
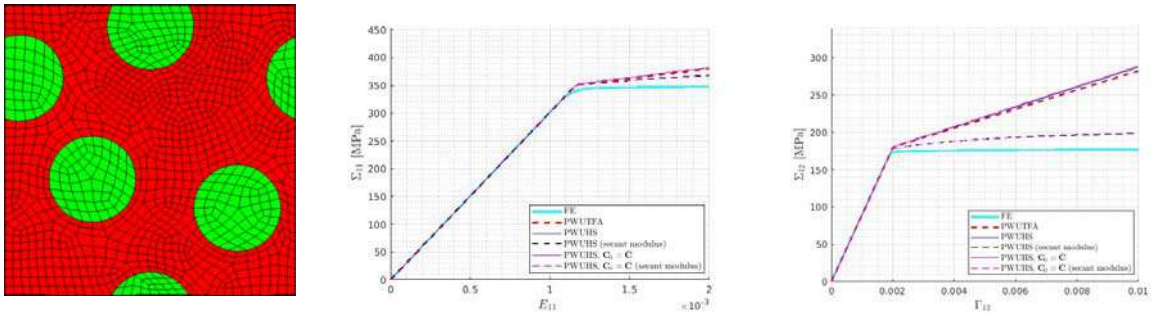
(a) (b) (c)

Figure 1. Geometry of the UC-1 (a). Analysis of convergence for an increasing horizontal average strain using the secant modulus approach (b) or using the initial $\mathbf{C}_0$ (c).

The results of the PWUHS are compared with a nonlinear finite element analyses (FE). It can be pointed out that the results of the PWUHS approach converge to the FE results increasing the number of clusters. The convergence is significantly faster in Figure 1(b) when the elastic properties of the reference medium are updated during the analyses according to the secant modulus.



(a) (b) (c)

Figure 1. Geometry of the UC-2 (a). Analysis of convergence for an increasing horizontal average strain using the secant modulus approach (b) or using the initial $\mathbf{C}_0$ (c).

A comparison between the PWUHS and PWUTFA approaches is presented for the UC in Figure 2(a), when two clusters, one for the matrix and one for the inclusions, are considered having volume fractions respectively equal to 0.72 and 0.28. The material properties of the matrix remain unchanged if compared to UC-1 while the inclusions Young modulus and Poisson coefficient are, respectively, 300 GPa and 0.25. Results in terms of the macroscopic stresses are reported in Figure 2(b) for a horizontal increasing average strain and in Figure 2(c) for a monotonically increasing average shear strain. It can be noted that the two techniques give results in very good accordance, furthermore the correction of the elastic reference matrix sensibly increases the accuracy of the PWUHS.

CONCLUSIONS

Advantages and disadvantages of the two approaches, PWUHS and PWUTFA, are examined with the aim of developing an efficient novel Reduced Order Method. Further investigations on different microstructures are needed in order to build up a robust two-scale reduced order technique.

Summary Zircaloy are used to make containers for nuclear fuel in nuclear reactors. Hydride formation can make them susceptible to failure, giving the need for continuous monitoring of the hydride content. Denuded zones sometimes found in surfaces of these tubes affect this monitoring process. We carried out a study which determines the effect of oxygen on hydrogen diffusivity in Zr, to check the validity of a hypothesis, suggesting that O slows the diffusion of H causing the hydrides formed to be smaller in size, and forms denuded zones. We estimated H diffusivity for different O concentrations, which shows that H diffusivity in Zr reduces with O concentration. Comparing these diffusivities against O profiles found in pressure tubes, we found that the reduction in diffusivity rates are insufficient to change the size of the precipitates to form denuded zones, in contradiction of the hypothesis.

INTRODUCTION

Zirconium alloys are used to make pressure tubes, which contains the nuclear fuel in the reactors, due to many advantageous properties [1, 2]. In the harsh service conditions of nuclear reactors, these alloys react with water to form zirconium oxide, while releasing hydrogen. Some of this hydrogen enters the metal which adversely changes its properties like the fracture toughness. Delayed hydride cracking can also occur if sharp flaws, cuts, and nicks suffered during operation coincide with regions under tensile stresses [3, 4, 5]. Hence, the hydride content in these pressure tubes are continuously monitored through scrape samples taken from their surfaces. Optical micrographs suggest that the size of hydrides close to the metal-oxide interface can be smaller than in the bulk which hinders the monitoring process [6, 7]. While the reasons for these hydride "denuded" zones are not exactly known, it is hypothesized that oxygen slows down the diffusion of H, forming smaller intragranular hydrides instead of the usual intergranular hydrides [6]. After an extensive literature review we didn't find any studies which has investigated this hypothesis through experimental or computational means.

We conducted a study to ascertain the diffusivities of H in hexagonal close packed (hcp or α phase) Zr at zero to moderate O concentrations. We also looked at the reasons for the variation in H diffusivity due to the presence of O by looking at the diffusion mechanics and diffusion paths taken by H atoms. Finally we determined the effect the changes in diffusivities calculated against the O concentrations expected in Zr pressure vessels to determine the effect it has on the sizes of the precipitates formed. Using these results we evaluated the validity of the above mentioned hypothesis and found that this hypothesis is unlikely to be the main reason for the formation of denuded zones in Zr pressure vessels.

METHODS

H atoms, which have a very small size, will diffuse via an interstitial mechanism in Zr, hopping between the available occupancy locations/interstitial sites. We used a multi-scale method to determine the diffusivity of H in α-Zr for three different O concentrations. This method was validated in our previous paper which looks at H diffusivity in pure Zr [8]. First-principles calculations were carried out to identify the occupancy locations and determine the rate constants for the transitions between these sites. The identified rate constants were used to estimate the diffusivity of H for each concentration with the use of Kinetic Monet Carlo (KMC) Simulations. Using oxygen concentration profiles found in Zr pressure vessels, we checked the effect on the hydride sizes found along the the pressure tube,using the determined diffusivity values, to look at the validity of the hypothesis being tested.

RESULTS AND DISCUSSION

From the first principles studies we identified the H occupancy sites for each O concentration and the possible transition mechanism between these sites. Rates for these transitions are then calculated with the semi classical Harmonic Transition State Theory (SC-HTST). These were used in KMC simulations to determine the diffusivities for the considered cases. The change of the diffusivity (logarithm of diffisivity) against the temperature (inverse of temperature) is as shown in figure 1. We can see the the change in diffusivity is relatively small for the low O concentrations (0.775% atm and 1.82% atm), where it is considerable for the 5.88% atm O concentration case.

If the size if the precipitates (hydrides) depend on the catchment volume, the size of the precipitates will be proportional to $D^{1.5}$. If we look at how this value changes with the O concentration we can understand the size variation to be

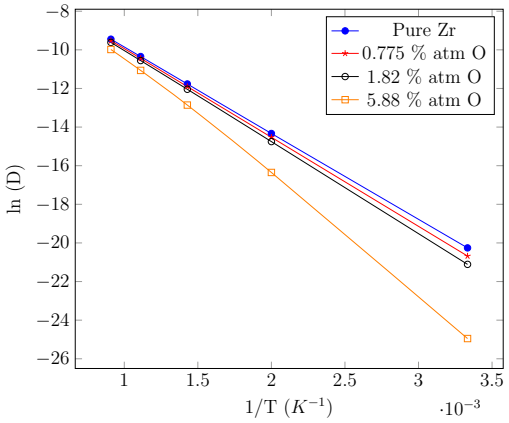

Figure 1: change in $ln(D)$ against $1/T$ for H diffusion in pure Zr, and for Zr with interstitial O

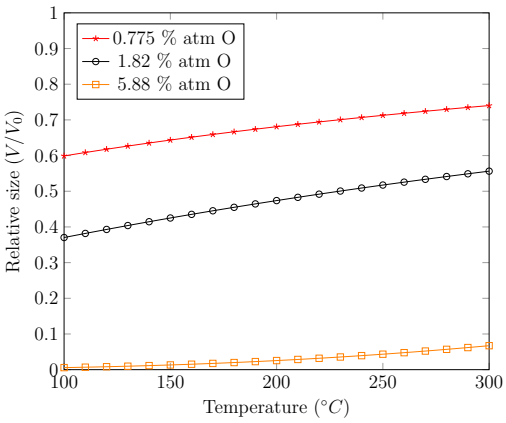

Figure 2: Relative size of the precipitates to the size of precipitates expected in pure Zr

expected in the precipitate sizes. Figure 2 looks at the relative size of precipitates expected for each different O concentration against the size of precipitates expected in pure Zr, where V is the size of the precipitates with O and V_0 is the size of precipitates in pure Zr at the same temperature. To have a noticeable decrease in the size of the precipitates they have to be smaller by a magnitude in the order of 10^{-2} (0.01 times). We can only see this in the case with 5.88% atm O concentration.

Looking at the O concentration profile found in Zr pressure vessels we find that it has is very high at the surface (approximately 27% atm) and decays exponentially to reach a value of 0.6% atm at a depth of about 32 μm. Comparing these distances with the denuded zone thickness (which can reach about $100 - 200$ μm) the depth is considerably lower. With this we can see that the amount of oxygen present in the denuded zones is not sufficient to slow the diffusion rates of H to cause significant reduction in the sizes of hydrides formed.

CONCLUSIONS

We looked at diffusivity of H in Zr with and without the influence of O using a combination of first principles methods and KMC simulation. The first principles calculations have been successfully used to determine the hopping rates for individual diffusion steps, validated from previous work carried out for H diffusion in pure Zr. This study show that H diffusion in Zr can be decreased by the presence of interstitial O and further decreased as the O concentration increases. We looked at the paths taken by H atoms and found that in addition to the decrease in hopping rates, H traps are formed by the amalgamation of occupancy sites, decreasing the diffusivity.

While this study proves that diffusivity of H in Zr is decreased by O, the amount of reduction in the diffusivity is not seen to be sufficient to decrease the size of the precipitates to be noticeable in the denuded zones. The O concentration profile suggests that the amount of O present in the denuded zone is not sufficient to decrease the diffusivity to a sufficient level to decrease the size of precipitates noticeably. Hence, we can disprove the hypothesis which sets forward the idea that denuded zones are formed by decrease of hydrogen diffusivity caused by the presence of interstitial oxygen.

This gives rise to the need to look at other mechanisms which could explain the formation of denuded zones in Zr pressure vessels.

COMPUTATIONAL HOMOGENIZATION FOR THE MULTISCALE ANALYSIS OF METAMATERIAL PLATES WITH LOCAL RESONANCES

Varvara Kouznetsova*[1], Lei Liu[1], Tom Lenders[1], and Marc Geers[1]
[1]Department of Mechanical Engineering, Eindhoven University of Technology, Eindhoven, The Netherlands

Summary This work presents a dynamic computational homogenization framework for transient and steady-state multi-scale analysis of locally resonant metamaterial panels. The approach relies on the relaxed separation of scales and combines the transient computational homogenization scale transition relations with the static-dynamic decomposition and mode synthesis, resulting in a computationally efficient closed-form formulation for a macroscopic shell continuum enriched with emergent degrees of freedom capturing the local resonance micro-inertia effects.

INTRODUCTION

Attenuation of low-frequency flexural waves in lightweight thin structures, such as beams or plates, presents an important engineering challenge. New promising solutions addressing this problem may be found in the emergent field of dynamic metamaterials. Dynamic metamaterials are materials designed for manipulation of elastic waves through specific interactions between propagating mechanical waves and fine scale micro-inertia mechanisms, based on either localized resonance or Bragg scattering, or their combination. This leads to exotic emerging phenomena, such as band gaps, negative refraction index etc., and opens possibilities for tunable waveguides, adaptive passive vibration control, superdamping, acoustic diodes, cloaking and focussing, noise insulation and (vibro-acoustic) energy harvesting. In particular, locally resonant metamaterials may be promising candidates for the low-frequency flexural wave attenuation in beam and plate structures, since they present exceptional wave manipulation properties in a subwavelength regime compared to the size of the unit cell.

The development and design of such metamaterials in general, and the locally resonant materials in particular, and devices/structures made thereof, requires advanced computational techniques. Such techniques should, on one hand, be capable to deal with complex geometries, boundary conditions and excitations, and on the other hand be computationally more efficient than direct numerical simulations. The latter become quickly computationally infeasible for locally resonant metamaterials due to the need to accurately resolve the fine scale resonator features, which are much smaller than the size of the large scale structure.

DYNAMIC HOMOGENIZATION FRAMEWORK

In this work, a computational framework for multi-scale dynamic analysis of locally resonant beams/plates is presented. As a point of departure, two previously developed computational homogenization methodologies have been used, i.e. a computational homogenization for plates/shells under static conditions [1] and dynamic computational homogenization for a general 3D continuum [2]. The homogenization framework proposed here employs a thin continuum shell description at the macroscale, while the (locally resonant metamaterial) microstructure is modelled as a full 3D solid continuum representing the full shell thickness. The application of the homogenization methodology is justified by the relaxed separation of scales regime, typically satisfied for locally resonant metamaterials, i.e. in the relevant frequency regime of interest, the matrix host medium is in the long wavelength regime, while the wavelength in the locally resonant inclusions can be comparable to the inclusion size, leading to non-negligible micro-inertia effects. Moreover, for the applicability of the thin shell theory, an additional condition is needed, restricting the analysis to flexural wavelengths much smaller than the shell thickness, which is obviously satisfied in the subwavelength regime.

The macroscopic and microscopic scales are coupled by consistent scale transition relations, involving the application of a localization operator to provide the macro-to-micro kinematic relations, and the Hill-Mandel condition, which establishes the micro-to-macro homogenization relations through energy consistency between the scales. For the dynamic homogenization of shells, the macroscopic kinematic quantities to be imposed on the microscopic unit cell consist of the macroscopic in-plane deformation gradient tensor, curvature tensor, the translational displacement of the reference lamina and the rotation of the director. The macroscopic resultant stress quantities extracted from the microscale include the thickness integrated stress and moment, as well as the translational and rotational momenta. The above described framework is formulated in the time domain. It is general and can be applied to a broad variety of transient problems, also those involving material and geometrical non-linearities. The computational costs are, however, rather high due to the need of the nested, coupled two-scale analysis at each time increment and at each macroscopic (integration) point.

In the linear elastic, small strain regime the computational costs can be significantly reduced through the use of the static-dynamic decomposition and mode synthesis at the micro-scale allowing the derivation of closed-form homogenized equations representing an enriched micromorphic continuum, in which additional field variables emerge to account for the micro-inertia effects [3]. In this case, the microscale problem has to be solved in the 'off-line' stage only, to obtain the static properties and identify the relevant local resonant modes and their frequencies. The microscale problem

*Corresponding author. E-mail: v.g.kouznetsova@tue.nl

is subsequently eliminated resulting in a compact closed-form description of the micro-dynamics that captures the local resonance phenomena. Upon substitution of the reduced microscale model into the scale transition relations, the resulting macroscale equations represent an enriched shell continuum with additional field variables accounting for the local resonance effects, which are absent in a classical shell continuum. Such an approach retains the accuracy and robustness offered by a two-scale coupled computational homogenization implementation, while significantly reducing the problem size and the computational time to the 'on-line' solution at the macro-scale only. Moreover, the obtained closed-form enriched formulation can be written in the time, as well as the frequency domains, thus enabling an efficient solution of transient or steady-state problems.

RESULTS

The developed framework has been validated against direct numerical simulations (DNS) and standard Bloch analysis by comparing the dispersion and transmission spectra of the homogenized model and the fully resolved model for a variety of microstructural unit cell designs and macroscopic beam/plate structures. An example is shown in Figure 1. The locally resonant unit cell and the macroscopic structure with its boundary conditions and applied harmonic excitation at the corner are shown in Figure 1a. For the numerical implementation of the macroscopic shell continuum, an isogeometric formulation has been used, while the microscale unit cell and DNS were solved using regular finite elements. The dimensions are such that the DNS problem involves 25x25 unit cells resulting in over 3 million degrees of freedom. The simulation results are shown in Figures 1b,c. In Figure 1b, an almost perfect match between the homogenized model and the reference DNS can be observed in the low frequency regime and the two locally resonant band gaps (shaded green). The slight discrepancy outside the band gap regions at higher frequencies is most probably due to the coarse macroscopic discretization. The computational gain achieved by the homogenized model compared to the DNS is almost a factor 50.

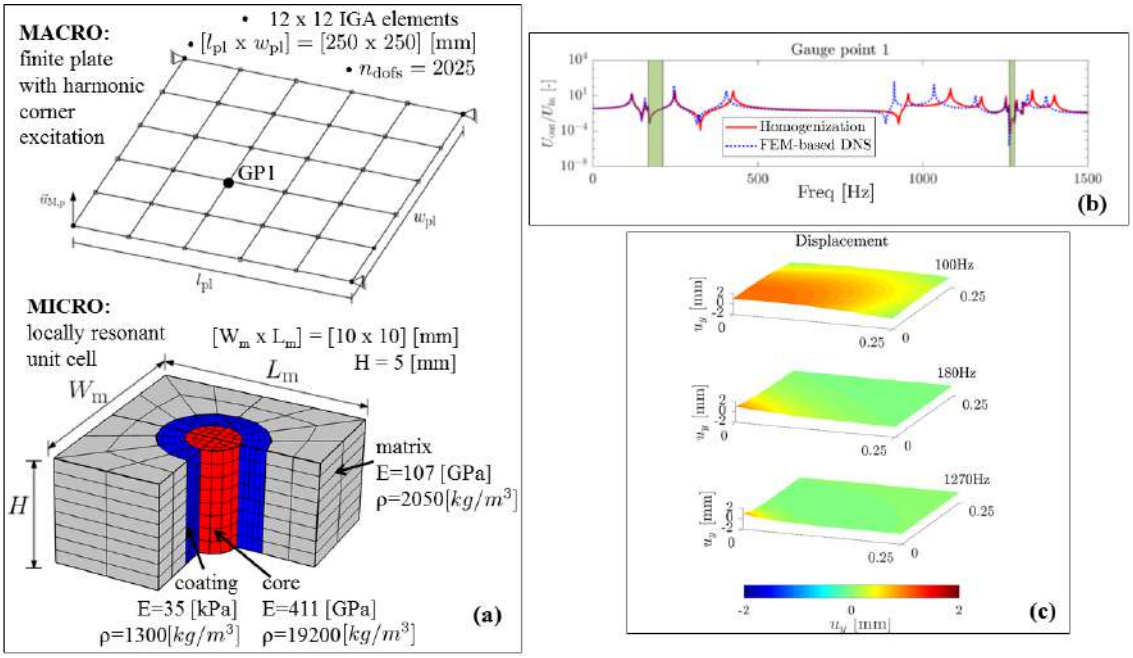

Figure 1: Application of the developed homogenization framework to a problem of a macroscopic plate with locally resonant substructure. (a) The macroscopic and microscopic problems. (b) Transmission at gauge point 1, compared to DNS. (c) Displacement of the plate at several excitation frequencies.

CONCLUSIONS

A new efficient dynamic computational homogenization framework for the multi-scale analysis of locally resonant metamaterial panels has been developed and validated. This approach can be used in the future for the design of metamaterial panels and beams for low-frequency flexural wave attenuation.

AN ENHANCED MAXIMUM-ENTROPY-BASED MESHLESS TECHNIQUE FOR STABLE SIMULATIONS OF SEVERE DEFORMATION

Siddhant Kumar[1], Yannick Hollenweger[1], Kostas Danas[2], and Dennis M. Kochmann*[1]
[1]Mechanics & Materials,Dept.of Mechanical & Process Engineering ETH Zürich,Zürich,Switzerland
[2]Laboratoire de Mécanique des Solides,C.N.R.S.,Ecole Polytechnique,Palaiseau,France

Summary We discuss a computational framework based on an enhanced local maximum-entropy approximation scheme for particle method-type simulations of severe elastic and inelastic deformation. Exploiting both total-Lagrangian and updated-Lagrangian settings, we demonstrate that this meshless approach not only enables the accurate prediction of large-deformation and large-rotation scenarios but it also comes with computational efficiency comparable to finite element-based schemes. We illustrate the performance of the technique through a suite of examples from metal forming and metal processing as well as extreme deformation of rubbery materials.

INTRODUCTION: MESHLESS TECHNIQUES

Meshless methods are popular computational mechanics tools for simulating scenarios in which classical mesh-based techniques – such as the finite element method (FEM) – reach their limits. This particularly applies to boundary value problems involving large deformation such as during metal forming (involving severe plastic deformation), the deformation of rubber (displaying even severe (visco-)elastic behavior), or fluid-structure interactions (in which the two worlds of classically Eulerian and Lagrangian settings collide). The large number of available meshfree techniques include, e.g., smoothed-particle hydrodynamics, the element-free Galerkin method, reproducing kernel particle methods, and material point methods – all of which circumvent mesh-related problems by treating nodes as interacting particles. However, such meshfree methods encounter alternative challenges that involve, among others, the treatment of discontinuities and boundary conditions as well as numerical instabilities. Specifically, all kernel-based meshfree methods experience a rank-deficiency instability that causes spurious modes[1]; when the discretization is formulated in an updated-Lagrangian setting, a purely numerical instability called *tensile instability* further arises from the changing nodal spacing and the associated localization of the shape function support [1]. Meshfree schemes also face challenges in accurately capturing material interfaces due to the smearing of discontinuous gradients induced by the nonlocal support.

ENHANCED LOCAL MAXIMUM-ENTROPY APPROXIMANTS

More recently, maximum-entropy approximation schemes have gained interest, which formulate meshless interpolants based on the maximization of information entropy [2]. Their extension to a Pareto compromise between shape function locality and maximization of information entropy resulted in the local maximum-entropy (*local max-ent*) shape functions [3], which we extend and exploit here. The local max-ent scheme is particularly attractive because it provides a seamless transition between a nonlocal approximation and a simplicial interpolation on a Delaunay triangulation (such as in classical FEM). The local max-ent interpolants further possess the weak Kronecker property, thus allowing for the direct application of essential boundary conditions and making the scheme attractive for fluid-structure interactions [4].

We recently introduced an improved meshfree approximation scheme [5] which adopts the original local maximum-entropy strategy as a compromise between shape function locality and entropy in an information-theoretical sense. This improved version is specifically designed for severe, finite deformation and offers significantly enhanced stability as opposed to the original formulation. This is achieved by (i) formulating the quasistatic mechanical boundary value problem in a suitable *updated-Lagrangian* setting, (ii) introducing *anisotropy in the shape function* support to accommodate directional variations in nodal spacing with increasing deformation and *eliminate tensile instability*, (iii) spatially bounding and *evolving the shape function support* to restrict the domain of influence and increase efficiency, (iv) *defining shape functions only locally* at material points, and (v) *truncating shape functions at interfaces* in order to stably represent multi-component systems like composites or polycrystals.

In a nutshell, the max-ent interpolation of all fields of interest is based on a set of *nodes*. The constitutive behavior is evaluated at a second, independent set of *material points* (the integration points), as in the classical optimal transportation meshfree (OTM) scheme [4]. Unlike previous implementations, the max-ent shape functions are defined only *locally* at the material points, and their *shape and support changes* with the current local state of deformation. The result is a versatile particle-type computational mechanics technique for the solution of static and dynamic boundary value problems, which we formulate in an *update-Lagrangian setting* (see Figure 1 for a schematic illustration). Beneficially, our formulation overcomes the phenomenon of tensile instability found in most competing meshless interpolation schemes.

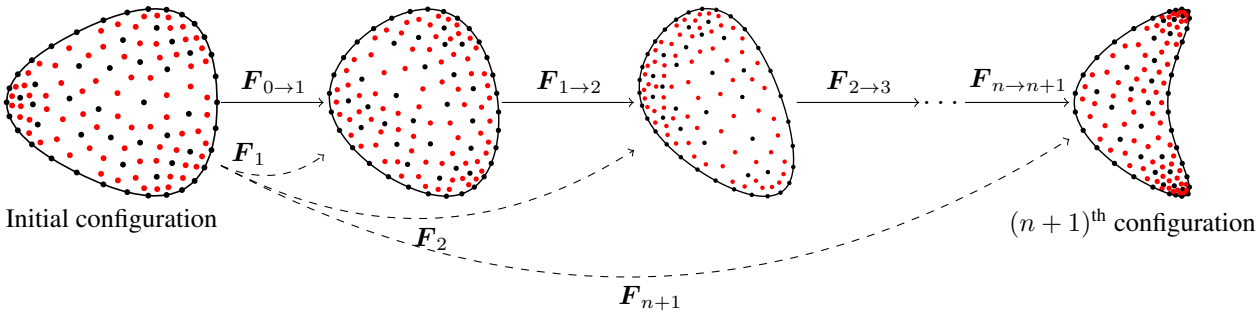

Figure 1: Illustration of the total-Lagrangian (dahsed lines) and updated-Lagrangian (solid lines) descriptions of the meshfree scheme based on improved local maximum-entropy interpolants [5]. Red and black points denote material points and nodes, respectively.

BENCHMARK EXAMPLES

We demonstrate the performance of our numerical scheme through a series of benchmark problems involving severe elastic and inelastic deformation. The accuracy of simulated results is evaluated by comparing, where applicable, to exact solutions or FEM simulations. In particular, we present simulations of rubber (hyper)elasticity [5] involving the extension of a rubbery block by several hundred percent strain, and the torsion of a rubbery block by more than 200° twist angle. In both cases, the meshless scheme outperforms state-of-the-art FEM techniques in a stable manner. We further showcase the capability of representing elastic-plastic behavior by simulating the classical Taylor-Anvil test of a metal sample impacting a rigid wall at high speed (which admits a quantitative accuracy assessment by comparison to prior simulations and to experiments). Finally, we apply the scheme to simulate equal-channel angular extrusion (ECAE) applied to polycrystalline pure copper billets [6, 7]. In addition to capturing boundary and end effects well, this latter scenario also serves as a demonstration of the ability to incorporate complex constitutive laws – we adopt a multiscale setting in which the local constitutive behavior at each material point is derived from an extended crystal plasticity model at the polycrystalline mesoscale including dynamic recrystallization [7] (of importance during ECAE at elevated temperature). We compare simulated results to experiments to highlight the applicability and accuracy of our approach.

CONCLUSIONS

We have extended the classical local maximum-entropy interpolation scheme into a versatile meshless framework which enables stable updated-Lagrangian (and total-Lagrangian) simulations of severe elastic and inelastic deformation [5], as demonstrated through examples from hyperelasticity, elasto-plasticity, and multiscale models for metal processing. Besides its superb accuracy and avoidance of the classical tensile instability, the efficiency of our particle-type scheme is comparable to competing finite element implementations.

THERMODYNAMICAL MODEL FOR STRAIN-INDUCED CRYSTALLIZATION IN POLYMERS

Serhat Aygün and Sandra Klinge*
Institute of Mechanics, TU Dortmund University, Dortmund, Germany

Summary The present work deals with the continuum mechanical model for the strain-induced crystallization covering mechanical and thermal properties of this phenomenon. The approach proposed relies on the minimum principle of the dissipation potential, which requires the Helmholtz free energy and the dissipation potential to be defined. These relationships are expressed in terms of external variables along with two internal variables, the network regularity and the thermal expansion. Advantageously, the model is able to simulate the reduction of crystalline regions followed by the heat release during the unloading phase, which is achieved by introducing shift terms in corresponding thermodynamic driving forces. The numerical results provide insights into the phenomena by illustrating the microstructural evolution within selected RVEs with a randomly generated initial microstructure.

THERMODYNAMICAL MODELING OF THE STRAIN-INDUCED CRYSTALLIZATION

High stretching of certain polymers, such as natural rubber, causes a partial transformation of the amorphous polymer chain structure, also known as strain-induced crystallization (SIC). Under a constant load, the crystalline regions remain stable, however, they gradually degrade and finally disappear during the unloading stage. The whole process is dissipative as shown by the experimental results on the stress strain behavior [1]. The proposed thermodynamically consistent model capturing mentioned properties of the process relies on the minimum principle of the dissipation potential. According to this approach, the Lagrangian $\mathcal{L}$ including the rate of Helmholtz energy $\dot{\psi}$ and the dissipation potential Δ is minimized with respect to the rates of internal variables $\dot{\boldsymbol{x}}$. The procedure yields the expressions for thermodynamic forces $\boldsymbol{q_x} \in \arg\min\{\mathcal{L} = \dot{\psi} + \Delta \mid \dot{\boldsymbol{x}}\}$ and, consequently, evolution equations for internal variables.

In the current work, the set of internal variables $\boldsymbol{x}$ includes the regularity of the polymer chain network (χ) and thermal expansion (α) due to the heat change by the SIC. Regularity χ takes the values in the range $[0, 1]$, such that zero value corresponds to the completely amorphous structure, and that the unity-value corresponds to a regular crystal structure. Moreover, the model uses the concept of large deformations and assumes a triple decomposition of the deformation gradient $\boldsymbol{F} = \boldsymbol{F}^{\mathrm{e}} \cdot \boldsymbol{F}^{\mathrm{c}} \cdot \boldsymbol{F}^{\mathrm{th}}$. Here, $\boldsymbol{F}^{\mathrm{e}}$ is the elastic deformation gradient, $\boldsymbol{F}^{\mathrm{c}}$ is the deformation gradient due to the crystallization and $\boldsymbol{F}^{\mathrm{th}}$ is the thermal deformation gradient. Quantities $\boldsymbol{F}^{\mathrm{c}}$ and $\boldsymbol{F}^{\mathrm{th}}$ are not listed in the set of internal variables, since they are defined in terms of χ and α as shown in the continuation.

Free energy and derivation of driving forces

For the previously defined framework, the Helmholtz free energy is assumed in the following form

$$\psi(J^{\mathrm{e}}, \boldsymbol{C}^{\mathrm{e}}, \chi, \alpha, \Theta) = \psi^{\mathrm{e}}_{\mathrm{AB}}(J^{\mathrm{e}}, \boldsymbol{C}^{\mathrm{e}}) + \psi^{\mathrm{th}}(\Theta) + c_1\,\chi + c_2\,\Theta\,\alpha + c_3\,\alpha\,. \tag{1}$$

Here, the Arruda-Boyce elastic energy $\psi^{\mathrm{e}}_{\mathrm{AB}}$ depends on the elastic Jacobian J^{e} and the elastic right Cauchy-Green tensor $\boldsymbol{C}^{\mathrm{e}}$, whereas the thermally stored energy ψ^{th} is used to define the heat capacity $c_p = -\Theta\frac{\partial^2\psi}{\partial\Theta^2}$, commonly assumed as a constant. The linear terms in (1) are responsible for shifts in driving forces, c_1 is the deformation dependent material parameter and c_2 and c_3 are material constants.

The model furthermore includes coupling conditions for velocity gradients and rates of corresponding internal variables: The crystalline velocity gradient $\boldsymbol{L}^{\mathrm{c}}$ is coupled to the rate of the regularity and the thermal velocity gradient $\boldsymbol{L}^{\mathrm{th}}$ to the rate of the thermal expansion

$$\boldsymbol{L}^{\mathrm{c}} := \dot{\boldsymbol{F}}^{\mathrm{c}} \cdot (\boldsymbol{F}^{\mathrm{c}})^{-1} = k_1\,\dot{\chi}\,\frac{\boldsymbol{M}^{\mathrm{c,dev}}}{\|\boldsymbol{M}^{\mathrm{c,dev}}\|}\,, \quad \boldsymbol{M}^{\mathrm{c,dev}} = \boldsymbol{M}^{\mathrm{c}} - \frac{\mathrm{tr}(\boldsymbol{M}^{\mathrm{c}})}{3}\boldsymbol{I}\,, \quad \boldsymbol{L}^{\mathrm{th}} := \dot{\boldsymbol{F}}^{\mathrm{th}} \cdot (\boldsymbol{F}^{\mathrm{th}})^{-1} = k_2\,\dot{\alpha}\,\boldsymbol{I}\,. \tag{2}$$

These conditions are expressed in terms of the Mandel stress tensor $\boldsymbol{M}^{\mathrm{c}}$ representing the thermodynamical couple of the $\boldsymbol{L}^{\mathrm{c}}$. Furthermore, $\boldsymbol{M}^{\mathrm{c,dev}}$ denotes the deviatoric part of $\boldsymbol{M}^{\mathrm{c}}$ and k_1 and k_2 are proportionality constants. Finally, the expressions for the reduced dissipation $\mathcal{D}^{\mathrm{red}}$ and thermodynamic forces q_χ and q_α are derived by using standard principles of thermodynamics and assumptions (1) and (2) [2, 3]:

$$\mathcal{D}^{\mathrm{red}} = \boldsymbol{M}^{\mathrm{c}} : \left(k_1\,\dot{\chi}\,\frac{\boldsymbol{M}^{\mathrm{c,dev}}}{\|\boldsymbol{M}^{\mathrm{c,dev}}\|}\right) + \boldsymbol{M}^{\mathrm{th}} : (k_2\,\dot{\alpha}\,\boldsymbol{I}) - \frac{\partial\psi}{\partial\chi}\dot{\chi} - \frac{\partial\psi}{\partial\alpha}\dot{\alpha} = q_\chi\,\dot{\chi} + q_\alpha\,\dot{\alpha} \geq 0\,, \tag{3}$$

$$q_\chi = k_1\|\boldsymbol{M}^{\mathrm{c,dev}}\| - c_1\,, \quad q_\alpha = k_2\,\mathrm{tr}(\boldsymbol{M}^{\mathrm{th}}) - c_2\,\Theta - c_3\,. \tag{4}$$

Here, $\boldsymbol{M}^{\mathrm{th}}$ is the thermodynamic couple of $\boldsymbol{L}^{\mathrm{th}}$ and c_1 and c_3 are shift terms chosen such that the unloading phase is characterized by negative driving forces.

Dissipation potential and derivation of evolution equations

The following dissipation potential including the absolute value of the regularity rate and a quadratic term of the expansion rate is proposed according to the behavior of crystalline regions under the different loading regimes:

$$\Delta(\dot{\chi},\dot{\alpha}) = (A+B)\,|\dot{\chi}| + \frac{D}{2}\dot{\alpha}^2\,, \quad \dot{B} = \frac{b}{f(\chi)}\,|\dot{\chi}|\,, \quad f(\chi) = a-(\chi-c)^d\,, \quad b = \begin{cases} b_1 & \text{if} \quad \dot{q}_\chi \geq 0\,, \\ b_2 > b_1 & \text{else}\,. \end{cases} \tag{5}$$

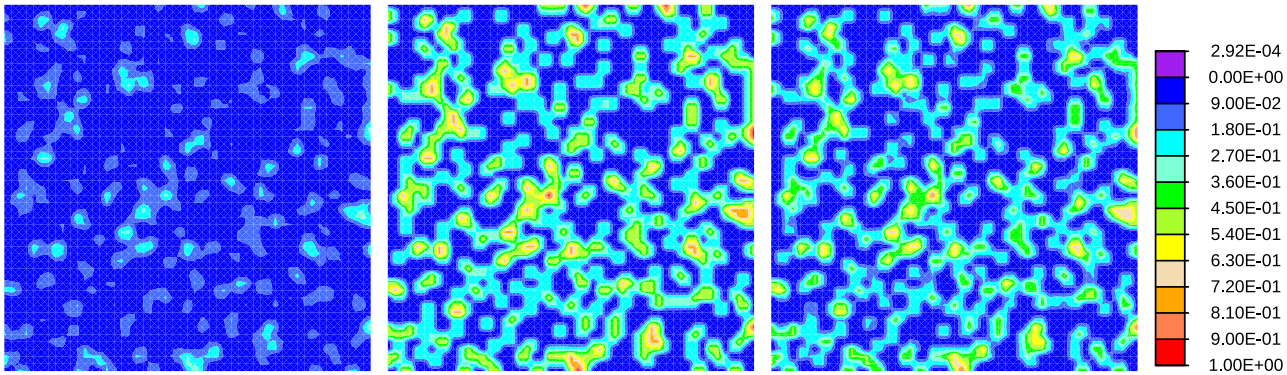
The definitions take the following notation: A is the crystallization limit, whereas B defines its evolution. Parameter b and function $f(\chi)$ regulates the change of B depending on the load type and the current value of regularity. Finally, D is a viscous type constant and a, c and d are material parameters. The minimization of the C^0 continuous Lagrange function is obtained by calculating the subdifferential, finally leading to the evolution equations

$$\dot{\alpha} = \frac{1}{D} q_\alpha\,, \qquad \dot{\chi} = \begin{cases} 0\,, & \text{if} \quad |q_\chi| \leq A+B\,, \\ \lambda\, q_\chi\,, \quad \lambda = \dfrac{f(\chi)\, q_\chi\, \dot{q}_\chi}{b\,(A+B)^2} \geq 0\,, & \text{else}\,. \end{cases} \tag{6}$$

The crystallization parameter λ in the expression for $\dot{\chi}$ is the result of the consistency condition $q_\chi\,\dot{q}_\chi = (A+B)\,\dot{B}$. Both evolution equations depend on thermodynamical driving forces defined in (4). Due to the influence of thermal effects, the full formulation of the problem also requires the consideration of the energy balance [3].

NUMERICAL RESULTS

The selected numerical example deals with the finite element simulation of a cyclic tensile test for a square sample with the dimensions 100×100 nm. The lower and the upper boundaries are constrained and the vertically applied stretch λ linearly increases and subsequently decreases in the interval $[1.0,\ 6.0]$. The total time amounts to 10 s and the time increment is 2×10^{-3} s. The initial values of the regularity are randomly generated over the sample. During the loading phase the regularity increases and its growth is favored in regions with the higher initial values (Fig. 1a). Figure 1b shows the state of the network regularity in the final (maximal) loading step, where fully crystalline regions are present. The crystalline regions decrease at a lower rate during the unloading phase (Fig. 1c).



a) $\lambda = 4$ b) $\lambda = 6$ c) $\lambda = 4$

Figure 1: Cyclic tension test for a sample with the random initial microstructure. Snapshots: a) $\lambda = 4$ - loading stage, b) $\lambda = 6$ - end of the loading, c) $\lambda = 4$ - unloading stage. Applied material parameters: $A = 2 \times 10^5$ Pa, $b_1 = 5 \times 10^4$ Pa, $b_2 = 6 \times 10^4$ Pa, $k_1 = 6 \times 10^{-2}$, $k_2 = 0.1$, $D = 2 \times 10^6$ Pa, $c_2 = 4 \times 10^5$ Pa/K, $c_3 = -1.2 \times 10^8$ Pa and $c_p = 2 \times 10^7$ J/(kg K).

The present work shows a thermodynamical model for the SIC based on the assumptions for the Helmholtz energy and the dissipation potential. The model enables the simulation of the evolution of the microstructure during a complete cyclic tension test including the degradation of crystals and temperature reduction during the unloading phase. As a next step, the model will be implemented within the multiscale concept in order to study the influence of crystallization on the effective material behavior of polymers.

COMPUTATIONAL THERMODYNAMICS OF STRAIN-INDUCED CRYSTALLIZATION

Vu Ngoc Khiêm*[1], Mikhail Itskov[1], and Jean-Benoît Le Cam[2]

Summary As a type of phase transition in natural rubbers, strain-induced crystallization is a phenomenon where amorphous polymer molecules transform to perfect order structures (crystallites) under the course of extension. Strain-induced crystallites are very important for the elastomer reinforcement and crack growth resistance in natural rubbers. This contribution presents a computational thermodynamic framework for filled natural rubbers. The proposed model is based on the analytical network-averaging theory [1,2,3]. In contrast to previous works on thermomechanics of natural rubbers, this model explicitly derives internal energy and entropy of polymer molecules in terms of state variables. Such methodology would allow for microscopic boundary conditions of the representative volume element, and shed new light on the multiaxiality of strain-induced crystallization.

INTRODUCTION

The thermomechanics of strain- induced crystallization in natural rubbers has not been properly described so far in spite of much effort applied to develop the kinetic theory [4, 5]. Most of the proposed theories fail to elucidate the Gough-Joule effect due to their isothermal nature. Besides, elastoplasticity-based models contradict calorimetric measurement [6] since they predict positive mechanical dissipation.

THERMOMECHANICAL FRAMEWORK

Free energy

The Helmholtz free energy of natural rubber in a material point of the continuum can be given by [2]

$$\Psi = U\left(\mathbf{F}, \Xi, T\right) - T\eta\left(\mathbf{F}, \Xi, T\right), \tag{1}$$

where U is the internal energy per unit referential volume and η is the network entropy. $\mathbf{F}$ is the deformation gradient, Ξ denotes an internal variable and T is the absolute temperature. The quantities $\mathbf{F}$, Ξ and T are state variables.

Energy balance

The energy transfer during the strain-induced crystallization can be analyzed by means of the first law of thermodynamics [2] as

$$\dot{U} = \mathbf{P} : \dot{\mathbf{F}} - \mathrm{Div}\,\boldsymbol{Q} + \hat{R}, \tag{2}$$

where $\boldsymbol{Q}$ is the heat influx per unit referential area, $\hat{R}$ denotes the heat supply per unit referential volume of the body, $\mathbf{P}$ is the first Piola-Kirchhoff stress tensor and the superposed dot indicates the material time derivative.

CRYSTALLIZATION KINETICS

This work assumes a two-step crystallization kinetics [2]. First, solid clusters of polymer segments (primary crystallites) are formed in the amorphous network at the onset of strain-induced crystallization. Afterwards, secondary crystallites grow from the nuclei. These steps are referred to as crystallization nucleation and growth, respectively.

Crystallization nucleation

The primary crystallite is assumed here to be bundle-like with a cylindrical geometry. Each crystallite is formed by K neighbouring polymer chains aligned in the stretching direction. Therefore, the primary crystallinity is proportional to the fraction of aligned chains.

By means of the nucleation theory [2], the primary crystallinity in each spatial direction i can be calculated as

$$\zeta_{Bi} = \zeta_{\mathrm{B}} \exp\left(-\frac{8\pi\gamma_t\gamma_s^2}{k_{\mathrm{B}}T\Delta\Psi_{\mathrm{i}}^2}\right), \tag{3}$$

where ζ_{B} denotes a material constant, γ_t is the surface tension at the top surfaces of the crystallite. γ_s is the surface tension on the side of the crystallite. $\Delta\Psi_{\mathrm{i}}$ is the difference in bulk free energies between the semicrystalline and the amorphous subnetworks.

*Corresponding author. E-mail: vu@km.rwth-aachen.de.

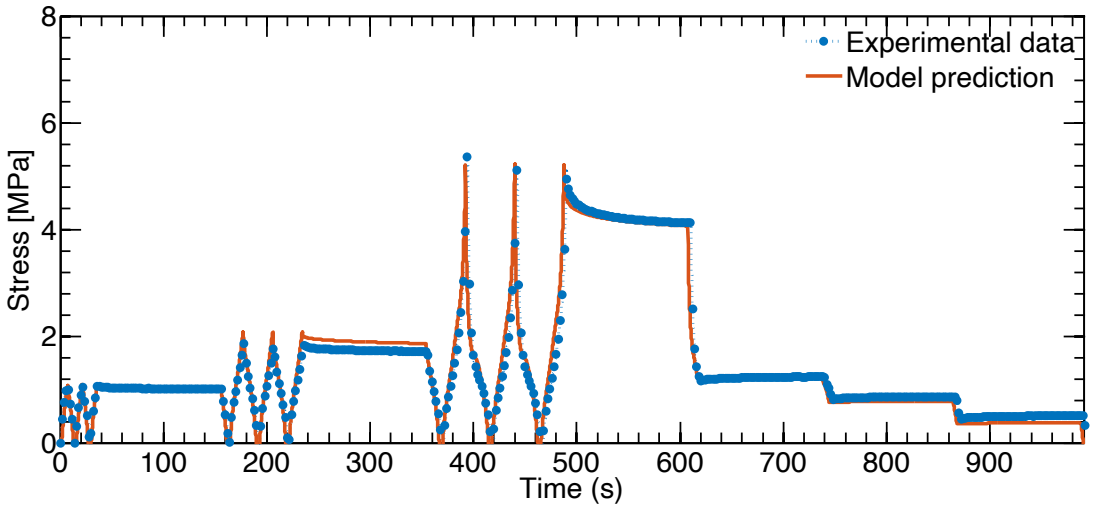

Figure 1: Comparison between model prediction and experimental data of a filled natural rubber under a multiple relaxation test.

Thus, the fraction of chains aligned in each spatial direction is proportional to ζ_{Bi} as

$$w_i = w_B \exp\left(-\frac{8\pi\gamma_t\gamma_s^2}{k_B T \Delta\Psi_i^2}\right), \tag{4}$$

where w_B is the limit of the chain alignment. According to the analytical network averaging theory [1, 2, 3], the microscopic boundary condition $\bar{\mathbf{\Lambda}}$ of the representative volume element (i.e. representative polymer molecule) is given by

$$\bar{\mathbf{\Lambda}} = \bar{\mathbf{\Lambda}}\left(\mathbf{F}, w_i\right). \tag{5}$$

Crystallization growth

The secondary crystallites grow from the primary nuclei. Thus, the secondary crystallinity ζ_{Ci} in each spatial direction i is a multiplication of the number of nuclei and the number of grown crystallites from each nucleus in this direction [2] as

$$\zeta_{Ci}\left(\mathbf{F}, \Xi\right) = \zeta_{Bi}\left(\mathbf{F}\right) \cdot \zeta_{Gi}\left(\mathbf{F}, \Xi\right). \tag{6}$$

The total crystallinity in each spatial direction is the sum of the primary and secondary crystallinity as

$$\zeta_i = \zeta_{Bi} + \zeta_{Ci}. \tag{7}$$

RESULTS

Finally, the proposed model is validated by comparing its prediction with a multiple relaxation test of a filled natural rubber (see Figure 1). Good agreement to the experimental data can be observed.

HYPERLEASTICITY IN TOPOLOGY OPTIMIZATION: A VARIATIONAL APPROACH

Philipp Junker*, Daniel Balzani
Institute of Continuum Mechanics, Ruhr University Bochum, Bochum, Germany

Summary A novel approach to the topology optimization of hyperalstic structures is presented. Applying variational techniques, an evolution equation for the density parameter is obtained that is solved simultaneously to the balance of linear momentum. Whereas for the latter a finite element strategy is employed, we make use of a newly introduced method using the strong form of the evolution equation for the density parameter. This neighbored element method allows for a fast numerical treatment.

TOPOLOGY OPTIMIZATION

Topology optimization is a key component in the design of structures. Here, the optimal shape is to be computed for a given design space and boundary conditions. Several approaches to solve this problem are available, such as SIMP (Solid Isotropic Material with Penalization), phase field methods, or level set strategies to mention just a few [1]. A huge challenge is to accurately treat the problem in a numerical sense since usually non-convex functions are used in order to find discrete black/white solutions with a minimum of gray transition regions between full and void material. The non-convex energies, however, render the problem ill-posed such that filter techniques or, more generally speaking, regularization strategies are inevitable. A prominent example is the checkerboard phenomenon that is present when no regularization is employed.

VARIATIONAL APPROACH

In the current talk, we present a variational approach to topology optimization which is based on methods known from material modeling [2-5]. We regularize the problem by introducing a convex gradient term to the optimization functional rendering the problem well-posed. Furthermore, we discuss how a parameterization of the density function allows for fulfilling the constraint of boundedness of the density function in]0,1]. This novel method for topology optimization is applied to hyperelastic structures, i.e. we are using a Neo-Hooke material for optimization. Along with the model derivation, several numerical examples and comparisons with results for Hookean materials proof the validity of our approach.

A DISCRETE BOUNDARY ELEMENT METHOD FOR 3D ATOMISTIC/CONTINUUM COUPLING

Ankit Gupta *[1], Max Hodapp[2], and W. A. Curtin[1]
[1]Laboratory for Multiscale Mechanics Modeling, EPFL, Lausanne, Switzerland
[2]Center for Energy Science and Technology, Skolkovo Institute of Science and Technology, Moscow, Russia

Summary The Coupled Atomistic/Discrete Dislocation (CADD) method has been successfully used to study multiscale phenomena such as plasticity in metals, but practical computational applications are currently limited to plane strain or infinite-space problems [2]. Here, we discuss a new Discrete Boundary Element Method (DBEM) that is combined with the flexible boundary condition method to enable efficient large-scale concurrent coupling of atomistic and DD domains, greatly reducing the computational cost of 3d plasticity problems.

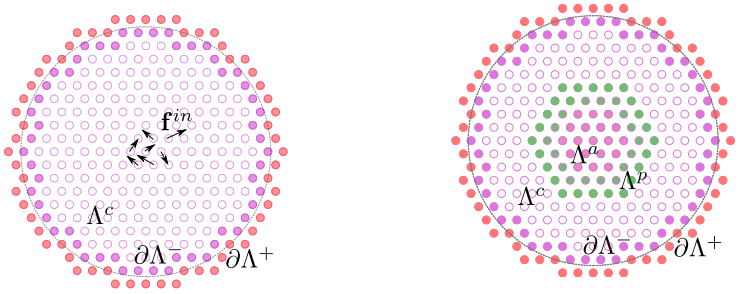
THE DBEM AND ITS INTEGRATION WITH THE FLEXIBLE BOUNDARY CONDITIONS METHOD

The CADD method [5] concurrently couples atomistic and discrete dislocation domains which enables the study of non-linear, intrinsically atomistic, phenomena, such as dislocation emission near crack tips, using an atomistic material description while treating remote regions with the less-expensive DD method. Previously, the FEM which requires discretisation of entire domain, has been used to solve 3d DD problems in small systems, with large systems being computationally intractable. The problem of dealing with such large systems can be overcome by using the boundary element method based DBEM [4] in the continuum DD region and Sinclair's [7] flexible boundary condition method at the atomistic-continuum interface.

The governing equations for a general bounded DBEM problem shown in Fig. 1(a) containing finite lattice sites, represented by set Λ^c (inside dotted line), are as follows. The lattice sites comprise atoms interacting harmonically leading to a linear force displacement relationship represented by the force constant matrix $[\underset{\sim}{\boldsymbol{L}}_{\xi|\eta}]$ between atoms at sites ξ and η. We assert that the corresponding lattice green function matrix is $[\underset{\sim}{\boldsymbol{G}}_{\xi|\eta}] = [\underset{\sim}{\boldsymbol{L}}_{\xi|\eta}]^{-1}$. The $\partial\Lambda^- \subset \Lambda^c$(blue) and $\partial\Lambda^+$(green) outside the bounded region are sets of lattice sites that have non-zero forces when any atom in the other set are displaced. The displacement $\mathbf{u}_\xi$ of any atom at $\xi \in \Lambda^c$, subjected to external forces $[\mathbf{f}_\eta]$ and displacements $[\mathbf{u}_\eta]$ for atoms in $\eta \in \partial\Lambda^-$ and any internal forces $[\mathbf{f}^{in}_\eta]$ for atoms at $\eta \in \Lambda^{in}$, is given by

$$\mathbf{u}_\xi = -\sum_{\eta\in\partial\Lambda^-} \underset{\sim}{\boldsymbol{G}}_{\xi|\eta}\,\mathbf{f}_\eta + \sum_{\eta\in\partial\Lambda^-} \underset{\sim}{\boldsymbol{F}}_{\xi|\eta}\,\mathbf{u}_\eta + \sum_{\eta\in\Lambda^{in}} \underset{\sim}{\boldsymbol{G}}_{\xi|\eta}\,\mathbf{f}^{in}_\eta, \qquad \forall\xi\in\Lambda^c. \tag{1}$$

where $\underset{\sim}{\boldsymbol{F}}_{\xi|\eta} = \sum_{\zeta\in\partial\Lambda^+} \underset{\sim}{\boldsymbol{G}}_{\xi|\zeta}\underset{\sim}{\boldsymbol{L}}_{\zeta|\eta}$. This method requires no explicit discretisation $inside$ the domain, only the boundary conditions (displacements and/or forces) on the outer surface (set $\partial\Lambda^-$) are treated explicitly.



