, for example the Hodgkin-Huxley model [6] and endothermic reactions, etc. Several possible modifications will be discussed in the talk.

Summary The development of *in vitro* models for the study of cardiac cells is essential to the understanding of cardiomyocyte function in healthy and diseased states as well as changes in cell behavior as a result of exposure to drugs, toxins, or genomic editing. We provide a two-dimensional culture platform, amenable to a range of characterization assays, that emulates *in vivo* cardiac behavior through the use of patterned extracellular matrix and multiple cell types differentiated from human induced pluripotent stem cells. The utility of this platform is illustrated through functional readouts that span immunohistochemistry-assisted assessment of both extracellular and intracellular organization, optical mapping of calcium transients to measure critical parameters such as conduction velocity, and digital image correlation to assess strain output during contraction events.

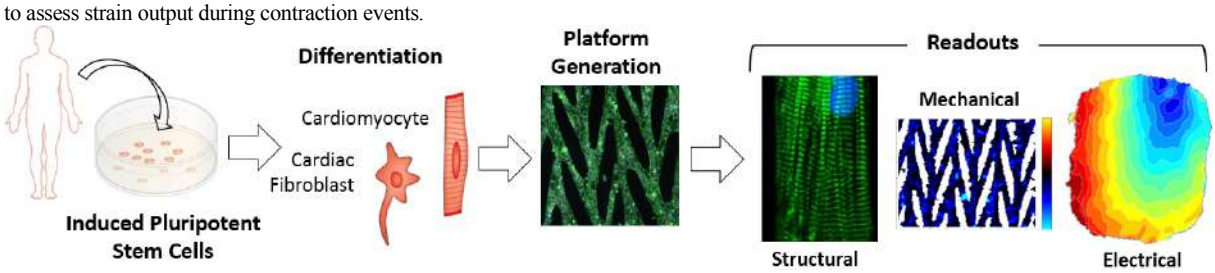

Figure 1. Human iPSCs are differentiated into cardiomyocytes and cardiac fibroblasts for timed introduction into the micropatterned platform for *in vitro* culture. At later time points, functional readouts are performed to determine extracellular and intracellular organization, mechanical strain measures, and electrophysiological outputs.

Human induced pluripotent stem cells (hiPSCs) are capable of being differentiated into all cell types present in the body including those of the heart. Prior work in the field has enabled the reliable differentiation of both cardiomyocytes, the muscle cells of the heart, and cardiac fibroblasts, the most prevalent support cell in the heart, at high levels of purity[1, 2]. These cells exhibit relevant cardiac electrical and mechanical function enabling the desired assays to be performed. Furthermore, they exhibit functional properties of the human heart, which are distinct from many common animal models including rodent models where calcium cycling and cellular electrophysiology exhibit important differences [3-5].

For *in vitro* experiments to be reliable, engineered systems must guide cells to create an organized internal structure similar to that of adult cardiomyocytes *in vivo.* This provides control over intracellular features and a means to design well-controlled, repeatable experiments. We have focused on a two-dimensional platform because it enables the observation of multicellular interconnected networks of cells and is more amenable to *in situ* characterization by optical methods. Additionally, two-dimensional constructs can be more readily manipulated given the lack of diffusion barriers present in three-dimensional constructs, can have its cellular composition and organization more readily adjusted, and are more readily scalable.

As illustrated in Figure 1, we have developed a repeatable, organized, integrated, multicellular culture platform that enables robust assessment of the major functional readouts for cardiomyocyte physiological behavior – structural, mechanical, and electrical - using advanced optical methods. This culture platform bridges the gap between single-cell studies, which do not account for critical mechanical and electrical coupling between cardiomyocytes nor interactions with other cell types, and engineered three-dimensional heart tissue studies, which are not as amenable to full optical characterization. Using multicellular aggregates in a defined micropattern offers the advantages of tissue-like connectivity and coordinated cell-cell functionality.

Cardiomyocytes (CMs) are differentiated from hiPSC using a modified version of the small molecule GSK3β inhibition / Wnt inhibition (GiWi) method [6] and then subjected to lactate purification [7]. Purified hiPSC-CM cultures are washed with PBS and a 10-15 minute exposure to TrypLE (Life Technologies) dissociates and singularizes CMs before seeding them onto micropatterned substrates in a 10% serum-containing media. Soft lithography techniques are used to create the platform on which 30-day differentiated cardiomyocytes and cardiac fibroblasts and seeded [8].

*Corresponding author. E-mail: crone@engr.wisc.edu

Micropatterned extracellular matrix (ECM) (Matrigel, BD Biosciences) promotes preferential cell attachment to the pattern upon seeding onto a PDMS substrate to model healthy (E = 10 kPa) and diseased (E = 30-50 kPa) tissue stiffnesses.

Digital image correlation (DIC) is used to measure full-field displacements and provide strain mapping. This allows characterization of maximum contractile strain and variability in contractility among CMs in the multicellular platform. To measure full-field displacements, we use Fast Iterative DIC (FIDIC) [9], along with a custom algorithm for strain analysis [8]. As illustrated by Figure 2, large data sets are generated for a contractile event and then analyzed to determine the full field principal contractile strain values as well as scalar measures for comparison between different experimental conditions. These results show how the detailed data maps can also be used to produce a scalar value so that quantitative comparisons can be made across different conditions, such as the substrate stiffness.

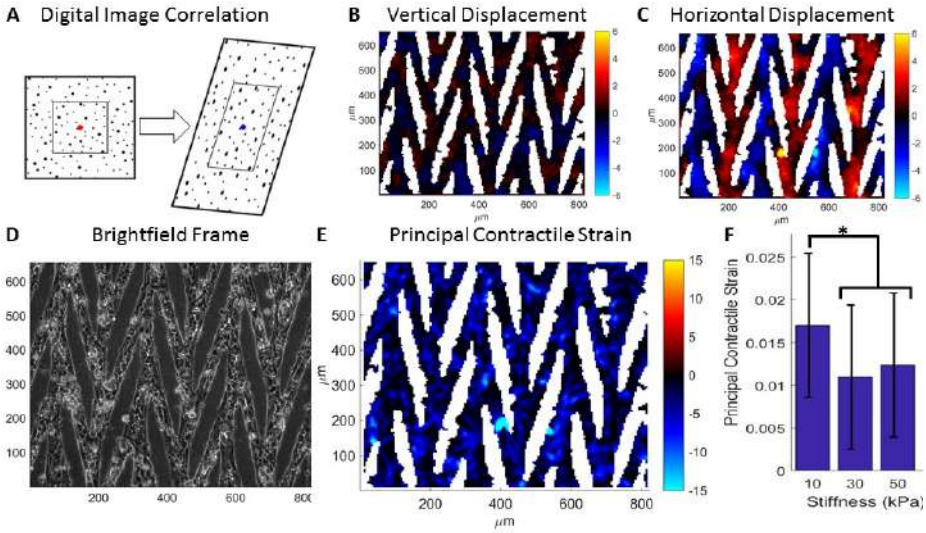

Figure 2. Conceptual sketch of the DIC method (A) used on every brightfield frame of video captured during a contractile event (e.g. D). Using a relaxed frame as reference, local displacements are calculated for each subsequent frame to create 2D maps (B-C). These displacements are then used to determine normal and shear strains at each location and then calculate the principal strains, of which the second principal strain is used as a measure of contractility for CM studies (E). The scalar value representing the median strain for the frame of peak contraction can be calculated and compared over many samples and conditions. Here we show how the maximum contractile strain is influenced by substrate stiffness (F). * $p < .05$

CONCLUSIONS

Stem cell differentiation techniques combined with this micropatterned platform enable precisely controlled seeding of desired cell types to generate reproducible highly organized and interconnected cardiomyocyte arrays, and in co-culture with other cell types such as cardiac fibroblasts, to produce a collection of cardiac cells mimicking the microenvironment in the heart. Experimental results using this culture platform have already demonstrated how micropatterning dimension influences intracellular alignment and cell-cell attachment; as well as mature functional status of cardiomyocyte contraction amplitude, calcium transient amplitude, and calcium release and sequestration upon exposure to beta-adrenergic stimulation [8]. Here we show changes in mechanical functionality of an *in vitro* cardiac syncytium through modification of the substrate stiffness between 10 kPa (healthy model) and 30-50 kPa (disease model). Our other recent findings also illustrate that this platform can control cardiac fibroblast migration and alignment of remodelled extracellular matrix; increased contractility when cardiomyocytes are cocultured with cardiac fibroblasts; and changes in strain production as a result of genomic editing.

AN APPROACH TO MODELING RECANALIZATION IN ACUTE ISCHEMIC STROKE THROUGH CYCLIC ASPIRATION

Francesco Costanzo*[1], Bryan Good[2], Scott Simon[3], and Keefe Manning[2]
[1]Department of Engineering Science and Mechanics, Penn State University, University Park, PA, USA
[2]Department of Biomedical Engineering, Penn State University, University Park, PA, USA
[3]Department of Neurosurgery, Penn State Hershey Medical Center, Hershey, PA, USA

Summary An acute ischemic stroke (AIS) occurs when a thrombus (blood clot) occludes a cerebral artery. AIS is the 2nd leading cause of death worldwide and 80% of patients eligible for a thrombectomy (clot removal) with current methods will either die or suffer major disability. Using *cyclic* aspiration in thrombectomies is a promising new approach to achieve better recanalization outcomes. We present a first study of this process using a nonlinear viscoelastic model for the thromboembolus and treating the thromboembolus–artery interface as a nonlinear viscoelastic cohesive zone (CZ) with damage accumulation. An initial experimental validation was conducted and the effect of the various CZ constitutive parameters was investigated computationally to determine the most prevalent effects.

INTRODUCTION

Stroke causes 6.5 million death each year [1]) and 87% of all stroke-related deaths are due to AIS [2]. Mechanical thrombectomy can achieve recanalization, typically in larger vessels or in patients with contraindications to systemic thrombolysis. Current devices, e.g., Solitaire (Medtronic) and Trevo (Stryker) stent retrievers and suction thrombectomy (Penumbra), typically achieve recanalization only in 85% of patients [3]. These devices could be improved by using *cyclic* aspiration instead of static suction. In a benchtop model [4] cyclic aspiration significantly outperformed static aspiration in removal speed, overall clearance, and with lower operating pressures. There are very few computational studies of aspiration in AIS. To our knowledge, there have been no experimental studies of AIS aspiration, and no computational models of cyclic aspiration in AIS. Here we present a first attempt to fill this gap by modeling the nonlinear viscoelastic behavior of the thrombus and the rate-dependent response of the thrombus-artery interface. The latter was modeled as a cohesive zone (CZ)[5] inspired by studies on coarsely ligated biofilms [6] and tearing in atherosclerotic plaques [7]. The computational solver was initially validated in an experimental flow chamber tracking a thromboembolus analog's surface motion. A range of simulations were then conducted to ascertains the most prevalent model parameters. The result we will present also include some calculations with physiological-relevant clot and interface CZ models [8].

MODELING FRAMEWORK

Our simplified axisymmetric system consists of a thrombus lodged in a cerebral artery (Fig. 1) subject to a uniform

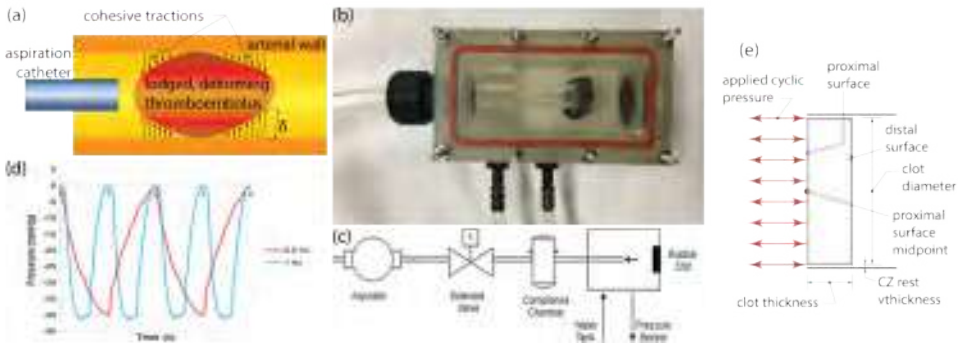

Figure 1: (a) A thromboembolus lodged in a cerebral artery: the shape is exaggerated to show the arterial wall/thrombus interface. (b,c) Experimental aspiration chamber with a neoprene clot analog. (d) Aspiration pressures and frequencies. (e) Clot and CZ reference and loading configurations used in the calculations.

pressure imposed on its proximal surface by a catheter. The distal surface is assumed to be traction-free. The thrombus is modeled via the theory of evolving natural reference configurations (see [8] for details) with a stress response given by

$$\sigma = -pI + \lambda_0(B - I) + \lambda_1(B_e - I) + 2\eta D \quad \text{and} \quad \dot{B}_e - LB_e - B_eL^T = \frac{1}{\tau}(I - B_e). \tag{1}$$

The dot is the material time derivative (time is t). σ is the Cauchy stress, p is a multiplier for enforcing incompressibility, I is the identity, $B = FF^T$ (F being the familiar deformation gradient), $D = (L + L^T)/2$, with $L = \nabla v$, namely the (Eulerian) gradient of the material velocity v, B_e is a symmetric 2nd order tensor analogous to B, but pertaining to a putative deformation allowing the current configuration to relax to its companion evolving natural reference configuration.

*Corresponding author. E-mail: fxc8@psu.edu.

The constant constitutive parameters λ_0 and λ_1 are elastic moduli, η is the dynamic viscosity, and τ is a relaxation time. This model recovers the Kelvin–Voigt (KV) solid for $\lambda_0 > 0$ and $\lambda_1 = 0$, and the Oldroyd-B (OB) fluid for $\lambda_1 > 0$ and $\lambda_0 = 0$. The KV model is also recovered for $\lambda_0 = 0$, $\lambda_1 > 0$ and $\tau \to \infty$. We note that the left-hand side of the 2nd of Eqs. (1) is the Oldroyd upper-convected time derivative of B_e. For the CZ we adopt a conceptually similar model:

$$\vec{s} = (k\delta_e + \eta_{cz}\dot{\delta})\,\vec{g} \quad \text{and} \quad \dot{\delta_e} = \dot{\delta} - \delta_e/\tau_{cz}, \tag{2}$$

where $\vec{s}$ is the cohesive traction, $\delta\,\vec{e}$ ($\|\vec{e}\| = 1$) the CZ opening displacement, δ_e the recoverable part of δ. The constant constitutive parameters k, η_{cz}, and τ_{cz} are the CZ stiffness, viscosity, and relaxation time, respectively. For $0 < \tau_{cz} < \infty$, and under loading conditions promoting opening, the CZ can open without restriction but without a well-defined failure condition. We model the CZ failure using a damage accumulation approach. We call $0 \le \phi \le 1$ the CZ (dimensionless) damage parameter and posit that the CZ stiffness $k = k_i(1-\phi)$, k_i being the initial stiffness and $k = 0$ identifying failure. We assume that $\phi = 0$ everywhere over the interface at $t = 0$. Then, $\phi = (\delta - \delta_{cr})/\ell$ whenever $\delta \ge \delta_{cr} + \bar{\phi}\ell$, $\bar{\phi}$ being the damage at the previous iteration step and δ_{cr} the opening displacement triggering damage accumulation. The governing equations consist of the balance of momentum (with inertia), the continuity equation, and the stated constitutive equations. We implemented our model in a large deformation Lagrangian finite element formulation with the geometry sketched in Fig. 1(e). The formulation was verified using the Method of Manufactured Solutions (see [8] for details).

RESULTS AND CONCLUSIONS

Once verified the correctness of our code, we proceeded to ascertain whether or not the model was adequate for the study of AIS. We created an experimental chamber to subject a neoprene clot analog (Fig. 1(b,c,d)) to a variety of loading conditions. The stress/strain and creep data were collected and fit to the KV and OB limit cases. Using the result of these tests, we predicted the deformation of the clot analog under cyclic loading with the wave forms in Fig. 1(d) but without the presence of a CZ. These predictions, consisting of the displacement of the entire proximal surface of the clot, were compared to corresponding experimentally measured deflections and we found excellent agreement (absolute worst discrepancy was to within 11% error) [8]. We then explored the response of the clot for various values of both the clot relaxation time τ and the various parameters defining the CZ displacement. We will present the full spectrum of the 24 cases we analyzed [8]. In this this extended abstract, we report only the sample shown in Fig. 2. These simulations

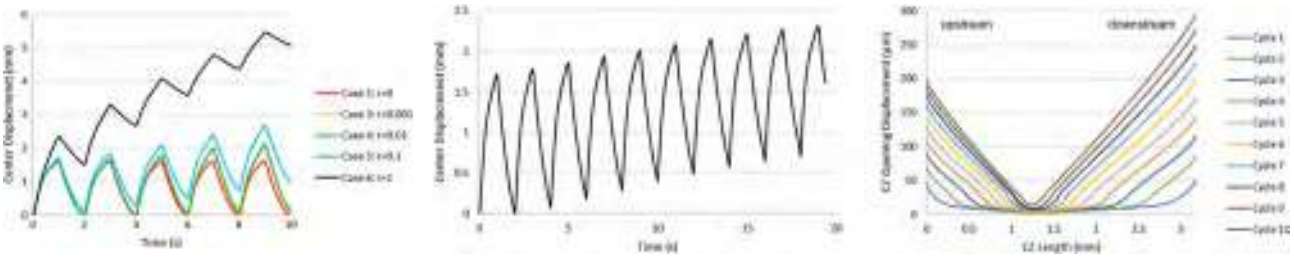

Figure 2: **Left:** Displacement of the clot's center point (cf. Fig. 1(e)) (b,c) under an applied cyclic pressure of 40 mmHg with 0.5 Hz frequency (cf. Fig. 1(d)) for a KV model with $\lambda_0 = 377$ MPa and $\eta = 3.6$ MPa·s for Case 1, and an OB model with $\lambda_1 = 377$ MPa, $\eta = 3.6$ MPa·s and τ are indicated (in seconds) for Cases 3–6. For these simulations no CZ was present and the clot's edges were fixed. **Center and right:** Simulation for a KV clot analog with $\lambda_0 = 377$ MPa and $\eta = 3.6$ MPa·s under an applied cyclic pressure of 40 mmHg with 0.5 Hz frequency, but with a CZ with $k_i = 2.7\,\text{kPa}/\mu\text{m}$, $\eta_{cz} = 10^{-9}\,\text{kPa·s}/\mu\text{m}$, $\ell = 10\,\mu$m, and $\delta_{cr} = 10\,\mu$m.

show that both the constitutive behavior of the clot and that of the interface can both strongly affect the overall system's response under to cyclic pressures. Furthermore, the simulations confirm that, under the assumption that the interface suffers damage accumulation, conditions for the clot removal can be achieved by cyclic loading with applied pressures that are physiologically acceptable. Some simulations seem to indicate that the damage accumulation is more prominent at the distal end of the clot, this being a somewhat surprising result that requires further investigation by properly modeling the deformability of the blood vessel. The results with parameters relevant to AIS used dimensions and mechanical properties of the internal carotid artery and removed thromboemboli [8]. In these AIS cases, more upstream CZ opening was observed compared to the clot analog cases and greater displacement was also achieved with the lower-frequency aspiration (0.5 Hz vs. 1 Hz).

MICROSTRUCTURE OF HUMAN AORTIC TISSUE AT DIFFERENT SCALES IN RELATIONSHIP TO MECHANICAL PROPERTIES

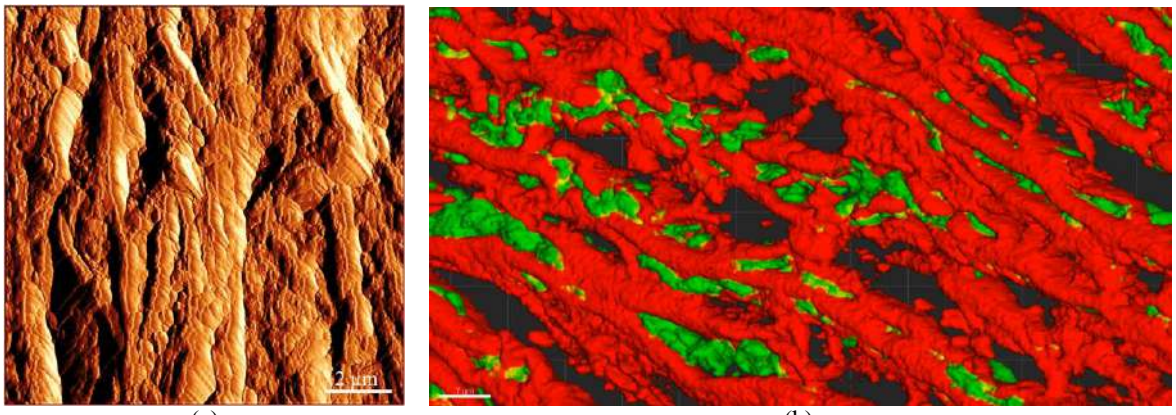
Ivan D. Breslavsky*[1], Meisam Asgari[2], Francesco Giovaniello[1], and Marco Amabili[1]
[1]Department of Mechanical Engineering, McGill University, 817 Sherbrooke St. W, Montreal, Quebec, Canada
[2]Department of Mechanical Engineering, Northwestern University, 2145 Sheridan Road, Evanston, Illinois, USA

Summary Microscopic imaging of the three layers of several human descending thoracic aortas was performed by second harmonic generation, two-photon and atomic force microscopy to receive a better understanding of the collagen and elastin structure, distribution and role in the mechanical response of the aortic tissue. Results show a significant inhomogeneity of collagen fiber orientations taking samples of 300 μm in size. These differences are homogenized on larger images of 2 mm in size. This suggests a further refinement of hyperelastic material models currently used to take into account this feature.

METHODS

The mechanical strength and stiffness of biological tissues are governed by their constituting protein molecules that form fibrils with a hierarchical structure. The most contributing into mechanical response of the arterial tissue protein is collagen, often organized in fibrils and fibers. The entanglement of the fibrils is reflected in the tissue matrix that inherits its stiffness from the concentration and orientation of collagen strands.

Different microscopic imaging techniques were used on in order to obtain collagen structure in aortic tissues since couple of decades. In this work, we apply a combination of (i) second harmonic generation imaging (SHG) [1], (ii) two-photon microscopy, and (iii) atomic force microscopy (AFM) [2] to several samples of healthy human aortic tissue obtained from heart-beating donors (from Transplant Québec), in order to better visualise the structure and orientation of collagen and elastin fibers in the three layers. Since most aortic hyperelastic material models include the collagen fiber mean orientation and dispersion, the identification of these global parameters from local imaging is a primary goal of microscopy image processing. We used SHG to get the global picture of collagen distribution and AFM, which is able to deliver the image at much smaller scaler (see Figure 1(a)), to clarify the local structure. In parallel, two-photon images provide the elastin distribution, which can be superimposed to collagen in order to obtain the three-dimensional structure (see Figure 1(b)). Static and dynamic uniaxial tensile tests were performed on each layer and on the full aortic wall on strips taken in axial and circumferential directions. They allow for the hyperelastic and viscoelastic material characterization. Cameras were used to measure the strains orthogonal to the tensile direction.



(a) (b)

Figure 1. (a) Microscopic image of the collagen fibers (adventitia, male patient, 39 years) obtained by AFM; (b) aorta microstructure obtained with two-photon and SHG imaging, (media, female, 40 years). Green – collagen, red – elastin.

RESULTS

A widely used assumption in the literature is that every layer (intima, media, adventitia) of aortic tissue has two families of collagen fibers with main angles that are symmetrical with respect to circumferential direction [3, 4]. The in-plane fiber dispersion is significant around these two angles, while the out-of-plane dispersion is small. Microscopic images show a more complex structure. Figure 2(a) shows a much more intricate distribution of fibers. As it can be observed, there are locations with two families of fibers, as well as with only one visible family. Moreover, the angles of the families are different for fibers in different zones. There is no certain structure peculiar to the layer as a whole. Figure 3(b) shows the histogram of the in-plane fiber distribution in four distinct zones of the image with dimension of the order of 300 μm, as well as for the whole image that is about 2 mm of size.

(a) (b)

Figure 2. Large-scale SHG image on media tissue (media, female patient, 42 years) showing different fiber structure at different zones (a) and histograms of the fiber distributions in these zones and over the whole image (b).

We observe that cases similar to the one in Figure 2 are common. Typical size of blood vessel tissue used for fiber recognition shown in the literature is 500 µm or less [5-8]. Several areas of similar size are marked out in Figure 2(a), giving completely different patterns. In any of them the fibers seems to be pretty organized, but assuming this organization to all the tissue is wrong.

Uniaxial tensile tests on axial and circumferential strips, together with the Holzapfel et al. material model [3], were used to characterize the hyperelastic behaviour of the three aorta layers for each donor. Uniaxial harmonic excitations at different frequency, superimposed to initial stretch values, were used to characterize the viscoelastic behaviour. The storage modulus and the loss factor were obtained for each layer in both directions for all the donors. The generalized Maxwell model, within the framework of nonlinear viscoelasticity with internal variables, was used to obtain the constitutive material parameters. The materials parameters were obtained by using unconventional real-valued genetic optimization algorithms [9]. Data for fiber distribution obtained from microscopy were used to fit the material model to the uniaxial tensile tests.

CONCLUSIONS

Large-size microscopic images are necessary in order to obtain average values of fiber orientations in aortic tissues. The fact that collagen fibers presents locally organized structures suggest the use of more refined material models based homogenization criteria to take into account for this inhomogeneity. In addition, the interaction of elastin and collagen can be used to develop advanced viscoelastic material models. The mechanical properties of healthy aortas significantly vary with age [10] and are fundamental to develop a new generation of mechanically compatible grafts for aortic repair.

ASSESSMENT OF SAINT-VENANT PRINCIPLE FOR BIOLOGICAL TISSUES: EXPONENTIAL DECAY OF INCREMENTAL END PERTURBATIONS

Neta Blum[1], David Durban *[1], and Baruch Karp [2]
[1]Department of Aerospace Engineering, Technion, Haifa, Israel
[2]Department of Mechanical Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Summary The present research aims at an initial theoretical analysis of diffusion with distance of self-equilibrating incremental loads applied to bio-tissues. Setting follows the classical Fadle-Papkovich eigenfunction analysis, in plane linear elasticity, of a semi-infinite strip loaded by self-equilibrating end stresses. Thus, we attempt to determine exponential decay rates of incremental self-equilibrating loads imposed over the edge of an axially pre-stretched strip made of soft tissue. Exposing the nature of strain redistribution near local irregularities can help with understanding of local defects in arteries walls, onset of aneurysm, stents insertion, and membrane perforation that induce local self-equilibrating loads in bio-tissues. Likewise, evaluating applicability of SVP in an aorta could help in studying mechanics of cardiovascular pathologies, possibly improving treatments.

ABSTRACT

Saint-Venant Principle (SVP) is commonly accepted as a central and useful idea in structural mechanics. However, while considerable research on the validity of this principle is available for standard structural materials, only few studies have examined the validity of SVP for biological tissues. This is surprising since there are numerous situations, like presence of defects in arteries walls, onset of aneurysm, stent insertion, skin injuries and bio-membrane perforation, which impose local self-equilibrating loads on bio-tissues.

There appears to be a definite need to understand how localized stress and strain fields decay with distance from loaded zone. Unlike metals, bio-tissues admit large strains and become progressively convex as stretches increase. Earlier studies noted that decay of local effects depends on material orthotropic axes orientation. It has also been reported that decay length is higher in presence of anisotropy in bio-tissues. In a different direction, work by Humphrey and co-workers, on redistribution of localized stresses and strains near circular plane irregularities, indicates sensitivity to both anisotropy and initial stretch.

The present research aims at an initial theoretical analysis of diffusion with distance of self-equilibrating incremental loads applied to bio-tissues. Setting follows the classical Fadle-Papkovich eigenfunction analysis, in plane linear elasticity, of a semi-infinite strip loaded by self-equilibrating end stresses. Thus, we attempt to determine the exponential decay rates (and associated decay lengths) of incremental self-equilibrating loads imposed over the edge of an axially pre-stretched strip (including presence of transverse stretch) made of soft tissue.

Material response is assumed to be hyperelastic, incompressible, and isotropic in the unloaded reference state. Formulation is within the framework of finite strain continuum mechanics, employing laboratory verified hyperelastic constitutive relations for representative biological tissues like the aorta, brain, fat tissues, liver and skin.

We start with a long rectangular strip uniformly stretched in the axial direction, completely constrained in the transverse direction yet accounting for associated changes in thickness. Self-equilibrating incremental disturbances are then imposed over the end of the strip, inducing a set of exponentially decaying incremental eigen-fields. The validity of SVP is determined by the lowest axially decaying eigenfunction, as evaluated from the solution of the corresponding linear eigenvalue system.

Results, over a range of bio-tissues, reveal considerable sensitivity of exponential decay rates, in axial direction, as influenced by material properties and level of pre-stretch. it appears that presence of axial finite strain weakens the applicability of SVP, especially at large stretch levels. That sensitivity stands in marked contrast with the original linear elastic result obtained from the Fadle-Papkovich solution. Furthermore, in this setting the SVP validity is dictated by the first antisymmetric eigenfunction which is the lowest decaying component of the end disturbance. Another noteworthy observation is the direct connection between decay rates and convexity of strain energy function. In fact, our findings indicate that convexity tends to lower decay rates; an extreme example is the Gent tissue for which there is almost no decay near the critical stretch. Essential results have been evaluated numerically and supported by simple and accurate asymptotic expansions.

Next, we relax the transverse deformation constraint on the primary field, allowing for arbitrary pre-stretch in transverse direction. The configuration is now of a bi-axially stretched semi-infinite strip perturbed by a self-equilibrating end disturbance. Analysis is along the lines of previous case and the main conclusion is that presence of transverse stretch

*Corresponding author. E-mail: netab@campus.technion.ac.il.

(simulating aorta circumferential stretch induced by blood pressure) lowers the axial decay rate, again due to convexity of the strain energy function in bio tissues.

Important issues like soft tissues compressibility, anisotropy due to fibers distribution, multilayer structure and age deterioration, growth and remodeling, are not considered in this work. However, we believe that we have presented a start of systematic assessments of SVP validity and sensitivities in soft biological tissues.

Exposing the nature of strain redistribution near local irregularities can help with understanding of local defects in arteries walls, onset of aneurysm, stents insertion, skin injuries and membrane perforation that induce local self-equilibrating loads in bio-tissues. Likewise, evaluating applicability of SVP in an aorta could help in studying the mechanics of cardiovascular pathologies, possibly improving treatments. Research results can contribute also in fixing boundary conditions in experimental procedures.

As a practical by-product, the central observation of our research could be useful in structural health monitoring by providing a theoretical base for technologies aiming at detecting irregularities in living tissues and improving treatment. While this research is only an initial step in assessing the validity of Saint-Venant Principle in soft biological tissues, it provides new and challenging observations that call for further study on the applicability of that fundamental principle in biomechanics. In particular, the role of strain energy function convexity deserves a comprehensive investigation in context of SVP validity for soft biological tissues.

A SIMPLE ELASTIC-CONTINUUM MODEL TO EXPLAIN CELL REORIENTATION UNDER CYCLIC STRETCHING

Vageesh Singh Baghel and G. K. Ananthasuresh
Mechanical Engineering, Indian Institute of Science, Bengaluru, India

Summary We present a simple homogeneous, isotropic elastic-continuum model to explain the cell reorientation under cyclic stretching. Our hypothesis is that cells tend to minimize energy by re-arranging their focal adhesion points. By using topological derivative with Dirichlet boundary condition, the new locations of focal adhesion points can be found.

Introduction

It has been observed through experiments that cells reorient to specific angle relative to the stretch direction when subjected to cyclic stretching of the substrate [1]. The reorientation angle varies from 60° to 90° depending upon the type of cells as well as the frequency and magnitude of cyclic stretch [1-5]. There are models explaining such cell behaviours, e.g., zero strain model [1,3] and zero stress model [4]. Livne et al. [2] claimed that there is a clear difference between zero strain and zero stress models pertaining to the experimental results. They presented a relaxational dynamics model which suggests that the dissipative strain energy leads to change in cell orientation angle with time converging to the final angle [2]. It has also been shown that the focal adhesion alignment precedes cell reorientation [6]. By combining both the findings, we present here a simple elastic-continuum model to find the focal adhesion (FA) locations such that strain energy (SE) is minimized. Mathematically, by referring to Fig. 1, it can be expressed as an optimization problem:

$$\underset{\text{FA points}}{Min} \; SE = \frac{1}{2}\int_{\Omega} \varepsilon : \sigma \, d\Omega$$

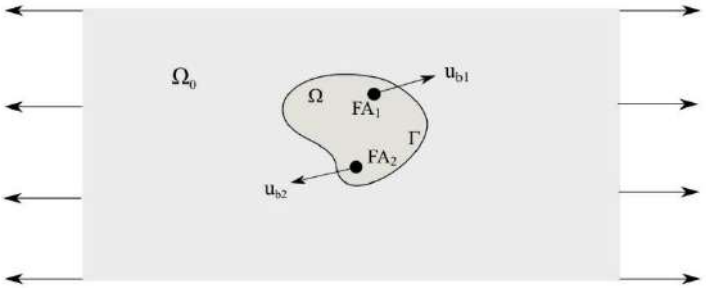

Figure 1: Schematic of cell attached to the background substrate through focal adhesions.

Here in Figure 1, we have a substrate with domain Ω_0 being uniaxially and cyclically stretched, cell with domain Ω and boundary Γ, and two focal adhesions (FA_1 and FA_2) with background displacements u_{b1} and u_{b2} as per the substrate stretching.

Methods

We know that the focal adhesion serves as an interactive interface between cell and substrate to communicate the mechanical changes and transmit the substrate displacement to the cell. As focal adhesion changes its location, the background displacement from substrate to cell also changes and we get different strain energies at different focal adhesion locations. We apply this approach to calculate strain energy exhaustively in the continuum domain of cell. Our interest here is to search for the focal adhesion locations with minimum strain energy.

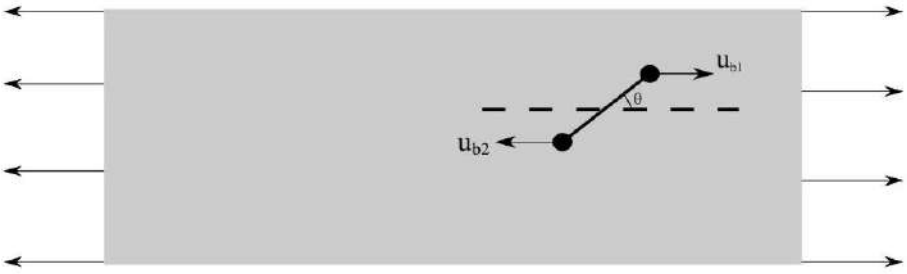

Figure 2: Schematic of stress fiber as dipole with focal adhesion at the end.

We investigate this first for 1D case where we assume stress fiber as a dipole with focal adhesions at the end of it [Figure 2] and calculate strain energy for every orientation of the stress fiber. Strain energy is minimum at 90° orientation angle [Figure 3].

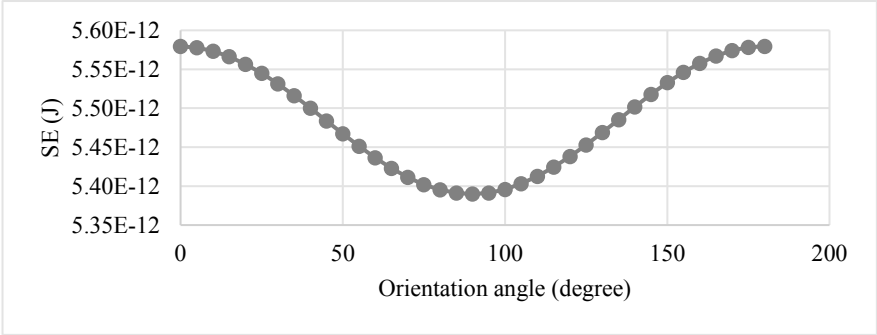

Figure 3: Plot between strain energy and orientation angle of stress fiber.

We use a similar approach to search for focal adhesion location in 2D circular domain with the boundary conditions shown in Figure 1. We found focal adhesions aligning in perpendicular direction relative to the stretch direction [Figure 4].

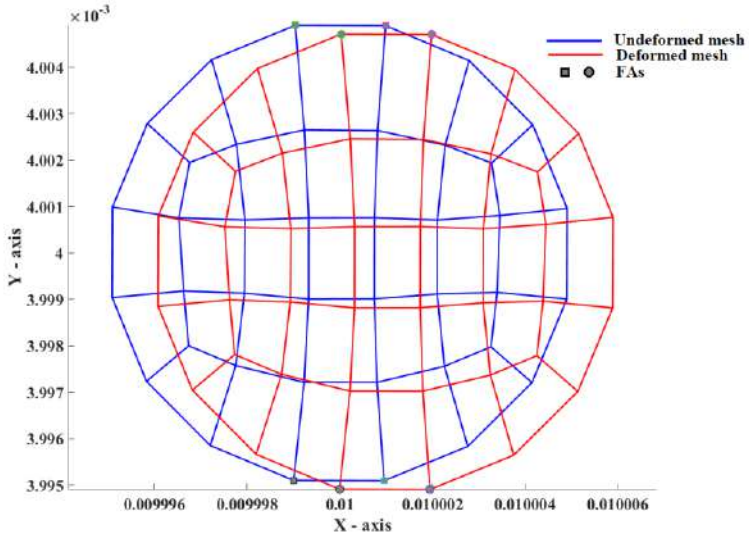

Figure 4: Cell's focal adhesions attaching to the point with minimum strain energy which is the perpendicular direction to the stretched direction.

We use topological derivative to put in more constraint such as focal adhesion area, cell polarity, etc. into our problem. Topological derivative is an analytical approach to measure the sensitivity of the performance functional with respect to an infinitesimal perturbation [7]. In our case, performance functional is strain energy and perturbations in the domain are focal adhesions. Topological derivative (T_D) expression for Dirichlet boundary condition is as follows:

$$T_D = 4\pi E \frac{(1-\nu)}{(1+\nu)(3-4\nu)} \left[\{u(x) - u_b(x)\} \cdot \{u(x) - u_b(x)\} \right]$$

CONTRACTION OF ACTIVE GELS VIA MOLECULAR MOTOR ACTIVITY: A THEORY BASED ON TRANSIENT MICROSTRUCTURAL EVOLUTION

Mattia Bacca, Gwynn J Elfring, Albert Kong, Mehadi Hasan
Department of Mechanical Engineering, University of British Columbia, Vancouver, BC - Canada

Summary Active polymeric gels have been prototyped to recreate cytoskeletal contraction from in-vitro experiments. These gels are composed of a loose polymer network largely swollen by the presence of an aqueous solvent, which includes molecular motors and ATP (adenosine triphosphate). These motors bind to the chains of the polymer and catalyze ATP hydrolysis. Thanks to this reaction they create motion, which results in local polymer chain shortening and the consequent macroscopic contraction. To quantitatively describe this phenomenon, we propose a theory based on *transient microstructural evolution*, where the mechanical properties of the gel, described by chain density and average chain length, are subject to change due to molecular motor activity. We finally compare this theory with experiment and observe good agreement.

Introduction

Cytoskeletal gels are synthetic prototypes that mimic the active contractile behaviour of biological cells [1]. They are composed of a polymer network swollen by the absorption of an aqueous solvent containing molecular motors (MM) and their fuel, ATP (adenosine triphosphate). The mechanical behaviour of the gel is characterized by the stiffness of the polymer network and by the mobility of the solvent molecules inside the network. MM can alter the configuration of the polymer network by pulling its chains, therefore changing the stiffness of the gel. This evolution of the microstructure is transient since the motors will detach from the chains once the tension in the chains is sufficient to overcome the intermolecular bonds between chains and motors. Stiffness evolution is characterized by an evolution of chain density [2] and chain length [3], which then increments the osmotic pressure of the fluid, thereby motivating its flow. This finally creates macroscopic contraction in the gel.

Mechanical theory and results

We take chain density and chain length to be *microstructural variables* in the material. The energetic cost, per unit time and unit volume, p, for a transient evolution of the microstructure in the gel is

$$p = \frac{\partial \psi^{el}}{\partial \xi_i} \dot{\xi}_i \qquad (1)$$

where ψ^{el} is the gel free energy due to network elasticity, ξ_i the i-th microstructural variable, and $\dot{\xi}_i$ its rate of change, per unit time. An evolution of ξ_i increments gel stiffness, which increments its free energy. Gel stiffening therefore only occurs if $p > 0$ and this energetic cost is provided by the MM pulling the polymer chains.

The principal components of the Cauchy stress in the gel, homogenized from the stress sustained by the polymer network and the solvent, are

$$\sigma_i = \frac{NkT}{J}\left(\lambda_i{}^2 - 1\right) - \Pi 3 \qquad (2)$$

where N is the number of chains in the unit volume of the dry polymer (our reference state), before it swells by absorption of solvent molecules, k is Boltzmann's constant, T is the temperature, J is the swelling ratio of the polymer, λ_i is the i-th component of the principal stretch, and Π is the total pressure [2]. In Eq. (2) we describe the elastic behaviour of the gel via neo-Hookean elasticity, which implies the polymer chains are loose inside the gel and therefore in their Gaussian state. If no external loads are applied to the gel, it will only sustain the pressure of the solvent bath in which is embedded, which we call Π^{ext}. Hence $\sigma_i = -\Pi^{ext}$ for all principal directions. This, substituted into Eq. (2), implies $\lambda_i = J^{1/3}$ in all directions. The osmotic pressure in the solvent is therefore $\Pi^{osm} = \Pi - \Pi^{ext}$ with

$$\Pi^{osm} = NkT\left(J^{-1/3} - J^{-1}\right) \qquad (3)$$

This pressure is proportional to the tension sustained by the polymer chains due to swelling by solvent absorption and corresponds to the pressure sustained by the solvent inside the network. As long as the chemical potential of the solvent molecules, proportional to Π^{osm}, is equivalent to the chemical potential of the solvent molecules in the surroundings, the solvent will be in chemical equilibrium, hence will not flow. However, an evolution of the chemical potential can alter chemical equilibrium, *i.e.* when Π^{osm} increments due to an evolution of N, and this can prompt solvent flow. The evolution of N is due to the increment of crosslink density by MM binding to the polymer chains (dynamic crosslinks) and to the reduction of the mean spacing among crosslinks, which can be seen as an increment in chain density. This evolution is transient since the MM are attached to the polymer chains via intermolecular bonds and these will break once the chain will carry sufficient tension to prompt motor detachment. At this point, the microstructure of the gel will recover its initial state until the motors will bind to a new chain and will repeat the process.

Stiffness evolution in the gel can also be described more accurately by considering an evolution of the average chain density, *i.e.* of the average number of monomers n in each polymer chain. Considering again a Gaussian network, the probability associated with the i-th end-to-end chain vector, $\boldsymbol{r}_i$, is described by the function

$$f_n(\boldsymbol{r}_i) = \left(\frac{3}{2\pi 3na^2}\right)^{3/2} \exp\left(-\frac{33\boldsymbol{r}_i\cdot\boldsymbol{r}_i}{23na^2}\right)3 \qquad (4)$$

with a the average length of a chain monomer in the network. The elastic free energy of the Gaussian network is

$$\psi^{el} = -kT3\sum_{i=1}^{N} \ln\left(\frac{f_n(\boldsymbol{r}_i)}{f_{n_0}(\boldsymbol{r}_{0,i})}\right) \qquad (5)$$

with $\boldsymbol{r}_{0,i}$ and n_0 the i-th chain vector and the average number of monomer per chain, respectively, in the reference state. A change in network configuration due to affine deformation via stretching, which components in the principal directions are $\tilde{\lambda}_i$, will generate the stresses at Eq. (2), with $\lambda_i = \tilde{\lambda}_i$, if $n = n_0$, *i.e.* if the average number of monomers in the network is unchanged. Conversely, if $n < n_0$, associated with the shortening of a chain by MM activity, we will have

$$\lambda_i = \tilde{\lambda}_i/\lambda_m \text{ and } J = \tilde{J}/{\lambda_m}^3 \qquad (6)$$

with $\lambda_m = (n/n_0)^{1/2} < 1$ the *micro stretch* of the network due to chain length evolution. From Eq. (6) we can conclude that an evolution of λ_m with $\dot{\lambda}_m < 0$ will increment λ_i and J and result in an increment of Π^{osm} from Eq. (3). This will again create macroscopic contraction as previously discussed for an evolution of N.

Both the evolutions of N and λ_m occur due to energy transduction, as described by Eq. (1) with substitution of ξ_i with these quantities. We considered these two cases separately for simplicity.

In Figure 1*c* we report the results of dynamic contraction by solving the coupled problem of the evolution of N and solvent transport, for the case of uniaxial contraction and compare these results with experiments [1-2]. In Figure 1*d* we show the relation between the mechanical work provided by MM and gel stiffness for an evolution of N and for an evolution of λ_m [3]. Here we analyze two simplified cases for solvent diffusion. Solvent diffusivity $D = 0$, where no solvent flow can occur, and $D = \infty$, where solvent flow is instantaneous with respect to MM activity.

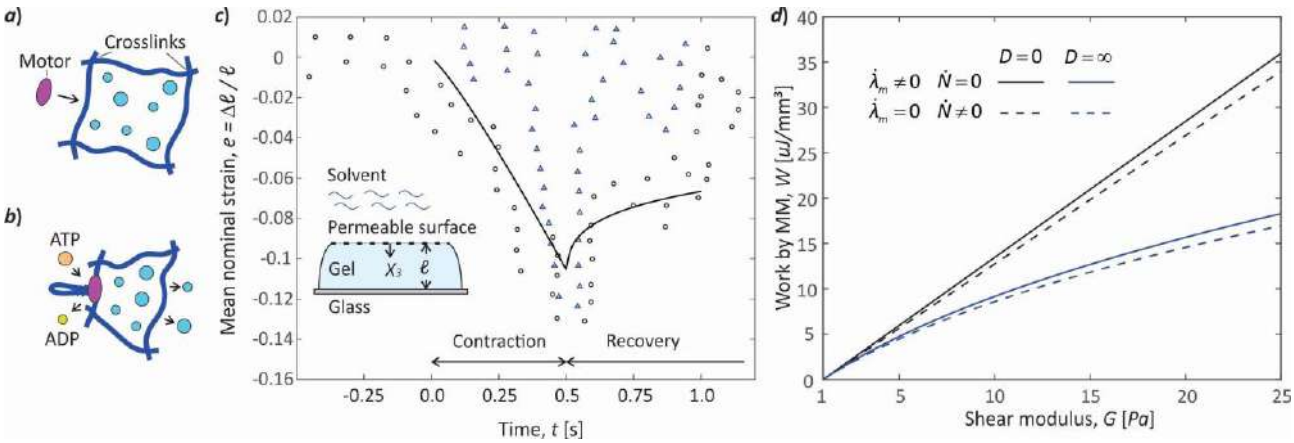

Figure 1: *a*) Gel structure; blue lines indicate the polymer chains while cyan circles indicate solvent molecules; *b*) Molecular motor (MM) activity involving chain shortening via ATP hydrolysis and local expulsion of solvent molecules to accommodate contraction; *c*) Comparison of our theoretical prediction with experiments [1-2]; *d*) Gel shear modulus versus mechanical work by MM [3].

Discussion and conclusions

Our prediction in Figure 1*c* shows good agreement with the experiments during the contraction phase, however, underestimates the rate of recovery. The experimental results are taken from 2 peaks of active contraction [1] since we consider the contraction to be periodic. We also consider all the motors to be synchronized during contraction and recovery (after the motors detach from the chains). This simplification is justified by the assumption of cascade detachment of all motors (see [2] for more details). This model can also be extended to describe the active mechanical behaviour of a real cytoskeleton, by considering the concurrent evolution of N and λ_m. The former can be associated mainly with actin polymerization while the latter can be associated with myosin contraction. In this case, however, Eq. (1) must be divided into two equations describing the energetic contribution of actin polymerization and myosin contraction as distinct phenomena. Figure 1*d* compares both phenomena energetically and can provide a good reference.

COMPUTATIONAL MODELING OF THE EFFECTS OF HEMODYNAMICS ALTERATION ON ANEURYSM GROWTH IN THE ASCENDING THORACIC AORTA

S. Jamaleddin Mousavi[1], Jayendiran Raja[1], Ataollah Ghavamian[1], and Stéphane Avril*[1]
[1]Mines Saint-Etienne, University of Lyon, University Jean Monnet, INSERM, Saint-Etienne, France

Summary In this work, we present a numerical framework combining computational fluid dynamics coupled with arterial growth and remodelling (G&R) to model the adaptation of patient-specific ascending thoracic aortas to altered hemodynamics during aneurysm development. A sensitivity study is conducted on the respective roles of smooth muscle cells (SMCs) and of matrix degradation in the aneurysm fate. Predictions of aneurysm growth and of stiffness evolution are in good agreement with experimental data on the same patient.

INTRODUCTION

The thoracic aorta is complex and susceptible to localized dilation, especially from the root of the ascending aorta to the aortic arch and it is referred to as ascending thoracic aortic aneurysms (ATAAs). Three aetiologies predominate in human ATAAs [1]: (i) genetic causes in heritable familial forms, (ii) an association with bicuspid aortic valves (BAV), and (iii) a sporadic degenerative form linked to the aortic aging process. In condition (ii) related to BAV, hemodynamics is altered and this is believed to induce damage in the aortic wall, the resulting aortic dilation potentially leading to dissection or rupture. In the hemodynamics assumption, changes of the local wall shear stress (WSS) distribution induce a cascade of signalling events leading to arterial weakening and further development of the aneurysm. Several mechanisms were proposed to explain arterial weakening: a first one is an increase in wall permeability leading to transmural advection of plasma proteins which could interact with matrix and cell components and induce elastin degradation; a second one is a decrease of the contractility of smooth muscle cells (SMCs) leading to deficient mechanosensing and mechanoregulation. Our objective is to evaluate these two assumptions in patient-specific models.
Different modeling frameworks were proposed to capture fundamental features of arterial growth and remodelling (G&R) responses to altered hemodynamics based on the constrained mixture theory [2-4]. However, existing models did not consider complex patient-specific geometries of ATAAs and they did not integrate the layer-specific properties in their models to distinguish the media and adventitia layers. Moreover, fluid-solid-growth simulations previously developed by different authors for cerebral or abdominal aneurysms did not fully couple G&R model with hemodynamics. Consequently, the objective of the present work is to fully couple a constrained mixture G&R model of ATAA with a computational fluid dynamics to study the effects of altered hemodynamics on ATAA growth.

MATERIALS AND METHODS

A 3D numerical model based on homogenized constrained mixture theory was implemented in ABAQUS through a coupled UEL to predict anisotropic G&R of arteries [4]. At the Gauss points level, the passive behavior was assumed hyperelastic and a strain energy function (SEF) was assumed for each constituent with decoupled contributions of the purely volumetric and isochoric parts. Although the same SEF was assumed for every element across the geometry of the artery, different material properties and mass fraction were applied at each layer. It was assumed that the arterial wall was composed of a constrained mixture of elastin, collagen fibers and SMC and included the *in situ* internal stresses existing in the reference configuration. Four families of collagen fibers with different mass fractions in the media and adventitia layers in the axial, circumferential and angular directions were considered. The contractility of SMC and turnover of collagen fibers were assumed to be stress-dependent.
Simulations were performed on a bilayer thick-wall geometry reconstructed from the CT scan of patients harboring an ascending thoracic aortic aneurysm (ATAA), subjected to boundary conditions in homeostatic conditions.
Two different mechanisms were considered for the initiation of aneurysm enlargement, namely loss of SMC contractility and elastin proteolytic injury. The regional distribution of these effects was related to local WSS distribution obtained from computer fluid dynamics [5]. Different gain parameters for collagen turnover were considered to account for possible variations of mechanosensitivity.

RESULTS

The G&R response of a patient-specific ATAA to localized elastin degradation is shown in Fig. 1. Due to change in shape, the stress distribution is in continuous adaptation and the largest stress values concentrate at the point of most intense remodelling (Fig 1a) where the WSS peak was located.
For all cases simulated, a transfer of stress was obtained from the media to the adventitia in the damaged region. Moreover, an increase in maximum principal stresses was obtained when increasing the elastin degradation rate. In Fig. 1b, the distribution of collagen mass density shows that most of the collagen was deposited in the media where elastin has been lost (recall that ~97% of the elastin is in media), causing finally a thickening of the arterial wall (Fig. 1c). It is noteworthy

*Corresponding author. E-mail: avril@emse.fr.

that the increase in gain parameter (modelling for instance a larger mechanosensitivity of SMCs or a larger concentration of growth factors) accelerates collagen deposition and consequently wall thickening.

DISCUSSION

Results obtained in this study showed that the typical shape of an ATAA can be obtained in regions of deranged hemodymanics either by localized elastin proteolysis or by localized deficiency of SMC contractility. This is the first time that computational G&R models are coupled with computer fluid dynamics to simulate realistic ATAA evolutions and to study the mechanobiological effects involved in these aortopathies. The most interesting result is that although the effects induced by deranged hemodynamics occur locally in the ATAA around the hotspot of WSS, the whole ATAA globally undergoes G&R due to redistribution of stresses, leading to ATAA dilatation. In our model, G&R is driven by the homeostasis principle, where collagen deposition tends to compensate the elastin loss to maintain stress metrics at constant values despite the change of morphology and composition.

CONCLUSIONS

A robust computational model based on the homogenized constrained mixture theory was presented and its potential was shown to predict ATAA evolution for a patient-specific aortic geometry, leading to results which are in agreement with a follow-up performed on the same patient. Therefore, the present model has the potential for clinical applications to predict G&R of patient-specific geometries and should be applied on a larger number of cases for further validation. The future work will focus on identifying patient-specific values for the rates of elastin loss, collagen deposition and SMC contractility as these parameters directly determine ATAA fate in a patient.

DYNAMIC CHARACTERIZATION OF HUMAN AORTAS TESTED ON A MOCK CIRCULATORY LOOP

Marco Amabili[1], Prabakaran Balasubramanian[1], Isabella Bozzo[2], Ivan D. Breslavsky[1], Giovanni Ferrari[1], Giulio Franchini[1], Francesco Giovanniello[1], and Chloe Pogue[1]

[1]Department of Mechanical Engineering, McGill University, 817 Sherbrooke St. W, Montreal, Quebec, Canada
[2]Faculty of Medicine, McGill University, 3605 de la Montagne, Montreal, Quebec, Canada, H3G 2M1

Summary This study presents the results obtained from eleven human thoracic aortas tested on a mock circulatory loop that was developed to simulate physiological pulsatile conditions. Results showed cyclic axisymmetric diameter changes, which satisfactorily compared to *in-vivo* measurements at a resting heart rate. Additionally, a large reduction of the cyclic diameter change during the heart pulsation at rest and a significant reduction of the energy dissipation was noted with age. Large damping was observed with increased age and at higher pulse rates due to the combined effects of fluid-structure interaction and viscoelasticity of the aortic wall. The findings expand upon new avenues in advanced materials, with the aim of creating mechanically compatible cardiovascular devices.

INTRODUCTION

An escalating interest in cardiovascular surgery is replacing widely used synthetic grafts, like Dacron, with innovative biomaterials or tissue engineering [2], as Dacron fails to correctly mimic the dynamic behaviour of the aorta. This negatively affects the local blood pressure and flow through a large reduction of the Windkessel effect [3-5]. Cardiomyopathies and replacement surgeries may ensue from prolonged usage of synthetic grafts, thus inciting research in understanding aortic tissue behavior to design mechanically compatible grafts [6]. This study aimed to characterize the nonlinear viscoelastic properties and the nonlinear dynamics of human descending thoracic aortas.

METHODS

The aortas of eleven different donors (VI-XXI), 51.5 ± 17.3 years, were obtained from Transplant Québec. All specimens were tested in the MCL within 24 hours to minimize necrosis. A custom MCL was built to study the nonlinear dynamics of human descending thoracic aortas was built including a Harvard Apparatus volumetric pump, expansion chamber, test section, second expansion chamber, pinch valve, atmospheric tank with thermal heater and temperature control. The loop was tuned to accurately reproduce physiological flow and pressure at different pulse rates, covering the full range of physiological heart rates. Four Polytec laser Doppler vibrometers (model OFV 505/PSV 500) equipped with displacement decoders, were installed at 90° to capture the bending and axisymmetric diameter changes at the center of the aorta. These were used to compute the storage modulus and the loss factors. The storage modulus of the aorta, E', was found as: $E' = \frac{3R_i^2 R_e}{2hR_m}\frac{dp}{d\,\Delta d}$, where p is the internal pressure, Δd is the diameter change of the aorta, R_i is the inner radius of the aorta, R_e is the external radius of the aorta, h is the thickness of the wall of the aorta, and R_m is the mean radius of the aortic wall. Then, the loss factor η was obtained by: $\eta = \frac{\Delta W_d}{2\pi W_s} = \frac{A_{inside\ loop}}{\pi(S_1+S_2)}$. The loss factor coincides with the loss tangent in case of linear viscoelasticity. A comparison of the mechanical properties of human descending thoracic aortas to commercial Dacron aortic grafts was also performed with the MCL. A Hemashield Platinum woven double velour straight graft, made by Maquet (model 175428P) for descending thoracic aorta replacement surgeries, with a nominal diameter of 28 mm, was tested in [5] at different pulse rates by using a MCL. The axial pre-stretch was 1.3 and the straight portion without branches was tested.

RESULTS

The correlation between age and the normalized cyclic diameter change, the loss factor, and the storage modulus at 60 bpm is given in Fig. 1. The maximum cyclic diameter change is shown to be inversely correlated with the age of the donor. For the older donors, the diameter exhibited smaller cyclic amplitude changes per pulsation. This result is consistent with *in-vivo* CT images at rest for fourteen individuals, comparing the average diameter change with age [7]. The experimental data obtained fell within the same bounds as [7], confirming that the MCL was capable of reproducing *in-vivo* conditions. The reduction of the diameter expansion with age gave a reduced Windkessel effect in the elderly. The dependence between age and the viscoelastic material properties was evaluated for all the donors. The loss factor was shown to decrease with age, Fig. 1(b), whereas the storage modulus increased, Fig. 1(c). At 60 bpm the loss factor can be mainly attributed to the dissipation by the aorta wall, while the fluid-structure interaction contribution dominated at larger heart rates. The loss factor seemed to show a dependency from the radial expansion of the aorta, such that the material internal damping capacity decreased with age. The larger storage moduli for older donors reflected the development of pathologies causing aortic tissue to stiffen, like atherosclerotic plaque. Increased aortic stiffness has a major effect on pulse pressure, wave reflections, and above all, cardiovascular disease risk [8].

The variation of relative diameter change, the loss factor and the storage modulus with the pulse rate is shown in Figs. 2(a-c). A modest increase in the diameter change (normalized with respect to the external central diameter at 30 mm Hg) is observed in Fig. 2(a) for the two highest pulse rates, 145 and 170 bpm, for all the three age groups, showing that dynamics play a role. From Fig. 2(b), as the pulse rate increased from 60 bpm to 170 bpm, the loss factor values more

*Corresponding author. E-mail: marco.amabili@mcgill.ca

than doubled. This trend impacted the younger donors more than the elder ones. At higher pulse rates the contribution of fluid-structure interaction on the loss factor was larger, and the reduced diameter change during pulsation seemed like the cause of the reduced dissipative effect of the flow for the elder group. On the other hand, the pulse rate had little impact on the storage modulus. As observed in Fig. 2(c), the variation of the storage modulus with increasing pulse rates was negligible. The storage modulus was dependent upon the age of the donors: the younger the donor, the smaller the storage modulus. Therefore, the stiffness of the aortas was intrinsic to the tissue, as the effect of the fluid-structure interaction was negligible in the physiological regime. Instead, a significant change of the storage modulus occurred from static to dynamic conditions. This reaffirmed the importance of a viscoelastic material characterization for the aorta, rather than a purely static one. Figure 2(d) presents the variation of relative diameter change with the pulse rate for the 60-85 years old group of aorta donors, which are the stiffest ones in the present study, versus the two similar Dacron aortic grafts subjected to different axial pre-stretches. The results show a major mismatch between the cyclic expansion of the human aorta for elder humans versus commercial Dacron grafts. This discrepancy is largely magnified for younger age groups, as seen by comparing Fig. 2(a) and Fig. 2(d). Figure 2(c) shows that the storage modulus of the tested human aortas was always below 3 MPa. This reaffirms that Dacron grafts are much stiffer in circumferential direction as compared to human aortas. Therefore, Dacron grafts provided no Windkessel effect, and altered the nonlinear dynamics of the aorta and the flow.

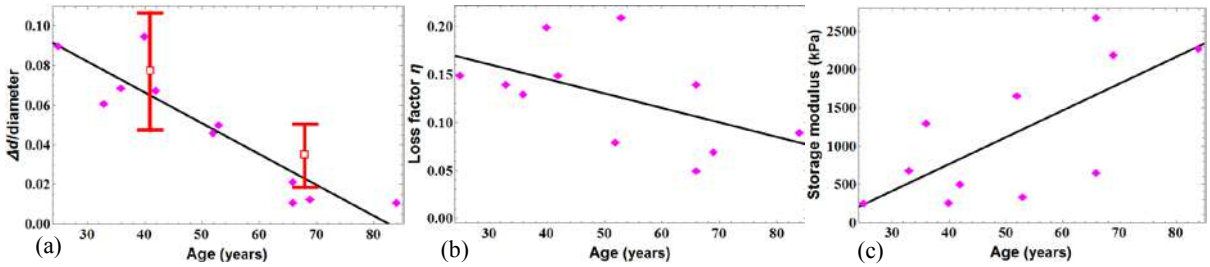

Figure 1. Correlation for cyclic diameter change and viscoelastic parameters with age at 60 bpm, for the eleven donors: (a) maximum diameter change at 60 bpm pulse rate normalized with respect to the diameter (Δd/diameter, experimental points ♦) with linear regression. The data was obtained as the average of diameter changes at the proximal and distal extremities of thoracic descending aortas from *in-vivo* CT images [7]; average values and standard deviations for two age groups of seven individuals each are given (two red error bars). (b) Loss factors with linear regression. (c) Storage modulus with linear regression.

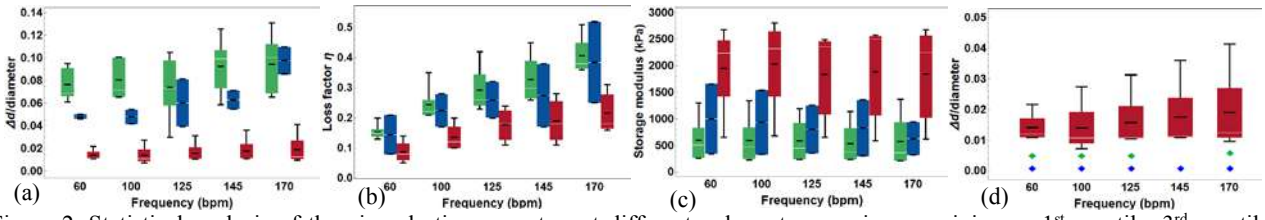

Figure 2. Statistical analysis of the viscoelastic parameters at different pulse rates; maximum, minimum, 1st quartile, 3rd quartile, average (black horizontal line inside the box) and median (white horizonal line in the box) are reported for 3 age groups, ——, 25-44 years old; ——, 45-59 years old; ——, 60-85 years old: (a) maximum relative diameter change; (b) loss factor; (c) storage modulus. (d) Comparison of the maximum relative diameter change for human aortas within the 60-85 years age group and woven Dacron aortic grafts at different pulse rates. ——, statistical analysis of the data for human aortas for the 60-85 years group; ♦, Dacron graft tested in [5] with an axial pre-stretch of 1.3; ♦, Dacron graft tested by the present authors with an axial pre-stretch of 1.33.

CONCLUSIONS

The aims of the experiment were successfully met: the viscoelastic material parameters for the human descending thoracic aorta were identified by using a MCL specifically conceived to reproduce physiological pulsatile flow. The dependency of the loss factor from age was never observed before. The dynamics and the material properties of the aorta obtained from these experiments are essential for advancing cardiovascular medical device designs and improving surgical outcomes [9].

COMPUTATIONAL MODELLING OF THE MECHANICAL BEHAVIOUR OF TURTLE SHELLS

Benjamin Alheit*[1], B. Daya Reddy[2], and Swantje Bargmann[3]
[1]Department of Mechanical Engineering, University of Cape Town, Cape Town, South Africa
[2]Department of Mathematics and Applied Mathematics, University of Cape Town, Cape Town, South Africa
[3]Department of Mechanical Engineering, University of Wuppertal, Wuppertal, Germany

Summary The turtle shell is a highly effective bio-composite, with the sutures between adjacent plates playing a significant role. This work presents results of a computational investigation of the behaviour and influence of sutures having a geometry and material properties representative of that in turtle sutures. Both hyperelastic and viscoelastic behaviour are considered. Results presented here are in relation to the response to indentation of the shell; further results will focus on oscillatory and impact loading, the effects of viscoelastic modelling, and the effects of different fibre alignments.

INTRODUCTION

The turtle (or tortoise) shell exhibits impressive mechanical performance as a protective structure. As a result, there is interest in gaining an understanding of the geometrical and material features that enable tortoise shells to carry and distribute loading efficiently, with a view to assessing their feasibility as candidates for biomimetic design. Of particular interest are the sutures of interdigitating protrusions between adjacent ribs. As shown in Figure 1, these bone protrusions are bound together by a soft collagenous tissue, which also serves as a skin over the skeleton and is, in turn, coated by a hard keratinous tissue.

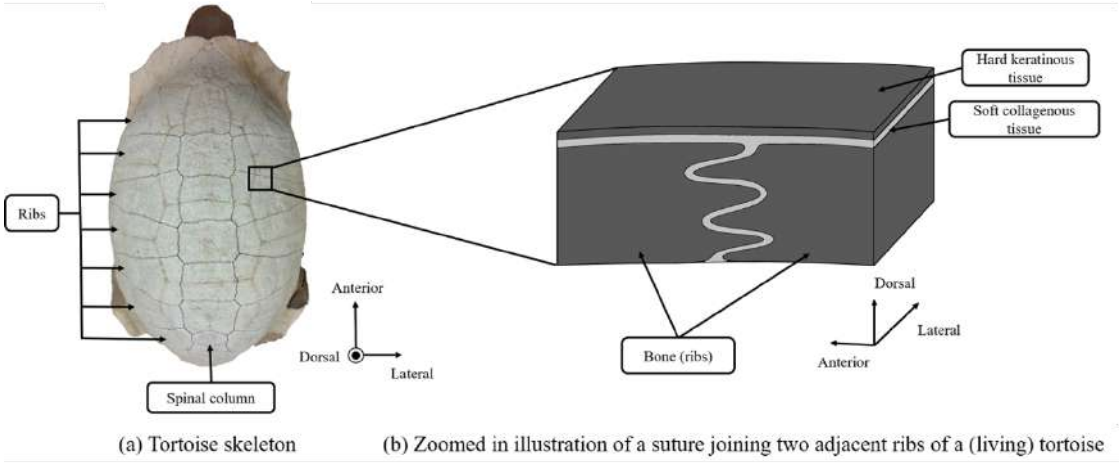

Figure 1: Display of the structure of a tortoise shell.

Numerous mechanical tests have been carried out on turtle shells to elucidate aspects of their properties. However, to the best of the authors' knowledge, there have been no detailed theoretical and computational studies of the mechanics of turtle shells, nor in particular of the role played by sutures in optimizing shell behaviour.

The aim of this work is to undertake a study of the mechanical behaviour of sutures, as components in a heterogeneous structure. For this purpose the model studied comprises a single interdigitated suture, located in a surrounding homogeneous bony structure, and with a geometry representative of that found in turtle shells. The response of the heterogenous structure to both static and dynamic loading are studied, using constitutive models appropriate to the relevant materials.

THE MODELS

The geometry is based on parameters such as protrusion length, soft tissue thickness, and degree of interdigitation, and is generated using the ABAQUS Python Application Programming Interface (API). A finite element mesh is then generated, using tetrahedral elements with piecewise quadratic approximation. The skin and hard keratinous tissue are modelled using triangular shell-type elements with piecewise quadratic approximation generated by copying the upper face of the base mesh. The resulting geometry and mesh are shown in Figure 2. Spring-type conditions are applied at relevant boundaries to account for adjacent material.

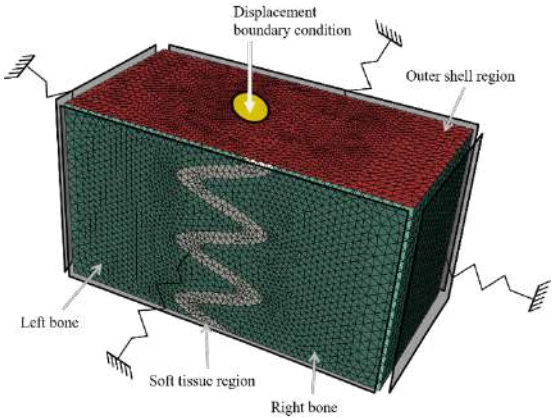

Figure 2: Diagram of ABAQUS model.

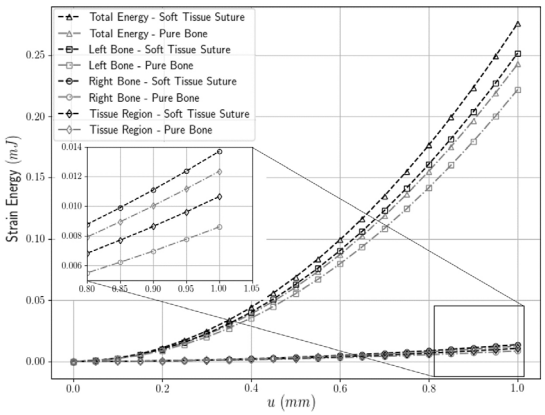

Figure 3: Strain energy vs indent displacement

Two material models are developed for the suture. The first, in which the material is assumed to be transversely isotropic and hyperelastic, is based on a model originally developed with reference to vascular structures [2], and the material constants are determined by means of nonlinear least squares fits to test data [1, 3]. The second is an extension of the hyperelastic model to make provision for viscoelastic behaviour.

It has been found that the fibres in the soft tissue of sutures tend to arrange themselves so that they are loaded in tension [4]. This is replicated by first running a setup simulation assuming isotropy. Another simulation is then run, with the degree of anisotropy set to the optimal value determined by the non-linear least squares fit. The fibre direction at each integration point is then set to be in the direction of the maximum principal stretch of the prior setup simulation.

The bone and hard keratinous tissue are modelled as linear elastic with material constants found from the literature [1].

SOME RESULTS

The results of various simulations, intended to replicate particular scenarios such as impact, oscillatory motion, or a predator attack, are presented. An example, given here, pertains to quasistatic indentation of a small region to represent the tooth of a predator. Figure 3 shows curves of strain energy against indentation, and gives an indication of the energy-absorbing ability of the suture, by comparing with results obtained for a pure bone model. It is observed that the energy-absorbing ability of the suture is due to a greater dispersion of stress throughout the suture region relative to the pure bone model.

Figure 4 shows that defining the fibre directions as described above does indeed lead to stretching of the fibres throughout the soft tissue.

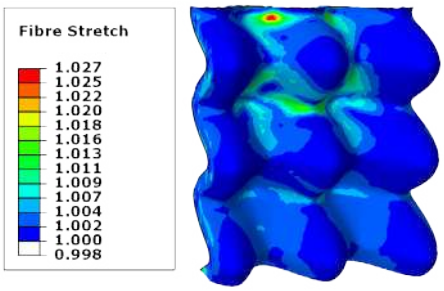

Figure 4: Fibre stretch during quasi-static indentation loading.

Further details in the presentation will include the results of investigations under conditions of oscillatory and impact loading, the effects of viscoelastic modelling, and the effects of different fibre alignments.

MECHANO-CHEMISTRY OF ACTIVE SWELLING IN HYBRID GELS

Horacio Lopez Menendez *[1] and Francisco Monroy[1]
[1]Physical Chemistry Department, Complutense University of Madrid

Summary The fabrication of mechano-active hydrogels is dependent on the potency of internal actuators to exert localized stresses inside the polymer network. We describe a novel hybrid class of mechano-active extensile matter, based on a soft polycramide hydrogel matrix driven by the action of FtsZ, a genuine prokaryote cytokinetic protein able to form living filaments. Interestingly we found that after the GTP activation, the FtsZ filaments unexpectedly the pores of the microstructure soften and fluidize, showing an extensibility that enhances with protein concentration. Here we propose a theoretical model for the active hybrid gel where we consider that the active swelling effect is a consequence of the interplay between a mechanical instability, chemically promoted by the fluidization of the gel, due to the activation/polymerization of the FtsZ and the osmotic pressure.

INTRODUCTION

Mechano-active gels represents a new type of internally-driven active matter. Success in the fabrication of mechano-active hydrogels is dependent on the potency of internal actuators to exert localized stresses inside the polymer network. Often, nature uses reversibly polymerizing filaments fueled by metabolic energy, also named living polymers, as powerful molecular actuators to produce forces at different biological scales. We describe a novel hybrid class of mechano-active extensile matter, based on a soft polycramide hydrogel matrix driven by the action of FtsZ, a genuine prokaryote cytokinetic protein able to form living filaments. The FtsZ, is a cytoskeletal protein found in all bacteria, which assembles as dynamical filaments into a cytokinetic ring at the membrane during bacteria division by contributing to generate the force needed for membrane constriction. The FtsZ monomers can bundle together for strength and flexibility, but that can also reversibly depolymerize in a dynamical balance driven by the extent of GTP hydrolysis. This reversible polymerization, or living polymerization of FtsZ, happens under the hydrolysis of one GTP molecule by every FtsZ monomer bounded, requires the presence of Mg2+ as a catalyst, and occurs only above a critical concentration of the monomer [1]. Once the activation of the FtsZ filaments takes place the hybrid hydrogel fluidize, showing an extensibility that enhances with protein concentration. These new mechano-active metamaterials clearly can open an avenue of innovative applications in smart drug delivery and regenerative medicine, showing also promise in emerging fields such as soft robotics, and bionics.

Interestingly we found that after the GTP activation, the FtsZ filaments unexpectedly the pores of the microstructure soften and fluidize, showing an extensibility that enhances with protein concentration. In addition, to better understand the underlying mechanism rheological experiments the behavior of the passive gel in comparison with the hybrid gel with and without GTP activation, we found that the passive becomes stiffer as much as the concentration of FtsZ increases, but during the activation fluidize the structure towards values below the stiffness of the passive gel. Here we propose a theoretical model for the active hybrid gel where we consider that the active swelling effect is a consequence of the interplay between a mechanical instability, chemically promoted by the fluidization of the gel, due to the activation/polymerization of the FtsZ and the osmotic pressure.

THEORETICAL MODEL

In a first approximation we consider a Helmholtz free energy as follows:

$$\Psi(\mathbf{C},\Gamma,c) = \Psi_{mech}(\bar{\mathbf{C}},\Gamma) + \Psi_{mix}(\bar{\mathbf{C}},J) + \Psi_{int}(\chi,\Gamma) + \Psi_{chem}(\chi) + U(J), \tag{1}$$

This function accounts the elastic strain energy function associated with the elasticity of the hybrid gel, where its mechanical strain deformation is described by the Cauchy-Green tensor $\mathbf{C}$. The swelling effect is described by the energy Ψ_{mix} following the Flory-Rehner formalism. Also, an energy term associated with the interaction between passive and active components which is proportional to the chemical potential that allow us to define an interaction parameter (Γ). Finally the chemical energy associated with the active components and the volumetric part.

We describe the expansion effect produced by the hybrid gel as a mechanical instability induced by the activation of the FtsZ produced by the rise of the chemical potential above the critical value. Under these conditions the shells that made the pores of the hydrogel achieve a metastable state by which undergoes an expansion in a similar manner as during the inflation of a rubber ballon [3].

In order to capture the typical non-monotonic response we propose a model that takes as a starting point a neo-hookean elastic strain energy function where the stiffness scale as $G \sim Nk_BT$. Nevertheless, in this case we split $N = m + n$ where m describe the number of chains that contribute with the passive response and n the number of chains that soften due to the activation of the FtsZ. As $m > n$ due to the hybrid gel do not collapse the resultant response manifest a metastable response that allow to define a phase diagram showing a spinodal regime. The way in which we describe the functional form of N is described in the figure (see $[2-4]$ for details).

*Corresponding authors. E-mail: holopez@ucm.es; monroy@quim.ucm.es

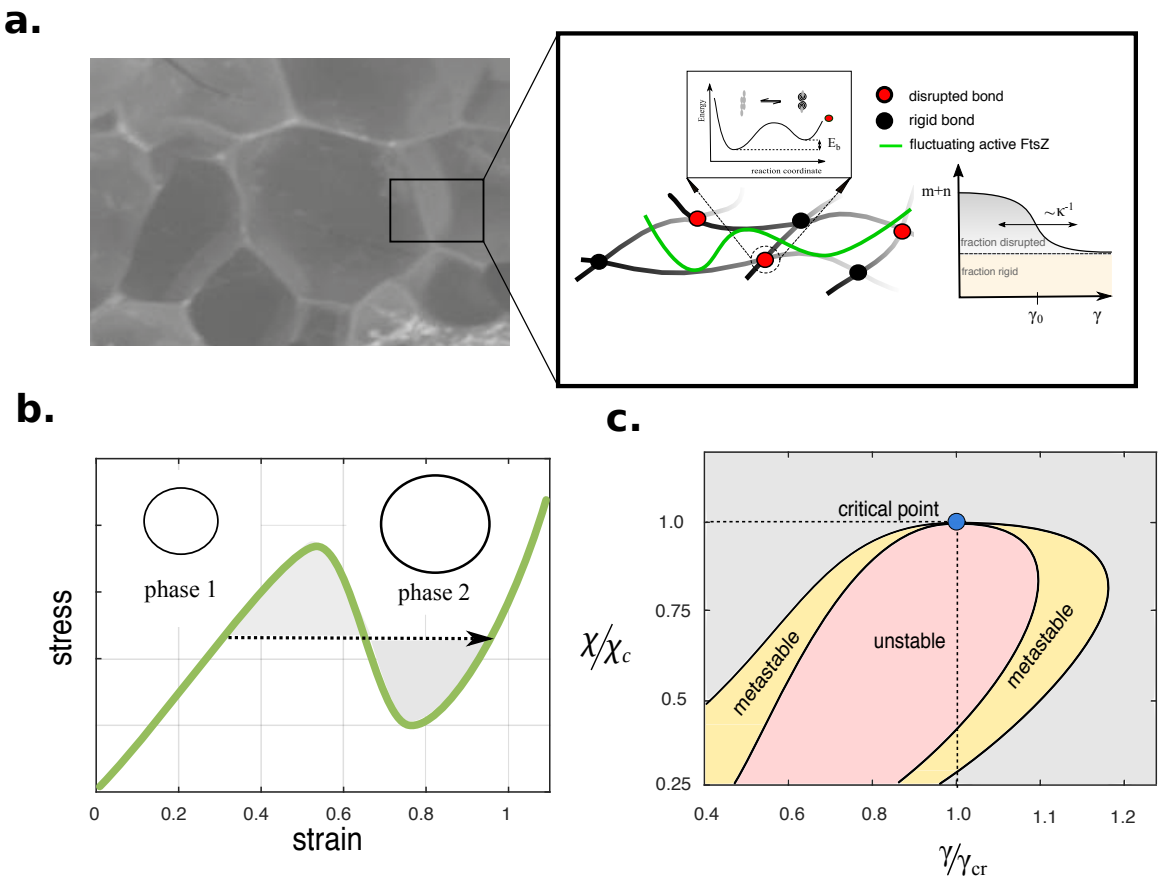

Figure 1: a. Cartoon describing the interaction between the passive and active polymers. b. Stress-strain relation that show the softerning-stiffening instability c. Phase diagram showing the spinodal region.

In addition we defines an interaction energy following the formalism of Landau for phenomenological phase transition where the interaction parameter emerge from a double well potential expressed as $\Psi_{int} \sim \alpha(\chi - \chi_{cr})\Gamma^2 + \beta\Gamma^4$. The model is able to capture the sort of interaction of stiffening or softening depending the activation or not of the living polymer is described by using concepts of phase transition, where we define an interaction parameter Γ that depends of a chemical potential χ that weights the level of GTP and the ratio of concentration between FtsZ and the passive gel. For values of $\chi < \chi_{cr}$ the living polymer is not active enough and the interaction between the two polymers increase the level of gelation and its stiffness increase, and the interaction parameter $\Gamma(\chi) > 0$. But once $\chi > \chi_{cr}$ the activation of the FtsZ is higher enough to allow the fluidization of the passive gel, the interaction parameter $\Gamma(\chi) > 0$ and the stiffness of the hybrid gel suddenly falls.

The characteristic time for the expansion involves the combination of at least to process that scale apparently in the same order. On the one hand the swelling time $\tau_{poroel} \sim L^2/D$ defined by the water permeation across the gel, where L is in the order of the radius and D is the poroelastic diffusion that depends of the solvent viscosity and the effective mesh-size. On the other hand the remodeling time that seems to be plausible to scale according with the reptation time τ_{rep} (if we consider that the chemical dynamics is very fast). In order to simplify the model at this stage we consider that $\tau_{proel} \sim \tau_{rep}$ and in this way we can describe the measurements for $G'(\omega, \Gamma; \chi)$ and $G''(\omega, \Gamma; \chi)$.

By considering the the associated energy terms and its time evolution we obtain the stress tensor and we can describe the ways to control the swelling dynamics of this novel hybrid biomaterial where soft and living matter meets.

PATIENT-SPECIFIC FEM/FBEM-BASED EVALUATION OF PERIPROSTHETIC FEMUR FRACTURE RISK IN TOTAL HIP ARTHROPLASTY

R. Zona*[1], L. Esposito[1], , P. Ferla[1], E. Ruocco[1], S. Palladino[1], E. Totaro[1] and V. Minutolo[1]
[1]Department of Engineering, Università della Campania "L. Vanvitelli", Aversa, Italy

Summary Total hip arthroplasty is one of the most used and successful orthopaedic surgeries. The incidence of intraoperative periprosthetic femur fractures in the case of cementless prosthesis, however rare they are, lead to revision surgery with high rates of morbidity and mortality. The study aims to support surgeons in the THA pre-operative decision making process, avoiding early perioperative fractures, by means of a numerical forecast of the effect of the implant on the surrounding bone tissue based on Field Boundary Element Method. The applied method has taken into account the variability of the mechanical properties of the spongy bone. The obtained results, expressed in terms of colour flag maps, provide a first aid tool to the surgeon for the assessment of intra-operative femur fracture risk.

ABSTRACT

Total hip arthroplasty (THA) is one of the most successful orthopedic procedures with effective results in terms of durability and improvement in the quality of life [1]. However, perioperative periprosthetic femur fractures (PPFs) after THA present high rates of morbidity and mortality and often seem to go unreported or unrecognized [2].
Typically, when a cementless stem is implanted, the fracture events occur during femoral canal broaching or implant insertion while trying to obtain a tight press fit [3]. Cracks in the proximal femur due to press-fit stem implantation are often recognized only after surgery when patients already have started to mechanically load their prosthesis [4]. Summing up, surgeons rely mainly on their experience without the support of quantitative measures for guiding their making-decision process, that is, "older and less-healthy" patients receive cemented implants while for "younger and healthier" are preferred un-cemented prostheses.
Hence, this study aims to pursue fracture risk maps [5,6], so to help the medical decision-making process, in particular with respect to the choice of adopting cemented or cementless implant. The numerical model is based on the 2D-Field Boundary Elements Method that is a procedure able to calculate heterogeneous elastic materials by means of boundary elements and field equations arising from heterogeneity [7]. The femur cross sections have been considered and approximated as circular Functionally Graded Material annuli, see Figure 1. The applied strategy allows highlighting the zones most subject to high stress and strain within patient-specific femur sections.
The evaluation of resistance is possible even by using a novel fem strategy based on discontinuous FEM calculation.
With this strategy, one can evaluate the stress state of a solid, in this case a human femur modeled as a poro-elastic material, using the maximum dissipation of strain energy theorems.
The results are resumed into maps (Figure 2) of fracture risk zones, expressed in term of traffic lights color code. The code consists of the comparison between the calculated actual strain and bone-dependent strain thresholds. The final result represents a tool for the surgeons to assess intra-operative femur fracture risk due to cementless implant.

FEM ANALYSIS OF A DENTAL ARC WITH PERIODONTAL TEMPORARY RIGID SPLINT

L. Esposito[1], R. Zona*[1], P. Ferla[1], M. Musilli,G. Paolantoni and V. Minutolo[1]
[1]Department of Engineering, Università della Campania "L. Vanvitelli", Aversa, Italy

Summary In patients with periodontitis, in addition to satellite pathologies of inflammation, one of the consequences is increased teeth mobility. In this study, in order to practice a methodology for the treatment of periodontitis, a non-prosthetic device, a Periodontal Temporary Rigid Splint (PTR Splint), is tested. The proposed approach is aimed to reach the best shape of the device, the optimal material behaviour and the best adhesion to withstand stress and help patients to improve the prognosis and success of the therapy. Numerical analyses have been conducted through FEM simulation that takes place through a model of the dental arc, of the device and the adhesive material, reading results in terms of stress between the components and the displacements of the teeth under physiological loads.

ABSTRACT

Periodontal disease is considered an infectious pathology caused by the alteration of the balance between a predisposed host and bacterial factors present in the dental plaque. [1,2]. As a result of the inflammatory process, there is a disorganization of the periodontal fibres, destruction of the epithelial cells near the mesenchyme and ultimately the induction of bone resorption.

Occlusal forces also play an important role because they can exacerbate a pre-existing periodontal injury when they exceed the compromised resistance threshold of the system tooth - periodontal ligament – gingiva [3], affecting both the normal functioning of the microcirculation and the composition of the saprophytic microbiome, in opportunistic bacterial species more pathogenic [4].

In the presence of an anomalous load due to intensity and/or frequency, the time for adaptation of the periodontium may not be sufficient, and therefore give rise to a rearrangement of the deep support [5]. In the presence of a reduced periodontal link (rehabilitated or inflamed), it can result in increased migration and/or mobility of the teeth which consequently can increase the risk of creating altered occlusal relationships that hinder the normal trophism of the periodontal, the homeostasis between resorption and bone remodelling [6] and finally the reorganization of periodontal fibres [3].

Excessive mobility can also hinder the outcome of the periodontal therapeutic course in all the phases that make it up:

-in the Non-Surgical Periodontal Therapy (NSPT) phase it can hinder the normal performance of the patient's home hygiene manoeuvres, and alters the clot's stability during the early stages of wound healing induced by the above and below gingival debridement [7- 8];

- in regenerative therapy (GTR) and in its stages of organization of the clot that composes it, it does not allow the formation of a new link, by favouring the formation of an epithelial link less performing than the connective one [9,10].

Therefore, the treatment of tooth mobility in periodontal patients becomes essential to improve the prognosis and non-prosthetic devices which this mobility can be reduced with. A possible approach to this aim is the dental splinting.

The procedure known as dental splinting is used to treat teeth with increased mobility, by joining them together. The splint stabilizes teeth so that they are less likely to move, which can weaken teeth and cause them to loosen or even fall. It may be used for temporary stabilization of loose teeth, or to address ongoing issues.

In this study, a Periodontal Temporary Rigid Splint (PTR Splint), which has the function of compensating for periodontal problems in the treatment and healing phase, was FE modelled. The PTR Splint consists of a titanium bar glued to the 6 front teeth: 4 incisors and 2 canines. The FEM modelling involves the analysis of three bodies: titanium bar, glue and teeth., as shown in Figure 1. The three bodies are to be understood as sub-structures of a single overall structure which is the splinted dental arc.

The study is aimed at analysing the system in terms of absolute and relative displacements measured at the base of the teeth. A parametric elastic-linear analysis has been performed, as the dimensions of the splint, as the characteristics of the glue vary. As a result, the differences between the displacements induced by the loads in the presence and absence of the splint, as well as the stress at the interface between teeth and splint, have been evaluated.

The main objective of the present study consisted of the evaluation of the optimization of the shape of the splint to obtain the optimal stress distribution, in the splint-glue and glue-teeth interfaces, and minimal displacements of teeth over their support.

SIZE-DEPENDENT TEMPERATURE EFFECT ON VIRAL DNA'S STIFFNESS

Cheng-Yin Zhang[1,2] and Neng-Hui Zhang*[1,2]
[1]School Mechanics and Engineering Science, Shanghai University, Shanghai 200444, China
[2]Shanghai Key Laboratory of Mechanics in Energy Engineering, Shanghai Institute of Applied Mathematics and Mechanics, Shanghai 200027, China

Summary The mobility of the packaged DNA is indispensable for virus infections. The paper is aimed to respond to a recent controversy on temperature-dependent mobility of viral DNA found in single-molecule experiments. We present a multi-scale correlation between the macroscopic stiffness of viral DNA and its microscopic structure, which is characterized by an alternative two-zone structural model with the temperature-dependency. Our model shows that thermal rise can enlarge the interchain spacing, which leads to the increase of the disordered zone volume, and these changes in DNA structure reduce its energy density accompanied with the weakness of its macroscopic stiffness. In addition, the size of the viral or phage capsid will impact the efficiency of temperature effect.

INTRODUCTION

Accompanied with deep insights into structural biology of proteins and nucleic acids related to gene regulation, delicate experiments by single molecule or other biophysics techniques have been carried out to probe the mechanical properties or dynamic processes of viruses and their genes. Typical activities of viruses are often associated with temperature variation. By using AFM to measure the stiffness of the packaged DNA of herpes simplex virus type 1 (HSV-1) and phage λ at a given temperature range, Evilevitch et al. found that the increasing temperatures resulted in a decline of the stiffness of the packaged DNA, especially at temperatures close to that of viral infection (37 °C) [1, 2]. Simultaneously, the area of the DNA scattering peak by small angle X-ray scattering (SAXS) undergoes a prominent decrease with the increasing temperature, which suggests a remarkable structural transition of the packaged DNA in capsid [1, 2]. Livolant et al. repeated the SAXS experiments on four bacteriophages, T5, λ, T7, and Φ29, however did not observe any significant evolution of the scattering area in the temperature range of 20−40℃, so they suggested the reconsideration of temperature effect on DNA organization [3]. In this paper, we aim to quantitatively reveal a multi-scale theoretical correlation between temperature-dependent microstructure and the resultant macroscopic stiffness of the packaged DNA in virus, thereout to elucidate the controversy in the academic community of virus.

MATHEMATICAL MODEL

First, different from the classical single inverse spool model [4], a two-zone model of packaged DNA structure is developed. In response to two distinct regions revealed in the cryo-EM experimental images, here the two zones, respectively, are termed as the ordered zone and disordered zone as shown in the inset of Fig. 1., which statistically represent different liquid crystal phases of the packaged DNA. This two-zone structural model can be described in terms of three undetermined structural variables: DNA length in the ordered zone L_{ord}, interchain spacing in the ordered zone d_{ord} and that in the disordered zone d_{dis}. The minimum energy theorem is applied to determine the microscopic structural variables in the ordered and disordered zones of viral DNA:

$$\frac{\partial(E_{\mathrm{ord}}(d_{\mathrm{ord}},d_{\mathrm{dis}},L_{\mathrm{ord}})+E_{\mathrm{dis}}(d_{\mathrm{ord}},d_{\mathrm{dis}},L_{\mathrm{ord}}))}{\partial(d_{\mathrm{ord}}\ \text{or}\ d_{\mathrm{ord}}\ \text{or}\ L_{\mathrm{ord}})}=0\cdot \tag{1}$$

Second, the energy model of viral DNA is expressed in terms of three structural parameters. Parsegian's mesoscopic potential energy model of DNA liquid crystals [5] is updated by using temperate-dependent persistence length of DNA chain and temperate-dependent Debye length of salt solution. The energy stored in the respective zone includes the interactional energy [5] and the elastic bending energy [4], expressed as

$$E_{\mathrm{ord}}=(G_0-\sqrt{3}A(\lambda_{\mathrm{A}}^2+\lambda_{\mathrm{A}}d_{\mathrm{ord}})e^{-d_{\mathrm{ord}}/\lambda_{\mathrm{A}}})L_{\mathrm{ord}}+\frac{2\pi k_{\mathrm{c}}}{\sqrt{3}d_{\mathrm{ord}}}f(L_{\mathrm{ord}},d_{\mathrm{ord}}),$$

$$E_{\mathrm{dis}}=(G_0+ck_BT\frac{\pi^{5/2}}{20\pi\sqrt{3}}k_{\mathrm{c}}^{-1/4}\sqrt[4]{\frac{\partial^2G_0}{\partial^2d_{\mathrm{dis}}}-\frac{1}{d_{\mathrm{dis}}}\frac{\partial G_0}{\partial d_{\mathrm{dis}}}})(L-L_{\mathrm{ord}})+\frac{2\pi k_{\mathrm{c}}}{\sqrt{3}d_{\mathrm{dis}}}f(L_{\mathrm{dis}},d_{\mathrm{dis}}),\tag{2}$$

$$G_0(d)=a\sqrt{\frac{\pi}{2}}\frac{e^{-d/\lambda_{\mathrm{H}}}}{\sqrt{d/\lambda_{\mathrm{H}}}}+b\sqrt{\frac{\pi}{2}}\frac{e^{-d/\lambda_{\mathrm{D}}}}{\sqrt{d/\lambda_{\mathrm{D}}}},$$

where the coefficients a, b, A are the hydrated, electrostatic and attractive amplitude coefficients, respectively, λ_{D} is the Debye length, λ_{H} and λ_{A} are the hydrated length and attractive decay length, respectively, $k_{\mathrm{c}}=\xi_{\mathrm{p}}k_{\mathrm{B}}T$ is the intrinsic bending stiffness of DNA, in which ξ_{p} is the persistence length of DNA, k_{B} is the Boltzmann constant, T is the environmental temperature. Note that the temperature as an external conditional variable is introduced via a modified persistence length of DNA and the Debye length of the solution.

*Corresponding author. E-mail: nhzhang@shu.edu.cn.

Finally, the stiffness caused by the confined DNA is obtained in terms of the above-mentioned DNA structural variables. The stiffness caused by DNA in capsid is contributed by two parts: the osmotic pressure and DNA bending elasticity energy, i.e.

$$k_{\mathrm{DNA}} = \Pi_{\mathrm{osmotic}} \frac{\pi R_{\mathrm{capsid}}}{2} + G_{\mathrm{bend}} \frac{\pi R_{\mathrm{capsid}}}{2}, \quad \Pi_{\mathrm{osmotic}} = \frac{\partial (E_{\mathrm{int\,chain}} / L)}{\sqrt{3} d \partial d}, \quad G_{\mathrm{bend}} = \frac{E_{\mathrm{bend}}}{V_{\mathrm{DNA}}}, \tag{3}$$

in which Π_{osmotic} is the osmotic pressure derived from DNA energy and G_{bend} is DNA elastic bending energy density.

NUMERICAL RESULTS

In computation, the parameters are taken as follows [6]: R_{capsid} = 47 nm, L_{DNA} = 51500 nm for HSV-1 , R_{capsid} = 29 nm, L_{DNA} = 16500 nm for λ phage and R_{capsid} = 22 nm, L_{DNA} = 14960 nm for T7 phage, $a = 1.1 \times 10^{-7}$ J/m, λ_{H} = 2.88 Å, $b = 0.41 \times 10^{-9}$ J/m, c = 0.8, A = 300005.168 J/m, λ_{A} = 4.8 Å, and the temperature rises from 298 K to 314 K. Substituting these parameters into Eqs. (1) and Eq. (2) yields the structural variables, then the two-zone volume ratio $V_{\mathrm{ord}}/V_{\mathrm{dis}}$ is calculated in Fig. 1 to reflect the global change of DNA structure. Obviously, the volume of the ordered zone in a larger capsid decrease dramatically than that in a smaller capsid. Because the virus with a larger capsid allow more space to fluctuate DNA structure when temperature rises. It's the size effect make previous researchers see different responses for viruses with different sizes [1−3]. Note that the size effect not only means capsid size, but also means DNA size, and they are in a complex coupling relationship. After determining structural variables, the stiffness change of the confined DNA is obtained from Eq. (3) as shown in Fig. 2, the results show that the stiffnesses of three viral DNAs decrease consistently as temperature rises, the downward trends agree well with the experiment [1]. However, the stiffness change of HSV-1 decreased more remarkably than the others. The difference of temperature-dependent stiffness for different viruses or phages is attributed to size effect on DNA structure.

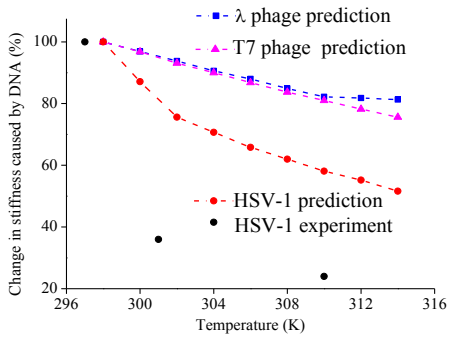

Fig. 2. Variation of DNA stiffness with temperature for three viruses (phages)

CONCLUSIONS

A two-zone structural model of viral DNA is presented in this paper to reveal a multi-scale correlation between temperature-dependent microscopic structure and the resultant macroscopic stiffness of viral DNA. The results show that the size effect makes the complex dependency of the macroscopic stiffness of viral DNA on temperature variation. In other words, we elucidate the controversy in previous literatures by our multi-scale model.

AN EFFECTIVE PREDICTION FACTORS FOR DIAGNOSIS OF THE VERTEBRAL COLUMN PATHOLOGIES USING DATA MINING CLASSIFICATION TECHNIQUE

Malgorzata Zdrodowska*[1], and Agnieszka Dardzinska [1]
[1]Institute of Biomedical Engineering, Bialystok University of Technology, Bialystok, Poland

Summary Knowledge Discovery in Databases (KDD) is the process of discovering useful knowledge from a collection of data. The major phase of KDD process is Data Mining, which use the proper algorithm for finding dependencies and schemas in the prepared data set. Data mining techniques are developing very quickly and are more often used not only in typical fields such as customer relationship or management, but also in medicine, biomechanics, industry, materials sciences or mechanical engineering. The paper presents the use of data mining in biomechanics. The study analyzed the data of 310 patients using five known classification algorithms, which allowed to build an exploration model given with an accuracy of over 87%. Potential features of the occurrence of disk hernia and spondylolisthesis are also pointed out.

INTRODUCTION

Data Mining uses many different techniques that build specific types of knowledge. Depending on the purpose of the discovered knowledge, it can map classifications, regressions, clustering, characteristics, discrimination, associations, etc. The most popular Data Mining technique is classification. Classification is techniques that maps the data into the predefined classes and groups. It is used to predict group membership for data instances. There are many areas that adapt data mining techniques. For example, in the medical database, we found the rules that classify individual diseases, and then the diagnosing of subsequent patients can be carried out automatically using the found rules [1,3].

Due to the development of data mining techniques, it will achieve higher and higher popularity - not only in the typical areas (customer relationship, management), but also in others fields, like medicine, biomechanics, industry or mechanical engineering [4,5].

The aim of this study is to evaluate the effectiveness of selected data mining techniques for predicting the occurrence of disk hernia and spondylolisthesis, as well as to identify those features of the patient that have the greatest impact on the occurrence of those disabilities.

METHODOLOGY

For research we use public data set of human balance evaluations [2]. Our dataset contains data of 310 patients. Each patient is represented in the data set by 6 biomechanical attributes derived from the shape and orientation of the pelvis and lumbar spine: pelvic incidence, pelvic tilt, lumbar lordosis angle, sacral slope, pelvic radius and grade of spondylolisthesis, and classified into three groups: normal – healthy (100 patients) disk hernia (60 patients) and spondylolisthesis (150 patients). In addition, the data was divided into two separate data sets: a set of training data (80%) to build the model and a set of test data (20%) for model evaluation. In this work classification was made for two models: model 1 – all available variables (6 attributes) and model 2 – variables extracted by means of attributes selection – chi-square test (4 attributes: grade of spondylolisthesis, pelvic incidence, lumbar lordosis angle and pelvic radius). The data classification was made using WEKA software. Due to the high accuracy, for classification were used the following algorithms [1]: C4.5(J48), Random Forest, JRip, PART and Naive Bayes. The ACC (Total Accuracy) measure was used to assess the above classifiers. ACC is the total efficiency of the classifier, which determines the probability of correct classification, ie the ratio of correct classifications to all classifications.

RESULTS AND DISCUSSION

The results of classification for both models are presented in Figure 1. It was compared the results obtained on the test set, because it show us the correct accuracy and usefulness of the model.

As we can see in Fig. 1., the most accurate classification (87,10%) was obtained using the Random Forest and JRip algorithm for model 1, i.e. working on all available attributes. A slightly lower accuracy (85,48%) was obtained for the JRip algorithm and model 2, which contains only attributes extracted using the feature selection - the chi-square. We can also see, the small difference between accuracy for the model containing all features and for models after feature selection. In several cases, classifiers for models after feature selection give very similar accurancy as models in which all attributes are included. It shows the usefulness of using attributes selection, which not only saves time but also gives good predictive results.

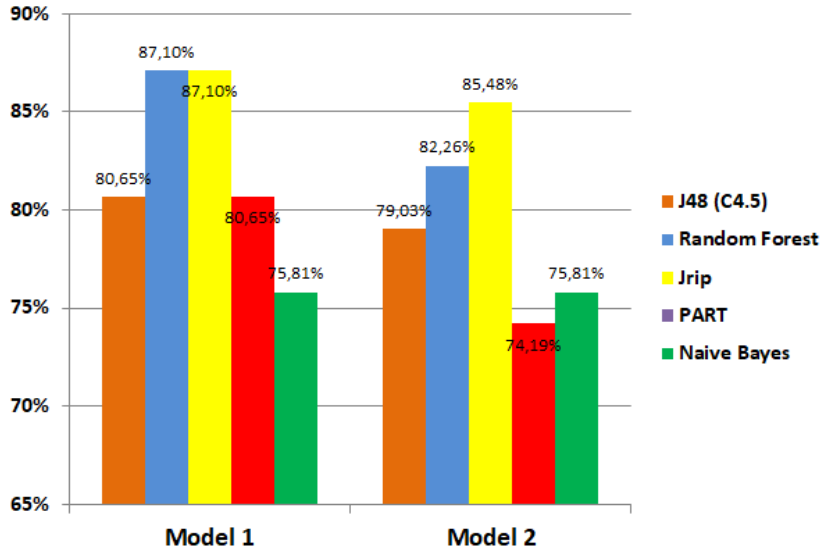

Figure 1. Comparison of correctly classified objects in individual models (for test set)

CONCLUSIONS

Discovering knowledge in databases is a dynamically developing field, whose rapid development is related to the growing number of databases and the size of information collected in them. Increasingly, data mining finds its application in engineering sciences. The analysis of classification algorithms carried out shows that they can be a very important tool supporting, e.g. vertebral column pathologies analysis. Detailed data analysis, proper preparation and proper classification allow achieving very accurate results. The research done with WEKA software also allowed to show the attributes most important in diagnosing of disk hernia and spondylolisthesis. Grade of spondylolisthesis, pelvic incidence, lumbar lordosis angle and pelvic radius proved to be important features.

BLOOD FLOW AND DRUG ELUTION IN COATED STENTS

Anna Maria Ranno[1] and Marek Behr[1]
[1]Chair for Computational Analysis of Technical Systems, RWTH Aachen University, 52056 Aachen, Germany,
{ranno,behr}@cats.rwth-aachen.de, www.cats.rwth-aachen.de

Summary The treatment of coronary artery disease largely involves coronary stents. The usage of stents often gives rise to in-stent restenosis, which can lead to long-term lesions or stent thrombosis. The analysis of blood flow microdynamics in stented arteries is carried out for both Newtonian and shear-thinning constitutive models. In order to help the healing process and reduce the risk of restenosis, stents are coated with a layer of drug, whose elution and deposition on the vessel wall is analyzed. Given the two different time scales required for the drug elution process and the blood microdynamics, a MOR technique is proposed.

BLOOD FLOW IN STENTED ARTERIES

Cardiovascular diseases are the most common cause of death worldwide, and more specifically, 30% of global mortality is due to coronary artery disease [1]. The treatment of such disease largely involves the implantation of coronary stents.

The usage of such devices often gives rise to in-stent restenosis or thrombosis. The critical areas where such side-effects occur highly depend on the shear stresses inside the artery. For this reason, the analysis of blood flow dynamics in stented arteries is of great interest. In-stent restenosis is due to the vessel inflammatory reaction after the implantation of the stent, which can lead to long-term lesions (40% occurance rate). Thrombus formation can be predicted by identifying the areas of rapid platelet aggregation.

The stent mainly considered here is the *Xience V* stent (shown in fig. 1). The mesh is obtained from a CAD geometry, using the commercial software Hypermesh. The Navier-Stokes equations serve as the mathematical model. The model is tested for both steady and unsteady scenarios. Pulsatile inflow boundary conditions aim at describing the flow in coronary arteries. Particular emphasis is given to the influence of stent struts on microdynamics: the analysis of streamlines show that recirculation areas and vortices are often located near the stent struts and that their geometry strongly influences them.

All the simulations are performed by means of finite element method and implemented in an in-house code.

Figure 1: Crimped geometry of the *Xience V* stent. The stent struts are highlighted in red.

Blood flow constitutive models

Blood is a suspension of red blood cells, white blood cells, and platelets, in a Newtonian fluid (plasma). In large arteries, blood can be approximated as a Newtonian fluid, without altering the overall flow. The choice of the blood constitutive model, in fact, mainly influences the local microdynamics and variables, e.g., the viscosity and the shear stress. The latter is of great importance, since coronary arteries are characterized by a specific healthy shear stress. Both lower and higher shear stress can lead to inflammation, restenosis, or platelets aggregation.

In order to investigate the local flow behavior, a generalized Newtonian model [2] is taken into consideration. In particular, a shear-thinning constitutive model takes into consideration the dependence of the blood viscosity with respect to the shear rate.

Both Newtonian and shear-thinning constitutive models are compared, with particular focus on wall shear stress, viscosity and shear rates. Shear rates and wall shear stress are analyzed as an indicator of the possible areas of inflammation and thrombosis.

DRUG ELUTION

To help the healing process and reduce the risk of restenosis, coated stents have a layer of drug that is slowly released into the blood stream.

The elution and deposition of the drug in the vessel wall is analyzed by means of an advection-diffusion equation and tailored boundary conditions. The convective field is obtained coupling the drug equation to the Navier-Stokes equation used to describe the blood flow. Once again, both the Newtonian and the shear-thinning consitutive models are compared: blood flow microdynamics can influence the drug deposition on walls. These scenarios are tested for both a test case, where a simplified one-strut stent geometry is used (see fig. 2), and for the *Xience V* stent (see fig. 3).

Figure 2: Drug elution in a cross-section of a one-strut simplified stent configuration.

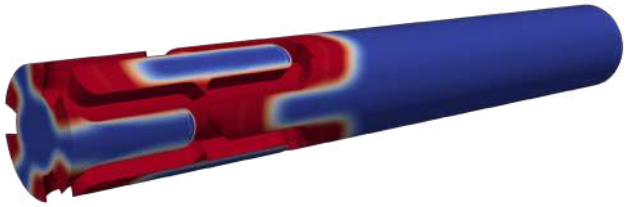

Figure 3: Drug elution in a cross-section of a *Xience V* stent. The figure shows a downstream clip of the stent.

Since the healing process spans a time frame of weeks, an appropriate time scale has to be considered and adapted to the boundary conditions. For example, starting from the Higuchi formula, a multiscale model with simplified Robin boundary conditions can be derived to simulate the drug release into the blood stream [3].

Coupling the blood flow, whose characteristic time scale is in the order of seconds, and the drug elution process, which can last up to three months, requires the usage of multiscale techniques. Here, a model order reduction (MOR) technique is proposed.

Summary The regulating mechanisms of neutrophils (PMN) adhesion and crawling dynamics remain unclear in sinusoids. To address this issue, binding kinetics measurement and *in vitro* liver models were conducted to investigate the roles of distinct adhesive molecules and hepatic cellular interactions in the liver-specific PMN recruitment. Binding kinetics measurements showed that binding of hepatic or cerebral ICAM-1 to β2-integrin follows distinct kinetics. The 2D *in vitro* liver sinusoidal model demonstrated that LFA-1 dominates the static or shear resistant adhesion of PMNs while Mac-1 decelerates PMN crawling on LSEC monolayer. The 3D *in vitro* liver sinusoidal model suggested that each type of hepatic cells may contribute to PMN recruitment differently. Our data furthers the understandings in the distinct functions of β2 integrins in PMN accumulation within liver sinusoids and other tissues.

INTRODUCTION

Liver microcirculation is unique in human body due to the complicated structure of sinusoidal nodes, in which multiple types of hepatic and hemapoietic cells interact with each other under blood flow. The liver sinusoid is a specialized capillary network with narrow luminal diameter (7-15 μm), slow blood flow (0.1-1 dyn/cm^2), and consists of four major types of cells, including liver sinusoid endothelial cells (LSEC), liver resident macrophage Kupffer cells (KC), hepatic stellate cells (HSC), and hepatocytes (HC)[1-2]. Polymorphonuclear leukocytes (neutrophils, PMN) recruitment in the liver sinusoid is widely observed in almost all liver diseases and contributes to pathogen clearance or tissue damage. It is known that two β2 integrins lymphocyte function-associated antigen-1 (LFA-1) and macrophage-1 antigen (Mac-1) play distinct functions that LFA-1 initiates PMN slow rolling and firm adhesion but Mac-1 mediates cell crawling in PMN recruitment in the most of organ-specific microcirculations. In a liver sinusoid, however, Mac-1 seems to be predominant in PMN adhesion and crawling in localized inflammation while the role of LFA-1 is controversial [3]. The regulating mechanisms of PMN adhesion and crawling dynamics are still unclear from those *in vivo* studies. To address this issue, binding kinetics measurements were conducted to elucidate the biophysical characteristics of β2-integrin-intercellular adhesive molecule 1 (ICAM-1) in mediating PMN recruitment in liver and brain[4]. *In vitro* two-dimensional (2D) and 3D reconstructed sinusoidal models were developed to recapitulate key features of the liver microenvironment and to investigate the roles of distinct adhesive molecules and hepatic cellular interactions in the liver-specific PMN recruitment [5-6].

MATERIALS AND METHODS

PMNs, cerebral microvascular endothelial cells (BMEC) and hepatic cells were freshly isolated from the bone marrow, brain and liver of 8–12-week old male C57BL/6 mice. LSEC, HC, KC and HSC were isolated by a two-step collagenase perfusion of whole liver, a density gradient centrifugation and a cytometry sorting.

We used micropipette aspiration technique to compare the binding kinetics of LFA-1 and Mac-1 coupled on human red blood cells (RBC) to ICAM-1 expressing on BMEC or LSEC for comparing the distinct functions of β2 integrins in different tissues.

A 2D live-cell flow chamber system was established to perfuse PMNs under shear flow and record the interplay between PMN and LSEC alone or co-cultured with KC. PMN adhesion and crawling were quantified for fMLF-activated PMN on TNF-α-stimulated LSEC. Related molecular regulations of LFA-1, Mac-1, and CD44 and the impact of KC were also analyzed.

An *in vitro* 3D liver model was developed to further mimic liver microenvironment with well-organized cell composition and physical interactions. Two microfabricated polydimethylsiloxane (PDMS) layers were bonded together with a polyethylene (PE) porous membrane between them, forming two fluidic channels separated by a permeable membrane, which represents liver sinusoids with an endothelium separating microvenule and Disse Space. To replicate the physiological structure and cellular composition, the 3D microfluidic device was constructed by integrating LSEC monolayer with sparsely distributed KC and HSC on either side of extracellular matrix (ECM)-coated PE membrane into HC monolayer immobilized on lower PDMS substrate. Typical liver specific functions and multi-typed cell interactions in protein secretion, drug metabolism and immune responses were analyzed under shear flow. Moreover, the evolution dynamics of LSEC fenestrae was tested using total internal reflection fluorescence structured-illumination microscopy (TIRF-SIM) and atomic force microscopy (AFM).

RESULTS AND DISCUSSION

Binding kinetics measurements showed that binding of hepatic or cerebral ICAM-1 to β2-integrin follows distinct kinetics. ICAM-1 on murine LSECs binds to LFA-1 with higher on- and off-rates but lower effective affinity compared

with Mac-1, whereas ICAM-1 on BMECs binds to LFA-1 with higher on-rates, similar off-rates, and higher effective affinity compared with Mac-1.

The 2D *in vitro* liver sinusoid model demonstrated that LFA-1 dominates the static or shear resistant adhesion of PMNs while Mac-1 decelerates PMN crawling on LSEC monolayer. Any one of LFA-1, Mac-1, and CD44 molecules alone is not able to work effectively for mediating PMN transmigration across LSEC monolayer. The presence of KC only affects the randomness of PMN crawling.

The 3D *in vitro* liver sinusoid model suggested that shear flow fostered albumin secretion for HC alone or even higher when combining with nonparenchymal cell (NPC) co-culture, implying that co-culture and shear flow could work cooperatively. Shear flow enhanced dramatically CYP1A2 activity when HC were cultured alone or co-cultured with NPC, while co-culture with NPC alone had no effects on CYP activities. Under LPS stimulation, co-culture of LSEC with HSC, KC or HC, or all the three cell types increased PMN accumulation, implying that each type of hepatic cells may contribute to PMN recruitment differently. The fenestrae number decreased with culture time, which could be rescued by HC co-culture. PMN adhesion was reduced after fenestrae degeneration, suggesting an extra role of fenestrae in PMN recruitment.

CONCLUSIONS

Our results clarified the molecular mechanisms of PMN recruitment in the liver sinusoids using well-defined biophysical approaches, which provide a mechanistic insight into relating binding kinetics of hepatic sinusoidal and cerebral microvascular ICAM-1 to free PMN crawling, shear-induced PMN adhesion and crawling on primary LSEC, and the distinct impacts of each type of hepatic cells. Moreover, the 3D microfluidic device replicates the key architecture of liver sinusoids by integrating four major types of cells into two separated flow channels, which could serve as a functional platform to investigate the short-duration functional maintenance, hepatic cellular interplay, cytotoxic metabolism, and inflammatory cascade under physiologically-like microenvironment

STUDY OF MECHANICAL PROPERTIES OF A CHITOSAN-VANCOMYCIN- NANOCELLULOSE NANOPARTICLES COMPOSITE MATERIAL OF BACTERIAL ORIGIN TO CLOSE DURA MATER DEFECTS

Daniil Parshin[1,2*], Lipovka Anna[1,2], Alexey Kharchenko[3],
[1]Lavrentyev Institute of Hydrodynamics, Novosibirsk, Russia
[2]Novosibirsk State University, Novosibirsk, Russia
[3]Neurosurgical Department No. 1, Novosibirsk Research Institute of Traumatology and Orthopaedics, Novosibirsk, Russia

Summary In neurosurgical practice often arises the need for dura mater restoration. The lack of integrity of the dura mater leads to infectious complications: cerebrospinal fluid, meningitis, and meningoencephalitis which can lead to death of the patient. The restoration of the patient's meninges is not always possible precisely because of injuries. In such cases, it is imoirtant to synthesize membranes that would be universal in the sense of biocompatibility and antibacterial for the purpose of clinical use. The aim of this work is to investigate properties of a biopolymer analogue of the dura mater.

EXPERIMENTAL METHODS

Material synthesis:

Bacterial nanocellulose is a nanoscale biopolymer that has similar properties with collagen, obtained by culturing in a medium containing carbohydrate (glucose, fructose, sucrose, etc.) the bacteria Komagataeibacter xylinus under static conditions.

Bacterial cellulose is widely used as a material for the treatment of burns and cosmetology, as well as a scaffold, because various body cells grow well on it. There are experimental studies of the use of bacterial nanocellulose as a vascular prosthesis, menisci. Bacterial cellulose also shows good results in animal models during experimental restoration of a damaged peripheral nerve.

The thickness measurement was carried out on the device "laser complex for high-speed cutting of biological tissue." The thickness measurement sensor (LD200) of the biological material at the time of measurement produces a sinusoidal voltage of a certain value, the value of which is directly proportional to the thickness of this material. The measurement result is transmitted to a computer, where the data is processed by software. This method allows to accurately determine the thickness of the material. This installation also produces precise cutting of the material.

Mechanical Testing:

For mechanical testing a universal rupture machine Zwick&Roell is used. The dog-bone shaped specimen is cut from the sheet, its size is measured. Then the specimen is fastened in custom made (3d-printed) clamps (Pic. 1), which is placed in the jaws of the rupture machine. During the experiment the specimen is fully immersed into the sodium solution of normal body temperature (37C). The loading is divided into the several stages, with the preconditioning technique used at the initial stages.

RESULTS AND CONCLUSIONS

A prospective, randomized, double-blind, controlled clinical trial performed on the dura mater defect plastics registered on the ClinicalTrials.gov website under the number NCT00859508 showed that bacterial nanocell in the form of a SyntheCelproduct is not inferior to other implants.

Since after implantation into the patient's body the sample will experience certain mechanical stress, it is critically necessary to assess the mechanical properties of the samples depending on the parameters of their synthesis. Tests for more than 30 tissue samples with various parameters of its synthesis were conducted during this study.

After mechanical tests, differences in the strength characteristics of the samples were determined depending on the synthesis parameters of the material. A comparison was made with the cadaveric material of the dura mater.

A COLLAGEN RECRUITMENT MODEL OF FAILURE IN TENDONS AND LIGAMENTS

James Gregory*[1], Andrew L. Hazel[1], and Tom Shearer[1]
[1]Department of Mathematics, University of Manchester, UK

Summary Collagen fibrils are microstructural components of tendons and ligaments that we model as elastoplastic solids, assumed to be continuously distributed within the tissue. We compute the stress in the tendon by assuming that the yield stretch and rupture stretch of the collagen fibrils follow distributions, rather than being single-valued. This approach allows us to fit to a larger range of tendon stress-strain data than was previously possible using similar models, whilst only including parameters that can be measured experimentally.

INTRODUCTION

Tendons and ligaments, connecting bone to muscle and bone to bone, respectively, are vitally important soft tissues found in the body. When a tendon or ligament is subjected to unusually high loads, such as during strenuous activities like running and jumping, micro-tears can appear within the tissue. These micro-tears can be responsible for injuries varying in severity from tendinitis to catastrophic total rupture [1]. Mathematical models of soft tissue typically seek to model their mechanical response over the physiological range of strains observed during everyday motion. This means that the commonly used models are only applicable up to the initial onset of damage and they cannot be used to make predictions on how tendons or ligaments will behave under continued loading.

Tendons and ligaments have a complex hierarchical structure, the main mechanical component of which is collagen, making up 65-80% of the dry weight [2]. Collagen fibrils, made of mostly type-I collagen, are bound within fascicles which make up a tendon/ligament. The fibrils are crimped within the fascicle, with the amount of crimp varying between fibrils [2]. This varying amount of crimp is responsible for the gradual stiffening of tendons as more fibrils are recruited over the course of a deformation. When the applied strain goes beyond the physiological range (>4% for some positional tendons), damage is likely to occur. Injuries due to overloading are prevalent for strains in the region of 4-8%. When a strain of over 8% is applied, a combination of both yielding in the fibrils and shear failure in the matrix leads to tendon rupture. There are two main ways in which an unusually high load can cause damage to tendon microstructure, leading to a debate over the main mechanism leading to rupture. If fibrils are discontinuous then it is argued that the mechanism that leads to yielding is the breakdown of interfibrillar components and the subsequent slippage of fibrils past one another, whereas if fibrils are continuous, yielding in the tendon will occur due to yielding of the fibrils themselves [3].

THE MODEL

We assume that the tendon is composed of a family of parallel fibres embedded within a mechanically inactive matrix. Each fibril has a critical stretch λ_c, equal to the tendon stretch required to remove the slack in the fibril. Once a fibril is taut, it exhibits a linearly elastic response until it has been stretched by a factor of λ_Y, where it yields. The fibril then deforms plastically until it ruptures, after having been stretched by a factor of λ_R. The stress in a fibril σ_f is given by

$$\sigma_f(\lambda,\lambda_c,\lambda_Y,\lambda_R) = \begin{cases} E\left(\dfrac{\lambda}{\lambda_c}-1\right) & \lambda_c \le \lambda \le \lambda_c\lambda_Y, \\ p(\lambda,\lambda_c,\lambda_Y,\lambda_R), & \lambda_c\lambda_Y \le \lambda \le \lambda_c\lambda_R, \\ 0, & \text{otherwise}, \end{cases} \tag{1}$$

where $p(\lambda,\lambda_c,\lambda_Y,\lambda_R)$ is a function that describes the plastic behaviour of an individual collagen fibril. We assume that the critical stretch λ_c, the yield stretch λ_Y, and the rupture stretch λ_R, all follow a joint distribution given by $\Lambda(\lambda_c,\lambda_Y,\lambda_R)$. We then compute the stress in the tendon σ_T using

$$\sigma_T(\lambda) = \phi \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{1}^{\lambda} \sigma_f(\lambda,\lambda_c,\lambda_Y,\lambda_R)\Lambda(\lambda_c,\lambda_Y,\lambda_R)\mathrm{d}\lambda_c\mathrm{d}\lambda_Y\mathrm{d}\lambda_R, \tag{2}$$

where λ is the applied tendon stretch, and ϕ is the collagen volume fraction. This model is similar to those of Hurschler et al. [4] and Hamedzadeh et al. [5], in that we exclude fibrils from the integral in equation (2) once they have been stretched by a factor of λ_R. We were able to fit these existing models to data from Goh et al. [6] in cases where there was a well-defined peak in the stress-strain curve, however, a significant proportion of the data contained features that could not be accounted for. These include plateaus instead of well-defined peaks, and step-like failure behaviour. By including distributions for the yield and rupture stretch, we can account for these features by adjusting the shape of these distributions, and how much they overlap.

*Corresponding author. E-mail: james.gregory@manchester.ac.uk

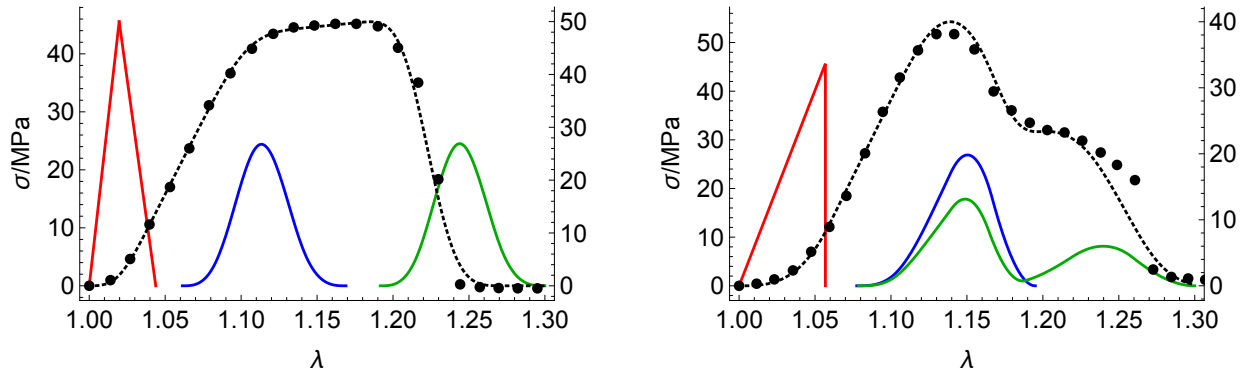

Figure 1: Our model (black dashed lines) fitted to data from Goh et al. [6] (black markers). The red curves show the distribution of critical stretch λ_c. The blue and green curves show the distributions of yield and rupture stretch, respectively, transformed to be in terms of tendon stretch. The right hand axis refers to these distributions. Both sets of data contain features that could not previously be accounted for using collagen recruitment models: (a) contains a plateau instead of a well-defined peak, and (b) contains step-like failure behaviour.

Figure 1 shows the model fitted to stress-strain data from Goh et al. [6], taken from mouse tail tendons stretched to failure. By modelling the fibrils as bilinear elastoplastic, it is possible to produce a macroscale stress-strain curve containing a second linear region/plateau by ensuring that there is no overlap between the yield and rupture stretch distributions, once they have been transformed to be in terms of tissue stretch. This means that all of the fibrils yield before any have ruptured. By allowing the transformed distributions to overlap, we can produce a more well-defined peak, as can be seen in Figure 1b. By using a bimodal distribution for the fibril rupture stretch, we can achieve step-like failure behaviour, also present in Figure 1b.

CONCLUSIONS

We have derived a general model of tendon failure, capable of fitting to a much wider array of stress-strain data than was previously possible using similar collagen recruitment models. By splitting the fibril stress into elastic and plastic parts, and by introducing distributions for the yield and rupture stretch, we are able to produce macroscale stress-strain curves that closely resemble those determined experimentally by Goh et al. [6]. There is a large amount of variability in the reported values of fibril yield and rupture strain, and so using distributions for these parameters, rather than single values, means that the microstructure is better represented. This model has the added benefit of only using parameters that can be measured experimentally. This means that if we know how a certain process, such as ageing or disease, affects the microstructure, we can use this model to predict how the macroscale tendon properties will be affected.

FLEXURE OF BIOLOGICAL GLASS FIBERS LEADS TO SAWTOOTH FORCE-DISPLACEMENT RESPONSES RELATED TO SLIP INSTABILITIES, NOT TOUGHNESS ENHANCEMENT

Wenqiang Fang[1], Haneesh Kesari *[1], Michael A. Monn[1], and Sayaka Kochiyama[1]
[1]School of Engineering, Brown University, Providence, RI, USA

Summary Layered architectures are prevalent in biological composites, such as nacre and bone. The skeletal elements—called spicules—from the sponge *Euplectella aspergillum* are another example of a biological composite with a layered architecture. We performed three-point bending tests on the spicules and also observed nonlinear force-displacement responses containing jagged, sawtooth shapes. However, based on the analysis of micrographs obtained during the tests, we found that the sawtooth pattern of the force-displacement response is actually a consequence of slipping interactions between the spicule and the test fixture, not from toughening mechanisms like crack arrest and crack deflection. We propose a nonlinear bending-sliding model to illustrate how is the sawtooth pattern related to the heterogeneous friction between the spicule and the test fixture.

INTRODUCTION

There are few engineering materials that are both strong and tough. However, some biological materials have been shown to possess both high strength and high toughness [1, 2, 3, 4]. For example, nacre—the iridescent portion of some mollusk shells—has a flexural strength similar to aluminum (around 280 MPa) and a specific fracture initiation toughness similar to nylon (around 2-5 MPa $\mathrm{m}^{1/2}$).

Often, these biological materials are composites that are made up of a combination of a brittle ceramic phase, such as calcium carbonate or hydroxyapatite, and a compliant protein phase, like collagen or chitin. It has been hypothesized that like nacre, the marine sponge *Euplectella aspergillum* (*Ea.*) anchor spicules' layered architecture enhances its fracture toughness [5, 6].

We investigated whether the sawtooth pattern in the *Ea.* spicules' mechanical response is connected to toughness enhancement by 1) performing flexural tests on the spicules and 2) analyzing this data and data obtained from previous three-point bending tests performed on the spicules [7]. Our analysis shows that the sawtooth pattern can arise as a consequence of the spicule slipping on the flexural test fixture. Therefore, the presence of the sawtooth pattern alone cannot be used as proof that the spicule's toughness is enhanced.

MATERIALS AND METHODS

In a conventional three-point bending test, a specimen is held/supported by a test fixture that consists of either two rollers or "knife edges" that are set a fixed distance apart. We performed three-point bending tests on a group of *Ea.* spicules using this type of test configuration, which we refer to as "simply supported". In this work, the test fixture supports consisted of the edges of a trench cut in a metal plate. We then measured the arc length of the spicule specimen between the trench edges at every stage displacement step from micrographs taken during the tests. We also conducted the same measurements on data previously presented in [7] for 33 additional *Ea.* specimens. From these measurements, we found that discontinuities in the F-w_0 response corresponded with discontinuous changes in the arc length of the specimen (see Figure 1 (D)–(F)).

We also present data from 12 experiments in which we glued the ends of the spicules to the test fixture to prevent them from sliding during the test. In this glued configuration, the spicules fail without any sawtooth pattern in their F-w_0 response. This suggests that the sawtooth pattern can be a pathology of the simply support test configuration and in a previous study [7], and not a characteristic of the spicule's failure process.

DISCUSSION AND CONCLUSIONS

We propose a nonlinear bending-sliding model, in which we assume that the deformation of the spicule is governed by Euler's Elastica theory in cooperation with kinetic friction between the spicule and the test fixture. We found that the fluctuation in frictional coefficient causes waviness in the equilibrium dimensionless force-displacement ($\hat{F}$-$\hat{w}_0$) curves. By considering the loading strategy, displacement controlled loading with finite machine compliance, we provide an explanation of discontinuities in the $\hat{F}$-$\hat{w}_0$ curves. We assume the frictional coefficient along the arc length of the spicule varying in a sinusoidal form and fit the parameters to experimental data. The best fitting parameters we choose to qualitatively capture the sawtooth pattern are in reasonable ranges for the tested samples. With the nonlinear bending-sliding model, we are able to explain the existence of the sawtooth pattern and how it is related to the heterogeneous friction between the spicule and the test fixture. This further supports our experimental observation that the sawtooth jumps in the $\hat{F}$-$\hat{w}_0$ response is mostly a consequence of sliding instead of crack growth.

ANALYTICAL SOLUTIONS MIMICKING MORPHOLOGICAL EVOLUTIONS OF TWO MUSHROOMS-A. MUSCARIA AND M. CHLOROPHOS

Xiaoyi Chen[1] and Hui-Hui Dai *[2]
[1]Division of Science and Technology, BNU-HKBU United International College, Guangdong, China
[2]Department of Mathematics, City University of Hong Kong, Kowloon Tong, Hong Kong

Summary A theory for stress-free axisymmetric configurations induced by locally incompatible growth fields is developed. Through polar decomposition of the growth tensor and appropriate choice of base vectors, we derive two constraints on the growth functions and a system of equations for the current configuration and elastic rotation. Under a particular case, a family of analytical solutions are constructed, which can mimic the morphological evolutions of two mushrooms-A. muscaria and M. chlorophos with a turnup cap and a depressed cap respectively. The growth functions (heterogeneous and anisotropic) and explicit analytical results reveal clearly the relationship between parameters and growth patterns. It is also found that the slightly turnup cap and the depressed cap of the mushrooms are well captured by two parameters, which turn out to be driven by the circumferential growth function.

INTRODUCTION

The multiplicative decomposition model proposed by Rodriguez *et al.* [1] is widely used to understand pattern formations of biological tissues (algae, intestine, skull *etc*). When applying this model, the growth functions are usually taken to be constants and numerical methods are adopted. Only in some exceptional cases, analytical solutions were obtained. Here, within the framework of this growth theory, we intend to construct analytical solutions which can mimic the morphological evolutions of two mushrooms-A. muscaria and M. chlorophos, from which some insights are deduced.

A. muscaria is one of the most iconic toadstool species and is noted for its hallucinogenic and M. chlorophos is among the oldest bio-luminescent fungus and emits pale green light in the darkness. Both the two mushrooms initially have ellipsoidal cap and expand outward during the growth, but at the final stage, the former mushroom "chooses" to turn up the cap slightly while the latter one "chooses" to depress its cap in the central part. We will establish a theory for stress-free $3D$ axisymmetric configurations induced by growth, from which some special analytical solutions are obtained to describe the above-mentioned two processes. We point out that a theory for stress-free 2D configurations induced by growth is given in a previous work [2].

STRESS-FREE 3D AXISYMMETRIC DEFORMATION

We adopt the multiplicative decomposition method [1], according to which the deformation gradient $\mathbf{F}=\mathbf{AG}$ where $\mathbf{G}$ is the growth tensor and $\mathbf{A}$ is the accommodating elastic tensor. Our goal is to find appropriate forms of $\mathbf{A}$ and $\mathbf{G}$ so that the current configuration is 3D axisymmetric and stress-free under the condition $\nabla\times\mathbf{G}\neq\mathbf{0}$ (the growth tensor is locally incompatible [3]). Given the eigenvalues $(\mu_1^2,\mu_2^2,\mu_3^2)(\mu_i>0,i=1,2,3)$ and orthonormal eigenvectors $(\mathbf{p}^1,\mathbf{p}^2,\mathbf{p}^3)$ of the growth metric $\mathbf{M}=\mathbf{G}^T\mathbf{G}$, we have the polar decomposition (see [4]) of the growth tensor as

$$\mathbf{G}=\mu_1\mathbf{q}^1\otimes\mathbf{p}^1+\mu_2\mathbf{q}^2\otimes\mathbf{p}^2+\mu_3\mathbf{q}^3\otimes\mathbf{p}^3,\quad \mathbf{q}^i=\mathbf{Q}\mathbf{p}^i,\ i=1,2,3, \tag{1}$$

where $\mathbf{Q}$ is an orthogonal tensor. One key step of our derivation is the appropriate choice of the base vectors. Based on (1), the curvilinear coordinates $(\Theta^1,\Theta^2,\Theta^3)$ in the initial configuration R_0 (assumed to be Euclidean) are chosen such that the contra-variant base vectors are $\{\mathbf{g}^i=|\mathbf{g}^i|\mathbf{p}^i,i=1,2,3\}$, where $\mathbf{g}^i\cdot\mathbf{g}_j=\delta^i_j$, $\mathbf{g}_j=\partial\mathbf{X}/\partial\Theta^j$ and $\mathbf{X}=R(\Theta^1,\Theta^3)\mathbf{e}_R+Z(\Theta^1,\Theta^3)\mathbf{e}_Z$ is the initial position vector ($\{\mathbf{e}_R,\mathbf{e}_\Theta,\mathbf{e}_Z\}$ are the cylindrical base vectors with $\Theta^2=\Theta$). For the virtual state R_g ($\mathbf{G}$ is the defromation gradient from R_0 to R_g) and current configuration R_t, base vectors are chosen repectively to be $\{\mathbf{q}^i,i=1,2,3\}$ and $\{\mathbf{e}_R,\mathbf{e}_\Theta,\mathbf{e}_Z\}$.