(a) bounded general DBEM problem

(b) coupled atomistic-continuum problem

Figure 1

We then consider the coupling of the continuum to an internal atomistic domain, represented by atoms Λ^a interacting according to specified interatomic potentials (Fig. 1(b)). The atoms in Λ^p around the interface are "pad" atoms that are in the continuum, and slaved to the continuum degrees of freedom, but serve to transmit forces and displacements to the atoms in Λ^a . This interface coupling is achieved using flexible boundary condtions, originally described by Sinclair [7].

The entire coupling methodology has been implemented with the molecular dynamics code LAMMPS [1]. As a demonstration case, we model a two-dimensional hexagonal lattice of atoms interacting via a Morse potential [6]. We subject the coupled problem to a rigid shift, i.e. a displacement boundary condition in which all the atoms on $\partial\Lambda^-$ are displaced by the same amount in the same direction. Fig. 2 shows various steps during the simulation: (a) initial undeformed system, (b) after displacement of the boundary atoms, (c) during iteration toward the solution, and (d) the final solution. The final solution has all atoms rigidly displaced by the displacment imposed on the boundary.

EFFICIENT TREATMENT OF THE OUTER BOUNDARY

The governing equation for the DBEM requires atomic scale discretization of the entire outer surface (set $\partial\Lambda^-$). For 3d applications of CADD which are of practical interest, there can be millions of degree of freedom, and this is not computationally tractable. In most boundary value problems, the boundary conditions on the outer surface are varying very slowly over the atomic scale-it is only in the atomistic region and near dislocations where deformations are varying rapidly. Therefore, the atomistically-resolved boundary can be coarse grained. Specifically, the imposed forces and displacements can be approximated using local shape functions. Fig. 3 shows a schematic representation of $\partial\Lambda^-$ surface atoms represented by crosses with a reduced set of atoms chosen to form $\partial\Lambda_h \subset \partial\Lambda^-$(represented by squares) and local shape functions $\mathbf{\Phi}^\alpha$ defined for each lattice site α. $\partial\Lambda_\alpha$ denotes the atoms contained in support of $\mathbf{\Phi}^\alpha$. The displacement and forces for every atom on $\eta \in \partial\Lambda^-$ can be represented as $\mathbf{u}_\eta = \sum_{\alpha\in\partial\Lambda_h} \mathbf{u}_\alpha \mathbf{\Phi}^\alpha(\mathbf{x}_\eta)$ and $\mathbf{f}_\eta = \sum_{\alpha\in\partial\Lambda_h} \mathbf{f}_\alpha \mathbf{\Phi}^\alpha(\mathbf{x}_\eta)$. The local shape functions satisfy following property, $\mathbf{\Phi}^\alpha(\mathbf{x}_\eta) = \delta_{\alpha|\eta} \forall \eta, \alpha \in \partial\Lambda_h$. Using these shape function the governing equations are reduced to

$$\mathbf{u}_\xi = -\sum_{\eta\in\partial\Lambda_h} \tilde{\underset{\sim}{G}}_{\xi|\eta}\, \mathbf{f}_\eta + \sum_{\eta\in\partial\Lambda_h} \tilde{\underset{\sim}{F}}_{\xi|\eta}\, \mathbf{u}_\eta + \sum_{\eta\in\Lambda^{in}} \underset{\sim}{G}_{\xi|\eta}\, \mathbf{f}^{in}_\eta, \qquad \forall \xi \in \Lambda^c. \tag{2}$$

Here, $\tilde{\underset{\sim}{G}}_{\xi|\eta} = \sum_{\alpha\in\partial\Lambda_\eta} \underset{\sim}{G}_{\xi|\alpha} \mathbf{\Phi}^\eta(\mathbf{x}_\alpha)$ and $\tilde{\underset{\sim}{F}}_{\xi|\eta} = \sum_{\alpha\in\partial\Lambda_\eta} \underset{\sim}{F}_{\xi|\alpha} \mathbf{\Phi}^\eta(\mathbf{x}_\alpha)$. This matrix can be efficiently constructed using Hierarchical matrices [3], which involve low-rank approximations to $[\underset{\sim}{G}_{\xi|\eta}]$ and $[\underset{\sim}{F}_{\xi|\eta}]$. This reduces the number of degrees of freedom to $\mathcal{O}(N_h^2 \log(N))$ compared to $\mathcal{O}(N^2)$ required for exact solution of Eq. (1), where N and N_h are number of atoms in $\partial\Lambda^-$ and $\partial\Lambda^h$, respectively.

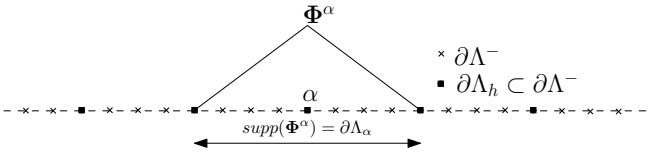

Figure 3

This new method for treatment of the outer boundary will be demonstrated on various sample problems to show the reductions in computational and memory costs and the relative error of the approximate solution with respect to an exact reference solutions.

CONCLUSIONS

We have successfully combined a DBEM method and Sinclair's scheme for large-scale 3d coupled Atomistic/Continuum boundary value problems. The implementation has been made within the open-source code LAMMPS, which will eventually enable wide dissemination of the methodology. The overall method has been demonstrated using various test problems, which serve as validation of the method and its computational efficiency.

COMPUTATIONAL MODELING OF CHEMO-THERMO-MECHANICAL CRACKING IN EARLY-AGE CONCRETE

Mehran Ghasabeh[1] and Serdar Göktepe*[1]
[1]Department of Civil Engineering, Middle East Technical University, 06800, Ankara, Turkey

Summary In this contribution, a chemo-thermo-mechanical modeling approach coupled with a cohesive phase field model is developed to address thermal cracking observed in massive concrete structures. The computational risk analysis of thermal cracking is of cardinal importance for massive concrete structures whose lifetime may be drastically reduced by early-age cracksif necessary precautions are not taken. The existing phase field-based approaches applied to multi-physics problems are predominantly restricted to brittle fracture. In this work, however, we extend the recently proposed cohesive phase field approach coupled with chemo-thermo-mechanical effects to predict thermal cracking in a roller-compacted concrete (RCC) structures where the stress concentrations arise from high temperature gradients generated by the highly exothermic hydration process.

INTRODUCTION

In cementitious composite materials, the durability problems generally arise from uneven volume changes that may result from heat generation and transfer due to hydration, moisture transfer, or chemical reactions at different ages of concrete. In the presence of restrictive boundary conditions, in particular on deformation, these non-uniform volumetric strains may result in stress concentrations. As the principal tensile stress values exceed the tensile strength of concrete, gained during the course of hydration, cracks start to onset [1]. This study is concerned with the computational prediction of thermal cracks that are initiated by high temperature gradients due to the heat generated through hydration and it convection and conduction in massive concrete structures. Therefore, the coupled problem of interest is governed by three equations where besides the displacement and temperature fields, the crack phase field is included to account for thermal cracking. To this end, a coupled chemo-thermo-mechanical approach [2] is developed to investigate the cross-effect of the evolution of both temperature and the degree of hydration on the durability and mechanical properties of concrete structures. Over a couple of decades, the phase-field approach has become popular in modeling failure mechanisms in solid bodies [3]. This approach has pronounced advantages over the other methods of the computational fracture mechanics in predicting complex crack topologies, curvilinear crack paths, crack kinking, and branching without requiring special extensions of discretization methods. In the literature, most of the studies tackling with coupled multi-physics problems employ the brittle phase field approach. The novel aspect of the proposed approach is that it extends the recently proposed quasi-brittle phase field approach [4] to account for thermal cracking in massive concrete structures within the framework of coupled chemo-thermo-mechanics. The capabilities of the developed model is demonstrated through a crack risk analysis of a roller-compacted-concrete dam [5].

GOVERNING EQUATIONS AND CONSTITUTIVE MODEL

A coupled problem of chemo-thermo-mechanics accompanied by the phase-field approach to the fracture is formulated in terms of four field variables, namely the total strain tensor $\boldsymbol{\varepsilon}(\boldsymbol{x},t) := \mathrm{sym}(\nabla_{\boldsymbol{x}}\boldsymbol{u})$, the absolute temperature field $\theta(\boldsymbol{x},t)$, the crack phase field $d(\boldsymbol{x},t)$, and the degree of hydration $\xi(\boldsymbol{x},t)$. While the evolution of the first three field variables is governed by the balance of linear momentum $\mathrm{div}(\boldsymbol{\sigma}) + \boldsymbol{b} = \boldsymbol{0}$, the transient heat conduction equation $\mathrm{div}(\boldsymbol{q}_\theta) + f_\theta = 0$, the non-local damage evolution equation $\mathrm{div}(\boldsymbol{q}_d) - \mathcal{H}_d + f_d = 0$, respectively, the evolution of the degree of hydration is described by an additional ordinary differential equation. To be able to solve these differential equations by discretizing them using the finite element method, the constitutive equations for the total stress $\boldsymbol{\sigma}$, the heat flux $\hat{\boldsymbol{q}}_\theta$, the crack phase-field diffusion $\hat{\boldsymbol{q}}_d$, the viscous heat resistance $\hat{f}_\theta$, and the crack phase-field resistance $\hat{f}_d$ must be specified. For this purpose, the positive and negative parts of the total stress tensor along with the elastic strain tensor are defined as follows

$$\begin{aligned} \boldsymbol{\sigma} = \hat{\boldsymbol{\sigma}}(\boldsymbol{\varepsilon},d,\theta,\xi) := \hat{\omega}(d)\,\boldsymbol{\sigma}_0^+ - \boldsymbol{\sigma}_0^- \quad \text{with} \quad \boldsymbol{\sigma}_0^\pm = \hat{\lambda}(\xi)\langle \mathrm{tr}\boldsymbol{\varepsilon}^{\mathrm{e}}\rangle_\pm + 2\hat{\mu}(\xi)\langle \boldsymbol{\varepsilon}^{\mathrm{e}}\rangle_\pm \\ \boldsymbol{\varepsilon}^e := \boldsymbol{\varepsilon} - \alpha\Delta\theta\boldsymbol{1} - \boldsymbol{\varepsilon}^{\mathrm{sh}} - \boldsymbol{\varepsilon}^{\mathrm{ttc}} \quad \text{with} \quad \boldsymbol{\varepsilon}^{\mathrm{sh}} := \langle \frac{\xi-\xi_0}{1-\xi_0}\rangle_+ \boldsymbol{1} \quad \text{and} \quad \dot{\boldsymbol{\varepsilon}}^{\mathrm{ttc}} := \lambda^{\mathrm{ttc}} \mid \dot{\theta} \mid \boldsymbol{\sigma}_0 \end{aligned} \tag{1}$$

where $\boldsymbol{\varepsilon}^{\mathrm{ttc}}$ and $\boldsymbol{\varepsilon}^{\mathrm{sh}}$ denote the transient thermal creep strain and the autogenous shrinkage strain, respectively. In the transient heat conduction, the heat flux vector $\boldsymbol{q}_\theta$ is defined according to the Fourier's law $\boldsymbol{q}_\theta = \hat{\boldsymbol{q}}_\theta(\theta) := -k_\theta \nabla_{\boldsymbol{x}}\theta$ in terms of the non-negative coefficient of thermal conductivity k_θ and the temperature gradient $\nabla_{\boldsymbol{x}}\theta$. Furthermore, the thermal energy storage is defined in terms of the the volume-specific heat capacity ρc, the latent heat of hydration Q_ξ, and the degree of hydration ξ

$$f_\theta = \hat{f}_\theta(\theta;\dot{\theta}) = \rho c\,\dot{\theta} - Q_\xi \dot{\xi} \tag{2}$$

*Corresponding author. E-mail: sgoktepe@metu.edu.tr

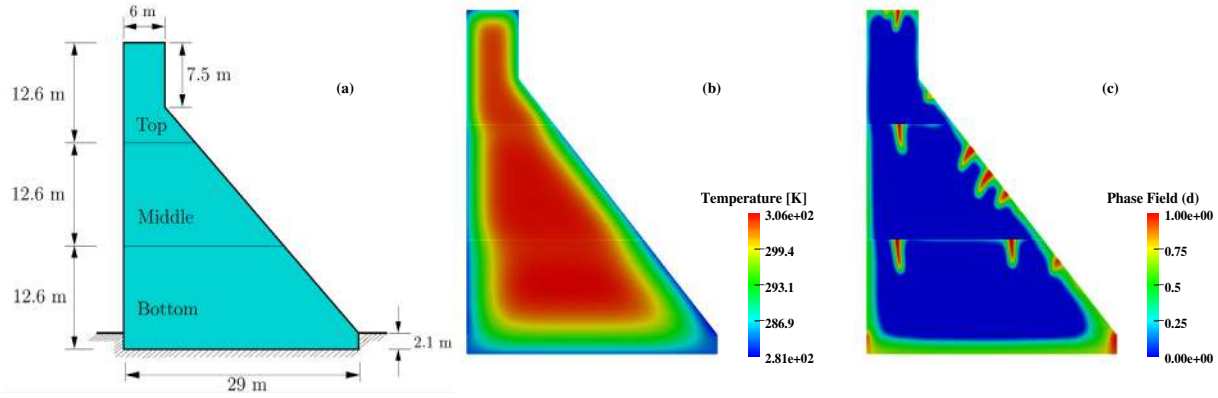

Figure 1: Roller-compacted-concrete dam: **(a)**: geometric dimensions, **(b)**: temperature distribution, **(c)** cracks propagation under coupled chemo-thermo-mechanical effect on 77th day.

where the last term represents the effect of hydration process on the evolution of temperature. Moreover, the crack phase-field flux $\boldsymbol{q}_d$ in the non-local damage evolution equation is defined as

$$\boldsymbol{q}_d = \hat{\boldsymbol{q}}_d(d, \xi) := -\frac{1}{c_0}\hat{G}_c(\xi)\,\ell\,\nabla_{\boldsymbol{x}} d \tag{3}$$

where $\hat{G}_c(\xi)$ is the age-dependent critical fracture energy, ℓ indicates an internal length scale regularizing the sharp crack, $c_0 > 0$ is a scaling parameter, and $\nabla_{\boldsymbol{x}} d$ stands for the spatial gradient of crack phase-field. The crack resistance is expressed as

$$f_d = \hat{f}_d(d; \dot{d}) = \frac{\hat{G}_c(\xi)\,\hat{\alpha}_d(d)}{\ell c_0} \tag{4}$$

where $\hat{\alpha}_d(d)$ represents the geometric crack function characterizing homogeneous evolution of the crack phase-field.

REPRESENTATIVE NUMERICAL EXAMPLES

To illustrate the capabilities of the proposed model, the thermal crack risk analysis of the roller-compacted-concrete (RCC) dam [5] is carried out. The geometric dimensions, the temperature distribution, and thermally induced cracks pattern in RCC dam are represented in Fig. 1. As shown, the RCC dam is mechanically fixed at the boundaries interacting with the soil. It is constructed in three parts. These parts from bottom to top were constructed in 42, 21, and 14 days, respectively. At the RCC-air boundaries of the model, the heat loss is simulated to investigate the effect of the ambient temperature on the behavior of the dam during its construction. In this problem the ambient temperature is dropped to 5°C as the interior part of the dam undergoes the temperature increase up to 33°C. The high temperature gradients between the interior and exterior of the dam causes cracks to initiate at the boundaries of the dam and to propagate towards interior part of the dam.

CONCLUSION

Through the numerical example represented above, it is demonstrated that the proposed coupled chemo-thermo-mechanical model along with the cohesive zone phase-field approach is capable of predicting the potential crack paths in the RCC dam under the coupled chemo-thermo-mechanical effects primarily governed by the ambient temperature at early ages.

BIPENALTY EXPLICIT FINITE ELEMENT ALGORITHM FOR THE SOLUTION OF CONTACT-IMPACT PROBLEMS

Dušan Gabriel*[1], Ján Kopačka[1], Radek Kolman[1], and Jiří Plešek[1]
[1]Institute of Thermomechanics of the Czech Academy of Sciences, Prague, Czech Republic

Summary In dynamic transient analysis, recent comprehensive studies have shown that using mass penalty together with standard stiffness penalty, the so-called bipenalty technique, preserves the critical time step in conditionally stable time integration schemes. In this paper, the bipenalty approach is applied in the explicit contact-impact algorithm based on the pre-discretization penalty formulation for the solution of 2D/3D problems. Several numerical examples are presented including the longitudinal impact of two thick plates, for which analytical solution is available and the Taylor high-velocity impact test with elastic-plastic flow model. In all the cases the superiority of the bipenalty method over the standard stiffness penalty method is demonstrated.

INTRODUCTION

In contact problems the contact constraints can be enforced either by the Lagrange multiplier method or by the stiffness penalty method. In practise the latter approach has gained in substantial popularity, because its implementation is easy, straightforward and has a clear physical meaning. On the other hand, the choice of the penalty parameter influences the accuracy of the approximate solution. In addition, in contact-impact applications the stiffness penalty method tends to decrease the critical time step in conditionally stable time integration schemes. This is due to the fact that the stiffness-type penalty can greatly enlarge the maximum eigenfrequency of a system.

In dynamic transient analysis, the penalty method can also be applied to the mass matrix. This technique is known as the mass penalty or the inertia penalty method. In contrast to the stiffness penalty approach, it significantly reduces one or more eigenfrequencies. In Reference [1] the bipenalty technique was introduced, where the both penalty formulations were used simultaneously. The goal of this method is to find the optimum of the so-called critical penalty ratio (CPR) defined as the ratio of stiffness and mass penalty parameters so that the maximum eigenfrequency and the critical time step are preserved. The calculation of CPR requires an analysis of the full bipenalised problem. Owing to mathematical difficulty, it limits the classes of elements that can be taken into account. In order to overcome this problem, a simple relationship between the CPR of an element and its maximum unpenalised eigenfrequency was derived in [2]. Thus, the multiple constraints and more complex element formulations can be directly accounted for [3]. In Reference [4] the stability of the bipenalty method has been studied for one-dimensional contact-impact problems. The main attention has been paid on an upper bound estimation of the stable Courant number for the bipenalty method with respect to stiffness penalty and mass penalty parameters.

BIPENALTY METHOD

Next, a brief description of the bipenalty method follows. Let us assume that the contact boundary Γ_c is known. The standard stiffness penalty method adds an extra term to the strain energy to enforce the zero gap g_N on the contact boundary

$$\mathcal{U}_p(\mathbf{u}) = \int_\Omega \frac{1}{2}\boldsymbol{\sigma} : \boldsymbol{\varepsilon}\, dV + \int_{\Gamma_c} \frac{1}{2}\epsilon_s g_N^2\, dS \tag{1}$$

Further, the inertia penalty term can also be added to the kinetic energy to enforce the zero gap rate $\dot{g}_N$ on the contact interface

$$\mathcal{T}_p(\dot{\mathbf{u}}) = \int_\Omega \frac{1}{2}\rho\dot{\mathbf{u}}\cdot\dot{\mathbf{u}}\, dV + \int_{\Gamma_c} \frac{1}{2}\epsilon_m \dot{g}_N^2\, dS \tag{2}$$

The penalised Lagrangian functional can be defined as

$$\mathcal{L}_p(\mathbf{u},\dot{\mathbf{u}}) = \mathcal{T}_p(\dot{\mathbf{u}}) - (\mathcal{U}_p(\mathbf{u}) - \mathcal{W}(\mathbf{u})) \tag{3}$$

where $\mathcal{W}(\mathbf{u})$ is the work done by external body forces $\mathbf{b}$ and traction forces $\mathbf{t}$. The unknown displacement field can be found as one which renders the penalised action functional stationary

$$\delta \int_0^T \mathcal{L}_p(\mathbf{u},\dot{\mathbf{u}})\, dt = 0 \tag{4}$$

where δ denotes the first variation or the directional derivative in the direction of virtual displacement $\delta\mathbf{u}$. Using the standard procedures one arrives to the principle of virtual displacement

$$\int_\Omega \rho\delta\mathbf{u}\cdot\ddot{\mathbf{u}}\, dV + \int_\Omega \delta\boldsymbol{\varepsilon} : \boldsymbol{\sigma}\, dV + \int_{\Gamma_c} \delta g_N(\epsilon_m\ddot{g}_N + \epsilon_s g_N)\, dS = \int_\Omega \delta\mathbf{u}\cdot\mathbf{b}\, dV + \int_{\Gamma_\sigma} \delta\mathbf{u}\cdot\mathbf{t}\, dS \tag{5}$$

Figure 1: Taylor high-velocity impact test with elastic-plastic flow model.

which serves the base for the finite element discretization. The integrals (5) represent the virtual work of the inertia forces, internal forces, contact forces, body forces, and traction forces, respectively. Note that the integral of the virtual contact work is expressed with the aid of the inertia ϵ_{m} and the stiffness penalty ϵ_{s} simultaneously. The details concerning finite element implementation, explicit time integration including analysis of numerical stability can be found in Reference [4].

In this work, use of the bipenalty technique is extended for the solution of 2D/3D contact-impact problems. To this end, symmetry preserving explicit contact algorithm [5] has been modified to consider bipenalty treatment of contact constraints. Several numerical examples are presented including the longitudinal impact of two thick plates, for which analytical solution is available and the Taylor high-velocity impact test with elastic-plastic flow model shown in Figure 1.

CONCLUSIONS

In this paper, explicit symmetry-preserving contact-impact algorithm based on the bipenalty treatment of contact constraints was presented. It was shown that proposed algorithm preserved the stable critical time step during time integration by the central difference method regardless the values of stiffness penalty parameter. The effectiveness of proposed algorithm was tested by means of several numerical examples including the longitudinal impact of two thick plates, for which analytical solution is available and the Taylor high-velocity impact test. In all the cases the superiority of the bipenalty method over the standard stiffness penalty method is demonstrated.

A PRIORI ENRICHMENTS FOR MACROSCOPIC PROBLEMS WITH EXPLICITLY RESOLVED MICROSTRUCTURAL DETAILS GENERATED BY THE CONCEPT OF WANG TILES

Martin Doškář*[1], Jan Novák[2], and Jan Zeman[1]
[1]Department of Mechanics, Faculty of Civil Engineering, Czech Technical University in Prague, Prague, Czech Republic
[2]Experimental centre, Faculty of Civil Engineering, Czech Technical University in Prague, Prague, Czech Republic

Summary We present a numerical scheme that accelerates simulations of macroscopic problems with a resolved microstructural geometry generated by means of Wang tiles—an extension of the classical Periodic Unit Cell approach to microstructural characterization. Our approach builds on precomputed microstructure-informed enrichments that are extracted as a collective response of the compressed representation to a prescribed macroscopic loading represented by constant and linear macroscopic gradients. These enrichment fields are then combined with a macroscopic discretization using the ansatz of Generalized Finite Element method to produce reduced modes for a given macroscopic problem. Albeit universal in the sense they are extracted without any knowledge of the shape of a macroscopic domain or its loading, the introduced enrichments allow for a significant reduction in the number of unknowns.

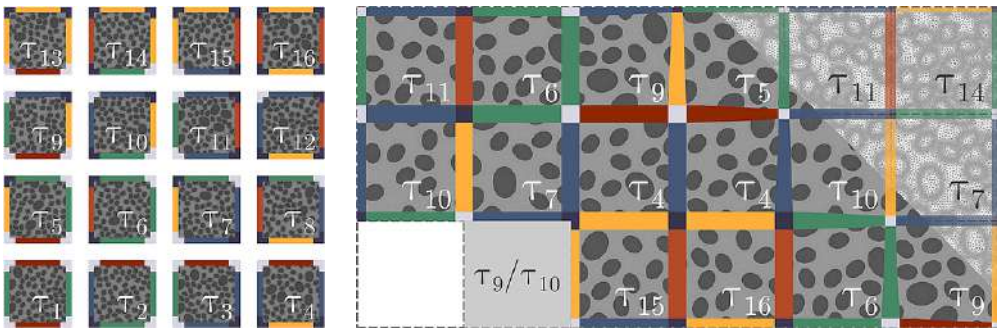
MICROSTRUCTURAL REPRESENTATION

The macroscopic response of materials is predominantly dictated by their microstructural composition. Consequently, numerical models tend to incorporate more knowledge of the underlying material microstructure in order to increase their predictive capability. While the microstructural representation based on a Periodic Unit Cell (PUC) proved to be sufficient for nested multi-scale simulations, it induces an artificial periodicity and determinism when utilized for generating virtual samples of materials with a random heterogeneous microstructure.

In our previous works, e.g. [1, 2], we have generalized the standard PUC-based microstructural representation by replacing a single cell with the concept of Wang tiles, in which the microstructural information is stored in a set of small domains with pre-defined compatibility constraints. Using a stochastic algorithm, the domains—Wang tiles—can be almost instantly assembled into microstructural realizations (along with the corresponding finite element discretization) of an arbitrary size with suppressed periodicity artefacts. This approach thus represents a compromise between generating microstructural samples by the periodic extension of a PUC and methods that create a microstructural sample each time anew such as optimization algorithms. Consequently, it appeals to applications where a multitude of microstructural realizations are needed, such as identification of Representative Volume Element size [3, 4] or Monte-Carlo like analyses of the influence of microstructural randomness on the macroscopic response.

NUMERICAL SCHEME

In this contribution, we present a numerical scheme that exploits the repeating occurrence of individual tile types in the generated microstructural samples and accelerates solutions to problems with a fully resolved underlying microstructural geometry that was generated with the Wang tile concept. The proposed scheme consists of two parts.



(a) (b)

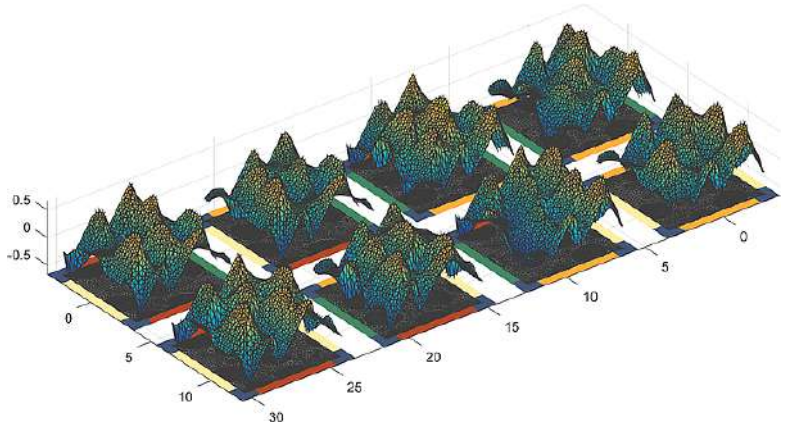

Figure 2: Illustration of a pre-computed characteristic fluctuation field, defined tile-wise and obtained for a unit macroscopic first-order gradient.

First, inspired in computational homogenization, we precompute the characteristic responses of a compressed microstructural representation to a prescribed loading parametrized with the first- and second-order macroscopic gradients. By construction, we constrain the responses to be continuous across the compatible tile edges, i.e., edges with the same attributed code. For the linear problems, as discussed in this contribution, it is sufficient to consider only the unit macroscopic excitations that form a basis in the parametrization space of the macroscopic gradients; however, the same procedure applies also to non-linear material behaviour of individual constituents except for the need for sampling the parametrization space and post-processing the sampled results with, e.g., Proper Orthogonal Decomposition. Since only the fluctuation part of the responses is stored, the tile-wise defined fields obtained for the same macroscopic loading can be subsequently assembled in the macroscopic domain in the same way the microstructural geometry was generated, forming a continuous approximation to the fluctuation part of the solution if the assembled domain was uniformly loaded.

However, the shape and loading of the macroscopic problem rarely yield a uniform distribution of macroscopic gradients, hence it is necessary to interpolate between the approximation fields. To facilitate such an interpolation, we adopt the ansatz of Generalized Finite Element Method (GFEM) as the second part of our scheme. In addition to a fine finite element discretization of a macroscopic domain, which comes from the assembled tiles and for which the characteristic fields are precomputed, we also define a coarse macroscopic discretization that does not resolve any microstructural details and serves mainly to capture the overall solution of the macroscopic problem and to interpolate between the precomputed fluctuation fields. The fields thus take the role of microstructure-informed enrichments, similar to the handbook solutions of Strouboulis et al. [5] or the global-local enrichments of Plews and Duarte [6]. Yet, we use the GFEM ansatz only to construct the problem-specific basis and the final problems is posed in the spirit of reduced order modelling, hence bypassing the need for a specific quadrature and the issues related to imposing Dirichlet boundary conditions by a simple Galerkin projection.

RESULTS AND CONCLUSIONS

We illustrate the proposed scheme with a scalar, elliptic, two-dimensional problem represented by a steady-state heat equation. We show that, albeit the considered microstructure-informed enrichment fields are universal in the sense they are extracted from the compressed system, i.e. without any knowledge on the shape of a macroscopic domain or its loading, the introduced enrichments allow for significant reduction in unknowns while achieving less than 3% relative error in the L_2-norm and energy difference, when compared to the results of the direct numerical simulation. Further improvements can be achieved by a progressive refinement of the coarse macroscopic discretization or by resorting to the fully resolved model in selected subdomains.

RECOVERY-BASED ERROR ESTIMATION AND MESH ADAPTIVITY FOR THE VIRTUAL ELEMENT METHOD

Antonio Maria D'Altri*[1], Stefano de Miranda[1], Luca Patruno[1], Edoardo Artioli[2], and Carlo Lovadina[3]
[1]Department of Civil, Chemical, Environmental, and Materials Engineering (DICAM), University of Bologna, Bologna, Italy

Summary In order to drive adaptive mesh refinement processes in 2D elasticity problems within the Virtual Element Method (VEM), a Recovery by Compatibility in Patches (RCP)-based *a posteriori* error estimator is herein proposed. RCP recovers stresses through the minimization of the complementary energy of patches of elements over a set of assumed equilibrated stress modes. RCP naturally appears suitable for the VEM, as the explicit knowledge of displacements is only requested along the patch boundaries. The error estimation is performed through the comparison of the stress field of a displacement-based VEM solution and the stress field obtained through RCP. The potential of this error estimator to drive mesh adaptivity is shown by means of several examples.

INTRODUCTION

The Virtual Element Method (VEM) is a recent and efficient discretization scheme, in which the shape functions are not known pointwise everywhere, while they are typically explicitly determined on the element boundary. The VEM is well known for its flexibility in handling general polygonal meshes, hanging nodes and non-conforming grids. Particularly, the VEM appears specifically suited for mesh adaptivity, as the use of hanging nodes and polygonal elements can facilitate the adaptive refinement, given that only local mesh modifications are generally required [1]. Accordingly, the development of reliable error estimators to drive adaptive mesh refinements in the VEM appears significant. However, only few *a posteriori* recovery-based error estimators have been developed for the VEM, see for example [1,2].

Recently, the Recovery by Compatibility in Patches (RCP) procedure [3], in which the stresses are recovered by enforcing compatibility over patches of elements, has been extended to the VEM [4]. Particularly, in RCP the stresses are recovered by minimizing the complementary energy functional associated to the patch considered as a separate system, leading to project the error between the displacement-based VEM strains and the strains coming from smoothed (equilibrated) stresses defined over the patch. Accordingly, the explicit knowledge of displacements is only needed along the patch boundaries, thus making the RCP naturally suitable for the VEM [4].

Here, an RCP-based *a posteriori* error estimator is proposed for the VEM, and it is utilized to drive adaptive mesh refinement processes in 2D linear elastic problems. The error estimation is *a posteriori* performed through the comparison of the stress field of a displacement-based VEM solution and the stress field obtained through RCP. The favourable features of the RCP procedure are exploited, e.g. its simplicity, the unnecessary *ad hoc* modification for small patches, and the unnecessary recourse to least-squares schemes. The potential of this error estimator to drive mesh adaptivity is shown by means of several examples.

ERROR ESTIMATION

The error in the displacement-based VEM solution can be suitably evaluated by adopting an integral measure of the distance between the stress field computed via the constitutive relationship and the exact stress field. The basic concept of the recovery-based error estimators consists of replacing the exact stress field by an improved (recovered) solution obtained by a suitable post-processing of the solution, in this case RCP.

The key idea of RCP is to consider each patch of elements (defined as the union of the elements surrounding a central element) as a separate system on which improved stresses are recovered by enhancing equilibrium and relaxing compatibility, i.e. by minimizing the complementary energy associated to the patch, among a set of equilibrated stress modes [3]. In order to minimize the patch complementary energy, the stress field to be recovered can be written as the sum of two contributions, which correspond to the divergence-free homogeneous part of the stress and a particular solution of the equilibrium equation. Various orders of approximation can be adopted for the homogeneous part, leading for example to linear (RCP1) and quadratic (RCP2) approximations.

An extensive numerical campaign is conducted to check the effectiveness of the RCP-based error estimator, see an example in Figure 1 (for a concave polygonal mesh) where the exact displacement field $\mathbf{u}(x,y) = \left[x(1-x)y(1-y)\tan^{-1}\left(\frac{20(x+y-1)}{\sqrt{2}} - 0.8\right), 0\right]^T$ is considered (θ is the effectivity index, defined as the ratio of the estimated to the exact error). A good performance of the RCP-based *a posteriori* error estimator is generally observed for both linear (RCP1) and quadratic (RCP2) approximations for the RCP recovery.

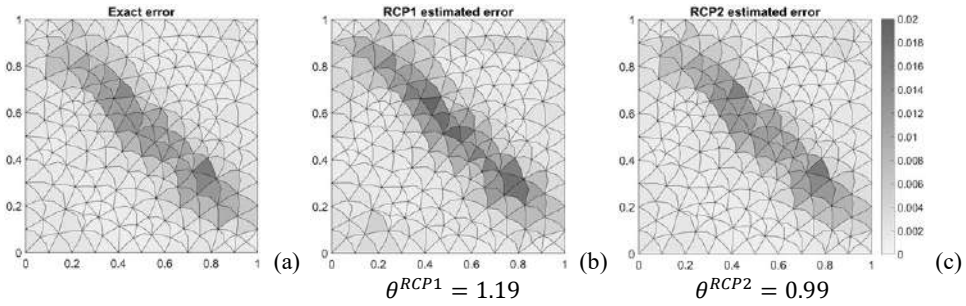

Figure 1. Error maps in energy norm: (a) exact error, (b) RCP1 estimated error, and (c) RCP2 estimated error.

MESH ADAPTIVITY

A "solve → estimate → mark → refine" mesh adaptivity strategy is herein implemented. Once the mesh is refined, it can be used as new input for the adaptive strategy, leading to an iterative adaptive procedure. A standard marking strategy is used to select the elements to be refined, i.e. the elements which show an error exceeding α times the maximum error recorded in the domain are marked for refinement, with $0 \leq \alpha < 1$ a user-defined threshold.

Several mesh refinement strategies can be followed within the VEM framework. In this study, the elements marked for refinement are split by connecting the middle point of each edge of the element to the element centroid. To save degrees of freedom and optimize the procedure, the hanging nodes belonging to elements marked for refinement are treated in a peculiar way, so that the aligned edges which have a hanging node in (at least) one extremity are considered as a unique edge, i.e. they are subdivided through just one middle point. In case the middle point corresponds with an existing hanging node, the existing node is used to describe the connectivity of the new elements.

A wide numerical campaign is conducted to test the efficacy of the RCP-based *a posteriori* error estimator to drive adaptive mesh refinements, see an example in Figure 2 where a cantilever deep beam benchmark is used to highlight the effectiveness of adaptive mesh refinement with respect to uniform mesh refinement (for a structured regular hexagon mesh). As can be noted in Figure 2, both RCP1 and RCP2 show good performances in driving mesh refinements within the VEM framework. Indeed, refinements are automatically performed around the two points with stress singularity (at the two corners of the clamped edge on the left), as expected. Furthermore, adaptive refinements appear to be able to restore the optimal convergence rate (i.e. 1), unlike the cases of uniform refinements.

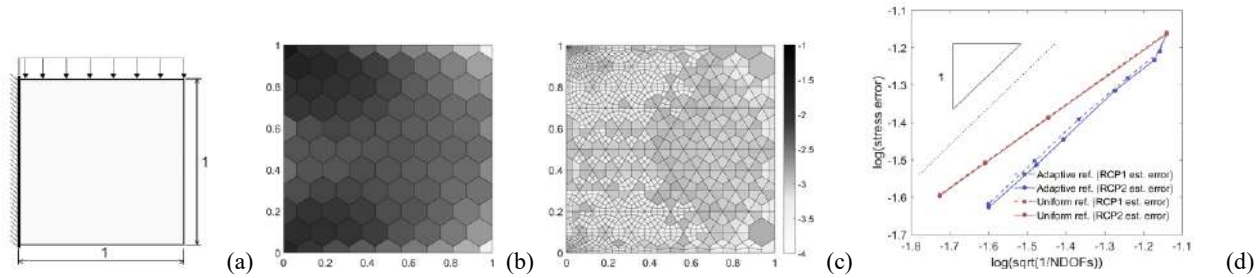

Figure 2. Cantilever deep beam: (a) boundary conditions, logarithmic error maps in energy norm (RCP1) for (b) the initial mesh, and (c) the final refinement, and (d) convergence of estimated error along with adaptive and uniform refinements.

CONCLUSIONS

In this research, a recovery-based *a posteriori* error estimator has been proposed to drive mesh adaptivity in the VEM. The recently developed RCP stress recovery procedure for VEM [4] has been used to recover stresses. The error estimation has been *a posteriori* performed through the comparison of the stress field of a displacement-based VEM solution and the stress field obtained through RCP. The potential of this RCP-based error estimator to drive adaptive mesh refinements has been demonstrated through a wide selection of meaningful numerical examples.

MODELLING RANDOM FIBRE NETWORKS BASED ON SEGMENT STRETCH DISTRIBUTIONS

Ben R. Britt*[1,2], Edoardo Mazza[1,2], and Alexander E. Ehret †[1,2]
[1]Empa, Swiss Federal Laboratories for Materials Science and Technology, 8600 Dübendorf, Switzerland
[2]ETH Zurich, Institute for Mechanical Systems, 8092 Zürich, Switzerland

Summary A new, generally non-affine modelling approach is proposed for random fibre networks. The approach is based on a mathematical description of the distribution of quantities that determine the energy of single fibre segments when the network deforms. For illustration, the new approach is exemplified in application to the affine microsphere model. If the strain-energy function depends on the segment stretch and is analytic, this special case provides a new physical perspective on existing full network models. Additionally, in this context a novel technique for the (spherical) integration of piecewise defined strain-energy functions, typically found in models with tension-compression asymmetry, is proposed.

INTRODUCTION

Network-like structures of randomly arranged and connected fibres are prevalent in a variety of natural as well as technical materials [1]. To understand, analyse and predict the behaviour of these materials, efficient and reliable models are of great interest for both fundamental research and applied engineering.

The random fibre network characteristics result from the network structure and the individual fibre material properties. Discrete network models to simulate these materials employ numerical multi-scale simulations with a finite amount of connected fibres and subsequent homogenization or averaging procedures [2]. Due to the statistical background of these simulations, the generalisability of the corresponding results is often difficult or limited, and additionally, the associated computational costs are high. Analytical approaches are based on physically motivated continuum mechanical models. Here, a constitutive assumption that relates the micro-kinematics of the single fibres with the macroscopic deformations of the network replaces simulations with discretised networks. While this approach is favourable with regard to computational costs, it is prone to oversimplifying the mechanisms responsible for the scale transition. Indeed, comparing the micro-kinematics revealed in multi-scale simulations and those stemming from common continuum mechanical models reveals large discrepancies [3, 4]. This highlights the need to reevaluate and reformulate the assumptions that govern the micro to macro transitions.

A NEW APPROACH TO NETWORK MODELLING

Here we propose a novel approach for constitutive modelling of random fibre networks that generally applies to non-affine fibre kinematics and includes affinity as a special case. Instead of defining the motion of a single fibre depending on its initial spatial orientation, the method developed here focuses on finding the probability distributions of energetically relevant quantities, such as the segment stretch, within the random fibre network. For example, given a central force network formed by homogeneous segments, the expected segment energy $E[\psi]$ is determined by the stretch distribution μ within the network, i.e.

$$E[\psi] = \int_0^\infty \psi(x) d\mu(x) \, .$$

APPLICATIONS AND RESULTS

Despite the generally non-affine deformation behavior of random fibre networks, we introduce the novel approach here by providing a new perspective on affine microsphere models [5]. The associated integration of constitutive equations $f(\lambda) = g(\Lambda)$ over the surface of the d-dimensional unit sphere $\mathcal{S}^{d-1}$ has been used as an averaging method in many branches of physics and engineering, including continuum mechanics. It is, e.g., the basic ingredient of the microsphere and full-network models for rubber-like materials [5] and the structural approach in biomechanics [6]. Only in few cases, the integral can be solved analytically so that, typically, quadrature is employed. If the integrand can be expressed as a finite power series, an invariant-based analytical integration can be performed, leading to an invariant-representation of the constitutive equations [7]. However, in many cases relevant to the mechanics of soft materials, the integrands are not analytic, e.g. due to piecewise definitions or asymptotic behaviour.

With the new approach the domain of integration changes from $\mathcal{S}^{d-1}$ to the one-dimensional open half-space formed by the stretch λ, respectively, its square $\Lambda = \lambda^2$ (Fig. 1). For the special case of the affine microsphere, the domain is bounded between the minimum and maximum (squared) principal stretch, and the value of the integral is the expectation of $f(\lambda) = g(\Lambda)$ given the affine distribution of the (squared) stretch. Interestingly, an investigation of the

Figure 1: Segment stretches for a global deformation characterised by the three squared principal stretches $\Lambda_3 = 0.7$, $\Lambda_2 = 1.1$ and $\Lambda_1 = 1.3$ under the affine assumption. (a) Directional squared stretch Λ for directions depicted on the surface of the three-dimensional unit sphere $\mathcal{S}^2$. (b) Density of the corresponding stretch distribution given an isotropic fiber distribution.

three-dimensional distribution of the stretch (square) reveals the very strong accumulation of stretches near the mid, i.e. non-extreme, principal stretch (Fig. 1b).

Based on this analysis, we recover the integration method proposed in [7] which is valid in case of an isotropic fibre distribution, and supplement it by a closed form expression, as well as a physical explanation. This enables the exact integration of polynomial functions of any order and allows an arbitrarily close approximation for analytic functions. Moreover, we show the benefits of the new approach for the integration of functions $g(\Lambda)$ or $f(\lambda)$ that are piecewise defined as polynomials, as they occur in case of a tension-compression asymmetry typical for e.g. collagenous networks, and the consequences for the tension-compression switch of fibres [8].

CONCLUSIONS

In the present contribution we delineate a new approach for constitutive modelling for random fibre networks, which provides a basis for the development of generally non-affine computationally efficient models. To validate and introduce the underlying concepts, the approach is employed here to revisit the affine microsphere model. This not only reveals interesting features of the affine stretch distribution but also provides an alternative justification of a previously proposed integration method. Finally, for piecewise defined integrands that are typically used in models to capture tension-compression asymmetry or that implement a tension-compression switch, we demonstrate the advantages concomitant with the new approach.

ROBUST FINITE ELEMENT MODELING OF CABLE SYSTEMS

Charlèlie Bertrand*[1],Claude Henr iLamarque[1],Vincent Acary[2],and Alireza Ture Savadkoohi[1]
[1]Univ Lyon, ENTPE, LTDS UMR CNRS 5513, Rue Maurice Audin 69518 Vaulx-en-Velin Cedex, France
[2]Univ. Grenoble Alpes, CNRS, Inria, Grenoble INP (Institute of Engineering Univ. Grenoble Alpes) , GIPSA-Lab, 38000 Grenoble, France

Summary Numerical simulation of cable systems remain delicate due to the effects of their curvature. Indeed finite element approaches (if not implemented carefully) fail to predict correct responses of cable structures. The major issue to be addressed is the ill-conditioning, starting configuration and wrong choice of descent direction during iterative methods. Some strategies to overcome spurious solutions for cable system will be presented accompanied with comparisons and potential experimental results.

CONTEXT

"Cable" stands for a slender structure which cannot resist compression and torque. Its equilibrium relies on the balance between its internal axial force and external forces and/or forcing [1]. Analytical studies account for the high diversity of its dynamics contents [2]. However, purely numerical methods for cable suffer from ill-conditioning, spurious solutions [3] and high frequency contents interference [4] regardless the type of finite element approach. Cable systems should be treated numerically in the framework of unilateral material (no tension materials [5, 6] or no-compression [7]). Main contribution of this work is the coupling between these conditions and the geometrical non linearity of the cable. Governing equation accompanied by unilateral dilatation condition reads:

$$\forall S \in \Omega, \forall t \quad \begin{cases} \rho\ddot{x} = EA\left((\|x'\| - 1)\dfrac{x'}{\|x'\|}\right)' + b \\ \varepsilon = \|x'\| - 1 \geq 0 \end{cases} \tag{1}$$

where space and time dependencies, resp. S and t, have been removed for conciseness. $\cdot'$ and $\dot{\cdot}$ respectevily stand for the derivation with respect to S and t. The latter may be understood as taking the following constitutive law for the cable:

$$T = \begin{cases} EA\varepsilon & ; \quad \varepsilon \geq 0 \\ 0 & ; \quad \varepsilon \geq 0 \end{cases} \tag{2}$$

FINITE ELEMENT IMPLEMENTATION OF NON-COMPRESSIBLE CABLE

The Finite Element Method [8] (FEM) formulation for an elastic non-compressible cable is derived accounting the fact that a cable can only undergo stretching (no compression). A cable element is formulated with regards to curvilinear mechanics [9], thus providing a Lagrangian viewpoint that may be used to compute large displacements. This unilateral formulation ($\varepsilon \geq 0$) results in a kind of active set FEM procedure [10]. Constrained optimization methods are used to impose connexion between cables and boundary conditions. The whole process yields to solve:

$$\begin{cases} 0 = \mathbf{M}\ddot{\mathbf{X}} + \mathbf{K}(\mathbf{X})\mathbf{X} - \mathbf{f} - \mathbf{A}^t\lambda \\ 0 = \mathbf{A}\mathbf{X} - \mathbf{c} \end{cases} \tag{3}$$

Where the $\mathbf{A}$ matrix embeds boundary condition and imposed connections between cables and $\mathbf{c}$ is a fixed column vector.
Modal analysis of such system can be performed provided suitable projection on the constraint operator null-space [11], i.e.:

$$\text{Find } (\omega, \mathbf{U}) \text{ such as: } \begin{cases} \omega^2 = \min\limits_{\mathbf{U}} \dfrac{\mathbf{U}^\top(\nabla\mathbf{K})\mathbf{U}}{\mathbf{U}^\top(\mathbf{M})\mathbf{U}} \\ 0 = \mathbf{A}\mathbf{U} \end{cases} \tag{4}$$

This methodology has been proven efficient to compute static cable equilibrium (Figure 1), modal analysis of cables or even cable networks (Figure 2) and also to perform some time integration (Figure 3) without violating the non compression condition.

CONCLUSIONS

Implementation of a numerical tool for a non-compressible cable equilibria have been discussed. Applications are possible for static analysis, modal analysis and time-integration.

CONSTITUTIVE ARTIFICIAL NEURAL NETWORKS (CANNS)

Kian P. Abdolazizi*[1], Kevin Linka[1], and Christian J. Cyron[1,2]
[1]Institute of Continuum and Materials Mechanics, Hamburg University of Technology, Hamburg, Germany
[2]Institute of Materials Research, Materials Mechanics, Helmholtz-Zentrum Geesthacht, Geesthacht, Germany

Summary This contribution aims to balance theory- and data-driven approaches to describe a material's mechanical response. We introduce so-called Constitutive Artificial Neural Networks (CANNs), a novel machine learning architecture. CANNs incorporate substantial prior knowledge from materials theory to reduce the need for experimental data while simultaneously taking account of material symmetries and internal constraints. Functional relations between stress and strain are not postulated a priori but rather learned from experiments. CANNs have the ability to incorporate stress-strain but also non-mechanical data, e.g., parameters from manufacturing processes or imaging data. Therefore, CANNs may serve not only as descriptive but also as predictive tool and open perspectives for the virtual design of new materials.

INTRODUCTION AND THEORETICAL BACKGROUND

The classical, theory-driven approach to describe the deformation of a material body relies on the formulation of constitutive equations connecting kinematic and kinetic quantities. Both phenomenological and micromechanically motivated constitutive equations typically exhibit a set of material parameters that have to be calibrated from experiments [1]. A drawback of this classical, theory-driven approach is the efforts that are typically required to develop appropriate functional relations that can describe the behavior of complex new materials. Furthermore, in this classical approach it is often difficult to incorporate information which is well-known to be strongly correlated with the behavior of the material but whose exact relation to the mechanical properties of a material cannot be strictly quantified. This is, for example, often the case for manufacturing parameters.

By contrast, current model-free data-driven methods [2, 3, 4] permit the numerical simulation based on experimental stress-strain measurements only, without postulating any constitutive model at all. These data-driven methods rely on material data bases that have to be sufficiently large in order to reflect the characteristics of a material appropriately. So far proposed methods of data-driven constitutive modeling often require a relatively large amount of (sufficiently accurate) material data, which may in practice often not be available.

In this contribution, we propose a novel hybrid approach that can help overcome the shortcomings and combine the strengths of both classical theory-driven and modern data-driven constitutive modeling by introducing so-called Constitutive Artificial Neural Networks (CANNs), a novel machine learning architecture. CANNs can learn constitutive models from given data while incorporating already significant prior theoretical knowledge, which reduces the amount of data required substantially.

Constitutive modeling

Anisotropic hyperelastic materials may be described by strain energy functions of the type

$$\Psi = \Psi\big(\tilde{I}_r, \tilde{J}_r, \mathrm{III}_{\mathbf{C}}\big) \tag{1}$$

with so-called (generalized) invariants [5]

$$\tilde{I}_r = \mathrm{tr}[\mathbf{C}\tilde{\mathbf{L}}_r], \qquad \tilde{J}_r = \mathrm{tr}[(\mathrm{cof}\,\mathbf{C})\tilde{\mathbf{L}}_r], \qquad \mathrm{III}_{\mathbf{C}} = \det\mathbf{C}, \qquad r = 1, 2, \ldots \tag{2}$$

Therein, $\mathbf{C}$ and $\tilde{\mathbf{L}}_r$ denote the right Cauchy-Green tensor and generalized structural tensors, respectively. The latter are defined as convex combinations of structural tensors $\mathbf{L}_i$ and corresponding weighting factors $w_i^{(r)} \geq 0$:

$$\tilde{\mathbf{L}}_r = \sum_{i=0}^{n} w_i^{(r)} \mathbf{L}_i, \qquad \sum_{i=0}^{n} w_i^{(r)} = 1, \qquad r = 1, 2, \ldots \qquad \mathbf{L}_0 = \frac{1}{3}\mathbf{I}, \tag{3}$$

where $\mathbf{L}_j = \boldsymbol{l}_j \otimes \boldsymbol{l}_j,\ j = 1, 2, \ldots, l$, is referred to as structural tensor and is represented by unit vectors $\boldsymbol{l}_j$ reflecting preferred material directions. Accordingly, the second Piola-Kirchhoff stress tensor $\mathbf{S}$ and the fourth-order material tangent tensor $\mathbb{C}$ are given by

$$\mathbf{S} = 2\frac{\partial\Psi}{\partial\mathbf{C}} - p\mathbf{C}^{-1}, \qquad \mathbb{C} = 2\frac{\partial\mathbf{S}}{\partial\mathbf{C}}, \tag{4}$$

with the Lagrange multiplier p enforcing incompressibility.

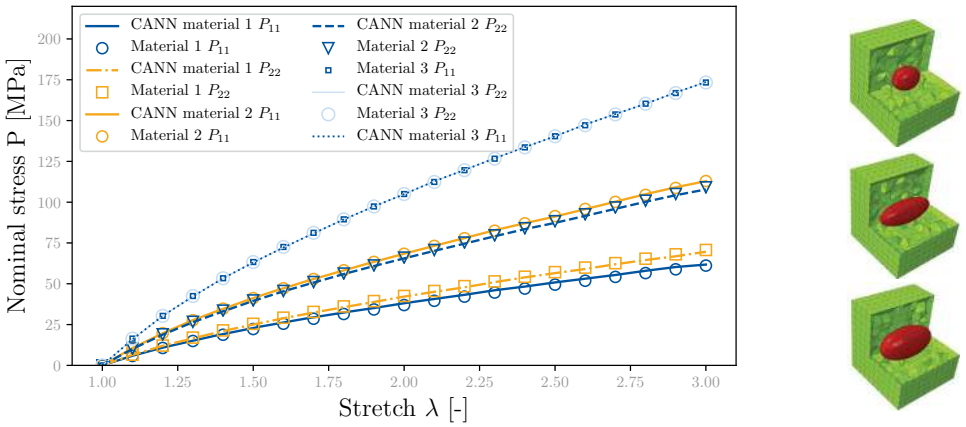
Machine learning architecture

In this contribution, we are proposing a novel machine learning architecture based on feed-forwards artificial neural networks (ANNs), referred to as CANNs. By their very design CANNs incorporate theoretical domain knowledge as reflected by the above equations (1) – (4). Thereby, the amount of required training data is reduced, while the output of the CANNs is restricted to physically meaningful values, e.g. symmetric $\mathbf{S}$. Preferred material directions $\tilde{\boldsymbol{l}}_i$ and associated weights $w_i^{(r)}$ required for generalized invariants are learned automatically from given data by sub-ANNs. CANNs can receive as input not only stress-strain data but in fact also any additional information regarding the material of interest. During the training process the main network as well as the sub-ANNs are trained simultaneously by minimizing the mean squared error of the CANN in terms of stress response.

In-silico study

We tested the ability of CANNs using several examples. One was computational homogenization of representative volume elements (RVEs) for computing the macroscopic mechanical behavior of incompressible matrix inclusion composites. We considered the simple test case of a periodic composite material with spheroid inclusions centered in cubic RVEs. The length of the semi-axes of the inclusions was allowed to vary in a large range. We generated 500 different samples of this type of material with varying inclusion geometry. The inclusion geometry, the phase contrast of matrix and inclusion stiffness as well as the simulated mechanical behavior under a series of loading states (obtained from computational homogenization) of these 400 samples were provided as training data to a CANN. From these data, the CANNs were able to learn the constitutive behavior not only of matrix-inclusion composites with the phase contrasts and inclusion geometries as reflected by the training data but also to predict the constitutive behavior of matrix-inclusion composites (of the above type) with microstructures and phase contrasts not covered by the training data. In particular, CANNs proved able to identify from the training data automatically material symmetries. The predictive abilities of the CANN are illustrated in Figure 1a for three materials unknown to the CANN.



(a) (b)

Figure 1: Simulated stress-stretch responses (symbols) and CANN predictions (lines) for the three RVEs on the right, which did not form part of the CANN training data

CONCLUSIONS

CANNs are a novel machine learning architecturs capable to infer constitutive laws from stress-strain data (using thereby also additional non-mechanical data if provided). In contrast to other machine learning approaches in the field of constitutive modeling, which often aim for a mapping of strain tensor components to stress tensor components, the dimensionality of the feature space, from whom training data has to be sampled, is considerably reduced by incorporating knowledge from continuum mechanics. CANNs can easily and efficiently be implemented into widely-used finite element packages via user subroutines. Moreover, CANNs cannot only be used to describe the constitutive behavior of a given material but also to predict the one of new materials, opening up application scenarios in the area of virtual materials design.

SYSTEMATIC EXTENSION OF THERMOELASTIC-VISCOPLASTIC CONSTITUTIVE LAWS AT FINITE DEFORMATION: FORMULATION AND IMPLEMENTATION IN A COMMERCIAL FE CODE

Mohamed Abatour[1], Samuel Forest*[1], Kais Ammar[1], Cristian Ovalle[1], Nikolay Osipov[2], and Stéphane Quilici[2]
[1]MINES Paris Tech, PSL University, Centre des matériaux, CNRS UMR 7633, BP 87 91003 Evry, France

Summary Most commercial finite element codes are based on hypoelastic formulations of thermoelasto-viscoplastic constitutive laws for metals or polymers. Their spurious effects, like unexpected ratcheting under cyclic loading, are well-known but generally overlooked for the sake of computational ease. An alternative systematic framework for the extension of nonlinear thermoelastic-(visco)plastic constitutive equations to finite deformations is proposed, based on a multiplicative decomposition of the deformation gradient into a thermoelastic part and an inelastic part. The questions of the choice of suitable hyperelastic potential, of hardening variables and of anisotropy evolution are discussed. The method is applied to a commercial FE code as an illustration.

SHORTCOMINGS OF EXISTING EXTENSIONS IN FE CODES

There is today no unified framework for the implementation of nonlinear constitutive equations at finite deformations in commercial finite element codes. A wealth of elastoviscoplastic constitutive equations are available for simulations at small strain involving kinematic and isotropic hardening variables, static and dynamic recovery and strain rate sensitivity. They are suitable for the thermo-mechanical behaviour of metallic alloys and polymers. They involve internal variables dedicated to dissipative processes including plasticity and damage.

Many codes rely on the so-called corotational extension of the laws developed at small strains, i.e. the pull-back of Eulerian variables in rotating objective frames [1]. The drawbacks of such a formulation are well–known: absence of elastic potential (hypoelasticity) and associated spurious ratcheting effects under cyclic non-proportional [2, 3]. The strain rate tensor D is pulled back in a cororational frame and split additively into thermal, elastic and (visco)plastic strains rates:

$$\dot{\boldsymbol{e}} = \boldsymbol{Q}\boldsymbol{D}\boldsymbol{Q}^T = \dot{\boldsymbol{e}}^e + \dot{\boldsymbol{e}}^{th} + \dot{\boldsymbol{e}}^p$$

As a consequence, the non-holonomic plastic strain $\boldsymbol{e}^p$ has no clear mechanical interpretation. This framework provides only limited description of anisotropy due to the absence of plastic spin in the standard framework. The use of extended anisotropic yield functions then assumes that the anisotropy axes rotate at the corotational rate. These limitations have been recently highlighted in [5]. The main advantage is that any set of nonlinear constitutive equations formulated at small strains (for example the whole sets of material descriptions proposed by Lemaitre and Chaboche [4]) can be translated into the corotational frame and deliver material frame-indifferent models for large deformations. This explains the wide use of these laws in commercial finite element codes [12].

There is a real need for thermodynamically consistent and systematic extensions of small strain constitutive laws for large deformations, that remain transparent for the user, namely engineers who often do not have a sufficient background for choosing intentionally specific finite deformation formulations.

MULTIPLICATIVE DECOMPOSITION AND CHOICE OF THE HYPERELASTIC LAW

Hyperelastic-viscoplastic constitutive laws are classically based either on additive decomposition of Lagrangian strain measures [6] or on Mandel's multiplicative decomposition of the deformation gradient:

$$\boldsymbol{F} = \boldsymbol{F}^{eth}\boldsymbol{F}^p$$

where $\boldsymbol{F}^{eth}$ is the thermoelastic part of deformation whereas $\boldsymbol{F}^p$ denotes all inelastic contributions due to viscoplasticity and damage. The attention is focused on the latter because it is more relevant for metallic alloys possessing isomorphic elastic ranges [7]. This avoids arbitrary multiple decompositions of the form $\boldsymbol{F} = \boldsymbol{F}^e\boldsymbol{F}^{th}\boldsymbol{F}^p\boldsymbol{F}^d$ or associated permutations that are often found in literature [8, 9]. Instead the inelastic deformation rate $\dot{\boldsymbol{F}}^p\boldsymbol{F}^{p-1}$ can be taken as the sum of the various viscoplastic and damage contributions, including corresponding spins accounting for anisotropy.

Inelastic strain is dominant in most metals and polymers (except elastomers) so that the choice of the hyperelastic law can be limited to a two–parameter elastic potential extending the small strain elastic moduli. Hence, the use of Saint-Venant Kirchhoff elastic law, or, preferably a polyconvex potential as proposed by [10], is recommended. The Helmholtz free energy potential is a function $\psi(\boldsymbol{E}^{eth} = \boldsymbol{F}^{ethT}\boldsymbol{F}^{eth}, T, \boldsymbol{\alpha})$ of thermoelastic strain, temperature and internal variables $\boldsymbol{\alpha}$. A quadratic elastic potential is retained in the theory:

$$\psi^{eth}(\boldsymbol{E}^{eth}, T) = \frac{1}{2}\boldsymbol{E}^{eth}\cdot\boldsymbol{C}\cdot\boldsymbol{E}^{eth} + (T - T_0)\boldsymbol{P}\cdot\boldsymbol{E}^{eth}$$

The inelastic flow rule follows from an assumption of normality for (possibly porous) metallic alloys. The question of plastic spin for anisotropic materials will be discussed at the light of the archetypal example of single crystal behaviour.

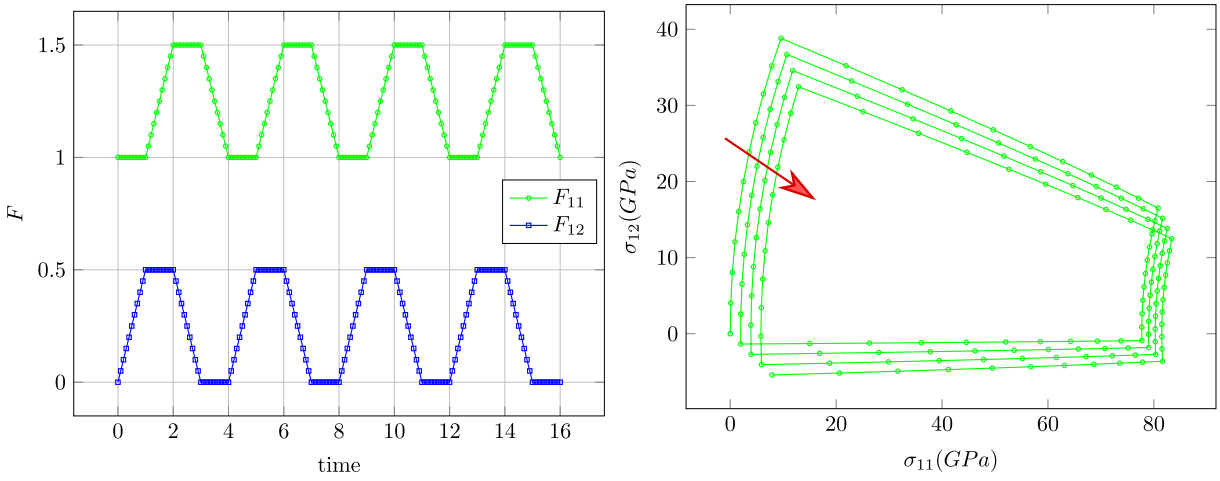

Figure 1: Spurious ratcheting under non-proportional cyclic loading for a hypoelastic formulation (Green-Naghdi rate). $E = 210GPa$, $\nu = 0.3$. The applied loading is shown left: all the other components are null except $F_{22} = F_{33} = 1$.

EXTENSION OF HARDENING LAWS DEVELOPED AT SMALL STRAINS

Extension of isotropic hardening rules based on scalar internal variables is rather straightforward. In contrast, kinematic hardening is associated with tensor internal variables and several large deformation extensions are possible as discussed in [11]. It can be shown that hypoelastic-plasticity with (non)linear kinematic hardening can lead to (pseudo)periodic stress response under simple shear [1].

A construction method of consistent tangent matrices for implicit integration of evolution equations and of the tangent operator for implicit global resolution is proposed, based solely on the associated small strain operator and appropriate pull back and push forward transports.

The proposed methodology is implemented in the commercial FE object-oriented code Zset [12]. It is shown in particular how the rich library of small strain nonlinear constitutive laws can be readily extended to finite deformations.

AN ENERGY-BASED DETWINNING MODEL FOR GRANDIENT NANOTWINNED METALS

Panpan Zhu[1], and Haofei Zhou*[1]
[1]Center for X-mechanics, Department of Engineering Mechanics Zhejiang University, Hangzhou, Zhejiang, PR China

Summary: Detwinning has been widely observed in both bulk and low-dimensional nanotwinend metals. The physical origin of detwinning is generally known to be the consecutive nucleation and movement of Shockley partial dislocations on the twin plane under a finite resolved shear stress. Here, we propose a detwinning model based on the concept of strain energy release rate in gradient nanotwinned metals, which is subjected to uniaxial loading nearly parallel to the twin boundaries. Although no apparent resolved shear stress is present on the twin plane, the difference in the elastic energy stored in neighboring grains is able to drive the migration of twin planes, leading to substantial detwinning in the gradient nanotwinned structure. We demonstrate the model with results from large-scale molecular dynamics simulations. Our findings not only point out the critical role of detwinning in the plasticity of gradient nanotwinned metals, but also shed light on previous experimental observation of detwinning in nanotwinned metals.

INTRODUCTION

Gradient nanostructured (GS) metals, including both gradient nanograined (GNG) and gradient nanotwinned (GNT) metals, have recently emerged as a new class of materials with tunable distribution of microstructures and have been shown to possess substantially enhanced mechanical properties compared to their gradient-free counterparts [Fang et al., 2011; Wei et al., 2014; Wu et al., 2014]. Due to their unique gradient microstructures, GS metals could be designed to exhibit an unusual combination of ultrahigh strength, good tensile ductility, enhanced strain hardening, superior fatigue and wear resistance. Our recent work [Cheng et al., 2018] shows that GNT metals exhibit extra strengthening and work hardening behaviors compared with uniform nanotwinned metals. The extra strengthening and work hardening of GNT metals was revealed to be controlled by high density of geometrically necessary dislocations in the form of concentrated dislocation bundles distributed in the grain interiors. Here, using large-scale molecular dynamics (MD) simulations, we report a strain energy release controlled detwinning mechanism that is dominant in the plasticity of GNT metals at large strains.

MD SIMULATION RESULTS

We performed MD simulations on fully three-dimensional GNT Cu samples with various structural gradients. We first created two homogeneous columnar-grained nanotwinned components, and then combined them together to form a GNT structure (Figure 1a). By varying the twin thickness of the individual components, GNT samples with various structural gradients can be generated. The same relaxation, tension, and visualization methods were adopted for the simulated samples [Cheng et al., 2018]. We performed uniaxial tensile loading on the structure with a large gradient in yield strength to demonstrate the detwinning-induced plasticty in GNT structures. The grain size and twin size of the two components NT-A and NT-B were selected such that the large gradient in yield strength ensures extensive detwinning process of GNT structures at large strains (Figure 1b). Twinning partial dislocations were emitted either from the GBs or the intersections of TBs and stacking faults.

AN ENERGY-BASED DETWINNIING MODEL

The extensive twin boundary migration and detwinning-governed deformation is unexpected because resolved shear stress along the twin planes is negligible with the loading axis parallel to the twin planes. Recently, an anomalous tensile detwinning mechanism governed by the migration of a unique TB-GB-TB structure was reported in a bitwinned metallic nanowire, which is apparently not the case in our simulations [Cheng et al., 2017]. Here, we develop a theoretical model

based on the concept of strain energy release rate to explain the substantial detwinning observed in the simulated GNT structures. Suppose the GNT structure has two components A and B with twin thickness $\lambda_A < \lambda_B$ and yield strength $\sigma_A > \sigma_B$. The stored strain energy density of the two components is different. The driving force for detwinning in GNT structure due to the gradient in yield strength can be derived as $\tau_d = \frac{\sigma_A^2 - \sigma_B^2}{2E}$, where E is the Young's modulus of the material. The detwinning rate can be related to the driving force as $n = A(\frac{\tau_d}{\tau_0})^\alpha$, where A, α, and τ_0 are material parameters. We created three different GNT samples with different structural gradients. NT-B is fixed. The twin thickness in NT-A varies from 0.63nm-1.25nm. Figure 1c shows the variation of the number of h.c.p. atoms in NT-A in these three GNT samples. The predicted detwinning rates at large strains match well with the simulations results, demonstrating that the proposed strain energy release driven detwinning mechanism is indeed dominant in the plasticity of GNT metals.

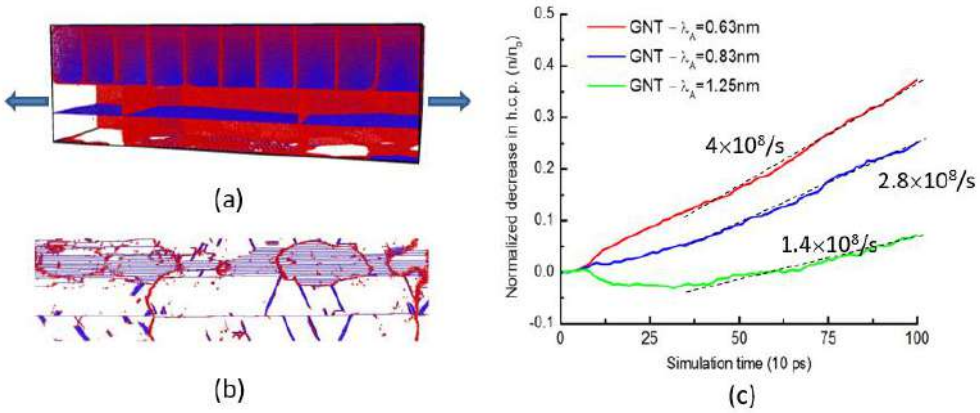

Fig. 1 (a) Three-dimensional GNT Cu samples. (b) Cross sectional snapshots of the detwinning process of GNT structures at 50% strains. (c) The number of h.c.p. atoms in NT-A change with simulation time of three GNT samples.

CONCLUSION

In this work, using MD simulations and theoretical modeling, we have demonstrated that a sufficiently large gradient in the stored strain energy in neighboring grains is able to induce substantial detwinning in a GNT Cu sample. In nanotwinned metals synthesized by electrodeposition or magnetic sputtering, the distribution of nanotwins is not ideally uniform but with local gradients in twin thickness and stored strain energy density. Our energy-based detwinning model may help understand the observation of detwinining in nanotwinned metals.

AUTOMATIC DIFFERENTIATION FOR SOLID MECHANICS

Andrea Vigliotti*[1] and Ferdinando Auricchio[2]
[1] Innovative Materials Laboratory, Italian Aerospace Research Center, Capua, Italy
[2] Department of Civil Engineering and Architecture, University of Pavia, Pavia, Italy

Summary Automatic differentiation (AD) is an ensemble of techniques that allow to evaluate accurate numerical derivatives of a mathematical function expressed in a computer programming language. In this study we use AD for stating and solving solid mechanics problems. Given a Finite Element (FE) discretization of the domain, we evaluate the free energy of the solid as the integral of its strain energy density and we make use of AD for directly obtaining the residual force vector and the tangent stiffness matrix of the problem as the gradient and the Hessian of the free energy respectively. The result is a remarkable simplification in the statement and the solution of complex problems involving non trivial constraints systems and both geometrical and material non linearities.

Forward automatic differentiation through dual numbers

As opposite to finite differences, AD does not approximate the continuous derivatives with discrete differences, thus it does not suffer from truncation error, and it is capable of delivering machine precision exact derivatives. AD techniques exist in different fashions [1], nonetheless, in the current study we use dual numbers for the implementation of a forward mode AD scheme, which allows seamless integration with existing software programs. Dual numbers are an extension of the complex field with multiple higher dimensional parts [2]. In this work, dual numbers are the structure chosen to store, and operate, both on the value of a given parameter and on its derivatives. We define dual numbers of the second order and dimension N the quantities of the kind

$$\boldsymbol{x} \equiv x_0 + x_i \boldsymbol{\imath}_i + x_{ij} \boldsymbol{\imath}_{ij} \qquad \text{where } \boldsymbol{\imath}_i \text{ is the canonical base of } \mathrm{R}^N \text{ and } \boldsymbol{\imath}_{ij} \equiv \boldsymbol{\imath}_i \otimes \boldsymbol{\imath}_j + \boldsymbol{\imath}_j \otimes \boldsymbol{\imath}_i \,, \tag{1}$$

where the summands in the above expression are independent parts of $\boldsymbol{x}$, x_0 is the value part of $\boldsymbol{x}$, $x_i \boldsymbol{\imath}_i$ is the gradient part of $\boldsymbol{x}$, and $x_{ij} \boldsymbol{\imath}_{ij}$ the Hessian of part, sum on repeated index applies. Numbers of the type of (1) can be structured as to induce an algebra that allows to simultaneously evaluate the value, the first and the second derivatives, where they exist, with respect to the identified independent variables, of any function expressed in a computer programming language, in an automated way [3].

Equilibrium as a free energy minimum

Thermodynamics ensures that free energy is stationary for equilibrium configurations. Therefore, given a functional expression for the free energy of a body, subjected to given boundary conditions and to some external actions from the environment, stable equilibrium configurations can be found by minimizing this functional. Using a FE discretization we can approximate the free energy of a solid as a function of the nodal Degrees of Freedom (DoFs) of the FE model, $\boldsymbol{u}$, as follows

$$\Psi = \int_{V_0} (\phi - b_0) \, \mathrm{d}V_0 \quad \underset{\text{discretization}}{\overset{\text{Finte Elements}}{\Longrightarrow}} \quad \Psi(\boldsymbol{u}) = \sum_{k=1}^{N_E} \sum_{i=1}^{N_W^k} w_l^k \left[\phi - b_0\right]_{r_l^k} \,, \tag{2}$$

where surface forces have been neglected for brevity, V_0 is the volume occupied by the body in its reference configuration, ϕ is the strain energy density, and b_0 is the potential of the external body forces, per unit reference volume. The equation on the right side of the arrow in (2) expresses the Gauss-Legendre quadrature rule for Ψ, where N_E is the number of elements, N_W^k the number of Gauss points of the k-th element, w_l^k are the integration weights, and r_l^k are the positions where the bracket is evaluated. With reference to the FE discretization of Ψ, the minimum free energy principle can then be stated as follows

$$\delta\Psi = \frac{\partial \Psi}{\partial \boldsymbol{u}} \cdot \delta\boldsymbol{u} = 0 \quad \forall\, \delta\boldsymbol{u} \qquad \Longleftrightarrow \qquad \boldsymbol{r} = \frac{\partial \Psi}{\partial \boldsymbol{u}} = 0 \quad \text{with} \quad \boldsymbol{K}_t = \frac{\partial \boldsymbol{r}}{\partial \boldsymbol{u}} = \frac{\partial^2 \Psi}{\partial \boldsymbol{u} \partial \boldsymbol{u}} \tag{3}$$

where $\boldsymbol{r}$ is the residual force vector and $\boldsymbol{K}_t$ is the tangent stiffness matrix, that coincide with the gradient and the Hessian of the free energy, respectively, and can be *automatically calculated* from the last expression in equation (2), once the DoFs of the model, collected in $\boldsymbol{u}$, are treated as dual quantities of the type of (1).

Thus, with the approach described here, it is not necessary to explicitly write code for the evaluation of the components of the residual force vector and of the tangent stiffness matrix for a given configuration of the solid, but it suffices to write the functions that calculate the free energy of the configuration - which is a scalar quantity - and evaluate it over the dual number field, while its gradient and Hessian are automatically obtained as the higher order parts of the result [3]. We also remark that the methodology presented here allows to state and solve a FE problem without introducing the notion of a stress tensor, which is the usual starting point of FE formulations. This is an interesting effect of always remaining within the weak form of the problem.

Examples

In this section we illustrate a selection of solid mechanics problems that have been solved by means of the method outlined above. All problems include both geometric and material non-linearities, along with non trivial boundary conditions. All the script for the solution of the examples have been written in the Julia programming language [4], and are available, along with the input files, from [5] under a collaborative licence.

The non linear truss

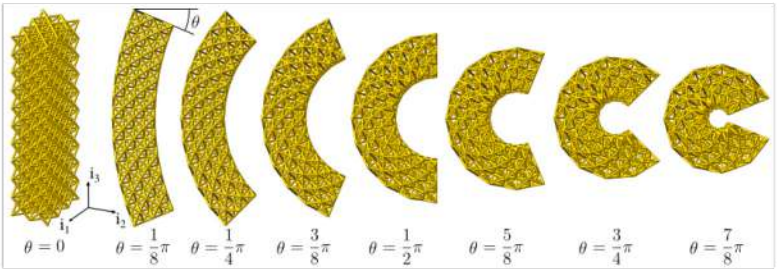

Figure 1: Deformation of a truss with large geometrical non linearities

Figure 1 shows the deformed configuration of a regular lattice structure. The truss is made of rod elements in a linear elastic material that can store deformation energy only because of length variations. The structure is obtained by replicating a regular octet cell along the coordinate directions. The boundary conditions have been applied to the nodes of the top and the bottom end, constraining them to remain on planes forming the same angle θ with direction i_3, with opposite sign.

Cylindrical symmetry problem with internal volume constraint

Figure 2 illustrates the modelling of a solid with cylindrical symmetry around the i_2 axis, featuring an internal cavity with circular cross section, in a Neo-Hookean material. Thanks to the symmetry of the problem, we only model a generic cross section of the solid with a plane including the symmetry axis, and the cylindrical formulation for the deformation tensor. The presence of an incompressible fluid within the cavity can be modelled by constraining the cavity volume to remain constant. Results are presented with and without the internal volume constraint.

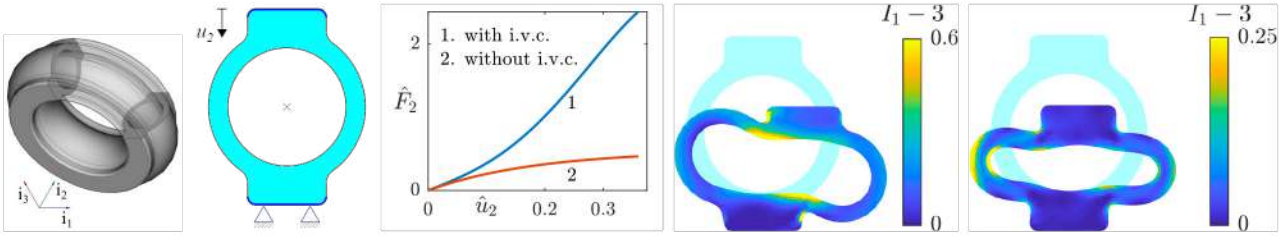

Figure 2: Axi-symmetric problem, simulation results. (a) Undeformed domain, (b) cross section and boundary conditions, (c) normalized force displacement plot, (d) deformed cross section with internal volume constraint (i.v.c.), and (e) without i.v.c. at maximum deformation, I_1 is the first invariant of the deformation tensor.

Three-dimensional solid with large geometrical non-linearities

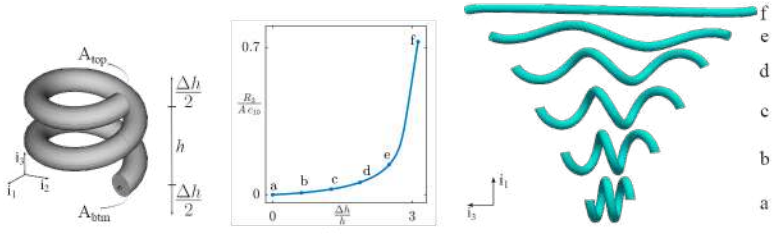

Figure 3: Three-dimensional solid. (a) Undeformed domain, (b) normalized force displacement plot, (c) deformed configurations at the stages of the simulation marked in (b).

Figure 3 shows the results of the simulation of a model made of continuous hexahedral elements in a Neo-Hookean material. The boundary conditions have been applied by constraining the centre of gravity of the top bottom section to produce the displacements shown in Figure 3a. As it can be observed the model captures the complex non linear geometry of the unfolding of the spring, followed by the material stiffening.

Conclusions

In this study we used AD for the implementation of the FE method for the solution of solid mechanics problems. The advantage in such approach is that it only requires to explicitly evaluate the free energy of a body in a given configuration, which is a simple scalar quantity, while the corresponding residual force vector and the tangent stiffness matrix are obtained automatically. In this way it is possible to state and solve complex problems, including geometrical and material non linearities and non trivial boundary conditions in a fast and simple way. This approach also exposes an interesting insight on the nature of the general problem of FE for solid mechanics, which is that the stress tensor can be seen as an intermediate variable, playing a lesser fundamental role in a formulation totally based on the energy balance.

ON THE UNIQUENESS PROBLEM ABOUT CENTRAL CONFIGURATIONS IN THE PLANAR CONVEX FOUR-BODY PROBLEM

Agnieszka Siluszyk*[1]
[1]Institute of Mathematics, Faculty of Exact and Natural Sciences, Siedlce University, Siedlce, Poland

Summary The classification of the planar central configurations consisting of two pairs of bodies located on parallel lines has been presented by M. Corbera, J.M. Cors, J. Llibre and E. Perez-Chavela. They have proved the existence of acute and obtuse trapezoid central configurations in the case of four positive masses and of non-symmetric trapezoid central configuration with two pairs of equal masses. Here, we deal with a quadrilateral configuration in the shape of a isosceles trapezoid. We consider the planar motion of four interacting material points when the masses m_1 and m_2 lie on the X-axis at $(R,0)$ and $(-R,0)$-vertices whilst the masses m_3 and m_4 lie at the $(\pm R\cdot cos\theta, R\cdot sin\theta)$ respectively, with $\theta\in(0,\pi)$. In this way, we consider the model which is constructed in the circle with the radius R. We show that there exist at most one convex central configuration for each cyclic order.

1.

Investigations of the N-body problem for $N=2,3$ which were initiated by I. Newton and continued by L. Euler, J.L. Lagrange, H. Poincare, A.M. Lyapunov, A. Wintner, and by others gave us the most complete analysis of these problems. The investigations of N bodies motion with masses m_i, $i=1,...,N$ in R^d, moving under the influence of the Newton's gravitational law, when $N\geq 3$ and $d=1,2,3$, are still open. A continuation of the famous Smale's list of problems concerned with relative equilibrium, under the potential, different from the Newtonian one, and may be with a weaker symmetry, the uniqueness problem, singularities, bifurcations, stability of relative equilibria have been proposed by A. Albouy, H.E. Cabral, A.A. Santos *Some problems on the classical n-body problem*, Celestial Mechanics and Dynamical Astronomy, 113(4), (2012), pp. 369-375.
To the list of classical central configurations given in XVIII- XX c. (see, e.g., [17], [13]), B. Elmabsout and E.A. Grebenikov have added some new ones with poorer symmetry, these configurations consisting of $2n$ equal point-masses, where n particles, with mass m_1 each, are located at the vertices of a n-gon, and others n particles with common mass m_2 lie at the vertices of another n-gon. Both n-gons are regular and concentric. Finally, a mass m_0 lies at the center of masses of such configuration. They have proved that such a configuration exists if and only if these two polygons are homothetic or differ by an angle of $\frac{\pi}{n}$ (see, [7, 10, 14]). Nowadays, such central configurations in the N-body problem are called *spiderweb central configurations* (see, [11]). A development of the numerical computer methods makes it possible to obtain the *N-body choreographies*, i.e., a periodic solution of the equal mass N-body problem in which all bodies follow the same path (see, [3, 16]).
In the list of new open problems, as the 10^{th} question, A. Albouy, H.E. Cabral, A.A. Santos formulate the following one: *For given four masses m_1,m_2,m_3,m_4 and with $a=-\frac{3}{2}$ does it exist only one convex central configuration for each cyclic order*? (Here, a is the value occurring in the potential of the Newtonian N-body problem, in the general case the potential have the form $U=-\frac{1}{2a}\sum_{i<j}m_im_jr_{ij}^{2(a+1)}$). One counts central configurations up to rotation and rescaling. Earlier, this uniqueness problem was considered by O. Dziobek [6] and W.D. Macmilian, W. Bartky [12]. Recently, the uniqueness and ordering questions of the bodies in the convex central configurations of the four-body problem has been studied by A. Albouy, Y. Fu, S. Sun [1], M. Corbera, J.M. Cors, J. Llibre and E. Perez-Chavela [4] and others [5, 8].

2.

The central configurations are very important in the analysis of simultaneous collisions, because it turns out that the configuration of gravitating points at the instant of a simultaneous collision is central (in the asymptotic sense). The points which in the beginning formed a central configuration and were at rest have their configuration which clearly does not change up to the instant of a simultaneous collision. [2]. Recall that by a planar central configuration in the N-body problem under the Newtonian potential $U=\sum_{1\leq i<j\leq N}\frac{m_i\,m_j}{|q_i-q_j|}$, $q_i\neq q_j$, $i\neq j$ we mean *an arrangement of N bodies $q_i\in R^2$, $i=(1,\ldots,N)$ with masses m_1, m_2,...,m_N satisfying the equation*

$$\nabla U(q)=\lambda\cdot m\cdot(q-c), \tag{1}$$

for some $\lambda\in R$, where $q=(q_1,q_2,\ldots,q_N)\in R^{2N}$, $m=diag(m_1,m_2,\ldots,m_N)$, and $c=(c_x,c_y)$ is the center of masses. The problem of counting the convex configurations and of their cyclic order of masses could be posed once the existence problem would be solved. In [15], we have stated necessary and sufficient conditions on the parameters for such a configuration to exist, in the case of four interacting material points with the masses m_1 and m_2 lying on the X-axis at $(R,0)$ and $(-R,0)$-vertices whilst the masses m_3 and m_4 lay at the $(-R\cdot cos\theta, R\cdot sin\theta)$ and $(R\cdot cos\theta, R\cdot sin\theta)$, respectively, with $\theta\in(-\frac{\pi}{2},\frac{\pi}{2})$. If the two ends of a diagonal have equal masses then the uniqueness problem of convex central configuration is known, but it is not known if, the masses being numbered 1,2,3,4 in cyclic order, satisfy or not the equalities $m_1=m_2$ and $m_3=m_4$ [1].

3.

For an isosceles trapezoid central configuration $q_i = (x_i, y_i)$, $(i = 1, 2, 3, 4)$ to exist, its parameters must satisfy the following system of equations [9]

$$\begin{cases} \omega^2(x_i - c_x) &= -\sum\limits_{j=1, i\neq j}^{N} m_j \frac{x_i - x_j}{q_{ij}^3}, \\ \omega^2(y_i - c_y) &= -\sum\limits_{j=1, i\neq j}^{N} m_j \frac{y_i - y_j}{q_{ij}^3}. \end{cases} \tag{2}$$

where $\omega^2 = -\frac{U(q)}{2I(q)}$ and $I(q) = \sum_{i=1}^{n} m_i \cdot \mid q_i \mid^2$ means the moment of inertia. By using CAS *Mathematica* we present below for $N = 4$ in Oxy a homographic interpretations of the system (2) for geometrical and physical values of the parameters.We have shown that if $\theta \in (-\frac{\pi}{2}, \frac{\pi}{2})$ then there don't exist a convex isosceles trapezoid central configuration with all positive masses.

In these figures we can see the functions ω and m_4 which are fulfilled eq.(2). These two parameters describe our

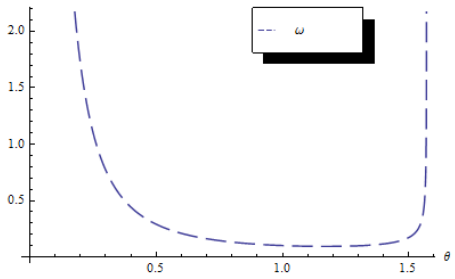

Figure 1: Function ω for $m_1 = m_2 = 0.1$, $R = 1$ and $\theta \in (0, \frac{\pi}{2})$

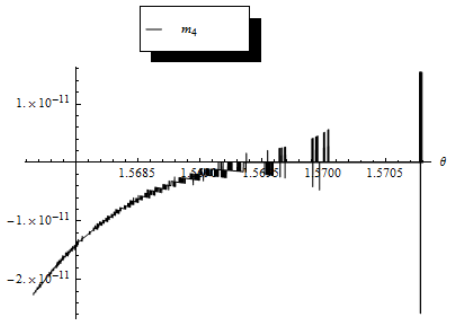

Figure 2: Function m_4 for $m_1 = m_2 = 0.1$, $R = 1$ and $\theta \in (\frac{499\pi}{1000}, \frac{\pi}{2})$

configuration.

NONDIMENSIONAL ANALYSIS OF TWO-DIMENSIONAL ELASTIC POROUS MATERIALS WITH REGULARLY DISTRIBUTED CIRCULAR HOLES

Mertol Tüfekci [1,2], Inci Pir*[1] and Ekrem Tüfekci[1]
[1]Faculty of Mechanical Engineering, Istanbul Technical Engineering, Istanbul, Turkey
[2]Department of Mechanical Engineering, Imperial College, London, United Kingdom

Summary In this study the static behaviour of two-dimensional (2D) elastic porous materials are investigated by using finite element models. The porous material is modelled using a 2D representative element (RE) which includes two quarter circular holes at diagonal corners and analysed under plane stress assumptions. The REs are prepared with different porosities from 5% to 70%. Effects of volume fraction of the pores on the maximum stresses occurring on the material are investigated. The results are nondimensionalized to generalise the behaviour of porous materials.

INTRODUCTION

Foams are becoming more popular over the last decades and widely used in more industrial applications. One of the most important reasons behind this is the need for construction of lighter structures. Another important reason for using foams is the need for wastewater treatment. There, porous membranes are used. properties of those porous materials are not the same or even similar to the bulk forms of the materials. There are numerous studies that investigate the mechanical behaviour of such materials with voids. Majority of the research using numerical methods to model those materials employ representative elements (RE) applying periodic boundary conditions (PBC) on them [1]. The REs can be categorised in two groups based on the distribution of the pores/voids, namely, REs with randomly distributed voids and REs with regularly distributed voids [2]. The distribution of particles are usually random in real materials and the distribution of the voids also affect the mechanical properties of the material [3,4]. However, generating modelling REs with randomly distributed voids is a lengthy process since they require multiple repetitions to find accurate averaged results. Considering that the mechanical properties of the REs with randomly distributed voids lie around an average value. Therefore, in some cases, random REs can be represented with regular REs to estimate the averaged effective properties [2,5]. This, of course, reduces the time to calculate the effective properties whereas it also reduces the accuracy of the estimations.

In this study, elastic foam materials are studied employing the finite element method. REs of these materials were modelled under PBC and a prescribed strain. The material is defined as isotropic and linear elastic. As the goal of this paper is to generalise the results for any linear elastic and isotropic material that are used to manufacture such 2D foams, the resultant stresses are plotted in nondimensional form.

ANALYSIS

The effect of porosity on the mechanical behaviour of REs of 2D materials is studied with finite element method. The REs that are analysed have the volume fractions from 5% to 70% with 5% incrementation. The radius and RE parameter are calculated to meet those volume fraction requirements and the REs are drawn. REs are modelled with 2D plane stress quadratic quadrilateral elements. It is also to be noted that, the necessary convergence studies for each RE are performed to check the meshing is done properly. The only parameter that is changed for this analysis procedure, is the volume fraction of the pores. A typical mesh of the 2D RE is represented in Figure 1.

Figure 1. A typical meshed RE.

The elastic properties are only defined for the execution of the numerical analysis. However, Young's modulus has no effect on the results presented in this paper as the results will be presented without dimensions. The only important elastic material parameter is the Poisson's ratio and it is kept constant as 0.44. The nondimensionalisation is done by

*Corresponding author. E-mail: pirin@itu.edu.tr.

dividing the resultant stresses and the effective elastic moduli by the elastic modulus of the material in bulk form which is the initial elastic modulus defined in the stiffness matrix.

The four sides are subjected to PBC where the sides that belong to the pores are set free. On one of the four sides, a tensional displacement which is the equivalent a strain 0.1% is applied.

RESULTS AND DISCUSSION

The maximum nondimensional Von Mises Stress values and nondimensional principal stress values are calculated for each RE under the conditions that are defined earlier. From those results, the approximate stress concentrations in the material structure can be estimated. As expected and as it is present in the literature, with increasing porosity, all types of stress values decrease. This is, of course, due to reduced stiffness and the imposed constant displacement which is the same for each RE. It is also to be noted that, since the stiffness is reduced, the capabilities of the structure/material to carry loads and the strength of the material will be also in question with increasing porosities. Therefore, it is an important issue to be taken care of during the design of components made of such foams. The plotted results are presented in Figure 2.

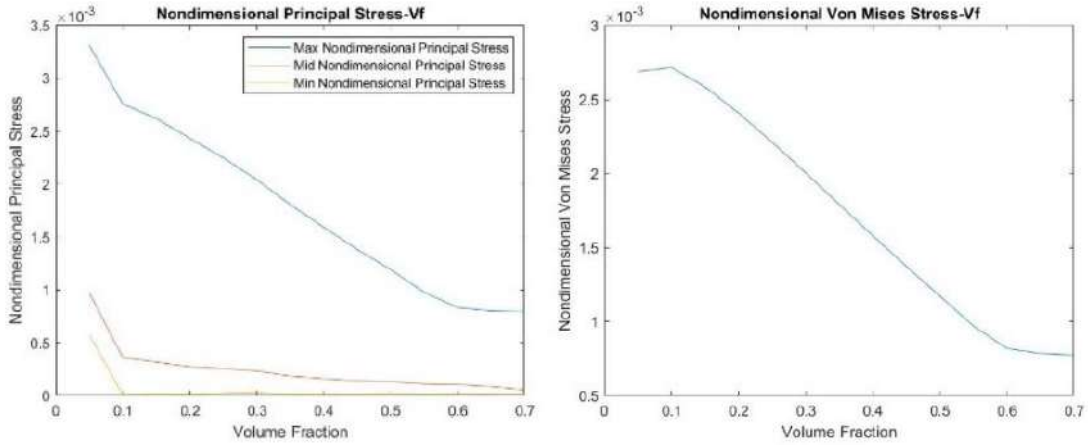

Figure 2. Nondimensional principal and Von Mises stresses.

CONCLUSIONS

The nondimensional results obtained in this paper can be used for any type of foams which are manufactured using linearly elastic and isotropic materials. The stress intensities that expected to occur near the voids are to be assessed with some resemblance. Under constant strain, the increasing amount of gaps in the material structure reduce the stiffness and therefore the stresses. Reduced stiffness also limits capacity to carry loads. Hence, if this analysis were run under the same loading conditions instead of prescribed displacement, the results would look different. For future works, this procedure can be applied with three-dimensional REs and also the dependence of the mechanical properties and stresses on Poisson's ratio can be investigated.

LATERAL COMPRESSION OF TUBES - NUMERICAL PREDICTIONS: REID AND REDDY REVISITED

Rokesh laishram [*1]
[1]Robert Bosch Centre for Cyber-Physical Systems, Indian Institute of Science, Bangalore-India

Summary Numerical validation is carried out to ensure the agreement between the predicted results and the actual observations in the experiment. This paper predicts some of the observations of T.Y. Reddy [1] on the experiments conducted on lateral compression of circular single tubes and crossed layers of tubes crushed between flat parallel platens. Quasi-static experimental results are predicted using the finite element LS_DYNA simulation software package. Other prediction includes the deformed shape of single tube and single crossed layer tubes. The predictions are carried out for aluminium specimens. The predicted load-displacement data matches well with the experimental results. It also captures small details like the change in load-deflection curve when the bottom tube touches the top platen and top tube touching the bottom rigid plate in cross tube experiment.

INTRODUCTION

The predicted load displacement curves of a single tube and of two overlapping crossed tubes being compressed laterally at a constant rate are predicted and presented in this paper. The main motivation of this article is the use of advanced computational tools to predict the coarse experimental data as well as other finer details observed experimentally, but that could not be predicted due to lack of technology at the time of experiment. Well designed and carefully conducted experiment, see Refs [1, 2] showed commendable observations, especially of contact, during the experiment. Above that, the emerging use of single circular tube as legs for Quaterpad robot Refs [8] or arms in Drone Refs [9] in major robotics industries and institutes (especially in Robert Bosch Centre for Cyber Physical Systems, IISc see Refs [10]) has triggered to work on this particular research area.

NUMERICAL PREDICTIONS

The shapes of a single tube at various stages of compression and deforming when compressed laterally between two flat parallel plates are shown in Fig. 1. The corresponding load curve with respect to deflection is shown in Fig. 4a. Fig. 4b shows correlation of the experiment and simulation (of two crossed tubes under compression) with details of contact between tubes with the platens, while Fig. 2 shows the physical deformations of the two tubes. In a crossed tube scenario, the analysis predicts that, of the two tubes, one tube deforms initially at the contact portion while the other starts when the first one deforms considerably. The physical dimensions of the tube and material properties used for numerical prediction are Density = 2700 kg/m^{3,} Young's modulus= 70 GPa, Yield strength = 350 MPa, Tangent modulus = 750 MPa, Tube length = 150mm, Tube outer diameter = 25mm and Thickness = 0.9mm.

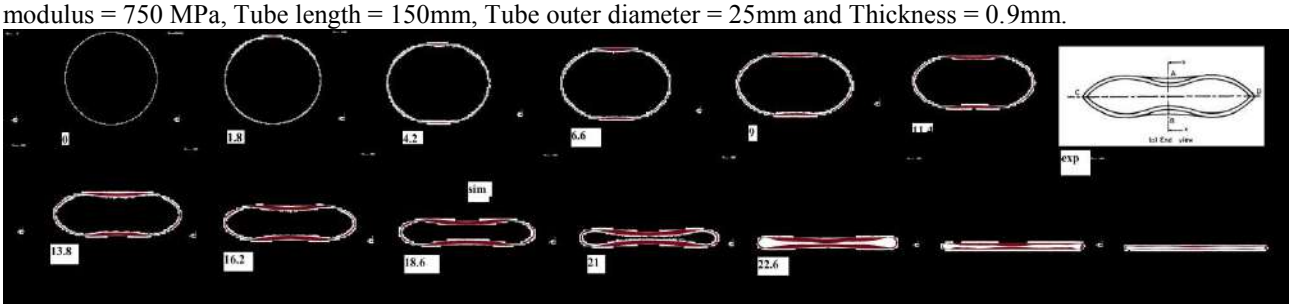

Figure 1: Simulated deforming shapes of a single tube upon compression by platen in mm (sim) and experiment (exp) Refs[2].

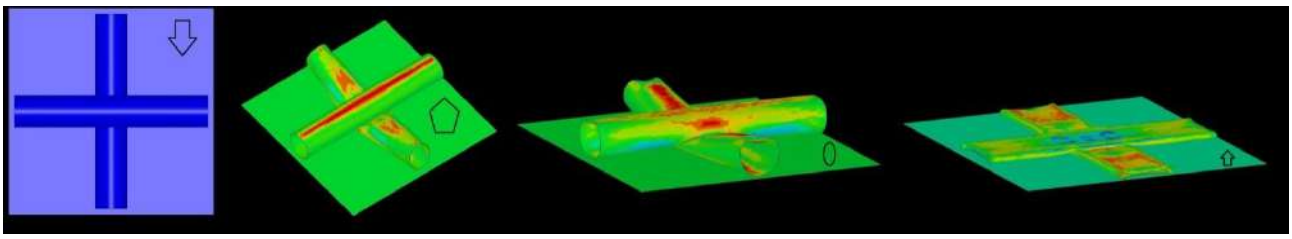

Figure 2: Deformed single crossed layer tubes upon compression.

The modelling details are as follows. The top platen is considered as non-deformable rigid body with material card MAT_20 MAT_RIGID and for aluminium MAT_24 MAT_ELASTIC-PLASTIC material card is used. 4 noded co-rotational shell elements are used for simulation with element form 16 (Fully integrated shell element) with HOURGLASS type 8. Contact is CONTACT_AUTOMATIC_GENERAL. Number of elements in a tube is 11849 with mesh size 1. Load collector used is BOUNDARY_PRESCRIBED_MOTION_RIGID where a constant load is being applied.

*Corresponding author. E-mail: **laishrams@iisc.ac.in / thoilai3@gmail.com**

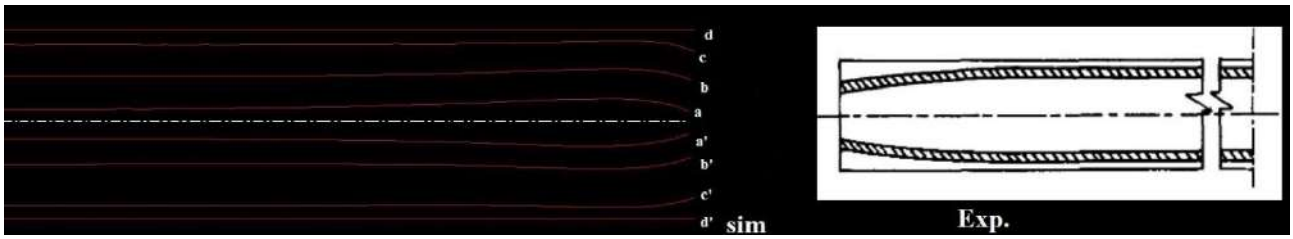

Figure 3: Sim – Sectional deformation view at the middle of tube from side at different stages a, b, c and d, Exp. – sectional view in Refs. [2]

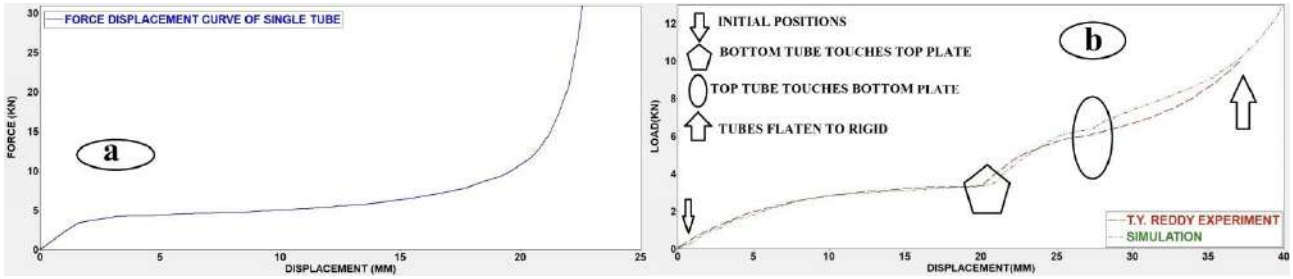

Figure 4: a) Load displacement curve of single tube, b) Experimental and predicted load displacement curve of crossed single tubes.

The anticlastic curvature effect could be seen clearly in the side sectional view of the tube upon compressing gradually both in simulation and experiment Refs [2]. Fig 3 sim shows the changes in curvature of the tube upon being compressed gradually at different stages Fig 3(d/d') initially the platen has whole length contact with the tube later at fig 3 (c/c') (b/b') the end of the tube starts bending and continued the bending in the middle of the tube as well at fig 3(a/a').

CONCLUSIONS

The work reported here is the prediction of some experimental data published in Refs. [1]. A lot of works related to lateral compression have been reported in Refs. [1-5] and the prediction of the experiments would be analysed numerically in future papers. The study would include loading laterally on nests of tubes (multiple layers of several tubes in each layer), compression of tubes with side constraint and dynamic behaviour with strain rate effects. Other observations like crack development on the side of the tubes and development of contact zone between two crossed tubes upon increasing compression load would also be studied. The study could be useful in designing drone arms and robot legs Refs. [6] where the arms/legs are circular and held tightly between two plates (also side constraints) which are similar to the experiments and numerical prediction done in this article. The main advantages for using circular tubes in robotic legs would be because of its ability to take lateral load uniformly from all directions i.e. when the robot is moving forward and sidewise and of its high axial load bearing capacity. The simulation result correlates well with the experimental data though slight disagreements are visible after the tube started touching the top platen and thus this model is validated and the properties could be used for further investigation of lateral compression of tubes with holes (.i.e. coupling point) and foam filled for robotic applications.

ACKNOWLEDGEMENT

I would like to thank Dr. Tirumagondanahalli Yella Reddy for allowing me to use his experimental results as well as for giving clarification on the experiments conducted and Dr. Debiprosad Roy Mahapatra (iMEMS lab, Aerospace Dept., IISc-Bangalore) for providing the computational facility for this article. I express my sincere thanks to Dr. S. Bharadwaj Amrutur (Chairman, RBCCPS, IISc.-Bangalore) for encouraging this research work.