To ensure the stress-free deformation of a hyperelastic material, we set $\mathbf{A}$ to be a locally rotation tensor (excluding rigid body rotations), and for an axisymmetric deformation we have $\mathbf{A}=\cos\alpha\mathbf{e}_R\otimes\mathbf{q}^1+\sin\alpha\mathbf{e}_R\otimes\mathbf{q}^3-\sin\alpha\mathbf{e}_Z\otimes\mathbf{q}^1+\cos\alpha\mathbf{e}_Z\otimes\mathbf{q}^3+\mathbf{e}_\Theta\otimes\mathbf{q}^2$. Then from $\mathbf{F}=\mathbf{AG}$ and $\mathbf{F}=\nabla\mathbf{x}$ where $\mathbf{x}=r(\Theta^1,\Theta^3)\mathbf{e}_R+z(\Theta^1,\Theta^3)\mathbf{e}_Z$ is the current position vector, we have equations for $\mathbf{x}$ and one constraint for the circumferential growth function

$$\frac{\partial z}{\partial\Theta^1}=-\lambda_1\sin\alpha,\quad \frac{\partial z}{\partial\Theta^3}=\lambda_3\cos\alpha,\quad \frac{\partial r}{\partial\Theta^1}=\lambda_1\cos\alpha,\quad \frac{\partial r}{\partial\Theta^1}=\lambda_3\sin\alpha,\quad r=\lambda_2, \tag{2}$$

where $\lambda_i=\mu_i/|\mathbf{g}^i|,i=1,2,3$. Then the compatibility conditions $\frac{\partial^2 z}{\partial\Theta^1\partial\Theta^3}=\frac{\partial^2 z}{\partial\Theta^3\partial\Theta^1}$, $\frac{\partial^2 r}{\partial\Theta^1\partial\Theta^3}=\frac{\partial^2 r}{\partial\Theta^3\partial\Theta^1}$ and $\frac{\partial^2\alpha}{\partial\Theta^1\partial\Theta^3}=\frac{\partial^2\alpha}{\partial\Theta^3\partial\Theta^1}$ lead to respectively the equations of α and the other constraint for growth functions

$$\frac{\partial\alpha}{\partial\Theta^1}=\frac{1}{\lambda_3}\frac{\partial\lambda_1}{\partial\Theta^3},\quad \frac{\partial\alpha}{\partial\Theta^3}=-\frac{1}{\lambda_1}\frac{\partial\lambda_3}{\partial\Theta^1},\quad \frac{\partial}{\partial\Theta^1}\left(-\frac{1}{\lambda_1}\frac{\partial\lambda_3}{\partial\Theta^1}\right)=\frac{\partial}{\partial\Theta^3}\left(\frac{1}{\lambda_3}\frac{\partial\lambda_1}{\partial\Theta^3}\right). \tag{3}$$

It is noted that $(3)_{1,2}$ can also be obtained from $\nabla\times\mathbf{F}=\mathbf{0}$ and $(3)_3$ can also be derived from $\mathcal{R}=\mathbf{0}$ where $\mathcal{R}$ is the Riemann curvature tensor associated with the growth metric $\mathbf{M}$.

*Corresponding author. E-mail: mahhdai@cityu.edu.hk

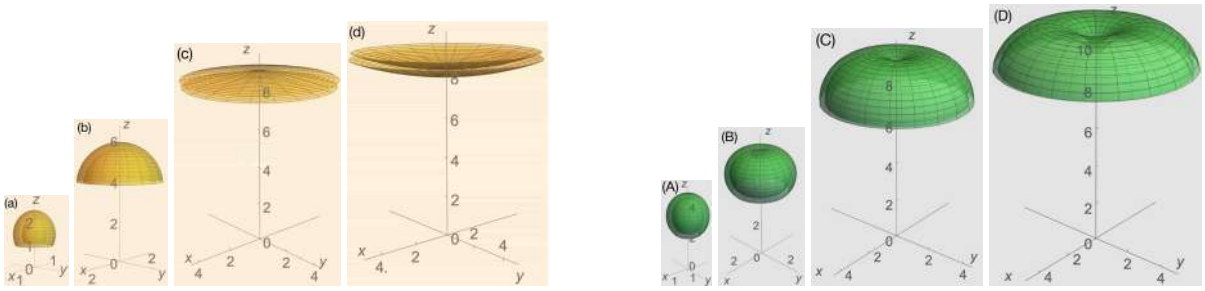

Figure 1: Simulation of growth patterns of A. muscaria (a-d) and M. chlorophos (A-D) based on the result of (4-5) together with the determination of C_1, C_2, α_0 and the properly chosen values of s, k, d_1.

A FAMILY OF ANALYTICAL SOLUTIONS

In this section, we construct analytical solutions to (2-3) for the particular case $\lambda_3 = \lambda_3(\Theta^3)$. We have from $(3)_3$ that $\lambda_1 = h_1(\Theta^1)\int \lambda_3(\Theta^3)\mathrm{d}\Theta^3 + h_2(\Theta^1)$, where $h_i(\cdot)(i = 1, 2)$ are two arbitrary functions. To further simplify the result, we consider $h_2 = d_0 \cdot h_1$ where d_0 is a constant. Then taking λ_1, λ_3 back to $(3)_{1,2}$ and $(2)_{1-5}$, α, (r, z) and λ_2 are obtained. In summary, we have

$$\begin{aligned} &\lambda_3 = \lambda_3(\Theta^3), \quad \lambda_1 = h_1(\Theta^1)\left[\int \lambda_3(\Theta^3)\mathrm{d}\Theta^3 + d_0\right], \quad \alpha = \int h_1(\Theta^1)\mathrm{d}\Theta^1 + \alpha_0, \\ &z = \cos\alpha\left[\int \lambda_3(\Theta^3)\mathrm{d}\Theta^3 + d_0\right] + C_1, \quad \lambda_2 = r = \sin\alpha\left[\int \lambda_3(\Theta^3)\mathrm{d}\Theta^3 + d_0\right] + C_2, \end{aligned} \tag{4}$$

with the trajectory of r and z being $(z - C_1)^2 + (r - C_2)^2 = [\zeta(\Theta^3)]^2$, $\zeta(\Theta^3) = \int \lambda_3(\Theta^3)\mathrm{d}\Theta^3$, and α_0, C_1, C_2 being integration constants. In order the current configuration is Euclidean, one also needs to impose the restriction that the mappings of $r(\Theta^1, \Theta^3)$ and $z(\Theta^1, \Theta^3)$ are invertible. Also, it is needed that $\lambda_1, \lambda_2, \lambda_3$ are all positive. In the following, to obtain biologically relevant solutions, we further let $\lambda_3 = s > 0$ (constant) and $h_1 = k \neq 0$ (constant).

MIMICKING THE GROWTH PATTERNS OF TWO MUSHROOMS

In this section, analytical solutions in (4) are applied to generate growth patterns. For the axisymmetric deformation, the initial configuration on the cross section in the $Z - R$ plane is set to be an elliptic strip $Z = c \cdot \cosh(\Theta^3)\cos(\Theta^1) + D_1$, $R = c \cdot \sinh(\Theta^3)\sin(\Theta^1) + D_2$, where $(\Theta^1, \Theta, \Theta^3)$ are orthogonal curvilinear coordinates and $0 < \Theta^1 \leq \eta_0 < \pi$, $0 \leq \Theta \leq 2\pi$, $\xi_0 \leq \Theta^3 \leq \xi_1$, and (D_1, D_2) is the center point and c is the distance between the foci and the center point. The principal directions of growth and growth functions are derived based on results of previous two sections

$$\begin{aligned} &\mathbf{g}^1 = \tfrac{2}{c}\cdot\tfrac{\sinh\Theta^3\cos\Theta^1}{\cosh 2\Theta^3 - \cos 2\Theta^1}\mathbf{e}_R - \tfrac{2}{c}\cdot\tfrac{\cosh\Theta^3\sin\Theta^1}{\cosh 2\Theta^3 - \cos 2\Theta^1}\mathbf{e}_Z, \ \mathbf{g}^2 = \tfrac{\mathbf{e}_\Theta}{R} = \tfrac{1}{c\cdot\sinh(\Theta^3)\sin(\Theta^1) + D_2}\mathbf{e}_\Theta, \\ &\mathbf{g}^3 = \tfrac{2}{c}\cdot\tfrac{\cos\Theta^3\sin\Theta^1}{\cosh 2\Theta^3 - \cos 2\Theta^1}\mathbf{e}_R + \tfrac{2}{c}\cdot\tfrac{\sinh\Theta^3\cos\Theta^1}{\cosh 2\Theta^3 - \cos 2\Theta^1}\mathbf{e}_Z, \ \mu_1 = \lambda_1\cdot|\mathbf{g}^1| = \tfrac{k\cdot s\,\Theta^3 + d_1}{c}\sqrt{\tfrac{2}{\cosh(2\Theta^3) - \cos(2\Theta^1)}}, \\ &\mu_2 = \lambda_2\cdot|\mathbf{g}^2| = \tfrac{r}{R} = \tfrac{(s\,\Theta^3 + d_1/k)\sin(k\Theta^1 + \alpha_0) + C_2}{c\cdot\sinh(\Theta^3)\sin(\Theta^1) + D_2}, \ \mu_3 = \lambda_3\cdot|\mathbf{g}^3| = \tfrac{s}{c}\sqrt{\tfrac{2}{\cosh(2\Theta^3) - \cos(2\Theta^1)}}, \end{aligned} \tag{5}$$

where $d_1 = k \cdot d_0$. The integration constants C_1, C_2, α_0 can be determined by introducing the resctriction that the point $(R, Z) = (D_2, c \cdot \cosh(\xi_1) + D_1)$ and the line $R = D_2$ in the initial configuration correspond respectively to $(r, z) = (P_{1r}, P_{1z})$ and the line inclined an angle γ with the z-axis in the current configuration. Then designating proper values for growth parameters s, k, d_1, the current configurations are obtained from (4). The results are shown in Fig. 1 (a-d) and (A-D) which respectively mimic the morphological evolutions of two mushrooms-A. muscaria and M. chlorophos.

From (4) and (5), we may derive the following insights. (i) The turnup of a cap (a-d) corresponds to the reverse of the sign of k and the formation of a depressed cap (A-D) corresponds to a positive and growing γ. (ii) Behaviors of μ_1, μ_3 for (a-d) and (A-D) are similar, and μ_2 is responsible for the behaviors of k and γ.

CONCLUSIONS

A theory for stress-free 3D axisymmetric configurations induced by locally incompatible growth functions is developed. Some special analytical solutions are constructed, which mimic the morphological evelutions of two types of mushrooms. Some interesting insights are deduced from the analytical results.

Summary Using previously proposed mechanical oscillatory model of corymb type of inflorescence, in this paper we study the influence of different branching angle on amplitudes of forced oscillations for four different values of circular frequencies of external force. Oscillatory behavior of this complex system in horizontal plane under external force can be described by a system of linear differential equations using influence deflection coefficients and reduced inertia forces. Displacement influence coefficients were determined on the basis of equations of elastic line of cantilever load with unit force and unit momentum. Increasing the branching angle of inflorescence, amplitudes of oscillations change non-linearly or linearly depending on external force frequency values.

.

INTRODUCTION

Herbaceous plants that grow in nature, concretely in valleys, are exposed to different external forced conditions like wind, insects, animals etc. Under such circumstances plant stems that carry flowers or complex flowers called inflorescence oscillate. Oscillating behavior will depend on plants' structural and anatomical properties - type of inflorescence, number of flowers in it… Bending process of crops' stems are significantly influenced by crop species growing conditions, stem diameter and wall thickness [1]. Elastic properties of sunflower tissues [2] and stems of different herbaceous pants [3] are determined by other factors. Recently mechanical oscillatory model of corymb type of inflorescence [4] was proposed. We were interested how anatomical variations of stem branching of inflorescence (different branching angle) will affect the amplitudes of forced oscillations. Analyses were done for four different values of circular frequencies of external force.

Description of the mechanical oscillatory model of corymb type of inflorescence

Schematic representation of the mechanical oscillatory model of a corymb type of inflorescence is shown on Fig 1 [3]. Model is in in the form of complex light elastic cantilever fixed in point A at which unit force is applied. In cross-section 2 and 3, rigid rods with material particles at the end of the rods (corresponds to the lateral branches of the inflorescence) are rigidly fixed to the corresponding sections of the elastic cantilever. At the end of the elastic cantilever a material particle is attached (corresponds to the apical part of the inflorescence). This complex system belongs to the discrete complex oscillatory systems and have certain assumptions: lateral branches have negligible mass and are rigidly connected to the cantilever (corresponds to the main stem of herbaceous plant); oscillations of cantilever and system are small, tilts of deformed axis of banded cantilever are very small and negligible, tilts of cantilever cross-section during cantilever banding according to x and y axis of cross sections are very small and negligible. Nonlinearities are considered to be small, as well as the amplitude of the external excitation force and the bends of the base ideal elastic and light cantilever. The bending stiffness of the elastic cantilever is equal in horizontal and vertical plane; mass of the apical part of inflorescence is higher than the masses of lateral branches of inflorescence; displacements of material particles are equal to the displacements of points - the section of the cantilever in which each light rigid rod with neglected mass, that carries the material particle, is attached. Oscillatory behavior of this complex system in horizontal plane, can be described by a system of linear differential equations.

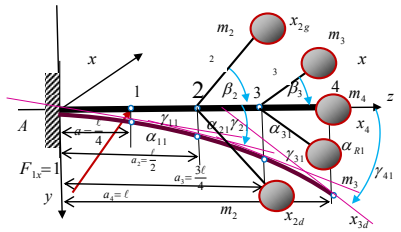

Figure 1. Mechanical oscillatory model of inflorescence. Oscillations in horizontal plane. $m_2 = m_3 < m_4$; $\beta_2 = \beta_3$-branching angles of lateral branches of inflorescence. x-coordinates in horizontal plane. Pint 1, 2, 3 and 4. points of which amplitudes of oscillations are analyzed; -length of the plants' stem.

For oscillations in horizontal plane:

$$x_i = \alpha_{i1}F_{01x}\sin\Omega_x t + \alpha_{i2}\left(-2m_2\ddot{x}_2\right) + \alpha_{i3}\left(-2m_3\ddot{x}_3\right) + \alpha_{i4}\left(-m_4\ddot{x}_4\right) + \\ + \delta_{i2}\left(-2m_2\ddot{x}_2\ell_2\sin\beta_2\right) + \delta_{i3}\left(-2m_3\ddot{x}_3\ell_3\sin\beta_3\right) \qquad i = 1\ldots4 \qquad (1)$$

Where α_{ik} and δ_{ik} are influence coefficients of deflection on cross section "i" under unit force $F_{k=1}$ and under unit

momentum. $M_{k=1}$ respectively, on section 'k'. For calculating the influence coefficients of deflection, the bending stiffness of the elastic console is needed and is equal to: $B_x = B_y = EI_x = EI_y = E\frac{r^4\pi}{4}$ where $I_x = I_y = \frac{r^4\pi}{4}$ is the axial moment of inertia for the surface of cross-sectional area for the corresponding central axis passing through the center of the circle. E is Young's module of elasticity, r is half a diameter of the cantilever- stem. We analyze influence of branching angle on amplitudes of horizontal forced oscillations at the certain points of the plant stem.
Numerical analysis was done for the plant *Sorghum halepense* [4], r=0,0016m, $_2 = _3 = 0.08m$, $=1m$:, E=7,7x10^{9}Pa, (average value for stem of grass plants taken from [4] , for inflorescence masses approximatively values of $m_2 = m_3 = 0,075kg$ $m_4 = 0,15kg$, were used. $\beta_2 = \beta_3$. For different branching angles (from $\frac{1}{12}\pi$ to $\frac{5}{12}\pi$) under each of the circular frequencies $\Omega_y = 5/s$, $\Omega_y = 10/s$; $\Omega_y = 15/s$, and for $\Omega_y = 20/s$ of external forces the amplitudes of forced oscillations were done in points 1, 2, 3 and 4 of the model.

RESULTS

Results of our numerical analyses are shown on Fig2. Some characteristic extreme values are present for branching angle near $\frac{4}{12}\pi$. For $\Omega_y = 15/s$ and for $\Omega_y = 20/s$ amplitudes in point 3 (second branching) show almost linear increasing character as branching angle in this point increases, while amplitudes in other points decrease.

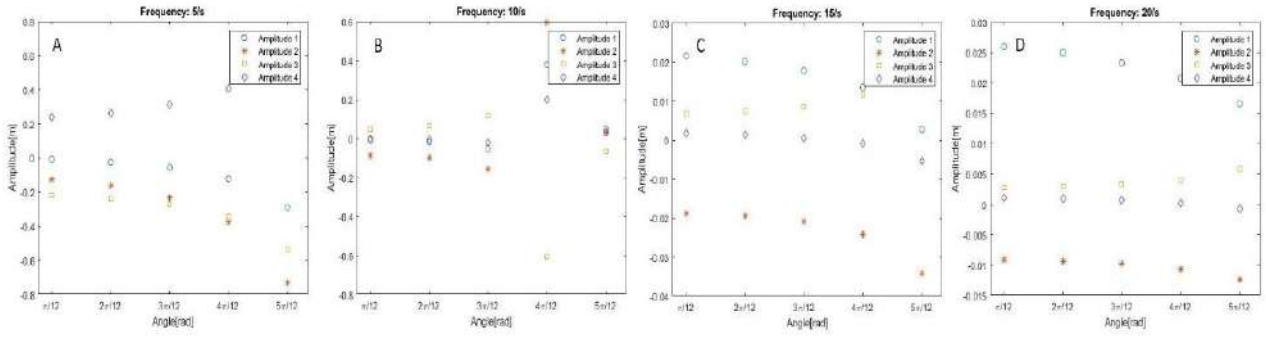

Figure 2. Amplitudes of forced horizontal oscillations for different external force circular frequencies values at different branching angles from $\frac{1}{12}\pi$ to $\frac{5}{12}\pi$. A. for $\Omega_y = 5/s$ .B. for $\Omega_y = 10/s$ C. for $\Omega_y = 15/s$. D. for $\Omega_y = 20/s$.

CONCLUSIONS

We study the influence of different branching angle on amplitudes of forced oscillations for four different values of circular frequencies of external force using previously proposed mechanical oscillatory model of corymb type of inflorescence. Our numerical results show that amplitudes of forced oscillations are frequency dependent, showing linear or non-linear character of amplitude oscillations depending on frequencies of external force excitation. Non-linear character of amplitudes changing have local minimums and maximums as value of branching angle increase. This model may be used for studying oscillations of different herbaceous plants which have corymb, or corymb-like type of inflorescence.

KHALLWA: DESIGN OF AN AERIAL ROBOT FOR THE PREVENTING BIRD DAMAGE TO BLUEBERRY CROPS

Jason Valera[1]
[1]Department of Engineering, Pontificia Universidad Católica del Perú, Lima, Perú

Summary Preventing bird damage to crops has remained a top priority for farmers since the dawn of time. When poultry feeding is not mitigated, crop yields are greatly reduced, a major economic blow. Currently, in Peru, up to an eighth of crops are lost each year due in part to bird activity. When the birds are comfortable enough near an abundant source of food and a safe environment, then they begin to settle. Then nesting begins and then they produce more young that feed on the crops. However, by using Khallwa to impose a sense of predation on resident birds, nesting is prevented and populations are reduced.

INTEGRATED DESIGN

The system presented consists of an unmanned aerial vehicle of the bird type. This aerial robot is composed of a lightweight and resistant expanded polypropylene and carbon fiber structure. Its flap wing flight mechanism allows it to fly lightly and with maneuverability. The flight control will be carried out by an autopilot, in this way, the system will be able to have an autonomous flight and travel the indicated cultivation area.

The robot will begin its movement when through a Wi-Fi connection between the embedded system and the computer, the flight parameters such as coordinates of the start of the flight, average height, distance to be traveled and coordinates of the destination are delivered. Once the system is configured with the flight parameters, the next step is the flight of the aerial robot. Once the aerial robot finishes its journey or the battery sensor indicates that the LiPo battery does not have enough energy for it to continue moving, the system will fly to its destination point.

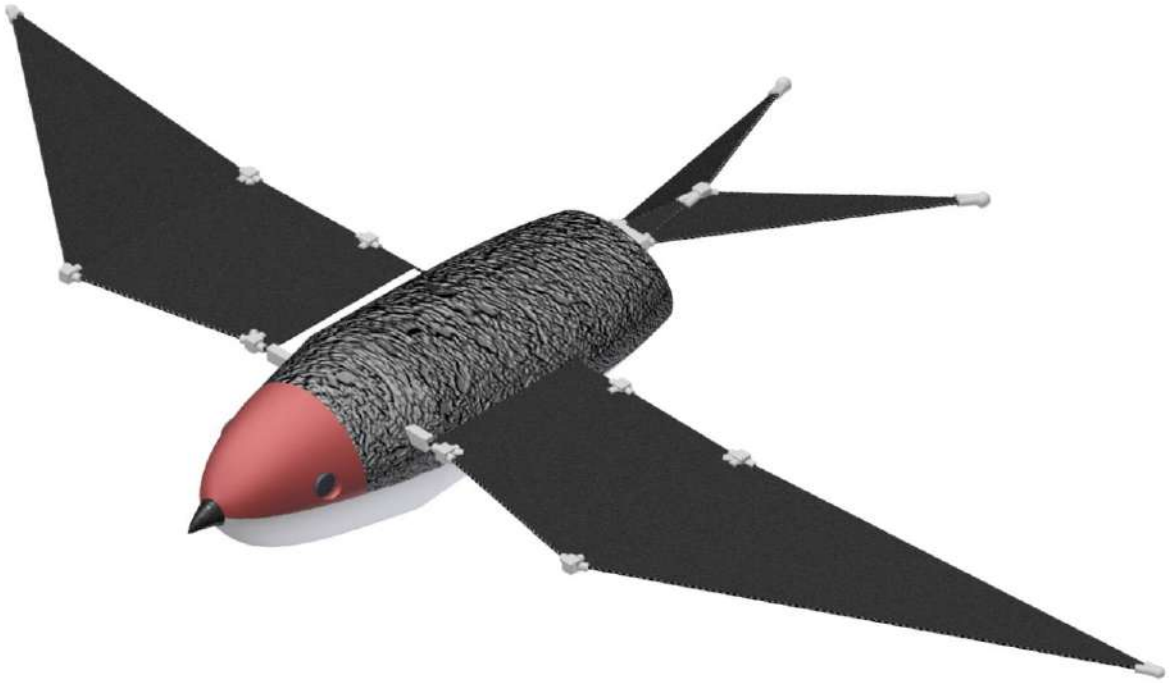

Figure 1. 3D Design (“Khallwa”)

Mechanical design

An unmanned aerial vehicle of the bird type is a flight vehicle that generates aerodynamic forces and moments to fly. The flexibility of the wings helps to gain sufficient lift and thrust. As a starting point you start with the main fundamental forces that must be balanced for flight. The lift force generated by the wings is equal to the weight of the system and the thrust generated by it is equal to the drag force or air resistance- This is so because the lift force occurs in a direction perpendicular to the of airflow, therefore, there is a component of lift force in the direction of horizontal flight. To achieve a high thrust effect, a high speed should be aimed. That means a high-impact wingbeat. As can be seen, with a noticeable "V" wing position, the main lift force, which is decisive for the model, is significantly less than the secondary lift force generated in the wing. Therefore, it is advisable to keep a small flap angle to generate lift; flap angles between ± 20 ° and ± 40 ° are considered adequate [1].

The flapping mechanism is the most critical part of the system, as it converts the electrical energy provided by the battery into the flapping motion of the wings. The design of the mechanism corresponds to a DC motor with a transverse

shaft that allows the double gear crank mechanism to perform the turning movement. The rotating gears and flapping wings are not in the same plane, so the connector rod must be able to rotate. The connector rod has ball joints to ensure the operation of the mechanism. The tail design is of the swing type, causing a swinging moment when swinging either side. The tilting tail works like a rudder, when tilted to the right it causes the system to turn to the right and vice versa. Also, lift can be added providing maneuverability and balance. The recommended starting angle for maneuverability is -20 ° [2].

Electronic design

The electronic design consists of the selection of the various electronic components. The power of the system is provided by the lithium-polymer (LiPo) battery, which will be connected to a power module that has a voltage and current sensor, which in turn will transmit the information on the state of the battery to the controller. Of flight. The flight controller is powered by the power module, feeds and communicates with a GPS module, allowing it to know its location at all times, it will also communicate with the electronic speed controller (ESC) to control the speed of the engine. DC. The servomotors are powered by the ESC voltage regulator and communicated with the flight controller.

CONCLUSIONS

A system was designed that allows navigating the blueberry field in such a realistic and unpredictable way that the birds perceive it as a true hunting bird of prey. Pilots can circle and dive, chasing birds off the ground, trees, and airspace over farmland.

AN OSCILLATION-FREE FULLY STAGGERED ALGORITHM FOR THE NUMERICAL SIMULATION OF CARDIAC ACTIVE MECHANICS

Francesco Regazzoni*[1] and Alfio Quarteroni[1,2]
[1]MOX - Dipartimento di Matematica, Politecnico di Milano, P.zza Leonardo da Vinci 32, 20133 Milano, Italy

Summary We address an unresolved problem in the numerical simulation of cardiac electromechanics, that is the onset of numerical oscillations due to the dependence of force generation models on the fibers shortening velocity. Despite these oscillations can be cured by resorting to monolithic schemes for the solution of the coupled problem of active-passive mechanics, staggered strategies (in which the submodels are solved sequentially) are preferable because of their reduced computational cost and low implementation effort. In this work we propose a cure for this issue, by introducing, with respect to the standard staggered scheme, a numerically consistent stabilization term. We prove that the proposed scheme is unconditionally absolutely stable, yet within a fully staggered framework, as we verify by means of 0D and 3D numerical tests.

INTRODUCTION

In silico models of cardiac electromechanics couple together mathematical models describing different physics. One instance is represented by the model describing the generation of active force, coupled with the one of tissue mechanics. For the numerical solution of the coupled model, partitioned schemes, that foresee the sequential solution of the two subproblems, are often used. However, this approach may be unstable. For this reason, the coupled model is commonly solved as a unique system using Newton type algorithms, at the price, however, of high computational costs. In light of this motivation, in this work we propose a new numerical scheme, that is numerically stable and accurate, yet within a fully partitioned (i.e. segregated) framework. A detailed derivation of the scheme and proofs of its stability properties can be found in [4].

THE STABILIZED-STAGGERED SCHEME

To derive our stabilized scheme, we move from energetic considerations on the coupling, at the microscale, between active and passive mechanics models. We show that instabilities are linked to the mismatch between macroscopic and microscopic strains, inconsistently expressed in Lagrangian and Eulerian coordinates, respectively. Hence, we formulate a novel scheme, in which all the variables are framed in a coherent fully Lagrangian reference system.

More precisely, in the standard staggered scheme, at each time step k one first updates the state variables of the force generation model (using an extrapolation from the previous time steps to account for the feedback of the mechanical model); then one updates the displacement variables, employing the updated active tension (that we denote by $T_{\mathrm{a}}^{(k)}$). Our proposed scheme only differs in this second step, in which one replaces the active tension $T_{\mathrm{a}}^{(k)}$ by the following term:

$$T_{\mathrm{a}}^{(k)} + K_{\mathrm{a}}^{(k)}(\lambda^{(k)} - \lambda^{(k-1)}), \tag{1}$$

where $K_{\mathrm{a}}^{(k)}$ denotes the *active stiffness* (i.e. the stiffness of all the attached molecular motors) and where λ is the tissue strain in the muscle fibers direction. The additional term can be regarded as a correction term, by which the active tension is not expressed as a constant anymore, rather it depends on the tissue strain in the fibers direction, more coherently with the microscopic phenomenon that generates the macroscopic force. We remark that such additional term is numerically consistent, as it is first order infinitesimal with respect to the time step size Δt. A formula for K_{a} can be based upon physical considerations, or can be derived formally from the force generation model, as the sensitivity of the rate of change of the tension with respect to the rate of change of the tissue strain, i.e. $K_{\mathrm{a}} = \frac{\partial \dot{T}_{\mathrm{a}}}{\partial \dot{\lambda}}$.

STABILITY ANALYSIS

Our stability analysis focuses on the eigenvalues of the transition matrices between two consecutive time steps. By considering a model problem of active mechanics, we show that the monolithic scheme is unconditionally absolutely stable. Conversely, when the active stiffness is larger than the passive stiffness in the fibers direction, the standard staggered scheme is only conditionally stable (i.e. stable for small enough Δt) and even unconditionally unstable in the case of quasistatic mechanics. Consequently, in the case of quasistatic mechanics the staggered scheme cannot be convergent when the active stiffness is larger than the passive stiffness in the fibers direction – as it happens during systole for realistic values of the parameters. We show that the stabilization term proposed in this paper brings all the eigenvalues of the transition matrix associated with the staggered scheme back into the unit circle, thus ensuring numerical stability.

Figure 2: Results of multiscale cardiac electromechanics simulations obtained with the staggered scheme (blue lines) and the stabilized-staggered scheme (red lines). The three lines refer to the minimum, average and maximum value over the computational domain.

NUMERICAL TESTS

We apply the proposed method to several force generation models available in the literature, namely the Niederer-Hunter-Smith model [2], the model of Land and coworkers [1] and the mean-field model that we proposed in [3]. We show, by means of several numerical tests, that the proposed stabilization term successfully removes the nonphysical numerical oscillations characterizing the non stabilized segregated scheme solution. This is verified in two different test cases, namely an isotonic twitch and a test case where a contracted fiber shortens as a consequence of a gradual decrease of the external load, similarly to what happens in the ejection phase of the heart cycle. We show that the new scheme preserves the first order convergence with respect to Δt of the non-stabilized staggered scheme. The numerical error is only slightly larger than the error obtained with the monolithic scheme and it tends to zero with the same rate. Finally, we apply the proposed scheme in the context of a three-dimensional multiscale electromechanical simulation of the left ventricle.

EFFECTIVE ELASTIC PROPERTIES OF EXTRACELLULAR MATRIX SIMULATED AS A FIBER NETWORK

Daria Orlova*[1], Sadik Omairey [2], Ayelet Lesman [1], Igor Berinskii [1]
[1]School of Mechanical Engineering, Tel Aviv University, Tel Aviv, Israel
[2]Brunel Composites Centre, Brunel University London, London, United Kingdom

Summary In this work, we investigated the effective elastic properties of a fiber periodic network. The randomly distributed network of the linear elastic elements represents the extracellular matrix on a microscopic level. In order to measure how the local anisotropy is changed at the scale of a cell, the square network samples were stretched up to 50% and the homogenization was performed at each stretching step. This allowed calculating the effective anisotropy parameter of the sample and the network effective elastic properties. It was shown, that for uniaxial stretching the maximal effective constant C_{11} exists, and corresponds to 10-20% strain, whereas the maximal anisotropy occurs at 30%.

INTRODUCTION

Cells respond to the physical characteristics of their surrounding environment in a manner that strongly affects the formation and repair of tissues. Environment's stiffness, porosity, and fibrous connectivity are important characteristics in tissue engineering and regenerative medicine. Accordingly, computational and experimental studies help determine the role of physical characteristics in directing multiple cell activities, such as cell reorientation, signaling, and extracellular matrix (ECM) remodeling [1]. The ECM is a cross-linked biopolymer network in which cells are embedded and provides support for the growing tissue.

The ECM fibers are mechanically connected to the cells and respond to contractile forces applied by cells [2]. When cells contract, they deform the surrounding matrix, which leads to large displacements and anisotropy that can propagate to long-distances. The anisotropy, which is a structural change of ECM fibers under mechanical forces, plays a significant role in cell migration and communication. However, it remains unclear how the external stretching influences the local anisotropy of the ECM between contractile cells.

The purpose of this work is to study the local anisotropy generated due to cell contraction and how this would change the structure of the surrounding environment for the cell's own benefit. For this, numerical homogenization of a periodic fiber cell is performed, to estimate the effective elastic moduli of the material, which will be used to further study the behavior of the material under various tension steps.

DISCRETE FIBER SIMULATION

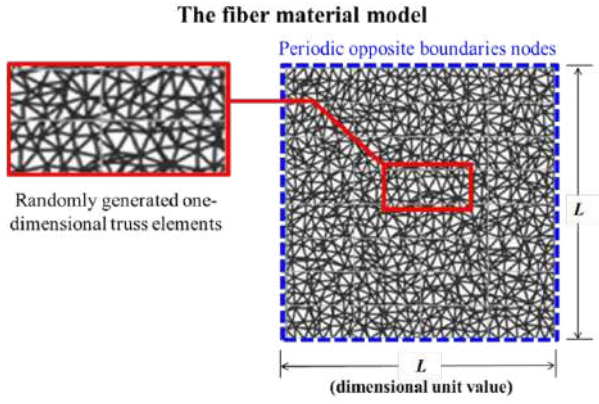

Figure 1. An illustration of fiber discrete periodic cell

A model of fiber material is developed to consider the response of the ECM to the external stretching induced by contractile cells. For the fiber periodic cell modelling we used Python program code, which was based on an algorithm that builds a triangular mesh using the Delaunay triangulation method. Then, the existing nodes were spatially displaced to simulate the random fibrous network of the ECM (Fig.1). The resulting model was transferred to ABAQUS CAE software for further tensile and homogenization calculations. Each fiber was modeled as a one-dimensional truss element, having an assumed cross-sectional area of 3.14E-05 μm. At this stage of the study, a linear mechanical model [2] is considered, with the fibers having an elastic moduli E = 0.0115 kPa, and Poisson's ratio $\nu = 0.475$

LINEAR HOMOGENISATION

In order to understand how the material responds to external forces, homogenization of the periodic cell was developed. For this purpose, EasyPBC plugin that implemented to the ABAQUS CAE software [3] is used. The plugin adopts the Representative Volume Element (RVE) homogenization method by, imposing periodic boundary conditions and external strains to calculate effective elastic properties of the randomly distributed fiber material model. As this numerical homogenization method assumes that the RVE is a part of periodic a material, the fiber model (Fig.1) is also modelled with periodic opposite boundary edges.

Five periodic fiber samples with different random distributions were considered. Each fiber sample was stretched up to 50% and considered for every 10% step along X-axis. It is assumed that the cells that stretch the matrix fibers are located

*Corresponding author. E-mail: dariaegorova@mail.tau.ac.il

on the X axis. During stretching, the fiber samples changed their shape to a rectangular one, so square regions of the same area were cut to satisfy the periodic boundary conditions for the following homogenization step.

Initially, the homogenized random fiber network has isotropic elastic properties. During tension, the effective material becomes anisotropic; namely, it reveals an orthotropic symmetry. The dimensionless parameter η was chosen, to measure the degree of anisotropy [4]:

$$\eta = 3\frac{2C_{66}}{C_{11}-C_{12}}$$

The value of the anisotropy parameter ranges from 0 to 1. The latter value corresponds to the isotropic case.

The elastic properties of the effective continuum corresponding to the studied fiber network. For each stage of stretching, a stiffness matrix was calculated for the two-dimensional material. The elastic constants (C11, C12, and C66) used to estimate the anisotropy parameter were calculated using the effective elastic properties estimated by the homogenization method and the stress-strain relation.

CONCLUSIONS

Using a finite element periodic cell, we explored how the external tension influences the local anisotropy. The fibrous material in the undeformed state was close to isotropy corresponding to the anisotropic parameter around 1. With an increase of uniaxial strain, the anisotropy parameter gradually decreased, indicating the appearance of local anisotropic properties. However, after deformation of 40%, the anisotropy parameter began to increase again (Fig.2 a). The maximum value of C_{11} is observed between 10-20% strain steps, making this configuration most preferable for cells to contact one another. On the other hand, a continues decrease in C_{11} is observed between 20-50% (Fig.2 b), which means that there is less material in the cut-out square of material during stretching. The graphs also show that the maximum of C_{11} does not coincide with the minimum of the anisotropy parameter.

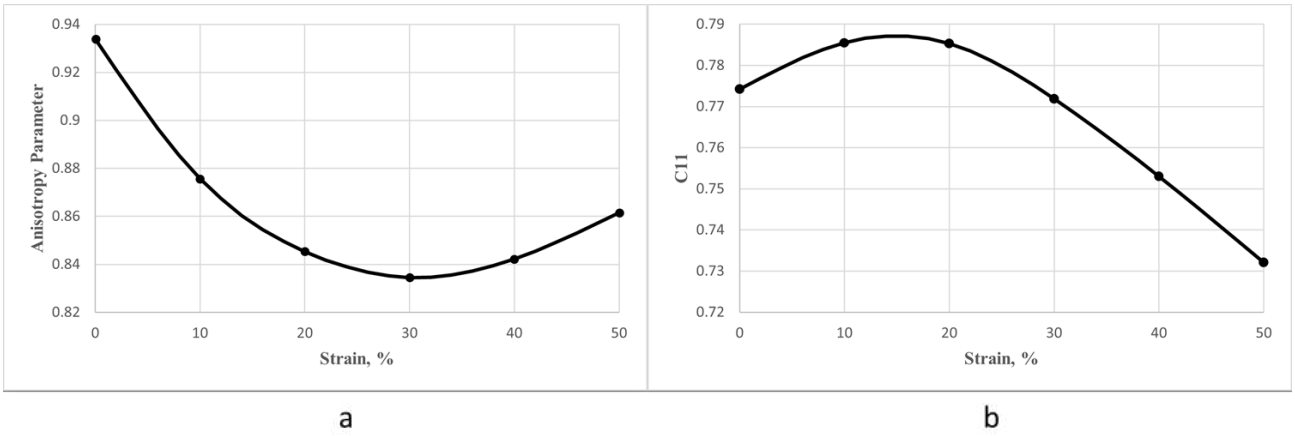

Figure 2. (a) – Average anisotropy parameter values versus the strain steps of 5 different randomly distributed periodic cells; (b) – Average C11 element value of the Stiffness matrix versus the strain steps of 5 different randomly distributed periodic cells.

The next step of our work is to perform homogenization using a nonlinear material model. The nonlinear characteristics of the material will help to study the local anisotropy between long-range cells. Additionally, using the obtained homogeneous material properties, the behavior of the nonlinear fiber material at the macro level can be investigated, which will significantly facilitate the study of fiber materials and allow considering large scale models.

DEVELOPMENT AND IMPLEMENTATION OF A FINITE ELEMENT CODE TO SIMULATE THE CARDIOBAND® PROCEDURE FOR MITRAL VALVE REGURGITATION: FIRST HUMAN PLANNING CASES

Emanuele Gasparotti[1,2], Sergio Berti[3], and Simona Celi*[1]
[1]BioCardioLab, Bioengineering Unit, Heart Hospital, Fondazione Toscana Gabriele Monasterio, Massa, Italy

[3]Adult Cardiology Unit, Heart Hospital, Fondazione Toscana Gabriele Monasterio, Massa, Italy

Summary The Mitral Valve (MV) regurgitation is a disease produced by the dilatation of the MV annulus ring. In recent years new techniques have been proposed to correct MV regurgitation. Among these, the Cardioband® system (Edwards Lifesciences, Irvine, USA) is a promising technique able to reduce the MV regurgitation by using a transcatheter approach. In this study we present an in-silico tool able to reproduce the Cardioband® procedure. Our tool is based on the integration of image processing and a finite element simulation. The specific aim of this study is to evaluate the accuracy of the tool by simulating the procedure of three different patients.

INTRODUCTION

Mitral valve regurgitation disease is one of the most common heart valve pathology [1]. Cardioband® system is a surgical-like direct annuloplasty adjustable device, implanted via transcatheter on beating heart [2]. This procedure consists by fixing the polyester sleeve (PS) of the device around the mitral annulus through specific metal anchors (about 12-17) and to contract the annulus by pulling a guide-wire (GW) sewed on the PS. Due to the complexity of the implant, this procedure requires skilled operators and an accurate planning phase. Currently, the implant size (anchors number) and the anchors position is defined on the base of the CT dataset by analysing the site of access and the annulus commissure to commissure length. In this study, for the first time in literature, we have developed an in-silico tool to fully reproduce the Cardioband® procedure starting from conventional medical images and the FE simulations. The accuracy of the tool was evaluated via simulation of the procedure performed on three different patients underwent to Cardioband® procedure.

WORKFLOW AND COMPUTATIONAL SET-UP

The considered patients' geometries include left atrium, mitral annulus, left ventricle and aortic root. These were obtained from a 3D segmentation of CT pre-procedural datasets, at maximal diastolic opening of the valve. A specific finite element routine was developed in Matlab® to simulate the biomechanical behaviour of the entire Cardioband® procedure. The routine applied the Cardioband® system equations (equilibrium and geometrical constrains) with the resolution of finite element equations of left heart mesh model. A 3D shell elements (Triangular 3-node 18 DOF [3]) was implemented and used to mesh the geometries. Different thickness and material properties were applied on the meshed domains to describe the different structures: the annulus ring, the left atrium, the aortic root and the ventricle were modelled with hyperelastic isotropic model [4]. The model was constrained with fixed nodal displacements in the interface areas between the right and the left ventricle. To simulate the force that anchor acts on the annulus, the relative node sub-selection was defined and then, the load interactions were imposed by compatibility equations. The behaviour of the Cardioband® device during the cinching phase of the guide wire was reproduced by the resolution of equation system. These equations govern the physics of a schematized model able to reproduce the interaction between the PS, the anchors and the GW. In particular, the GW was schematized as a 3D ideal inextensible cable with zero flexural and torsional rigidity. The cable can also slide through the sewn points during the cinching phase. The PS has the function to link the anchors to the GW. It is composed by a fabric able to transmit traction loads only. For this reason, in the simulation, the PS is considered as tie-rod structures connecting each anchor point to the corresponding sewn point of GW (Fig. 1a).

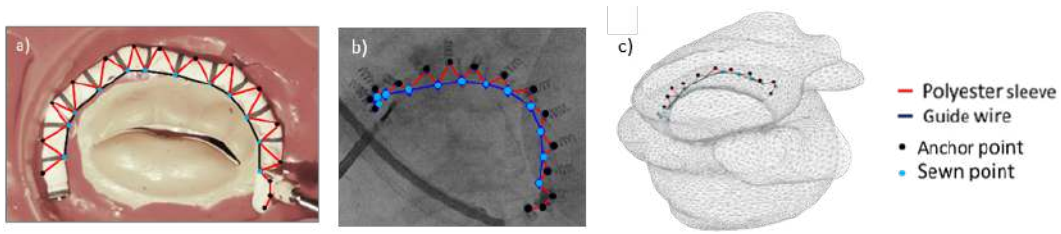

Figure 1: Cardioband® scheme (a), X-ray projection (b) and 3D Cardioband® models (c).

Three different patients were simulated. To evaluate the accuracy of the developed routine the initial device position was selected by the device projection, visible in the pre-cinching X-ray image (Fig. 1b). Fig. 1c depicts the initial

*Corresponding author. E-mail: s.celi@ftgm.it

configuration of the device, obtained by the registration between the 3D mesh of the left heart model and the X-ray projections. Finally, the resulting anchors and sewn point positions were compared with the corresponding ones found in the post procedure X-ray images.

RESULTS AND DISCUSSION

The simulation workflow, including medical images availability, the 3D geometries creation, the device positions definition and equations system resolution, was carried out with success through the developed tool. As regards the post-procedure, is it possible to observe a good overlapping between the patient's clinical procedure and the corresponding simulation in terms of the anchor positions and wire curves (Fig. 2a-f).

Tab. 1 summarizes the assessment of the accuracy by showing for each case, the position error was evaluated as the absolute distance between the simulated and actual final position of the anchor and the sewn points. These values are reported as the average ± the standard deviation. The average value error is less than 2 mm both anchor and sew positions.

Table 1: Device position error comparison (mm).

Moreover, the results of simulations allow to evaluate the influence of the device procedure on the left heart chambers and vessels (Fig. 2g-i). For all simulated patients it is possible to observe a left atrium displacement along the anterior direction (maximum value: 20 mm) and a left ventricle compressive displacement (maximum value: 10 mm). The left ventricle apex does not undergo to any displacements as well as the aortic root. The work presented here confirms that the routine of the Cardioband® procedure can reproduce the clinical procedures with a good accuracy. It is worth to point out that, the error committed by the routine to predict the anchor and sewn positions, is mainly affected by the intrinsic errors of the segmentation and by the identification of the anchors in the x-ray projection. The variability of the cases' outcomes suggests that the Cardioband® device capability to reduce the MV regurgitation is highly dependent on the patient's geometries, on anchors' positions and on anchors' number. The routine permits to foresee the procedure outcomes in terms of annulus shape and geometrical displacements; it gives the possibility to better understand the influence of the anchors position on the final annulus shape to increase the device effectiveness in the reduction of mitral regurgitation during a pre-planning phase in a clinical environment.

MODELLING MORPHOGENESIS OF SOFT CONNECTIVE TISSUES

Shuvrangsu Das*[1], Vikram S. Deshpande[1]

Summary In this work, we develop a statistical mechanics framework for the stochastic interaction of cells with extracellular matrix (ECM) in a developing connective tissues. The resident cells fluctuate in their positions and morphologies as well as subcellular cytoskeletal protein distributions while exchanging nutrients with its surroundings and sensing their mechanical environment. We hypothesize that the cellular behaviour is determined by the fact that the whole system of the cells and ECM maintains a homeostatic equilibrium, which in turn requires that the cellular morphologies depend strongly on the ECM stiffness. In particular, while on average the cellular areas remain similar for a range of ECM stiffness, the cells become progressively more elongated with a decrease of the ECM stiffness, contrary to what has been observed in in vitro experiments for cells on Petri dish.

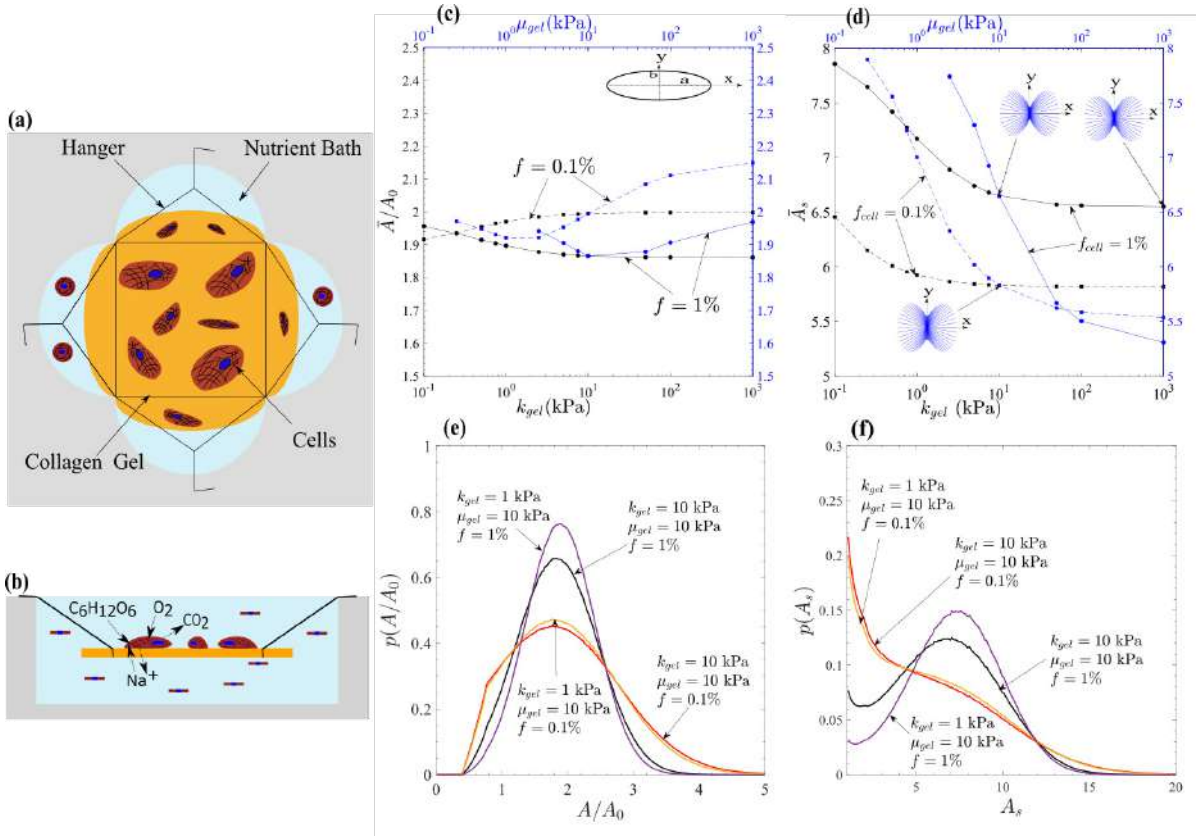

Fig 1. Cell expansion and elongation in a tissue construct. Sketch of the experimental setup: **(a)** top view **(b)** cross-sectional view. Collagenous gel, submersed in a nutrient bath, is seeded with cells to create a tissue construct, with its deformation is restricted by hangers on its edges. The cells exchange nutrients with the bath to maintain a homeostatic equilibrium. For simplicity, we present results only for the cases when cells are confined within the gel. **(c)** The ensemble averages of cellular areas $\bar{A}$, normalized by the area of undeformed cell A_0, for different substrate stiffness at seeding density of $f = 0.1\%$ and 1%. The cells are approximated by ellipses, with major and minor axes a and b, respectively, as shown in inset, such that each morphological area $A/A_0 = \pi ab$. The results are shown for varying bulk moduli of gel k_{gel} (kPa) for a constant gel shear modulus $\mu_{gel} = 10$ kPa, with the corresponding results are shown by black lines, and for varying μ_{gel} (kPa) for a constant $k_{gel} = 10$ kPa, with the corresponding results shown by blue lines. **(d)** The ensemble averages of cellular elongations $\bar{A}_s$, with elongation for each morphology $A_s = a/b$, are shown as well for varying k_{gel}, with $\mu_{gel} = 10$ kPa, and for varying μ_{gel}, with $k_{gel} = 10$ kPa. Insets show circular histogram for stress-fibre concentrations. **(e)** The probability density function for cellular areas $p(A/A_0)$. **(f)** The probability density function for cellular elongations $p(A_s)$.

Introduction

Soft connective tissues maintain homeostatic equilibrium in its dynamic steady state. The resident cells, such as fibroblasts, exchange nutrients with its surroundings and generate proteins and other substances to develop ECM, thereby establishing the mechanical environment they live in. The cells, driven by intracellular biochemical processes, fluctuate their positions and morphologies and continuously assess their mechanical environment by exerting forces and deforming the ECM. On the other hand, the mechanical loads acting on tissues are supported by the ECM components, such as collagen, elastin, and transmitted to the subcellular structures, such as stress fibres, via focal adhesions. The ECM deformation also leads to long-range cell-cell interactions through substrate deformation [1], especially at relatively large seeding density of cells. However, most of the studies to unravel the interaction between the ECM and cells are performed by seeding cells with a low density on relatively stiff substrates [2], thus failing to account for the effects of substrate deformation. The aim of this work is to develop a statistical mechanics framework based on homeostatic equilibrium [3], including the cell-substrate interaction as well as cell-cell interaction through the substrate. We report the cellular morphologies for a range of the ECM stiffness for two different seeding densities of cells.

Methodology

We consider an in vitro experiment concerning a 2D tissue in a nutrient bath. Extending the concept for the homeostatic ensemble for cells [3] to tissues, the cellular migration, morphologies and interactions are hypothesized to be dictated by a probability distribution such that the entropy of the system of the tissue and bath is maximized under the constraint that the total number of cells in the tissue remain constant and the homeostatic condition for the tissue is satisfied. However, for simplicity, here we restrict ourselves to the cases when all cells reside on the tissue.

Results

To account for complex cell-cell interactions for a large number of cells, we approximate each cellular morphology by ellipses. Fig. 1 shows the ensemble averages and distribution of area and aspect ratio of elliptical cells. The collagenous gel is modelled as compressible Ogden material with bulk and shear modulus given by k_{gel} and μ_{gel} kPa, respectively. The results indicate that

- The average cell expansions depend weakly on substrate stiffness, at least for seeding density of $f = 0.1\%$ and 1%, as shown in Fig. 1**(c)**.
- Fig. 1**(d)** shows that the average aspect ratio depend strongly on the substrate stiffness, where the cell elongation increases with decreasing substrate stiffness. This can be argued to be originated from stronger cell-cell interactions at highly deforming substrate. Moreover, Fig. 1**(d)** shows that circular histograms for stress-fibres concentrations and they are predominantly concentrated along the major axis of the ellipse, where the concentrations along the major axis relative to the minor axis increase with cell elongations.
- The cell areas exhibit unimodal distributions with similar mean and modes, as shown in Fig. 1**(e)**. In addition, the distributions are increasing peaked with decreasing substrate stiffness and increasing cell density.
- Finally, Fig. 1**(f)** shows that the cell aspect ratios could exhibit unimodal distributions at low cell density, with mode and mean being very different. However, with an increase of cell density, at relatively low substrate stiffness, the distribution become bimodal.

Conclusion

This work demonstrates that the cell-cell interactions are strong when complaint substrates are seeded with a high density of cells. Our statistical framework captures these interactions as well as cell-ECM interactions by developing a homeostatic ensemble for cellular position and morphologies, which enables us to obtain the underlying distributions of cellular morphologies as well.

Summary Mechanical characterization of human skin based on suction experiments was shown to be useful for detection of structural changes in the dermis, as it occurs in fibrotic tissue. Several suction devices are commercially available, however so far no one is used for a clinical assessment. This is mainly due to high inter- and intra-observer variability, but the cause of these problems is poorly understood. The present work provides a thorough analysis of the factors influencing the mechanical response of human skin to suction. The results are used to improve and optimize existing measurement protocols and to develop a more effective suction device.

MECHANICAL CHARACTERIZATION OF HEALTHY AND DISEASED SKIN

Human skin consists mainly of three layers, the epidermis, the dermis and the subcutaneous tissue layer. While the epidermis functions, inter alia, as a barrier for our body against environmental influence, the dermis provides the mechanical structure of the skin. Consisting of collagen, elastin, proteoglycans and ground substances, the interaction of these components determines a complex mechanical behaviour. Several skin diseases modify the microstructure of the dermis and therefore the mechanical behaviour of the skin. For example, in patients with systemic sclerosis (SSc) skin fibrosis leads to massive deposition of collagen fibres in the dermis [1] and therefore to a stiffer tissue behaviour compared to healthy skin. In hypertrophic scars, similar processes can be observed, where the structure of the dermis, mainly density and organisation of collagen fibres, is altered and therefore leads to higher stiffness of the scar tissue. Quantification of such alterations associated with skin diseases can be based on mechanical measurements. A suitable measurement principle is the suction method [2, 3], where a negative pressure draws the tissue into a geometrically defined probe opening while the elevation of the skin is measured. With such measurement tools, the elastic and viscoelastic deformation behaviour of the tissue can be captured. One specific mechanical parameter is the skin stiffness, based on the pressure needed for a certain tissue elevation. Suction is pain-free, non-invasive and thus a highly promising in-vivo measurement method. Unfortunately, existing devices show limitations in their handling, which lead to issues when operating in a clinical environment. The main limitation was shown to be related to the contact force between the aspiration probe and the skin surface while placing the probe [4, 5]. To improve existing measurement protocols and facilitate clinical application of suction devices, we aim at a better understanding of the measurement procedure and its impact on the investigated tissue. To this end, we used measurement outcomes of a load and a displacement controlled suction device.

METHODS

Skin mechanical characterization was performed with the Cutometer®, a commercially available device, and the *Nimble*, a novel suction device [5]. The Cutometer® operates load-controlled (Figure 1 A): a predefined negative pressure draws the skin into the probe opening. The light source tracks the tissue elevation through the entire measurement cycle. For calculation of the tissue stiffness, $k^{Cutometer}$, the maximum pressure in *mbar* is divided by the maximum reached elevation in *mm*. The *Nimble* operates displacement-controlled, where a negative pressure draws the skin into the probe opening until a defined height h is reached. The outcome measure is the pressure needed for the specific tissue elevation, and the tissue stiffness, k^{Nimble}, can be calculated as the ratio of this pressure in *mbar* and the elevation h in *mm* (Figure 1 B).

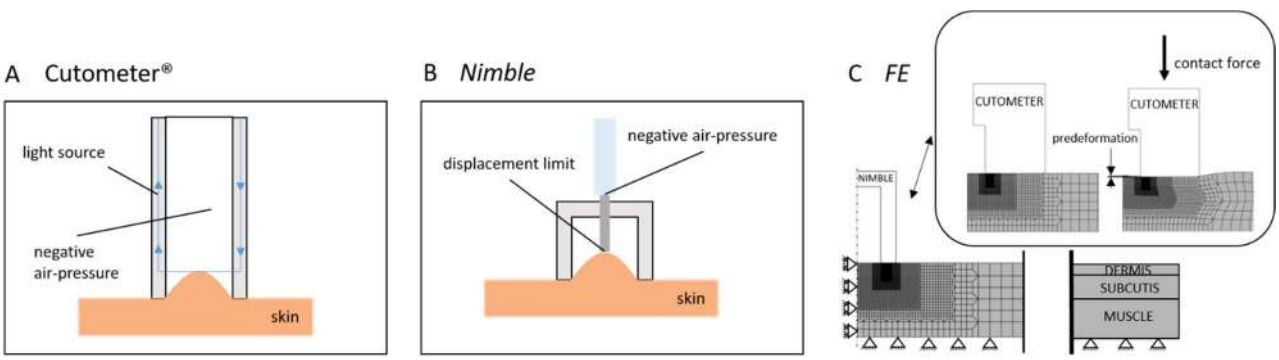

Figure 1. Schematic representation of the working principle of the suction devices Cutometer® (A) and *Nimble* (B). (C) *FE* models for the suction simulations of Cutometer® (top) and *Nimble* (bottom).

A data set from suction measurements with tightly controlled contact conditions on healthy skin and scar tissue was used for an *FE* based inverse analysis (Figure 1 C) determining the parameters of a hyperelastic viscoelastic model[6]. *FE* simulations with the calibrated material model helped to understand factors influencing the measurement procedure on healthy skin and scars.

RESULTS

Results from a clinical trial including 26 burn patients [7] to evaluate the potential of suction measurements for assessment of hypertrophic scar formation, and a clinical trial including 30 SSc patients [8] to investigate the diagnostic potential of the suction method, showed correspondences, but also clear differences between measurement outcomes of the two suction devices. One important deviation concerns the stiffness, which was systematically higher from Cutometer® measurements. The reason for this is the higher deformation level in Cutometer® measurements (Figure 2 A). Skin's response is nonlinear, leading to higher stiffness for larger tissue's elevation. The second observation is related to the effect of predeformation due to the contact force in suction measurements. Based on *FE* analyses it was possible to identify a correction procedure, minimizing the effect of the predeformation. *FE* simulations also enabled to rationalize the higher sensitivity of displacement- when compared to load-controlled suction measurements (Figure 2 B). Wider range parametric studies demonstrated that a displacement-controlled system with low elevations captures changes in tissue stiffness much better than a load-controlled system.

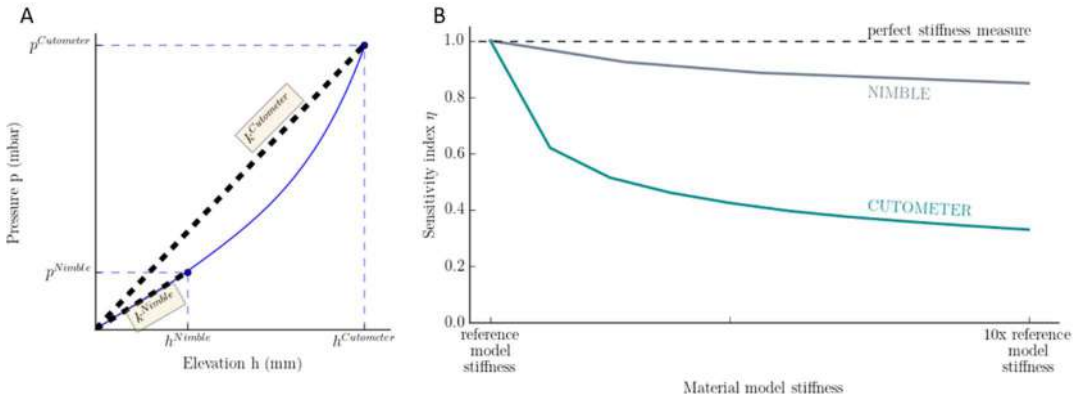

Figure 2. (A) Pressure - elevation curve of the fitted healthy skin model. Elevation and pressure measure of the two suction devices are indicated, and the evaluation of tissue stiffness measure k^{Nimble} and $k^{Cutometer}$ are shown. (B) Sensitivity index shows the different ability of the devices to capture variations of skin stiffness.

CONCLUSION

The suction method is suitable for characterization of human skin. It is a non-invasive in-vivo measurement method and can be applied for clinical assessment. However, clinical use is limited due to measurement uncertainties, the most important one being due to the contact force induced at probe placement. Our studies investigate different factors influencing suction measurements. *FE* based simulations of the suction response of healthy and fibrotic skin provided methods to improve data analysis towards higher reliability and sensitivity of suction measurements. More importantly, simulations indicated that lower level of deformations and a displacement controlled measurement procedure significantly enhance the ability of suction to detect clinically relevant tissue modifications. Current investigations focus on the diagnostic relevance of parameters associated with the dissipative tissue behaviour, which might be quantified in long duration suction or cyclically repeated measurements.

THE INTERPLAY OF SOLID AND FLUID MECHANICS IN CONTACT INTERFACES AT THE ROUGHNESS SCALE

Summary Solid Mechanics SM02 Tribology - Contact and Friction

We study the normal contact between representative rough surfaces in presence of a fluid flow in the contact interface. Both one- and two-way couplings of fluid and solid equations are considered via the boundary and finite element methods as well as via the self-consistent homogenization scheme. Some general results are obtained for the transmissivity of rough contact interfaces for incompressible creeping fluid within the one- and two-way coupling frameworks. One of the main novelties is a careful account for fluid "lakes" representing pockets of fluid, which are trapped within non-simply connected contact zones. An appropriate non-linearly compressible liquid model is used there to ensure physically meaningful results. This framework enables us to study the effect of trapped fluid on the macroscopic static friction of the interface both for elastic and elasto-plastic material models.

INTRODUCTION

Contact and friction interactions play an essential role in many quotidian contexts, including those related to industry (e.g., tire-road and wheel-rail contacts, electric switches, bearings, and brake systems), everyday human activity (e.g., walking, handling, touching, and sitting) and natural phenomena (e.g., earthquakes, landslides, and glacier motion). Regardless of such prevalence, contact-related mechanisms (friction, adhesion, and wear) are still not fully understood and thus are among the most cutting-edge research topics in the mechanical community. This is explained by the fact that those processes are inherently of multi-scale and multi-physical nature and thus are very challenging to be modelled in their integrity. One of particular multi-physical problems related to contact and friction is the fluid flow through the contact interface which involves, from mathematical point of view, a concurrent resolution of fluid and solid equations which is further complicated by the non-smooth nature of contact constraints which have to be respected by the solution. The deformation of the solid constrained by the contact interaction determines the available paths for the fluid to flow, the flow pattern determines the repartition of the fluid pressure and shear tractions, which deform in its turn the contacting solid. At the roughness scale, in the first approximation, the interfacial flow of an incompressible creeping fluid can be accurately modelled using relatively simple Reynolds equation, which is further simplified when there is no tangential motion of the walls (normal contact). However, for complex surface geometries, such a random self-affine roughness, this simplest fluid-solid coupling problem has a particular difficulty related to the fact that the fluid can be trapped within non-simply connected contact clusters (zones). The "lakes" of trapped fluid add additional constraints to the problem and, being coupled to the surrounding contact, result in a strongly non-linear and computationally challenging problem. The laws governing creeping fluid flow and diffusion through contact interfaces between rough surfaces brought in contact are essential not only for sealing engineering but also for understanding mass transport through porous media consisting of networks of percolating cracks encountered in many geological materials.

The objective of this study is multi-fold. First, we make a link between the roughness characteristics of contacting surfaces and its mechanical characteristics, and further with the transmissivity of the contact interface for different externally applied pressures and fluid pressures. Second, we characterize various effects of the trapped fluid, notably, how they affect the macroscopic transmissivity of the interface and its static friction limit. Moreover, the possibility of hardly compressible fluids to escape from the contact trap is analysed. Finally, the necessity of the strong, two-way coupling between fluid and solid equations is investigated in detail in the present context.

METHODS

In the case of *one-way coupling*, we use a spectral-based boundary element method [4] to solve frictionless and non-adhesive normal contact between two elastic half-spaces with rough surfaces in the framework of infinitesimal deformations. Numerical simulations of contact are carried out on synthetic rough surfaces with controlled spectra. The study is focused on the analysis of the evolution of the true contact area and the free-volume field under increasing squeezing pressure, which together determine the transmissivity of the interface and could be used in the analytical self-consistent homogenization model. To improve the accuracy of the contact area simulations, we used a simple technique which is based on the estimation and correction of the discretization error [5]. This technique enables us to study rough surfaces within unprecedentedly *wide* range of parameters without loss of accuracy. Therefore, this analysis could be done using moderate computational grids of only 2048×2048 points on the surface. The fluid problem on the resulting free-volume

Figure 1: Left: weakly-coupled simulation of the fluid flow in rough contact interface, pockets of trapped fluid are shown in blue, contact area is shown in black, reddish colours correspond to the fluid flux; right: fully coupled finite element simulation of a creeping fluid flow in contact interface between a rigid wall (not shown) and an elasto-plastic substrate.

field is solved using the finite element method. A complete statistical study of (1) the contact area growth, (2) the force-separation evolution and (3) the change in transmissivity is carried out, the mean value and the standard deviation are estimated. A novel monolithic finite element formulation ensuring a strong coupling between fluid and solid equations is used to solve the two-way coupled problem for the creeping flow in the contact interface [3, 1]. Within this framework, based on the mortar-like contact discretization which relies on the monolithic augmented Lagrangian method to handle contact and friction, we successfully handle three types of interface elements: contact, fluid flow and trapped fluid, which are in permanent evolution and change, but the resulting scheme is shown to converge even in most challenging situations.

RESULTS

The obtained results can be split into two categories: first, related to the mechanical contact of rough surfaces and, second, related to the fluid flow in the interface. For the first category, we obtained relatively universal phenomenological equations for the evolution of the contact area with increasing applied pressure, which is valid for different spectral contents [6]. Moreover, we estimated the growth of the "conducting" area, i.e. the interface area excluding the contact area and the trapped area; this area can be used in the self-consisted homogenization model for the estimation of transmissivity. The force-separation curves are also obtained and compared to models available in the literature. Novel results on the asymptotics of the opening field near zero values are obtained analytically and compared with the simulations. For the case of incompressible and non-linearly compressible trapped fluid, we found analytically the external pressure needed to "untrap" the fluid. This theoretical possibility for the fluid's escape implies a decrease of the frictional resistance of the interface with the increasing pressure, which presents an interesting results. This case is analysed both for elastic and elasto-plastic material models; for the latter, an interplay of non-linear fluid compressibility and the plastic flow produces a non-monotonous change in the friction coefficient [2]. Finally, for the case of trapped fluid in frictional interface, using the linear elastic fracture mechanics we predict emergence of shear-stress peaks near the zone where the fluid penetrates in the contact under the increasing pressure; this results is important for the fatigue of contact interfaces subjected to a cyclic load. In what concerns the results for the fluid transmissivity, we obtain novel results making a link between roughness parameters, applied pressure, pressure drop in the fluid and the mean fluid pressure. A very accurate phenomenological model is constructed and generalized for the permeability of cracks with initially conformal geometry. A fine analysis is carried out to characterize the effect of trapped fluid, critical junctions and transitional regimes of the transmissivity, including the near-percolation asymptotics. The one- and two-way coupling strategies are compared.

MULTIPHYSICAL FINITE ELEMENT MODEL FOR AIR FOIL THRUST BEARING OPTIMIZATION

Markus Rieken*[1], Pascal Zeise[1], Marcel Bauer[1], and Bernhard Schweizer[1]
[1]Institute of Applied Dynamics, Technical University Darmstadt, Darmstadt, Germany

Summary Air foil bearings are applicable in high speed turbomachinery and oil-free environments. Detailed thermo-elasto-hydrodynamic (TEHD) finite element models can be used to optimize bearing geometry. Results for an air foil thrust bearing (AFTB) are presented in this work. Deformations and temperatures of the foils and the rotor as well as the temperature and the pressure of the lubricating air film are calculated. Moreover, the rotation-induced laminar/turbulent flow on the backside of the runner disk is part of this multiphysics model. Results show the strong connection between the lubricating gap height and thus the pressure buildup with top foil sagging. Thermal bending of the runner disk is a key factor in performance reduction.

MULTIPHYSICS MODEL OUTLINE

For the modeling of an AFTB (see Fig. 1), physical equations from 3 disciplines are used, namely thermo-elasticity (deformations of the top and bump foils and of the rotor disk), hydrodynamics (pressure distribution in the air film and backside flow) and thermodynamics (temperature of top foil, air film, backside flow, radial gap, rotor and rotor disk). Figure 1 gives an overview over the bearing components. The governing partial differential equations (PDEs) are discretized using finite elements (FE). The resulting nonlinear FE model has approximately 425 000 degrees of freedom in 260 field equations for which stationary studies are carried out. The investigated rotor-bearing system has the following main parameters: rotor diameter $d_R = 27\,\mathrm{mm}$, disk radius $r_D = 31\,\mathrm{mm}$, disk thickness $t_D = 4\,\mathrm{mm}$, inner top foil radius $r_i = 15\,\mathrm{mm}$, outer top foil radius $r_o = 30\,\mathrm{mm}$ and maximum rotational speed $\Omega_{max} = 120\,\mathrm{krpm}$. In this study, only a single bearing pad (a single top foil with bump foil underneath) is investigated. While the base plate of Fig. 1 (blue) is treated as a rigid body, deformations of the thin bump and top foils (yellow/orange) due to pressure forces cannot be ignored. The governing equations used in the current model for the foil deformations originate from Reissner-Mindlin shell theory. The normal contact force between bump and top foil on the one hand and bump foil and base plate on the other hand are both implemented using a penalty formulation. The tangential behavior between top and bump foil is modeled via a stick-slip approach (regularized Coulomb friction). Using the generalized Reynolds equation of lubrication theory [1] combined with an averaging approach [2, 3] for the air temperature, a simplified Reynolds equation in 2D Cartesian coordinates is obtained to calculate the pressure distribution $p(x, y)$ in the lubricating gap with height profile $h(x, y)$. For the temperature calculation in the lubricating gap, the 3D energy equation (without external heat source terms) is solved. Radial and axial deformations of the rotor disk are calculated based on the Navier-Lamé equations with an account for thermal stresses. Temperatures of the rotor disk and the top foil are calculated using a 2D energy equation. At the backside of the rotor disk, the disk rotation causes an airflow. The velocity field consisting of the radial, the circumferential and the axial velocity is calculated from the boundary layer equations for steady incompressible axisymmetric flow (neglecting a radial pressure gradient), see Ref. [4].

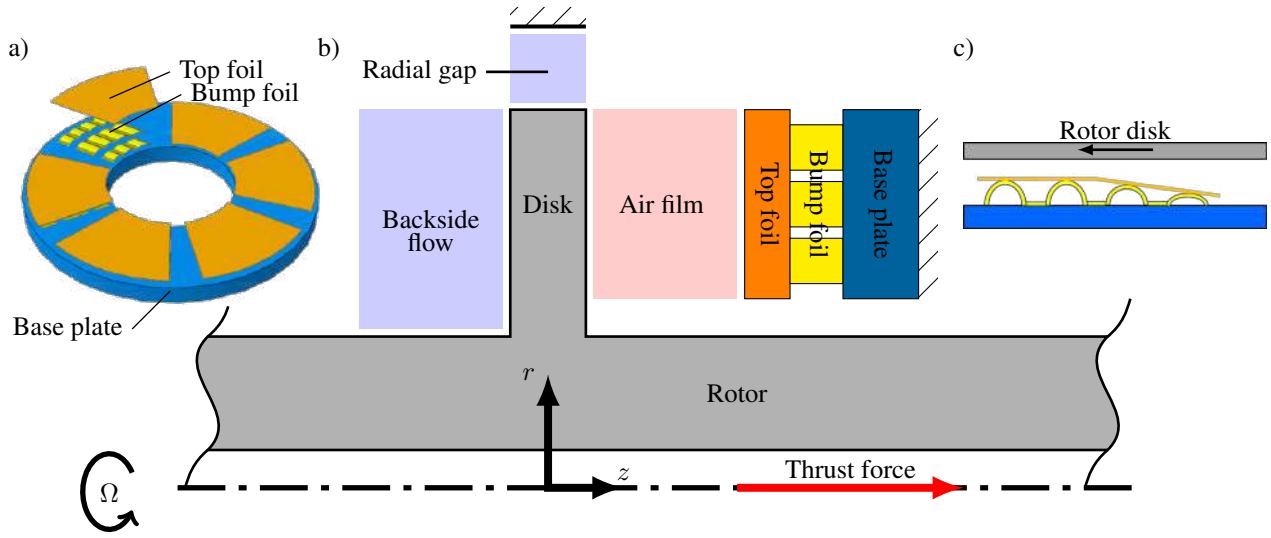

Figure 1: Overview over AFTB components (not to scale). a) Bearing with 6 identical pads, b) section view of bearing in assembly and c) converging gap between top foil (stationary) and rotor disk.

*Corresponding author. E-mail: rieken@ad.tu-darmstadt.de.

SIMULATION RESULTS

Fig. 2 shows simulation results for a stationary study at a rotational speed of $\Omega = \Omega_{max}$. Fig. 2 a) shows the lubricating gap height h which is a combination of the taper-land geometry through bump height variation as well as the top foil and rotor disk deflections. It is clearly visible that the top foil sags between its contact lines with the underlying bump foil (depicted in the line scheme at the bottom of Fig. 2 a)). Due to the thermally induced bending of the rotor disk away from the lubricating gap, gap height increases towards the outer radius of the pad. Therefore, the minimal gap height (in this case $5\,\mu$m) is found close to the trailing edge at the inner radius of the pad which is likely to be the first point of contact between top foil and runner disk in an overload scenario.
Fig. 2 b) shows the 2D pressure increase (with regard to ambient pressure) over a pad with two distinct pressure peaks near the trailing edge. These originate from the wavelike deflection of the top foil and occur at the contact lines of top and bump foil (cf. Fig. 2 a)).
Fig. 2 c) shows 3 slices through the 3D temperature field of the air film. At the top, a radial pattern results from the temperature distribution in the runner disk. Due to the more efficient heat transfer near the outer radius of the disk (on its backside), temperature drops despite higher velocities. At the bottom, the interface to the top foil is visible. While the temperature generally increases from leading to trailing edge, the pattern of contact lines clearly shows as colder spots. This is because most of the heat flux at this bottom interface is conducted through the bumps, cf. [5]. Thus, the hottest spots are not observed at the spot of the smallest gap height, but at the trailing edge and between the contact lines. As can be seen from the intermediate slice, this pattern eventually fades out when the interface to the disk is reached.

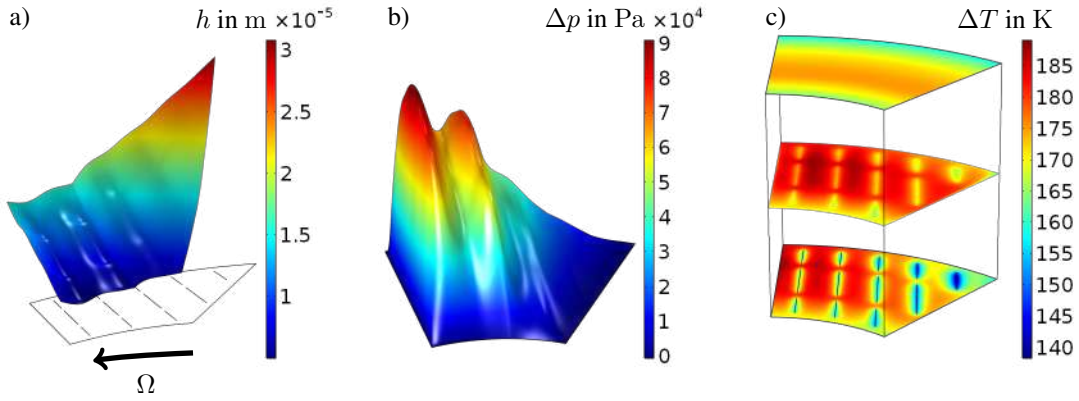

Figure 2: a) Gap height h, b) air pressure increase Δp and c) air temperature increase ΔT.

CONCLUSIONS

The performance of AFTBs is significantly influenced not only by the hydrodynamic, but also by the elastic and thermal behavior of its components. Pressure induced top foil sagging between the bump support lines and, more importantly, thermally induced rotor disk bending are two key contributors to a decrease in load capacity and can eventually lead to bearing and (consequently) machine failure.

Summary Surface energy plays an important role in instability phenomena in liquids and soft matters, but rarely has similar effects in solids. Here, a novel mechanical instability controlled by surface energy is reported which is valid for a large class of solid materials, in particular two-dimensional layered materials. When sliding a top flake cleaved from a microscale graphite mesa by a probe through a point contact, we observe that the flake moves without rotation for a certain distance, and then suddenly rotates when a critical displacement is reached. The theoretical analysis is consistent with experiments and reveals that this instability is an interesting effect of superlubricity (a state of nearly zero friction). The uncovered mechanism provides useful knowledge for manipulating and controlling these sliding joints, and can guide the design of future superlubric devices.

INTRODUCTION

Surface energy plays an important role in a number of instability phenomena observed in liquids and soft matters, but rarely has similar effects in solids. For a micro/nano system, the surface-to-volume ratio is increased significantly, and thus surface energy is expected to have a greater effect. However, in sliding devices, this effect is usually overwhelmed by interfacial friction. In order to observe the effect of surface energy in these sliding joints, friction has to be ultralow. This is exactly the case in superlubric systems, where the incommensurability of the solid contact results in systematic cancellation of interfacial friction, thus the total friction of the contact is almost zero[1]. This fascinating phenomenon was theoretically predicted and then observed on nano-contacts[2–4]. Microscale superlubricity was later achieved on graphite mesa system, which contains pillar-like mesas fabricated on the surface of highly orientated pyrolytic graphite (HOPG) through micro-fabrication[5].

EXPERIMENTAL OBSERVATION

During the manipulation of graphite mesas, rotational instability was observed. The experimental setup is shown in Fig.1(a). The square shaped graphite mesa (with typical width 4 μm) is sheared by a tungsten tip quasi-statically under an optical microscope. As shown in Fig.1(b), when sheared by a nearly centric tip (centric loading), the top flake with side length of a, slides without rotation for a displacement up to a critical value. When the critical point is reached, the top flake suddenly rotates, showing a rotational instability. On the other hand, when shearing using an eccentric tip (eccentric loading) with eccentricity, e, one might expect the top flake to rotate immediately due to the eccentric loading. However, a different behavior was observed in fact. As shown in Fig.1(c), the top flake still slides without rotation for a considerable displacement, until similar rotational instability occurs at a critical displacement, which is smaller than that in centric loading case. This can be better seen from the curve of the top flake rotation angle θ vs. displacement δ. As shown in Fig.1(d), θ remains nearly zero before a discontinuity in the curve corresponding to the rotational instability.

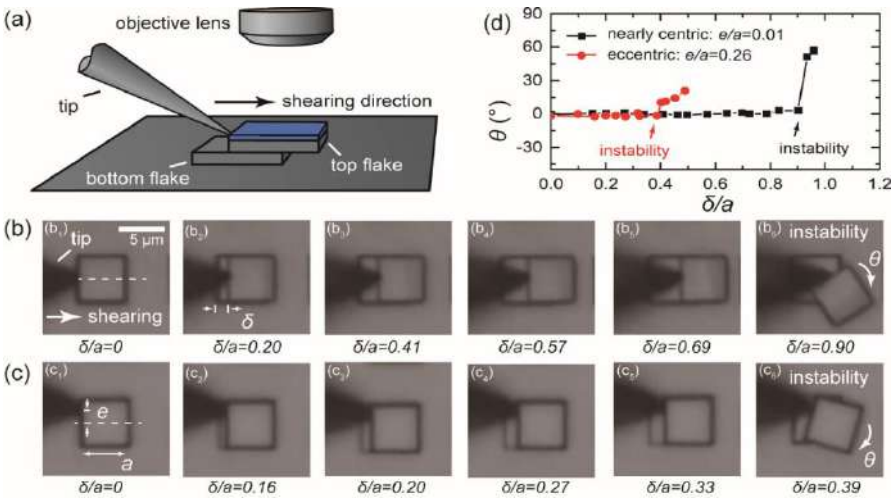

Figure 1. (a) Experimental setup. (b)(c) Images from top view for the case of centric loading and eccentric loading, respectively. Scale bar 53μm. (d) Top flake rotation angle θ vs shearing displacement δ. The sudden rotation (rotational instability) happens at a critical displacement, while before the instability, the top flake stays unrotated.

MECHANISM & APPLICATIONS

The experimental observations can be rationalized by a kinematic model. We model the system as a fixed bottom flake and a rigid but movable top flake with two degrees of freedom, i.e. the displacement along with the tip δ, and the rotation around the tip contact point θ, as shown in Figs. 2(a)(b). For an arbitrary configuration (δ, θ), the total potential energy of the system[6] is $U = 2\gamma_{sa}(A - A_{ss}) + \sigma A_{ss}$, where γ_{sa} is the surface energy of graphite, σ is the interfacial energy of the incommensurate graphite-graphite interface, i.e. the overlapping area, A_{ss}, between the top and bottom flakes during sliding, and $A = a^2$, as shown in Fig. 2(b). By noting that $\Gamma = 2\gamma_{sa} - \sigma$ which is the cleavage energy of graphite, we have

$$U(\delta, \theta) = 2\gamma_{sa}a^2 - \Gamma A_{ss}(\delta, \theta). \quad (1)$$

By defining the normalized total excess potential $U^* = (U - 2\gamma_{sa}a^2)/(\Gamma a^2) = -A_{ss}/a^2$, the calculation of U^* comes down to the calculation of the overlapping area A_{ss}, which is conducted either analytically or with numerical algorithms. Neglecting kinematic energy, the equilibrium configuration of the system is determined by the potential minima in (δ, θ) space.

Figure 2(c) shows the calculated U^* as a function of θ in the case of perfectly centric tip loading ($e/a = 0$, left) and eccentric tip ($e/a = 0.225$, right), respectively. When the loading is centric, $\theta = 0$ is always a local energy minimum regardless of δ, thus un-rotated sliding is always stable/metastable. On the other hand, in the case of $e/a = 0.225$ (eccentric loading), an energy minimum is still found at $\theta = 0$, but only for $\delta < \delta_{cr} \approx 0.329a$. At δ_{cr}, such an this energy minimum vanishes, leading to the sudden rotation of the top flake.

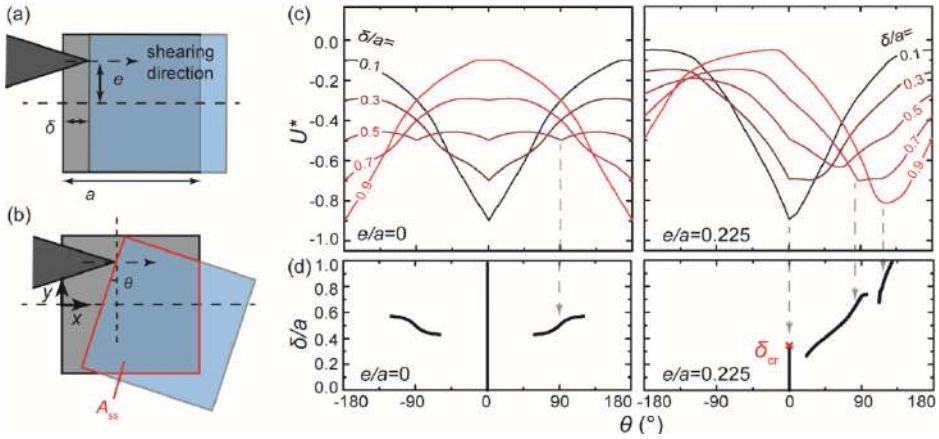

Figure.2 (a)(b) The kinematic model. The bottom flake is fixed and the top flake is a rigid but movable body with two degrees of freedom, i.e. the displacement δ, and the rotation around the tip contact point θ. (c) Calculated normalized total potentials (U^*) as functions of θ for centric loading ($e/a = 0$, left) and eccentric loading ($e/a = 0.225$, right), respectively. In the former case, an energy minimum is always found at $\theta = 0$. In the latter case, an energy minimum is found at $\theta = 0$ for $\delta < \delta_{cr} \approx 0.329a$. When δ_{cr} is reached, this energy minimum vanishes, leading to the sudden rotation. (d) Branches of stable/metastable points are indicated by the black lines that correspond to the left- and right-hand sides of (c) in (δ, θ) space where local energy minimum is met.

The mechanism behind the rotational instability provides an elegant idea for effectively constraining the relative rotation of a superlubric joint through surface energy. This is very important in the design of superlubric devices since one of the main challenges in superlubric devices is to control the sliding direction and constrain the relative rotation without introducing extra mechanical contacts (where friction cannot be avoided). Through simple geometric design, the superlubric joint can be made rotation-proof in certain range of parameters. For example, a case study performed on a superlubric slider sliding on a guide rail shows that the slider is expected to stay on track thanks to the constraining effect of surface energy[7,8].

CONCLUSIONS

In conclusion, a rotational instability was observed in microscale graphite sliding joints. The comparison between experimental observation and theoretical modelling reveals that such instability is controlled by the surface and interfacial energies of graphite. The result is independent of the specific material and is fully scalable. Thus, it is not limited to graphite, and is also applicable to other superlubric sliding systems. Our results provide useful knowledge for manipulating and controlling these sliding joints, especially for constraining relative rotation through interfacial energy and design of the device geometry.

WHAT IS THE BENDING RIGIDITY OF A BOOK? MECHANICS OF STACKED PLATES COUPLED BY FRICTION

Summary Multi-layered structures have long been exploited to design stiff and lightweight devices. When inter-layer sliding occurs, friction must also be considered, making this a challenging problem. Here, we focus on rationalizing the mechanical response of a stack of a large number ($n \sim 50$) of elastic plates interacting through dry friction; a system akin to a book. We ask: "What is the bending rigidity of this *book*?" We perform precision nonlinear bending tests to measure the mechanical response of our stacks. Our findings deviate from both the purely elastic case and the thick Timoshenko beam cases, with nontrivial stiffening effects and hysteretic behavior. Taking friction as a perturbation, we develop a reduced model involving the coupling between the geometric nonlinearities, elasticity, and friction that is in excellent agreement with experiments.

EXPERIMENTAL EVIDENCE OF INTER-PLATES FRICTIONAL INTERACTIONS

We study multi-layered systems in which, in contrast to classic sandwiched structures [1], the layers are not bonded together. In this case, the friction of the layers sliding against each other is crucial to understand their mechanical properties [2]. Conversely, by carefully tracking how the inter-layer interactions yield a mechanical response that is different from the purely elastic situation, it is possible to retrieve the tribological properties of the layers [3].

Here, we focus on stacked elastic plates interacting through friction and subjected to bending tests. The layers of this stack are $220 \times 30 \times 0.3\,\mathrm{mm}$ plates made of a thermoplastic polymer (PET), which behave elastically throughout the experimental tests, despite the large deformations imposed. Both surfaces of the plates are carefully scrapped with sandpaper to get as close as possible to the realm of so-called dry-friction [4]. The full stack is then subjected to a 3-point bending test (Fig. 1a), with an imposed displacement w_0, and the resulting vertical force Q is recorded during loading and unloading. In these experiments, the layers can slide freely against each other as they are not constrained laterally. The test is also carried out far into the non-linear regime, which highlights the hysteretic behavior of the mechanical response (Fig. 1b). Since we are interested primarily in the interaction between the layers, the external supports must not be dissipative: the two supports comprise two cylindrical steel shafts mounted onto air bearings, hence ensuring moment-free pins. Moreover, these shafts are coated with a thin ($\sim 100\,\mu\mathrm{m}$) layer of elastomer (VinylPolySiloxane) to prevent any sliding with the bottom plate of the stack. In this way, all the measured dissipation originates from the inter-layer frictional interactions within the stack.

The bending tests are performed on stacks composed of n layers, with n ranging from 1 to 70. As a first step to characterize how stacking the layers affects the mechanical behavior, the response curve $Q(w_0)$ is normalized by the number of layers (Fig. 1b). These curves would remain identical if the response of the stack were only the sum of the responses of the individual plates. Instead, while the overall shape of the measured load curve resembles what would be expected for a standard non-linear 3-point bending test, the behavior of our stacks exhibits significant quantitative differences. Specifically, the amplitude of the hysteresis increases, the maximal force also increases for both loading and unloading, and the initial slope of the curve (proportional to the bending stiffness) splits for the loading and unloading curves.

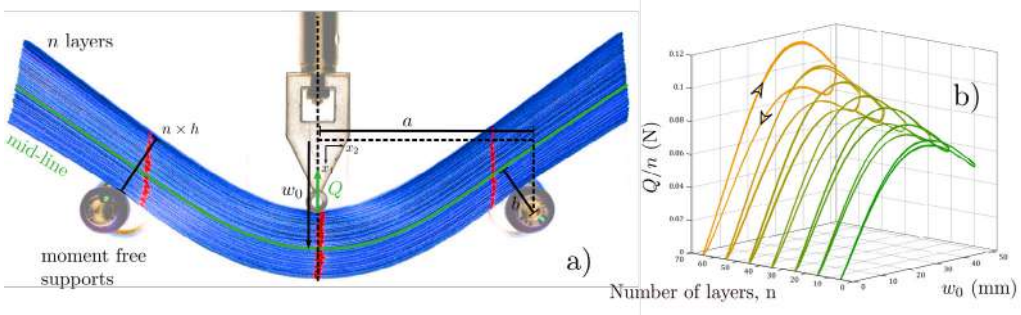

Figure 1: a) Front view of the experimental set-up. A stack of $n = 70$ plates (thickness $h = 0.3\,\mathrm{mm}$) is placed on moment-free supports separated by a distance $2a = 130\,\mathrm{mm}$. An indenter loads the stack in its center by imposing a displacement w_0 while recording the vertical force Q needed to deform the stack. To visualize the shear occurring inside the stack, vertical red lines are painted on the stack at rest. b) Loading and unloading force-displacement curves $Q(w_0)$ normalized by the number of layer in the stack n and plotted for selected values of n. The curves displayed are the superposition of several tests carried with the stack shuffled in-between and for 3 loading cycles, the good overlap of the curves demonstrates the reproducibility of the experiments.

PREDICTION OF THE EFFECTIVE BENDING STIFFNESS AND DISSIPATION IN THE STACK

We have developed a reduced model to rationalize the experimental measurements, in particular the change in bending stiffness (Fig. 2a), capturing the phenomenology of our observations. The inter-layer interactions are treated as a perturbation to the elastic deformation of the stack, meaning that the equilibrium shapes of the layers and the response force upon loading are first solved without taking friction into consideration. Subsequently, assuming a simple Amontons-Coulomb law between the layers, the energy dissipated by the frictional forces can be estimated from the known inter-layers displacements and normal forces. The dissipated energy is then added (loading) or subtracted (unloading) to the elastic energy. The resulting total energy is finally differentiated with respect to w_0 to retrieve the vertical force Q, which can now be compared to the experimental data. This force has an analytical solution if we restrict ourselves to linear deformation and assume that all the plates are simply supported and deformed similarly:

$$Q = \frac{6}{a^3} n B_0 \cdot \left(1 \pm \mu(n-1)\frac{3}{4}\frac{h}{a}\right) w_0, \tag{1}$$

where B_0 is the bending stiffness of a single plate, μ is the inter-layer kinetic friction coefficient, and the $+$ and $-$ signs correspond to loading and unloading, respectively. The effective bending stiffness of the stack, $B^{\pm} = nB_0\left(1 \pm \mu(n-1)\frac{3}{4}\frac{h}{a}\right)$, contains a correction factor from the purely elastic case that is a function of the friction μ and the slenderness of the plates $\frac{h}{a}$. While this reduced model captures the linear variations of $B^{\pm}(n)/n$, it misses the asymmetry between in the slopes for loading vs unloading observed experimentally (Fig. 2a).

To understand this asymmetry, it is necessary to consider how staking an increasing number of layers modifies the geometry of the problem. To address this, we have developed a homogenized model of the stack by reducing it to its mid-line. The curvature of all the plates is written with respect to this mid-line by assuming they are parallel and separated by their thickness h. The primary adjustment induced by the homogenized model turns out to be that the effective radii, b, of the supports in-between which the mid-plane is bent (Fig. 1a), increases with the number of plates n. As a result, even in the absence of friction, $B(n)/n$ increases linearly with n in a way (Fig. 2a, dashed) that lies in-between the loading and unloading experimental curves. Thus, with the symmetry restored, measuring $B^{\pm}(n)$ and using an adjusted version of Eq. 1 that takes into account the geometrical correction, provides a way to estimate the friction coefficient μ of the stacks by simply measuring the slope of the functions $B^{\pm}(n)/n$.

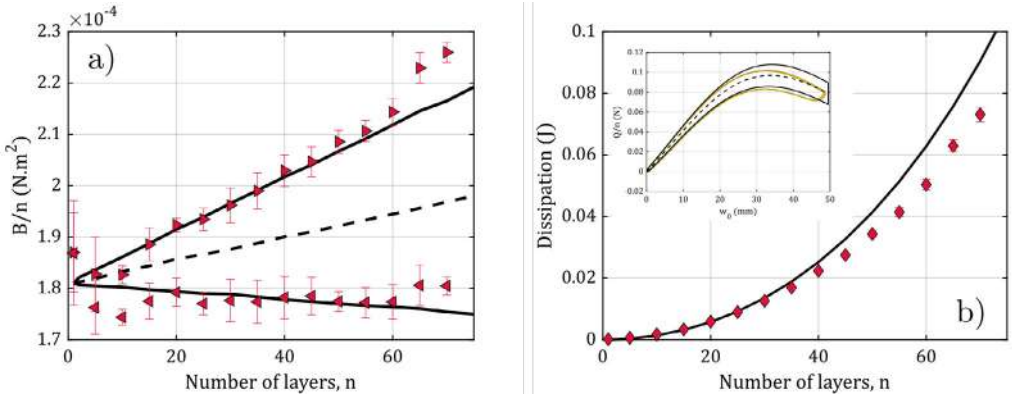

Figure 2: a) Normalized bending stiffness of the stack B/n as a function of the number of plates n for loading and unloading. The bending stiffness of a single plate is $B_0 = 1.8 \times 10^{-4}\,\mathrm{N.m}^{-2}$. Experimental data are the red triangles (loading $\triangleright$, unloading $\triangleleft$). The dashed lines is the result from the perturbative model without friction, the solid lines, with friction. b) Inset, Comparison between the experimental mechanical response (for $n = 50$) and the prediction using the perturbative model (dashed line without friction, solid lines, with). Energy dissipated by the stack upon one cycle, measured experimentally ($\Diamond$) and predicted (solid line). The error bars are the standard deviations over a multitude of tests made for the same set of parameters.

Finally, the estimated friction coefficient is introduced into the perturbative approach to compute the full non-linear mechanical response of the stack. The calculated response is in excellent agreement with the experimental data (Fig. 2b, inset), especially for the bending stiffness of the stack (Fig. 2a, solid lines). Our approach also enables us to predict the energy dissipated in the stack upon cycling far into the non-linear regime (Fig. 2b). We believe that our quantitative description for the mechanical response of a stack of frictional plates opens an exciting avenue to design optimized dampers that rely on the interplay between elasticity and frictional interactions in multilayered systems.

OPTIMAL CONTROL OF CROSS ROLL STRAIGHTENING PROCEDURE

Jindrich Petruska,*[1] and Tomas Navrat
Institute of Solid Mechanics, Mechatronics and Biomechanics, Faculty of Mechanical Engineering, Brno University of Technology,Brno, Czech Republic

Summary Cross roll straightening of bars with circular cross section on multi-roller straightening machines is described in the paper. First, a quick review of possible analytical approaches is described and the fast computational algorithm based on the Eulerian description of the material flow through the straightening machine is presented. The fast algorithm is used for analysis of a large number of straightening problems. These results serve in the next step as training data for a neural network, which provides an efficient tool for correct optimal adjusting of intermeshing rollers of the straightening machine to obtain acceptable output curvature of the straightened bar together with the residual stress and roller loading being as low as possible.

INTRODUCTION

The problem we try to solve is to find an optimal intermeshing w_C, w_E of the straightening machine with two bending sections according to Figure 1. By the term "optimal" we mean to obtain a final product with acceptable output curvature (typically 0.5 mm/m) with minimal loading od the working rollers to minimize their wear and minimal residual stress in the bar to keep the stability of its shape in the next technological steps. To solve this problem for different diameter, material and input curvature of the bar is not an easy task due to its inherent nonlinearity. Many approaches have already been applied to it, from classical analytical models based on simplified suggestions combined with empirical knowledge [1] up to fully nonlinear 3D Finite Element models. With the Finite Elements, many of the nonlinear effects can be now included, but the analysis is still rather a time-consuming procedure [2], [3]. It can be used for academic and research purpose, but hardly for a fast suggestion of possible intermeshing strategy of multi roller straightening machines in real industrial situations. To fill this gap, a fast algorithm of straightening problem analysis

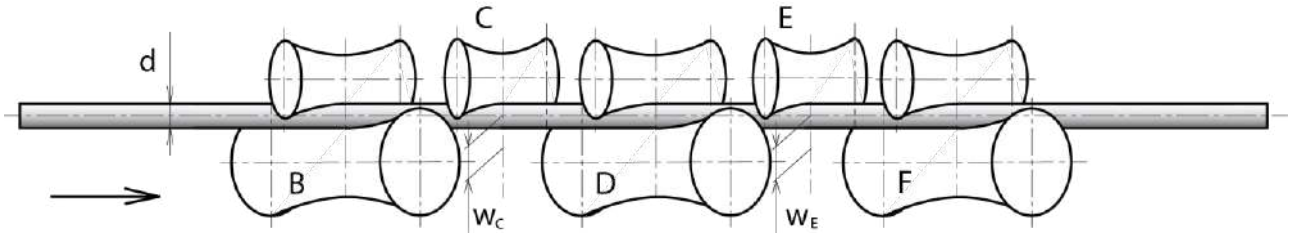

Figure 1. Straightening machine with two intermeshing rollers C, E.

was suggested and applied first to section and rail straightening processes [4]. The main idea of the algorithm is based on the Eulerian description of material flow through the axial direction of beam elements, which represent the position of the straightened long product within the leveling machine. The elements are fixed in axial direction, but their transversal displacements and slopes are described by a standard Lagrangean approach. Some of the simplifying assumptions are still adopted: the long product deflection and curvature can be described by a bending theory of beams with uniaxial state of stress, without the influence of shear force and planar deformation of the cross-section. The decisive nonlinear effect of material plasticity is modelled by a bilinear stress-strain diagram with linear plastic hardening and kinematic hardening rule. Adding the rotation of material around the longitudinal axis of the bar with circular cross section enabled the application of the algorithm to cross roll straightening of circular bars. Detailed description of this algorithm together with its validation and experimental verification was described in [5].

SELECTION OF OPTIMAL STRAIGHTENING PARAMETERS

The algorithm described above is very efficient in solution of straightening problems with two bending sections according to Figure 1, or even more of them. Nevertheless, we start the solution from known intermeshing of rollers C, E, which is not a typical problem to solve for the operators of straightening machine. They have to answer the inverse question: what intermeshing will lead to acceptable output curvature k_{OUT} less than 0.5mm/m, together with the sum of roller loading R and residual stress S being as low as possible? The initial known values for this task is the input curvature k_{IN}, diameter and material parameters of the bar.

In the following, we illustrate possible way of solving this inverse problem on the example of the bar with diameter 70 mm, yield stress 900 MPa and ultimate strength 1200 MPa. We suppose the input curvature of the bar can reach maximal value of 10 mm/m and maximal intermeshing of both adjustable rollers in Figure 1 can be 10 mm, too. Within these limits, repeated Monte Carlo simulations of the direct problem of straightening process were realized, with random distribution of the input parameters of w_C, w_E and k_{IN}. Discrete solutions of the Monte Carlo simulations were

*Corresponding author. E-mail: petruska@fme.vutbr.cz

then fitted by Neural Network. The sets of inputs (w_C, w_E and k_{IN}) and outputs (output curvature k_{OUT} [mm/m], roller loading R [kN] and residual stress in straightened product S [MPa]) were randomly divided into three sets. 70% were used for training, 15% for validation and last 15% for independent test of network generalization.

In Figure 2 we can see the results of acceptable output curvature (left) and response surfaces of roller loading (center) and residual stress (right). In the left figure we can clearly see that different intermeshing combinations can lead to acceptable output curvature results. This is well known from the industrial experience. The central picture proves the expected increase of roller loading with the growth of intermeshing values, whereas the residual stress response shows rather unpredictable shape for intermediate values of intermeshing.

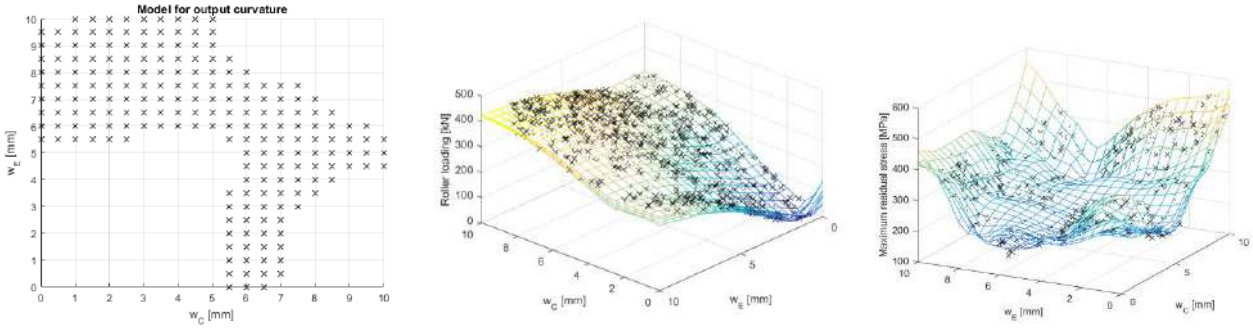

Figure 2. Intermeshing combinations with acceptable k_{OUT} (left) and response surfaces of roller loading and residual stress

To minimize both the output curvature k_{OUT}, roller loading R and residual stress S, all the values are normalized and a new weighted variable Z is formulated as

$$Z = \frac{1}{3}\left(\frac{k_{out}}{max(k_{out})} + \frac{S}{max(S)} + \frac{R}{max(R)}\right) .$$

Here the expression $max(\,)$ represents the maximal value reached by the appropriate variable in the domain $w_C - w_E$. Distribution of Z in Figure 3 then shows possible combinations of intermeshing w_C, w_E with minimal output curvature, roller loading and residual stress. The domain is limited strictly to acceptable results of $k_{OUT} <$ 0.5 mm/m.

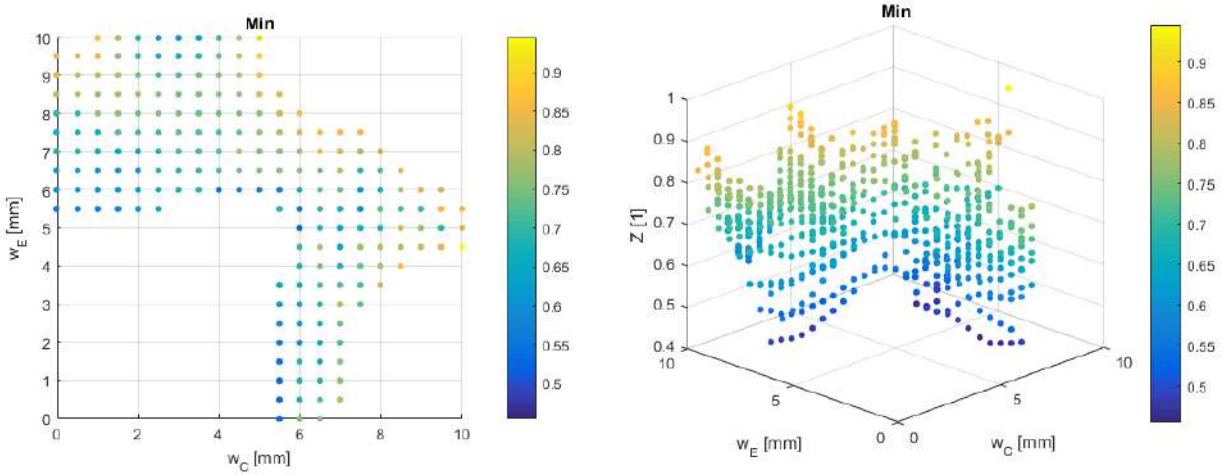

Figure 3. Possible combinations of intermeshing values with minimal response of normalized output variable Z.

CONCLUSIONS

Optimal adjusting of the cross roll machine intermeshing parameters was illustrated on the example of the two bending sections machine and selected material and diameter of the straightened bar. The results prove that there are more possible strategies of intermeshing (i.e. more combinations of adjusting of intermeshing rollers), which lead to similar and acceptable results of the procedure. This corresponds to known industrial experience. Possible generalization of presented method to other types of straightening problems will be the topic of the conference talk.

ON THE MOSSAKOVSKII METHOD FOR CONTACTS SUPPORTING A MOMENT

Matthew Moore*[1] and David Hills[2]
[1]Mathematical Institute, University of Oxford, Oxford, UK
[2]Department of Engineering Science, University of Oxford, Oxford, UK

Summary The Mossokovskii solution of the half-plane formulation for contacts between elastically-similar materials is extended to contacts supporting a moment. We reduce the Cauchy singular integral formulation of the problem to a non-symmetric Abel integral relating the indenter geometry to the applied normal force. We use the formulation to derive simple expressions the applied normal force and moment as functions of the contact extent and indenter tilt. We also for the coefficients of the square-root terms in the pressure expansion local to the ends of contact, which may be of use in asymptotic analyses of the partial-slip problem.

INTRODUCTION

The usual starting point for analysing contact problems is the Flamant solution for a force applied to the apex of a wedge, specialised to a half-plane, from which a Cauchy integral equation is derived where the primary unknown is the contact pressure distribution [2]. This approach works well for problems in which the normal load is established first, with the shearing force then developed as the normal force is held constant. However, if both the normal load and shearing force are simultaneously varying functions, an alternative incremental method originally formulated by [4] and extended by [3] is more suited. In this analysis, we adapt the method to contacts that support a moment and hence are, in general, non-symmetric.

PROBLEM FORMULATION

Consider the configuration illustrated in figure 1a for a general indenter with profile $y = g(x)$. We suppose the profile is tilted by an angle α with respect to the horizontal, and we shall assume α is known. Our aim will be to derive the necessary applied normal force and applied moment to sustain a contact over $-b < x < a$ with tilt angle α. We assume that the indenter and the material it is indenting are elastically similar and that a half-plane idealisation is suitable. The assumption of elastic similarity uncouples the normal and tangential displacement problems [3]; we shall concentrate on the normal displacement problem here, although the ideas readily extend to consider an applied tangential force and differential remote bulk stresses.

The standard relation between the relative normal displacement gradient and the contact pressure, $p(x)$, is

$$\frac{\mathrm{d}v}{\mathrm{d}x} = \frac{\kappa+1}{2\mu\pi}\fint_{-b(a)}^{a} \frac{p(s)}{s-x}\,\mathrm{d}s \text{ such that } v'(x) + g'(x) = 0 \text{ for } -b < x < a. \tag{1}$$

The integral above is interpreted in a Cauchy principal value sense, and can be inverted in the usual manner assuming the pressure is bounded at both ends of the contact set. This yields a consistency condition, which, along with the equilibrium condition to balance the applied normal force, yields two equations for the size of the contact set

$$0 = \int_{-b}^{a} \frac{v'(s)}{\sqrt{(a-s)(s+b(a))}}\,\mathrm{d}s, \quad P = \int_{-b}^{a} p(s)\,\mathrm{d}s. \tag{2a, b}$$

The form of the consistency condition (2a) allows us to say that, if we know a, we can derive $b(a)$. We can then utilise the equilibrium condition (2b) to find a, and hence b, as a function of P.

We can use the knowledge of the size of the contact set as a function of the applied normal force to avoid the difficulties associated with singular integrals by approximating the indenter using a series of rectangular punches as we increase P (and hence a), see figure 1b. The contact pressure is then given by

$$p(x,a) = \int_0^a F(s) m_0(x,s)\,\mathrm{d}s, \quad m_0(x,a) = \begin{cases} \dfrac{1}{\sqrt{(a-x)(x+b(a))}} & \text{for } -b(a) < x < a, \\ 0 & \text{otherwise} \end{cases}, \tag{3}$$

where $m_0(x,s)$ is the contact pressure induced by a flat punch of size $(-b(s), s)$ and $F(\cdot)$ is an unknown coefficient that encodes the geometry of the indenter. We utilise (1) to show that

$$\frac{2\mu g'(x)}{\kappa+1} = \int_0^x \frac{F(s)}{\sqrt{(x-s)(x+b(s))}}\,\mathrm{d}s \text{ for } 0 < x < a, \tag{4}$$

which is a non-symmetric Abel integral equation for $F(\cdot)$, and a direct analogue to the moment-free case considered in [3].

(a) a) (b) b)

Figure 1: a) An indenter of profile $y = g(x)$ contacts an elastically similar half-space under an applied normal force, P, and an applied moment, M. b) A schematic showing the Mossakovskii method. We approximate the contact by considering an infinite number of flat punches that conform to the geometry of the indenter, enforced by $(2a)$ and (4).

GENERAL RESULTS

For a general geometry, (4) must be tackled numerically. However, we can use (4) to derive a number of useful results that have applications in considerations of the partial slip problem for contacts where the applied normal and shearing forces are varying functions of time [3, 4].

Firstly, integrating (3) and, recalling the equilibrium condition $(2a)$, yields

$$P = \pi \int_0^a F(s)\,\mathrm{d}s, \text{ that is, } F(a) = \frac{1}{\pi}\frac{\mathrm{d}P}{\mathrm{d}a}, \tag{5}$$

so that we can remove $F(\cdot)$ from the problem entirely by replacing it with the applied normal force in (3)–(4). Secondly, the applied moment M necessary to sustain the contact is thus given by

$$M = \frac{1}{2}\left[P(a)(a - b(a)) - \int_0^a P(s)(1 - b'(s))\,\mathrm{d}s\right]. \tag{6}$$

Hence, given that the tilt angle was encoded in the original geometry, (4)–(6) can be viewed as a way to find P and M as functions of a and α (or vice versa).

Finally, we can expand the contact pressure solution (3) locally at the contact ends to find the coefficients of the square-root terms, $K_{n,a}$ and $K_{n,b}$, which gives

$$p = \frac{2}{\pi}\frac{P'(a)}{\sqrt{a + b(a)}}\sqrt{a - x} + o(\sqrt{a - x}) \text{ as } x \to a^-, \text{ so that } K_{n,a} = \frac{2}{\pi}\frac{P'(a)}{\sqrt{a + b(a)}}, \tag{7}$$

while

$$p = \frac{2}{\pi}\frac{P'(a)}{b'(a)\sqrt{a + b(a)}}\sqrt{b(a) + x} + o(\sqrt{b(a) + x}) \text{ as } x \to -b(a)^+, \text{ so that } K_{n,b} = \frac{2}{\pi}\frac{P'(a)}{b'(a)\sqrt{a + b(a)}}. \tag{8}$$

In particular, we note that $K_{n,b} = K_{n,a}/b'(a)$. Such simple relations for the K_n-coefficients are of use when considering asymptotic models of contacts for particular geometries, where we only consider one end of the contact and consider the tractions there. This has applications in problems where the differential bulk tensions are large enough to reverse the direction of slip at one end of the contact, so that the Ciavarella-Jäger theorem is no longer applicable [1].

CONCLUSION

We have extended the Mossakovskii method to half-plane contact problems that allow for an applied moment. The singular integral formulation is reduced to a non-symmetric Abel integral equation by assuming that the left-hand contact point is known as a function of the right-hand contact point using the standard consistency condition. The resulting solution has been used to derive general expressions for the K_n-coefficients in the contact pressure expansion local to the contact edges, as well as relating the applied normal force and moment, to the contact extent and tilt of indenter.

ROLLING OF ELASTIC BODIES WITH SLIPPAGE IN THE PRESENCE OF AN INTERMEDIATE VISCOELASTIC LAYER

Almira Meshcheryakova[1,2]
[1]Moscow Institute of Physics and Technology (National Research University), Moscow,Russia
[2]Laboratory of Tribology, Ishlinsky Institute for Problems in Mechanics RAS, Moscow,Russia

Summary The three-dimensional problem of stationary rolling of an elastic body along a viscoelastic layer bonded to an elastic half-space is considered. The Coulomb friction law is used to describe friction in the slip subregion within the contact region. The relative slippage has longitudinal and lateral components. An algorithm based on a variational method is developed to calculate the shear stress and configuration of slip and stick subregions. The effect of relative slippage on the shear stress distribution and the shape and location of the stick and slip subregions is studied. The results calculated with developed algorithm are compared with known solutions for limiting cases.

INTRODUCTION

The exact solution for two-dimensional rolling problem for bodies with equal modulus of elasticity and the configuration of stick and slip subregions were obtained by Carter [1]. The variational approach to solve sliding and rolling contact problems was formulated and applied by Kalker. In rolling contact for a circular contact region, the location of stick and slip subregions for various combinations of creepage and spin were obtained with the variational theory based on virtual work [2]. The solution based on the variational method for rolling contact of two elastic bodies with an elliptic contact region was developed in [3]. The contact problem for the elastic cylinder rolling over the elastic half-space covered by the viscoelastic layer was studied in [4]. The results of an analysis of the viscoelastic layer effect in rolling contact were presented in [5].

In this study the variational method was developed to solve the rolling contact problem for elastic bodies with an elliptical contact area taking into account the intermediate layer.

PROBLEM FORMULATION AND METHOD OF SOLUTION

Problem formulation

The elastic body rolls over the layer bonded to the elastic half-space with friction. The body has a form of solid of revolution, and the axis of revolution is moving with the constant linear velocity V. When rolling, the contact region consists of stick and slip subregions, which boundaries are unknown in advance. In the slip subregion, the normal and shear stresses are related with Coulomb's law. In tangential direction the compliance of the layer is described by the Maxwell model.

$$s_l(x,y) = \frac{h}{VT_\tau E_l}\tau(x,y) - \frac{h}{E_l}\frac{\partial\tau(x,y)}{\partial x}, \tag{1}$$

where E_l is the modulus of elasticity of the layer's material, s_l is the vector function of derivative of the layer shear displacements, T_τ is the relaxation time of the layer's material, h is the thickness of the layer.

We consider the case when the modulus of elasticity of the rolling body and the half-space are equal, therefore the normal and shear stresses are calculated independently. We also assume that the layer compliance in normal direction is negligibly small.

Method of solution

The normal stress distribution for elliptic contact region is calculated according to Hertz contact theory:

$$p(x,y) = p_0\sqrt{1-\left(\frac{x}{a}\right)^2-\left(\frac{y}{b}\right)^2}, \quad \left(\frac{x}{a}\right)^2+\left(\frac{y}{b}\right)^2 \le 1, \tag{2}$$

where maximum normal stress p_0 and the semi-major a and semi-minor b axes of elliptical contact region depend on the geometry of the rolling body and the normal load.

To calculate the shear stress, the variational method is used. The problem of determining the vector function of shear stresses in the contact region of a sphere and a viscoelastic layer is considered equivalent to the problem of minimizing the following functional, when the boundary conditions are fulfilled [3]:

$$\min_{|\tau|\le\mu p}\left\{F[\tau, s(\tau)] = \iint_\Omega \left[\mu p|s(\tau)| - \langle\tau, s(\tau)\rangle\right]dxdy\right\} \tag{3}$$

where μ is the coefficient of sliding friction, τ (τ_x, τ_y) is the vector function of shear stresses, p is the normal stress, s (s_x, s_y) is the vector function of the slippage, Ω is the contact region. The gradient projection method [3] is used to calculate the shear stress vector function which minimizes the value of the functional in (3).

RESULTS AND DISCUSSION

In calculations we assume that there is no lateral slippage. The shear stress distribution within the elliptic contact region is illustrated in Figure 1 for various intermediate layer properties and also without layer.

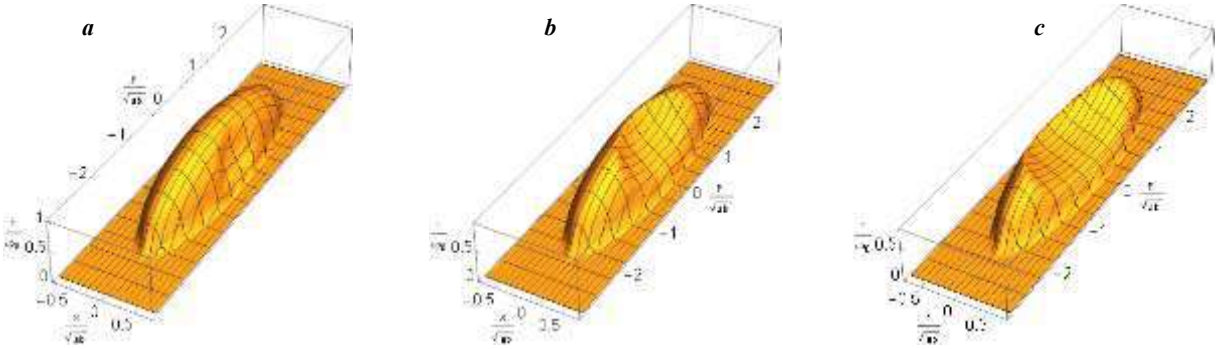

Figure 1. Shear stress distribution for $ab\omega/(2R_y v_{0x}) = 0.5$, $\mu p_0 V/(G v_{0x}) = 1$, $\alpha = h/(VT_\tau E v_{0x})$, $\sqrt{a/b} = 0.5$ and α = 0 (no layer) (*a*), α = 1 (*b*), α = 2 (*c*)

The results demonstrate that in rolling contact the contact region consists of the slip and stick subregions. The stick subregion is located closer to the front side of the contact region relatively to the rolling direction.

The configuration of stick and slip subregions for various layer parameters is shown in Figure 2.

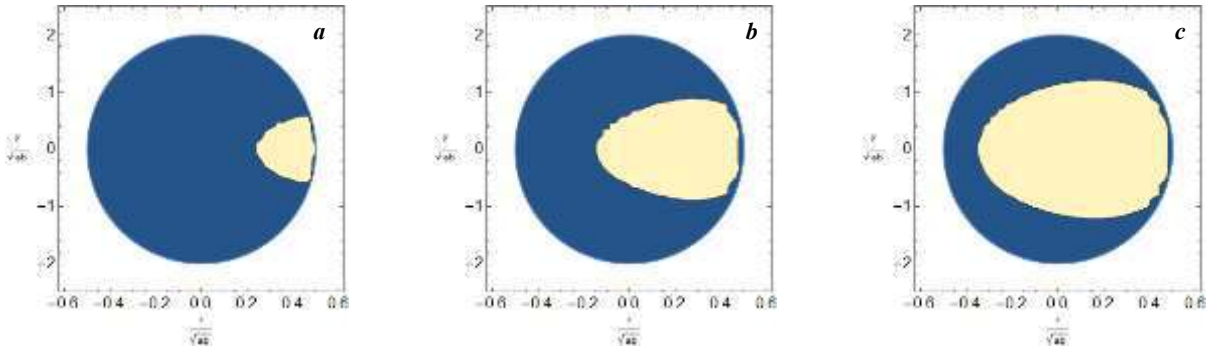

Figure 2. Configuration of stick and slip subregions for $ab\omega/(2R_y v_{0x}) = 0.5$, $\mu p_0 V/(G v_{0x}) = 1$, $\alpha = h/(VT_\tau E v_{0x})$, $\sqrt{a/b} = 0.5$ and α = 0 (no layer) (*a*), α = 1 (*b*), α = 2 (*c*)

Figure 2 illustrates that the stick subregion is prolonged in the rolling direction. The area of the stick subregion increases with the growth of the layer viscosity parameter α, which is inversely proportional to the relaxation time of the layer material.

CONCLUSIONS

The solution of the three-dimensional contact problem for the elastic body, rolling over the viscoelastic layer bonded to the elastic half-space is presented. It is based on the variational approach which allows us to obtain the shear stress distributions within the contact region taking into account slippage in the longitudinal and lateral directions with respect to the rolling direction of the body. The effect of a viscoelastic layer on the shear stresses and the configuration of stick and slip subregions in rolling contact has been studied. The dependence of the shear stress on the friction coefficient, characteristics of the interacting bodies material and the load can be used to determine a wear rate, a friction loss, an origin of cracks and the patterns of their propagation.

The reported study was funded by RFBR, project number 19 31 90015.

ESTIMATING FRICTION PROPERTIES FROM LARGE-SCALE ROCK EXPERIMENTS

David S. Kammer*[1], Chun-Yu Ke[2], and Gregory C. McLaskey [2]
[1]Institute for Building Materials, ETH Zurich, Switzerland
[2]School of Civil and Environmental Engineering, Cornell University, Ithaca, USA

Summary We present result from two large-scale friction experiments. In both experimental setups, two rock blocks are placed side-by-side to form a frictional interface. External load is applied such that the interface is subjected to normal and shear stress, which can be controlled independently. The shear stress is slowly increased until local slip spontaneously occurs. The onset of sliding is rupture-like: it nucleates at a critical point and then propagates along the interface until it potentially arrests spontaneously. During this rupture propagation, we measure the strain at multiple locations close to the interface but slightly offset. We compare these measurements with analytical fracture mechanics theory for near-tip strain fields to determine local interface properties. Further, we analyze rupture arrest to provide a second independent measurement of these local friction properties.

INTRODUCTION

The macroscopic frictional strength of an interface between two solids depends on both instability-driven local failure mechanisms and local friction properties at various scales. For instance, the onset of frictional sliding, which is often described by the macroscopic static friction coefficient, is characterized by the nucleation and propagation of a shear-crack-like rupture front along the interface [1]. The nucleation of this rupture front, which is key for the overall strength of the interface, depends on local properties and stress distributions. The macroscopic static friction coefficient does not provide direct evidence of these local properties since it is an integrated quantity of a potentially non-uniform shear stress along the interface. Experimentally measuring local friction properties is therefore crucial for a better understanding of the macroscopic strength of an interface.

METHOD

In this work, we present experimental observations from two different large-scale rock experiments and develop a fracture-mechanics-based interpretation that provides estimates of important local friction properties [2,3]. In both experimental setups, two meter-scale rocks were brought into contact by a normal load. The interface was then slowly sheared until slip spontaneously nucleated and propagated dynamically along the interface.

In the first experimental system [2], the stress distribution along the interface is relatively uniform due to the applied loading configuration. Once a critical level of stress was exceeded at a given point, a slip instability was spontaneously nucleated and a frictional rupture front propagated along the interface. These rupture fronts eventually reached the edges of the interface, where they were reflected and propagated in the opposite direction as so-called secondary rupture fronts. We measured the dynamic strain evolution at multiple locations along the interface with strain gages that were installed slightly away from the interface.

In the second experimental system [3], the spatial distribution of stresses along the interface is non-uniform due to the structural compliance of the loading frame, and various loading procedures were used to generate a range of different spatial stress distributions. This led to a variety of different rupture phenomena. In some cases, unilateral contained ruptures nucleated near the loading end of the interface, propagated unilaterally toward the leading end, and arrested before reaching the edge. In other cases, bilateral contained ruptures nucleated close to the middle of the interface, propagated bilaterally, and arrested before reaching both edges. We used local slip measurements and static strain measurements along the interface to determine the nucleation and arrest location of these slip instabilities.

RESULTS

In the first experimental system [2], we use dynamic shear strain measurements from strain gages that are installed slightly away from the interface and apply analytical fracture mechanics theory for near-tip fields to determine local interface properties. These results show that the measurements at these offset strain gages do not resemble the stress evolution as expected along the interface (Figure 1) but provide a direct measurement of local friction properties when combined with fracture-mechanics theory.

In the second experimental setup [3], we use fracture-mechanics-based energy considerations to describe the arrest position [4]. Fundamentally, these rupture fronts propagate dynamically when the region with a rupture-favored stress state is larger than a critical nucleation length. Further, arrest occurs when the rupture reaches regions with more friction (specifically, higher fracture energy), or unfavorable stress states. The detailed fracture-mechanics-based models, as applied here, contain a single free parameter, which is the local fracture energy of the interface. By comparing the model with experimental observations, we can constrain the local fracture energy [3]. Finally, we compare our estimates with observations from experiments on other materials [5].

WEAR AND SURFACE FRACTURE OF FIBER COMPOSITES IN FRICTIONAL INTERACTION

Irina Goryacheva*[1] and Yulia Makhovskaya[1]
[1]Ishlinsky Institute for Problems in Mechanics of the Russia Academy of Sciences, Moscow, Russia

Summary Wear of a fibrous composite material is theoretically studied based on two mechanisms – due to different wear rates of structural components of a composite and due to detachment of fibers during friction. An intermediate layer between the matrix and fibers is taken into account. The effect of the microstructure parameters of the composite on the worn surface shape, effective wear rate of the material, and local stress field near surface fibers is analyzed.

INTRODUCTION

Fiber composites are widely used in industry, e.g., in aviation brake systems consisting of carbon-carbon composite disks. Wear process in such composites depends on their microstructure (size and density of fibers, existence of intermediate layer between matrix and fibers, mechanical and thermal properties of all components). There exist only a few theoretical models in the literature, which relate wear of composites to their microstructure (e.g., [1,2]), they are focused on particular wear mechanisms under given friction conditions.

In the present study, based on the contact mechanics approaches presented in [3], two mechanisms of wear of fiber composites are considered. The first one is associated with different wear rates of the matrix, fibers, and intermediate layers. The second mechanism is due to surface fracture and detachment of fibers from the surface during friction.

MODELING STEADY-STATE WEAR OF A FIBER COMPOSITE

A model of wear process of a fiber composite is developed for steady-state conditions. The composite is modeled by an elastic half-space with a variable wear coefficient which has different values for the fibers (K_{w1}), matrix (K_{w3}), and intermediate layer (K_{w2}). A plane surface of a rigid counter body slides over the composite material surface with the constant velocity V and wears the composite material (Fig. 1).

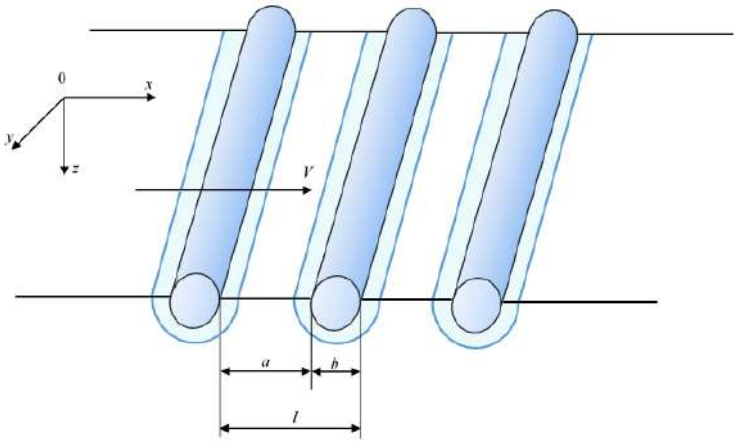

Figure 1. Surface structure of a fiber composite.

Analytic relations are obtained for the shape of the worn surface, the effective wear rate of the composite, and the magnitude of contact pressures acting on the fiber and matrix. These values are calculated as functions of the parameters of the composite microstructure. In particular, it is established that the worn surface of the composite strongly depends on the size and concentration of fibers, as well as on the ratio of the wear coefficients of fibers and intermediate layer to matrix ($m_1 = K_{w1}/K_{w3}$ and $m_2 = K_{w2}/K_{w3}$). The calculated shapes of the worn surface are compared to the results of surface profilometry (Fig. 2). It is shown that the effective wear rate as a function of the fiber concentration increases if the fibers are harder than the matrix and decreases in the opposite case. Results of the calculation and analysis of the pressures acting upon the fibers and matrix in the steady state wear process are used to model the stress state near a separate fiber during wear which is presented in the next section.

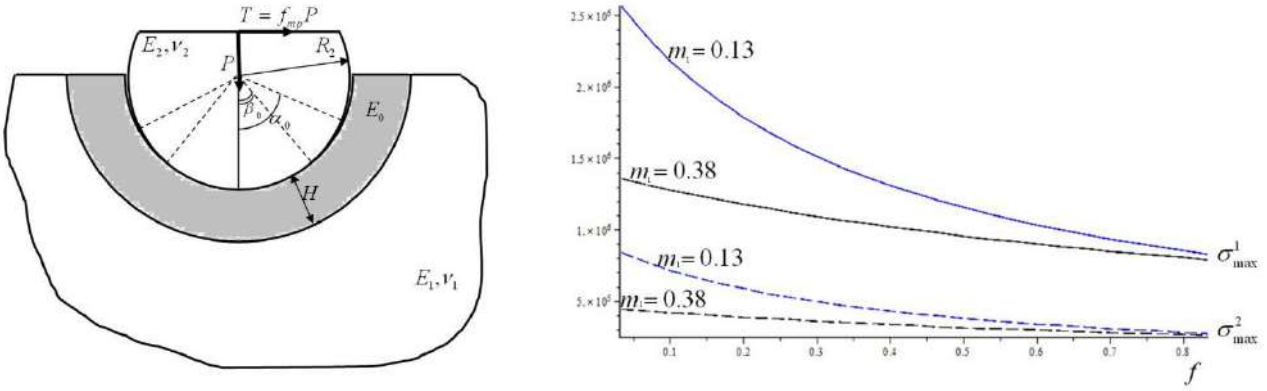
Figure 2. (a) Calculated shape of the worn surface for $m_1 = 2$ with no intermediate layer (curve 1) and with an intermediate layer with $m_2 = 5$ and 10 (curves 2 and 3). (b) Measured profile for a carbon-carbon fiber composite worn surface

MODELING THE STRESS STATE NEAR A SEPARATE FIBER

The local stress field near a separate fiber embedded into the surface of the composite (Fig. 3,a) is analysed with and without an intermediate layer. The maximum tensile stresses (in Pa) in the matrix (solid lines) and fiber (dashed lines) as a function of the fiber concentration are presented in Fig. 3,b for the nominal contact pressure $p_0 = 0.5$ MPa, radial gap between the fiber and matrix $\varepsilon_0 = 0.1$ μm, fiber radius $R_2 = 5$ μm, the elastic characteristics $E_1 = 10$ GPa, $\nu_1 = 0.25$, $E_2 = 15$ GPa, $\nu_2 = 0.35$, and two different values of the ratio of the wear coefficient of fiber to matrix m_1. The results indicate that the maximum tensile stresses considerably increase with decreasing fiber concentration, especially when the wear coefficients of the fiber and matrix differ substantially from each other.



(a) (b)

Figure 3. (a) Sheme of contact of a separate fiber and the matrix in the presence of an intermediate layer. (b) Maximum tensile stresses in the fiber and matrix vs. the fiber concentration

Based on the stress field obtained, possibility of detachment of the fiber is analyzed, depending on the microstructure parameters as well as the nominal pressure and temperature on the friction surface. Note that the surface temperature itself is a function of the composite microstructure [4].

CONCLUSIONS

The theoretical study of a fiber composite wear is presented which makes it possible to analyse the influence of the microstructure parameters of the composite on the shape of the worn surface, the effective wear rate of the material, and the local stress field near surface fibers. The results obtained are used to predict the process of wear, including the possibility of fracture and detachment of fibers from the surface of the matrix.

The work was carried out under the financial support of the Russian Science Foundation (grant No. 19-19-00548).

A FULLY COUPLED BEM FORMULATION FOR NORMAL AND TANGENTIAL CONTACT PROBLEMS

Jacopo Bonari* and Marco Paggi
IMT School for Advanced Studies Lucca, Lucca, Italy

Summary A boundary element formulation has been developed for solving contact problems between a rigid indenter and an elastic layer of finite thickness, under the hypotheses of linear elasticity and plane strain assumption, subject to imposed normal and tangential displacements. The normal contact problem is fully coupled with the tangential one, allowing for the study of an arbitrary sequence of loading. As a consequence, the application of a normal pressure causes not only vertical, but also in-plane displacements, providing a rigorous methodology to quantitatively investigate the effect of tangential and normal coupling with indenters of arbitrary shapes.