THERMOMECHANICAL ANALYSIS OF TWISTED BLADE

Aalok Kumar Jha *and Chandra Shekhar Upadhyay
Department of Aerospace Engineering, Indian Institute of Technology Kanpur, India

Summary It is always challenging to analyze twisted blade like structures and predict their life accurately due to their complex shapes, especially in high temperature and hostile environment. In the present study, the authors present a methodology by which finite element(FE) based geometric approximation as well as analysis approach has been efficiently and effectively implemented for the blade under thermomechanical load. The developed tool is an effort towards creating a reliable FE based analysis tool, which can be used to aid the design process.

INTRODUCTION

Thermomechanical analysis of a complex geometrical structure is still a challenging issue and the finite element (FE) method is one of the most popular and powerful methods for analysing such a problem. Accuracy in capturing curved boundaries and their discretization is a source of error in FE method, therefore approximation of geometry along with the approximation of solution field should be done carefully. A novel three dimensional FE tool has been developed for the thermomechanical analysis of generally twisted blade like structures, which creates a consistent representation of geometry, allowing for effective control of error emanating from inexact representation of the boundaries. The method further uses directional enrichment in order to capture localized three-dimensional effect due to change in material, boundary conditions or defect. Any extruded section which is tapered, bent and twisted can be efficiently analyzed by this technique. The computed stress and strain gives interesting and expected result which may be used for design and life prediction of such blade, specially in thermal environment, such as in gas turbine compressor and low pressure turbine blade.

GEOMETRICAL MODELLING

Inspired by the current focus on isogeometric formulation which has exciting possibilities of unifying both geometry description and the analysis, authors constructed a formulation which uses conventional FE representation up to higher order for both geometry as well as the analysis. Following the desire for unified modelling and analysis approach the authors have created a FE regime for representation of the geometry. The geometry will be represented in terms of FE basis functions, so that again analysis and geometry representation is done in same function space. This allows for easy manipulation of geometry data with desired accuracy in both representation of geometry and solution. It ensures that curved boundaries can be easily modelled for a given level of refinement of the mesh ensuring guaranteed bounds on the errors that arise due to both the geometrical approximation as well as the analysis.

Capturing the geometry of cross section

The cross-section of most of the gas-turbine(GT) engine blades are complicated aerofoil shapes, whose boundary surface data can be in the form of an explicit curve or in terms of point cloud. The developed tool is capable of fitting a curve which represents the actual boundary accurately. It is assumed that the given point cloud has sufficient data points to start with, i.e. it is not starved of data points. Fig. 1(a) shows fitted cubic curve from the tool. Utilizing the nodal points obtained from the boundary curve discretization the point set for the cross section has been generated. Fig. 1(b) shows point set for meshing of elliptical cross section by developed method. Once mapping of cross sectional area has been generated, for getting 3D representation an extrusion of 2D cross-sectional fit has been done. The extrusion can handle pre-bend,twist and taper. This gives the special element which is used for 3D thermo-mechanical analysis. Extruded twisted-tapered-bent beam obtained by this method can be seen in Fig.2, which shows the obtained thermomechanical field in the beam.

THERMO-MECHANICAL MODEL

In classical thermoelasticity the displacement field and thermal field are strongly coupled in transient condition and these fields can be expressed as

$$d = d(x, y, z, T, t)$$
$$T = T(x, y, z, t)$$

Where d is displacement, T is temperature, $X(x, y, z)$ is spatial co-ordinate and t is time. The classical coupled thermoelastic equation is derived in [3-5] and given by following coupled equations.

$$\sigma_{ij,j} + f_i - \rho\ddot{u}_i = 0 \quad (1)$$
$$q_{i,j} + \rho C\dot{\theta} + \beta_{ij}T_0\dot{\epsilon}_{ij} - Q^* = 0 \quad (2)$$

Where $[\sigma]$ is stress tensor, $\boldsymbol{f}$ is body force, $\boldsymbol{u}$ is displacement, $\boldsymbol{q}$ is heat flux, Q* is internal heat generation, θ is change in temperature, T_0 is initial temperature, ρ, C and β_{ij} are material constants.

CONCLUSIONS

The methodology developed for creating an optimised mesh with special element gives the exact representation of complex geometry and it's general nature allows for thermo-mechanical analysis of any arbitrary, curved 3D-beam of blade like structures. Meshing is automatically generated in this method. Hence, rigours meshing technique can be avoided, which saves time and resources. Further interaction with CAD model is not needed for analysis purpose. These features make the whole process very fast in comparison with the existing methods. This novel FE method predicts good results for elastic and thermoelastic problems. A typical result obtained from this method is shown in Fig.2.

A STUDY ON COMPOSITEMATERIAL NON-LINEAR MECHANICAL RESPONSE BASED ON MICROMECHANICS FINITE ELEMENTMETHOD

Heyuan HUANG*[1], Meiying ZHAO [1],and Wenzhi WANG [1]
[1]Northwestern Polytechnical University,Xi'an,China

Summary The non-linear mechanical performance of a composite material, i.e. ZT7H/5429, was investigated in present paper in the micro-scale. Combining numerical simulation results with experimental data demonstrated that micro-crack accumulation and plasticity of matrix were the two dominant factors which can lead to nonlinear mechanical performance of ZT7H/5429.

1 Numerical analysis method

The paper provided an examination on the fiber random distribution modeling method. Particularly, an algorithm was developed for generating the equivalent RVE. With experimental statistical inputs, this algorithm generated RVE was statistically equivalent to real structures by probability equations, and solved the problem of smaller distance distribution, the generated finite RVE element model was shown in Figure 1(a). The corresponding model based on this RVE generation method was subsequently developed and used to accurately predict the mechanical properties of ZT7H/5429. Furthermore, a damage constitution was implemented into the RVE of this model to simulate the mechanical responses in transvers and in-plane directions as well as the damage evolution procedure, three dimensional periodic boundary conditions were shown in Figure 1(b).

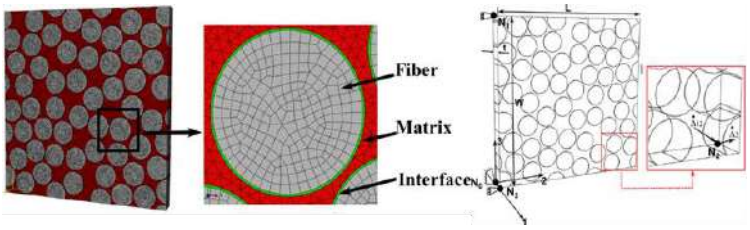

Fig.1 The RVE model schematic diagram: (a) finite element model; (b) periodic boundary conditions

2 Numerical simulation results and analysis

2.1 Damage propagation analysis

Compared with the experimental results, the RVE models could accurately simulate the damage propagation law of laminates under different loads. At the same time, it could be seen that the initiation of internal cracks in the element was gradually expanded from the beginning of the interface. Fig. 3~Fig. 5 were damage propagation schematic diagrams of RVE models under different load conditions.

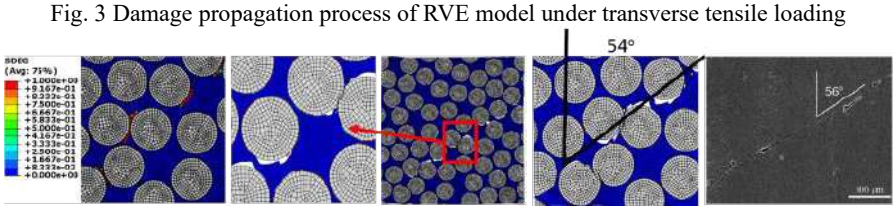

Fig. 4 Damage propagation process of RVE model under transverse compresssion loading

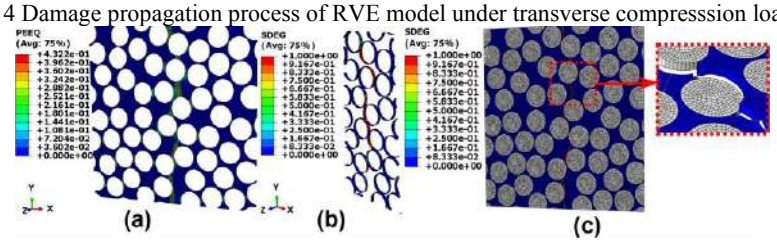

Fig. 5 Damage propagation process of RVE model under shear loading: (a) matrix damage; (b) interface damage; (c) failure mode

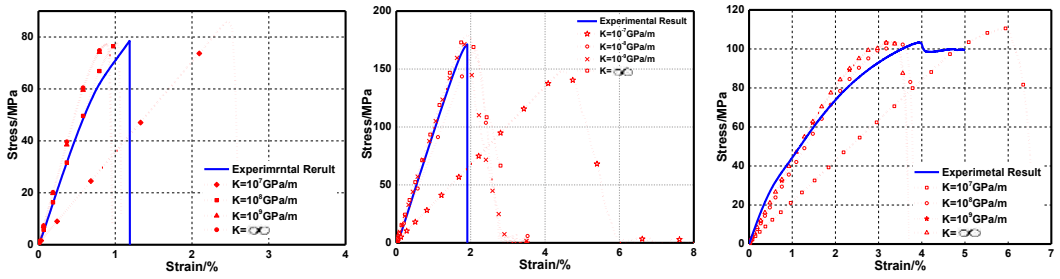
2.2 Analysis of nonlinear influence factors

By controlling the interface stiffness, a perfect interface was established to prevent crack initiation and the influence of the linear-elastic constitutive relation of the matrix was considered. The relationship between the micro-crack accumulation in the

*Heyuan HUANG. E-mail: huangheyuan@nwpu.edu.cn.

element and the plasticity of the matrix material and the macroscopic stress-strain curve nonlinearity are comprehensive researched.

Fig.6 compared the stress-strain curves of ZT7H/5429 composites of different interface stiffness. With the changes of interface stiffness, the strength limit of composite material was almost unchanged, but the curve slopes were obviously different, which proved that the micro crack initiation and accumulation have important influence on the non-linearity of the composite macro mechanical response. Fig.2-49 shown the stress-strain curves under different loads. As can be seen from the figures, stress-strain curves have weakly non-linear characteristics in elastic constitutive, but there was obvious error with the plastic constitutive, which indicated that the plasticity of matrix material is also an important reason for the non-linear stress-strain of materials.



(a) (b) (c)

Fig.7 Stress-strain curves for different constitutive equations：(a) Longitudinal Tension;(b) Transvers Compression;(c) In-plane Shear

3 Conclusion

In this paper, the damage propagation mechanism of ZT7H / 5429 composites is analyzed comprehensively. The nonlinear characterization of macroscopic stress-strain curves of composite laminates was verified that the micro-crack accumulation and matrix plasticity were the two main factors caused of laminates macroscopic nonlinear mechanical characterization.

MODELING OF TRANSVERSALLY LOADED AXIALLY MOVING BEAM WITH CREEP

Helmut J. Holl*[1] and Gottfried Simon[2]
[1]Institute of Technical Mechanics, Johannes Kepler University, Linz, Austria
[2]Plasser & Theurer, Export von Bahnbaumaschinen GmbH, Linz, Austria

Summary For an axially moving beam which is supported by periodic discrete elastic springs and a given transversal load two mechanical models are derived, analysed and discussed. The first beam model applies global Ritz approximations for the spans between the spring supports whereas the second beam model uses a conventional FE description. Gauss integration points are used in longitudinal and transversal direction. The temperature distribution and pressure loads cause stresses, which lead to strain rates due to creep of the material so that a time dependent deformation between the discrete elastic supports results. The deflection of the axially moving beam model is computed considering various spans separated by elastic spring supports. The computed results of the two mechanical models are compared for a beam with two and ten spans.

INTRODUCTION

Transversally loaded beams under axial motion are studied in two different models. In [1] the axially moving viscoelastic web is simulated with varying normal force a high axial speed so that inertia terms are important in the equation of motion. For the process simulated here the axial motion is considered to be so slow that inertia effects can be neglected in the computation. The axial transport of the inelastic creep-strains has been considered in the computation in accordance with the axial speed. The temperature field is assumed to be constant in the beam and it is considered that the beam has a constant thickness.

MECHANICAL MODEL OF A MOVING BEAM WITH CREEP

The equations for an axially moving beam with transversal load considering creep deformations are given in [2], where also a method for the computation of ε^{cr} is proposed. The mechanical stress in the beam cross-section is computed by

$$\sigma_{XX} = E\left[-Zw''(X) - \varepsilon^{cr}(X,Z) - \varepsilon^{th}(X,Z)\right], \tag{1}$$

where E is the Young's Modulus, $w(X)$ is the deformation of the beam in transverse direction, ε^{cr} is the creep strain and $\varepsilon^{th}(X,Z)$ is the thermal strain. With the virtual displacement $\delta\varepsilon = -Z\delta w''$ the formulation of virtual work results to

$$\delta A = -\int_V \sigma_{XX}\delta\varepsilon dV + \int p_z \delta w dX - \sum_{k=1}^{N_k} F_k \delta w(X_k) \tag{2}$$

with the external transveral load p_z and the concentrated spring element forces F_k at the position X_k. The temperature is assumed to be constant in the computed examples so that $\varepsilon^{th}(X,Z) = 0$. The bending moment is computed from the stress distribution in the beam eq. (1) and $dV = dXdA$, where the part for the bending moment caused by the creep strain is $M^{cr} = \int EZ\varepsilon^{cr}dA$. Two different approximations are implemented and compared. In a first approach global shape-functions are derived, see [3], and inserted into the eq. (2). In a second approach local Ritz approximations analogous to the FE method are used. These two kinds of shape functions are arranged in the vector $\mathbf{W}(\mathbf{X}) = W\left(P_1, P_2, \ldots PN\right)^T$ for the global and $\mathbf{W}(X) = W\left(N_1, N_2, N_3, N_4\right)^T$ for local Ritz' approximation where the deflection is $w = \sum_0^n W_i q_i = \mathbf{W}(X)\mathbf{q}(t)$. Inserting $w(X)$ in eq. (2) gives a force term caused by the creep strain $\mathbf{f^{cr}} = \int M^{cr}\mathbf{W}''dX$. With these shape-functions the consistent force of the external load $\mathbf{f^0} = \int p_z \mathbf{W}(X)dX$ and the force caused by the spring elements $\mathbf{Q}_{Sk} = k\ \mathbf{W}(X_k)$ is computed. Finally the stiffness matrix results to $\mathbf{K} = \int EI \cdot \mathbf{W}''\left(\mathbf{W}''\right)^T dX$. The number of coordinates neccesary for a converged solution defines the size of the system of equations to be solved, $\mathbf{q}$ is the vector of the generalized coordinates or nodal degrees of freedom respectively, so we derive the system of equations

$$\mathbf{K}\,\mathbf{q} + \mathbf{Q}_S = \mathbf{f}^{cr} + \mathbf{f}^0. \tag{3}$$

DESCRIPTION OF THE AXIAL MOTION

In eq. (1) the stress depends on the longitudinal coordinate of the beam and is computed at the Gauss-points in the X,Z-plane of the beam. The integrals over the cross-section and the length are evaluated by Gauss-integration. The creep strain is computed from the constitutive equation of the material $\dot{\varepsilon}^{cr} = \gamma(\sigma, \varepsilon, t)$, see [5]. This ordinary differential equation is integrated in time with an implicite Runge-Kutta-Method to get the local creep increment $\Delta\varepsilon^{cr}_{t+\Delta t}$. Because of

*Corresponding author. E-mail: helmut.holl@jku.at.

the axial velocity v_0 the creep strain is transported with the material along the beam axis. The one-dimensional transport equation with homogeneous initial and boundary conditions

$$\frac{\partial \varepsilon^{cr}}{\partial t} + v_0 \frac{\partial \varepsilon^{cr}}{\partial x} = 0, \qquad \varepsilon^{cr}(x=0) = 0 \tag{4}$$

is used to compute the actual values of ε^{cr}. The Finite-Difference-Method (FDM) is applied to get a system of ODE's. Again the Gauss-points are used for the discretisation. This system of ODE's again has to be integrated in time to get the convective part of the inelastic strain. The total creep strain is

$$\varepsilon^{cr}_{t+\Delta t} = \varepsilon^{cr}_{con} + \Delta\varepsilon^{cr}_{t+\Delta t}. \tag{5}$$

COMPUTED RESULTS

A parametric study is carried out and two examples are presented. A two-span beam with a height of $h = 30$ mm is considered which is supported by one spring element with the stiffness $k = 4 \cdot 10^{12} \frac{\mathrm{N}}{\mathrm{m}}$. The lenght of the beam span is $a = 0.3$ m. Clamped boundary conditions on both ends. The applied constitutive relation taken for secondary creep is $\dot{\varepsilon}^{cr} = Ce^{-\frac{Q}{T}}|\sigma|^{n-1}\sigma$. and the parameters are taken form [5]. A constant transversal load of $p_z = 115.5 \frac{\mathrm{kN}}{\mathrm{m}}$, constant axial velocity of $v_0 = 1.6 \frac{\mathrm{m}}{\mathrm{min}}$ and a constant temperature of 1300 °C is applied. Due to the axial motion there is a steady state transversal deflection which means that the deformation does not change with time and $w(x,t) = w(x)$. The axial motion in combination with creep leads to an asymmetric result, see Fig. 1, whereas the load and the mechanical boundary conditions are symmetric. 14 global Ritz approximations are applied and for the FEM Method 50 beam elements are used to get a suitable convergence. The difference in the computed results between the Ritz- and the FE-Method in Fig. 1 is caused by a different discretisation with Gauss-points. For the second example of a ten-span beam the height is again $h = 30$ mm, the temperature is 1350 °C, the transversal load is $p_z = 700 \frac{\mathrm{kN}}{\mathrm{m}}$, the axial velocity is $v_0 = 0.85 \frac{\mathrm{m}}{\mathrm{min}}$. In the results in Fig. 2 the elastic and the total deflection of the beam is shown. Due to the axial velocity and creep again the transversal deformation is not symmetric with respect to the position of the supports.

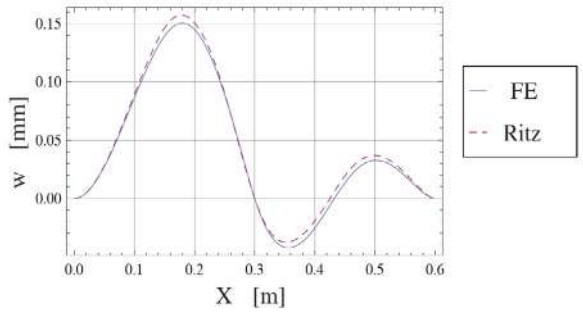

Figure 1: Deformation of the two-span beam

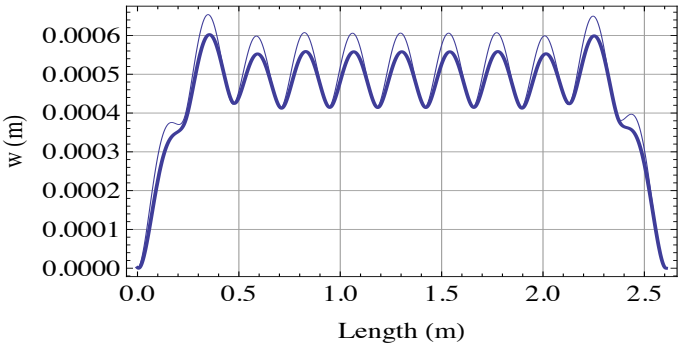

Figure 2: Deformation of the ten-span beam

CONCLUSIONS

The computation of the transversal deformation of an axially moving beam is performed for two different mechanical models applying local and global Ritz approximations. The computation results of the parametric study show that for the model with up to three spans the global Ritz approximations are computationally more efficient whereas for more spans the local Ritz approximations are preferable. A material with constitutive relations of secondary creep is used in the computation. The creep deflection depends on the axial velocity and shows a non-symmetric deflection within each span.

DYNAMICS OF PARTICLE-STRUCTURE INTERACTIONS WITH LARGE-DEFLECTION CANTILEVER BEAMS: A DEM PERSPECTIVE

Prasenjit Ghosh*[1], Gondi K. Ananthasuresh[1]
[1]Department of Mechanical Engineering, Indian Institute of Science, Bengaluru, India

Summary The discrete element method (DEM) is a general discrete modelling technique widely used to model granular material and discontinuum phenomena such as fracture and fragmentation. This study investigates the efficacy of DEM to model deformable elastic continua like cantilever beams and capture geometric nonlinearity in their large-deflection response. It presents a numerical example to demonstrate the utility of this approach in particle-structure problems involving large structure displacements. The example simulates the capture of particles by slender protrusions called cilia present in living organisms. A DEM model consisting of cantilever beams that oscillate elastically in a particulate environment is constructed. The dynamics of the ensuing particle-structure interactions are simulated and factors governing the efficiency of particle capture are examined.

INTRODUCTION

The mechanical behaviour of deformable solid bodies in a particulate environment has been an area of increasing interest in recent years. Examples where discrete entities or particles interact with these bodies are ubiquitous in biology and more particularly, cell biology [1]. Mechanical microstructures like microcantilevers operate on biological elements and experience interactions with particles of myriad sizes and shapes. Examples also abound in the macroscopic world: debris flow mitigation by flexible barriers, dam-break tests, sea-ice loads on marine structures, etc.

Problems involving deformable solid continua present in conjunction with particles often necessitate a coupled continuum-discrete approach to describe the mechanics entailed. This study presents the discrete element method (DEM) as an alternative approach, especially in cases where (a) the mechanical responses of the solids and particles are coupled, and (b) the resulting interactions are dynamic in nature. DEM provides a natural route to modelling the dynamics of discrete entities [2]. For solids, it undertakes a mesoscopic discretization that is computationally tractable and characteristic of the macroscopic response [3]. This offers the advantage to recast all possible interactions as particle-particle interactions, which are naturally handled using the DEM technique. Furthermore, the interaction relations prescribed at the particle level are relatively simple and unencumbered by a large number of unknown parameters. Nonlinearity and complexity evolve dynamically in such a system. It may thus be worthwhile to explore the modelling of deformable solids, their capability to undergo large deformation, and their nature of interactions in a particulate environment, all using DEM.

GEOMETRICALLY NONLINEAR LARGE-DEFLECTION RESPONSE

In many problems of particle interactions, solids undergo small elastic deformation and large rotations and displacements. This commonly gives rise to an important class of nonlinear effects in the system: geometric nonlinearity. The first half of our work models an Euler-Bernoulli cantilever beam using DEM and examines the possibility of capturing geometric nonlinearity in its large-displacement behaviour. Deformation under static, dynamic and impact loading scenarios, each applied at the free end, is simulated. For static loading, we consider transverse force (P), axial force (nP), bending moment (M), and torsional moment (T), acting individually or in combination. For dynamic loading, we consider a sinusoidally varying transverse force. For impact loading, we consider a sphere transversely impacting the beam from a distance. Results for a beam with length L, area moment of inertia I, Young's modulus E, shear modulus G, and torsion constant K are shown in Figure 1.

Our numerical investigations with DEM-modelled cantilever beams capture geometric nonlinearity in large deformation under multiple loading scenarios. It is worthwhile to note that the nonlinearity emerges from the simple contact relations specified in the particle level. DEM is shown to reproduce this nonlinear behaviour in good agreement with solutions obtained from analytical and numerical methods within the framework of continuum mechanics. This provides us the necessary groundwork to subject flexible cantilever beams to a particulate environment and analyse the associated mechanics within the DEM framework.

PARTICLE-STRUCTURE INTERACTION: AN ILLUSTRATIVE EXAMPLE

The second half of our work presents a numerical example to demonstrate the utility of this approach in particle-structure problems involving large structure displacements. The genesis of this example lies in the capture of particles by beating cilia – slender and elastic hair-like structures that protrude from the surfaces of various cells in living organisms. An assemblage of beating cilia possesses two fundamental characteristics: (a) each cilium deforms asymmetrically in a periodic manner to generate a net effect of directed motion, and (b) neighbouring cilia oscillate with a difference in phase to generate a metachronal wave motion. To a first approximation, we model the cilia as an array of 10 cantilever beams, each of which undergoes large deflection sequentially and periodically due to a sinusoidal force F_n at the free end. To model metachronal motion, a constant phase difference is specified in the loads of consecutive beams such that for the n-th beam,

$$F_n = F_o \sin(\omega t + n\pi/10) \quad \text{where } n=1,2,3\ldots,10$$

*Corresponding author. E-mail: prasenjitg@iisc.ac.in

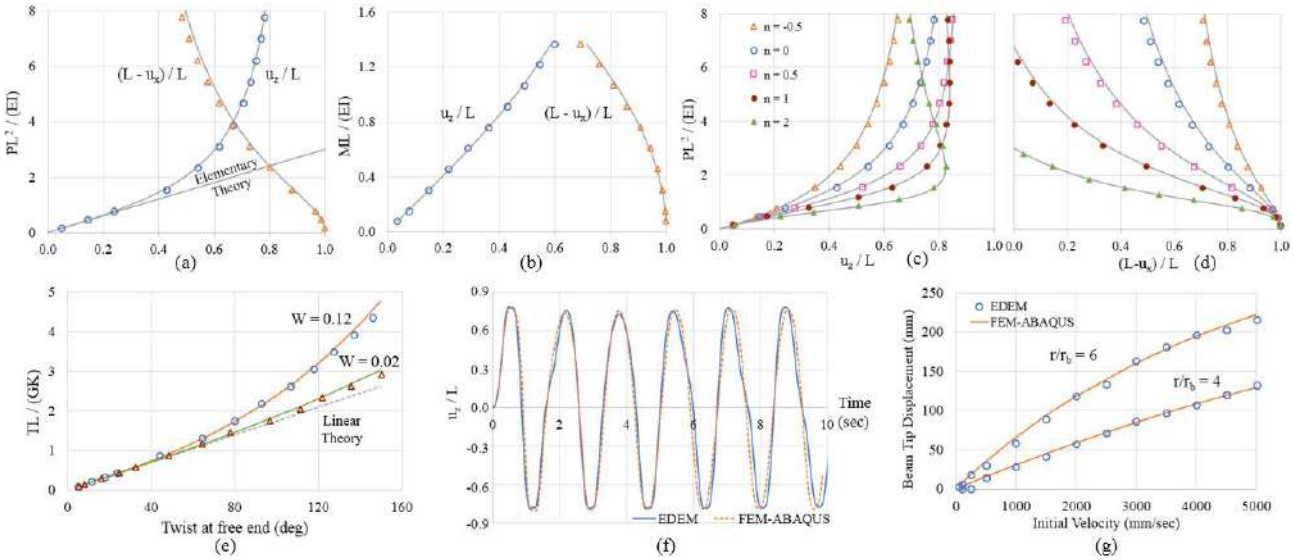

Figure 1: Generalized large-displacement solutions for an Euler-Bernoulli cantilever beam subjected to loading at free end. (a) and (b) correspond to transverse force and bending moment loads respectively. (c) and (d) correspond to combined transverse and axial forces. (e), (f) and (g) correspond to torsional moment, dynamic transverse force and transverse impact of a sphere respectively. The solid lines, unless otherwise indicated, represent continuum solutions.

The beam array oscillating in a rhythmic manner impacts a stream of incoming particles with the objective to drive them inside a particle collector placed underneath (Figure 2(a)-(b)). The impact dynamics determine whether particles are captured in the collector or thrown off. We are interested in analysing the capture characteristics of the array. We compute the capture fraction, the number of particles captured relative to a total of 100 incoming particles. We examine its dependence on three parameters: the frequency of oscillation, the flow velocity of incoming particles, and the incline angle denoting the asymmetry of oscillation. It is challenging to estimate a priori how a combination of these factors will affect the capture of particles. DEM enables the nonlinear dynamics of these factors of capture to be determined from the solution (Figure 2(c)-(d)).

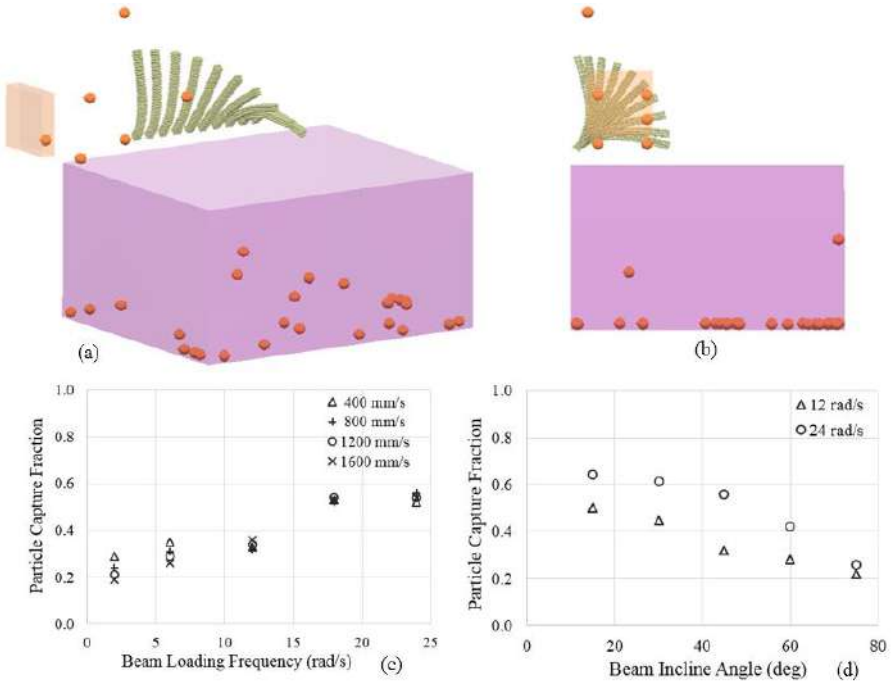

Figure 2: Particle interactions of an array of oscillating cantilever beams. (a) and (b) show a snapshot of the dynamic simulation from two views. (c) plots the variation of capture fraction with the frequency of oscillation and the flow velocity of incoming particles. (d) plots the variation of capture fraction due to change in the incline angle of each beam.

CONCLUSION

A DEM model is developed for the deformable solid continuum of a cantilever beam. This is shown to depict geometric nonlinearity in its large-deflection response for various cases of static, dynamic and impact loading applied at the free end. The DEM-modelled cantilever is further introduced in a particulate environment to simulate the capture of particles by biological cilia. Our results highlight the rich dynamics present in a simple model of a ciliated system capturing particles. This is where numerical experimentation using DEM can gain utility as an effective tool to capture the coupled dynamics of particle-structure systems.

THE DISCONTINUITY LAYOUT OPTIMIZATION (DLO) FOR THE EVALUATION OF LIMIT LOAD OF NON-PERIODIC TEXTURES MASONRIES

Mattia Schiantella[1], Federico Cluni *[1], and Vittorio Gusella[1]
[1]Department of Civil and Environmental Engineering, University of Perugia, Perugia,Italy

Summary The Discontinuity Layout Optimization (DLO) is used to estimate the failure load of masonry walls having three different textures: periodic, quasi-periodic and chaotic. In particular, DLO belongs to the upper bound methods of limit analysis. The discontinuities associated with the failure mechanism can appear both in the mortar joints and inside the bricks. A Mohr-Coulomb failure criterion is used. The results are compared with those obtained with small samples made of one-fourth scaled down bricks.

INTRODUCTION

When dealing with cultural heritage constructions, very often the engineer has to face masonries realized with a non-periodic texture. In particular, when dealing with multi-leaf masonries, the exterior curtain is usually made with stones having equal size arranged in periodic pattern, while the inner leaf very often consist of quasi-periodic masonry, which is realized with blocks having different size arranged in such a way that blocks having approximately the same height are aligned to form horizontal rows; anyway, the length of the blocks inside a row and the height of each row vary in each sample. Moreover, is some cases the texture is chaotic, with absence of continuity in bed mortar joints due to the presence of stones having very different dimensions.

Since these masonry textures are not periodic, the usual methods available in literature (see, for example, [1] for a recent discussion) to estimate the failure surface cannot be used. Recently, in [2], the Authors proposed an approach where the effective texture of the masonry is taken into account, and the upper bound of the failure surface is estimated by means of Discontinuity Layout Optimization (DLO).

In DLO approach, which belongs to the field of limit analysis and was proposed in [3, 4], all possible discontinuities (according to an hypothesized failure mechanism) that can appear in the considered portion of the wall are considered, and by minimizing a suitable function the effective pattern of discontinuities at failure is estimated. One of the main advantage is that, if the function is a linear one, it can be minimized through linear programming techniques.

APPLICATION OF DLO TO MASONRY WALLS

In the present paper, the results of the application of DLO to masonries with different textures are reported. In particular the following textures have been analyzed, as shown in Fig. 1:

- periodic texture;
- quasi-periodic texture;
- chaotic texture.

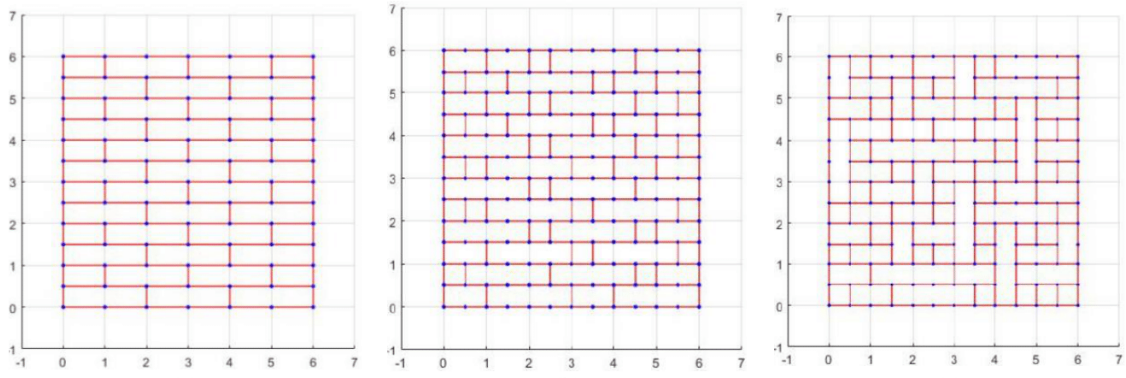

Figure 1: Masonry with periodic (a), quasi-periodic (b) and chaotic (c) textures.

The effect of the width-to-height ratio of the entire walls is evaluated. Moreover, the influence of the width-to-height ratio of the single brick is also taken into account. As an enhancement of the results shown in [2], it is assumed that the

*Corresponding author. E-mail: federico.cluni@unipg.it.

discontinuities could also appear inside the brick. The assumed failure criterion is the Mohr-Coulomb one, which allows to obtain a linear problem which could be solved by means of linear programming.

In order to validate the results, the obtained estimates of failure load are compared with the results of experimental tests, where specimens of small dimensions, realized with the bricks scaled down to about one-fourth of the real dimension to match exactly the texture used in the numerical simulations, are loaded until failure occurs.

CONCLUSIONS

The Discontinuity Layout Optimization approach is used to investigate the failure load of masonry having several different textures. The possible failure of both bricks and mortar joints is taken into account, adopting a Mohr-Coulomb criterion. The effects of geometric variability is taken into account. The results are compared with those obtained by means of experimental tests.

A METHOD OF PROCESSING RIGID BOUNDARY CONDITIONS IN THE MATERIAL POINT METHOD

Mengdi Zhou[1], Linfang Qian[1],Guangsong Chen [*1],Shijie Zhou[1]
[1]School of Mechanical Engineering, Nanjing University of Science and Technology, Nanjing, China

Summary A method for handling rigid boundaries in the cubic B-spline material point method (MPM) is proposed in the paper. The corrected shape function overcomes the inherent drawback that it is difficult for the original cubic B-spline function to deal with the rigid boundary conditions. Numerical tests are made to prove the feasibility and accuracy of this method. Results show that, when employed in MPM, the proposed method is superior to the original cubic B-spline function in preventing particles from crossing rigid boundaries.

CUBIC B-SPLINE CORRECTION SHAPE FUNCTION

MPM takes advantage of both Eulerian methods and Lagrangian methods [1]. The original version of MPM employs piecewise shape functions and suffers from noise when particles move through grid nodes. To eliminate noise and improve accuracy, the cubic B-spline is introduced as the shape function. However, it's difficult to deal with particles near rigid boundaries as the cubic B-spline spans four grid cells in each dimension.

A cubic B-spline function and its derivative have the following form [2]

$$N_{Ip}=\begin{cases}\frac{h^3}{6}+h^2+2h+\frac{4}{3}, h\in[-2,-1)\\ -\frac{h^3}{2}-h^2+\frac{2}{3}, h\in[-1,0)\\ \frac{h^3}{2}-h^2+\frac{2}{3}, h\in[0,1)\\ -\frac{h^3}{6}+h^2-2h+\frac{4}{3}, h\in[1,2)\\ 0, others\end{cases},\quad \nabla N_{Ip}=\begin{cases}\frac{h^2}{2}+2h+2, h\in[-2,-1)\\ -\frac{3h^2}{2}-2h, h\in[-1,0)\\ \frac{3h^2}{2}-2h, h\in[0,1)\\ -\frac{h^2}{2}+2h-2, h\in[1,2)\\ 0, others\end{cases} \tag{1}$$

where

$$h=\frac{x_p-x_I}{L} \tag{2}$$

where x_p denotes the spatial coordinates of a particle p , x_I denotes the spatial coordinates of the grid nodes which in the influence domain of p ,and L is a grid spacing.

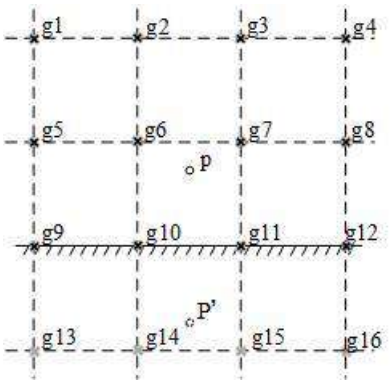

Figure 1. Particles and nodes

In 2D space, each particle should be related to sixteen nodes. When a particle is close to the boundary, its influence domain is beyond the computational domain. To handle rigid boundary conditions, Eulerian methods employ ghost cells while Lagrangian methods use mirror particles. As MPM is a mixed Eulerian-Lagrangian method, both ghost cells and mirror particles should be considered. This poses a challenge to computational efficiency.

For a long time, there has been a lack of one simple and efficient method to handle rigid boundary conditions in cubic B-spline MPM. Therefore, under this circumstance, the corrected shape function is proposed. When a particle is more than one cell away way from the boundary, the shape function and its derivative are expressed as Equation (1) ~ (2). When a particle moves into the cell adjoining the boundary, the shape function is corrected to replace the effect of ghost cells and mirror particles.

As shown in Figure 1, taking a particle near the bottom as an example. p' is the mirror particle of p, while $g13$ $g16$ are ghost nodes of $g5$ $g8$. There exist $x_{2,g14}=x_{2,g6}-2L$, $x_{2,p'}=2x_{2,g6}-2L-x_{2,p}$, and N_{Ip} is calculated as follows:

$$\left.\begin{aligned}h_{14p}&=h_{6p}+(0,2)^T\\ h_{6p'}&=-h_{6p}-(0,2)^T\end{aligned}\right\}\Rightarrow\begin{aligned}&N\left(h_{14p}\right)=N\left(\varphi\left(h_{6p}\right)\right)\\ &N\left(h_{6p'}\right)=N\left(-\varphi\left(h_{6p}\right)\right)=N\left(\varphi\left(h_{6p}\right)\right)\end{aligned} \tag{3}$$

where $\varphi(\xi)=\xi+2n$. n denotes the normal vector of boundary. ∇N_{ip} is calculated as follows:

$$\begin{aligned}\nabla N\left(h_{14p}\right)&=\nabla N\left(\varphi\left(h_{6p}\right)\right)\\ \nabla N\left(h_{6p'}\right)&=\nabla N\left(-\varphi\left(h_{6p}\right)\right)=-\nabla N\left(\varphi\left(h_{6p}\right)\right)\end{aligned} \tag{4}$$

*Corresponding author. E-mail: cgsnjust@njust.edu.cn

Obviously, $\nabla N\left(h_{6p'}\right)$ is the opposite of $\nabla N\left(h_{14p}\right)$. Meanwhile considering that the direction of variables such as normal velocity and normal force of ghost nodes is opposite to that of real grid nodes, the coefficient matrix C_{ij} is

$$C_{ij}=\begin{cases}1, j=\{1,2,\quad 12\}\\ |\tau_i|-|n_i|, j=\{13,14,15,16\}\end{cases} \tag{5}$$

where τ is the tangent vector of boundary and i denotes the dimension. The shape function of p is given by

$$N_{Ip}=C\left[N_{1p}\left(h_{1p}\right),N_{2p}\left(h_{2p}\right),\quad ,N_{13p}\left(\varphi\left(h_{5p}\right)\right),\quad ,N_{16p}\left(\varphi\left(h_{8p}\right)\right)\right] \tag{6}$$

Since the mass of mirror particles equals that of real particles, when calculating the grid nodal mass by mapping particles mass to grid nodes, Equation (6) becomes

$$N_{Ip}=\left[N_{1p}\left(h_{1p}\right),N_{2p}\left(h_{2p}\right),\quad ,N_{13p}\left(\varphi\left(h_{5p}\right)\right),\quad ,N_{16p}\left(\varphi\left(h_{8p}\right)\right)\right] \tag{7}$$

Numerical Examples

To test the performance of this correction shape function, we consider the compressible ring test, which involves a hollow elastic ring and a rigid boundary. The ring is made of a compressible Neo-Hookean with bulk modulus $K=121.7$Mpa , shear modulus μ=26.1Mpa and density ρ=1010kg/m^3 . The ring crashes to the rigid boundary at 30 miles per second. The comparative test is carried out by adopting the original cubic B-spline shape function and the corrected shape function.

Figure 2 shows the position of particles in the contrast test. Obviously, the proposed shape function succeeds in preventing particles from penetrating the boundary, thus improving the computational accuracy. To check the energy conservation, the internal and kinetic energy are computed for each time step. The evolution of these energies are given in Figure 3. The minimum time step used in our correction shape function increased as well.

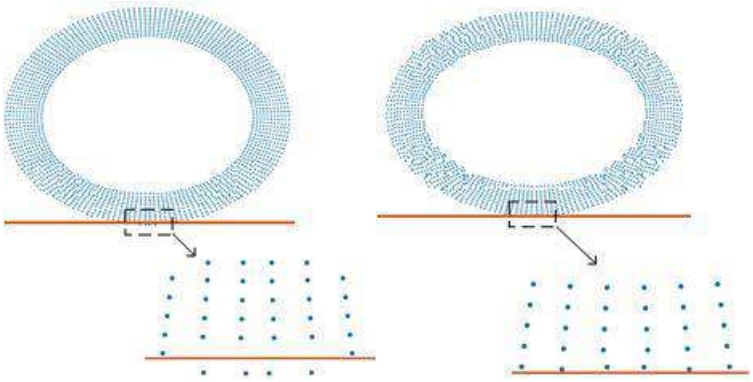

Figure 2. Comparison between original shape function (left) and correction shape function (right)

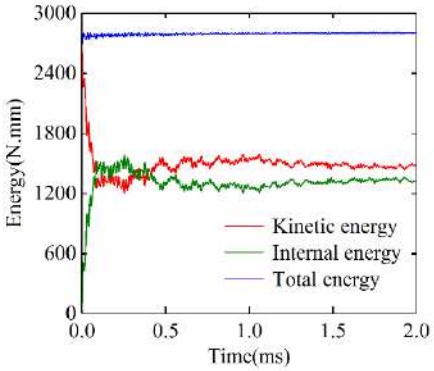

Figure 3. Energy evolution of ring

CONCLUSIONS

In this paper, a corrected cubic B-spline shape function is proposed to handle rigid boundary conditions in MPM. We replace the effect of mirror particles and ghost cells with corrected shape functions of particles near boundaries. The numerical results show that particles do not cross boundaries when our corrected shape function is employed, and the calculation efficiency is improved as well. The research could provide references for further development of MPM and other numerical simulation methods.

A MULTI-BRANCHED CRACK TIPS TRACKING METHOD FOR DYNAMIC PHASE-FILED FRACTURE MODEL

Jun Zeng [1,2], Mengnan Zhang [1,2], Erjie Yang [1,2], Fucheng Tian[1,2]
[1]National Synchrotron Radiation Lab, University of Science and Technology of China, Hefei 230029, China
[2]Anhui Provincial Engineering Laboratory of Advanced Functional Polymer Film, University of Science and Technology of China, Hefei 230029, China

Summary The position of the diffuse crack tip is difficult to be accurately located, the currently widely used scheme is to consider the iso-contour endpoint (ICE) of a certain phase-field value as the crack tip [1, 2]. Despite the above method determines the crack tip quickly and easily, searching in the entire domain limits it to only track the tip at the forefront, which means it is unsuitable for branched cracks. A novel multi-branched crack tips tracking method termed multi-CTTM is proposed in this work, it allows locating the corresponding crack tip in each crack tip region (CTR) via ICE to track all tips of multi-branched crack. An instance of multi-branched crack propagation is simulated by dynamic phase-filed fracture model (PFM), and all tips of the multi-branched crack are tracked accurately utilizing the multi-CTTM.

Tracking process of multi-CTTM

For tracking the multi-branched crack tips, the discrimination of crack bifurcation is essential that is implemented by introducing a concept called the crack tip reference point in this work. As shown in Fig. 1, the one-dimensional phase-field curve along a straight line passing through the crack paths can be drawn within the CTR, which takes the y-coordinate of the nodes in the line as the horizontal axis and the phase-field value as the vertical axis. Thus, crack bifurcation is identified by judging the number of peaks in the one-dimensional profile curve which is consistent with the number of crack tips. The two-dimensional coordinates corresponding to peak sites of the phase-field-y curve are regarded as the mentioned crack tip reference point $\mathbf{P}_{CT}$.

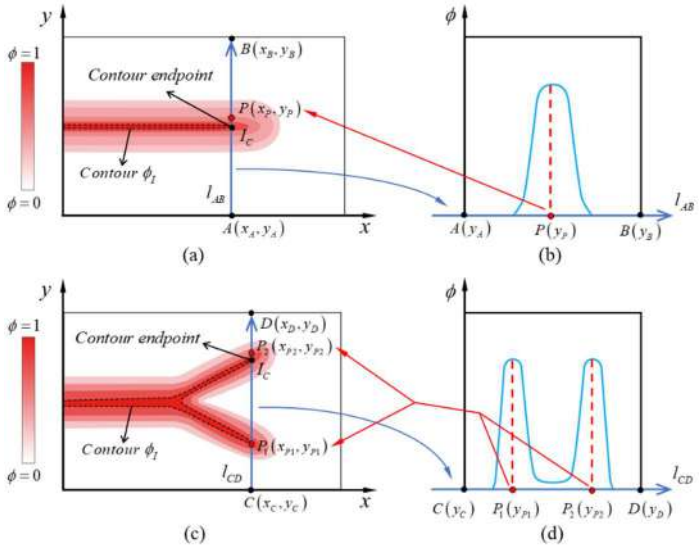

Figure 1. Schematic of the process of drawing the one-dimensional phase-field-y curves based on the two-dimensional diffuse cracks. (a), (b) and (c), (d) correspond to the single crack and the simple bifurcation crack, respectively.

The update of CTR relies on the tracking result of the previous step, implying that an initial CTR should be preset. For clarity, a schematic in Fig. 2 that demonstrates the update of the CTR with crack propagation and bifurcation is presented. Two reference points need to be introduced during the tracking process of CTR, one is the $\mathbf{P}_{CT}$ mentioned above and the other is called the crack tip region reference point donated as $\mathbf{P}_{CTR}$, where $\mathbf{P}_{CTR}$ are reference points used to calculate the coordinates of CTR corners, and they coincide with the side midpoint or corner of CTR. Once the crack starts, $\mathbf{P}_{CT}$ immediately moves forward while $\mathbf{P}_{CTR}$ and CTR remain unchanged until the distance d_{13} between $\mathbf{P}_{CT}$ and $\mathbf{P}_{CTR}$ exceeds a threshold d_0. For a single crack, the new CTR can be positioned with the new $\mathbf{P}_{CTR}$, and the CTR tracking process can be completed by looping the process described in Figs. 2(b) to (c). An increase in the number of $\mathbf{P}_{CT}$ from 1 to 2 indicates this crack is branched, the new $\mathbf{P}_{CTR}$ is no longer the midpoint of CTR-side but coincides with CTR-corner points of the upper and lower crack branch, respectively. Then, the number of CTR increases with the appearance of crack bifurcation and the tracking process of bifurcation can be completed according to Fig. 2(d) to (h). The CTR in Fig. 2(c) and (i) are in the same state, so the subsequent tracking process only needs to repeat the Fig. 2(c) to (i). The distinctive local positioning style of the multi-CTTM, which is based on the idea of tracking CTR and locating the crack tip within each CTR, endows its ability in tracking all crack tips of multi-branched crack.

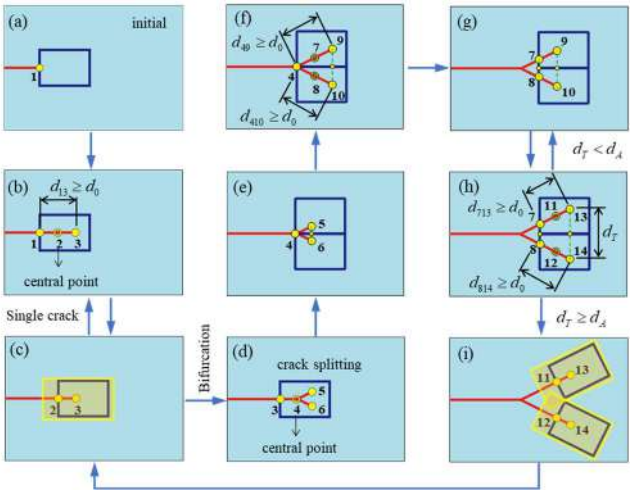

Figure 2. Illustration of automatically tracking the CTR with crack propagation. (a) is the initial CTR set in advance. (b)-(c) is the propagation process of single crack. (d)-(h) indicates crack bifurcation with a small opening, and (i) is the bifurcation of further opening. The CTR on each crack branch in (i) is essentially the same as that in (c), thus the process of (c)-(i) will proceed until the end of crack propagation.

Tracking result for the simulation of dynamic PFM

We employ the AT2 model to simulate the propagation of multi-branch cracks, and the distributions of CTR and crack tips at different time steps tracked by multi-CTTM are presented in Fig. 3.

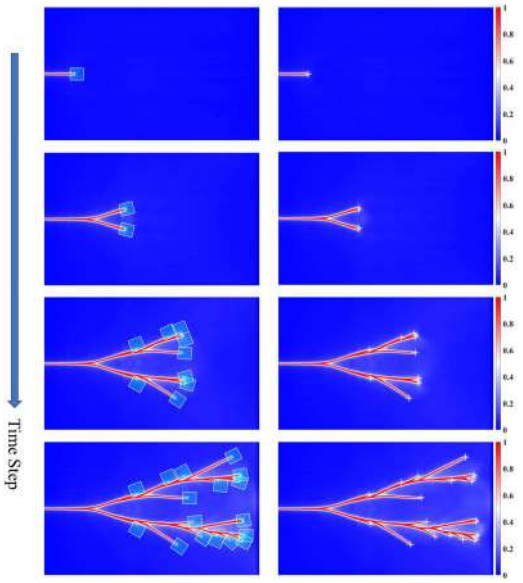

Figure 3. The distributions of CTR (light blue rectangle) and crack tips (white symbol '+') tracked by multi-CTTM at different time steps.

STRESS ANALYSIS NEAR THE CRACK TIP OF NACRE-LIKE BIOMATERIALS USING INCREMENTAL FEM

Xiaoyan Ye[1], Yusuke Doi[1], and Akihiro Nakatani *[1]
[1]Division of Mechanical Engineering, Graduate School of Engineering, Osaka University, Osaka, Japan

Summary This study is focused on the toughening mechanism of nacre-like biomaterials associated with crack expansion, which has attracted increasing attention in these years. This research simulated crack expansion using a two-dimensional model and studied the toughening mechanism of nacre-like biomaterials associated with crack expansion. And we found a huge process zone affected by the mechanical properties of debond cohesive zones (DCZ), which may be one reason why the toughness of nacre-like biomaterials is so excellent.