KERNEL FUNCTIONS

In the general case of a two-dimensional frictional contact problem involving a rigid indenter pressed against an elastic layer, the vertical and horizontal displacements of the elastic frontier can be described by u_z and u_x. These quantitities are linked to the relative components of surface tractions p_z and q_x by appropriate Green functions. If the discretisation of a selected portion of the boundary is introduced, the surface displacement, defined by an index i, can be expressed by the sum of the contribution of the tractions acting in the other points, multiplied by the respective influence coefficients. Thus, in matrix form, it is possible to write:

$$\begin{bmatrix} \mathbf{u}_z \\ \mathbf{u}_x \end{bmatrix} = \begin{bmatrix} \mathbf{H}_{zz} & \mathbf{H}_{zx} \\ \mathbf{H}_{xz} & \mathbf{H}_{xx} \end{bmatrix} \begin{bmatrix} \mathbf{p}_z \\ \mathbf{q}_x \end{bmatrix}$$

where the four $\mathbf{H}$ matrices collects the influence coefficients resulting from the discretisation of the Green functions. In the present work, they are relative to the application of a traction of uniform intensity over the length of a single element of the boundary, for an elastic layer of finite thickness in z direction and semi-indefinite in x direction. This framework has been chosen because semi-analytic solutions of the convolution integrals representing the four Green functions have been determined, guaranteeing a high level of accuracy and a fast computation of the influence coefficients.

SOLUTION ALGORITHM

The application of the classic Coulomb friction law over a two-dimensional domain leads to its partition in 4 different states, according to [1]: *(i)* a zone of *separation*, where contact does not occur; *(ii)* a zone of *stick*, with no relative tangential displacements between the indenter and the half plane; *(iii)* and *(iv)* zones of *backward* and *forward slip*, characterised by negative and positive relative tangential displacements, respectively. Since coupling is accounted for, tangential tractions affect the normal displacements, thus requiring an iterative solution of the normal contact problem. A fixed point iteration scheme has been implemented for evaluating contact tractions. At the initial step, all points are assumed to be in *separation* and the tangential tractions to be null. The normal contact problem is then solved and the states are updated, moving the point in contact to the *stick* domain. With the value obtained for $\mathbf{p_z}$, $\mathbf{q_x}$ in the *stick* domain is evaluated. At this point, a check is performed on the state of every node, and, if a violation of the friction law is encountered, the domain is updated accordingly, *e.g* if a point is in the stick domain, $|q_{x,i}| \leq \mu p_{z,i}$ must hold for that node: if it is not so, $q_{x,i}$ is set equal to $\mathrm{sgn}\,(q_{x,i})\mu p_{z,i}$ and the state is modified to *forward slip*. The procedure stops when the difference between the norm of the tractions for two consecutive steps lies below a certain threshold.

RESULTS

The classical ironing problem has been used as benchmark for testing the algorithm using two different indenters. The first is parabolic, while the second has a Weierstrass-Mandelbrot profile, made up, for the sake of representation, using only two terms, with a fractal dimension $D = 0.4$ and $\gamma = 15$. In Fig. 1a and 1b, the results are shown in terms of vertical tractions (black dashed lines) and horizontal tractions (red solid lines). The problem has been discretised using 10 time steps. In the first stage of loading, a vertical far field displacement is imposed on the indenter. It rises from 0 to $5 \times 10^{-3} b$, being b the thickness of the elastic layer. The first five inner concentric black lines correspond to the increasing vertical pressure. The five polarsimmetric overlapping red lines correspond to them, representing the horizontal tractions resulting from the application of the vertical load only. In the second stage of loading, the vertical far field displacement is held constant, while a horizontal imposed far field displacement linearly rises from 0 to $1 \times 10^{-2} b$. Since in this second phase the vertical load is constant, the vertical tractions almost overlap except for a slight difference, given by the effect of coupling. On the other hand, the horizontal tractions start shifting leftwards.

(c) *Parabolic profile, coupled* vs *uncoupled tractions*

(d) *W-M profile, coupled* vs *uncoupled tractions*

Figure 1: Distribution of tractions for two different rigid indenters, with or without coupling

The horizontal tractions have been normalised with respect to the friction coefficient μ, in such a way that, in slip regime, they coincide with the vertical pressure when positive, and with its opposite when negative. Given that, the identification of the state of a node is straightforward. For example, in Fig. 1a, the solid lines overlapping with the dashed lines are in forward slip, the solid lines which follow the shape of the vertical pressure but with opposite sign in the third quadrant are in a state of backward slip, while the lines that link them are related to nodes which are still in a state of stick. As the horizontal load rises, the area of stick first shifts leftward and then start shrinking, representing the evolution of the system from a state of *partial* slip to one of *full* or *gross slip*.

In Fig. 1c and 1d, a comparison has been made, for a selected time step (the number 8), between the coupled and the uncoupled version of the same algorithm, simply obtained by zeroing the terms H_{xz} and H_{zx}. The first result obtained is the remarkable difference in the distribution of the horizontal tractions which, in the backward slip zone, reach their maximum when the horizontal load is yet to be applied. The same trend can be observed both for the parabolic and the W-M profiles. Non negligible differences can be noticed in the distribution of the vertical pressures as well: indeed, the coupled case presents vertical traction values higher, in the stick zone, than the ones predicted by the uncoupled model. Finally, the contact area is influenced as well, with a light shift towards, again, the stick zone.

CONCLUSION

A fully coupled boundary element algorithm for the evaluation of the surface tractions in a frictional contact problem has been presented. As a first preliminary result, significant differences have been found in terms of both vertical and horizontal tractions with respect to the uncoupled models usually found in literature, due to the non-negligibility of the terms in the coupling matrices H_{xz} and H_{zx}.

INTERPLAY BETWEEN WALL SLIP AND SURFACE TEXTURING: A NOVEL ALGORITHM BASED ON VARIATIONAL INEQUALITIES

Luca Biancofiore*[1], Matteo Giacopini[2], and Daniele Dini[3]
[1]Department of Mechanical Engineering, Bilkent University 06800 Bilkent, Ankara, Turkey

Summary In this work we develop an innovative and accurate numerical model, based on complementary variables, to predict simultaneously the slip at the wall, by using the Tresca model, and the formation of cavitation, through a mass-conserving formulation. To show the flexibility of our model, several bearing geometries have been analysed, such as a cosine profile used to mimic a bearing, and a pocketed slider bearing employed to study the effect of surface texture. We observe that the lubrication performance (i.e. low friction coefficient) can be improved by using materials that promote slippage at the moving wall. The location of the slippage region can be optimised to find the lowest value of friction coefficient.

INTRODUCTION

Around 23% of the world's total energy consumption originates from tribological contacts, most of it used to overcome friction [1]. More and more efficiency savings must be made in mechanical systems, since stricter emissions standards are enforced. Particularly in the long term the implementation of advanced tribological technologies for friction reduction and wear protection, could bring in the long term to (i) saving about 8.7% of the total energy consumption (1.4% of the world GDP) and (ii) reduce the CO_2 emissions globally by as much as 1,460 MtCO2 (i.e. 450,000 million Euros cost savings) [1].

Experimental and theoretical studies have shown that, if properly optimised, both surface texturing and artificially induced slip can individually reduce the friction of a system. A fundamental aspect to consider in modelling contacts with surface texturing or slip at the walls is cavitation, which is usually referred to describe a complex thermodynamical process including nucleation, growth and implosion of vapour or gas bubbles within a liquid.

But is it possible to combine the effect of wall slip and surface textures? Several papers on the subject have showed that both surface texture and slip can theoretically cause a significant reduction in the friction coefficient, see the review by Senatore & Rao [2]. However still a careful optimisation of the surface parameters is needed before conducting expensive and time-demanding experiments. Particularly it is necessary to understand how - and if - it is possible to maximise the bearing performance while minimising the increase in manufacturing cost. The aim of the present work is to fill this gap by producing robust and innovative numerical schemes to enable researchers to explore a wide parameter space for the optimisation of patterned surfaces in the presence of micro-textures and oleophobic coatings.

BASIC EQUATIONS AND NUMERICAL METHOD

In this work we develop a 1D algorithm, based on a Finite Elements approach, to model the two intertwined problems (i.e. cavitation and slippage at the upper wall) in terms of complementarity. The flexibility of the complementary algorithm is fundamental to predict the behaviour of contact with extreme thickness gradients, typical of textured surfaces (such as dimple or pockets, for instance).

Following Giacopini *et al.* [3], we can write the complementary formulation related to the problem of cavitation in lubricant films in a compact functional form

$$p(x) = L_c r(x) + Q_c, \tag{1}$$

with $p(x) \geq 0$, $r(x) \geq 0$ and $p(x)r(x) = 0$, where the two complementary variables p and r, are, respectively, the pressure and the density ratio, i.e. $r(x) = 1 - \frac{\rho(x)}{\rho_0}$, $\rho(x)$ is the fluid density, ρ_0 is the density in the liquid region and x is the streamwise direction. The operators L_c and Q_c can be found from examining Ref. [3] but in our case they depend on the possible relative velocity of the fluid at the upper fixed surface U_s.

We use the Tresca model for the possible slippage at the wall. Briefly, if the shear stress at the upper wall τ is lower than the critical value τ_c no slippage occurs, and therefore $U_s = 0$. If τ reaches its critical upper bound τ_c, the fluid velocity can be higher than that of the upper boundary, $U_s \geq 0$. Particularly, following Strozzi *et al.* [4], we can arrive to the complementary formulation

$$M^{-1}U_s(x) + M^{-1}P = \tau_c(x) - \tau(x), \tag{2}$$

$(\tau_c(x) - \tau(x)) \geq 0$, $U_s(x) \geq 0$, and $U_s(x)(\tau_c(x) - \tau(x)) = 0$. Note that in our formulation the critical value $\tau_c(x)$ depends on the streamwise direction. The operators M and P can be found similarly to Ref. [4], but in our work they depend on the density ratio r.

Finally, we have validated our algorithm presented in this section with comparing our results to Bayada [5].

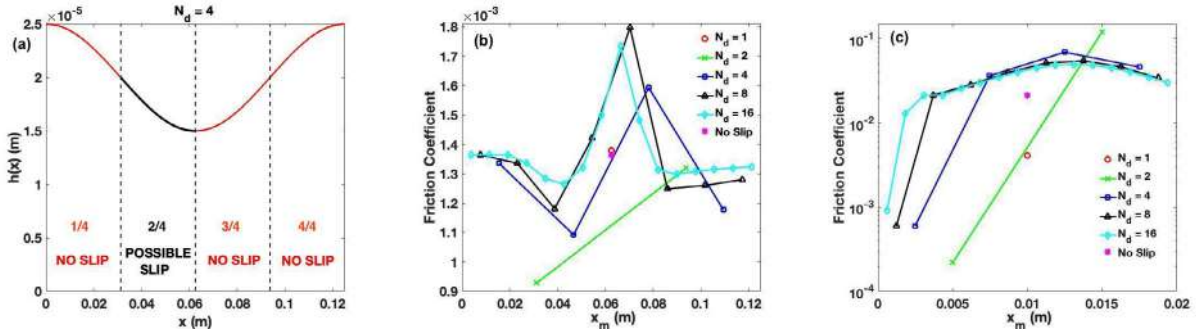

Figure 1: (a) The bearing modelled as a cosine profile. Note that the critical shear stress can be uniform or non-uniform. In particular, in this figure a specific non-uniform configuration ("$2/4$") is depicted. Friction coefficients (b) for the cosine profile for $\tau_c = 1$kPa and (c) for the pocketed slider for $\tau_c = 2$ kPa.

RESULTS AND DISCUSSIONS

Obtaining a slippage condition by using superoleophobic surfaces is expensive and not easy to be manufactured. For this reason it would be worthwhile to optimise the surface in order to reach good lubrication performance (i.e. low friction coefficient, defined as the ratio between friction and load) while minimising the superoleophobic region. For this reason a possibly non-uniform τ_c is considered. Particularly, the profile is divided in N_d equal parts and just in $1/N_d$-th of the profile a finite value of the critical shear stress is considered, while in the other parts a no-slip boundary condition is implemented, i.e. $\tau_c = \infty$. An example is shown in fig.1(a) where the black line depicts the possible slippage region. This configuration mimics the case in which just a partial surface of the bearing is superoleophobic. A specific notation is used to identify the area where slip can occur as exemplified below. For instance if we divide the profile in $N_d = 4$ parts and we apply the slippage in the second quarter only, we define this configuration as "$2/4$".

Bearing

In this section we model a bearing by using a cosine profile shown in figure 1(a). We illustrate in fig.1(b) the friction coefficient for several N_d and $\tau_c = 1$kPa. In particular every marker depicts a different configuration in which the slippage zone is on a different $1/N_d$-th of the profile. Note that each configuration is associated to the median abscissa of the slippage zone x_m. The fully slip (i.e. $N_d = 1$) and the purely no slip cases have a very similar value of the friction coefficient. Interestingly the lowest values of the friction coefficient are for super-oleophobic regions in the second quarter of the bearing. Particularly the case "$1/2$", "$2/4$", "$3/8$" and "$6/16$" are the configurations for each N_d in which the friction coefficient is minimal. They show a gain in friction coefficient with respect to both the no slip and fully slip cases of 31%, 20%, 13% and 7%, respectively, but having a significant shorter slippage zone.

Pocketed slider

We consider a pocketed slider already studied by Giacopini et al. [3], but implementing the possible slippage at the upper wall. This profile is analyzed to mimic a surface texture. Fig. 1(c) shows the value of the friction coefficient for several values of N_d and for $\tau_c = 2$ kPa, compared with the pure no slip case. If the slippage zone is located close to the entry of the domain the friction coefficient could decrease by one or two orders of magnitudes with respect to the uniform critical shear stress case, depending on the number of parts in which the domain is divided.

CONCLUSIONS

We have shown that the performance of bearings in which there is interplay between slip at the wall and cavitation can be significantly improved (up to two orders of magnitude reduction in the friction coefficient) while minimising the slippage region. This can reduce cost in manufacturing superoleophobic bearings since surface treatments can be confined to specific (small) regions to strongly improve bearings' performance. Furthermore, our model has showed that the values of the critical shear stress necessary to achieve a significant decrease of the friction coefficient are not prohibitively small and can be achieved using conventional processes, pointing out further the possibility of reduction in manufacturing cost.

REDUCED NONLINEAR FEM-MODEL FOR BEAM-TYPE AIR FOIL BEARINGS: SIMULATION AND OPTIMIZATION OF BEARING HYSTERESIS CURVES

Marcel Bauer*[1], Marcel Mahner [1], Pascal Zeise [1], and Bernhard Schweizer [1]
[1]Department of Mechanical Engineering, Technical University of Darmstadt, Darmstadt, Germany

Summary A reduced two-dimensional nonlinear FEM-model of a beam-type air foil journal bearing including contact and stick-slip friction is presented. The main goal of the model is the investigation of the nonlinear force-deflection characteristic, which provides important insight into the stiffness and damping/friction behaviour of air foil bearings. The force-deflection curves (bearing hysteresis curves) of the developed 2D-model are compared with a detailed 3D-model. In addition, a test-rig for measuring hysteresis curves of air foil bearings is presented. Experimental results are compared with the 2D and 3D simulation results.

INTRODUCTION

In high-speed turbomachinery applications, air foil bearings are an interesting alternative to classical oil-lubricated bearings. Air foil bearings consist of a bearing housing, a compliant foil structure and a top foil. The purpose of the compliant foil structure is to compensate both manufacturing deviations and thermal and mechanical growth of the rotating shaft. It also defines the stiffness and damping behaviour of the whole bearing. The coated top foil, which is placed between the compliant foil and the shaft, provides the necessary surface for the pressure build-up of the air film.

The compliant foil structure can be designed in different ways. One design option is the bump foil, which is investigated numerically and experimentally in [1] and [2]. Another design option is the beam foil [3]. With static load-displacement measurements and comparisons between different foil designs, Shalash and Schiffmann experimentally showed the high robustness of beam-type bearings. Equivalent measurements for other beam foil designs are depicted in [4]. Despite the recent studies on beam-type bearings, there is still a lack of detailed models for the prediction of the nonlinear force-deflection characteristic. Numerical models can provide a deeper understanding of the physics of air foil bearing systems and may further be used for design optimizations.

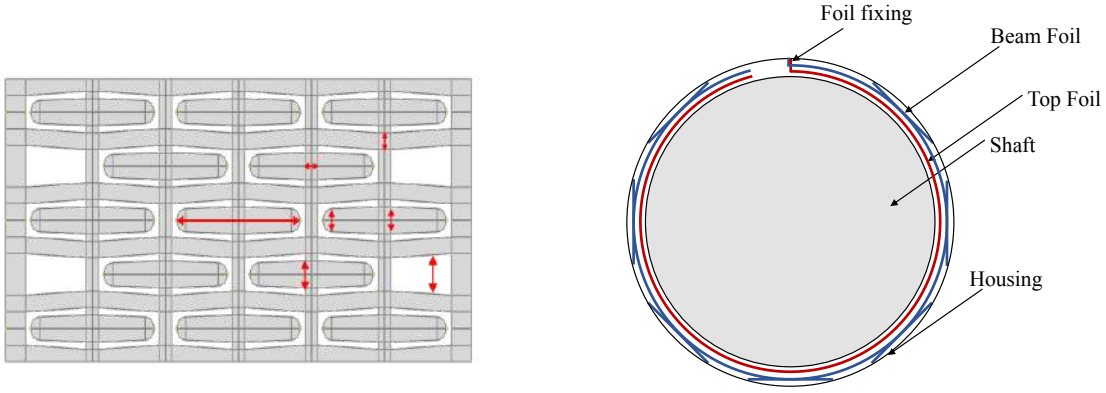

Figure 1. a) Beam foil, b) 2D-modell of a beam-type air foil bearing

STRUCTURAL FEM MODEL OF AIR FOIL BEARINGS

Firstly, a detailed three-dimensional structural FEM model is presented, which is used as a reference model. Although this model considers many important features (nonlinear deformations, contact and friction, etc.), its use is limited due to the high computational effort, especially with respect to structural optimization. A further drawback of the 3D-model lies in the difficulty to expand the model by further physical aspects (air film, temperature effects, etc.).

Secondly, a reduced 2D model is presented. The regular structure of the beam foil enables a straightforward reduction to a two-dimensional model. Here, both foils (top foil and beam foil) were described by a nonlinear beam theory according to Reissner [5]. The left picture in Figure 1 depicts a typical design of a beam foil. In its initial, stress-free configuration the beam foil is plane. When the beam foil is bent for the insertion into the bearing housing, the beams remain almost plane and are supported on the inner wall of the housing. In this position they act like leaf springs, see the right graphic in Figure 1.

Bearing dissipation is mainly caused by friction, which occurs during relative motions between the bearing components as a result of radial shaft deflections. In order to investigate the effect of friction, appropriate contact

*Corresponding author. E-mail: bauer@ad.tu-darmstadt.de.

conditions have to be formulated. The inequality constraints for the contacts are implemented with the augmented Lagrange method [6]. Friction is calculated by the Coulomb friction law.

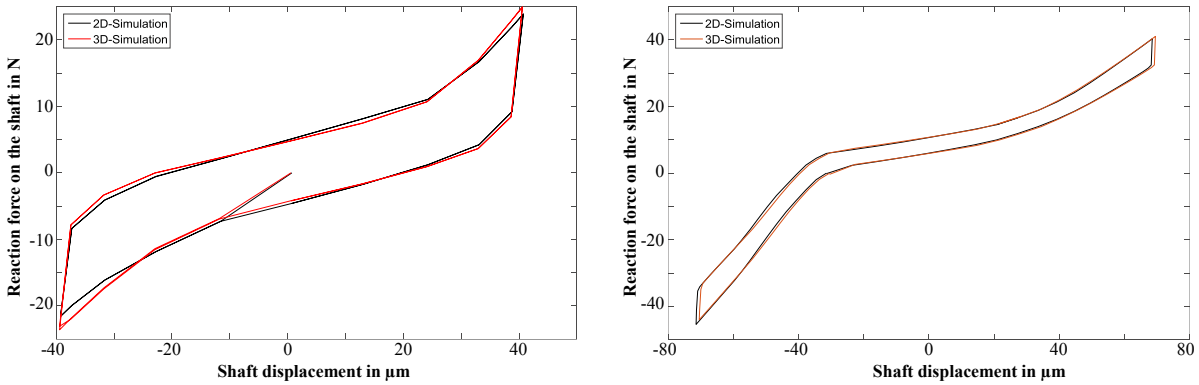

Figure 2. Load-displacement curve of a beam-type air foil bearing: a) horizontal, b) vertical displacement

RESULTS AND CONCLUSION

The simulated load-displacement curves generated with the two- and three-dimensional model are depicted in Figure 2. A hysteresis effect and a nonlinear stiffness behaviour can be clearly observed, which are both dependent on the direction of the shaft displacement. The results of the two-dimensional and three-dimensional model are in good agreement. The simulation time for the 3D model (approximately $3.7{\cdot}10^6$ DOF) is approx. 60 hours, while the computation time for the 2D model (approximately $30 \cdot 10^3$ DOF) is only 1 hour. The simulated hysteresis curves also show a good agreement with experimental results, which have been carried out on a special test rig for air foil bearings.

INFLUENCE OF DIFFERENT FITTING METHODS ON THE IDENTIFICATION OF THE SYNCHRONOUS DYNAMIC COEFFICIENTS OF TILTING PAD JOURNAL BEARINGS

Michele Barsanti*[1], Enrico Ciulli[1], Paola Forte[1], and Matteo Nuti[2]
[1]Dipartimento di Ingegneria Civile e Industriale, University of Pisa, Largo Lazzarino, 56122 Pisa, Italy
[2]AM Testing s.r.l., Pisa, Italy

Summary Tilting pad journal bearings (TPJB) are mechanical components of fundamental importance for the proper operation of turbomachinery and the knowledge of bearing stiffness and damping coefficients is essential for rotor design. A high performance test bench has been designed specifically to carry out the experimental activity necessary for their determination. The tests carried out show a dependence of the dynamic coefficients on the excitation frequency of the dynamic load. In this work, different data fitting methods for the identification of synchronous dynamic coefficients are compared in order to evaluate the corresponding error in the predictions.

INTRODUCTION

The stiffness and damping coefficients of TPJBs are computed by applying dynamic loads (at several excitation frequencies) to the bearing, measuring the rotor-stator relative displacement and processing results in the frequency domain [1, 2]. The dependence of dynamic coefficients on the excitation frequency shows a non-linear trend [2] which makes it difficult to determine the synchronous coefficients (at an excitation frequency equal to the rotor rotational frequency) usually obtained by interpolation among the coefficients corresponding to excitation frequencies slightly lower and higher than the synchronous frequency. In this work different fitting functions have been compared to investigate their influence on the results.

CLASSICAL EXPERIMENTAL IDENTIFICATION OF DYNAMIC COEFFICIENTS

Several tests were performed at the University of Pisa on a test bench specifically designed for large size journal bearings operating at high peripheral speeds and static loads [1]. The test rig is shown in Fig. 1 (a); a sketch of actuators and sensors is shown in Fig. 1 (b). Details on the experimental activity are reported in [3]. The linear model used for the

(b) 
Figure 1: (a) Photo of the test rig. (b) Test section, showing actuators and sensors.

identification of the dynamic coefficients and described in [4] is based on the impedance matrix H that can be computed using

$$\begin{bmatrix} H_{xx} & H_{xy} \\ H_{yx} & H_{yy} \end{bmatrix} = \begin{bmatrix} F_{b1x} & F_{b2x} \\ F_{b1y} & F_{b2y} \end{bmatrix} \begin{bmatrix} X_1 & X_2 \\ Y_1 & Y_2 \end{bmatrix}^{-1} \text{ where } \begin{bmatrix} H_{xx} & H_{xy} \\ H_{yx} & H_{yy} \end{bmatrix} = \begin{bmatrix} k_{xx} & k_{xy} \\ k_{yx} & k_{yy} \end{bmatrix} + i\omega \begin{bmatrix} c_{xx} & c_{xy} \\ c_{yx} & c_{yy} \end{bmatrix}, \quad (1)$$

in which F indicates the amplitude of the force (acting on bearings) Fourier transform, X, Y indicate the amplitudes of the displacement Fourier transforms for the two perturbation tests respectively in horizontal (subscript 1) and vertical direction (subscript 2). The determination of the stiffness k and damping c coefficients at each of the excitation frequencies ω are obtained as respectively the real and the imaginary parts of the impedance direct and cross-coupled coefficients. The need to improve the accuracy and precision of the synchronous coefficients estimates leads to the development of increasingly elaborate models.

STATISTICAL PROCEDURE FOR DYNAMIC COEFFICIENTS IDENTIFICATION

A new identification procedure, based on a statistical approach, was developed in [4] to improve the classical identification procedure and to estimate the associated random uncertainties as well. The statistical model, adopted at each excitation frequency, has been generalized in this work analyzing simultaneously the measurements at all the excitation

*Corresponding author. E-mail: michele.barsanti@unipi.it.

frequencies and introducing a class of functions to fit the dependance of dynamic coefficients on the excitation frequency ω of the dynamic coefficients:

$$\begin{cases} \mathrm{Re}(F_{b1x}) = k_{xx}(\omega)\mathrm{Re}(X_1) - \omega c_{xx}(\omega)\mathrm{Im}(X_1) - \omega c_{xy}(\omega)\mathrm{Im}(Y_1) + k_{xy}(\omega)\mathrm{Re}(Y_1) \\ \mathrm{Im}(F_{b1x}) = k_{xx}(\omega)\mathrm{Im}(X_1) + k_{xy}(\omega)\mathrm{Im}(Y_1) + \omega c_{xx}(\omega)\mathrm{Re}(X_1) + \omega c_{xy}(\omega)\mathrm{Re}(Y_1) \\ \mathrm{Re}(F_{b2x}) = k_{xx}(\omega)\mathrm{Re}(X_2) - \omega c_{xx}(\omega)\mathrm{Im}(X_2) - \omega c_{xy}(\omega)\mathrm{Im}(Y_2) + k_{xy}(\omega)\mathrm{Re}(Y_2) \\ \mathrm{Im}(F_{b2x}) = k_{xx}(\omega)\mathrm{Im}(X_2) + k_{xy}(\omega)\mathrm{Im}(Y_2) + \omega c_{xx}(\omega)\mathrm{Re}(X_2) + \omega c_{xy}(\omega)\mathrm{Re}(Y_2) \\ \mathrm{Re}(F_{b1y}) = k_{yx}(\omega)\mathrm{Re}(X_1) - \omega c_{yx}(\omega)\mathrm{Im}(X_1) - \omega c_{yy}(\omega)\mathrm{Im}(Y_1) + k_{yy}(\omega)\mathrm{Re}(Y_1) \\ \mathrm{Im}(F_{b1y}) = k_{yx}(\omega)\mathrm{Im}(X_1) + k_{yy}(\omega)\mathrm{Im}(Y_1) + \omega c_{yx}(\omega)\mathrm{Re}(X_1) + \omega c_{yy}(\omega)\mathrm{Re}(Y_1) \\ \mathrm{Re}(F_{b2y}) = k_{yx}(\omega)\mathrm{Re}(X_2) - \omega c_{yx}(\omega)\mathrm{Im}(X_2) - \omega c_{yy}(\omega)\mathrm{Im}(Y_2) + k_{yy}(\omega)\mathrm{Re}(Y_2) \\ \mathrm{Im}(F_{b2y}) = k_{yx}(\omega)\mathrm{Im}(X_2) + k_{yy}(\omega)\mathrm{Im}(Y_2) + \omega c_{yx}(\omega)\mathrm{Re}(X_2) + \omega c_{yy}(\omega)\mathrm{Re}(Y_2) \end{cases} . \quad (2)$$

The relationship can be linear, polynomial or spline. In order to obtain the best estimates of all the quantities, a constrained minimum of the following weighted sum of squared residuals S as a function of the dynamic coefficients, displacements and forces is searched, in a similar way to what was already developed in [4]:

$$S = \sum_{i=1}^{N} \left[\left| \frac{\hat{X}_{1,i} - X_{1,i}}{\sigma_X} \right|^2 + \left| \frac{\hat{X}_{2,i} - X_{2,i}}{\sigma_X} \right|^2 + \left| \frac{\hat{Y}_{1,i} - Y_{1,i}}{\sigma_Y} \right|^2 + \left| \frac{\hat{Y}_{2,i} - Y_{2,i}}{\sigma_Y} \right|^2 + \left| \frac{\hat{F}_{b1x,i} - F_{b1x,i}}{\sigma_{Fx}} \right|^2 + \left| \frac{\hat{F}_{b2x,i} - F_{b2x,i}}{\sigma_{Fx}} \right|^2 + \left| \frac{\hat{F}_{b1y,i} - F_{b1y,i}}{\sigma_{Fy}} \right|^2 + \left| \frac{\hat{F}_{b2y,i} - F_{b2y,i}}{\sigma_{Fy}} \right|^2 \right] \quad (3)$$

in which N is the total number of measurements (at all the frequencies) and the relationships (among the hat variables) shown in equation (2) are the constraints. Standard deviations σ_X, σ_Y and σ_F have the same value for all the measured displacements and forces. This methodology can then be extended to determine an estimate of the random error as well.

RESULTS AND CONCLUSIONS

An example of preliminary result is shown in Figure 2. For given test conditions, the dynamic coefficients at various excitation frequencies (estimated using the conventional technique) [2] are reported in black dots, simply connected by segments. The coloured curves show the various predictions of the different modeling of the relationship between dynamic coefficients and excitation frequency: in blue quadratic models, in magenta cubic models. Polynomials are drawn in full lines, splines are reported using dashed lines. The black dashed line, drawn in correspondance of synchronous frequency, highlights that the prediction of the synchronous dynamic coefficients depends on the choice of the model. The difference among the various predictions can be of the same order of the random or systematic uncertainty [2, 4] and therefore these preliminary results indicate that the choice of the fit model can be critical.

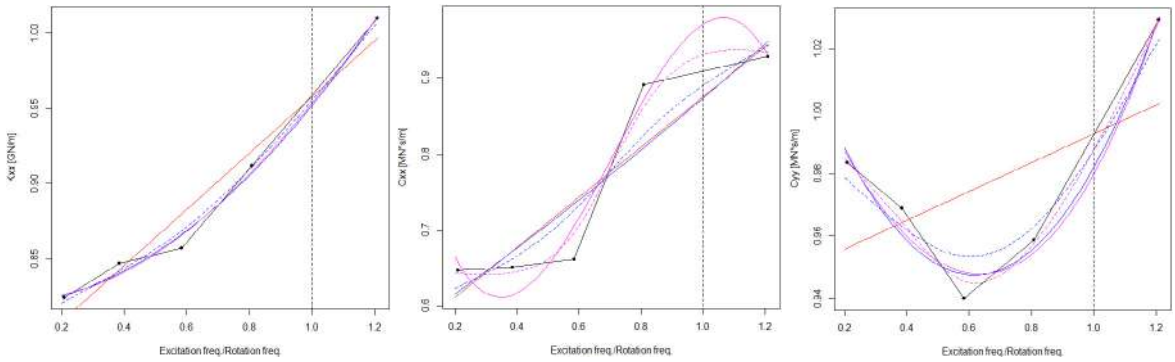

Figure 2: Examples of prediction of stiffness and damping coefficients as a function of the excitation frequency.

RING BASED MODEL FOR COMPUTING POWER LOSS INLATERALLY COMPRESSED GEL-FILLED OPTICAL FIBERCABLES

Anshul Agrawal[*†], Shakti S. Gupta[†], Ishan Sharma[†], and Manoj Mittal[§]
[†]Department of Mechanical Engineering, IIT Kanpur, Kanpur - 208016, India
[§]Sterlite Technologies Limited, Dadra and Nagar Haveli - 396230, India

Summary We model a critical orientation of outer sheath and loose tubes of an optical cable as thin elastic rings. The laterally compressed sheath between two flat rigid plates circumscribes the diametrically placed vertical loose tubes, separated by a rigid core at the cable's center. Sheath-flat plate, sheath-loose tube, and loose tube-core interactions are modelled as point contacts transitioning to line contacts during deformation. The nonlinear equilibrium equations are solved satisfying deformation compatibility to compute fraction of applied load on the gel filled loose tubes. This is used to find the excess pressure in the tubes which eventually acts on the optical fibers in those. Using this pressure the field of refractive index over the cross-section of the fiber is computed employing stress-optic law which is further used in COMSOL to compute the power loss in the optical fiber.

INTRODUCTION

Optical fiber cable as shown in Fig. 1, consists of an outer sheath, an inner rigid core and loose tubes between them which carry optical fibers. Depending on situations these cables may come under constant external loads for example, crushing due to a heavy vehicle passing or a boulder falling over it. These external loads deform the components of the structure of the cable leading to excess pressure in the gel filled in the loose tubes. This excess pressure is exerted onto the optical fibers, stressing those which leads to the loss in signal transmission.

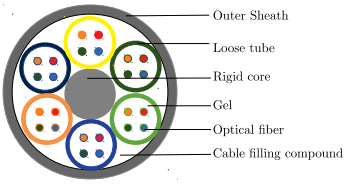

Figure 1: Schematic of the cross-section of an optical fiber cable and its components.

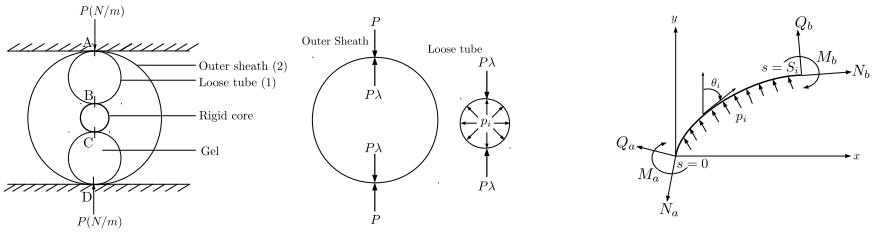
Problem formulation

Assuming plane strain state in the cable, a set of three elastic thin rings with one rigid circular core at the center, pressed between two rigid plates is shown in Fig. 2(a) is chosen as the critical orientation of the cable. This symmetric arrangement of rings is subjected to the externally applied distrubuted line load of P (N/m) perpendicular to the plane of the paper as shown in Fig. 2(a). The loose tubes and the sheath are denoted by the numbers 1 and 2, respectively. The rings are characterized by their constant bending stiffness D_i and unloaded radii of curvature ρ_i. It is also assumed that the rings are inextensible and the contact at various interfaces is frictionless.



(a) (b) (c)

Figure 2: (a) Structural model of the cross-section of the cable, (b) FBD of the sheath and a loose tube, and (c) Forces and moments on an arc of the ring.

The static equilibrium equations for the outer and the inner rings can be written as follows [1]:

$$\frac{\partial Q_i}{\partial \theta_i} + N_i + p_i \rho_i = 0, \quad \frac{\partial M_i}{\partial \theta_i} + Q_i \rho_i = 0, \quad \frac{d\theta_i}{ds} = \frac{1}{\rho_0} + \frac{M_i}{D_i}, \tag{1}$$

*Corresponding author. E-mail: anshula@iitk.ac.in.

where θ_i is the local slope, s_i is the arc-length, N_i the membrane force, Q_i the shear force, M_i the bending moment, p_i the internal gel pressure, ρ_0 the original radius of curvature, ρ_c the raidius of curvature of core. Note that while writing the equilibrium of the sheath p_i will be set to zero.

While solving the above equations the inextensibility condition is enforced by maintaining the initial and the final arc-lengths equal. Additionally, at any step of deformation AB = AC + CD + DB is maintained (see Fig. 2(a)). These equilibrium equations are solved using elliptic integrals [3] to compute fractional load parameter λ.

To compute the gel pressure the equilibrium equations for the loose tube are written as below:

$$D_1 \frac{d^3\theta_1}{ds^3} - \frac{N_1}{\rho_1} - p_1 = 0, \quad \mu = \frac{-p_1}{(\Delta V/V)}, \tag{2}$$

where for unit depth of the loose tube we write the change in volume $\Delta V = \Delta A$, the change in cross-sectional area for unit length of cylinder, and the initial volume $V = A$, the initial area. Equation (2) is solved satisfying the constraint in Eq. (3) and the boundary conditions in Eq. (4) resulting in the deformed configuration of the ring.

$$\frac{P}{2D_1} - \sqrt{-\frac{k_L^4}{4} + \frac{2p_1k_L}{D_1} + c_1k_L^2 + c_2} = 0, \quad \frac{P}{2D_1} + \sqrt{-\frac{k_R^4}{4} + \frac{2p_1k_R}{D_1} + c_1k_R^2 + c_2} = 0, \quad k_L = \frac{d\theta_L}{ds}, \quad k_R = \frac{d\theta_R}{ds}, \tag{3}$$

L, R corresponds to $s = 0$, S_i, respectively.

$$\text{At} \quad s = 0, \quad \theta_i = \pi, \quad \text{At} \quad s = S_i, \quad \theta_i = 0, \tag{4}$$

For a given value of bulk modulus μ of gel, excess pressure p_1 is computed using the second of Eq. (2). This excess pressure is further used to compute the stress from the problem of a disk (optical fiber) under radial compression [5] ($\sigma_{rr} = -p_1, \sigma_{\theta\theta} = 0, \sigma_{r\theta} = 0$) and hence strain tensor using linear constitutive relation (σ = E ϵ) over the cross-section of the optical fiber.

Using the strain computed above and employing the stress-optic law [4] for an isotropic material the change in refractive index is given by

$$\Delta n_k = \frac{n_k^3}{2} \sum_{m=1}^{4} P_{km}\epsilon_m. \tag{5}$$

where Δn_k is the change in refractive index of the k^{th} component tensor in Voigt notation, ϵ_m are the four components of the strain tensor in Voigt notation, and P_{km} the photo-elastic constants comprising the photo-elastic tensor. Equation (5) is used to compute refractive index profile over the cross-section of the optical fiber which in turn is used in COMSOL to compute power loss in the cable.

RESULTS AND CONCLUSIONS

For the parameters $D_1 = 5.95 \times 10^{-5}\, Nm^2$, $D_2 = 1 \times 10^{-3}\, Nm^2$, $\rho_1 = 0.682\, mm$, $\rho_c = 1\, mm$, $\rho_2 = 2.6\, mm$.

Figure 3: (a) Load (P) versus λ, (b) Modified refractive index profile, and (c) For Young's modulus of fiber = 21 GPa, wavelength = 1550 nm, fiber diameter = 125 μm.

Ring based model to compute optical power loss in optical cables is studied. The optical cable is modeled as an array of thin elastic rings. The fraction of total load (parameter λ) on the loose tube is computed solving governing nonlinear equations. This parameter is used to derminine the excess gel pressure inside loose tubes which is used to evaluate the field of refractive index change over the cross-section of the fiber employing stress-optic law. This is further used in COMSOL to compute the power loss in the optical fibers.

FROM A PERFECT JUNCTION TO A TILTED ASPERITY: EXPERIMENTAL, ANALYTICAL, AND NUMERICAL STUDIES

Mohammad Malekan*[1], Michal K. Budzik[1], and Ramin Aghababaei[1]
[1]Department of Engineering, Aarhus University, 8000 Aarhus C, Denmark

Summary Friction and wear of brittle materials during sliding contact are often associated with the fracture-induced failure of interlocking asperities under shear loading. This paper presents analytical, numerical and experimental studies of an idealized asperity under lateral load. The material under study was chosen as PMMA. Both experimental and numerical studies were done for different asperity base angle (θ), from 60 to 90 degrees. Maximum force to initiate the crack and also crack initiation angle were derived from analytical, numerical, and experimental investigations. The results showed that the maximum force went higher for smaller θ angle, along with good agreements between all the three approaches.

INTRODUCTION

Brittle fracture is a major mode of failure in cracked brittle materials like PMMA. In many practical applications related to brittle materials, such as material cutting processes and hydraulic fracturing, the fracture strength is an important material property. Moreover, for applying the crack growth retardation methods an estimate of the direction of the fracture initiation and early propagation is required. Hence, the investigation of the fracture trajectory is an interesting topic for researchers involved in the field of fracture mechanics of brittle and quasi-brittle materials. Under pure mode-I loading conditions, cracks sometimes grow along curvilinear paths and not necessarily along the direction of the initial cracks. This paper presents analytical, numerical and experimental studies of an idealized asperity under lateral load. The material under study was chosen as PMMA.

THEORETICAL MODEL

A theoretical model is derived here using general Euler-Bernoulli beam theory, aiming to determine the maximum loading magnitude that derives the crack initiation in the problem. The geometrical setup for our theoretical analysis is illustrated in Fig. 1. We assume that the asperity width (d_x) varies as a function of height, where d_0 is the base width (the asperity is prismatic when $d(x) = d_0$). We note a geometrical constraint that h should be smaller than the asperity height. A constant out-of-plane thickness t is considered in this study.

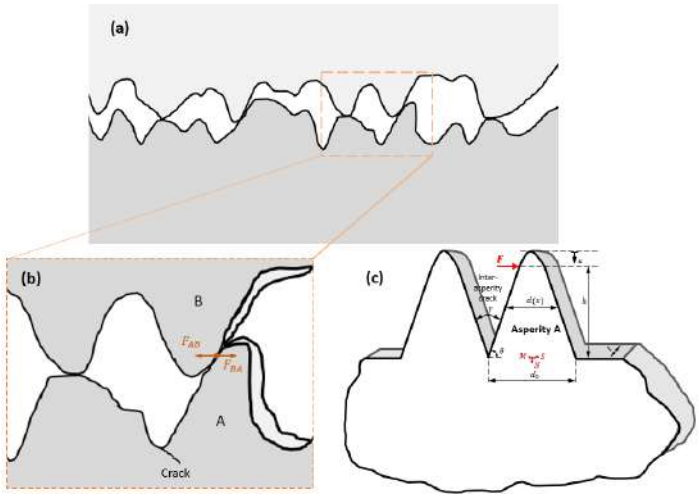

Figure 1: Schematic of the sliding contact between two rough solid surfaces at **(a)** multi-asperity and **(b)** single asperity levels. **(c)** an idealized asperity model used to develop the theoretical model.

Considering the case of two prismatic asperities [i.e. $d(x) = d_0$] with an interfacial sharp crack (i.e. $\gamma = 0$, $\theta = 90$), the energy release rate G can be obtained similar to the problem of interlaminar crack propagation in a double cantilever beam setup [1, 2], as

$$G = \frac{1}{Et^2 d_0}\left(N^2 + S^2 + \frac{12M^2}{d_0^2}\right) \tag{1}$$

where N, S and M represent the magnitude of the normal and shear forces and the bending moment at the asperity base and E is the elastic modulus. Our analysis shows that the energy release rate is only a function of the beam width at the location of the crack tip (d_0) and is independent of the asperity shape.

*Corresponding author. E-mail: m.malekan@eng.au.dk

Considering a contact force laterally applied to the asperity side, the crack tip forces and moment can be replaced by $M = Fh$, $S = F$ and $N = 0$ in Eq. (1). Accordingly, the critical force at the onset of crack propagation for non-zero crack opening angles ($0 \leq \gamma \leq \pi$) can be obtained as [3, 4, 5, 6]

$$\widetilde{F}_c = \frac{F_c}{K^*_{IC}\, t\, d_0^{1-\lambda(\gamma)}} = \frac{\alpha}{\sqrt{12+\alpha^2}} \tag{2}$$

where λ represents the degree of stress singularity at the crack tip which varies between $1/2$ (when a sharp crack and square-root stress singularity presents, i.e. $\gamma = 0$) and zero (when the stress singularity is absent, i.e. $\gamma = \pi$) and can be calculated from the following eigen-equation [5]

$$(1-\lambda)\sin(2\pi-\gamma) = \sin[(1-\lambda)(2\pi-\gamma)] \qquad K^*_{IC} = [1-\lambda(\gamma)]\,\sigma_{ult}\left(\frac{2K_{IC}}{\sigma_{ult}}\right)^{2\lambda(\gamma)} \tag{3}$$

As seen in Eq. (2), the normalized fracture force $\tilde{F}_c$ is independent of the asperity shape and is only a function of the ratio between the asperity width at its base and the height of the loaded part of the asperity.

EXPERIMENTAL AND NUMERICAL STUDIES

We study experimentally the fracture failure of tapered asperities made of PMMA (polymethylmethacrylate) using a set of in-situ experiments. Test specimens are cut from PMMA sheets of 1.8 mm thickness by laser cutting. Dictated by the minimum resolution of the cutting line, all base corners have a radius of curvature of about $100\mu m$. We fixed the height of the applied load ($h = 8$ mm) and the width of asperity tip (5 mm) and systematically varies the θ angle from 60^o to 90^o with 5^o increments. The asperity base width d and the aspect ratio α (i.e., d/h) change accordingly.

To study the evolution of deformation and failure, we also performed numerical simulations using the extended finite element method (XFEM) implemented in the Abaqus® commercial package. The geometrical model and boundary conditions are presented in Fig. 2. A fixed displacement and rotation are assumed at the asperity base where a displacement rate of 2 mm/min is applied at a fixed distance of 2mm from the asperity tip. A linear elastic material with brittle behavior and parameters corresponding to PMMA properties is assumed. FE model is discretized using plane stress CPS4 elements (4-node bilinear quadrilateral element) with an average size of $0.015 \sim 0.03$mm for the corner areas (i.e. crack nucleation site) and $0.075 \sim 0.1$mm for the rest of the domain.

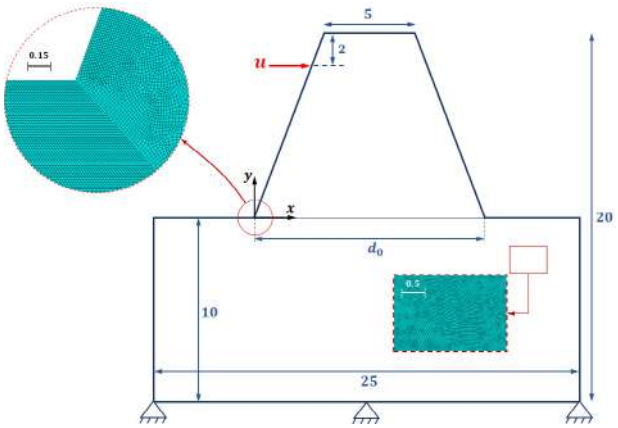

Figure 2: Geometry schematic of the problem under study along with mesh representation for different parts of the problem. All dimensions are in mm

CONCLUSIONS

The aim of this paper was to demonstrate a package of theoretical, experimental, and numerical studies of idealized asperities in order to investigate their fracture behavior, in terms of maximum force to fracture and also the crack initiation angle. The results will include comparison between all the three approaches and final goal is to propose a proven theoretical formulae that can be used for similar conditions.

INDENTATION OF A SPHERICAL PUNCH INTO A VISCOELASTIC BASE IN THE PRESENCE OF ADDITIONAL LOADING

Anastasiya Yakovenko*[1,2], Irina Goryacheva [1]
[1]Laboratory of Tribology, Ishlinsky Institute for Problems in Mechanics RAS, Moscow, Russia
[2]Phystech School of Aerospace Technology, Moscow Institute of Physics and Technology (National Research University), Moscow, Russia

Summary A numerical-analytical solution of the problem of indentation of a spherical punch into a viscoelastic base in the presence of additional loading outside a circle of a given radius is presented. The influence of the viscoelastic properties of the base on the dependence of the contact characteristics (radius of the contact area, contact pressure distribution) on time for the exponential creep function. The analysis of the dependence of the pressure distribution under the punch at different instants of time on the radius of the additional loading is also presented.

The effects of mutual influence of the microcontacts in contact interaction of the surfaces with irregularities are well studied for the elastic bodies. Many works have been devoted to modeling of an indentation of the surfaces with regular relief into elastic base. 2-D periodic contact problems were considered in [1], and 3-D discrete contact problems with limited and unlimited nominal contact region were studied in [2]. However, when analysing the indentation of rough bodies into the viscoelastic base, the effect of the mutual influence of microcontacts is poorly studied. To analyse the effect of the additional loading on the indentation of the punch into the viscoelastic base the model of the interaction of a punch with a viscoelastic base loaded outside the contact region is developed.

The indentation of an axisymmetric punch into viscoelastic half-space under the action of a given force P is considered. Simultaneously, the half-space is loaded by the uniform pressure $\bar{p}$ outside the circle of a given radius A. The shape of the indenter contact surface is described by the function $f(r)$. For spherical punch under the assumption of small indentation depth, we assume $f(r)=r^2/2R$, where R is the indenter radius of contacting surface curvature. Material of the base is linearly viscoelastic. The load P applied to the indenter is constant, so $P=P_0H(t)$ ($H(t)$ is the Heaviside function), while the value of the additional pressure $\bar{p}$ is also constant and it is expressed in terms of the load applied to the indenter as $\bar{p}=P/\pi A^2$.

To solve the problem of indentation of the axisymmetric punch into the half-space in the presence of the additional nominal pressure distributed over a given area, the superposition method is used, in other words, two problems are considered. The first problem is the determination of the displacement of the half-space boundary under the action of a nominal pressure outside the circle of a given radius. The second problem is the penetration of the spherical indenter into a curved half-space boundary. The solution of this problem for the elastic half-space has been developed in [2], and has the following form

$$\frac{a^3}{\arccos\frac{a}{A}+\frac{a}{A}\sqrt{1-\left(\frac{a}{A}\right)^2}}=\frac{3}{2\pi}\left(1-\nu^2\right)R\frac{P}{E}, \qquad (1)$$

$$p(r)=\frac{P}{\pi^2}\left(\frac{3}{a^2}\left(\arccos\frac{a}{A}+\frac{a}{A}\sqrt{1-\left(\frac{a}{A}\right)^2}\right)\sqrt{1-\frac{r^2}{a^2}}+\frac{2}{A^2}\arctan\sqrt{\frac{a^2-r^2}{A^2-a^2}}\right), \qquad (2)$$

$$D(t)=\frac{a(t)^2}{R}-2\frac{\left(1-\nu^2\right)\bar{p}(t)}{E}\sqrt{A^2-a(t)^2}, \qquad (2)$$

where a is the radius of the contact region, D is the additional displacement which is a difference between the displacement of the punch tip and the boundary of the half-space loaded by the nominal pressure $\bar{p}$ inside the circle of radius A, ν and E are the Poisson ratio and the Young's modulus of the base, respectively.

The analysis of Eqs.(1)-(3) shows that the contact region is monotonically increasing if the load P does not decrease. So the Volterra method [4] can be used to solve the contact problem for viscoelastic half-space in similar formulation. Assuming that the Poisson's coefficient is constant, we replace the elastic constants in formulas (1)-(3) with the integral operator. As the result we obtain

$$\frac{a(t)^3}{\arccos\left(\frac{a(t)}{A}\right)+\frac{a(t)}{A^2}\sqrt{A^2-a(t)^2}}=\frac{3R\left(1-\nu^2\right)P_0J(t)}{2\pi}, \qquad (4)$$

*Corresponding author. E-mail: anastasiya.yakovenko@phystech.edu.

$$p(r,t)=\frac{2}{\pi(1-\nu^2)}\int_0^t E(t-\tau)\frac{d}{d\tau}\left(\frac{\sqrt{a(\tau)^2-r^2}}{R}+\frac{P_0(1-\nu^2)}{\pi A^2}J(\tau)\arctan\left(\frac{\sqrt{a(\tau)^2-r^2}}{\sqrt{A^2-a(\tau)^2}}\right)\right)d\tau,\quad r\le a(t),\qquad(5)$$

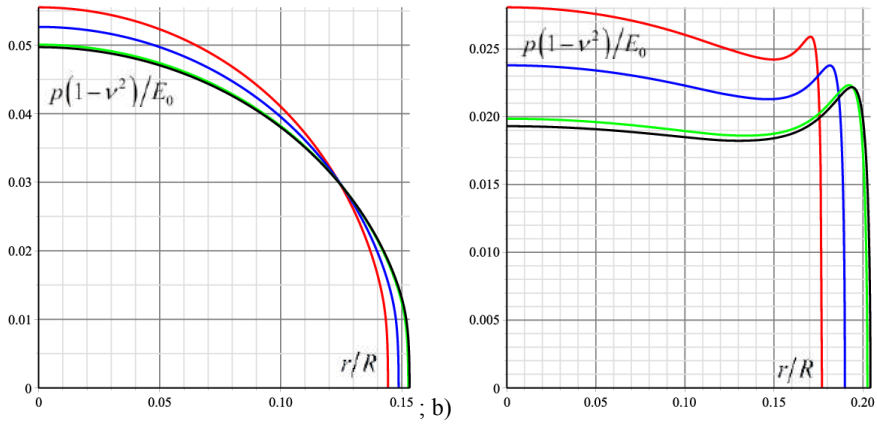
$$d(t)=\frac{a(t)^2}{R}-\frac{2(1-\nu^2)P_0J(t)}{\pi A^2}\sqrt{A^2-a(t)^2},\qquad(6)$$

where $E(t)$ and $J(t)$ are the relaxation and creep functions, which describe the mechanical properties of the viscoelastic material. Here we consider the model of the standard viscoelastic body. The relaxation and creep functions of this model have the form [5]

$$E(t)=E_0\left(\frac{\beta-\alpha}{\beta}+\frac{\alpha}{\beta}e^{-\beta t}\right)\quad\text{and}\quad J(t)=\frac{1}{E_0(\beta-\alpha)}\left(\beta-\alpha e^{-(\beta-\alpha)t}\right),\qquad(7)$$

where $\alpha=1/T_\sigma-1/T_\varepsilon$, $\beta=1/T_\varepsilon$, T_σ and T_ε are the relaxation and creep times of the half-space. E_0 is the instantaneous modulus of elasticity, and $E_\infty=E_0(\beta-\alpha)/\beta$ corresponds to the long-term modulus of elasticity.

The expressions (4) and (7) allows us to calculate the value of the radius of the contact area in the indentation process. Then the contact pressure and the additional displacement are calculated from (5) and (6).



a) ; b)

Fig.1 Contact pressure distribution at $A=0.2$ (red line), $A=0.3$ (blue line), $A=0.5$ (green line), $A\to\infty$ (black line); $T=2$ (a) and $T=10$ (b)

The following dimensionless parameters are introduced: $r=r/R$, $t=\beta t$, $p=p(1-\nu^2)/E_0$, $A=A/R$, $P=P(1-\nu^2)/R^2E_0$, and $T=T_\varepsilon/T_\sigma=\beta/(\beta-\alpha)$. The results show that the contact characteristics are affected by three dimensionless parameters: the value of load P_0, the radius of the circle A outside of which the additional nominal pressure acts, and the viscoelastic coefficient T. Fig.1 presents graphs of the dimensionless contact pressure distribution for three values of the radius A and two values of the coefficient T at given instant of time ($t=5$) for the fixed value of the load $P_0=0.0025$. It follows from the results that the additional loading effect is more significant for materials with a higher coefficient T ($T=1$ corresponds to the elastic case). It is established for fixed time of loading that the larger is the coefficient T, the greater is the radius of the contact area and the less is the maximum contact pressure. It also follows from the results that if the additional pressure radius A decreases, the maximum contact pressure increases and the contact radius decreases. If $A\to\infty$, the pressure tends to the case of the indentation neglecting additional loading (black line).

Thus, based on the obtained solution of the problem of indentation of an axisymmetric indenter into a viscoelastic half-space in the presence of an additional load the influence of the loading parameters on the contact characteristics in indentation were studied. The results can be used to analyse the stress state of polymer materials under loading by rigid body with surface irregularities and to analyse the limits of applicability of simplified models, which do not take into account the mutual influence of microcontacts.

EFFECT OF THE CONTOUR CONTACT AREA VARIATIONS ON THE TEMPERATURE DURING BRAKING

Aleksander Yevtushenko, Michal Kuciej and Katarzyna Topczewska*
Department of Mechanics and Computer Science, Faculty of Mechanical Engineering, Bialystok University of Technology, Bialystok, Poland

Summary In this study a new analytical model was proposed to determine temperature during single braking with exponential growth of contact pressure with account of time-dependent contour surface of friction. For this purpose, an initial problem of motion and a boundary-value problem of heat conduction were formulated and solved. Results obtained based on performed analysis were compared with corresponding data found without account of contour surface variations during process. This allowed to determine the effect of time-dependent contour contact area of the friction pair elements on the attained temperature distribution.

INTRODUCTION

Friction process in the braking systems takes place on the real disk–pad contact area. At the micro level, friction surfaces of the disc and pads are not perfectly flat and mutually matched. In fact, the real contact area is only a small part of the nominal surface of contact determined by the geometrical dimensions of frictional elements. Surface waviness causes the limitation of contact spots occurrence area by the so–called contact plateaus [1] that are located on the nominal friction surface. These plateaus form surface contours that determine the boundaries of the contact zone. The real contact area is composed of tiny contact spots between surface peaks and asperities within the friction contour surface [2]. Wear and deformations of surface asperities associated to the friction process, result in irregular fluctuations of the size and location of the contact points. Thus, the contact area of friction changes the space-time distribution, as well as the properties during braking [3]. This has a significant impact on the distribution of generated frictional heat and the tribological characteristics of the brake system.

DEVELOPMENT OF THE CALCULATION MODEL

The increase of contact pressure during braking causes more plateaus to be incorporated into the contour friction surface over time. In addition, it results in the growth of load on previously engaged plateaus and this leads to an increase of their contribution within the nominal friction surface. Therefore the actual contact area, as wells as the contour area increase during braking. Known from the literature review [4] analytical solutions to thermal friction problems, for determining the temperature and thermal stresses distributions, have been developed with the assumption that the contact area is constant during braking and equal to the nominal friction surface. In this study, a new analytical model was developed to predict the temperature achieved during braking on the friction surface, which area increases during the process. In order to determine the sliding velocity and friction power, the initial problem of motion was considered for the process of single braking with an exponential growth of pressure on the contour contact surface, which increases linearly over time. Such a function of changing the contour surface was proposed in the article [5] for a disc brake system with friction elements made of carbon composite. The obtained results allowed for the formulation of an appropriate one–dimensional, boundary–value problem of heat conduction for a system consists of two semi–spaces under the conditions of perfect thermal contact of friction. The solution to this problem was found analytically using the Duhamel's theorem. Based on achieved formula, the analysis was performed to investigate the effect of the contact area variations on the main tribological characteristics during braking, such as friction power and temperature distributions.

EXPERIMENTAL AND NUMERICAL INVESTIGATION OF FRETTING FATIGUE FAILURE IN LUG-BUSH JOINTS

Emine Burcin Ozen[1], Demirkan Coker*[1,2], and Yezdan Medet Korkmaz [1,3]
[1]Department of Aerospace Engineering, Middle East Technical University, Ankara, Turkey
[2]METU Center for Wind Energy, Middle East Technical University, Ankara, Turkey
[3]Turkish Aerospace Industries, Ankara, Turkey

Summary In aerospace industry, load transfer between two parts can be provided by several components. One example to these components is lug joints with interference-fitted bushes. This type of components fails due to fretting fatigue under small amplitude cyclic loadings due to relative motion at the contact surfaces of the lug and the bush. In this study, failure mechanism of lug-bush joints is investigated by macroscopic and microscopic evaluations and compared with the FEA results. Four different lug-bush joints are tested under high cycle tensile fatigue loading until failure. Investigation of the contact surfaces of lugs and bushes under SEM and conducting EDS analysis showed that tribolayers are formed at distinct regions of the contact surfaces. Fracture of the lug occurred at the vicinity of these tribolayer patches. FEA results showed good agreement with the experimental evidence.

INTRODUCTION

Fretting fatigue occurs between two contacting bodies under constant normal load and cyclic tangential load. For fretting to occur, the applied tangential load should not overcome the force required to create a bulk motion. However, at some regions of the contact surface the applied tangential load is at least equal or greater than the required force to create a bulk motion. Therefore, regional stick and slip zones form at the contact surface. For example, in the case of a spherical body and a flat surface contact, a central stick region and a slip annulus occur at the contact surface under constant normal load and cyclic tangential load according to the Hertz and Mindlin analytical solutions [1]. Periodical changes in the slip amplitude at these slip zones due to applied cyclic loads cause fretting fatigue [2].

Fretting fatigue failure is observed in lug joints with interference-fitted bushes which are used widely in aerospace industry, for example, at the rotor to body connections of the helicopters.

The objective of this study is to investigate the failure mechanism of different lug-bush joints. Investigated lug-bush joints are made of Ti and Al lugs with Al and steel bushes, as shown in Figure 1, and subjected to high-cycle tensile fatigue loading. Figure 1 also shows crack locations of the lugs.

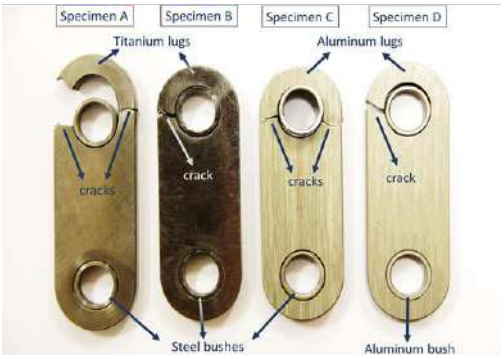

Figure 1. Investigated lug-bush joints consisting Ti and Al lugs combined with Al and steel bushes.

METHODOLOGY

Photographs of the failed lug-bush joints are taken using a camera with macro lenses. Black residues lying discontinuously in the direction of the cyclic loading are observed at the contacting surfaces of both lugs and bushes. Matching surfaces of the lugs and bushes are detected with the help of these pictures and residues. Using the matching residues on the lug and bush surfaces, the corresponding location of the cracks of lugs are identified on bush surfaces.

A digital microscope, Huvitz HDS 5800, is used to investigate the surfaces at high magnifications. In addition, scanning electron microscope (SEM) is used for further observations of the surface as well as the determination of the elemental composition, using energy dispersive spectroscopy (EDS) analysis.

RESULTS AND DISCUSSION

Experimental Results

Observations of the lug and bush mating surfaces using both camera and digital microscope revealed that the fracture of all lugs occurred near the boundary of an intense residue and a clean surface, as shown in Figure 2 for specimen A.

*Corresponding author. E-mail: coker@metu.edu.tr

The two distinct regions of black residues and clean parts raised the question of whether the residues are product of relative motion and the clean parts are product of sticking of the contacting surfaces.

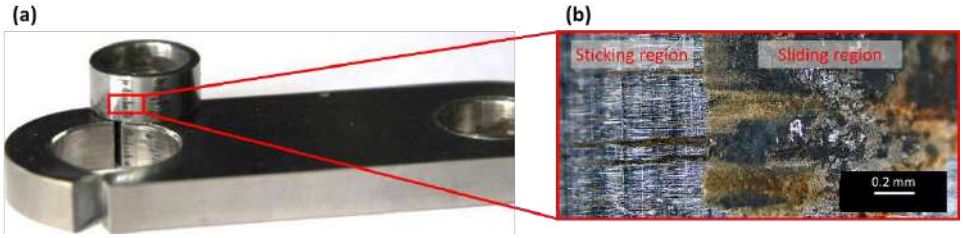

Figure 2. (a) Photograph of the matching lug-bush contacting surfaces and (b) boundary of the sticking and sliding regions on the steel bush surface of specimen A under digital microscope at 200x magnification.

In order to determine the differences between sticking and sliding regions in terms of elemental composition, EDS analysis is conducted under SEM. According to the results of the EDS analysis, sliding regions contain 20% of oxygen whereas the sticking regions do not have any oxygen content. These results indicate that at the sliding region, oxidation of wear debris occurred due to relative motion of the contacting bodies. The final product is called tribolayer which contains fine metallic particles from the two contacting surfaces and oxides [3].

Locations of fracture and sticking-sliding regions of these four members made of Ti and Al lugs with Al and steel bushes are mapped, as shown in Figure 3. The red lines in the maps represent the sliding regions where tribolayer is observed on the contacting lug and bush surfaces. Remaining surfaces were free from any residues and are represented with blue, indicating the sticking surfaces. All specimens are fractured at the vicinity of the boundary of sticking and sliding regions.

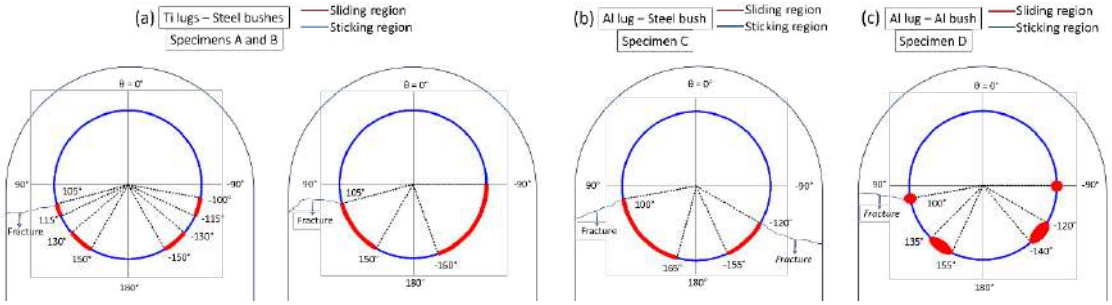

Figure 3. Locations of sticking and sliding regions of tested specimens.

Finite Element Analysis Results

3-D finite element model of statically loaded lug-bush assembly is generated using ABAQUS/Standard. Half of the lug and bush are modelled separately using their original dimensions, where the outer bush diameter is greater than the inner lug diameter. Both parts are discretized with 8-noded 3-D linear solid elements (C3D8 from ABAQUS library). In the analysis, the interface of the bush into the lug hole is defined prior to the application of a cosine pressure distribution to the bush. Master-slave algorithm is defined between the inner surface of the lug hole and the outer surface of the bush with a coefficient of friction of 1. The magnitudes of the maximum pressure and friction coefficient are defined by trial and error in order to differentiate the sticking and sliding regions clearly.

Relative slip amount between the lug and bush surfaces under the applied static loading is plotted around the bush. Slip amplitude reaches a peak value around ±115° for Ti lug and steel bush combination.

CONCLUSIONS

High cycle tensile fatigue loading of the lug-bush joints creates partial stick and slip zones at the contacting surface. In sliding regions, relative motion between contacting lug and bush surfaces create wear debris and oxidation of this debris leads to tribolayer formation. In the sticking regions, the surface remains clean due to lack of relative motion between contacting lug and bush surfaces. Fracture of all lugs occurred in the vicinity of these sticking and sliding region boundaries, approximately 100°. FEA results estimate the sticking and sliding region locations consistently with the experimental results. Peak locations of the slip amplitudes at the contact surfaces are included in the sliding regions of the tested specimens.

ON THE STATISTICAL CHARACTERIZATION OF PLAIN GRINDING SURFACES

Xuan-Ming Liang[1], Wei-Ke Yuan [1], Yue Ding [1], and Gang-Feng Wang [*1]
[1]Department of Engineering Mechanics, SVL, Xi'an Jiaotong University, Xi'an, China

Summary In tribology, it is of importance to properly characterize the topography of rough surfaces. In this work, the three-dimensional topographies of plain grinding surfaces are measured through a white light interferometer, and their geometrical statistical features are analyzed. It is noticed that only when the total measured area is larger than a threshold value, is the statistical characterization reasonable and stable. For various plain grinding surfaces, the height of asperity-summit obeys a Gaussian distribution, and the equivalent curvature radius follows a modified *F*-distribution. These statistical characteristics are helpful to analyze the contact and friction behaviors of rough surfaces.

INTRODUCTION

Surface topography has a significant influence on the mechanical and physical performances of contacting bodies, such as friction, wear, lubrication, sealing, electricity transfer, heat transfer, etc. However, precisely characterizing the topography of rough surfaces is still a challenging task on account of the geometric complexity and randomness. There are several different theoretical models available for this issue and these can be grouped into two main categories: multi-asperity models and fractal models [1]. In addition to the theoretical models mainly based on assumptions and conjectures, experimental researches [2] on the accurate description of rough surfaces have also been conducted. Usually a two-dimensional profile is measured to extract the geometrical features of isotropic surfaces, in this study, the 3D topographies were measured to characterize anisotropic surfaces.

TECHNIQUES

Surface specimens were prepared by applying standard plain grinding processing on the 45 quality carbon structural steel (C45E4, ISO 683-18-1996). Six specimens with increasing roughness were produced, and their size is 20 mm × 8 mm. In this work, the 3D surface topography was recorded by using a white light interferometer (NanoMap-1000WLI, AEP) with a 50× interference objective lens. It should be pointed out that the scanned region in each operation is much smaller than the specimen size. To ensure the statistical and random nature, a randomized algorithm was utilized to choose multiple positions for scanning.

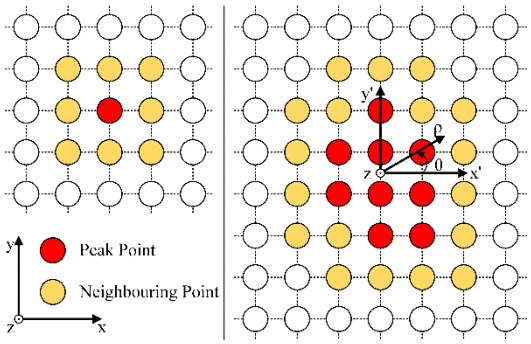

Figure 1. Identification of the asperity summits on 3D surfaces: left for 9-point rectangular asperity summit [2], right for an irregular asperity summit.

According to our scanning result, the peak of one asperity may consist of several points instead of one single point as shown in Fig. 1. For a summit with only one highest point, the 9-point rectangular approach [2] was widely used to calculate its curvature. However, for asperity-summits with a cluster of peak points, the 9-point rectangular approach is no longer applicable. Herein, we developed a new criterion using an elliptic paraboloid to approximate each asperity-summit and in the meantime calculate its height and principal curvature.

RESULTS

Before summarizing the statistic information of rough surface, a necessary preparation is conducted to check how large a scanned area is required. It is found that the specimen with higher surface roughness requires a larger area to achieve a stable surface statistic. Fig. 2a displays the distribution of summit height h. It is found that, for six specimens with different roughness, h follows a Gaussian distribution. In addition, it is found that most ratios of the principal curvature k_1/k_2 are smaller than 10. For an asperity-summit like this, it is appropriate using $R_g = (k_1k_2)^{-1}$ to account for the

*Corresponding author. E-mail: wanggf@mail.xjtu.edu.cn.

asperity radii [3]. The normalized equivalent radius R_g/p follows an F-distribution with degrees of freedom being (8.0, 2.2) as shown in Fig. 2b. The fitting parameters for six specimens are given in Table 1.

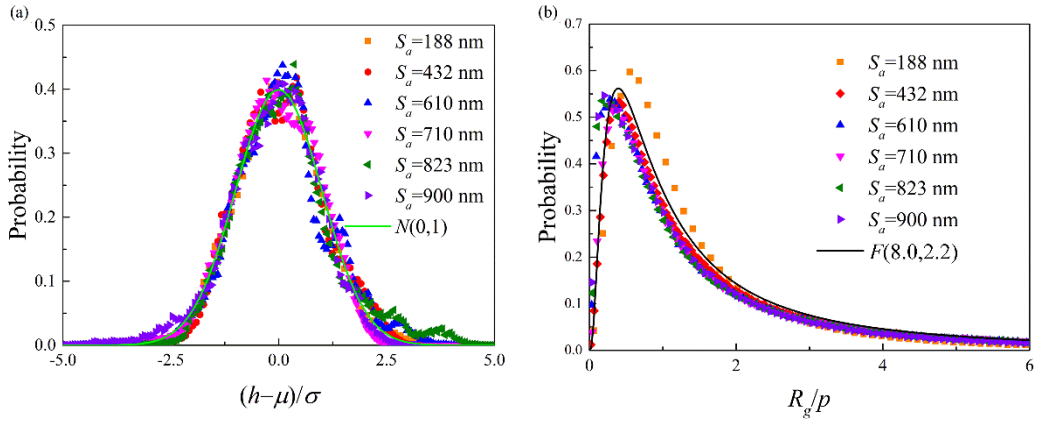

Figure 2. Probability density distribution of (a) normalized summit height $(h-\mu)/\sigma$, (b) normalized equivalent radius R_g/p.

Table 1. Fitting parameters of the probability density distributions of h and R_g (nm)

S_a	188	432	610	720	823	900
σ	227	542	727	921	937	1065
μ	72	37	75	187	-10	285
p	1632	4663	3204	2801	2871	2472

The joint probability density distribution of h and R_g, denoted as $p(h, R_g)$, can be obtained either numerically or by simply multiplying these two distribution function, $f(h)$ and $g(R_g)$. The distributions $f(h)\times g(R_g)$ and $p(h, R_g)$ of the specimen with S_a = 188 nm are shown in Fig. 3. For all these specimens measured, $f(h)\times g(R_g)$ shows little distinction from $p(h, R_g)$. This leads to the conclusion that $p(h, R_g) \approx f(h)\times g(R_g)$.

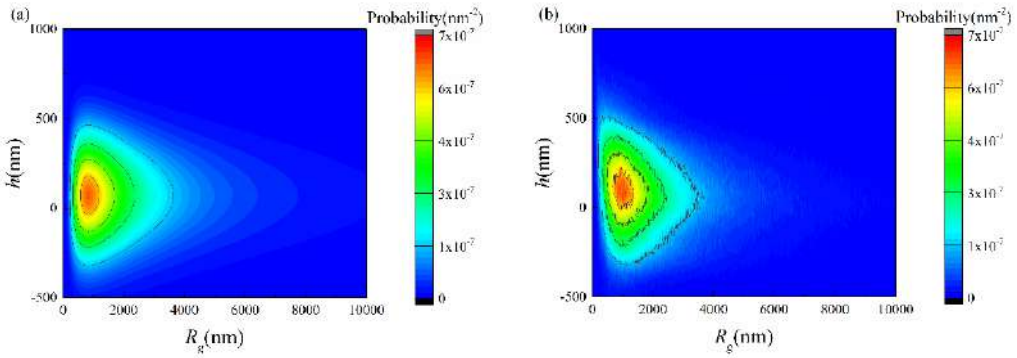

Figure 3. The joint probability density distribution of h and R_g (a) $f(h)\times g(R_g)$, (b) $p(h, R_g)$.

CONCLUSIONS

The three-dimensional topographies of plain grinding surfaces are characterized by combing the experimental measurement with statistical analyses. The results suggest that the statistical characterization of rough surfaces should be conducted on a sufficiently large sampling area. With a new asperity identification criterion employed, it is found that the height of asperity-summit follows a Gaussian distribution, while the equivalent radius of asperity-summit follows a modified F-distribution. Moreover, we demonstrate the height and equivalent radius of asperity-summit are nearly independent, and the joint probability density function is derived directly. These findings can be utilized for developing simplified contact models of anisotropic rough surfaces and provide a new perspective for the characterization of rough surfaces.

STUDY ON THE EFFECT OF TEMPERATURE ON THE FRICTIONAL CHARACTERISTICS OF RAILWAY DISC BRAKE PADS

Aleksander Yevtushenko[1], Michał Kuciej[*1], and Piotr Wasilewski[2]
[1]Faculty of Mechanical Engineering, Bialystok University of Technology (BUT), Białystok, Poland
[2]Research and Development Department, Frimatrail Frenoplast S.A., Majdan, Poland

Summary Characterisation of the temperature-dependent properties of the friction elements is crucial in the design of braking systems. In this study three types of railway disc brake pads were designed, manufactured and tested on a full-scale dynamometer. Two materials contained copper fibre in different concentration, third was a non-metallic material. Drag brake appllication was performed to determine how the coefficient of friction changes with the increase in temperature. It is concluded that copper fibre has beneficial effect on the frictional properties of railway disc brake pads by improving high-temperature stability of the friction coefficient.

INTRODUCTION

As operating speed of contemporary passenger rolling stock increases, braking systems are exposed to higher thermal loads. When kinetic energy is converted into heat during braking, it is dissipated to the elements of the friction pair leading to increase in their temperature, which has in turn influence on the coefficient of friction [1]. Characterisation of the temperature-dependent coefficient of friction is useful in FE-based calculations of temperature fields in brakes or clutches [2, 3].

The purpose of this study was to investigate the effect of temperature on the coefficient of friction of railway disc brake pads manufactured from three types of organic composite material.

EXPERIMENTAL

Formulations and prototypes

Three friction mixtures denoted Material A, Material B and Material C were manufactured for the purpose of the study. The mixtures were produced by adding certain amount of copper fibre and calcite to 70 kg of the premix (Table 1). The premix contained two binders, namely rubber and phenolic resin, mineral fibre to provide mechanical strength, graphite and antimony trisulfide (Sb_2S_3) as friction modifiers, calcite and curing agents. The formulations were designed to establish equal volume of the added fillers (total volume of added calcite and copper fibre, considering their specific density).

The prototypes were moulded from friction mixtures (Material A, B and C as described in Table 1) to a standard UIC200 shape designed for railway disc brake pads [4]. The parts were processed through thermal treatment to cure the thermosetting phenolic resin. The final stage of the manufacturing process was grinding of the brake pads to 35 mm thickness.

Table 1: Modification of the basic formulation.

Friction mixture	Filler	Specific density, kg/m^3	Amount added, kg
Material A	Calcite	2800	10.8
Material B	Copper fibre	8900	17.1
	Calcite	2800	5.4
Material C	Copper fibre	8900	34.2

Test conditions

Frictional characteristics of the prototype disc brake pads were determined in the course of the test performed on a full-scale dynamometer at Instytut Kolejnictwa (the Railway Institute) in Warsaw, Poland. Cast iron brake disc of 640 mm nominal outer diameter was the counterface element. A complete set of brake pads for testing consisted of two "right-hand" and two "left-hand" items. The test discussed in this study concerned a single drag brake application. To investigate solely the effect of temperature on the coefficient of friction, velocity and force exerted on the brake pads were maintained constant at 80 km/h and 10 kN respectively. The total time of brake application was 1200 s. Ventilation and cooling condtions of the friction pair were in compliance with the requirements presented in the railway standard [4]. In the course of the test instantaneous coefficient of friction was determined by measuring the braking torque related to the contact force. Temperature was measured by six K-type thermocouples embedded in the brake disc 1 mm below the contact surface, three per friction ring. Two of the thermocouples were installed at the equivalent braking radius (r_{eq}), two were positioned 40 mm outside r_{eq} and the remianing two 40 mm inside r_{eq}. The thermocouples were displaced 120° along the circumference.

*Corresponding author. E-mail: m.kuciej@pb.edu.pl.

DISCUSSION OF RESULTS

Change in the value of the friction coefficient with the increase in average temperature of the brake disc up to 300°C is presented on Fig. 1. Average brake disc temperature was calculated as the mean value from measurements by 6 thermocouples.

In general Material C is characterised by the highest coefficient of friction and the lowest value was exhibited by Material A. Final average brake disc temperature during the test of Material A (at t=1200 s) was below 300°C. It is explained by lower coefficient of friction of Material A – hence lower heat flux – but also due to the slower increase in temperature of the brake disc as compared to the other two tested materials.

Increase in the coefficient of friction up to approx. 150°C can be observed for each of the tested materials. After exceeding this temperature level, each of the materials exhibits slightly different characteristics: friction coefficient of Material A sharply drops, it steadily increases for Material B and it is quite stable for Material C up to approx. 280°C when it starts to decline.

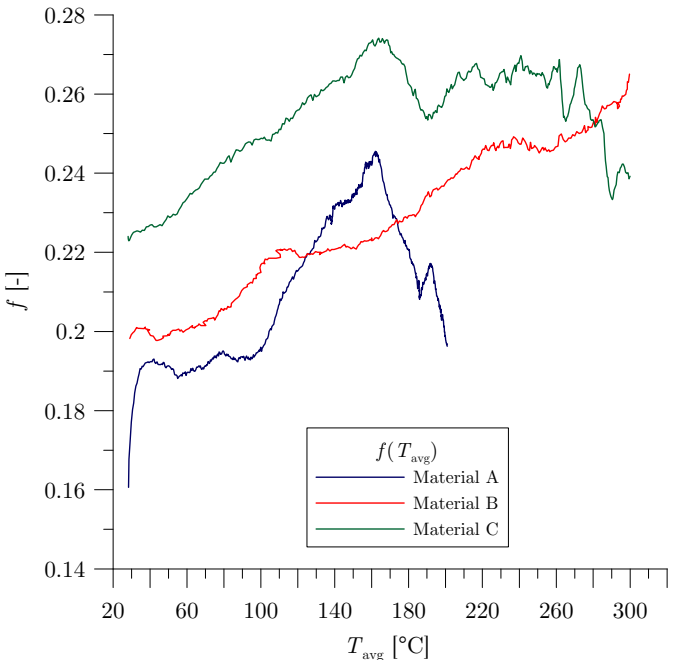

Figure 1: Temperature-dependence of the coefficient of friction.

CONCLUSIONS

Three friction material formulations were tested on a full-scale railway dynamometer to investigate effect of temperature on the coefficient of friction. It can be concluded that apart from enhancing high-temperature stability of the friction coefficient, introducing of the copper fibre to the formulation leads also to increase in its value. Further study will be focused on thermophysical properties of the materials discussed in this paper.

A NOVEL ROTATING BLADE-CASING RUBBING MODEL CONSIDERING ABRADABLE SEAL COATINGS

Yanhong Kang[123], Shuqian Cao *[123]
[1]Department of Mechanics, Tianjin University, Tianjin 300354, China
[2]Tianjin Key Laboratory of Nonlinear Dynamics and Control, Tianjin 300354, China
[3]National Demonstration Center for Experimental Mechanics Education, Tianjin University, Tianjin 300354, China

Summary Aiming at rubbing fault between the rotating blade and casing with abradable seal coatings, a new nonlinear rubbing model is established. In this paper, the blade is assumed to be a cantilever beam with an equal section under centrifugal load, the bending deformation of the blades, the elastic deformation of the casing, and the effects of abradable coatings are considered. Then, the influence of system parameters such as Young's modulus of the coating and the stiffness of the casing on the rubbing force model is analyzed. Finally, by comparing with the existing blade-casing rubbing model and experiment, the accuracy of the model is verified.

INTRODUCTION

To improve the efficiency of aero-engines, the clearance between the rotating blade and casing is designed to be smaller and smaller, resulting in an increased probability of rubbing fault. It is of great significance for the structural design of blades and the diagnosis of rub impact fault to establish a reasonable model of blade-casing rubbing model and predict the vibration response of the system under typical working conditions. For the rigid casing without coatings, Padovan [1] assumed that the blade was a cantilever beam and derived a rubbing model of normal contact force and blade deformation. Jiang [2] based on the model of Padovan and considered the centrifugal stiffness effect of the blade, a modified normal rubbing force model was obtained. Ma [3] considered the flexibility of the casing and the blade, and used the equivalent stiffness of the casing to describe the contact force between the casing and the blade, and proposed a new blade-casing rubbing model. Li [4] considered the rotating effect of the blade, and used a flexible ring with spring support to simulate the casing, and derived a new rubbing force model between the rotating blade and the flexible casing. However, as an important functional material, the abradable seal coatings often participate in aero-engine rubbing fault. When a rubbing fault occurs, the blade first contacts with the coating, and the impact of the coating on the rubbing mechanism and system vibration characteristics cannot be ignored. In this paper, the geometry of rotating blades is considered, and the blade-casing rubbing model with abradable coatings is established.

BLADE-CASING RUBBING MODEL CONSIDERING ABRADABLE COATINGS

The contact diagram of the blade-coated casing is shown in Fig. 1. Assuming that the blade is a cantilever beam of equal section. The blade is subjected to centrifugal force, normal contact force, and friction force. Taking the root of the blade as the coordinate origin and analyzing the moment balance of the beam at any cross-section, the radial displacement of the blade due to the bending of the blade is obtained. Based on the elastic compatibility conditions, considering the elastic deformation of the blade and the casing and the impact of the abradable coating, the expression of the rubbing force model is:

$$F_{\mathrm{n}}=\frac{5\Gamma L(\alpha\frac{\delta}{L}+3\frac{\Gamma}{K})-\sqrt{5}L\Gamma\sqrt{\frac{15\Gamma}{K}(\frac{3\Gamma}{K}-2\alpha\frac{\delta}{L})+12\frac{\delta}{L}\mu^2\cos^2\beta}}{-2\mu^2\cos^2\beta+10\alpha\frac{\Gamma}{K}+\frac{5}{6}\alpha^2\frac{\delta}{L}} \tag{1}$$

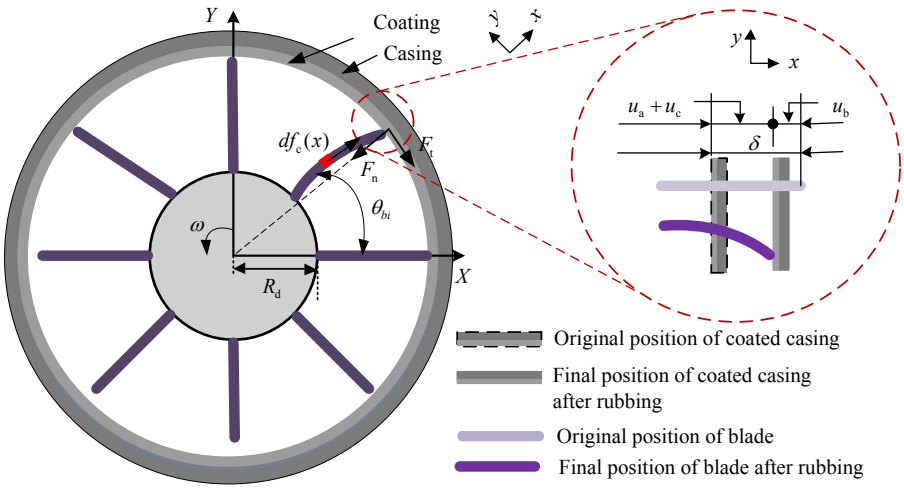

Fig 1. The contact diagram of the blade-coated casing

*Corresponding author. E-mail: sqcao@tju.edu.cn

Among them, $\alpha = \frac{L+3R_{\mathrm{d}}}{R_{\mathrm{d}}+L}$, $\Gamma = \frac{EI}{L^3} + \frac{1}{6}\rho A\omega^2(R_d + \frac{1}{4}L)$. Where ρ, ω, A, R_d, L are blade density, working speed, blade cross-sectional area, disk radius respectively and length of blade; K is the equivalent stiffness of the coated casing; u_b, u_c, u_a are bending deformation of the blades, the elastic deformation of the casing, and the deformation of abradable coatings.

VALIDATION OF THE MODEL

Under the condition of rotating speed $\omega = 2000\mathrm{r/min}$, the rubbing force model in this paper is compared with the existing rubbing model (see Fig.2 and Fig.3) [5]. It can be seen that the model without considering coating in this paper has the same overall change trend, the rubbing force of considering coating is lower than that without considering the influence of coating. Therefore, choosing an appropriate coating is of great significance to reduce the rubbing impact and protect the blade. Besides, the model is verified by the experimental bench in Fig.4.

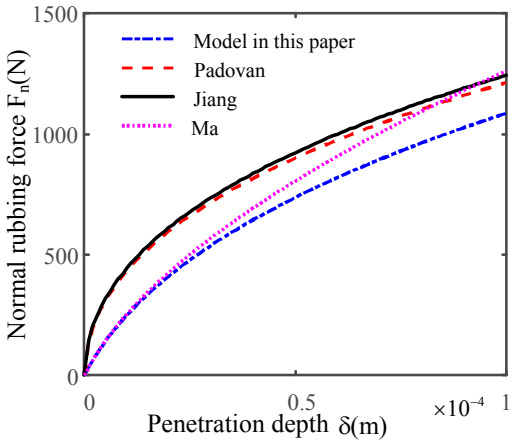

Figure 2. Comparison of rubbing model without coating

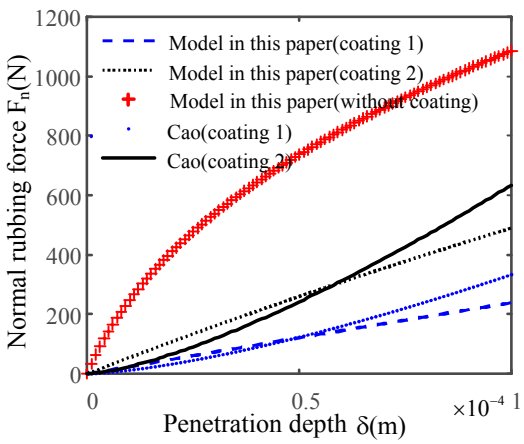

Figure 3. Comparison of rubbing model with coating

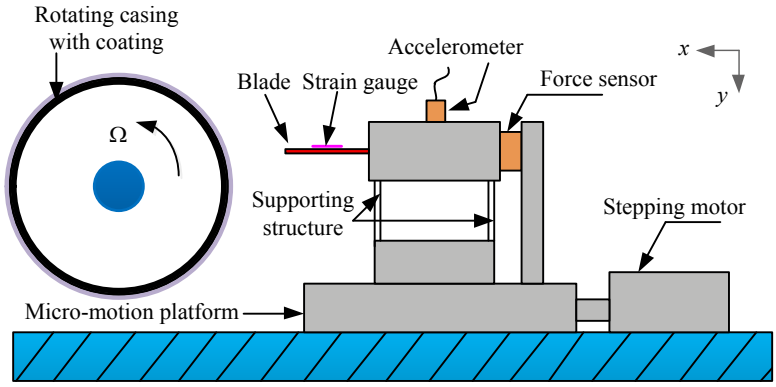

Figure 4. Schematic diagram of the test rig

CONCLUSIONS

The blade-casing rubbing model established in this paper can comprehensively consider the contact deformation of the coated casing and the blade geometry. By comparing with the existing blade-casing rubbing model and experiment, the accuracy of the model is verified.

Summary In this paper, numerical model of railway vehicle disc brake was proposed. The objective was to analyse the effect of metallic fibres in the brake pads material on temperature of the brake. The studies were carried for five different brake lining materials. The calculated temperature fields of the brake components were verified by temperature changes measured at specified points in the disc using the thermocouples on a full-scale dynamometer test rig. During the experimental studies the braking torque, velocity of the vehicle, clamping force acting on the brake pads, instantaneous friction coefficient, simulated mass per one brake disc and velocity of the airflow through the friction pair were recorded and selected parameters were incorporated in the computational model.

INTRODUCTION

Properties of brake pads and disc materials have an effect on the separation of heat and thermal state of the friction elements in sliding contact. Therefore when developing new materials it is essential to determine their properties and identify their influence on the friction characteristics of the brake. In this work, a computational model of railway vehicle disc brake was proposed to simulate changes in transient temperature fields of the disc and brake linings. The purpose of temperature calculations was to estimate the effect of material properties on the basis of five different formulations of the organic composite linings on the friction characteristics of the brake [1, 2].

EXPERIMENTAL STUDY

The brake pads used for experimental tests were manufactured from friction mixtures by moulding to comply with standard UIC200 shape of railway brake pads [3, 4]. Moulded parts underwent thermal treatment to ensure curing of the thermosetting phenolic resin. The basic formulation contained rubber, phenol-formaldehyde resin, vulcanizers and curing agents, mineral fibres, graphite, antimony sulphide and calcite.

To study the effect of the steel and copper fibres on the properties of the brake pad material, five mixtures denoted Recipe 1, Recipe 2, Recipe 3, Recipe 4 and Recipe 5, were manufactured by adding specified amount of filler to 70 kg of the basic formulation. The amounts of filler added were defined to ensure that their volume remains equal. In order to establish a reference case, non-metallic material (Recipe 1) was manufactured, where additional amount of calcite instead of metallic fibres was included. The dependence of the thermophysical properties of the developed materials (thermal diffusivity, thermal conductivity, specific heat capacity) on temperature were determined experimentally in the range between 25°C and 250°C (Fig. 2).

Parameters set in the test program were: mass of rail vehicle per brake disc (braking to stop); total pressure exerted on the brake pads; braking torque, braking speed and braking time per friction pair; diameter of the rail vehicle wheel; medium friction radius; braking start speed; average temperature of the friction surfaces of the brake disc at the beginning of braking; velocity of air ventilating friction pair; number of brakes; etc.

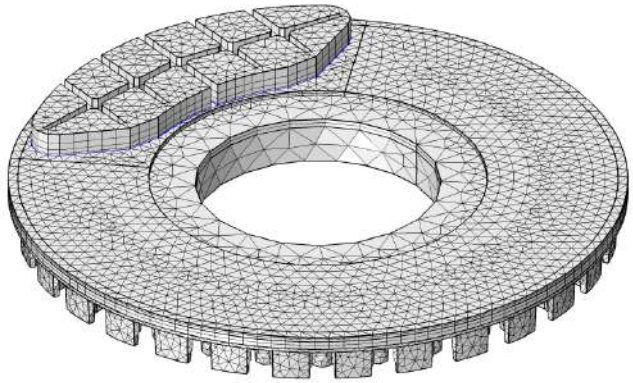

Figure 1. Finite element mesh of the analysed railway disc brake.

*Corresponding author. E-mail: p.grzes@pb.edu.pl.

During the tests the following parameters were recorded: the beginning of braking; the moment of reaching 95% of the nominal total brake lining pressure; angular and rotational speed of the wheel; vehicle linear speed for a given wheel diameter; braking distance; braking time; brake cylinder pressure; total clamping force; simulated mass per brake disc; temperatures at six points of the friction surfaces of the disc and their instantaneous average value; instantaneous friction coefficient; velocity of air ventilating friction pair; etc.

The measurements of brake disc temperature were carried out at the Rolling Stock Testing Laboratory of Railway Institute at the test bench for rail vehicle brake friction pairs (for testing disc and tread brake friction pairs) up to a maximum speed of 420 km/h. The UIC homologated BSI 640/350x110 brake disc was used for the tests. The subject of the research were 5 sets of organic brake linings by Frimatrail, in "UIC200" shape (4 pieces per set): Recipe 1, Recipe 2, Recipe 3, Recipe 4 and Recipe 5.

FINITE ELEMENT ANALYSIS

The numerical calculations of the spatial temperature fields of the railway disc brake were carried out in COMSOL Multiphysics® using the *Heat Transfer in Solids* and *Mathematics* modules [5]. Three conditions of friction contact were assumed: 1) perfect friction contact of brake components assuming that the temperature of points in contact is equal and the sum of heat fluxes directed to the linings and disc is equal to the friction power density; 2) contact taking into account thermal resistance; 3) the issue of separate heating of the disc and lining with the introduction of the heat flux distribution coefficient [6]. Out of the contact surface, convection according Newton's law of cooling was applied. In order to simulate sliding motion of the components of the brake it was assumed that the pads are stationary and the contact surface of the disc deforms according to its rotating motion (*Deformed Geometry* module) [2, 5]. The obtained temperature evolutions from the specific points of the region of the disc were compared with the temperature measured during the full-scale dynamometer tests.

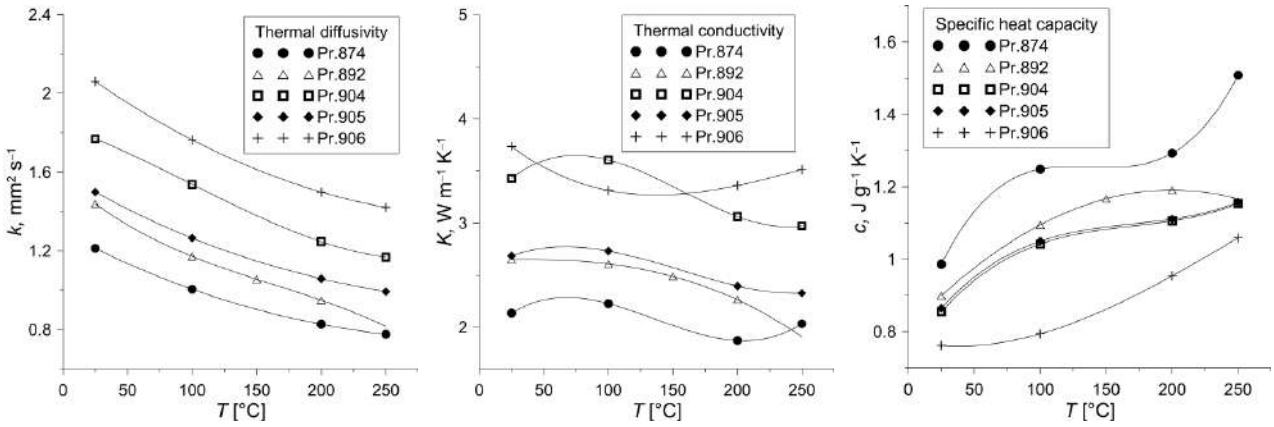

Figure 2. Experimental dependencies of thermal diffusivity, specific heat capacity and thermal conductivity on temperature of the five mixtures for pads materials approximated by third order polynomial function.

CONCLUSIONS

The calculations of changes in brake disc temperature using 3D finite element model of the brake and the corresponding values of temperature measured in six points of the disc region revealed good agreement. This allows to state that the proposed model can be used to determine thermal state of the railway disc brake when developing new linings materials.

SOFT LUBRICATION IN PRESENCE OF VISCOELASTIC BODIES

Carmine Putignano[1] and Giuseppe Carbone [1]
[1]Department of Mechanics, Mathematics and Management, Polytechnic University of Bari, Italy.

Summary Soft materials often exhibit a viscoelastic time dependent behaviour, which determines dramatic deviations in comparison with classic elastic solutions. Specifically, in this work, we focus on what occurs when two viscoelastic bodies are in lubricated contacts: a new viscoelasto-hydrodynamic is defined. Numerical simulations, carried out by means of a coupled boundary element-finite difference approach, are corroborated by experimental outcomes.

Assessing the main peculiarities of lubrication between soft viscoelastic solids is a crucial issue that has only recently raised the attention of the lubrication science community. Indeed, in the last decades, massive research efforts have been dedicated to understand the role of non-Newtonian lubricants, but very little has been done to determine what occurs when the lubricated solids are not linearly elastic, and are instead characterized by a different rheology.
In this work, as shown in Figure 1, an innovative numerical methodology is presented to analyze the lubrication regimes between linear viscoelastic layers. In detail, an explicit finite difference scheme is coupled to a Boundary Element solver: this enables the study of the viscoelastic lubrication without any limitation in terms of material properties, geometry and viscosity. The results and, specifically, the film thickness, the contact pressure and, ultimately, the friction force show marked differences in comparison with classic lubrication theory. All this is validated by means of experiments specifically developed to deal with soft matter. In particular, to measure the film thickness, an innovative technique based on interferometry for soft solids [1] has been employed.

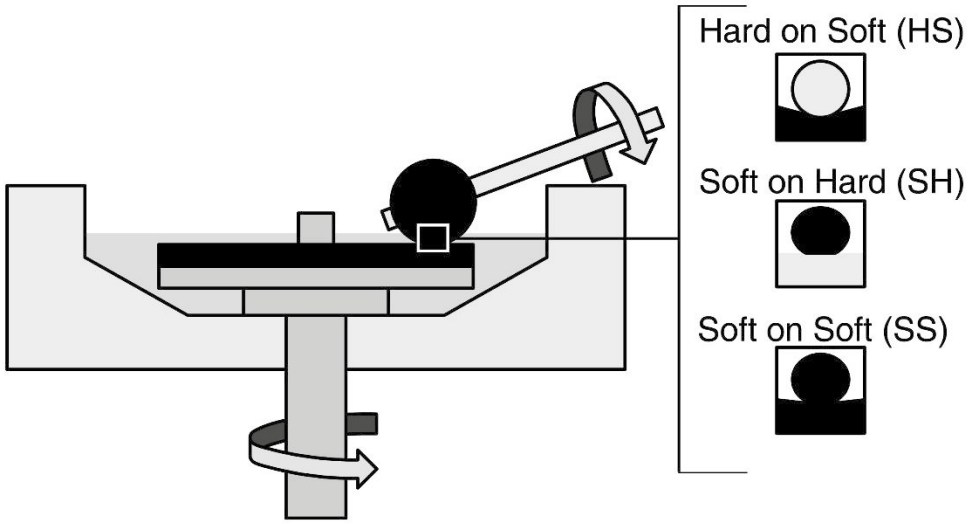

Figura 1: Schematic of a typical tribo-system involving soft materials. Three different configurationscan be considered: hard ball on soft disk (HS), soft ball on hard disk (SH) and soft ball onsoft disk (SS).

To point out the main features of the proposed numerical approach, it is possible to focus on a simple problem: this is the description of the physics governing the lubrication of a rigid sphere in pure rolling over a one-relaxation-time viscoelastic half-space. For very low values of the speed, the deformable solid is in the elastic rubbery region and behaves, consequently, as a soft elastic body: no viscoelastic effect is present. When looking at the lubricating film, as expected (see e.g. Ref. [3,4,5]), we observe an almost perfectly circular shape and, due to the flow conservation, a minimum at the fluid inlet can be observed. However, something different occurs when the speed is increased. Indeed, the contact zone gradually evolves towards a shape that is increasingly far from a circle and is affected by a sharp shrinkage at the fluid outlet. The contour plots of the fluid pressure clearly reveal a pressure peak that increases with the speed and produces, ultimately, a strong asymmetry towards the contact inlet. Such a trend is in agreement with analogous results in dry conditions [6] and marks the peculiarity of soft viscoelastic lubrication.

THERMAL PROBLEM OF FRICTION DURING BRAKING FOR FUNCTIONALLY GRADED MATERIALS

Aleksander Yevtushenko, Katarzyna Topczewska* and Przemysław Zamojski
Department of Mechanics and Computer Science, Faculty of Mechanical Engineering, Bialystok University of Technology, Bialystok, Poland

Summary The aim of this study is to develop the analytical model of frictional heating during braking in a system consist of a pad and disc made of functionally graded materials. For this purpose, the one–dimensional heat conduction problem of friction for a semi–space/semi–space were formulated and solved. Obtained solutions allow to calculate temperature distribution on the contact surface and inside the friction elements. The influence of exponential variation of thermal properties along the thickness of friction elements on thermal behaviour of a brake system was investigated based on obtained results.

FUNCTIONALLY GRADED MATERIALS

Functionally graded materials (FGMs) are the group of nonhomogeneous materials with properties dependent on the spatial position. Expected distributions of FGMs properties are obtained by changing porosity, microstructure or composition across the volume of the material structure [1]. Mainly, functionally graded materials are composites where the contribution of the component materials changes so that a specific variation of the material properties is achieved. Many results proved that properly controlled gradients of thermo–mechanical properties in the FGM can significantly improve the resistance to contact deformation and damage [2]. FGMs are consider as advanced materials, resistance to wear and extreme temperature conditions. Often these materials are manufactured of the composition of two different materials. One is a ceramic to resist the severe thermal environment, and the other is a metal to maintain the structural rigidity. Due to their exceptional properties, functionally graded materials are widely used in lots of technology areas, including sliding systems under frictional heat loading, such as braking systems. Application of FGMs with thermal properties dependent on the distance from friction surface, allow to improve dissipation of generated heat, thus avoid overheating of the frictional elements and reduce the magnitude of thermal stresses. Therefore, thermoelastic contact behavior of functionally graded materials is an up–to–date scientific problem [1–4]. In considered models, changes of thermal and mechanical material properties are assumed to be expressed by appropriate functions. Typically, the exponential or power dependencies of FGMs properties on the spatial position are incorporated to the analysis [3].

DEVELOPMENT OF MODEL

In recent years, the thermal problems of friction during braking have been concerned by many researchers. Modeling of the temperature and thermal stress distributions in such heavy–loaded frictional system is essential. Most of obtained exact solutions, known in literature, have been found for a homogeneous materials properties, due to the complexity of the solution achievement in case of heterogeneous properties [5].

The purpose of this study is to investigate thermal behavior of pad/disc tribosystem made entirely of functionally graded materials during single braking. Proposed model is based on the one–dimensional boundary–value problem of heat conduction for two semi–infinite bodies with frictional heat generation on their contact surface. The perfect thermal contact conditions on the friction surface and uniform contact pressure during braking was assumed. Thermal properties of frictional materials are considered to be nonlinear with an exponential distribution along the thickness. In order to solve formulated problem, the Laplace transform technique was used. Exact solution was obtained in the analytical form involving the modified Bessel functions. Based on developed model, the influence of exponential variations of thermal conductivities and diffusivities of friction materials along the thickness of the elements on the transient temperature distributions in a pad/disc system during braking was investigated.

FLUID VISCOELASTICITY IN LUBRICATED CONTACTS IN THE PRESENCE OF CAVITATION

S. S. Gamaniel[1], D. Dini[2], and L. Biancofiore[1,2]
[1]Department of Mechanical Engineering, Bilkent University, Bilkent 06800, Ankara, Turkey.
[2]Department of Mechanical Engineering, Imperial College London, SW7 1AL, United Kingdom.

Summary The use of lubricants in machine components is essential in reducing wear and friction between solid surfaces in moving parts. Lubricants which contain polymer additives exhibit strong viscoelastic effects. A model is proposed to study the influence of fluid viscoelasticity on the performance of lubricated contacts in the presence of cavitation. The proposed model uses the Oldroyd-B constitutive relation to describe the effect of viscoelasticity. To properly define the presence of film cavitation, this model incorporates the mass-conserving Elrod-Adams algorithm. Studies are carried out for the flow of viscoelastic lubricants in: (i) a parabolic profile representing a journal bearing unwrapped geometry, (ii) a pocketed profile to model a textured surface, and (iii) the oscillatory squeeze motion of two flat surfaces. As viscoelastic effects increase, results indicate that: (i) in the parabolic slider there is an increase in the load carrying and a decrease in the cavitation region, (ii) the load capacity in the surface textured bearing depends on the location of the pocket, and (iii) there is a reduction in the load carrying capacity in the oscillatory squeeze motion.

INTRODUCTION

A technique to enhance the performance of lubricants is to add polymers to mineral oils. Lubricants with polymer additives can present viscoelastic effects and, generally, have been shown to exhibit superior lubrication properties when compared to lubricants without additives [1, 2]. Since viscoelastic lubricants possess different mechanical properties we need to make modifications to the classical lubrication theory.

The Navier-Stokes equations and the constitutive equations can be coupled linearly to account for the viscoelasticity of the lubricants. By using the Oldroyd-B constitutive model and assuming that the product between ϵ, i.e. the ratio of the vertical and horizontal length scales, and the Deborah number (De), i.e the ratio of the polymer relaxation time to the flow time scale, is small, a linearized set of the thin film equations can be achieved, similar to the approach pioneered by Tichy et. al. [3].

Several studies on viscoelastic lubricants have been conducted but have failed to account for the presence of cavitation. Cavitation describes the process of the formation of gaseous and vapor bubbles in a liquid due to rapid depressurization usually below the saturation pressure of the liquid. This study proposes a model for viscoelastic lubricants where the presence of cavitation is accounted for using the Elrod-Adams algorithm [4]. In addition, a new set of boundary conditions for the evolving rupture and reformation locations of the viscoelastic lubricant is introduced.

MODEL AND NUMERICAL METHOD

The non-dimensional thin film equations for the isothermal flow of a viscoelastic lubricant are

(i) Continuity equation

$$\frac{\partial \theta}{\partial t} + \nabla \cdot (\theta \mathbf{u}) = 0, \tag{1}$$

(ii) Momentum equation

$$\nabla p = \beta \nabla^2 \mathbf{u} + \nabla \cdot \tau, \tag{2}$$

(iii) Oldroyd-B constitutive equation

$$\tau + \epsilon De \left(\frac{\partial \tau}{\partial t} + \mathbf{u} \cdot \nabla \tau - (\nabla \mathbf{u}) \cdot \tau - \tau \cdot (\nabla \mathbf{u})^T \right) = (1-\beta) \left(\nabla \mathbf{u} + \nabla \mathbf{u} \right)^T, \tag{3}$$

where $\mathbf{u}(u_x, u_y)$ is the velocity vector, t is time, θ is the film fraction or non-dimensional density, p is the pressure, τ is the stress tensor, $\beta = \frac{\eta_s}{\eta}$ is the solvent concentration, $De = \lambda \frac{U_{ref}}{H_{max}}$, λ is the characteristic fluid relaxation time, H_{max} is the maximum film height, η_s is the solvent viscosity and η is the overall viscosity. Note that Eqs. 1-3 are obtained by assuming that the film height H_{max} is much smaller than the contact length L, making it possible then to apply the lubrication approximation.

The set of governing equations (Eqs. 1-3) can then be linearized by using ϵDe as the perturbation parameter. This results in a zeroth-order and first order set of governing equations. Solutions are obtained by applying the boundary conditions for (i) a pure sliding motion and (ii) the oscillatory squeeze flow cases. The solution to the zeroth-order equations corresponds to the Reynolds solution for Newtonian lubricants.

Viscoelasticity is expected to have an effect on the location of both the film rupture and reformation. To define the presence of cavitation in the viscoelastic lubricant we use the mass conserving Elrod-Adams computational scheme. A new set of boundary conditions capable of accurately capturing the transition from Newtonian to non-Newtonian for the cavitation region are introduced. The two possible cases of either (i) an expansion, or (ii) a shrinking of the cavitation region are both addressed by the model.

RESULTS

To understand the effect of fluid viscoelasticity when cavitation is present, an analysis is conducted using (i) a parabolic profile to mimic an unwrapped journal bearing, (ii) single and multiple pockets to represent textured surfaces, and (iii) an oscillatory squeeze flow between two flat plates.

Results for the parabolic profile configuration in Fig. 1a shows there is an increase in the maximum pressure and a decrease in the cavitation region as viscoelastic effects are increased (see Fig. 1b). This leads to an overall increase in the load capacity as the viscoelastic effects get stronger (see Fig. 1c).

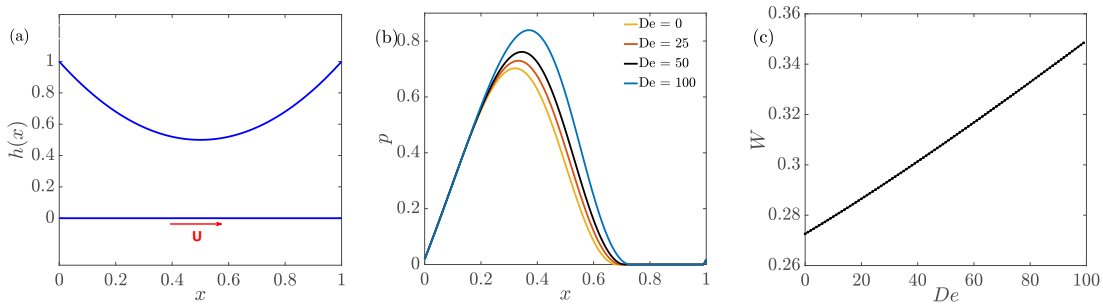

Figure 1: (a) A parabolic profile geometry representing an unwrapped journal bearing, (b) lubricant film pressure for the parabolic slider at several values of De, and (c) the load W for the parabolic slider over several values of De.

The lubrication performance in a surface textured bearing depends on the location of the pocket. The maximum pressure is observed to increase before the pocket location and decreases after the pocket. This suggests that the sign of dh/dx is important in determining the lubrication performance. The maximum increase in the load capacity with increasing viscoelastic effects is observed when the pocket is located at the rear section of the channel. It is also shown that viscoelastic effects do not have a detrimental effect on the lubricant friction.

In the oscillatory squeeze motion of two parallel plates, viscoelasticity reduces the maximum pressure in the lubricant (see Fig. 2a). There is also an observable delay in the reformation of the lubricant film, causing a larger cavitation region as viscoelastic effects become stronger. For very large values of De, the cavitation region widens, until reaching a value of De at which a full-film reformation does not occur after the initial film rupture as shown in Fig. 2b. The observed effects result in a reduction of the load capacity when De is increased (see Fig. 2c).

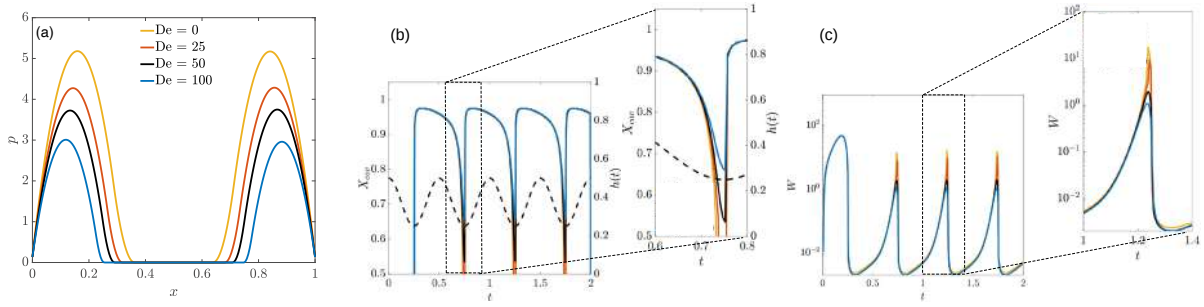

Figure 2: (a) Pressure at $t = 1.22$, (b) location of the right cavitation boundary X_{cav}, and (c) the load evolution for an oscillatory squeeze flow over several values of De. Note that the dashed line in (b) represents the position of the oscillating upper plate.

CONCLUSIONS

A model for viscoelastic lubricated contacts when cavitation is present has been proposed. Viscoelastic effects are modeled using the Oldroyd-B constitutive relation, whereas cavitation is described by using the mass conserving Elrod-Adams algorithm. Viscoelasticity increases the load capacity in a parabolic profile mimicking an unwrapped journal bearing. The lubrication performance in a surface textured profile is shown to depend on the location of the texture. Load capacity in an oscillatory squeeze film flow is observed to decrease with increasing viscoelastic effects due to the delay in the film reformation at larger values of De.

A NOVEL FINITE ELEMENT APPROACH FOR THE ANALYSIS OF NORMAL AND SLIDING CONTACTS

Jacopo Bonari* and Marco Paggi
IMT School for Advanced Studies Lucca, Lucca, Italy

Summary A finite element procedure is exposed, capable of tackling the challenging problem of the contact between an indenter characterised by an arbitrarily complex shape and a deformable layer, considering all the possible phases of contact, starting to simple normal load up to finite sliding displacements. The method relies on a novel interface discretisation method, that allows an accurate representation of the contacting geometries, yet significantly reducing the complexities related to contact detection and the difficulties and pitfalls proper of the representation of complex boundaries.

INTRODUCTION

The importance of considering accurate geometries at increasingly smaller length-scales in the context of mechanics of interacting surfaces in real life and industrial applications has considerably grown in the recent years, such that nowadays it is not possible anymore to treat surface features as waviness and roughness as simple side-effects. For this reason, computational frameworks capable of dealing with these characteristics in efficient yet accurate manner are gaining importance. In this contribution, a recently developed finite element procedure is presented, capable of addressing the problem of a deformable layer making contact with a rigid indenter characterised by an arbitrarily complex boundary surface, in presence of interface friction. The cornerstone of the method consists in considering a simplified equivalent geometry at the mesh level, while the exact original contact conditions are retrieved at the interface level thanks to a precise modification of the normal gap function.

CONTACT PROBLEM FORMULATION

The eMbedded Profile for Joint Roughness (MPJR) interface finite element presented in [1] and furtherly developed in [2,3] is exploited in the present contribution as a useful tool in the framework of the finite element method applied to contact mechanics. From the computational contact standpoint, the strategy relies on a node-to-node approach with penalty constraints. The strength of the method lies in its capability of re-casting the geometry of the contact problem into the simpler one of two equivalent surfaces undergoing conformal contact. This operation is performed at two different levels. At the mesh level, the actual shape of the indenter is replaced by a smooth profile, conformal with respect to the deformable boundary, in such a way that the interface can be easily discretised employing a standard approach with, for example, simple low-order linear elements. In function of the relative displacements of the two opposite sides composing the equivalent interface, a standard normal gap function can be defined. If a common abscissa is set along the interface,

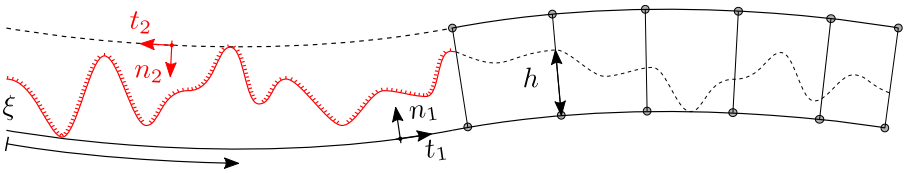

Figure 1: Contacting surfaces discretisation. Subscripts 1 refer to the lower body, while 2 to the upper rigid indenter

mapping both the normal gap and the actual profile elevation, the original contact condition can be restored adding the profile elevation to the gap function, and the contact problem solved using a standard approach. For example, if the deformable layer has a flat interface and a datum of zero elevation is set in correspondence of the point of first contact, the modified gap reads $g_z^*(x,t) = g_z(x) + h(x,t)$, where $h(x,t)$ maps the indenter's elevation field at position x and time t. It is important to remark that the elevation field can be given either as an analytic expression, like has been done in the example below, or, more relevantly for real applications, as a discrete heights field coming, for example, from profilometric data or AFM measurements, with the only requirement that the discretisation of the interface should be fine enough to properly capture the relevant geometric features of the profile. Once the definition of modified normal gap is issued, the interface tractions can be evaluated, and, given a penalty approach for normal tractions and a regularised Coulomb friction law for the tangential tractions, they read:

$$p_z = \begin{cases} \varepsilon_{\mathrm{n}} g_z^*, \text{ if } g_z^* < 0, \\ 0, \text{ if } g_z^* \geq 0, \end{cases} \qquad q_x = f p_z \tanh\left[\frac{\dot{g}_x(x,t)}{\dot{\varepsilon}_{\mathrm{t}}}\right] \tag{1a}$$

where p_z and q_x are the normal and tangential tractions, respectively, ε_{n} is the penalty parameter, f is the coefficient of friction, $\dot{g}_x(x,t)$ is the sliding velocity and finally $\dot{\varepsilon}_{\mathrm{t}}$ is a tangential regularisation parameter.

APPLICATION TO VISCOELASTIC MATERIALS

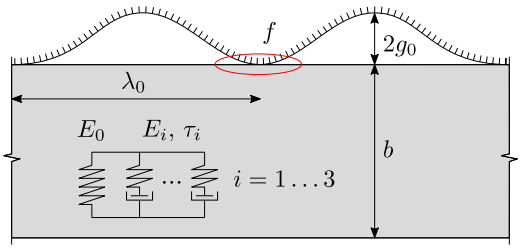

Figure 2: Sketch of the model geometry with $\lambda_0 = 1$, $b = \lambda_0$, $g_0 = 5 \times 10^{-4}\lambda_0$, a Maxwell model with three arms is employed for modelling viscoelasticity

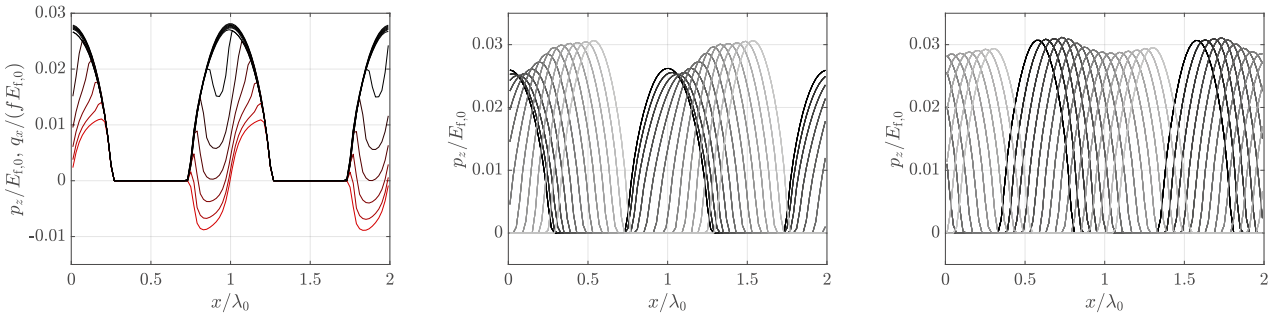
To give an example of the variety of problems that can be addressed with the present formulation, the non-conformal partial contact problem of an indenter with harmonic profile sliding over a viscoelastic layer of finite thickness is presented. A sketch of the model is shown in Fig. 2, together with the geometric and mechanical parameters which are necessary for characterising the problem. In a first loading step, the indenter is pressed downward by an imposed vertical far field displacement, which is then held constant while a rightward shift with constant velocity is applied. All the relevant stages concerning the transient regime in which the transition from a state of *stick/slip*, proper to normal loading, to *full sliding* can be perfectly captured by the model, together with the features strictly related to viscoelasticity. Representative distributions of contact tractions are shown in Figs. 3a, 3b and 3c. In all the selected plots, different curves correspond to different time steps of the simulation. The first plot is related to the beginning of the horizontal loading. The red curve represents an anti-symmetric distribution of self-equilibrating tangential tractions, proper of a purely normal load condition. As the tangential load is applied, the tangential tractions rise in intensity until a condition of full slip is reached, in which they coincide with the vertical distribution of pressures scaled by the friction coefficient f, black curves. The transition is marked by a colour gradient that from red, shifts toward black. In the subsequent picture, the horizontal sliding proceeds. The tangential tractions coincide with the vertical ones scaled by f. Here the viscoelastic effect can be appreciated. If right after the end of the normal loading stage a certain degree of relaxation is observed, a recovery in stiffness takes place as virgin material is disturbed. Advancing in time, the last figure captures the overlapping of a new contact zone with a portion of the material which had already been excited, resulting in a appreciable decrease of the vertical reaction, which marks a clear difference with an elastic material lacking of memory effects.



(a) From *stick/slip* to full sliding

(b) Relaxation and recovery in stiffness

(c) Material memory effect

Figure 3: Distribution of normal and vertical interface tractions for different time steps, scaled by the coefficient of friction f and a reference Young's Modulus $E_{f,0}$. As the simulation advances in time, different effects can be appreciated

CONCLUSION

The study proposes a finite element procedure capable of analysing all the different phases of the contact problem describing an indenter sliding over a deformable material. In particular, a viscoelastic material has been chosen as case study. The methodology offers a straightforward solution for a class of problems for which results would be difficult to be addressed using different techniques. The use of the finite element method overcomes the difficulties which are proper of different solutions schemes, dealing with mixed linear and nonlinear boundary value problems. On the top of that, the proposed interface interface finite element opens new perspectives thanks to its ability of taking into account arbitrarily complex contacting geometries, considering them either via their analytical expression or as the result of a real surface sampling with AFM or profilometer technology.

LIPSCHITZ REGULARIZATION FOR SOFTENING ELASTIC AND PLASTIC MATERIAL MODELS: THE LIP-FIELD APPROACH

Nicolas Moës[1,2*] and Nicolas Chevaugeon [1]
[1]Ecole Centrale de Nantes, GeM Institute, UMR CNRS 6183, Nantes, France
[2]Institut Universitaire de France (IUF)

Summary *Softening material models are known to trigger spurious localizations. This may be shown theoretically by the existence of solutions with zero dissipation when localization occurs and numerically with spurious mesh dependency and localization in a single layer of elements. A new way to avoid spurious localization is presented. The idea is to enforce a Lipschitz regularity on the internal variable responsible for the material softening. The regularity constraint introduces the needed length scale in the material formulation. Bounds on the domain affected by the constraint may be a priori obtained. Several one- and two-dimensional examples will demonstrate the capabilities of the new Lip-field approach both for softening elasticity and softening plasticity.*

LIPSCHITZ REGULARITY

Consider a field d defined over a domain Ω. This field is said to be Lipschitz regular with constant 1/l if it satisfies

$$|d(\mathbf{x})-d(\mathbf{y})|\leq \mathrm{dist}(\mathbf{x},\mathbf{y})/l, \quad \forall \mathbf{x},\mathbf{y}\in\Omega \tag{1}$$

where dist indicates the length of the shortest path joining **x** and **y** inside Ω. The basic idea of the Lipschitz regularization for softening material models is to enforce the above condition on the field responsible for softening [1]. The condition, which is convex, introduces the length l inside the model.

MINIMIZATION OF THE INCREMENTAL VARIATIONAL ENERGY

As is classically done, [2], the mechanical model is formulated as the minimization of an incremental potential, (2). The variables are the displacement field u, the damage variable responsible for softening d and possible other internal variables α. Knowing the three fields at some step n, the fields at the next time step are giving by the global minimization (2). The potential F is assumed convex with respect to the pair (u, α) and with respect to d. It is however not necessarily convex with respect to all three variables (explaining the softening).

$$(\boldsymbol{u},\alpha,d)=\arg\min F(\boldsymbol{u},\alpha,d) \text{ under the constraints } (\boldsymbol{u},\alpha)\in U_n\times A_n \text{ and } d\in D_n\cap L \tag{2}$$

Convex constraints are also imposed on the unknown fields. They are linked to kinematics, U_n, and linked to internal variables, A_n. The set D_n enforces damage growth and bounded damage (below 1). Finally, the set L indicates the Lipschitz condition (1). Using the strategy developed for variational fracture, [3], the above is solved by alternate minimization leading to a sequence of convex minimization: finding the pair $(\boldsymbol{u},\alpha)$ for a given d field and finding d for a given pair $(\boldsymbol{u},\alpha)$. When solving the latter, once can show that a priori bounds on the domain over which L is active may be computed thus reducing dramatically the cost of the minimization over d. Moreover, the irreversibility condition on d is taken into account exacly and does not require any approximation of this constraint.

The presentation will compare the Lip-field approach to other existing approaches to alleviate spurious localization. It will also illustrate the capability of the approach on several one- and two-dimensional simulation examples. One such example is given below.

EXAMPLE OF A SOFTENING PLASTICITY MODEL

Figure 2 illustrates the response of a bar of length L under tension with a non-uniform body force. The left column gives the results for a local model whereas the right column gives the Lipschitz regularized response. The first row gives the load - average strain response. The second and last row give the damage and cumulative plasticity field, respectively. The local response suffers from spurious localization of the damage and plastic fields when the limit point is reached. On the contrary, the Lip-field approach ensures a non-zero dissipation in the post-peak response. Note that the local and Lip-regularized field are equal before the limit point.

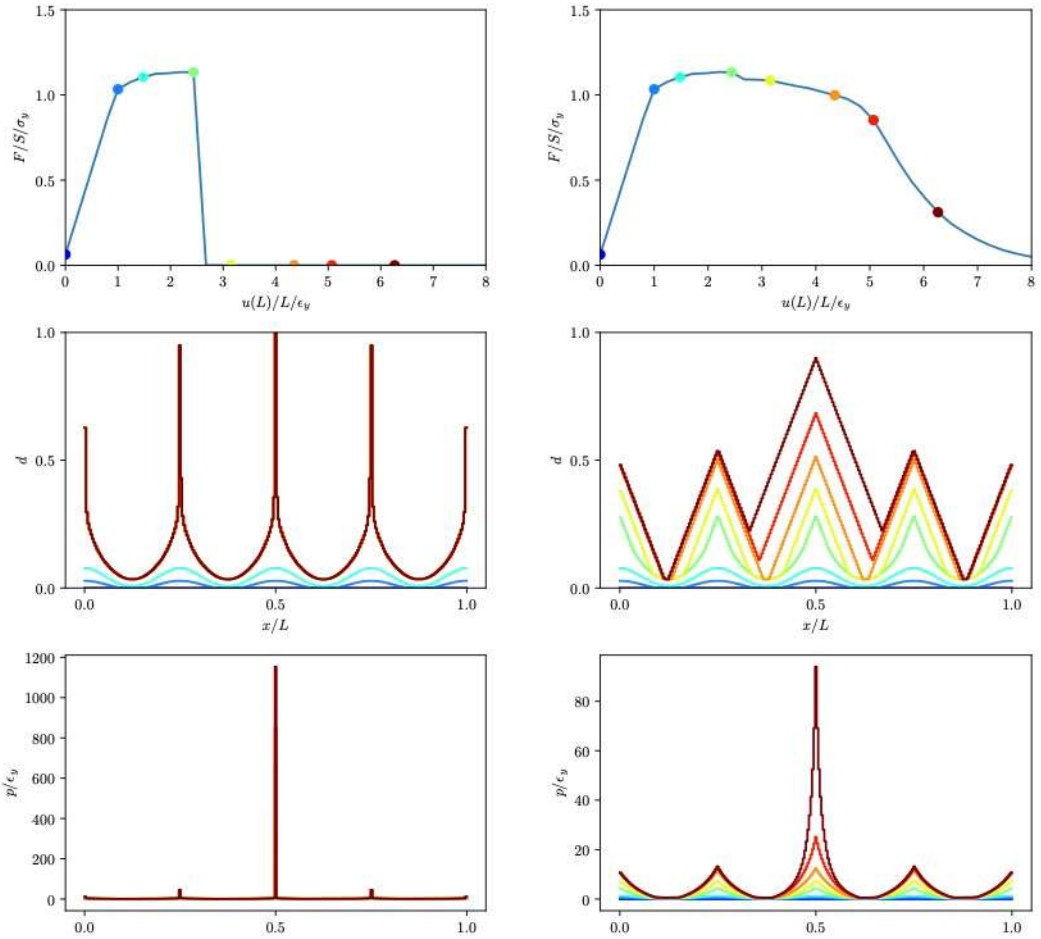

Figure 1. Local (left column) and Lip-regularized (right) response for a softening plasticity model. The bar is loaded with a non-uniform body force.

AN OVERVIEW OF THE MODELLING OF FRACTURE BY GRADIENT DAMAGE MODELS

Jean-Jacques Marigo
Laboratoire de Mécanique des Solides, École polytechnique, Palaiseau, France

The lecture is devoted to gradient damage models which allow us to describe all the process of degradation of a body including the nucleation of cracks and their propagation. The construction of such model follows the variational approach to fracture [2] and proceeds into two stages: (1) definition of the energy; (2) formulation of the damage evolution problem. The total energy of the body is defined in terms of the state variables which are the displacement field and the damage field in the case of quasi-brittle materials [5], whereas they contain also the plastic strain field in the case of ductile materials [1]. That energy contains in particular gradient damage terms in order to avoid too strong damage localizations. The formulation of the damage evolution problem is then based on the concepts of irreversibility, stability and energy balance, as well in quasi-static as in dynamic [4]. That allows us to construct homogeneous as well as localized damage solutions in a closed form and to illustrate the concepts of loss of stability, of scale effects, of damage localization, and of structural failure. Moreover, the variational formulation leads to a natural numerical method based on an alternate minimization algorithm. Several numerical examples will illustrate the ability of this approach to account for all the process of fracture including a 3D thermal shock problem where the crack evolution is very complex [3].

CHARACTERIZATION OF THE SOLUTION NON-UNIQUENESS IN PHASE-FIELD MODELING OF BRITTLE FRACTURE

Tymofiy Gerasimov*[1], Ulrich Römer[2], Hermann Matthies[3], and Laura De Lorenzis[1]
[1]Institute of Applied Mechanics, Technische Universität Braunschweig, Braunschweig, Germany
[2]Institute of Dynamics and Vibration, Technische Universität Braunschweig, Braunschweig, Germany
[2]Institute of Scientific Computing, Technische Universität Braunschweig, Braunschweig, Germany

Summary The variational phase-field formulation of brittle fracture [1, 2, 3] may have non-unique solutions, which is indicated by the non-convexity of the associated incremental minimization problem. In practice, only one representative of all possible solutions is computed numerically. In this contribution, we trigger non-uniqueness in a simple problem and characterize it by switch to a stochastic setting, using the Monte Carlo method.

INTRODUCTION

The phase-field approach to brittle fracture dates back to the seminal work of Francfort and Marigo [4] on the *variational formulation of quasi-static brittle fracture* and to the related *regularized formulation* of Bourdin et al. [1]. The former is the mathematical theory of quasi-static brittle fracture mechanics, which recasts Griffith's energy-based principle as the minimisation problem of an energy functional. The latter presents an approximation, in the sense of Γ-convergence, of the energy functional and is designed to enable the numerical treatment.

Non-uniqueness of the solution in phase-field modeling of brittle fracture is a result of the lack of convexity of the energy functional to be minimized, and has been occasionally reported in the literature. Possible triggers were found to be the finite element mesh, the numerical solution strategy and its parameters, and round-off errors. However, to the best of the authors' knowledge no attempt has been made so far to investigate and characterize the multiple solutions. This is our objective in this work.

We were inspired by [5, 6] in fluid mechanics, where the field problem was reformulated with Young measure-valued solutions and a Monte Carlo method was used to compute its mean and variance field, removing the solution non-uniqueness. We propose a similar numerical approach, but omit any interpretation in the sense of measure-valued solutions. Instead the reasoning here is based on the observation that assuming fixed values for input data is unrealistic. Hence, input data such as the geometry, boundary values or loading terms are modeled as random quantities. The solution may then be numerically much more difficult to obtain, however, it may carry more information as different crack patterns may be triggered during the simulation. The result of such an analysis are probabilities associated to each crack pattern which ideally display crack patterns of all possible types.