INTRODUCTION

As a variety of biomaterials that attracts increasing attention from many researchers, the nacre-like biomaterials show two distinctive characteristics. One is the hierarchical structure, comprised of hard and brittle tablet-like aragonite crystals and a small amount of soft proteins. The tensile force might cause these tablets to slide on each other, and then macroscopic deformation occurs. The other is excellent toughness[1], which is significantly higher than aragonite crystals. Many researchers have noticed the relationship between the toughness of nacre-like biomaterials and crack patterns like branches in recent studies. However, the toughening mechanism is still unclear. Therefore, it is necessary to conduct further study on the connection between the nacre-like biomaterials' crack patterns and toughness.

MODEL AND METHOD

In order to simulate the crack expansion, we simplify the actual nacre-like biomaterials into a two-dimensional model, as shown in Fig.1. The microstructure of the model consists of unit structures shown in Fig.1(b). Several kinds of cohesive zone (CZ) elements are introduced in the positions where cracks may occur to simulate the crack's expansion. This model consists of 20 layers of aragonite tablets, each layer contains 10 debond cohesive zones (DCZ) to simulate tensile fracture between tablets. Protein layers exist between the aragonite layers, and shear cohesive zones (SCZ) are introduced between protein and aragonite layers to mimic shear fracture. There is a pre-crack with a length of 5 layers at top center of the model (see Fig.1(e)). Furthermore, two kinds of boundary conditions are applied. Under constant displacement condition (see Fig.1(c)), the upper and lower boundaries are set as free boundaries, the left boundary is fixed horizontally, and the right boundary is given a forced displacement in the horizontal direction. Under the K-displacement field condition (see Fig.1(d)), the elastic asymptotic Model I in-plane displacement field is prescribed on the outer boundary. The CZ model used is the exponential model offered by Xu and Needleman[2]. The cohesive law is determined by the maximum traction

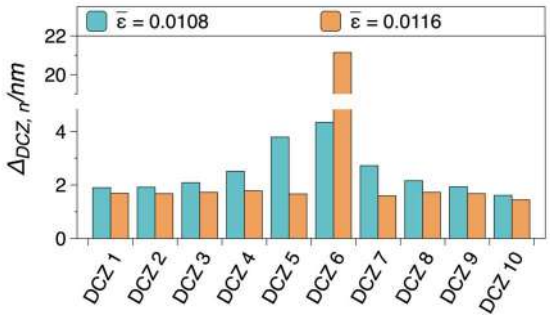

Figure 3: Separation of DCZs on the sixth layer before and after DCZ6 is weakened.

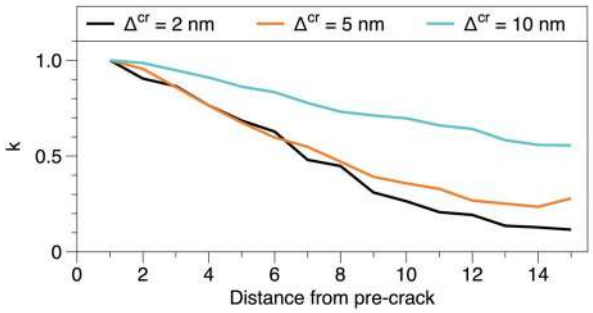

Figure 4: The strain concentration state of each layer before the pre-crack tip when the crack expands.

$\sigma^{\max}$ and critical weaken separation Δ^{cr} (see Fig.2(a)). Tensile deformation in the case of plane strain of the model is studied using the incremental finite element method.

A boundary value problem is solved in which the continuum Ω is fixed by the S_u boundary and deformed under the external load P existing on the S_p boundary (see Fig.2(b)). CZ elements exist at the interface where cracks may occur. $\mathbf{t}_0$ and $\mathbf{n}_0$ are the tangent unit vector and the normal unit vector of this interface, respectively. Under small deformation assumption,

$$\int_{\Omega} \dot{\sigma}_{ij}\delta\varepsilon_{ij}\mathrm{d}V = \int_{S_{\mathrm{coh}}} \left(\dot{\overline{T}}_{\mathrm{n}}\delta\Delta_{\mathrm{n}} + \dot{\overline{T}}_{\mathrm{t}}\delta\Delta_{\mathrm{t}}\right)\mathrm{d}S + \int_{S_p} \dot{P}_i\delta u_i \mathrm{d}S. \tag{1}$$

is obtained using the principle of virtual power at time t, where $\dot{(\cdot)}$ means material time derivative. Here, S_p is the outer surface, S_{coh} is the interface where CZ is introduced. σ_{ij} is the stress component, u_i is the displacement component, and P_i is the external force component. For CZ elements, P_i is always equal to 0. Therefore the nodal displacement under load conditions can be obtained by the incremental finite element method using Eq.1.

RESULT OF STRESS ANALYSIS

In this study, we have investigated the spatial distribution and temporal development of stress and strain near the crack tip in the early stages of crack extension when the model is under constant displacement boundary condition. Fig.3 shows the strain distribution in DCZs of the sixth layer before the crack extension. We found that the crack expansion process consists of two stages. The first is the "stable stage" (see Fig.3, $\bar{\varepsilon} = 0.0108$). Despite the stress concentration, there is a larger process zone near the crack tip than brittle ceramics. As the deformation increases, it enters the "unstable stage"(see Fig.3, $\bar{\varepsilon} = 0.0116$), the strain suddenly concentrates, and eventually, crack expansion occurs. In the "stable stage", the unique hierarchical structure avoids strain concentration, and it facilitates the lateral expansion of the crack. It means that more energy is released, making the material's toughness increase[3].

Also, we studied the influence of the critical weaken separation Δ^{cr} of DCZ on the size of the process zone near the crack tip. We keep the maximum traction $\sigma^{\max}$ constant and make the critical displacement equal to 2 nm, 5 nm, and 10 nm, respectively. When the crack expands to the sixth layer, each layer's strain concentration is shown in Fig.4. The horizontal axis means the distance to the crack tip. $k = \Delta^{\max}_{\mathrm{DCZ},n}/\Delta^{\max}_{\mathrm{DCZ},6}$, where $\Delta^{\max}_{\mathrm{DCZ},n}$ is the maximum separation of the DCZs of the n-th layer, while $\Delta^{\max}_{\mathrm{DCZ},6}$ is the maximum separation of the sixth layer. As the relative displacement of the critical softening of DCZ increases, the number of layers affected by cracks rises, and the size of the process zone also increases significantly.

CONCLUSIONS

In this study, we have investigated the spatial distribution and temporal development of stress and strain near the crack tip in the early stages of crack extension. We found a huge process zone, which is affected by the mechanical properties of CZ. It may be one reason of nacre-like biomaterials' excellent toughness, which will inspire subsequent studies on the toughness mechanism of nacre-like biomaterials and make it possible to design nacre-like artificial materials.

A GRADIENT SMOOTHED GFEM FOR 2D SOLID MECHANICS PROBLEMS

Jinsong Tang[1], Linfang Qian[1], Guangsong Chen*[1] and Shijie Zhou[1]
[1]School of Mechanical Engineering, Nanjing University of Science and Technology, Nanjing, China

Summary A gradient smoothed GFEM (GS-GFEM) without extra DOFs based on Taylor expansion is proposed in this work. The displacement field function of GS-GFEM consists of the finite element shape function and the node displacement function. The Taylor expansion is adopted for the nodal displacement function. The derivative term in Taylor expansion is obtained by using gradient smoothed technique. The finite element interpolation is employed for gradient smoothed operation. Through several typical numerical experiments and comparison with other methods (FEM-T3, FEM-Q4 and NS-FEM), the advantages of the proposed GS-GFEM including high accuracy, rapid error convergence, temporal stability etc. are demonstrated.

Displacement Function Discrete Strategy

The displacement field function can be expressed as the combination of the finite element shape function and the node displacement function:

$$u(\mathbf{x}) = \sum_{i=1}^{m} N_i(\mathbf{x}) u^i(\mathbf{x}) \tag{1}$$

The nodal displacement function is obtained by the second-order Taylor expansion:

$$\begin{aligned} u^i(\mathbf{x}) = u(\mathbf{x}_i) + (x-x_i)\tilde{u}_{,x}(\mathbf{x}_i) + (y-y_i)\tilde{u}_{,y}(\mathbf{x}_i) + \frac{1}{2}(x-x_i)^2 \tilde{u}_{,xx}(\mathbf{x}_i) + \frac{1}{2}(y-y_i)^2 \tilde{u}_{,yy}(\mathbf{x}_i) \\ + (x-x_i)(y-y_i)u_{,xy}(\mathbf{x}_i) \end{aligned} \tag{2}$$

According the gradient smoothed operation [1], the first order smoothed derivative term in the Taylor expansion can be expressed as:

$$\begin{aligned} u_{,l}(\mathbf{x}_i) &= \frac{1}{A}\int_{\Omega_i} u^i_{,l}(\mathbf{x})\mathrm{d}\Omega = \frac{1}{A}\int_{\Gamma_i} u^i(\mathbf{x}) n_l \mathrm{d}\Gamma \\ &= \frac{1}{A}\int_{\Gamma_i} \sum_{j=1}^{n_i} N_j(\mathbf{x}) u_j n_l \mathrm{d}\Gamma = \sum_{j=1}^{n_i} \frac{1}{A}\int_{\Gamma_i} N_j(\mathbf{x}) n_l \mathrm{d}\Gamma u_j \\ &= \sum_{j=1}^{n_i} N^l_j u_j \end{aligned} \tag{3}$$

where Ω_i is the smoothed domain, and its boundary is Γ_i, as shown in Figure 1. n_i is the number of nodes in the supported domain of node *i*. $N_j(\mathbf{x})$ is the linear finite element shape function and triangular element is adopted. $N^l_j(\mathbf{x})$ the smoothed derivation of $N_{j,l}(\mathbf{x})$ and $l = \{x, y\}$. The second-order smoothed derivative term can be obtained in the similar way.

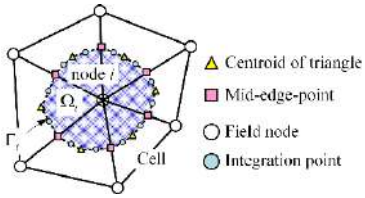

Figure 1. Nodal supported domain

Numerical Examples

Static analysis of cantilever beam

The geometric model of a cantilever beam is as shown in Figure 2. The right free end is subjected to a shear force. Some geometric and material parameters are listed in Table 1. Define the displacement error norm e_d and the strain energy norm e_e:

$$e_d = \sqrt{\frac{\sum_{i=1}^{N_d}\left(u_i^{\mathrm{ref}} - u_i^{\mathrm{num}}\right)^2}{\sum_{i=1}^{N_d}\left(u_i^{\mathrm{ref}}\right)^2}}, \quad e_e = \sqrt{\frac{\left|E_{\mathrm{num}} - E_{\mathrm{exact}}\right|}{E_{\mathrm{exact}}}}$$

in which, 'ref' represents the analytical solutions [1].

Figure 3 shows the convergence curves of displacement and strain energy error norms with four methods under different number of meshes. *R* represents the slope of each curve, namely the error convergence rate, which is obtained by linear fitting. Compared with the other three methods, the advantages of the proposed GS-GFEM in terms of accuracy and error convergence are intuitively reflected in results.

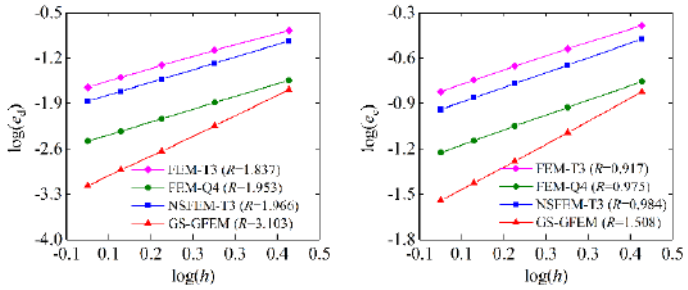

Figure 3. Convergence rate of displacement(left) and strain energy(right) error norms

Dynamical analysis of cantilever beam

As shown in Figure 4, a shear wall with four openings is studied. The boundary condition is set to the bottom edge fully clamped. The geometrical and material parameters are $E=10000\,\mathrm{N/m^2}$, $v=0.2$ and $\rho=1.0\ \mathrm{kg/m^3}$.

Firstly, the free vibration analysis of shear wall is carried out. The first eight mode frequencies are calculated as shown in Table 2. There is a severe temporal instability problem in the dynamical analysis of the NS-FEM method, and the free vibration analysis of the method have spurious non-zero energy modes, which is highlighted in bold in Table 2. The modes corresponding to spurious non-zero energy modes are shown in Figure 5. In contrast, the GS-GFEM method avoids this problem and the calculation results are in good agreement with the reference results.

Furthermore, the dynamic response of shear wall under a harmonic concentrated load is analyzed. The displacement response at point A is shown in Figure 6. Obviously, compared with NS-FEM, the proposed GS-GFEM offers superior performance on dynamic analysis.

CONCLUSIONS

In this work, a GS-GFEM is proposed for 2D solid mechanics problems. Both static and dynamic analyses are conducted using the proposed GS-GFEM and compared with other methods. Some important conclusions can be summarized as follows:

(1) The GS-GFEM method proposed in this paper has the advantages of high accuracy and rapid error convergence, which are reflected from the static analysis results of the cantilever beam and the comparison with other numerical methods.

(2) GS-GFEM overcomes the temporal instability problem in NS-FEM. There are no spurious non-zero energy modes in free vibration analysis of GS-GFEM, showing brighter prospects in dynamic analysis.

(3) No extra DOFs are introduced in the derivation of GS-GFEM, and the formulation is very straightforward and the procedure is easy to implement.

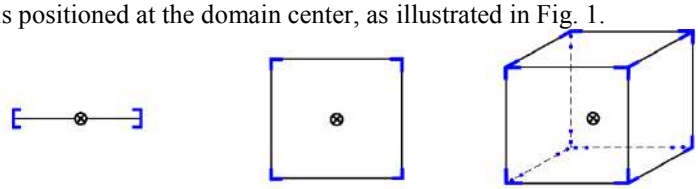
AN EFFICIENT PARTICLE SUBDOMAIN QUADRATURE SCHEME FOR THE MATERIAL POINT METHOD

Zheng Sun* and Xiaomin Zhou
School of Civil and Surveying & Mapping Engineering, Jiangxi University of Science and Technology, Ganzhou, Jiangxi 341000, China

Summary MPM has been proved to be an effective numerical method for large deformation problems. However, MPM suffers from cell crossing error as that material particles are used to represent deformed material and perform particle quadrature. An efficient subdomain quadrature MPM is proposed to eliminate cell crossing error. Particle domain is approximated to be line segment, rectangle, and cuboid for 1-, 2-, and 3- D problems, respectively, which are divided into several different subdomains based on topological relationship between particle domain and background grid. A single Gauss quadrature point is placed at center of each subdomain and used for information mapping. Material quantities of each Gauss quadrature point are determined by corresponding material particle and subdomain volume without reconstruction algorithm. Numerical examples demonstrate effectiveness of the proposed method.

1 SUBDOMAIN QUADRATURE MATERIAL POINT METHOD (SQMPM)

The particle domain is assumed to be the line segment, rectangle, and cuboid for the 1D, 2D, and 3D problems, respectively, and the particle is positioned at the domain center, as illustrated in Fig. 1.



(a) Line segment for 1D **(b)** Rectangle for 2D **(c)** Cuboid for 3D

Fig. 1 Schematic illustration for (a) 1-dimensional, (b) 2-dimensional, and (c) 3-dimensional particle domain.

The changing of particle domain is tracked by:

$$\boldsymbol{r}_p^k = \boldsymbol{F}_p^k \boldsymbol{r}_p^0 \tag{1}$$

where $\boldsymbol{r}_p^k$ and $\boldsymbol{r}_p^0$ denote volume domain vectors of the particle p at the k-th time step and the initial state, respectively. $\boldsymbol{F}_p^k$ is the deformation gradient tensor of the particle p at the k-th time step. It should be noted that, for rectangular and cuboid particle domains, only diagonal terms of $\boldsymbol{F}$ are non-zero that means the rotation of the particle domain is neglected in this paper.

The code structure of particle domain partitioning strategies for the 1D case is presented as follows, and the bivariate and trivariate for the 2D and 3D cases could be obtained by tensor product structure.

Algorithm structure of the particle domain partitioning strategies for 1D case

Input: the background node position vector: $\{x_J\}$; the current position of particle p: x_p; the initial line segment domain of particle p: r_p^0; the current deformation gradient tensor of particle p: $\boldsymbol{F}_p$.

(1). Calculate the current line segment domain of particle p: $r_p = \boldsymbol{F}_p r_p^0$.

(2). Calculate the coordinate of the left boundary x_{pl} and the right boundary x_{pr} of the particle p: $x_{pl} = x_p - \frac{r_p}{2}$ and $x_{pr} = x_p + \frac{r_p}{2}$.

(3). Identify the J-th and K-th background elements that contain the x_{pl} and x_{pr}, respectively.

(4). Determinate the number of background nodes that are contained in the particle domain: $M=K-J$

(5). Divide the line segment domain of particle p into M+1 subdomain as:

$$\begin{cases} V_p = [x_{pl}, x_{pr}], & M = 0 \\ V_1 = [x_{pl}, x_{J+1}],\ V_2 = [x_{J+1}, x_{J+2}], \cdots, V_{M+1} = [x_K, x_{pr}], & M \geq 1 \end{cases}$$

Output: the number of particle subdomains: M; the size for each subdomain: $V_1, \ldots, V_i, \ldots, V_{M+1}$

2 NUMERICAL EXAMPLES

2.1 Two-dimensional bending beam

The dynamic bending of a two-dimensional elastic beam is studied, which is induced by the initial velocity in the transverse direction. The simulating parameters of the beam are as follows: Length L = 0.06 m, Height H =0.01 m, Young's modulus E = 318 GPa, Poisson's ratio μ=0.054, density ρ= 1845 kg/m3, Y_{max}= 0.005 m, the background mesh size dx×dy=0.625 mm×0.625 mm, the particles per cell ppc=4×4, and the simulated time step $0.001\mu s$.

The distributions of the particle stress at t=8 μs calculated by the MPM and sqMPM method are presented in Fig. 2, where a close-up of particle domain at the top of the curved boundary segment for sqMPM is given in Fig. 2(c). The results show that severe stress oscillations are observed in the standard MPM, especially in the large deformation area. As expected, the oscillations of the particle stress found in the standard MPM is noticeably reduced by the sqMPM.

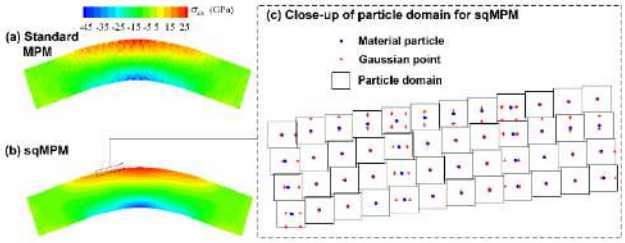

Fig. 2 Distributions of stress σ_{xx} at t = 8 μs obtained by (a) standard MPM and (b) sqMPM, and (c) a close-up of particle domain for the sqMPM method where the solid blue dot, red asterisk, and black rectangle denote the material particles and its corresponding Gaussian point and particle domain, respectively.

2.2 Three-dimensional cantilever beam

This example is the bending of a three-dimensional cantilever beam under the quasi-static concentrated force, which is linearly increased from zero to 1.5 kN in 30 seconds and is split across the material particles within the cells closest to the right boundary of the beam. The beam has an initial dimension l×b×h of 10 m×1 m×1 m. The material properties for the beam are Young's modulus E = 10 MPa, Poisson's ratio μ=0.2, and density ρ= 1000 kg/m^3, respectively. The background grid size dx=dy=dz=0.05 m, the particles per cell ppc=2×2×2, and the simulated time step 0.1 ms are chosen in both the standard MPM and sqMPM. The neutral axis of the beam is fixed at its left-hand edge, and roller boundary conditions are imposed on the other background grid nodes at the root of the beam. The static solution of the FEM method for this problem is also presented with a mesh of 0.05 m×0.05 m×0.05 m.

Fig.3 compares the distribution of the normal stressobtained by the standard MPM, sqMPM at t =30s, and the FEM method, respectively. As we can see, the sqMPM exhibits good agreements with the FEM, while the results obtained by the standard MPM are quite noisy, especially in the large deformation region.

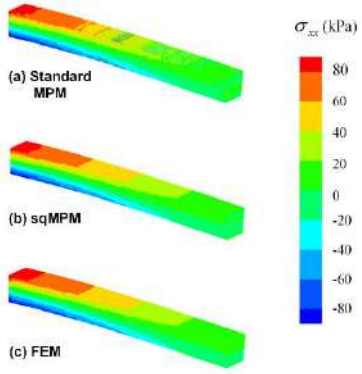

Fig. 3 Distributions of normal stress obtained by (a) standard MPM and (b) sqMPM at t =30s, and (c) the FEM method, respectively.

3. Conclusion

An efficient subdomain quadrature Material Point Method (sqMPM) has been developed to eliminate the cell crossing error of the standard MPM in this study. In the proposed method, the particle domain is assumed to be the line segment, rectangle, and cuboid for the 1D, 2D, and 3D problems, respectively. The particle domain is divided into several different subdomains based on the topological relationship of the particle domain and background grid. A single Gauss quadrature point is placed at the center of each particle subdomain and employed for the information mapping. The material quantities of each Gauss quadrature point are determined by the corresponding material particle and the subdomain volume without the cumbersome reconstruction algorithm as that in MLS. Numerical examples involving large deformation problems have been used to verify and demonstrate the proposed method. It is shown that the sqMPM eliminates the cell crossing error and exhibits better convergence than the MPM.

INFORMATION FUSION FOR COMPUTATIONAL RELIABILITY ANALYSIS

Carsten Proppe*[1]
[1]Chair of Engineering Mechanics, Karlsruhe Insitute of Technology, Karlsruhe, Germany

Summary Multifidelity estimation combines the output of simulation models of different approximation quality and from different sources in order to obtain efficient estimators for a quantity of interest. It relies on a model hierarchy that is established either by means of an approximation parameter or the Pearson correlation of the model outputs. Information fusion combines the results from the model hierarchy based on differences of the quantity of interest or on conditional probabilities. In this presentation, information fusion is combined with importance sampling and importance splitting (notably the moving particles method) in order to yield efficient estimators for reliability analysis. Importance sampling and importance splitting based multifidelity reliability estimation methods are developed and critically assessed based on numerical examples.

INFORMATION FUSION

Reliability estimation deals with the evaluation of the failure probability $P_F = \int_F p(\boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}$, where $F = \{\boldsymbol{\theta} \in \mathbb{R}^n | g(\boldsymbol{\theta}) < 0\}$ denotes the failure region and $p(\boldsymbol{\theta})$ the joint probability density function of the random vector $\boldsymbol{\Theta}$. In general, the performance function $g(\boldsymbol{\theta})$ is not known exactly, but is computed by numerical approximation. In the following, an ordered family of approximated performance functions $g_l(\boldsymbol{\theta})$, $l = 0, ..., L$ is considered, where the index l refers to the performance function of the lth model of the model hierarchy. The index $l = 0$ denotes the model with lowest fidelity and $l = L$ the high-fidelity model.

Additive Information Fusion

For additive information fusion, denote by Q_l a quantity of interest related to the lth model. In the context of reliability estimation, the quantity of interest could be the indicator function $I_{g_l<0}(\boldsymbol{\theta})$, i.e. $I_{g_l<0}(\boldsymbol{\theta}) = 1$, if $g_l(\boldsymbol{\theta}) < 0$ and $I_{g_l<0}(\boldsymbol{\theta}) = 0$ elsewhere. An estimator for such a quantity of interest that combines the information from the model hierarchy in an additive manner is obtained from the telescoping sum $E[Q_L] = E[Q_0] + \sum_{l=1}^{L} E[Q_l - Q_{l-1}]$. The aim is to compute each of the estimates on the right-hand side of this equation individually by Monte Carlo simulation. A reduction of the overall computational effort can be expected from the fact that the variance of the differences decreases to zero with increasing index l and thus, for a given coefficient of variation, estimates of the contributions from highly accurate performance function will require less samples.

Multiplicative Information Fusion

For multiplicative information fusion, one has with

$$p(\boldsymbol{\theta}_L) = \int ... \int p(\boldsymbol{\theta}_L, ..., \boldsymbol{\theta}_l, ..., \boldsymbol{\theta}_0)\mathrm{d}\boldsymbol{\theta}_L ... \mathrm{d}\boldsymbol{\theta}_l ... \mathrm{d}\boldsymbol{\theta}_0 = \int p(\boldsymbol{\theta}_L|\boldsymbol{\theta}_{L-1}) ... \int p(\boldsymbol{\theta}_1|\boldsymbol{\theta}_0)p(\boldsymbol{\theta}_0)\mathrm{d}\boldsymbol{\theta}_{L-1} ... \mathrm{d}\boldsymbol{\theta}_0 \qquad (1)$$

an expression for the high-fidelity probability density function that is computed from the low-fidelity contributions and can then be utilized to estimate the quantity of interest of the high-fidelity model.

INFORMATION FUSION AND IMPORTANCE SAMPLING

The aim of importance sampling is to reduce the variance of Monte Carlo simulation by sampling from an alternative density, the importance sampling density. To this end, the importance sampling density $p_{IS}(\theta)$ is introduced: $P_F = \int_F \frac{p(\boldsymbol{\theta})}{p_{IS}(\boldsymbol{\theta})} p_{IS}(\boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}$ and samples are drawn from $p_{IS}(\boldsymbol{\theta})$.

Additive information fusion

For additive combination of the model outputs, the importance sampling density for each expectation has to focus on the differences of the performance functions of neighboring models. Alternatively, the importance sampling estimators might be computed separately for each level and then the differences of the estimators are weighted. In the first case, the regions where the performance functions differ are small and widespread and it is difficult to cover these regions well. This may lead to an increase of the coefficient of variation of the estimator and also of the relative approximation error. In the latter case, a weighted sum of importance sampling estimates is computed. This approach requires unbiased importance sampling estimates. Thus, the importance sampling densities are calibrated by means of the different approximations of the performance function $g_i(\boldsymbol{\theta})$, $i = 1, ..., n$; however, the samples generated with the different importance sampling densities are evaluated with respect to the performance function $g_n(\boldsymbol{\theta})$ of highest fidelity. This is different from the other methods, where the generated samples are either evaluated by the performance function of the same or the next higher level. In order to be efficient, a reduction of the coefficient of variation for the weighted multifidelity estimator compared to the single level approach is therefore mandatory, such that in total, less samples are evaluated by the high-fidelity performance function.

*Corresponding author. E-mail: proppe@kit.edu.

Multiplicative information fusion

For multiplicative information fusion, the importance sampling density is based on the model with lower fidelity and pairs of output quantities for neighboring models are obtained for samples generated by means of the importance sampling density. These pairs of samples are then utilized to find a functional expression by regression that relates the high fidelity model output to the low fidelity model output. The relative error is comparable to that of the high fidelity model. Thus, the method considerably improves the approximations of the failure probability. However, the coefficient of variation of the multifidelity estimator is higher than that of the single level estimator. It scales with the coefficient of determination and thus might be attributed to the regression error.

INFORMATION FUSION AND IMPORTANCE SPLITTING

The idea of importance splitting in reliability estimation is to discard samples that are far away from the failure region and to split at least some of the remaining ones. This procedure is repeated gradually by introducing thresholds and retaining only those samples that pass the threshold. Importance splitting can also be interpreted as a special adaptive importance sampling procedure, where the final samples are drawn from the importance sampling density. The moving particles algorithm applies importance splitting to obtain an estimate of P_F. It starts with an initial Monte Carlo simulation (MCS) with N_m samples. These initial samples are then moved to the failure region by the following procedure: The values $g(\boldsymbol{\theta}_j)$, $j = 1, ..., N$, of the N samples are ranked. The sample with the maximum value of the performance function is moved: a Markov chain Monte Carlo simulation (MCMC) is carried out starting from one of the remaining samples and the final state of the Markov chain is accepted, if the value of the performance function could be reduced. Otherwise, the sample is simply replaced by the initial value of the Markov chain. The Markov chain can be generated either by application of the classical Metropolis-Hastings algorithm or by direct sampling from a normal transition kernel. For each initial sample, the number M of moves until the sample reaches the failure region is count. The number of moves to get an initial sample into the failure region follows a Poisson distribution with parameter $\lambda = -\log P_F$. The estimator for the parameter of the Poisson distribution can thus be obtained from $\lambda = E[M]$.

Additive information fusion

For the moving particles algorithm, the quantity of interest is the number of moves to reach the failure region. Denote by M_l the number of moves when the numerically computed performance function $g_l(\boldsymbol{\theta})$ is applied. Applying additive information fusion, the estimator for the Poisson distribution parameter at level L and thus for $-\log P_{F_L}$, where P_{F_L} denotes the failure probability computed with the approximated performance function $g_L(\boldsymbol{\theta})$ at approximation order L is obtained from the telescoping sum, where the quantity of interest is the number of moves ($Q_l = M_l$).

Multiplicative information fusion

For information fusion with multiplicative combination of the model outputs, consider again without loss of generality the bilevel situation with a high-fidelity and a low-fidelity model. M_h and M_l denote the random variables for the moves of the particles related to the high-fidelity and the low-fidelity model, respectively. As the low-fidelity model is assumed to be computationally more efficient, suppose that samples M_{l_i}, $i = 1, ..., N$, are generated for particles with the low-fidelity models and pairs of samples (M_{l_i}, M_{h_i}), $i = 1, ..., M$ that were obtained with both the low- and the high-fidelity model , where $M \ll N$. The objective is to estimate the parameters λ_l and λ_h of the two dependent Poisson distributed random variables M_h and M_l. To this end, three independent Poisson distributed random variables are introduced and the parameters of the three Poisson distributions are estimated by maximum likelihood estimation via the expectation maximization algorithm.

CONCLUSIONS AND OUTLOOK

This paper combines additive and multiplicative information fusion with importance sampling and importance splitting in order to efficiently obtain reliability estimates. Obtaining a good importance sampling density is still a challenging task, especially in high dimensions. This is also the case, if the importance sampling density should focus on level differences. It therefore appears to be more advantageous to combine different importance sampling estimators by a weighted sum, even if this approach requires unbiased estimators and thus the evaluation of all samples by the high-fidelity performance function. Multiplicative information fusion might have advantages compared to additive information fusion as it reduces the relative error and requires less samples to be evaluated by the high-fidelity performance function. However, multiplicative information fusion relies on establishing a relationship between the values of the performance function obtained with the model of lower and of higher fidelity. Importance splitting is a rather robust method to yield accurate reliability estimates. Taking advantage of Poisson process theory, both additive and multiplicative information fusion can be combined with the moving particles method in order to further increase the efficiency of the moving particles method.

In a Bayesian setting, the approaches can be extended by taking the data and model error into account. It is also noted that the methods presented in the paper can be applied to sensitivity analysis and Bayesian inference.

PHASE-FIELD STUDY OF HIGH TEMPERATURE OXIDATION AND AQUEOUS CORROSION OF METALS CONSIDERING MECHANICO-CHEMICAL COUPLING

Chen Lin*[1], Haihui Ruan [2], Sanqiang Shi [2]
[1]Sino-French Institute of Nuclear Engineering and Technology, Sun Yat-Sen University, Zhuhai, China
[2]Department of Mechanical Engineering, The Hong Kong Polytechnic University, Hong Kong, China

Summary Phase-field models were proposed to study high temperature oxidation and aqueous corrosion of metals. The reaction rate was expressed as a function of the electrochemical potentials of reactants and products and conforms to the generalized Butler-Volmer relationship. The Gibbs free energy was expressed as a sum of chemical potential, interfacial energy, electric potential energy, and mechanical energy of system. The governing equation of phase order parameter was derived from the equivalence of reaction rate and phase transformation rate, which captured the effects of reaction kinetics, elemental concentration, electric potential, and mechanical deformation. The mechanisms of chemo-mechanical coupling have been revealed for two typical scenarios: (i) the stress-oxidation interaction in growth of oxide and (ii) the localized corrosion in wet environment.

INTRODUCTION

Numerous experimental investigations indicate that corrosion (or oxidation) can be influenced by stress. However, the harsh service-environments and complex structures of materials lead to that all factors, involving: chemical, mechanical, and phase-field-kinetic, are generally interrelated and interactive during the corrosion (or oxidation). The major challenge stands out in revealing the mechanism of chemo-mechanical corrosion is to establish a multi-field coupling theory and develop its numerical method. In present talk, we propose the phase-field models to explore the chemo-mechanical coupling in high temperature oxidation and aqueous corrosion. We presented a set of examples to show the capability of our model to capture the effects of varies mechanical loading on complicated corrosion scenarios.

RESULTS AND CONCLUSIONSN

In a reactive system, the forward and backward reactions take place simultaneously, leading to the net reaction rate:

$$r = r - r = k_0\left(e^{-(\mu_{TS}-\mu_R)/RT} - e^{-(\mu_{TS}-\mu_P)/RT}\right), \quad (1)$$

where r and r represent the forward and backward reaction rate, respectively. They are further expressed in an Arrhenius form in Eq. (1), where k_0 is the rate coefficient; μ_R, μ_P are the chemical potentials of reactants and products, respectively; μ_{TS} is the chemical potential at the transition state. For a reaction involving multiple reactants and products, μ_R and μ_P, are $\mu_R = \sum_i n_i \mu_{R_i^{X_i}}$ and $\mu_P = \sum_j n_j \mu_{P_j^{Z_j}}$, respectively, where the chemical potential, μ_*, is the variational derivative of the total free energy, Ψ, with respect to the concentration, c_*. The reaction rate can be recast as generalized Allen-Cahn equation to govern the phase transformation. This reaction rate can also be expressed in the form of generalized BV equation, in which the overpotential is correlated with not only the species diffusion, electric field, but also the interfacial energy, mechanical deformation [1].

The proposed PF model was applied to two typical case:

In first case, we use the PF model to study a zirconia-zirconium bilayer with the initial thickness of zirconia. Through this numerical study, many experimentally observed but insufficiently understood phenomena can be well explained. Specifically, the numerical simulations (Fig. 1) reveal quantitatively the causes of interface roughening or smoothening during the inward oxide growth, the roughness-dependent oxide growth rate, and the nucleation sites of premature cracking. These numerical findings indicate that the durability of oxide scale can be significantly improved by the variation in the initial surface roughness and creep properties of zirconium alloy which can prolong the service life of zirconium-based alloy cladding used in the nuclear power plant.

*Corresponding author. E-mail: linch67@mail.sysu.edu.cn

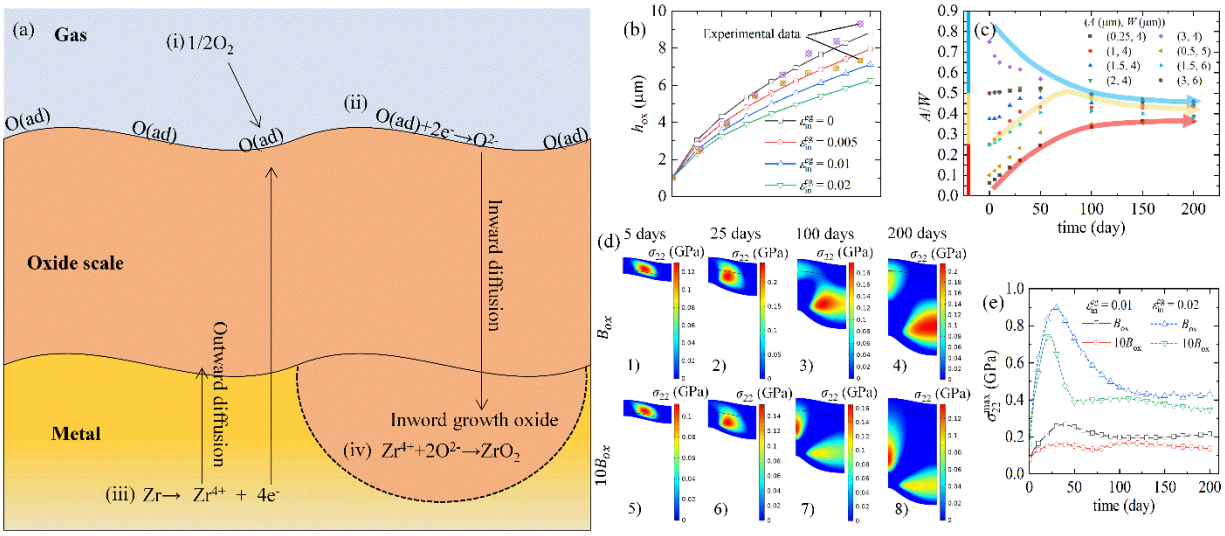

Fig. 1 (a) Schematics of zirconium oxidation; (b) Variations of oxide scale thickness different eigenstrains; (c) Variations of oxide interfacial roughness considering different initial interface morphologies; (d) Contour plots of the normal stress σ_{22} after different periods of oxidation for two creep rate coefficients; (e) Variations in the maximum tensile stress over time for different eigenstrains and creep rates.

In the case of aqueous corrosion [2]. We study a complex occluded cell corrosion process (Fig. 2) that involves mechano-electrochemical coupling, anodic dissolution, insoluble depositions formation, and resulted Galvanic-pitting corrosion. Based on a quantitative investigation into the effects of Cl^- concentration, pH value, mechanical loading, and electric field, we reveal the autocatalytic process of pitting assisted by increasingly aggressive chemical environment and concentrated stress and study how the external electric field can arrest assisted corrosion and prolong service lifetime. The computational model would be helpful for the lifetime management of metallic components serving in the ocean or other more aggressive environment.

[3]Res Ctr Ubiquitous MEMS Micro Engn, Natl Inst Adv Ind Sci and Technol, Tsukuba Science City, Ibaraki, Japan

Summary The mass sensing based on the eigenmode shift in weakly coupled resonators has been attractive which is much higher sensitive than that based on the frequency shift of a single resonator. In a previous study, we have proposed the method based on the eignemode shift in coupled resonators to achieve a highly sensitive atomic force microscope (AFM). For the detection of the eigenmode shift, the self-excited oscillation has been utilized because the amplitude ratio between the coupled resonators under the self-excitation corresponds to the eigenmode in the state with small response amplitude. The self-excited oscillation produced by positive velocity feedback grows with time until the limitation of power in the actuator driver. In the present study, by adding the nonlinear feedback to the linear one, we restrict the amplitude growth using stable limit cycle and reduce the steady state amplitude. Experimental results by using coupled macrocantilevers demonstrate the reduction of the response amplitude.

INTRODUCTION

In the measurement methods as mass sensor, atomic force microscope (AFM), and so on, a single resonator has been utilized for the high sensitive measurement [1]. In AFM, the sensitivity, that is the natural frequency shift of the resonator due to the stiffness perturbation of the resonator due to the variation of the probe-sample distance, is $\frac{d\omega}{dk} = \frac{1}{2\sqrt{mk}}$, where ω, m, and k is the equivalent natural frequency, mass, and stiffness of the resonator. To increase the sensitivity much more, the miniaturization is essential, but restricted due to the limitation of fabrication techniques. There is the same situation in the mass sensing, in which the weakly coupled resonators have been introduced to improve the sensitivity not relying on the miniaturization. In most cases, two identical cantilevers as a coupled resonators are utilized. When a measured mass is attached to one of them, the eigenmode is changed from 1:1. The sensitivity of the eignmode shift with respect to the attached mass is increased by decreasing the coupling stiffness between the cantilevers [2]. We have introduced a weakly coupled cantilevers to realize the highly sensitive AFM [3]. For the detection of the eigenmode without being influenced by viscosity in measurement environments, the self-excitation is applied by using a positive linear velocity feedback. Then, the amplitude ratio of the self-excited coupled cantilevers corresponds to the eigenmode in the state where the response amplitude is small. Also for the noncontact sensing between the probe and sample, it is very important to produce the self-excited oscillation with small steady state amplitude. For the self-excited single resonator, the gain of the positive velocity feedback can be automatically changed in real time; this is called automatic gain control [1]. In this research, we add the nonlinear velocity feedback to the linear velocity feedback and produce the stable limit cycle. As a result, the steady state amplitude under the self-excitation can be decreased. The efficiency of the proposed amplitude control method is experimentally confirmed by using weakly coupled macrocantilevers.

ANALYTICAL MODEL AND EQUATIONS OF MOTION FOR COUPLED RESONATORS

Figure 1 show the analytical model of coupled resonators, where m, k, Δk, k_c and c are the mass of the resonator, the stiffness, the perturbation of the stiffness due to the atomic force, the coupling stiffness between the cantilevers, and the equivalent damping, respectively. x_1 and x_2 are the displacements of the resonators. The equations of motion for the cantilevers are expressed as

$$m\frac{\mathrm{d}^2(x_1+\Delta x)}{\mathrm{d}t^2} + c\frac{\mathrm{d}x_1}{\mathrm{d}t} + (k+k_c)x_1 - k_c x_2 = 0, \tag{1}$$

$$m\frac{\mathrm{d}^2(x_2+\Delta x)}{\mathrm{d}t^2} + c\frac{\mathrm{d}x_2}{\mathrm{d}t} - k_c x_1 + (k+k_c+\Delta k)x_2 = 0. \tag{2}$$

By applying the displacement excitation Δx as

$$\Delta x = \alpha \int x_1 dt, \tag{3}$$

*Corresponding author. E-mail: yabuno@esys.tsukuba.ac.jp.

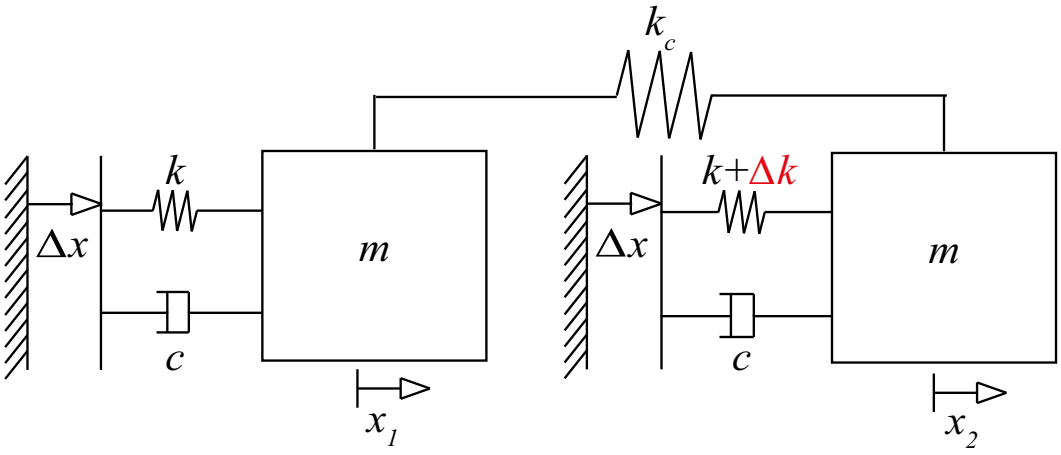

Figure 1: Analytical model of weakly coupled cantilevers.

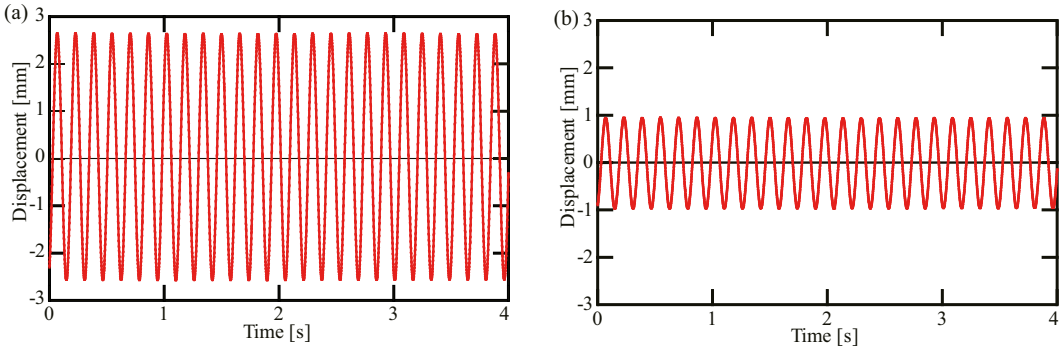

Figure 2: Experimental results. (a) without nonlinear feedback. (b) with nonlinear feedback.

we can apply the positive velocity feedback [3]. In this study, by adding the cubic nonlinear velocity feedback to Eq. (3) as

$$\Delta x = \alpha \int x_1 dt + \alpha_n \int x_1^3, \tag{4}$$

the resonators receive the force proportional to $x_1^2 \dfrac{\mathrm{d}x_1}{\mathrm{d}t}$, which is the same as the nonlinear damping in van der Pol oscillator and can make a stable limit cycle.

EXPERIMENTAL RESULTS

We use weakly coupled phosphor bronze macrocantilevers to compare the response amplitudes under self-excitation for the cases with and without nonlinear feedback. The length, width, and thickness of each cantilever are 215, 15, and 0.5mm, respectively [3]. Figures 2(a) and (b) show the time histories in the steady state for the cases without and with nonlinear feedback control, respectively. In the case without nonlinear feedback, the amplitude growth is restricted by the limited power supply to the actuator for the resonators. On the other hand, Fig. 2(b) shows the reduction of the steady state amplitude by the nonlinear feedback. The reduction eliminates the effect of the nonlinear stiffness of the cantilevers and realizes the accurate detection of the eigenmode.

ACKNOWLEDGEMENTS

The present study was supported in part by a Grant-in-Aid for Scientific Research B (Grant No. 19H0209B) from the Japan Society for the Promotion of Science (JSPS).

WEAKLY NONLINEAR VIBRATIONS OF THERMOMECHANICALLY COUPLED PLATES: ASYMPTOTIC FORMULATION AND NUMERICAL CHARACTERIZATION

Valeria Settimi[1] and Giuseppe Rega*[1]
[1]Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy

Summary Weakly nonlinear vibrations of composite plates with thermomechanical coupling are dealt with analytically and numerically, describing the main dynamical phenomena which characterize the involved pre- and post-buckling response scenarios. Static buckling and two resonance conditions around the unbuckled and buckled equilibria are investigated by the asymptotic method of multiple time scales and verified towards numerical bifurcation diagrams. Local and global aspects of the mechanical response are characterized in terms of attractors and cross-sections of the 4D basins of attractions, respectively.

INTRODUCTION

The nonlinear dynamical behavior of reduced order models of composite plates under different excitation conditions in a thermomechanical environment has been the subject of recent papers aimed at highlighting the role of multiphysics coupling and the main local and global features of the nonlinear response [1, 2]. The numerical analyses, carried out in strongly nonlinear regime and under different mechanical and thermal conditions, highlighted a rich and involved scenario characterized by multistability and possible chaos. Yet, the analytical treatment of the dynamical response can also represent a useful tool to predict, describe and possibly modify the behavior of the coupled system. Within this general framework, three main response phenomena in the weakly nonlinear regime are detected herein via the asymptotic method of multiple time scales [3], and the relevant mechanical and thermal vibrations are numerically characterized in both local and global dynamics terms.

ASYMPTOTIC AND NUMERICAL INVESTIGATION

With reference to a reduced model of rectangular laminated plate with von Kármán nonlinearities, third-order shear deformability and consistent cubic variation of the temperature along the thickness [4], the assumption of isothermal edges and free heat exchange on the upper and lower surfaces leads to the following nondimensional equations of motion describing the plate dynamics around primary resonance:

$$\begin{aligned} &\ddot{W}(t) + a_{12}\dot{W}(t) + (\Omega^2 - p)W(t) + a_{14}W(t)^3 + a_{15}T_{R1}(t) + a_{16}T_{R0}(t)W(t) - f\cos\Omega t = 0 \\ &\dot{T}_{R0}(t) + a_{22}T_{R0}(t) + a_{23}\alpha_1 T_\infty + a_{24}W(t)\dot{W}(t) = 0 \\ &\dot{T}_{R1}(t) + a_{32}T_{R0}(t) + a_{33}\dot{W}(t) = 0 \end{aligned} \tag{1}$$

in terms of the nondimensional reduced variables $W(t)$ (deflection of the center of the plate), $T_{R0}(t)$ (membrane temperature) and $T_{R1}(t)$ (bending temperature). The mechanical excitations consist of a uniform compressive force p on the plate edges and a distributed harmonic transverse excitation of amplitude f and frequency Ω. The thermal excitation is represented by the constant thermal difference between plate and environment T_∞, while a_{ij} are coefficients which incorporate the geometrical and physical properties of the model.

Local and global nonlinear dynamics have been investigated by considering the single or combined presence of thermal and mechanical excitations. In particular, the transition to mechanically- or thermally-induced buckled responses has been analyzed, with a variety of multistable scenarios being detected. With the aim to unveil the bifurcation phenomena

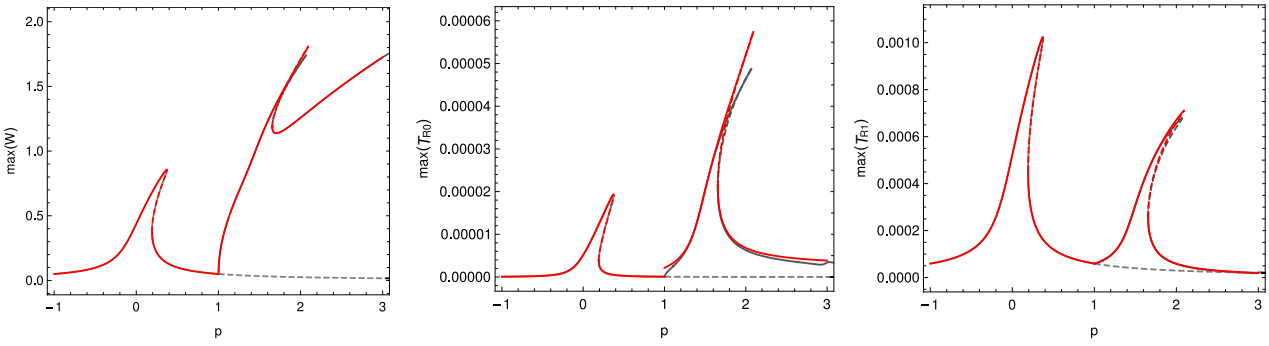

Figure 1: Numerical (gray) and analytical (red) bifurcation diagrams of mechanical and thermal variables. $\Omega = 1$, $f = 0.05$.

triggering the development of such a rich scenario, identified in a strongly nonlinear regime, a lower forcing amplitude is considered herein, and three main dynamical phenomena are detected,i.e., a static pitchfork bifurcation inducing the mechanical buckling, and two resonance peaks occurring in the pre- and post-buckling branches. The first phenomenon occurs when the mechanical pretension p nullifies the linear mechanical stiffness, while the two peaks correspond to primary resonances of the external harmonic excitation with the pre- and post-buckling system frequencies, respectively.