DETERMINISTIC AND PROBABILISTIC PHASE-FIELD MODELING OF BRITTLE FRACTURE

The model example is as follows. We consider a two-dimensional rectangular domain $(0, 2\mathtt{a}) \times (0, 2\mathtt{a})$ containing a slit along $\{\mathtt{a}\} \times (3\mathtt{a}/2, 2\mathtt{a})$ and a circular hole with center $(0.3\mathtt{a}, 0.3\mathtt{a})$ of radius $R = 0.2\mathtt{a}$. The incremental anti-plane shear displacement $\mp\bar{u}_n$, with $n \geq 1$ as the discrete pseudo-time step parameter, is applied on $\Gamma_D^- := (0, \mathtt{a}) \times \{2\mathtt{a}\}$ and $\Gamma_D^+ := (\mathtt{a}, 2\mathtt{a}) \times \{2\mathtt{a}\}$, respectively, see Figure 1. Following [1], the energy functional used in the incremental minimization problem reads:

$$\mathcal{E}(u, \alpha) = \int_\Omega \frac{1}{2}(1-\alpha)^2 \mu |\nabla u|^2 \, \mathrm{d}\mathbf{x} + \frac{G_c}{2} \int_\Omega \left(\frac{\alpha^2}{\ell} + \ell |\nabla \alpha|^2 \right) \mathrm{d}\mathbf{x} + \frac{\gamma}{2} \int_\Omega \langle \alpha - \alpha_{n-1} \rangle_-^2 \, \mathrm{d}\mathbf{x}, \tag{1}$$

where $u : \Omega \subset R^2 \to R$, $\nabla := (\frac{\partial}{\partial x}, \frac{\partial}{\partial y})$, μ is the second Lamé constant, and G_c is the material fracture toughness. The last term enforces the irreversibility constraint $\alpha \geq \alpha_{n-1}$ via penalization with $\langle y \rangle_- := \min(0, y)$ and $\gamma \in R_+$ as the penalty parameter, see [7]. In the computations, we set $\mathtt{a} = 1$, $\mu = 1$, $\ell = 2\mathtt{a}/50 = 0.04$, $G_c = 1$ and $\gamma = \frac{G_c}{\ell}\left(\frac{1}{\mathtt{TOL}_{\mathrm{ir}}^2} - 1\right)$ with $\mathtt{TOL}_{\mathrm{ir}} = 0.01$. The applied displacement is given by $\bar{u}_n = n\Delta\bar{u}$, $n = 1, ..., \frac{1.5}{\Delta\bar{u}}$ with $\Delta\bar{u} = 0.1$. For solving the coupled system of equations resulting from the (necessary) stationarity conditions of the energy functional we apply the so-called staggered solution algorithm which implies alternately fixing u and α and solving the corresponding equations until convergence. Both the displacement field u and the crack phase-field α are approximated using P_1-triangles. Perturbation of the minimal mesh size leads to a change in the final crack pattern, as depicted in Figure 2. From the energy-displacement curves (not shown here), we conclude that the Type 1 (nearly vertical) crack path is not energetically favorable in comparison with Types 2 and 3 (curved paths). Also, the latter ones seem to have almost identical energy levels.

*Corresponding author. E-mail: t.gerasimov@tu-braunschweig.de.

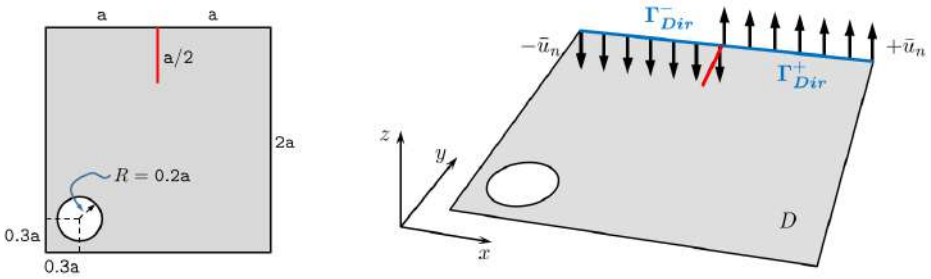

Figure 1: Geometry and loading setup for the anti-plane shear experiment.

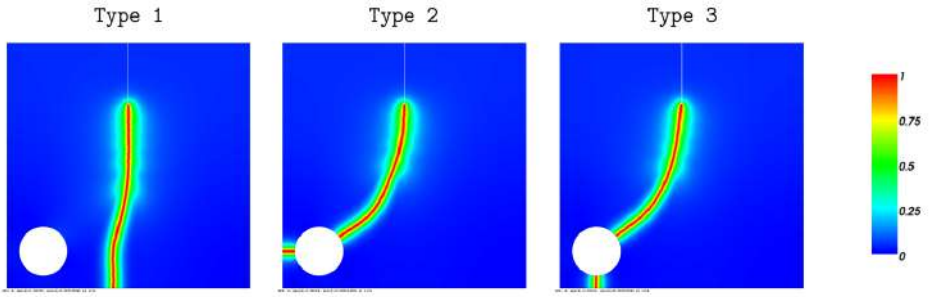

Figure 2: Three different fracture mechanisms as an examples of non-unique solutions (in terms of crack path) are computed on the perturbed meshes.

In view of the above, we use the Monte Carlo approach as a method to capture and characterize all possible solutions. We choose to randomly perturb the hole geometry of our specimen assuming that, in the polar coordinates (r, ϕ) with $\phi \in [0, 2\pi)$,

$$r(\theta, \varphi) = R + \varepsilon \sum_{j=1}^{J} c_j Y_{2j-1}(\theta) \cos(j\varphi) + s_j Y_{2j}(\theta) \sin(j\varphi), \tag{2}$$

where R refers to the unperturbed radius and c_j, s_j are deterministic coefficients which weigh the influence of the different harmonics, with $c_j = s_j = \frac{1}{j}$. Finally, $\theta \in \Theta$ and $Y_k : \Theta \to R, k = 1, \ldots, 2J$ are assumed to be uniformly distributed random variables on $[-1, 1]$.

In presence of a random geometry of the domain, the phase-field model turns into a stochastic partial differential equation. Hence, (u, α) represent random fields: $u : \Theta \times \Omega \to V_{\bar{u}_n}$, $\alpha : \Theta \times \Omega \to H^1(\Omega)$, for which we assume the existence of the mean value μ_z and variance. For $\mathbf{x} \in \Omega$ and $z \in \{u, \alpha\}$ they are defined as $E[z](\mathbf{x}) = \int_\Omega z(\theta, \mathbf{x}) \, \mathrm{d}P(\theta)$, $V[z](\mathbf{x}) = \int_\Omega (z(\theta, \mathbf{x}) - E[z](\mathbf{x}))^2 \, \mathrm{d}P(\theta)$, respectively. Moreover, as we distinguish between Type 1, 2 and 3 cracks, we can compute Monte Carlo approximations of the associated crack probabilities, which can be assumed to characterize the non-uniqueness of the solution.

CONCLUSIONS

The phase field approach to britte fracture delivers in general a non-unique solution. Through an illustrative test case, we have exposed this non-uniqueness due to competing energy levels of different crack paths. Resorting to a stochastic setting turned out to be a viable method to capture various crack paths at once. This was achieved in a standard Monte Carlo framework, which delivered approximate probabilities of occurrence of the different crack paths.

THE THERMO-CHEMO-MECHANICAL FAILURE MECHANISM OF THERMAL BARRIER COATINGS: APPLICATION TO CRACK PROPAGATION CAUSED BY CMAS CORROSION

Yichun Zhou*[1], Guangnan Xu[1]and Li Yang [1]
[1]Key Laboratory of Key Film Materials & Application for Equipment (Hunan province), School of Materials Science and Engineering, Xiangtan University, Xiangtan, Hunan 411105, China

Summary In this work, a mechanism-based constitutive theory is proposed for crack growth and CMAS corrosion process based on phase field method and thermodynamic laws. Stress distributions, infiltration of CMAS, dissolution of ceramic grain and crack growth in thermal barrier coatings (TBCs) are simulated simultaneously by finite element method. By variational operation of free energy we have the governing equation of field variables. The results obtained by theory model validate spalling phenomena thermal barrier coating by CMAS corrosion.

INTRODUCTION

A considerable amount of researches on corrosion issue of TBCs have been performed during the last decades. As reported by Shan (2016), during the process of CMAS corrosion in TBCs, ceramic coating generates swelling deformation by separating grain boundaries and exfoliating the t'-ZrO_2 grains. Compressive stress accumulates in the corrosion area with corroded ceramic coating being restricted by substrate and uncorroded coating. In addition, when CMAS reaches the bottom of ceramic coating, thermally grown oxide (TGO) caused by bond-coat oxidation will be corroded by CMAS, and reaction products like $CaAl_2Si_2O_8$ and $MgAl_2O_4$ appear. Cracks prefer to grow along the interface of $CaAl_2Si_2O_8/Al_2O_3$, $CaAl_2Si_2O_8$/MCrAlY and $MgAl_2O_4/Al_2O_3$ which can reduce interface adhesive strength (Chen et al., 2018). Consequently, compressive stress and interface defects induced by corrosion may cause coating spallation from interface.

The theory of phase field method for crack propagation was first proposed by Francfort and Marigo[25] in 1999, and further developed and improved by Bourdin (2000) to form a crack propagation criterion based on variational principle. The central idea is to introduce a continuous order parameter to represent the discontinuous crack. When the order parameter is equal to 1, it means that the material is damaged; When the order parameter is equal to 0, it means that the material is intact; Miehe (2014) obtained the evolution equation of crack propagation based on the variational principle from the perspective of thermodynamics, and simulated the crack by writing a finite element program. His work greatly promoted the development of phase field method in the treatment of cracks.

In this work, a thermodynamically-consistent constitutive theory of coupled infiltration, corrosion dissolution and deformation is presented for describing CMAS corrosion process in TBCs. The governing equations of crack order parameter is derived by the variational calculus of constructed free energy.

RESULTS AND DISCUSSION

As shown in figure 1, Spatial distribution of σ_{yy}(Pa) at different time is displayed. During the process of CMAS corrosion, stress concentration happens near the bottom of ceramic coating. The Maximum tensile stress appears at the interface under the corroded area. But out of the corroded area, compressive stress is induced accordingly. Spatial distribution of order parameter of crack d at different time is shown in figure 2.

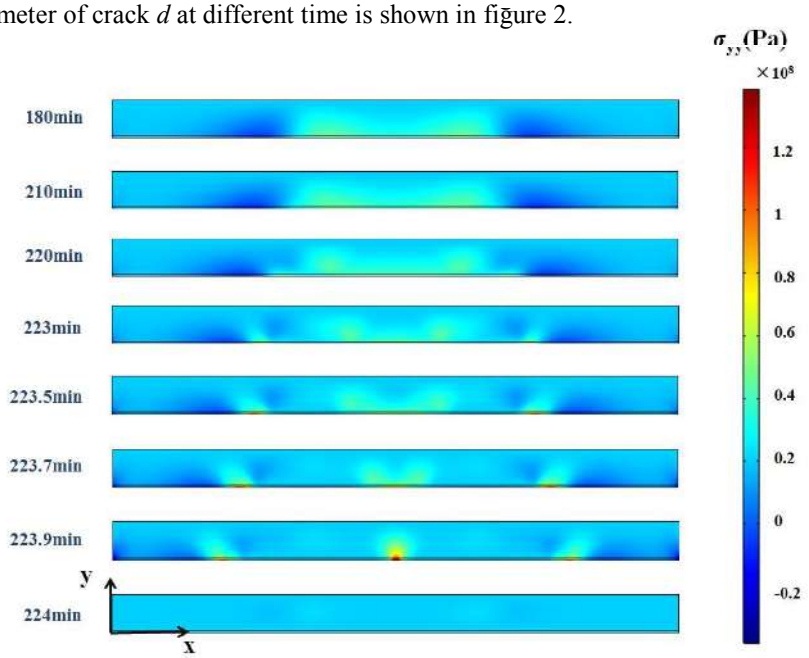

Fig. 1. Spatial distribution of σ_{yy}(Pa) at different time.

*Correspondingauthor. E-mail: zhouyc@xtu.edu.cn

Crack spreading on both sides of corroded area starts to happen at about 210min. At a short time, the cracks connect to each other and extend out to uncorroded area. Note that corresponding to the development of crack, the area of stress concentration starts to broke down at 220min. The stress value drops sharply in the region of crack propagation. But at the tip of crack, the stress value has a sudden increase. At last, the crack spreads throughout the whole interface of ceramic coating and the stress is completely released at 224min.

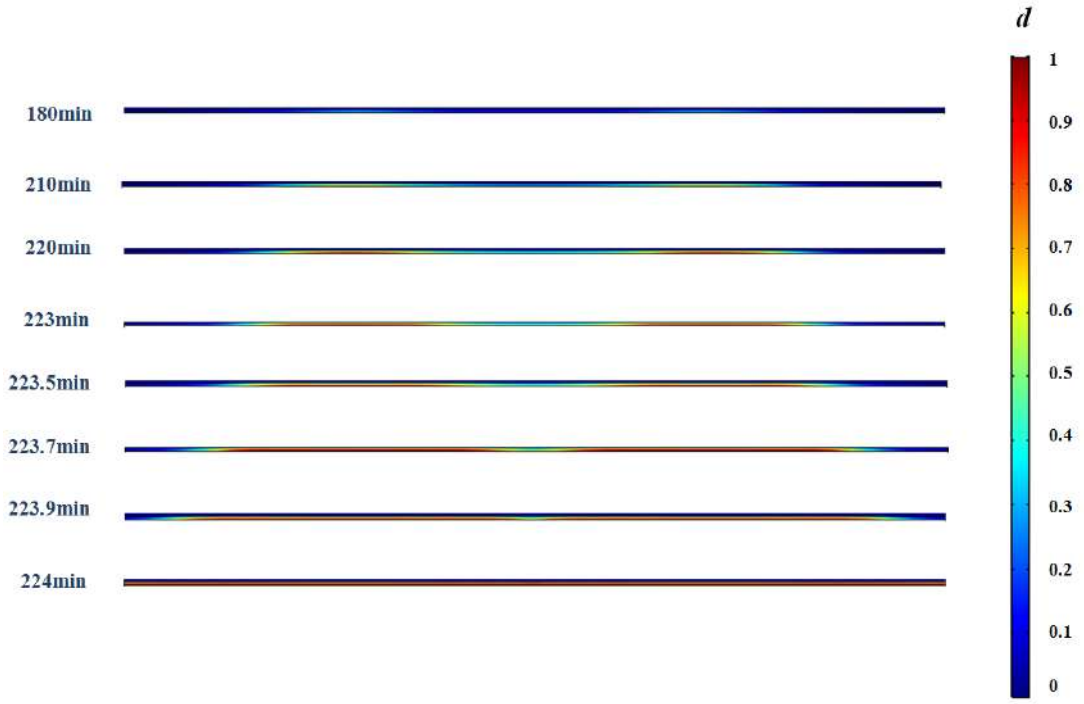

Fig. 2. Spatial distribution of order parameter of crack *d* at different time.

CONCLUSIONS

In this work, a thermodynamically-consistent constitutive theory combined with phase field method is presented for describing crack growth during CMAS corrosion process in TBCs. The main results can be summarized as follows: (1) During the process of CMAS corrosion, out-plane tensile stress is induced in the interface of corroded coating. (2) Induced stress is released in the region of crack propagation and the stress has sharp increase around the crack tip. (3) Cracks appear on both sides of corroded area and then connect with each other and extend out.

HOMOGENIZATION-BASED ANALYSIS OF THE INFLUENCE OF MICROCRACKING ON THERMAL CONDUCTION AND THERMOELASTICITY

Hélène Welemane*, Sharan Raj Rangasamy Mahendren, Olivier Dalverny, and Amévi Tongne
Université de Toulouse; INP/ENIT; LGP; 47 Avenue d'Azereix, F-65016, Tarbes, France

Summary Microcracks are known to affect the behaviour of the materials and several modelling studies are devoted to finding their effective elasticity. This paper aims to extend such investigation to thermal properties, concerning both the steady-state conduction and the thermoelasticity. Accounting simultaneously for the anisotropy induced by microcracks orientation and for their unilateral effect (different behaviour whether they are open or closed) remains a difficult task. In this work, 3D homogenization-based approaches are developed to derive closed-form estimations of the effective thermal properties of a microcracked media with arbitrarily oriented microcracks, either open or closed.

INTRODUCTION

Effects of microcracks on the elastic properties have been extensively studied through experiments and modelling approaches. In the latter case, the homogenization (up-scaling) technique appears as an effective tool to provide the overall properties from the microstructural features of the Representative Volume Element (RVE) [1]. Especially for microcracks, main difficulties arise from: (i) the anisotropy induced by the oriented nature of defects, (ii) their ability to be open or closed (according to tension or compression stresses) and to influence differently the overall response of the material. Regarding the thermal steady-state conduction and thermoelastic properties of microcracked media, very few investigations of these effects have been done in the literature, even on the experimental point of view. Some micro-macro modelling works have been proposed to derive effective properties of a given RVE but they consider only the open state of microcracks [2]. This work aims at exploring homogenization-based approaches to derive anisotropic thermal conductivity and thermoelasticity accounting for unilateral effect.

MICROMECHANICAL FRAMEWORK

Assuming length scale separation, let us consider a 3D RVE composed of an isotropic matrix weakened by N number of randomly distributed families of parallel microcracks. Such media exhibits a matrix-inclusion topology in which each phase (matrix, microcracks) is homogeneous, allowing the use averaging techniques. Two conditions can be imposed on the outer boundary of the RVE, i.e. uniform macroscopic temperature gradient G (for the thermal conduction problem) and uniform macroscopic strain $\mathbf{E}$ with constant temperature difference ΔT over the RVE (for the thermoelastic problem). Under equilibrium condition, the macroscopic quantities $(G, \mathbf{E})$ correspond to the average value of their respective microscopic quantity $(g, \boldsymbol{\varepsilon})$ over the RVE, i.e. $G = \langle g \rangle$, $\mathbf{E} = \langle \boldsymbol{\varepsilon} \rangle$. The microscopic and macroscopic quantities can be linked linearly as $g = \mathbf{A} \cdot G$ and $\boldsymbol{\varepsilon} = \mathbb{A} : \mathbf{E}$, where $\mathbf{A}$ and $\mathbb{A}$ are the second-order gradient and fourth-order strain localization tensors, respectively. Regarding the steady-state heat conduction problem, the microscopic heat flux q is given by Fourier's law:

$$q = -\boldsymbol{\lambda} \cdot g \tag{1}$$

where $\boldsymbol{\lambda}$ is the symmetric second-order thermal conductivity tensor. On the other hand, thermoelasticity is classically described by the following linear constitutive equation:

$$\boldsymbol{\sigma} = \mathbb{C} : \boldsymbol{\varepsilon} - \boldsymbol{\kappa}\, \Delta T \tag{2}$$

where $\boldsymbol{\sigma}$ is the microscopic stress tensor, $\mathbb{C}$ is the fourth-order stiffness tensor and $\boldsymbol{\kappa} = \mathbb{C} : \boldsymbol{\alpha}$ is the second-order thermoelasticity tensor with $\boldsymbol{\alpha}$ being the thermal expansion tensor.

Based on the boundary conditions, the overall heat flux $Q = \langle q \rangle$ and stress $\boldsymbol{\Sigma} = \langle \boldsymbol{\sigma} \rangle$ of the RVE can be expressed as:

$$Q = -\boldsymbol{\lambda}_{hom} \cdot G \qquad \text{and} \qquad \boldsymbol{\Sigma} = \mathbb{C}_{hom} : \mathbf{E} - \boldsymbol{\kappa}_{hom}\, \Delta T \tag{3}$$

where $\boldsymbol{\lambda}_{hom}$, $\mathbb{C}_{hom}$, and $\boldsymbol{\kappa}_{hom}$ are the effective tensors related to the thermal conductivity, stiffness and thermoelasticity of the microcracked media, respectively. Taking all simplifications into account, the effective thermal properties $\boldsymbol{\lambda}_{hom}$ and $\boldsymbol{\kappa}_{hom}$ are given as:

$$\boldsymbol{\lambda}_{hom} = \boldsymbol{\lambda}_m + \sum_{i=1}^{N} f_{c,i}\, (\boldsymbol{\lambda}_{c,i} - \boldsymbol{\lambda}_m) \cdot \langle \mathbf{A} \rangle_{c,i} \qquad \text{and} \qquad \boldsymbol{\kappa}_{hom} = \boldsymbol{\kappa}_m + \sum_{i=1}^{N} f_{c,i} \big(\boldsymbol{\kappa}_{c,i} - \boldsymbol{\kappa}_m \big) : \langle \mathbb{A} \rangle_{c,i} \tag{4}$$

where $\boldsymbol{\lambda}_m$ (resp. $\boldsymbol{\lambda}_{c,i}$) and $\boldsymbol{\kappa}_m$ (resp. $\boldsymbol{\kappa}_{c,i}$) are the thermal conductivity and thermoelasticity tensors of the matrix (resp. of the i^{th} family of parallel cracks) and $f_{c,i}$ is the cracks volume fraction for the i^{th} family.

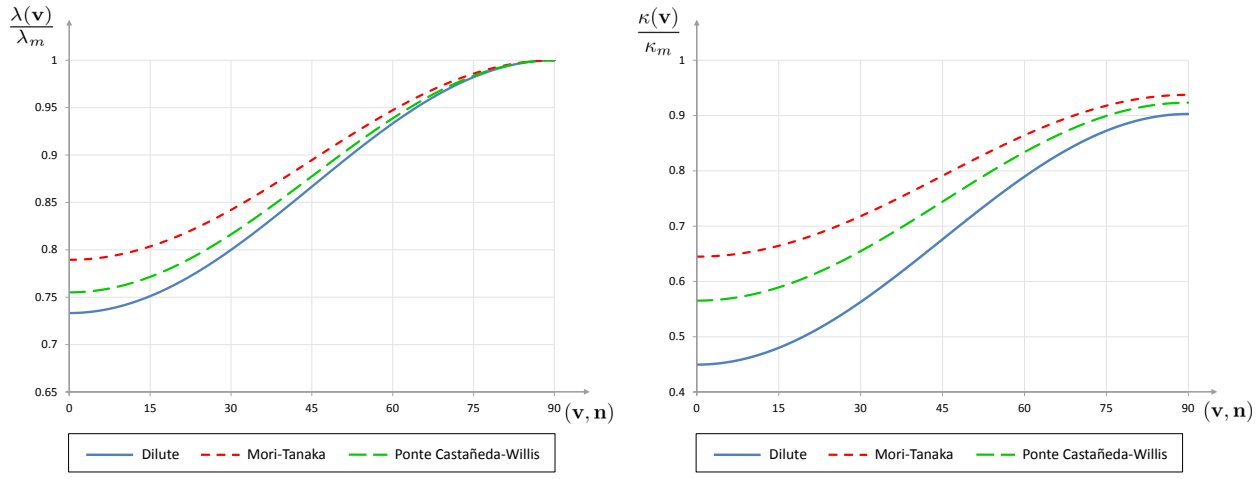
Estimations of localization tensors $\mathbf{A}$ and $\mathbb{A}$ can be obtained using the works of Eshelby on the single-inhomogeneity problem [3]. In line with the recent study of [4], each family of microcracks is modelled as a flat oblate ellipsoid with

*Corresponding author. E-mail: Helene.Welemane@enit.fr

unit normal $\mathbf{n}_i$, crack density d_i and aspect ratio $\omega_i \to 0$. We assume both the matrix and cracks are isotropic and their properties can be given by $\boldsymbol{\lambda}_r = \lambda_r\, \mathbf{I}$, $\boldsymbol{\kappa}_r = \kappa_r\, \mathbf{I}$ and $\mathbb{C}_r = 3k_r\, \mathbb{J} + 2\mu_r\, \mathbb{K}$ with $r = \{m; c, i\}$ (where λ_r and κ_r are scalars while k_r and μ_r are the bulk and shear moduli). The unilateral effect is taken into account via the $\lambda_{c,i}$ and $\kappa_{c,i}$. For open cracks, it is assumed adiabatic (for thermal conduction) and stress-free (for thermoelasticity) conditions on the microcracks lips, so $\lambda_{c,i} = 0$, $\mathbb{C}_{c,i} = \mathbb{O}$ ($k_{c,i} = 0, \mu_{c,i} = 0$) and $\kappa_{c,i} = 0$. Inspired by the works of Deudé *et al.* [5], the closed cracks (frictionless contact) are considered as a fictitious isotropic material such that $\lambda_{c,i} \neq 0$, $\kappa_{c,i} \neq 0$ and $\mathbb{C}_{c,i} = 3k_m\, \mathbb{J}$ ($k_{c,i} = k_m, \mu_{c,i} = 0$), which accounts for some heat (for conduction) and stress (for thermoelasticity) transfer continuity across the closed microcracks lips.

RESULTS

From these assumptions, closed-form expressions of the whole thermal properties (Eq (4)) are derived for dilute and Mori-Tanaka (MT) schemes and Ponte Castañeda-Willis (PCW) bound. For a single family of open microcracks, $\boldsymbol{\lambda}_{hom}$ is function of $d, \mathbf{n}, \boldsymbol{\lambda}_m$ and $\boldsymbol{\kappa}_{hom}$ is function of $d, \mathbf{n}, \boldsymbol{\kappa}_m$ and matrix Poisson ratio ν_m. Also the material shows a damage-induced anisotropy, irrespective of the estimation. To be precise, the effective thermal properties are transversely isotropic around the axis $\mathbf{n}$ of the crack. As an illustration, Fig. 1 presents the generalized scalar thermal conductivity $\lambda(\mathbf{v})$ and thermoelasticity $\kappa(\mathbf{v})$ in any direction of unit vector $\mathbf{v}$ defined by: $\lambda(\mathbf{v}) = \mathbf{v} \cdot \boldsymbol{\lambda}_{hom} \cdot \mathbf{v}$ and $\kappa(\mathbf{v}) = \mathbf{v} \cdot \boldsymbol{\kappa}_{hom} \cdot \mathbf{v}$ respectively. While both properties are mostly degraded along the direction $\mathbf{n}$ normal to the crack surface, the cracks influence is stronger on thermoelastic properties for a given cracks density. We should also note the differences for both properties according to the estimations, related to the account (MT and PCW) or not (dilute) of interactions between microcracks and, in the former case, to the considered spatial distribution of microcracks (ellipsoidal for MT and spherical for PCW).



(a) $\dfrac{\lambda(\mathbf{v})}{\lambda_m}$ (b) $\dfrac{\kappa(\mathbf{v})}{\kappa_m}$

Figure 1: Generalized thermal conductivity $\lambda(\mathbf{v})$ and coefficient $\kappa(\mathbf{v})$ normalized by their initial values for a material weakened by a single family of parallel open microcracks of unit normal $\mathbf{n}$ (cracks density $d = 0.1$, matrix Poisson ratio $\nu_m = 0.15$).

On the other hand, it is demonstrated that closed cracks do not contribute to the degradation of the thermal conductivity or thermoelasticity. This result is irrespective of the estimation (dilute, MT, PCW), fictitious cracks properties or space direction, i.e. effective conductivity and thermoelasticity in any direction $\mathbf{v}$ recover their respective values for the virgin material: $\lambda(\mathbf{v}) = \lambda_m$ and $\kappa(\mathbf{v}) = \kappa_m$, $\forall\, \mathbf{v}$. While elastic properties are only fully recovered in the direction $\mathbf{n}$ normal to closed microcracks [6], we observe here a total deactivation of microcracking influence on thermal properties.

CONCLUSIONS

Using Eshelby approach, we have derived in this work several homogenization-based expressions for effective thermal properties of a microcracked media, both regarding steady-state conduction and thermoelasticity. Special attention has been paid to the unilateral effect and its consequences on the overall behaviour. This study provides some relevant information to further develop a fully coupled thermo-mechanical model with evolving damage.

Summary Predicting impact damage in composite structures is a challenging topic that has received a significant amount of attention. Only little effort, however, is directed toward thick composite structures (i.e., 20-50mm) that start to appear in aerospace applications. This work aims to provide accurate and efficient modelling techniques to predict impact damage in thick composite structures. Analytical and numerical methodologies are compared with experimental results and it is shown that each model shows potential for certain applications. Overall these methodologies improve the understanding of impact events on thick composite structures, could decrease uncertainties in the design process, and reduce cost by minimising the amount of tests required.

INTRODUCTION

Innovations in the aerospace sector are necessary to reduce the environmental impact of aviation. One approach is to reduce the weight by using composite structures in the latest generation aircraft. However, the theoretical benefits of composite materials are not utilised to their full extent because of uncertainties in damage tolerance predictions. In particular, risk associated to accidental impact events are critical in designing a damage tolerant composite structure. Despite significant effort focussed on predicting impact on composite structures with thickness in the range of a few millimetres, it is unclear if these methodologies are suitable for thick composites in the range of 20-50mm.

Thick composite structures are becoming more prevalent in aircraft, such as the landing gear and wing component illustrated in Figures 1 and 2. The challenges, especially regarding the trade-off between accuracy and efficiency, are even more evident for simulating impact events on these structures. Therefore, the goal of this contribution is to provide an efficient analytical and a detailed numerical methodology which are compared to each other and to experimental results.

EXPERIMENTS AND MODELLING TECHNIQUES

Due to the many variables involved in impact events, a simplified impact problem is defined, as shown in Figure 3. It concerns a perpendicular impact with a spherical steel impactor with a 16mm diameter on a 150×100mm specimen on a frame with a 125×75mm opening and clamped at four corners. This complies with the ASTM D7136/D7136M-15 standard used for impact experiments. One-dimensional (1D) and two-dimensional (2D) approximations allow for a more computationally efficient solution to the impact problem compared to a three-dimensional (3D) simulation.

Impact Experiments

Impact experiments that focus on thick composites are limited to a few studies in literature [2]. To ensure that the modelling techniques can be validated and compared to suitable experimental data, extensive experimental impact tests were conducted at Royal NLR. The specimens were produced with a quasi-UD 2/2 twill weave fabric, infused by a low viscosity toughened liquid epoxy resin and cured using Resin Transfer Moulding (RTM). As a result, multiple data points are available including 55 and 100J large-mass drop-tower and small-mass gas cannon impacts on 20 and 40mm thick specimens with two different layups. The impact response characteristics of each data point were obtained, such as contact force and impactor displacement histories, as well as absorbed energy and the characteristic damage state (i.e., dent depth and delaminated area, width, height, and depth obtained from C-scans, CT-scans, and visual inspection of cross-sections).

Analytical Impact Response Prediction

An analytical impact response model, that represents the 1D approximation of the impact problem in Figure 3, is used to provide a computationally efficient solution. The model of Christoforou and Yigit [3] is used in combination with the Sun-Christoforou contact law proposed by Talagani [4]. This model is capable of predicting the impact response characteristics, such as, contact force and impactor displacement histories. However, due to a missing stress solution and implementation of failure criteria, no predictions of the characteristic damage state can be given.

Numerical Impact Response and Damage Prediction

A numerical model is developed in Abaqus/Explicit that uses a discrete cracking approach. Delaminations as well as in-ply failure (i.e., fibre breakage and transverse matrix cracks) are simulated by cohesive interface elements (i.e., COH2D4 or COH3D8). Properties of these cohesive elements have been carefully selected based on material characterisation data available and guidelines provided by Turon *et al.* [5, 6]. Contact definitions allow for these cohesive elements to be deleted once fully failed. The drop-tower impactor is modelled in full such that its eigenfrequencies are included in the simulation, while the gas cannon impactor (i.e., steel ball) can be assumed rigid. Behaviour analogous to an elasto-plastic response is included in the bulk material by Von Mises plasticity with isotropic hardening. In the full 3D numerical model, the bulk material is represented by solid elements (i.e., C3D8R and C3D6R) in a ply-oriented mesh. However, a 2D approximation in the xz-plane in Figure 3 gives a simplified model that is computationally more efficient. This model uses axisymmetric elements for a correct representation of the impactor.

COMPARATIVE ANALYSIS AND CONCLUSIONS

The analytical model and the 2D/3D numerical models are compared in terms of accuracy and computational efficiency. In terms of efficiency, the analytical model provides a solution in 10-100 seconds, while the 2D numerical model requires approximately two orders of magnitude longer time. The extension to 3D increases the computational time by another order of magnitude. The accuracy is assessed by comparison with experimental results. Preliminary results show that all three models are capable of a relatively accurate prediction of the impact response characteristics. Noteworthy is that the analytical impact response model in many cases gives the best prediction of force and displacement histories. At the time of writing this abstract, a thorough evaluation of the impact damage predictions is still on-going. Due to the computational efficiency of the analytical model an extensive sensitivity analysis of impact characteristics is possible in early stages of design. The 2D numerical model gives, in addition to the force and displacement histories, a relatively efficient prediction of the characteristic damage state. However, the only model that can give an accurate and realistic representation of the characteristic damage state including all damage types is the 3D numerical model.

MICRODAMAGE AND FRACTURE INITIATION IN THE MATERIALS SUBJECTED TO ION-IRRADIATION

Aneta Ustrzycka*[1] and Marcin Nowak[1]
[1]Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, Poland

Summary In this work defects induced by ion-irradiation in the elastic-plastic materials are investigated by using the nano-indentation technique. Radiation induced damage level is expressed in terms of displacements per atom (dpa), afterwards, the radiation induced damage is defined in the framework of Continuum Damage Mechanics (CDM) to solve the problem of further evolution of damage fields under mechanical loads. The new mathematical relation between radiation damage (dpa) and porosity parameter is proposed. Deformation process experienced by the ion irradiated materials during the indentation test is then simulated by Gurson–Tvergaard–Needleman (GTN) model. Moreover, a novel material model with radiation induced damage based on nonlocal peridynamic theory is proposed to study of ion-irradiated materials. The peridynamic theory based on integro-differential equations without spatial derivatives is a powerful tool for the modelling of materials involving discontinuities. The conditions of fracture, the onset and the propagation of macro-crack are investigated.

INTRODUCTION

In general, radiation induced damage causes profound changes of the macroscopic response, reflected by progressive material degradation. Radiation damage creates the threats for structural components working under mechanical loads. Moreover, damage evolution causes degradation of mechanical properties and severely compromises the lifetime of structural components. Radiation-induced defects serve as strong obstacles to dislocation motion. Irradiation invariably renders a metal less ductile and leads to drastic modifications of mechanical properties, e.g., growth of porosity, fracture toughness and increase in yield stress. Depending on the degree of irradiation, fracture can have the brittle or ductile characteristics. A microcrack can rapidly propagate across the entire component, or it can occur as result of stress and or large plastic deformation.

IRRADIATION INDUCED POROSITY

The irradiation of metals by high energy particles leads to the interaction of energetic incident particles with lattice atoms. The pair of interstitial atom and vacancy in irradiated crystalline solids is known as the Frenkel defect. After the end of the collisional phase (cascade) the point defects (vacancies and interstitials) may migrate in the material leading to the formation of various forms of defect clusters: e.g. clusters of voids. In this way, the process of damage initiation is created. To evaluate radiation damage, a damage variable that characterizes the material degradation is required. Radiation induced damage level is expressed in terms of displacements per atom (dpa) parameter. The nature of radiation induced damage is close to porosity because of formation of clusters of vacancies. The porosity ξ of the material expressed by dpa function takes the form

$$\xi = q_c \frac{4}{3}\pi C (dpa)^n$$

where q_c is the density of vacancy clusters caused by irradiation, C and n are material parameters. The processes of the defects formation and initial clustering as well as the interaction between point defects which are the basis of the fracture are considered.

ELASTIC-PLASTIC DEFORMATION DURING INDENTATION

In the irradiated ductile materials, the plastic deformation is based on similar mechanisms like in the virgin materials. In particular, the main mechanism of plastic flow is still slip. However, due to the presence of radiation induced defects, like the groups of interstitial atoms or vacancy clusters containing impurities, strong hardening is usually observed. The motion of dislocations within the easy slip planes is hindered by numerous types of obstacles, causing substantial increase of the flow stress. The experimental characterization of the deformation process of the ion irradiated materials during the nano-indentation test is carried out (Fig.1).

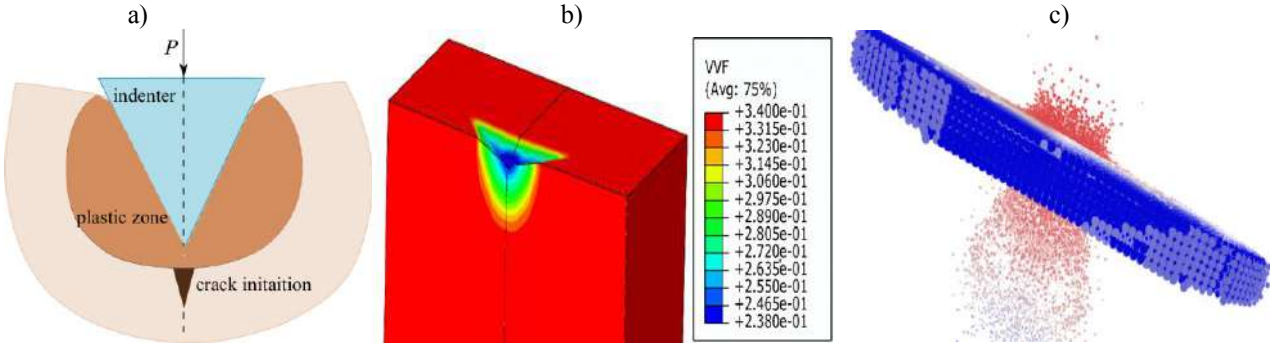

Figure 1. a) Indentation of an elastic-plastic solid by a rigid cone; b) Evolution of porosity in the damaged material subjected to indentation in the framework of CDM; c) Indentation test results of peridynamics simulation (PD)

*Corresponding author. E-mail: austrzyc@ippt.pan.pl

Afterwards, the radiation induced damage is defined in the framework of Continuum Damage Mechanics (CDM) and peridynamics theory (PD) to solve the problem of further evolution of damage fields under mechanical loads [1]. A novel material model based on nonlocal peridynamic theory is proposed to study of irradiated materials. The peridynamic theory is particularly powerful in modelling problems where spontaneous formation of discontinuities, like micro-damage, voids and cracks, occurs. Numerical simulation of indentation test results of PD is shown in Fig. 1c. Emphasis is placed on the macroscopic behaviour, like the evolution of damage and fracture through the plate.

ELASTIC-PLASTIC DAMAGE MODEL OF INDENTATION OF THE ION-IRRADIATED MATERIAL

The nature of radiation induced damage is close to porosity because of formation of clusters of vacancies and helium bubbles. For this reason, the models describing the porosity evolution appear most suitable. The kinetics of radiation induced damage involves essentially two models describing the evolution of porosity in the materials: the Gurson–Tvergaard–Needleman (GTN) model and - for comparison – the Rice and Tracey (R-T) model [2]. Both of them address the evolution of porosity in the form of spherical or ellipsoidal voids in a different way. GTN proposed a constitutive model of porous materials including the micro-voids. The porosity rate is controlled by the appropriate GTN yield function. Moreover, the GTN kinetics is accompanied by the yield surface that retracts in the course of increasing porosity. On the other hand, the R-T model predicts the evolution of radius of spherical void as a function of triaxiality and the plastic strain. The R-T model is expressed in the form of a differential equation and has, therefore, implicit character. Main drawback of the R-T model consists in the fact, that there is no full coupling between the plasticity and the damage. The reasons for which the GTN kinetics appears far better for the irradiated materials are as follows:

- the nature of radiation induced damage is close to porosity because of formation of clusters of voids, without generation of cracks,
- the GTN model represents a dilatational constitutive model based on the yield function formulated for a porous solid, with the volume fraction of voids reflecting randomly distributed spherical voids,
- the void growth in the GTN model is driven by the volumetric plastic strain rate, combined with type GTN yield surface,
- the current porosity value is computed and can be easily converted to damage parameter.

The numerically obtained loading-unloading curves were imposed on the experimental data in order to verify their consistence, both for the loading and for the unloading stages. The curves were corrected for the initial stage of the indentation process, where the indenter cuts through the surface layer and the hardware adjustment takes place (Fig. 2). Quite good agreement between the numerical and the experimental curves is obtained, which confirms validity of the GTN model.

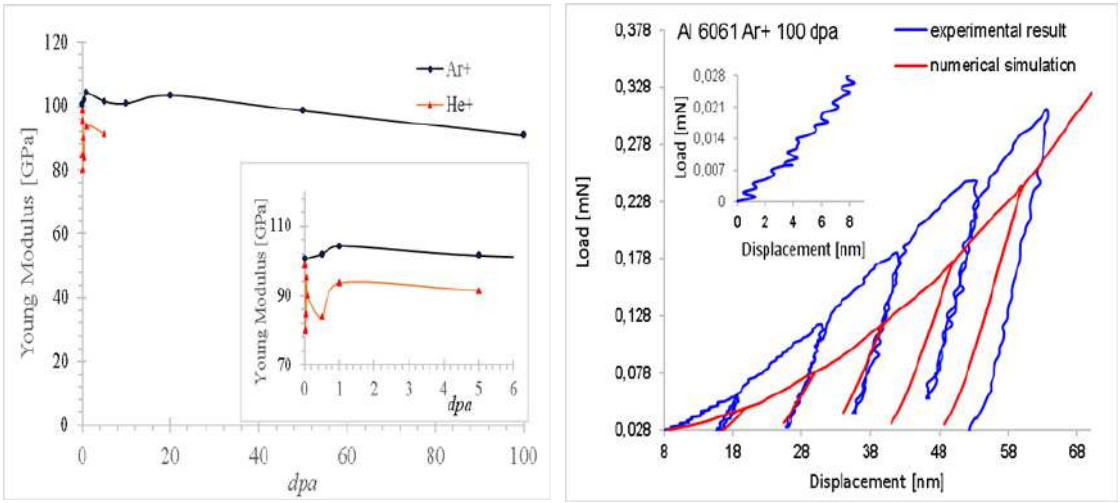

Figure 2. Young's modulus as a function of the irradiation dose; Load-indentation depth curves - experimental results and numerical simulations

THE ONSET OF FRACTURE AND THE MACROCRACK PROPAGATION

In view of the above model of irradiated elastic-plastic material, the conditions of fracture are to large extent determined by the radiation induced porosity. This phenomenon largely affects the conditions of the onset and the evolution of macrocrack, that depend on the level of irradiation (porosity). Therefore, the conditions of fracture, including the fracture toughness as well as the propagation of the micro-crack, are investigated. A criterion of the macro-crack initiation is proposed and implemented.

A THREE-DIMENSIONAL CONTINUUM DAMAGE-HEALING MODEL FOR SELF-HEALING MATERIALS

Harini Subramanian[1] and Shantanu S. Mulay [*1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Madras, India

Summary A three-dimensional continuum damage-healing mechanics (CDHM) model is proposed to study the behaviour of self-healing materials. The present work focuses on the class of materials undergoing self-healing at lower strain values, where the damaged surfaces wet each other and partially recover the bond strength. The concept of effective configuration is extended, defining a healing configuration to study the healing effects. The principle of strain equivalence and strain energy equivalence are adopted to establish the relation between stiffness moduli in current and healing configurations. The damage and healing variables evolve according to different evolution surfaces. The proposed model has been successfully validated under different types of strain histories. The developed model is employed to solve boundary value problems by ABAQUS through user material subroutines (UMAT).

INTRODUCTION

The ability of a material to recover/repair autonomously or with an external intervention upon the damage is called healing. Different types of materials, such as polymers, concrete, ceramics, and metals have unique self-healing mechanisms. The potential of self-healing materials to delay failure and increase a component's lifecycle warrants theoretical models of self-healing materials that are applicable under different loading conditions. The present work aims to model the self-healing behavior of materials during unloading and rest periods. The proposed model ensures a *kinetic* coupling between the damage and healing variables through the use of damage energy release rate Y in the damage evolution. The developed model is also applied to analyze the effect of healing in textile composites with a self-healing matrix. The model will be further extended in future to account for the viscoelastic effect of the polymer matrix and the effect of temperature on healing.

CONTINUUM DAMAGE-HEALING MODEL

An isotropic damage variable is defined based on continuum damage mechanics (CDM) to measure the material degradation due to damage under loading. An isotropic healing variable is also defined capturing the amount of damaged area that has undergone healing. The concept of effective configuration in CDM is extended, and a healing configuration is introduced eliminating damaged and unhealed area from the current configuration as shown in Figure 1 [1].

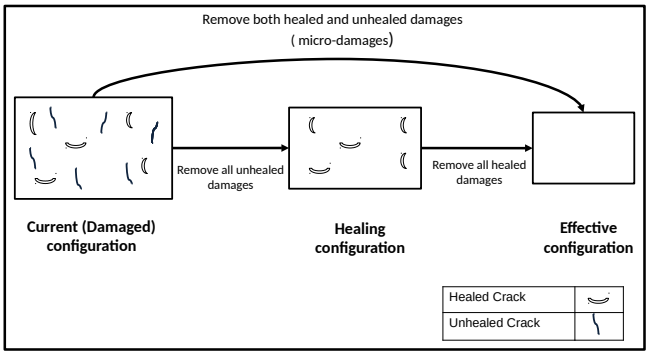

Figure 1: Schematic representation of the current-, healing-, and effective- configurations

The effective damage variable is defined as

$$\phi = D(1-h) \tag{1}$$

where D and h are damage and healing variables. The stress tensors in the current and healing configurations are related by the principle of mechanical equivalence as

$$\tilde{\tilde{\boldsymbol{\sigma}}} = \underline{\underline{\underline{\underline{\mathcal{Q}}}}}\ \boldsymbol{\sigma}, \quad \text{and} \quad \underline{\underline{\underline{\underline{\mathcal{Q}}}}} = \left[\underline{\underline{\underline{\underline{M}}}}^{-1} + \left(\underline{\underline{\underline{\underline{I^s}}}} - \underline{\underline{\underline{\underline{M}}}}^{-1}\right) \underline{\underline{\underline{\underline{H}}}}^{-1}\right] \tag{2}$$

where $\underline{\underline{\underline{\underline{\mathcal{Q}}}}}$ is the damage-healing effect tensor [2], and $\underline{\underline{\underline{\underline{M}}}}^{-1}$ is the inverse damage effect tensor defined as

$$M^{-1}_{ijkl} = I^s_{ijkl} - D_{ijkl}, \quad \text{and} \quad I^s_{ijkl} = \frac{1}{2}\left(\delta_{ik}\,\delta_{jl} + \delta_{il}\,\delta_{jk}\right) \tag{3}$$

*Corresponding author. E-mail: ssmulay@iitm.ac.in

where I^s_{ijkl} is the 4^{th}-order identity tensor. The energy-based damage criterion is employed [3], and extended to account for the healing effect on the evolution of damage. The damage evolution *during loading* is thus governed by the evolution of healing *during unloading and rest periods* ensuring *kinetic* coupling between the damage and healing variables. The damage evolution function is thus given as

$$f^D\left(D;\boldsymbol{\epsilon},h\right)=\left(1-D\right)^{m(D)}Y\left(\boldsymbol{\epsilon},h\right)-W\leq 0,\quad m\left(D\right)=m_1(1-D)^{m_2}+m_3 \tag{4}$$

where W is the damage initialization threshold energy $(\mathrm{J/m^3})$, $Y\left(\boldsymbol{\epsilon},h\right)$ is the damage energy release rate $(\mathrm{J/m^3})$, and $m(D)$ is the exponential material parameter controlling hardening and softening regions [3]. The phenomenological-based healing increment equation and the corresponding initiation condition are given as [1]

$$\dot{h}=\beta_h\left[\left(1-D\right)\left(1-h\right)\right]^p,\quad f^h=\boldsymbol{\epsilon}^h_{th}-\boldsymbol{\epsilon}_{eff}\leq 0 \tag{5}$$

where β_h is the healing viscosity parameter controlling the rate of healing and p is a material constant. f^h is the healing loading surface, $\boldsymbol{\epsilon}^h_{th}$ is the healing threshold strain, and $\boldsymbol{\epsilon}_{eff}$ is the effective strain.

RESULTS AND DISCUSSION

(a) (b)

Figure 2: (a) Strain input equal unloading-reloading with rest period (b) Stress vs strain response

(a) (b)

Figure 3: (a) Variation of effective damage with time (b) Variation of algorithmic tangent modulus with time

The model is demonstrated in one dimension for a cyclic loading strain input with unloading-reloading coupled with a rest period. The stress increases linearly with strain, and damage is initiated when $f^D \geq 0$. The algorithmic tangent modulus E^T remains constant (E_0) until damage initiates and then evolves with progressive damage. The healing process is initiated during unloading (phase 3) when the strain is lower than a threshold value, until which ϕ remains constant. The healing evolution in phase 3 results in a decrease of ϕ. The effect of healing is thus observed in the next loading cycle (phase 4), when E^T during reloading is higher than the corresponding value during unloading. The effective damage ϕ is thus found to decrease during the rest period and increases when further damage occurs.

CONCLUSION

A CDHM model has been formulated focussing on the class of materials undergoing self-healing at lower strain values, where the damaged surfaces wet each other and partially recover the bond strength.

A TWO-WAY COUPLED CHEMICAL-MECHANICAL MODEL FOR SULFURIC ACID CORROSION OF CONCRETE

Frits Rooyackers*[1], Emanuela Bosco[1], Akke Suiker[1], and Francois Clemens[2,3]
[1]Eindhoven University of Technology, Department of the Built Environment, Eindhoven, the Netherlands
[2]Delft University of Technology, Department of Civil Engineering and Geosciences, Delft, the Netherlands
3Deltares, Department of Hydraulic Engineering, Delft, the Netherlands

Summary A computational approach is proposed to describe the chemo-mechanical corrosion of concrete subjected to sulfuric acid. The framework is based on a set of coupled (diffusion-)reaction equations, two-way coupled with a continuum damage model by means of a staggered scheme. At each timestep, the chemical problem is solved first. As a result of phase transformation, a chemical strain is introduced, which triggers the deterioration of the material, and further increases the ionic transportation through concrete containing micro-cracks. This model is applied to a simple benchmark problem of a concrete cube submerged in a sulfuric acid solution. A parametric study is currently being performed, in parallel with an experimental program in order to calibrate the input parameters required for the numerical model.

INTRODUCTION

This work focuses on the numerical modeling of the degradation of concrete sewer pipes, due to sulfuric acid attack, and its implications on the residual load bearing capacity of the system. Sulfuric acid, which is produced by bacteria present in the sewage environment [1], may diffuse through the pore structure of the cement matrix of concrete. The chemical reaction of sulfuric acid with the calcium-hydroxide contained in the cement paste produces gypsum. This reaction product occupies a larger volume than the original cement paste and induces stresses and strains in the remaining cement matrix, leading to the formation of micro-cracks. The presence of micro-cracks promotes additional transport of sulfuric acid, thereby further accelerating the deterioration process.

METHODOLOGY

The modeling approach used in this study is based on the two-way coupling of a chemical model and a mechanical model, defined within a finite element setting. A staggered scheme is used. Several studies have already been proposed in the literature on the chemo-mechanical degradation process of cement as due to sulfate attacks [4, 5, 6]. This study aims to develop a model that extends earlier work from a chemical point of view by considering some additional complex chemical considerations occurring in the process, in order to determine the effect on the mechanical response. A summary of the adopted modeling strategy is given in the following.

The chemical process is described by means of a set of (diffusion-)reaction equations, which simulate the formation/dissolution of the relevant chemical species in the cement paste into their ionic components. The source and sink terms of these (diffusion-)reaction equations couple the equations and satisfy the mass balance of the system as a whole.

The chemical problem is solved first, providing the local concentrations of the chemical species. The coupling between the chemical and the mechanical models is achieved by:

- introducing a chemically-induced growth strain, proportional to the gypsum concentration, which quantifies the effect of gypsum formation on the stress field in the system,
- defining a chemical damage parameter, proportional to the concentration of calcium-silicate-hydrate, which quantifies the loss of structural integrity of the domain.

Finally, the mechanical problem, based on a continuum damage model, is solved. For this, a mechanical damage parameter is defined for which a regularisation method similar to that presented in [7] is used. This parameter represents the amount of micro-cracks in a region. The presence of damage accelerates additional transport of dissolved ions through the micro-cracks of the material. Therefore, the diffusion coefficient is assumed to degrade from the diffusion coefficient of the intact material as a function of mechanical damage. This makes the framework two-way coupled.

RESULTS

The proposed model is applied on a benchmark geometry, based on an ongoing experimental program. In the future, the model will be used to simulate realistic geometries of sewer systems. Figure 1 shows the formation of a corrosion front in a concrete block (from the exterior to the interior of the domain), which can be identified with respect to several key

*Corresponding author. E-mail: F.A.M.Rooyackers@tue.nl

parameters such as the gypsum concentration and mechanical damage. It can also be seen that stresses can only develop in the remaining intact concrete.

A parameter variation study is currently being performed in addition to an experimental campaign, which will be used in the future to calibrate the model.

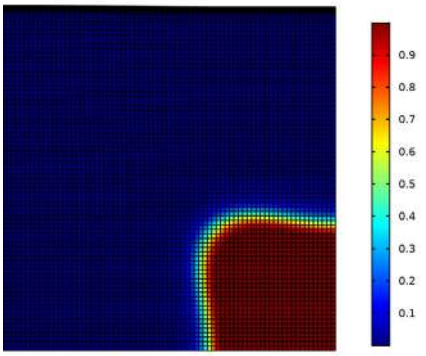
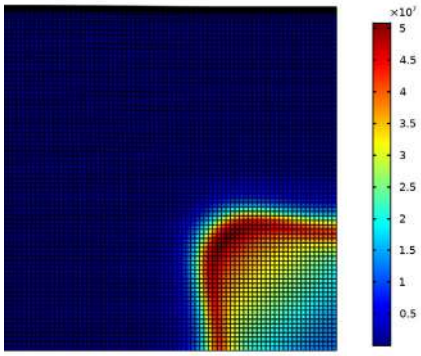
(b) $CaSO_4$ (gypsum) Solid concentrations



(c) Mechanical Damage Parameter



(d) Tresca Stress

Figure 1: Corrosion front (in terms of different relevant parameters) on a concrete domain subjected to a sulfuric acid solution of pH of 1, after a simulation time of 12 years. A square concrete block has been considered. Due to symmetry, only a fourth of it has been modeled.

CONCLUSIONS

In conclusion, the model presented in this study is capable of representing a corrosion front in concrete subjected to sulfuric acid attack, while accounting for the mechanical degradation of structural properties in the damaged zone. The proposed framework may be used in the future to improve the guidelines for the design of concrete sewer systems.

COMPARISON OF CONSTITUTIVE MODELS DESCRIBING STRESS SOFTENING OF RUBBER MATERIALS

Alexander Ricker*[1,2], Nils Kröger[1], and Peter Wriggers[2]
[1]Deutsches Institut für Kautschuktechnologie e.V., Eupener Straße 33, 30519 Hannover, Germany
[2]Institute of Continuum Mechanics, Leibniz Universität Hannover, Appelstraße 11, 30167 Hannover, Germany

Summary Several authors presented benchmarks of hyperelastic models for rubberlike materials, see e.g. [4, 2]. This contribution continues these comparisons and analyzes nine softening models describing the well-known Mullins Effect. For this purpose, multi-hysteresis experiments in several loading modes were conducted. The softening models are combined with the most promising strain energy functions and fitted to this data. Besides the fitting quality and parameter correlation, theoretical background, thermodynamic aspects and numerical details are discussed.

INTRODUCTION AND SCOPE OF CONSIDERED MODELS

Earliest constitutive models for rubber materials which are suitable for large deformation in three-dimensional analyses date back to the 1940s, e.g. Mooney-Rivlin and Neo-Hooke model. These simple models reproduce nonlinear, but purely elastic behaviour applicable for unfilled rubber under moderate loads. Since then, many authors invested much time and effort in more realistic and sophisticated models reproducing the inelastic phenomenology of filled rubber, see [1].

One important branch of models includes those which describe the typical material softening of rubber, commonly called Mullins effect. This contribution reviews such softening models which reproduce the idealized Mullins effect, viz. neither permanent set nor equilibrium hysteresis nor continuous softening will be considered, see for instance Fig. 1 and the associated explanation in [5]. Further, the considered models can be combined with any basic strain energy function. They are classified into three groups depending on the type of the internal variable: 1. Virgin state variable (pseudo-elasticity), 2. Damage variable, 3. Amplification variable. All tested models are listed in Tab. 2. They are compared with respect to several benchmark assessment criteria like fitting quality, number of parameters and their correlation, run time, robustness and others.

Table 1: Considered hyperelastic models and fitting results. *slightly modified due to numerical reasons, **generalized

EXPERIMENTS AND CHOICE OF BASIC STRAIN ENERGY FUNCTION

The most important criterion is probably the fitting quality to experimental findings. For this purpose, quasi-static multihysteresis experiments with carbon black filled, sulphur-linked EPDM under uniaxial, planar (also pure shear) and equi-biaxial tension were conducted. Load amplitudes up to 400 %, 200 % and 70 %, respectively, were considered. See Fig. 1(left) for the test procedure in case of uniaxial loading.

The fitting quality depends crucially on the employed basic strain energy function. Therefore, a short list from the huge number of strain energy functions which can be found in literature (see e.g. [4]) is compiled in Tab. 1. On the one hand, these models are fitted simultaneously to the very last cycle of the multihysteresis experiments. On the other hand, the peaks of each load amplitude are extracted and considered for fitting. In both cases, the least-squares method is used to minimize the error sum regarding the absolute 2nd Piola-Kirchoff stress. The results are given in terms of the root mean square error and the average parameter correlation. Very good fits are obtained from the strain energy function proposed by Amin et al. (2006). Hence, this one serves as the basic strain function in the following section.

PARAMETER FITTING OF SOFTENING MODELS AND CONCLUSION

Next, the softening models listed above are fitted to the experimental data. Instead of extracting particular cycles or data points, the whole experiments are considered now. The results are listed in Tab. 2. The class of softening models using a virgin state variable yields clearly the best results. Within this class, the model by Wrubleski and Marczak (2015) stands out from the rest. Even reducing its number of parameters by fixing $q = \frac{1}{2}$ leads to very good results with $\mathrm{RMSE} = 0.16335$ MPa and a comparatively low average parameter correlation of 0.3748969. The fitting quality is depicted in Fig. 1(right).

OUTLOOK

Other relevant criteria for material models are their run time and robustness, viz. sensitivity to the mesh and time step size. For testing purposes, FE simulations of a rotating shear test with various spatial and temporal discretisations were carried out. To ensure similar test conditions for all models, the automatic code generation toolbox AceGen [3] is used guaranteeing fast codes and analytical material tangents. These results as well as theoretical background, thermodynamic aspects and numerical details will be discussed at the conference.

A MODEL APPROACH FOR THE FAILURE BEHAVIOR OF CERAMIC MATRIX COMPOSITES UNDER THERMAL AND MECHANICAL LOADING

Marie-Christine Reuvers*[1], Theron Guo[1], Shahed Rezaei[1], Tim Brepols[1], and Stefanie Reese[1]
[1]Institute of Applied Mechanics, RWTH Aachen University, Aachen, Germany

Summary Higher demands on material components in aerospace application result in extensive research for new materials to replace metallic engine parts. A well suited class of materials for this challenging environments are ceramic matrix composites (CMCs). Their fracture toughness compared to classical ceramics is increased by an additional fibrous reinforcement. Although the additional fibers are also of ceramic origin, the resulting composite improves in ductility, due to the interface manufacturing process. The result is a pseudo-plastic material response, similar to metal. This contribution focusses on the development of a thermomechanical model for the various failure mechanisms of CMCs. Therefore two damage formulations are combined: a continuum damage approach to account for brittle matrix failure and an interface model based on classical cohesive elements.

INTRODUCTION

Ceramic matrix composites (CMCs) or technical ceramics were developed as an enhancement of classical ceramic materials to overcome previous limitations such as for example low fracture toughness and brittle failure under mechanical or thermomechanocal loading. This enables this new class of materials for use in aerospace engines which are exposed to high temperatures, oxidizing environments and have to withstand numerous load cycles during their lifetime. Until now most engine components are made out of metal alloys, resulting in a rather short component lifespan. The use of CMCs in these kind of surroundings increases the temperature resistance and therefore allows for higher service temperatures leading to a better utilisation factor of the engine. In addition to the high temperature stability, their corrosion resistance as well as their low weight makes CMCs attractive for aerospace application. On the other hand ceramic materials are considered relatively brittle in comparison to metals. To counteract this phenomenon CMCs consist of ceramic fiber bundles, the so called tows embedded in a ceramic matrix, often in a woven manner. To achieve a plastic material response similar to metals, the interface of technical ceramics is designed to be weak. In the case of damage, a crack that develops in the matrix, evolves until it reaches the interface, there it deflects, leaving the fiber undamaged. This way the fibers can separate individually from the matrix and still carry load until the final damage state, the fiber sliding and rupture, is reached. There are two different ways to generate a weak interface. Either by using a highly porous matrix material or through an additional coating on the fibers with a lower fracture energy compared to the ceramic material. For our application, the latter method is more relevant. Still the coating interphase is neglected during simulation, its effect however is captured in the modelig of the inteface. [1, 2]

This work focusses on the development of a general modeling strategy for various CMC scales using multiple damage models. As can be seen in Fig.1 the delamination between several plies or the separation of the weak interface between matrix and tow is modeled using an interface model based on [3] which predicts cohesive behavior. The brittle matrix is repesented by an elastic gradient-extended damage formulation based on a more general model by [4, 5]. Both formulations are thermocoupled to realistically account for the material degradation under high thermal loading.

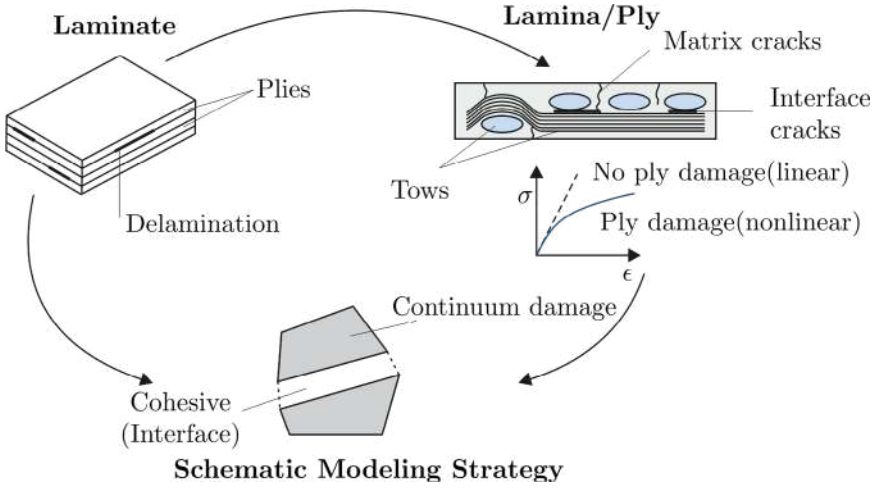

Figure 1: Schematic modeling strategy for different CMC scales using continuum damage and cohesive behavior.

INTERFACE BEHAVIOR

Based on the work of [3] and [4] a thermodynamically consistent interface formulation was derived, in accordance with the principals of [6]. The model predicts the separation in the interface of delaminating materials under thermal and mechanical loading. Taking the frictional behavior between the two components into account, also the subsequent failure mode after the interface separation is considered. The mechanical part of the Helmholtz free energy can be divided into four parts:

$$\psi = \psi_e(\boldsymbol{g}, D, \theta) + \psi_d(\xi_d, \theta) + \psi_g(\boldsymbol{g}) + \psi_f(\boldsymbol{g}^e).$$

The elastic part $\psi_e(\boldsymbol{g}, D, \theta) = (1-D)^b \, \frac{1}{2} \, \boldsymbol{g}^T \, \boldsymbol{K}^\theta \, \boldsymbol{g}$ depends on the damage variable D, as well as the damage exponent b. With the vector $\mathbf{g}$ the gap between the separating bodies is indicated, split into normal (N) and tangential (T) direction while the temperature dependent interface stiffness for both directions is embedded in $\mathbf{K}^\theta$. A nonlinear damage hardening $\psi_d(\xi_d) = \frac{r_i^\theta}{1-\exp(-s_i)} \left(\xi_d + \frac{\exp(-s_i \xi_d) - 1}{s_i} \right)$ is given through as a function of the interface material specific damage parameters r_i^θ and s_i. By $\psi_g(\boldsymbol{g}) = \frac{1}{2} K_p \langle -g_N \rangle$ a penalty term is given, that prevents penetration of the two bodies, depending on the opening in normal direction and the penalty stiffness K_p. To capture frictional behavior between the components a split of the gap in tangential direction in an elastic and a frictional part $g_T = g_T^e + g_T^f$ is proposed after [7]. With the use of the modified Coulomb's law of friction, the last part of the Helmholtz free energy follows to $\psi_f(\boldsymbol{g}^e) = H(-g_N) \left(\frac{1}{2} c_T \, (g_T^e)^2 \right)$, $H(-g_N) = \begin{cases} 1 & \text{if } g_N \leq 0 \\ 0 & \text{if } g_N > 0 \end{cases}$, depending on the initial stiffness c_T. In analogy to [8] the parameters $\mathbf{K}^\theta$, r_i^θ and the onset of damage Y_0^θ are dependent on the temperature to capture thermal effects. To complete the model equations a heat flow $q(g_\theta, D^\theta) = -((1-D^\theta)k_s + k_a) g_\theta$ based on [9] is introduced, depending on the thermal damage variable D^θ, the thermal conductivity of the solid k_s and the gaseous k_a phase as well as a temperature jump g_θ.

BRITTLE MATRIX DAMAGE

The damage in the matrix material is captured using an elastic gradient-extended damage formulation, based on a more general model by [4, 5]. Note that the plastic part of the model is neglected here, due to the brittle nature of the ceramic material. The free energy

$$\psi = (1-D)^2 \psi_e(\boldsymbol{\varepsilon}_e) + \psi_d(\xi_d) + \psi_{\bar{d}}(D - \bar{D}, \nabla \bar{D})$$

is split into an elastic part $\psi_e(\boldsymbol{\varepsilon}_e) = \frac{1}{2} \boldsymbol{\varepsilon}_e \cdot \mathbb{C} \, [\boldsymbol{\varepsilon}_e]$ and a damage hardening term $\psi_d(\xi_d) = r_m \left(\xi_d + \frac{\exp(-s_m \xi_d) - 1}{s_m} \right)$ depending on the matrix material specific damage parameters r_m and s_m. To conclude a micromorphic extension $\psi_{\bar{d}}(D - \bar{D}, \nabla \bar{D}) = \frac{A}{2} \nabla \bar{D} \cdot \nabla \bar{D} + \frac{H}{2} (D - \bar{D})^2$ is introduced as a function of the micromorphic damage $\bar{D}$ and its first gradient. To capture the thermal degradation of CMCs a thermocoupling of the respective elastic material parameters as well as the onset of damage is implied. In addition due to the high Young's modulus temperature differences in the material lead to high local stresses, which needs to be accounted for.

MECHANISTIC ORIGIN OF THE APPARENT SUBSTRUCTURE BOUNDARY SLIDING OF MARTENSITE IN HIGH-STRENGTH STEELS

Francesco Maresca*[1], Varvara Kouznetsova [2], William Curtin[3], and Marc Geers[2]
[1]Faculty of Science and Engineering, University of Groningen, Groningen, The Netherlands
[2]Department of Mechanical Engineering, Eindhoven University of Technology, Eindhoven, The Netherlands
[3]Institute of Mechanical Engineering,Ecole Polytechnique Fédérale de Lausanne,Lausanne,Switzerland

Summary Lath martensite is a key constituent phase in advanced high strength steels, providing the high strength. Furthermore, its combination with other phases, such as austenite and ferrite, enables to overcome the strength-ductility trade-off of conventional steels. Understanding the complex mechanical response of martensite in multi-phase steels is therefore essential to enable the control of the damage behaviour of steels. Experiments have shown that martensite has an extremely anisotropic deformation behaviour. The easiest deformation mode is the apparent sliding occurring at lath boundaries. By developing a multi-scale model that includes thin austenite films at lath boundaries, we show that the apparent boundary sliding can be rationalized by the dislocation-mediated plasticity and/or the phase transformation of the austenite, acting as a greasy layer on which the stiffer laths slide.

INTRODUCTION

New advanced high strength steels (AHSS) that are characterized by good strength and deformability are being constantly developed and improved in order to fulfill the growing demands for light-weight and safe materials. Lath martensite is a main constituent of such steels, since it provides the high strength and plays a key role in controlling the fracture behaviour. It is therefore essential to understand the fundamental mechanisms that control martensite plasticity and damage, in order to be able to improve the damage behaviour of high strength steels.

Lath martensite is characterized by a hierarchical microstructure [1], which originates from the symmetries of the martensitic transformation [2]. The body-centered-cubic (BCC) martensite crystals form after rapid quenching of the face-centered cubic (FCC) austenite, and organize into subgrains consisting of parallel stacks of elongated BCC (the laths) belonging to the same crystallographic variant – a fact that marks an important difference with the so-called "plate" martensite, where twin-related variants are found instead. Even in the presence of low alloying elements, which is the case of AHSS, all internal lath martensite boundaries can be decorated with thin, nanometer-sized films of retained austenite [3]. The hierarchical microstructure, containing subgrains with stacks of BCC martensite alternating with thin austenite film, is the focus of the modelling work presented here.

In the first part of the presentation, the lath martensite microstructure is modelled using continuum crystal plasticity, assuming dislocation-mediated plasticity to occur within the interlath retained austenite films [4]. In the second part of the presentation, the martensite microstructure with the austenite films is modelled by assuming that plasticity is carried by the phase transformation of the thin, retained austenite films [5]. Both cases lead to apparent grain boundary sliding, thus providing a mechanistic framework that rationalizes the recent observations of subgrain boundary sliding of martensite in low carbon steels [6].

LATH MARTENSITE WITH DISLOCATION SLIP IN THE AUSTENITE FILMS

One lath martensite sub-grain (called "sub-block", M) is modelled as a locally infinite laminate where both the overall deformation $\mathbf{F}^M$ and the (first Piola-Kirchhoff) stress $\mathbf{P}^M$ are the weighted averages (over the volume fraction f) of the austenite (A) and the lath (L) single-phase deformations and stresses, under the conditions of interface compatibility and equilibrium

$$\begin{aligned} &\mathbf{F}^M = f^A\mathbf{F}^A + f^L\mathbf{F}^L\,, && \mathbf{P}^M = f^A\mathbf{P}^A + f^L\mathbf{P}^L \\ &\mathbf{F}^A\cdot(\mathbf{I}-\mathbf{n}_0\otimes\mathbf{n}_0) = \mathbf{F}^L\cdot(\mathbf{I}-\mathbf{n}_0\otimes\mathbf{n}_0)\,, && \mathbf{P}^A\cdot\mathbf{n}_0 = \mathbf{P}^L\cdot\mathbf{n}_0 \end{aligned} \tag{1}$$

where $\mathbf{n}_0$ is the interface normal in the reference configuration, which is assumed parallel to a $\{111\}_A$ plane normal, thus about $\theta = 10°$ from the typical habit plane normal in FeC steels [2]. Slip in the austenite occurs parallel to such an interface. Both the austenite films and the laths are modelled using a continuum crystal plasticity framework respecting the experimental orientation relationship [4]. A rate-dependent, smeared-interface damage model is also used, that models failure at the A/L interface within the martensite [7]. Microstructural configurations with multiple sub-grains are then modelled, based on experimental micrographs, and simulated under quasi-static tensile loading conditions. Figure 1 shows the comparison between the simulation results and the experiments performed on such microstructures. The figure shows that the multi-scale model of lath martensite, including multiple sub-grains and dislocation-mediated plasticity in the thin interlath retained austenite films, can capture the stress-strain response and the global onset of necking of actual lath martensite microstructures.

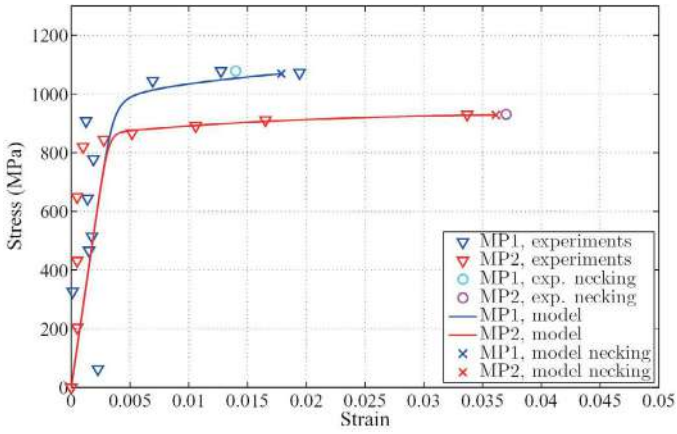

Figure 1: Comparison between simulations and experiments, reproduced from [7].

LATH MARTENSITE WITH TRANSFORMING RETAINED AUSTENITE FILMS

In low C, low-alloyed steels, the interlath austenite films can be so thin that they can hardly accommodate any dislocation plasticity. We have therefore performed detailed Molecular Dynamics (MD) simulations of the austenite-martensite interface, reproducing all the main features observed in experiments [2], see Figure 2.

A combination of crystallographic theory and atomistic modelling [2] shows that, even in absence of any dislocation in the thin retained austenite films, large deformations amounting to $\sim 90\%$ shear can be accommodated by phase transformation of the austenite, which is driven by interface migration.

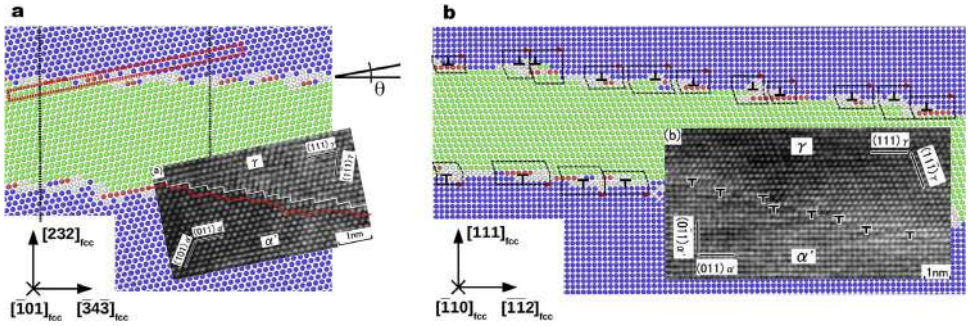

Figure 2: MD simulation of the FCC austenite/BCC martensite interface, compared with high-resolution transmission electron micrographs, viewed along **a** $[\bar{1}01]_A$ and **b** $[\bar{1}10]_A$ directions. Reproduced from [2].

CONCLUSIONS

The characteristic deformation mode of lath martensite is substructure boundary sliding at lath boundaries. We have shown, by means of multi-scale crystal plasticity and atomistic simulations, that the substructure boundary sliding can originate by the deformation of thin, nanoscale retained austenite films at lath boundaries. The austenite films can accommodate this deformation either by dislocation-mediated plasticity, or by phase transformation.

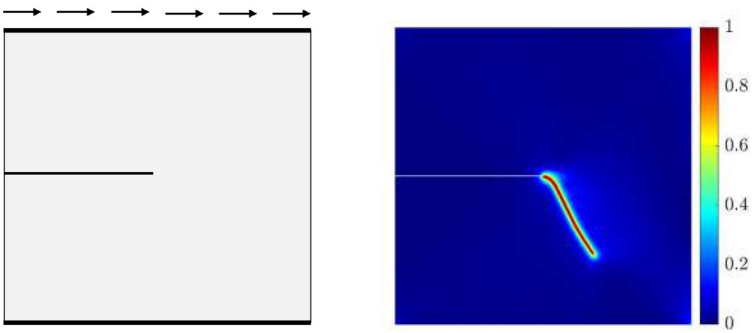
A ROBUST EXPLICIT ALGORITHM FOR PHASE-FIELD MODELING OF QUASI-BRITTLE FRACTURE

Alessandro Marengo*[1], Alessia Patton [2], Matteo Negri[3], Umberto Perego [1], and Alessandro Reali [2]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
[2]Department of Civil Engineering and Architecture, University of Pavia, Pavia, Italy 3Department of Mathematics, University of Pavia, Pavia, Italy

Summary The phase-field modeling of quasi-brittle fracture accounting for the irreversible growth of the regularization variable is considered. As a consequence of this irreversibility, the minimization problem turns into a variational inequality. A staggered solution scheme is employed to decouple the optimization algorithm. This leads to two sub-problems for the displacement and the phase field. The spatial discretization transforms the phase-field sub-problem into a symmetric linear complementarity problem. The present paper shows a robust and explicit algorithm to solve this problem.

INTRODUCTION

The phase-field model is used here for a variational approach to quasi-brittle fracture. The topology of a sharp crack is regularized or diffused into the bulk of the body with a transition function that can be interpreted as a damage variable (see [1]). A consistent thermodynamic formulation requires the damage to be a non-decreasing function during any transformation. This property is here referred to as *irreversibility* and acts as a constraint in the mechanical model.
The variational approach to fracture interprets the crack evolution within the elastic body as a minimization problem of a suitable energy functional. The irreverstibility makes the approach a constrained minimization problem and turns it into a variational inequality. This constraint is enforced in [2] with a monotonically growing driving force of the phase field (so-called history variable), while in [3] a penalty functional is introduced into the formulation to replace the constraint. Inspired by the work of [4], the current paper presents a robust and explicit iterative algorithm [5] to rigorously enforce the constraint and solve the variational inequality.



(a) *Static Scheme* (b) *Phase-Field*

Figure 1: Shear test on 2D square specimen in plane strain. The initial notch has length equal to half the domain side. The bottom edge is clamped, while the top edge undergoes a uniform horizontal displacement. The phase field ranges from $d = 0$ (undamaged material) to $d = 1$ (fully broken material).

MECHANICAL MODEL

The state variables are the displacement vector $\mathbf{u}$ and the scalar phase field d. Irreverstibility requires that $\dot{d} \geq 0$. The variational approach minimizes the total energy functional defined as follows:

$$\Pi(\mathbf{u}, d) = \mathcal{E}(\mathbf{u}, d) + \mathcal{D}(d, \nabla d) - \mathcal{W}(\mathbf{u}) \tag{1}$$

The internal energy functional $\mathcal{E}(\mathbf{u}, d) = \int_\Omega \psi(\mathbf{u}, d)\, \mathrm{d}\Omega$ measures the energy stored into the body, while the dissipation functional $\mathcal{D}(d, \nabla d) = \int_\Omega \phi(d, \nabla d)\, \mathrm{d}\Omega$ accounts for the energy dissipated due to crack propagation. The functions ψ and ϕ are respectively the free and dissipated energy per unit volume. The free energy of the unbroken material is split into its volumetric and deviatoric parts. The damage degrades the positive volumetric and the deviatoric parts only.
The dissipation functional $\mathcal{D}(d,\nabla d)$ depends on the phase field and its gradient (see [1]). The presence of the gradient term makes the constitutive behavior non-local, eliminating the pathological mesh-dependence of the softening models, at the cost of the introduction of a new field variable in the problem. Finally, the work of volume and surface actions resides

*E-mail: alessandro.marengo@polimi.it

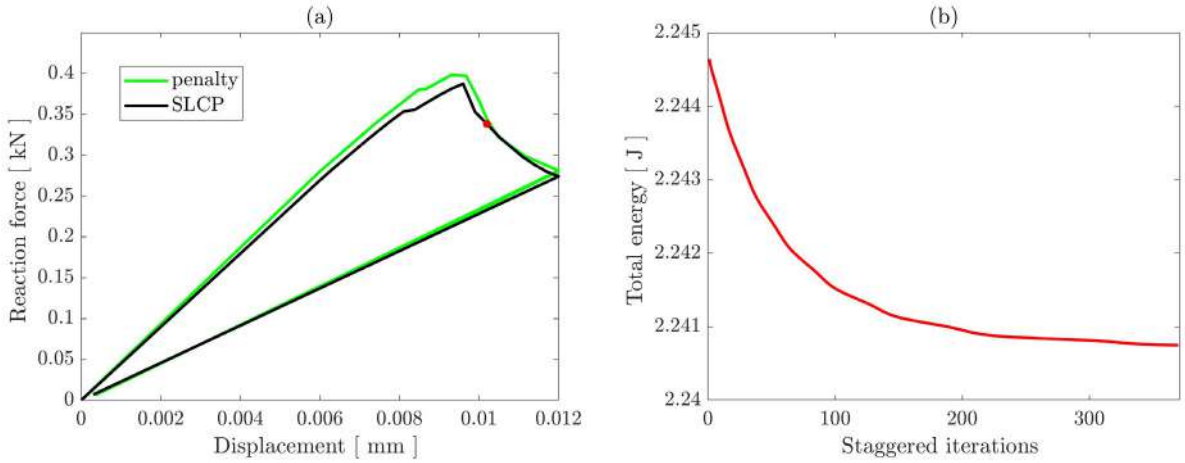


Figure 2: Loading-unloading shear test: (a) reaction force versus imposed displacement, (b) minimization of the total energy. The red marker denotes increment 15.

in the external work functional $\mathcal{W}(\mathbf{u})$.
Introducing the notation $\delta_x \Pi(x) := \Pi(x + \delta x) - \Pi(x)$, stationarity of (1) can be written as follows:

$$\delta_{\mathbf{u}} \Pi = 0 \tag{2a}$$

$$\delta_d \Pi = 0 \quad \text{with} \quad \dot{d} \geq 0 \tag{2b}$$

The irreversibility condition on the phase-field variable leads the optimization problem (2) to be a constrained minimization principle. While the stationarity with respect to the dispacement (2a) leads to a variational equation (i.e., the balance of linear momentum), the stationarity with respect to the constrained phase-field variable (2b) leads to a variational inequality (i.e., the well-known set of Kuhn-Tucker conditions).

NUMERICAL IMPLEMENTATION

Staggered Iterative Scheme A staggered scheme is adopted for the solution, since the non-convex total energy becomes convex whenever a state variable is kept fixed and the other is free. For each load increment the balance of linear momentum (2a) and the Kuhn-Tucker conditions (2b) are solved alternatively until a convergence criterion is met.

Symmetric Linear Complementarity Problem (SLCP) The spatial discretization turns the variational inequality (2b) into a so-called *Symmetric Linear Complementarity Problem*. Its standard form reads:

$$\mathbf{f}(\Delta \mathbf{d}) \cdot \Delta \mathbf{d} = 0 \quad , \quad \mathbf{f}(\Delta \mathbf{d}) \geq \mathbf{0} \quad , \quad \Delta \mathbf{d} \geq \mathbf{0} \tag{3}$$

where $\Delta \mathbf{d}$ is the vector of nodal phase-field increments; $\mathbf{f}(\Delta \mathbf{d}) := \mathbf{Q}\,\Delta \mathbf{d} + \mathbf{q}$ is the activation function; $\mathbf{Q}$ is a symmetric, positive definite matrix and $\mathbf{q}$ is a vector accounting for the driving force. The problem is *symmetric* due to the symmetry of matrix $\mathbf{Q}$ deriving from the variational nature of the approach and is *linear* because of the linearity of the activation function $\mathbf{f}(\Delta \mathbf{d})$ in the phase-field increment $\Delta \mathbf{d}$. In the current paper, (3) is solved using the explicit and iterative algorithm proposed by Mangasarian in [5], where the irreversibility constraint $\dot{d} \geq 0$ is rigorously enforced.

SIMULATIONS AND RESULTS

Numerical simulations are perfomed under the hypotesis of small displacements and quasi-statics. The phase-field profile of a loading-unloading shear test on a 2D specimen in plane strain is shown in Figure 1. In Figure 2(a) the reaction force is plotted versus the imposed displacement and is compared with the corresponding result in [3], while the evolution of the total energy during the staggered iterations for a typical load increment is reported in Figure 2(b).

REGULARIZATIONAL APPROACH TO ANISOTROPIC DUCTILE DAMAGE: APPLICATION TO LOW-CYCLE-FATIGUE

Kai Langenfeld[1], Kerstin Möhring[2], Frank Walther[2], and Jörn Mosler[*1]
[1]Institute of Mechanics, TU Dortmund University, Dortmund, Germany
[2]Department of Materials Test Engineering, TU Dortmund University, Dortmund, Germany

Summary Low cycle fatigue is in general associated with large plastic strains accompanied by the formation and coalescence of pores. Considering continuum damage mechanics, there are many local constitutive models for ductile damage in the literature. These local models, that do not involve any length scale are ill-posed from a mathematical point of view. In order to regularize the resulting mesh dependency, the micromorphic approach will be applied. Within this talk, it will be shown that a straightforward implementation of the micromorphic approach is not suitable to regularize ductile damage models of Lemaitre-type. A modified version will be thus proposed and applied to an anisotropic model for ductile damage. This modified model will be adapted to low cycle fatigue and its capabilities are shown by illustrative examples.

KINEMATICS

Let $\boldsymbol{u}(\boldsymbol{X})$ be the displacement field of all points $\boldsymbol{X}$ of body $\mathcal{B}$. Then, the Hencky strain tensor follows as $\boldsymbol{\varepsilon} = \frac{1}{2}\ln(\boldsymbol{C})$ with $\boldsymbol{C}$ being the right Cauchy-Green tensor. The additive split of the Hencky strain tensor in an elastic part and a plastic part $\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^{\mathrm{e}} + \boldsymbol{\varepsilon}^{\mathrm{p}}$, cf. [1], allows to extend linearized kinematics to finite strains while preserving the local constitutive framework.

CONSTITUTIVE MODEL

The constitutive model is adopted from [2, 3] and based on the principal of strain energy equivalence, cf. [4]. The gradient-enhanced Helmholtz energy reads

$$\psi = \psi^{\mathrm{e}}(\boldsymbol{\varepsilon},\, \boldsymbol{\varepsilon}^{\mathrm{p}},\, \boldsymbol{b}) + \psi^{\mathrm{p}}(\boldsymbol{a},\, \boldsymbol{k};\, \boldsymbol{b}) + \psi^{\mathrm{pen}}(\boldsymbol{b},\, \boldsymbol{\varphi_b}) + \psi^{\mathrm{grad}}(\nabla\boldsymbol{\varphi_b}) \tag{1}$$

with $\boldsymbol{a}$ and $\boldsymbol{k}$ being two second-order tensors associated with kinematic and isotropic hardening. The tensor $\boldsymbol{b}$ describes the integrity of material points, i.e., $\boldsymbol{b} = \boldsymbol{I}$ denotes intact material points and $\boldsymbol{b} \to \boldsymbol{0}$ fully damaged material points. Tensor $\boldsymbol{\varphi_b}$ is coupled to integrity tensor $\boldsymbol{b}$ in terms of the micromorphic regularization technique [5, 6]. The dual variables then follow as

$$\boldsymbol{\sigma} = \frac{\partial\psi}{\partial\boldsymbol{\varepsilon}},\quad \boldsymbol{\omega} = \frac{\partial\psi}{\partial\boldsymbol{\varphi_b}},\quad \boldsymbol{\alpha} = -\frac{\partial\psi}{\partial\boldsymbol{a}},\quad \boldsymbol{\kappa} = -\frac{\partial\psi}{\partial\boldsymbol{k}},\quad \boldsymbol{\beta} = -\frac{\partial\psi}{\partial\boldsymbol{b}}\,. \tag{2}$$

The model is completed in terms of evolution equations falling into the framework of Generalized Standard Materials, cf. [7], i.e., the dissipation inequality is automatically fulfilled. The corresponding plastic potential g reads

$$g = \Phi(\boldsymbol{\sigma}, \boldsymbol{\omega},\, \boldsymbol{\alpha},\, \boldsymbol{\kappa};\, \boldsymbol{b}) + \Gamma_{\boldsymbol{\alpha}}(\boldsymbol{\alpha};\, \boldsymbol{b}) + \Gamma_{\boldsymbol{\beta}}(\boldsymbol{\beta};\, \boldsymbol{b})\,, \tag{3}$$

and consists of the yield function Φ and the non-associative parts $\Gamma_{\boldsymbol{\alpha}}$ and $\Gamma_{\boldsymbol{\beta}}$. The aforementioned modification of the

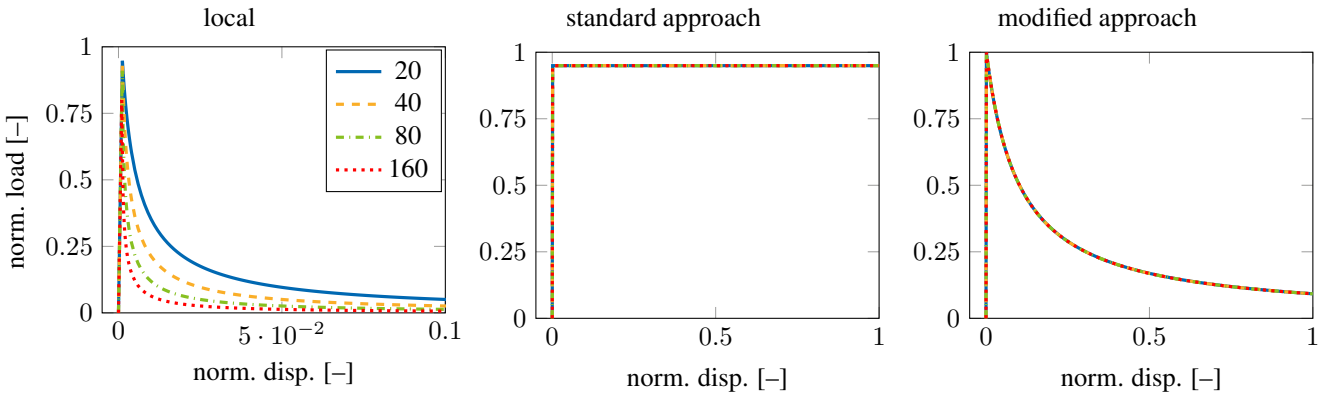

Figure 1: One-dimensional truss with an imperfection: Load-displacement diagrams predicted by: (left) the local model, (middle) the standard micromporphic model and (right) the modified micromorpic model for different finite element meshes (20, 40, 80 and 160 finite elements)

micromorphic approach is the direct dependence of the yield function on ω, that can be rewritten as a gradient contribution, cf. [8].

Fig. 1 highlights this effect by the example of a one-dimensional truss with an imperfection. The left figure shows the typical localization effect when considering models without internal length scale. Contrary, both the standard micromorphic approach and the modified version yield mesh independent results. Yet, only the modified version shows a softening response. By considering two-dimensional boundary value problems, it is shown in [8] that the standard approach leads, similar to the local model, to mesh-dependent results.

EXTENSION TO LOW CYCLE FATIGUE

In order to adapt the model to low cycle fatigue, certain changes to the constitutive equations are introduced. To be more precise, the adapted model is able to simultaneously represent linear and non-linear isotropic hardening as well as non-linear kinematic hardening. Furthermore the damage evolution is triggered in dependence on the dissipated plastic work during deformation, i.e., the damage evolution starts as soon as the dissipated plastic work exceeds a material specific parameter as suggested by [9].

A first impression of the final model is given in Fig. 2, in which the model is calibrated with respect to a cyclic tensile test. The left plot shows the load-displacement diagram at 77 cycles and the right plot the load-displacement diagram

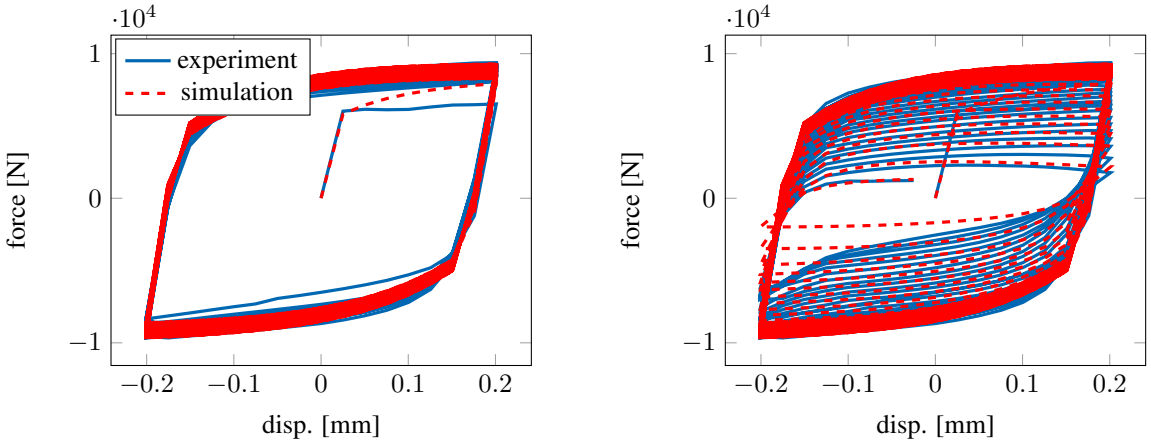

Figure 2: Cyclic tensile test – left: load-displacement diagram at 77 cycles; right: load-displacement diagram at 93 cycles (failure)

until failure after 93 cycles. It can be seen that the extended model is able to simulate the cyclic hardening as well as the material degradation in a mesh objective manner.

CONCLUSION

A constitutive model suitable for the analysis of ductile damage with respect to low cycle fatigue was presented. It is based on the local constitutive framework proposed in [2, 3] and it has been gradient-enhanced by means of the micromorphic regularization suggested in [5, 6]. It was shown, that a straightforward implementation of the micromorphic approach fails in regularizing the aforementioned model and an alternative method was thus elaborated. The resulting gradient-enhanced model was adapted to low cycle fatigue, i.e., the evolution equations for isotropic and kinematic hardening as well as the evolution equation for anisotropic ductile damage have been amended. It was shown that the final model indeed captures the low cycle fatigue behaviour observed in experiments – qualitatively as well as quantitatively.

VARIATIONAL FORMULATIONS AND COMPARISON OF REGULARIZED DAMAGE MODELS

Patrick Kurzeja*[1], Kai Langenfeld[1], and JörnMosler[1]
[1]Institute of Mechanics, Technical University Dortmund, Dortmund, Germany

Summary Gradient-enhanced models and viscous regularization are two prominent and yet conceptually different examples for regularization approaches in fracture modeling. They implement a regularization length using a gradient or a viscosity combined with a characteristic loading time scale, respectively. This work aims at providing a comparison between these methods and the classical fracture energy concept by deriving and utilizing a variational formulation. This allows to evaluate the well posedness of the problem at hand and to analyse the capabilities to rigorously capture localization and regularization. A numerical example of crack propagation will demonstrate individual peculiarities of the different approaches by means of the evolving fracture energy.

REGULARIZATION APPROACHES

Predicting failure is crucial to determine the limitations and performance of mechanical components during their design, production and application processes. The variety of loading conditions (e.g., static/dynamic, mechanical/thermal, uniaxial/mulitaxial) can yield complex stress states and equally complex responses of the material of interest that drive the evolution of damage until failure. Several underlying microscopic mechanisms can interact, e.g., multiple slip planes in crystals or material discontinuities such as interfaces between the host matrix and inclusions that support the nucleation of micro cracks by stress amplification at high cycles. After potential elastic and/or plastic pre-deformation, failure can finally emerge in the form of cracks or shear bands showing strain localization [1]. The present work aims at the investigation of quasi-static crack propagation in the context of brittle damage evolution and its implementation into a finite-element framework. This evolution, however, can cause a drastic change in the set of the governing equations that breaks, amongst others, the well posedness of the mathematical problem by loss of ellipticity and the mesh independence of the numerical implementation.

Various modelling approaches have been developed to address crack propagation in brittle materials of which we can only review selected examples. Models for damage in brittle materials typically capture the interaction of void nucleation and growth, micro-cracking, micro-scale yielding, interface leakage and others leading to degradation of the material. Also the numerical implementation offers different approaches, e.g., the location of the displacement discontinuities within finite bulk elements or in the form of surface elements [2], not to mention phase field and elaborated X-FEM methods.

The fracture energy concept, e.g., according to the Griffith criterion [3], provides an explicit (surface-based) energy criterion with a dissipation potential that implicate a characteristic length scale. Crack growth is initiated by reaching a critical energy release rate with suitable constraints (irreversibility, energy bounds, non-interpenetration). Its advantages are a straight-forward interpretation of the associated energy related to the fracture domain and the availability of comprehensive analytical studies of benchmark problems and mathematical properties [4]. It will thus serve as a reference for comparison. Gradient-enhanced regularization serves as a well-known, representative candidate in the class of generalized continua that provide higher-order regularization (e.g., micromorphic) and fully non-local regularization (e.g., integral based) to introduce the necessary additional length scale [5]. Damage is usually coupled to an additional field variable by a penalty term, while the gradient of the variable allows to account for the non-local nature. Viscous regularization approaches, in contrast, employ an aritificial viscosity that is combined with a dynamic load, following the ideas of visco-plasticity [6]. They utilize a time derivative instead of a spatial derivative, introducing the additional length scale by coupling to a viscosity [7, 8, 9].

VARIATIONAL FORMULATION

Damage models can often be recast into a variational format. Based on a rate potential that is composed of the rate of the (damage-reduced) Helmholtz free energy and the dissipation potential, $\dot{\mathcal{I}} = \dot{\Psi} + \mathcal{D}$, we can briefly introduce an initial potential for body $\mathcal{B}$ under volumetric loading $\mathbf{b}$ and tractions $\mathbf{t}^*$ at its Neumann-boundary

$$\mathcal{E} = \int_{\mathcal{B}} \dot{\mathcal{I}} \, \mathrm{d}V - \int_{\mathcal{B}} \rho \, \mathbf{b} \cdot \dot{\mathbf{u}} \, \mathrm{d}V - \int_{\partial \mathcal{B}_{\mathrm{N}}} \mathbf{t}^* \cdot \dot{\mathbf{u}} \, \mathrm{d}A, \tag{1}$$

where $\mathbf{u}$ is the displacement field and ρ is the density. Starting from strain $\boldsymbol{\varepsilon}$ and internal variables $\boldsymbol{\alpha}$ for strain-softening, extensions like convexifications with artificial stiffness, artificial viscosity via relaxation or gradient-based extensions can be introduced to achieve different types of regularizing damage models [9]. The variational formulation (if available) is then beneficial to evaluate the models by the stationarity condition and its (first and second) variation with respect to:

- well posedness (existence, uniqueness, stability), convexity, localization, regularization.

*Corresponding author. E-mail: patrick.kurzeja@tu-dortmund.de.

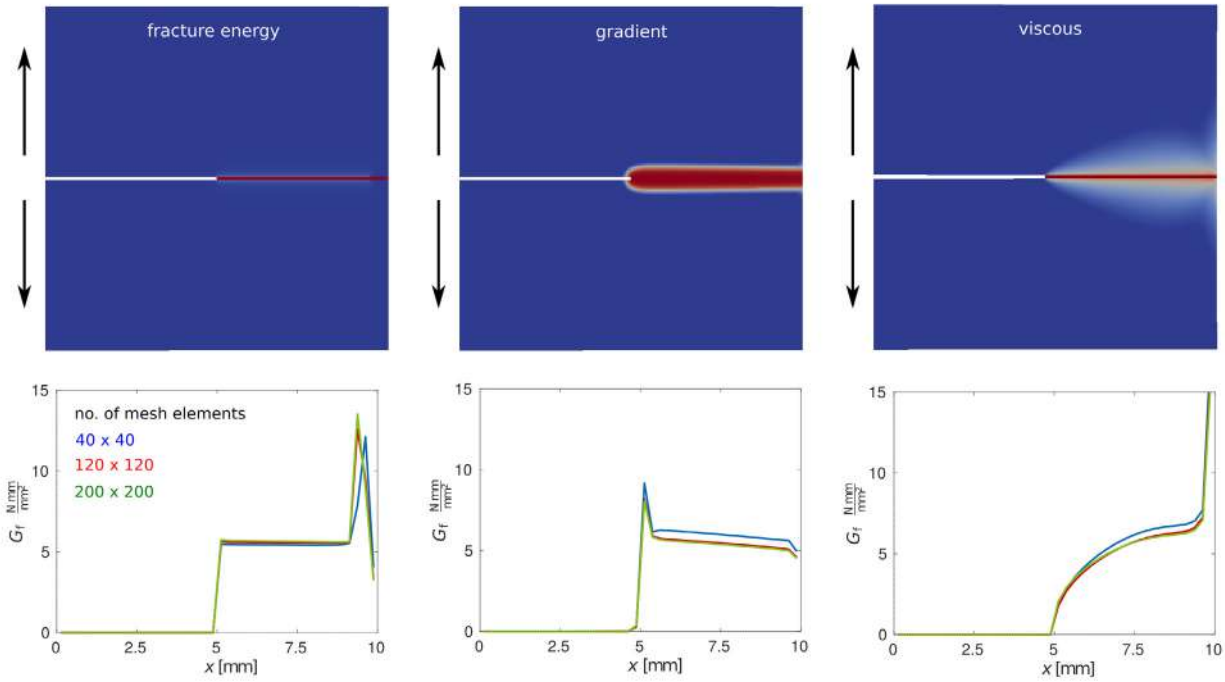

Figure 1: Numerical simulation of the fracture energy concept, a gradient-enhanced method and viscous regularization for a single propagating crack in a notched plate. Top row: damage field; bottom row: fracture energy integrated over vertical axis.

NUMERICAL EXAMPLE

In addition to the analytical investigation of the aforementioned modelling approaches, their numerical implementation and the study of more complex boundary value problems provide further interpretation of the physical behaviour. More specifically, the integrated fracture energy along the crack path can be studied and shows characteristic peaks depending on the regularizatoin technique, see Fig. 1. It peaks at the end of the crack path for the fracture-energy approach, strongly increases at the same location for the viscous approach and exhibits a less pronounced peak at the crack initiation tip for the gradient-enhanced model. A constant energy plateau is only observed for the fracture-energy and shows a strong incline for the viscous damage model. Accordingly, the damaged zone of the viscous regularization resembles the thin damage distribution of the fracture-energy approach with additional branching while the gradient-enhanced model predicts a distinct but broader damage zone. Mesh independence has been assured for all concepts.

CONCLUSION

Models for damage in brittle materials face various analytical and numerical challenges as they aim at predicting strain softening and guaranteeing mesh independence within a well-posed framework. Their variational formulation allows to compare their individual mathematical properties and to highlight differences. The present work highlights the gradient-enhanced and viscuous regularization against the background of the fracture-energy concept. The crack propagation of the numerical boundary value problem shows quantitative similarity with qualitative differences with respect to the evolution of the integrated fracture energy and the corresponding damage zones.

HYDROGEN-ASSISTED CRACKING OF ELASTIC-GRADIENT PLASTIC SOLIDS

Philip K. Kristensen[1], Christian F. Niordson[1], and Emilio Martínez-Pañeda [2*]
[1]Department of Mechanical Engineering, Technical University of Denmark, Kgs. Lyngby, Denmark
[2]Department of Civil and Environmental Engineering, Imperial College London, London, UK

Summary A novel framework for modelling hydrogen-assisted cracking (HAC) in elastic-plastic solids has been developed based on recent advances in solid mechanics. A stress-driven hydrogen transport model is utilized in conjunction with strain gradient plasticity, which is crucial for accurate crack-tip stress predictions. Initiation and propagation of cracks are captured using a novel phase field fracture model with a hydrogen dependent fracture energy. A quantum-mechanically informed approach is utilized for determining the relation between fracture energy and local hydrogen occupancy. The framework is shown to capture the quasi-cleavage fracture mode often observed in HAC failure at realistic material values when realistic hydrogen concentrations are present.

INTRODUCTION

The adverse influence of hydrogen on the fracture resistance of steels and other metals is an important issue in several industries. Hydrogen has been known to reduce the fracture toughness of modern high-strength steels by up towards 90%. The phenomenon spans multiple material scales and is highly interdisciplinary; predictive models that can capture crack initiation and growth at engineering scales have yet to be developed. A tool that has been gaining significant attention in recent years is the phase-field fracture model. Phase field provides a robust framework for capturing arbitrarily complex crack patterns, including initiation and branching of cracks. The framework has been applied to a wide variety of problems, including hydrogen embrittlement in elastic solids [1].
For elastic-plastic solids, crack tip stresses in the plastic zone are significantly reduced when geometrically necessary dislocations (GNDs) are not accounted for. The influence of GNDs as expressed in strain gradient plasticity (SGP) theories have been shown to have a critical effect on the propagation of sharp cracks [2]. In the case of HAC, accurate crack tip stresses are doubly important, as the diffusion of hydrogen in the metal lattice is known to depend on the stress field [3]. HAC models incorporating the role of plastic strain gradients have shown an unprecedented agreement with experiments [4]. However, a model able to explicitly capture crack growth, hydrogen transport and strain gradient plasticity has yet to be developed; this motivates the present work.

MATERIAL MODEL

An advanced material model is developed using four main elements. First, a phase field fracture model, which expresses material damage using a scalar field to approximate the Griffith criterion in a continuous manner. Second, a higher order SGP model based on [5], implemented using a viscoplastic law. Third, a mass transport model, based on an extended version of Fick's law, in which the gradient of the stress fields acts as a driving force for hydrogen diffusion. Fourth, A quantum-mechanically informed approach for coupling the fracture energy of the solid to the occupancy of hydrogen in a critical lattice plane, in the manner proposed in [6].
The material model is numerically implemented in a finite element framework, as described in [7]. A moving boundary condition prescribing the hydrogen concentration of the environment to the growing crack surface has also been implemented using a penalty approach. The model is applied to a series of small-scale yielding problems in plane strain where an infinite domain with a crack is approximated by a large semicircular domain. A remote K-field is applied to the far boundary, corresponding to pure mode I loading. The purpose of these simulations is to obtain a series of fracture resistance curves to determine the influence of important material and model parameters, as well as the influence of hydrogen.
In addition, to showcase the potential engineering applications of the model, the example of a pipeline which has suffered pitting corrosion damage has been considered. The problem has been emulated by modelling a quarter section of a pipe and prescribing a series of small pseudo-random pit-like defects to the inner surface. A combined load of tension and internal pressure is applied, leading to growth and coalescence of critical corrosion defects under the effect of an internal environment in the pipeline which is assumed to contain hydrogen.

NUMERICAL RESULTS

The application of this advanced deformation-diffusion-damage model to plane strain mode I fracture under small-scale yielding has provided a series of fracture resistance curves that show that the model complies with expected trends. Increases in plastic length scales relative to the plastic zone size lead to reduced fracture resistance, as would be expected due to the associated increased gradient hardening, which also increases. More importantly, the size of the length scale of the phase field model relative to the plastic zone size can be set such that the effective critical strength in the absence of hydrogen is on the order of the lattice strength (approximately 10 times the initial yield strength). At such an effective critical strength, it is shown that even for realistically small plastic length scales the presence of modest amounts of

*Corresponding author. E-mail: mail@empaneda.com.

hydrogen is sufficient to make crack propagation possible, as shown in figure 1a. The implication of this finding is that the quasi-cleavage fracture mode common to HAC specimens is rationalized by accounting for GNDs and the deleterious effect of hydrogen on the cohesive strength of the metal lattice.
In addition to capturing crucial features such as increased crack-tip stresses, sub-critical crack initiation and quasi-cleavage, diffusion-controlled crack growth where transport of hydrogen is the rate-limiting component of crack growth is also captured.
In the example of the damaged pipeline, an example crack pattern can be seen in figure 1b. The pipe has initially formed a radial tension-dominated crack, after which ongoing loading from internal pressure causes some defects to grow through the thickness and coalesce axially.

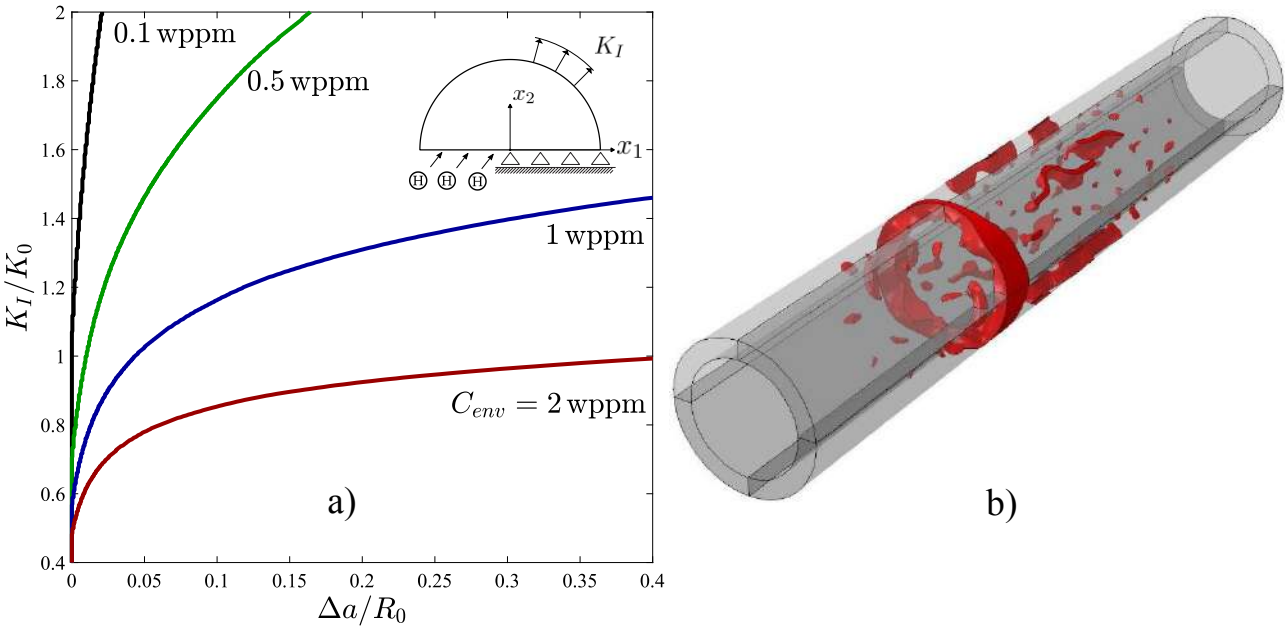

Figure 1. **a)** Representative results in small scale yielding. Increase in crack length Δa relative to initial plastic zone size R_0 at realistic material values for varied applied hydrogen concentrations. At an environment hydrogen concentration of 0.5 wppm or above, steady state fracture toughness tends towards a reasonable finite value. **b)** Damage caused by ongoing load by tension and internal pressure to a pipeline which has initially suffered pitting corrosion damage. Red areas signify damaged material. The small defects shown are representative of the size of all initial defects.

CONCLUSIONS

An advanced continuum model has been developed and implemented in a finite element framework. The model incorporates key elements necessary to capture the physics of hydrogen-assisted cracking, among which strain gradient plasticity is crucial. The increased crack tip stresses predicted by SGP in conjunction with the reduced fracture energy due to the effects of hydrogen jointly serve to rationalize the quasi-cleavage fracture mode, which is commonly observed in HAC failures. By virtue of being cast within a phase field fracture model, the framework can be applied to complex cracking problems as illustrated by the above pipeline example, making it a promising tool for engineering applications in the presence of hydrogen.

Summary In this paper the behaviour of the Kachanov-Rabotnov type continuum damage constitutive model are studied. Dispersion analysis as well as numerical finite element study of one-dimensional dynamic problem have been performed. In the case of non-gradient solid, it is found from numerical simulations that the width of the localisation zone is independent of the mesh size only if the loading rate is below a certain threshold value.

INTRODUCTION

In the late 1950's Kachanov and Rabotnov [4, 8] introduced a well known model to describe continuous degradation of a material. Originally they used the model to predict the creep rupture time. Since then, continuum damage mechanics has developed into an important and active field of continuum mechanics, see e.g. [5, 6, 7]. Progressing degradation of elastic properties will eventually lead to strain softening behaviour, which can result to ill-posedness of the underlying partial differential equation system. In numerical solution the ill-posedness caused by strain softening produces severe mesh size dependency. Several remedies have been proposed to alleviate or remove this deficiency: non-local integral constitutive models, adding spatial gradients, rate-dependency, etc. In the case of the Kachanov-Rabotnov continuum damage model, the evolution equation for damage has the following form

$$\dot{D} = \frac{1}{t_\mathrm{d}(1-D)^p}\left(\frac{Y}{Y_\mathrm{r}}\right)^r, \tag{1}$$

where $Y = -\rho\partial\psi/\partial D$ is the thermodynamic force dual to the damage rate $\dot{D}$, Y_r a freely chosen reference value for Y. Material parameters are p, r (dimensionless) and t_d, which has dimension of time. The most important parameters for stress-strain behaviour are r and t_d, while p effects to behaviour in the post-peak strain softening region.

Even though the Kachanov-Rabotnov damage model (1) involves rate-dependency, it does not completely resolve the pathological mesh sensitivity from the numerical solution. As it is shown in [2], to obtain a mesh independent numerical solution, the loading rate should be below a certain threshold. This is in contrast to numerical solutions in viscoplasticity.

GRADIENT ENHANCEMENT

One approach to obtain a well-posed model is to add gradient terms to the constitutive model. In damage mechanics the effect of higher-order strain gradients has been studied in [1]. Damage gradient is used in [3], however, their approach needs an additional balance equation. Here, the following gradient enhancement to the classical Kachanov-Rabotnov model is proposed:

$$\dot{D} = \frac{1}{t_\mathrm{d}(1-D)^p}\left(\frac{Y}{Y_\mathrm{r}}\right)^r \langle 1 + \ell^2\Delta D\rangle, \tag{2}$$

where Δ is the Laplace operator, ℓ is an additional material parameter having dimension of length and $\langle\bullet\rangle$ denotes the Macaulay brackets, i.e. the positive part of its argument.

To investigate the regularizing behaviour of the Kachanov-Rabotnov continuum damage model, a one-dimensional finite element and finite difference analyses are carried out. A bar fixed at $x = L$ and subjected at $x = 0$ to a linearly increasing displacement $u(0) = \eta\epsilon_\mathrm{r}L/t_\mathrm{d}$ ($L = c_\mathrm{e}t_\mathrm{d}$, where c_e is the elastic wave speed) has been analysed with different uniform mesh sizes [2]. A standard central difference scheme is used to integrate the equations of motion and in the gradient model the simple Euler forward method is used to integrate the evolution equation (2).

For the non-gradient damage model (1), the width of the localisation zone is shown as a function of the loading rate η in figure 1 for three different mesh sizes $h = L/100, L/1000$ and $L/10000$ and for the cases $r = 2, p = 1$, and $r = 4, p = 1$. As it can be seen, the width of the damage localisation zone is mesh-size independent if the loading rate satisfies $\eta \lessapprox 0.75$. Linearly interpolated finite elements for the spatial discretisation are used.

In figure 2 the damage profiles at time intervals $t_\mathrm{d}/100$ have been shown for the gradient model (2) when finite element and finite difference approach for the spatial discretisation is used. The additional material parameter has been $\ell = L/10$. Homogeneous natural boundary conditions have been used for the damage.

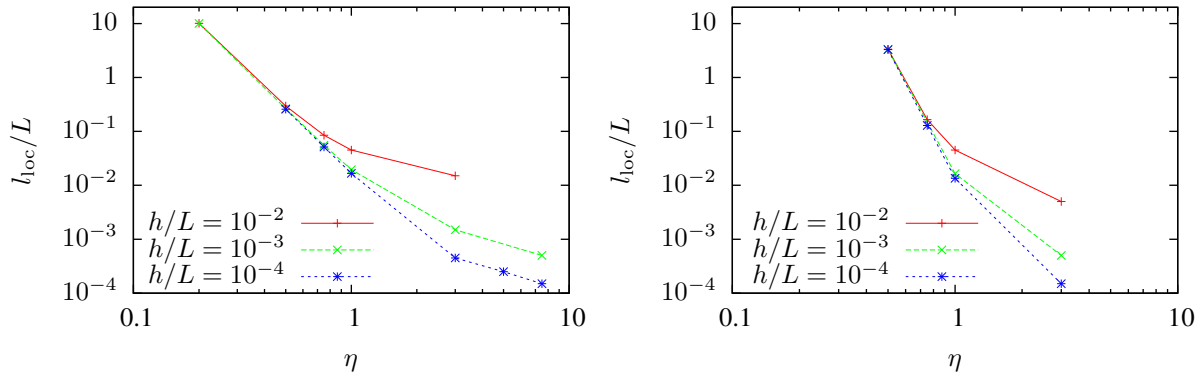

Figure 1: Damage localisation width as a function of the prescribed loading rate for the non-gradient model, $r = 2$ (lhs), $r = 4$ (rhs). In both cases $p = 1$.

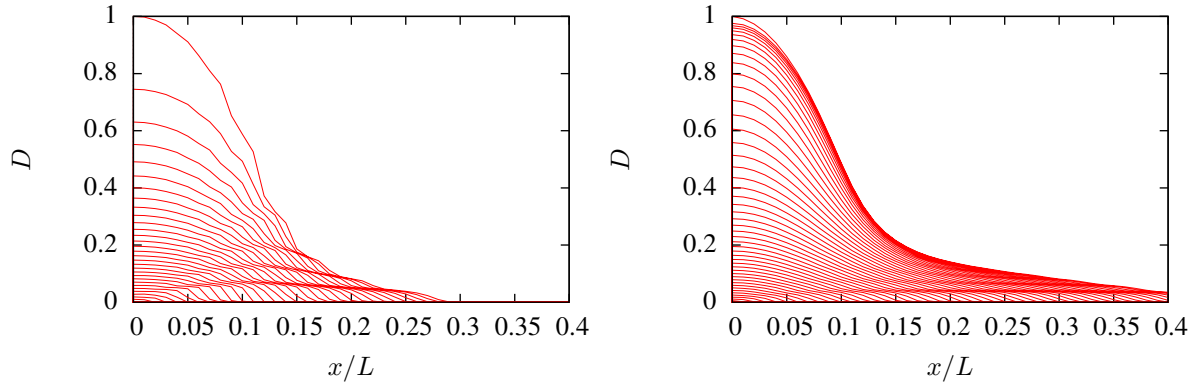

Figure 2: Damage profiles at different time instances for the gradient model, $h/L = 1/100$, $r = 4, p = 1, \ell = L/10$ and $\eta = 1$. Finite element (lhs) and finite difference solutions (rhs) shown.

CONCLUDING REMARKS

The classical Kachanov-Rabotnov continuum damage model has been shown to yield mesh-independent numerical solutions only if the loading rate is below a certain threshold. The dispersion analysis shows that the wave speeds of damaging material exceeds the elastic wave velocity. Based on a preliminary numerical study, addition of second-order derivatives to the damage evolution equation seems to result in mesh-independent solutions for a larger loading rate range. Further study will be focused on the dispersion analysis as well as on developing efficient numerical methods to solve the gradient enhanced model in 3D.

Summary Advanced high-strength steels are widely used in the automotive industry, as an adequate compromise between light-weight, strength and ductility. This contribution focuses on some mechanisms that affect the ductility of dual-phase steels. First, the underlying mechanisms controlling necking-driven global ductility and shear-driven local ductility are examined. The yield stress phase contrast and the strain hardening of martensite are thereby key parameters. Local shear-driven failure of martensite often occurs at the interface with ferrite. Martensite has a complex hierarchical morphology with multiple substructure boundaries. Interfacial damage initiation has been analysed for different interfacial morphologies using crystal plasticity simulations, revealing that substructure boundary sliding triggers plastic deformation localization in the near-interface ferrite matrix.

INTRODUCTION

Advanced high-strength multi-phase steels are of key importance in e.g. the automotive industry, where a compromise needs to be found between light-weight and high-strength. However, automotive steels also need to be ductile since this strongly affects the crash performance and accompanying energy dissipation. Such advanced steels typically consist of multiple phases. Two phases are typically present: ferrite as the soft ductile phase; martensite as the hard phase. The failure of these steels is largely governed by its multi-phase nature, whereby necking may be triggered by the soft phase, fracture by the hard phase, or decohesion by the interfaces. This presentation focuses on these mechanisms, providing some novel insights explaining the peculiar behaviour of these steels in edge cracking problems and on the martensite mechanisms that may induce interfacial decohesion.

EDGE CRACKING: GLOBAL VERSUS LOCAL DUCTILITY

Failure of sheet metal is typically initiated by either localized necking or shear fracture, also respectively termed as global and local ductility. Dual-phase steels outperform conventional steel grades (of comparable strength) in necking-controlled formability tests. They often reveal more strain hardening, leading to a high global ductility. This is not the case when they are subjected to a localized failure test where necking does not occur, e.g. in shear loading. They often reveal a poor performance in such a local ductility test. This apparent contradictory behaviour is known in the steel community as the edge cracking phenomenon (reflecting the higher tendency to damage initiation at a sheared edge) [1]. The literature attributes this phenomenon to the intrinsic incompatibilty between the properties of the constituing phases, but a precise explanation is still lacking. Therefore, an in-depth analysis was carried out on simplified dual-phase microstructures to unravel the edge cracking mechanism, reproducing observations reported in literature. Some of the results are presented in Figure 1. A higher global ductility (necking-driven) is obtained upon delaying the onset of martensite plasticity (higher

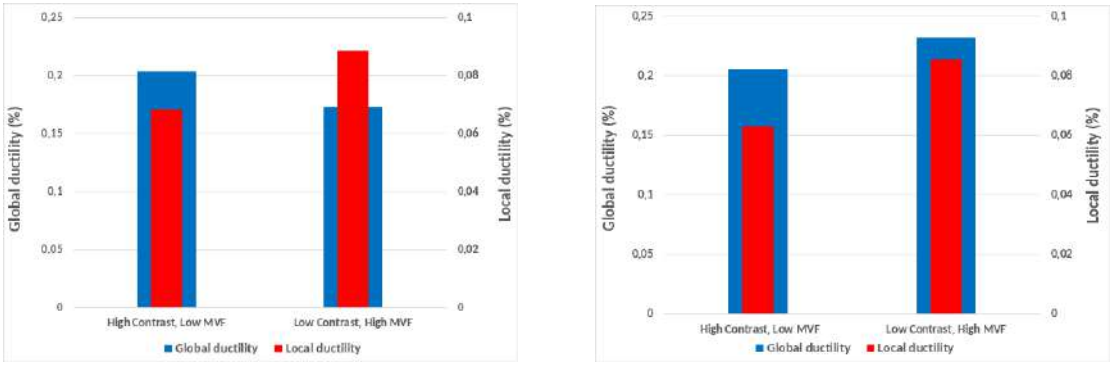

Figure 1: Influence of phase contrast and martensite volume fraction (left); Influence of a higher strain hardening in martensite (right)

yield stress). This entails an increased mechanical phase contrast (Figure 1, left) and more heterogeneous stress-strain distributions, through which one of the phases or interfaces will more rapidly reach its fracture limit in shear loading. Hence, local ductility decreases. In order to seek for a better compromise between global and local ductility, the strain hardening of martensite needs to be increased to a level that is comparable to that of ferrite (Figure 1, right).

INTERFACIAL FRACTURE IN DUAL-PHASE STEELS

The failure limit (stress or strain) of martensite is still a debated subject. Whereas martensite is commonly known as a brittle phase, it has a complex hierarchical structure, in which the substructures boundaries may slide due to the presence of very thin interlath austenitic films [2, 3, 4]. Since these films are fully embedded in the martensite phase, this triggers an apparent ductility of martensite for some load configurations activating glide in the substructure boundaries. A second important aspect is the morphology of the martensite-ferrite interface. Unlike the commonly accepted straight interfacial morphology, experimental evidence reveals that martensite forms sharp wedges instead, whereby substructure boundary sliding may already appear during phase transformation. The resulting morphology is a jagged martensite-ferrite interface. To study the role of the substructure boundary glide and the jagged morphology, four configurations are considered with one martensite island embedded in the ferrite matrix. Single variant martensitic laths are considered, stacked in the vertical direction and separated by the interlath retained austenite films enabling substructure boundary sliding. The four configurations, shown in Figure 2, only differ through the interfacial morphology and phase composition. Crystal plasticity simulations reveal that the interfacial damage is essentially triggered by substructure boundary sliding. Indeed the sliding in between the martensitic laths entails large stress concentrations at the interface, inducing plastic deformation localization as a precursor to damage. This observation holds regardless of the morphological shape of the interface, the phase contrast or the residual stress state.

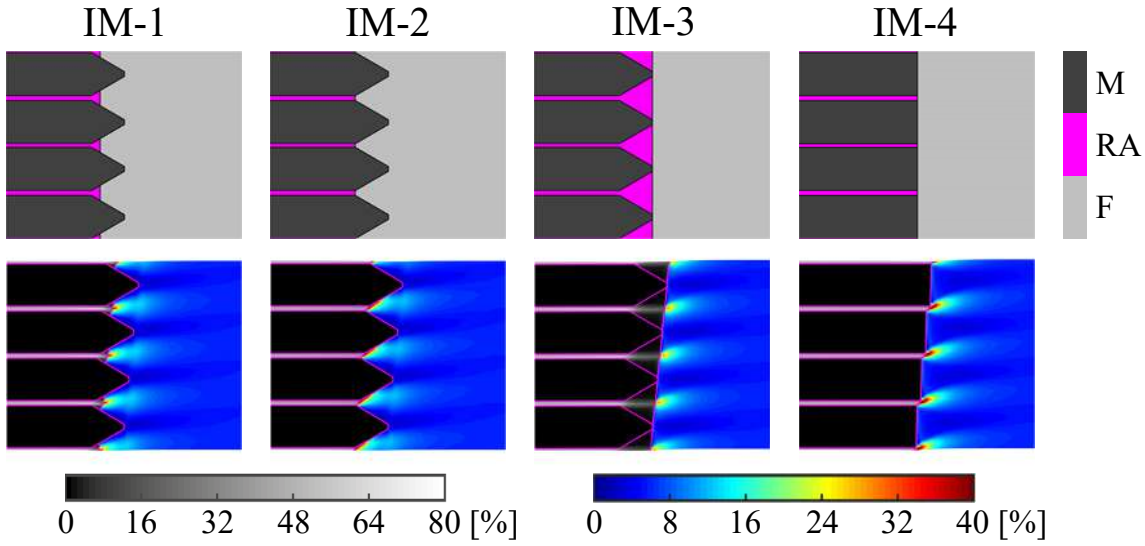

Figure 2: Local interfacial equivalent plastic strain fields for 4 different interface morphologies (IM), at a macroscopic shear strain of 5.7% (simple shear). The top row visualizes the different morphologies, with martensite (M), retained austenite (RA) and ferrite (F). The gray and jet colormaps are used for the martensite/austenite and the ferrite matrix, respectively.

CONCLUSIONS

The failure behaviour of advanced high-strength steels governs their ductility, which is of prime importance for applications exploiting energy dissipation. This contribution focused on the underlying mechanisms discerning necking-driven global ductility from shear-driven local ductility in dual-phase steels. The phase contrast and the strain hardening of martensite are thereby the governing parameters. The local failure of martensite often happens at the interface with ferrite. It has been shown that the substructure gliding triggers plastic deformation localization in the near-interface ferrite matrix, ultimately initiating damage.

ON THE COUPLING OF DAMAGE AND SINGLE CRYSTAL PLASTICITY FOR DUCTILE POLYCRYSTALLINE MATERIALS

Bjørn Håkon Frodal*[1], Tore Børvik[1], and Odd Sture Hopperstad[1]
[1]Structural Impact Laboratory (SIMLab), Department of Structural Engineering, Norwegian University of Science and Technology (NTNU), Trondheim, Norway

Summary A crystal plasticity formulation accounting for damage evolution and failure in the single crystal due to the presence of voids or micro-cracks is developed. An efficient and robust rate-dependent single crystal plasticity implementation is used and extended to model the behaviour of a textured aluminium alloy. Tensile tests on axisymmetric smooth and notch specimens are modelled in Abaqus/Explicit. Prior to failure a significant damage induced softening is observed in the tests. Due to the crystallographic texture, distinct fracture surfaces are observed for the different specimens with each specimen having unique features.

INTRODUCTION

The thermo-mechanical processing of metals influences microstructural characteristics such as the grain structure and the crystallographic texture, and determines the plastic behaviour of these materials. The process of ductile fracture includes nucleation, growth and coalescence of microscopic voids at second-phase particles or inclusions, and depends markedly on the local stress state and microstructural characteristics. For typical metals such as aluminium, the second-phase particles and voids present within the material could be several orders of magnitude smaller than the grain size. Thus, in a single grain there can reside some thousand particles and voids. It then becomes apparent that the yielding and plastic flow of the single crystal around these smaller constituents are important for the ductile fracture process.

One of the advantages of the crystal plasticity theory is its intrinsic ability to predict the change of plastic anisotropy by evolving the crystallographic texture and rotation of the grains. In turn, this allows studying phenomena which are outside the scope of phenomenological plasticity models, like surface roughening, and their influence on ductility. In addition, the discrete representation of the crystallographic texture can evoke phenomena important for ductile failure, such as strain localization and shear banding [1].

MATERIAL AND CRYSTAL PLASTICITY

In this work, we introduce damage mechanics in the crystal plasticity formulation, accounting for damage evolution and failure in the single crystal due to the presence of voids or micro-cracks. Plastic deformation is assumed to occur by plastic slip on certain crystallographic slip systems, determined by the crystal structure. An efficient and robust rate-dependent single crystal plasticity implementation [2] is used and extended to model the behaviour of a polycrystalline aluminium alloy. The AlMgSi alloy investigated is from an extruded profile that has a recrystallized grain structure with a sharp cube texture and a minor Goss component. The strong crystallographic texture leads to a significant plastic anisotropy [2], which can also induce failure anisotropy [3], i.e., a variation in the failure strain with loading direction.

FINITE ELEMENT MODELLING

The coupled damage and rate-dependent crystal plasticity (RDCP) model described above is used in the following to model the response of the textured aluminium alloy. Tensile tests on axisymmetric smooth and notched specimens are modelled in Abaqus/Explicit. The initial diameter of the minimum cross section is 6 mm and 6.4 mm for the smooth and notched specimens, respectively. The notch radius is 3.6 mm for the notched specimen and the gauge length is 40 mm for the smooth specimen, see [2] for further details. The specimens were oriented and pulled along the transverse direction of the extruded profile. To reduce the computational time, only 1/8th of the specimens was modelled with symmetry boundary conditions on the appropriate planes. In the gauge area of the specimens, the element size is set to $100 \times 100 \times 100$ μm^3, and one grain is represented by an element. Each element is given an initial crystallographic orientation so that several elements will recreate the crystallographic texture of the textured aluminium alloy. Elements are eroded upon material failure, i.e., when a material integration point has reached a critical damage level.

RESULTS AND DISCUSSION

Figure 1 depicts the true stress versus logarithmic strain curves from the crystal plasticity finite element simulations of the axisymmetric smooth and notched specimens with and without damage and failure included. Due to the triaxial stress field created by the notch, the notched specimen experiences a higher stress level and has a lower failure strain than the smooth specimen. Prior to failure a significant damage induced softening is observed in the tests including damage.

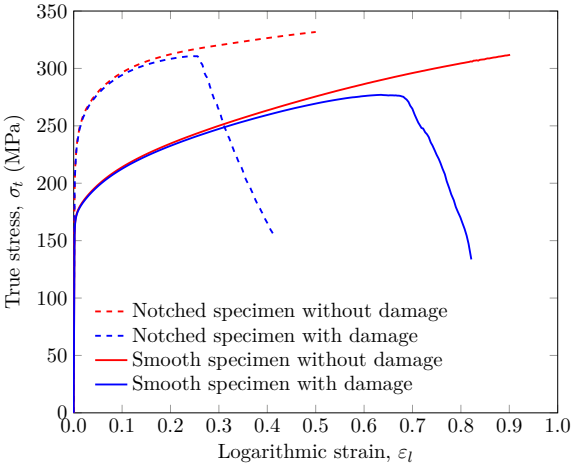

Figure 1: Stress - strain curves from the crystal plasticity finite element simulations of the tensile tests on smooth and notched specimens.

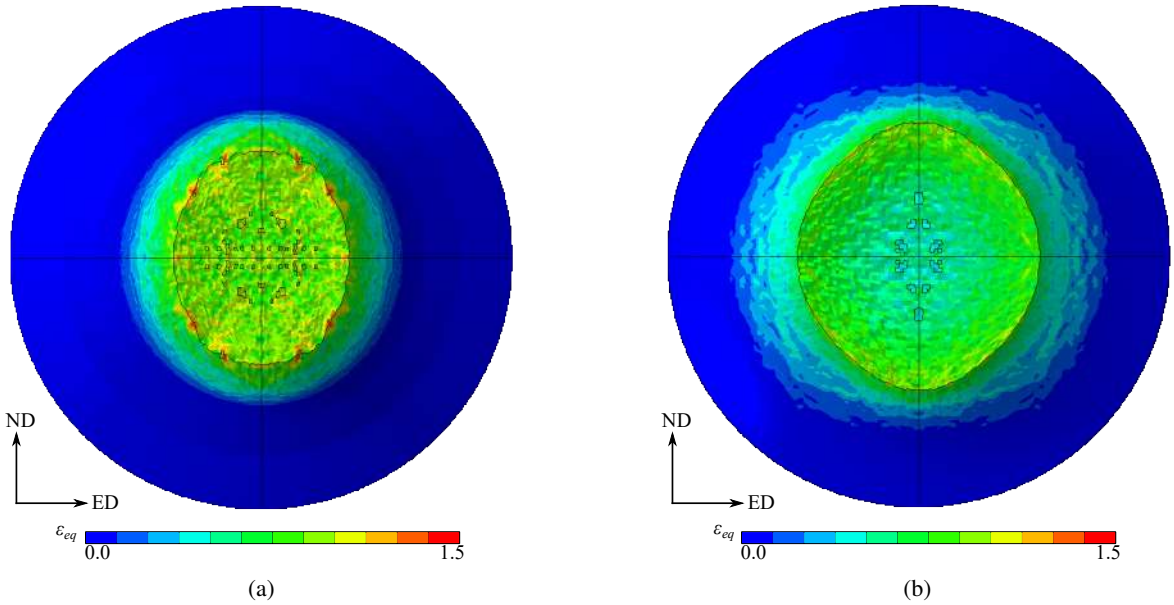

Figure 2: Fracture surfaces of the axisymmetric (a) smooth and (b) notched specimens predicted by the crystal plasticity finite element simulations. Contours of the plastic equivalent von Mises strain are shown.

Figure 2 shows the fracture surfaces predicted by the crystal plasticity finite element simulations of the axisymmetric smooth and notched specimens. Due to the strong crystallographic texture, distinct fracture surfaces are observed for the different specimens with each specimen having unique features. For the smooth specimen, a fracture surface that is somewhere between an ellipse and a rectangle is observed. In contrast, the notched specimen displays a more diamond-shaped fracture surface typically observed experimentally for aluminium alloys with this crystallographic texture and notched specimens [2]. Due to grain rotations during deformation, the outer surface of the specimens close to the fracture surface has developed a surface roughness, i.e., orange peel.