The static buckling analysis is performed by obtaining the three equilibria $\boldsymbol{e} = \{\boldsymbol{W}_{\mathbf{e}}, \boldsymbol{T}_{\mathbf{R0e}}, \boldsymbol{T}_{\mathbf{R1e}}\}$ of the coupled system (1), which correspond to the pre-buckling configuration representing the mechanical rest position, and to the two stable buckled non-trivial (positive and negative) solutions arising after the pitchfork bifurcation. The two resonance conditions are analytically investigated by means of the asymptotic multiple scales method, in order to study the system nonlinear dynamics around the pre-buckling and post-buckling equilibria. The perturbation equations around the pre-buckling equilibrium have the same structure of Eqs. (1), while the analysis around the buckled position implies the presence of additional terms in the varied mechanical and membrane thermal equations. Consequently, the two asymptotic procedures require different assumptions in the scaling of variables and parameters, and consequently different expansions to higher orders in order to account for some main dynamic effects (due, e.g., to the occurrence of both quadratic and cubic nonlinearities). In both cases, they have been guided by the previous numerical investigations of strongly nonlinear scenarios, which have pointed out the contemporary presence of slow (thermal) and fast (mechanical) dynamics, and have allowed to discuss the role of the coupling terms inside the three equations [5]. They result to be crucial into the thermal equations in order to determine the temperature response, while they have a marginal effect on the mechanical equation, whose dynamics evolves much quicker than the coupled thermal one. The two procedures are developed separately, and the amplitude modulation equations are obtained together with the reconstructed steady state mechanical and thermal responses. Figure 1 shows a good agreement between analytical (red) and numerical (gray) bifurcation diagrams, also in the post-buckling scenario where the mechanical response is moderately severe.

The multistability regions are numerically characterized in global and local terms by the planar sections in the mechanical plane of the 4D basins of attraction, with trivial thermal initial conditions, and the mechanical phase portraits of the detected periodic solutions, shown in Fig. 2. In the pre-buckling region, the resonance condition induces a bistable behavior with (resonant, gray) high-amplitude and (nonresonant, pink) low-amplitude symmetric solutions (Fig. 2(a,b)). After buckling, the resonance peaks on the positive and negative branches cause the arise of a multistable regime characterized by two pairs of mirrored 1-period responses oscillating around the varied equilibria (Fig. 2(c,d)). The basin organization highlights an involved scenario on both sides of the two-well mechanical oscillator, with a substantially symmetric organization of the basins and a dominance of the low-amplitude buckled solutions in the post-buckling response.

CONCLUSIONS

Some main phenomena of the rich multistable scenario occurring in the weakly nonlinear dynamics of thermomechanically coupled plates are analyzed with the multiple scale method and verified through numerical bifurcation diagrams. The main periodic unbuckled and buckled responses are characterized in local and global terms via phase portraits and proper cross-sections of the 4D basins of attraction.

EXPERIMENTAL STUDIES OF MASS EXCITED IMPACT OSCILLATOR

Dimitri Costa[1,2], Ekaterina Pavlovskaia*[1], Vahid Vaziri[1], Marcin Kapitaniak[1], and MarianWiercigroch[1]
[1]Centre for Applied Dynamics Research, University of Aberdeen, Aberdeen, Scotland, United Kingdom
[2]Center for Nonlinear Mechanics, COPPE, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Summary This work presents the dynamics of a new mass excited impact oscillator proposed in [1] which can be used for fundamental studies of impact phenomena including grazing. In this rig, the excitation force is generated electromagnetically and it acts directly on the mass in contrast to the most of the experimental set-ups where the excitation passes through the structure. A comparison with the previous base excited impact oscillator studies confirms that the rig is much more accurate as well as it has capability to generate a wide range of excitation patterns. The results obtained using a simple impact oscillator model are in a good agreement with the experimental findings, which indicates that the rig can also serves as a tool to study nonlinear control including bifurcation control and control of co-existing orbits.

INTRODUCTION

The study of impact systems represents an interesting field of research that has a wide range of applications including machining, drilling, and rotor dynamics among others. The understanding of impact phenomena and grazing occurrence is essential for getting a deeper insight into the intricacies of dynamical systems with impacts. In some cases, impacts are an essential part of system's operation, but in other instances, they can be a side effect due to ageing of the mechanical parts, thermal deformation or design tolerances. This work is motivated by the need to further enhance the understanding of impact phenomena and it focuses on the investigations of the dynamics of a newly constructed mass excited impact oscillator, its parameters characterisation and comparison with the results obtained using previous base excited impact oscillator rig [2, 3].

EXPERIMENTAL RIG

In this work dynamics of the impact oscillator rig shown in Fig. 1 is studied. It includes a stabilizing rigid structure mounted on the base plate to suppress any spurious external vibrations that may affect the main mass (highlighted in grey in Fig. 1). The main mass is attached to the leaf springs (coloured in red), which themselves are clamped between two beams and a grooved base, ensuring their proper alignment. A strong permanent cylindrical neodymium magnet, with a 15 kg pull is attached to one side of the main mass by a stainless steel rod and fixed by two stainless steel nuts. The magnet itself is placed approximately in the middle of an in-house built coil (coloured in orange), capable of generating a variable magnetic field that provides direct excitation to the system.

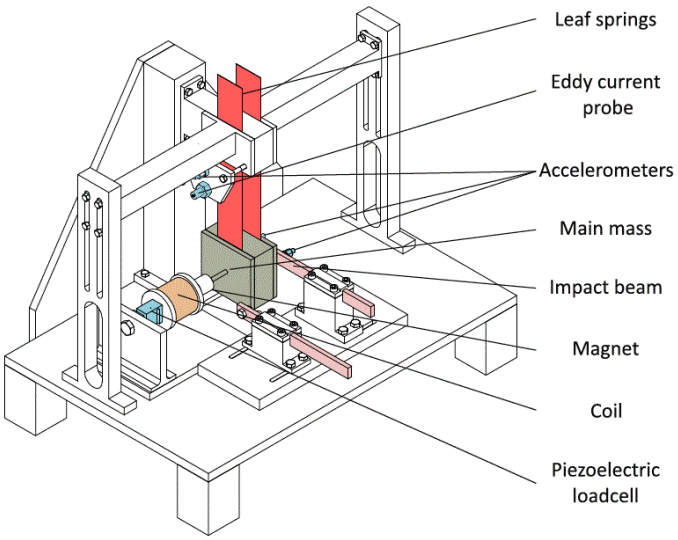

Figure 1: Schematic diagram of the experimental rig. The main components of the system are highlighted as: sensors (eddy current probe, piezoelectric load cell and accelerometers mounted on the mass, frame and impact beam) in blue, coil in orange, main mass in grey, impact beams in pink, leaf springs in red and permanent magnet in white.

The current I running through the coil is provided by a signal generator composed of a current amplifier, two power supplies and an NI® PCI-6251 board which can produce the desired signal. There are secondary supports on either side of the main mass (coloured in pink) made of the beams which can be inserted to produce impact.

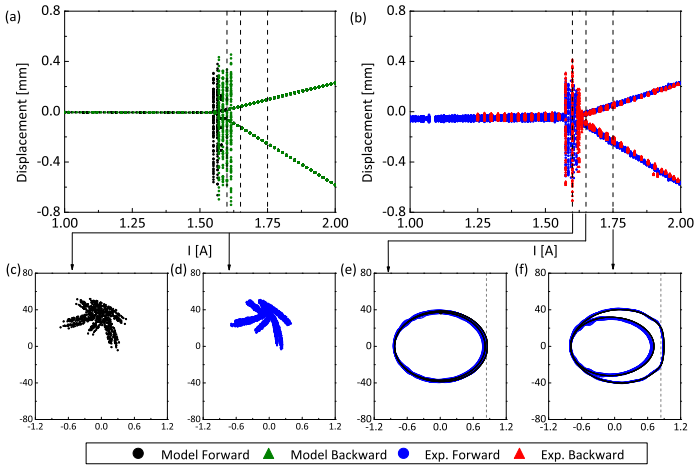

Figure 2: Bifurcation diagram obtained with input current amplitude as branching parameter with a gap of $g = 0.84$ mm and forcing frequency $f = 7.3$ Hz. Forward and backward (a) numerical and (b) experimental bifurcation diagrams. Here the black dashed vertical lines indicate the amplitude values where the trajectories on the phase planes are shown. (c) Numerical and (d) experimental Poincaré sections of chaotic response at the current amplitude of 1.605 A. (e) Period-2 orbits near internal grazing at 1.635 A. (f) Period-2 solutions recorded at 1.755 A. The dashed grey line on phase planes represents the impact boundary. Colours of the trajectories and Poincaré sections are the same as for the system responses shown in the bifurcation diagrams.

An acquisition system composed of an NI® PCI-6251 board and a LabVIEW® program is used to collect the experimental data. The coil input current is measured by a multi-meter, while the displacement of the main mass is measured by an eddy current probe attached to the structure close to the base of the leaf springs. Accelerometers are placed on the structure, the main mass and the impact beam, as shown in Fig. 1. Finally, a piezoelectric load-cell is also placed between the coil and the rigid structure to measure the reaction force due to the mass excitation.

EXPERIMENTAL AND NUMERICAL RESULTS

A piecewise linear impact oscillator model is used to describe the experimental rig. Here the displacement of the main mass m is X, the excitation force, F_{coil}, is applied directly onto the main mass, while the leaf springs are characterised by a linear stiffness k_1. The impact beam can be described by another linear spring of stiffness k_2, separated from the main mass by gap g. A linear viscous damping coefficient c is used to represent an equivalent damping in the system, leading to the equation of motion:

$$m\ddot{X} + c\dot{X} + k_1 X + k_2(X - g)H(X - g) = F_{coil}(t), \tag{1}$$

where H is a Heaviside step function and dot represents derivative with respect to time t.

The diagrams shown in Fig. 2a-b demonstrate an example of a comparison between the experimental and numerical results and are obtained for a forcing frequency of 7.3 Hz around the first grazing incidence. At lower amplitudes, the linear non-impacting response is observed up to the first grazing incidence where a narrow band region of chaotic behaviour [4] appears. As the current amplitude increases, it is followed by a period-2 response with one impact per period which is observed until the end of the diagrams. As can be seen from this figure, the experimental bifurcation diagrams and phase portraits have a good agreement with the numerical results obtained using the calibrated model.

CONCLUSIONS

In this work, the dynamics of a newly constructed mass excited impact oscillator was investigated both experimentally and numerically. It was shown that in this case a precise control of the excitation through the coil current becomes possible resulting in improvements in obtained resolution of the excitation amplitude and frequency for the construction of bifurcation diagrams. The comparison with previous base excited impact oscillator confirms that the rig has an ability to provide much more flexible excitation. Also, the rig is able to capture co-existent attractors and multi-stability experimentally by reproducing various predicted numerical responses, which was not possible before.

IS IT REALLY CHAOS?
THE COMPLEXITY OF TRANSIENT DYNAMICS OF DOUBLE PENDULA

Dawid Dudkowski*[1], Jerzy Wojewoda[1], Krzysztof Czołczyński[1], and Tomasz Kapitaniak[1]
Division of Dynamics, Lodz University of Technology, Stefanowskiego 1/15, 90-924 Lodz, Poland

Summary We study the dynamics of mechanical double pendula with parametric excitation (induced by the external shaker). The motion of the single oscillator has been investigated, showing that the system can behave chaotically, as well as periodically. Different types of patterns have been confirmed both numerically and experimentally. The bifurcation analysis of the double pendulum allowed to observe, that the character of dynamical response strictly depends on the excitation parameters, leading to the regions where the transitions from one type of pattern into another take place (periodic windows). In our research we have also examined a small network of two coupled double pendula, connected through a linear components (both upper and lower bobs of each unit), investigating the transient synchronization phenomenon. Our results exhibit, that the problem of transient dynamics may become very complex even for the simplest nonlinear systems, like the ones considered.

We investigate the numerical and experimental transient dynamics in parametrically excited double pendulum, which has been shown in Fig. 1.

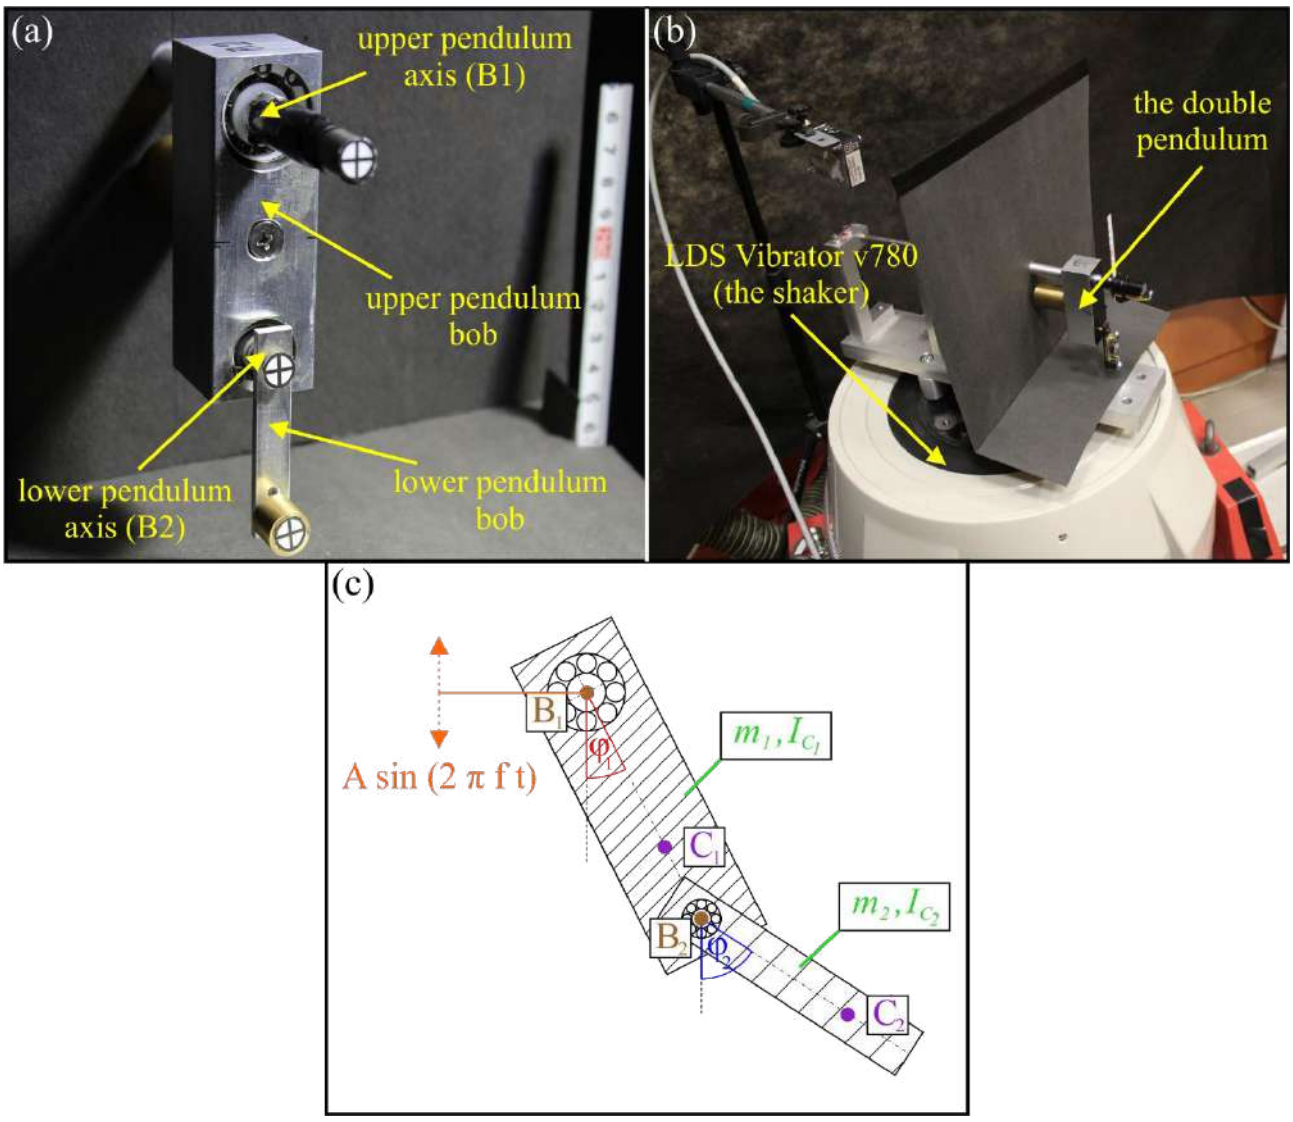

Fig. 1. A single experimental double pendulum (a) and the experimental rig of an oscillating platform with suspended unit (b). In (c) the scheme of considered model used to perform numerical research is presented.

*Corresponding author. E-mail: dawid.dudkowski@p.lodz.pl.

The double pendulum shown in Fig. 1 consists of two elements, i.e., the larger pendulum (upper bob) which holds the smaller one (lower bob). The upper bob can rotate or oscillate around the axis B1 (the upper bearing) connected to the periodically oscillating platform and the lower bob can rotate or oscillate around the axis B2 (the lower bearing). Both axis B1, B2 are perpendicular to the figure's plane. The larger and smaller bobs have respectively masses m_1, m_2 [kg] and moments of inertia I_{C1}, I_{C2} [kgm^2] (around the perpendicular axes which crosses bob's mass centers C_1, C_2). The oscillations of the platform are described by the harmonic function $A\sin(2\pi ft)$, where A [m] and f [Hz] are respectively amplitude and frequency.

In our research we present typical types of behaviors of the single double pendulum, including chaos, rotations and periodic oscillations. The bifurcation analysis is performed, exhibiting complex transitions from one type of motion into another. The character of observed dynamics is analyzed using Lyapunov exponents, which confirms the hyperchaotic nature of the system. We study the transient behaviors, showing that the length of the irregular motion can be extremely sensitive on both parameters and initial conditions. Apart from the single oscillator, in our numerical research we consider also the case of two coupled double pendula, connected by a typical linear scheme. Our results show, that depending on the network's parameters, one can observe the phenomenon of a transient chaotic synchronization, during which the units spontaneously synchronize and desynchronize. The loss of coherence is strictly related with the motion of the pendula around the unstable equilibrium of the system, which has been confirmed in the scenario of pure chaotic oscillations. We determine the regions of the occurrence of transient synchronization in the coupling parameters' plane, as well as study the statistical properties of observed patterns. Our analysis exhibits, that due to the unpredictable character of the phenomenon, the problem of determining the final dynamical attractor of the model can become not straightforward. Research presented in our study indicates the complexity of transient behaviors in nonlinear dynamical systems, which should be expected also in more complex models, including single and coupled oscillators.

NONLINEAR DYNAMICS OF A BEAM-LIKE TUBE WITH NON-RIGID CROSS-SECTION

Arnaldo Casalotti[1], Daniele Zulli*[1], and Angelo Luongo[1]
[1]Department of Civil, Construction-Architectural and Environmental Engineering, University of L'Aquila, Italy

Summary Nonlinear dynamics of a tubular beam are analyzed here via perturbation methods. The tube is modeled as a beam-like structure, with possibility of change in shape of the cross-section. In particular it becomes oval and performs warping under bending. Use of a nonlinear and coupled response function for the hyperelastic material is made, as it comes from a homogenization procedure from a three-dimensional, corresponding, body. Large amplitude vibrations are analyzed, with possible occurrence of loss of stability close to the Brazier limit point.

INTRODUCTION

Tubular beams are very common structures in civil and industrial applications, and their mechanical performance under external solicitations is a key point to be addressed for structural designers. The thin-walled nature of such structures requires, for engineers, to consider some specific aspects during analysis, being local effects and change in shape of the cross-section generally not negligible. Conveniently, beam-like models might be helpful in considering those aspects, possibly keeping the dynamic equations moderately handy. For instance, it is well known that ovalization of the cross-section, taking places when thin-walled circular tubes are bent over, may lead to instability phenomena, with consequent loss of carrying capacity of the whole structure. This behavior, known as Brazier effect [1], is due to the occurrence of a limit point in the bending moment-curvature relationship, as a consequence of the softening nature of such a law. In [2], this behavior is described in case of anisotropic materials. In [3, 4], multi-layered beams and cross-sectional models are addressed in the same framework. In [5], a homogeneous beam-like coarse model is adopted to describe the mechanics of thin-walled beams with possibility of cross-section distortion. In [6], static and free dynamic analysis of a homogeneous beam-like model is performed, after an identification procedure from a companion three-dimensional continuum. The same model is then extended in [7], where further parameters are introduced in order to take into account shear deformations in the multi-layered case.

Starting from the one-dimensional, non-standard, beam-like model presented in [7], where only static analysis is performed, inertial effects are here considered as well. The nonlinear equations of motion are taken on, and perturbation methods are used to evaluate approximated solutions, to be compared with outcomes of numerical integration. Dynamics close to the Brazier limit point are addressed, where possible intriguing dynamic response may occur.

EQUATIONS OF MOTION

A beam-like model is considered for describing the nonlinear dynamics of a thin annular tube. The beam model is shown in Fig. 1a, where the axis-line, spanned by the abscissa s running from 0 to l, is sketched together with the generic cross-section. In order to coarsely consider non-rigid behavior of the cross-sections, two s- and time-functions are introduced, a_p and a_w, besides the kinematic descriptors of planar Timoshenko beams, namely the longitudinal and transversal displacements of the axis line (u, v) and the cross-section bending rotation (ϑ). The kinematic equations are posed and the dynamic equilibrium equations of the beam evaluated from the consequential use of the virtual power theorem. The constitutive relations come from a homogenization procedure from a corresponding 3D model, shown in Fig. 1b, where the annular tube is assumed as realized by longitudinal rods and transversal ribs. For the homogenization purposes, the change in shape of the cross-section is described as in the GBT theory [8], namely the kinematic variables a_p and a_w multiply assumed functions, describing ovalization and warping, respectively, as shown in Fig. 2. The equations of motion are written below, where the linear part is made explicit:

$$\begin{aligned}
&c_1 u'' - m\ddot{u} + \mathcal{F}_1(u, v, \vartheta, a_p, a_w) + p_u = 0\\
&c_4(v'' - \vartheta') + c_5 a_g' + m\ddot{v} + \mathcal{F}_2(u, v, \vartheta, a_p, a_w) + p_v = 0\\
&c_7\vartheta'' + c_4(v' - \vartheta) + c_{11}a_g'' + c_5 a_g - I\ddot{\vartheta} + \mathcal{F}_3(u, v, \vartheta, a_p, a_w) + c = 0\\
&c_{19}a_p'' - c_{17}a_p + c_{20}a_w' - \mu\ddot{a}_p + \mathcal{F}_4(u, v, \vartheta, a_p, a_w) + q_p = 0\\
&c_{30}a_w'' - c_{26}a_w - c_{20}a_p' - \mu\ddot{a} + \mathcal{F}_5(u, v, \vartheta, a_p, a_w)_w + q_w = 0
\end{aligned} \tag{1}$$

while the nonlinear terms, expanded up to the third order, are collected in the functions $\mathcal{F}_n$, $n = 1, \ldots, 5$. Relevant boundary conditions are combined to Eqs. (1). The Multiple Scale Method is applied to Eqs. (1), when a shear force is exerted on the free tip, being the other terminal cross-section clamped. In particular, the shear force is assumed to be constituted by a static component, which modifies the equilibrium configuration of the beam and let the response close to the limit point, plus a time-harmonic, fluctuating component, which triggers intriguing dynamic evolution.

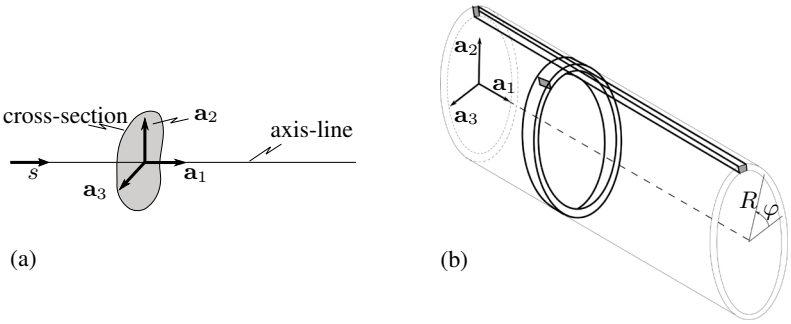

Figure 1: (a) The one-dimensional beam-like model; (b) the three-dimensional model with fibers and ribs.

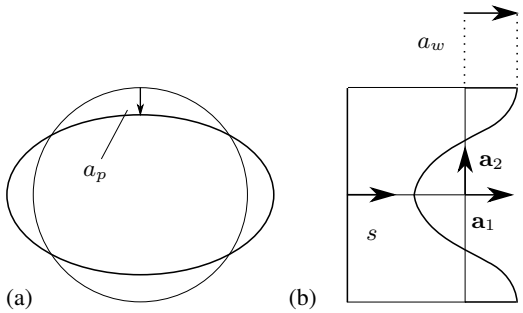

Figure 2: The change in shape of the cross-section: (a) ovalization; (b) warping.

CONCLUSIONS

Nonlinear dynamics of an annular thin tube is analyzed here. A beam-like model is introduced, where specific kinematic functions coarsely describe the change in shape of the cross-section, namely ovalization and warping. The nonlinear material response function comes from a homogenization procedure. Perturbation methods are applied to the equations of motion, in order to describe dynamic evolution close to the Brazier limit point .

NONLINEAR VIBRATIONS AND CONTROL OF ROTATING FLEXIBLE BEAMS

Jerzy Warminski *[1], Lukasz Kloda[1], Andrzej Mitura[1], and Jaroslaw Latalski[1]
[1]Department of Applied Mechanics, Faculty of Mechanical Engineering, Lublin University of Technology, Lublin, Poland

Summary Nonlinear dynamics of a rotor composed of a rigid hub and three flexible blades is presented in the paper. The model of blades which are made of isotropic and homogenous material, is based on Bernoulli-Euler beam theory. However, the model is extended and the beams are treated as extensional, and due to possible large oscillations, nonlinear curvatures are taken into account as well. The model considers also a lumped mass at the beams tip which allows studying more general case with dynamical boundary conditions. In order to control beams' vibrations active elements are embedded in each single beam. Free and forced oscillations and nonlinear normal modes are studied first analytically by the multiple time scale method and next the results are validated by a finite element model. Based on the developed model a strategy for active vibrations control is proposed.

INTRODUCTION AND PROBLEM FORMULATION

Rotating structural elements play a very important role in many aerospace, mechanical or civil engineering systems, for example arms of robotic manipulators, wind turbines, helicopter rotors, drones. Also micro or nano systems, or bio-inspired structures, include rotating flexible elements. Therefore, more and more sophisticated models are developed to get a proper description of a real object. The rotation of the structure may cause in some cases unexpected and not intuitive results. A numerical model with 'weak' formulation of a homogenous rotating beam, with coupling of bending-stretching, bending-twist and twist-stretching deformations taken into account, was presented in [1]. The importance of Coriolis effect and centrifugal stiffening were confirmed by that model. The effect of increased angular speed on the rotating nonlinear inextensible beam was presented in [2] and the hardening and also not intuitive softening phenomenon was presented in that paper.

The development of new materials and active elements enable to design a system with required properties. Furthermore, new active composite elements, which are very light and flexible, can be easily embedded into a rotating blade and, then used as sensors or/and actuators. The mathematical model of a rotating thin-walled blade made of composite material and embedded active piezoceramic layers was recently presented in paper [3]. Authors developed the two way coupled elecro-mechanical model considering linear constitutive equations for mechanical domain and nonlinear constitutive equations for electric field. The nonlinear electric characteristics of piezolayers affected the resonance curves leading to the softening phenomenon. In [4] active elements embedded into the beam were used to reduce forced vibrations by a simple PD control algorithm.

Rotation of the structure may lead to complex oscillations of the beams and therefore other control methods taking into account nonlinear and rotation effects should be tested. To reach this goal an enhanced model of a flexible rotor with active blades is developed in this paper. The model is composed of a rigid hub and a flexible blades oscillating in the plane defined by a preset angle θ as presented in Fig.1.

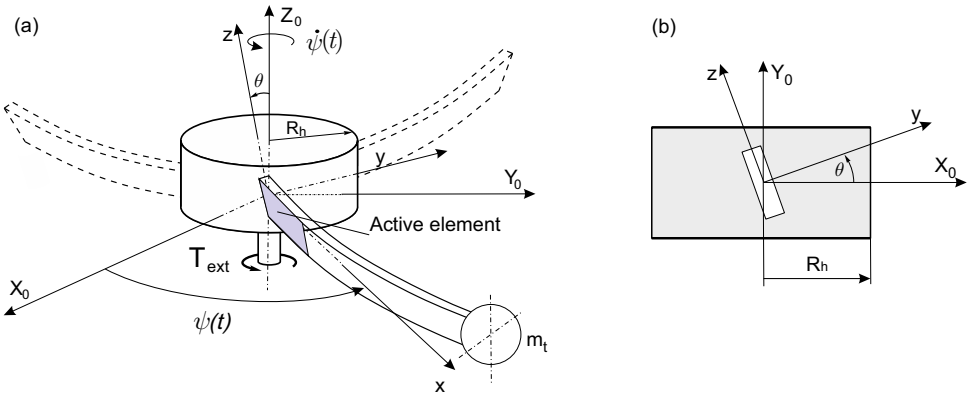

Figure 1: Rotor with blades and active elements, (a) general and (b) side view with coordinates and preset angle θ.

A lumped mass is added to the beam tip which allows to study more general case with dynamic boundary conditions. Furthermore, the mass can be used to tune the structure to the specific resonance conditions. The beam with a rectangular cross-section is made of isotropic material with linear material properties and is assumed to be slender thus, its mathematical model is based on Bernoulli–Euler beam theory. Nevertheless, due to possible large oscillations, the formulation is extended and takes into account geometric nonlinear terms and also both flexural and longitudinal deformations. It means

*Corresponding author. E-mail: j.warminski@pollub.pl.

that the beam is treated as *extensional* which can be crucial in some specific cases [5]. The rotation and oscillations of the system arise from the external torque imposed to the hub or periodic force applied directly to the beam. A pair of piezoelectric actuaturs/sensors are embedded into every single beam. The proposed mathematical model is rich and can be considered in many variants, in terms of nonlinear modes of the multi–bladed rotor, internal and external resonances with coupled transversal and longitudinal modes, vibrations control by using the active elements.

Dynamics of the rotor is governed by a set of nonlinear partial differential equations (PDEs) and associated dynamical boundary equations (BCs) not present in this abstract due to their long and complex forms. The PDEs together with BCs are solved analytically by the multiple time scales method up to the third order perturbation. Tip mass m_t, preset angle θ and angular velocity Ω are kept as bifurcation parameters and are varied in numerical analysis.

NUMERICAL EXAMPLE

As an numerical example we present dynamics of a single rotating nonlinear blade with tip mass and constant angular velocity $\dot{\psi} = \Omega$. The fixed parameters of the rotor take values: length of the beam - $L = 0.35$ m, mass per length - $\rho_1 = 0.04131$ kg/m, stiffness coefficients - $EI = 0.127883$ N/m^2, $EA = 1.89457 \times 10^6$ N. In this example we study the first and the second bending mode with light tip mass m_t equal to of 5% of beam's mass. The radius of the hub is fixed as 0.1 of the beam length L. Natural frequencies of the first bending modes take values: $\omega_{01} = 46.12$ rad/s, $\omega_{02} = 282.48$ rad/s.

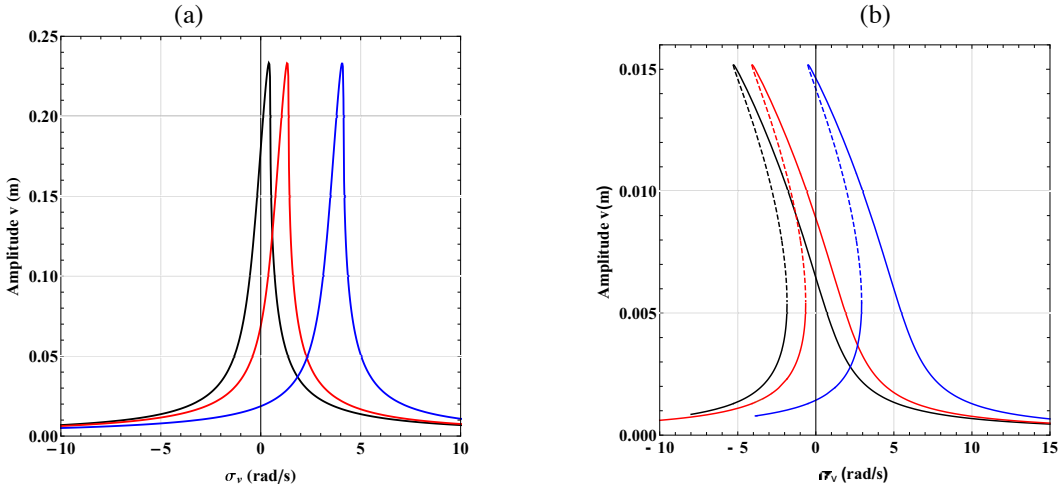

Figure 2: Resonance curves for selected angular velocity and tip mass $m_t = 0.05$, (a) first and (b) second flexural mode: $\theta = 45°$. $\Omega = 0$ - black, $\Omega = 10$ - red, $\Omega = 20$ - blue.

The resonance curves against detuning parameter σ_v defined as difference between excitation frequency ω and natural frequency ω_0, computed for fixed amplitude of transversal excitation ξ_v, and modal damping c_v, are presented in Fig. 2.

CONCLUDING REMARKS

The proposed mathematical model of the rotor takes into account large flexural displacements and *extensionality* of the beams. The influence of angular velocity, tip mass and preset angle on bifurcation scenario is analysed for selected resonance zones. The studied case of a single rotating beam with small tip mass and constant velocity demonstrates either stiffening effect, for the first flexural mode, or softening one, for the second flexural mode. The increased angular speed does not change the nature of the resonance curves but shifts them into higher frequencies direction. In the case of free vibrations of the multi–bladed rotor the hub inertia plays important role in nonlinear normal modes formulation. For forced vibrations mode localisation and synchronisation phenomena are observed. The embedded active elements enable blades vibration reduction or control.

COLOR SYMMETRY IN NONLINEAR NORMAL MODE VIBRATIONS OF A HYPERELASTIC MATERIAL

Ryuichi Tarumi*[1]
[1]Graduate School of Engineering Science, Osaka University, Osaka, Japan

Summary This study conducts numerical analysis for nonlinear normal mode vibrations of St.Venant−Kirchhoff hyperelastic material. The material has a two-dimensional rectangular shape which belongs to the point group $\mathbb{C}_{2v}$. A resonant state is obtained from a stationary condition to the action integral. A boundary condition requires that the stationary solution must satisfy the time reversal and time periodic symmetries. We solved the variational problem numerically using the Ritz method, where the basis functions include the higher-order harmonics. This analysis revealed that the vibration symmetry is classified on the basis of single color magnetic point group, $\mathbb{C}_{2v}(\mathbb{C}_{2v})$, and three types of bicolor magnetic point groups, $\mathbb{C}_{2v}(\mathbb{C}_2)$, $\mathbb{C}_{2v}(\mathbb{C}_{1h})$ and $\mathbb{C}_{2v}(\mathbb{C}'_{1h})$, rather than the conventional irreducible representations of $\mathbb{C}_{2v}$.

INTRODUCTION

Normal modes plays a central role to understand acoustic vibration of solids and structures. It is well known that the vibration symmetries are explained by group theory, *i.e.*, irreducible representations (IRs) of the point group. In other words, a dynamical matrix can be divided into a direct sum of sub-matrices which are spanned by invariant sub-spaces. This is the algebraic understanding for normal mode vibration of a linearized system. Normal modes in a nonlinear system is, however, still unclear and further investigation is required. In our recent studies, we revealed that the vibration symmetry of a nonlinear hyperelastic material is explained by the *magnetic point group*, rather than the conventional IRs of a point group [1, 2]. In the present study, we briefly summarizes our formulation as well as the results of numerical analysis.

MATHEMATICAL PRELIMINARIES

We consider normal mode vibration, or free-vibration acoustic resonance, of a two-dimensional St.Venant−Kirchhoff hyperelastic material. The material has a rectangular shape which is expressed as $\Omega = \{(x_1, x_2) | -L_i < x_i < L_i,\ i = 1, 2\}$. It belongs to the point group $\mathbb{C}_{2v}$, Let $u_i = u_i(x_i, t)$ be the displacement and let $\dot{u}_i$ and $u_{i,j}$ be the derivatives defined by $\dot{u}_i = \partial u_i/\partial t$ and $u_{i,j} = \partial u_i/\partial x_j$. Then, the action integral is define in the following form

$$I[u_i] = \int_0^{2\pi/\omega} \int_\Omega \left[\frac{1}{2}\rho \dot{u}_i^2 - \frac{1}{2}\lambda (E_{ii})^2 - \mu E_{ij} E_{ij} \right] dV dt. \tag{1}$$

Here, λ and μ are Lamé constants and E_{ij} is Green−Lagrange strain tensor defined by $E_{ij} = (u_{i,j} + u_{j,i} + u_{k,i}u_{k,j})/2$. The time domain $t \in (0, 2\pi/\omega)$ includes the angular frequency ω which is unknown in advance. Hence, Eq. (1) is defined on a variable time domain. A resonant state of the hyperelastic material is obtained from a stationary condition and which is solved numerically using the Ritz method. Note that, according to the boundary condition, the stationary solution must satisfy the time reversal symmetry with respect to $t = 0$ and time periodicity condition; $u_i(x_1, x_2, -t) = u_i(x_1, x_2, t)$. Hence, we assume that the solution $u_i = u_i(x_1, x_2, t)$ is expressed in the form of separation of variables such that

$$u_i(x_1, x_2, t) = \sum_{n=0}^{N} \sum_{m=1}^{M} F_i^{m,n}(x_1, x_2) \cos(n\omega t) \tag{2}$$

where $\sum_{m=1}^{M} F_i^{m,n}$ is Fourier series and $n \in \mathbb{N}$ is the order of harmonics up to $N = 3$. In order to avoid the trivial solution $u_i = 0$ $(\forall x \in \Omega)$, we impose a subsidiary condition at $t = 0$ such that $\|u_i\|_{L^2} = \text{const}$. Obviously, this condition defines the magnitude of vibration amplitude.

RESULTS AND DISCUSSION

Figure 1 shows the result of numerical analysis. Here, (a) shows a nonlinear vibration pattern of bending mode for half a period. (b) to (e) correspond to $n = 0, 1, 2, 3$ components in Eq. (2). In other words, the summation of (b) to (e) yields (a). As seen in the figure, the principal harmonic component (c) $n = 1$ shows bending mode vibration and which is expressed by B_1 in terms of IRs of the point group $\mathbb{C}_{2v}$. The same holds for the third-order harmonics of (e) $n = 3$. To our surprise, however, the (b) $n = 0$ and (d) $n = 2$ components show totally symmetric A_1 mode vibrations. Hence, the nonlinear normal mode vibration (a) includes two types of vibration symmetries, B_1 and A_1 symmetries, depending on the parity of the harmonics n.

*Corresponding author. E-mail: tarumi@me.es.osaka-u.ac.jp

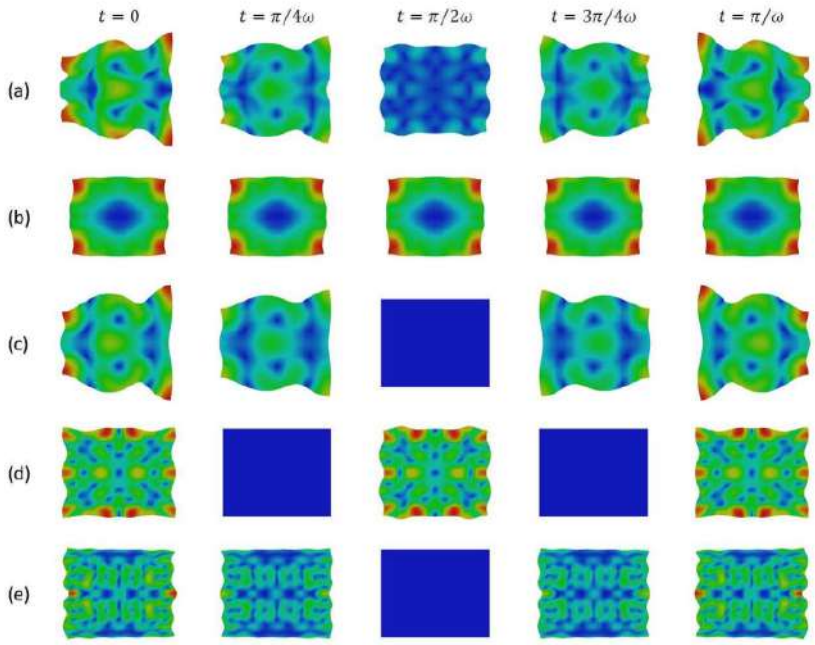

Figure 1: (a) Nonlinear vibration pattern obtained at the vibration amplitude $\|u_i\|_{L^2} = 0.05$ for half a period $t \in (0, \pi/\omega)$. (b)-(e) Displacement components for $n = 0, 1, 2, 3$; their superposition yields (a). The vibration symmetry for $n =$ odd components, namely (c) $n = 1$ and (e) $n = 3$, have B_1 symmetry. However, that for $n =$ even components, namely (b) $n = 0$ and (d) $n = 2$ have A_1. It indicates that two types of vibration symmetries are included in the nonlinear normal mode vibration (a).

As mentioned above, IRs span the invariant subspace of a linearized system. Hence, the mixing of vibration symmetries does not happen. It indicates that mode classification by conventional IRs no longer holds in the present nonlinear system. In this study, we introduce the magnetic point group (MPG) for the complete mode classification. The point groups $\mathbb{C}_{2v}$ consists of four symmetry operations including identity E, π-rotation C_2, mirror with respect to the x-plane σ_x and y-plane σ_y; $\mathbb{C}_{2v} = \{E, C_2, \sigma_x, \sigma_y\}$. Let us introduce the time reversal operator T which acts on the displacement such that $Tu_i(\cdot, t) = u_i(\cdot, -t)$ with respect to $t = \pi/2\omega$. According to the group theory, we can construct a magnetic point group (MPG) from the point group $\mathbb{C}_{2v}$ such that $\mathbb{C}_{2v}(\mathbb{C}_{1h}) = \{E, \sigma_y, TC_2, T\sigma_x\}$. Projection operator of the MPG is given by $P_{B_1} = \frac{1}{4}(E + \sigma_y + TC_2 + T\sigma_x)$. A direct calculation reveals that the operator P_{B_1} project-out the parity-dependent vibrations, *i.e.*, B_1 for $n =$ odd and A_1 for $n =$ even, from the overall displacements given in Eq. (2). Hence, the MGP $\mathbb{C}_{2v}(\mathbb{C}_{1h})$ completely explains the vibration symmetry shown in Fig. 1. Note that the point group $\mathbb{C}_{2v}$ has other three MPGs, $\mathbb{C}_{2v}(\mathbb{C}_{2v})$, $\mathbb{C}_{2v}(\mathbb{C}_2)$ and $\mathbb{C}_{2v}(\mathbb{C}'_{1h})$, in addition to $\mathbb{C}_{2v}(\mathbb{C}_{1h})$. Our numerical analysis revealed that vibration symmetry of the hyperelastic material can be classified by one of the four MPGs without any exception. It is worthwhile to note that the MPG also explains the symmetry of nonlinear normal mode vibration of molecules [3]. This result validates the results of present analysis.

CONCLUSIONS

In this study, we investigated the nonlinear normal mode vibration of a two-dimensional hyperelastic material. Present numerical analysis revealed that the vibration symmetry can be classified on the basis of magnetic point group, rather than the conventional IRs for linearized system. It demonstrates that there exists a new class of vibration symmetry, *i.e., the color symmetry*, in nonlinear normal mode vibrations of hyperelastic materials.

NONLINEAR DYNAMICS OF A CANTILEVERED BEAM WITH A TIP MASS: THEORY AND EXPERIMENTS

M. Reza Talebi Bidhendi*[1] and A. Srikantha Phani[1]
[1]Department of Mechanical Engineering, University of British Columbia, Vancouver, Canada

Summary Nonlinear dynamics of a cantilevered beam with an end mass excited through an electromagnetic shaker at its tip is investigated in this paper. Shaker-structure interaction imposes a near 2:1 frequency ratio between the first vertical and lateral modes of the structure. Experiments show the the lateral mode activation after a vertical force threshold with excitation frequency close to the first vertical natural frequency. Shaker-structure interaction in the multi-body dynamic model is through the external supports. Further, a minimal model which includes a mass restrained by linear spring-damper pairs is developed. The resultant restoring-damping force components produced by each pair introduce kinematic nonlinear terms in the governing equations. We find that the multi-body dynamic and minimal model are able to qualitatively explain the experimentally observed nonlinear responses.

PROBLEM STATEMENT

Cantilevered beam with tip mass is a canonical structure extensively studied under the tip excitation and under the base excitation [1]. Nonetheless, the present problem of a tip excited cantilevered beam with a tip mass connected to an electromagnetic shaker has not received much attention, and we are led to it through a friction control application in railways [2]. Similar systems can arise in the vibration energy harvesting, vibration mitigation, and sensing or actuating mechanisms [3]. Restoring force due to the elastic support leads to nonlinear forces of kinematic origin in the governing differential equations (DEs) of motion [4, 5]. A similar situation arises in our problem due to shaker-structure interaction, sketched in Fig.1(a). A long steel beam with a diameter of 4 mm and length of 254 mm is connected to an aluminum tip mass ($70\times50\times20$ mm^3) and a rigid rod of density of 7800 kg/m^3 and diameter of 4 mm and length of 40 mm. Shaker-structure interaction is through the external supports at the tip in the multi-body dynamic modelling, see Fig.1(b). The associated values of the support elements (c_x, c_y, k_x, k_y) are then found by making the frequency response functions of the multi-body dynamic model close to the experimental ones, Fig.1 (e) and Fig.1 (f). The experimental linear modal parameters of the structure (damping ratio(ζ), stiffness(k), natural frequency (f_n)) are $k_1 = 5328\ N/m, \zeta_1 = 0.1346, f_1 = 24.80\ Hz, k_2 = 2202\ N/m, \zeta_2 = 0.1234, f_2 = 12.37\ Hz$. Indices one and two refer to the vertical and the lateral directions, respectively. Using the linear modal properties of the structure, a minimal two-degree-of-freedom (DOF) model as shown in Fig.1(c) can be developed, with the governing equations:

$$m_2\ddot{x} + k_2(L_2 - x)\left(\frac{L_2}{\sqrt{(L_2-x)^2+y^2}} - 1\right) - k_1 x\left(\frac{L_1}{\sqrt{(L_1-y)^2+x^2}} - 1\right) + \left(\frac{c_2(x-L_2)}{(L_2-x)^2+y^2}\right)((x-L_2)\dot{x} + y\dot{y}) + \left(\frac{c_1 x}{(L_1-y)^2+x^2}\right)((y-L_1)\dot{y} + x\dot{x}) = 0 \tag{1}$$

$$m_1\ddot{y} + k_1(L_1 - y)\left(\frac{L_1}{\sqrt{(L_1-y)^2+x^2}} - 1\right) - k_2 y\left(\frac{L_2}{\sqrt{(L_2-x)^2+y^2}} - 1\right) + \left(\frac{c_1(y-L_1)}{(L_1-y)^2+x^2}\right)((y-L_1)\dot{y} + x\dot{x}) + \left(\frac{c_2 y}{(L_2-x)^2+y^2}\right)((x-L_2)\dot{x} + y\dot{y}) = -F\cos(2\pi f t) \tag{2}$$

where $m_i,\ L_i,\ c_i,\ i = 1, 2$ are the masses, initial lengths of the support elements, and damping coefficients respectively; F is the excitation amplitude, and f is the excitation frequency. The above equations are solved numerically for non-zero initial conditions, and compared with the full-scale multi-body dynamics model (no modal truncation) in ADAMS software and experiments.

RESULTS AND CONCLUSIONS

Force-response curves are calculated by fixing the excitation frequency (f) and increasing the excitation amplitude (F) [6]. When the excitation frequency is close to the first vertical natural frequency, ($f \approx f_1$), the first lateral mode is excited through a 2:1 internal resonance after a force threshold as shown in Fig.2(a). Furthermore, multi-body dynamic simulation and the minimal model show the activation of the lateral mode after a certain threshold. These validate the experimentally observed responses qualitatively, Fig.2(b) and Fig.2(c) . However, discrepancies in the vertical nonlinear response exist between the simulations (ADAMS model and the minimal model) and the experiments. This issue is to be addressed in the future studies through experimental quantification of nonlinearity [7] and considering the electro-mechanical coupling effects imposed by the external exciter [8]. Structure response due to the 2:1 internal resonance between two flexural modes with displacements in mutually orthogonal planes is almost similar to Froude oscillations of a ship. However, the reduced model does not show the saturation in the vertical response. This difference has to do with the retaining of all nonlinear terms in our minimal model.

BLOCH WAVE PROPAGATION IN MICROSTRUCTURED WAVEGUIDES WITH NONLINEAR INERTIA AMPLIFICATION

Valeria Settimi*[1], Andrea Bacigalupo[2], and Marco Lepidi[2]
[1]Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy
[2]Department of Civil, Chemical and Environmental Engineering, University of Genoa, Genoa, Italy

Summary The free propagation of Bloch waves in acoustic metamaterials with nonlinear inertia amplification is investigated. A Lagrangian model is formulated to describe the nonlinear dynamics of a periodic chain of elastically coupled point masses (atoms), realizing a minimal acoustic waveguide with local inertia-amplifying oscillators. First, the nonlinear equations of motion governing the free undamped vibrations of the tetra-atomic periodic cell are formulated, and the linear frequency spectrum governing the small-amplitude range of wave propagation is determined in the complex wavenumber space via the linear map approach. Second, the harmonically-periodic solutions characterizing the high-amplitude range of wave oscillations are investigated, via the nonlinear map approach.

INTRODUCTION

The dispersion spectrum of periodic microstructured materials has long been attracting the scientific research in the fields of linear and nonlinear dynamics. Recently, a renewed interest has been paid to the parametric and computational design of architectured cellular materials, targeted at fine-tuning the periodic cell architecture to achieve unconventional, superior of functional dispersion properties. In particular, the growing technological request for low-density artificial materials serving as mechanical low-frequency filters or isolators has boosted the rapid diffusion and success of elastic microstructures locally coupled with undamped oscillators (*acoustic metamaterials*). Indeed, the mechanism of local resonance provided by the tuned oscillators (*resonators*) allows the opening, shifting and widening of frequency stop bands in the dispersion spectrum [1, 2]. From the physical viewpoint, low-frequency resonators suited for high-pass filtering applications tend to combine high flexibility with large inertial masses, conflicting with the requirement of low-density materials. In order to by-pass this stalemate, an effective dynamic solution leverages the panthographic mechanisms to artfully amplify the inertial properties of the material microstructure [3]. In this framework of high-performing functionalities, the combination of high microstructural flexibility, pantographically-amplified vibrations and minimal dissipative capabilities can also be the natural scenario for the development of nonlinear dynamic phenomena.

LAGRANGIAN MODEL OF THE ACOUSTIC METAMATERIAL

A Lagrangian model is formulated to describe the nonlinear dynamics of a periodic chain of undamped oscillators (Figure 1), in which only linear forces of attraction/repulsion are exchanged between any pair of adjacent point masses (*primary atoms*). The atomic chain represents a minimal physical realization of acoustic waveguide with inertia-amplifying auxiliary oscillators (*secondary atoms*), rigidly connected to the primary atoms by a panthographic mechanism.