Summary In this work, we present a study on initiation and propagation of cracks in brittle materials under thermal shock. Based on the variational approach to fracture mechanics, a damage model was formulated and implemented into a finite element code. This damage model verifies the conditions of irreversibility, stability and conservation of total energy. By using this numerical model, the evolution of cracks in a thin cylindrical specimen quenched with cold water was simulated. The numerical simulations allow a presentation on whole the process of crack initiation and propagation. It has been shown that there are three phases during the evolution of the damage. First an elastic response without any damage, then a phase of homogeneous damage, followed by several bifurcations where cracks distributed periodically. We studied the influence of the material and loading parameters on the damage evolution. The present study leads to an understanding of the formation and evolution of thermal shock crack patterns in brittle materials such as ceramics.

INTRODUCTION

In this paper, a damage model based on the variational approach was used and implemented into a finite element code and then extended to simulate the evolution of cracks in ceramics exposed to a thermal shock. We perform numerical simulations of thermal shock cracking by using the phase field model where the cracks are replaced by high gradient damage areas. This damage model verifies the conditions of irreversibility, stability and conservation of total energy. The developed numerical model was used to simulate the evolution of cracks in a thin cylindrical specimen quenched in cold water. This numerical model allows predicting the periodic and hierarchical characteristics of the crack models with a satisfactory prediction. The numerical simulations successfully reproduce the cracking process of the quenched specimens in agreement with experiments[1].

CONTEXT OF THE GRADIENT DAMAGE MODEL

Numerical quenching experiments have been conducted in order to observe crack development in ceramic materials [1,2].For numerical simulation of cracking phenomena in solids, damage models are often used. Energy approaches based on a variation formulation provide a clear theoretical framework for determining the relationships between damage models [3,4] and fracture models [5]. The purpose of this paper is to illustrate, as part of the variational approach to fracture mechanics, the modelling and numerical simulation of brittle fracture phenomena under thermal shock. We consider a damage model whose quasi-static evolution is formulated as a problem of minimizing following under an irreversible constraint on the damage energy.

$$W\left((\varepsilon(\mathbf{u}^t)-\varepsilon^{th}(t)),\alpha^t,\nabla\alpha^t\right)=\frac{1}{2}a(\alpha^t)\mathsf{A}(\varepsilon(\mathbf{u}^t)-\varepsilon^{th}(t)).(\varepsilon(\mathbf{u}^t)-\varepsilon^{th}(t))+w(\alpha^t)+\frac{1}{2}w_1\ell^2\nabla\alpha^t.\nabla\alpha^t \tag{1}$$

Where $\mathbf{u}^t$ denoted the displacement field, α the damage field, $\varepsilon(\mathbf{u}^t)$ the linearized deformations, $\varepsilon^{th}(t)$ thermal deformation, A the undamaged elasticity tensor, G_c the toughness of the material, and ℓ a material parameter that has the physical dimension of a length. The functions $a(\alpha^t)$ and $w(\alpha^t)$ indicate the behaviour law of the damage model, representing the modulation of the rigidity and the bulk density of disspated energy, respectively. We study the quasi-static evolution of damage in a circular disc determined by the local minimization of (1) under the constraint of irreversibility, demonstrating that it is possible to account for the phenomena of crack initiation and propagation with complex morphologies without any additional assumption. We will show that the periodic and hierarchical evolution of crack models can be predicted with satisfactory accuracy.

THE THERMOELASTIC PROBLEM

A flat cylindrical specimen is assumed, to be composed of a homogeneous material without pre-stress in its initial state. In the experiments [1], a number of plates are piled together, heated uniformly to the temperature T_i, then they are deposited in a cold water bath in free fall thus inducing a temperature drop T_B on the lateral surfaces. The thermal shock in the structure generates a tensile stress in the edge of the disc, causing a complex pattern of cracks to appear. These cracks propagate inside the spicemens periodically and arrest in the vicinity of the center. The shrinkage of the material generated by thermal effects is determined by thermal deformations as a function of time in the form of :

$$\varepsilon^{th}(t)=\beta(T(t,r)-T_i)\mathbf{I}\qquad T(t,r)=T_B+\sum_{n=1}^{N}\frac{2\Delta T J_0(\lambda_n r)\exp(-k_c\lambda_n^2 t)}{\lambda_n R J_1(\lambda_n R)},\qquad \Delta T=T_i-T_B \tag{2}$$

*Corresponding author. E-mail: marwa.dhahri@lspm.cnrs.fr

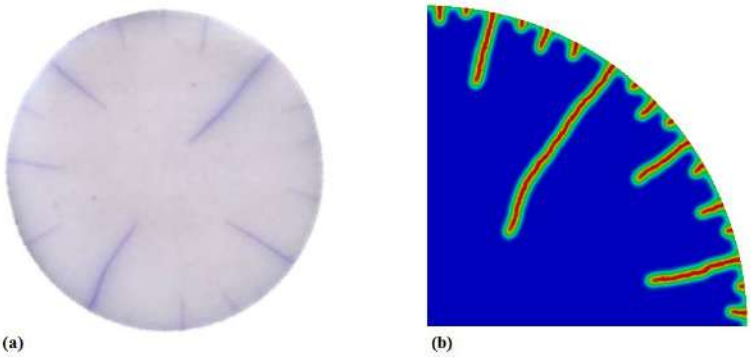

Figure 1: (a) Experimental tests in the specimens with initial temperatures $T_i = 250C$ and bordering temperature $T_B = 15C$, (b) The crack patterns obtained from numerical simulations for a quater of the specimen.

where β is the thermal expansion coeffcient, $T(t,r)$ is the temperature field in the cylindrical structure, and J_0, J_1 are the Bessel function of first unmodified species of order 0 and 1 respectevely, λ_n are the roots of $J_0(\lambda_n R) = 0$, k_c is the thermal diffusivity, and it is supposed that the evolution of damage does not influence the temperature field.

THE EVOLUTION OF CRACKS

It has been demonstrated analytically and verified numerically that there is a cracking threshold ΔT_c above which there is cracking:

$$\Delta T_c = \frac{\sigma_c}{E\beta\sqrt{\mathcal{S}(t=0, r=R, \nu)}} \tag{3}$$

Where $\mathcal{S}(t,r,\nu)$ is expressed by:

$$\mathcal{S}(t,r,\nu) = 8\sum_{n=1}^{N} \frac{\exp(-k_c\lambda_n^2 t)^2}{r\lambda_n^4 R^4 J_1(\lambda_n R)}\{(1-\nu)rJ_1(\lambda_n R) - (1+\nu)RJ_1(\lambda_n r) + \frac{J_1(\lambda_n r)(\nu + J_1(\lambda_n r))R^2}{rJ_1(\lambda_n R)} + \tag{4}$$
$$\frac{J_1(\lambda_n r)J_0(\lambda_n r)\lambda_n R^2}{J_1(\lambda_n R)}(1+\nu) \ -2\nu J_0(\lambda_n r)\lambda_n rR - R - J_1(\lambda_n r)R\}$$

Where σ_c presents the critical stress of the structure, E is the Young's module, R is the radius of specimen, and ν is the poisson coefficient. Therefore, for a thermal shock intensity $\Delta T < \Delta T_c$, we obtain a stable elastic solution at any time t in the entire structure. In the case when $\Delta T > \Delta T_c$ it is demonstrated that there are three phases during the evolution of the damage. First an axisymmetric damage phase presented by a formation of a homogeneous band of damage to the surface exposed to thermal shock, followed by several bifurcations, ie.the localization phase of damage and finally the propagation of the cracks by developing a periodic array of crack bands. These crack bands propagate with a phenomenon of period doubling. Figure (1) shows the evolution of cracks with thermal shock intensitie $\Delta T = 235K$. These crack patterns is compared with the image experimentally obtained. It can be observed that the crack model achieved from the numerical test is in good agreement with the experimental result.

CONCLUSIONS

In this work, we showed that the proposed numerical simulations can faithfully reproduce the crack patterns in the ceramic specimens [1]. The periodic and hierarchical form of the crack models were precisely predicted. From the numerical results, the spacing between the two consecutive cracks and the length of the cracks were well estimated. The obtained results agree qualitatively with the experiment.

UNIFYING BREAKAGE MECHANICS WITH THE COSSERAT CONTINUUM TO PREDICT SHEAR BAND LOCALISATION

Nicholas Anton Collins-Craft[1,2], Ioannis Stefanou[2,3], Jean Sulem[2], and Itai Einav*[1]
[1]Particles and Grains Laboratory, The School of Civil Engineering, The University of Sydney, Sydney, Australia

[3]GeM (Institute de Recherche en Genie Civile et Mécanique),Ecole Centrale de Nantes,Université de Nantes, CNRS, Nantes, France

Summary In this work, we present a combination of two previously separate continuum mechanical theories, Breakage Mechanics and Cosserat continuum mechanics. The Cosserat continuum is typically employed as a means of obtaining an internal length that serves to regularise the equations of continuum mechanics, which removes issues such as pathological mesh-dependence that frequently arise in constitutive models that feature softening or non-associated behaviour . Historically, Cosserat models for geomechanics have used internal lengths that are related to the mean grain size of the underlying distribution, and which are fixed properties of the system. We adopt the Breakage Mechanics family of models to take into account the evolution of the grain size distribution in a consistent and thermodynamic way, and include this more refined physics in an evolving internal length.

We start by providing an energetic upscaling method that is comparable with the original formulation of Breakage Mechanics [1, 2], extended to capture the energetic contribution of the elastic curvatures that arise as a result of the Cosserat continuum. Through the upscaling procedure, we define a new material constant θ_κ that acts in concert with the internal breakage variable B to include the contribution of the entire grain size distribution to the energy at the continuum level. Importantly, this material constant allows us to define a new internal length scale that includes the entire grain size distribution, and evolves as that distribution evolves towards an well-defined ultimate distribution.

In a similar fashion we also perform an upscaling of the rotational inertia to take into account the contributions of the entire grain size distribution, defining a second new material constant θ_I, for use in dynamic analysis.

The energetic upscaling provides a generic framework in which to specify Breakage Mechanics models. We then proceed to detail a model within the framework of rate-independent thermodynamic processes. This model is an extension of previous Breakage Mechanics models [3] into the Cosserat continuum. In order to achieve this extension, we define the second deviatoric stress invariant and the second deviatoric strain invariant in a manner consistent with [4], which serves to include both contributions from the stresses and the couple-stresses that arise as a consequence of the Cosserat continuum. The couple-stresses are made dimensionally consistent with the stresses through a length scale, which we select to be the length scale defined through our energetic upscaling.

We proceed to define certain relationships between the additional stiffnesses that arise in linear Cosserat elasticity, such that by measuring the classical bulk modulus K and shear modulus G, the additional Cosserat moduli G_c, H, H_c are also obtained. The result of this is that the new Cosserat model requires no additional calibration over the same model phrased in the classical continuum. All the remaining parameters have straightforward physical interpretations and can be obtained via standard geotechnical testing apparatus such as the triaxial test.

At this point, our model is fully specified and calibrated, and we move on to using it to study a system of interest, specifically shear under constant volume. This corresponds to fast undrained shear that occurs during seismic slip. We analyse our system using two techniques, linear stability analysis (LSA) and the finite element method (FEM).

We first apply LSA to determine which parts of the yield surface are capable of supporting localisation into shear bands under this load condition. We find that this localisation type occurs only on the lower confining pressure side of the yield surface, and the extent of this region depends on the value of the internal breakage variable B, and the system parameter ω, which allocates dissipation between grain crushing and plastic volumetric straining. In general, systems that have more crushed grains have a relatively smaller part of the yield surface that will support band localisation. Similarly, systems that favour grain crushing over plastic volumetric straining as a means of dissipation have smaller localisation regions than systems that favour plastic straining.

We then turn our attention to following individual load paths, and using LSA to obtain their predicted widths. In the case of changing values of ω, we find that systems with higher values (and hence "softer" behaviour localise at smaller values of strain and have thinner initial shear band widths, but also tend to grow more rapidly than bands in systems with lower values of ω.

*Corresponding author. E-mail: itai.einav@sydney.edu.au

Of particular interest to us is the effect of polydispersity on the width of shear bands. Classically it is considered that the width of shear bands scale as a function of mean grain size. However, the range of apparent scalings found in the literature [5, 6] suggest that this single grain size is insufficient to fully characterise the width. Using our model, we can vary the polydispersity in several different ways. Starting by changing only the ratio of minimum to maximum grain size (and thus changing our material parameter θ_κ, we find that normalisation by our evolving internal length scale collapses all the predicted shear band widths onto a single curve. However, when we adopt a more complex measure of polydispersity, by changing the initial value of the breakage variable B, no normalisation scheme is sufficient to collapse all the curves. We find that normalisation by the largest grain size d_{Max} is most indicative of the initial localisation width, while the evolving internal length scale causes different values of B to converge faster post-localisation at increasing shear. In all cases, the mean grain size (either initial or evolving) is the least effective normalisation, which may help to explain why no fixed scaling relationship between d_{50} and shear band width has been found.

Finally, by implementing our model using the FEM, we explain the formation of double-cataclastic shear bands in certain rock formations in the field. We observe that for values of ω favouring grain crushing, our system progresses from homogeneous to a single shear band, which is then followed by two shear bands at the edge of the initial band, before finally one of these bands becomes dominant and saturates.

CONCLUSIONS

By defining this Cosserat Breakage Mechanics model, we have added physical fidelity to the Cosserat modelling tradition and predictive power post-localisation to the Breakage Mechanics family, allowing us to gain insight into several physical phenomena that were previously unexplained.

A CONTINUUM MECHANICAL FRAMEWORK FOR GRADIENT-EXTENDED DAMAGE COUPLED WITH PLASTICITY

Tim Brepols*[1], Stephan Wulfinghoff[2], and Stefanie Reese[1]
[1]Institute of Applied Mechanics, RWTH Aachen University, Aachen, Germany
[2]Institute for Materials Science, Computational Materials Science, Kiel University, Kiel, Germany

Summary A novel continuum mechanical framework is presented which is suitable for modeling gradient-extended damage coupled with plasticity. The geometrically nonlinear formulation is based on sound thermodynamic principles and applicable to arbitrarily large elastic and plastic deformations. Damage and plasticity are treated as truly independent yet coupled mechanisms by considering separate damage and plastic yield criteria as well as individual sets of loading / unloading conditions. Such a 'two-surface' approach makes the model formulation very flexible, as it can be applied in cases in which the material exhibits an either more brittle- or more ductile-like damaging behavior. An exemplary model derived on the basis of this framework is carefully examined in a structural finite element computation for its mesh-regularizing properties in case of large plastic strains and severe damage.

CONSTITUTIVE ASPECTS

The model framework presented in the following can be regarded as the geometrically nonlinear variant of a corresponding version for small strains, which was presented earlier by the same authors (see [1]).

General gradient-extended model framework for combined damage and plasticity

The gradient-extension of the model formulation is based on Samuel Forest's well-established micromorphic approach (see [2, 3]). As such, an additional global field variable $\bar{D}$ is introduced which is considered a primary unknown of the problem in addition to the displacements $\boldsymbol{u}$ and shall here be referred to as the 'micromorphic damage'. It can be interpreted as the 'nonlocal' counterpart of the 'local' internal damage variable D, the latter of which accounts for the rather complicated effects of damage in a material (e. g., occurrence and evolution of microcracks and microvoids during the deformation) in an averaged sense only. Via a micromorphic balance equation, which can be derived by applying an extended version of the principal of virtual work and which needs to be solved in addition to the classical balance of linear momentum, the spatial developments of D and $\bar{D}$ are linked.

The weak form of the problem is obtained by multiplying the balance of linear momentum and the just mentioned micromorphic balance equation by appropriate vectorial and scalar test functions $\delta\boldsymbol{u}$ and $\delta\bar{D}$, respectively, and by integrating over the reference domain B_0 of the body under consideration. This leads to:

$$g(\boldsymbol{u},\bar{D},\delta\boldsymbol{u}) := \int_{B_0} \mathbf{S}\cdot\delta\mathbf{E}\,\mathrm{d}V - \int_{B_0} \boldsymbol{f}_0\cdot\delta\boldsymbol{u}\,\mathrm{d}V - \int_{\partial B_{0_\mathrm{t}}} \boldsymbol{t}_0\cdot\delta\boldsymbol{u}\,\mathrm{d}A = 0 \qquad \forall\delta\boldsymbol{u} \tag{1}$$

$$h(\boldsymbol{u},\bar{D},\delta\bar{D}) := \int_{B_0} \left(H\left(D-\bar{D}\right)\delta\bar{D} - A\,\mathrm{Grad}\left(\bar{D}\right)\cdot\mathrm{Grad}\left(\delta\bar{D}\right)\right)\mathrm{d}V = 0 \qquad \forall\delta\bar{D} \tag{2}$$

Here, g is the weak form of the balance of linear momentum whereas h is the weak form of the micromorphic balance equation. Furthermore, $\mathbf{S}$ is the second Piola-Kirchhoff stress tensor, $\mathbf{E}$ is the Green-Lagrange strain tensor, $\boldsymbol{f}_0$ and $\boldsymbol{t}_0$ are volume distributed forces and prescribed tractions, respectively, and $\mathrm{Grad}(\bullet)$ denotes the gradient operator with respect to the coordinates in the reference configuration. Parameters A and H are the micromorphic moduli whose meaning will be described later. Since the the weak form (1) - (2) is generally nonlinear, it needs to be linearized with respect to the global unknowns $\boldsymbol{u}$ and $\bar{D}$ which in the end leads to a coupled set of equations that need to be solved iteratively for the increments $\Delta\boldsymbol{u}$ and $\Delta\bar{D}$. At that point, independent finite element approximations of the global field variables can be introduced, as usual. Further details are omitted here for brevity.

In accordance with a geometrically nonlinear theory of elastoplasticity, the deformation gradient $\mathbf{F}$ is assumed to be multiplicatively separable into an elastic ($\mathbf{F}_e$) and a plastic ($\mathbf{F}_p$) part, i. e. $\mathbf{F} = \mathbf{F}_e\,\mathbf{F}_p$. Furthermore, in order to consider nonlinear kinematic hardening, an additional physically-motivated split of the plastic part of the deformation gradient into recoverable ($\mathbf{F}_{p_e}$) and irrecoverable ($\mathbf{F}_{p_i}$) parts is presumed, leading to $\mathbf{F}_p = \mathbf{F}_{p_e}\,\mathbf{F}_{p_i}$. With this at hand, the following general form of the Helmholtz free energy per unit reference volume is assumed:

$$\psi = f_\mathrm{dam}(D)\left(\psi_e\left(\mathbf{C}_e\right) + \psi_p\left(\mathbf{C}_{p_e},\xi_p\right)\right) + \psi_d\left(\xi_d\right) + \psi_{\bar{d}}\left(D-\bar{D},\mathrm{Grad}\left(\bar{D}\right)\right) \tag{3}$$

Here, ψ_e is the elastic part of the free energy expressed in terms of $\mathbf{C}_e = \mathbf{F}_e^\mathrm{T}\,\mathbf{F}_e$. Furthermore, ψ_p denotes the plastic energy stored due to kinematic and isotropic hardening which depends on both $\mathbf{C}_{p_e} = \mathbf{F}_{p_e}^\mathrm{T}\,\mathbf{F}_{p_e}$ and ξ_p, the latter of which being the isotropic hardening variable. As indicated above, both ψ_e and ψ_p are affected by damage via a monotonically decreasing, but otherwise freely selectable, degradation function $f_\mathrm{dam}(D)$. Moreover, ψ_d accounts for stored energy due to damage hardening and depends on the damage hardening variable ξ_d, which plays a similar role as ξ_p in plasticity. Finally, $\psi_{\bar{d}}$ is the energy related to the micromorphic extension of the model. It depends on both the gradient of $\bar{D}$ and on the difference between the micromorphic and the local damage variable $D-\bar{D}$, thus enforcing a coupling between the two quantities in the formulation.

Particular gradient-extended 'two-surface' damage-plasticity model in this study

The above model framework is quite flexible and generally allows adaptation to a variety of conditions by an appropriate selection of the energetic components. For a meaningful discussion of the numerical results in the present paper, it is reasonable to make an exemplary selection at this point. A Neo-Hookean type format is chosen for the elastic part of the energy, i. e., $\psi_e := \mu/2\left(\operatorname{tr}\mathbf{C}_e - 3 - 2\ln\left(\sqrt{\det\mathbf{C}_e}\right)\right) + \Lambda/4\left(\det\mathbf{C}_e - 1 - 2\ln\left(\sqrt{\det\mathbf{C}_e}\right)\right)$ where Λ and μ are the Lamé constants. The plastic part of the energy reads $\psi_p := a/2\left(\operatorname{tr}\mathbf{C}_{p_e} - 3 - 2\ln\left(\sqrt{\det\mathbf{C}_{p_e}}\right)\right) + e\left(\xi_p + \left(\exp\left(-f\,\xi_p\right) - 1\right)/f\right)$ and is composed of two parts: the first is related to kinematic hardening, whereas the second accounts for nonlinear isotropic hardening of Voce type (a, e and f are corresponding plastic material parameters). A nonlinear damage hardening energy is chosen, i. e., $\psi_d := r\left(\xi_d + \left(\exp\left(-s\,\xi_d\right) - 1\right)/s\right)$ (r and s are damage related material parameters) and $\psi_{\bar{d}} := H/2\left(D - \bar{D}\right)^2 + A/2\,\mathrm{Grad}(\bar{D}) \cdot \mathrm{Grad}(\bar{D})$ represents the energy due to the micromorphic extension of the model: the first term penalizes the difference between D and $\bar{D}$ via parameter H, whereas parameter A controls the influence of the gradient term in the formulation. The damage degradation function is chosen as $f_{\mathrm{dam}}(D) := (1 - D)^2$. Following a 'two-surface' strategy, in which damage and plasticity are treated as individual dissipative mechanisms, separate damage and plastic yield criteria as well as individual loading / unloading conditions are defined.. Finally, thermodynamically consistent evolution equations for all strain-like internal variables are postulated (nonlinear kinematic hardening of Armstrong-Frederick type is considered in the model). Further details are omitted here for brevity and can be found in a paper which was very recently accepted for publication (see [4]).

NUMERICAL EXAMPLE

In order to demonstrate the mesh-regularizing properties of the gradient-extended damage-plasticity model introduced above, exemplary structural finite element computations of a 2D plane strain problem are considered in this study. More specifically, a uniaxial tensile test of a specimen which has two symmetrical notches in its middle is performed. The specimen is clamped at the bottom and pulled with a force F at the top (further details about the geometry and the setup of the boundary-value problem are omitted here for brevity). Simulations with different meshes ranging from 928 up to 70372 elements are carried out and compared to each other.

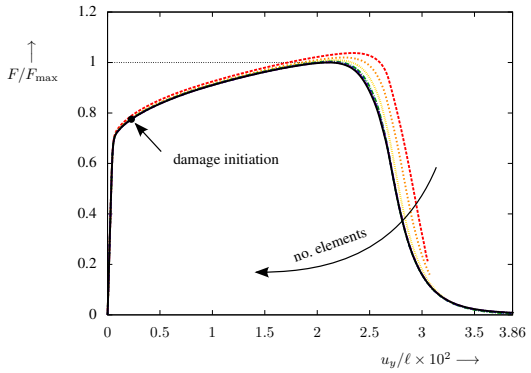

Figure 1: Normalized load-displacement curves.

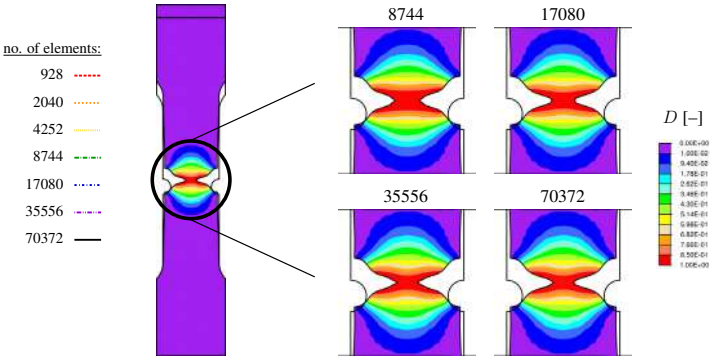

Figure 2: Damage contours D at end of process.

Fig. 1 shows the normalized load-displacement curves which are obtained in the simulations ($F_{\max}$ denotes here the load maximum, whereas u and ℓ are the displacement at the top and the original length of the specimen, respectively). Convergence towards a unique solution with a finite amount of energy dissipation during the damage process becomes clearly visible and the simulations can robustly be performed up to almost complete loss of load-bearing capacity of the specimen. A comparison of the damage contours D at the end of the process is shown in Fig. 2 for the four finest mesh discretizations. As can be seen, large plastic deformations and high damage occur in the middle area of the specimen and the results for the different discretizations agree very well. The numerical example therefore serves as a good first indicator that the proposed continuum mechanical framework for geometrically nonlinear gradient-extended damage-plasticity indeed works as desired: it leads to models which can adequately regularize the mesh size dependence of results in finite element simulations involving arbitrarily large plastic deformations and severe damage.

EXPERIMENTAL INVESTIGATION OF DYNAMIC DELAMINATION UNDER IMPACT LOADING

Mirac Onur Bozkurt[1,2] and Demirkan Coker *[1,2]
[1]Department of Aerospace Engineering, Middle East Technical University, Ankara, Turkey
[2]METU Center for Wind Energy, Middle East Technical University, Ankara, Turkey

Summary The paper presents the experimental investigation of failure process in $[0/90]_s$ CFRP beams subjected to static and low-velocity impact (LVI) type flexural loadings. A drop-weight impact test setup is designed and built, and the same line load fixture is used in a static testing machine. During the experiments, failure events are captured with an ultra-high-speed (UHS) camera at frame rates up to half a million fps. Using the UHS pictures, in-situ damage characterization is performed and crack tip speeds during delamination propagation are measured. Digital image correlation analysis is carried out prior to failure to elucidate damage driving mechanisms. As a result, no distinct failure mechanisms exist for $[0/90]_s$ CFRP beams under static and LVI loadings. It is also shown that dynamic delamination propagation occurs at same speeds in this configuration independent of loading rate.

INTRODUCTION

In design of aerospace structures, composite laminates are stacked in order to fulfil some stiffness requirements with limited weight allowance. However, this might cause the laminate to be inefficient in terms of strength. Such weakness become prominent when the laminate is subjected to an out-of-plane impact load. Furthermore, static response of an impacted laminate may get dramatically worse especially under compressive loads. Thus, it is essential to understand impact damage very well to design damage tolerant structures.

In the literature, there are several experimental works dealing with parameters affecting and mechanisms of impact damage in composite laminates [1-5]. Results of the impact experiments conducted in such studies are used as benchmark for numerical simulations alongside of their use for understanding damage formation. In this study, we conduct in-situ line-load experiments with up-to-date experimental techniques to elucidate impact damage mechanisms. Moreover, we claim that crack tip speed during delamination propagation is a property that can be used in modelling of high-fidelity simulations.

EXPERIMENTAL METHOD

To conduct LVI tests, a non-standard drop-weight impact setup, shown in Figure 1, is designed and built. The flat beam specimen fixture, which consists of two couples of top and bottom rectangular steel plates placed on linear guideways, allows visualization of the damage process from the side of the beam specimen. Two ends of the specimen are sandwiched by the top and bottom plates and squeezed via bolt and nut fasteners passing through the holes located at corners of each plate. Impactor crosshead assembly consists of a steel crosshead, an in-line load cell and a hemi-cylindrical steel impactor located at the tip of the assembly and weighs 1865-g. Linear bearings are embedded at both ends of the crosshead and slide almost frictionless over two parallel guiding shafts. In static tests, the same boundary conditions are created by installing the impactor and the specimen fixture to 10-kN Shimadzu electromechanical testing machine.

The test matrix, given in Table 1, is constituted considering the number of specimens, parameters affecting the damage and the techniques used for better understanding of damage formation. In all impact and static tests, in-situ formation and progression of damage are captured at either 70,000 or 525,000 fps via the UHS camera system. In one static and one impact test, strain distribution on the specimen is computed during elastic loading using two-dimensional DIC method.

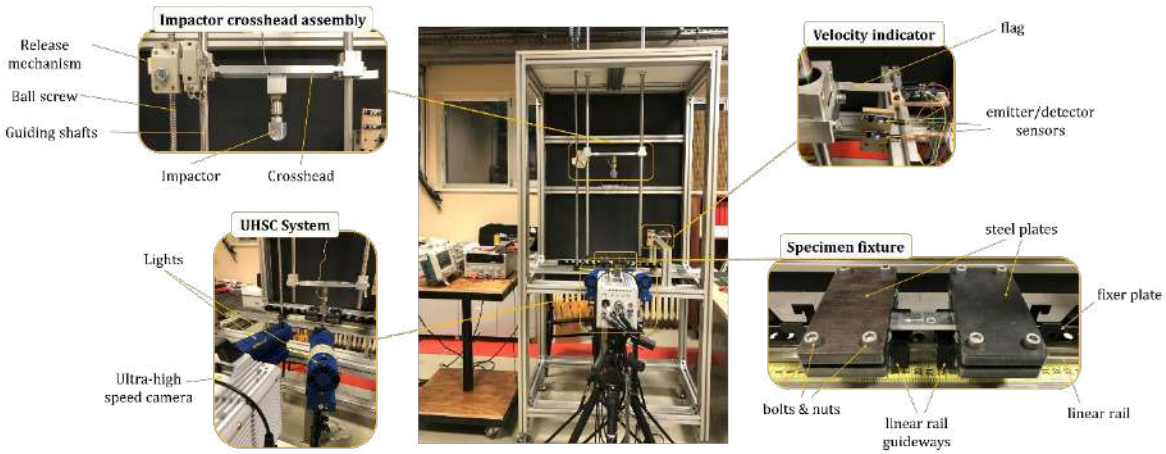

Figure 1. In-house low-velocity impact test setup with its sub-components.

Table 1. Test matrix for impact and static loading of CFRP composite beams.

Layup	Specimen	Energy	UHSC capturing rate [fps]	DIC
$[0_5/90_3]_s$	Imp1	9.15 J	70,000	No
	Imp2	9.15 J	70,000	Yes
	Imp3	9.15 J	525,000	No
	Sta1	Static	525,000	No
	Sta2	Static	70,000	Yes

RESULTS AND CONCLUSIONS

Strain distributions on $[0/90]_s$ – Sta2 prior to failure on the left and right-hand sides of the specimen are obtained using DIC method and shown in Figure 2a. It is observed that initiation of diagonal matrix cracks occurs at the location of one of the hot ε_{xy} spots. Regarding to this coincidence and higher ε_{xy} magnitudes, it can be deduced that formation of these 'shear cracks' are controlled by the shear component of the strain in the case of these specimen and testing configurations. In addition to these observations, absolute ε_{xy} and ε_{yy} and concentrations at the delamination tips which point out the existence of opening and shearing modes exist in such fracture are observed.

UHS camera pictures showing the evolution of impact induced damage process in $[0/90]_s$ beam taken at 525,000 fps are presented in Figure 2b. The crack tip position data used in the first plot of Figure 2c are extracted from the UHSC pictures by visual assessment. Variation of the delamination crack tip speeds with crack length is also shown in Figure 2c. It is shown, under both static and impact loadings, that delaminations are not only dynamic but also reach the same speed plateau of 850 m/s. This concludes that the experimental data consisting of the crack tip positions and the crack tip speeds can be used as a benchmark for the simulations of the experiments conducted on $[0/90]_s$ beams.

A NOVEL ANISOTROPIC ELASTOPLASTIC DAMAGE FE MODEL FOR WOOD

Elena Benvenuti*[1], Nicola Orlando[1], Michael Kaliske[2], and Clemens Gebhardt[2]
[1]Department of Engineering, University of Ferrara, Ferrara, Italy
[2]Technische Universität Dresden,Dresden,Germany

Summary We propose a novel constitutive model for wood based on a multi-surface failure criterion resulting from a set of plastic laws for compressive failure modes and orthotropic damage laws for tensile/shear failure modes. We show that the proposed formulation satisfactorily simulates compression and Mode I debonding tests until failure.

INTRODUCTION

Wood is increasingly being used for both restoration purposes and design of advanced wood-based materials. It is an inhomogeneous, anisotropic and porous material with moisture-, temperature- and time-dependent behaviour [1]. Common features of state-of-the-art FE-models for wood structures are the assumption of material orthotropy and the recognition that both structural behavior and failure modes change depending on direction and sign of the prevailing stress component [2].

The present study can be ascribed to the category of multi-surface anisotropic constitutive models for wood combining plasticity and damage. The plasticity constitutive law draws inspiration from the multi-surface plasticity model [3], while the orthotropic Continuum Damage Model model extends the approach in [4]. In the two-dimensional case, we introduce three damage variables d_θ associated with the directions $\theta = L, R, LR$ (Fig. 1a) and define five failure surfaces, three associated with damage and two with the plastic strain $\boldsymbol{\varepsilon}^p$ evolution. Given the sets $\mathcal{I}^p$ and $\mathcal{I}^d$ indexing the active failure functions f plastic and damaging type, respectively, we cast the generic i-th failure surface F_i $i \in \mathcal{I} = \mathcal{I}^p \cup \mathcal{I}^d$ and the equivalent-stress scalar $\bar{\tau}_i$ as

$$\bar{\tau}_i = \begin{cases} f_i(\boldsymbol{\sigma}) & i \in \mathcal{I}^p \\ f_i(\tilde{\boldsymbol{\sigma}}) & i \in \mathcal{I}^d \end{cases}, \quad F_i = \begin{cases} \bar{\tau}_i + q_i - 1 & i \in \mathcal{I}^p \\ \bar{\tau}_i - r_i & i \in \mathcal{I}^d \end{cases},$$

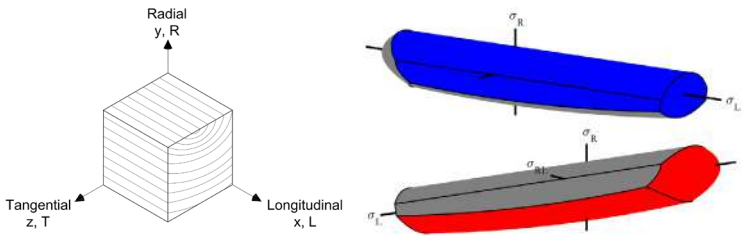
where r_i is a non-decreasing, history-dependent, state variable. We formulate the rate form of the evolution of damage and plasticity state variables in the compact form

$$\dot{\boldsymbol{\varepsilon}}^p = \sum_{i \in \mathcal{I}^p} \dot{\lambda}_i^p \frac{\partial F_i}{\partial \boldsymbol{\sigma}}, \qquad \dot{d}_\theta = \dot{\lambda}_{i_\theta}^d \dot{\bar{\tau}}_{i_\theta} \frac{\partial G_{i_\theta}(\bar{\tau}_{i_\theta})}{\partial \bar{\tau}_{i_\theta}}, \ \theta = L, R, LR,$$

where the loading/unloading conditions

$$\begin{aligned} &\dot{\lambda}_i^p \geq 0, \quad F_i \leq 0, \quad \dot{\lambda}_i^p F_i = 0, \quad i \in \mathcal{I}^p, \\ &\dot{\lambda}_i^d \geq 0, \quad F_i \leq 0, \quad \dot{\lambda}_i^d F_i = 0, \quad i \in \mathcal{I}^d, \end{aligned}$$

hold. The resulting failure domain is shown in Fig. 1b. Most available FE models for wood use cohesive elements to



(a) (b)

Figure 1: a) Adopted reference system; b) Failure surface.

simulate tensile and shearing cracks. Cohesive elements require an explicit, mesh-dependent, representation of the crack geometry. Alternatively, the crack geometry can be implicitly represented by means of the extended finite element method (XFEM) [5], a mesh-independent tool for propagating cracks and discontinuities. While the number of applications of the XFEM to concrete and steel elements is, nowadays, countless, applications of the XFEM to timber mechanics are not so diffused. The regularized XFEM captures strain localization [6], and debonding along finite width interfaces [7]. In

*Corresponding author. E-mail: elena.benvenuti@unife.it

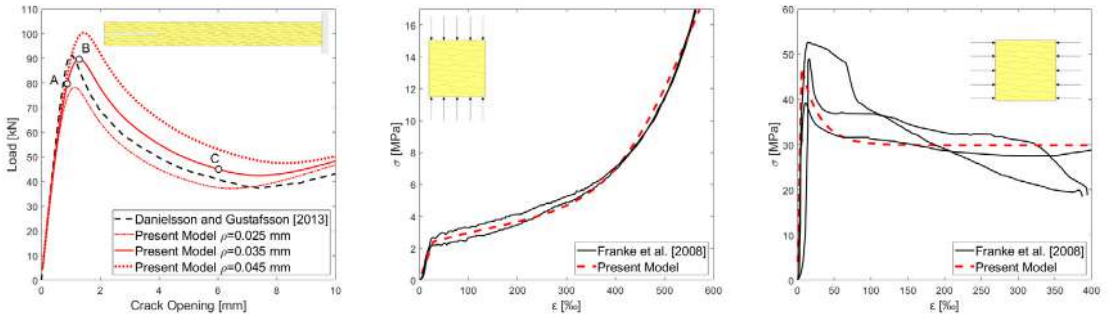
particular, let the displacement $\boldsymbol{u}$ jump across the surface Γ and $d_\Gamma(\boldsymbol{x})$ be the signed distance function of $\boldsymbol{x}$ from Γ. The regularized XFEM is based on the following discrete approximation of displacement $\boldsymbol{u}$ [6]

$$\boldsymbol{u}(\boldsymbol{x}) = \boldsymbol{N}(\boldsymbol{x})\boldsymbol{V} + \mathcal{H}_\rho(d_\Gamma(\boldsymbol{x}))\boldsymbol{N}\boldsymbol{A},$$

where $\mathcal{H}_\rho$ is a regularized Heaviside function depending on the length parameter ρ, $\boldsymbol{V}$ and $\boldsymbol{A}$ denote the vectors collecting the standard and enriched nodal degrees of freedom, respectively, and $\boldsymbol{N}$ are the standard FE shape functions. Since crack development in wood comes along with fiber-bridging, and fiber-bridging spreads the cracking process over a Fracture Process Zone (FPZ), in the present methodology, joints and interfaces are simulated by means of the regularized XFEM.

APPLICATIONS

Fig. 2a shows the load-displacement results obtained with different regularization lengths ρ for the double cantilever beam test [8]. The proposed model correctly reproduces wood behavior also at compressive loading. This is illustrated by Fig. 2b and Fig. 2c for the tests performed by Franke et al. [9], corresponding to compression along the radial and longitudinal direction, respectively.



(a) (b) (c)

Figure 2: a) Load-displacement result for the DCB test [8]. Stress-strain results obtained for the test with compression along b) the radial and c) the longitudinal direction.

CONCLUSIONS

The proposed multi-surface orthotropic CDM model combined with the regularized XFEM correctly captures loading-directionality dependence, ductile failure induced by compressive stresses, as well as brittle failure associated with tensile stress states. The use of the regularized XFEM ensures a smooth continuous-discontinuous transition and reproduces a physically-consistent FPZ.

Summary Lumped Damage Mechanics (LDM) is a formulation that merges ideas of both fracture and damage mechanics with the concept of plastic localization zone. A typical finite element in LDM for analyses of framed structures is the assembly of an elastic beam-column with two inelastic hinges at the ends of the element. This paper proposes an innovative extension of this framework to two and three dimensional continuum. Accordingly, in a two-dimensional continuum a plastic hinge becomes a localization band and in a three-dimensional continuum it becomes a localization surface. The finite element hereby described for LDM-2D analysis is a four-node quadrilateral with bands of damage localization on its sides. Damage evolution laws are introduced for describing the constitutive behavior of each band. The element formulation can also be applied to three-node triangles and four-node tetrahedra. The feasibility of the resulting formulation is confirmed through numerical analyses, in particular showing the mesh-independence of the numerical results.

BACKGROUND INFORMATION

Classical Damage Mechanics (CDM), [1], evolved from the theory of plasticity including material deterioration in a continuous approach. The CDM constitutive models comprise a softening constitutive response associated to a homogeneous strain state. However, those models have failed in describing non-homogeneous strain states, leading to ill-posed problems and mesh-dependent numerical algorithms.

An alternative for circumventing the ill-posed issue was the introduction of a non-local approach, [2]. Next, a strong discontinuity framework was coined to directly account for localization phenomena, [3]. Furthermore, a finite element based scheme for describing a transition from damage to crack is also an important contribution to be mentioned [4].

However, the alternative form of damage mechanics addressed in this paper is radically different. Lumped Damage Mechanics (LDM) was proposed in the early nineties and has been developed since then, [5, 6]. The major assumption is that localization is a separate phenomenon that needs the introduction of specific state variables with their respective evolution laws. Unlike the classical damage mechanics, constitutive modeling in LDM does not use the concept of strain, or curvature as in beam models, but rather the inelastic elongation of the localization band, as hereby considered, or inelastic rotation of the hinge. Under this assumption, the derived models lead to mathematically objective results.

So far, LDM has been limited to the analysis of framed structures, in which both damage as well as plasticity are localized in zones of zero length: the inelastic hinges. This paper shows that LDM is a general framework that can be extended to the analysis of any continuum. Actually, in a two-dimensional continuum the inelastic hinge concept transforms into a localization band and in a tridimensional solid, into a localization surface.

ON THE LDM EXTENSION

Focusing on the referred extension, the localization of damage in a narrow band with a nil initial thickness, while the rest of the element remains elastic, is a major aspect to be accounted for. A hypothesis of elongation equivalence instead of strain equivalence as in CDM is then introduced. It means that the total elongation is composed by the elastic elongation plus a measure of the elongation of the damage localization band.

Aiming numerical simulations, an extension of LDM to plane analysis can be done firstly by revisiting the conventional four node bilinear quadrilateral element shown in Figure 1a. An important modification is to consider elongations instead of strains. The equivalent truss system conceived as shown in Figure 1b helps in this way. The element strains can then be related to the truss-bars elongations, and these to the nodal displacements of the element. Following such conception, the kinematic and equilibrium equations leading to the internal forces vector and stiffness matrix of the conventional quad-element may now involve an equivalent matrix of gradient operators expressed in terms of elongations.

Next, as damage variables are supposed to describe inelastic phenomena lumped on localization bands, four fixed localization bands of null volume are added at the sides of the revisited element (see Fig 1c). In order to apply a deformation equivalence hypothesis and to compute the elongations in each band, the elongation at the extremities of a localization band are related to the elongations of the equivalent truss-bars crossing those sections. Moreover, the nature of the shape functions of the element impose a linear variation of the elongation at any section across a band (see Fig 1d). The constitutive equations are then completed with eight damage functions, in correspondence to the two elongations at each node in reference directions of the element.

Finally the same kinematic and equilibrium equations of the revisited quadrilateral element may be used. An analogous procedure can be adopted to generate LDM three-node triangle elements and even LDM four-node tetrahedron aiming three-dimensional analysis.

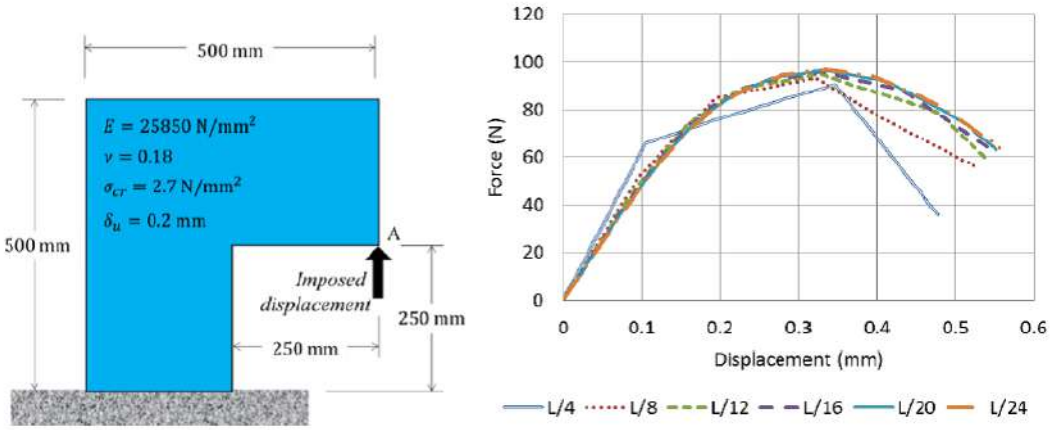

Figure 2: Left) L-shaped solid; Right) Displacement vs. force for several meshes.

CONCLUSIONS

Six meshes were used in the problem depicted in Figure 2. The finite elements present square shape, dividing the larger sides forming the L-shaped solid equally. For instance, for the mesh L/4 the larger sides were divided by 4 equal segments, leading to a total of 12 elements in the discretization. Also in Figure 2 the convergence of the global response with mesh refinement is shown .

The formulation hereby presented is remarkable for its simplicity and physical correctness, which are clear advantages with respect to other approaches.Regarding further efforts in this direction, for instance, a more complex formulation involving mode II too could be considered since the bands of the elements addressed in this paper are loaded on mode I. Additionally, outside the localization bands the elements do not need to have exclusively an elastic behavior. It can be elastic-plastic or even exhibit continuous damage. In this more general scenario, merging CDM modeling to LDM formulation can be envisaged.

Finally, the extension to the tridimensional case opens the possibilities for a significant number of new applications.

COMPARATIVE THERMODYNAMICS-BASED ANALYSIS OF TWO TYPES OF GRADIENT DAMAGE MODELS

Kossivi Kpotufe[1,3], Radhi Abdelmoula[2], Nadjime Pindra[1], and Djimédo Kondo*[3]
[1]Université de Lomé, Département de Mathématiques, Togo
[2]Université Paris 13, LSPM, Villetaneuse, France
[3]Sorbonne Université, Institut Jean le Rond d'Alembert, Paris, France

Summary The present study is devoted to a comparative analysis of two types of gradient damage models. To this end, we first rely on the Generalized Standard Materials framework recently overviewed by Nguyen [9] for gradient plasticity models and which includes the corresponding variational formulation. For the first class of gradient damage models, the regularization term enters in the dissipation potential, while in the second class it is in the form of a stored energy (then as the part of the material free energy). For comparison purpose, we performed various simulations among which those shown below for an elastic matrix containing a rigid inclusion. The numerical results allow to investigate the differences between the two types of models, notably from an energetic point of view.

A GENERALIZED STANDARD MATERIALS FRAMEWORK FOR GRADIENT DAMAGE MODELS

Due to induced stress softening, local damage models exhibit pathological sensibility to mesh size or orientation. A common way to regularize such damage models consists in adding gradient-damage based contribution which involves a length scale (see for instance [5]). An interesting aspect of such regularized damage models is their link to variational approach to fracture [2], as established by [10] (see also [8]) by relying to the so-called Drucker-Ilyushin postulate. Owing to the importance of the above cited works and their corresponding variational formulation, it can be hepful to provide their thermodynamics-based formulation in the context of Generalized Standard Materials. This will allow to clarify the place of the regularization terms in the free energy and/or the dissipation potential. Though, ideas of formulating the gradient damage models at the global level of a structure Ω can be found in [6], we refer here to the recent study [9]. With the condensed notation $U=(\underline{u},d)$, $\underline{u}$ being the displacement field and d the damage one in Ω, let us introduce the global free energy $\boldsymbol{W}(U)=\int_\Omega \rho w\big(\underline{\underline{\varepsilon}},d,\underline{\nabla} d\big)d\Omega$ and the overall dissipation potential $\boldsymbol{D}(\dot{U})=\int_\Omega \varphi\big(\underline{\dot{\underline{\varepsilon}}},\dot{d},\underline{\nabla}\dot{d}\big)d\Omega$.
By considering the so-called generalized Biot equations, $\boldsymbol{W}_{,U}+\boldsymbol{D}_{,\dot{U}}=0$ under quasi-static conditions, and the global normality rule, it can be shown (based on [9]) that for all t, the quasi-static response $U(t)$ of the solid submitted to a given displacement loading path satisfies the evolution variational inequality:

$$\forall \dot{U}^*,\quad \boldsymbol{W}_{,U}\cdot(\dot{U}^*-\dot{U})+\boldsymbol{D}(\dot{U}^*)-\boldsymbol{D}(\dot{U})\geqslant 0. \tag{1}$$

THE TWO CONSIDERED TYPES OF GRADIENT DAMAGE MODELS

We consider two types of time-independent gradient damage models whose main elements at a material point are:

- Dissipative model: $\rho w\big(\underline{\underline{\varepsilon}},d\big)=\frac{1}{2}\underline{\underline{\varepsilon}}:\mathbb{C}(d):\underline{\underline{\varepsilon}}$; $\quad\varphi(\dot{d},\underline{\nabla}\dot{d})=Y_c(d)\dot{d}+2w_1{l_D}^2(\underline{\nabla}d\cdot\underline{\nabla}\dot{d})+I_+(\dot{d}),\quad Y_c(d)>0.$
- Energetic model: $\rho w\big(\underline{\underline{\varepsilon}},d,\underline{\nabla}d\big)=\dfrac{1}{2}\underline{\underline{\varepsilon}}:\mathbb{C}(d):\underline{\underline{\varepsilon}}+E_0{l_E}^2\big|\big|\underline{\nabla}d\big|\big|^2$; $\quad\varphi(\dot{d})=Y_c(d)\dot{d}+I_+(\dot{d}),\quad Y_c(d)>0$

where, as usually, $I_+(\dot{d})$ stands for an irreversibility condition. l_D and l_E are the internal lengths in the dissipative and energetic models, respectively. Note that in φ the quantities d and $\underline{\nabla}d$ may be considered as (state) parameters.
First, by reporting the above expressions of ρw and φ in the global potentials and then in (1) one gets the rate form of the variational inequality. Then, owing to the particular homogeneity of degree one of the above dissipation potentials (see [3] for definition of "Simple Dissipative" systems), the later can be integrated in time. This results in a variational formulation consisting to minimize the following functionals with respect to the fieds $\underline{u}$ and d on the domain Ω:

- Dissipative model: $\xi\big(\underline{u},d\big)=\int_\Omega\left(\frac{1}{2}\underline{\underline{\varepsilon}}(\underline{u}):\mathbb{C}(d):\underline{\underline{\varepsilon}}(\underline{u})+w(d)+w_1{l_D}^2\big|\big|\underline{\nabla}d\big|\big|^2\right)d\Omega$
- Energetic model: $\xi\big(\underline{u},d\big)=\int_\Omega\left(\frac{1}{2}\underline{\underline{\varepsilon}}(\underline{u}):\mathbb{C}(d):\underline{\underline{\varepsilon}}(\underline{u})+E_0{l_E}^2\big|\big|\underline{\nabla}d\big|\big|^2+w(d)\right)d\Omega$

The above formulations have the form of the so-called Ambrosio-Tortorelli approximation introduced by [2] (see also [8]) for fracture mechanics problems. For comparison purpose, we consider $\mathbb{C}(d)=(1-d)^2\mathbb{C}_0$ in which $\mathbb{C}_0$ is the elastic stiffness of the sound material. Moreover, we choose for simulations $Y_c(d)=2w_1d,$, that is $w(d)=\int_0^d Y_c(\alpha)d\alpha=w_1d^2$.

APPLICATIONS AND COMPARATIVE ANALYSIS

Let us first note that models considered by [8] or [10] are dissipative ones, while those introduced in [5] or [7] belong the class of energetic models. As an example, we consider a model-problem adopted by a number of authors, such as [2], [1] and [4]. It consists in a traction experiment on a fiber-reinforced matrix. The studied domain is composed of a squared linear-elastic matrix of side $L = 300mm$ with a cylindrical rigid inclusion of radius $R = L/6$. The materials properties and the boundary conditions are the same as in [4]. In particular, the young modulus $E = 12000MPa$, the Poisson ratio $\nu = 0.25$, the characteristics length $l_D = 5mm$ and the fracture energy $G_c = 25.10^{-3}N/mm$ (equivalent to $w_1 = G_c/(2l_D) = 2,5.10^{-3}MPa$).

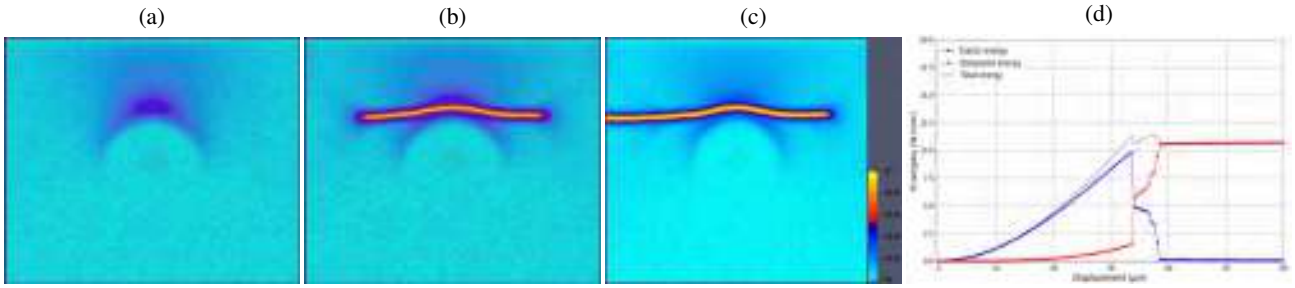

Figure 1: Elastic matrix reinforced by a rigid inclusion: evolution predicted by dissipative model. (a) $u = 31\mu m$, (b) $u = 34\mu m$, (c) $u = 38\mu m$, (d) evolution of the different energies

Fig.1 shows damage distribution and the different energies evolution predicted by the dissipative model. The damage starts early and concentrates at the bottom of the inclusion (see figure 1a); from a detailed examination of the numerical results, it appears that fracture starts for a displacement about $u = 33\mu m$ and the complete fracture is observed for $u = 39\mu m$. This is confirmed by the evolution of energies (see figure 1d)) whose overall trend is the same as in [4].

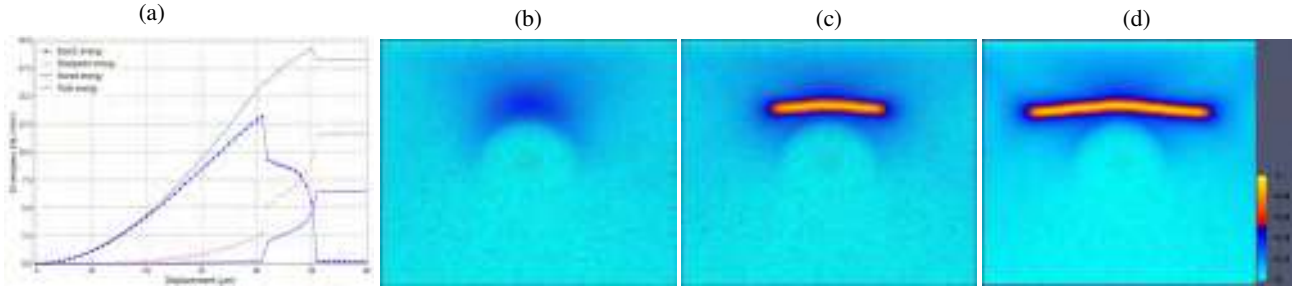

Figure 2: Elastic matrix reinforced by a rigid inclusion: evolution predicted by energetic model. (a) evolution of the different energies, (b) $u = 38\mu m$, (c) $u = 42\mu m$, (c) $u = 50\mu m$.

Let us come now to the energetic model for which one needs not only to consider the previous material parameters, but also E_0 which affects the amount of the stored energy. It must be emphasized that, a priori, the order of magnitude of E_0 is not that of the Young modulus E, but rather that of w_1. For the energetic model, the stored energy must not be taken into account in the interpretation of the fracture energy G_c. From the theoretical study of 1D bar, it can be shown that the internal length l_E is given by $l_E = 2l_D\sqrt{w_1/E_0} = G_c/\sqrt{E_0 w_1}$. For illustrative purpose, we choose $E_0 = w_1$. Fig.2 illustrates the evolutions of damage pattern and energies predicted by the energetic model. Though, the results are qualitative comparable to the those on fig.1, it is observed here that fracture occurs later ($u = 42\mu m$) and ends at $u = 51\mu m$. Moreover, it appears from Fig.2a that the stored energy is not negligible during fracture growth.

IMPACT ABSORPTION IN AUXETIC DAMAGEABLE MATERIALS

David Faraci*[1] and Claudia Comi [1]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary In this work we study the behaviour of elastic and quasi-brittle auxetic metamaterial under impact. Particular reference is made to the use of these structured materials for facial protector devices for sport activities. Impact analyses of a ball over an auxetic and a non-auxetic honeycomb material show the potential benefit of the densification mechanism occurring in the auxetic material below the impacted region. Moreover, when the bulk material is assumed to have a brittle behaviour, the auxetic lattice in compression develops a smaller damage with respect to the honeycomb, non-auxetic lattice. This can be another advantage in impact absorption applications.

AUXETIC AND NON-AUXETIC STRUCTURED MATERIALS

Auxetic metamaterials, i.e. micro-structured materials with the unusual negative Poisson's rate property, thanks to a significant densification mechanism occurring when they are compressed, have extremely good performances under impact, [1]. We consider two different periodic lattice materials, with two-dimensional (2D) and three-dimensional (3D) microstructures, that may exhibit an equivalent global auxetic behaviour and traditional (non-auxetic), behaviour. The lattices and the unit cells for the re-entrant honeycomb (RHC), originally proposed in [2], and the honeycomb (HC) structures are shown in Figs.1a,c and Figs.1b,d, respectively. For fixed geometries of these lattices, an equivalent density, ρ_{eq}, defined as the mass of the unit cell divided by the volume, can be easily computed.

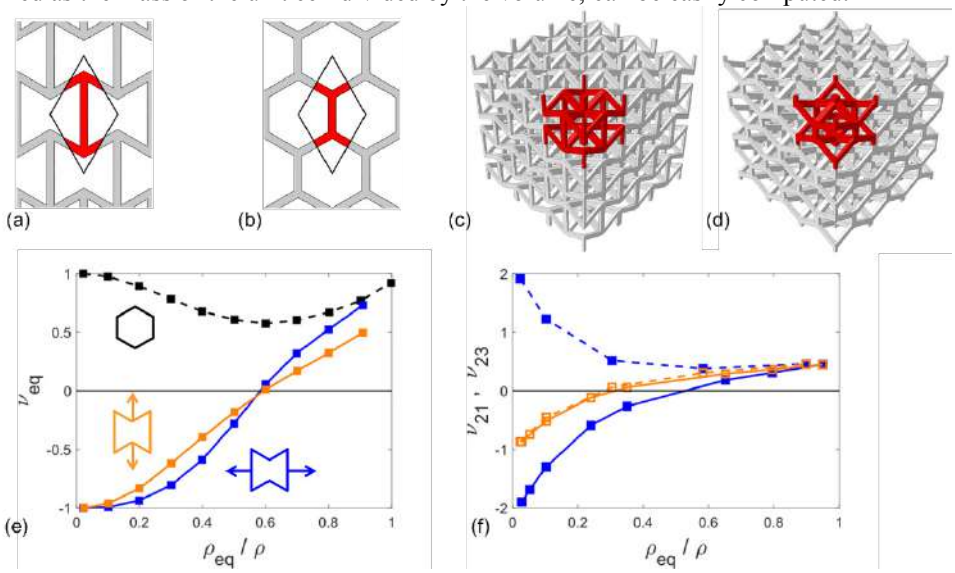

Figure 1. Lattice with unit cell in red of: (a) 2D RHC, (b) 2D HC, (c) 3D RHC, (d) 3D HC. Equivalent Poisson's ratios versus normalized equivalent mass density: (e) 2D lattices, plane strain conditions, (f) 3D lattices (dotted lines: HC, solid lines: RHC, ν_{21} in blue, ν_{23} in orange).

Elastic behaviour: equivalent Poisson's ratio

Several lattices, endowed with different thickness of the beam elements inside the cell, are considered and a linear-elastic analysis allows computing the equivalent Poisson's ratios. The results are shown in Figs. 1e and 1f in terms of equivalent Poisson's ratio versus normalized equivalent density. Note that the microstructure makes the homogenized or equivalent behaviour non-isotropic, with the exception of the 2D HC. For low values of the equivalent density, the 2D RHC lattice exhibits auxetic behaviour in both directions (orange and blu curves in Fig. 1e) and the same holds true for the 3D RHC lattice (solid lines in Fig. 1f). While in the 2D case the HC lattice always has a non-auxetic behaviour (black curve in Fig. 1e), the 3D HC lattice, which is transversally isotropic, can have an auxetic behaviour (i.e. $\nu_{23}<0$) in the horizontal plane of isotropy.

Damageable 2D-lattice micro-structured materials

With the aim to study the effect of damage on the different lattices, we consider the geometries shown in Fig. 1a with $\rho_{eq}=0.27\rho$ and in Fig. 1b with $\rho_{eq}=0.22\rho$ and we assume that the constituent bulk material is brittle, with a tensile strength of 10 MPa and a mode I fracture energy of 0.01 Nmm. In compression, the behaviour of the bulk material is assumed linear elastic. We numerically simulate the response of the two damageable metamaterials under compression. A specimen constituted by 5 x 5 cells is considered, a uniform displacement, inducing shortening, is imposed on the upper boundary and the global reaction is computed. A brittle-crack model is used in the finite element code, with the option of element deletion to avoid over distorted mesh. Figure 2 shows the obtained force vs displacement curves that

*Corresponding author. E-mail: david.faraci@polimi.it.

can be interpreted as uniaxial compression stress-strain curves of the structured materials. For comparison, the linear elastic response is also shown (dashed line). One can observe that the auxetic effect provides an additional strength mechanism in compression that results in a higher global force, with a reduced equivalent damage at equal global displacement. The equivalent damage at the peak of the force, estimated from the secant stiffness, is 0.23 for the RHC and 0.41 for the HC. The global behaviour is however quite brittle. The plots in Fig. 2 (right) show the failure patterns corresponding to the points marked in the global curves.

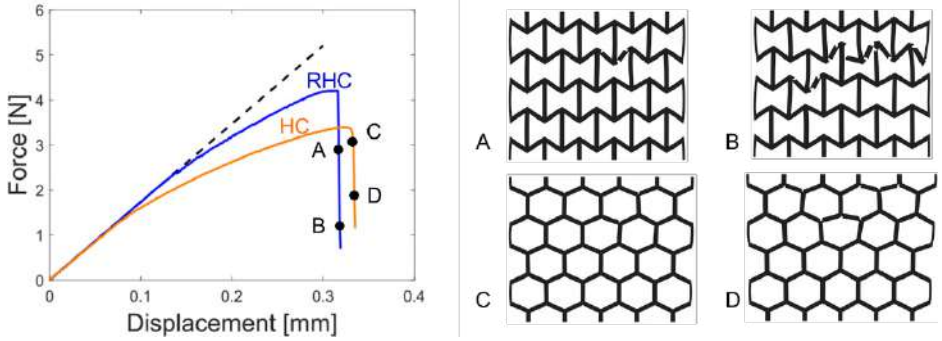

Figure 2. Force vs displacement of 2D-RHC (orange curve) and 2D-HC (blue curve) lattices in compression. Dashed line represents the linear elastic response, solid lines represent the response with a damage model. Failure patterns for RHC and HC materials.

IMPACT ON STRATIFIED MATERIALS WITH AUXETIC CORE

The problem considered is related to the choice of optimal materials for protector facial masks to be used by athletes. The real functional requirement sets a limit on the thickness of the device and a limit to the transmitted force in case of impact. In this context, [3] proposed a mask made of two layers of flexible and rigid ethylene vinyl acetate (EVA) and compared the stresses on the face in case of impact with and without the mask.

In [4], we proposed a different solution, with the inclusion of an intermediate layer of structured material, see Fig. 3a and analysed the impact of a rigid sphere on a small portion of the mask, assuming an elastic behaviour of the bulk material used to fabricate 3D HC and RHC lattices and large deformations. Figure 3b shows the results in terms of the time evolution of the reaction force transmitted to the internal surface. A more efficient impact absorption in obtained with the RHC lattice (lower value of the peak of transmitted force). This is due to the densification of the material in the impacted region, with activation of self-contact inside the highly deformed metamaterial.

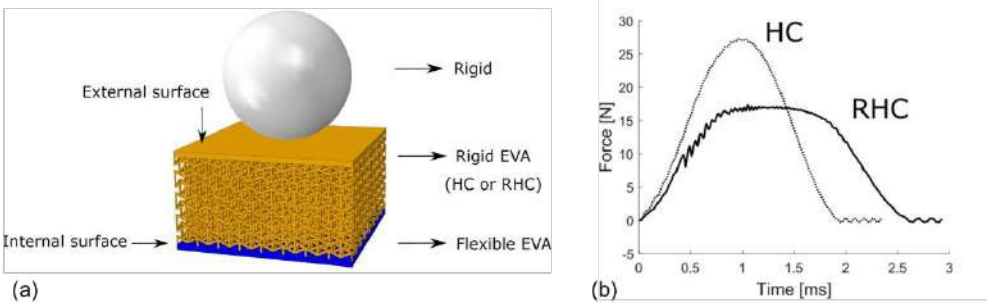

Figure 3. (a) Scheme of analyzed portion of mask. (b) Time evolution of reaction force at internal surface of protector device

To set the safefy margin of a real protector device one has to include also the non-linear behaviour of the bulk material. The effect of non-linear material behaviour, possibly with damage, has to be properly taken into account. As here shown, assuming small strain, the auxetic behaviour can induce additional strength mechanisms to prevent damage development, but can also result in a brittle final failure. The combined effect of large displacements and damage deserves further study and is currently under development.

CONCLUSIONS

The densification mechanism of auxetic material under compression can improve the impact absorption performance and modify the damage mechanism. This opens the way to possible application to protector devices for athletes. The real design of such devices however would require proper identification of the actual nonlinear behavior of the bulk material and the definition of homogenized constitutive law for the micro-structured materials.

MULTILE CRACK AND DEBONDING MECHANISMS IN QUASI-BRITTLE COATINGS

Guido Borino*[1] and Francesco Parrinello [1]
[1]Department of Engineering, University of Palermo, Palermo, Italy

Summary The mechanical failure of coatings is analyzed in its main features together with the proposal of new strengthening strategies. The quasi-brittle behavior of ceramic-type coatings is the source of the nucleation and propagation of tensile vertical cracks. A second type of weakness is given by the imperfect adhesion coating/substrate, which can produce decohesion and eventually spallation of the fragmented coating. The study is conducted mainly by a nonlinear computational approach based on finite elements with nonlocal damage and cohesive-frictional interface elements. Finally, new techniques of reinforcements are proposed and their effectiveness numerically verified.

THE MECHANICAL PROBLEM

There are many circumstances in which structural elements need a boundary surface protection from external agencies, such as high temperature variations, chemical aggressive environment, small particle impacts, extreme moisture environment and so on. The function of the coating is to protect the integrity and the functionality of the structural element but, however the coating has also to carry mechanical loads transmitted by the structural system without failure or suffering damage. Only minimal damage could be accepted provided that the coating maintains its overall function. It would also desirable an easy restoration which does not compromise the structural safe function.

Typically the structural element is constituted by a material with high mechanical performance, namely with high strength and stiffness, designed for giving an appropriate structural safe response to the external loadings. On the other hand, the coating layer is usually a quasi-brittle material with moderate strength and small ductility, but with high thermal and chemical resistant performances. For ensuring the high thermal insulation properties, the coating is usually realized by ceramic-type materials.

Two main weakness are therefore to be considered. The first it the quite small strength of the coating to sustain tensile stress and therefore the coating is prone to multiple tensile cracking localization. The second weakness is related to the adhesion between the coating and the structural stiff substrate. This means that a decohesion mechanism may develop along the interface between the coating layer and the substrate, which in turn can produce a spallation of the coating.

The present paper presents a computational approach to evaluate and optimize the mechanical efficiency of thermal coating with respect to the above mentioned possible failure weakens. In particular the substrate is treated as a linear elastic continuum, the coating behaves as a quasibrittle material and therefore is modelled by a nonlocal elastic-damage material model. The possible dechoesion is reproduced inserting a cohesive-frictional interface between the elastic substrate and the coating thin layer. The problem is analyzed by means of Finite Element simulations showing the qualitative and quantitative response and the main failure mechanisms which develops as function of the material property variation and of the thickness of the coating.

Finally, it will be shown how specific type of micro-reinforcements can effectively improve the mechanical performance of the coating.

MECHANICAL MODELLING

The problem analyzed consists of a plate formed with different layers subjected to uniform traction/bending and thermal variation through the thickness. The basic layers is the elastic high-performance substrate followed by a zero thickness interface which represents a potential dechoesion surface and finally on the top the quasibrittle coating film. The analyses are performed employing 2D nine-node finite element discretization for the substrate and for the coating and a six-node interface elements between substrate and coating. The constitutive assumption employed for the coating and the interface are briefly reported in the following subsections.

Nonlocal elastic-damage constitutive relations for the coating film

A symmetric thermodynamically consistent nonlocal damage formulation is adopted for modelling the quasi-brittle coating [1]. The nonlocality is obtained by employing a spatial integral operator applied to the damage variable and it require the introduction of an iternal lenght parameter ℓ. The nonlocal regularization allows to reproduce, in an objective way, the strain localization/diffusion. The stress - strain relation reads

$$\boldsymbol{\sigma}(\boldsymbol{x}) = \left(1 - \bar{\omega}(\boldsymbol{x})\right) \boldsymbol{E}\, \boldsymbol{\varepsilon}(\boldsymbol{x}) \tag{1}$$

where $\boldsymbol{\sigma}$ is the Cauchy stress tensor, $\boldsymbol{E}$ is the elastic moduli tensor, $\boldsymbol{\varepsilon}$ is the infinitesimal strain tensor and $\bar{\omega}$ is the scalar nonlocal measure of the isotropic damage ω, defined as

$$\bar{\omega}(\boldsymbol{x}) = \int_V W(\boldsymbol{x}, \boldsymbol{y})\, \omega(\boldsymbol{y})\, dV(\boldsymbol{y}) \tag{2}$$

*Corresponding author. E-mail: guido.borino@unipa.it

where $W(\boldsymbol{x},\boldsymbol{y})$ is an appropriate positive value spatial weight function in which the amplitude of the spatial interactions is governed by the value of the internal length parameter ℓ. For $\ell \to 0$ the weight function $W(\boldsymbol{x},\boldsymbol{y}) \to \delta(\boldsymbol{x},\boldsymbol{y})$, where δ is the Dirac's delta function and therefore eq. (2) becomes an identity, whereas eq. (1) collapses in the standard local elastic damage constitutive equation. See [2] for details on nonlocal damage formulations. The constitutive model requires a damage activation function of the type:

$$\phi_d(\bar{Y},\chi) = \bar{Y} - \chi - Y_0 \leq 0 \tag{3}$$

where $\bar{Y}$ is a nonlocal measure, obtained with the same integral averaging procedure of eq. (2), of the energy release rate $Y = 1/2\,\boldsymbol{\varepsilon}^T \boldsymbol{E}\,\boldsymbol{\varepsilon}$, χ is an internal variable which describes the post peak stress-strain softening law and Y_0 is the initial threshold for damage activation.

The constitutive relations are completed by associative damage flow rule and by loading/unloading conditions.

Cohesive-frictional interface constitutive model

The potential development of a delamination mechanism at the bounding plane between the elastic substrate and the quasi-brittle coating, is modeled by a zero thickness cohesive-frictional interface. The model adopted in this paper is a recent extension of the thermodynamically consistent mixed-mode model developed by the authors [3, 4, 5, 6]. The basic idea is that a unit interface element can be subdivided in two fractions. A cracked fraction $\omega_s\, dS$ and a sound fraction $(1-\omega_s)\, dS$. The traction vector transmitted by the interface $\boldsymbol{t}$ is therefore additively represented by the sum of the contribution of the two interface surface fractions $\boldsymbol{t} = \boldsymbol{t}_s + \boldsymbol{t}_c$. Each fraction has its own constitutive relation given as

$$\boldsymbol{t}_s = (1-\omega_s)\boldsymbol{K}_s\boldsymbol{\delta}_s^e; \qquad \boldsymbol{t}_c = \omega_s \boldsymbol{K}_c \boldsymbol{\delta}_c^e \tag{4}$$

$\boldsymbol{K}_s$ and $\boldsymbol{K}_c$ are diagonal stiffness matrices and $\boldsymbol{\delta}_s^e$ and $\boldsymbol{\delta}_c^e$ are the vector displacement jump of the two interface fractions.

For reproducing delamination and frictional sliding two activation functions are required. The first is:

$$\phi_d^s = Y_s - \chi_s - \tilde{Y}_{s0}(\boldsymbol{u}) - Y_{s0} \leq 0 \tag{5}$$

where Y_{s0} is the initial interface damage activation threshold, χ_s is the internal variable governing the interface softening law and $\tilde{Y}_{s0}(\boldsymbol{u})$ is a positive term which allows to drive fracture mixity. Y_s is the surface energy release rate defined $Y_s = \frac{1}{2}\boldsymbol{\delta}_s^{eT}\boldsymbol{K}_s\boldsymbol{\delta}_s^e - \frac{1}{2}\boldsymbol{\delta}_c^{eT}\boldsymbol{K}_c\boldsymbol{\delta}_c^e$.

The second activation function for the frictional sliding has the form of a Mohr-Coulomb law given as

$$\phi_p^s(\boldsymbol{t}_c) = |t_{ct}| + \alpha t_{cn} \leq 0 \tag{6}$$

where α is the frictional coefficient and t_{ct} and t_{cn} are the tangential and normal components of the traction vector $\boldsymbol{t}_c$ which acts on the damaged fraction.

The interface constitutive relations are completed by nonassociative (for dilatancy effects) flow rule and by loading/unloading conditions.

CONCLUSIONS

The formulation proposed is able to elucidate the main weakness of quasibrittle coating. The influence of the coating thickness is shown as a parameter that can discriminate different failure mechanisms. Once understood the mechanical features which promote the failure, possible new strategies for reinforcing are proposed and numerically verified. Namely, tensile cracking can be prevented by inserting a very thin ductile film, [5], whereas debonding can be combatted by micro-pin reinforcements.

EXPERIMENTAL EVIDENCE OF NON-LOCAL INTERACTIONS DURING THE COMPRESSIVE FAILURE OF ELASTO-DAMAGEABLE SOLIDS

Ashwij Mayya[1], Estelle Berthier[2], and Laurent Ponson *[1]
[1]Institut Jean le Rond d'Alembert,Sorbonne Université,CNRS,Paris,France
[2]Department of Physics, North Carolina State University, Raleigh, North Carolina, USA

Summary We study experimentally the compressive failure of cellular solids by damage accumulation and then localization. We observe that damage spreads by bursts separated by elastic phases before it localizes in a narrow band. We investigate the spatial organization of these bursts within the specimen and show that they are characterized by regions of size ξ where the damage increases cooperatively. As failure approaches, the non-local length ξ increases until it reaches the specimen size. Our results provide a detailed characterization of the non-local effects involved during damage growth and open new perspectives for the multi-scale modelling of compressive failure.

INTRODUCTION

Quasi-brittle materials such as rocks wood, mortar or ceramics under compression fail through the accumulation and then the localization of a large number of microcracks in interaction. These interactions affect the evolution of the damage within quasi-brittle solids, and ultimately, control their load-bearing capacity. However, damage mechanics relies on the introduction of a representative volume element, neglecting the long-range interactions between the material elements constituting a specimen [1]. Recently, it was shown that these non-local effects do impact the failure response of quasi-brittle solids like the inclination of localization band [2]. To capture these interactions, several non-local damage models have been proposed, but they all remain largely phenomenological [3]. In addition, there are very few quantitative investigations of the non-local effects during the spreading of damage that could be used to discriminate and feed competing non-local approaches. This study intends to fill this gap by exploring experimentally the non-local effects involved during the spreading of damage using compressive tests of 2D cellular solids. We evidence a growing length scale ξ that emerges from the cooperative evolution of the damage field within the specimen before localization. In addition, we show that ξ reaches the specimen size at the onset of failure. To interpret this behaviour, we develop a micro-mechanical model that takes into account both the long-range elastic interaction within the specimen and the disordered failure properties of the material. It successfully captures our experimental observations, thus challenging non-local damage models considering a constant (non-evolving) non-local length scale.

EXPERIMENTAL INVESTIGATION OF NON-LOCAL EFFECTS DURING DAMAGE SPREADING

The failure of elasto-damage solids is investigated through compressive tests carried on 2D cellular materials made of hollow cylinders (Fig. 1(a)). As the compressive load is slowly increased, the specimen shows a linear elastic response and then a softening behavior until the emergence of a localization band at peak load (Fig. 1(b) and (c)). The detailed investigation of the mechanical response of the specimen shows that damage accumulates through a series of failure bursts manifesting as load drops, as shown in the inset of Fig. 1(b). The energy S_{global} dissipated during each of these bursts is first estimated macroscopically, using the mechanical response of the specimen. It is shown to increase as the specimen is driven to failure (Fig. 1(d)). In parallel, using particle tracking from image analysis and coarse-graining techniques [4], we compute the evolution of the mechanical fields at the scale of the unit cell. This provides an independent measurement of the size S_{local} of the damage bursts that correlates with the value S_{global} obtained at the macroscopic scale (See Fig. 1(d)).

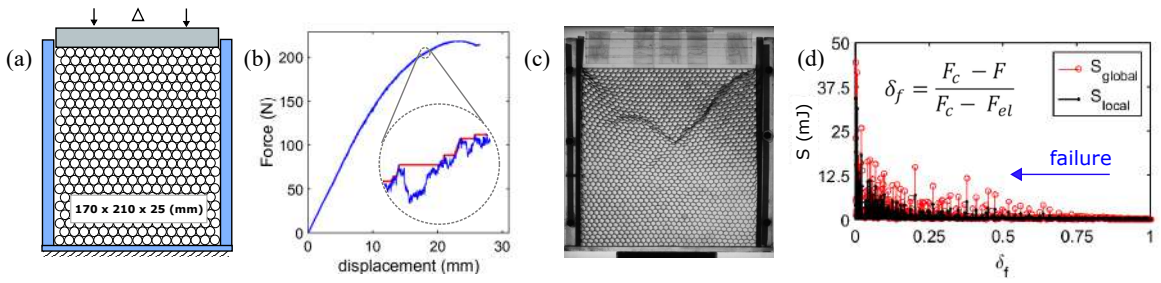

Figure 1: (a) Schematic representation of the compression test. (b) Force-displacement response. (c) Pattern of damage localization observed shortly after the peak. (d) Evolution of dissipated energy during each burst as obtained from global and local analysis.

Interestingly, this local analysis also provides the spatial organization of these bursts, i.e. the location of the local failure events within the specimen at a coarse-grained scale (Fig. 2(a)). This analysis reveals that each individual burst is

*Corresponding author. E-mail: laurent.ponson@upmc.fr.

actually composed of several clusters of characteristic size ξ that corresponds to regions of the specimen where damage grew cooperatively. ξ emerges from the spatio-temporal evolution of the damage field and is reminiscent of the elastic interactions between material elements. It is shown to grow as the specimen is driven close to failure, following the power law behaviour $\xi \sim 1/\delta^{1/2}$ (Fig. 2(b)). Changing the specimen size shows that the non-local length scale ξ reaches the specimen size at localization. Alternatively, the energy S dissipated during each individual burst is represented in Fig. 2(c) and is also shown to grow with a power law behaviour $S \sim 1/\delta^{1/2}$. This is consistent with the scaling relation $\xi \sim S$ between the correlation length of the damage bursts and their energy represented in inset of Fig. 2(c).

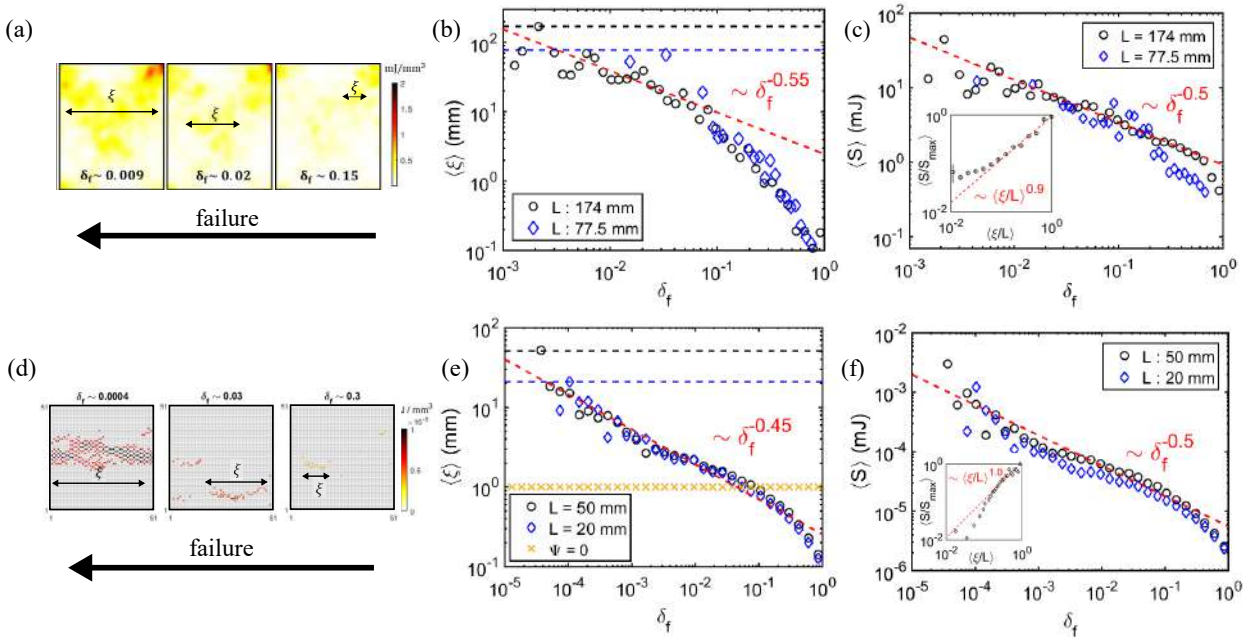

Figure 2: Spatial organization of damage bursts at different distances to failure (a - experiments, d - simulations). Variation of correlation length (b - experiments, e - simulations) and burst sizes with distance to failure (c - experiments, f - simulations). Insets in (c) and (f) : Scaling of correlation length with burst size.

How to interpret these observations? Figures 2(d)-(f) show numerical results drawn from a micro-mechanical model of damage spreading in 2D disordered elasto-damageable specimen. Our simulations rely on two main ingredients: (i) the critical stress at which damage takes place is heterogeneously distributed within the specimen; (ii) each individual damage event induces a local softening of the material. This leads to a redistribution of the stress through the specimen that in turn leads to other damage events through a domino effect. Here, the new mechanical fields are computed after each damage events using a Green function computed from damage mechanics [2]. This model leads to localization at peak load and captures fairly well the macroscopic response of the specimen. More interestingly, it also captures the increase of the length ξ and the size S of the bursts measured from the evolution of the damage field, as well as the associated scaling laws (Figs. 2(e) and (f)). Note that when the stress redistribution is shut down or if the material is homogeneous, the non-local length ξ remains constant (see Fig. 2(e)).

IMPLICATIONS AND PERSPECTIVES

What are the implications of our work? The cooperative spreading of damage in elasto-damageable solids is characterized by a length scale ξ that results from the interplay between the material disorder and the elastic interactions. This size ξ increases and even reaches the specimen size at localization. This evolution challenges current non-local damage models that assumes a finite and constant correlation length. As a perspective, I will discuss how the complex dynamics of damage growth in elasto-damage specimens can be harnessed to estimate and predict their residual life time.

THE EFFECT MECHANISM OF PRESTRESS ON THE DEFORMATION OF METAL BEAMS SUBJECTED TO IMPULSIVE LOAD

Jian Zheng, Fangyun Lu*, Xiangyu Li, and Kefang Zhang
College of Liberal Arts and Sciences, National University of Defense Technology, Changsha, China

Summary During the service time of engineering structures, most structural members are under prestress conditions. In order to figure out the effect mechanism of prestress on the damage of metal beams subjected to impulsive loading, a series of numerical simulations with different prestress conditions and different impulse intensity are conducted. A prestress coefficient and a dimensionless impulsive loading, normalized by energy, are introduced to organised the results. A reasonable relationship between α, Φ and the residual central deformation is found, as well as a small counter-intuitive phenomenon. Because of the correspondence between deformation and internal energy, a simple analysis on the aspect of stress transition and energy absorption is performed and effectively explained the effect mechanism of prestress on the deformation on the mental beams subjected to impulsive loading.

BACKGROUND IMFORMATION

Metal beams are basic structural members, and the study of its damage mechanism to impulsive loading is an important issue in engineering. Since Menkes and Opat [1] published their findings on damage modes of beams in 1973, there follows lots of researches concerned about the deformation prediction and the damage modes segmentation of intensity loaded beams and plates. In these researches, prestress is a rarely talked topic. But in fact, while subjected to impulsive loading, these structural members have mostly been under prestress condition during their service time. In order to figure out the effect mechanism of prestress on the damage of metal beams subjected to impulsive loading, two typical prestress conditions are employed by axial and transverse pre-loading, as shown in figure 1, and only the inelastic deformation damage mode is concerned in this article.

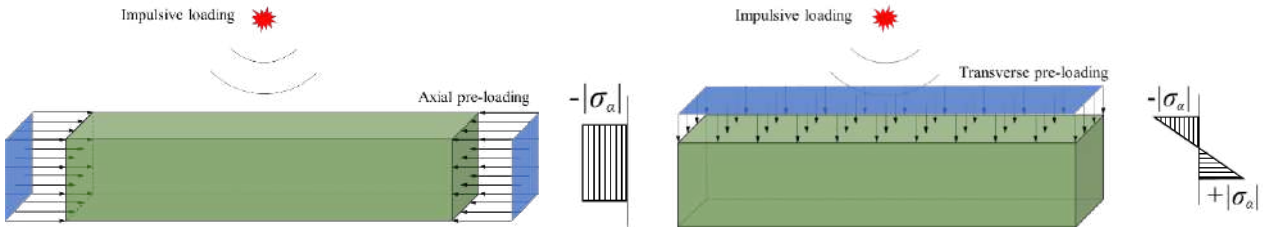

Figure 1. Fully clamped beams under impulsive loading with initial prestress condition.

In the axial pre-loading condition, the prestress can be described by the axial stress σ_α, which can be written as:

$$\sigma_\alpha = \alpha\sigma_0$$

where σ_0 is quasi static yield stress, α is prestress coefficient, $-1 \le \alpha \le 1$. The σ_α is positive when tension, negative when compression. While in the transverse pre-loading condition, the σ_α is the bending stress in the lowest end of section at the central beam.

METHODS

Numerical models were built to simulate plenty of conditions by AUTODYN software, and Aluminium beams with a width, thickness and length of 10mm, 10mm and 100mm were employed. In the axial pre-loading conditions, a series of constant stress boundary condition σ_α was applied to both ends of the beam to perform the axial prestress. In the transverse pre-loading conditions, a series of constant stress boundary condition q was applied to the upside of the beam to perform the transverse prestress, the relation of q and σ_α can be written as: $\sigma_\alpha = ql^2/4bh^2$, where b, h and l are the width, thickness and length of the beam. After the stress condition of the beam have been stabilized, the impulsive loading was performed by apply analytical blast boundary condition on the upside of the beam. The charge weight and coordinates of blast were accurately controlled in the analytical blast definition.

The dimensionless central deformation of the beam ($\delta = W/h$) is the main variable to analysis the effect of prestress. The impulsive loading is normalized by the energy theoretically induced by the charge and the maximum energy absorbed by the beam before yield, which can be calculated by:

$$\Phi = \sqrt{\frac{E_T}{bhl\sigma_0}} = \sqrt{\frac{3mE_m}{4\pi R^3\sigma_0}}$$

where E_T is the theoretical energy given by the charge, m is the charge weight, R is the blast distance. and E_m is the C-J energy per unit mass. The dimensionless impulsive loading Φ and prestress coefficient α are used to show the results of the deformation of the beam.

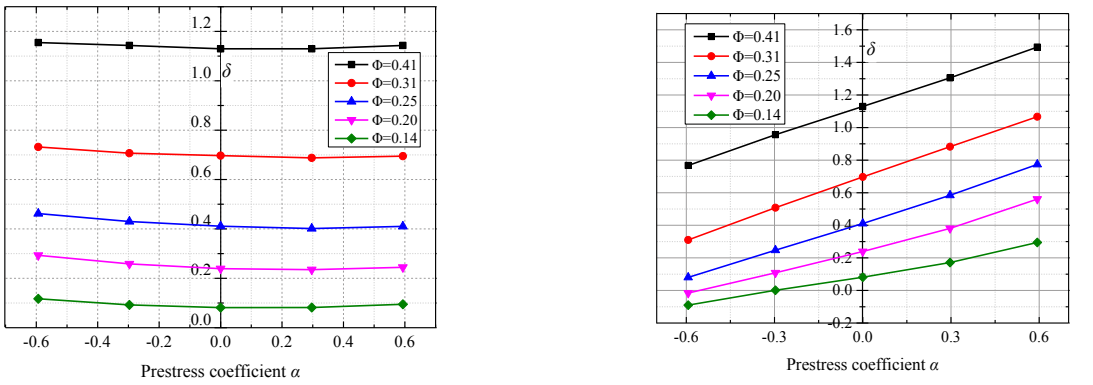
RESULTS AND CONCLUSIONS

Deformation results of two typical prestress conditions

The deformation data is organized by variables mentioned above, and the final results are shown in figure 2. Figure 2a) shows the residual central deformation of beams subjected to different impulsive intensity under axial pre-loading, while figure 2b) under transverse pre-loading. At all events, the deformation is obviously increased with the increasing Φ. In transverse prestress condition, a negative α always reduces the deformation while a positive α increasing the deformation. However, in axial prestress condition, opposite α doesn't always bring in opposite influence on the deformation (In figure 2a), the δ at α=0.6 are slightly higher than the left points).



a) Results under axial prestress conditions

b) Results under transverse prestress conditions

Figure 2. The central deformation of beams under different prestress conditions subjected to different impulsive loadings.

Effect mechanism of the prestress on the energy absorption

To make clear the different effect mechanism of two prestress, a simplify analysis on the change of stress and a contrast of the energy absorption were performed, shown in figure 3. In the axial prestress condition, the impulsive loading made the stress of the beam section changing from the uniformly distributed elastic stress to the plastic stress, separated by the neutral axis, with one side of being positive and the other side negative. During this transition, the stress on one side of the neutral axis continues to increase, while the stress on the other side is released first and then increased. Therefore, the initial internal energy caused by axial prestress is not fully contributed to the final energy. In the transverse prestress condition, the stress changed from linearly distributed elastic stress to neutral-axis-separated plastic stress. The stress on both sides of the neutral axis change in the same pace, so the initial internal energy caused by transverse prestress is totally contributed to the final energy.

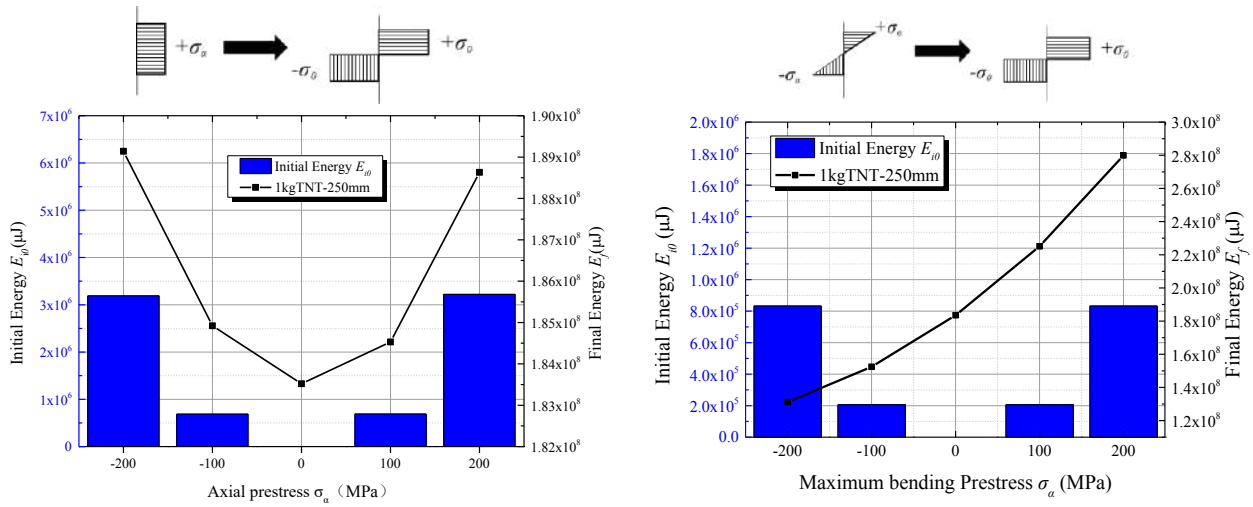


Figure 3. The transition of stress and energy in beams. Up: stress transition. Down: energy transition. The initial internal energy in axial $E_{i0} = \sigma_\alpha^2 bhl/2E$, and in transverse $E_{i0} = \sigma_\alpha^2 bhl/8E$

EFFECTS OF STRESS TRIAXIALITY ON DAMAGE BEHAVIOUR OF HDPE

Yi Zhang[1]*, Shifeng Xue[1]& P.-Y. Ben Jar[2]
Department of Engineering Mechanics, College of Pipeline and Civil Engineering, China University of Petroleum (East China), Qingdao, China
Department of Mechanical Engineering, University of Alberta, Edmonton, Alberta, Canada

Summary This paper examines the influence of stress triaxiality on damage behaviour of high-density polyethylene (HDPE) using notched round bar specimens with different notch radii. A two-stage test method was developed to quantitatively assess damage evolution under different stress triaxialities. The first-stage tests were to introduce damage by subjecting the specimens to different prestrain levels under monotonic tensile loading condition. Two months later, the second-stage tests apply monotonic tensile loading at a crosshead speed of 0.01 mm/min to characterize the change in mechanical properties. The results indicate that both yield stress and elastic modulus decrease with the increase of the prestrain. The results also suggest that the extent of decrease of yield stress and elastic modulus, and the damage evolution, strongly depend on the stress triaxality.

INTRODUCTION

Semi-crystalline polymers are increasingly used in a broad range of applications such as pressure tubing, pipeline systems and parts in nuclear power plant. Nowadays, majority of low-pressure natural gas pipes with a 50-year service life are made of polyethylene (PE). It is well-known that characteristics of damage and failure mechanisms depend on the stress state acting in a material point. Although a number of research work have been conducted to investigate effects of stress state on damage and fracture behaviour, majority of them were focused on metallic materials [1–5]. Very few studies have been conducted to reveal the influence of stress state on the damage and fracture behaviour of polymeric materials, let alone its influence on the damage evolution and undamaged constitutive equations [6–8]. Scarcity of information in this area provides motivation for the current study.

EXPERIMENTAL DETAILS

This study concerns a semi-crystalline polymer, high density polyethylene (HDPE). As shown in Figure 1, Notched round bar specimens with notch radii of 0.5, 2, 5 and 20mm are used in this study. The specimens are of the same minimum diameter of 6 mm in the gauge sections, the same diameter of 10 mm in the shoulder parts and the same length of 150 mm. The variation of the minimum diameter was measured using an extensometer.

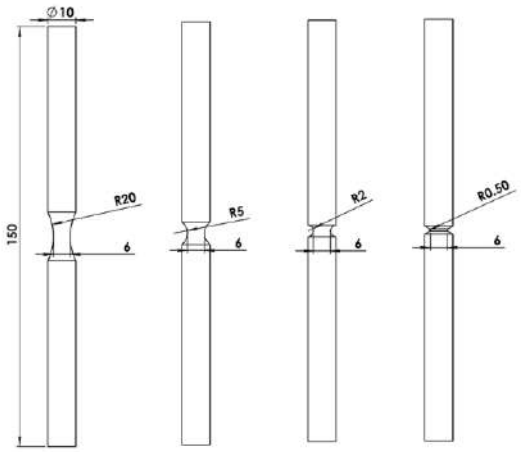

Figure 1 Notched round bar specimens with different notch radii

A two-stage test procedure was proposed to quantitatively determine damage evolution based on the degradation of elastic modulus. The first-stage tests were to apply monotonic tensile loading to five displacements (1.8, 2, 2.3, 2.5 and 2.7mm for specimen with radius of 0.5mm, 1.5, 2, 2.5, 3, 3.5 and 4mm for specimens with radius of 2mm, 1, 2, 3, 4 and 5mm for specimens with radius of 5mm, and 2, 3, 4, 5, 6 and 8mm for specimens with radius of 20mm) at a crosshead speed of 1 mm/min. In contrast, condition used for the second-stage test was monotonic tensile loading at the crosshead speed of 0.01mm/min. Yield stress and elastic modulus were determined from the second-stage tests, to evaluate influence of the prestrain level and stress triaxiality on variation of their values.

[a)] Corresponding author. Email: zhangyi@upc.edu.cn.

RESULTS AND DISCUSSION

Yield stress and elastic modulus determined from the second-stage tests are summarized in Fig. 2(a) and 2(b), respectively, as a function of prestrain introduced in the first-stage tests. The figures suggest that both yield stress and elastic modulus decrease with the increase of the prestrain. The degradation of yield stress and elastic modulus is more severe when the notch radius is reduced. Damage parameter (D) is determined based on the variation of elastic modulus, as shown below [6]:

$$D = 1 - \frac{E}{E_0} \tag{1}$$

where E and E_0 are elastic moduli of the specimens with and without the prestrain, respectively.

Fig. 2(c) presents variation of D value as a function of the prestrain introduced in the first-stage test. The figure also includes curves generated using Equation (2) [7], with values for A and B determined by fitting the curves to the trend of change of measured values. Fig. 2(c) indicates that both prestrain and stress state have a significant effect on the change of D values.

$$D = A\left[1 - \exp\left(-B\varepsilon\right)\right] \tag{2}$$

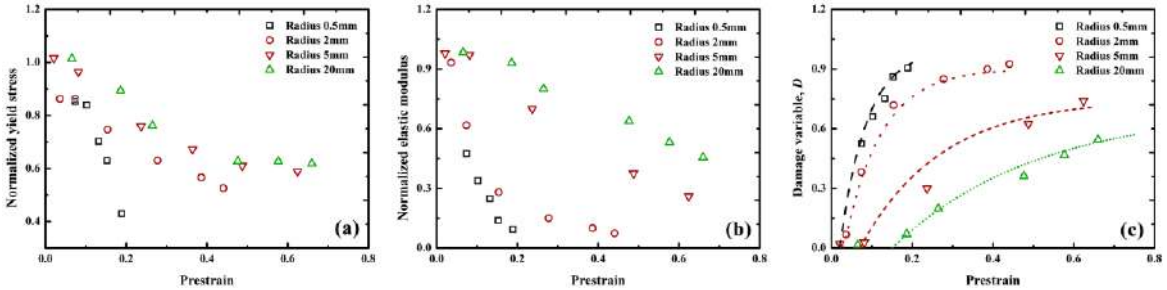

Figure 2 Effects of prestrain applied in the first test on the yield stress (a), elastic modulus (b) and the damage parameter *D* determined based on the variation of elastic modulus (c)

CONCLUSIONS

Effects of stress triaxiality on damage behaviour of HDPE have been assessed using the two-stage test method, on notched round bar specimens with different curvature radii. The results show that mechanical properties of HDPE are strongly affected by the stress state of specimens used in the first-stage test. In particular, elastic modulus from the second-stage test, measured at the strain of 0.5%, decreases significantly with the increase of prestrain applied in the first-stage test. Damage evolution in the first-stage test is established using a phenomenological damage model based on the variation of the elastic modulus measured from the second-stage test. The results suggest that increase of stress triaxiality, i.e., decrease of the curvature radii, causes acceleration of the damage evolution, thus increasing the extent of damage in the HDPE material. Further investigation will be conducted to evaluate effects of stress triaxiality on damage mechanism in HDPE from microscopic point of view, and the results will be presented in the conference.

STABILITY AND DAMAGE EVALUATION ON FULL-SCALED ASYMMETRIC SANDWICH PANELS UNDER COMPRESSION

Jian Deng*[1,2] and Tian Jian Lu[1,2]
[1]State Key Laboratory of Mechanics and Control of Mechanical Structures, Nanjing University of Aeronautics and Astronautics, Nanjing, China
[2]Nanjing Center for Multifunctional Lightweight Materials and Structures, Nanjing University of Aeronautics and Astronautics, Nanjing, China

Summary In practical applications, asymmetric sandwich panels (ASPs) with tapered and junction regions are frequently used. For structure safety consideration, it is necessary to systematically investigate the stability and damage behaviour of full-scaled asymmetric sandwich panels under uniaxial compression experimentally and numerically. Comparisons between numerical predictions and experimental measurements were conducted with a good agreement achieved. Results showed the tapered region intensified the asymmetry and introduced additional bending moments into ASPs and thus caused early local buckling. Large amounts of matrix cracking, fibre push-out and core-skin delamination were captured numerically and experimentally.

INTRODUCTION

One of the biggest challenges in modern times is how to create products that are lighter, faster and stronger, and a technical revolution to realize this goal is composite materials. Sandwich structures characterizing in light weight and high performance are universally introduced and continuing to be in demand in high-performance industries [1, 2]. Due to the asymmetry in nature, sandwich panels with junction regions are susceptible to buckle, that may cause damage and ultimate failure of sandwich panels. This intensifies the necessity of evaluation on stability and damage mechanism of asymmetric sandwich panels. This is the main objective of present study. Uniaxial compression tests and numerical modelling were conducted. Numerical predictions are compared to experimental results, and the findings are discussed.

EXPERIMENTS AND NUMERICAL MODELLING

The test specimens were foam-core sandwich panels skinned with carbon fibre reinforced plastics (U3160/5284). As illustrated in Fig. 1, the ASP can hypothetically be divided into three different regions, namely central region (pure sandwich), tapered region and junction region. The junction region composed of monolithic fibre-reinforced composites are functionally used to introduce loads to the central pure sandwich through the tapered region. It should be noted that the lower smooth skin is generally applied with thick laminates, named as working face-sheet (WFS). On the other hand, the upper fluctuant face serves as stabilizing skin with fewer layups, named as the stabilizing face-sheet (SFS). The core material is PMI foam, commonly used in aerospace industry.

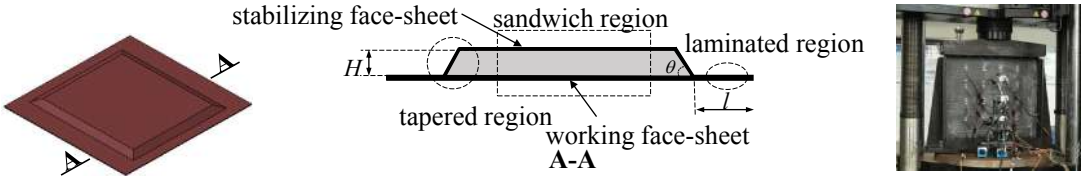

Figure 1: Schematic illustration of the asymmetric sandwich structure and test setup.

For sandwich panels subjected to compression, damage may initiate in the skins at intra-laminar level (i.e. fibre breakage and matrix cracking), in the core layer and at the interface between the core and skins. Cohesive zone model is applied to predict the core-skin interfacial damage initiation and evolution. The initiation of intra-laminar damage is determined with Hashin [3] and Puck criteria [4]. An energy-based smeared crack approach is then employed to simulate the damage evolution. The fracture energy release rate is assumed constant during the softening procedure. Numerical analysis are conducted in ABAQUS® coupled with a UMAT subroutine.

RESULTS AND DISCUSSION

A good agreement is achieved from the comparison between numerical predictions and experimental measurements regarding both linear-elastic and nonlinear responses of the load vs. end-shortening curves in Fig. 2(a). For axial strains, numerical results are embedded by the experimental measurements since the loading starts as shown in Fig. 2(b),. Discrepancies exist in experimental and numerical results. The possible reason is that the micro manufacturing defects cannot be completely taken into account in the FEM simulation. A quasi-linear response is found in the thicker WFS

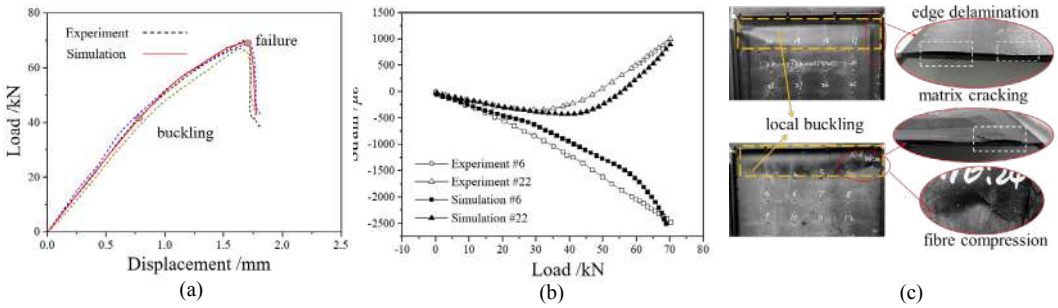

Figure 2: (a) Comparison of numerical and experimental results of end-load vs. end-shortening curves; (b) Comparison of numerical and experimental strains vs. end-load; (c) Typical failure modes in experiments.

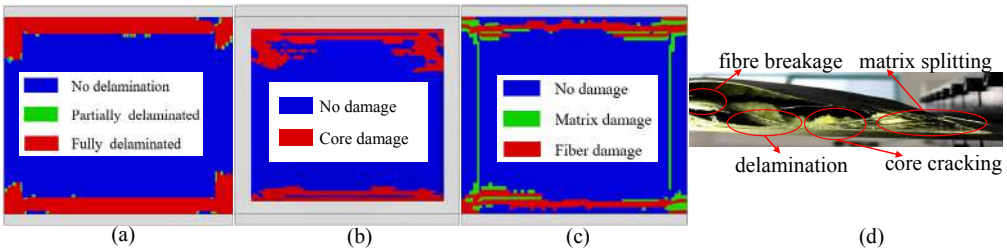

Figure 3: Damage patterns at the ultimate failure load: (a) Delamination at the WFS-core interface; (b) Core damage; (c) Intra-laminar damage in face-sheets; (d) Experimental observation of failure mechanisms.

while remarkable nonlinearity occurs in the SFS prior to ultimate failure. Prior to ultimate failure, the SFS remains in tension with strains at low levels while extreme compression occurs on WFS, causing more damage in WFS. Intermittent sounds occurred after buckling. As loading continued, the panel surface was locally bulged with a continuous cracking sound. Various types and amounts of damage observed across the width direction near the tapered region, including delamination, matrix cracking and fibre compression as shown in Fig. 2(c).

Fig. 3(a) illustrates the failure patterns of skin-core interfacial delamination. With delamination accumulating, the face-sheets are losing support from the core, and fibre and matrix damage initiates and propagates in the laminates while the foam core fails by shearing and compression. As shown in Fig. 3(b), large amount of damage accumulated in the core through width direction. The location of core cracking is quite identical to detailed experimental observation that validates the numerical accuracy of the FE model. Without the core support, critical fibre breakage and matrix splitting are dramatically developed in the face-sheets, further leading to ultimate failure of the sandwich panel as shown in Fig. 3(c). Compared to experimental results in Fig. 3(d), the proposed numerical model can feasibly predict the failure mechanisms.

CONCLUSIONS

Full-scaled asymmetric sandwich panels (ASPs) with tapered and junction regions under compression were investigated experimentally and numerically in this work, regarding stability, load capacity and damage mechanism. Results showed that the tapered region intensifies the asymmetry and introduces additional bending moments into ASPs, causing early local buckling. Large amounts of matrix cracking, fibre push-out and core-skin delamination occurred. Optimal parameters of the tapered region will be studied in the future.

A SIMPLE EXPLICIT HOMOGENIZATION SOLUTION FOR THE MACROSCOPIC ELASTIC RESPONSE OF ISOTROPIC POROUS ELASTOMERS

Victor Lefèvre*[1], Bhavesh Shrimali[2], and Oscar Lopez-Pamies[2]
[1]Department of Mechanical Engineering, Northwestern University, USA
[2]Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, USA

Summary An approximate homogenization solution is put forth for the effective stored-energy function describing the macroscopic elastic response of isotropic porous elastomers comprised of incompressible non-Gaussian elastomers embedding equiaxed closed-cell vacuous pores. In spite of its generality, the solution is fully explicit and remarkably simple. Its key theoretical and practical features are discussed in detail and its accuracy is demonstrated by means of direct comparisons with novel computational solutions for porous elastomers with four classes of physically relevant isotropic microstructures wherein the underlying pores are: (i) infinitely polydisperse in size and of abstract shape, (ii) finitely polydisperse in size and spherical in shape, (iii) monodisperse in size and spherical in shape, and (iv) monodisperse in size and of oblate spheroidal shape.

A *fully explicit*, *remarkably simple*, and *accurate* approximate homogenization solution was recently put forth [1] for the effective stored-energy function describing the macroscopic elastic response of porous elastomers. More specifically, the solution pertains to isotropic porous elastomers comprised of incompressible non-Gaussian elastomers embedding non-percolative equiaxed — but of arbitrary shape otherwise — closed-cell vacuous pores with initial porosity f_0; see Fig. 1 for a schematic.

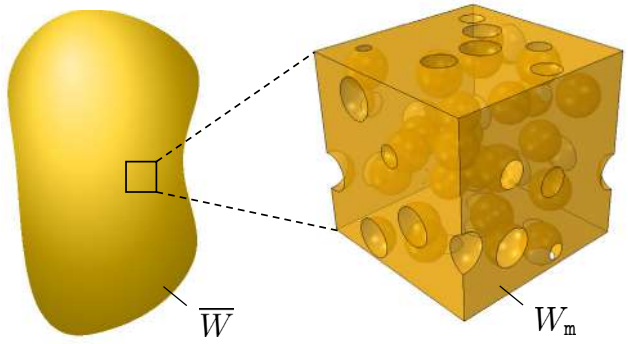

Figure 1: Schematic of a porous elastomer with initial porosity $f_0 = 0.15$ with spherical and monodisperse pores.

For an isotropic incompressible non-Gaussian elastomeric matrix with stored-energy function $W_{\rm m}$ of the form[1]

$$W_{\rm m}(\mathbf{F}) = \begin{cases} \Psi_{\rm m}(\mathbf{F}\cdot\mathbf{F}) & \text{if } \det\mathbf{F} = 1 \\ +\infty & \text{otherwise} \end{cases}$$

where $\mathbf{F}$ denotes the deformation gradient, the approximate homogenization solution for the effective stored-energy function $\overline{W}$ of the porous elastomer is given by

$$\begin{cases} \overline{W}(\overline{\mathbf{F}}, f_0) = (1-f_0)\,\Psi_{\rm m}\left(\dfrac{\mathcal{I}_1}{1-f_0}+3\right) & \text{with} \\ \mathcal{I}_1 = \dfrac{3(1-f_0)}{3+2f_0}\left[\overline{I}_1-3\right] + \dfrac{3}{\overline{J}^{1/3}}\left[2\overline{J}-1-\dfrac{(1-f_0)\,\overline{J}^{1/3}\left(3\overline{J}^{2/3}+2f_0\right)}{3+2f_0} - \dfrac{f_0^{1/3}\overline{J}^{1/3}\left(2\overline{J}+f_0-2\right)}{\left(\overline{J}-1+f_0\right)^{1/3}}\right] \end{cases}$$

in terms of the standard macroscopic principal invariants $\overline{I}_1 = \overline{\mathbf{F}}\cdot\overline{\mathbf{F}}$ and $\overline{J} = \det\overline{\mathbf{F}}$ of the macroscopic deformation gradient $\overline{\mathbf{F}}$. The above effective stored-energy function implies the simple explicit expression

$$\overline{\mathbf{S}} = \frac{6(1-f_0)}{3+2f_0}\Psi'_{\rm m}\left(\frac{\mathcal{I}_1}{1-f_0}+3\right)\overline{\mathbf{F}} + \left[\frac{3+6\overline{J}+2f_0(1+7\overline{J})}{(3+2f_0)\overline{J}^{1/3}} + \frac{f_0^{1/3}\overline{J}(4-5f_0-4\overline{J})}{(\overline{J}+f_0-1)^{4/3}}\right]\Psi'_{\rm m}\left(\frac{\mathcal{I}_1}{1-f_0}+3\right)\overline{\mathbf{F}}^{-T} \tag{1}$$

for the macroscopic stress $\overline{\mathbf{S}} \doteq \partial\overline{W}/\partial\overline{\mathbf{F}}$.

[1] $\Psi_{\rm m}$ is a non-negative function of choice satisfying the standard linearization and strong ellipticity conditions.

With the objective of illustrating the accuracy of the proposed simple explicit homogenization solution for arbitrary finite deformations, the general macroscopic stress-deformation response (1) is confronted to FE solutions for a porous elastomer comprising an elastomeric matrix characterized by the stored-energy function[2]

$$W_{\rm m}(\mathbf{F}) = \begin{cases} \Psi_{\rm m}(\mathbf{F}\cdot\mathbf{F}) = \displaystyle\sum_{r=1}^{2} \frac{3^{1-\alpha_r}}{2\alpha_r}\mu_r\left[(\mathbf{F}\cdot\mathbf{F})^{\alpha_r} - 3^{\alpha_r}\right] & \text{if } \det\mathbf{F} = 1 \\ +\infty & \text{otherwise} \end{cases}$$

and embedding pores that are monodisperse in size and spherical in shape. Figure 2 shows plots of the macroscopic stress-deformation response for the porous elastomer subjected to two types of loading conditions that are accessible by standard experimental techniques and three values of initial porosity, $f_0 = 0.05$, 0.15, and 0.25. Corresponding FE stress-deformation results for isotropic distributions of polydisperse spherical pores and monodisperse oblate spheroidal pores are virtually indistinguishable from those presented in Fig. 2 for monodisperse spherical pores.

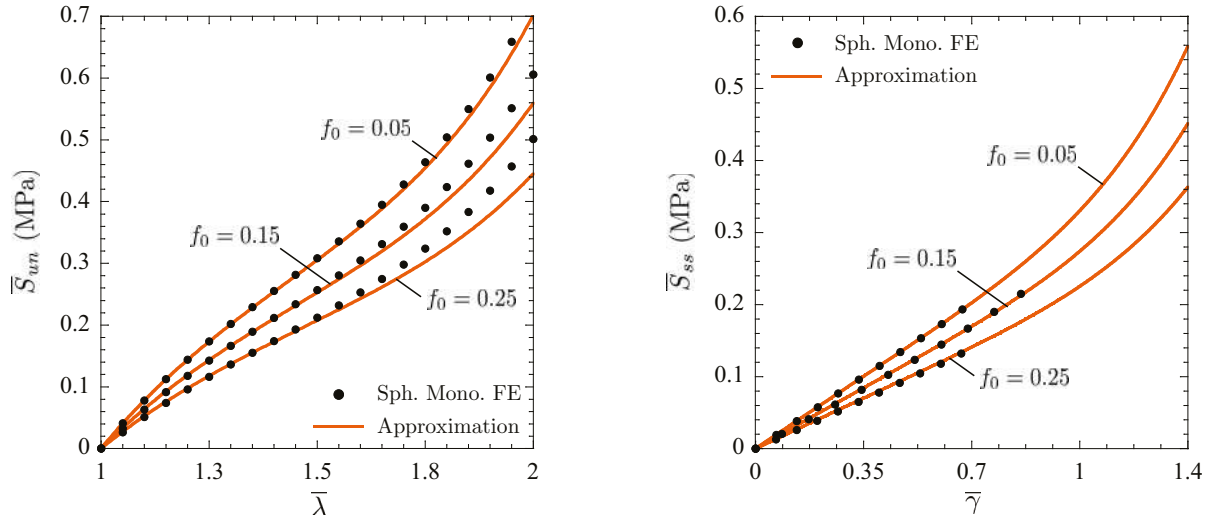

Figure 2: Macroscopic response of porous silicone elastomers with various values of initial porosity f_0 under: (a) uniaxial tension and (b) simple shear. Plots are shown for the appropriate component of the stress-deformation relation (1) — labeled "Approximation" and displayed as solid lines — together with corresponding FE solutions (solid circles) for isotropic distributions of pores of monodisperse size and spherical shape.

ESHELBY'S INCLUSION PROBLEM IN LARGE DEFORMATIONS

Mawafag F. Alhasadi and Salvatore Federico*
Department of Mechanical and Manufacturing Engineering, The University of Calgary, Calgary, AB, Canada

Summary In the framework of large deformations, we propose a multiplicative decomposition of the deformation gradients corresponding to the additive decomposition that Eshelby (1957, *Proc. Roy. Soc. Ser. A*, 241: 376-396) used to investigate the theory of inclusions in the case of infinitesimal deformations. We show that the proposed decomposition is a hybrid between the Bilby-Kröner-Lee and the Noll-Epstein-Maugin ones and encompasses those proposed by other Authors as particular cases.

INTRODUCTION

In a classical paper, Eshelby [3] studied the problem of a body in which a region (the inclusion) has a geometrical misfit with the surrounding material (the matrix). Eshelby represented the geometrical misfit in terms of a *transformation strain* (or *eigenstrain*) $\boldsymbol{\epsilon}_t$ (in our notation), transforming the shape of a cavity in a body into a different shape. In order to implant this misfitting inclusion into the original cavity, one first applies surface tractions causing a strain exactly equal to $-\boldsymbol{\epsilon}_t$ in the inclusion, then implants the inclusion, and finally releases the surface tractions, which causes a strain $\boldsymbol{\epsilon}_c$ (in our notation), called *constrained strain*, discontinuous at the interface between the inclusion and the matrix.

In the setting of large deformations, Eshelby's inclusion problem has been formulated in terms of a multiplicative decomposition $\boldsymbol{F} = \boldsymbol{F}^e\boldsymbol{F}^*$ of the deformation gradient (in the notation of [1]), where $\boldsymbol{F}^*$ and $\boldsymbol{F}^e$ correspond to Eshelby's $-\boldsymbol{\epsilon}_t$ and $\boldsymbol{\epsilon}_c$, respectively. This approach is based on the classical Bilby-Kröner-Lee (e.g., [4]) decomposition $\boldsymbol{F} = \boldsymbol{F}_e\boldsymbol{F}_a$, originally devised for plasticity, in which $\boldsymbol{F}_a$ is the anelastic deformation and $\boldsymbol{F}_e$ the purely elastic one, and both are generally *non-integrable*. In Noll's theory of material uniformity [5], Epstein and Maugin [2] defined the *implant* tensor $\boldsymbol{P}$ as the tensor mapping an *archetypal* point with tangent space $\mathcal{A}$ (a fixed vector space) into the body, causing a generally *non-integrable* distortion $\boldsymbol{F}_e$. In this formulation, the purely elastic deformation of the theory of plasticity reads $\boldsymbol{F}_e = \boldsymbol{F}\boldsymbol{P}$. Comparison with the Bilby-Kröner-Lee decomposition shows that, for the case of a uniform body, the implant tensor is the inverse of the plastic deformation, i.e., $\boldsymbol{P} = \boldsymbol{F}_a^{-1}$ (Figure 1).

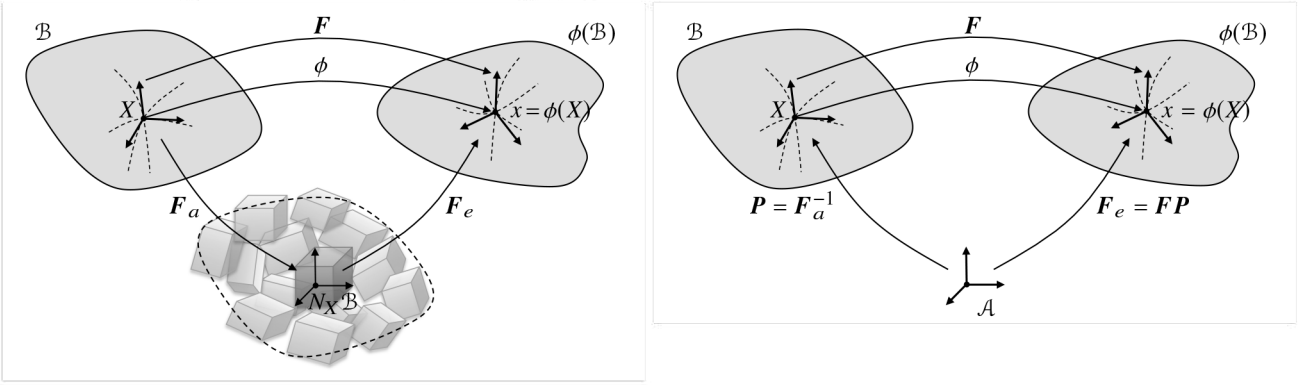

Figure 1: Left: Bilby-Kröner-Lee decomposition, with the generally incompatible collection of natural states $N\mathcal{B}$, disjoint union of the vector spaces $N_X\mathcal{B}$. Right: Implant tensor $\boldsymbol{P}$ in a uniform material, mapping, at every $X \in \mathcal{B}$, the archetype $\mathcal{A}$ into the tangent space $T_X\mathcal{B}$ and equivalence of the Bilby-Kröner-Lee and Noll-Epstein-Maugin decompositions, for the case of a uniform body.

Our goal is twofold. First, we show that Eshelby's inclusion problem admits a multiplicative decomposition of the deformation gradient that is *piecewise* (matrix/inclusion) compatible, i.e., each resulting deformation gradient is in fact the tangent map of a certain configuration map in the matrix or the inclusion. Second, we show that Eshelby's original additive decomposition of the infinitesimal strain [3] is most naturally represented, in large deformations, via a *mixed* formulation, in which the deformation corresponding to the transformation strain $\boldsymbol{\epsilon}_t$ is an $\boldsymbol{F}$-type tensor of the Bilby-Kröner-Lee (BKL) decomposition, while the deformation corresponding to the constrained strain $\boldsymbol{\epsilon}_c$ is a $\boldsymbol{P}$-type implant tensor of the Noll-Epstein-Maugin (NEM) decomposition.

ESHELBY'S PROCEDURE IN LARGE DEFORMATIONS

We build the body $\mathcal{B}$ with a homogeneous inclusion with reference to Figure 2 (left). We start from a body $\tilde{\mathcal{M}}$ with a cavity described by $\tilde{\mathcal{R}}$ and another body $\mathcal{D}^*$ which *does not fit* the cavity $\mathcal{R}$. The set $\mathcal{B}^* = \tilde{\mathcal{M}} \cup \mathcal{D}^*$ is an *incompatible* configuration of our body $\mathcal{B}$. In order to fit $\mathcal{D}^*$ into the cavity $\tilde{\mathcal{R}}$ of $\tilde{\mathcal{M}}$, we apply tractions on the boundary $\partial\mathcal{D}^*$ of the inclusion. As a result, the inclusion $\mathcal{D}^*$ undergoes a deformation described by

$$\varphi_t = \begin{cases} \varphi_t^{(i)} & : \mathcal{D}^* \to \tilde{\mathcal{D}}, \quad \text{in } \mathcal{D}^*, \\ \varphi_t^{(m)} \equiv \mathrm{Id} & : \tilde{\mathcal{M}} \to \tilde{\mathcal{M}}, \quad \text{in } \tilde{\mathcal{M}}, \end{cases} \qquad \boldsymbol{P}_t = \begin{cases} \boldsymbol{P}_t^{(i)} & : T\mathcal{D}^* \to T\tilde{\mathcal{D}}, \quad \text{in } \mathcal{D}^*, \\ \boldsymbol{P}_t^{(m)} \equiv \boldsymbol{I} & : T\tilde{\mathcal{M}} \to T\tilde{\mathcal{M}}, \quad \text{in } \tilde{\mathcal{M}}, \end{cases} \tag{1}$$

*Corresponding author. E-mail: salvatore.federico@ucalgary.ca

where the *transformation map* $\varphi_t^{(i)}$ in the inclusion transforms $\mathcal{D}^*$ precisely into $\tilde{\mathcal{D}} \equiv \tilde{\mathcal{R}}$ while the $\varphi_t^{(m)}$ is the identity map and leaves the matrix untouched, and thus the *transformation implant* $\boldsymbol{P}_t$ is integrable and defined *piecewise*, with $\boldsymbol{P}_t^{(i)}$ being a deformation and $\boldsymbol{P}_t^{(m)}$ being the identity tensor. We denote $\tilde{\mathcal{B}} = \tilde{\mathcal{M}} \cup \tilde{\mathcal{D}}$ the configuration in which the matrix $\tilde{\mathcal{M}}$ is still stress-free but the inclusion $\tilde{\mathcal{D}}$ is subjected to the stresses caused by the transformation map $\varphi_t^{(i)}$ and transformation implant $\boldsymbol{P}_t^{(i)}$. Once the transformed inclusion $\tilde{\mathcal{D}}$ has been fit into the cavity $\tilde{\mathcal{R}}$, we impose *perfect bonding* between matrix and inclusion and relax the surface tractions on $\partial\tilde{\mathcal{D}}$. This causes *both* $\tilde{\mathcal{D}}$ and $\tilde{\mathcal{M}}$ to relax elastically, according to

$$\varphi_c : \tilde{\mathcal{B}} \to \mathcal{B}, \qquad \boldsymbol{P}_c = \begin{cases} \boldsymbol{P}_c^{(i)} & : T\tilde{\mathcal{D}} \to T\mathcal{D}, \quad \text{in } \tilde{\mathcal{D}}, \\ \boldsymbol{P}_c^{(m)} & : T\tilde{\mathcal{M}} \to T\mathcal{M}, \quad \text{in } \tilde{\mathcal{M}}, \end{cases} \tag{2}$$

where the *constrained map* φ_c is everywhere continuous but is non-differentiable on $\partial\tilde{\mathcal{D}}$, i.e., its tangent map $\boldsymbol{P}_c \equiv T\varphi_c$ is not defined on $\partial\tilde{\mathcal{D}}$ and presents a *jump condition* on $\partial\tilde{\mathcal{D}}$. The resulting configuration $\mathcal{B}$ is the sought reference configuration of our body with a misfitting inclusion, and is subjected to *residual stresses*, which are *continuous* on the matrix-inclusion interface $\partial\mathcal{D}$. When $\mathcal{B}$ is subjected to a deformation described by the configuration map ϕ and its tangent map $\boldsymbol{F} = T\phi$, it attains the *current configuration* $\phi(\mathcal{B})$.

PROPOSED MULTIPLICATIVE DECOMPOSITION

Let us refer to Figure 2 (right). For the case of the BLK decomposition, we have $\boldsymbol{F} = \boldsymbol{F}_e\boldsymbol{F}_t\boldsymbol{F}_c$, where $\boldsymbol{F}_t\boldsymbol{F}_c$, given by the *transformation deformation gradient* $\boldsymbol{F}_t$ and the *constrained deformation gradient* $\boldsymbol{F}_c$, replaces the anelastic deformation $\boldsymbol{F}_a$ of the classical BLK decomposition $\boldsymbol{F} = \boldsymbol{F}_e\boldsymbol{F}_a$. For the case of the NEM multiplicative decomposition, we have $\boldsymbol{F}_e = \boldsymbol{F}\boldsymbol{P}_c\boldsymbol{P}_t$, where the implant tensor $\boldsymbol{P}$ has been replaced by the product $\boldsymbol{P}_c\boldsymbol{P}_t$ of the constrained implant $\boldsymbol{P}_c$ and transformation implant $\boldsymbol{P}_t$ described in Eqs. (1) and (2). Thus, we have that $\boldsymbol{P}_c = \boldsymbol{F}_c^{-1}$ and $\boldsymbol{P}_t = \boldsymbol{F}_t^{-1}$.

In order to match Eshelby's original additive decomposition of the infinitesimal strain, we propose a *mixed* BKL-NEM formulation, in which we consider as primary objects the transformation deformation $\boldsymbol{F}_t = \boldsymbol{P}_t^{-1}$ and the constrained implant $\boldsymbol{P}_c$, and write the decomposition as

$$\boldsymbol{F}_e = \boldsymbol{F}\boldsymbol{P}_c\boldsymbol{F}_t^{-1}, \tag{3}$$

in which we recall that $\boldsymbol{F}_t^{-1} = \boldsymbol{P}_t$ is defined *piecewise* in the matrix and in the inclusion, according to Eq. (1). Linearising, we see that Eq. (3) is the large-deformation counterpart of Eshelby's decomposition $\boldsymbol{\epsilon}_e = \boldsymbol{\epsilon} + \boldsymbol{\epsilon}_c - \boldsymbol{\epsilon}_t$ (in our notation).

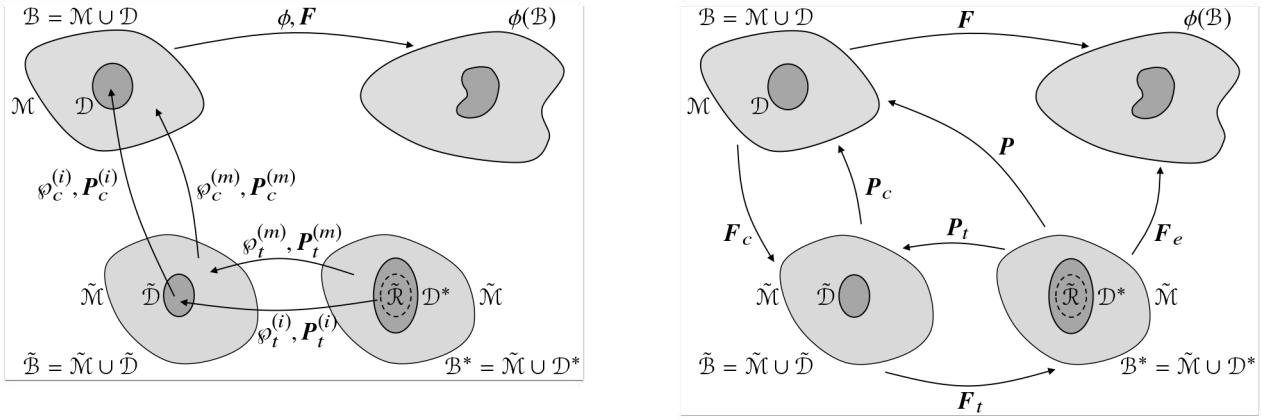

Figure 2: Left: Eshelby's procedure to *implant* an inclusion in a homogeneous matrix. Right: Mixed BKL-NEM decomposition for the inclusion problem in large deformations, corresponding to Eshelby's additive decomposition in in infinitesimal deformations.

REMARKS AND CONCLUSIONS

In his original presentation Eshelby [3] actually deformed the shape of the cavity $\tilde{\mathcal{R}}$ into the shape of the misfitting inclusion $\mathcal{D}^*$ by means of the transformation strain $\boldsymbol{\epsilon}_t$, corresponding, in our framework, to $\boldsymbol{F}_t = \boldsymbol{P}_t^{-1}$. Thus, Eq. (3) shows that Eshelby's formulation was in fact a *mixed* formulation, with the (*implant*) constrained strain $\boldsymbol{\epsilon}_c$, corresponding to our constrained implant $\boldsymbol{P}_c$, and the transformation strain $\boldsymbol{\epsilon}_t$, corresponding to our transformation deformation $\boldsymbol{F}_t$.

POLARIZATION RATIO OF RAYLEIGH WAVES IN VERTICALLY-INHOMOGENEOUS AND WEAKLY-ANISOTROPIC ELASTIC MEDIA

Kazumi Tanuma*[1], Chi-Sing Man[2], and Yue Chen[3]
[1]Department of Mathematics, Faculty of Science and Technology, Gunma University, Kiryu, Japan

[3]Department of Mathematics and Computer Science, Auburn University at Montgomery, Montgomery, USA

Summary The polarization ratio r_R of Rayleigh waves is defined as the ratio of the maximum longitudinal and maximum normal component of the displacements at the surface on which the Rayleigh waves propagate. Herein we present a procedure by which a high-frequency asymptotic formula can be derived for the polarization ratio of the Rayleigh waves that propagate along the free surface of a vertically-inhomogeneous, prestressed, and weakly-anisotropic elastic half-space. The vertical inhomogeneity of the half-space induces dispersion or frequency (f) dependence of r_R, for which the high-frequency formula can be used to obtain asymptotic approximations. We illustrate the procedure by using it to generate dispersion curves of $r_R(f)$ for Rayleigh waves that propagate in various directions along the surface of a prestressed thick-plate sample of an AA 7075-T651 aluminum alloy.

INTRODUCTION

There are simulation studies [1, 6] which indicate that for many materials the polarization ratio of Rayleigh waves could be a promising means for nondestructive evaluation of stress. As compared with Rayleigh-wave velocity, the polarization ratio r_R enjoys the advantages that it is more sensitive to the state of stress (up to an order of magnitude bigger per MPa shift in stress in various steels, CP titanium, etc.), less sensitive to uncertainties in third-order elastic constants, and independent of wave-path distance, the culprit that limits the accuracy in absolute velocity measurements. On the other hand, both the aforementioned studies pertain to *homogeneous* media.

In this paper we study dispersion of polarization ratio $r_R(f)$, where f is the frequency, for Rayleigh waves that propagate in various directions along the surface of a vertically-inhomogeneous, prestressed, and weakly-anisotropic elastic half-space. We present a procedure to derive a high-frequency asymptotic formula by which asymptotic approximations to $r_R(f)$ can be generated when all the relevant information on material constants and prestress are known.