Free wave propagation

Collecting the nondimensional displacement variables $u = U_1/L$, $w = (U_3 - U_1)/L$, $u_\ell = U_\ell/L$ and $u_r = U_r/L$ in the vector $\mathbf{u} = (u, w, u_\ell, u_r)$, the exact nonlinear equation governing the motion of the generic cell can be formulated. Expanding in Taylor series around the rest position $\mathbf{u} = \mathbf{0}$ and retaining terms up to the third order, the equation reads

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}\mathbf{u} + \mathbf{m}_2(\dot{\mathbf{u}}, \dot{\mathbf{u}}) + \mathbf{n}_2(\ddot{\mathbf{u}}, \mathbf{u}) + \mathbf{m}_3(\mathbf{u}, \dot{\mathbf{u}}, \dot{\mathbf{u}}) + \mathbf{n}_3(\ddot{\mathbf{u}}, \mathbf{u}, \mathbf{u}) = \mathbf{0} \tag{1}$$

The quasi-static equilibrium at the cell boundary nodes is instead governed by the linear equation $\mathbf{K}_p\mathbf{u} = \mathbf{f}_p$, where the external forces $\mathbf{f}_p = (f_\ell, f_r)$ can easily be related to the internal stresses $\boldsymbol{\sigma} = (\sigma_\ell, \sigma_r)$. Partitioning the displacement vector $\mathbf{u}$, the inner and outer displacement subvectors read $\mathbf{u}_a = (u, w)$ and $\mathbf{u}_p = (u_\ell, u_r)$, respectively. Collecting all the outer variables in the vector $\mathbf{v} = (u_\ell, u_r, \sigma_\ell, \sigma_r)$, the quasi-static equilibrium equations can be inverted to obtain the static condensation rule $\mathbf{u}_a = \mathbf{S}\mathbf{v}$. After condensation, the nonlinear equations of motion reads

$$\mathbf{M}\ddot{\mathbf{v}} + \mathbf{K}\mathbf{v} + \mathbf{p}_2(\dot{\mathbf{v}}, \dot{\mathbf{v}}) + \mathbf{q}_2(\ddot{\mathbf{v}}, \mathbf{v}) + \mathbf{p}_3(\mathbf{v}, \dot{\mathbf{v}}, \dot{\mathbf{v}}) + \mathbf{q}_3(\ddot{\mathbf{v}}, \mathbf{v}, \mathbf{v}) = \mathbf{0} \tag{2}$$

Focusing the analysis on the only periodic solutions in the nondimensional τ-time domain, the real-valued unknown $\mathbf{v}(\tau)$ can conveniently be expressed in Fourier series (truncated to account for the first harmonic terms)

$$\mathbf{v}(\tau) = \sum_{-\infty}^{\infty} \mathbf{a}_k \, \mathrm{e}^{\imath k\omega\tau} \simeq \mathbf{a}\,\mathrm{e}^{\imath\omega\tau} + \bar{\mathbf{a}}\,\mathrm{e}^{-\imath\omega\tau}, \qquad \text{with} \quad k \in \mathbb{Z} \tag{3}$$

where the Fourier coefficient $\mathbf{a} = (A_\ell, A_r, B_\ell, B_r)$ serves as (unknown) amplitude of the first harmonic term and bar indicates complex conjugate. The nondimensional parameter ω plays the role of circular frequency for the mono-harmonic motion.

LINEAR AND NONLINEAR MAP APPROACH

The nonlinear equations of motion (2) can be linearized in the small-amplitude oscillation range. Therefore, the linear dispersion functions $\omega(\beta)$ relating the frequency ω to the nondimensional wavenumber β can be determined by applying either the Floquet-Bloch theory [4] or the linear map approach [5]. The latter technique employs the formal analogy between the wave periodicity (in the β-space) and the Lyapunov stability (in the τ-space) for discrete systems (Figure 2).

.5 The map approach can also be applied to the nonlinear systems governed by explicit equations $\dot{\mathbf{y}} = \mathbf{f}(\mathbf{y})$ to analyze the periodic solutions in the high-amplitude range of wave oscillations [6]. However, the nonlinear equations (2) can be manipulated to achieve only the implicit form $\mathbf{g}(\dot{\mathbf{y}}, \mathbf{y}) = \mathbf{0}$, which may require a different mathematical treatment [7]. Specifically, according to the most general definition of discrete implicit map, $\mathbf{y}_0$ is a p-periodic point of the implicit dynamic system $\boldsymbol{g}(\dot{\mathbf{y}}, \mathbf{y}, \boldsymbol{\alpha}) = \mathbf{0}$ if

$$\begin{cases} \boldsymbol{g}(\mathbf{y}_0, \mathbf{y}_1, \boldsymbol{\alpha}) = \mathbf{0} \\ \boldsymbol{g}(\mathbf{y}_1, \mathbf{y}_2, \boldsymbol{\alpha}) = \mathbf{0} \\ \dots \\ \boldsymbol{g}(\mathbf{y}_{p-2}, \mathbf{y}_{p-1}, \boldsymbol{\alpha}) = \mathbf{0} \\ \boldsymbol{g}(\mathbf{y}_{p-1}, \mathbf{y}_0, \boldsymbol{\alpha}) = \mathbf{0} \end{cases} \tag{4}$$

Therefore, the $\mathbf{y}_0$ stability can be analysed by introducing bifurcation conditions in order to assess the critical values of the parameter set $\boldsymbol{\alpha}$. The periodic points can be searched for the nonlinear system under investigation by setting $\dot{\mathbf{y}} = (A_r, B_r, \bar{A}_r, \bar{B}_r)$ and $\mathbf{y} = (A_\ell, B_\ell, \bar{A}_\ell, \bar{B}_\ell)$ and assuming ω as control parameter in the $\boldsymbol{\alpha}$-set.

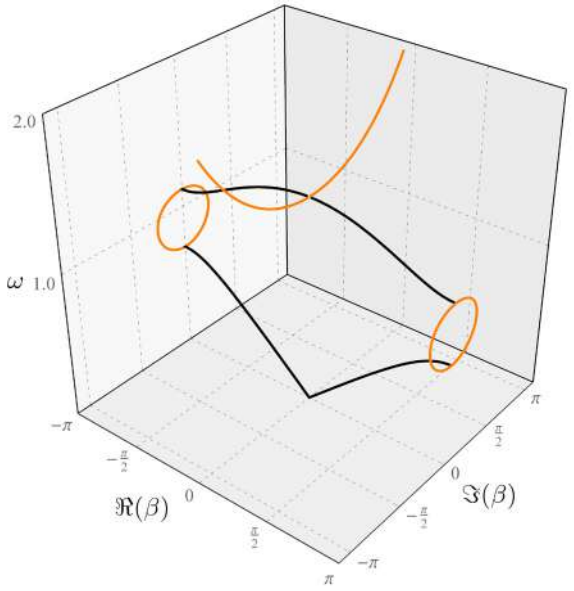

Figure 2: Linear spectrum in the ω-$\Re(\beta)$-$\Im(\beta)$ space.

Equations (4) can be stated and solved for particular p-cases ($p = 1, 2$), giving solutions $\omega(\mathbf{y}_0, \mathbf{y}_1)$ corresponding to $\beta = 2\pi/p$. Using polar representations $A_\ell = a_\ell \, \mathrm{e}^{\imath\phi}$ and $B_\ell = b_\ell \, \mathrm{e}^{\imath\varphi}$, the amplitude-dependent frequency solutions $\omega(a_\ell)$ or $\omega(b_\ell)$ are obtained by setting $\mathbf{y}_1 = \mathbf{y}_0 \, \mathrm{e}^{\imath \, 2\pi/p}$. The amplitude-dependent frequency curves have dominant softening behaviour for small amplitudes, as expected for inertial nonlinearities, and originate from the linear spectrum for null amplitudes. The softening behaviour may enlarge the amplitude-dependent stop bandwidth.

CONCLUSIONS

Nonlinear periodic solutions for the free Bloch wave propagation have been determined for an acoustic metamaterial waveguide with inertia amplification. The map approach has been employed to achieve the linear dispersion spectrum and nonlinear amplitude-dependent frequency functions for particular oscillation periodicities.

SECOND-ORDER PERTURBATION BASED RECURSIVE UPDATE OF EIGEN-DECOMPOSITION FOR VIBRATION ANALYSIS

Paul Mucchielli[1], , Basuraj Bhowmik[1], Vikram Pakrashi[2], Budhaditya Hazra[3]
[1]Dynamic Systems Risk Laboratory, University College Dublin, Dublin, Ireland

[3]Department of Civil Engineering, Indian Institute of Technology Guwahati, Guwahati, India

Summary This manuscript describes the work that was undertaken by the authors towards recursive eigen-decomposition update of a vibration signal. A Structural Health Monitoring (SHM) approach was adopted to extract the eigen-decomposition of a multivariate signal. This real-time implementation, requiring the intervention of a composite algorithm, can provide timely information as to the state of the structural system under study. This algorithm gathers both eigen-perturbation principles and the well-known Jacobi algorithm. Through the analysis of simulated signals of a 5 degrees of freedom system under white noise excitation, we explore the performance of such an algorithm in the extraction of accurate eigen-decomposition.

INTRODUCTION

The analysis of a system through its dynamical response to surrounding excitation has previously shown that external events could be correlated with changes in the dynamical behaviour of the system. In this context, we proposed to observe the dynamical response of a 5 degrees of freedom system through the analysis of a multivariate acceleration signal. The covariance matrix of this signal encloses information about the interaction between these degrees of freedom. In SHM, the modification of the dynamical response can often be assessed through the analysis of the covariance matrix through its principal components [1]. Indeed, a system under excitation, represented in time through a multivariate signal contained in the matrix $X^{n\times k}$ of n output acceleration traces has covariance matrix $C = {}^{1}/_{k}\, XX^{T}$ [1]. The update of eigenvalues and eigenvectors of the covariance matrix under a small perturbation is enabled using perturbation theory. The covariance matrix of a zero mean and unit variance multivariate signal can be updated over time according to,

$$C_{i+1} = \frac{i-1}{i} C_i + \frac{1}{i}\delta C, \tag{1}$$

The quantity $\delta C = {}^{1}/_{i}\, X_i X_i^{T}$ where X_i is the ith sample vector will experience a decrease proportional to the inverse of the time stamp. Therefore, the amplitude of the perturbation δC applied to C_i will reduce over time. We can update the eigenvectors (i.e. principal components) of the matrix C perturbed by δC at each time step. This process, known as eigen-perturbation, has been explored in previous works in the form of First Order Eigen-Perturbation (FOEP) for the approximation of eigenvalues and eigenvectors of a perturbed covariance matrix [1]. The works described here established the performance of Second Order Eigen-Perturbation (SOEP).

THEORY

The core of this method resides in computing extra perturbation terms to the FOEP formulation.

$$\underbrace{C}_{\substack{Original\\ covariance\ matrix}} \times \underbrace{V}_{\substack{Original\\ eigenvectors}} = \underbrace{\Lambda}_{\substack{Original\\ eigenvalues}} \times \underbrace{V}_{\substack{Original\\ eigenvectors}} \tag{2}$$

$$(C+\delta C)\left(\mathrm{V} + \underbrace{\delta \mathrm{V}}_{\substack{1^{st}\ order\\ perturbation}} + \underbrace{\delta^2 \mathrm{V}}_{\substack{2^{nd}\ order\\ perturbation}}\right) = \left(\Lambda + \underbrace{\delta\Lambda}_{\substack{1^{st}\ order\\ perturbation}} + \underbrace{\delta^2\Lambda}_{\substack{2^{nd}\ order\\ perturbation}}\right)\left(\mathrm{V} + \underbrace{\delta \mathrm{V}}_{\substack{1^{st}\ order\\ perturbation}} + \underbrace{\delta^2 \mathrm{V}}_{\substack{2^{nd}\ order\\ perturbation}}\right) \tag{3}$$

While FOEP would only see the terms marked as first order terms appear in the computations, the terms marked as second order would offer extra precision to the approximation of the new eigen-decompositions [2]. Expanding and simplifying this equation allows to develop simple rules for the calculation of $\delta\Lambda$, δV, $\delta^2\Lambda$, $\delta^2 V$ recursively by using the update in Equation (1).

As mentioned in perturbation literature, the one major disadvantage of perturbation bounds derived for the eigenvalue problem is their reliance on the spacing between two consecutive eigenvalues [3]. Indeed, the theory that governs the perturbation of an eigen-decomposition gravitates around the assumption of linear independence of the eigenvectors [4]. Once two or more eigenvalues are repeated or close, the rules obtained from Equation (3) cannot be used. That is why the Jacobi algorithm is used to handle those cases where eigen-perturbation is not appropriate. Consequently, in this specific situation, we rearrange the problem to display strong diagonal dominance and use the well-adapted Jacobi algorithm to compute the results [5], [6]. Since the Jacobi algorithm operates to eliminate the off-diagonal terms of the matrix, it is better suited to this problem than techniques requiring tridiagonalization. The detection of close eigenvalues was

performed using perturbation bounds that limited the maximum 2-norm relative eigenvector error to 1 % [7]. We refer to the algorithms that include Jacobi intercession as FOEPS and SOEPS.

RESULTS

We processed a 100 s-long simulation of a 5-DOF building system under white noise excitation and sampled at 100 Hz. The results for FOEP, FOEPS and SOEPS were compared against the sample wise eigen-decomposition of C performed by the QR algorithm [6]. Figure 1 shows the results in terms of Mean Absolute Percentage Error (MAPE) and Modal Assurance Criterion (MAC) [8].

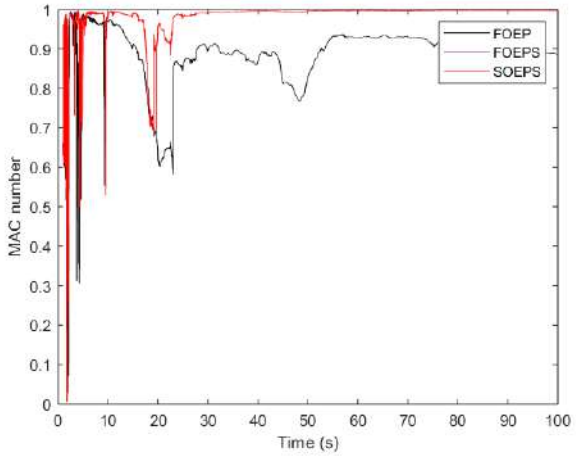

Figure 2. Plot of the MAC number with respect to the system modes against time for FOEP, FOEPS and SOEPS

DISCUSSION

Figure 1 shows that the first and second order frameworks that included Jacobi intercession performed quite significantly better. Indeed, while the first order technique output a median error of 29.3 %, including the intervention of the Jacobi algorithm reduced it to 1.29×10^{-2} % while the second order run reached 3.02×10^{-5} %. Considering the MAC, while FOEP is reaching a final 88.63 score, the FOEPS and SOEPS techniques both scored 99.76. This shows the potential of the FOEPS and SOEPS algorithm to provide more accurate and consistent (with the system modes) updates at each time step in a time series.

CONCLUSIONS

The superiority of SOEPS and its linking to a real-time recursive framework may be able to allow a more precise damage detection in all types of systems. Indeed, one can use recursive damage sensitive in conjunction with time-varying autoregressive coefficients all of which can be implemented with an eigen-perturbation framework [1].

Summary This paper deals with the free vibration of a beam which is discretized by finite rigid granular elements and compared its exact solution to continuum local elasticity. This problem, which can be considered as a simple model to rigorously study the effect of the microstructure on the dynamic behavior of a equivalent continuum structural model, can be referred to Cosserat discrete chain or a lattice elastic model with shear interaction. This micro structured system consists of uniform grains elastically connected by shear and rotation springs. First the critical frequencies of the system which change the nature of the results, are obtained. Next, the natural frequencies of such as granular model are analytically calculated whatever the considered modes for the granular beam resting on two supports, starting from the resolution of the linear difference eigenvalue problem. It is shown that the discrete equations of this granular system, for an infinite number of grains, converge to the differential equations of the Bresse-Timoshenko beam resting on Winkler foundation (such a Bresse-Timoshenko beam can be also classified as a continuous Cosserat beam model). A gradient Bresse-Timoshenko model is constructed from continualization of the difference equations of the granular system. This continuous gradient elasticity Cosserat model is obtained from a polynomial or a rational expansion of the pseudodifferential operators, stemming from the continuualization process. The natural frequencies of the continuous gradient Cosserat models are compared with those of the discrete Cosserat model associated with the granular chain. Scale effects of the granular chain are clearly captured by the continuous gradient elasticity model. The results clarify the dependency of the beam dynamic responses to the beam length ratio.

***Keywords*:** Cosserat continuum, Discrete Cosserat formulation, Gradient elasticity, Timoshenko beam.

Introduction

In order to adapt a theory of continuous media to granular materials, it is necessary to introduce independent degrees of freedom of rotation, in addition to those conventional translation. Indeed, the relative movements between the microstructure and the average macroscopic deformations can be apprehended by additional degrees of freedom. Such enriched kinematics leads to non-classical continuous media or Cosserat-type theories [1], [2] which introduce intrinsic length scales via higher order gradients or additional degrees of freedom. Conversely, the classical mechanics of continuous media does not incorporate a rotational interaction between the particles, and does not allow to understand the size effects in these media.

The Bresse-Timoshenko beam model admits kinematics with two independent fields of transverse displacement and rotation [3], [4]. The exact calculation of natural frequencies for a Bresse-Timoshenko beam with any boundary conditions and in elastic interaction with a rigid medium was obtained by Wang and Stephens [5], [6]. Timoshenko beam is an example of Cosserat one-dimensional continuum considering the independent double rotation-displacement kinematics. The present study focuses on the vibration of the granular beam model resting on a linear Winkler foundation. Note that the difference equations of this granular chain coincide with the difference equations of the granular model of Pasternak and Mühlhaus [7] in the absence of elastic foundation, while differ from the ones of Duan et al [8] or Bacigalupo and Gambarotta [9].

Granular Model

A granular beam of length L resting on two simple supports is modeled by a finite number of grains interacting together. Such a model could be presented by considering the microstructured granular chain comprising $n+1$ rigid grain with diameter a ($a=L/n$) that are connected by n shear and rotational springs, as shown in figure 1.

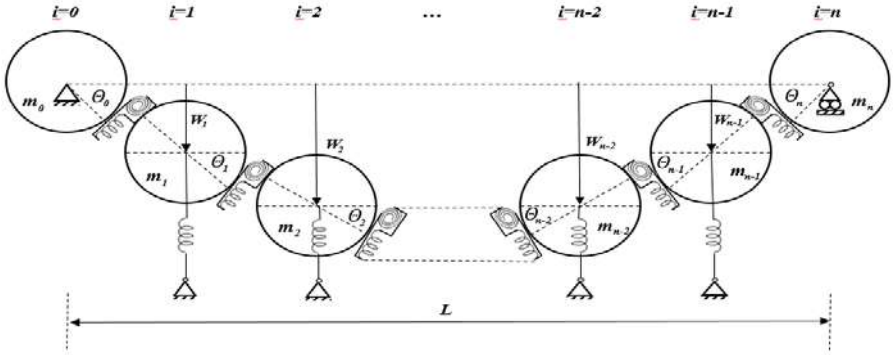

Figure 1. A discrete shear granular chain composed of n+1 grain

The Lagrangian relation of the granular system may be defined as

$$L = \left[\frac{1}{2}\sum_{i=0}^{n} m_i \dot{W}_i^{\,2} + \frac{1}{2}\sum_{i=0}^{n} I_{m_i}\dot{\Theta}_i^2\right] - \left[\frac{1}{2}\sum_{i=0}^{n-1} S\left(W_{i+1} - W_i - a\frac{\Theta_{i+1}+\Theta_i}{2}\right)^2 + \frac{1}{2}\sum_{i=0}^{n-1} C(\Theta_{i+1}-\Theta_i)^2 + \frac{1}{2}\sum_{i=0}^{n} KW_i^{\,2}\right] \quad (1)$$

where S is the shear stiffness and defined by $S = \frac{K_s GA}{a} = \frac{nK_s GA}{L}$. G is the shear modulus; A is the cross-sectional area of the beam and K_s is an equivalent shear correction coefficient. C is the rotational stiffness and can be expressed as $C = \frac{EI}{a} = \frac{nEI}{L}$, where E is Young's modulus and I is the second moment of area. $K=ka$ is the discrete stiffness of the elastic support.

From the Euler-Lagrange of the granular system by assuming a harmonic motion $W_i = w_i e^{j\omega t}$ and $\Theta_i = \theta_i e^{j\omega t}$ with $j^2=-1$, the following deflection equation could be obtained

$$[EI\delta_2{}^2 + \left(\rho I\omega^2 - \frac{kEI}{K_s GA} + \frac{EI\rho\omega^2}{K_s G}\right)\delta_2 + (k - \rho A\omega^2)\delta_0 - \frac{k\rho I\omega^2}{K_s GA} + \frac{\rho^2 I\omega^4}{K_s G}]w_i = 0 \quad (2)$$

The pseudo-difference parameters are defined as:

$$\delta_0 W_i = \frac{W_{i+1}+2W_i+W_{i-1}}{4}, \quad \delta_1 W_i = \frac{W_{i+1}-W_{i-1}}{2a}, \quad \delta_2 W_i = \frac{W_{i+1}-2W_i+W_{i-1}}{a^2} \quad (3)$$

The fourth-order difference equation (2) is equivalent to the one of Challamel et al. [10] in the static range ($\omega = 0$). Considering infinite number of grains ($n \to \infty$) for the continuum beam, the fourth-order differential equation valid for a Bresse-Timoshenko beam on Winkler elastic foundation is given by (4) which also could be compared well by [5], [6].

$$\frac{d^4w}{dx^4} + \left(\frac{\rho\omega^2}{E}\left(1 + \frac{E}{k_s G}\right) - \frac{k}{k_s GA}\right)\frac{d^2w}{dx^2} - \left(\frac{\rho\omega^2}{E}\left(\frac{A}{I} + \frac{k}{k_s GA} - \frac{\rho\omega^2}{k_s G}\right) - \frac{k}{EI}\right)w = 0 \quad (4)$$

Exact solution

For simply supported boundary conditions by assuming $w_0 = 0$; $\delta_1\Theta_0 = 0$ and $w_n = 0$; $\delta_1\Theta_n = 0$ the frequencies of the discrete system could be obtained by (5). The results are shown in figure 2.

$$\omega = \frac{1}{L^2}\sqrt{\frac{EI}{\rho A}}\sqrt{-\frac{n^2}{\mu_s r^{*2}}\left(1+\mu_s-\frac{1}{4r^{*2}n^2}\right)cos\left(\frac{p\pi}{n}\right)+\frac{k^*}{2}+\frac{1}{4\mu_s r^{*4}}+\frac{n^2}{\mu_s r^{*2}}(1+\mu_s) \pm \sqrt{\left(\frac{n^2}{\mu_s r^{*2}}\left(1+\mu_s-\frac{1}{4r^{*2}n^2}\right)cos\left(\frac{p\pi}{n}\right)-\frac{k^*}{2}-\frac{1}{4\mu_s r^{*4}}-\frac{n^2}{\mu_s r^{*2}}(1+\mu_s)\right)^2-\frac{n^4}{\mu_s r^{*4}}\left(\left(-\frac{r^{*2}k^*\mu_s}{n^2}+\frac{k^*}{4n^4}-4\right)2cos\left(\frac{p\pi}{n}\right)+\frac{k^*}{2n^4}+\frac{2r^{*2}k^*\mu_s}{n^2}+4+4\left(cos\left(\frac{p\pi}{n}\right)\right)^2\right)} \quad (5)$$

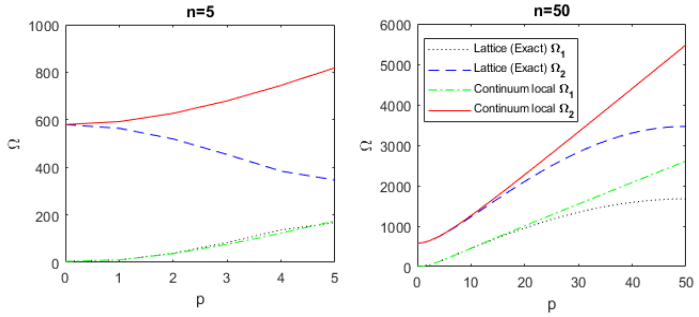

Figure 2. Comparison of the natural frequencies for the discrete exact and continuum solutions with respect to the mode number (p) and grain number $(n \in \{5,\ 50\})$ for $\mu_s = 4.28$, $r^* = 0.029$ and $k^* = 15$

CONCLUSIONS

This paper investigates the macroscopic free vibration behavior of a discrete granular system resting on a Winkler elastic foundation. It is shown that the discrete deflection equation of this granular system (Cosserat chain) is mathematically equivalent to the finite difference formulation of a shear deformable Bresse-Timoshenko beam resting on Winkler foundation. Next, the natural frequencies of such a granular model with simply supported ends are first analytically investigated, whatever considered modes through the resolution of a linear difference equation. The scale effects of the granular chain are clearly captured by the continuous gradient elasticity model. This scale effect is related to the grain size with respect to the total length of the Cosserat chain.

Summary The energy dissipation in assembled metal structures is mainly related to various physical phenomena on the contact surfaces. To evaluate the role of contact in damping and to find a connection between the contact-related increase of modal damping and the mode shapes, the modal damping ratios of a monolithic body and a shrink-fitted assembly are compared in this paper. Based on the experiments, a finite element model was developed that is able to reproduce the measured modal damping values of the assembled structure at all the natural frequencies in the frequency range of the measurement. Moreover, a dimensionless quantity is introduced that seems to correlate with the contact-related component of damping.

INTRODUCTION

The modal analysis of monolithic structures by finite element method belongs to the routine tasks. However, in case of assemblies, there is no off-the-shelf solution: on the one hand, there is the uncertainty of the contact stiffness, on the other hand, the modelling of contact-related damping is extremely challenging. The present paper focuses on the latter problem, by comparing the measured damping characteristics of a monolithic structure and a shrink-fitted assembly. Two disc-shaped test specimens with identical material properties and macroscopic geometry (see Figure 1) had been carefully designed and manufactured for the experiments.

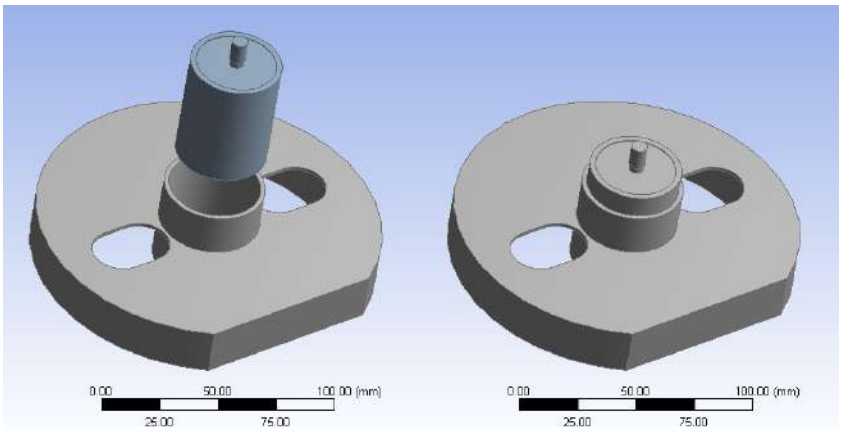

Figure 1: Test specimens. Left: shrink-fitted disc, right: monolithic disc.

An automated pneumatic ball shooter [1] was used for the excitation to ensure the initial conditions to be as identical as possible, while the vibrations were measured by lightweight accelerometers. Short-time Fourier transform was applied on the acquired acceleration signals, and the characteristic amplitude peaks – that had been identified by the finite element modal analysis of the monolithic disc – were traced during the decays.

EXPERIMENTAL RESULTS

The frequency range of the measurement made the analysis of the first five natural frequencies of both specimens possible. In Figure 2, the measured decays of the acceleration magnitudes are shown on a logarithmic scale for the first and the fifth natural frequencies. Different colours belong to different measurement locations, and solid lines represent the average decays. The fitted modal damping factors are listed in the legends of these charts.

As it can be seen, the damping was found to be linear in the whole range of the decay experiments. However, the corresponding damping factor values for the shrink-fitted disc are significantly higher compared to the monolithic specimen. The results also showed that the individual vibration modes are differently influenced by the contact damping.

Assuming that the dissipation at the contact surface depends on the local variation of stresses and strains, we found that an energy-like quantity may characterize the contact-related increase of damping. Thus, we defined a dimensionless strain energy $\tilde{u}_c$ as the ratio of a local strain energy in the neighbourhood of the contact surface and the total strain energy. $\tilde{u}_c$ could be calculated easily by the finite element analysis of the monolithic body for each vibration mode. The experimentally obtained relative increases of the damping ratio are plotted in Figure 3 versus the calculated values of $\tilde{u}_c$.

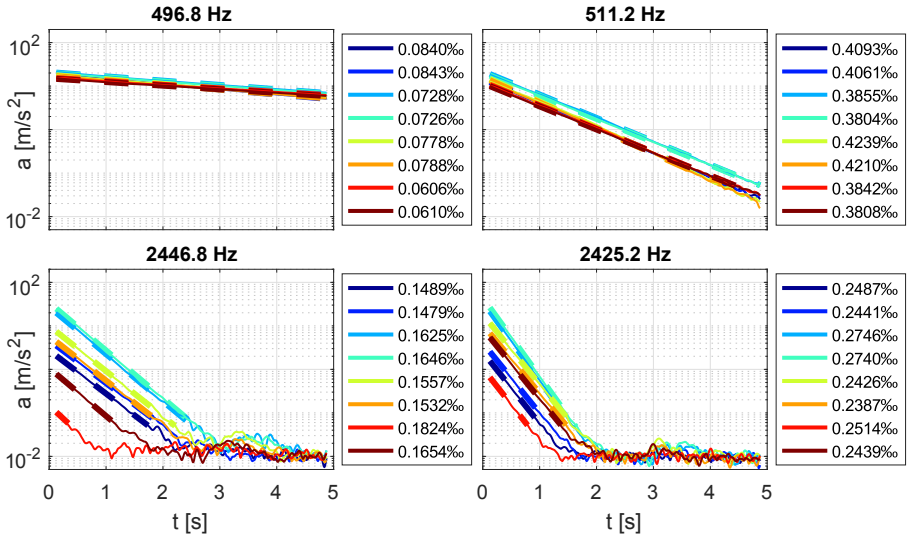

Figure 2: Free vibration decays of the acceleration magnitude peaks at eight points of the specimens. Left: monolithic disc, right: shrink-fitted assembly.

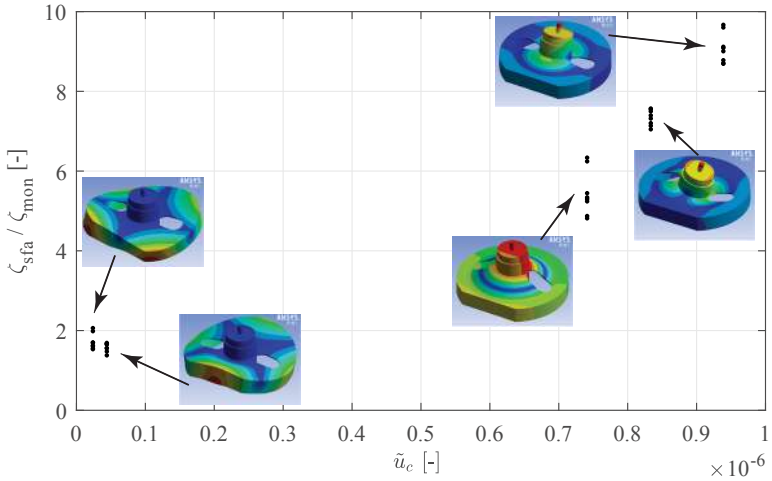

Figure 3: The measured increase in damping ratios due to contact versus the calculated dimensionless strain energy values for the first five modes. ζ_{sfa} and ζ_{mon} denote the damping ratios regarding to the shrink fitted assembly and the monolithic body, respectively.

CONCLUSIONS

The lowest vibration amplitudes that could be reliably measured were cca. 0.05 m/s^2 at 2450 Hz, hence the corresponding displacements were only cca. 200 pm = $2 \cdot 10^{-10}$ m. This value is in the order of magnitude of the atomic distances in the crystal structure. Even in the case of the first natural frequency, the smallest measured displacements were approximately 5 nm. Thus, a linear contact damping must be present besides the material damping even without macroscopic slips. We refer to this phenomenon as *quasi-slip*. To characterize the effect of contact on modal damping ratios, a dimensionless strain energy $\tilde{u}_{\mathrm{c}}$ was introduced. The correlation between the damping increase and $\tilde{u}_{\mathrm{c}}$ appears to be convincing, especially for relatively large values of $\tilde{u}_{\mathrm{c}}$. We claim that this result opens the possibility to predict how the individual modes are influenced by the contact damping.

STABILITY OF TURNING PROCESS ON WORKPIECE SUBJECTED TO TIME-PERIODIC COMPRESSION

Bence Beri*, Gergely Meszaros, and Gabor Stepan
Department of Applied Mechanics, Budapest University of Technology and Economics, Budapest, Hungary

Summary The paper investigates the stability of turning processes where the workpiece is subjected to time-periodic axial force. Based on the Euler-Bernoulli beam theory, the workpiece is modelled as a beam with clamped end at the chuck and pinned end at the tailstock. To increase the stable parameter domain of the cutting operation in turning processes, the beam is excited by periodic compression. This results in the periodic change of the lateral stiffness of the workpiece, which varies the natural frequency of the system, too. It is shown that it has a positive effect on chatter avoidance at low cutting speeds.

MOTIVATION

Surface regeneration is almost always present is machining, which often results in self-excited vibrations called chatter. Chatter generally degrades the surface of the workpiece and might also decrease the lifespan of the cutting tool. It may arise due to the compliance of the tool and/or the workpiece due to the occurring relative vibrations between the workpiece and the tool. The regeneration effect was first modelled by Tobias [1] via time-delay equations. The tool cuts the surface that was machined in the previous revolution, thus, the chip thickness is given by the difference of the present and the previous position of the workpiece. The delay is the time period of workpiece rotation.

In machining, to increase productivity without undesired vibrations, the so-called stability lobe diagram is considered. It helps the machinist to avoid chatter by modifying the corresponding technological parameters: the spindle speed Ω and the depth of cut w at a given feed rate. An effective manner is the periodic modulation of the spindle speed Ω around a certain mean value with a given frequency and amplitude. Spindle speed variation is also dependent on the type of the modulation waveform such as triangular [2] or sinusoidal [3]. Segalman *et.al.* [4] applied the method of impedance modulation where the mechanical impedance of the underlying system is varied continuously. It results in the change of the natural frequency of the system, which may lead to an extended stable parameter region.

The purpose of the study is to propose an alternative way to increase the chatter-free domain by the application of time-periodic compression to the rotating workpiece. The effect of compression is taken into account through the lateral stiffness variation of the workpiece. For constant compression, the lateral stiffness, and thus the natural frequency of the system decreases, which leads to the reduction of the stable parameter region [5]. However, when the compressive force is modulated periodically with an appropriate time period, the destabilising nature of compression can be overcome, and it can even improve the stability properties of the system for the lower spindle speeds relevant in turning.

The approach may become beneficial in case of cutting slender shafts or tubes having low bending stiffness. For higher spindle speeds, the effect of the periodic axial excitation converges to the case when only constant compression is applied. Consequently, the stability analysis of the material removal process in question has to be carried out to reveal the viable spindle speed ranges where cutting efficiency can be increased.

MODELLING AND ANALYSIS

A one degree-of-freedom mechanical model is constructed for turning slender workpieces. The workpiece is modelled by a stepped beam that is compliant in the y direction shown in Fig. 1(a). This represents the most common configuration of turning where the workpiece is clamped at the chuck and pinned at the tailstock [6]. The tool position is given with the parameter a measured from the chuck. The normal cutting force F_y acting on the workpiece has empirical formulas in practice: while it is linearly proportional to the depth of cut w, it has a nonlinear dependence on the chip thickness h. An approved cubic approximation is $F_y(t) = w(\rho_1 h(t) + \rho_2 h^2(t) + \rho_3 h^3(t))$ where ρ_i, $i = 1,2,3$ are the cutting force parameters [1]. The regeneration effect develops in the chip thickness h that is given by the present and the previous position of the flexible workpiece. Thus, $h(t) = h_0 + y(t-\tau) - y(t)$ where h_0 is the desired chip thickness and $\tau = 2\pi/\Omega$.

The periodic axial force F_a causes the stiffness variation of the workpiece. The workpiece is assumed to be an inextensible, linearly elastic and isotropic beam. Based on the Euler-Bernoulli beam theory, the point-by-point lateral stiffness k_y of the workpiece can be calculated analytically. The compression F_a affects the lateral stiffness of the system linearly: $k_y = k_0 + k_1(F_a - F_0)$ where k_0 and k_1 are constant coefficients and F_0 is a precompression, while $F_a = F_0 + F_1\cos(2\pi t/T)$ (see Fig. 1(a)) where F_1 is the amplitude of excitation and T is the time-period of excitation. All this leads to a time-periodic delay differential equation. The motion of the workpiece can be decomposed into $y(t) = y_p(t) + \eta(t)$ where y_p is a periodic solution, and η is the small perturbation. Accordingly, the variational system yields

$$\dot{\mathbf{q}}(t) = \begin{bmatrix} 0 & 1 \\ -\left(\frac{k_0 + w(\rho_1 + 2h_0\rho_2 + 3h_0^2\rho_3)}{m} + F_1\frac{k_1\cos\left(\frac{2\pi}{T}t\right)}{m}\right) & -\frac{c_y}{m} \end{bmatrix}\mathbf{q}(t) + \begin{bmatrix} 0 & 0 \\ \frac{w(\rho_1 + 2h_0\rho_2 + 3h_0^2\rho_3)}{m} & 0 \end{bmatrix}\mathbf{q}(t-\tau) \qquad (1)$$

THEMATIC SESSION SM

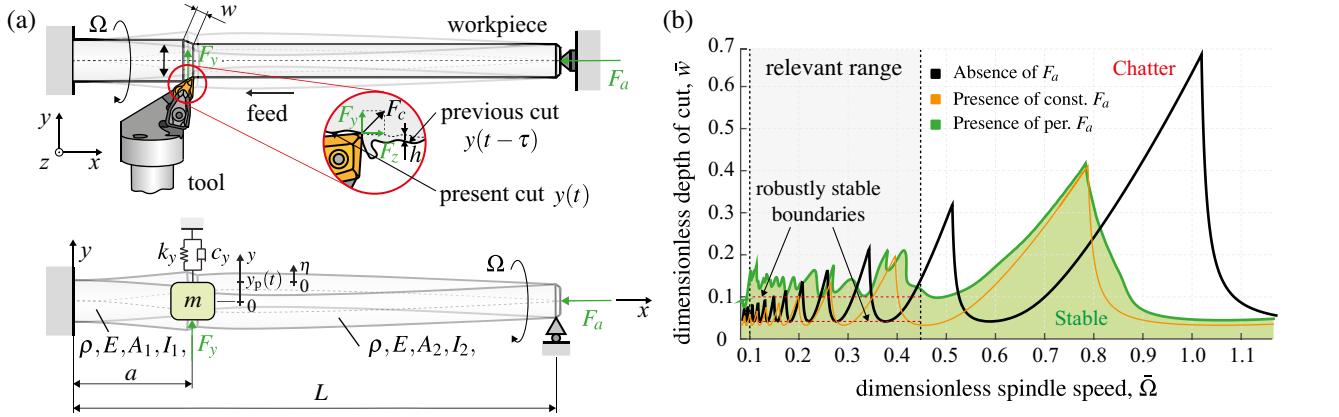

Figure 1: (a) 1 DoF dynamical model of turning process with flexible workpiece. (b) Stable parameter region of the material removal process for a certain tool position a and reliable precompression F_0.

where $\mathbf{q} = \mathrm{col}[\eta\ \dot{\eta}]$ is the state vector. It has to be noted that if τ and T are rationally dependent, the Floquet-theory can be applied [2, 7].

To identify the modal mass m of the workpiece at different tool positions a, the bending vibrations of a corresponding continuum beam model are investigated in the presence of a constant compression F_0. Since a one degree-of-freedom approximation is assumed in Fig 1(a), the first natural frequency of the system has to be fitted. It depends not only on the axial force but also on the cutting tool position because the length of the uncut segment of the workpiece changes.

The stability analysis of Eq. (1) is achieved by means of the semi-discretization method [7]. The dimensionless linearly stable parameter region of the operation can be seen in Fig. 1(b) where the lobe diagram indicated in black shows the stable domain in the absence of the axial force. When constant compression is applied, the natural frequency of the system decreases. It destabilizes the process in a way that the lobe diagram is shifted to the left and somewhat downward [5] (indicated in orange in Fig 1(b)). In contrast, when the compressive force is periodic about a precompression F_0 with a certain frequency, the stability boundary of the operation becomes more intricate (green region in Fig. 1(b)). While it does not mean too much for higher spindle speeds, a dedicated range can be found for operational turning where the compressive excitation predicts a reasonable increase in the size of the stable domain.

The lower envelope of the stability lobes represents robustly stable boundaries with respect to the spindle speed as shown in Fig. 1(b). For realistic parameters, the robust region is 2.5 times larger for periodic compression than for the non-compressed case.

CONCLUSIONS

The research presented was motivated by a novel option to achieve an increase in the stable parameter region for turning flexible workpieces. The workpiece is subjected to time-periodic compression. Even though compression has a destabilizing effect, periodic forcing improves the stability properties of the system. The results show that a dedicated parameter region can be proposed where high material removal rates can be attained for operational turning.

VIBRATION CHARACTERISTICS STUDY OF AIRCRAFT ELECTRIC BRAKE SQUEAL SYSTEM CONSIDERING MODALCOUPLING

Qiaozhi Yin*[1], Hong Nie[2], Xiaohui Wei[3] and Shuai Chen[4]
[1234]State Key Laboratory of Mechanics and Control of Mechanical Structures, Key Laboratory of Fundamental Science for National Defense-Advanced Design Technology of Flight Vehicle, Nanjing University of Aeronautics and Astronautics, Nanjing, P.R. China

Summary Based on the modal coupling theory, the rotor and stator contact stiffness and relative velocity are considered to build an electric aircraft brake dynamic system model in this study. The complex modal analysis is used to study the aircraft brake squeal performance and vibratory mechanism. Results show that the feed in energy is larger than the output energy in the brake rotor/stator module so that brake squeal takes place. Finally the transient dynamic analysis is adopted to verify the modeling approach and the complex modal analysis results.

INTRODUCTION

Aircraft brake squeal may cause the attrition and looseness of landing gear and brake components, influencing braking system security and passenger comfort[1]. Research on brake squeal performance and vibration system stability prediction can provide with theoretical foundation for the design of landing gear, braking system and system vibration reduction.

The complex modal analysis (CMA) and transient dynamic analysis (TDA) are usually used to study brake squeal[2]. Liu[3] built a set of perturbation equations of a hydraulic brake squeal system to study the vibration stability. Mercier[4] took the deviation of the relative velocities of each point at the interface into consideration and used springs to connect the rotors and the stators. The CMA is widely used in brake squeal study. But due to the difficulties in building a precise friction model between a rotor and a stator, the modal frequencies are not perfectly accurate. In this study, the contact stiffness and interface characteristics are considered to improve the accuracy of the brake squeal model.

The brake squeal model in TDA method is more precise but time consuming. A large amount of incrementation are used to calculate the motion states of every node in time domain. Nagy[5] proposed the TDA method to study brake squeal. The nonlinearity of brake pads interface is included. Sinou[6] adopted both stability and nonlinear TDA methods and pointed out that new fundamental frequencies can emerge due to the nonlinear contact of a frictional interface. Oberst[7] built a numerical model of a disc brake system to study the in-plane pad vibrations and the out-of-plane disc mode.

In this study, the aircraft electric brake squeal is analyzed. The rotor and stator contact stiffness and relative velocity are considered based on the modal coupling theory. Both the CMA and the TDA are applied to study the aircraft electric brake squeal mechanism.

AIRCRAFT ELECTRIC BRAKE SQUEAL MODEL

Aircraft electric brake mechanism consists of an electric actuator and a rotor/stator module, shown in Fig.1. The brake pressure P_b produced by the motor acts on the rotor/stator module to generate brake torque M_b. Brake squeal occurs during this braking process, resulting from the friction and relative motion at the interface of the rotors and stators. The modal coupling is considered so that a set of springs K_b connecting a rotor and a stator is built to simulate the interaction force in the brake squeal model. After discretizing the brake pads, the friction force matrix $\boldsymbol{F_f}$ can be expressed as:

$$\boldsymbol{F}_f = \mu_b \boldsymbol{P}_b + \mu_b K_b (\boldsymbol{U}_{sn} - \boldsymbol{U}_{rn}) \tag{1}$$

where, μ_b is the frictional coefficient. $\mu_b \boldsymbol{P_b}$ is the external excitation. $\boldsymbol{U_{sn}}$-$\boldsymbol{U_{rn}}$ is the relative displacement of the rotor and stator along the wheel axial direction. Therefore, the brake squeal dynamic model of a local mass block is:

$$\boldsymbol{MU} + \boldsymbol{CU} + (\boldsymbol{K} - \boldsymbol{K}_F)\ \boldsymbol{U} = 0 \tag{2}$$

where, $\boldsymbol{M}$, $\boldsymbol{C}$ and $\boldsymbol{K}$ are mass, damping and stiffness matrixes respectively. $\boldsymbol{U}$ is the nodal displacement vector. $\boldsymbol{K_F}$ is the coupling stiffness matrix, indicating the relationship between $\boldsymbol{F_f}$ and $\boldsymbol{U}$. $\boldsymbol{K_F}$ couples the nodal axial displacement and tangential friction force, thus $\boldsymbol{K}$-$\boldsymbol{K_F}$ is asymmetric. The aircraft brake rotor/stator FE model is illustrated in Fig. 2. Figure 3 shows the brake pressure distributes unevenly when braking and the separation takes place at the edge of the pads.

COMPLEX MODAL ANALYSIS

The system natural frequencies and the complex eigenvalues are obtained by complex modal analysis. The results are demonstrated in Fig. 4. If the real part of a complex eigenvalue is positive, the damping ratio is negative, indicating that the vibration system is unstable and brake squeal will occur. The modes with damping ratio ξ<-0.01 are regarded as the unstable modes. Figure 4 shows 21 unstable modes that may lead to brake squeal, among which most unstable modes are located at the frequencies of 4500Hz, 7300Hz, 8000Hz, 9700Hz and 11200Hz. Since the modal coupling exists in the brake squeal system, the intervals between these frequencies are different. In addition, the second-order modal frequency is much higher than that of the first-order.

The modal analysis is conducted and some typical unstable vibration modes are shown in Fig. 5. The out-of-plane vibration plays an important role in these modes. Only when the modal frequency is about 7574Hz, the pads vibrate with node-circles. At other frequencies lower than 10kHz, all the brake pads vibrate with 4-6 node-diameters. As the frequency increases, the vibration modes become more complex. The node-diameters increase and the modes among each pad are various. Therefore, the wheel axial direction modal coupling mainly results in aircraft brake squeal. From the perspective of modal coupling, the feed in energy is larger than the output energy in the system, so brake squeal finally takes place.

TRANSIENT DYNAMIC ANALYSIS

The TDA method is used to verify the correctness of the CMA results. The FE model is built considering the nonlinearities. The diagonal concentrated mass matrix and the central difference method are adopted to solve the vibration system responses. The reference points (RPs) on the rotor/stator and the reference frame are shown in Fig. 2. The vibrations along the y- and z-directions are slight, while the brake squeal appears along the x-direction. Figure 6 illustrates the x-directional displacement of RP on the stator. The results indicate that the squeal takes place mainly out of the plane, which is consistent with the CMA results. The amplitude-frequency curve in Fig. 6(b) shows that except a 13000Hz modal frequency appearing in TDA, the other modal frequencies all match the results in Fig. 4. This indicates that the aircraft brake dynamic system model considering the modal coupling can predict the brake squeal relatively accurately.

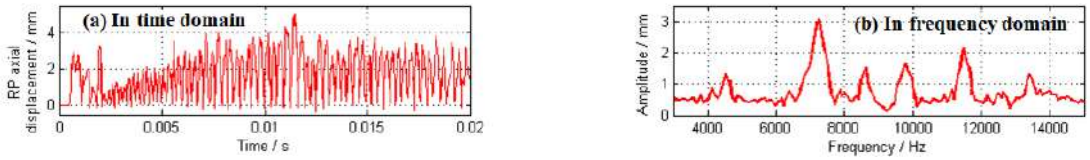

Figure 6. Transient dynamics analysis results.

CONCLUSIONS

The aircraft electric brake squeal system is studied based on the modal coupling theory. Both the CMA and the TDA are carried out to study the vibration performance. Results show that the brake dynamic model considering the modal coupling can predict the brake squeal relatively accurately. The vibration suppression methods will form part of our future work.

NON-AXISYMMETRIC FREE VIBRATIONS OF A SPHERICAL SHELL UNDER PRESSURE

Suresh Shrivastava
Department of Civil Engineering, McGill University, Montreal, Quebec, Canada

Summary In a recent conference paper, Shrivastava [1], has derived the non-axisymmetric mode shapes and frequencies of a complete composite spherical shell under external or internal uniform pressure. The exact analysis took into account the transverse shear deformations and the rotary inertias. The analysis here is again exact, but is simpler by restricting it to homogeneous shell and neglecting the last two effects. Multiple non-axisymmetric modes exist for single frequencies.

1 INTRODUCTION

Many papers have appeared on the subject of frequencies of axisymmetric vibrations of thin elastic spherical shells beginning with the work of Lamb in 1893. Here, general frequencies and mode shapes are derived for a homogeneous elastic spherical shell under an all-around pressure. Transverse shear deformations and rotary inertia effects are neglected.