THE DIRECT PROBLEM

In a Cartesian coordinate system let (x_1, x_2, x_3) be the Cartesian coordinates of place $\mathbf{x}$. We consider Rayleigh waves which propagate along the traction-free surface of the material half-space $x_3 \leq 0$. We assume that the material half-space carries a density $\rho(x_3)$ and prestress $\overset{\circ}{\boldsymbol{T}}(x_3)$, which are smooth functions[1] of x_3 and $\overset{\circ}{\boldsymbol{T}}$ satisfies the equation $\operatorname{div}\overset{\circ}{\boldsymbol{T}} = \mathbf{0}$. We assume also that the superimposed small elastic motion pertaining to the Rayleigh wave in question obeys the theory of linear elasticity with initial stress (cf. [2, 3]). In addition, we suppose that the incremental elasticity tensor $\mathbb{L}$ can be written as a sum of two terms: a principal part $\mathbb{C}^{\text{Iso}}$ which is *homogeneous* and isotropic, and a perturbative part $\mathbb{A} = \mathbb{A}(x_3)$ which is a smooth function of x_3 ($x_3 \leq 0$) and is generally anisotropic. Then $\mathbb{L}$ can be expressed as a fourth-order tensor on the infinitesimal strain $\boldsymbol{E}$ in the form

$$\mathbb{L}(x_3)[\boldsymbol{E}] = \mathbb{C}^{\text{Iso}}[\boldsymbol{E}] + \mathbb{A}(x_3)[\boldsymbol{E}] = \lambda(\operatorname{tr}\boldsymbol{E})\mathbf{I} + 2\mu\boldsymbol{E} + \mathbb{A}(x_3)[\boldsymbol{E}], \tag{1}$$

where $\mathbf{I}$ is the identity matrix, λ and μ are the Lamé constants that pertain to $\mathbb{C}^{\text{Iso}}$, and $\mathbb{A} = \mathbb{A}(x_3)$ has 21 generally independent components. Moreover, at the free surface $x_3 = 0$ of the material medium $\mathbb{A}(0)$ and $\overset{\circ}{\boldsymbol{T}}(0)$ are assumed to be sufficiently small as compared with $\mathbb{C}^{\text{Iso}}$ that for all expressions and formulas which depend on $\mathbb{A}(0)$ and $\overset{\circ}{\boldsymbol{T}}(0)$ it suffices to keep only those terms linear in the components of these tensors. See [7] for details about this constitutive assumption.

Let $\boldsymbol{u} = e^{ik(x_2 - v_R t)}\boldsymbol{a}(\mathbf{x}, v_R, k)$ be a time-harmonic solution to the elastic wave equations which describes the displacement at $\mathbf{x}$ and time t of the superimposed small elastic motion pertaining to the Rayleigh wave that propagates in the direction of the 2-axis with phase velocity v_R, where $k = \frac{2\pi f}{v_R}$ is the wave number. The polarization ratio r_R of Rayleigh waves on the surface $x_3 = 0$ is defined as the ratio of the maximum longitudinal component to the maximum normal component of the displacements on $x_3 = 0$ (see [1]):

$$r_R = \left|\frac{(\boldsymbol{a})_2}{(\boldsymbol{a})_3}\right|_{x_3=0},$$

where $(\boldsymbol{a})_i$ denotes the i-th component of the vector $\boldsymbol{a}$ and $|z|$ denotes the absolute value of a complex number z.

*Corresponding author. E-mail: tanuma@gunma-u.ac.jp

[1]Here by a smooth function of the coordinate x_3 ($x_3 \leq 0$) is meant an infinitely differentiable function all of whose derivatives are bounded and continuous.

Herein we present a procedure for obtaining a high-frequency asymptotic formula for r_R, more specifically, for expressing each term r_i $(i = 0, 1, 2, \cdots)$ in the asymptotic formula of the polarization ratio

$$r_R \,=\, r_R(k) \,=\, r_0 \,+\, r_1\, k^{-1} \,+\, r_2\, k^{-2} \,+\, r_3\, k^{-3} \,+\cdots \tag{2}$$

in terms of $\mathbb{C}^{\mathrm{Iso}}$ and $\mathbb{L}(x_3), \mathring{\boldsymbol{T}}(x_3), \rho(x_3)$ at $x_3 = 0$ and their first and higher-order x_3-derivatives at $x_3 = 0$.

Let $\mathbf{Z}(v) = \mathbf{Z}(v, k)$ be the 3×3 surface impedance matrix that expresses a linear relationship between the displacements at the free surface and the surface tractions needed to sustain them. In [4, 7] an algorithm is given by which each Hermitian matrix $\mathbf{Z}_i(v)$ $(i = 1, 2, 3, \cdots)$ of the asymptotic expansion

$$\mathbf{Z}(v) \,=\, k\,\mathbf{Z}_0(v) \,+\, \mathbf{Z}_1(v) \,+\, k^{-1}\,\mathbf{Z}_2(v) \,+\, k^{-2}\,\mathbf{Z}_3(v) \,+\cdots \tag{3}$$

can be computed iteratively through Lyapunov-type equations once $\mathbf{Z}_0(v)$ is determined. Note that $k\,\mathbf{Z}_0(v)$, which is also Hermitian, is the surface impedance matrix of the comparative homogeneous elastic half-space which has its incremental elasticity tensor, mass density, and initial stress equal to $\mathbb{L}(0)$, $\rho(0)$, and $\mathring{\boldsymbol{T}}(0)$, i.e., their value at the surface $x_3 = 0$, respectively. We keep terms up to those linear in $\mathring{\boldsymbol{T}}(0)$ and $\mathbb{A}(0)$ to write $k\,\mathbf{Z}_0(v) \,=\, k\,\mathbf{Z}_0^{\mathrm{Iso}}(v) + k\,\mathbf{Z}_0^{\mathrm{Ptb}}(v)$. Here $k\,\mathbf{Z}_0^{\mathrm{Iso}}(v)$, which is of zeroth order in $\mathring{\boldsymbol{T}}(0)$ and $\mathbb{A}(0)$, is the surface impedance matrix pertaining to the homogeneous isotropic elastic half-space with constitutive equation $\boldsymbol{S} = \mathbb{C}^{\mathrm{Iso}}[\boldsymbol{E}]$ and density $\rho = \rho(0)$, whereas $k\,\mathbf{Z}_0^{\mathrm{Ptb}}(v)$ is of first order in $\mathring{\boldsymbol{T}}(0)$ and $\mathbb{A}(0)$. The formulas of $\mathbf{Z}_0^{\mathrm{Iso}}(v)$ and $\mathbf{Z}_0^{\mathrm{Ptb}}(v)$ are given in Propositions 3.1 and 3.2 of [7], respectively.

From vanishing of the determinant of the right hand side of (3) at $v = v_R$, which leads us to an approximate secular equation, we have obtained in [4] a high-frequency asymptotic formula for v_R:

$$v_R = v_R(k) = v_0 \,+\, v_1\, k^{-1} \,+\, v_2\, k^{-2} \,+\, v_3\, k^{-3} \,+\, \cdots . \tag{4}$$

Rayleigh waves produce no traction on the free surface $x_3 = 0$, which implies that the polarization vector $\boldsymbol{a}|_{x_3=0}$ generates the null-space of $\mathbf{Z}(v_R)$. On the basis of this assertion we get

Proposition 1 *For $N = 1, 2, 3, \cdots$, an algorithm for computing the truncated sum of the asymptotic formula (2) up to the order k^{-N} is described as follows:*

1st step *Substitute (4) into $r_R = \dfrac{|N(v_R)|}{|D(v_R)|}$, where*

$$N(v) = \Big(\overline{\ell_{12}} + \sum_{n=1}^{N} k^{-n}\overline{(\mathbf{Z}_n)_{12}}\Big)\Big(\ell_{13} + \sum_{n=1}^{N} k^{-n}(\mathbf{Z}_n)_{13}\Big) - \Big(s_{11} + \ell_{11} + \sum_{n=1}^{N} k^{-n}(\mathbf{Z}_n)_{11}\Big)\Big(-is_{23} + \ell_{23} + \sum_{n=1}^{N} k^{-n}(\mathbf{Z}_n)_{23}\Big),$$

$$D(v) = \Big(s_{11} + \ell_{11} + \sum_{n=1}^{N} k^{-n}(\mathbf{Z}_n)_{11}\Big)\Big(s_{22} + \ell_{22} + \sum_{n=1}^{N} k^{-n}(\mathbf{Z}_n)_{22}\Big) - \Big|\Big(\ell_{12} + \sum_{n=1}^{N} k^{-n}(\mathbf{Z}_n)_{12}\Big)\Big|^2.$$

Here s_{11}, s_{22} and $-is_{23}$ denote the $(1,1), (2,2)$ and $(2,3)$ components of $\mathbf{Z}_0^{\mathrm{Iso}}(v)$, respectively, ℓ_{ij} the (i,j) component of $\mathbf{Z}_0^{\mathrm{Ptb}}(v)$, $\overline{z}$ the complex conjugate of a complex number z, and $(\mathbf{Z})_{ij}$ the (i,j) component of a matrix $\mathbf{Z}$.

2nd step *Expand the resulting form with respect to k^{-n} $(n = 0, 1, 2, \cdots, N)$.*

3rd step *In each coefficient of the order of k^{-n} $(n = 0, 1, 2, \cdots, N)$, we retain terms up to those linear in $\mathbb{A}(0)$ and $\mathring{\boldsymbol{T}}(0)$ and neglect the higher order terms, to obtain r_n $(n = 0, 1, 2, \cdots, N)$ in (2).*

The perturbation formulas for v_0 and that for r_0 of the comparative homogeneous half-space, which are correct to within terms linear in $\mathbb{A}(0)$ and $\mathring{\boldsymbol{T}}(0)$, are given in [5] and [6], respectively.

As illustration, Proposition 1 is applied to generate dispersion curves of Rayleigh-wave polarization ratio (i.e., graphs of the functions $r_R(f)$) for a thick-plate sample of an AA 7075-T651 aluminum alloy that carries a residual stress imparted by prior surface treatment of low plasticity burnishing.

GEOMETRY OF THE NONLINEAR MECHANICS OF ACCRETION

Fabio Sozio*[1] and Arash Yavari[1,2]
[1]School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, GA 30332, USA
[2]The George W. Woodruff School of Mechanical Engineering, Georgia Institute ofTechnology, Atlanta, GA 30332, USA

Summary By accretion we mean the growth of a deformable solid by the gradual addition of material on its boundary. The result of such a process is the creation of a residually stressed solid. To this extent, accretion can be seen as the study of the formation of "non-Euclidean solids"—an expression coined by Poincaré [1]—through the continuous joining of infinitely many two-dimensional layers. Examples of accretion processes in Nature are the growth of biological tissues, crystal growth, the formation of rocks; in technology we mention additive manufacturing (3D printing), metal solidification, the build-up of concrete structures in successive layers. Our formulation of the nonlinear mechanics of accretion explicitly uses a Riemannian material manifold with an a priori unknown metric that describes this material structure. This work is based on references [2, 3, 4, 5].

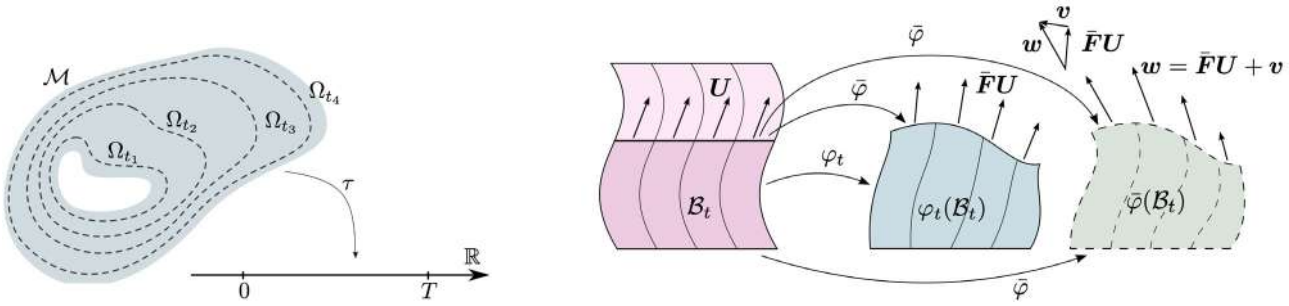

Figure 1: Left: The material manifold of an accreting body as a foliation. Right: Material and spatial kinematics of an accreting body.

THE MATERIAL MANIFOLD

An accreting body is represented by a foliated manifold, where every leaf is given by a two-dimensional level set of the function τ assigning to every point its time of attachment (see Fig. 1). This bundle of layers is in turn endowed with a material flow describing the way layers are added atop each other. The material motion is then combined with the standard spatial kinematics, to obtain the motion of the growing boundary (see Fig. 1). The novelty in our formulation is represented by the introduction of the accretion tensor $\mathbf{Q}$, expressing the local deformation gradient of a particle at a time immediately before its time of attachment (see Fig. 2). It can be proved that the accretion tensor depends on the deformation gradient at the time of attachment $\mathbf{F}(X, \tau(X))$, and on the rate and direction at which the new material is being added (the growth velocity $\mathbf{u}$). The fundamental assumption of our work is the following: For the addition of stress-free material, the accretion tensor represents a local isometry for the material manifold, so the material metric can be built by pulling back the ambient metric via $\mathbf{Q}$. Being built using the accretion tensor, the material metric in turn depends on the growth velocity and on the deformation of a particle at its time of attachment. In general, such deformation is unknown, and so is the material metric.

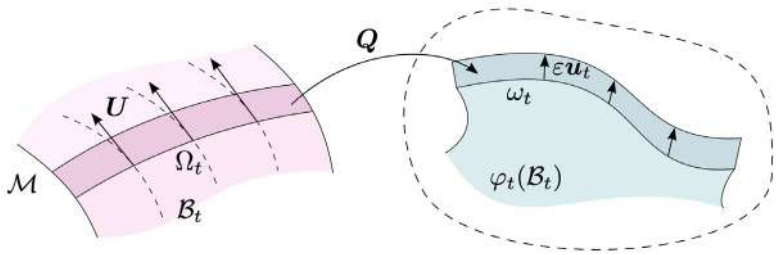

Figure 2: Addition of an infinitesimally thin layer to the boundary of a deforming body. The local deformation gradient is expressed by the two-point tensor $\mathbf{Q}$.

*E-mail: fsozio3@gatech.edu

THE CURVATURE TENSOR

As already mentioned, the Riemannian manifold is not necessarily Euclidean. A non-Euclidean solid is characterized by local natural distances (encoded in the material metric) that are not realizable in the three-dimensional ambient space. This implies the impossibility to minimize the energy at every point at the same time, leading to the presence of residual stress (see Fig. 3). It should be noted that a non-Euclidean manifold is the mathematical object that represents an anelastic solid. Anelasticity is usually modeled through the multiplicative decomposition of the deformation gradient. To this extent, the tensor $\mathbf{Q}$ can be seen as the plastic part of the deformation gradient in accretion-induced anelasticity. From a geometric perspective, the presence of residual stress is equivalent to the non-vanishing of the Riemann curvature tensor built on the material metric. In our framework, the partition into infinitely many layers with different times of attachment allows one to express the geometry of a deformable 3D body with respect to its layer-wise structure. The nonflat structure of an accreted solid is then studied using an approach similar to the ADM formalism of general relativity by Arnowitt et al. [6]. The Riemannian structure is first decomposed in layer and out-of plane quantities, allowing one to express the 3D geometry in terms of the geometry of each layer, and in terms of the tangent and normal components of the growth velocity. In some cases, when the geometry of the accreted body is know a priori, these expressions provide a useful tool for quantifying the lack of flatness of the material structure. In some other cases, one is first required to solve the accretion initial boundary value problem.

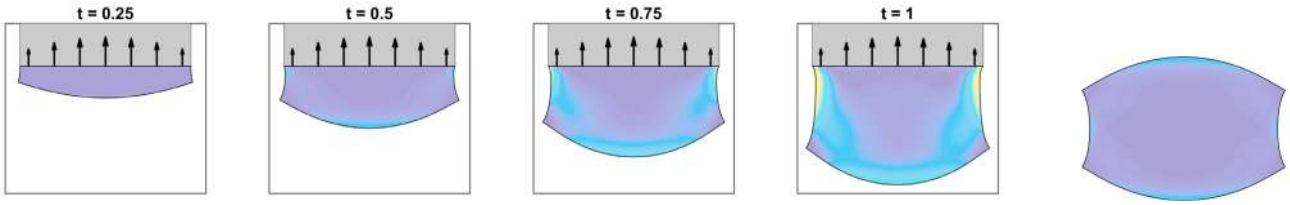

Figure 3: Growth through a fixed straight line. Left: The deformed configuration during accretion at four different dimensionless times. Right: The residually-stressed configuration.

NUMERICAL RESULTS

In order to solve examples and calculate the residual stresses (see Fig. 3), a pure accretion IBVP and a thermal accretion IBVP have been formulated. These are solved numerically using a two-step scheme based on a finite difference method (see Fig. 4). At each time step i, we start from the solution at the time step $i-1$ adding layer of hot material to the outer boundary of the accreting solid and updating the grid for this new geometry. In the first step, we solve the thermal problem discretizing the heat equation. In the second step, we use thermal data to solve the mechanical problem in a weak form. When we reach the final time, we remove the constraints, impose ambient temperature everywhere, and calculate the residually-stressed configuration through a load control procedure.

SMOOTH AND SINGULAR DISTRIBUTIONS OF DISLOCATIONS

Marcelo Epstein[1] and Reuven Segev *[2]

[2]Department of Mechanical Engineering,Ben-GurionUniversity of the Negev,Beer-Sheva,Israel

Summary A continuum geometric theory for the representation of the distribution of dislocations in crystalline solids is presented. The theory applies to bodies represented by general n-dimensional manifolds and the distribution of dislocations may be either smooth or singular. For the smooth case the theory is based on calculus of differential forms on manifolds and for the singular case it is based on the notion of a de Rham current.

INTRODUCTION

We present below a mathematical framework for the description of the geometry of the distributions of dislocations from the continuum mechanics, macroscopic, point of view (see also [1, 2]). A material body is modeled by a general n-dimensional differentiable manifold $\mathcal{B}$ and the mathematical framework does not require that a Riemannian metric or a connection be specified on $\mathcal{B}$. Thus, the description is independent of any particular configuration of the body in the physical space and the distribution of dislocations is viewed as a part of the material structure of the body.

The distribution of each family of Bravais hyper-planes describes the crystalline structure of the body. We refer to such a family of Bravais hyper-planes as a *layering*. Dislocations occur when hyper-planes belonging to such a layering are not conserved, that is, hyper-planes are created or annihilated within the body. The distributions of hyper-planes and dislocations specified by a layering may be singular, and clearly, as a special case, they may be smooth. For example, one may consider the case where a singular half hyper-surface is removed from the body.

The point of view adopted here differs from some approaches to the continuum description of the geometry of dislocations by not considering any configuration, neither continuous nor discontinuous, of the body in space, and being independent of mechanical constitutive relations. Other works do consider purely geometric structures (such as a crystal basis at each point), but we consider the atomic planes as basic. Thus we assume, right from the start, that a distribution of a family of Bravais hyper-planes, specifying the material structure of the body, is given.

The next section considers the case of a smooth layering. Such a smooth distribution of hyper-planes is specified by a differential 1-form on the manifold $\mathcal{B}$. Then, we consider the more general singular case using the theory of de Rham currents (see [3]).

SMOOTH DISTRIBUTIONS OF DISLOCATIONS

In accordance with the paradigm described above, we consider a layering of the material body $\mathcal{B}$. This is done mathematically by a differential 1-form

$$\varphi : \mathcal{B} \longrightarrow T^*\mathcal{B}, \tag{1}$$

to which we refer as the *layering form*. Thus, at each body point $X \in \mathcal{B}$, $\varphi(X) : T_X\mathcal{B} \to \mathbb{R}$ is a linear mapping of tangent vectors to the real numbers. The solutions, v, of the linear equation $\varphi(X)(v) = a$, for the various constants $a \in \mathbb{R}$, describe the family of Bravais hyper-planes at X. The components of φ relative to any basis are related to the Miller indices of this family of hyper-planes. The particular number $\varphi(X)(v) = a$ may be interpreted as a measure of the quantity of hyper-planes penetrated by the vector v.

Absence of dislocations is indicated if for any close circuit $c : [0, 1] \to \mathcal{B}$, $c(0) = c(1)$, the total amount of hyper-planes penetrated by the tangent to the curve c, vanishes. Specifically, for a given circuit c, the total amount of hyper-planes penetrated is computed by

$$I_c := \int_{t=0}^{1} \varphi(c(t))(\dot{c}(t))\mathrm{d}t, \tag{2}$$

where $\dot{c}(t)$ denotes the tangent to the curve at $c(t)$. It is noted that the orientation of the penetration is taken into account by the sign of the evaluation $\varphi(c(t))(\dot{c}(t))$. Assuming $\dot{c}(t) \neq 0$ for all t, one may view the parameter t as a coordinate on the 1-dimensional manifold $\tilde{c} :=$ Image $c \subset \mathcal{B}$. Thus, we may write, using integration of differential forms,

$$I_c = \int_{\tilde{c}} \varphi. \tag{3}$$

Let $\mathcal{S}$ be a 2-dimensional submanifold with boundary of $\mathcal{B}$ such that $\partial\mathcal{S} = \tilde{c}$. Then, by Stokes's theorem,

$$I_c = \int_{\mathcal{S}} \mathrm{d}\varphi, \tag{4}$$

*Corresponding author. E-mail: rsegev@bgu.ac.il.

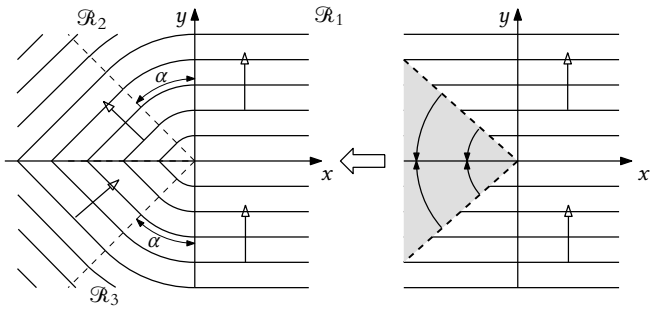

Figure 1: Example

where $\mathrm{d}\varphi$ is the exterior derivative of φ—a differential 2-form. Hence, the condition $\mathrm{d}\varphi = 0$, guarantees that for any circuit c, we have $I_c = 0$.

It is concluded that the exterior derivative $\mathrm{d}\varphi$ indicates the distribution of dislocations and its integration over a hyper-surface $\mathcal{S}$ indicates the total amount of planes created inside $\mathcal{S}$. If $\mathrm{d}\varphi = 0$, at least locally, there is a real valued function u so that $\varphi = \mathrm{d}u$. The function u is viewed as an enumeration of the Bravais hyper-surfaces. A 2-form $\psi = \mathrm{d}\varphi$ specifying the distribution of dislocations will be referred to as a *dislocation form*. It is recalled that for any differential form ω, $\mathrm{d}^2\omega = 0$. Thus, if ψ is a dislocation form, we have a compatibility condition $\mathrm{d}\psi = 0$.

SINGULAR DISTRIBUTIONS OF DISLOCATIONS

In order to adapt the foregoing paradigm to singular distributions of dislocations, we now view the differential 1-form φ as an object inducing a linear functional T_φ on the space of differential $(n-1)$-forms having compact supports in $\mathscr{B}$. Specifically,

$$T_\varphi(\omega) := \int_{\mathscr{B}} \varphi \wedge \omega, \tag{5}$$

for any $(n-1)$-form ω having a compact support. Here, $\wedge$ denotes the exterior product of forms so that $\varphi \wedge \omega$ is indeed an n-form that may be integrated over the body manifold. Such linear functionals on vector spaces of differential $(n-1)$-forms are referred to as $(n-1)$-*de Rham currents* (see [3]).

Thus, in order to generalize the foregoing to the singular case, we no longer consider only de Rham currents induced by smooth form as in (5) but admit any $(n-1)$-de Rham current T as a layering current. In contrast with a current induced by a smooth 1-form as above, one may consider a current $T_{\mathscr{V}}$ induced by an $(n-1)$-dimensional submanifold with boundary $\mathscr{V} \subset \mathscr{B}$ in the form

$$T_{\mathscr{V}}(\omega) = \int_{\mathscr{V}} \omega. \tag{6}$$

This current represents a singular layering which consists of the single layer $\mathscr{V}$. As a generalization of the exterior derivative as a measure of the dislocations, one uses now the *boundary* ∂T of the layering current T, an $(n-2)$-current defined by $\partial T(\alpha) := T(\mathrm{d}\alpha)$, for any $(n-2)$-form α of compact support in $\mathscr{B}$. Thus, in particular, for the current $T_{\mathscr{V}}$ defined above and any $(n-2)$-form α,

$$\partial T_{\mathscr{V}}(\alpha) = \int_{\mathscr{V}} \mathrm{d}\alpha = \int_{\partial\mathscr{V}} \alpha = T_{\partial\mathscr{V}}(\alpha). \tag{7}$$

Thus, the boundary of $T_{\mathscr{V}}$ is the current induced by the boundary $\partial\mathscr{V}$ as expected of a single hyper-surface $\mathscr{V}$ with boundary $\partial\mathscr{V}$ inside the body—an edge dislocation.

It is noted that the boundary operator for currents also generalizes the exterior derivative in analogy with the smooth case. Thus, for the current T_φ above, ∂T_φ acts by

$$\partial T_\varphi(\alpha) = \int_{\mathscr{B}} \varphi \wedge \mathrm{d}\alpha = -\int_{\mathscr{B}} \mathrm{d}(\varphi \wedge \alpha) + \int_{\mathscr{B}} \mathrm{d}\varphi \wedge \alpha = -\int_{\partial\mathscr{B}} \varphi \wedge \alpha + \int_{\mathscr{B}} \mathrm{d}\varphi \wedge \alpha = T_{\mathrm{d}\varphi}(\alpha), \tag{8}$$

where we have used the identity $\mathrm{d}(\varphi \wedge \alpha) = \mathrm{d}\varphi \wedge \alpha - \varphi \wedge \mathrm{d}\alpha$ and the fact that α vanishes on $\partial\mathscr{B}$.

The presentation will consider further aspects of singular dislocations and various examples such as illustrated in Figure 1.

SAINT-VENANT'S PRINCIPLE FOR GENERALIZED THERMOELASTICITY WITH MEMORY-DEPENDENT DERIVATIVE

Indranil Satrkar*[1]
[1]Indian Institute of Engineering Science and Technology, Shibpur

Summary The spatial behavior of the thermal signals related to the topic "Saint-Venant's principle" [1] in the generalized thermoelasticity theory is interesting from the both thermomechanical and mathematical viewpoints. The research is theoretically developed on two mathematical aspects in order to study the spatial behavior of the thermal signals in an isotropic, homogeneous, thermoelastic continuum in the context of a very recently proposed heat conduction model [2] with memory-dependent derivative (MDD). To prove the finite propagation speeds of thermal signals in the present model, a domain of influence theorem is established and to analyze the spatial propagation of thermal signals inside the domain of influence, a spatial decay theorem is established. As an immediate outcome from this theoretical analysis, a uniqueness theorem for the present model is also derived.

INTRODUCTION

The thermoelasticity theory is mainly focussed on dealing with the interaction between the mechanical and thermal field variables in the deformable bodies. As a result of the parabolic nature of the heat conduction equation in the classical dynamic thermoelasticity theory, based on the Fourier's heat conduction law, the impact of thermomechanical loading on an isotropic and homogeneous body reaches instantaneously to all points of the body from the point of application. In the case of coupled thermoelastic problems, it describes that the impact of thermomechanical loading influences the magnitude and pattern of the displacements, stresses and temperature distribution instantaneously everywhere in the solution domain. Its physical interpretation is that the thermal signals occupy the whole space for any time $t > 0$. i.e. the propagation speed for the thermal signals is infinite. This inconsistent behavior of the heat transfer mechanism contradicts physical phenomena. In order to overcome the mathematical inconsistency connected with the infinite speed propagation for the thermal signals, generalized thermoelasticity theories involving finite speed propagation for the thermal signals have been developed in the literature by several researchers. In recent decades memory-dependent derivative (MDD) proposed by Wang and Li [3] is at the height of popularity among the researchers due to its enormous applications in real world problems. The aim of the present contribution is to to establish the following **Saint-Venant's principle** of the proposed model for an isotropic, homogeneous body subjected to an external thermomechanical loading having a bounded support $\hat{\Delta}_T$, $\hat{\Delta}_T \subset \mathscr{D}$: (i) **Domain of influence theorem:** The entire thermoelastic disturbance or thermal signals vanishes beyond a well-defined bounded domain Δ_{vt}, $\hat{\Delta}_T \subset \Delta_{vt} \subset \bar{\mathscr{D}}$, $t \in [0, T]$, where v is a constant of velocity dimension, (ii) **Spatial decay theorem:** The suitable energetic measure $\mathscr{E}(r, t)$ related with the thermoelastic problem involving memory-dependent derivative (MDD) decays spatially along the distance r from the bounded support $\hat{\Delta}_T$ and the factor $1 - \frac{r}{vt}$ controls the decay rate. From the theoretical analysis of the article, a uniqueness theorem is also proved for the present model.

GOVERNING EQUATIONS

The governing equations for the present model model with MDD over a bounded regular region $\mathscr{D}$ in the Euclidean space are formulated as follows:
The kinematic relation:

$$\varepsilon_{ij} = \frac{(u_{i,j} + u_{j,i})}{2}, \tag{1}$$

The Hooke's law:

$$\sigma_{ij} = \lambda \varepsilon_{kk} \delta_{ij} + 2\mu \varepsilon_{ij} - \gamma \theta \delta_{ij}, \tag{2}$$

The equation of motion:

$$\sigma_{ij,j} + \rho f_i = \rho \ddot{u}_i, \tag{3}$$

The heat conduction equation of the proposed model with MDD:

$$\rho C_E \dot{\theta} + \gamma T_0 \dot{\varepsilon}_{k,k} - \rho Q = k\theta_{,ii} + k^* \nu_{,ii} + k^* \tau D_\omega \nu_{,i} + k^* \frac{\tau^2}{2} D_\omega^2 \nu_{,ii} \tag{4}$$

where, the memory-dependent derivative operator D_ω in association with the the time-delay parameter $\omega(\omega > 0)$ and the differentiable kernel function $K(t - \varsigma)$ over the delayed interval $[t - \omega, t]$ is defined in the article [2].
The adjoined initial-boundary conditions for the thermoelastic problem with MDD are $u_i(x, 0) = u_i^0(x)$, $\dot{u}_i(x, 0) = u_i^1(x)$, $\theta(x, 0) = \theta^0(x)$ for $x \in \bar{\mathscr{D}} = \mathscr{D} \cup \partial\mathscr{D}$, $u_i = \bar{u}_i$ on $\partial\mathscr{D}_1 \times [0, T]$, $\sigma_{ij} n_j = \bar{\sigma}_i$ on $\partial\mathscr{D}_1^c \times [0, T]$, $\theta = \bar{\theta}$ on $\partial\mathscr{D}_2 \times [0, T]$, $q = q_i n_i = \bar{q}$ on $\partial\mathscr{D}_2^c \times [0, T]$, where, $\partial\mathscr{D}_1 \cup \partial\mathscr{D}_1^c = \partial\mathscr{D}_2 \cup \partial\mathscr{D}_2^c = \partial\mathscr{D}$, $\partial\mathscr{D}_1 \cap \partial\mathscr{D}_1^c = \partial\mathscr{D}_2 \cap \partial\mathscr{D}_2^c = \emptyset$, $\emptyset$ denotes the empty set.

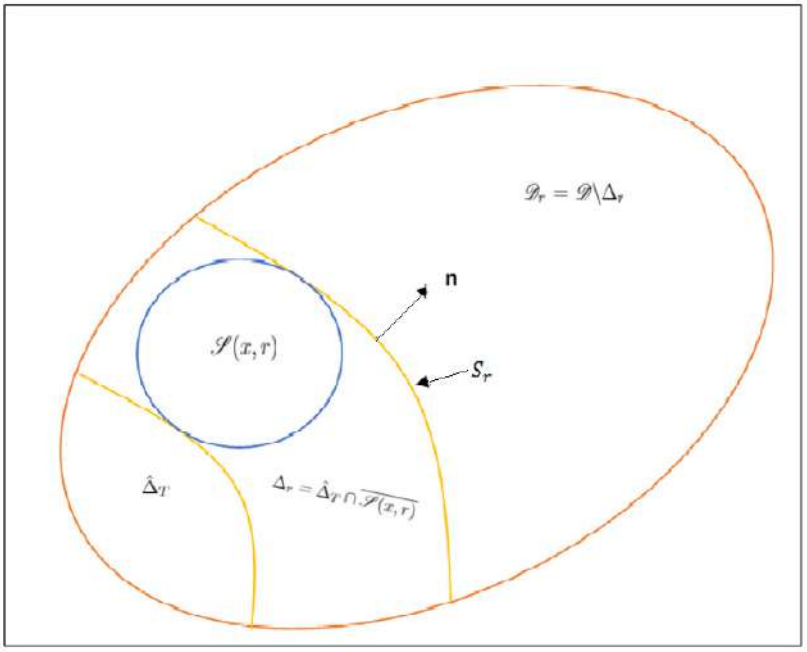

Figure 1: Schematic diagram of the considered sets

SPATIAL BEHAVIOR

For a fixed time $T > 0$, the support of the initial and boundary data of the initial-boundary value problem of generalized thermoelasticity with MDD on the time interval $[0, T]$ is defined by the set $\hat{\Delta}_T$, such that:
i. if $x \in \mathscr{D}$, then $u_i^0 \neq 0$ or $u_i^1 \neq 0$ or $\theta^0 \neq 0$ or $\exists\, t' \in [0, T]$ such that $f_i(x, t') \neq 0$ or $Q(x, t') \neq 0$, ii. if $x \in \partial\mathscr{D}_1$, then $\exists\, t' \in [0, T]$ such that $\bar{u}_i(x, t') \neq 0$, iii. if $x \in \partial\mathscr{D}_1^c$, then $\exists\, t' \in [0, T]$ such that $\bar{\sigma}_i(x, t') \neq 0$, iv. if $x \in \partial\mathscr{D}_2$, then $\exists\, t' \in [0, T]$ such that $\bar{\theta}(x, t') \neq 0$, v. if $x \in \partial\mathscr{D}_2^c$, then $\exists\, t' \in [0, T]$ such that $\bar{q}(x, t') \neq 0$. Then, the spatial behavior of the thermal signals in the present model is described by the **Saint-Venant's principle** and the proof is established by following the Lemmas:

Lemma 1

For each $t \in [0, T]$, $r \in [0, \mathscr{D}]$ $\mathscr{E}(r, t)$ is the nonincreasing function with respect to r on the interval $[0, \mathscr{D}]$.

Lemma 2

Let A_{ij} denote the components of a symmetric tensor, y_i denote the components of a vector, $(x) = (x_i) \in R^3$, $|x| = r$ and $i, j = 1, 2, 3$, then for any arbitrary parameter $p' > 0$, the following inequality holds: $\frac{A_{ij}x_iy_j}{r} \leq \frac{1}{2}[p'A_{ij}A_{ij} + \frac{1}{p'}y_iy_i]$.

UNIQUENESS

The thermoelastic mixed initial-boundary value problem with MDD subjected to the initial-boundary conditions posses a unique solution and it is established by proving associated problem subjected to the homogeneous initial-boundary conditions posses only the trivial solution.

CONCLUSIONS AND POSSIBLE FUTURE INSIGHTS

The thermal signals in generalized thermoelasticity theory with memory-dependent derivative (MDD) propagates with finite speeds which is deduced by proving domain of influence theorem [4] and decays inside the domain of influence. The analysis is considered for homogeneous and isotropic materials. Based on appropriate hypotheses upon the material coefficients, the results can also be extended to the class of anisotropic and inhomogeneous materials.

Summary The two-scale asymptotic homogenization method (AHM) is used to find closed-form formulas for effective transport complex properties of periodic multi-phase fibre-reinforced composites (FRC). Examples for three- and four-phase composites with complex constituents and periodic parallelogram unit cells (PUCs) are considered. Numerical validations are carried out through comparisons with other methods. Good agreement is obtained. The formulas may be useful as benchmarks for checking experimental and numerical results.

INTRODUCTION

The knowledge of effective transport properties of composites is important in applications. Models have been developed for the study of multi-phase FRC in the wide field of transport problems [1–5]. The main aim of this work is the prediction of effective transport complex properties of periodic multi-phase FRC with complex constituents and PUCs with microstructure by AHM. Anisotropic interphase effects on effective properties quality in relation to complex shear and anisotropic conductivity of biological tissue comprising tubular cells, such as skeletal muscle, are studied as a multi-phase FRC. Validation and analysis of results are given and discussed.

STATEMENT OF THE PROBLEM AND METHOD OF SOLUTION

AHM is applied to obtain effective transport properties of periodic $n-$phase FRC. Phases are composed of transport materials belonging to crystal symmetry class 6*mm* along fibre $3-$direction with complex-valued properties. PUC is made up of a central circular core and its complement to the parallelogram. Former is occupied by phase 1 and later by circularly nested $n-1$ phases, as a generalization of results in [2, 3]. Hence, it yields simple closed-form formulas for three- and four-phase composites under perfect contact conditions across the interfaces. However, Hashin's imperfect interface analysis is carried out [6] wherever necessary. The porous material limit case is analyzed using a three-phase composite. The analytical formulae are also used in order to find the effective shear moduli, conductivity, permittivity and the like for three-phase FRC.

NUMERICAL ANALYSIS

The broad applicability and accuracy of results by AHM is determined by comparison with other methods reported earlier for three- and four-phase FRC where good agreement is found. From now on, let matrix properties be p_α, q_α (diagonal) and r_α (off-diagonal) entries of $\alpha-$phase; p, q and r are effective transport properties, respectively.

Shear. Fig. 1 shows interphase effect on effective shear for a four-phase FRC with either a hard or soft phase p_2. The effective shear moduli p/p_1, q/p_1 and r/p_1 as a function of p_3/p_1 are shown. PUC is defined by periods $(1,0), (\cos(\pi/4), \sin(\pi/4))$. Material properties are taken from [1]. In Fig. 1(a), effect on shear is very small for low p_3/p_1 values. In contrast, a strong anisotropic behaviour is displayed for high p_3/p_1 values, that is, the axial properties differ noticeably and $p_1 < p < q$, $r < 0$. The opposite occurs in Fig. 1(b). For low p_3/p_1 values, interphase effect induces a composite anisotropic behaviour and $p_1 < p < q$, $r < 0$ instead. When p_3/p_1 increases, then $p \approx q \approx p_1$ is attained. This radical change in the effective properties is due to the interphase property p_2 being softer in the composite of Fig. 1(b) than in Fig. 1(a), while a rest of parameter remain fixed.

Conductivity. Fig. 2 plots real and imaginary parts of normalized effective complex conductivity p/p_1 and q/p_1 versus dimensionless frequency $\Omega(=\omega C L/\sigma_m)$ for several periodic PUCs with periods $(1,0), (\cos\theta, \sin\theta)$, where L is composite microstructural dimension and σ_m is matrix conductivity, showing a comparison with results in [5] (red circles, BC) for isotropic composite with hexagonal cell $(p = q)$. Good agreement is obtained. Fig. 2(a) and (b) also display a composite orthotropic behavior when $\theta = 45^o$ and $\theta = 50^o$ due to $p \neq q$. In both PUCs, real and imaginary parts of p and q are different. The complex conductivities p, q and r of the biological tissue (skeletal muscle) with interfacial admittance K studied in [5] are determined here using the three-phase FRC with a thin interphase via [6], where $K = B + i\omega C$, $B(C)$ is conductance (capacitance) per unit area and ω is circular frequency. A thin interphase admittance caused by electric potential to jump across the interfaces can be referred to as an imperfect interface as well

as impedance interface [6]. The relationship between K and interphase property p_2 is $K = p_2 R_2 / h$ with $h = 10^{-4}$, as in [6].

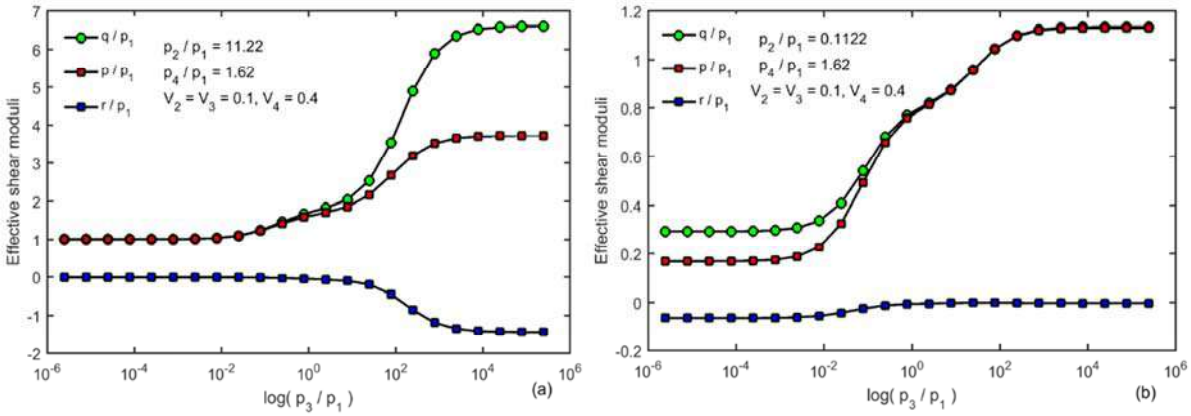

Fig. 1. Dimensionless effective shear moduli as function of p_3 / p_1 (a) p_2 hard phase, (b) p_2 soft phase.

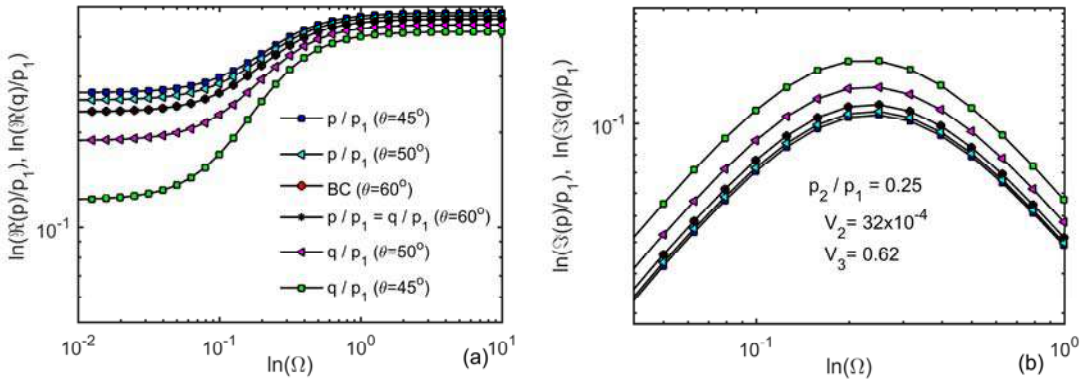

Fig. 2. Real and imaginary parts of normalized effective p and q versus dimensionless circular frequency for different PUCs.

CONCLUSIONS

Complex transport properties of periodic multi-phase FRC with different PUCs with microstructure are found by AHM. The general formulas of local problems and associated effective coefficients for transport problems are derived. Simple closed-forms formulas for three- and four-phase FRC are found. The broad applicability and efficiency of the model are tested against results obtained from other method for periodic multi-phases FRC. The formulas may be useful as benchmarks for checking experimental and numerical results. This model illustrates anisotropic interphase effects on effective complex shear properties quality and orthotropic conductivity of an idealized model of biological tissue with interfacial impedance (periodic tubular cells, such as skeletal muscle), in a proper way.

Summary Elastic instability is a fascinating phenomenon playing an important role in pattern formations in soft biological systems. The phenomenon also has been actively used to design new (meta-) materials with switchable microstructures, properties, and functions. Here, we investigate the elastic instability phenomenon in soft heterogeneous materials. These deformable composites typically combine soft deformable matrix and stiffer phase (such as fibers or inclusions). We specifically focus on the influence of the geometrical microstructure parameters and material composition on the instability phenomenon giving rise to the microstructure switches.

INTRODUCTION

Soft materials have attracted significant attention in recent decades due to their ability to sustain extremely large deformations, thus, allowing us to actively alter their properties and functionalities. Potential applications of the wide class of materials include soft and human-interactive robotics, sensors and actuators, tunable acoustic devices, and noise and vibration canceling systems, among many others.

The rich and complicated mechanical behavior of soft materials poses numerous challenges related to various intrinsic aspects of soft material mechanics and physics such as material and geometrical nonlinearities, characteristic inelastic behavior, and the fascinating instability phenomenon. The latter is of a specific interest due to the unusual behavior of the materials in the unstable or post-instability extreme regimes; for example, exotic properties such as negative Poisson's ratio, negative stiffness, and induced negative group velocities and band gaps in elastic waves are predicted and observed in a variety of instability transformed microstructured materials. Motivated by these predictions and observation, here, we specifically focus on the elastic instabilities in soft microstructured composites with a specific focus on utilizing the instability phenomenon for triggering reversible and controllable microstructure transformations.

RESULTS

To predict and analyze the stability behavior of soft heterogeneous materials we employ the so-called "small-on-large" framework, when incremental small deformations are super-imposed on the finitely deformed state. The corresponding linearized equilibrium equations in the deformed state yield the macroscopic stability condition through the effective tensor of elastic moduli; the condition is also referred to as the loss of ellipticity condition. This allows providing estimates for the onset of elastic instabilities for the longwave mode. However, many composites develop instabilities at smaller length scales comparable with their microstructure characteristic length. This microscopic type of instability is usually analyzed by employing the Bloch-Floquet analysis superimposed on finite deformations. We note that, for the specific case of wavenumber approaching zero value (the long wave mode), the Bloch-Floquet technique reproduces the predictions of the loss of ellipticity analysis, thus, establishing the connections between these distinct methods. While the analysis can be performed analytically for a limited set of microstructured (such as periodic laminates), typically the finite element (FE) method is used to examine the mechanical stability of soft materials and structures. Here, we employ the numerical analysis to perform a detailed study the elastic instability phenomenon in we perform a detailed study of the dependence of pattern formations on material properties and geometrical parameters of soft composites such as hyperelastic (i) periodic laminates [1,2], (ii) 3D transversely isotropic (TI) fiber composites [3,4],

*Corresponding author. E-mail: **rudykh@wisc.edu**

(iii) void-matrix-particles soft periodic systems [5,6], hexagonal stiff networks embedded in soft matrix [7], and, finally, (iv) periodic particulate soft composites [8]. Moreover, we employ the multi-material 3D printing to fabricate the periodic soft-stiff microstructured composites, and we further externally test these systems. For example, wavy patterns develop in layered materials upon achieving the critical compressive strain level. Moreover, we show that the buckled shapes in the relatively simple material system with rate-dependent constituents can be tuned and controlled by the applied strain-rate through inelastic rate-dependent behavior of the laminate constituents [2]. In laminates, the critical wavelength of the instability induced wavy patterns varies with the applied strain-rate. It is possible, however, to design composites, in which the critical wavelength remains the same independent of the applied strain rate, while the critical strain varies with a change in the strain-rate. Thus, a wider range of wavy patterns with various wavelengths and amplitudes can be archived through the combination of the instability and viscoelastic phenomena [2].

We expend the stability analysis to the 3D setting and examine the response of 3D transverse isotropic soft fiber composites in a fully 3D deformation setting. We find that the primary buckling mode in the fiber composites is determined by the fiber volume fraction and the contrast between elastic moduli of fibers and matrix [3]. We show that for composites with fiber volume fractions exceeding a threshold value (which depends on elastic modulus contrast) the primary buckling mode corresponds to the long wave or macroscopic instability. Composites with a lower amount of fibers, however, experience microscopic instabilities corresponding to either wavy or helical buckling shapes [3]. In addition, instability modes and critical wavelengths are shown to be highly tunable by material composition. The numerical results showed a good agreement with experimental observations in 3D printed soft composite [4].

Next, we explore the instability-induced pattern transformations in 3D-printed soft composites consisting of stiff inclusions and voids periodically distributed in a soft matrix. These soft auxetic composites are prone to elastic instabilities giving rise to negative Poisson's ratio (NPR) behavior [5,6]. Upon reaching the instability point, the composite microstructure rearranges into a new morphology attaining an NPR regime. Remarkably, identical composites can morph into distinct patterns depending on the loading direction. These fully determined instability-induced distinct patterns are characterized by significantly different NPR behaviors, thus, giving rise to enhanced tunability of the composite properties. In addition, we illustrate a potential application of these reversible pattern transformations as tunable acoustic-elastic metamaterials capable of selectively filtering low-frequency ranges controlled by deformation [5].

The idea of using the instability induced switches in materials microstructures has been further extended to a class of soft composites with stiff networks embedded in a soft matrix [7]. Two distinct types of instability patterns were observed, dependent on the geometry and the material combination. While Type I patterns retain the original periodicity (developing wrinkles in the network walls), Type II patterns transform the original periodicity. The elastic wave propagation analysis showed that a change in frequency band gaps is for both instability-induced pattern transformations, but differs for each type due to their dramatic difference in structure transformation (i.e. Type I wall wrinkling vs. Type II periodicity switching).

Finally, we report experimental observations of domain formations and pattern transitions in soft particulate composites under large deformations. We observe the formation of microstructures with anti-symmetric domains [7], and its geometrically tailored evolution into a variety of patterns of cooperative particle rearrangements. We show that these fully determined new patterns can be achieved by fine-tuning of the initial microstructure

CONCLUSIONS

In this work, we investigated the elastic instability phenomenon in soft heterogeneous materials. These deformable composites combine soft deformable matrix and stiffer phase (such as fibers or inclusions). Figure 1 shows the experimentally observed wavy patterns forming in (a) soft 3D printed laminates [2] and (b) 3D-fiber composites [4], (c) twining pattern in particulate composites [8], and (d) auxetic microstructure transformations in inclusion-matrix-void soft systems [5,6]. In this presentation, we will discuss the influence of the geometrical microstructure parameters and material composition on the instability phenomenon giving rise to the microstructure transformations.

EFFECT OF WALL LIQUID REDISTRIBUTION ON THE PRESSURE INFLATION RESPONSE OF A PORO-HYPERELASTIC SHELL

Vahid Zamani[1] and Thomas J. Pence*[1]
[1]Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA

Summary We consider a spherical shell composed of a poro-hyperelastic material in order to examine how the through-wall distribution of liquid affects the pressure-expansion response. It is shown that different through-thickness distributions of the same overall amount of liquid can significantly alter this response. Uniform liquid distributions give the most compliant structural response whereas sequestering liquid near either the inner or outer wall stiffens the overall behavior. Liquid redistribution can also alter the basic monotonicity properties of the resulting inflation graphs.

We consider an internally pressurized spherical shell with "gel-type" walls. That is to say that the walls consist of a liquid infused poro-hyperelastic material. The overall amount of liquid in the structure as a whole is fixed. However, this fixed liquid may redistribute itself within the cell wall. At issue is how the liquid distribution affects the amount of overall expansion that is due to an internal pressurization.

We follow a continuum mechanical treatment that tracks change in the local liquid content in terms of the associated material volume change [1]. Both the soft porous ground substance and the mobile liquid constituent are regarded as incompressible. Material swelling from a nominally dry reference state then correlates with the current local amount of liquid that is present. When liquid migration is active, a standard treatment is to invoke some form of Darcy's law to describe the liquid seepage [2]. For our purposes, attention is restricted to static distributions of liquid (i.e., all such migration has ceased) and to states for which the overall system is in mechanical equilibrium.

For the case of spherical symmetry this gives a boundary value problem that admits to a certain amount of direct analysis. The corresponding hyperelastic problem (no liquid and hence no swelling) is the classical nonlinear elastic spherical balloon – a much beloved problem that has been analyzed extensively [3]. The poro-hyperelastic problem with swelling due to a uniform distribution of liquid is examined in [4]. In the present work we specifically consider nonuniform liquid distributions where the goal is to contrast different distributions, all of which correspond to the same overall amount of liquid. Although usually acting on very different time scales, certain aspects of this mechanics treatment of swelling are closely related to problems in growth mechanics [5].

The technical approach makes use of a swelling field v where $v = 1$ is the nominally dry state (no mobile liquid being present). Swelling due to the presence of mobile liquid gives $v > 1$. Because of this, the usual incompressiblity condition of volume preservation is generalized to $\det\mathbf{F} = v$, where $\mathbf{F}$ is the deformation gradient. The poro-hyperelastic theory then generalizes the hyperelastic energy $W = W(\mathbf{F})$ so as to admit an additional dependence upon v. The particular constitutive model considered here takes the well known hyperelastic Mooney-Rivlin model and extends it to include the swelling effect via

$$W(I_1, I_2, v) = \frac{1}{2}\alpha\mu\Big(\frac{I_1}{v^{2/3}} - 3\Big) + \frac{1}{2}(1-\alpha)\mu\Big(\frac{I_2}{v^{4/3}} - 3\Big).$$

Here $\mu > 0$ is the infinitesimal shear modulus in the absence of swelling and α obeying $0 \le \alpha \le 1$ is the Mooney-Rivlin parameter that distinguishes between the I_1 and I_2 content of the material.

We consider a finite thickness spherical shell with inner radius $R_i > 0$ and outer radius $R_o > R_i$ prior to any loading or swelling. Attention is restricted to radially symmetric swelling $v = v(R)$. The total added volume due to the swelling

$$\Delta V = 4\pi \int_{R_i}^{R_o} (v(R) - 1) R^2 dR, \tag{1}$$

is thus identified with the total amount of mobile liquid in the system.

The surface loading consists of an internal pressurization ΔP. Spherical symmetry motivates the consideration of radial deformations such that the deformed radius location r is a function of reference radius R. The volumetric swelling constraint determines this $r(R)$ function in terms of the location of the deformed inner surface $r_i \equiv r(R_i)$, namely

$$r^3 = r_i^3 + 3\int_{R_i}^{R} v(\zeta)\,\zeta^2\,d\zeta.$$

Thus the "total loading input" on the structure consists of both the volumetric swelling field $v(R)$ and the surface pressurization ΔP. The "deformation output" is the single value r_i that characterizes the inflationary expansion.

We examine swelling fields of the form

$$v(R) = A/R + B, \tag{2}$$

where A and B are constants. This is a *harmonic swelling field*, because the form (2) provides the general spherically symmetric solution to $\nabla^2 v = 0$. We consider the range of harmonic swelling fields that distribute a fixed amount of liquid

*Corresponding author. E-mail: pence@egr.msu.edu

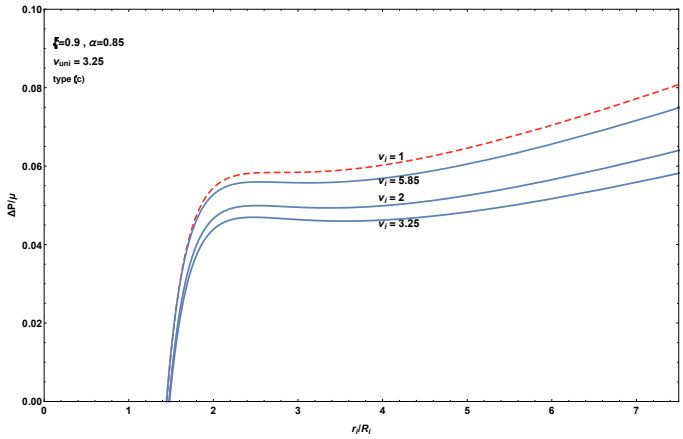

Figure 1: The family of inflation graphs for $\alpha = 0.85$, $\xi = 0.9$, $\Delta V/R_i^3 = 3.53$. This makes $v_i^{max} = 5.85$ and corresponds to a structure wall that is 70% mobile liquid.

ΔV throughout the structure wall in different ways. Thus A and B provide two degrees of freedom that are constrained by the single condition (1). Consequently, there will be a one degree of freedom – or one parameter family – of harmonic swelling fields that so redistribute the liquid. Letting $v_i = v(R_i)$ and $v_o = v(R_o)$, we may let either v_i or v_o parameterize this family. Choosing v_i as the parameter, it then follows that

$$A = \left[-\frac{3\Delta V}{2\pi R_i^3} \left(\frac{\xi^3}{2 - 3\xi + \xi^3} \right) + v_i \left(\frac{2(1-\xi^3)}{2 - 3\xi + \xi^3} \right) - \frac{2(1-\xi^3)}{2 - 3\xi + \xi^3} \right] R_i, \tag{3}$$

with a similar expression for B. Here $\xi = R_i/R_o$ so that $0 < \xi < 1$ with ξ close to one describing a thin shell and ξ close to zero describing a thick shell. In order for $v(R) \geq 1$ for all R it follows that the parameterization range for v_i is $1 \leq v_i \leq v_i^{max}$ where v_i^{max} is a function of the same parameters appearing in (3). Values v_i close to one correspond to liquid that is heavily concentrated near the outer wall. Values v_i close to v_i^{max} correspond to liquid that is heavily concentrated near the inner wall. An intermediate value corresponds to the uniform fluid distribution.

Integrating the stress equations of equilibrium leads to

$$\Delta P = 2\mu \int_{R_i}^{R_o} \frac{R}{r^2} \left[\alpha \left(\frac{r}{R v^{2/3}} - \frac{R^5 v^{4/3}}{r^5} \right) + (1-\alpha) \left(\frac{r^3}{R^3 v^{4/3}} - \frac{R^3 v^{2/3}}{r^3} \right) \right] dR,$$

which enables the construction and analysis of pressure-inflation graphs for the family of swelling fields. One such set of graphs is shown in Figure 1. The value $\alpha = 0.85$ is standard for hyperelastic modeling with the Mooney-Rivlin form. The thickness ratio $\xi = 0.9$ corresponds to a relatively thin shell. In the classical hyperelastic theory this gives a nonmonotone pressure-inflation graph. Each of the poro-hyperelastic graphs in the figure also exhibit such a nonmonotone behavior. Note that the overall structural stiffness is highly variable as seen in the range of heights to the various graphs. The stiffest response corresponds to the highest curve, in this case that for $v_i = 1$. The most compliant response corresponds to the lowest curve, for which the liquid distribution is essentially uniform. Changes in material (α), structural geometry (ξ) and total liquid content (ΔV) cause the overall family of harmonic swelling distributions to exhibit qualitative changes, sometimes within the same family. These behaviors can be organized in terms of phase diagrams in parameter spaces [6]. In fact, the set shown in Figure 1 is key to one such analysis as a slight increase in ΔV will cause the uppermost curve (that corresponding to $v_i = 1$) to become monotonic.

ON THE MECHANICS OF NARROW ELASTIC RIBBONS

Roberto Paroni *[1]
[1]Dipartimento di Ingegneria Civile e Industriale,Università di Pisa,56122 Pisa,Italy

Summary The classical theory of ribbons, developed by Sadowsky and Wunderlich, has recently received renewed attention. Here, we re-examine the derivation of the limit energy of an inextensible elastic strip as the width goes to zero, without making any symmetry assumption. We further study the equilibrium configurations of a thin elastic strip subject to combined twist and traction and show that two types of equilibrium states are possible: the straight-helicoid and the spiral-ribbon.

Geometrically a ribbon is a body with three length scales: it is a parallelepiped whose length ℓ is much larger than the width ε, which, in turn, is much larger than the thickness h. That is, $\ell \gg \varepsilon \gg h$. Since two characteristic dimensions are much smaller than the length, ribbons can be efficiently modelled as a one-dimensional continuum.

The starting point for the study of elastic ribbons can be either the three-dimensional nonlinear theory of elasticity or, taking advantage that the thickness h is much smaller than the other two dimensions, a nonlinear theory for plates. Within the latter framework, since energetically stretching 'costs' much more than bending, one can further assume that the plate is inextensible.

The (bending) energy of an inextensible elastic strip $S_\varepsilon = (-\ell/2, \ell/2) \times (-\varepsilon/2, \varepsilon/2)$, is

$$u \mapsto \frac{1}{\varepsilon} \int_{S_\varepsilon} Q(A_u(x))\, dx, \tag{1}$$

where Q is the bending energy density and A_u denotes the second fundamental form of $u : S_\varepsilon \to \mathbb{R}^3$. For isotropic strips the energy density Q depends only on the determinant and the trace of A_u: the Gaussian curvature $K_u := \det A_u$ and the mean curvature $H_u := 1/2 \operatorname{tr} A_u$. Since inextensible, and hence developable, surfaces have null Gaussian curvature we have that Q only depends on H_u. By assuming the material to be isotropic and the energy density to be quadratic, the bending energy is proportional to

$$u \mapsto \frac{1}{\varepsilon} \int_{S_\varepsilon} |H_u(x)|^2\, dx. \tag{2}$$

In 1930, in a seminal paper, Sadowsky argued that as $\varepsilon \to 0$ the energy of the ribbon reduces to

$$y \mapsto \int_{-\ell/2}^{\ell/2} \frac{(\kappa^2 + \tau^2)^2}{\kappa^2}\, ds \tag{3}$$

where κ and τ are the curvature and the torsion, respectively, of the centerline y of the strip, and s is its arc length. This functional is now known as Sadowsky's functional. The model was formally justified in 1962 by Wunderlich.

Wunderlich's technique is quite ingenious, but it leads to a singular energy density, as (3) reveals. In this talk we shall briefly show what is the correct energy that is obtained by letting $\varepsilon \to 0$ in (2). We will also drop the isotropic assumption and deduce a one dimensional model for an anisotropic ribbon. We shall study the equilibrium configurations of a thin elastic strip subject to combined twist and traction and we shall recover two types of equilibrium states: the straight-helicoid and the spiral-ribbon. Finally, we will identify the critical value of the twist at which the transition from one state to another takes place for a prescribed traction.

The talk is based on joint works with R. Barsotti, L. Freddi, P. Hornung, M.G. Mora, and G. Tomassetti.

CONFIGURATIONAL FORCES ON 2-D ELASTIC LINE SINGULARITIES

Youjung Seo [1], Shubhada Garnaik[2], and Y. Eugene Pak[2]*
[1]Graduate School of Convergence Science and Technology, Seoul National University, Suwon, Republic of Korea
[2]Department of Mechanical Engineering, SUNY Korea, Incheon, Republic of Korea

Summary Configurational forces acting on two-dimensional (2-D) elastic line singularities are evaluated by path-independent J-, M-, and L-integrals in the framework of plane strain linear elasticity. The elastic line singularities considered in this study are the edge dislocation, the line force, the nuclei of strain, and the concentrated couple moment that are subjected to far-field loads. The interaction forces between two similar parallel elastic singularities are also calculated. Self-similar expansion force, M, evaluated for the line force shows that it is exactly the negative of the strain energy prelogarithmic factor as in the case for the well-known edge dislocation result. It is also shown that the M-integral result for the nuclei of strain and the L-integral result for the line force yield interesting nonzero expressions under certain circumstances.

INTRODUCTION

It is well known that the energy release rates or the configurational forces associated with translation, self-similar expansion, and rotation of cavities or defects are expressed by the path-independent integrals, J, M, and L, respectively [1–3]. These path-independent integrals are useful in characterizing various defects and elastic singularities in that they are related to the total energy change (change in strain energy plus work done by external loads) resulting from the configurational change of these defects and singularities; hence, the name energy release rate or configurational force [4].

To demonstrate the usefulness of these integrals in studying the configurational forces acting on elastic line singularities, we evaluated these integrals for the edge dislocation, the line force, the nuclei of strain, and the concentrated couple moment that are subjected to far-field mechanical loads. The interaction forces between two similar parallel elastic singularities are also calculated. Closed-form expressions for the configurational forces on each elastic singularity are obtained in the framework of two-dimensional (2-D) plane strain linear elasticity.

This concise work provides an interesting insight into the behavior of interacting elastic line singularities by evaluating particularly the less-utilized M-integrals that can give explicit expressions for self-similar expansion force. There have been similar studies on the in-plane and the out-of-plane line forces [5] as well as on 2-D and three-dimensional (3-D) nuclei of strain [4]. Here, we present some novel M-integral results for 2-D line singularities [6].

FORMULATIONS

Path-Independent Integrals Using Decomposed Energy Momentum Tensor

The path-independent J-, M-, and L-integrals for 2D linear elastic solid are

$$P_{ij} = \frac{1}{2}\sigma_{kl}\varepsilon_{kl}\delta_{ij} - \sigma_{i\gamma}u_{\gamma,j}$$

$$J_j = \int_c P_{ij}n_i dS$$

$$M = \int_c P_{ij}n_i x_i dS$$

$$L_k = \int_c e_{kij}P_{ij}n_i x_i dS$$

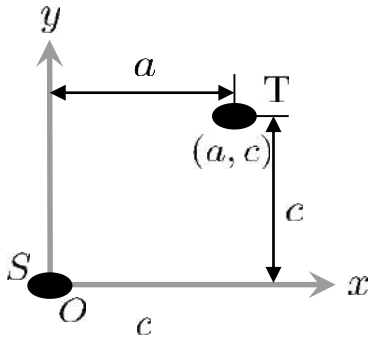

Figure 1. Elastic singularity T located at (a, c) interacting with singularity S at the origin.

These path-independent integrals for the interacting singularities S and T can be calculated by summing up the elastic fields generated by each singularity. Here, S denotes the elastic singularity at the origin of the coordinate system for which the configurational forces are calculated and T denotes other interacting singularities or far-field loads. The integrands of these integrals are then composed of the singular self-field and the regular field due to singularity T or the far-field loads. We calculated the above path-independent integrals on a contour C with vanishingly small radius that completely surrounds the singularity S at the origin. We can further simplify the calculations by assuming that the elastic field induced by T is constant along the contour C.

Forces Between Two Parallel Elastic Line Singularities

Interacting configurational forces between two similar parallel elastic singularities are evaluated by the path-independent integrals along the contour C surrounding the elastic singularity S (Table 1). It can be seen that the M-integral

*Corresponding author. E-mail: eugene.pak@sunykorea.ac.kr

expressions for the edge dislocation and the line force do not recognize other interacting fields, i.e., the elastic field due to singularity T, hence, only the self-field contributes to the M value. Interestingly, and perhaps for the first time, it is observed that the M-integral expression for the line force is identical to the negative of the prelogarithmic strain energy factor. This is analogous to the well-known dislocation result given by Rice [7]. Our result also shows that the self-similar expansion force, M, acting on the nuclei of strain exists only when the normal stresses are present. This is because the nuclei of strain, which equivalently model the misfitted cylinder in an infinite matrix, induces a state of pure shear in the matrix resulting in no volume or scale change. Only in the presence of volume changing normal stresses, the self-similarly expanding force is realized. A similar M-integral result was obtained for the case of a three-dimensional misfitted spherical inclusion embedded in an infinite solid [8]. Contrary to the line force, the M-integral for the nuclei of strain does not provide the coefficient of strain energy factor. At the same time, the M-integral result for the concentrated couple moment under far-field loads is interestingly zero.

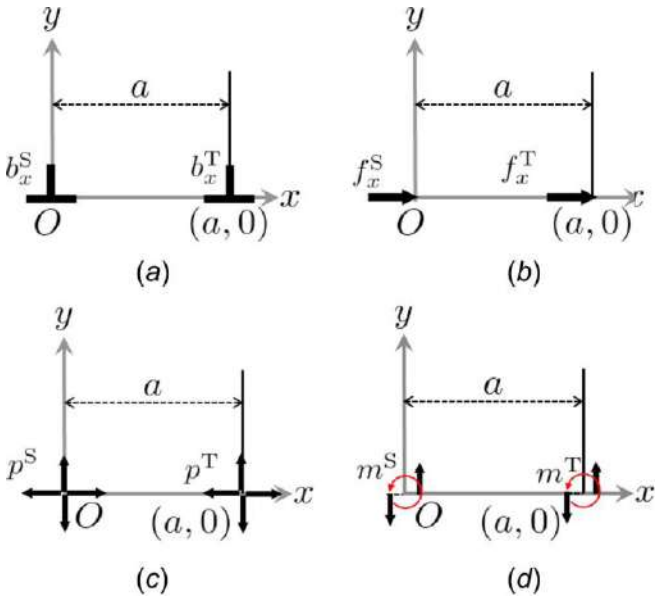

Figure 2. In-plane elastic singularities: (a) edge dislocation, (b) line force, (c) nuclei of strain, and (d) concentrated couple moment, interacting with identical parallel line singularities in an infinite medium.

Table 1. Configurational forces between two parallel elastic line singularities in the absence of far-field loads

Summary We define what is a *generic separating set* of invariant functions (a.k.a. a *weak functional basis*) for tensors. We produce then two generic separating sets for 3D elasticity tensors, one of them constituted of 21 polynomial invariants, the second comprising a minimal number of 18 rational invariants.

SEPARATING SETS OF ELASTIC MATERIALS

In the classical linear theory, the elastic behaviour of a material is described by a fourth-order tensor $\mathbf{E}$ having major and left/right minor indicial symmetries

$$E_{ijkl} = E_{ijlk} = E_{klij}.$$

In 3D, and with respect to a given basis, such a tensor is defined by 21 components. However, as pointed out for instance by Boehler–Kirilov–Onat [2], any other orientation of the material with respect to the reference basis, will define a new tensor $\overline{\mathbf{E}}$ given by

$$\overline{E}_{ijkl} = g_{ip}g_{jq}g_{kr}g_{ls}E_{pqrs} \quad \text{denoted} \quad \overline{\mathbf{E}} = g \star \mathbf{E} \tag{1}$$

where $g \in \mathrm{SO}(3)$ is some rotation of the space.

For anisotropic materials, there's no reason for $\mathbf{E}$ and $\overline{\mathbf{E}}$ to be the same: tensors' components do not characterize elastic materials independently of their spatial orientation. To give different names to different elastic materials require to define a finite set of $\mathrm{SO}(3)$-invariant *functions* $f_1, \dots, f_n$ such that

$$f_i(\mathbf{E}_1) = f_i(\mathbf{E}_2) \iff \mathbf{E}_2 = g \star \mathbf{E}_1.$$

A classical set of functions solving this problem is the *integrity basis* of the elasticity tensor, which is a finite set of polynomial invariants having the property of generating the algebra of *polynomial invariants*.

For instance, for a second order symmetric tensor $\mathbf{a}$, such an integrity basis is $\mathrm{tr}(\mathbf{a}), \mathrm{tr}(\mathbf{a}^2), \mathrm{tr}(\mathbf{a}^3)$. Nevertheless, for the elasticity tensor a minimum integrity basis includes 297 polynomial invariants [6], so it is not very usable. To have a basis of lower cardinality, it is possible to consider *rational invariants* instead of polynomial ones. The resulting set is known as a *weak separating set*, since it allows only to distinguish tensors in generic position. A weak separating set constituted of 39 polynomial invariants was already obtained by Boehler–Kirilov–Onat [2].

RATIONAL INVARIANTS AND WEAK SEPARATING SETS

The relation (1) defines a *linear representation* of the rotation group $\mathrm{SO}(3)$ on the real vector space $\mathbb{E}\mathrm{la}$ of elasticity tensors. In this specific case, any rational invariant r of an elasticity tensor can be written $r = p/q$, with p and q being polynomial invariants. From invariant theory [7], we know that the *field of rational invariants* is finitely generated by some family $s_1, \dots, s_k$.

A very important result [7, Lemma 2.2] indicates that such a family $s_1, \dots, s_k$ is a *weak separating set*: there exists an open dense set $\mathcal{Z}^c \subset \mathbb{E}\mathrm{la}$ such that

$$\forall \mathbf{E}_1, \mathbf{E}_2 \in \mathcal{Z}^c, \quad s_i(\mathbf{E}_1) = s_i(\mathbf{E}_2) \iff \exists g \in \mathrm{SO}(3), \quad \mathbf{E}_2 = g \star \mathbf{E}_1.$$

The open dense set $\mathcal{Z}^c$ defines a set of *generic tensors*, so that a random elasticity tensor belongs to $\mathcal{Z}^c$ almost surely.

In fact, this is a purely theoretical result, and two questions naturally arise :

1. What is the minimal number k of elements of a generating set ?
2. How to explicitly construct the rational invariants s_j?

In the case of the elasticity tensors, we answer both questions: the minimal number corresponds to the transcendence degree 18 (which is the dimension of $\mathbb{E}\mathrm{la}$ minus the dimension of $\mathrm{SO}(3)$). The effective computations are finally obtained using a strong relationship between the tensor space and the space of *binary forms* (homogeneous polynomials in two complex variables [5]).

*Corresponding author. E-mail: marc.olive@math.cnrs.fr

RESULTS

The first step is to consider an *harmonic decomposition* of elasticity tensors [1]. Any elasticity tensor can be expressed

$$\mathbf{E} = (\lambda, \mu, \mathbf{d}', \mathbf{v}', \mathbf{H}) \in \mathbb{H}^0 \oplus \mathbb{H}^0 \oplus \mathbb{H}^2 \oplus \mathbb{H}^2 \oplus \mathbb{H}^4, \quad d_{ij} := E_{kkij}, \quad v_{ij} := E_{kikj} \tag{2}$$

$$\lambda := \operatorname{tr}(\mathbf{d}), \quad \mu := \operatorname{tr}(\mathbf{v}), \quad \mathbf{d}' := \mathbf{d} - \frac{\lambda}{3}\mathbf{1}, \tag{3}$$

where $\mathbb{H}^n$ is the space of n-th order harmonic tensors (traceless and totally symmetric).

Before exhibiting a weak separating set of 18 rational invariants, a first (not minimal) weak separating set of 21 polynomial invariants will be considered. Our result are formulated using the following notation

$$(\mathbf{ab})^s := \frac{1}{2}(\mathbf{ab} + \mathbf{ba}), \quad [\mathbf{a}, \mathbf{b}] := \mathbf{ab} - \mathbf{ba}.$$

Theorem 1 *Let* $\mathbf{E} = (\lambda, \mu, \mathbf{d}', \mathbf{v}', \mathbf{H})$ *be an elasticity tensor,* $\mathbf{d}_2 = \operatorname{tr}_{13} \mathbf{H}^2$ *and* $\mathbf{d}_3 = \operatorname{tr}_{13} \mathbf{H}^3$.

Then, the following 21 polynomial invariants, $\lambda = \operatorname{tr} \mathbf{d}$, $\mu = \operatorname{tr} \mathbf{v}$,

$$I_2 := \operatorname{tr} \mathbf{d}_2, \quad I_3 := \operatorname{tr} \mathbf{d}_3, \quad I_4 := \operatorname{tr} \mathbf{d}_2^2, \quad I_5 := \operatorname{tr}(\mathbf{d}_2\mathbf{d}_3), \quad I_6 := \operatorname{tr} \mathbf{d}_2^3, \quad I_7 := \operatorname{tr}(\mathbf{d}_2^2\mathbf{d}_3)$$
$$I_8 := \operatorname{tr}(\mathbf{d}_2\mathbf{d}_3^2), \quad I_9 := \operatorname{tr} \mathbf{d}_3^3, \quad I_{10} := \operatorname{tr}(\mathbf{d}_2^2\mathbf{d}_3^2), \quad D_3 := \operatorname{tr}(\mathbf{d}'\mathbf{d}_2), \quad D_4 := \operatorname{tr}(\mathbf{d}'\mathbf{d}_3), \quad D_5 := \operatorname{tr}(\mathbf{d}'\mathbf{d}_2^2),$$
$$D_6 := \mathbf{d}' : (\mathbf{d}_2\mathbf{d}_3)^s, \quad D_{11} := \mathbf{d}' : [\mathbf{d}_2, \mathbf{d}_3]^2, \quad V_3 := \mathbf{v}' : \mathbf{d}_2, \quad V_4 := \mathbf{v}' : \mathbf{d}_3, \quad V_5 := \mathbf{v}' : \mathbf{d}_2^2,$$
$$V_6 := \mathbf{v}' : (\mathbf{d}_2\mathbf{d}_3)^s, \quad V_{11} := \mathbf{v}' : [\mathbf{d}_2, \mathbf{d}_3]^2,$$

separate generic tensors $\mathbf{E}$*, satisfying the following conditions:*
(1) the pair $(\mathbf{d}_2, \mathbf{d}_3)$ *is triclinic (i.e no common eigenvector), and (2)* $\mathbf{d}_2$ *is orthotropic (i.e three distinct eigenvalues).*

In this result, the 9 polynomial invariants I_k (introduced in [2]) are used to separate the fourth-order harmonic part $\mathbf{H}$ of (2). This set is completed by a family D_l, V_m of 10 polynomial invariants. The minimum separating set is then obtained by reducing the family $I_2, \ldots, I_{10}$ to a set of 6 rational invariants. This reduction is achieved by translating a result obtained by Maeda [4, 3] in the domain of *classical invariant theory* [5]. This gives us a set of 6 rational separating invariants for $\mathbb{H}^4$:

$$i_2, \quad i_3, \quad i_4, \quad k_4, \quad k_8, \quad k_9,$$

all defined with denominator being some power of the same polynomial invariant. We finally obtain:

Theorem 2 *The following 18 rational invariants*

$$\lambda, \quad \mu, \quad i_2, \quad i_3, \quad i_4, \quad k_4, \quad k_8, \quad k_9,$$
$$D_3, \quad D_4, \quad D_5, \quad D_6, \quad D_{11}, \quad V_3, \quad V_4, \quad V_5, \quad V_6, \quad V_{11}$$

separate generic tensors $\mathbf{E} = (\lambda, \mu, \mathbf{d}', \mathbf{v}', \mathbf{H})$*, satisfying the following conditions: (1) the pair* $(\mathbf{d}_2, \mathbf{d}_3)$ *is triclinic, and (2)* $\mathbf{d}_2$ *is orthotropic.*

CONCLUSIONS

To separate *generic elastic materials*, the notion of *weak separating set*, classical in invariant theory, has been used. A first weak generating set of 21 *polynomial invariants* is obtained, which is an improvement over the 39 polynomial invariants of Boehler–Kirilov–Onat in [2]. By exploiting the field of rational invariants and results from binary forms, a minimal weak generic separating set of 18 rational invariants is finally obtained. From this, we can even deduce a weak separating set of 19 *polynomial invariants* [3, Corolary 4.6], so to be as close as possible to the transcendence degree of the space of Elasticity tensors.

THREE-DIMENSIONAL SOLIDS AND STRUCTURES WITHIN STRAIN GRADIENT ELASTICITY: A CONFORMING ISOGEOMETRIC IMPLEMENTATION WITH MODEL COMPARISONS AND APPLICATIONS

Jarkko Niiranen[1] and Seyyed B. Hosseini[1]
[1]Department of Civil Engineering, Aalto University, Finland

Summary The three-dimensional theory of strain gradient elasticity is formulated as a weak formulation and discretized by isogeometric Galerkin methods. The formulation and its numerical implementation are compared to the corresponding dimension reduction models – beam, plate and shell models – and to the associated numerical methods with a set of benchmark problems and applications.

THEORETICAL MODELS

The three-dimensional theory of strain gradient elasticity is formulated as a weak formulation within an H^2 Sobolev space setting. The corresponding three-dimensional solid model is compared to the corresponding dimension reduction models: gradient-elastic beam, plate and shell models [1–4].

NUMERICAL METHODS

The formulation is discretized by adopting the framework of isogeometric NURBS-based Galerkin methods. This numerical approach is implemented and verified via a set of benchmark problems. The comparisons, accomplished with respect to the most essential – non-classical – features of the models, serve as a validation for the gradient-elastic dimension reduction models. The comparisons rely on the numerical results obtained with the isogeometric finite element implementations for both the structural models [1–4] and for three-dimensional solids. For lattice applications [5, 6], the strain gradient models are compared to the corresponding (unhomogenized or full-field) fine-scale models based on classical elasticity.

GEOMETRICAL APPROACH ON KINEMATICS OF DEFECTED MATERIAL

Van Hoi Nguyen[1], Guy Casale[1], and Loïc Le Marrec *[1]
[1]Université deR ennes,CNRS,IRMAR-UMR6625,F-35000 Rennes,France

Summary In the present continuum mechanical model, the body is idealized as a collection of material points for which a frame is attached to illustrate the local lattice structure. Frames and points behave independently. Points transformation is governed by map ϕ and vector fields transformation is associated with Ψ. The motion is said inconsistent if $\Psi \neq D\phi$. This allows potential distribution of defects in the current medium. In the reference configuration the body is a material manifold $\mathcal{B} = (G, \nabla)$. The corresponding induced set $(\overline{g}, \overline{\nabla})$ as well as torsion are defined on the current state $\phi(\mathfrak{B})$. In a next step, strains associated to this general (large) transformations are introduced in terms of ϕ and Ψ. Equation of motion for infinitesimal transformation is briefly presented.

MATHEMATICAL MODEL

Let (G, ∇) be the metric and metric-compatible connection on $\mathfrak{B}$. We denote $\{X^A\}$, $\{E_A\}$, $\{dX^A\}$ and $T\mathfrak{B}$ (respectively $\{x^a\}$, $\{e_a\}$, $\{dx^a\}$ and $T\mathcal{S}$) the coordinates system, basis tangent, its dual and tangent bundle defined on $\mathfrak{B}$ (respectively $\mathcal{S}$). Here $\mathcal{S}$ is the ambient space with a metric g. A mechanical transformation is a bundle map

$$\Upsilon : T\mathfrak{B} \to T\mathcal{S},\ (X, W) \mapsto \big(x = \phi(X), \Psi(X)W\big), \quad \forall X \in \mathfrak{B}, \quad \forall W \in T_X\mathfrak{B}. \tag{1}$$

Where $\phi : \mathfrak{B} \to \mathcal{S}$ is C^1-regular. The vector transformation $\Psi : T_X\mathfrak{B} \to T_x\mathcal{S}$ is C^1 linear and satisfies $\det \Psi \neq 0$. The map Ψ can be expressed by $\Psi^a{}_A(X) e_a \otimes dX^A$. Its inverse $\Psi^{-1} : T_x\mathcal{S} \to T_X\mathfrak{B}$ can be written $\Psi^{-1} = \Psi^{-1B}_b(x) E_B \otimes dx^b$, with $\Psi^{-1B}_b \Psi^a{}_B = \delta^a_b$. The deformation gradient of ϕ is $\mathbf{F} = D\phi$ (or denoted by ϕ_*). It is a linear map from $T_X\mathfrak{B}$ into $T_x\mathcal{S}$. In terms of components, $\mathbf{F} = F^a{}_A(X) e_a \otimes dX^A$, where $F^a{}_A = \partial_A \phi^a$. Its inverse is $\phi^* = F^{-1A}_b(x) E_A \otimes dx^b$, with $F^{-1A}_b F^a{}_A = \delta^a_b$. Hereafter, the transformation is called consistent if $\Psi = \mathbf{F}$, in contrary it is called inconsistent: in physical terms, the micro-structure is not convected by the macro-scale transformation.

Let u, v be vector fields on $\phi(\mathfrak{B})$. A metric $\overline{g}$ and a connection $\overline{\nabla}$ are defined on $\phi(\mathfrak{B}) \subset \mathcal{S}$ following, [1]:

$$\begin{aligned} &\overline{g}(x)(u, v) = G(X)\big(\Psi^{-1}(x)u, \Psi^{-1}(x)v\big), && \overline{g}_{ab} = \Psi^{-1A}_a \Psi^{-1B}_b G_{AB}, \\ &\overline{\nabla}_v u = \Psi(X)\big(\nabla_{\phi^*(x)v} \Psi^{-1}(x)u\big), && \overline{\Gamma}^c{}_{ba} = \Psi^c{}_C F^{-1A}_b \big(\Psi^{-1B}_a \Gamma^C_{AB} + \partial_A \Psi^{-1C}_a\big). \end{aligned} \tag{2}$$

Such a connection is metric-compatible $\overline{\nabla}\overline{g} = 0$. For a perfect body and appropriate coordinates system $\Gamma^C_{AB} = 0$ and the induced connection becomes $\overline{\Gamma}^c{}_{ba} = \Psi^c{}_C \partial_b \Psi^{-1C}_a$.

The current torsion is related to the induced connection as $\overline{T}(u, v) = \overline{\nabla}_u v - \overline{\nabla}_v u - [u, v]$ or in components $\overline{T}^a{}_{bc} = \overline{\Gamma}^a{}_{bc} - \overline{\Gamma}^a{}_{cb}$. It must be emphasized that for a consistent transformation, $\overline{T}$ is related to the torsion T of $\mathfrak{B}$ by:

$$\overline{T}(u, v) = \phi_*\big(\nabla_{\phi^* u}\phi^* v - \nabla_{\phi^* v}\phi^* u - [\phi^* u, \phi^* v]\big) = \phi_* T(\phi^* u, \phi^* v). \tag{3}$$

The induced curvature tensor is defined by $\overline{R}(u, v)w = \overline{\nabla}_u \overline{\nabla}_v w - \overline{\nabla}_v \overline{\nabla}_u w - \overline{\nabla}_{[u,v]} w$, we have the following relation

$$\overline{R}(u, v)w = \Psi\Big(\nabla_{\phi^* u}\nabla_{\phi^* v}\Psi^{-1}w - \nabla_{\phi^* v}\nabla_{\phi^* u}\Psi^{-1}w - \nabla_{[\phi^* u, \phi^* v]}\Psi^{-1}w\Big) = \Psi R(U, V)W. \tag{4}$$

with $U = \phi^* u$, $V = \phi^* v$ and $W = \Psi^{-1} w$. It' straigth forward that the curvature $\overline{R}$ vanishes *iff* R is zero.

Let consider an initial state given without initial defect (for example $G = \delta$ and $T = 0$). For consistent transformation, (3) imposes $\overline{T} = 0$: the current state is defect free. However for an inconsistent transformation $\overline{T}$ is not necessary zero. This is illustrated by a classical example where the reference manifold supports no point-motion: $\mathbf{F} = \mathbb{I}$ but transformation is inconsistent as $\Psi \neq \mathbf{F}$ is given as follow:

$$\Psi^a{}_B = \begin{pmatrix} 1 & -\psi & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad \text{hence} \qquad \overline{g}_{ab} = \begin{pmatrix} 1 & \psi & 0 \\ \psi & 1+\psi^2 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{5}$$

In [2] $\psi : \mathfrak{B} \to \mathbb{R}$ is C^∞ and depends on X^2, here we consider a slightly more general case as $\psi(X^1, X^2, X^3)$. *A priori* non-zero connection coefficients are $\overline{\Gamma}^1{}_{b2} = \partial_b \psi$ yielding to *a priori* non-zero torsion component $\overline{T}^1{}_{\alpha 2} = \partial_\alpha \psi$ with $\alpha = 1$ or 3. In particular if $\psi \equiv \psi(X^2)$, the current state is defect free ($\overline{T} = 0$) but inconsistent ($\Psi \neq \mathbf{F}$). However, if $\psi \equiv \psi(X^1)$ we observe a density of edge dislocations: $\overline{T}^1{}_{12} \neq 0$ (see Fig.1). Last, for $\psi \equiv \psi(X^3)$, a density of screw type dislocations is created: $\overline{T}^1{}_{32} \neq 0$.

*Corresponding author. E-mail: loic.lemarrec@univ-rennes1.fr

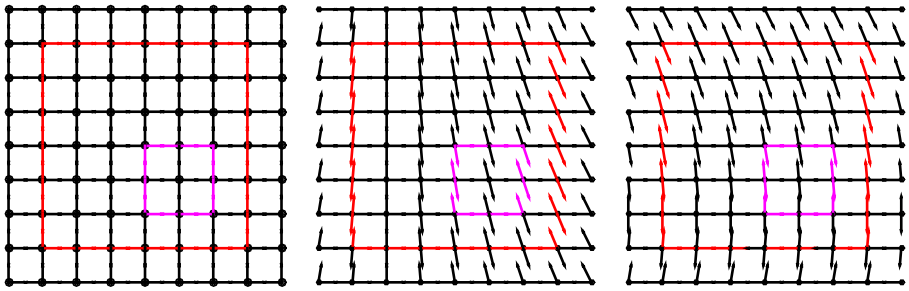

Figure 1: Left: material manifold $\mathcal{B}$ for which are depicted one horizontal and one vertical vector fields attached to each material point (dots). Center and left: current state for transformation with $\psi = X^1$ and $\psi = X^2$ respectively. For the two cases points are unchanged but vectors are transformed. Center: along any closed material loops (colored example) the total vectors gap is non-zero denoting the presence of screw-dislocation densities. This is not the case for the left figure for which the transformation is dislocation free.

STRAINS AND EQUATIONS OF MOTION

The classical strain $\mathbf{E} = (\phi^* g - G)/2$ refers to the macro-stretch of the body caused by the motion ϕ. It measures the change of the distance and angle between a material point and its neighborhood. As the motion is not defined only by ϕ, the strain $\mathbf{E}$ is not sufficient. A so-called consistent strain is given:

$$\mathcal{E}(U,V) = \frac{1}{2} g\big(\Psi - \mathbf{F})U, (\Psi - \mathbf{F})V\big), \qquad \forall U, V \in T_X\mathfrak{B}. \tag{6}$$

It measures the difference between the point and frame motion: it vanishes *iff* the transformation is consistent. This tensor defined on $T\mathfrak{B}$ and invariant under arbitrary body rotation. It is symmetric in contrary to the relative strain $\mathbf{F} - \Psi$ introduced in [3]. If $\mathcal{E} = 0$ no torsion is observed after transformation of a defect-free body but the converse is not true: see previous example for which the only non-zero component of $\mathcal{E}$ is $\mathcal{E}_{22} = \frac{1}{2}\psi^2$. In order to measure the non-homogeneity of Ψ and following [3, 4] a wryness tensor $\mathcal{M}$ is introduced with $\mathcal{M}^L{}_{KA} = \Psi^{-1L}_{\ \ l}\partial_A \Psi^l{}_K$.

Functional of the energy density Ξ per unit reference volume on $\mathfrak{B}$ is assumed to be of the form $\Xi(\mathbf{E}, \mathcal{E}, \mathcal{M})$. Accordingly, the set of stress tensors are defined as follows

$$\mathbf{S} = \frac{\partial \Xi}{\partial \mathbf{E}}, \qquad \mathfrak{S} = \frac{\partial \Xi}{\partial \mathcal{E}}, \qquad \mathfrak{T} = \frac{\partial \Xi}{\partial \mathcal{M}}. \tag{7}$$

The linear approximation for the stress, couple stress fields requires a quadratic approximation for the stored energy Ξ, in its variables. In terms of strain, $\mathbf{F} \simeq \mathbb{I} + \mathfrak{u}$, with $\mathfrak{u}_{ij} = u_{i,j}$ and u is displacement vector field. Similarly, $\Psi \simeq \mathbb{I} + \mathfrak{a}$, and $\Psi - \mathbf{F} \simeq \mathfrak{d} = \mathfrak{a} - \mathfrak{u}$. With these, the strain tensors are approximated by

$$\mathbf{E}_{AB} \simeq \varepsilon_{ab}\delta^a{}_A\delta^b{}_B\,, \qquad \mathcal{E}_{AB} \simeq \mathfrak{c}_{ab}\delta^a{}_A\delta^b{}_B\,, \qquad \mathcal{M}^K{}_{LM} \simeq \mathfrak{a}_{kl,m}\delta^k_K\delta^l_L\delta^m_M\,, \tag{8}$$

with $\varepsilon_{ab} = \frac{1}{2}(u_{a,b} + u_{b,a})$, $\mathfrak{c}_{ab} = \frac{1}{2}(\mathfrak{d}_{ab} + \mathfrak{d}_{ba})$ and $\mathfrak{a}_{mkl} = \partial_m \mathfrak{a}_{kl}$. For the homogeneous isotropic material, the linear constitutive equations for stresses read

$$\sigma_{ab} \simeq \frac{\partial \Xi}{\partial \varepsilon_{ab}}\,, \qquad \tau_{ab} \simeq \frac{\partial \Xi}{\partial \mathfrak{c}_{ab}}\,, \qquad \mu_{pqr} \simeq \frac{\partial \Xi}{\partial \mathfrak{a}_{pqr}}\,, \tag{9}$$

where σ and τ are both symmetric. In terms of inertia, the microacceleration reads $\Lambda^B_a = \mathcal{I}^{bb}\ddot{\mathfrak{a}}_{ab}\delta^b_B$ with $\mathcal{I}_{bb}$ is a constant. Then, for this material, the local equations of motion on $\mathfrak{a}$ and $\mathfrak{u}$ are given by

$$\mathfrak{b}_a + \sigma_{ab,b} - \tau_{ab,b} = \rho_0 \ddot{u}_a \tag{10a}$$

$$\mathfrak{Z}_{ab} - \tau_{ab} + \mu_{lab,l} = \rho_0 \mathcal{I}^{bb}\ddot{\mathfrak{a}}_{ab}. \tag{10b}$$

where $\mathfrak{b}$ is the body force per unit volume and $\mathfrak{Z}$ is interpreted as a double forces per unit volume.

CRACK TIP FIELDS IN A FIBER-REINFORCED NEO-HOOKEAN SHEET

Yin Liu[1], Brian Moran, Luca Di Stasio
Division of Physical Sciences and Engineering, King Abdullah University of Science and Technology, Thuwal, 23955-6900, Kingdom of Saudi Arabia

Summary The asymptotic crack tip fields in a fiber-reinforced neo-Hookean sheet are derived, where a strain energy function motivated by composite mechanics (Guo et al., 2006, 2007) is employed. The resulting asymptotic deformation and stress fields depend quantitatively on the degree of fiber reinforcement and orientation angle. For suitable choice of parameters, the asymptotic fields reduces to those obtained by Knowles and Sternberg (1983). Both asymptotic path-independent *J*-type integrals and interaction energy integrals are derived to evaluate the crack tip amplitude parameters. The analytical results agree well with the finite element results for a stretch long strip with an edge crack. The result obtained may prove useful in providing a framework for future exploration in modeling the mechanical behaviour near a slit or tear in soft biological tissue reinforced by collagen fibers.

INTRODUCTION

Mechanical anisotropy like fiber-like inclusions or specifically oriented microstructures plays a key role in achieving specific functions in muscles, cartilage and arteries [1]. It is important to understand the influence of material anisotropy on the fracture behaviors of soft solids and thus to provide a basis for guidance on the design of highly tough soft composites through introducing anisotropic microstructures.

In the present paper, we analyze the crack tip fields of an anisotropic hyperelastic sheet using the neo-Hookean fiber-reinforced neo-Hookean matrix material model developed in [2]. For the case of a thin sheet in which plane stress conditions hold, the asymptotic governing equations at the crack tip field for the fiber-reinforced material reduce to those obtained by Knowles and Sternberg [5] for a pure neo-Hookean material by a suitable scaling of the coordinate system. Furthermore, following the observation by Liu and Moran [3], where the asymptotic governing equations separate into two independent Laplace equations, we use the asymptotic path-independent integrals derived in that paper to evaluate the crack tip parameters. The analytical deformed coordinates and stress fields agree well with finite element results for different stretch levels, loading modes, and material parameters.

THE ASYMPTOTIC CRACK TIP FIELDS

We are interested in the crack tip fields of a material which consists of a neo-Hookean matrix reinforced by neo-Hookean fibers and for which the strain energy is given by [2,4]

$$W=\frac{\mu}{2}[(I_1-3)+\kappa(I_4+2I_4^{-1/2}-3)] \tag{1}$$

where μ is the shear modulus, κ is a material constant which represents the relative shear stiffness of the fiber to the matrix, $I_1=\mathrm{tr}\mathbf{C}$, $I_4=\mathbf{a}_o.\mathbf{C}.\mathbf{a}_o$, $\mathbf{C}=\mathbf{F}^{\mathrm{T}}.\mathbf{F}$, $\mathbf{F}$ is the deformation gradient and $\mathbf{a}_o$ denotes the orientation of the aligned fibers. Thus, the first Piola-Kirchhoff stress is given by $\mathbf{P}=\mu\mathbf{F}+\mu\kappa(1-I_4^{-3/2})\mathbf{F}.\mathbf{a}_o\otimes\mathbf{a}_o-p\mathbf{F}^{-\mathrm{T}}$, where p is a Lagrangian multiplier. The equilibrium equation and surface traction are expressed by

$$y_{\alpha,\beta\beta}+\kappa(1-\lambda_f^{-3})_{,\beta}y_{\alpha,u}a_u^oa_\beta^o+\kappa(1-\lambda_f^{-3})y_{\alpha,u\beta}a_u^oa_\beta^o-\lambda^3\varepsilon_{\beta u}\varepsilon_{\alpha v}y_{u,v\beta}-3\lambda^2\lambda_{,\beta}\varepsilon_{\beta u}\varepsilon_{\alpha v}y_{u,v\beta}=0 \tag{2}$$

$$t_\alpha=P_{\alpha\beta}n_\beta=\mu[y_{\alpha,\beta}n_\beta+\kappa(1-\lambda_f^{-3})y_{\alpha,v}a_v^oa_\beta^on_\beta-\lambda^3\varepsilon_{\beta u}\varepsilon_{\alpha v}y_{u,v}n_\beta] \tag{3}$$

where $I_4=\lambda_f^2$ and $\varepsilon_{\alpha\beta}$ is the two-dimensional alternating symbol.

The out of plane stretch exhibits the asymptotic form $\lambda=J^{-1}=O(r^q)$ as $r\to0,(-\pi\le\theta\le\pi)$ for some real $q>0$ [5], where (r,θ) are polar coordinates in the reference configuration centered at crack tip. This implies that the fiber stretch $\lambda_f\to\infty$ as $r\to0$ and consequently, the out of plane stretch $\lambda\to0$ as $r\to0$.Using these results, we can rewrite the governing equation and the traction free boundary conditions on the crack surfaces, i.e.,

$$c_{55}y_{\alpha,11}+2c_{45}y_{\alpha,12}+c_{44}y_{\alpha,22}=0,\quad c_{45}y_{\alpha,1}+c_{44}y_{\alpha,2}=0 \tag{4}$$

where $c_{44}=1+\kappa\cos^2\phi, c_{45}=\kappa\sin\phi\cos\phi, c_{55}=1+\kappa\sin^2\phi$.

Based on a linear transformation of the original coordinates $x_i,i=1,2$ to scaled coordinates $\eta_i,i=1,2$, that is $d\eta_i=A_{ij}dx_j,\ i,j=1,2$, where $A_{11}=\sqrt{c_{44}/(c_{44}c_{55}-c_{45}^2)},\ A_{12}=-c_{45}\omega_{11}/c_{44},\ A_{21}=0,\ A_{22}=\sqrt{1/c_{44}}$, the asymptotic governing equation is given by

$$\frac{\partial^2y_\alpha}{\partial\eta_1^2}+\frac{\partial^2y_\alpha}{\partial\eta_2^2}=0,\quad \text{as } \left(\eta_1^2+\eta_2^2\right)^{1/2}\to0 \text{ and } \frac{\partial y_\alpha}{\partial\eta_2}=0,\quad \text{on } \eta_1\le0,\ \eta_2=0 \tag{5}$$

[1]Corresponding author. E-mail: yin.liu@kaust.edu.sa

which has a general solution $v_m = p_m \sin(\frac{m}{2}\psi)$, when $m = 1,3,5,...$ and $q_m \cos(\frac{m}{2}\psi)$ when $m = 2,4,6,..$, where p_m and q_m are amplitude coefficients, $\rho^2 = r^2[(A_{11}\cos\theta + A_{12}\sin\theta)^2 + (A_{22}\sin\theta)^2]$, $\psi = \text{atan}(A_{22}\sin\theta/(A_{11}\cos\theta + A_{12}\sin\theta))$ and $x_1 = r\cos\theta$ and $x_2 = r\sin\theta$. Thus, the crack shape and the Cauchy stress can be described by

$$\begin{aligned} y_1 &\sim p_1\rho^{1/2}\sin\tfrac{\psi}{2} + q_1\rho\cos\psi \\ y_2 &\sim p_2\rho^{1/2}\sin\tfrac{\psi}{2} \end{aligned}, \qquad \begin{aligned} \sigma_{11}/\mu &\sim \tfrac{1}{4}p_1^2\rho^{-1} - p_1q_1\rho^{-1/2}\sin\tfrac{\psi}{2} + q_1^2 \\ \sigma_{22}/\mu &\sim \tfrac{1}{4}p_2^2\rho^{-1} \\ \sigma_{12}/\mu &\sim \tfrac{1}{4}p_1p_2\rho^{-1} - \tfrac{1}{2}\rho^{-1/2}p_2q_1\sin\tfrac{\psi}{2} \end{aligned} \tag{6}$$

Using the these results, the J-integral is given by $J = \frac{\mu\pi\sqrt{c_{44}}}{4}\left(p_1^2 + p_2^2\right)$. The asymptotic path-independent integrals developed in [3] can be used to extract the crack tip parameters

$$J^{y_\alpha} = \sqrt{c_{44}}J^{y_\alpha} = \frac{\mu\pi\sqrt{c_{44}}}{4}p_\alpha^2,\ \alpha = 1,2 \tag{7}$$

$$I_1^{y_\alpha} = \sqrt{c_{44}}I_1^{y_\alpha} = \frac{\sqrt{c_{44}}\pi\mu p_\alpha}{2},\ \alpha = 1,2,\ \text{for}\ y^{\text{aux}} = \rho^{1/2}\sin\tfrac{\psi}{2} \tag{8}$$

$$I_2^{y_\alpha} = \sqrt{c_{44}}I_2^{y_\alpha} = -2\sqrt{c_{44}}\pi\mu q_\alpha,\ \alpha = 1,2,\ \text{for}\ y^{\text{aux}} = \ln\rho \tag{9}$$

ANALYTICAL AND NUMERICAL RESULTS

To verify the theoretical results and compute the crack tip parameters, we use the finite element method to model the crack tip fields of a long cracked strip under combined stretch and shear (Fig. 1a). In this case, the J-integral evaluation along the contour shown in red and green gives $J_{\text{far}} = W(\mathbf{F}_s)H_0$. The J-integral (Fig. 1b) shows good agreement between the results by different calculation methods for several combinations of ϕ and κ. The deformed crack shape is not symmetric due to the anisotropic effects (Fig. 1c and d) and the analytical and finite element results for the crack shapes (Fig. 1d) agree with each other for different parameters, indicating the accuracy of the asymptotic solution (6) for characterizing the deformed shape of the crack. The angular variation of the stress components σ_{22} (Fig. 1e-g) also show good agreement for the analytical and the finite element results and follow periodic patterns with peaks related to the fiber orientations.

DIFFERENTIAL GEOMETRY AND STRESS FIELDS OF DISLOCATED MEDIUM

Shunsuke Kobayashi*[1] and Ryuichi Tarumi[1]
[1]Graduate School of Engineering Science, Osaka university, Osaka, Japan

Summary We conduct the stress fields analysis of dislocation in three-dimensional hyperelastic material. Our formulation is based on the theory of elasto-plasticity and differential geometry. Continuous distribution of dislocations is introduced into a Weitzenböck manifold using the equivalence between the dislocation density tensor and torsion of the Weitzenböck connection. Riemannian metric of the intermediate configuration is obtained from the integration of Cartan first structure equation by the homotopy operator. The variational problem is solved numerically using the isogeometric analysis. We conduct the numerical analysis for stress field around a dislocation loop. The result shows fair agreement with a prediction given by the classical elasticity. This result demonstrates that this framework is applicable for stress field analysis of less-symmetric configuration of dislocations.

INTRODUCTION

Stress fields around a dislocation play a central role in plastic deformation of crystalline solids. A pioneering work of the subject is conducted by Volterra. He reported the analytical expression of the stress fields of dislocation using the classical elasticity. Although this is a standard theory of dislocation in continuum mechanics, it fails to express the stress fields near the core of dislocation due to a failure of linear approximation. Kondo, Bilby and Kröner introduced the continuous distribution of dislocation and considered the problem on the basis of differential geometry. The key concept here is the equivalence between the dislocation density tensor and non-vanishing torsion of an affine connection of a differentiable manifold [1]. Recently, Yavari and Goriely employed the theory of geometrical elasto-plasticity and obtained some analytical expressions for nonlinear stress fields of dislocation [2]. Their analysis is, however, limited to highly symmetrical problems. In the present study, we implement the theory into numerical analysis so as to develop a framework for practical applications. After a brief review of the geometrical elasto-plasticity, we conduct the numerical analysis for the stress fields around a dislocation loop. The result verify the present formulation and numerical implementation.

MATHEMATICAL PRELIMINARIES OF GEOMETRICAL ELASTO-PLASTICITY

Let us introduce the initial, intermediate and current configurations denoted by $\overline{\mathcal{S}}$, $\mathcal{B}$ and $\mathcal{S}$, respectively. Here $\overline{\mathcal{S}}$ and $\mathcal{S}$ are simply connected open subsets in the Euclidean 3-space $\mathbb{R}^3$. It means that we have global coordinates for the two configurations; $(\overline{x}^1, \overline{x}^2, \overline{x}^3)$ and (x^1, x^2, x^3). Let $\overline{x}^i$ be the Cartesian coordinates and let x^i be a smooth curvilinear coordinates written as $x^i = x^i(\overline{x}^j)$. Then, the total deformation gradient is expressed by $F^i_j = \partial x^i / \partial \overline{x}^j$. Note that the deformation gradient defines the transformation of dual frames; $dx^i = F^i_j d\overline{x}^j$. Following to the standard theory of elasto-plasticity, we conduct the multiplicative decomposition of the deformation gradient in such a way that $F^i_j = (F_e)^i_k (F_p)^k_l$, where $(F_e)^i_k$ and $(F_p)^k_j$ are elastic and plastic parts of the deformation gradient, respectively. The intermediate configuration $\mathcal{B}$ is a 3-dimensional material manifold which equips a Riemannian metric g. It shows a plastically deformed configuration and, therefore, free from elastic stress. Let $\varphi \colon \mathcal{B} \to \mathcal{S} \subset \mathbb{R}^3$ be an embedding map of the material manifold to the Euclidean 3-space with the Euclidean metric h. Here the embedding map φ is nothing but the elastic deformation. We express the pullback of Euclidean metric h to the intermediate configuration by $\varphi^* h$. Then, the Green strain tensor is given by the difference between the induced metric $\varphi^* h$ and Riemannian metric g such that $E := (\varphi^* h - g)/2$. It is convenient to introduce the dual frame ϑ^i which is an orthonormal frame in $\mathcal{B}$ with respect to the metric g. Namely, $g = \delta_{ij} \vartheta^i \otimes \vartheta^j$ where δ_{ij} is the Kronecker delta. The plastic distorsion F_p, which is a matrix of C^∞ functions on $\overline{\mathcal{S}}$, is defined using the dual frame ϑ^i such that $\vartheta^i = (F_p)^i_j d\overline{x}^j$. In a local coordinate representation on $\overline{\mathcal{S}}$ we have

$$\overline{\varphi^* h} = \delta_{ij} F^i_k F^j_l \, d\overline{x}^k \otimes d\overline{x}^l, \quad \overline{E} = \delta_{ij} (F^i_k F^j_l - (F_p)^i_k (F_p)^j_l) d\overline{x}^k \otimes d\overline{x}^l. \tag{1}$$

In the present formulation, a continuous distribution of dislocations, which is included in F_p, induces elastic deformation. Hence, we need to relate the plastic distorsion F_p and dislocation density for a given distribution of dislocations. It is known that the dislocation density is equivalent to the torsion 2-form τ^i in differential geometry. Following to a previous study by Yavari and Goriely, we obtain the plastic distorsion from a geometric consideration on Weitzenböck manifold, that is, Cartan first structure equation. This equation relates the torsion 2-form τ^i and plastic distorsion F_p in the following way; $\tau^i = d\vartheta^i$, where d is the exterior derivative. Integration of the first structure equation yields F_p for a given τ^i. We employed the homotopy operator H and solved the first structure equation explicitly [3].

The coordinate function $x^i(\overline{x}^j)$ is determined by using the standard framework of nonlinear elasticity and the calculus of variations. To simplify the analysis we assume that the medium is St.Venant-Kirchhoff hyperelastic material. This material has a linear relation between the second Piola-Kirchhoff stress tensor S and the Green strain tensor E such that

*Corresponding author. E-mail: kobayashi@nlsm.me.es.osaka-u.ac.jp

$S = C(E)$ where C is the elastic stiffness tensor. We also assume that the material is free from external forces, *i.e.*, elastic deformation is induced solely by F_p. Then, the strain energy W becomes a functional of the coordinate of the current configuration; $W[x^1, x^2, x^3] := \int_{\mathcal{B}} S(E)/2\vartheta^1 \wedge \vartheta^2 \wedge \vartheta^3$. For the numerical analysis, it is useful to express $W[x^1, x^2, x^3]$ in the initial configuration:

$$\overline{W}[x^1, x^2, x^3] = \int_{\overline{\mathcal{S}}} \frac{1}{2}\overline{S}(\overline{E}) \det(F_p) d\overline{x}^1 \wedge d\overline{x}^2 \wedge d\overline{x}^3. \tag{2}$$

Weak form stress equilibrium equation is derived from a stationary condition to the functional (2) and which is solved numerically using the isogeometric analysis [4], *i.e.*, Galerkin method which uses non-uniform rational B-spline (NURBS) as the basis functions.

RESULTS AND DISCUSSION

We conduct stress field analysis around a dislocation loop using the framework of geometrical elasto-plasticity. To simplify the analysis, we employed a cubic shape initial configuration, $\overline{\mathcal{S}} = \{(\overline{x}^1, \overline{x}^2, \overline{x}^3) | -1/2 < \overline{x}^i < 1/2\}$, and set the shear modulus $\mu = 1$ and Poisson ratio $\nu = 0.3$. A circular dislocation loop is inserted into the center of the material with the radius of $\overline{r} = 0.125$. We assume that the dislocation loop generates a continuous distribution of dislocation density $f = f(\overline{r})$ which is reported by Lazar *et. al.* [5]. Magnitude of Burgers vector is $(b^1, b^2, b^3) = (0.01, 0, 0)$. Then the torsion 2-from of the dislocation loop is expressed by $\tau^i = f(r) b^i l^l \epsilon_{ljk}/2 d\overline{x}^j \wedge d\overline{x}^k$, where l^i denotes the tangent vector along the dislocation line. Figure 1 shows the result of stress field obtained by the isogeometric analysis. Here, (a) shows the distribution of 2nd Piola-Kirchhoff stress S_{13}. The shear stress component is highly localized near the core of the dislocation loop. A cross section of the stress fields is shown in (b). In this figure, a pair of two edge dislocations are located at $(\pm 0.0625, 0, 0)$. This result shows a fair agreement with the prediction given by the classical elasticity under the same configuration of dislocation. Another cross section is shown in (c), where two screw dislocations are located at $(0, \pm 0.0625, 0)$. Again, the stress field is close to the classical system. These results verify the present formulation as well as the numerical implementation to the isogeometric analysis.

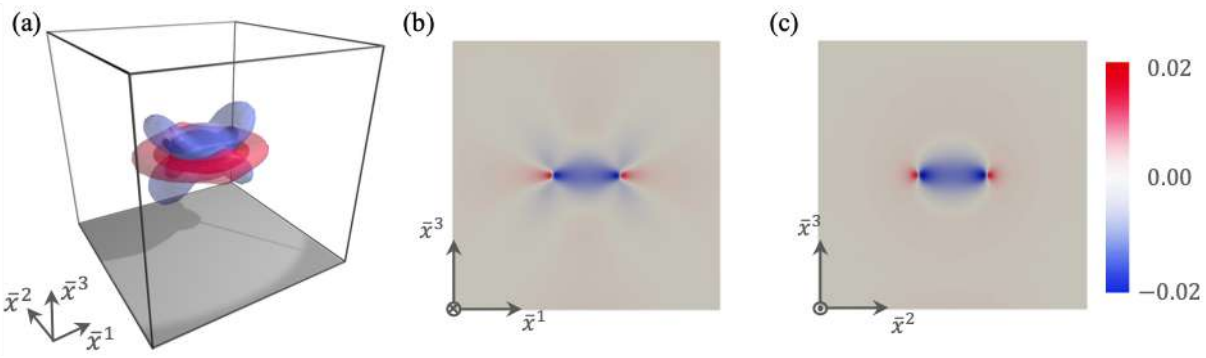

Figure 1: Distribution of the 2nd Piola-Kirchhoff stress component S_{13} with respect to the Cartesian coordinate system. (a) iso-surfaces of the shear stress S_{13}, (b) cross section of the stress distribution including two edge dislocations and (c) cross section of the stress distribution including two screw dislocations.

CONCLUSIONS

We conduct the stress field analysis around a dislocation loop on the basis of geometrical elasto-plasticity. Continuous distribution of dislocation density is converted into the torsion 2-form τ^i and plastic distorsion F_p is obtained from the integration of Cartan first structure equation by the homotopy operator. Embedding map of the Weitzenböck manifold to Euclidean 3-space is determined so as to minimize the strain energy functional. Numerical analysis for a dislocation loop revealed that the stress fields agree qualitatively well with the prediction given by the classical elasticity. This result demonstrates that the implementation of the geometrical elasto-plasticity theory enables us to analyze the stress fields for less-symmetric configuration of dislocations.

IDENTIFICATION OF A MODEL OF NONLINEAR ELASTIC MATERIAL

Dmitrii Khristich*, Alexey Markin, Marina Sokolova, and Yuri Astapov
Department of Computational Mechanics and Mathematics, Tula State University, Tula, Russia

Summary The paper demonstrates how to determine the constants of a model of a nonlinear elastic body from experiment on inhomogeneous deformation. The formulation of the problem of finite strain of an elastic body, using a generalized model of Hencky material, is presented. A numerical model is constructed for taking into account the boundary conditions of the contact type in the interaction of an elastic body with absolutely rigid stamps. To solve the inverse problem of determining constants, an optimization algorithm is used. The material constants are determined from uniaxial compression test. The results of the numerical solution and the experimental data are in good agreement.

The reported study was partially funded by the grant from the President of the Russian Federation according to the Research Project MD-1803.2019.1 and by RFBR according to the Research Project No. 18-31-20053.

INTRODUCTION

Rubber-like materials are widely used to produce critical components of modern mechanisms. In most cases these materials can be described by a model of weakly compressible isotropic elastic medium. Such models are based on constitutive relations connecting stresses and strains in elastomers. Among the known materials in the nonlinear theory of elasticity, hypoelastic and hyperelastic models are distinguished, as well as various generalizations of Hooke's law to the case of finite strains. However, there are no unambiguous recommendations regarding the choice of a variant of constitutive relations adequately describing the mechanical behavior of elastomers at final elastic strains. The use of the Hencky logarithmic tensor as a measure of deformations makes it possible to simplify the description of materials with significantly different reactions to changes in volume and shape. The linear version of the relations associates the generalized stress tensor with energetically conjugated Hencky logarithmic strain measure. This model is similar to the Neo-Hookean model of material and contains two material constants too. A generalized nonlinear version of the constitutive relations is also obtained by keeping third-order terms in expansion for the specific potential strain energy.

Elastic constants are usually determined from experiments on uniaxial and biaxial tension, compression and bending. Recently, more and more researchers [1] use an indentation experiment to verify the reliability of numerical solutions. Processing of such experiments is reduced to the necessity of solving the initial-boundary-value problem with mixed contact-type boundary conditions. We present results of a comparison of the numerical solution of the problem of a spherical stamp indentation into a cylindrical sample with experimental data obtained on a designed test bench.

CONSTITUTIVE RELATIONS

It was shown in [2, 3] that in an isotropic material, the generalized "rotated" stress tensor $\mathbf{\Sigma_R} = e^{\theta}\mathbf{R}\cdot\mathbf{S}\cdot\mathbf{R}^{-1}$ and the Hencky logarithmic strain tensor $\mathbf{\Gamma}=\ln\mathbf{U}$, where $\mathbf{U}$ is the left a measure of distortion included in the polar decomposition of the strain gradient, are energetically conjugated. Assuming the potential strain energy by the analytic function of the Hencky strain tensor, we obtain a decomposition of the form

$$W = W_0 + \boldsymbol{A}\cdot\cdot\,\mathbf{\Gamma} + \frac{1}{2!}\boldsymbol{N}\cdot\cdot\cdot\cdot\,\mathbf{\Gamma\Gamma} + \frac{1}{3!}\boldsymbol{L}\cdot\cdot\cdot\cdot\cdot\cdot\,\mathbf{\Gamma\Gamma\Gamma} + \cdots,$$

where $W_0 = 0, \boldsymbol{A} = 0$ for the initial unstressed state, and the tensors $\mathbf{N}$ and $\mathbf{L}$ are the tensors of the elastic constants of the material. If we confine ourselves only to a second-order term with respect to the logarithmic strain tensor in the expansion for W and take into account the expression for the components of the tensor $\mathbf{N}$ in terms of the constants K and G in an isotropic material, we obtain a constitutive relation in the form:

$$\mathbf{\Sigma_R} = K\theta\boldsymbol{E} + 2G\,dev\mathbf{\Gamma}, \tag{1}$$

where $dev\mathbf{\Gamma} = \mathbf{\Gamma} - \frac{1}{3}\theta\mathbf{E}$ is the deviator of the Hencky tensor, $\theta = \mathrm{I}_1(\mathbf{\Gamma}) = \ln\left(\frac{dV}{dV_0}\right)$ is the first invariant of the Hencky tensor, K is the bulk modulus, and G is the shear modulus.

In the issue [4], a variant for generalizing the model of the Hencky material (1), obtained by keeping the third-order terms in the expansion for the specific potential strain energy:

$$\mathbf{\Sigma_R} = \sigma_0\boldsymbol{E} + \tau_e\,dev\mathbf{\Gamma} + \tau_q\,dev((dev\mathbf{\Gamma})^2), \tag{2}$$

was proposed. In the relation (2) $\sigma_0 = K\theta + \frac{C_1}{6\sqrt{3}}\theta^2 + \frac{C_2}{6\sqrt{3}}e^2$, $\tau_e = 2G + \frac{C_2}{3\sqrt{3}}\theta$, and $\tau_q = C_3$ are functions of the invariants of the strain measure: relative changes in the volume θ and intensity of the form change $e^2 = dev\mathbf{\Gamma}\cdot\cdot\,dev\mathbf{\Gamma}$. The model contains five elastic constants: K, G, C_1, C_2, C_3. If we assume a weak compressibility of the material, i.e., assume $\theta \approx 0$, then only two of them are subject to determination: G and C_3.

EXPERIMENTAL AND NUMERICAL SIMULATION RESULTS

The constants of model G and C_3 for natural rubber are determined from a series of uniaxial compression experiments of a set of cylindrical samples at a kinematic loading bench. The points in Fig. 1 show the results of the

* Corresponding author. E-mail: dmitrykhristich@rambler.ru.

compression experiments. For the problem of compression of a cylinder made of a material that obeys (2), an analytical solution is known, obtained under the assumption of homogeneity of the stress-strain state and allowing simple parameter fitting of the material. It is shown in the work that in real experiments it is possible to obtain only close to homogeneous states when using samples with a large radius to height ratio. In this case, the relative size of the inhomogeneity zone caused by friction with the support planes decreases. Therefore, it is possible to determine the model constants from the uniaxial compression experiment using an analytical solution, only if a sufficiently small slip coefficient of the sample with reference planes is provided.

It is required to consider the numerical implementation of the inverse problem, which is the problem of unconditional minimization. In this problem the target function is the standard deviation of the calculated curve $P(D)$ from the experimental data. The nature of the level surface of this function of two variables G and C_3 has been studied. It is found that it exhibits the character of a "ravine function" for which the gradient components at a certain point differ significantly. For such functions, it turns out to be difficult to achieve convergence using gradient methods, so the direct Hooke–Jeeves method of searching for unconditional minimum is chosen. The constructed computational procedure is applied to the problem of determining the elastic constants of models G and C_3 from experimental data obtained from a series of experiments on the indentation of natural rubber samples. Determined values of the constants are as follows: $G = 5 \cdot 10^5 Pa,\ C_3 = -2 \cdot 10^6 Pa$.

The determined values of the constants are used to verify the model in solving the problem of indentation a spherical stamp into an elastic plate. In the process of indentation, inhomogeneous stress and strain fields are observed in the deformable body. To determine them, an initial-boundary-value problem is solved, in which the constitutive relations are supplemented by the variational conditions of the equilibrium process flow [4], and by the initial and boundary conditions. The problem is solved numerically using finite element method and incremental loading method.

Tests are conducted to indent samples of natural rubber. The results are shown in Fig. 2 in the form of points reflecting the dependence of the force on the rod on the relative value of the draft. The red curve in Fig. 2 corresponds to the calculations according to relations (1), when $C_3 = 0$, that is, to the Hencky material model, and the black curve corresponds to the non-linear Hencky model (2). Comparison of calculated curves and indentation test data shows that the developed mathematical model of the process describes the experimental data with a sufficient degree of accuracy.

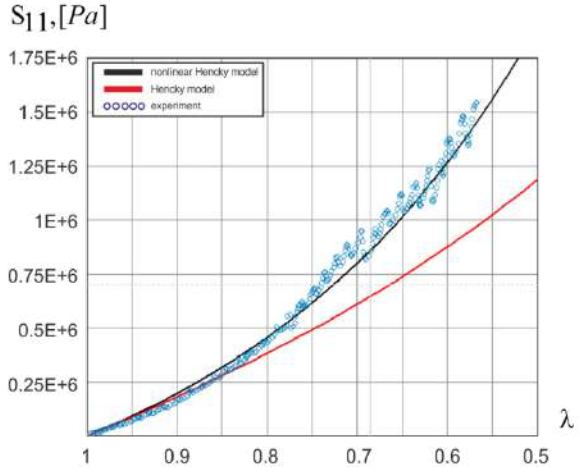

Figure 1. The dependence of the axial force on the ratio of elongation in the compression experiment

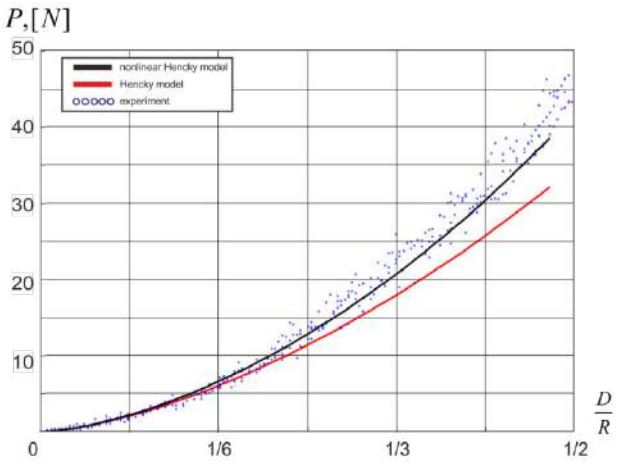

Figure 2. The dependence of the main vector of the acting force on the value of the relative depth in the indentation experiment

CONCLUSIONS

The article proposes a variant of the physically nonlinear Hencky model and its special case for weakly compressible materials. A series of experiments is carried out to determine the constants and to verify the proposed model. A numerical model of the process of indentation of a weakly compressible material with a hard rigid stamp of a spherical shape is developed. Comparison of experimental data and calculation results allows us to conclude that the proposed model is adequate. It describes the experimental data to deformations of the order of 50% with a sufficient degree of accuracy. The elastic constants of the model of a weakly compressible material can be determined from experiments on inhomogeneous deformation using the developed numerical model.

MODELING AND SIMULATION OF COSSERAT RODS BASED ON THE SPECIAL EUCLIDEAN ALGEBRA WITH APPLICATIONS TO THE ANALYSIS OF PIPES

Giulio G. Giusteri*[1], Edie Miglio[2], Nicola Parolini[2], Mattia Penati[2], and Raffaello Zambetti[2,3]
[1]Department of Mathematics,Università degli Studi di Padova,Padova,Italy

[3]Tenaris Dalmine, Dalmine, Italy

Summary We propose a method for the description and simulation of the nonlinear dynamics of slender beams that is based on interpreting the strains and the generalized velocities of the rigid cross sections as basic variables and elements of the special Euclidean algebra. The discretization of the corresponding equations for the three-dimensional motion of a Cosserat rod is performed, in space, by using a staggered grid that leads to a locking-free scheme. The time evolution can then be approximated with various semi-implicit methods. Within this approach we are able to include dissipative effects due to both the action of external forces and the presence of internal mechanical dissipation. Moreover, external constraints on the attainable configurations can be easily included via penalization schemes. All these features render this method effective for the mechanical analysis of long pipes.

BACKGROUND

The modeling and simulation of beams is of great importance in the engineering practice to analyze the configurations and stress distributions of a wide variety of mechanical structures, with sizes ranging from those of pipelines and cables to those of microactuators. When these structures are sufficiently slender or very flexible, they can undergo large displacements even in the small-strain and linear-response regime, and geometric nonlinearities must be taken into account to capture their mechanical behavior.

Since the seminal work by Simo and Vu-Quoc [1], the number of publications and the variety of numerical methods related to geometrically-exact beam models has been growing significantly. Nevertheless, given the variety of applications and the different features pertaining to each method, no universal standard is available for an efficient simulation of such models. On the other hand, it has become clear that the theory of Cosserat rods provides the optimal mathematical background to deal with slender structures, as it comprises all of the classical beam models as special cases.

Several discretization schemes represent the rod via the position and orientation of nodal cross sections. In this way, the computation of the strain and stresses associated with twist, bending, stretching, and shearing of the rod rely on interpolation procedures that introduce some important arbitrariness in the calculations [2]. Discretization methods that avoid the need for such an interpolation have been devised [3, 4, 5] and entail a piecewise constant approximation of the strains. Within those schemes, the strains are viewed as elements of the Lie algebra associated with the special Euclidean group of rigid body motions. Such a parametrization of the rod shape corresponds to a consistent finite-element approximation of the stresses, which is preferable to interpolation in the analysis of engineering structures.

Describing also the generalized velocity of the nodal cross sections in terms of the special Euclidean algebra allows to write the full Hamiltonian and Lagrangian functions of a moving rod using variables that live on a linear space, instead of a curved manifold, as pointed out by Simo *et al.* [6] and further clarified by Holm and Ivanov [7]. This has important advantages from the computational perspective, since numerical integration on manifolds would require much more sophisticated techniques.

THE COMPUTATIONAL MODEL

We propose a method for the description of the nonlinear dynamics of slender beams that is based on extensions of the $SE(3)$-strand equations described by Holm and Ivanov [7], with a suitable mechanical interpretation of stress and momenta as dual to strains and velocities. Within this approach we are able to include dissipative effects due to both the action of external forces and the presence of internal mechanical dissipation. Moreover, external constraints on the attainable configurations can be easily included via penalization schemes.

We view the rod as a collection of equally-shaped cross sections parametrized by a real variable $s \in [0, L]$, with L being the reference length of the rod. Differentiation with respect to s is indicated by a prime, while a superimposed dot denotes the time derivative. The twist density u_3, curvatures u_1, u_2, the stretching σ_3, and the shearing densities σ_1 and σ_2 are the six strains, function of s, that describe the shape of the rod. We will identify the collection of them with the six-component strain vector $U = (u_3, u_1, u_2, \sigma_3, \sigma_1, \sigma_2)$. The natural (relaxed) shape of the rod is given by fixing the strains $\bar{U}(s)$ for each value of s. Similarly, the generalized velocity of each cross section is given by three linear velocities v_i and three spins w_i $(i = 1, 2, 3)$. We will identify the collection of them with the generalized velocity vector $V = (w_3, w_1, w_2, v_3, v_1, v_2)$. We can now introduce the momentum and stress, P and Σ, as

$$P = \mathsf{M}V \qquad \text{and} \qquad \Sigma = \mathsf{A}(U - \bar{U}),$$

*Corresponding author. E-mail: giulio.giusteri@math.unipd.it.

where the diagonal matrices M and A represent, respectively, the rigid-body inertia (linear density) and the elastic stiffnesses at each cross section. The elastic response of the rod is thus modeled in a standard way as a linear function of the difference between the current strains and the relaxed ones. The field Σ represents torques and forces (tensions), while P is a linear density of angular and linear momenta.

We can introduce the Lie bracket $[U, V]$ between elements of the algebra and the adjoint-transpose operator ad^t defined by the pairing

$$\langle \mathrm{ad}^t_U \Sigma, Z\rangle = \langle \Sigma, \mathrm{ad}_U Z\rangle = \langle \Sigma, [U, Z]\rangle,$$

where $\langle \cdot, \cdot \rangle$ denotes the scalar product in $\mathbf{R}^6$. The evolution equations for the rod dynamics are

$$\dot{P} - \Sigma' = \mathrm{ad}^t_V P - \mathrm{ad}^t_U \Sigma - \mathsf{D}\dot{\Sigma} + F, \tag{1}$$

$$\dot{U} - V' = \mathrm{ad}_U V, \tag{2}$$

the second relation being a compatibility constraint between the rigid-body motion of each cross section and the fact that they should collectively move as a continuous rod. The six-component vector F represents external force and torque densities acting on each cross section, while the matrix D contains the damping coefficients associated with the internal mechanical dissipation.

We discretize the evolution equations using a standard semi-implicit time integration that linearizes the evolution operator. On the other hand, some care is in order when considering the spatial discretization. In fact, shear-locking phenomena can appear, partly enhanced by the presence of the constraint represented by equation (2). We avoided such complications by using finite differences on a staggered grid that mirrors the character of our variables: momenta and velocities are assigned to nodal cross sections, while stresses and strains are viewed as distributed on the intermediate segments.

Boundary conditions are imposed by adding ghost cells and nodes at the two ends of the rod. Within this method it is rather straightforward to drive or fix the motion of the rod ends or set free-end conditions.

MAIN FEATURES OF THIS APPROACH

Our target application is the structural analysis of long pipes and there are several features that make this approach an effective one. First of all, the theoretical setting based on concepts from differential geometry avoids, by means of a wise choice of the system variables, the need for interpolating between points on a curved manifolds (i.e. the group of rigid body motions) and, at the same time, links the computation directly to the quantities of practical interests, such as the distribution of mechanical stresses. Moreover, our very simple strain discretization produces rod segments of a general helical shape, such as those used by Borri and Bottasso [3], offering great flexibility in capturing non-straight constrained configurations. Secondly, the numerical discretization of the $SE(3)$-strand equations turns out to be advantageous if compared to discrete rod models (in which the mechanical structure is discretized in a multibody system) because it avoids the somewhat involved computation of nonlocal inertial terms [4, 5]. In fact the local nature of the evolution equations is reflected in a markedly banded structure of the discrete evolution matrix, which is at the heart of the computational efficiency of the scheme. Thanks to these features, we are able to simulate also long pipes, that require a comparatively large number of elements, in arbitrary three-dimensional configurations. Comparisons with benchmark data from earlier publications show the good performance of the scheme.

Summary We describe in this work a general methodology to obtain a minimal polynomial integrity basis of any 2D linear constitutive law, represented by real valued tensors of any order. To do so, we need to consider $\mathrm{SO}(2)$ or $\mathrm{O}(2)$ linear representations on considered tensors, and then the computation is based i) on an explicit harmonic decomposition of tensors, ii) the introduction of complex numbers to rewrite polynomial invariants, and finally iii) the use of diophantine equation and a step-by-step algorithm to obtain minimality.

MECHANICAL MOTIVATIONS

Linear constitutive equations write as linear mappings between tensorial state variables via constitutive tensors. For instance, in the case of standard linear elasticity, Cauchy stress tensor (of order 2) is related to the strain tensor (of order 2) via the elasticity tensor (of order 4), while in the case of strain-gradient elasticity, the stress and hyper-stress tensors (of order 2 and 3) are related to the strain and strain-gradient tensors (of order 2 and 3) via three constitutive tensors of order 4, 5 and 6. Such linear constitutive equations are also present for multiphysics coupling. For instance, three constitutive tensors (of order 2, 3 and 4) are involved in piezo-electricity. However, constitutive tensors $\mathbf{T}_1, \ldots, \mathbf{T}_n$ do not characterize materials independently of their spatial orientation [1].

Any transformation $g \in \mathrm{SO}(2)$ or $\mathrm{O}(2)$ —where $\mathrm{O}(2)$ and $\mathrm{SO}(2)$ stand respectively for the orthogonal and the special orthogonal groups in 2D— define a new set of tensors using the standard action $\star$ (e.g. for a second order tensor, $\tilde{T}_{ij} = g_{ip} g_{jq} T_{pq}$):

$$(\tilde{\mathbf{T}}_1, \ldots, \tilde{\mathbf{T}}_n) = g \star (\mathbf{T}_1, \ldots, \mathbf{T}_n) = (g \star \mathbf{T}_1, \ldots, g \star \mathbf{T}_n),$$

representing the same material.

Thus, characterizing a material requires the definition of a finite set of $\mathrm{SO}(2)$ or $\mathrm{O}(2)$-invariant functions such that

$$f_i(\mathbf{T}'_1, ..., \mathbf{T}'_n) = f_i(\mathbf{T}_1, ..., \mathbf{T}_n) \Leftrightarrow (\mathbf{T}'_1, ..., \mathbf{T}'_n) = g \star (\mathbf{T}_1, ..., \mathbf{T}_n).$$

It is known [2] that an integrity basis (i.e. a finite set of polynomial invariants generating the algebra of polynomial invariants) provides such a set of functions (see [3] for 2D non polynomial separating invariants, see [4, 5] for polynomial separating sets for 3D fourth order tensors).

An integrity basis also allows for the explicit characterization of specific material behaviors, e.g. the explicit characterization of membership to a symmetry class [6]. An other classical example in elasticity is that the uncoupling of spherical and deviatoric parts of the elastic energy is given by setting the value of a particular invariant to zero [7].

We propose in this work a general methodology to compute an explicit 2D integrity basis for any real valued tensors of any orders (a similar procedure was used in [8] in the particular case of 2D elasticity).

$\mathrm{SO}(2)$ INTEGRITY BASIS

The first step is to perform an explicit harmonic decomposition of the tensors $(\mathbf{T}_1, \ldots, \mathbf{T}_n)$ involved in the constitutive equations. Such a procedure leads to an identification

$$(\mathbf{T}_1, \ldots, \mathbf{T}_n) \simeq (\lambda_1, \ldots, \lambda_m, \mathbf{H}_1, \ldots, \mathbf{H}_r)$$

with scalars invariants $\lambda_i \in \mathbb{H}^0$ and p_j^{th}-order 2D harmonic tensors $\mathbf{H}_j \in \mathbb{H}^{p_j}$. For any $p \geq 1$, $\mathbb{H}^p$ is isomorphic to $\mathbb{R}^2$, so we can consider *complex coordinates* $z_j, \overline{z}_j$ for harmonic tensors $\mathbf{H}_j$ (instead of $\mathrm{Re}(z_j)$ and $\mathrm{Im}(z_j)$), so that $\mathbf{H}_j \simeq (z_j, \overline{z}_j)$ with action given by $g \star \mathbf{H}_j \simeq e^{i\theta} \star (z_j, \overline{z}_j) = (e^{ip_j\theta} z_j, e^{-ip_j\theta} \overline{z}_j)$ for all $g \in \mathrm{SO}(2)$.

Since any polynomial splits into a sum of monomials $z_1^{\alpha_1} \ldots z_r^{\alpha_r} \overline{z}_1^{\beta_1} \ldots \overline{z}_r^{\beta_r}$ and

$$e^{i\theta} \star (z_1^{\alpha_1} \ldots z_r^{\alpha_r} \overline{z}_1^{\beta_1} \ldots \overline{z}_r^{\beta_r}) = z_1^{\alpha_1} \ldots z_r^{\alpha_r} \overline{z}_1^{\beta_1} \ldots \overline{z}_r^{\beta_r} e^{i\theta(p_1\alpha_1 + \ldots + p_r\alpha_r - p_1\beta_1 - \ldots - p_r\beta_r)},$$

invariants are generated by the monomials with exponents satisfying *Diophantine equation*:

$$p_1\alpha_1 + \ldots + p_r\alpha_r - p_1\beta_1 - \ldots - p_r\beta_r = 0.$$

The monomials constructed from the finite set of the irreducible solutions of this Diophantine equation are real polynomials $I_k = z_k \overline{z}_k$ and complex polynomials J_m. We finally have the

*Corresponding author. E-mail: boris.desmorat@sorbonne-universite.fr.

Theorem 1 *The set* $\{\lambda_i, I_k, Re(J_m), Im(J_m)\}$ *constitutes a minimal* $\mathrm{SO}(2)$ *integrity basis of the algebra of* $\mathrm{SO}(2)$ *polynomial invariants of the* n*-tuple of real valued tensors* $(\mathbf{T}_1, \ldots, \mathbf{T}_n)$.

The minimal integrity basis is obtained as a set of SO(2)-invariant polynomials of the components of the initial n-tuple of tensors. The tensorial expressions of such invariant polynomials can be straightforwardly recovered from the complex expressions.

$\mathrm{O}(2)$ INTEGRITY BASIS

In the $\mathrm{O}(2)$-case, the harmonic decomposition derives directly from the harmonic decomposition of the restriction of the action to $\mathrm{SO}(2)$. Indeed, the group $\mathrm{O}(2)$ is obtained from $\mathrm{SO}(2)$ by adding a mirror symmetry σ across a given line. For each $\mathrm{SO}(2)$-invariant scalar we have to check whether $\sigma \star \lambda_i = \lambda_i$ or $-\lambda_i$. In the case of negative sign, we will use the notion of pseudo-scalar invariant, and denote it $\mu_i \in \mathbb{H}^{-1}$. Note that, in 2D, the harmonic decomposition under O(2) does not involve any pseudo-tensors. We have the following result:

Theorem 2 *The set* $\{\lambda_i, I_k, \mu_{j_1}\mu_{j_2}, \mu_j Im(J_m), Re(J_m), Im(J_{m_1})Im(J_{m_2}),\}$ *constitutes a (non-minimal)* $\mathrm{O}(2)$ *integrity basis of the algebra of* $\mathrm{O}(2)$ *polynomial invariants of the n-tuple of real valued tensors* $(\mathbf{T}_1, \ldots, \mathbf{T}_n)$.

The last difficulty lies in the fact that some of the invariant polynomials $Im(J_i)Im(J_j)$ can be reduced, i.e. can be expressed as invariant polynomials of other invariant polynomials. In order to perform this reduction step, all the invariant polynomials $Re(J_k)$ and $Im(J_i)Im(J_j)$ are tested using a reduction algorithm similar to the one developed in [9]. Once the reduction step is performed, a minimal integrity basis is obtained, i.e. any strict subfamily is no longer a generating family. Again, the minimal integrity basis is obtained as a set of O(2)-invariant polynomials of the components of the initial tensors n-tuple. The tensorial expressions of such invariant polynomials can be straightforwardly recovered from the complex expressions.

RESULTS

We present here the number of elements of $\mathrm{SO}(2)$ and $\mathrm{O}(2)$ integrity bases of a few linear constitutive laws:

Third order tensor (including piezoelectricity tensor), $T_{ijk} \simeq 3\mathbb{H}^1 \oplus \mathbb{H}^3$

- SO(2)-integrity basis is composed of 30 elements,
- O(2)-integrity basis is composed of 17 elements (all invariants $Im(J_i)Im(J_j)$ are reduced).

Fourth order tensor (including elasticity tensor), $T_{ijkl} \simeq 3\mathbb{H}^{-1} \oplus 3\mathbb{H}^0 \oplus 4\mathbb{H}^2 \oplus \mathbb{H}^4$

- SO(2)-integrity basis is composed of 43 elements,
- O(2)-integrity basis is composed of 78 elements (all invariants $Im(J_i)Im(J_j)$ are reduced).

Totally symmetric tensor of order 12 (such as fabric tensors), $\mathbb{H}^0 \oplus \mathbb{H}^2 \oplus \mathbb{H}^4 \oplus \mathbb{H}^6 \oplus \mathbb{H}^8 \oplus \mathbb{H}^{10} \oplus \mathbb{H}^{12}$

- SO(2)-integrity basis is composed of 211 elements,
- O(2)-integrity basis is composed of 113 elements (not all invariants $Im(J_i)Im(J_j)$ are reduced).

Note that the case of the fabric tensors of order 2, 4, 6, 8 (and of course 12) that describe directional datas densities [10] are included as particular cases of totally symmetric tensor of order 12.

Elasticity / Piezo-electricity coupling, $(T^{(1)}_{(ij)|(kl)}, T^{(2)}_{(ij)k}, T^{(3)}_{ij}) \simeq 3\mathbb{H}^0 \oplus 2\mathbb{H}^1 \oplus 2\mathbb{H}^2 \oplus \mathbb{H}^3 \oplus \mathbb{H}^4$
(where (ij) stands for the indical symmetry $T_{ij} = T_{ji}$, and $ij|kl$ stands for the indicial symmetry $T_{ijkl} = T_{klij}$)

- SO(2)-integrity basis is composed of 121 elements,
- O(2)-integrity basis is composed of 71 elements (not all invariants $Im(J_i)Im(J_j)$ are reduced).

ADAPTIVE CONTROL OF UNSTEADY STRESS OSCILLATION IN FUNCTIONALLY GRADED MULTIFERROIC COMPOSITE THIN PLATE

Fumihiro Ashida*[1], Takuya Morimoto [1], and Ryo Kuwahara [2]
[1]Department of Mechanical, Electrical, and Electronic Engineering, Shimane University, Matsue, Japan
[2]Interdisciplinary Graduate School of Science and Engineering, Shimane University, Matsue, Japan

Summary When a functionally graded material thin plate is subjected to impact pressure, an unsteady oscillation of dynamic stress with tensile stress is induced. In this paper, adaptive control of the unsteady stress oscillation with piezoelectric sensing and magnetic actuation is investigated for a functionally graded multiferroic composite (FGMC) thin plate subjected to uniform impact pressure of unknown magnitude. One-dimensional electro-magneto-elastodynamic problems are analyzed by employing the method of characteristics. Numerical results demonstrate that the maximum amplitude of the controlled unsteady stress oscillation is suppressed to about a half of the uncontrolled one.

INTRODUCTION

Many papers dealt with dynamic problems in functionally graded material (FGM) solids subjected to harmonic loadings, but a few papers investigated stress oscillations induced in FGM solids by elastic wave propagations. The first author et al. analyzed a direct control problem of an unsteady stress oscillation in a functionally graded piezoelectric thin plate and revealed that the unsteady stress oscillation was completely cancelled by applying appropriate voltage [1].

In this paper, one-dimensional magneto-electro-elastodynamic problems in functionally graded multiferroic composite (FGMC) thin plates subjected to uniform impact pressure are analyzed by employing the method of characteristics. The material properties are assumed to vary in the thickness direction according to a power law distribution. First, a direct control problem is analyzed, when known uniform impact pressure acts on the FGMC thin plate. It is seen from obtained numerical results that the actuation magnetic potential difference for controlling the unsteady stress oscillation to the minimum is given as a linear function of a volume fraction exponent. Next, an adaptive control problem is analyzed, when uniform impact pressure of unknown magnitude acts on the FGMC thin plate of an unknown volume fraction exponent and the output voltage between both plate surfaces and its period are measured in the first cycle. The volume fraction exponent and the magnitude of impact pressure are inferred from the knowledge of the period and output voltage. The unsteady stress oscillation is controlled from the third cycle by applying the actuation magnetic potential difference calculated from the previous linear function.

PROBLEM STATEMENT

Let us consider an FGMC thin plate depicted in Fig. 1, in which case its material properties $P_i(z)$ vary in the thickness direction as follows:

$$P_i(z)=P_{MSi}\hat{V}_{MS}+P_{PEi}\hat{V}_{PE},\ \hat{V}_{MS}=1-\left(\frac{z}{l}\right)^{\frac{1}{n}},\ \hat{V}_{PE}=\left(\frac{z}{l}\right)^{\frac{1}{n}}\quad(0<n\le 1)\quad(1)$$

where P_{MSi} are material properties of a magnetostrictive material at the top surface, P_{PEi} are those of a piezoelectric material at the bottom surface, and n is a volume fraction exponent.

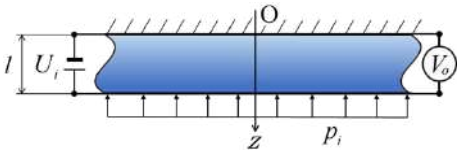

Figure 1. An FGMC thin plate.

The FGMC thin plate is considered to be initially in stress-free state. It is assumed that the bottom surface is subjected to uniform impact pressure p_i, the top surface is fixed to a flat rigid body, and an actuation magnetic potential difference U_i is applied between both surfaces. The initial and boundary conditions are then given by

$$u_z(z,0)=0,\ v_z(z,0)=0,\ \sigma_{zz}(z,0)=0,\ D_z(z,0)=0,\ B_z(z,0)=0 \quad (2)$$

$$u_z(0,t)=0,\ D_z(0,t)=0,\ \psi(0,t)=0,\ \sigma_{zz}(l,t)=-p_iH(t),\ D_z(l,t)=0,\ \psi(l,t)=U_iH(t-t_d) \quad (3)$$

where $v_z(z,t)=u_{z,t}(z,t)$, $u_z(z,t)$ is the displacement, $v_z(z,t)$ is the particle velocity, $\sigma_{zz}(z,t)$ is the stress, $D_z(z,t)$ is the dielectric flux density, $B_z(z,t)$ is the magnetic flux density, $\psi(z,t)$ is the magnetic potential, $H(t)$ is Heaviside's unit step function, t is time, t_d is the time delay, and a comma denotes partial differentiation.

The constitutive and governing equations for the elastic, electric, and magnetic fields are

$$\sigma_{zz}=c_{33}(z)u_{z,z}+e_3(z)\phi_{,z}+q_3(z)\psi_{,z},\ D_z=e_3(z)u_{z,z}-\eta_3(z)\phi_{,z}-\alpha_3(z)\psi_{,z},\ B_z=q_3(z)u_{z,z}-\alpha_3(z)\phi_{,z}-\mu_3(z)\psi_{,z} \quad (4)$$

$$\sigma_{zz,z}=\rho(z)v_{z,t},\ D_{z,z}=0,\ B_{z,z}=0 \quad (5)$$

where $\phi(z,t)$ is the electric potential, $c_{33}(z)$ is the elastic modulus, $e_3(z)$ is the piezoelectric constant, $q_3(z)$ is the piezo-magnetic coefficient, $\rho(z)$ is the density, $\eta_3(z)$ is the dielectric permittivity, $\alpha_3(z)$ is the magnetoelectric coefficient, and $\mu_3(z)$ is the magnetic permeability.

The output voltage $V_o(t)$ is induced between both plate surfaces by action of the mechanical and magnetic loads.

$$\phi(l,t)-\phi(0,t)=V_o(t) \quad (6)$$

*Corresponding author. E-mail:ashida@ecs.shimane-u.ac.jp.

Solving the constitutive and governing equations for the electric and magnetic fields under their initial and boundary conditions, the electric potential ϕ, dielectric flux density D_z, magnetic potential ψ, and magnetic flux density B_z are represented in terms of the particle velocity v_z and stress σ_{zz}. Finally, this problem is reduced to solving two coupled first-order partial differential equations. Employing the method of characteristics [1], the particle velocity and stress which satisfy their initial and boundary conditions are numerically obtained.

NUMERICAL RESULTS

For convenience in presentation of numerical results, the following dimensionless quantities are introduced:

$$\bar{z}=\frac{z}{l},\ \bar{t}=\frac{v_l t}{l},\ \bar{p}_i=\frac{p_i}{p_c},\ \bar{\sigma}_{zz}=\frac{\sigma_{zz}}{p_c},\ \bar{V}_o=\frac{d_3 Y_l V_o}{p_c l},\ \bar{U}_i=\frac{U_i}{p_c v_l d_3 l}$$

where p_c is a constant pressure and v_l, Y_l, and d_3 are respectively the velocity of elastic wave propagation, equivalent elastic modulus, and piezoelectric coefficient of a piezoelectric material at the bottom surface of the FGMC thin plate.

Numerical calculations have been carried out for the FGMC thin plate composed of barium titanite and cobalt ferrite [2].

Direct control of unsteady stress oscillation

Let us consider the FGMC thin plate subjected to the uniform impact pressure $\bar{p}_i=1$ and an actuation magnetic potential difference, simultaneously, namely the time delay is $\bar{t}_d=0$. The optimum actuation magnetic potential differences $\bar{U}_{io}(n)$ are determined for the cases of $n=1$, 0.75, 0.5, 0.25, and 0.1 by employing a trial-and-error approach in order to control the unsteady stress oscillation to the minimum. Obtained numerical results are illustrated in Fig. 2. It is seen from the figure that the optimum actuation magnetic potential difference is given as a linear function of the volume fraction exponent.

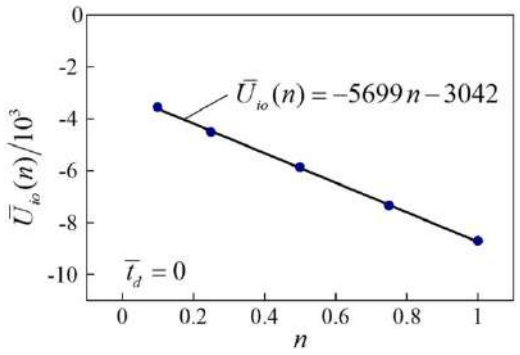

Figure 2. Optimum magnetic potential difference.

Adaptive control of unsteady stress oscillation

Let us consider a case where uniform impact pressure of unknown magnitude $\bar{p}_i$ acts on the FGMC thin plate of an unknown volume fraction exponent and the actuation magnetic potential difference is zero in the beginning. It is assumed that the output voltage $\bar{V}_o(\bar{t})$ and its period $2\bar{t}_p$ are measured in the first cycle, as shown in Fig. 3, in which case the period is $2\bar{t}_p=3.399$. The volume fraction exponent is calculated from the period as $n=0.5228$. The magnitude of the impact pressure is inferred from the knowledge of the output voltage, so that it is found to be $\bar{p}_i=1.3715$. For this case, the linear function given in Fig. 2 leads to $\bar{U}_{io}(0.5228)=-6022$ and thus the optimum actuation magnetic potential difference is $\bar{p}_i\cdot\bar{U}_{io}(0.5228)=-8259$. Applying it to the FGMC thin plate from the third cycle, namely $\bar{t}_d=4\bar{t}_p$, the unsteady stresss oscillation at $\bar{z}=0.5$ is controlled as illsutrated in Fig. 4. The maximum amplitude of the controlled unsteady stress oscillation is suppressed to 50.1 percent of the uncontrolled one.

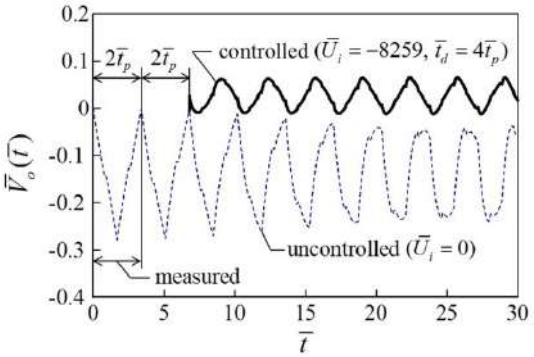

Figure 3. Time histories of output voltages.

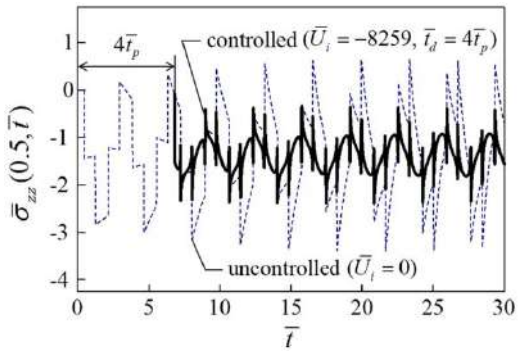

Figure 4. Time histories of stress oscillations.

CONCLUSIONS

This paper deals with adaptive control of the unsteady stress oscillation induced in the FGMC thin plate of an unknown volume fraction exponent by action of uniform impact pressure of unknown magnitude. The one-dimensional magneto-electro-elastodynamic problems are analyzed by employing the method of characteristics. Obtained numerical results demonstrate that the unsteady stress oscillation is adaptively controlled with piezoelectric sensing and magnetic actuation.

STATIC AND VIBRATIONAL ANALYSIS OF A CANTILEVERED THIN BEAM WITH A CREASED FOLD

Romeo Antier*[1], Benjamin Thiria[1], and Ramiro Godoy-Diana[1]
[1]PMMH Laboratory, ESPCI - PSL, CNRS, University of Paris, Sorbonne University, Paris, France

Summary Creases and folds confer rigidity to thin plates. We study experimentally the mechanical response of an elastic thin plate with a single crease subjected to external loading. The fold runs along the long symmetry axis of the slender plate, which has thus a V-shaped crosssection. Using quasi-static bending tests, vibration tests, and linear beam theory, we examine the strong correlation between the dynamical response of the system and its quasi-static mechanical behavior. In particular, we establish the role of the crease angle and its coupling with the bending rigidity on the bending and vibrational behaviors. Not surprisingly, the bending rigidity and thus the resonant frequency increases when the folding angle increases. However we bring evidence of a remarkable softening dynamics: the resonant frequency and thus the bending rigidity decreases when the amplitude of the external excitation increases in the vibration tests. We demonstrate that this softening is a consequence of the dynamical opening of the crease angle.

INTRODUCTION

A thin plate bends easily, and an interesting way to improve remarkably its rigidity is to fold it symetrically in the middle of its width. This capability is found in nature in the shape of a single blade of grass or of a single leaf of agave for plants, but also in the shape of insect wings where it seems to rigidify wings. For creased sheets with a long length compared to their width, those structures can be considered as cantilevered thin beams with a creased fold. The study of a single fold is at the foundation of the understanding of metamaterials inspired by nature.

Several works have been devoted to the study of creased sheets, origami, kirigami and miura ori. However the link between all of those structures, which is a single crease, remains not fully understood. Following the work of Lechenault et al. [1] and Jules et al. [2] who studied the mechanical response of a creased sheet in traction loadings, here we study the mechanical response of a creased thin elastic plate submitted to bending, then submitted to vibrations.

EXPERIMENTAL SETUP

We fabricated a series of creased plates by laser cutting sheets of $100\mu m$-thick Mylar and folding them by using 3D-printed molds, thus obtening a precise creased angle of the plate. The creased plates are set up on the test bench. All the experiments are carried out with one plate's end clamped to a fixed support, which is also 3D printed to fit to the plate. Two different tests are performed: a bending test to load periodically at different frequencies, and a vibrating test to study the effect of the frequency and of the input amplitude on the behavior of each creased plate of a specific folding angle.

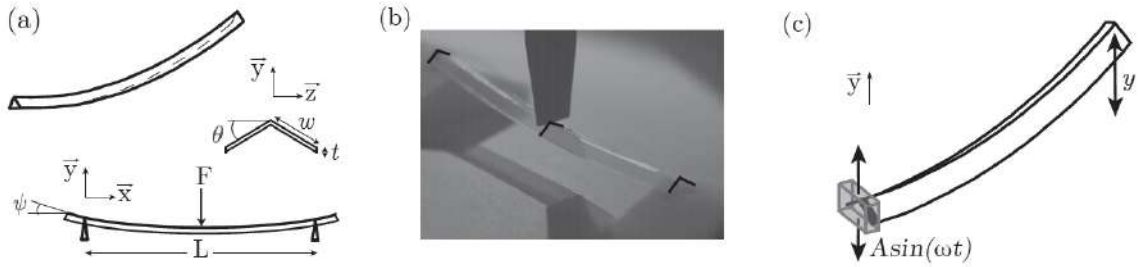

Figure 1: (a) Schematic of the creased sheet of thickness t, (b) Photograph of the three-points bending test highlighting the crease opening when the sheet undergoes a curvature, and (c) Schematic of the vibration experiments with a imposed forcing $A\sin(\omega t)$.

STATIC ANALYSIS

We characterize the bending rigidity of a controlled creased sheet and its dependence on geometrical and loading parameters. The narrower the folding angle, the higher the bending rigidity, for a same loading. This observation can be easily understood because the folding leads to increase the height of the flexural section that opposed to surface rotation while bending; entailing an increase in the moment of inertia and thus in the bending rigidity. A beam model allows to retrieved this conclusion in this case where the length of the thin plate is much higher than other dimensions. The moment of inertia is defined by:

$$I = \iint y^2 ds \approx t w^3 \sin^2\theta \cos\theta \left(\frac{2}{3} - \cos\theta + \frac{1}{2}\cos^2\theta\right) \quad (1)$$

*Corresponding author. E-mail: romeo.antier@espci.fr.

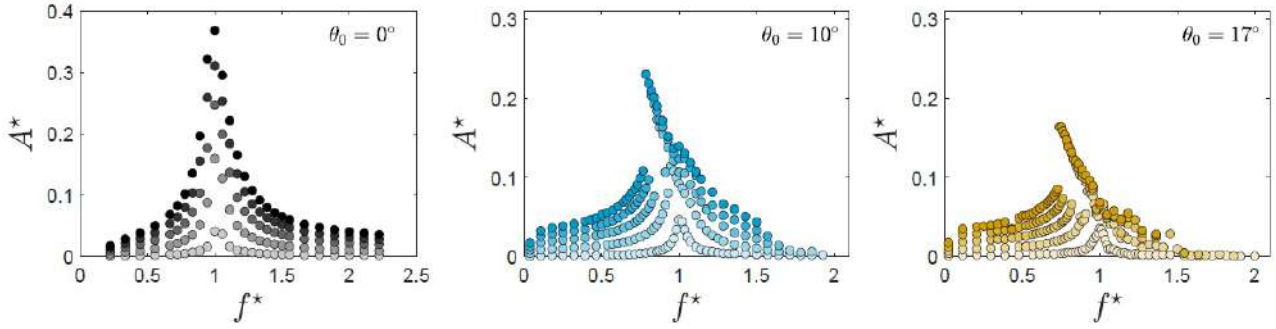

Figure 2: Upward sweep frequency response of creased sheets unfolded ($\theta = 0°$), and of crease angles θ of 10 and 17° from the unfolded reference, for forcing amplitude of $A_0 = 0.19$mm to $10 \times A0$ (from ligth to dark points). We define: $A^\star = y/L$ and $f^\star = f/f_0$ where f_0 is the linear resonance frequency.

Where I is the moment of inertia, t the thickness, w the half-width and θ the folding angle from the unfolding plate.

According to Jules et al [2], the geometrical conditions of our study leads to model the crease as a hinge spring where panels can not bend transversally. Thus one observes that for small curvatures, the folded sheet stretches and the crease angle opens from few degrees. It results from the competition between the longitudinal bending energy and the energy of the hinge. The bending tends to open the crease whereas the hinge tends to maintain the crease in its rest configuration. We found a relation linking the crease angle to the curvature for relatively small curvatures. When the bending displacement imposed to the structure is higher than a specific limit, the system changes suddenly its shape and snaps [3]. The snapping is accompanied by a quick opening of the crease until becoming totally flat. The snap causes the folded sheet to lose benefits of rigidity from the crease.

VIBRATION ANALYSIS

The vibration analysis aims characterizing the dynamical behavior of creased sheets determining the resonance frequencies of bending, which depend on experimental parameters. As expected from the bending analysis, resonance frequencies increase when the folding increases. Indeed, an increase in folding leads to an increase in the area moment of inertia, that leads to an increase in bending rigidity. However the sweep frequency response shows a non-linear behavior, likely to a Duffing oscillator, that is due to the non-linear geometry imposed by the fold; non-linear behaviors are the most noticeable for highest foldings. But the response is linear for small foldings or for very small input amplitudes of excitation.

For a given sample, a counter-intuitive phenomenon appears when the input amplitude of excitation is changed: the higher the input amplitude, the lower the bending resonance frequency, and thus the lower the bending rigidity; a creased sheet has a softening behavior. Experimental results are in agreement with numerical studies on geometrically non-linear plates charaterizing the behavior of such plates [4]. The softening is explained by the evolution of the crease angle when the beam vibrates near its resonance frequency. When the folded sheet vibrates close to its resonance, its curvature is no more small and its crease angle opens. During one cycle of vibration, the crease opens twice. We demonstrated the correlation between the crease angle evolution the softening behavior of folded sheets.

CONCLUSIONS

The intuive behavior of a simply folded sheet of paper, where the bending rigidity increases drasticaly when a fold appears, is retrieved and characterized in our work thanks to a well-controled creased elastic sheet. The more folded the thin plate, the higher its area moment of inertia, thus the higher the bending rigidity. The second conclusion, coming from the vibrational study, is that bending rigidity decreases when the loading increases, leading to a softening phenomenon: this softening is due to the opening of the plate angle. Competition between longitudinal bending and transverse hinge rigidity, that are coupled in such a struture, defines the behavior of a cantilevered thin beam with a creased fold.

EQUILIBRIUM OF A LINEARLY ELASTIC PERIDYNAMIC MATERIAL

Adair Aguiar *[1] and Alan B. Seitenfus[1]
[1]Department of Structural Engineering, University of São Paulo, São Carlos, SP, Brazil

Summary We investigate equilibrium solutions of an isotropic elastic material in the context of a state-based peridynamic theory. The response function of the material is derived from a quadratic free energy function that depends on measures of both length and relative angle changes and contains four material constants. For a particular class of polynomial displacement fields, differential equations found in this investigation become the classical equilibrium equations if two relations hold between the Lamé constants and the four peridynamic constants. These results are consistent with results of previous investigation that used energy-based arguments and homogeneous deformations. The determination of two peridynamic constants that are still arbitrary is the subject of ongoing investigation.

INTRODUCTION

The peridynamic theory is an extension of the classical continuum theory, in which a material point interacts directly with other material points separated from it by a finite distance. In parts of a body where the deformation is smooth, the peridynamic theory yields the same governing equations of the classical continuum theory in the limit of vanishing distances between material points. In this work, we consider small but not vanishing distances together with a class of second-degree polynomial displacements to show that the peridynamic and classical equations of equilibrium have similar forms for a linearly elastic peridynamic material with a free energy function that is quadratic in measures of both length and relative angle changes and depends on four peridynamic coefficients. The equations are the same provided that two relations hold between these coefficients and the Lamé constants. Two peridynamic coefficients are left undetermined, which seem to reflect the nonlocal nature of the theory. Relevant references are cited below.

PERIDYNAMIC EQUILIBRIUM EQUATION

Let $\mathcal{B} \subset \mathbb{E}^3$ be the undistorted reference configuration of an elastic solid body in its natural state and let $\boldsymbol{\chi}(\mathbf{x}, t)$ be the position of the particle $\mathbf{x} \in \mathcal{B}$ at time $t \geq 0$. Constitutive modeling within the peridynamic theory considers the collective deformation at each time t of all the material within a neighborhood of an arbitrary point $\mathbf{x}_0 \in \mathcal{B}$. We shall omit writing the time variable t. Here, this neighborhood is a sphere of radius δ centered at $\mathbf{x}_0$ and is denoted by $\mathcal{N}_\delta \subset \mathcal{B}$. For any $\mathbf{x} \in \mathcal{B}$ such that $|\mathbf{x} - \mathbf{x}_0| < \delta$, the vector $\boldsymbol{\xi} := \mathbf{x} - \mathbf{x}_0$ is called a bond to $\mathbf{x}_0$ and the collection of all bonds is denoted by $\mathcal{H}_\delta$. The displacement field $\mathbf{u}$ associated with the motion $\boldsymbol{\chi}$ at $\mathbf{x} \in \mathcal{B}$ is defined through $\mathbf{u}(\mathbf{x}) := \boldsymbol{\chi}(\mathbf{x}) - \mathbf{x}$. We also define the difference displacement state at $\mathbf{x}_0 \in \mathcal{B}$ as $\underline{\mathbf{u}}(\mathbf{x}_0)\langle\boldsymbol{\xi}\rangle := \mathbf{u}(\mathbf{x}) - \mathbf{u}(\mathbf{x}_0)$ for $\boldsymbol{\xi} = \mathbf{x} - \mathbf{x}_0 \in \mathcal{H}_\delta$.

Near a natural state of a body subjected to body force density $\mathbf{b}$, the peridynamic equation of equilibrium is given by

$$\mathbf{0} = \int_{N_\delta} [\underline{\mathbf{L}}(\mathbf{x}_0)\langle\mathbf{x} - \mathbf{x}_0\rangle - \underline{\mathbf{L}}(\mathbf{x})\langle\mathbf{x}_0 - \mathbf{x}\rangle]\, dv_x + \mathbf{b}(\mathbf{x}_0)\,, \qquad \mathbf{x}_0 \in \mathcal{B}\,, \tag{1}$$

where $\underline{\mathbf{L}}(\mathbf{x}_0)\langle\boldsymbol{\xi}\rangle$ is a linearized force vector state at $\mathbf{x}_0$ evaluated on bond $\boldsymbol{\xi}$. The integral equation (1) is analogous to the differential equilibrium equation from the classical linear theory. For a simple elastic material, $\underline{\mathbf{L}}(\mathbf{x}_0)\langle\boldsymbol{\xi}\rangle$ is given by

$$\underline{\mathbf{L}}(\mathbf{x}_0) = \underline{\widehat{\mathbf{L}}}_{\mathbf{x}_0}[\underline{\mathbf{h}}] \equiv \frac{\delta_{\underline{\mathbf{h}}} \widehat{W}_{\mathbf{x}_0}[\underline{\mathbf{h}}]}{|\underline{\mathbf{x}}|}, \tag{2}$$

where $\underline{\mathbf{h}} := \underline{\mathbf{u}}/|\underline{\mathbf{x}}|$ with $|\underline{\mathbf{h}}\langle\boldsymbol{\xi}\rangle|$ being small, $\underline{\mathbf{x}}\langle\boldsymbol{\xi}\rangle \equiv \boldsymbol{\xi}$, $\delta_{\underline{\mathbf{h}}}$ is the Fréchet derivative with respect to $\underline{\mathbf{h}}$ and, here, $\widehat{W}_{\mathbf{x}_0}$ is a quadratic free energy function given by

$$\widehat{W}_{\mathbf{x}_0}[\underline{\mathbf{h}}] = \int_{\mathcal{H}_\delta}\int_{\mathcal{H}_\delta} \omega(|\boldsymbol{\xi}|, |\boldsymbol{\eta}|)\Big[\frac{\alpha_1}{2}\big(\widehat{\underline{\varepsilon}}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi}\rangle\big)^2 + \alpha_2\, \widehat{\underline{\varepsilon}}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi}\rangle\, \widehat{\underline{\varepsilon}}[\underline{\mathbf{h}}]\langle\boldsymbol{\eta}\rangle + \frac{\alpha_3}{2}\big(\widehat{\underline{\gamma}}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle\big)^2 + \alpha_4\, \widehat{\underline{\gamma}}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle\, \widehat{\underline{\varepsilon}}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi}\rangle\Big]\, dv_{\boldsymbol{\eta}}\, dv_{\boldsymbol{\xi}}\,. \tag{3}$$

In (3), $\omega(\cdot,\cdot)$ is a given weighting function satisfying $\omega(|\boldsymbol{\xi}|, |\boldsymbol{\eta}|) = \omega(|\boldsymbol{\eta}|, |\boldsymbol{\xi}|)$, α_i, $i = 1, \ldots, 4$, are peridynamic constants to be specified, $\widehat{\underline{\varepsilon}}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi}\rangle := \underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle \cdot \underline{\mathbf{h}}\langle\boldsymbol{\xi}\rangle$ is an infinitesimal normal strain state with $\underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle := \boldsymbol{\xi}/|\boldsymbol{\xi}|$, and $\widehat{\underline{\gamma}}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle := \Big(\underline{\mathbf{e}}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle \cdot \underline{\mathbf{h}}\langle\boldsymbol{\xi}\rangle + \underline{\mathbf{e}}\langle\boldsymbol{\eta},\boldsymbol{\xi}\rangle \cdot \underline{\mathbf{h}}\langle\boldsymbol{\eta}\rangle\Big)\Big/2$ is an infinitesimal shear strain state with $\underline{\mathbf{e}}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle := \big(\underline{\mathbf{e}}\langle\boldsymbol{\eta}\rangle - \underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle \cos\alpha\big) / \sin\underline{\alpha}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle$ and $\underline{\alpha}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle$ being the smallest included angle between $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$.

Introducing the decomposition $\underline{\mathbf{h}}\langle\boldsymbol{\xi}\rangle = \underline{\varphi}\langle\boldsymbol{\xi}\rangle\, \underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle + \underline{\mathbf{h}}_d\langle\boldsymbol{\xi}\rangle$, where $\underline{\mathbf{h}}_d$ satisfies $\underline{\mathbf{h}}_d\langle\boldsymbol{\xi}\rangle \cdot \underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle = 0$, we readily find that $\widehat{\underline{\varepsilon}}[\underline{\mathbf{h}}] = \underline{\varphi}$ and that $\widehat{\underline{\gamma}}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle = \big(\underline{\mathbf{e}}\langle\boldsymbol{\eta}\rangle \cdot \underline{\mathbf{h}}_d\langle\boldsymbol{\xi}\rangle + \underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle \cdot \underline{\mathbf{h}}_d\langle\boldsymbol{\eta}\rangle\big) / \big(2\sin\underline{\alpha}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle\big)$. Substituting these expressions into (3) and then the resulting expression into (2), we obtain the linear elastic response function state given by

*Corresponding author. E-mail: aguiarar@sc.usp.br.

$$\widehat{\underline{\mathbf{L}}}_{\mathbf{x}_0}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi}\rangle = \int_{\mathcal{H}_\delta} \frac{\omega(|\boldsymbol{\xi}|,|\boldsymbol{\eta}|)}{|\boldsymbol{\xi}|}\Big\{\alpha_1\,\underline{\varphi}\langle\boldsymbol{\xi}\rangle\,\underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle + 2\,\alpha_2\underline{\varphi}\langle\boldsymbol{\eta}\rangle\,\underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle + \frac{\alpha_3}{2\,\sin\underline{\alpha}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle}\Big(\underline{\mathbf{e}}\langle\boldsymbol{\eta}\rangle\cdot\underline{\mathbf{h}}_d\langle\boldsymbol{\xi}\rangle + \underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle\cdot\underline{\mathbf{h}}_d\langle\boldsymbol{\eta}\rangle\Big)\underline{\underline{\mathbf{e}}}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle + \frac{\alpha_4}{2}\Big[\Big(\underline{\varphi}\langle\boldsymbol{\xi}\rangle + \underline{\varphi}\langle\boldsymbol{\eta}\rangle\Big)\underline{\underline{\mathbf{e}}}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle + \frac{1}{\sin\underline{\underline{\alpha}}\langle\boldsymbol{\xi},\boldsymbol{\eta}\rangle}\Big(\underline{\mathbf{e}}\langle\boldsymbol{\eta}\rangle\cdot\underline{\mathbf{h}}_d\langle\boldsymbol{\xi}\rangle + \underline{\mathbf{e}}\langle\boldsymbol{\xi}\rangle\cdot\underline{\mathbf{h}}_d\langle\boldsymbol{\eta}\rangle\Big)\underline{\underline{\mathbf{e}}}\langle\boldsymbol{\xi}\rangle\Big]\Big\}\,dv_{\boldsymbol{\eta}}\,. \tag{4}$$

In [1] we show that (4) reduces to the linearized version of the force response function state proposed by Silling *et al.* [3] if $\alpha_3 = \alpha_4 = 0$ and $\omega(|\boldsymbol{\xi}|,|\boldsymbol{\eta}|) = \widetilde{\omega}(|\boldsymbol{\xi}|)\,\widetilde{\omega}(|\boldsymbol{\eta}|)|\boldsymbol{\xi}|^2|\boldsymbol{\eta}|^2$, where $\tilde{\omega}:\mathbb{R}\to\mathbb{R}$ is a known weighting function.

A CLASS OF POLYNOMIAL DISPLACEMENTS

In this work we consider the special class of displacement fields given by

$$\underline{\mathbf{h}}(\mathbf{x}_0)\langle\boldsymbol{\xi}\rangle = \frac{1}{|\boldsymbol{\xi}|}\left(\frac{\partial\,u_i(\mathbf{x}_0)}{\partial\alpha_j}\xi_j + \frac{1}{2}\frac{\partial^2\,u_i(\mathbf{x}_0)}{\partial\alpha_j\partial\alpha_k}\,\xi_j\,\xi_k\right)\mathbf{e}_i\,, \tag{5}$$

where $\alpha_i := \mathbf{x}\cdot\mathbf{e}_i$, $\xi_i := \boldsymbol{\xi}\cdot\mathbf{e}_i$, $u_i := \mathbf{u}\cdot\mathbf{e}_i$, and $\{\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3\}$ is a fixed orthonormal basis in $\mathbb{E}^3$. The states $\underline{\varphi}$ and $\underline{\mathbf{h}}_d$ in the decomposition of $\underline{\mathbf{h}} = \underline{\varphi}\,\underline{\mathbf{e}} + \underline{\mathbf{h}}_d$ can then be determined from (5) and substituted into (4). A similar procedure also yields $\widehat{\underline{\mathbf{L}}}_{\mathbf{x}}[\underline{\mathbf{h}}]\langle-\boldsymbol{\xi}\rangle$, which together with $\widehat{\underline{\mathbf{L}}}_{\mathbf{x}_0}[\underline{\mathbf{h}}]\langle\boldsymbol{\xi}\rangle$ and $\boldsymbol{\xi} = \mathbf{x}-\mathbf{x}_0$ can be substituted in the integrand of the equation (1) with the help of (2). After integration and using $\omega_\delta := \pi^2\int_0^\delta\int_0^\delta \omega(\check{\rho},\hat{\rho})\check{\rho}^2\hat{\rho}^2 d\hat{\rho}\,d\check{\rho}$, the resulting equation becomes

$$\frac{8\,\omega_\delta}{45}\left[(20\,\alpha_2+\alpha_3+12\,\alpha_1)\,\frac{\partial^2 u_{j_{\mathbf{x}_0}}}{\partial\alpha_j\partial\alpha_i} + 3\,(\alpha_3+2\,\alpha_1)\,\frac{\partial^2 u_{i_{\mathbf{x}_0}}}{\partial\alpha_j\partial\alpha_j}\right] + b_i(\mathbf{x}_0) = 0\,,\quad b_i := \mathbf{b}\cdot\mathbf{e}_i\,,\quad i=1,2,3. \tag{6}$$

Seleson and Littlewood [2] have also used a class of second-degree polynomials to study equilibrium of the linearized model obtained from Silling *et al.* [3]. Because this linearized model is a particular case of the model considered in this work, they find differential equations that are particular cases of the equations in (6).

On the other hand, the equilibrium equations of classical linear elasticity theory at the point $\mathbf{x}_0\in\mathcal{B}$ are given by

$$(\lambda+\mu)\frac{\partial^2 u_j(\mathbf{x}_0)}{\partial\alpha_j\partial\alpha_i} + \mu\frac{\partial^2 u_i(\mathbf{x}_0)}{\partial\alpha_j\partial\alpha_j} + b_i(\mathbf{x}_0) = 0\,,\qquad i=1,2,3, \tag{7}$$

where λ and μ are the Lamé constants. The peridynamic equilibrium equations in (6) become the classical equilibrium equations in (7) provided that $3\,\lambda+2\,\mu = (\alpha_1+2\,\alpha_2)\,16\,\omega_\delta/15$, $(\lambda+\mu) = (2\,\alpha_1+\alpha_3)\,8\,\omega_\delta/15$. By using the relations $\mu = E/[2\,(1+\nu)]$, $\lambda = E\,\nu/[(1+\nu)(1-2\,\nu)]$, where E is the Young's modulus and ν is the Poisson's ratio, we find

$$\alpha_{11}+2\alpha_{12} = \frac{3\,E}{16\,(1-2\nu)\,\omega_\delta}\,,\qquad 2\alpha_{11}+\alpha_{33} = \frac{15\,E}{16\,(1+\nu)\,\omega_\delta}, \tag{8}$$

which were also found by Aguiar [1] using energy-based arguments together with homogeneous deformations. Differently from that work, here, we use the peridynamic equilibrium equation (1) together with the class of second-degree polynomial displacements given by (5). Observe from (8) that two constants remain undetermined. Aguiar [1] proposes an energy-based correspondence argument to determine these constants, which will be discussed at the meeting.

CONCLUSIONS

We have used a class of second-degree polynomial displacement fields to investigate equilibrium of a linearly elastic peridynamic material having a quadratic free energy function with four peridynamic constants. We have found equations for the second-order derivatives of the displacement fields that have the same form of the equilibrium equations from classical linear theory. By equating the coefficients of these differential equations, we have found two relations between the four peridynamic constants and the two Lamé constants, which are the same relations found in previous work through energy-based considerations. In addition of being consistent with the results found previously, the results of this work indicate that local equilibrium is not sufficient to determine the four peridynamic constants. The fact that two peridynamic constants are left undetermined reflects the nonlocal nature of the theory and is the subject of ongoing investigation.

EFFECTS OF MISFIT STRAIN ON QUANTUM MECHANICAL STATES OF SPHERICAL CORE/SHELL QUANTUM DOTS

[3]Department of Electronics Engineering, Catholic University of Daegu, Hayang, Kyeongbuk 712-702, Republic of Korea

Summary Effects of lattice-mismatched strain on optical properties of CdSe/CdS, CdSe/ZnSe, and CdSe/ZnS core/shell quantum dot nanostructures are investigated theoretically using simple continuum elasticity and effective mass models. This strain is calculated based on the spherically symmetric linear elasticity solution for a misfitted inclusion embedded in a finite matrix. The effective mass quantum mechanics model shows that the subband energy is blueshifted by the compressive strain in the core, whereas the corresponding tensile strain in the shell, albeit less influentially, shifts the conduction subband energy downward. It is also quantitatively shown that the shift in the subband energies is proportional to both the amount of lattice mismatch and the shell thickness.

INTRODUCTION

The core/shell nanostructure systems such as quantum dots (QDs) have been used extensively as stable light sources with color-tunable feature induced by their dimensional change. Lattice distortions induced by the structural lattice mismatch between the core and the shell give rise to an internal potential effect [1]. This leads to a shift of the conduction and valence subband energies in QD core/shell assembly by changing the interatomic distances, which alters the energy levels of the bonding electrons [2]. As a result, QD core/shell nanostructure can exhibit a large change in the emission properties because of the intrinsic strain fields.

Quantifying the strain effects that depend on the shell thickness and the core/shell lattice mismatch have not yet been theoretically analyzed in detail. Therefore, we developed the spherically-symmetric analytical model incorporating deformation potentials in the Hamilitonian to quantify the effects of strain on the energy states of light exciton confined in type I II-VI group semiconductors with spherical QDs core/shell structure. Assuming that the QD core/shell structure exhibits spherically hexagonal anisotropy, an exact solution is obtained through the eigenvalue decomposition method and the analytical expressions of the strain fields are found using appropriate boundary and continuity conditions [3]. To calculate the ground-state subband energies in the conduction and valence bands and the exciton binding energy that includes the strain effects in QD core/shell calculated previously, we used 1s hydrogenic-like wavefunctions, the variational method and the effective-mass approximation (EMA). Parametric studies on the ground-state subband and the binding energies considering variations in the hydrostatic strains and the parameters such as QD radius and shell thickness are also presented. Since the strains used in the analysis take into account of both QD size and shell thickness, this work can be useful for functional improvements by optimizing the geometries of the QD nanostructure. For future work, a closed-form solution for the strain field arising from lattice mismatch of the spherical QD core/shell structures with rectilinear material anisotropy embedded in an infinite matrix will be taken into account for a more realistic model [4].

FORMULATIONS

Let's consider a lattice-mismatched QD core/shell structure modelled as a size-mismatched, spherical inclusion embedded in a finite spherical matrix in the framework of linear elasticity [3], which satisfies the following assumptions:
1. Quantum dot core/shell assembly is regarded as a spherically symmetric concentric structure exhibiting spherically anisotropic material properties.
2. Linear elastic behavior is assumed in the quantum dot core/shell structure despite mismatch strain up to 4%.
3. Non-local nanoscale effects are not considered in this continuum model.

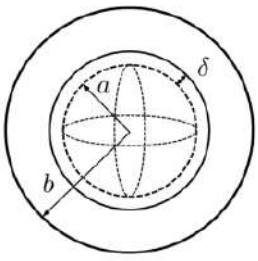

Figure 1. A spherical QD core/shell nanostructure with lattice-mismatched displacement, δ, and radii, a and b.

The constitutive equations relating elastic stresses, σ_{ij}, to strains, ε_{kl}, in a continuum body can be written as

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl} \quad (1)$$

where C_{ijkl} are the elastic constants. Due to the spherical symmetry of the QD structure, the displacement field, u_i, depends only on the radial direction ($u_\theta = u_\phi = 0$). The governing equation is then simplified as

$$\sigma_{ij,j} = \frac{d\sigma_{rr}}{dr} + \frac{2\sigma_{rr} - \sigma_{\theta\theta} - \sigma_{\phi\phi}}{2} = 0 \quad (2)$$

where σ_{rr}, $\sigma_{\theta\theta}$, $\sigma_{\phi\phi}$ are the stress components and C_{11} and C_{12} are cubic elastic constant. The general solution for Eq. (2) can be obtained as

*Corresponding author. E-mail: anh.nguyen.1@stonybrook.edu

$$u_r = Ar + \frac{B}{r^2} \tag{3}$$

By solving the boundary value problem for QD core/shell nanostructure subjected to a lattice-mismatched misfit strain, $\varepsilon_m = (l^C - l^S)/l^S$, where l^C and l^S are the lattice constants for the core and the shell, the radial displacement in the core, u_r^C, and in the shell, u_r^S, are found to be

$$u_r^C = \frac{2\delta}{D}(a^3 - b^3)\left(C_{11}^{S\,2} + C_{11}^S C_{12}^S - 2C_{12}^{S\,2}\right)\frac{r}{a}3$$
$$u_r^S = \frac{\delta}{D}(C_{11}^C + 2C_{12}^C)[b^3(C_{11}^S + 2C_{12}^S) + 2(C_{11}^C - C_{12}^C)r^3]\frac{a^2}{r^2}3 \tag{4}$$

where

$$D = 2a^3(C_{11}^S - C_{12}^S)(3C_{11}^C + 2C_{12}^C - C_{11}^S - 2C_{12}^S) + b^3(C_{11}^S + 2C_{12}^S)[C_{11}^C + 2(C_{12}^C + C_{11}^S - C_{12}^S)], \tag{5}$$

a is the core radius, b is the shell radius, and δ is the mismatch displacement created by the mismatched lattice at the interface. Subsequently, the closed-form expressions of the elastic strain distribution can be derived as

$$\varepsilon_{rr}^C = \varepsilon_{\theta\theta}^C = \varepsilon_{\phi\phi}^C = \frac{1}{D}\left[2(a^3 - b^3)\left(C_{11}^{S\,2} + C_{11}^S C_{12}^S - 2C_{12}^{S\,2}\right)\right]\frac{\delta}{a}$$
$$\varepsilon_{rr}^S = -\frac{2a^2}{D}(C_{11}^C + 2C_{12}^C)[b^3(C_{11}^S + 2C_{12}^S) - (C_{11}^S - C_{12}^S)r^3]\frac{\delta}{r^3} \tag{6}$$
$$\varepsilon_{\theta\theta}^S = \varepsilon_{\phi\phi}^S = \frac{a^2}{D}(C_{11}^C + 2C_{12}^C)[b^3(C_{11}^S + 2C_{12}^S) + 2(C_{11}^S - C_{12}^S)r^3]\frac{\delta}{r^3}$$

The dilatational strain, $\varepsilon_{ii} = \varepsilon_{rr} + \varepsilon_{\theta\theta} + \varepsilon_{\phi\phi}$, can be obtained as

$$\varepsilon_{kk}^C = \frac{6}{D}(a^3 - b^3)\left(C_{11}^{S\,2} + C_{11}^S C_{12}^S - 2C_{12}^{S\,2}\right)\frac{\delta}{a}$$
$$\varepsilon_{kk}^S = \frac{6a^2}{D}(C_{11}^C + 2C_{12}^C)(C_{11}^S - C_{12}^S)\frac{\delta}{a} \tag{7}$$

The QD core/shell nanostructure modeled as a single electron or a hole confined in a spherical finite potential well in the presence of a deformation potential yields the following transcendental equation solving for energy states E of the QD,

$$\sqrt{m_{(e,h)}^w(E - V_w)\frac{2m_o b^2}{\hbar^2}}\cot\left[a\sqrt{m_{(e,h)}^w(E - V_w)\frac{2m_o b^2}{\hbar^2}}\right]$$
$$= -\sqrt{m_{(e,h)}^b(V_b - E)\frac{2m_o b^2}{\hbar^2}} \tag{8}$$

where $\hbar$ is the Dirac constant, $m_{(e,h)}^w$ and $m_{(e,h)}^b$ are the effective masses for the core and the shell, respectively, normalized to the electron's true mass, m_o. The potential V corresponding to a mechanical deformation alters the band energy that is influenced by the strain field arising from the core/shell lattice misfit. The deformation potentials within the well, V_w, and within the potential barrier, V_b, are assumed to be influenced by the dilatational strains as follows

$$\text{for } r \le a \quad V_w = d_w^C(\varepsilon_{xx}^C + \varepsilon_{yy}^C + \varepsilon_{zz}^C),$$
$$\text{and for } r \ge a \quad V_b = \Delta E_{C,V} + d_w^S(\varepsilon_{xx}^S + \varepsilon_{yy}^S + \varepsilon_{zz}^S) \tag{9}$$

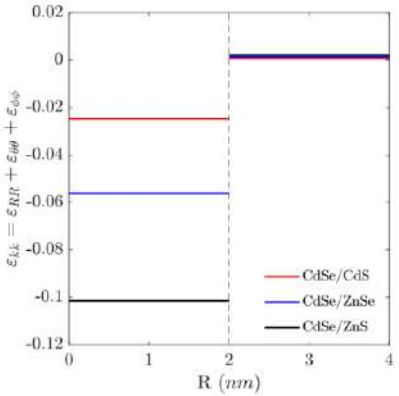

Figure 2. Dilatational strains as a function of radial dimension r, where a=2 nm and b=4 nm.

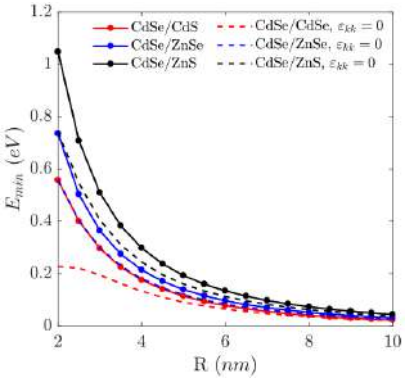

Figure 3. Ground-state energies, E_{min}, as a function of CdSe QD radius of various core/shell QD structures.

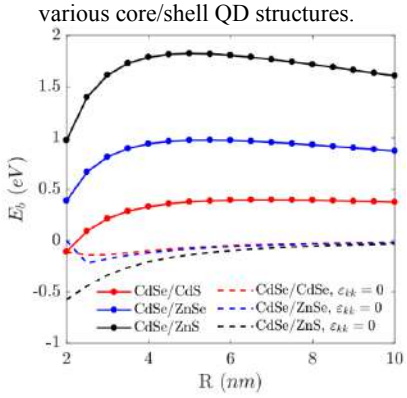

Figure 4. Binding energies, E_b, for an exciton in various core/shell QD structures with respect to QD radius, compared to those without the lattice-mismatch strain.

where ΔE_C and ΔE_V are the conduction and valence band offsets, and d_w^C and d_w^S are the deformation potential constants of the core and the shell, respectively. Eq. (8) will be solve numerically to find the eigenvalues corresponding to the respective energy states.

The ground-state binding energy for the exciton, E_b, is defined as

$$E_b = E_{1e} + E_{1h} - E(\alpha)_{min} = E_{1e} + E_{1h} + \bar{K} + \bar{V}_{conf} + \bar{V}_{e-h} \tag{10}$$

where E_{1e}, E_{1h}, and $E(\alpha)_{min}$ are the ground-state energies for the conduction and valence subbands and the exciton, and $\bar{K}$, $\bar{V}_{conf}$ and $\bar{V}_{e-h}$ are the kinetic energy, the confinement potential, and the coulomb interaction energy, which can be obtained using variational method. The numerical results are given in Figure 2-4.

Summary One open question remains regarding the theory of the generalized variational principle, that is, why can the stress-strain relation still be derived from the generalized variational principle while the method of Lagrangian multiplier method is applied in vain? This study shows that the generalized variational principle can only be understood and implemented correctly within the framework of thermodynamics. As long as the functional has one of the combination $A(\epsilon_{ij})-\sigma_{ij}\epsilon_{ij}$ or $B(\sigma_{ij})-\sigma_{ij}\epsilon_{ij}$, its corresponding variational principle will produce the stress-strain relation without the need to introduce extra constraints by the Lagrangian multiplier method. It is proved herein that the Hu-Washizu functional $\Pi_{HW}[u_i,\epsilon_{ij},\sigma_{ij}]$ and Hu-Washizu variational principle comprise a real three-field functional.

INTRODUCTION

Generalized variational mechanics began in the 1950s with the breakthrough works of Reissner [1] on two-field variational principles for elasticity problems, in which the displacement u_i and stress σ_{ij} are considered independent fields. Reissner introduced a functional F that is defined in terms of 12 arguments: six stresses σ_{ij} and six strains ϵ_{ij}: $F=\sigma_{ij}\epsilon_{ij}-B(\sigma_{ij})$, where $B(\sigma_{ij})$ is the elastic complementary energy density. Reissner proved the following theorem: Among all states of stress and displacement that satisfy the boundary conditions of the prescribed surface displacement, the actually occurring state of stress and displacement is determined by the variational equation: $\delta\left\{\iiint_V F dV-\iint_{S_p}\bar{p}_i u_i dS\right\}=0$, where the symbol V indicates the volume of the elastic body and S_p indicates that the surface integrals are to be taken over that part of the surface only where the appropriate surface stress is prescribed.

In 1954, Hu published a paper [3] (its English version appeared in 1955 [4]) that borrowed the idea from Reissner [1] and successfully extended Reissner's two-field (displacement-stress) theory to a three-field (displacement-stress-strain) theory by introducing a functional H_U given by $H_U=A(\epsilon_{ij})-f_i u_i-\sigma_{ij}(\epsilon_{ij}-\frac{1}{2}u_{i,j}-\frac{1}{2}u_{j,i})$. Hu [4]) proved a theorem as follows:$\delta\left\{\iiint_V H_U dV-\iint_{S_\sigma}\bar{p}_i u_i dS-\iint_{S_u}\sigma_{ij}n_j(u_i-\bar{u}_i)dS\right\}=0$. In 1955, Washizu [5] independently proposed the same functional and proved the same theorems as Hu [3, 4].

Regarding the history of the generalized variational principle, Felippa [9] published a dedicated paper on the original publication of the generalized variational principle and showed that de Veubeke had developed a much more generalized variational principle in a report dated 1951 [2], in which four fields, namely, displacement, stress, strain, and surface force, were included. de Veubeke's four-field $(u_i,\sigma_{ij},\epsilon_{ij},t_i)$ theory can be presented as follows [9]: $\delta\Pi=0$, where the functional: $\Pi_V[u_i,\sigma_{ij},\epsilon_{ij},t_i]=\iiint_V[A(\epsilon_{ij})+\sigma_{ij}(\frac{1}{2}u_{i,j}-\frac{1}{2}u_{j,i}-\epsilon_{ij})-f_i u_i]dV-\iint_{S_\sigma}\bar{t}_i u_i dS-\iint_{S_u}t_i(u_i-\bar{u}_i)dS$. The three-field standard form is obtained by setting $t_i=\sigma_{ij}n_j$ on S_u a priori. Hence, Fellippa proposed that the canonical functional be called the de Veubeke-Hu-Washizu functional Π_{VHW}. This proposal has been confirmed by The History of the Theory of Structures Searching for Equilibrium [10].

In 1983, Chien [7], who was Hu's supervisor and communicated Hu's paper to both the Chinese Journal of Physics [3] and Science Sinica [4], pointed out that, regarding all publications and reports of Reissner [1], Hu [3, 4] and Washizu [5] did not give any information on how to construct the functional. The formulation of the generalized variational seems mystical, and thus Chien indicated that the trial-and-error method was used when Reissner, Hu, and Washizu formulated their functional [7, 8].

To derive the generalized functional in a systematic way, Chien proposed to formulate the functional by using the well-known method of Lagrangian multipliers [7]. With the help of the Lagrangian multipliers, in 1983 Chien [7] successfully reformulated the two-field functional, namely, $\Pi[u_i,\sigma_{ij}]$ and $\Pi[u_i,\epsilon_{ij}]$, which are called the Hellinger-Resissner functional [1] and De Veubeke functional [2], respectively. However, Chien [7] found that the constitutive relation between stress and strain cannot be included to form a three-field functional $\Pi[u_i,\epsilon_{ij},\sigma_{ij}]$ due to the zero crisis of corresponding Lagrangian multipliers, as it is known to be impossible to incorporate this condition of constraint into a functional whenever the corresponding Lagrange multiplier turns out to be zero. Therefore, Chien claimed that the functional H_U is not a three-field, but rather a two-field, functional. To address this point of view, Chien elegantly wrote a monograph on the generalized variational principle [8] and, to overcome the difficulty, he proposed a method of a higher-order Lagrange multiplier, a four-field functional Π_Q that is suggested to be expressed as follows: $\Pi_Q[u_i,\sigma_{ij},\epsilon_{ij},\lambda]=\iiint_V H_U dV-\iint_{S_\sigma}\bar{p}_i u_i dS-\iint_{S_u}\sigma_{ij}n_j(u_i-\bar{u}_i)dS+\iiint_V\lambda[A(\epsilon_{ij})+B(\sigma_{ij})-\sigma_{ij}\epsilon_{ij}]dV$. Chien proved that for no zero $\lambda\neq 0$, the $\delta\Pi_Q[u_i,\sigma_{ij},\epsilon_{ij},\lambda]=0$ will produce balance equations, strain-displacement relations, stress-strain relations, and corresponding boundary conditions. Owing to the arbitrary nature of the Lagrangian multiplier λ, there are an infinite number of functionals $\Pi_Q[u_i,\sigma_{ij},\epsilon_{ij};\lambda]$.

Regarding Chien's questioning [7, 8], no explanation from Hu, to the best of our knowledge, has been found in the literature. Because the formulation of the generalized variational principle has been recognized as a key contribution by a Chinese scholar to mechanics worldwide, and in particular, considering its importance in finite-element formulation, it is vital that Chien's question can be clearly answered. Otherwise, it will continue to cause confusion to both scholars and students. The task of answering this question has become a newcomer's responsibility.

THERMODYNAMIC FOUNDATION OF GENERALIZED VARIATIONAL PRINCIPLE

Since thermodynamics is foundation of material constitutive theory, to solve Chien's question, let's go back to the original point of thermodynamics of continuum. Combining the first law and second laws of thermodynamics leads to an equation defined in the current configuration as follows: $\rho(\dot{\phi}+\eta\dot{\theta})-\boldsymbol{\sigma}:\dot{\boldsymbol{\epsilon}}+\frac{1}{\theta}\boldsymbol{q}\cdot\boldsymbol{\nabla}\theta\leq 0$, where $\phi(\boldsymbol{\epsilon},\theta)$ is the Helmholtz free energy, $\eta(\boldsymbol{\epsilon},\theta)$ the entropy, θ the temperature, $\boldsymbol{\sigma}$ the stress tensor, $\dot{\boldsymbol{\epsilon}}$ the rate of deformation, and $\boldsymbol{q}$ the heat flux vector. Since $\dot{\phi}=\phi_{,\boldsymbol{\epsilon}}:\dot{\boldsymbol{\epsilon}}+\phi_{,\theta}\dot{\theta}=\phi_{,\boldsymbol{\epsilon}}:\dot{\boldsymbol{\epsilon}}+\phi_{,\theta}\dot{\theta}$, one can obtain $(\rho\frac{\partial\phi}{\partial\boldsymbol{\epsilon}}-\boldsymbol{\sigma}):\dot{\boldsymbol{\epsilon}}+\rho(\frac{\partial\phi}{\partial\theta}+\eta)\dot{\theta}+\frac{1}{\theta}\boldsymbol{q}\cdot\boldsymbol{\nabla}\theta\leq 0$. Note that the left-hand side of the inequality is a polynomial of degree 1 in $\dot{\boldsymbol{\epsilon}}$ and $\dot{\theta}$. Because the inequality must hold for all choices of $\dot{\boldsymbol{\epsilon}}$ and $\dot{\theta}$, it will therefore be violated unless $\boldsymbol{\sigma}=\rho\frac{\partial\phi}{\partial\boldsymbol{\epsilon}}\ and\eta=-\frac{\partial\phi}{\partial\theta}$, which are the constitutive equations of simple materials. The purpose of this brief review of the formulation of constitutive equations is to show that the thermodynamic relation, $\rho(\dot{\phi}+\eta\dot{\theta})-\boldsymbol{\sigma}:\dot{\boldsymbol{\epsilon}}+\frac{1}{\theta}\boldsymbol{q}\cdot\boldsymbol{\nabla}\theta\leq 0$, has already contained the constitutive relations. In other words, the thermodynamic relation, $\rho(\dot{\phi}+\eta\dot{\theta})-\boldsymbol{\sigma}:\dot{\boldsymbol{\epsilon}}+\frac{1}{\theta}\boldsymbol{q}\cdot\boldsymbol{\nabla}\theta\leq 0$, is an implicit form of constitutive equation.

For isothermal reversible thermodynamics, $\dot{\theta}=0$, one has $\rho\dot{\phi}-\boldsymbol{\sigma}:\dot{\boldsymbol{\epsilon}}=0$, which can further be reduced to $\rho d\phi-\boldsymbol{\sigma}:d\boldsymbol{\epsilon}=\rho d\phi-\sigma_{ij}\epsilon_{ij}=0$. If one replaces $\rho\phi$ by the potential energy density $A(\epsilon_{ij})$, we have $dA(\epsilon_{ij})-\sigma_{ij}d\epsilon_{ij}=0$, the equivalent form of which is the stress-strain relation: $\sigma_{ij}=\frac{\partial A(\epsilon_{ij})}{\partial\epsilon_{ij}}$. Similar to the above-mentioned general case, $dA(\epsilon_{ij})-\sigma_{ij}d\epsilon_{ij}=0$ implies the stress-strain relation.

Furthermore, since $dA(\epsilon_{ij})-\sigma_{ij}d\epsilon_{ij}=dA(\epsilon_{ij})-[d(\sigma_{ij}\epsilon_{ij})-\epsilon_{ij}d\sigma_{ij}]=0$, and denoting $dB=\epsilon_{ij}d\sigma_{ij}$, after integration one has $A(\epsilon_{ij})+B(\sigma_{ij})-\sigma_{ij}\epsilon_{ij}=C$. Applying conditions $A(0)=0$ and $B(0)=0$, thus $C=0$. Hence, $A(\epsilon_{ij})+B(\sigma_{ij})-\sigma_{ij}\epsilon_{ij}=0$, where $A(\epsilon_{ij})$ and $B(\sigma_{ij})$ are the potential and complementary energy density, respectively.

Following the above thinking, it is easy to know that a functional has included a stress-strain relation if it contains either the terms $[A(\epsilon_{ij})-\sigma_{ij}\epsilon_{ij}]$ or $[B(\sigma_{ij})-\sigma_{ij}\epsilon_{ij}]$. In other words, if the structure of the functional was in the following form: $\Pi[u_i,\epsilon_{ij},\sigma_{ij}]=\iiint_V\left[\underline{A(\epsilon_{ij})-\sigma_{ij}\epsilon_{ij}}+...\right]dV+\text{Boundary tems}$, which implies that the stress-strain relation $\sigma_{ij}=\frac{\partial A(\epsilon_{ij})}{\partial\epsilon_{ij}}$ is included, since its variational $\delta\Pi[u_i,\epsilon_{ij},\sigma_{ij}]=0$, leads to $\iiint_V\left\{[\frac{\partial A(\epsilon_{ij})}{\partial\epsilon_{ij}}-\sigma_{ij}]\delta\epsilon_{ij}+...\right\}dV+\delta(\text{Boundary tems})=0$, and due to the arbitrary variation $\delta\epsilon_{ij}$, one therefore has the following stress-strain relation: $\frac{\partial A(\epsilon_{ij})}{\partial\epsilon_{ij}}-\sigma_{ij}=0$. With this understanding, an examination of the following Hu-Washizu functional is necessary:

$$\Pi_{HW}[u_i,\epsilon_{ij},\sigma_{ij}]=\iiint_V\left\{\underline{A(\epsilon_{ij})}-f_iu_i-\underline{\sigma_{ij}[\epsilon_{ij}}-\frac{1}{2}(u_{i,j}+u_{j,i})]\right\}dV-\iint_{S_\sigma}\bar{p}_iu_idS-\iint_{S_u}\sigma_{ij}n_j(u_i-\bar{u}_i)dS.$$

The combination of the underlined terms in the above functional is exactly the term of $A(\epsilon_{ij})-\sigma_{ij}\epsilon_{ij}$. Therefore, the Hu-Washizu functional $\Pi_{HW}[u_i,\epsilon_{ij},\sigma_{ij}]$ has already included the stress-strain relation $\sigma_{ij}=\frac{\partial A(\epsilon_{ij})}{\partial\epsilon_{ij}}$. The Hu-Washizu functional $\Pi_{HW}[u_i,\epsilon_{ij},\sigma_{ij}]$ is a real three-field functional. This key point might not be understood by Hu [3, 4], Reissner [1], and de Veubeke [2] when they constructed their own generalized functional by the trial-and-error method.

CONCLUSIONS

This study shown that the generalized variational principle can only be correctly understood and implemented within the framework of thermodynamics. As long as the functional has any one of the combination $A(\epsilon_{ij})-\sigma_{ij}\epsilon_{ij}$ or $B(\sigma_{ij})-\sigma_{ij}\epsilon_{ij}$, its corresponding variational principle can produce the stress-strain relation without the need to introduce extra constraints by the Lagrangian multiplier method. Therefore, the Hu-Washizu functional $\Pi_{HW}[u_i,\epsilon_{ij},\sigma_{ij}]$ is a real three-field functional and the Hu-Washizu variational principle is a three-field variational principle. In addition, that Chien's functional $\Pi_Q[u_i,\epsilon_{ij},\sigma_{ij},\lambda]$ is a much more general three-field functional has been confirmed.

Acknowledgments: It is my privilege to dedicate this paper to the memories of Prof. Chien and Prof. Hu for their great contribution to the establishment of the generalized variational principle.

Understanding how deformation patterns of highly deformable structures form when an external load is applied is crucial for designing metamaterials with unique properties. Here, we present a method to predict the linear deformation of finite 2D solid structures with circular holes and inclusions, using analogies with image charges and induction in electrostatics. Charges in electrostatics induce image charges near the boundaries and an external electric field induces polarization of conductive and dielectric objects. Similarly, charges in elasticity induce image charges near boundaries and an external stress induces polarization inside holes and inclusions. In the presented method, the induced polarization is expanded into a series of multipoles and interactions of the inclusions with the external stress field, between them, and with their images is systematically taken into account.

ELASTIC MULTIPOLE METHOD

In mechanical metamaterials the geometry, topology and contrasting elastic properties of adherent materials are exploited to achieve exceptional functionalities such as negative thermal expansion and Poisson`s ratio, shape morphing, mechanical cloaking, tuneable phononic band gaps etc. At the heart of these functionalities are deformation patterns of such materials with holes and inclusions. In this contribution we illustrate a method of describing linear deformations of finite planar solid structures by employing similarities between electrostatics and elasticity.

Analogies between electrostatics and 2D linear elasticity can be recognized when the governing equations are formulated in terms of scalar functions, namely the electric potential U and the Airy stress function χ. The electric field $\boldsymbol{E}$ in electrostatics is obtained from the gradient of the electric potential: $\boldsymbol{E} = -\boldsymbol{\nabla} U$. Similarly, the stress tensor field σ_{ij} is obtained by taking spatial derivatives of the Airy stress function: $\sigma_{xx} = \partial^2\chi/\partial y^2$, $\sigma_{yy} = \partial^2\chi/\partial x^2$ and $\sigma_{xy} = -\partial^2\chi/\partial x\partial y$. The most compelling aspect of these formulations in terms of scalar functions is that Faraday`s law in electrostatics and the force balance equation in elasticity are automatically satisfied. Furthermore, the governing equations for these scalar functions take simple forms. For the electric potential we have the well-known Gauss`s law $\Delta U = -\rho_e/\varepsilon_e$, where ρ_e is the electric charge density and ε_e is the permittivity of the material. The analogous equation in elasticity $\Delta\Delta\chi = E\rho$ describes the strain (in)compatibility conditions, where E is the 2D Young`s modulus and ρ is the elastic charge density associated with defects that are the sources of incompatibility.

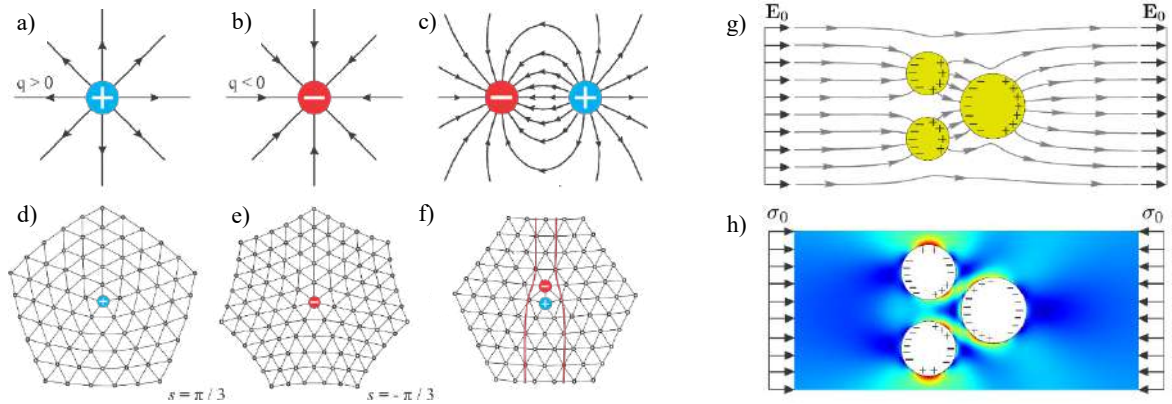

Figure 1. a) Positive electric monopole with charge q (arrows show the electric field), b) neg. electric monopole, c) electric dipole, d) positive elastic monopole (disclination) with $s = \pi/3$, e) negative elastic monopole ($s = -\pi/3$), f) elastic dipole (dislocation), g) induced polarization of conducting spheres (yellow), h) induced polarization due to external stress of holes in an elastic matrix.

In electrostatics a monopole is defined as the electric charge density distribution proportional to the Dirac delta function $\rho_e = q\delta(\boldsymbol{x} - \boldsymbol{x}_0)$ (Figs. 1a, 1b). Similarly, we can define a monopole in 2D elasticity, i.e. $\rho = s\delta(\boldsymbol{x} - \boldsymbol{x}_0)$ where s is the charge and $\boldsymbol{x}_0$ describes its position. The physical interpretation of monopoles in elasticity comes from condensed matter theory. When a wedge of angle s is cut from a 2D material and the newly formed boundaries are "glued" back together, a positive disclination defect (point elastic charge) of charge s is formed (Fig. 1d). The negative disclination with charge $s < 0$ corresponds to the insertion of a wedge with angle $|s|$ (Fig. 1e). An electrostatic dipole is formed by two opposite point charges $\pm q$ (Fig. 1c). Analogous elastic dipoles (Fig. 1f) consist of two elastic dipoles and are commonly known as dislocations. Similarly, higher order electric and elastic multipoles can be constructed. Elastic multipoles are closely related to the general solution of the biharmonic equation $\Delta\Delta\chi = 0$ due to Michell [1], since this solution contains the Airy stress functions of monopoles, dipoles and all higher order elastic multipoles.

*Corresponding author. E-mail: matjaz.cebron@fs.uni-lj.si.

An external electric field induces polarization in conducting and dielectric objects (Fig. 1g). Similarly, external stress with a stress function χ_{ext} induces elastic multipoles in holes and inclusions (Fig. 1h) which in turn interact with each other through their induced elastic multipoles. Let the induced stress function in the i-th inhomogeneity be χ_i. The total stress function in the material is then $\chi_{tot} = \chi_{ext} + \sum \chi_i$. The amplitudes of the induced elastic multipoles, i.e. the terms of the Michell solution, can then be determined from satisfying the boundary at the circumference of each of the inclusions. A detailed description of the elastic multipole method is given by the authors in [2].

Image charges

Image charges are commonly used in electrostatics to satisfy boundary conditions. For the same purpose image charges can also be introduced in 2D elasticity. Let us consider a 2D semi-infinite dielectric medium with permittivity ε_e filling half space $y < y_b$ with a monopole charge q at position $\boldsymbol{x}_0 = (x_0, y_0) = (x_0, y_b - h)$, which is at distance h from a perfectly conductive straight edge at $y = y_b$ (Fig. 2a). The electric potential for this case can be found by solving the governing equation $\Delta U = (-q/\varepsilon_e)\delta(\boldsymbol{x} - \boldsymbol{x}_0)$ subject to the boundary condition $E_x(x, y_b) = 0$. The solution for the governing equation in an infinite 2D medium is $U_m(\boldsymbol{x} - \boldsymbol{x}_0|q) = -(q/2\pi\varepsilon_e)\ln|\boldsymbol{x} - \boldsymbol{x}_0|$, however the resulting electric field does not satisfy the boundary conditions at the conducting edge. Boundary conditions can be satisfied by placing an image monopole charge $-q$ on the opposite side of the conducting edge at $\boldsymbol{x}_0^* = (x_0^*, y_0^*) = (x_0, y_b + h)$.

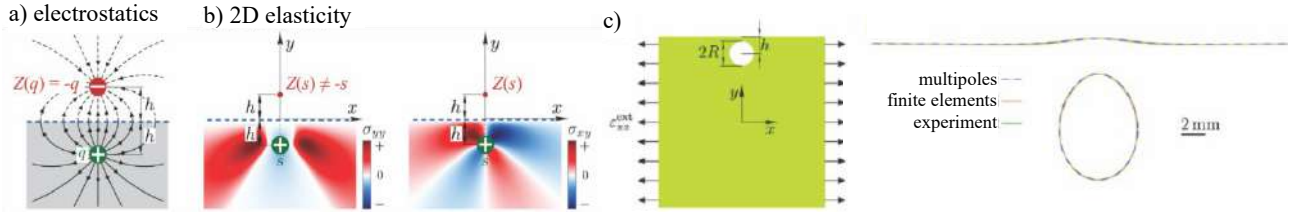

Figure 2. a) image charge of electric monopole b) image charge of disclination, c) contours of deformed hole and free edge obtained with elastic multipole method, finite elements and experiments ($2R = 8.113$mm, $h = 6.253$mm, $\varepsilon_{xx}^{ext} = -0.05$, 100x3x100 mm sample).

Let us look at a related problem in 2D elasticity for a semi-infinite elastic medium with Young`s modulus E with a monopole with charge s at $\boldsymbol{x}_0 = (x_0, y_b - h)$ which is at distance h from a traction free edge (Fig. 2b). The Airy stress function for this case can be found by solving the governing equation $\Delta\Delta\chi = Es\delta(\boldsymbol{x} - \boldsymbol{x}_0)$ subject to boundary conditions $\sigma_{xy}(x, y_b) = \sigma_{yy}(x, y_b) = 0$. Inspired by electrostatics we try placing an image disclination with charge $-s$ on the opposite side of the traction free edge. The resulting trial stress function satisfies only one boundary condition $\sigma_{yy}^{tr}(x, y_b) = 0$, while the other boundary condition is violated $\sigma_{xy}^{tr}(x, y_b) \neq 0$. This difference between electrostatics and elasticity stems from the fact that the electric potential is a harmonic function, while the Airy stress function is a biharmonic function. The additional multipoles needed for satisfying both boundary conditions can be found by calculating the Airy stress function that corresponds to the distributed tractions $f_y = -\sigma_{yy}^{tr}$ and $f_x = -\sigma_{xy}^{tr}$ along the free edge. This can be done with the help of the Boussinesq problem in 2D, where $\chi_B(\boldsymbol{x}|x', y_b)$ describes the stress function of a concentrated force $\boldsymbol{F} = (1,0)$ at point (x', y_b). The stress function of the additional image multipoles is obtained as $\chi^a(\boldsymbol{x}) = \int_{-\infty}^{\infty} \chi_B(\boldsymbol{x}|x', y_b) f_x(x') dx'$. The Airy stress function for the image of the disclination can then be used to systematically construct the Airy stress functions for the images of all other elastic multipoles [4]. The operator Z for constructing the Airy stress functions of images may be written in a compact form:

$$Z[\chi_0(x,y)] = -\chi_0(x, 2y_b - y) + 2(y_b - y)\frac{\partial \chi_0(x, 2y_b - y)}{\partial y} - (y_b - y)^2 \Delta\chi_0(x, 2y_b - y)$$

Similarly to electrostatics, the image of the image charge is the original charge $Z[Z[\chi_0]] = \chi_0$. For bounded structures, external load induces elastic multipoles at the centers of inclusions and holes, which further induce image multipoles in order to satisfy boundary condition at the edges. The amplitudes of induced multipoles are obtained from satisfying the boundary conditions at the interface between inhomogeneities and the elastic matrix.

CONCLUSIONS

In this contribution, we present how image charges and induction, commonly used in electrostatics, can be used for the analysis of linear deformations of bounded 2D elastic structures with inhomogeneities. The presented method shows good agreement with finite element calculations and experiments (Fig. 2c). While we focused on linear deformation, these concepts can also be extended to the nonlinear regime [3] and various geometries [4] thus the elastic multipole method has the potential to advance our understanding of deformation patterns in structures with holes and inclusions.

Summary Transverse intralaminar cracks in layers perpendicular to the main loading direction have a significant impact on the apparent ultimate strength of the corresponding laminate. This effect stems from the fact that such transverse cracks generally promote the occurrence of other failure mechanisms leading to specimen failure. A micro-mechanical analysis of cross-ply laminates is herein proposed for the onset and progression of transverse intralaminar cracking. Numerical simulations are carried out according to the recently proposed fracture mechanics approach coupling: (i) the phase field approach for matrix cracking, and the bilinear cohesive zone model for fibre-matrix decohesion. Relying on this framework, the influence of the transverse ply thickness on the onset and propagation of damage under tensile conditions is assessed and compared with experiments taken from the literature.

INTRODUCTION

Thin-ply laminate technologies in long fibre-reinforced composite materials (usually comprising carbon- and glass-reinforcements in polymeric-based matrix, i.e. CFRP and GFRP, respectively) has emerged as a potential alternative for the production of composite components due to their ability to preclude delamination and micro-cracking prior the corresponding collapsing points. However, there exist some unsolved issues associated with different mechanical effects in composite materials regarding their specific fracture responses. Associated with the analysis of transverse fracture response, the seminal work conducted by [1] on $[0/90]_s$ laminates showed that the reduction of the 90° layer thickness provokes an increase in the critical strain for transverse cracking initiation. Therefore, for sufficiently thin 90° layers, the actual strength response of the laminate would be that governed by the 0° supporting layers, this scenario being of crucial importance for the incorporation of thin and ultra-thin plies in composite structures. This characteristic behaviour is commonly denominated as *in-situ strength effect* in cross-ply composite laminates. Existing models in the literature [2-4] to interpret such a phenomenon differ from each other upon the fundamental hypotheses for their development. Therefore, from the authors' point of view, the physical soundness of such arguments should be revisited in a consistent manner, i.e. how cracks initiate and propagate within fibrous composites based on a micro-mechanical level of analysis.

METHODOLOGY AND BRIEF DESCRIPTION OF THE COMPUTATIONAL MODEL

This cracking sequence, i.e. the specific sequence of damage phenomena at the micro-mechanical level for this application, motivates the use of the coupling between the PF method for bulk fracture and the CZM for fibre-matrix decohesion proposed in [5,6], which can be denoted as PF-CZ technique. Specifically, the nonlocal PF method of fracture is considered in the current research for triggering matrix-cracking events, while a bi-linear CZM is implemented within interface finite elements to model decohesion at fibre-matrix interfaces.

The current FE model (Fig. 1) is generated through the adoption of a multi-scale embedded approach, with the aim at replicating the experimental configurations described in [7]. Tensile loading conditions in the specimen along the longitudinal direction experienced in the real tests is reproduced by transferring displacement conditions to the central portion of the specimen, providing the boundary conditions for the solution of the FE model.

MAIN RESULTS AND CONCLUSIONS

The analysis of the in-situ strength effect for the simulated specimens with different layer configurations led to predictions in very good agreement with the trend reported in [3] and with the experimental observations in [7], in terms of through-the-thickness fracture propagation pattern based on the thickness of the 90° central layer (see Fig. 2 for the $[0°_2/90°_4/0°_2]$ assembly configuration). The analysis of the numerical results shows the occurrence of a phenomenon of cracking propagation within the matrix significantly delayed by reducing the thickness of the specimen, which leads in its turn to an increase in the apparent critical strain for its development through-the-thickness. Nevertheless, current predictions presented deviations with respect to the strain levels at which these phenomena occurred. These differences are mainly attributed to possible 3D effects that haven not yet been taken into consideration in the present 2D modeling framework and that deserve further research.

WHEN AND HOW FRACTURE NUCLEATES AND PROPAGATES IN RUBBER

Aditya Kumar and Oscar Lopez-Pamies*
Department of Civil and Environmental Engineering, University of Illinois Urbana–Champaign, USA

Summary In a recent contribution, Kumar et al. [1] have introduced a phase-field formulation aimed at modeling the nucleation and propagation of fracture and healing in elastomers undergoing arbitrarily large quasistatic deformations, phenomena that have come into clear focus thanks to new experiments carried out at high spatiotemporal resolution [2, 3]. In this work, we present a specific model within the general formulation for the prominent case of isotropic and nearly incompressible rubbers capable of describing, explaining, and predicting fracture nucleation at large, be it within the bulk, from large pre-existing cracks, small pre-existing cracks, or from smooth and non-smooth boundary points. With the primary object of explaining when and how fracture nucleates and propagates in rubber, we then make use of the proposed model to perform 3D simulations of several famed experiments.

Guided by the experimental results presented in [2, 3], Kumar et al. [1] have recently introduced a regularized theory of fracture — of phase-field type — that views the nucleation and propagation of fracture as well as the possibility of healing in elastomers as three intertwined parts of the same phenomenon. The theory can be thought of as a generalization of the celebrated phase-field regularization [4] of the variational theory of Francfort and Marigo [5] in that it modifies the former on two pivotal counts, one pertaining to nucleation, the other to healing.

Indeed, it is now well understood that the standard phase-field regularization introduced in [4] cannot properly describe fracture nucleation because it is a purely energetic formulation and as a result it cannot account for one essential ingredient that is not energetic, but rather stress-based: the strength of the material. Furthermore, such a formulation describes fracture as an irreversible and purely dissipative process ruling out thus the possibility of healing. Kumar et al. [1] proposed alterations that circumvent these limitations on nucleation and healing while keeping undisturbed the remarkable proven ability of the standard phase-field formulation to model crack propagation. Roughly speaking, the idea behind the phase-field framework proposed in Kumar et al. [1] amounts:

- to consider the Euler-Lagrange equations — and not the underlying variational principle — describing the evolution of the deformation field $\mathbf{y}(\mathbf{X}, \mathtt{t})$ and the phase field $z(\mathbf{X}, \mathtt{t})$ in the material as the primal model,
- to add an external driving force $c_{\mathrm{e}}(\mathbf{X}, \mathtt{t})$ in the Euler-Lagrange equation governing the evolution of the phase field z that represents the macroscopic manifestation of the presence of the inherent microscopic defects in the material and hence that brings into the model direct dependence on its strength, and
- to remove the irreversibility constraint on the phase field z by introducing a critical energy release rate or toughness with two branches, $k(\dot{z}) = k_{\mathrm{f}} = G_c$ if $\dot{z} \leq 0$ and k_{h} if $\dot{z} > 0$, one to describe $\mathtt{f}$racture (when $\dot{z} < 0$), the other to describe $\mathtt{h}$ealing (when $\dot{z} > 0$).

In their original work, aimed at explaining the nucleation of internal fracture observed in the experiments of Poulain et al. [2, 3] on various synthetic rubbers, Kumar et al. [1] also proposed a specific constitutive prescription for the external driving force c_{e} that restricted attention to accounting for the strength of the given rubber of interest only under hydrostatic stress. In this work, we introduce a complete constitutive prescription for c_{e} that accounts for the entire strength of the rubber under arbitrary stress states. The resulting phase-field model is thus one capable of describing fracture nucleation at large, be it within the bulk (under arbitrary states of stress, not just hydrostatic), from large pre-existing cracks, small pre-existing cracks, or from smooth and non-smooth boundary points. With the object of explaining when and how fracture nucleates and propagates in rubber, we then make use of the proposed model to perform 3D simulations of several famed experiments wherein fracture nucleates and propagates in very different and very complex manners. Specifically, we work out simulations on very short, short, and long rubber bands of initially circular cross section. The very short and short rubber bands correspond to the so-called poker-chip specimens studied experimentally by many. The long rubber bands, on the other hand, are representative of the celebrated specimens — invented by Stephen Perry in the 1840s — that most of us have used and played with since childhood.

By way of an example, we present below sample 3D simulations on very short (see Fig. 1) and long (see Fig. 2) rubber bands made of a soft silicone rubber. Specifically, we consider rubber bands of circular cross with initial diameter $d_0 = 2$ mm and two different initial lengths $l_0 = d_0/35 = 0.057$ mm and $l_0 = 20 \times d_0 = 40$ mm. The bands are stretched by bonding their top and bottom boundaries to rigid plates which are pulled apart by a prescribed displacement u. The corresponding force required to do so is denoted by P. For consistency with the experimental literature, the results below are presented in terms of the "global" stretch λ and the "global" nominal stress s, which are defined in terms of u and P by the relations $\lambda = 1 + u/l_0$ and $s = 4P/(\pi d_0^2)$.

Consistent with the experimental observations reported in the literature for thin poker-chip experiments, the key observation from Fig. 1 is that fracture occurs exclusively around the midplane of the band, entirely within its bulk, in a cascading sequence of crack nucleation events that originates from the center and proceeds radially outward as the applied

*Corresponding author. E-mail: pamies@illinois.edu.

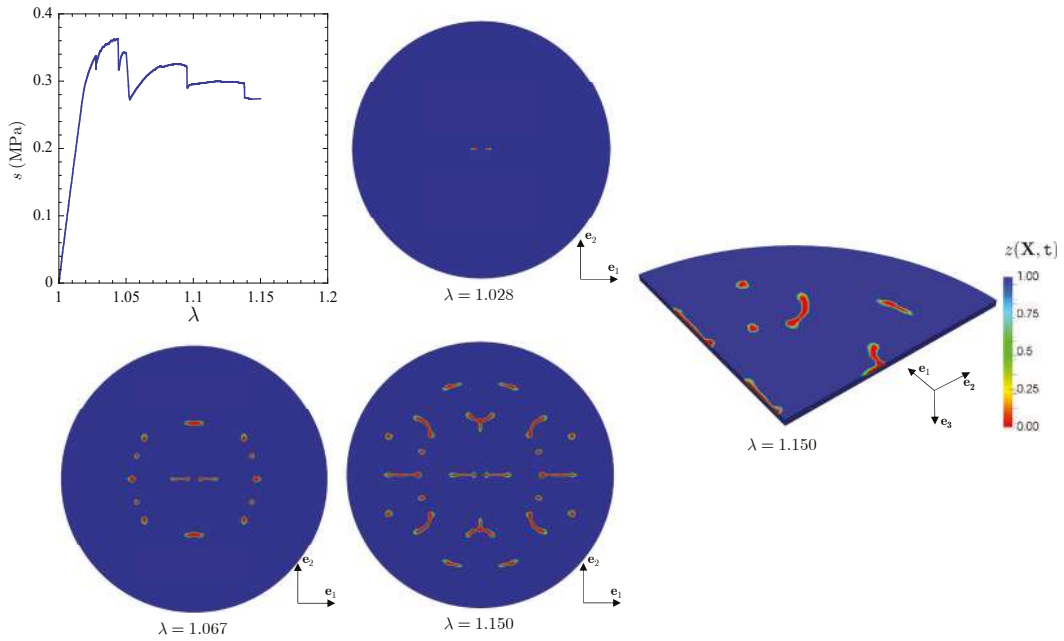

Figure 1: 3D simulation of a very short rubber band — or poker-chip specimen — under tension. The line plot shows the predicted stress s as a function of the applied stretch λ. The contour plots show the predicted phase field $z(\mathbf{X}, \mathtt{t})$ across the midplane of the band at three different applied stretches, $\lambda = 1.028, 1.067, 1.150$, and over an octant of the band at $\lambda = 1.150$.

stretch λ increases. Precisely, two cracks are first nucleated around the center of the band at a stretch of about $\lambda = 1.028$. As λ increases, more cracks are sequentially nucleated radially away from the center at random locations. At the stretch of about $\lambda = 1.150$, cracks are already present throughout the entire midplane of the band, save for a boundary layer around its lateral traction-free boundary. Once a crack is nucleated, it exhibits limited subsequent stable propagation, instead the nucleation of more cracks is preferred as λ increases.

In stark contrast with the preceding result, as expected from the experience of playing with rubber bands and consistent with the experimental observations reported in the literature on the tensile strength of elastomers, Fig. 2 shows that the long rubber band stretches uniformly — save for, of course, the localized heterogeneous stretching taking place near its top and bottom boundaries because of the bonding to rigid plates — until an applied stretch of about $\lambda = 4.01$, at which point a crack nucleates — in this case, near the bottom boundary — abruptly across the band severing it in two pieces.

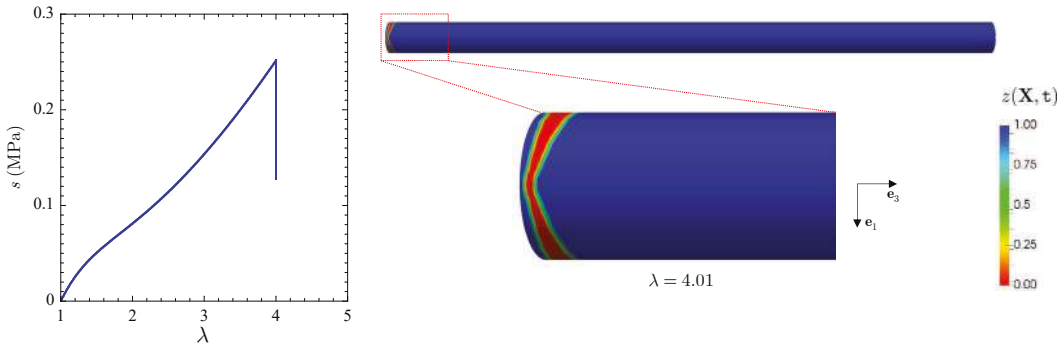

Figure 2: 3D simulation of a long rubber band under tension. The line plot shows the predicted stress s as a function of the applied stretch λ. The contour plot shows the predicted phase field $z(\mathbf{X}, \mathtt{t})$ over the entire band at $\lambda = 4.01$.

HOW MOVING CRACKS IN BRITTLE SOLIDS CHOOSE THEIR PATH

Lital Rozen-Levy[1], John M. Kolinski[2], Gil Cohen[1] and Jay Fineberg[1]
[1]The Racah Institute of Physics, The Hebrew University of Jerusalem, Givat Ram, Jerusalem Israel.
[2]École Polytechnique Fédérale de Lausanne, Lausanne, 1015, Switzerland.

Summary While we have an excellent fundamental understanding of the dynamics and structure of cracks propagating in brittle solids, we do not fully understand how the path of a moving crack is determined. Here we experimentally study cracks that are propagating between 10-95% of their limiting velocity within a brittle material. We deflect these cracks by either allowing them to interact with sparsely implanted defects or driving them to undergo an intrinsic oscillatory instability in defect-free media. By dense measurements of the strain fields surrounding the crack tips via high speed imaging, we determine what governs a crack's direction when it is strongly deflected. We reveal that the paths selected by these rapid and strongly perturbed cracks are entirely governed by the direction of maximum strain energy density and not by local symmetry of the fields. This fundamentally important result may potentially be utilized to either direct or guide running cracks.

We experimentally probe the effects of both dilute rigidly embedded inclusions and intrinsic instability in an unperturbed medium on the dynamic path selection of cracks in otherwise perfect (homogeneous) brittle isotropic materials. To reduce crack speeds while retaining fully dynamic propagation, we utilize polyacrylamide (*1, 2*) hydrogels. These materials are representative of brittle materials that undergo brittle failure, as has been demonstrated through direct verification of the predictions of fracture mechanics to describing the dynamic fields near crack tips, energy balance and the equation of motion for brittle cracks moving at velocities ranging from nearly zero to nearly their limiting velocity, (*1*).

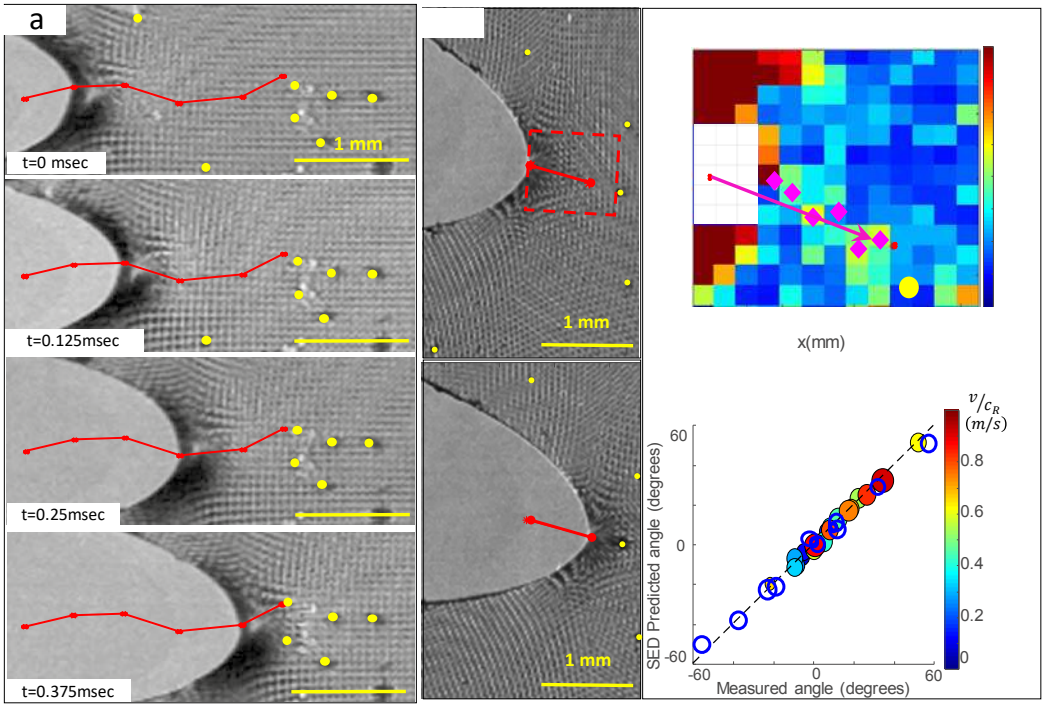

Figure 1: Comparing predictions of the crack propagation direction to maximum strain energy density. (a) A time series of images separated by 0.125 msec as a crack tip rapidly evolves while interacting with the particles (yellow dots) that it encounters. Its resulting path, denoted by the red line connecting successive crack tips (red dots), becomes tortuous. (b) 2 sequential images with the crack trajectory in red. (c) (top) Predicted crack directions in the reference frame for (b) using the maximal strain energy density (SED) criterion. The measured strain energy density (J/m^3) within the square section denoted in (b) diamonds denote the maximal SED for each x location. The purple arrow is a linear fit to these data. Crack tip locations in (b) are denoted by red points. (bottom) Predicted angles using the SED for 21 different experiments – each with significantly different ensembles of surrounding particles and propagation velocities, v. v of each point is indicated by the colors in the legend. Open symbols are additional experiments in homogeneous materials upon excitation of the oscillatory instability (See Fig. 2) The error bars are the size of the points.

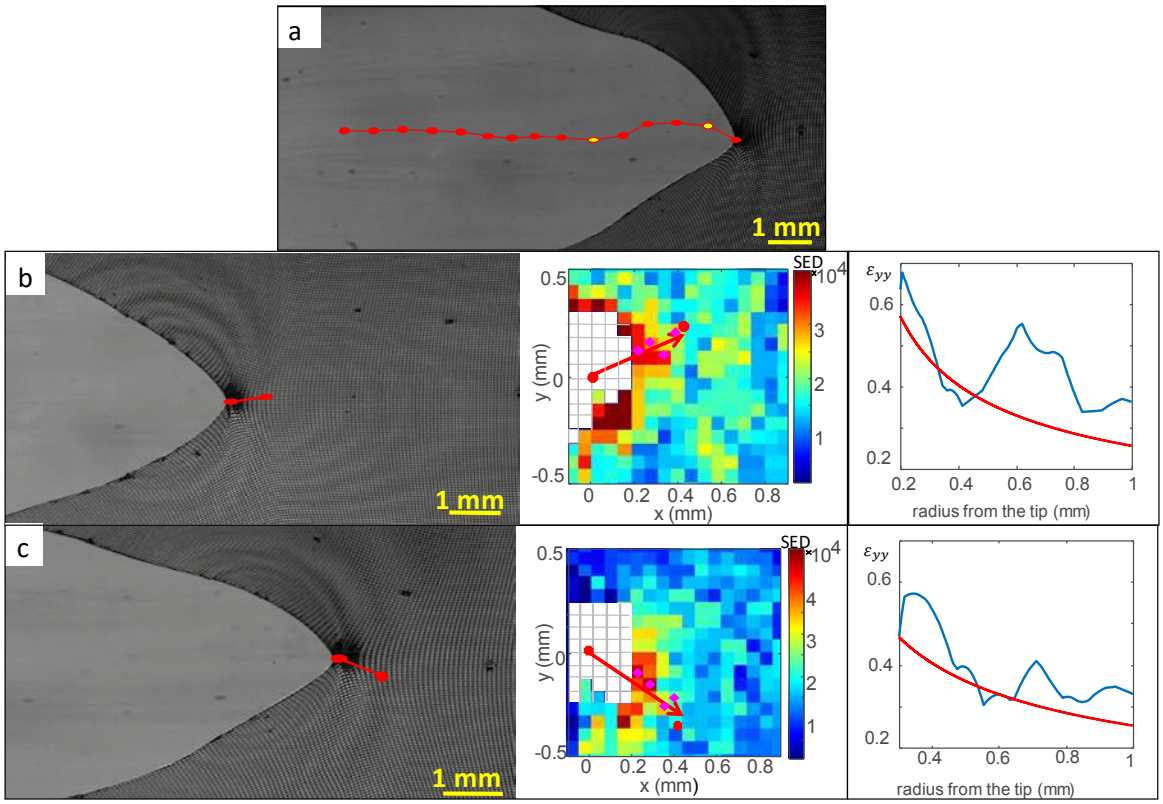

Figure 2 The local direction of oscillatory cracks are well-predicted by the maximum strain energy density (SED) condition. (a) The trajectory of a spontaneously oscillating crack propagating at approximately $0.9c_S$ at the onset of the oscillatory instability (*3, 4*). Shown is a snapshot of the vicinity of the tip of a crack undergoing this instability. The trajectory of successive crack tips leading to this instant is denoted in red. Note that this instability takes place spontaneously in a uniform medium, without the insertion of rigid particles. (b,c) Two typical instantaneous snapshots (left panels) of the crack tip at the locations denoted by the yellow dots in (a). The center panels demonstrate that the trajectory directions in both (b) and (c) are well-predicted by the SED criterion (SED units are in J/m^3). Predicted (measured) angles were $30°$ ($31°$) in (b) and were $-40°$ ($-36°$). The PLS predictions were, respectively were $4°$ and $3°$. (Right) Corresponding ε_{yy} as a function of the distance from the crack tip along the instantaneous direction of the crack tip.

Figure 1 shows that crack paths often become tortuous as a consequence of crack interactions with embedded inclusions. The near-tip strain fields of these rapidly propagating cracks reveal that nearby particles significantly affect the form and even existence of the singular fields predicted by Linear Elastic Fracture Mechanics (LEFM). When a crack approaches a particle, the stress fields surrounding its tip typically deviate from the singular, 'K-dominant' scaling predicted by LEFM (or its nonlinear extensions (*5-8*)) in homogeneous materials. Crack paths also deviate strongly when cracks become unstable to an oscillatory instability at high velocities (>0.9C_S where C_S is the material's shear wave speed), as presented in Fig. 2.

In all cases where a crack's path deviates, we find that its path is perfectly predicted by the direction of *maximum strain energy density* ahead of the crack tip, as demonstrated in both Figs. 1c and 2.

STRESS INTENSITY FACTORS FOR INTERACTING ARBITRARILY SHAPED 3D CRACKS - A SIMPLE, FAST AND ACCURATE FINITE ELEMENT-BASED METHOD

Mari Åman*[1], Kennie Berntsson [1]and Gary Marquis[1]
[1]Department of Mechanical Engineering, Aalto University, Espoo, Finland

Summary A finite element-based method for accurately determining stress intensity factors (SIF) for interacting arbitrarily shaped 3D cracks is proposed. The method utilizes the superposition principle and does not require fine meshes or singular elements. The foundation of the new method is that disturbances in an elastic stress field due to neighbouring cracks can be captured accurately by splitting the total stress at the crack tip element into two components, singular and non-singular terms. Computed results are in excellent agreement with the existing analytical solutions. In addition, novel SIF solutions for various crack geometries and configurations are presented and the conversion of size-independent solutions to the small crack model, $\sqrt{area}$ parameter model, is introduced. The proposed method can be applied to the SIF analysis for interacting cracks with various shapes often observed in additively manufactured (AM) components and the solutions will be useful for the standardization for such complicated defect configurations.

INTRODUCTION

Defect interaction has been a concern for fatigue experts for many decades. The need to understand defect interaction precisely has been recently underscored due to the significant reduction in fatigue strength of AM components due to defect interaction [1]. Current design rules rely on a British standard [2], which provides analytical interaction criteria based on the crack size, shape and proximity. Since fracture mechanic-based design criteria are often based on critical SIF values, it becomes important to be able to compute SIFs accurately. However, determination of SIFs for 3D cracks by FEM is typically time-consuming and the accuracy depends strongly on the mesh characteristics such as singular elements. It is easy to understand that SIFs for complex shaped cracks is even more difficult to obtain, and yet, the complexity increases when the interacting cracks are involved. This work provides an accurate tool for SIF analysis using the common FEM software ABAQUS. Previously, the method has been successfully applied to 2D cracks by Murakami [3]. The greatest advantages of the proposed method are that it does not require fine meshes, extrapolations or so-called singular elements. This work also presents novel SIFs for various crack geometries and configurations. Moreover, the conversion of size-independent solutions to the well-known small crack model, the $\sqrt{area}$ parameter model [4], is introduced. The solutions will be very useful for standardization of general rules for interacting defect guidelines.

PRINCIPLE OF THE METHOD

The new method utilizes the superposition principle that is applicable in linear-elastic problems, see Fig. 1. Although the SIF's for problems Fig. 1 (a) and (c) are the same, the stress distributions are different by the remote stress, as illustrated in Fig. 2. The total stress in a crack tip element can be divided into two components, a singular term and a non-singular term both of which are included, for example, in a constant stress element. The singular term is associated with the SIF whereas the non-singular term is obtained based on the stress which already exists at the same element by assuming that the crack does not exist. In FEM, the non-singular term is dominant and interferes with the accurate determination of SIF based on the singular term. Thus, the key of the method is to extract the non-singular term from the total stress, after which only the singular term remains. By comparing the two components with those of a basic single crack for which an exact SIF is known, the interaction factor is obtained. In the case of a single crack, the non-singular stress is equivalent to the remote stress. However, in the interacting crack problem, the neighbouring crack contributes to the non-singular stress field. In the problem of two cracks, first the non-singular term at the tip of an imaginary crack is calculated by solving the problem with only one crack. Secondly, the problem with two cracks is solved to obtain the total stress at the crack tip element. Finally, the non-singular term is subtracted from the total stress and only the singular term remains.

Traditionally, the stresses at the crack tip are obtained by using very fine meshed and singular elements. Since the exact stresses at the crack tip are unbounded, the SIF is obtained by extrapolating the results with different meshes until reasonable accuracy is obtained. Such analyses tend to be troublesome in interaction problems, because the two cracks *simultaneously* influence the stress distributions in the vicinity of other cracks. Thus, by traditional methods, it is impossible to separate the stress distribution caused by a crack itself and the magnification of the stress distribution caused by a neighbouring crack.

RESULTS

The results are in an excellent agreement with the known numerical solutions. Figure 3 shows the validation of some selected problems, for which SIF's are known. Body Force Method (BFM) solutions are from a previous work that focused on semi-elliptical cracks [5].

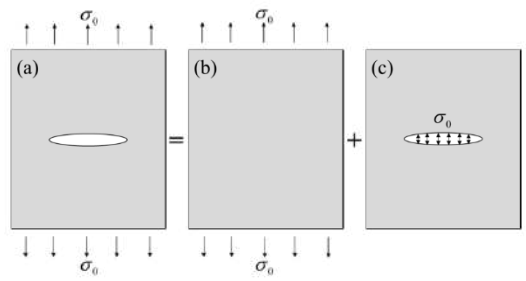

Figure 1. Superposition principle.

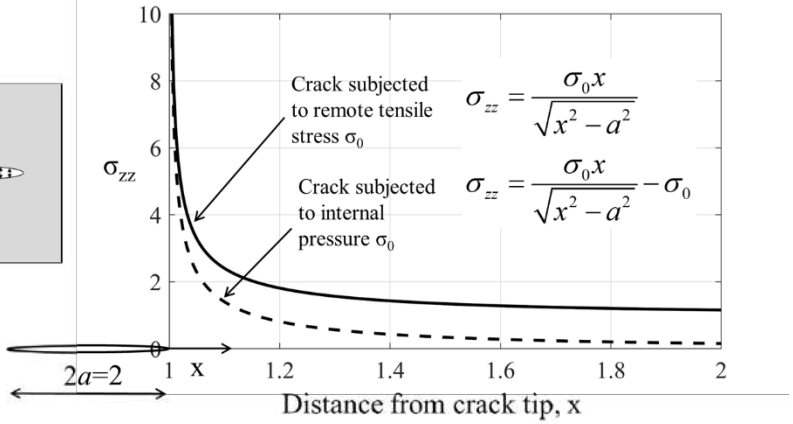

Figure 2. Stress distributions for problems in Fig. 1 (a) and (c).

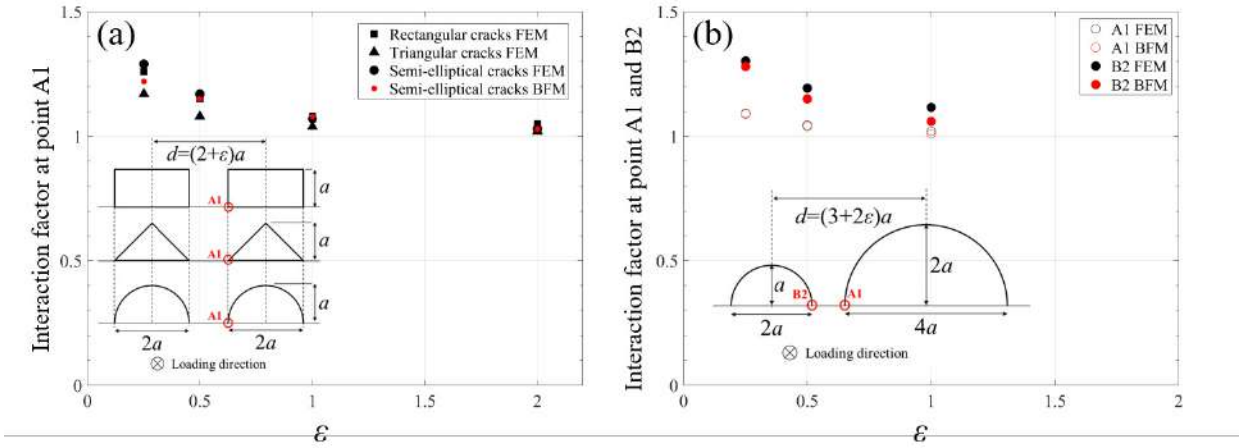

Figure 3. Validation of the new method and comparison with the known numerical solutions [5].

DISCUSSION & CONCLUSIONS

The SIF solutions for non-elliptical cracks can be obtained when the SIF for similar semi-elliptical crack and the stresses at the crack tip elements are known; $K_{\text{rectangle}} = \sigma_{\text{rectangle,tip}} * K_{\text{semi-ellipse}} / \sigma_{\text{semi-ellipse,tip}}$. Using the known solution $K_{\text{semi-ellipse}} = 0.730\sigma_0\sqrt{\pi a}$ [5], we obtain $K_{\text{rectangle}} = 0.809\sigma_0\sqrt{\pi a}$ and $K_{\text{triangle}} = 0.536\sigma_0\sqrt{\pi a}$ at A1 points. However, considering the size-dependency of small crack threshold SIF range, small cracks are commonly treated in a different manner than long cracks. Murakami [4] has established a well-known $\sqrt{area}$ parameter model for the fatigue limit evaluation of small cracks. Since the $\sqrt{area}$ parameter model literally uses the $\sqrt{area}$ of irregularly shaped defects, it is necessary to express SIF's in terms of the square root of the projected area of defects, $\sqrt{area}$. The solutions of the present method can be easily converted to corresponding values of the $\sqrt{area}$ even for interacting defects.

A CHEMO-THERMO-MECHANICALLY CONSTITUTIVE THEORY FOR CRACK PROPAGATION WITH INTERFACIAL OXIDATION IN THERMAL BARRIER COATINGS

Li Yang* [1], and Yichun Zhou[1]

[1]Key Laboratory of Key Film Materials & Application for Equipment (Hunan province), School of Materials Science and Engineering, Xiangtan University, Xiangtan, Hunan 411105, China

Summary During service at high temperatures, the thermal barrier coating oxidizes at the ceramic/bonding layer interface, forming a dense layer of thermal growth oxide (TGO). In this paper, the thermal barrier coating interface oxidation model and the numerical solution method are established: order parameter is introduced for crack, and the contribution of thermoelastic energy, diffusion energy and chemical reaction energy in the coating is superimposed to give the free energy of the coating as a whole. It was found that the thermal barrier coating was prone to crack at the ceramic layer /TGO trough and the TGO/ bonding layer peak during the interface oxidation.

INTRODUCTION

With the upgrading of aero-engines, the bearing capacity of high-temperature components is continuously increasing. Thermal barrier coating (YSZ) as a key thermal protection material has greatly improved the temperature bearing capacity of high-temperature components of the engine. During the high-temperature service of the thermal barrier coating, oxygen in the air passes through the ceramic layer, and an oxidation reaction occurs with the Al element in the bond coating on the ceramic/bond coating interface, forming a dense thermally grown oxide (TGO)[1]. Further, TGO growth and stress evolution will induce coating flaking failure. Flaking failure is an important bottleneck which restricts the safety application of thermal barrier coatings in advanced aero-engines. Therefore, the establishment of the thermal barrier coating interfaces oxidative failure theory is crucial to the accurate understanding of the thermal barrier coating interface oxidative spalling failure[2].

The TGO growth process is a complex thermo-mechanical multi-field coupling phenomenon, and the coating peeling failure caused by it is a complex interface and bulk material coupling failure process. Based on the thermal-mechanical-chemical multi-field coupled growth model of the thermal barrier coating (TGO), a thermal-mechanical-coupled failure model and numerical solution method for the interface oxidation of the thermal barrier coating are established. The interface auxiliary field variable is introduced as the substitution of the ceramics layer and TGO interface, distinguishing interface failure from material failure. We define crack auxiliary field variable and construct free energy functions. The governing equation and constitutive relationship of each field in the material have been obtained according to the variational principle. The cohesive force model was used to simulate the failure of the interface between the ceramic layer and TGO. Finally, the crack propagation model caused by interface oxidation has been achieved.

RESULTS AND DISCUSSION

As shown in figure 1, in TGO trough, The maximum average compressive stress near the TC/TGO interface changes from 2.4 GPa at 0 h to 1.15 GPa at 1000 h. In BC crest, the maximum average tensile stress near the BC/TGO interface change from 0.48 GPa at 0 h to 0.42 GPa at 1000 h. Causing by stress concentration place crack is produced. After crack extending, the average tensile stress and compressive stress are reduced.

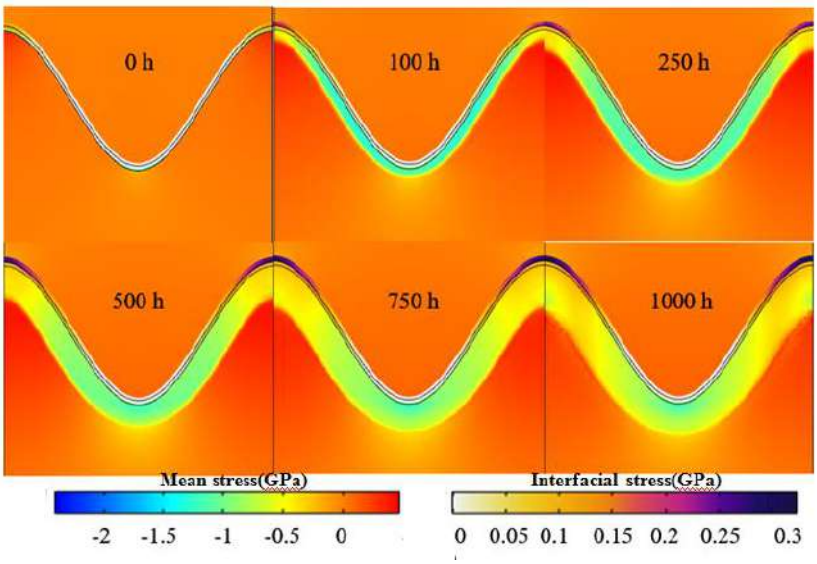

Figure 1. Average stress distribution of thermal barrier coating (bottom left) and interfacial stress distribution (bottom right)

*Correspondingauthor. E-mail: Lyang@xtu.edu.cn

As shown in Fig. 2, the thermal barrier coating will crack at the trough of the TC/TGO interface. When it is not completely disconnected, it will also crack at the peak of the TGO/BC interface.

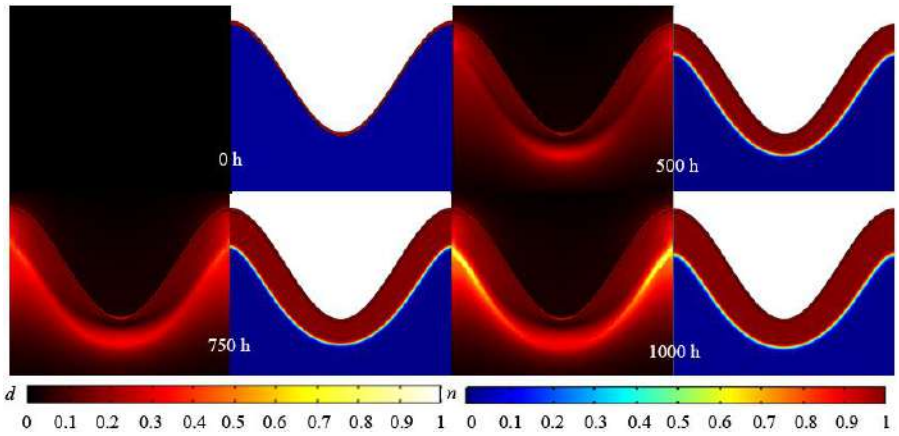

Figure 2. Thermal barrier coating crack (d) distribution over time (left) and TGO volume fraction (n) distribution over time (right)

CONCLUSIONS

In this work, combined with thermal growth model and phase field model, interface cohesion model is established for the crack growth causing by oxidation of interface in thermal barrier coating. The main results can be summarized as follows: (1) The thermal barrier coating at the trough of the TC/TGO interface produces the crack, but has not completely disconnect, in TGO/BC interface wave cracks can also produce, and gradually expand to the troughs. (2) At 1000 h, crack completely disconnect in TGO/BC interface wave, which will cause the coating reducing internal stress at the same time.

SIMULATION OF DUCTILE PLATE TEARING USING A STRAIN GRADIENT ENHANCED GURSON-TVERGAARD-NEEDLEMAN MODEL

Vishal Vishwakarma*[1] and Kim Lau Nielsen[1]
[1]Department of Mechanical Engineering, Solid Mechanics Section, Technical University of Denmark, DK-2800 Kgs Lyngby, Denmark

Summary The ductile failure process ahead of an advancing crack in a thin large scale plate subject to mode I loading is modeled using a newly proposed gradient enriched Gurson-Tvergaard-Needleman (GTN) material model that includes a constitutive length parameter to account for strain gradient hardening. The aim is to study the chronology of plate tearing from the first local thinning far ahead from the crack tip and until shear localization followed by slant fracture in the presence of strain gradient hardening. The details of the failure process are used to investigate the influence of the length scale on the fracture energy going into the tearing process as well as the forces involved.

ABSTRACT

The well known Gurson-Tvergaard-Needleman (GTN) model [1, 2, 3], incorporating the mechanics of void nucleation and growth to coalescence, is widely used in the assessment of structural integrity and the modeling of ductile failure. The complex void nucleation, growth and coalescence mechanisms takes place at the micron scale where strain gradient hardening can also play a significant role in the mechanical response. Essentially, the general trend is that "smaller is stronger" and a number of experiments on the micron scale have shown increased hardening and higher apparent yield stress at the small scale. The classical GTN model, however, only accounts for void volume fraction and, thus, cannot distinguish between length scales. But, since the fracture process zone ahead of the crack tip in a ductile specimen comprises of the micro-mechanisms outlined above, it is expected that the scale dependent hardening (coming from strain gradients) can have a significant effect on the fracture process during ductile tearing. The strain gradient effect is usually modeled by incorporating a length scale parameter in the constitutive law, and it is anticipated that the existing micro-mechanical material modeling techniques can substantially be improved by accounting for such effects. Recently, an effort was made to bring in the strain gradient effect in the void growth model of Gurson-Tvergaard (GT model) by introducing a constitutive length parameter in the yield function [4]. The gradient enriched GT model was later studied with analogous unit cell based calculations to show a strong influence of size effect on the rate of void growth and thus on hardening [5]. By incorporating the length parameter into the GT model, the door has opened to unravel the effect of microscale hardening on large scale plate tearing.

In this work, an investigation of the fracture process ahead of an advancing crack tip in a thin plate is conducted by adopting a two-dimensional plane strain finite element model along the lines of Nielsen and Hutchinson [6], but with the gradient enriched GTN material model describing the shear localization and failure process. A full three-dimensional FE model was employed by Andersen et al. [7], with the GTN model to study the plate tearing from crack initiation to steady-state crack growth. They observed a reasonably good agreement between a full 3D crack propagation simulation and the simplified 2D plane strain setup by Nielsen and Hutchinson [6] that mimics steady-state crack growth. The sequence of deformation steps ahead of the crack tip is shown in Fig. 1. The onset of necking and thinning starts far ahead of the crack tip, (i) & (ii), whereafter shear localization, (iii) sets in and controls slant fracture, (iv). The current study sticks to a 2D plane strain representation of this sequence. A slight development is made to the gradient enriched Gurson material model of Niordson and Tvergaard [4] in order to account for void coalescence. The gradient enriched void growth and coalescence model used here is as follows,

$$\Phi = \frac{\sigma_{eq}^2}{\sigma_y^2} + 2Q_1 q_1 f^\star \cosh\left(\frac{3Q_2 q_2}{2}\frac{\sigma_m}{\sigma_y}\right) - 1 - (Q_1 q_1 f^\star)^2$$

$$f^\star = \begin{cases} f, & \text{for } f \le f_C, \\ f_C + \dfrac{f_U^\star - f_C}{f_F - f_C}(f - f_C), \quad f_U^\star = \dfrac{1}{Q_1 q_1}, & \text{for } f > f_C \end{cases}$$

where, Q_1 and Q_2 are the gradient enriched factors that are functions of $\frac{L_D}{R_C}$. L_D and R_c are the constitutive length parameter and initial in-plane void distance respectively. (See [3, 4] for more details). It is worth mentioning that the enriched factor, Q_1, also enters into the expression for $f^\star$ controlling the void coalescence. Finite strain formulation of the enriched GTN model based on a total Lagrangian approach is used for solving the incremental boundary value problem shown in Fig. 2 (b). This is implemented into an in-house finite element code written in FORTRAN using MPI for parallel computing. The simulations performed here are motivated from Nielsen and Hutchinson [6], where they studied the sequence of ductile failure and characterized the cohesive zone using the shear modified Gurson model free from any length scale. Here, the primary focus is to investigate the strain gradient hardening effect on the fracture process.

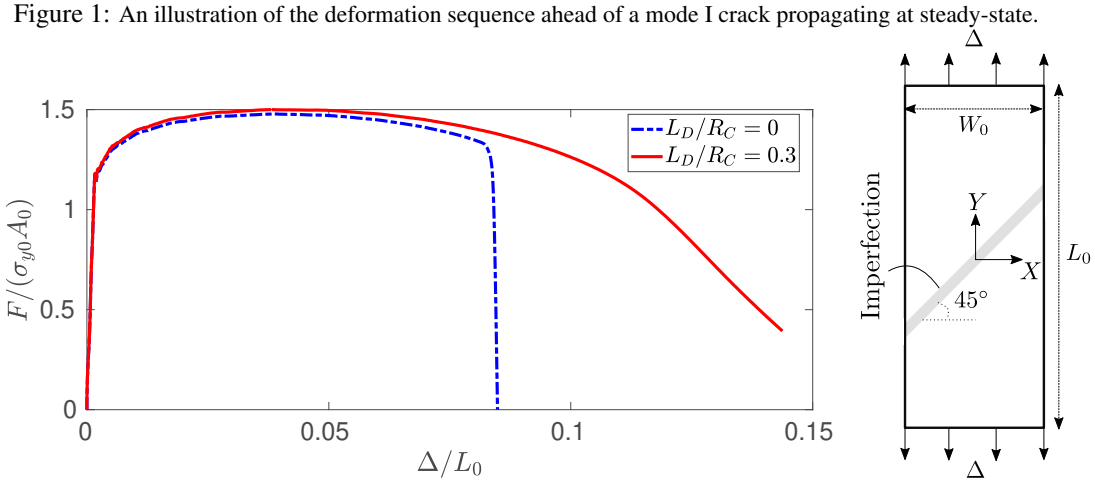

Figure 2: Load – Deflection curve obtained with (red) and without (blue) constitutive length scale parameter.

RESULTS

The sketch of the 2D plane strain problem considered here is shown in Fig. 2 (b), where the plate height to width ratio is taken as, $\frac{L_0}{W_0} = 3$. The section is subjected to a monotonically increasing displacement along the Y-axis as shown. The final fracture is triggered by introducing a small imperfection in the system by lowering the initial yield stress of the material along the 45° band by 2%. An assessment of the load-deflection behavior of the model for different values of the constitutive length parameter is made by considering two values of the length parameter: $\frac{L_D}{R_C} = 0$ representing the classical GTN model, and $\frac{L_D}{R_C} = 0.3$ representing the enriched GTN model. All other material parameters remain equal to those used by Nielsen and Hutchinson [6]. It is observed that with $\frac{L_D}{R_C} = 0.3$, the fracture is delayed significantly due to enhanced hardening in the material. In fact, shear localization is absent for such high values of $\frac{L_D}{R_C}$. The micro-mechanical unit cell calculations performed by Niordson and co-workers [4, 5] have shown a similar effect of $\frac{L_D}{R_C}$.

A detailed study showing the dependence of length parameter on response from the 2D plane strain section will be presented along with how this couple to the traction-separation relation and cohesive fracture energy related to ductile tearing. Moreover, the effect of having a length scale in the constitutive law on the mesh sensitivity will also be discussed.

PHASE-FIELD APPROACH FOR FRACTURE USING REPRESENTATIVE CRACK ELEMENTS FOR GEOMETRICAL AND MATERIAL NON-LINEARITIES

Johannes Storm[1] and Michael Kaliske *[1]
[1]Institute for Structural Analysis, Technische Universität Dresden, Dresden, Germany

Summary The contribution addresses challenges of the kinematic consistency of phase-field models for fracture. The framework of Representative Crack Elements is introduced in order to derive consistent phase-field fracture models. Applications of this approach to geometrical and material non-linearities are derived. Finally, results of a self-consistency test and of illustrative examples are presented.

INTRODUCTION

The phase-field method for fracture has been rapidly developing over the past 10 years. The regularised description of discrete cracks in a variational framework allows to develop thermodynamically consistent models. A small number of fundamental assumptions (restrictions) and straight forward integration into standard Finite Element Method (FEM) yielded an active scientific community in this field and various promising developments and results. Even though, phase-field fracture has been applied to non-linear, rate-dependent and multi-physical material behaviour in many publications, focus on some fundamental challenges is necessary so that the method can become a standard tool in fracture mechanics. The critical convergence behaviour of these bi-convex problems, the consistent formulation and implementation of fracture irreversibility and the investigation of conditions for the numerical discretisation are key tasks for upcoming developments.

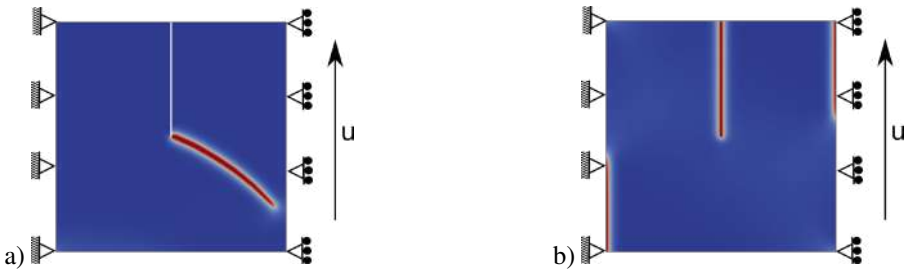

Figure 1: Comparison of crack propagation at a single-edge notch at shear load with a) a discrete initial crack and b) a phase-field initial crack applying phase-field fracture with the spectral strain split [1].

Another essential property for a fracture model is the realistic prediction of the kinematic mechanisms at the crack. Crack states, i.e. opening and closure, as well as material degradation, i.e. force transfer through and along crack surfaces, are considered by decomposition of the mechanical energy potential into a passive and an active portion

$$\psi^{\text{mech}} = \psi^{-} + g(s)\psi^{+}, \tag{1}$$

where $g(s)$ is the degradation function in dependence on the phase-field variable s. Various approximations for this decomposition are proposed in literature based on the deformation state [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13], e.g. strain and deformation gradient, or stress state [14]. However, Strobel and Seelig [15] and Steinke and Kaliske [16] have shown that those approximations lead to misleading predictions for force transfer through the crack for quasi-static and dynamic problems, respectively. In Storm et al. [17], the authors have proposed to compare the predictions of phase-field fracture models to those of corresponding discrete crack models in order to validate the kinematic consistency. The crack propagation of a shear plate with an initial discrete and an initial phase-field crack is compared in Fig. 1, which demonstrates the effects of unrealistic force transfer through the crack surfaces.

CONCEPT OF REPRESENTATIVE CRACK ELEMENTS

Two approaches for a consistent crack kinematic in a strain based [15] and a stress based formulation [16] are published for phase-field fracture with isotropic, linear elastic material behaviour. The concept to derive kinematically consistent crack behaviour from a discrete crack model is adopted and generalised to the computational framework of phase-field fracture with Representative Crack Elements (RCE) in Storm et al. [17]. The overall deformation behaviour of the RCE is coupled to the phase-field model by means of the variational homogenisation principle of virtual multi-scale power

$$\bar{\boldsymbol{P}} : \delta\dot{\bar{\boldsymbol{H}}} - \bar{\boldsymbol{b}} \cdot \delta\dot{\bar{\boldsymbol{u}}} \overset{!}{=} \frac{1}{V}\left[\int_{\Omega} \boldsymbol{P} : \delta\dot{\boldsymbol{H}}\, \mathrm{d}V - \int_{\Omega} \boldsymbol{b} \cdot \delta\dot{\boldsymbol{u}}\, \mathrm{d}V\right] \tag{2}$$

*Corresponding author. E-mail: michael.kaliske@tu-dresden.de.

presented by Blanco et al. [18]. Analytical solutions for the embedded RCE problem, compare Fig. 2, are derived for isotropic and anisotropic elasticity and thermo-elasticity [17], for RCE with crack surface friction and finite rotations [19] and for linear visco-elasticity [20]. Thus, these phase-field models, derived with the RCE framework, have similar computational costs like phase-field models with kinematic approximations mentioned above.

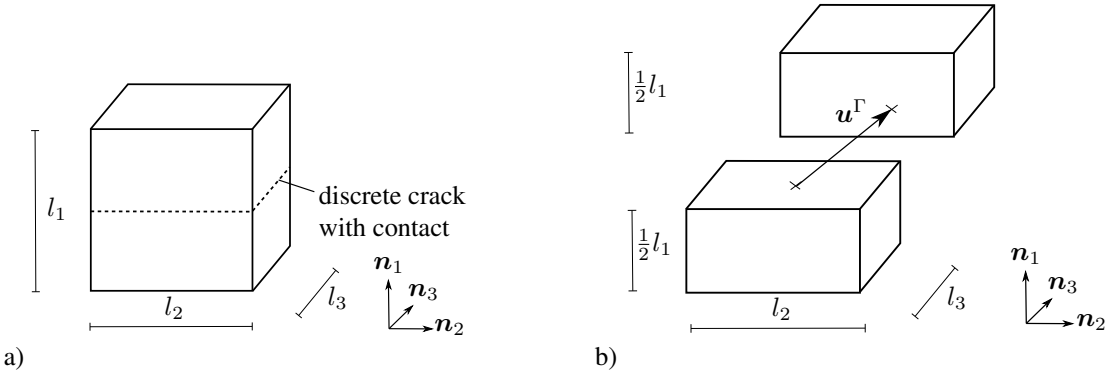

Figure 2: a) Sketch of the RCE with a discrete crack in local coordinates and b) definition of crack displacements and deformations.

In this contribution, the RCE framework is applied to geometrical and material non-linearities. A semi-analytical solution scheme for the embedded RCE problem

$$\Gamma_i(\bar{\boldsymbol{F}}, \boldsymbol{\chi}_{n+1}) = \arg\left\{ \min_{\Gamma_i \in \mathcal{R}} \; \hat{\psi}(\bar{\boldsymbol{F}}, \Gamma_i, \boldsymbol{\chi}_{n+1}) \right\}, \tag{3}$$

regarding the unknown crack deformations Γ_i, is derived, which preserves computational efficiency. The derived models are applied to self-consistency tests and representative examples are shown.

HYDROGEN INDUCED FAST-FRACTURE IN HIGH STRENGTH STEELS

Siamak S. Shishvan*[1,2], Gábor Csányi[2], and Vikram S. Deshpande[2]
[1]Department of Structural Engineering, University of Tabriz, Tabriz, Iran
[2]Department of Engineering, University of Cambridge, Cambridge CB2 1PZ, UK

Summary One of the recurring anomalies in the hydrogen induced fracture of high strength steels is the apparent disconnect between their toughness and uniaxial tensile strength in identical hydrogen environments. Here we propose, supported by detailed atomistic and continuum (Finite element) calculations, that unlike macroscopic toughness, hydrogen-mediated tensile failure is a result of a fast-fracture mechanism. Specifically, we show that failure originates from the fast propagation of cleavage cracks that initiate from cavities that form around inclusions such as carbide particles. A host of well-established experimental observations of hydrogen embrittlement are accurately predicted using the proposed fast-fracture mechanism without recourse to fitting parameters.

INTRODUCTION

While the adverse effects of hydrogen ingress on the mechanical properties of metallic alloys have long been recognized the mechanism of hydrogen embrittlement (HE), especially in steels and ferrous alloys, remains a highly controversial issue with numerous mechanisms having been proposed, e.g. [1]. The two commonly invoked mechanisms are: (a) Hydrogen Enhanced DEcohesion (HEDE) and (b) Hydrogen Enhanced Localized Plasticity (HELP). However, there exist a number of experimental observations that are not only apparently inconsistent with each other but also cannot be rationalized by the commonly proposed embrittlement mechanisms. We proceed to discuss some of these observations in order to set the background of this study. For the sake of conciseness, we restrict the discussion to very low rates of loading where the observed embrittlement is most severe.

A detailed assessment of the embrittlement of high strength steels carried out by Ayas et al. [2] confirmed that: (i) the level of hydrogen embrittlement scales with the lattice hydrogen and (ii) is independent of the hydrogen trapped in dislocations, grain boundaries or carbide particles. This is now widely recognized in the literature, i.e. the level of embrittlement scales with the diffusible hydrogen [3]. With the experimental data suggesting that embrittlement in ferritic steels scales with lattice hydrogen that typically is less than 1 appm, the mechanism by which such low concentrations of hydrogen cause embrittlement remains unclear. The main aim of the current study is to present a coherent mechanism for understanding the dependence of the tensile strength of steels in a hydrogen environment and thereby rationalize the apparent contradictions exposed in the literature.

THE HYDROGEN EMBRITTLEMENT MODEL

Detailed atomistic calculations carried out here for the effect of hydrogen on a mode-I loaded crack with a crack plane (110) and crack front direction $[\bar{1}10]$ in BCC Fe demonstrate that, consistent with findings in [4], cleavage can occur due to the presence of a crack-tip hydride with a direct competition between the rate of formation of a crack-tip hydride (and consequently the rate of crack propagation by cleavage) and crack blunting by dislocation emission. An estimate of the minimum crack velocity $v_{\text{blunt}}^{\text{crit}}$ required for preventing blunting by dislocation emission leads to the key result that a cleavage crack velocity $v_c > v_{\text{blunt}}^{\text{crit}} \approx 5.43\text{ms}^{-1}$ is required to frustrate blunting of the crack-tip by dislocation emission and allow any reasonable level of crack extension. However, when the hydrogen required to form the hydride is supplied via diffusive flux from the specimen bulk, a hydrogen-assisted cleavage crack is estimated to propagate at a speed $v_{\text{d}}^{\text{crit}} \leq 1203\mu\text{m3s}^{-1}$. Such a slow growing cleavage crack will blunt by dislocation emission and arrest after a negligible amount of crack extension. We therefore conclude that for hydrogen-assisted cleavage to occur, a mechanism is needed to rapidly supply H to the crack-tip so as to maintain a cleavage crack velocity of at-least 5.43ms^{-1}. Diffusive flux from the lattice is unable to maintain such a fast crack growth and this understanding forms the basis of the new model proposed in [5].

The overall mechanism is illustrated in Fig. 1 and comprises two stages: a hydrogen-assisted crack growth stage-A and crack growth in the absence of hydrogen supply in stage-B. These two stages can be summarized as follows:

(i) Remote loading results in the formation and growth of small cavities. These cavities form either by the expansion of pre-existing flaws or more likely by debonding of inclusions such as carbides from the surrounding matrix (Fig. 1a). Hydrogen gas (H_2) fills these cavities via diffusive flux of H from the surrounding material (Fig. 1b). Under equilibrium conditions, the H_2 gas pressure in the cavity equals the pressure p_{H} of the external hydrogen atmosphere.

(ii) The loading induces stress concentrations ahead of nanoscopic cracks/notches (associated with surface roughness) on the cavity surface. Cracks oriented along the (110) plane are very potent in initiating hydrogen-assisted cleavage due to the formation of a hydride (FeH_y where $y \approx 1-3$) over a nanometer size region at the crack-tips (Fig. 1c).

(iii) Hydrogen to form these hydrides is provided from the H_2 gas in the cavity. This is because the large crack-tip stresses reduce the barriers for the entry of H from the cavity as well as for diffusion of H in a nanometer region

*Corresponding author. E-mail: sshishvan@tabrizu.ac.ir

around the crack-tip. This implies that the crack-tip hydrides can form rapidly allowing for a hydrogen-assisted cleavage crack speed $v_c > 1003\text{ms}^{-1}$ (Fig. 1d). The key here is that this H supply route can sustain a cleavage velocity $v_c > v_{\text{blunt}}^{\text{crit}}$ and this significantly limits blunting via dislocation emission thereby allowing hydrogen-assisted cleavage to continue until the hydrogen supply within the cavity is exhausted. This is the end of stage-A. Predictions of this hydrogen-assisted crack growth mechanism are supported by atomistic calculations of binding energies, mobility barriers and molecular dynamics calculations of the fracture process.

(iv) Hydrogen-assisted fast crack growth induces a high strain-rate at the crack-tip which not only maintains a sharp crack-tip but also limits plasticity in the bulk around the crack-tip. Here, we show via macroscopic continuum (FE) crack growth calculations in a rate dependent elastic-plastic solid with fracture modelled using a cohesive zone that cleavage is possible if the crack propagates fast enough. This is because strain-rates at the tips of fast propagating cracks are sufficiently high for the drag on the motion of dislocations resulting from phonon scattering to limit plasticity. This implies that given a sufficiently high remote applied stress σ^{∞}, fast and brittle crack-growth can continue over large distances in stage-B even after the hydrogen supply within the cavity is exhausted. It is this macroscopic fast crack growth that results in the final failure of the specimen (Fig. 1e).

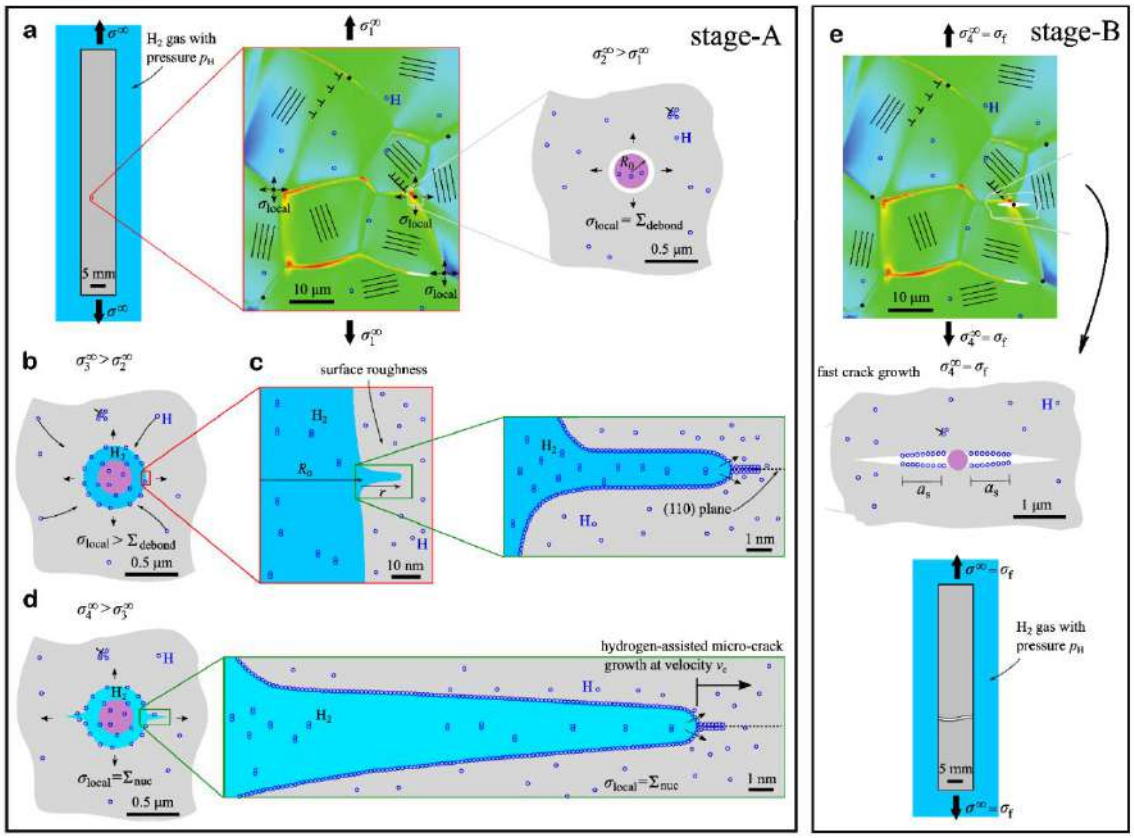

Figure 1. Summary of the overall mechanism for the tensile fracture of high strength steel in a hydrogen environment.

CONCLUDING REMARKS

The combined atomistic/continuum model developed here is used to explain a host of well-established experimental observations including (but not limited to): (i) the disconnect between the measured toughness and tensile strength of steels in identical hydrogen environments; (ii) the dependence of the level of embrittlement primarily on the lattice or diffusible hydrogen rather than trapped hydrogen; (iii) the extensive microcracking in addition to the final cleavage fracture event; and (iv) the higher susceptibility of high strength steels to hydrogen embrittlement. Moreover, our calculations point towards some critical experiments, with some counterintuitive expected findings, that have not been reported to-date: future experiments to confirm or refute these predictions will help gauge the validity of the model developed here.

THE CLEAVAGE ENERGY OF BRITTLE CRYSTALS: FROM GRIFFITH BARRIER TO LATTICE TRAPPING

Dov Sherman
School of Mechanical Engineering, Tel-Aviv University, Tel-Aviv 69978, Israel

Summary The ranges of the quasi-static and dynamic cleavage energies, Γ_0 and Γ_{DM}, of silicon crystal along two low energy cleavage systems (LECSs), were evaluated by sets of cleavage fracture experiments. An important variable in this study was found to be the gradient of the energy release rate (ERR) per unit length of crack advance, dG_0/da, denoted Θ. For $\Theta \leq 0.5$, the cleavage energy is either the Griffith barrier of $2\gamma_s$ (γ_s is the free surface energy) or lower due to stress corrosion cracking mechanisms. For $\Theta \geq 0.7$, the cleavage energy increased up to the 'lattice trapping' value of about $3\gamma_s$ for $\Theta \sim 2$. We attribute this behaviour to the way the bonds along the crack front are breaking; being curved, the crack front is actually constructed from planner atomistic scale steps, or kinks. We suggest that the cleavage energy is related to the kinks breaking sequence and energies.

We have recently completed an experimental study of dynamic crack propagation in quasi-statically loaded silicon crystal specimens where the cracks were propagated on the two LECSs, (110)[$1\bar{1}0$] and (111)[$11\bar{2}$]. These specimens served as a model material for the behavior of long range order brittle materials. The experiments were performed using our Coefficient of Thermal Expansion Mismatch (CTEM) method [1-3], where silicon specimens were adhered by two layers of epoxy resin in the middle of a rectangular hole in an aluminum loading frame, see **Fig. 1a and b**. When heating up the assembly on top of an electrical heating stage by only few centigrade, the thermal expansion coefficients mismatch between the aluminum loading frame ($26 \cdot 10^{-6}/^0$C) and silicon specimen ($2.6 \cdot 10^{-6}/^0$C) generates the required driving force to initiate and propagate the crack. Since the ERR, $G_0(a)$, is a monotonic increasing function (**Fig. 1c**), the crack propagate unstably. A significant variable in our experiments was found to be the gradient of the energy release rate (ERR) for unit length of crack advance, dG_0/da we denote Θ (in units of J/m^2/mm), which is the slope of the calibration function, $G_0(a)$. Θ in our specimens was evaluated by FEA, and is shown schematically in **Fig. 1c** for long (blue lines) and short (red lines) precracks. In specimens with long precrack Θ is low, while short precrack brings to much higher value of Θ. We were able to manipulate the precrack length in order to control Θ.

The experimental energy-speed relationships [1,2] were compared with Freund equation of motion to extract the varying cleavage energies at initiation and during propagation, denoted here Γ_0 and Γ_{DM}, respectively. We show, at first, that $\Gamma_0 = \Gamma_{DM}$, and that both Γ_0 and Γ_{DM}, are Θ dependent, namely:

$$\Gamma_0 = \Gamma_0(\Theta). \qquad (1)$$

Surprisingly, $\Gamma_0(\Theta)$ *is* independent of crack speed. Considering Freund equation of motion:

$$G_D = G_0(1-V/C_R), \qquad (2)$$

the dynamical ERR, $G_D = \Gamma(\Theta)$ during propagation, and the kinetic ERR $G_K = G_0 V/C_R = G_K(V)$, V is the crack speed. As discuss bellow, the cleavage energy depends upon Θ through atomistic bond breaking energies along the crack front, while the kinetic energy is that of particles in the entire specimen, hence during crack propagation Eq. (2) is now revised:

$$\Gamma_0(\Theta) = G_0(1-V/C_R = G_0 - G_K(V) \qquad (3)$$

The cleavage energy $\Gamma_0 \leq 2\gamma_s$ when $\Theta \leq 0.5$ J/m^2/mm in air due to stress corrosion cracking **(Fig. 2a and b)**. It significantly increases when $\Theta > 0.7$ J/m^2/mm, where the SCC mechanisms vanish, and approaching the 'lattice trapping' value for $\Theta \sim 2$ J/m^2/mm **(Fig. 2a and b)** [1,2]. Our results explain the large scatter appearing in the literature for the cleavage energy of silicon crystals of both LECSs due to possible large variations in Θ during these experiments. Therefore, following our experiments, we advise that reporting the cleavage energies should be accompanied by reporting Θ.

An important macroscopic physical occurrence in our experiments is the curvature of the crack front, as shown by confocal microscope images in **Fig. 3a to f** for cracks propagating on the two LECSs. The only topological explanation to the curvature is that it constructed from atomistic scale planar steps, or, kinks. These propagate by two major mechanisms: kink advance and kink formation, with distinct energy of propagation between the two [4] (see **Fig. 3b**).

We suggest that the macroscopic crack front curvature and the cleavage energy, and the microscopic bond breaking mechanisms and sequence in the atomistic scale, depend on the ratio between the number of kink advance to kink formation mechanisms. All are governed by the macroscopic variable Θ. For low value of Θ, the crack front is curved, while for high Θ, it is straitening up to become a straight crack front. A simple model relating the macroscopic cleavage energy to the king advance and formation energies using the rule of mixtures: $\Gamma = (1-f)\,\Gamma_{adv} + f\,\Gamma_{form}$, f being the fraction of kink formation mechanisms. Assuming $\Gamma_{adv} \sim 2\gamma_s$ and $\Gamma_{form} \sim 3\gamma_s$ explains the experimental results, where $f \alpha \Theta$.

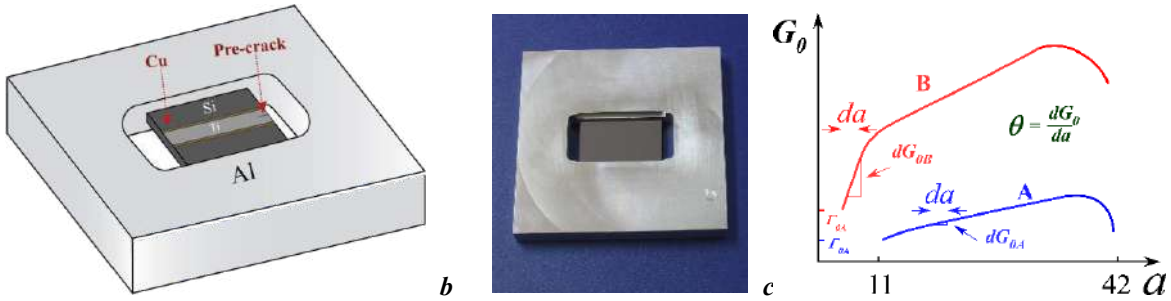

Fig. 1. ***a*** Optical picture of the loading frame and the adhered silicon specimen assembly, ***b*** schematic presentation of the assembly, and ***c*** G_0 vs. a, the calibration functions of the specimen for long precrack (blue-A) and short precrack (red-B) revealing $\Theta=dG_0/da$, the gradient of the ERR for unit length of crack advance in units of J/m^2/mm.

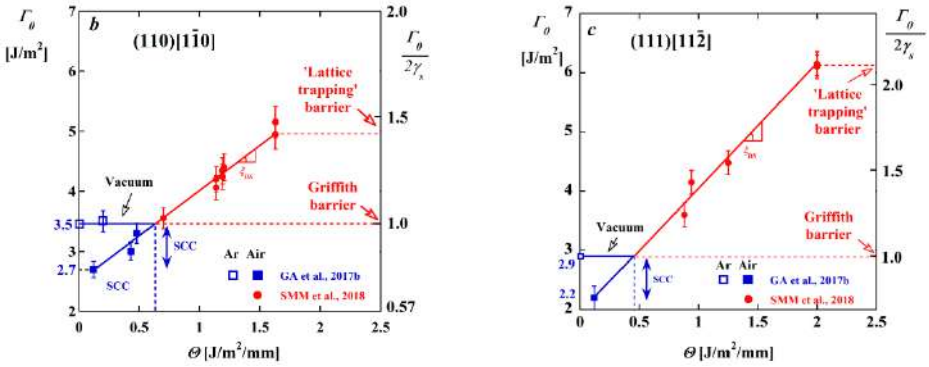

Fig. 2. The cleavage energy at initiation, Γ_0, as a function of Θ and environment for the two LECSs of silicon crystal, ***a*** (110)[1 $\bar{1}$ 0] and ***b***, the (111)[11 $\bar{2}$] [1,2]. A new material property: $\xi_{DS}=d\Gamma_0/d\Theta$ correlates the cleavage energy and the driving force.

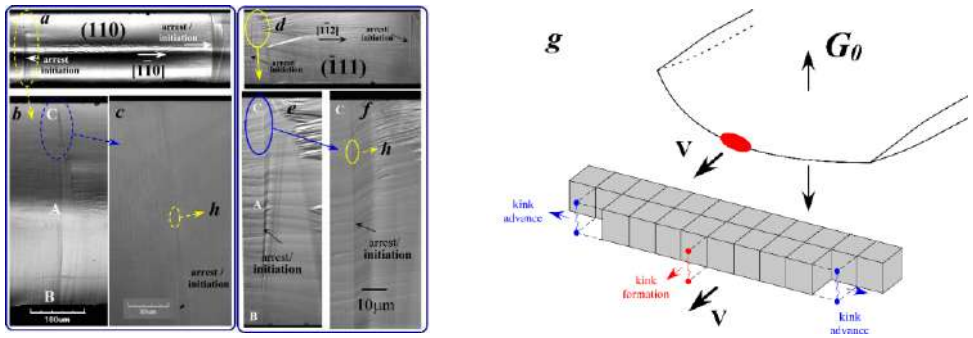

Fig. 3. Confocal optical microscope images of the fracture surfaces of silicon specimens fractured under Mode I during crack initiation, propagation, and arrest cycles: ***a-c*** The fracture surface of the (110) LECS between two initiation and arrest cycles whith varying magnifications; ***d-f*** same for the (111) LECS between two initiation and arrest cycles; ***g*** Schematic presentation of kinks: the grey cubes represents broken bonds along the crack front, while the red and blue bonds represent kink formation and kink advance mechanisms.

This investigation led to another, new material property, the dynamic free surface energy, γ_{ds}, which is considerably higher than the static one, γ_s, and is still free surface energy:

$$2\gamma_{ds}=2\gamma_{ds}(\Theta)=\Gamma_0(\Theta) \quad (4)$$

which is, in the atomistic scale, defined by the two kinking mechanisms energies: kink advance and kink formation [5].

A MICROMECHANICS-INFORMED PHASE FIELD APPROACH TO FRACTURE

Yongxing Shen*[1], Cheng Cheng [1], Yangyuanchen Liu [1]and Vahid Ziaei-Rad [1]
[1]University of Michigan – Shanghai Jiao Tong University Joint Institute, Shanghai Jiao Tong University, Shanghai, China

Summary The regularized variational theory of fracture [2], or so-called phase field approach to fracture, has gained popularity due to its ability to predict crack nucleation, propagation, and branching without extra criteria. This approach works by minimizing total energy functional with the displacement field and phase field as arguments, and eliminates the cumbersome geometric tracking. However, each of the prevailing models [4, 5] predicts a different crack path even under certain simple loadings. To obtain a new anisotropic phase field model for the unilateral constraint, we apply the homogenization theory on the representative volume element (RVE). The proposed model predicts reasonable crack paths for the three-point bending test and through-crack shear test. We will compare the prediction of our model with similar ones proposed by Strobl and Seelig [6, 7] and Steinke and Kaliske [8].

INTRODUCTION

The prediction of failure mechanisms due to crack initiation and propagation in solids is of great significance for engineering applications. Griffth's theory [1] provides a criterion for crack propagation but it is unable to predict crack initiation, merging, and branching. Based on the Griffth's theory [1], Francfort and Marigo [2] proposed a variational theory of fracture and Bourdin et al. [3] regularized this theory, the outcome of which is then the phase field approach to fracture. As is shown in Figure 1, this approach works by minimizing total energy functional with the displacement field and phase field (0=intact material, 1=crack) as arguments, and eliminates the cumbersome geometric tracking compared with traditional discrete crack methods such as the extended finite element method.

The phase field modeling of brittle fracture has shown its advantages on simulating complex fracture processes, see [3, 4, 5]. Nevertheless, the original model proposed in [3] adopts an isotropic response of the cracked solid, i.e., it assumes both tension and compression loads can contribute to cracking, leading to unphysical crack propagation under a compressive load. Early models that do distinguish tension vs. compression were those proposed in [4] and [5]. Amor et al. [4] built their model based on the volumetric-deviatoric split of the strain tensor, while Miehe et al. [5] based their model on the spectral decomposition of the strain tensor. Recently, more sophisticated models based on the local crack orientation were proposed. For example, in the model by Strobl and Seelig [6, 7], the crack orientation is assumed to coincide with the local gradient direction of the phase field, while in that by Steinke and Kaliske [8], a crack coordinate system is defined and is changeable, and the split is based on the decomposition of the stress tensor with respect to the crack orientation. Wu et al. [9] utilized a positive/negative projection based on the spectral decomposition to model the unilateral behavior, where the crack orientation is assumed to be the principal direction of the effective stress tensor.

In 2018, Cheng [10] and Cheng and Shen [11] proposed a phase field model with the tension-compression split and local crack orientations through the homogenization of cracked microstructures. Storm et al. [12] constructed a homogenization framework for their phase field model in a similar way.

In this work, we aim to construct a phase field strain energy density expression that is: (a) variationally consistent, (b) able to distinguish the loading as tension or compression and appropriately degrade the stress-strain response, and (c) is three-dimensional.

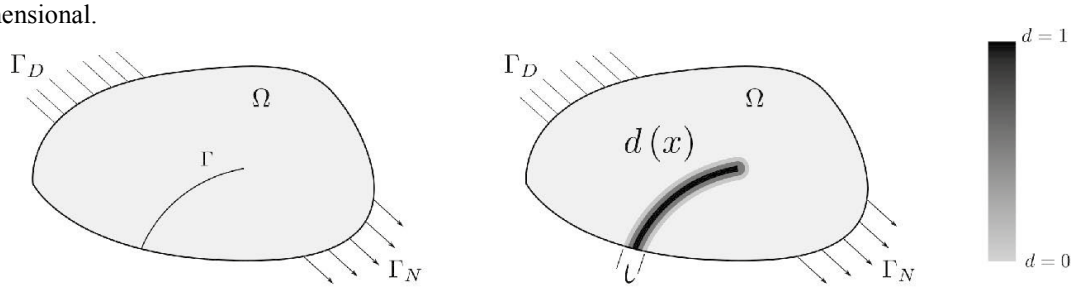

Figure 1. Comparison of a sharp crack and its phase field representation. The left figure illustrates the sharp crack model; the right figure shows the phase field representation of the crack through a smooth transition area, in which the phase field variable is between 0 and 1. The phase field is one of the arguments in the regularized variational theory of fracture, also named the phase eld approach to fracture.

CONSTRUCTION OF THE PROPOSED PHASE FIELD MODEL

Essentially we model a possibly curvilinear crack as a collection of fictitious small straight cracks with a particular spatial distribution. More precisely, we assume that a portion of the solid can be divided into many cube-shaped subdomains (or in 2D square-shaped), at the center of each of which there exists a said small plane (or in 2D straight crack). The behavior of the macroscopic crack is then described by the collection of such small cracks, see Figure 2. Here we borrow a terminology of the homogenization theory and call each cube-shaped subdomain a representative volume element (RVE), and will apply standard homogenization techniques to extract its response subjected to mechanical loading.

In a nutshell, we will establish a one-to-one relation between the crack length in the RVE and the local phase field d. Then for any macroscopic input strain $\bar{\boldsymbol{\varepsilon}} \in \mathbb{R}^{\eta\times\eta}(\eta = 2,3)$ with standard homogenization technique, we calculate the average stress $\bar{\boldsymbol{\sigma}} \in \mathbb{R}^{\eta\times\eta}$, and then obtain $\mathbb{C} \in \mathbb{R}^{\eta\times\eta\times\eta\times\eta}$ such that $\bar{\boldsymbol{\sigma}}(\bar{\boldsymbol{\varepsilon}}, d) = \mathbb{C}(\bar{\boldsymbol{\varepsilon}}, d) : \bar{\boldsymbol{\varepsilon}}$, where $\mathbb{C}$ is the effective secant modulus. The expression of $\mathbb{C}(\bar{\boldsymbol{\varepsilon}}, d)$ can be obtained by comparing with analytical expressions or by numerical fitting. This way the strain energy density $\Psi(\bar{\boldsymbol{\varepsilon}}, d)$ can also be obtained.

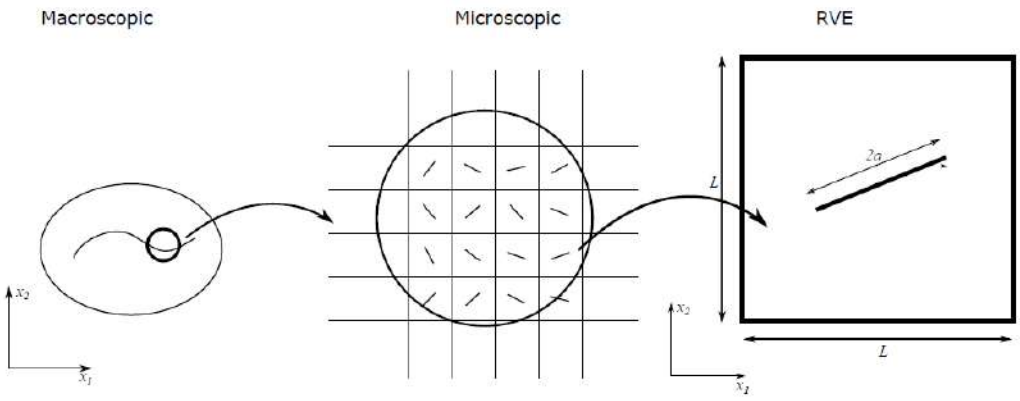

Figure 2. Modeling a macroscopic crack as a collection of fictitious small straight cracks, each in an RVE.

CONCLUSIONS

We have proposed a micromechanics-informed phase field model whose macroscopic constitutive relationship is fully determined by the fictitious microstructure. This model enjoys the following features:

1. The proposed model is the only that outputs a reasonable stiffness response and crack path among the models compared.
2. The performance is achieved via the introduction of a tension-compression discriminant that gives the correct behavior, namely whether the response should be degraded by the phase field.
3. The model can be expressed in terms of invariants and pseudo-invariants of the strain tensor, and hence easy to generalize to an arbitrary crack orientation and to three-dimensions.

FRACTURE TOUGHNESS OF SELF-SIMILAR HIERARCHICAL MATERIAL

Michael Ryvkin*[1], Puneet Kumar [1], and Leonid Kucherov [1]
[1]School of Mechanical Engineering Tel Aviv University, Tel Aviv, Israel

Summary The brittle fracture of the two-dimensional materials with a self-similar second-order hierarchy is considered. The microstructure with four-fold cubic symmetry is generated by a periodic system of macro- and microvoids in a homogeneous isotropic parent material. A semi-infinite crack terminates in a void, and the fracture toughness is determined in the framework of critical stress criterion. The analysis addresses a rectangular domain with hundreds of repetitive cells, which subjected to the K-field boundary conditions. The computationally expansive analysis of the domain is reduced to the multiple analysis of the single repetitive cell by the use of the discrete Fourier transform. A parametric study is carried out, and, in particular, the influence of parent material redistribution between the hierarchical levels is examined.

ANALYSIS

One of the design principles for the development of new materials with the desired mechanical properties is employing the structural hierarchy. The influence of the structural hierarchy on the bulk material properties has been much studied, while the fracture behavior of hierarchical materials is not entirely understood. A possible reason is serious computational difficulties arising in the modeling of a multiscale fracture phenomenon in a multiscale hierarchical material. The present work suggested a way to overcome these difficulties by employing the finite element method in conjunction with the representative cell approach based on the discrete Fourier transform.

Consider two-dimensional material with second-order self-similar hierarchical microstructure generated by periodic voids with the four-fold rotational symmetry. Two materials types are addressed. In material A macrovoids in a solid parent material filled with microvoided material generated from the same parent one, while in material B (see Fig. 1), the macrovoids are cavities surrounded by the microvoided material. The translational symmetry on the macro- and microscale is defined by the values L and l, respectively. The fracture toughness problem is formulated for a square

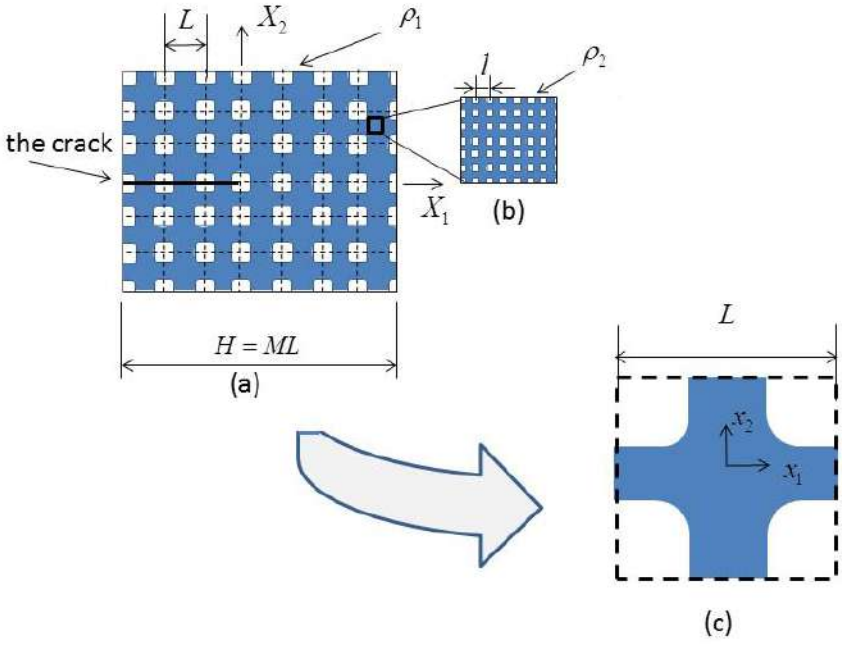

Figure 1: Analysis scheme for material B. (a) The analysis domain on a macrolevel with homogenaized microvoided constituent; (b) microvoides layout; (c) representative cell with the local coordinate system.

*Corresponding author. E-mail: ryvkin@tauex.tau.ac.il

domain $-H/2 \leq X_i \leq H/2, i = 1, 2$ with embedded crack subjected to K-field boundary conditions at its boundaries, and the critical maximal stress criterion for crack propagation is adopted. The number of repetitive cells in the domain must be sufficiently large so that the near tip stress field becomes insensitive to the domain size, and, consequently, corresponds to the case of a semi-infinite crack.

The remote K-field is calculated after evaluation of the effective elastic moduli of the hierarchical material, and then the problem where the microvoided material is replaced by the homogenized one is considered. It is resolved by the representative cell method [1,2]. To this end, the domain is viewed as an assemblage of repetitive cells, which perfectly bonded everywhere except the crack region. The finite discrete Fourier transform is applied, and the problem for the domain is reduced to the problem for the representative cell $-L/2 \leq x_i \leq L/2, i = 1, 2$ with the boundary conditions of Bloch-Floquet type. The numerical experiments have shown that in order to model a semi-infinite crack, one has to consider the domain including at least $M = 20$ cells along its boundary. Consequently, the number of degrees of freedom, which was addressed in the present analysis, is 400 times less than for the direct numerical simulation approach. After the solution of the representative cell problem by the finite element method, the displacements and stresses in any point of the domain are determined by the inverse discrete Fourier transform formula. Finally, the problem for the near tip zone with the actual microvoids layout is considered with the boundary conditions derived from the stress field obtained at the previous analysis step. The obtained maximal stress value yields the fracture toughness magnitude K_{IC} in terms of the critical rupture stress of the parent material σ_f.

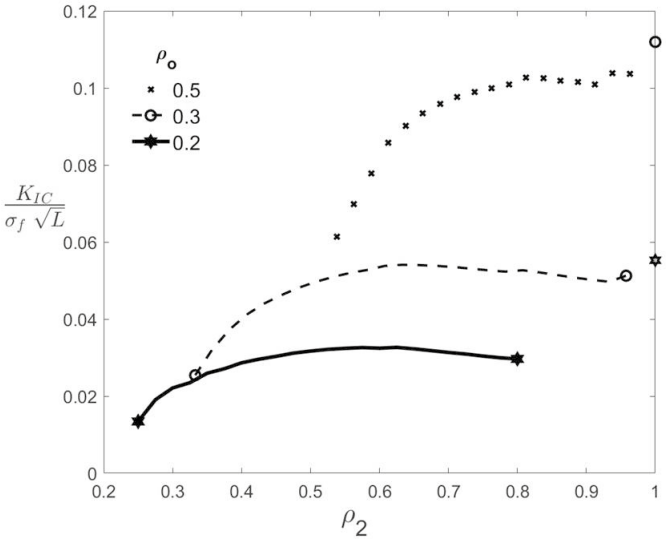

Figure 2: Dependence of the normalized fracture toughness upon the relative density on the microlevel ρ_2 for different values of the fixed total relative density $\rho_0 = \rho_1\rho_2$ (ρ_1 denotes macrolevel density - see Fig. 1). The values for the non-hierarchical voided materials with $\rho_2 = 1$ are shown for the reference.

RESULTS

The influence of parent material redistribution between the hierarchical levels on the fracture toughness was investigated. It was found that for material A growth of the relative density at the second hierarchical level (microdensity) accompanied by the macrovoids increase and microvoids decrease causes monotonic fracture toughness reducing, while for material B, the effect is opposite. It takes place for low and medium microdensity values, then the fracture toughness becomes insensitive to the material redistribution and depends upon the total relative density of hierarchical material only (see Fig. 2).

A comparison of the fracture toughness of the hierarchical and non-hierarchical voided materials of the same relative density shows that introducing hierarchy may have either a positive or negative effect. The final result is determined by the relation between two opposite tendencies: the toughness decrease due to the stress concentration in a material with more complicated microstructure and possible toughness increase due to an increase of the material periodicity length scale.

HETEROGENEOUS DYNAMIC FRACTURE: AMPLITUDE SCALING OF CRACK FRONT DEFORMATIONS

Thibault Roch[1] and Jean-François Molinari*[1]
[1]Civil Engineering Institute,Institute of Materials Science and Engineering,Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Summary We study numerically the deformation of a dynamic crack propagating through a planar heterogeneous interface. We investigate the evolution of the front shape due to variations of fracture toughness, represented by weak and strong stripes parallel to the rupture direction. When going from homogeneous to heterogeneous properties, the crack enters a transient regime during which the front evolves from a straight configuration to a sinusoidal shape. This process is governed by crack front waves that decay with time. Following this regime, the front reaches a stationary shape whose amplitude is determined by the heterogeneity size, the toughness variation between heterogeneities, the relative contraction of the process zone, and the process zone elasticity. We propose a unique scaling relation for the front amplitude that we support with an extensive parametric study.

The slow propagation of cracks through homogeneous media is quite accurately described by the Linear Elastic Fracture Mechanics framework. Dynamic rupture propagation, however, and in particular its interaction with material heterogeneities, remains still overlooked. In this study, we focus on the crack front perturbation due to the presence of local variation of toughness for a planar crack under mode II loading. Previous studies on front distortion, using the Rice perturbation approach ([1]) which is based on the weight function theory introduced by [2], consider the crack front as a one-dimensional object. However recent results highlight the importance of the fracture process zone size (the length along which damage is spread ahead of the crack tip) and its variation with crack velocity for dynamic heterogeneous fracture. We therefore investigate the complete dynamics of a planar heterogenous fracture, by accurately modeling the crack as a two-dimensional object including the process zone. For this purpose, we take advantage of a spectral boundary integral method coupled with a cohesive model model, which allows us to model efficiently the full dynamics with a good resolution of the damage zone. The heterogeneous interface behaves following a standard slip weakening law. The variations of properties consist of an alternation of weak and strong (in terms of fracture toughness) stripes parallel to the crack propagation. When entering this heterogeneous field of toughness, the shape of the crack front is altered. It evolves from a straight line to a sinusoidal shape during a transient regime. We show evidence that this regime, which features oscillations of the crack front shape, is dominated by the propagation of crack front waves. These waves decay exponentially in time and the front tends toward an equilibrium shape after this initial regime. We show that the amplitude of this sinusoidal profile is directly controlled by the rupture properties as well as the interface and bulk parameters. More specifically, the deformation amplitude scales with the heterogeneity size, the contraction of the process zone related to dynamic crack propagation, the process zone elasticity, and the variation of toughness. We validate these relations by providing evidence of a collapse of measured amplitudes, computed for various set-up, into a master curve depending only on physical parameters, without the need for fitting variables. This scaling illustrates the relevance of the process zone size as one of the controlling parameters related to dynamic front distortion. Similarly to evidence from previous studies [3], [4] that heterogeneities in the direction of the crack propagation only matters if their dimension is comparable to the size of the process zone size, we show that for small heterogeneities compared to the size of the process zone, the front perturbation is negligible. Although the interface used in this study is a regular and simplified heterogeneous pattern, it offers new insights into the underlying physical mechanisms behind the deformation of a crack front.

COMPUTATIONAL FRACTURE MECHANICS ANALYSIS OF TRANSIENT CREEP-FATIGUE CRACK GROWTH IN NICKEL-BASE SUPERALLOYS

Joshua D. Pribe*[1], Thomas Siegmund[1], and Jamie J. Kruzic[2]
[1]School of Mechanical Engineering, Purdue University, West Lafayette, Indiana 47907, USA
[2]School of Mechanical and Manufacturing Engineering, UNSW Sydney, Sydney, NSW 2052, Australia

Summary Creep-fatigue crack growth is a key failure mechanism in nickel-base superalloys at high temperature. While many crack growth laws have been developed for constant-amplitude and hold-time loading, load transients such as overloads must also be considered. The crack growth rate after load transients at high temperature can depend on the material and active damage mechanisms in a more complex manner than at low temperatures. In this study, a computational fracture mechanics model is used to investigate creep-fatigue crack growth following overloads. The results indicate that the presence of a classical retardation effect after the overloads depends strongly on the extent of viscoplastic deformation in the bulk material. In some situations, retardation is nearly absent. Further, hardening due to plastic strain gradients is shown to be important in predicting post-overload behavior.

INTRODUCTION

Realistic load spectra for engineering components include load transients, such as overloads and multi-step block loading. The effect of these transients on subsequent crack growth rates must be considered when predicting component lifetimes. This is particularly true for components expected to operate in an environment where they cannot be readily accessed for testing or replacement, such as nuclear power plants.

The current study is motivated by high-temperature crack growth experiments on two nickel-base superalloys that show seemingly contradictory behavior in steady-state versus post-overload crack extension. First, alloy 718 is a legacy alloy that is widely used in aerospace and land-based gas turbine engines. It exhibits creep-brittle behavior during crack extension, which is associated with environmental attack ahead of the crack tip and high crack growth rates relative to the expansion of the plastic zone. However, the material responds in a more ductile fashion following overloads, with notable crack growth retardation [1]. Second, alloy 617 has been proposed for use in the intermediate heat exchanger in the very high temperature nuclear reactor design. It exhibits creep-ductile behavior, meaning that substantial viscoplastic deformation accompanies high-temperature crack growth. However, this alloy seems to exhibit more brittle behavior following overloads, as a single overload does not produce any measurable retardation. Blocks of ten or more overloads do produce retardation, but this becomes less significant at higher loads [2].

This apparent contradiction is investigated in this study using finite element computations that combine viscoplastic constitutive material models and a cohesive zone model. In the computations, creep-fatigue crack growth emerges as the outcome of interactions between these model components. Two key research questions are addressed using this computational fracture mechanics model. First, how can the concepts of creep-ductile and creep-brittle materials be applied when load transients like overloads occur? Second how does hardening due to plastic strain gradients affect these outcomes? The predicted crack growth rates and crack-tip fields before, during, and after overloads provide insight into the differing behaviors of each alloy.

MODEL APPROACH

A power law viscoplasticity model is used for the bulk material. The model accounts for both statistically-stored dislocations (SSDs, associated with strain hardening) and geometrically-necessary dislocations (GNDs, associated with plastic strain gradients) in the material flow stress. GNDs are neglected in classical plasticity models, but they can significantly enhance hardening in regions of highly nonuniform plastic deformation, such as the crack-tip plastic zone [3]. Crack propagation is modeled using an irreversible cohesive zone model. Damage evolution equations for fatigue and creep allow subcritical crack growth under cyclic and hold-time loading to occur.

The incremental finite element model used in this study allows arbitrary waveforms to be discretized into a series of load steps. In this way, the model captures the evolution of crack-tip fields under both steady-state and transient loading, with crack extension as an outcome of the boundary value problem. This approach goes beyond correlations with conventional fracture mechanics parameters, providing more insight into both the crack extension and bulk deformation processes.

RESULTS AND CONCLUSIONS

The computational fracture mechanics model is first calibrated to the constant-amplitude and hold-time crack growth experiments for both alloys to demonstrate suitability of the model. Then, a parametric study is undertaken to understand how the viscoplastic deformation in the bulk, under hold-time and block-loading waveforms.

*Corresponding author. E-mail: jpribe@purdue.edu

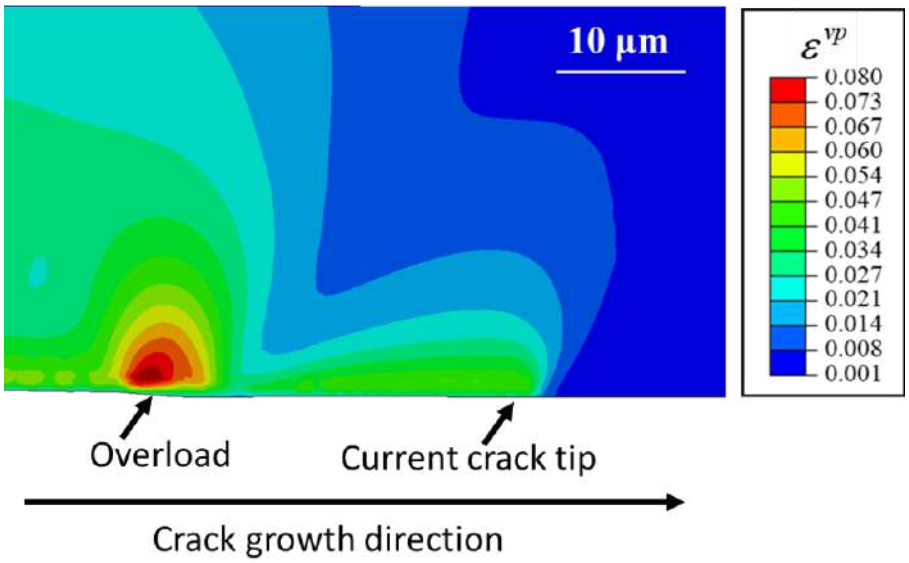

Figure 1: Equivalent viscoplastic strain contours for a computation of creep-fatigue crack growth in creep-brittle alloy 718 involving constant-amplitude cyclic loading interrupted by an overload. Due to symmetry, only half of the model is shown, with crack growth occurring along the symmetry line. Note the significant increase in viscoplastic strain near the location of the overload, followed by a region where crack growth retardation occurs while the steady-state plastic zone redevelops.

For creep-brittle materials like alloy 718, the small viscoplastic strains under constant-amplitude or hold-time loading do not significantly influence crack extension—energy dissipation associated with material separation dominates over the irreversible viscoplastic deformation in the bulk. However, overloads significantly increase the viscoplastic strain ahead of the crack tip, leading to compressive residual stresses that reduce the subsequent crack growth rate. The material separation process therefore becomes significantly affected by the overload-induced viscoplastic deformation, unlike in the steady-state crack growth regime. The differing viscoplastic strains during constant-amplitude loading and following an overload are shown in Figure 1.

On the other hand, for creep-ductile materials like alloy 617, a crack growing in steady state is embedded deep within an extensive plastic zone. Here, a single overload does not appreciably change the viscoplastic strain distribution ahead of the crack tip. This leads to the lack of crack growth retardation observed in the experiments. A larger number of overloads applied in a block does sufficiently increase the viscoplastic strains and thereby produces retardation.

Finally, hardening due to plastic strain gradients is also shown to play an important role in the development of the overload plastic zone, especially in the creep-brittle case. By restricting viscoplastic deformation, plastic strain gradients tend to mitigate crack closure and residual compressive stress ahead of the crack tip. The subsequent crack growth retardation is reduced compared with predictions using a classical plasticity model.

In summary, the key conclusions include the following. For creep-brittle materials, material separation dominates the response during steady-state crack growth, but interaction with viscoplasticity in the bulk material becomes important following overloads. For creep-ductile materials, there is significant viscoplastic deformation in the bulk material during steady-state crack growth, but a single overload does not sufficiently perturb the crack-tip fields to alter crack growth rates. Finally, neglecting plastic strain gradients renders the model predictions non-conservative, particularly during transient crack growth.

MODELLING OF MATERIALS SELF-HEALING AS CRACKS BRIDGED ZONES FORMATION

Mikhail Perelmuter *
Ishlinsky Institute for Problems in Mechanics RAS, Prospect Vernadskogo 101-1, 119526, Moscow, Russia

Summary The process of materials self-healing is considered as kinetic formation of bridged zones of cracks. In the crack bridged model it is assumed that the tractions that prevent a crack opening reduce the stress intensity factors, but the stress singularity at the crack tip is preserved. As the main characteristic of cracks self-healing efficiency is used the decreasing of the stress intensity factors as the crack bridged zone is formed . The mathematical background of the problem solution is based on the singular integral-differential equations. The analysis of the cracks self-healing processes at the different materials interface with the adhesive layer having the effect of self-healing is presented.

INTRODUCTION

Materials with self-healing properties can be used to avoid premature destruction of devices and to guarantee their stable long-term mechanical reliability. During the last decades wide range of self-healing materials (metals, polymers, ceramics, composites) have been developed. The analysis of various factors' influence on materials self-healing processes is necessary for increasing efficiency of these material application. In many cases the experimental investigations can be extremely long and labor-consuming. It is possible to mark out three basic stages of materials self-healing process: 1) formation and growth flaws/cracks under external loading; 2) activation of self-healing mechanisms; 3) healing of flaws/cracks with partial or total restoration of bonds between crack surfaces. Experimental results have been obtained at each of these stages, but physical-mechanical models and numerical techniques of cracks self-healing have only started to develop in the last decade. Known techniques are based, mostly, on the using of cohesive models in the framework of finite elements method. In this paper we use the bridged crack model (in this model it is assumed that the stress intensity factors do not vanish at the crack tip) for the efficiency evaluation of materials self-healing. The process of materials self-healing is considered as kinetic formation of bridged zones of cracks over time.

KINETIC MODEL OF BRIDGED ZONE FORMATION

Interface crack bridged model. It is assumed within of this model that [1]: 1) a zone of weakened bonds between materials is considered as an interfacial crack with distributed nonlinear spring-like bonds between the crack faces (bridged zone); 2) distributed bridging traction, which are functions of a crack opening, are imposed to the crack faces at the bridged zone; 3) materials ahead of the crack tips are considered as linearly-elastic; 4) the total stress intensity factor (due to the action of the external loading and the bridging tractions) is not zero; within the bridged model (in contrast to cohesive models) a stress singularity is accounted at the crack tip. To describe mathematically the interaction between the crack surfaces, we assume that the nonlinear deformation law of bonds between the surfaces of the crack at the bridging zone is given. The tractions appeared in the bonds between the interface crack surfaces under the external loads action have the normal q_n and tangential q_τ components, $\sigma = \sqrt{q_n^2 + q_\tau^2}$ is the modulus of the traction vector. The surfaces of the crack are loaded by the normal and tangential stresses, which are numerically equal to these components of the tractions. The relations between bonds tractions and displacements difference of the upper and lower crack surfaces at the crack bridged zone are used in the following generalized form [1] $u_{n,\tau}(x) = C_{n,\tau}(x,\sigma)\ q_{n,\tau}(x)$ where $u_{n,\tau}$ and $q_{n,\tau}$ are the components of traction vector and crack opening in the local coordinate system connected with the normal n and tangential τ directions to the crack surface and $C_{n,\tau}(x,\sigma)$ are the bonds compliances depending on the distance x from the crack tip, σ is the tractions vector modulus at the current point x.

Stresses analysis. The stresses at the interfacial crack bridged zone are analyzed for the given nonlinear bond deformation law and with accounting for bonds kinetic destruction (on the stage of a crack formation) or bonds kinetic restoration (on the stage of a crack self-healing). The bonds destruction kinetic model is the alliance of the Zhurkov's fluctuation model and the interface crack bridged model [2]. The kinetic model of bonds restoration is presented below, see also in [3]. The mathematical background of the bridged stresses analysis is the singular integral-differential equations (SIDE) [1] and the boundary element methods [4]. The stress intensity factors (SIF) for the bridged interfacial crack in 2D problem can be written due to the linearity of the problem in the following complex form as in [1]

$$K_{\rm I} + iK_{\rm II} = (K_{\rm I}^{ext} - K_{\rm I}^{\rm int}) + i(K_{\rm II}^{ext} - K_{\rm II}^{\rm int})\,, \quad K = \sqrt{K_I^2 + K_{II}^2}, \quad i^2 = -1; \tag{1}$$

where $K_{I,II}^{\rm ext}$ and $K_{I,II}^{\rm int}$ are the SIFs caused by the external loads and bonds stresses, K is SIFs modulus (MSIF). SIFs for an interface crack in (1) are calculated accounting the stresses ahead of the crack tip due to the external loads and the bonds stresses at the crack bridged zone. If the bonds properties dependent on time, then these SIFs also are time-dependent.

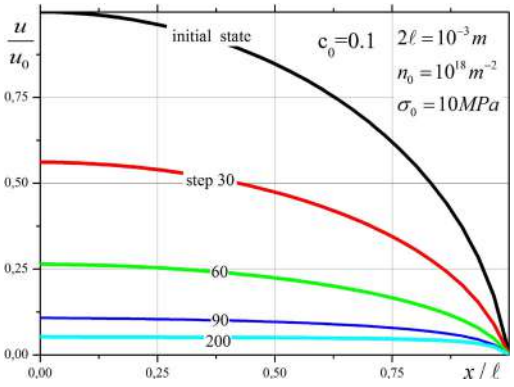

Figure 1: Decreasing of the crack opening during self-healing process, totally filling of a crack with a healing material, $d = \ell$.

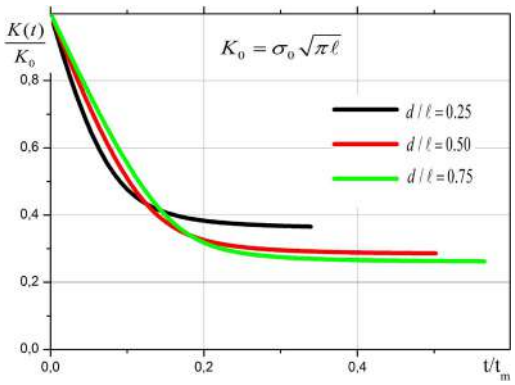

Figure 2: Bonds restoration effect. The relative MSIF versus time, different bridged zones sizes.

Kinetic of bonds restoration. The restoration of bonds inside of cracks (bridged zone formation) is considered on the basis of fluctuation kinetic model. We assume that the increasing in the density of bonds between the crack faces over time $n_h(x,t)$ is governed by the first-order kinetic equation [3]

$$\frac{dn_h(x,t)}{dt} = \frac{n_0 - n_h(x,t)}{\tau_h(x,\sigma)},\ \tau_h(x,\sigma) = \psi(x,\sigma)A(T),\ \psi(x,\sigma) = \frac{\sqrt{u_x^2(x,t) + u_y^2(x,t)}}{H},\ A(T) = \tau_0 \exp\left(\frac{U_h}{RT}\right), \tag{2}$$

Here n_0 is the maximum of bonds density between crack faces, τ_h is the characteristic time of bonds healing ($1/\tau_h$ is the healing rate) is defined by the Arrhenius type relation, $\tau_0 = \alpha h/kT$ is the characteristic time, h is Planck's constant, k is the Boltzmann constant, T is absolute temperature, α is a dimensionless coefficient depending on the material type (polymer, metal, or ceramics), U_h is the energy of bonds healing activation, R is the gas constant, H is a linear scale related to the thickness of the intermediate layer adjacent to the interface. Dimensionless function $\psi(x,\sigma)$ is introduced into (2) to define the dependence of bonds healing time on the distance to the crack tip and the external load. The solution of first equation in (2) (at the initial condition $n(x,0) = 0$) gives increasing bonds density between the crack faces over time [3]. The increasing in the bond density leads to the bonds compliance decreasing at the crack bridged zone. The crack bridged zone formation is modelling by means of bonds compliance variation over time. The system of SIDE is solved by the time-steps scheme as in [2]. The bond compliances at each time step depend on the density of bonds over the bridged zone. The decreasing of the stress intensity factors over time is used as the measure of the healing effect.

RESULTS OF MODELLING AND CLOSING

The proposed approach for cracks self-healing modelling has been used for several problems analysis. Specifically, a straight crack at the interface between different materials was considered. It was assumed that the adhesion layer between material has self-healing ability and at the initial time instant (when the crack surfaces are free of constraints) some healing process is activated inside of the crack, bonds between the crack surfaces are built (the crack bridged zone formation is started). The numerical calculations were performed for plane strain conditions and the elastic constants of the stainless steel-polymer junction, see details in [3]. During the self-healing process the initial crack opening without bonds considerably decreases due to bonds formation. For example, this decreasing is about $u/u_0 \approx 0.05$ at the crack center, for the restored bonds density up to $n(x,t) = 0.95n_0$ after 215 time-steps, see Fig. 1. The next part of calculations was performed for different lengths of crack parts filled with healing agent (bridged zones, d). If only the crack quarter length is involved in the self-healing process then the materials interface strengthening (decreasing of the MSIF) is reasonable in comparison with the cases $d/\ell = 0.5$ and $d/\ell = 0.75$, see Fig. 2.

The results of computations allow to estimate the MSIF decreasing due to bonds restoration over time. Since the computational parameters strongly depend on the initial data (which is caused by the exponential dependence in formula (2)), the comparative analysis of different self-healing methodology can be the major practical application in this model. The determination of the model parameters together with validation of the model will allow us to apply this model to analysis processes of self-healing in polymers, ceramics, metals and theirs joins.

HIGH CYCLE FATIGE PROPERTIES OF MEDICAL IMPLANT GRADE NITINOL

Robert M. McMeeking*[1,2,3]

Summary It is claimed that increasing the mean strain *increases* the fatigue life of Nitinol. To investigate this, cyclic bending tests were carried out on medical grade Nitinol at 37°C up to 400 million cycles at various mean strains. A constant life model was developed having 90% reliability at 95% confidence. The result is monotonic yet nonlinear for lives of 400 million cycles. We find that the strain amplitude limit *at zero mean strain* is 0.52% for a 400 million cycle life; however, to achieve the same life for a 3% or more mean strain, *the required strain amplitude limit is decreased* to 0.16%. For mean strains from 3% to 7%, the strain amplitude limit that allows a 400 million cycle life is ~0.16%, and essentially independent of mean strain. We conclude that the debatable claim that an increase in the mean strain can increase the fatigue life of Nitinol is not supported by our data.

FATIGUE OF NITINOL MEDICAL IMPLANTS

Nitinol is an alloy of almost equal fractions of nickel and titanium that is a shape memory material, but, within a specific temperature range, also has superelastic properties, in which strain induced transformation from austenite to martensite and back leads to a hysteresis loop in the stress strain behavior. In medical implant grade Nitinol the austenite start and finish temperatures and the martensite start and finish temperatures are designed so that the resulting superelastic stress strain hysteresis loop is closed at body temperature upon straining beyond the hysteresis loop followed by return to zero strain [1]. This permits the superelastic properties to be exploited for transcatheter delivery of implants. For example, Nitinol vascular stents, prosthetic heart valves with tissue leaflets and a Nitinol annulus, and clot-trapping inferior vena cava filters made from Nitinol are all squeezed into narrow sheaths, delivered through a catheter to the implant location, and then pushed out to expand towards their design shapes, thereby firmly locating themselves in the vasculature [1]. In all of the implants mentioned, the metal component experiences cyclic strain after implantation. The expansion and contraction of the heart tends to bend coronary artery stents. The design of prosthetic heart valves typically involves bending of stent posts that support the leaflets when the valve is closed during diastole. The inferior vena cava is squeezed during breathing such that its width expands and contracts, doing so to a degree that has been measured to be as high as a 9 mm change for a 35 mm wide vein. As a consequence of all of these situations, the fatigue properties of medical implant grade Nitinol are of great significance. In 10 years, one breathes more than 80 million times, and one's heart beats over 300 million times, making implant fatigue durability imperative.

ENDURANCE LIMIT OF NITINOL

The endurance limit for medical implant grade Nitinol, defined as 10 million cycles of completely reversed strain cycling without fracture, has been measured as anywhere from 0.2% alternating strain to 0.8% alternating strain, although the latter figure is for electropolished material that is laser-cut from tubes [2]. (Fatigue properties of Nitinol are always quoted in alternating strain due to the strain induced austenite-martensite phase transformation that makes fatigue properties ambiguous when stated in terms of stress.) The austenite-martensite phase transformation in Nitinol is thought to cause the Goodman diagram, a plot of the alternating strain versus mean strain at a fixed lifetime, to be non-monotonic. In some ranges of mean strain the endurance limit in terms of alternating strain is thought to increase with mean strain, an effect that is attributed to martensite, being harder, and having better fatigue resistance than austenite. The outcome is that in the literature there are Goodman diagrams for Nitinol with multiple non-monotonic features [2]. The situation is further complicated by the fact that fatigue testing of medical implant grade Nitinol, other than by use of rotating bend specimens, is a challenge given the small diameter wire and thin tubular material that is used in devices. As a consequence, fatigue testing is often carried out through use of specimens that have configurations similar to the implants, such as the diamond shaped lattice units that are common features in vascular stents and heart valve rings [3]. Unfortunately, in the case of the diamond lattice unit cell specimen the strains being experienced by the material has to be analyzed and interpreted through finite element calculations. Even though state-of-the-art superelastic constitutive laws, such as that due to Auricchio and Taylor and improvements upon it, are used in these computations, inaccuracies in the estimates of strain occur. As a result, the fatigue properties of medical implant grade Nitinol that have been established are quite inaccurate.

FATIGUE TESTS OF NITINOL

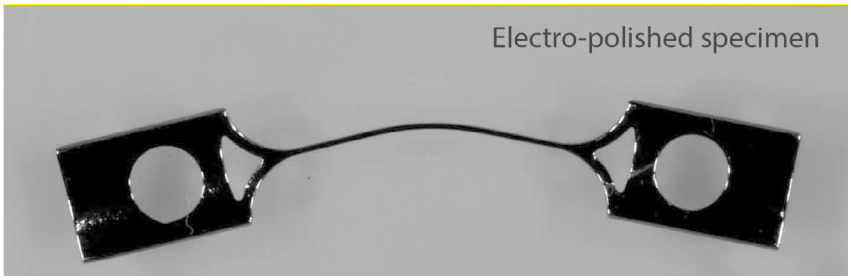

Figure 1. *C-shaped electro-polished Nitinol fatigue test specimen.*

Through use of a simpler, C-shaped specimen that enables the identification of strain levels more easily and more accurately, and via simpler finite element simulations that avoid the complex analysis necessary for specimens such as the diamond lattice unit cell, we have re-measured and re-evaluated fatigue data for medical implant grade Nitinol [4]. The C-shaped specimen is illustrated in Figure 1, and is deformed by compression of one end toward the other to establish a state of mean strain, followed by compression/extension deformation for up to 400 million cycles. In addition, prior to fatigue testing, the specimen is put through one severe cycle of compression and re-extension to simulate insertion into the delivery catheter. Every combination of mean and cyclic strain utilized in the fatigue tests is analyzed individually by finite element analysis to ensure as much accuracy as possible. In addition, the finite element solutions are validated by comparison with load deflection data for the C-specimen, augmented by measurements of strain by digital image correlation.

RESULTS

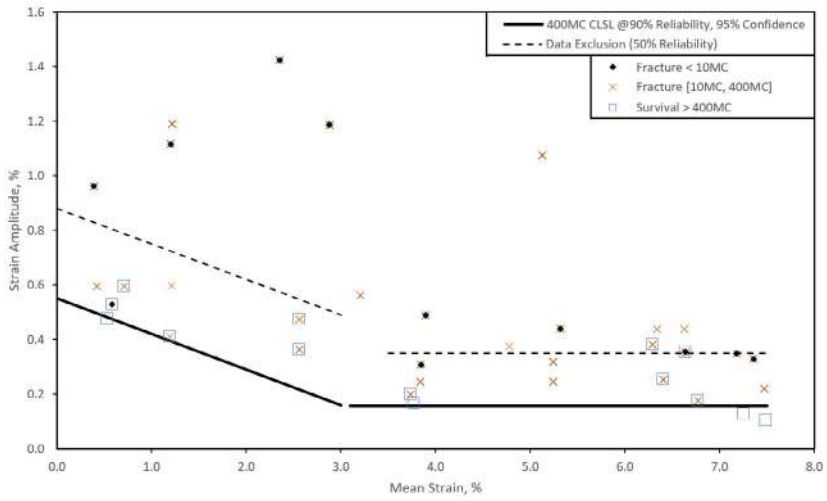

Figure 2. *Fracture diagram and constant life model for 400 x 10^6 cycles of straining. The cross symbols indicate that specimens fractured before reaching 400M cycles, the open square symbols indicate that specimens were runouts and the black diamonds represent specimens that fractured prior to 10 million cycles. Where there are multiple symbols plotted together, both or all of the specified events were experienced. The dashed lines are the constant life model at 400M cycles of straining with 50% reliability and 95% confidence. The solid lines are the constant life model at 400M cycles of straining with 90% reliability and 95% confidence.*

Our results for fatigue indicate that data from rotating bend specimens overestimate the endurance limit for material used at means strains typical of those prevailing in Nitinol medical implants [4]. We also deduce that the Goodman diagram for medical implant grade Nitinol, as shown in Figure 2, is monotonic, though nonlinear [4]. In addition, our Goodman diagram differs significantly from those already in the literature. Our Goodman diagram shows that the allowable alternating strain, at mean strains typical of Nitinol medical implants, is much less than the allowable at zero means strain, an important point, as many Nitinol implants are designed on the assumption that the endurance limit at zero mean strain is conservative [4]. As a result, the constraints on allowable alternating strains for medical implants made from Nitinol are tighter than has previously been believed. As a consequence, design limits on such Nitinol medical implants must be carefully reconsidered, and more conservative design allowables used than have previously been imposed for fatigue life.

Summary An efficient computational tool that combines a continuum representation of the far field with a discrete fibre network model of the crack near field is used to investigate the conditions leading to crack propagation in soft collagenous tissues, with a specific focus on human fetal membranes. Computational results are informed and validated through fracture experiments, including tests performed inside a multiphoton microscope. The results indicate that, for defect dimensions up to several mm, the analysis of fracture behaviour of soft biotissues cannot be based on conventional fracture mechanics approaches. The model helps rationalizing the influence of osmolarity, hydration level, as well as specific biochemical agents on the toughness of human fetal membranes.

INTRODUCTION

Soft collagenous tissues (SCT) are generally considered as highly defect tolerant [1,2], but a quantitative determination of the conditions leading to SCT fracture is relevant for medical applications involving tissue cutting, perforation or suturing. As an example, premature rupture of fetal membranes is a major reason for neonatal morbidity and death. Fetal membranes can fail as a consequence of perforation for amniocentesis, suturing during prenatal surgery, or "embrittlement" due to influence of biochemical agents [3, 4]. These problems motivated a wide range of biomechanical investigations aimed at an improved understanding of the deformation mechanisms and the fracture behaviour of human amnion (HA), the layer determining stiffness and strength of fetal membranes (e.g. [5]).

The multiaxial deformation behaviour of SCT was analysed in [8] showing that uniaxial tension causes very large lateral contraction associated with outflow of interstitial fluid. This mechanism is facilitated by the asymmetric stiffness of collagen fibers, which is very low in compression and high in tension. This leads to a strong compaction of the collagen fibres network in the nearfield of a defect, effectively avoiding propagation of cracks. This peculiar behaviour was analysed in [9] using a dedicated computational framework to rationalize experimental observations on the tearing energy of bovine liver capsule and collagen hydrogels, used as model systems for compliant collagenous membranes. Based on [6, 7], the present contribution extends previous experimental and computational methods to investigate HA and analyses relevant factors influencing its fracture behaviour.

METHODS

Figure 1 illustrates the collagen compaction and alignment in the defect nearfield in HA. Experiments were performed within a multiphoton microscope, which allows visualizing the collagen network through second harmonic generation, and the stained nuclei of epithelial cells. The latter can be used as markers to characterize the local kinematics. The data in Figure 1 demonstrate a rapid decay of collagen densification and nuclei deformation so that at about 200 μm from the notch tip the network and cells deformation corresponds to far-field conditions.

A dedicated computational approach was developed that allows reproducing the specific mechanisms observed in our experiments, which include strip biaxial mode I fracture tests and biaxial tension of membranes containing a crack-like defect. The model is based on a "hybrid" approach in that it combines a continuum (CM) with a discrete fibre network model (DNM) for the nearfield of the defect (Figure 2). The DNM represents collagen fibres as connectors embedded in an isotropic matrix able to bind and release water. While a continuum representation of the crack near field leads to a singularity, obviously also for the case of a non-linear analysis, the discrete model allows implementing a fiber-level failure criterion, which governs material failure. We performed corresponding parametric analyses and identified conditions promoting or resisting crack propagation, thus leading to either brittle or tough response. Model parameters for CM and DNM are selected to represent the behaviour in uniaxial and equibiaxial tension experiments, and the critical strain ε_c of the connectors is determined based on the failure stretch measured in uniaxial tests.

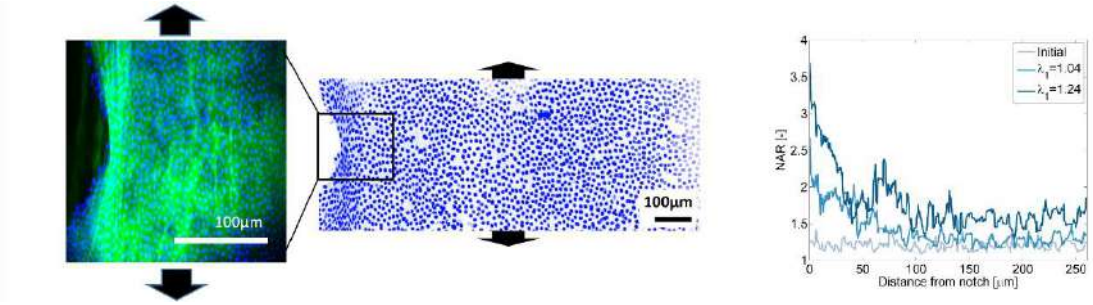

Figure 1. In-situ fracture experiments on HA within the multiphoton microscope. Collagen compaction in the nearfield of a notch in a mode I tear test is visualized through higher intensity of the second harmonic generation signal (green). Epithelial cell nuclei (stained in blue) deform to an elliptical shape. The corresponding aspect ratio of their main dimensions (NAR) is reported in the graph, demonstrating a rapid decay towards far field conditions.

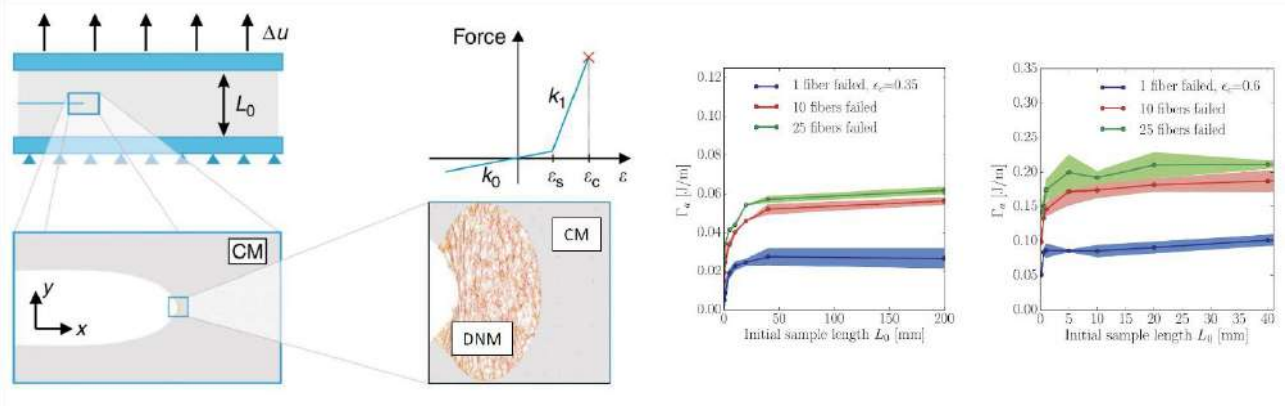

Figure 2. Left: Hybrid model for Mode I fracture experiments of SCT (adapted from [9]): the nearfield is represented through a discrete network model (DNM) and the farfield as a continuum (CM). The force-strain law of the connectors forming the DNM is shown. Right: Results of sample length dependence of the apparent tearing energy Γ_a, for different failure criteria (1, 10 and 25 failed fibers) and critical connector strain ε_c (0.35 and 0.6).

RESULTS AND DISCUSSION

As a consequence of the particular fiber compaction mechanism, the fracture process zone in HA (and in general for SCT) is very small, typically in the range of 100 µm, while the size of "short cracks" (i.e. cracks that are not governed by the material specific tearing energy Γ) is very large, i.e. >10 mm for HA. Biaxial tension experiments on defective membranes showed that the strength of HA is not significantly reduced when the defect size is <1 mm. Interestingly, a modification of the deformation law of the connectors in the DNM (with symmetric behavior for tension and compression) resolves this apparent contradiction and allows recovering the correspondence of process zone size and critical flaw size typically reported for synthetic materials.

Experimental and computational results show that the defect tolerance of SCT does not originate from major dissipative mechanisms on fibre or network scale. On the other hand, dissipative effects in the defect nearfield can increase the fracture toughness as indicated by our recent data on the loading rate-dependence of the apparent tearing energy Γ_a. The hybrid model was applied to analyse how network elastic deformation, brittle failure of collagen fibres and interstitial fluid flow interact towards the remarkable fracture properties of SCT. Specifically, the model is used to rationalize the influence of bath osmolarity, hydration level, as well as specific biochemical agents on the fracture behaviour of HA. The results contribute to a better understanding of the pathophysiology of premature rupture of fetal membranes, and to an optimization of surgical instruments and procedures in order to reduce the risk of iatrogenic preterm rupture.

CONCLUSIONS

The hybrid model was shown to provide results that are well in line with experimental observations both at macroscopic length scales and in the defect nearfield of SCT. The model was used for the analysis of factors influencing the defect tolerance of SCT. Experiments and computations demonstrate that fracture mechanics theories based on a continuum material representation might be inadequate to quantify and explain the remarkable defect tolerance of HA. In particular, the fracture mechanics concept of tearing energy fails in predicting rupture for small defects, as occurring naturally in HA [10], or iatrogenically induced when suturing in prenatal surgery or when puncturing the membranes for amniocentesis.

PARAMETER CHARACTERIZATION OF ONE-DIMENSIONAL THEORIES FOR SANDWICH COMPOSITES THROUGH BOUNDS AND ASYMPTOTIC MATCHING

Roberta Massabò*
Department of Civil, Chemical and Environmental Engineering, University of Genova, Genova, Italy

Summary Accurate upper and lower bounds are derived for the parameters of approximate structural theories used for fracture mechanics characterization of sandwich composites. The derivation takes advantage of novel 2D elasticity solutions for the decohesion of a thin layer from a half plane. The structural theories are the model of a beam on a Winkler elastic foundation and modified beam theory; they have been recently proposed to model the Single Cantilever Beam sandwich specimen, which is under consideration for possible standardization, and rely on the accurate definition of foundation modulus and crack length correction. A simple description of the transition from thick- to thin-core behaviour is obtained by asymptotic matching of the exact bounds. Results show important differences with respect to bounds derived for the description of other collapse mechanisms in sandwich composites.

INTRODUCTION

The model of a beam on a Winkler elastic foundation is used in various fields of engineering for its simplicity and accuracy in a large range of applications involving the interaction of beam type structures and elastic substrates. The action of the substrate on the beam is described by means of a distributed pressure which is related linearly to the beam deflection, u_{wf}, through a foundation modulus, k; the beam equilibrium equation is $\mathrm{d}^4u_{wf}/\mathrm{d}x^4 + ku_{wf}/K_\chi = 0$, with K_χ the flexural stiffness. The first application to fracture mechanics problems dates back to the work by Kanninen [1], where the model has been applied to describe the upper half of a homogeneous Double Cantilever Beam specimen of Young's modulus E, height $2h$ and width b; in the original model, the modulus $k = 2Eb/h$ describes the transverse stiffness of a uniformly stressed strip of material of thickness $h/2$ ahead of the crack tip. The definition of the foundation modulus has been recently improved in [2], by using the concept of root rotation and 2D fracture mechanics solutions in [3,4]; for a homogeneous isotropic material this accurate approach yields $k = 1.622Eb/h$. The Winkler foundation approximation has been applied to model various collapse mechanisms in sandwich composites, e.g. delamination fracture triggered by face wrinkling [5], face/core elastic/plastic indentation [6,7] and delamination fracture [8]. The foundation modulus has been defined by matching 2D elasticity solutions, e.g. [9], or case specific finite element results [8]. The dependence of the modulus on relative thickness and elastic mismatch of core and face-sheets has been highlighted in [5].

This work refers to recent applications of the Winkler foundation model to define the energy release rate in the Single Cantilever Beam sandwich specimen (Fig. 1a), which is currently under consideration for possible standardization [8]. In order to verify the accuracy of the approach and improve the description of the foundation modulus, which has been based on case specific finite element analyses only, reference is made to recently published 2D elasticity solutions for the decohesion of a thin layer from a half plane [10,11] and to 2D analytical and numerical solutions for a sandwich with a very thin core [12,13]. Matching the energy release of the approximate model to the exact solutions provides upper and lower bounds for the foundation modulus, which depend on the face/core elastic mismatch and can be used directly for composites with very thick or thin cores. The transition from thick- to thin-core behavior is described using asymptotic matching. The results are directly applicable to define the crack length correction of modified beam theory.

UPPER AND LOWER BOUNDS FOR THE MODEL PARAMETERS

The foundation modulus for the Single Cantilever Beam sandwich specimen in Fig. 1a,b, with isotropic core and face sheets and subjected to the force per unit width F/b, is defined as $k = \bar{E}_c b/\bar{h}$ and defines the transverse stiffness of an equivalent uniformly stressed strip of core material of thickness $\bar{h}$ which describes the actual non-uniformly stressed core/face material; $\bar{E}_c = E_c/(1-\nu_c^2)$ for plane strain. The energy release rate calculated using the model in Fig. 1b is [8]:

$$\mathcal{G}_F^{wf} = \frac{F^2}{2b^2}\left\{\frac{12}{\bar{E}_f h_f^3}\left(a+\frac{1}{\lambda}\right)^2\right\} \quad \text{with} \quad 1/\lambda = \sqrt[4]{\bar{E}_f b h_f^3/(3k)} \qquad [1]$$

The energy release rate of modified beam theory is given by Eq. 1 with $1/\lambda = \Delta$ the crack length correction. Matching Eq. 1 with the exact elasticity solution for the decohesion of a thin layer from a half plane [10]:

$$\mathcal{G}_F = \frac{6F^2}{\bar{E}_f b^2 h}\left[\left(\frac{a}{h}\right)^2 + 2\delta\left(\frac{a}{h}\right) + \left(\delta^2+\frac{1}{4}\right)\right] \quad , \qquad [2]$$

*Corresponding author. E-mail: roberta.massabo@unige.it.

where $\delta = \delta(\bar{E}_f / \bar{E}_c; \beta = 0)$ is given in closed form in [10] and shown in Fig. 1c for materials with second Dundurs' parameter $\beta = 0$, and using the results in [12,13], yield lower and upper bounds for foundation modulus and crack length correction, $k^{lb} = b\bar{E}_c / \bar{h}^{ub}$, $\Delta^{ub} = \delta h_f$, $k^{ub} = b\bar{E}_c / \bar{h}^{lb}$ and $\Delta^{lb} = 0.6h_f$ with $\bar{h}^{ub} / h_f = 3\delta^4 \bar{E}_c / \bar{E}_f$ and $\bar{h}^{lb} / h_f = 0.39$ [13]. Figure 1c shows upper and lower bounds for the crack length correction.

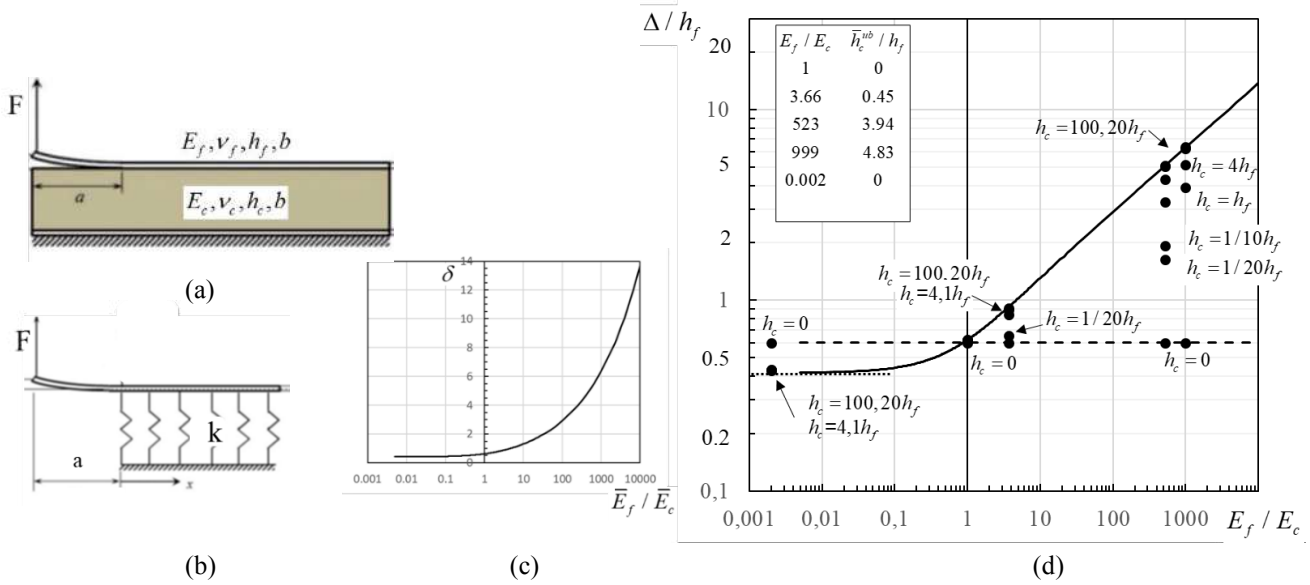

Figure 1. (a) Single Cantilever Beam sandwich specimen. (b) Beam on a Winkler foundation model. (c) Parameter $\delta = \delta(\bar{E}_f / \bar{E}_c)$ of the closed form solution in [10]. (d) Upper/lower bounds for the crack length correction (thick sold and dashed lines) and results obtained by matching finite element results for exemplary sandwich systems [13].

CONCLUSIONS

Upper and lower bounds have been derived for the elastic foundation modulus of the beam on a Winkler foundation model for fracture mechanics characterization of sandwich composites using the Single Cantilever Beam sandwich specimen. The results directly provide bounds for the crack length correction of modified beam theory. The derivation relies on novel 2D fracture mechanics solutions for the decohesion of a thin layer from a half plane [10,11]. The results show that bounds previously derived to describe face-sheet indentation/wrinkling are not applicable to the fracture problem. For face wrinkling [5], the upper bound modulus was found to correspond to an equivalent thickness equal to the core thickness while our results for fracture show that it can be much larger and correspond to an equivalent thickness equal to a fraction of the face thickness.

COMPETITION BETWEEN ADHESIVE AND COHESIVE FAILURE: AN INVESTIGATION BASED ON THE PHASE FIELD APPROACH TO FRACTURE ANDTHE COHESIVE ZONEMODEL

Maria Rosaria Marulli*[1], Marco Paggi[1]and José Reinoso [2]
[1]IMT School for Advanced Studies Lucca, Lucca, Italy
[2]Group of Elasticity and Strength of Materials, School of Engineering, University of Seville, Seville, Spain

Summary The present study is concerned with the numerical simulation of the steady-state fracture of adhesively bonded joints in peel test configuration. The fracture process that takes place inside the adhesive layer is modelled using a phase field approach in order to investigate the influence of the mechanical and geometrical properties of the adhesive. The numerical framework is further developed using a combined phase field-cohesive zone model approach in order to capture the adhesive/cohesive failure of the joint by examining the competition between crack propagation within the adhesive layer and delamination along the interfaces between such adhesive layer and the adherents.

INTRODUCTION

Computing the ultimate strength of a structural adhesive layers on a given substrate is of great importance in many applications. Among the different experimental procedures developed to characterize the bond behaviour of adhesives, one of the most popular configurations is the so-called peel test. This test configuration consists of a strip bonded to a substrate which is pulled from it at a certain angle (*peel angle*) and characterizing the *peeling force* required to produce debonding. The failure of an adhesive joints is generally classified as *cohesive* when it takes place inside the adhesive layer or *adhesive* when it develops at the interface between the adhesive and the adherent. In the most general case, the failure involves the weakest link between the adhesive, the substrate and the bonded strip, or even a combination of them if the crack propagates at some spots in a cohesive and in others in an interfacial manner.

A prediction of the mechanical behaviour of peel tests can be achieved using different fracture mechanics approaches. Initial studies for the peel geometry treated the film as an elastic beam attached to an elastic foundation representing the interaction between the film and substrate [1]. Subsequently, the condition for fracture of an adhesive joint had been derived considering an energy-balance approach in [2], the exploitation of the Linear Elastic Fracture Mechanics (LEFM) approach was conducted in [3], while the cohesive zone model (CZM) has been extensively applied for peel test simulations in several contributions, as in [4].

In the related literature, up to now, a limited attention has been given to the simulation of the adhesive layer as a bulk where, in the case of cohesive failure, the crack nucleates and propagates, especially when the adhesive layer thickness is not negligible compared to the dimensions of the adherents. In the present contribution, the phase field approach has been used to investigate the influence of the adhesive geometrical and mechanical properties on the joint strength, with the major focus on the influence of the adhesive layer thickness, t_a, and of the mechanical quantities: the fracture energy, G_{IC}, and the internal length scale, l_0 (which is closely related to the critical strength, σ_c, according to [5]). Furthermore, a numerical framework combining the phase field approach for modelling the fracture inside the adhesive layer and a cohesive zone model for the adhesive-adherent interfaces debonding is herein proposed.

COHESIVE FAILURE OF THE ADHESIVE LAYER: PHASE FIELD APPROACH

The 90-degree peeling test has been simulated through a preliminary 2D finite elements model using the phase field approach implemented within linear elastic plain strain 4-nodes finite elements. The simulations show the effects of different fracture energy values (Fig. 1a), which mainly affect the steady-state peeling force, and of different internal length scales (Fig.1b) which has a major influence on the peak peeling force. The adhesive thickness effects on the peeling force is shown in Fig. 1c, together with the crack path evolutions shown in (Fig. 2). For thick adhesive layers ($t_a = 3\text{mm}; 1\text{mm}$), the simulations predict that the crack nucleates close to the upper interface and propagates downwards reaching a steady-state perfectly horizontal. Conversely, for the thinnest adhesive layer, ($t_a = 0.3\text{mm}$), the crack path develops at the same distance from the upper interface and propagates horizontally.

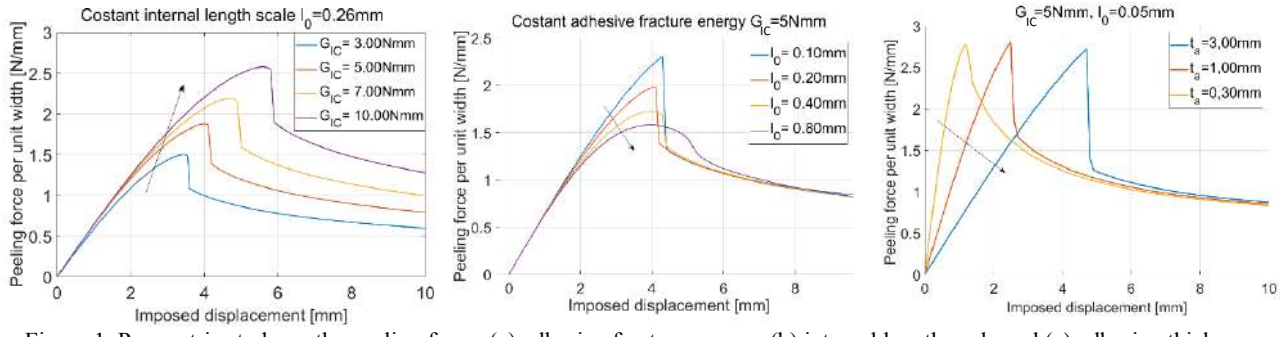

Figure 1. Parametric study on the peeling force: (a) adhesive fracture energy, (b) internal length scale and (c) adhesive thickness effects on the peeling force.

Figure 2. Details of the crack path evolution from the models with different thicknesses of the adhesive.

ADHESIVE/COHESIVE FAILURE OF THE ADHESIVE JOINT: COUPLED PHASE FIELD AND CZM

The previous numerical framework has been enhanced in order to consider the mechanical properties of the existing interfaces. The adhesive bond at the two interfaces (at the lower interface between the adhesive layer and the substrate, at the upper interface between the adhesive and the upper strip) has been modelled using zero-thickness interface finite elements compatible with the phase field model, developed in [6], using a tension cut-off cohesive zone model. A physical crack extension occurs at the interface when the fracture energy release rate reaches a critical value of the interface adhesive energy, G_a^i, which physically corresponds to the debonding of the adhesive layer from the substrate or the upper strip. The critical crack opening, g_0^i, represents also another parameter of the model that influences the adhesive/cohesive failure phenomenon of the joint. In order to capture the nucleation and propagation of the crack at the interface or inside the bulk layer and to better understand how the mechanical properties of the two interfaces influence the crack phenomena, different situations have been analysed: (i) via the consideration of the cohesive bond of the adhesive layer weaker than the interface adhesive bond or (ii) vice versa. Consistently, in the numerical model, the fracture energy of the adhesive bulk, G_{IC}, can be lower or higher than the interface adhesive energy which may also be different for the upper interface, $G_a^{i,up}$, and the upper one, $G_a^{i,low}$ (Fig. 3).

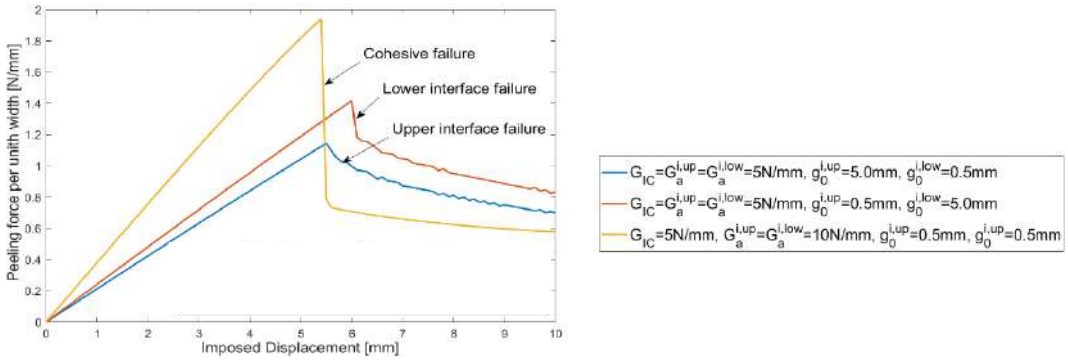

Figure 3. Adhesive/Cohesive failure: influence of fracture energy G_{IC}, adhesive interface energy G_a^i and critical opening g_0^i.

CONCLUSIONS

In this work, a novel numerical model has been proposed for the simulation of structural adhesive and, in particular, to reproduce the failure mechanisms of adhesive joints in 90-degree peeling test configuration. The phase field approach has been used for better understanding how the mechanical properties of the adhesive layer influence the peeling force and how the adhesive thickness affects the crack nucleation and propagation. Subsequently, a variational framework combining the phase field method of fracture and the cohesive zone model approach has been applied for modelling the competition between crack propagation in the adhesive layer and debonding at the interfaces. A tension cut-off cohesive zone model has been used to capture a brittle behavior of the adhesive bond at the two interfaces between the adhesive and the adherents.

The present simulations constitute a first step towards the generation of a more general model aiming at reproducing the different failure mechanisms at adhesive joints, i.e. adhesive and cohesive failures, that can arise in structural applications. This first analysis focuses on a linear elastic constitutive behavior for the adhesive, but a hyper elastic model will be introduced in a second step, in order to more accurately capture the non-linearity of a real system. The proposed framework can be further developed considering how the damage evolution inside the adhesive layer affects the mechanical properties of the interface. These aspects can also be analyzed in a 3D framework in order to capture with more details the failure of an adhesive join.

DIC-BASED J-INTEGRAL FOR THE EVALUATION OF THE FRACTURE TOUGHNESS OF ADDITIVELY MANUFACTURED WALLS

Pierre Margerit[1,2], Krishnaswa Ravi-Chandar *[2], Daniel Weisz-Patrault[1], and Andrei Constantinescu[1]
[1]Laboratoire de mécanique des solides,CNRS,Ecole Polytechnique,Institut Polytechnique de Paris,France
[2]Department of Aerospace Engineering & Engineering Mechanics, The University of Texas at Austin, USA

Summary An experimental procedure is proposed to evaluate the fracture toughness of thin specimens by means of J-integral evaluation on Digital Image Correlation results. First, the DIC mesh is defined at the final stage, where the crack surface geometry is known. Second, the DIC is run backward, from the final stage to the initial stage; so that displacements and strains can be deduced. Third, the stresses are computed using an a-priori known constitutive law, and the J-integral evaluated. It is shown that even if the plastic zone is spread over the entire observed region, the strain energy is mostly confined near the crack, thus ensuring the path-independence of the J-integrals.

INTRODUCTION

In the past decade, additive manufacturing of metals has evolved from a rapid prototyping technique to a process suited for the production of fully functional parts [1]. In the same time, additive manufacturing processes received a strong interest from the scientific community, with a number of challenges still needed to be solved. These include the understanding of the effect of the process parameters (e.g heat source power, scanning path, powder flow) on the mechanical properties of the produced parts [2]. At the end, the chosen printing strategy has consequences at different scales: (i) at the microstructure scale, where the grain growth is driven by the temperature gradient, resulting in epitaxial grains with an orientation highly influenced by the heat source path [3]; (ii) at the *meso* scale, where the layering process as well as the lack-of-fusion defects result in a high surface roughness responsible for stress concentrations [4]; (iii) at the *macro* scale, where the residual stresses associated to heating/cooling cycles are responsible for part distortion [5]. As a result, a particular research effort is given on the experimental characterization of produced parts and materials, for the needs of process modeling and optimization.

The present work focuses on the characterization of the fracture toughness of structures printed using Direct Energy Deposition (DED) [6], a promising process suitable for applications ranging from functionally graded parts [7] to structural repair [8]. The powder used for the print is AISI 316L stainless steel, preferred for its welding capacity, its relatively high mechanical properties and for its high-temperature performance. In the case of the Selective Laser Melting process (SLM), it has been observed that additively manufactured 316L exhibits higher yield stress and ultimate tensile strength than conventionally manufactured 316L, whereas having a lower elongation to failure and fracture toughness [9]. More precisely, the DED process is well suited for the production of thin walled structures (approx. thickness 0.8 mm); in this particular case, Compact Tension Tests (CPT) specimens cannot be used to determine the fracture toughness as they would buckle under the compressile stresses developing in the bending region. In addition, as a consequence of the high ductility of the 316L, the large plastic zone surrounding the crack forbids the use of classical formulas based on Linear Elastic Fracture Mechanics to determine the fracture toughness.

The proposed alternative consists in the evaluation of the material toughness by J-integral evaluation on a notched specimen. It is found that even if the plastic zone is spread over the entire specimen, the J-integral remains path-independent as soon as the contour is chosen sufficiently far from the crack path. A justification of this observation is given by observing that most of the strain energy is confined near the crack surface.

MATERIALS AND METHODS

In order to keep the mechanical properties as uniform as possible over the specimens, the printed structure is chosen so that the process is as stationary as possible. This can be achieved by printing cylinders following a helical scanning path; aiming to obtain flat specimens, cylinders with a square section are printed for the present study. The specimens are then extracted from the cylinder walls by water-jet cutting.

Due to the low thickness of the produced walls, the side dimension of the square section of the cylinder has to be kept small to prevent in-process buckling as the result of residual stresses. Thus, only small specimens can be extracted (with a total length of the order of 40mm). Consequently, test are performed *in-situ* under a Keyence VHX-6000 microscope (X50 magnification). The load is applied monotonically up to failure with a small-scale tensile machine (MTI SEMTester-1000).

Strains are measured via Global Digital Image Correlation [10]. By opposition with classical methods implementing adaptive meshing to follow DIC domain changes associated to crack opening and propagation [11], it is chosen here to define the DIC mesh on the *final* loading stage, just before specimen failure (see Fig. 1a). At this particular stage, the

Figure 1: J-integral evaluation results.

crack geometry is well defined, and no DIC domain change is expected to happen. The DIC is then ran in the *backward* direction, from the final stage to the initial stage. At the end, displacements and strains are computed with respect to the *initial* configuration $\underline{\mathbf{X}}$.

Finally, the J-integral is evaluated by processing the DIC maps. Once the subsequent configurations $\underline{\mathbf{x}}$ have been identified by means of the proposed DIC procedure, the strains and thus the corresponding stresses can be computed using a given constitutive law. For any contour Γ enclosing the crack path, the following J-integral, expressed in the *current* configuration, can be evaluated:

$$J_d = \int_\Gamma \underline{\mathbf{e}}_d \cdot \left[\mathcal{W}\, \underline{\mathbf{n}} - \underline{\mathbf{t}} \cdot \frac{\partial \underline{\mathbf{u}}}{\partial \underline{\mathbf{x}}} \right] d\Gamma \tag{1}$$

with $\underline{\mathbf{e}}_d$ the crack direction, the strain energy density $\mathcal{W} = \int \underline{\underline{\boldsymbol{\sigma}}} : d\underline{\underline{\boldsymbol{\varepsilon}}}$, the normal to the contour $\underline{\mathbf{n}}$, the stress vector $\underline{\mathbf{t}} = \underline{\underline{\boldsymbol{\sigma}}} \cdot \underline{\mathbf{n}}$ and $\underline{\mathbf{u}} = \underline{\mathbf{x}} - \underline{\mathbf{X}}$ the displacement.

RESULTS

Beforehand, tensile tests are performed on dog-bone specimens of different orientations with regard to the print direction. The obtained stress-strain curves show that the material exhibit almost no anisotropy, with a true stress-true strain behavior that can be well approximated by an isotropic power hardening law ($E = 150$ GPa, $\nu = 0.4$, $\sigma_y = 320$ MPa, $K = 880$ MPa, $n = 0.67$).

The material fracture properties are evaluated using a pre-notched specimen, loaded up to failure. DIC results show that the plastic region (defined as $\varepsilon_{\text{eq}} > 0.2\%$) spread across the entire specimen in the early stages of the loading; such an observation would normally break the path-independence of a J-integral using a contour close to the crack surface. However, it is observed that most of the strain energy $\mathcal{W}$ is confined in the crack region (see Fig. 1b). Hence any J-integral evaluated *sufficiently far* from the crack path should be path-independent.

J-integrals are finally evaluated using different contour paths represented in figure 1b. The result of eq. (1) is plotted in Figure 1c for the different contours, as a function of the loading stage. It is observed that the J-curves are very close to each other, showing the relative path-independence of the proposed J-integral evaluation procedure.

INSTABILITY IN DYNAMIC FRACTURE AND THE FAILURE OF THE CLASSICAL THEORY OFCRACKS

Yuri Lubomirsky*[1], Chih-Hung Chen[2], Aditya Vasudevan[2], Alain Karma[2], and Eran Bouchbinder†[1]
[1]Chemical and Biological Physics Department, Weizmann Institute of Science, Rehovot, Israel
[2]Department of Physics and Center for Interdisciplinary Research on Complex Systems, Northeastern University, Boston Massachusetts, USA

Summary Linear Elastic Fracture Mechanics (LEFM), the classical theory of cracks, is a powerful framework of great scientific and technological importance. Yet, it fails to account for various generic shape instabilities of propagating cracks, such as the micro-branching, the oscillatory and the tip-splitting instabilities. Using a new theoretical and computational framework, we show that the properties of the two-dimensional oscillatory instability, and in particular the oscillations wavelength, are controlled by small-scale elastic nonlinearity near the crack tip and the intrinsic lengthscale associated with it, signaling the failure of LEFM in strongly dynamic situations. We further show that the existence and properties of the oscillatory instability are largely independent of the form of the small-scale elastic nonlinearity near the crack tip.

Crack propagation is the main mode of materials failure. It has been a topic of intense research for decades because of its enormous practical importance and fundamental theoretical interest. The classical theory of brittle crack propagation, Linear Elastic Fracture Mechanics (LEFM), assumes that linear elastodynamics applies everywhere inside a stressed body except for a "process zone" near the crack tip. The latter is assumed to be negligible in size, only accounting for the dissipation associated with the fracture process, but is otherwise completely passive. A central prediction of this theory is that straight cracks smoothly accelerate to the Rayleigh wave-speed c_R. However, in practice cracks universally undergo symmetry-breaking instabilities before reaching their theoretical limiting velocity. Recent experiments in brittle gels have shown that, in thin "quasi 2D" system, cracks reaching ultra high propagation velocities ($v_c \approx 0.9c_s$) undergo an oscillatory instability, characterized by a well-defined intrinsic wavelength λ, which is independent of system geometry [1]. Such behavior cannot be explained by LEFM, even qualitatively, as it contains no lengthscales other than the external dimensions of the system.

To investigate dynamic fracture instabilities, we use the novel phase-field (PF) approach, which naturally incorporates two intrinsic length scales missing in LEFM: the size ξ of the microscopic dissipation zone around the tip, where elastic energy is dissipated while creating new fracture surfaces, and the size ℓ of the near-tip nonlinear zone, where linear

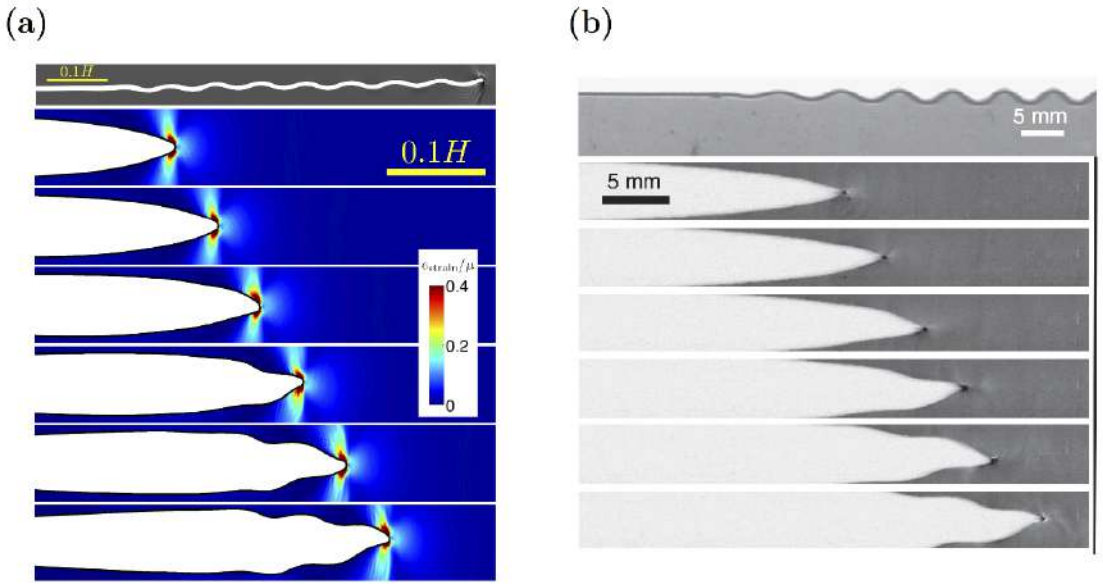

Figure 1: **Onset of the oscillatory instability.** (a) A zoom in on the 2D oscillatory instability in a phase-field simulation of brittle neo-Hookean (NH) materials under tensile (mode I) loading [2]. *contact information: yuri.lubomirsky@weizmann.ac.il
†contact information: eran.bouchbinder@weizmann.ac.il

elasticity breaks down when strains become large. ℓ scales with the ratio, Γ/μ, the fracture energy to the shear modulus, but is generally much larger than Γ/μ and also depends on crack velocity. In Fig 1a we present results of large scale PF simulations, using the neo-Hookean elastic model, which represents generic elastic nonlinearities and quantitatively describes the experiments of [1]. An oscillatory instability, which is strikingly similar to the oscillatory instability observed experimentally (shown in Fig 1b), emerges. The wavelength of the emergent instability is independent of system size and linearly varies with nonlinear lengthscale Γ/μ. Moreover, the properties of the instability are in quantitative agrement with the experimental results [1].

Next, we seek to determine whether the oscillatory instability is universal, i.e. observed independently of the nature and form of near tip elastic nonlinearity. To that end, we consider the Saint-Venant Kirchhoff (SVK) elastic model, whose nonlinearity is geometric in origin and stems only from the nonlinear nature of deformation, while being constitutively linear. While materials typically feature constitutive nonlinearity in addition to geometric nonlinearity, they should at least feature the latter, and hence the SVK constitutes the minimal possible elastic nonlinearity. Simulations preformed using the SVK model produce a high velocity oscillatory instability, whose salient properties are qualitatively identical to those observed for the NH model. Moreover, the wavelength of the oscillations was found to be a model-independent, universal function, of the actual nonlinear lengthscale ℓ.

The success of the new PF model in quantitatively explaining the 2D oscillatory instability raises the question whether there are additional, previously undiscovered instabilities in 2D dynamic fracture. Indeed, simulations preformed with various loading conditions show that there exists a range of driving forces for which steady-state oscillatory cracks exist. However, with increasing loading level, once a certain critical threshold is surpassed, a tip-splitting instability emerges, either after oscillations set in (asymmetric tip-splitting) or directly from the straight crack state (symmetric tip-splitting). This ultra-high-velocity tip-splitting instability in 2D dynamic fracture appears to be different from the well-known low velocity tip-splitting in 2D simulations and from the micro-branching instability in 3D experiments. Remarkably, such oscillations followed by tip-splitting have been recently observed under strong loading conditions in brittle NH materials (Fig 2b).

Taken together, we were able to construct a comprehensive stability phase diagram of 2D fracture in terms of the loading level and $\ell/\xi \sim \Gamma/\mu\xi$, whose topology is universal, irrespective of the form of near tip nonlinearity.

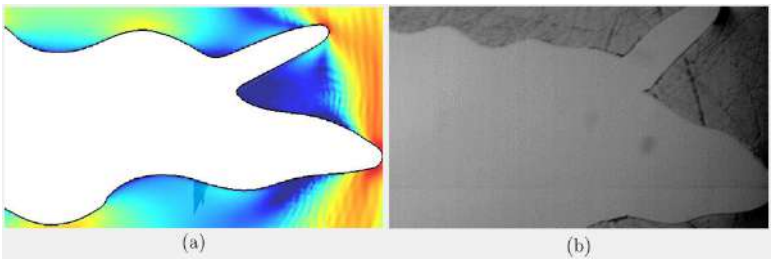

Figure 2: **Tip-splitting instability.** (a) Oscillations followed by tip-splitting in a phase-field simulation of NH materials under a large driving force. (b) The corresponding experimental observation (courtesy of Jay Fineberg). Adapted from [3].

CONCLUSIONS

In conclusion, we have shown that the properties 2D oscillatory instability, are determined by near tip nonlinearities, which are entirely absent is LFEM, hence demonstrating the failure of the classical theory fracture in explaining dynamic crack instabilities.

DIRECT EXTRACTION OF RATE-DEPENDENT COHESIVE LAWS AT ANY MODE-MIX

Tianhao Yang[1], Vatsa Gandhi [2], Rui Huang[1] and Kenneth M. Liechti[*1]
[1]Department of Aerospace Engineering and Engineering Mechanics, University of Texas, Austin, TX, USA
[2]GALCIT, California Institute of Technology, Pasadena, CA , USA

Summary The paper describes a novel approach for directly extracting the normal and shear components of the traction-separation relations for interfaces at any mode-mix. The approach is based on measuring the interactions between the contacting surfaces of two beams in a laminate that is clamped at one end with independently controlled displacements applied to the other end of each beam. Under certain conditions, the extraction of the normal and shear components of the traction-separation relations can be decoupled even if the interactions themselves are coupled. The efficacy of the approach is demonstrated for the interface between silicon and an epoxy by considering rate-dependent effects in addition to the influence of mode-mix on the interactions.

INTRODUCTION

Laminated materials have been used in a wide range of applications. A common failure mode has always been delamination between the layers. Thus, the adhesion between the layers has become crucial to the stability of such materials. Moreover, the loading/separation rate substantially influences the adhesion of interfaces involving polymers, which are commonly seen in transfer printing [1, 2] and transfer of 2D materials [3, 4]. The rate effect of polymeric interfaces has been addressed mostly for mode I fracture in previous studies. However, the loading conditions in real applications are more general, which brings the focus to the characterization of polymeric interfaces under mixed-mode fracture conditions.

EXPERIMENTAL

In the present work, a dual-actuator loading device was designed and used to provide the mixed-mode loading conditions to symmetric laminated beam specimens (Fig. 1) over a range of separation rates. Two load cells measure the reactive loads $(P_1, P)_2$ as the specimen is loaded in displacement control by each actuator. Digital image correlation was adopted to measure the rotations (θ_1, θ_2) and normal (Δ_1, Δ_2) and lateral displacements (U_1, U_2) at the loading points.

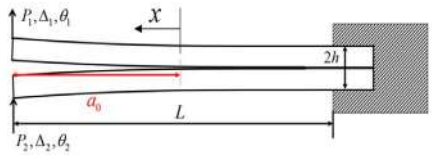

Figure 1. Silicon epoxy laminate under proportional displacement control $\Delta_2 = \alpha\Delta_1$.

As this is a balanced configuration [5], the normal and shear components of the J-integral are decoupled and are determined along with the associated crack tip openings based on the far field measurements. The normal and shear components of the traction-separation relations were then extracted by differentiating [6] each J-integral component with respect to its associated crack tip opening displacement.

RESULTS & DISCUSSION

The range of mode-mix that can be provided by the proportional loading is shown in Figure 2. Obtaining a full range of negative mode mixes is also possible. For this study, six mode-mixes were considered, each over five different separation rates.

The load-displacement data from a series of experiments at a global separation rate of 0.625 mm/are shown in Figure 3 for several proportional loading cases. The upper beam behaved in a similar way across all mode-mixes, with the force rising and reaching the peak when the crack started to grow, followed by a descending portion. The behavior of the lower beam was highly affected by the loading mode. When the mode II component dominated $\Delta_2/\Delta_1 = 0.95, 0.8$, the force still increased with the applied displacement. As more mode I component weighed in, the lower beam provided a "drag" force (e.g. $\Delta_2/\Delta_1 = 0.5$), even though the lower beam moved in the same direction as the upper beam. Space does not allow the corresponding rotation and lateral displacement data to be shown here, but in each case, along with the measured crack length, it was used to determine the normal and shear components of the crack tip displacements and J-integrals through

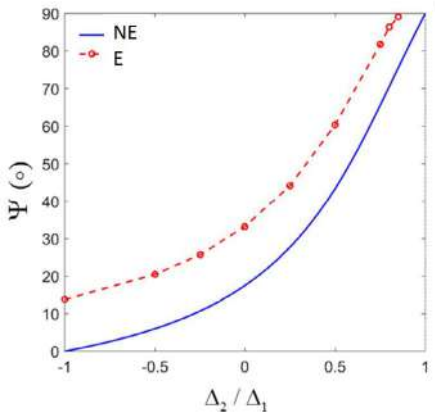

Figure 2. Achieving mode-mixes ranging from 0 to 90° by proportional separation paths. NE refers to an analysis that does not account for the presence of the epoxy, whereas E does.

$$\delta_n^* = \tilde{\Delta} + \frac{a^3}{6}\left(\frac{P_1}{D_1} - \frac{P_2}{D_2}\right) - a\left(\theta_1 - \theta_2\right),$$

$$\delta_t^* = \tilde{U} - \frac{\bar{P} h_1 a^2}{4 D_1}$$

$$J_1 = \frac{\hat{D}}{b}\left(\frac{P_1}{D_1} - \frac{P_2}{D_2}\right)\left(\theta_1 - \theta_2\right),$$

, where

$$J_2 = \frac{\hat{A} h_1}{2 D_1}\bar{P}\tilde{U}$$

$\tilde{\Delta} = \Delta_1 - \Delta_2$, $\tilde{U} = U_1 - U_2$, $\bar{P} = P_1 + P_2$,

$D_i = E_i I_i$, $\hat{D} = \left(\frac{1}{D_1} + \frac{1}{D_2}\right)^{-1}$ and

$\hat{A} = \left(\frac{1}{E_1 h_1} + \frac{1}{E_2 h_2} + \frac{b h_1^2}{4 D_1} + \frac{b h_2^2}{4 D_2}\right)^{-1}$ The normal and shear components of the traction-separation relation at any mode-mix is then obtained by taking the derivative of the corresponding components of J-integral and crack tip displacement.

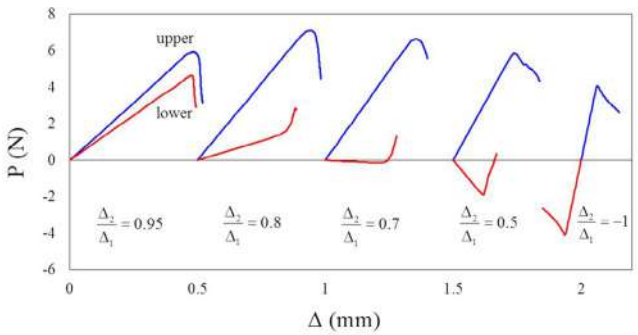

Figure 3. Force-displacement curves obtained at the upper (blue) and lower (red) beams, with different loading conditions but the same separation rate (0.625 mm/s) at the loading point.

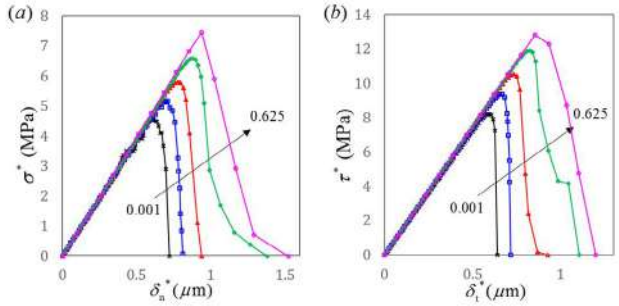

Figure 4. (a) Normal and (b) shear traction-separation relations, at the global separation rates: 0.001, 0.005, 0.025, 0.125, and 0.625 mm/s.

For purposes of illustration, we present the normal and shear components of the traction-separation relations at a displacement ratio of $\Delta_2 / \Delta_1 = 0.8$, or a nominal mode-mix of 65°, at different separation rates (Figure). In both cases, the steady state toughness, strength and range of the interactions increased with increasing separation rate. Similar results were obtained in a previous study [7] for the normal interactions. The rising portions of the two sets of data were very similar across the separation rates that were considered, but the shear stiffness was consistently higher. At each separation rate, the shear strengths were also higher than the normal ones. The interaction ranges of the normal traction-separation relations were longer than those experienced under shear. We will also present traction-separation relations as a function of mode-mix.

CONCLUSIONS

To conclude, a powerful and efficient approach has been developed for determining the traction-separation relations of interfaces at any mode-mix that has provided data that should stimulate the development of mechanistic models of crack growth at interfaces that go beyond potential or phenomenological damage based models.

PHASE FIELD APPROACH TO TENSILE FRACTURE AND COMPRESSIVE CRUSHING IN BRITTLE MATERIALS

Pietro Lenarda[1] and Marco Paggi *[1]
[1]IMT School for Advanced Studies, Lucca, Italy

Summary In phase field constitutive models the splitting of the strain energy density into active and passive parts plays an important role to activate cracking only in tension. Here, two of the most used phase filed models, the spectral and the volumetric-deviatoric decompositions are enhanced to extend their capabilities in capturing complex fracture patterns emerging not only in tension but also in compression. A novel strain energy decomposition is therefore intruduced to consistently simulate loading scenarios involving both damage in tension leading to cracking, and damage in compression responsible for crushing.

INTRODUCTION

In recent years, fracture mechanics has seen an increasing interest in phase field models for the numerical simulation of crack growth in brittle materials [1]. In the phase field framework, the crack evolution is described by an internal variable s representing damage of the material in the bulk and ranging from 0 (undamaged) to unity (fully damaged). To activate damage only in tension, among the methods that have been proposed so far for the decomposition of the strain energy density, there are two which are widely used. One is the spectral decomposition by Miehe et al. [2], while the other is the deviatoric-volumetric split by Amor et al. [3]. The choice of the strain energy decomposition method significately affects the numerical results. It will be shown here that both models become ineffective when the driving damage mechanism requires an energy dissipation not only in tension but also in compression, associated to cracking and crushing failure modes, respectively.

VARIATIONAL FORMULATION

The strain $\boldsymbol{\varepsilon} = \frac{1}{2}\left(\nabla\mathbf{u} + (\nabla\mathbf{u})^{\mathrm{T}}\right)$ is decomposed into its positive and negative parts defined as $\boldsymbol{\varepsilon}_{\pm} = \mathrm{P}\Lambda_{\pm}\mathrm{P}^{\mathrm{T}}$, where $\Lambda_{\pm} = \mathrm{diag}\left(\langle\varepsilon_1\rangle_{\pm}, \ldots, \langle\varepsilon_{\mathrm{d}}\rangle_{\pm}\right)$ is the diagonal matrix containing the positive and negative parts of the eigenvalues of $\boldsymbol{\varepsilon}$ and P is a matrix whose columns are the normalized eigenvectors of the strain tensor, while $\mathrm{d} = 2, 3$ is the spatial dimension and $\langle\cdot\rangle_{\pm} = (\cdot \pm |\cdot|)/2$ denote the McCauley brakets. In the spectral model [2], the strain energy density is decomposed into an active and passive part as: $\Psi^{\mathrm{act}} = \frac{\lambda}{2}\langle\mathrm{tr}(\boldsymbol{\varepsilon})\rangle_+^2 + \mu\mathrm{tr}(\boldsymbol{\varepsilon}_+^2)$ and $\Psi^{\mathrm{pas}} = \frac{\lambda}{2}\langle\mathrm{tr}(\boldsymbol{\varepsilon})\rangle_-^2 + \mu\mathrm{tr}(\boldsymbol{\varepsilon}_-^2)$. The stress is also decomposed into positive and negative parts as: $\boldsymbol{\sigma}_{\pm} = \lambda\langle\mathrm{tr}(\boldsymbol{\varepsilon})\rangle_{\pm}\mathrm{I} + 2\mu\boldsymbol{\varepsilon}_{\pm}$. Notice that $\boldsymbol{\varepsilon}_+$ represents the tensile strain component that is involved in crack initiation and propagation, while $\boldsymbol{\varepsilon}_-$ represents the compression strain component that in the formulation [2] does not contribute to damage. In the volumetric-deviatoric model in [3], the strain energy density function is decomposed as: $\Psi^{\mathrm{act}} = \frac{K}{2}\langle\mathrm{tr}(\boldsymbol{\varepsilon})\rangle_+^2 + \mu\mathrm{tr}(\boldsymbol{\varepsilon}_{\mathrm{dev}}^2)$ and $\Psi^{\mathrm{pas}} = \frac{K}{2}\langle\mathrm{tr}(\boldsymbol{\varepsilon})\rangle_-^2$ and the corresponding positive and negative stresses are: $\boldsymbol{\sigma}_+ = K\langle\mathrm{tr}(\boldsymbol{\varepsilon})\rangle_+\mathbf{I} + 2\mu\boldsymbol{\varepsilon}_{\mathrm{dev}}$ and $\boldsymbol{\sigma}_- = K\langle\mathrm{tr}(\boldsymbol{\varepsilon})\rangle_+\mathbf{I}$, where $K = 2\lambda/\mathrm{d} + \mu$ is the bulk modulus, $(\mathrm{d} = 2, 3)$, and $\boldsymbol{\varepsilon}_{\mathrm{dev}}$ is deviatoric strain. In this model, both the expansive volumetric and the deviatoric strain energies are assumed to be responsible for the creation of new cracks, whereas the compressive volumetric strain energy does not. In both models, the total stress is defined as $\boldsymbol{\sigma} = \{(1-s)^2 + \mathrm{k}\}\boldsymbol{\sigma}_+ + \boldsymbol{\sigma}_-$. The variational problem is to find the displacement field $\mathbf{u}$ and the phase field variable s such that, for all $\delta\mathbf{u}$ and δs test functions satisfy the following system of equations:

$$\begin{aligned} -\int_\Omega \boldsymbol{\sigma} : \delta\boldsymbol{\varepsilon}\, \mathrm{d}\mathbf{x} = 0 \\ -\int_\Omega 2\mathrm{H}(1-s)\delta s\, \mathrm{d}\mathbf{x} + \int_\Omega \mathrm{G_c}\left(l_0 \nabla s \cdot \nabla(\delta s) + \frac{1}{l_0} s\, \delta s\right)\, \mathrm{d}\mathbf{x} = 0, \end{aligned} \tag{1}$$

where $\mathrm{H} = \max_{\tau\in[0,t]}\Psi^{\mathrm{act}}(t)$ is an history field to ensure irreversibility of the crack path, l_0 is the internal lenght scale and $\mathrm{G_c}$ is the fracture energy.
Here, to model also damage in compression caused by crushing it is introduced another damage variable, s_c, whose evolution is governed by another equation formally similar to Eq. (1b) but with a different internal lenght scale l_0 and crushing energy $\mathrm{G_c}$, which is usually one order of magnitude higher than the fracture energy [6]. Damage in compression then affects the so-called passive part of the strain enegry density of the material. The stress state in the material point is used to select one of the two damege mechanisms.

NUMERICAL IMPLEMENTATION

A finite element procedure is adopted to solve numerically the system of equations in Eq. (1). The mechanical problem is solved first and then the displacement field is used to solve the phase field equation according to a staggered scheme. Despite the problem for the phase field is linear, this is not the case for the mechanical problem involving the calculation of eigenvalues and eigenvectors of the strain tensor and its positive and negative decomposition. To solve the eigenvalue problem for the strain, closed formulas are found to be very efficient both in $\mathrm{d} = 2$ and $\mathrm{d} = 3$ (Cardano and vector product formulas) compared to iterative solvers. The solution scheme has been implemented in FEniCS [7], which allows automatic symbolic computation of the Jacobian in the Newton's solver for the mechanical problem, which is very convenient to avoid lengthy calculations. In Figure 1. it is shown the evolution of the crack path in a plate with a regular distribution of holes subjected to compressive loading. The method in [1] is capable to simulate the correct vertical crack propagation which is experimentally observed. This test shows the capability of the method to nucleate cracks from undamaged microstructure.

CONCLUSIONS

The aim of the present work is to test and compare the capabilities of different models in capturing failure in materials under crushing or under combination of tension-compression loading. For this purpouse, it is required an extension of the existing formulations considering a modified decomposition of the strain energy density.

HOMOGENIZED TOUGHNESS PROPERTIES OF LARGE-SCALE DISORDERED BRITTLE SOLIDS

Mathias Lebihain*[1,2], Laurent Ponson[1], Djimédo Kondo[1], and Jean-Baptiste Leblond[1]
[1]Institut Jean Le Rond d'Alembert (SU/CNRS), Paris, France

Summary Homogenization theory constitutes nowadays a well-established theoretical framework to estimate the overall response of composite materials for a broad range of mechanical behaviors. However, such a framework is still lacking for brittle fracture properties. In this work, we propose a comprehensive theoretical framework inspired by micromechanics and statistical physics to predict the *intrinsic* effective toughness of large-scale disordered brittle composites, taking into account the decisive influence of both the *material disorder* and the *dissipative mechanisms* involved at the crack-tip. The theoretical predictions are successfully compared to the results of large-scale numerical simulations of crack propagation in composite materials displaying spatial variations of toughness.

EFFECTIVE TOUGHNESS OF LARGE-SCALE BRITTLE COMPOSITES

Being able to predict the macroscopic response of a material from the knowledge of its constituents at a microscopic scale has always been the Holy Grail pursued by material science, for it provides building bricks for the understanding of complex structures as well as for the development of tailor-made optimized materials. However, such a framework is still lacking for brittle fracture. In this work, we propose a homogenization framework for fracture properties of composite materials that builds on the specificities of brittle fracture, which is (i) a *dissipative evolution* problem that (ii) is related to a *structural one* and (iii) involves damage processes *localized at the crack tip*.

First, one has to model crack propagation in heterogeneous material to estimate the overall dissipation and deduce from it effective fracture properties. Recently, Lebihain et al. [1] proposed a semi-analytical method based on the perturbative approach of Linear Elastic Fracture Mechanics initiated by Rice [2] to model efficiently crack propagation under tensile Mode I loading in large-scale composites displaying local variations of toughness properties. The crack can interact with the tough inclusions through two mechanisms : a crossing one where it goes through the inclusion, and a by-pass one where it wanders out-of-plane and propagates along the inclusion/matrix interface (see Fig. 1.a). The numerical method allows to compute crack interaction with millions of inclusions in only few hours, and track the instantaneous macroscopic energy release rate G^∞ as well as the surface energy G_c^{frac} dissipated during material failure.

The proposed numerical method provides the core elements to investigate the effective fracture properties of large-scale disordered solids. However, no consensus has emerged yet to define the effective toughness of heterogeneous materials, which can be alternatively measured from the dissipation G_c^{frac} as the average surface energy dissipated during material failure $\langle G_c^{\text{frac}} \rangle$, or from the loading G^∞ as its maximal $G^\infty_{\max}$ or average G^∞_{mean} value. We show here that under the scale-separation condition :

$$\mathcal{L} = -G^\infty \Big/ \frac{\partial G^\infty}{\partial x} \gg d \tag{1}$$

all three definitions mentioned above converge towards a single value G_c^{eff} (see Fig. 1.b) that can be unambiguously referred to as the *intrinsic* effective toughness of the composite. The structural length $\mathcal{L}$ is related to the boundary conditions and the specimen geometry, while d is the heterogeneity characteristic size. This condition has strong implications on the experimental set-ups as well as on the numerical boundary conditions one has to use to measure intrinsic effective fracture properties.

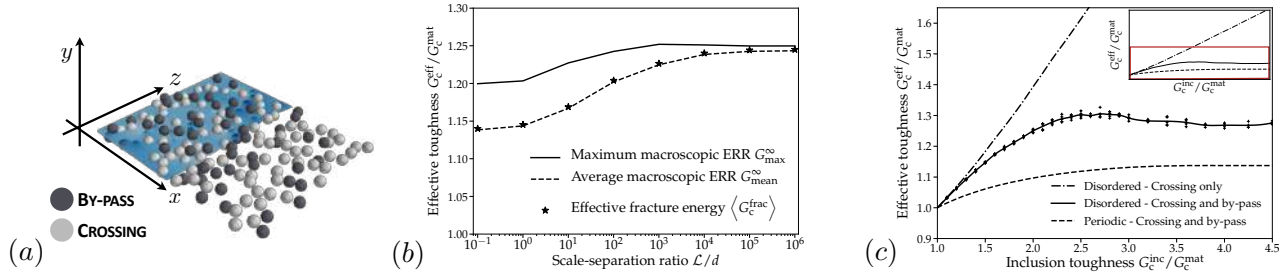

Figure 1: (a) Perturbative LEFM approach for crack propagation in disordered material displaying spatial variations of toughness properties under a macroscopic loading G^∞ : the crack can either cross (in light grey) or by-pass (in dark grey) the inclusion when interacting with it. (b) Scale-separation condition for effective toughness measurements : the structural length $\mathcal{L}$ has to be far larger than the heterogeneity size d to define an *intrinsic* effective toughness G_c^{eff}. (c) Influence of the inclusion toughness G_c^{inc} on the effective toughness G_c^{eff}, stressing out the decisive importance of the material disorder and the interaction mechanisms.

*Corresponding author. E-mail: mathias.lebihain@enpc.fr

We can then investigate the influence of microstructural features on the effective toughness G_c^{eff} and start with the inclusion toughness G_c^{inc} (see Fig. 1.c). By comparing the results with simulations of coplanar crack propagation in disordered materials where the sole crossing mechanism is modeled, and ones where the inclusions are positioned in a periodic ordered manner, we observe that both the material disorder and the interaction mechanisms localized at the crack tip play a decisive influence on the overall toughness of the composite.

HOMOGENIZING FRACTURE PROPERTIES OF DISORDERED SOLIDS

The influence of material disorder has already been studied by Démery et al. [3] using tools inspired by statistical physics in the case of coplanar crack propagation where the influence of the mechanisms of interaction is ignored. The effective toughness G_c^{eff} of the composite can be predicted from 4 statistical features of the local toughness field : its average value $\langle G_c \rangle$, its standard deviation σ, and its correlation lengths ξ_z and ξ_x in both the front and the propagation direction. We propose here a three-step homogenization procedure (see Fig. 2.a) that reconstructs the toughness field the crack actually experiences during its interaction with material heterogeneities.

First, we break down the full problem of the propagation of a crack in a disordered distribution of inclusions into multiple simpler problems, referred to as *fractured elementary volumes* (FEVs), considering all the possible ways a crack interacts with a single inclusion and its respective probability. This decomposition relies on the absence of interaction during the out-of-plane by-pass of neighboring inclusions and is referred to as the *non-collective mechanisms* hypothesis. Second, the three-dimensional cell problems provide equivalent coplanar ones, called *coplanar equivalent coplanar elements* (ECEs), which derive from the way the crack interacts with the single inclusion (crossing or by-pass). Third, the superposition of all the coplanar cell problems allows to get back to an equivalent coplanar toughness distribution, from which the statistical features $(\langle G_c \rangle, \sigma, \xi_z, \xi_x)$ can be inferred under the *ergodic assumption*. It ultimately allows to estimate the effective toughness of three-dimensional heterogeneous brittle materials using Démery et al.'s coplanar theory [3].

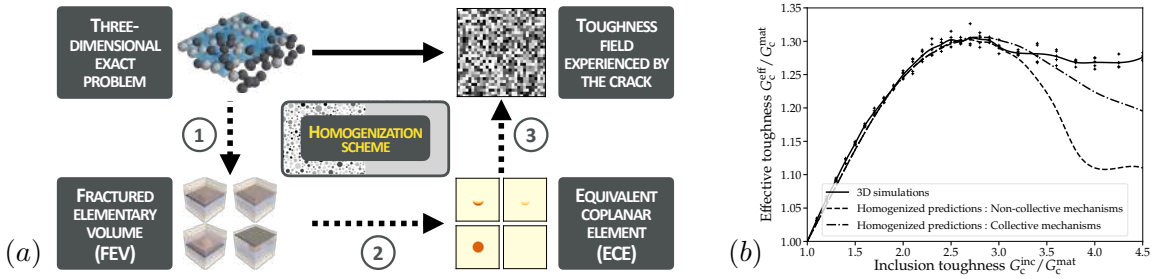

Figure 2: (a) Three-step homogenization procedure to predict the impact of microstructural features on the overall toughness of the brittle composite. (b) Application to the influence of the inclusion toughness on the effective toughness. Average numerical results (in solid lines) are compared to homogenized predictions (in dashed and dashed-dotted lines).

Predictions of the homogenized toughness are shown to be in perfect agreement with numerical results (see Fig. 2.b) as long as the *non-collective mechanisms* hypothesis is valid (i.e. inclusions 3 times tougher than the matrix). An alternate procedure can be derived from the one proposed here to take into account the collectivity in the mechanisms of interaction and thus improve the quality of the theoretical predictions. Such a framework paves the way to investigate the influence of the microstructural features (e.g. inclusion shape or density) on the homogenized toughness and design brittle composites with tailored fracture properties.

CONCLUSIONS

We proposed here a comprehensive homogenization framework that predicts the influence of microstructural features on the intrinsic effective toughness of large-scale disordered composites, taking into account the decisive impact of both the material disorder and the mechanisms of interaction localized at the crack tip. It has been shown to successfully match the results of large-scale LEFM-based simulations of a crack interacting with spatial heterogeneities of toughness. The proposed approach aims nonetheless at predicting the effective toughness in presence of a broader class of heterogeneities. For example, the case of elastic inclusions or pores could be addressed using much more adapted computational tools (e.g. phase-field models) in a periodic setting to estimate the mechanisms involved during the crack-inclusion interaction (FEV) as well as their individual contribution (ECE). The influence of the material disorder would then be taken into account using tools borrowed from statistical physics.

GRADIENT ENHANCED DAMAGE GROWTH MODELLING OF DUCTILE FRACTURE

Ragnar Larsson*[1] and Ahmet S. Erturk [1]
[1]Division of Materials and Computational Mechanics, Department of Industrial and Materials Science,
Chalmers University of Technology,SE-41296 Göteborg,Sweden

Summary A gradient enhanced damage model for ductile fracture modeling describing the material response including damage induced degradation is presented. The continuum damage evolution of Lemaitre type is focusing the degradation of the shear response eventually leading to shear induced ductile failure. The major incentive of the present paper is to examine the convergence and stability properties of both damage rate and gradient dependence in the fracture area production. In fact, this model can partly remove the pathological mesh dependence and have a stable behavior without the additional gradient effect. A major concern in this development is the choice of a nonlocal criterion for elastoplastic damage onset. The application in mind of the damage modeling is the modeling of impact problems, like split Hopkinson tests and machining process simulations.

INTRODUCTION

The micro-mechanics of fracture processes involve void nucleation/micro-crack development, coalescing, first on a micro-structural level, eventually forming a macroscopic crack or a diffuse damage zone on the macro-scale. Since ductile fracture is a frequently phenomenon in all fields of engineering, e.g. machining [1], it is of vital importance to efficiently and accurately control the fracture process to optimize the design and to reduce the weight of new components. From the key work of Gurson [2], ductile damage is attributed to the growth of micro voids, whose evolution are often formulated in (local) Gurson type plasticity models coupled to void volume growth. In the FE-application, the void formation is assumed to coalesce into fracture surfaces corresponding to localized deformation that is highly mesh dependent. As a remedy to the highly mesh dependent behavior, nonlocal extensions of the Gurson model have been proposed, [3, 4].

Another way to represent ductile fracture is to generalize recent developments of continuum phase field models for brittle fracture processes into the corresponding one for ductile fracture, e.g. [5, 6]. In Miehe et al. [6], the proposed phase field modeling is introduced into a thermoplasticity framework in conjunction with a nonlocal damage model. It has been argued that viscous regularization of the continuum material model coupled to damage via visco-plasticity may remove the pathological mesh dependence [7]. In a recent paper [8], rate dependent scalar damage for ductile fracture processes was proposed to overcome mesh dependence without gradient damage enhancement. Recent developments using the phase field approach to ductile fracture also indicates removed mesh dependence, even for highly refined meshes [5, 6]. Ductile fracture may also be modelled by extending continuum phase field models for brittle fracture processes so that ductile fracture characteristics are included [5, 6].

A SCALAR DAMAGE MODEL FOR DUCTILE FRACTURE