2 GOVERNING EQUATIONS, THEIR SOLUTION, DISCUSSION AND CONCLUSIONS

Let ϕ,θ,z be the meridional (+ zenith to nadir), azimuthal (+ counter clockwise), and radial (+ outward normal) coordinates of a shell point. The ratio of thickness h to the middle surface radius R is small. Let the coordinate displacements from equilibrium, after the uniform pressure is applied, be:

$$u(\phi,\theta)-z\alpha(\phi,\theta),v(\phi,\theta)-z\beta(\phi,\theta),w(\phi,\theta)$$

where u,v,w and α,β are the amplitudes of the middle surface displacements and rotations. The actual quantities are the amplitudes multiplied with $e^{i\omega t}$ where ω is a natural frequency. The displacement gradient and strain matrices are:

$$[L]=\begin{pmatrix} \frac{\partial u}{Rd\varphi}-z\frac{\partial\alpha}{Rd\varphi}+\frac{w}{R} & \frac{\partial u}{R\sin\phi d\theta}-z\frac{\partial\alpha}{R\sin\phi d\theta}-\frac{\cot\phi}{R}(v-z\beta) & -\alpha \\ \frac{\partial v}{R\partial\phi}-\frac{z\partial\beta}{R\partial\phi} & \frac{\partial v}{R\sin\phi\partial\theta}-z\frac{\partial\beta}{R\sin\phi\partial\theta}+\frac{\cot\phi}{R}(u-z\alpha)+\frac{w}{R} & -\beta \\ \frac{\partial w}{R\partial\phi}-\frac{u}{R} & \frac{\partial w}{R\sin\phi\partial\theta}-\frac{v}{R} & 0 \end{pmatrix}$$ and

$$[\varepsilon]=\begin{pmatrix} \frac{\partial u}{Rd\varphi}-z\frac{\partial\alpha}{Rd\varphi}+\frac{w}{R} & \frac{\partial u}{R\sin\phi d\theta}-z\frac{\partial\alpha}{R\sin\phi d\theta}-\frac{\cot\phi}{R}(v-z\beta) & 0 \\ \frac{\partial v}{R\partial\phi}-\frac{z\partial\beta}{R\partial\phi} & \frac{\partial v}{R\sin\phi\partial\theta}-z\frac{\partial\beta}{R\sin\phi\partial\theta}+\frac{\cot\phi}{R}(u-z\alpha)+\frac{w}{R} & 0 \\ \alpha=\frac{\partial w}{R\partial\phi}-\frac{u}{R} & \beta=\frac{\partial w}{R\sin\phi\partial\theta}-\frac{v}{R} & 0 \end{pmatrix}$$

where $[\varepsilon]=([L]^T+[L])/2$. The rotations $\alpha=(\partial w/R\partial\phi)-(u/R)$ and $\beta=(\partial w/R\sin\phi\partial\theta)-(v/R)$ have been chosen to render the transverse shear strains zero. The stresses due to pressure q are equi-biaxial compression (or tension) $P=h\sigma^o_{\phi\phi}=h\sigma^o_{\theta\theta}=qR/2$. For isotropic elastic shells, the additional stresses due to the above strains are $\sigma_{\phi\phi}=B\varepsilon_{\phi\varphi}+C\varepsilon_{\theta\theta},\sigma_{\theta\theta}=C\varepsilon_{\phi\varphi}+B\varepsilon_{\theta\theta},\sigma_{\phi\theta}=2F\varepsilon_{\phi\theta},\sigma_{zz}=\varepsilon_{\phi z}=\varepsilon_{\theta z}=\varepsilon_{zz}=0$ where $B=E/(1-\nu^2),C=\nu E/(1-\nu^2),$ $F=E/2(1+\nu),B-C=2F$, $\rho_a=\rho h$, where ρ is the mass density. $B_a=Bh,B_b=\frac{B_a}{12}$ etc. Washizu's formula gives the equilibrium equations $\int_V\{tr(([\sigma^o][L]^T[\delta L])+[\sigma][\delta L])\}dV=0$, δ denotes variation. D'Alembert's principle yields, the vibration equations, where ω is a natural frequency:

$$-\frac{\partial N_{\phi\phi}}{\partial\phi}-\cot\phi(N_{\phi\phi}-N_{\theta\theta})-\frac{\partial N_{\phi\theta}}{\sin\phi\partial\theta}-Q_\phi+P\{(\nabla^2-\cos ec^2\phi)\frac{u}{R}-2\frac{\cot\phi}{R\sin\phi}\frac{\partial v}{\partial\theta}+2\frac{\partial w}{R\partial\varphi}\}-R\rho_a\omega^2u=0,$$

$$-\frac{1}{\sin\phi}\frac{\partial N_{\theta\theta}}{\partial\theta}-\frac{\partial N_{\phi\theta}}{\partial\phi}-2\cot\phi N_{\phi\theta}-Q_\theta+P\{(\nabla^2-\cos ec^2\phi)\frac{v}{R}+2\frac{\cot\phi}{R\sin\phi}\frac{\partial u}{\partial\theta}+\frac{2}{R\sin\phi}\frac{\partial w}{\partial\theta}\}-R\rho_a\omega^2v=0,$$

$$-\frac{1}{\sin\phi}\frac{\partial Q_\phi\sin\phi}{\partial\phi}-\frac{1}{\sin\phi}\frac{\partial Q_\theta}{\partial\theta}+N_{\phi\phi}+N_{\theta\theta}+P\{(\nabla^2-2)\frac{w}{R}-\frac{2}{R}\frac{\partial u}{\partial\phi}-2\cot\phi\frac{u}{R}-\frac{2}{R\sin\phi}\frac{\partial v}{\partial\theta}\}-R\rho_a\omega^2w=0$$

where the stress resultants are:

$$N_{\phi\phi}=C_a\cot\phi\frac{u}{R}+(B_a+C_a)\frac{w}{R}+C_a\frac{\partial v}{R\sin\phi\partial\theta}+B_a\frac{\partial u}{R\partial\phi},N_{\theta\theta}=B_a\cot\phi\frac{u}{R}+(B_a+C_a)\frac{w}{R}+B_a\frac{\partial v}{R\sin\phi\partial\theta}+C_a\frac{\partial u}{R\partial\phi},,$$

$$N_{\phi\theta}=F_a(\cot\phi\frac{v}{R}+\frac{w}{R}+\frac{\partial u}{R\sin\phi\partial\theta}+\frac{\partial v}{R\partial\phi}),M_{\phi\theta}=\frac{h^2}{R}F_b(\frac{\partial u}{R\sin\phi\partial\theta}+\frac{\partial v}{R\partial\phi}+\cot\phi\frac{v}{R}+\frac{2\cot\phi\partial w}{R\sin\phi\partial\theta}-\frac{2\partial^2w}{R\sin\phi\partial\theta\partial\phi}),$$

$$M_{\phi\phi}=\frac{h^2}{R}(C_b\cot\phi\frac{u}{R}+C_b\frac{\partial v}{R\sin\phi\partial\theta}-C_b\frac{\partial^2w}{R\sin^2\phi\partial\theta^2}+B_b\frac{\partial u}{R\partial\phi}-C_b\cot\phi\frac{\partial w}{R\partial\phi}-B_b\frac{\partial^2w}{R\partial\phi^2}),$$

$$M_{\theta\theta}=\frac{h^2}{R}(B_b\cot\phi\frac{u}{R}+B_b\frac{\partial v}{R\sin\phi\partial\theta}-B_b\frac{\partial^2w}{R\sin^2\phi\partial\theta^2}+C_b\frac{\partial u}{R\partial\phi}-B_b\cot\phi\frac{\partial w}{R\partial\phi}-C_b\frac{\partial^2w}{R\partial\phi^2}),$$

$Q_\phi=\frac{\partial M_{\phi\phi}}{R\partial\phi}+\frac{1}{R\sin\phi}\frac{\partial M_{\phi\theta}}{\partial\theta}+(M_{\phi\phi}-M_{\theta\theta})\frac{\cot\phi}{R},Q_\theta=\frac{1}{R\sin\phi}\frac{\partial M_{\theta\theta}}{\partial\theta}+\frac{\partial M_{\phi\theta}}{R\partial\phi}+\frac{2\cot\phi}{R}M_{\phi\theta}$ $\nabla^2=\frac{\partial^2}{\partial\phi^2}+\cot\phi\frac{\partial}{\partial\phi}+\frac{1}{\sin^2\phi}\frac{\partial^2}{\partial\theta^2}$ is the Legendre operator. Substitution in the vibration equations gives the three governing equations in the variables u,v,w:

$$(-2F_a-2\frac{h^2}{R^2}F_b+B_a\cos ec^2\phi+\frac{h^2}{R^2}B_b\cos ec^2\phi)u-(F_a+\frac{h^2}{R^2}F_b)\frac{\partial^2u}{\sin^2\phi\partial\theta^2}-\frac{h^2}{R^2}B_b\frac{1}{\sin\phi}\frac{\partial}{\partial\phi}\sin\phi\frac{\partial u}{\partial\phi}-B_a\frac{1}{\sin\phi}\frac{\partial}{\partial\phi}\sin\phi\frac{\partial u}{\partial\phi}-R^2\rho_a\omega^2u+$$

$$(\frac{h^2}{R^2}(B_b+F_b)+(B_a+F_a))\frac{\cot\phi}{\sin\phi}\frac{\partial v}{\partial\theta}+\frac{h^2}{R^2}(-B_b+F_b-B_a+F_a)\frac{1}{\sin\phi}\frac{\partial^2v}{\partial\phi\partial\theta}-\frac{h^2}{R^2}2B_b\frac{Cot\phi}{\sin^2\phi}\frac{\partial^2w}{\partial\theta^2}-(2B_b-2F_a-2F_b\frac{h^2}{R^2})\frac{\partial w}{\partial\phi}-\frac{h^2B_b}{R^2}\frac{1}{\sin^2\phi}\frac{\partial w}{\partial\phi}$$

$$+\frac{h^2B_b}{R^2}\frac{1}{\sin^2\phi}\frac{\partial^3w}{\partial\theta^2\partial\phi}+\frac{1}{\sin\phi}\frac{\partial}{\partial\phi}(B_b\frac{h^2}{R^2}\sin\phi\frac{\partial^2w}{\partial\phi^2})+P\{(\nabla^2-\csc^2\phi)u-2\frac{\cot\phi}{\sin\phi}\frac{\partial v}{\partial\theta}+2\frac{\partial w}{\partial\phi}\}=0$$

$$(-\frac{h^2B_b}{R^2}-\frac{h^2F_b}{R^2}-B_a-F_a)\frac{\cot\phi}{\sin\phi}\frac{\partial u}{\partial\theta}+(-\frac{h^2B_b}{R^2}+\frac{h^2F_b}{R^2}-B_a+F_a)\frac{1}{\sin\phi}\frac{\partial^2 u}{\partial\phi\partial\theta}-\rho\omega^2 v-2F_a v-\frac{2h^2F_b}{R^2}v-\frac{h^2B_b}{R^2}\frac{1}{\sin^2\phi}\frac{\partial^2 v}{\partial\theta^2}-B_a\frac{1}{\sin^2\phi}\frac{\partial^2 v}{\partial\theta^2}-F_a\frac{\partial^2 v}{\partial\phi^2}-F_a\cot\phi\frac{\partial v}{\partial\phi}+\frac{F_a}{\sin^2\phi}v-$$
$$\frac{h^2F_b}{R^2}\frac{\partial^2 v}{\partial\phi^2}-\frac{h^2F_b}{R^2}\cot\phi\frac{\partial v}{\partial\phi}+\frac{h^2F_b}{R^2}\cos ec^2\phi v++\frac{2h^2B_b}{R^2}\frac{\cot\phi}{\sin\phi}\frac{\partial^2 w}{\partial\phi\partial\theta}+\frac{2h^2F_b}{R^2}\frac{\cot\phi}{\sin\phi}\frac{\partial^2 w}{\partial\phi\partial\theta}+2(\frac{h^2F_b}{R^2}-B_a+F_a)\frac{1}{\sin\phi}\frac{\partial w}{\partial\theta}+(\frac{h^2B_b}{R^2}\frac{1}{\sin^3\phi}\frac{\partial^3 w}{\partial\theta^3})(-2F_a-2\frac{h^2}{R^2}F_b+B_a\cos ec^2\phi+$$
$$\frac{h^2}{R^2}B_b\cos ec^2\phi)u-(F_a+\frac{h^2}{R^2}F_b)\frac{\partial^2 u}{\sin^2\phi\partial\theta^2}-\frac{h^2}{R^2}B_b\frac{1}{\sin\phi}\frac{\partial}{\partial\phi}\sin\phi\frac{\partial u}{\partial\phi}-B_a\frac{1}{\sin\phi}\frac{\partial}{\partial\phi}\sin\phi\frac{\partial u}{\partial\phi}-R^2\rho_a\omega^2 u+P\{(\nabla^2-\csc^2\phi)v+2\frac{\cot\phi}{\sin\phi}\frac{\partial u}{\partial\theta}+2\frac{\partial w}{\sin\phi\partial\theta}\}=0$$

$$-\frac{h^2}{R^2}B_b\frac{\partial^3 u}{\partial\phi^3}-\frac{2h^2B_b}{R^2}\cot\phi\frac{\partial^2 u}{\partial\phi^2}+(-\frac{2h^2F_b}{R^2}+2B_a-2F_a+\frac{h^2B_b}{R^2}+\frac{h^2B_b}{R^2}\cos ec^2\phi)\frac{\partial u}{\partial\phi}+(-\frac{2h^2F_b}{R^2}+2B_a-2F_a-\frac{h^2B_b}{R^2}\cos ec^2\phi)\cot\phi u-\frac{h^2B_b}{R^2}\cos ec^2\phi\frac{\partial^3 u}{\partial\phi\partial\theta^2}+(-\frac{2h^2F_b}{R^2}+2B_a-2F_a$$
$$-\frac{h^2B_b}{R^2}\cos ec^2\phi)\cot\phi u-\frac{h^2B_b}{R^2{}_b}\cos ec^2\phi\frac{\partial^3 u}{\partial\phi\partial\theta^2}-\frac{h^2B_b}{R^2{}_b\sin^2\phi}\frac{\cot\phi}{\partial\theta^2}\frac{\partial^2 u}{\partial\theta^2}-\frac{h^2B_b}{R^2{}_b}\frac{1}{\sin\phi}\frac{\partial^3 v}{\partial\theta\partial\phi^2}-\frac{h^2B_b}{R^2}\frac{1}{\sin^3\phi}\frac{\partial^3 v}{\partial\phi^3}+\frac{h^2B_b}{R^2}\frac{\cot\phi}{\sin\phi}\frac{\partial^2 v}{\partial\phi\partial\theta}+\frac{2h^2F_b}{R^2}\frac{\cot\phi}{\sin\phi}\frac{\partial^2 v}{\partial\phi\partial\theta}+(-\frac{2h^2F_b}{R^2}+2B_a-2F_a-$$
$$\frac{h^2B_b}{R^2}\cos ec^2\phi)\cos ec\phi\frac{\partial v}{\partial\theta}+\frac{h^2B_b}{R^2}\frac{\partial^4 w}{\partial\phi^4}+\frac{2h^2B_b}{R^2}\cot\phi\frac{\partial^3 w}{\partial\phi^3}+(-\frac{2h^2B_b}{R^2}+-\frac{2h^2F_b}{R^2})\frac{\partial^2 w}{\partial\phi^2}+(+\frac{h^2B_b}{R^2}+\frac{2h^2F_b}{R^2}++\frac{2h^2F_b}{R^2}\sin^2\phi)\frac{\cot\phi}{\sin^2\phi}\frac{\partial w}{\partial\phi}+\frac{h^2B_b}{R^2\sin^4\phi}\frac{\partial^4 w}{\partial\theta^4}+\frac{2h^2B_b}{R^2\sin^2\phi}\frac{\partial^4 w}{\partial\phi^2\partial\theta^2}-$$
$$\frac{2h^2B_b}{R^2}\frac{\cot\phi}{\sin^2\phi}\frac{\partial^3 w}{\partial\phi\partial\theta^2}+(\frac{2h^2B_b}{R^2}\cot^2\phi+\frac{2h^2B_b}{R^2}\cos ec^2\phi+\frac{2h^2F_b}{R^2}\cos ec^2\phi)\frac{1}{\sin^2\phi}\frac{\partial^2 w}{\partial\theta^2}+(4B_a-4F_a)w-R^2\rho\omega^2 w+P\{(\nabla^2-2)w-2\frac{\partial u}{\partial\phi}-2u\cot\phi-2\frac{\partial v}{\sin\phi\partial\theta})=0$$

Separation of variables can be made: $u(\phi,\theta)=u'(\phi)\cos(m\theta), v(\phi,\theta)=v'(\phi)\sin(m\theta), w(\phi,\theta)=w'(\phi)\cos(m\theta)$ where m is an integer. This results in three ordinary differential equations in ϕ. Equations belonging to u', v' can be manipulated (1) by eliminating w' from them, and (2) by forming an equation with terms like $\nabla^2 w'$ in it. A function $\chi(\phi)$ such that $u'(\phi)=\frac{d\chi(\phi)}{d\phi}, v'(\phi)=-\frac{m\chi(\phi)}{\sin(\phi)}$ satisfies the newly formed first equation identically. The second new equation and the old third equation are now the two homogeneous equations in variables χ and w', In matrix form:

$$\begin{pmatrix} -(\frac{h^2B_b}{R^2}+B_a-P)\nabla^4-(\frac{2h^2F_b}{R^2}+2F_a+R^2\rho_a\omega^2)\nabla^2 & \frac{h^2B_b}{R^2}\nabla^4+2(\frac{h^2F_b}{R^2}+F_a-B_a+P)\nabla^2 \\ -\frac{h^2B_b}{R^2}\nabla^4-2(\frac{h^2F_b}{R^2}+F_a-B_a+P)\nabla^2 & \frac{h^2}{R^2}B_b\nabla^4+(2\frac{h^2}{R^2}F_b+P)\nabla^2+4B_a-4F_a-2P-R^2\rho_a\omega^2 \end{pmatrix}\begin{pmatrix}\chi\\ w\end{pmatrix}=\begin{pmatrix}0\\0\end{pmatrix}$$

For a non-trivial solution, let $\chi=A_1P_m^n(\cos\phi), w=A_2P_m^n(\cos\phi)$ where A_1, A_2 are arbitrary constants, and $P_m^n(\cos\phi)$ are the Associated Legendre Functions. These have the property that $\nabla^2P_m^n(\cos\phi)=-\mu, \nabla^4P_m^n(\cos\phi)=\mu^2, \mu=n(n+1)$. Thus, the mode shapes clearly satisfy the above equations. The frequency equation (the determinant of the above matrix) contains only μ, i.e. only n but not m. The frequencies are independent of m as long as $0\le m\le n$. Frequencies obtained by presuming only the axisymmetric deformations ($m=0$) are therefore correct. For any $m>n$, the Associated Legendre Function is zero. Thus for every n^{th} frequency there are $n+1$ distinct modes, n non-axisymmetric and always one axisymmetric. For any one frequency, a linear combination of all permissible modes can appear simultaneously. The figure below shows the modes for $P=0$ and $n=12$, four distinct modes out of the possible 13 are shown.

For $n=\mu=m=P=0$, the vibration is purely radial with the frequency exactly that in Love. For $n=1$,regardless of the pressure, $\omega=0$, signifying two rigid body modes, one axisymmetric and the other non-axisymmetric. The present frequencies are compared with the axisymmetric theoretical results, and their experimental results given in Duffey et al. [2]. The experiments were done for a steel shell with $R=4.4688$ in, $h=0.0625$ in, psi, $\rho=0.000751$ lbf-sect/in^4, $E=28\times10^6$ psi, $\nu=0.28$ and $P=0$ were employed. As seen in Table 1, the present theoretical results match the reported ones, exactly with the refined analysis [1]. The theoretical results agree quite well with the experiments. Table 2 shows the frequencies under $\sigma_{\phi\phi}^o=\sigma_{\theta\theta}^o=15{,}000$ psi. Results are as expected; the frequencies increase with internal pressure and decrease with the external one. The conclusion is that the results of the present simpler theory are quite good.

Table 1. Theoretical and experimental verification, frequencies in Hz

ON THE CAUSE OF DISAGREEMENT BETWEEN SIMULATED AND EXPERIMENTAL RESULTS FOR THE STABILITY PROBLEM OF INVERTED STABILIZED PENDULUMS (BASED ON NATURE PAPER BY D. ACHESON, T. MULLIN)

Vladimir A. Gribkov* and Yaroslav D. Gordin
Department of Aerospace Systems,
Bauman Moscow State Technical University (National Research University), Moscow, Russia

Abstract This paper determined the cause of strong disagreement between simulated and experimentally determined regions of stability of inverted stabilized pendulums presented in a well-known Nature paper by D. Acheson and T. Mullin. The reason is a large error of experimental determination of higher natural frequencies of the double and triple pendulums using parametric resonance. The regions of stability determined using D. Acheson's pendulum theorem based on the corrected simulated natural frequencies have better agreement with the experimentally determined regions of stability. Additional experimental verification was done using pendulums with parameters different from those used by D. Acheson and T. Mullin. The verification confirmed the correctness of the proposed cause of disagreement and validated the D. Acheson theorem.

One of the most known papers devoted to the experimental investigation of the stability of vibration stabilized inverted pendulums is the paper by D. Acheson, T. Mullin published in Nature [1].

Although this paper was published a long ago, it is still one of the most reputable experimental investigations of the systems of this class. The goal of that study was to do an experimental verification of the pendulum theorem [2] proposed by D. Acheson.

Single, double, and triple inverted pendulums, which are parametrically stabilized by harmonic oscillations of the pivot axes, were chosen as study subjects in [1]. Fig. 1a shows the stability diagram made based on the results of [1]. This diagram is plotted as dimensionless amplitude excitation parameter vs. dimensionless frequency parameter.

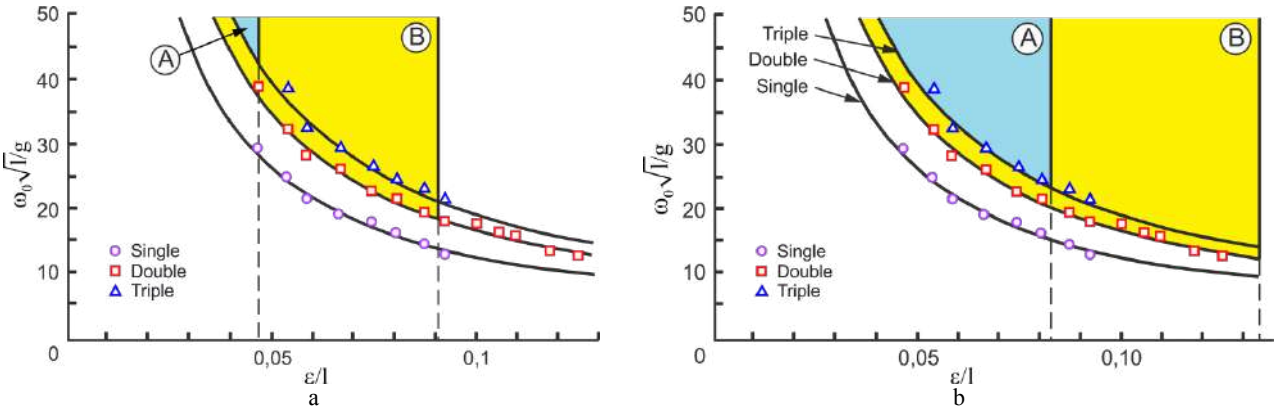

Figure 1. Calculated and experimental regions of stability of three pendulums from the paper by D. Acheson and T. Mullin; (a) – using data from [1], (b) – using refined parameters

The calculated stability boundaries were obtained using the pendulum theorem, and they are in good agreement with a set of experimental points (markers) on the quasi-static boundary of the stability region for a single, double, and triple pendulums. These are the left stability region boundary curves. Fig. 1a also shows two straight right boundary lines, which were also obtained using the pendulum theorem. When the right straight boundary lines are crossed, the double and triple pendulums lose dynamic stability (dynamic boundary line). The calculated results for plotting the second (dynamic) boundary line of the stability region were given in [1], but they were not shown at the stability diagram. In Fig. 1a, the stability regions of the triple and double pendulums are denoted as Region A (blue fill) and Region B (yellow fill), accordingly.

Based on results obtained by D. Acheson and T. Mullin, the pendulum theorem was not confirmed experimentally. Most of the experimental results for the double pendulum and all results for the triple pendulum lie beyond the boundaries of the calculated region of stability (Fig. 1a).

According to the pendulum theorem, the boundary lines of the region of stability are determined from natural frequencies of the pendulums in the gravity field in the natural (lower non-inverted) position with a stationary pivot axis. The quasi-static boundary lines are determined by the lowest pendulum natural frequency, and the dynamic boundary line is determined by the highest natural frequency. In [1], these frequencies were determined experimentally using parametric resonance.

The strong disagreement between the calculated and experimental regions of stability in [1] might have been caused by the error of measuring higher natural frequencies via parametric resonance. The assumption can be tested by calculating these natural frequencies of the pendulums. However, some of the pendulums' parameters required for the calculation were not given in [1]. The missing parameters (material properties of links and pivots, geometric and

*Corresponding author. E-mail: zenit-ab@mail.ru.

physico-mechanical parameters of the pendulums' elements) were obtained from the simulation in SolidWorks (SW) and MSC.Adams. Tables 1 and 2 present the refined parameters used for calculations. The parameters are denoted as follows: m_i – pendulum link mass; l_i – pendulum link length; l_{ci} – distance from link pivot to the link's center of mass; I_i – link's moment of inertia about its center of mass. Table 2 presents lower/higher natural frequencies determined using refined and restored pendulums' parameters.

Table 1. Pendulums' links' parameters

Link number	m_i, g	l_i, mm	l_{ci}, mm	I_i, g/mm^2
1	19.164	190	111.411	112848.476
2	19.164	190	111.411	112848.476
3	11.846	184	64.066	43034.804

Table 2. Natural frequencies

Number of links	Experiment, Hz	Modeling in SW, Hz
1	1.227	1.288
2	0.935/2.510	0.927/2.094
3	0.824/3.660	0.829/2.654

Fig. 1b shows the calculated boundary lines of the stability regions for the double and triple pendulums. The calculation results were obtained based on refined values of natural frequencies. It is evident that all experimental points for the double pendulum (Region A) and most of the points for the triple pendulum (Region B) are on the boundaries of the corresponding stability regions. The agreement between the calculated and experimental stability regions validates the pendulum theorem.

For additional verification of the pendulum theorem and harmonizing the boundaries of the calculated and experimental regions of stability, we used the results obtained in [3]. The results were obtained for the single, double, and triple (See Fig. 2a) pendulums with parameters given in [3]. The stability diagrams of dimensional frequency vs. amplitude of the pendulum's pivot axis are shown in Fig. 2(b-d). Here, the X-axes represent the excitation amplitude in mm, and the Y-axes represent the parametric excitation frequency in Hz. The calculated results are plotted with lines, and the experimental results are plotted with markers. The regions of stability are filled.

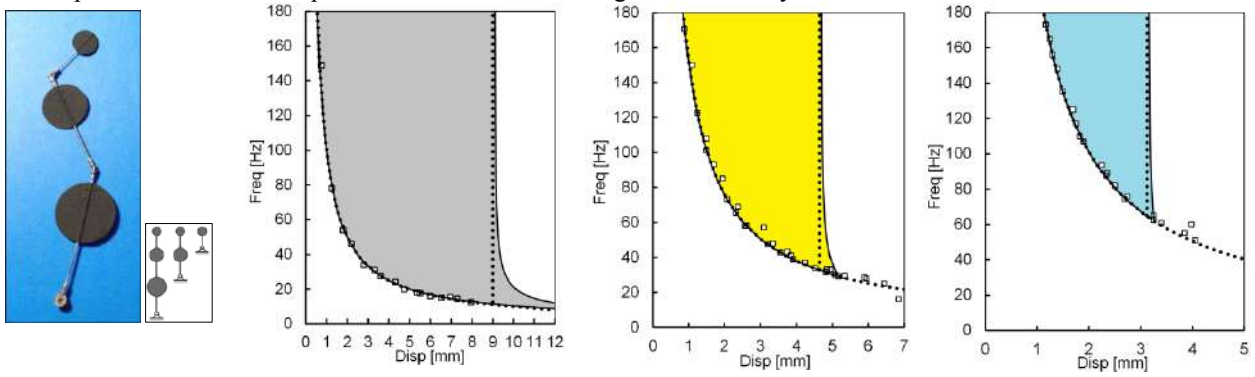

Figure 2. Stability regions of three pendulums: single (b), double (c) and triple (d)

The calculated results were obtained using the pendulum theorem (dotted line) and the method described in [4] (solid line). For the left (quasi-static) boundary line, the results coincide. For the right (dynamic) boundary, the results obtained with the pendulum theorem somewhat differ from the results obtained in [4]. The agreement between the calculated and experimental results is good. For the left boundary, they practically coincide, except for several experimental points for the double and triple pendulum, which have crossed the calculated stability region. This phenomenon is probably caused by neglecting dissipation in the system during simulations.

MULTI BALLS ROTATING IN A CIRCULAR TRACK EFFICIENTLY MITIGATE FLOW-INDUCED VIBRATIONS

Summary Galloping, as a critical type of flow-induced vibration (FIV), has a destructive effect on different structures subjected to wind. In this paper, we introduce a simple, low-cost device able to absorb the energy of vibrating structures and reduces its galloping amplitudes. This purely nonlinear energy sink (NES) consists of multi balls rotating freely in a circular track without direct coupling with the primary system. We assess the benefit of the proposed NES in mitigating galloping of a square prism through wind tunnel tests. NES balls rotate due to dynamic interaction with the vibrating structure providing a way of nonlinear energy absorption, enhanced by ball impacts in a multi-ball NES. We test different NES configurations varying the number of NES balls to demonstrate the effect of the balls' number. Whereas a single ball NES with a mass 8% that of the prism can increase the reduced velocity of large-amplitude galloping by 68%, a 2 or 3-ball NES of the same total mass increases this critical velocity by 87%.

INTRODUCTION

Transverse galloping generated during heavy winds can lead to natural disasters putting bridges and skyscrapers at risk. A linear tuned mass damper (TMD) is a simple solution for damping the vibration of high buildings. However, it works only in a narrow frequency band and changes the characteristics of the primary system adding new frequencies. A different type of vibration absorbers known as Nonlinear energy sinks (NES) can overcome the drawbacks of the TMD [1]. The non-linearizable stiffness of such a suppressor enables it to engage with the dynamics of the primary structure, mitigating its vibration amplitudes over a wide band of frequencies [3].

Developing a purely NES, composed of a metal ball rotating freely in a circular track without direct coupling with the primary structure, was a considerable simplification in the NES design [2]. That should extend the industrial applications of such types of NESs, taking into consideration their significant effect on mitigating FIV. As an extension of this research, we introduce a multi-ball NES that depends on the impact between balls to improve the energy absorption efficiency. In this paper, wind tunnel tests validate the effect of the multi-ball NES in mitigating the galloping of a square prism. Depending on the design of the presented NES, we change the NES track dimensions by swapping some parts to use a different number of balls without changing the NES total mass.

METHODOLOGY

We follow the same methodology presented in Ref.[2] performing the experiments in the closed-loop wind tunnel (Model 407-B, ELD, Lake City, MN, USA) of the mechanical engineering department of Polytechnique Montréal. Fig. 1(a) presents the experimental set up in detail; a lightweight model of a square prism of 5 cm side length and 58 cm height is mounted by two identical elastic supports, located at the upper and lower sides of the wind tunnel test section. The prism can oscillate only in the transverse direction to the flow, behaving as a single degree of freedom (DOF) system. We installed a pair of plates at the two ends of the square prism to prevent the escape of airflow from the wind tunnel test

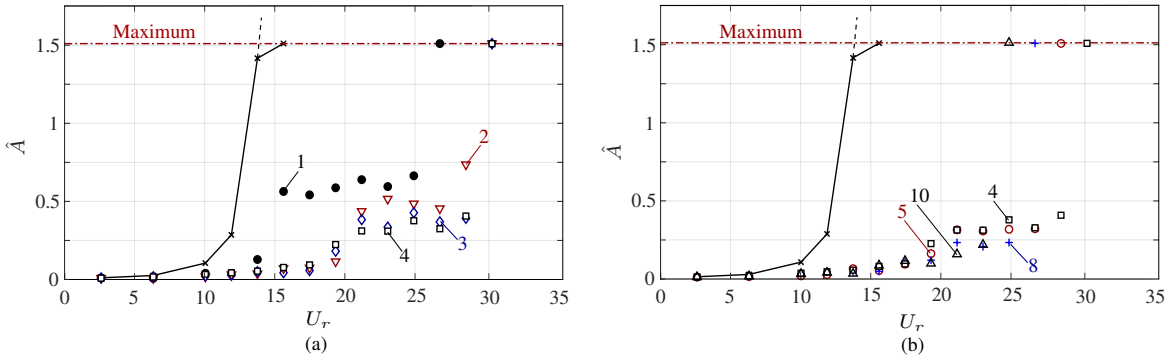

Figure 2: Amplitude response of: (a) the prism without NES ×, with 1-ball NES •, with 2-ball NES ▽, with 3-ball NES ◇, and with 4-ball NES □; (b) the prism without NES , with 4-ball NES □, with 5-ball NES ○, with 8-ball NES +, and with 10-ball NES △.

section. Two smaller plates were installed 8 cm away from each end to help approach two-dimensional flow conditions. Our experimental setup allows a maximum amplitude A of 7.5 cm (equal to 1.5 times the square prism side length). A high-speed Camera (Motion BLITZ Cube 4, MIKROTRON) recorded the motion of the vibrating prism with a resolution of 0.085 mm. A MATLAB code, developed for image analysis, traces the time histories of the prism vibration displacement y. We repeated the measurement at various flow speeds to illustrate the prism response by plotting the maximum amplitude A $versus$ flow speed U in the non-dimensional form for generalization.

The Multi-ball NES of Figure 1(b) consists of the main body (1), various size bushings (2), and steel balls (3). We printed the main body and the bushings using a 3D printer (Ultimaker3, Ultimaker) with white Poly-Lactic Acid (PLA) plastic. Swapping some parts allows easily changing the dimension of the NES track to accommodate different ball sizes. To figure out how the variation of ball quantity affects the NES behaviour, we tested various configurations of multi-ball NES, varying numbers and size of balls without changing the total mass of the NES.

RESULTS

We define the flow speed range where the NES can reduce the vibration amplitude of the prism as the NES working range. Figure 2(a) compares the responses of the prism with 1 ball, 2 balls, 3 balls and 4 balls at different flow speeds. Using two balls instead of one significantly reduces the prism vibration amplitudes and eliminates the amplitude jump which appears at a reduced velocity $U_r = 15.6$. The working range of the 2-ball NES increases to $U_r = 30$ as compared to 27 for the 1-ball NES. Increasing the number of balls to three then four, reduces the vibration amplitudes of the prism at $U_r \geq 20.5$ with no effect on the NES working range. However, the 2-ball NES shows better behavior at $U_r = 19$. Focusing on the flow speed range $16 < U_r < 20.5$, we can observe a gradual jump in the response of the prism with the 4-ball NES. This jump is more significant and delayed to $U_r = 22.5$ in the case of using the 2-ball NES. Figure 2(b) presents the responses of the prism with 4-balls, 5-balls, 8-balls and 10-balls at different flow speeds. At low flow speeds $U_r < 17$, no considerable change appears in the behavior of the prism with the different NESs. For higher flow speeds, increasing the number of balls above four reduces the vibration amplitudes of the prism. Additionally, it limits the NES working range to flow reduced velocities 24, 22.5 and 21 for the 5-ball, 8-ball, and 10-ball NESs, respectively.

CONCLUSIONS

The single ball NES presented in the literature is a simple, low-cost way for damping flow-induced vibration. In this paper, we propose a multi-ball NES as a more beneficial NES. The impact between balls is an efficient way of energy absorption that adds an advantage for the multi-ball NES. An increase in the number of NES balls reduces the vibration amplitudes of the prism. This trend remains throughout all the experiments using one to ten balls. Regarding the NES effective range, we observe two opposite trends. The use of two smaller balls instead of one large ball increases the NES working range then it remains the same for the 3-balls and 4-ball NESs. Any further increase in the number of NES balls reduces the NES working range. The overcrowdedness of the NES track results in fewer beneficial impact between balls at higher flow speeds. The 4-ball NES increases the reduced velocity of large-amplitude galloping by 10 % compared to the 1-ball NES of equivalent mass.

ANALITICAL SOLUTIONS OF AN OSCILLATING ELASTIC CABLE LOADED WITH A CONCENTRATED MASS

Enrico Pagani*[1] and Markus Wenin[2]
[1]Department of Mathematics, University of Trento, Trento, Italy [2]CPE Computational Physics and Engineering, Lana (BZ), Italy

Summary We present a new analytical study of the oscillations of an elastic cable, loaded with a point mass in the center of the span. The solutions of the equations of motion represent a generalization of the linear theory of Irvine [**?**], [**?**] for the empty elastic cable, i.e. we find the transcendental equations to determine the eigenfrequencies for symmetric/antisymmetric modes of oscillations, as well as the eigenfunctions to determine the displacement of the cable. To test our analytical results we used a simple model of discrete mass points in the gravitational potential, connected by massless elastic rods.

INTRODUCTION

We generalize the theory of Irvine which treats oscillations of empty suspended elastic cables with small midspan catenary sag. Here we consider an elastic cable loaded with a point mass in the center of the span and investigate the in–plane oscillations of this system. Problems of this kind arise in many practical situations, for example when one studies the motion and in particular the vehicle–oscillations of ropeways. For the authors the content of this paper represents a tentative of an analytic approach to the problem of oscillations of cables in presence of a concentrated mass fixed in a given point of the cable using the theory and the approximations of Irvine.

ELEMENTS OF THE THEORY

We introduce a material point of mass m, fixed in the center of the cable. The coordinates of the suspension points are $(x = 0, y = 0)$, $(x = l, y = 0)$, and the point mass, at the equilibrium, has coordinates $(x = l/2, y = D$, see Fig. **??**). Denoting (improperly) with K the horizontal component of the cable tension, constant along the whole cable, the static configuration of the cable is described by the formula

$$y_0(x) = \frac{\rho g(l + \frac{m}{\rho})}{2K}\left[x - \frac{x^2}{(l + \frac{m}{\rho})}\right], \quad x \in [0, l/2] \tag{1}$$

(symmetric for $x \in (\frac{l}{2}, l]$), in which the relation between K and the sag D is given by

$$D = y_0\left(\frac{l}{2}\right) = \frac{\rho g l^2}{8K}\left(1 + \frac{2m}{\rho l}\right) . \tag{2}$$

Concerning dynamics, let's denote with $x = x_0(s)$, $y = y_0(s)$ and $T(s)$ the parametric representation of the cable and the tension in the equilibrium configuration, and with $u = u(t, s)$, $v = v(t, s)$ and $T(s) + \tau(t, s)$ the horizontal and vertical displacements of the points of the cable and the tension at the point of curvilinear parameter s at time t. The functions $u = u(t, s)$, $v = v(t, s)$ and $\tau(t, s)$ satisfy the linearized equations of motion:

$$\frac{\partial}{\partial s}\left(T(s)\frac{\partial u(t,s)}{\partial s} + \frac{dx_0(s)}{ds}\tau(t,s)\right) = \rho\frac{\partial^2 u(t,s)}{\partial t^2} \quad s \neq s^* , \tag{3}$$

$$\frac{\partial}{\partial s}\left(T(s)\frac{\partial v(t,s)}{\partial s} + \frac{dy_0(s)}{ds}\tau(t,s)\right) = \rho\frac{\partial^2 v(t,s)}{\partial t^2} \quad s \neq s^* , \tag{4}$$

$$\left[\frac{dx_0(s)}{ds}\tau(t,s) + T(s)\frac{\partial u(t,s)}{\partial s}\right]_{|(t,s^*)} = m\frac{\partial^2 u(t,s^*)}{\partial t^2} , \tag{5}$$

$$\left[\frac{dy_0(s)}{ds}\tau(t,s) + T(s)\frac{\partial v(t,s)}{\partial s}\right]_{|(t,s^*)} = m\frac{\partial^2 v(t,s^*)}{\partial t^2} , \tag{6}$$

$[F(t,s)]_{|(t,s^*)} := F(t,(s^*)^+) - F(t,(s^*)^-)$ denoting the jump of the function $F(t,s)$ at s^*, namely at the point in which the concentrated mass m is present.

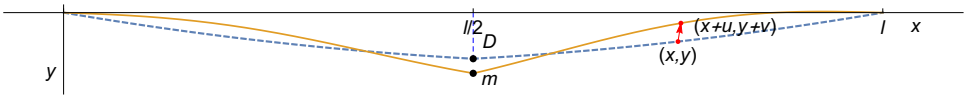

Figure 1: Sketch of the system under consideration. Dashed line: equilibrium configuration $y_0(x)$. Solid line: cable out of equilibrium, where a point undergoes the displacement $(x, y) \to (x + u(t, x), y + v(t, x))$.

RESULTS - SYMMMETRIC AND ANTISYMMETRIC MODES OF OISCILLATIONS

Adopting the definition of Irvine a mode of oscillation is called *symmetric (resp. antisymmetric)* if the vertical displacement $v(t, x)$ is symmetric (resp. antisymmetric) with respect to $x = \frac{l}{2}$. We have no space to present here in details the analytic approach and we give the results of a comparison of the analytic approach with a numerical example, using the following parameters: linear density $\rho = 1$ kg/m, span $l = 100$ m, $A_c E_c = 10^5$ N. The static midspan sag for the empty cable is $d =$ 5m and the horizontal component of the tension is $K = 2450$ N. We compare our analytical results with the ones obtained by evaluation of a model, consisting of a set of discrete mass points in a gravitational potential (each with a mass $m_p = 2.396$ kg) connected by massless rods with appropriate elastic constant and rest length. We consider the case of an empty cable, and with a concentrated load $m = 6m_p = 14.37$ kg. The resulting values are collected in the tables that appear below, together with the numerical values for the different loading cases and modes (symmetric (s) and antisymmetric (a)) of oscillation. Unfortunately, we have no space to exhibit the corresponding eigenfunctions.

A NUMERICAL EXAMPLE

The presented tables show a comparison of both approaches for the empty and the loaded cable respectively.

n	1 (s)	2 (a)	3 (s)	4 (a)	5 (s)	6 (a)
ω_n analytical	1.92	3.11	4.68	6.22	7.78	9.33

BAND-GAP CHARACTERISTICS OF A TRI-LIGAMENT CHIRAL STRUCTURE WITH FLEXURE HINGES

Tan Wangxi[1], Su Xunwen*[1], An Ning[1]
School of Technology, Beijing Forestry University, Beijing, China

Summary In order to study the characteristics of band gap of low frequency and wide bandwidth, we proposed a tri-ligament chiral structure with flexure hinges, which is convenient to adjust the band gap without changing the geometric parameters of the chiral structure. Finally, we performed a numerical simulation using the finite element method.

MODEL OF TRI-LIGAMENTS CHIRAL STRUCTURE WITH FLEXURE HINGES

Chiral structure, consisting of a node and ligaments tangent to the node, is a hotspot in engineering because of its light weight, good impact resistance and excellent vibration isolation performance. The difficult point is adjusting band gap of low frequency and broad bandwidth. The former researches suggest that the influence of the geometric parameters of the chiral structure on the band gap distribution is complex and coupled. So a new tri-ligament chiral structure with flexure hinges is proposed, as shown in figure 1. This structure makes it easier to adjust the band gap by adding an arc flexible hinge to the ligament.

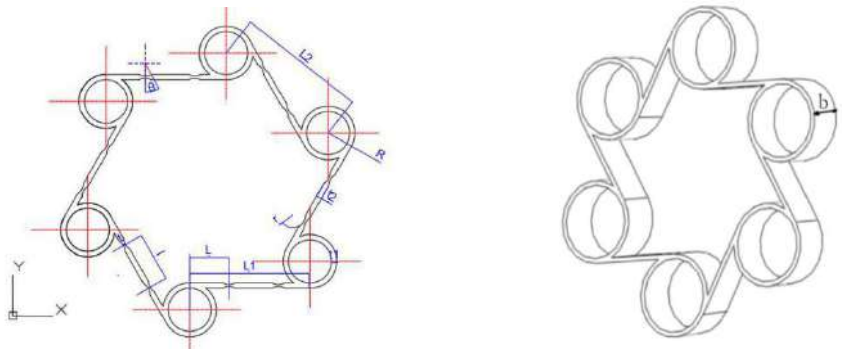

Fig. 1 Geometric parameters of the three-ligament chiral structure with flexure hinges

Calculation models are built by finite element method. According to the previous study of Su[1], a structure containing 23 cells is established in the part module of SolidWorks based on the two-dimensional shell element, and ANSYS is used to handle the model based on the harmonic response analysis, as shown in figure 2 . Four parameters are changed to observe the influence of the flexure hinge on the frequency response characteristics, including radius of the notch arc r, center angle of the notch arc θ, quantity of arc flexure hinges and length between centers of the notch arc of two flexure hinges l.

*Corresponding author: Su Xunwen, E-mail: suxw0703@gmail.com

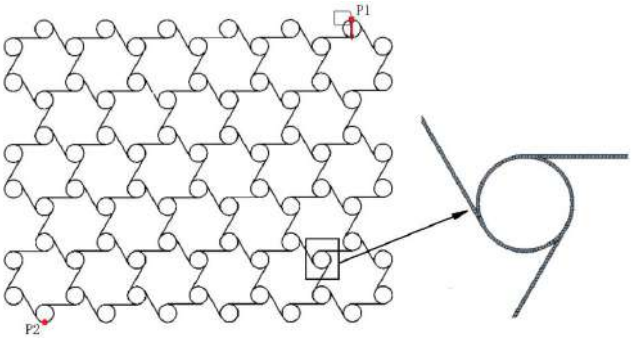

Fig. 2 Schematic diagram of the loading and mesh of the chiral structure with flexure hinges

CONCLUSIONS

The main results of the research are as follows. The research in this paper can provide basis and reference for the chiral structure design of variant aircraft in the aviation field in the future.

(1) When the radius of the notch arc r is 3mm, 4mm, 5mm, 6mm, 7mm and 8mm respectively, the starting frequency and bandwidth are shown in figure 3. The results show that as the radius increases, the starting frequency decreases and the bandwidth increases. When the radius increases to 6mm, the change is most dramatic.

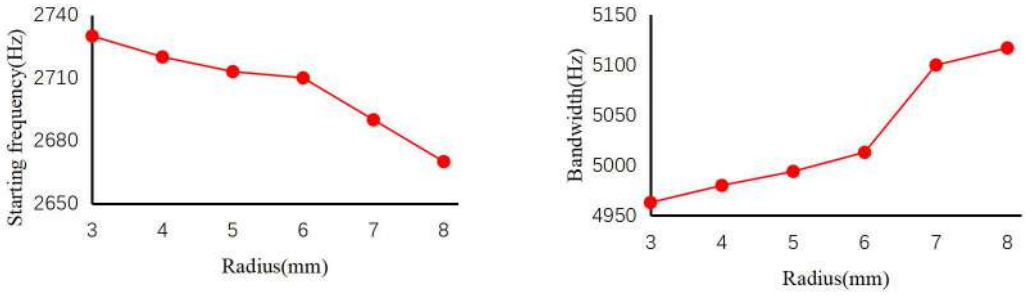

Fig. 3 Starting frequency and bandwidth under different radius of the notch arc

(2) Radius of the notch arc, center angle of the notch arc, quantity of the arc flexure hinges and length between the centers of the notch arc of two flexure hinges also have an impact on the starting frequency and bandwidth. As the parameters increase, the starting frequency decreases and the bandwidth increases. Results show that the most effective way to adjust the band gap probably is to change the number of flexible hinges., and adjusting center angle affects more than radius.

(3) The recommended structure is radius of the notch arc of 7mm, the center angle of the notch arc of 25°, 7 arc flexure hinges and the length between the centers of the notch arc of two flexure hinges 6.8mm.

APPLICATION OF VIRTUAL SENSING TO VIBRATIONAL DATA FROM A HIGH-SPEED AXIAL COMPRESSOR

Mona Amer*[1], Clemens Groß[2], and Joerg Seume[1]
[1]Institut für Turbomaschinen und Fluid-Dynamik,Leibniz Universität Hannover,Germany
[2]Institut für Land-und Seeverkehr,Technische Universität Berlin,Germany

Summary In order to reduce sensor count of acceleration sensors used to monitor the vibrational behaviour of industrial machinery, virtual sensing approaches are studied and employed. Virtual sensors are used to predict the vibrational behaviour virtually without using a physical sensor. The application of this approach aims at solving the conflict of interests: On one hand, a low number of sensors is required, among others, for economic reasons. On the other hand, the vibrational behaviour of the mechanical system should be represented as realistically as possible and, therefore, requires a high number of sensors. In the present case, analytical models like the statistic energy analysis using structural mechanics correlations as well as novel data-driven approaches based on artificial intelligence are applied to acceleration sensors on a high-speed axial compressor.

INTRODUCTION

Virtual sensors are often employed for economic, environmental, or technical reasons when the use of physical sensors is restricted. Liu et al. [4] reviewed different virtual sensing (VS) technologies focusing on active noise cancellation. The automotive industry also makes use of VS, e.g. torsional load data from power trains have been gained by using a nonlinear Kalman filter approach [1] and Hirsenkorn et al. [2] applied VS to driver assistance systems. VS is applied in civil engineering applications for structural health monitoring (SHM) as well. Kullaa et al. [3] presented a hybrid approach for SHM on the basis of VS. Large machines are also controlled by vibration sensor technology to ensure a safe operation because an increased vibration level over a long period of time can lead to mechanical failure. The objective of the operator will always be the minimisation of the sensor count, as accessability and economic reasons lead to increased cost. VS could offer suitable alternatives as studied below.

METHODOLOGY

The VS methodology is applied to an axial compressor test rig which is shown in Fig. 1. The objective is to eliminate

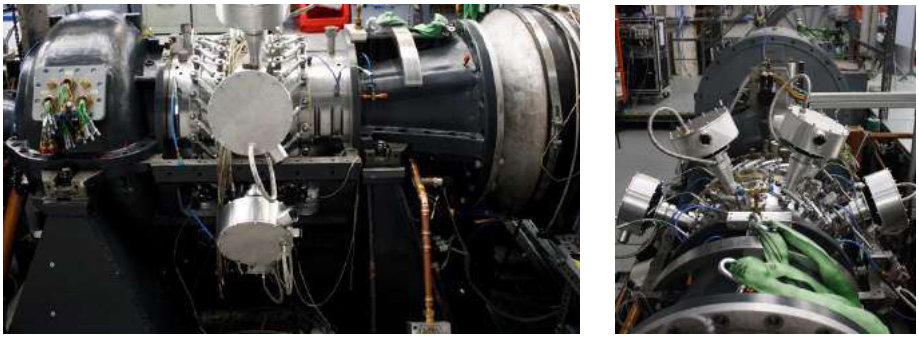

Figure 1: Axial compressor test rig at the Institute of Turbomachinery and Fluid Dynamics (TFD)

one or more physical sensors using a virtual model. The data set is derived from the monitoring system of the axial compressor. The highly resolved acceleration data is integrated and provides time-averaged root mean square (RMS) values $x_{\mathrm{RMS}} = \sqrt{\frac{1}{T}\int_0^T x^2(t)dt}$ sampled with 5 Hz. This data set is more suitable for VS than acceleration data with a high sampling frequency as the RMS values show less rapid fluctuations. Overall, 10 sensors are used, measuring the axial and horizontal vibration of the free and fixed bearing support, the gearbox, and the motor. The design of VS is split into two parts; firstly the dependence on other parameters has to be established and secondly a linking function between the predicted variable and the influencing variables has to be defined. Approaches to VS can be divided into model-driven, data-driven, and hybrid methods. Model-based and hybrid approaches assume a physical model, which is guided by data and physical laws at the same time. The statistical energy analysis (SEA) is a model-driven method, which considers the transmission behaviour of vibrations. It is based on the principle of energy conservation. The system is divided into subsystems described by an equation set for the input, storage, transmission and dissipation of energy within the subsystems. The coupling coefficients required are determined iteratively by comparing the reconstructed signal with the measured data. The acceleration can finally be derived from the energy Π^{in} into a subsystem $\Pi^{\mathrm{in}} = \frac{1}{2}\Re\{m\ddot{X}\dot{X}\}$ with $x(t) = X(\omega)e^{i\omega t}$. Data-driven approaches include, among others, statistical methods such as correlation models

*Corresponding author. E-mail: amer@tfd.uni-hannover.de.

(CM) and regression analysis (RA). For the use of CM, impulse response coefficients have to be determined by establishing a relationship between input and output. RA include, among others, polynomial and nonlinear methods. Another field of applied statistics provides artificial intelligence (AI) approaches such as neural networks (NN). Again, different approaches exist like feed-forward NN (FFNN), recurrent NN (RNN), the output of a layer can be fed back as an input, and long short-term memory (LSTM) NN, which is basically a further development of recurrent NN. Another version of NN, belonging to the hybrid approaches, is the physics-informed NN (PINN). These approaches are applied to a data set, consisting of approximately 1 million samples.

RESULTS

The vibration data from the fixed bearing can be replaced best by VS, therefore, it is the basis of the following comparison. To compare the different approaches, an error function is introduced

$$\epsilon = \frac{1 - n_{0.5}}{n} \cdot 100\% \tag{1}$$

with n being the length of a chosen interval and $n_{0.5}$ being the number of samples in this interval which are not outside the ± 5 % measurement uncertainty bound of the sensors. The value corresponds to an average of the horizontal and vertical sensor signal at the fixed bearing support. Table 1 summarises the quality of all approaches considered. For the

Method	Approach		ϵ
Model driven	SEA		23.4%
Hybrid	PINN		84.6%
Data driven	CM		62.4%
	RA	polynomial	76.3%
		nonlinear	76.6%
	NN	R	74.3%
		FF	87.5%
		LSTM	89.4%

Table 1: Comparison of the quality of the approaches applied

SEA, the mass of the different components needs to be determined in order to calculate the resulting energy $E = \frac{1}{2} m \dot{x}^2$. Hence, the weight of the entire motor is approximated to be 12 times the mass assumed for the fixed and free bearing support. It is assumed that the transmitted energy into the axial compressor and into the bearing support is dissipated into the foundation. Nevertheless, the SEA shows poor results, as the complexity of the test stand is too high for this approach. It can be noticed that it still gives a good estimation of the current RMS value. For the PINN, the result of the SEA is fed into a FFNN and shows good accordance with the real sensor data but also requires a high implementation effort. The phenomenon of overfitting excludes polynomial RAs of high order. Hence, order 3 is presented in Tab. 1. For the nonlinear RA wavelet functions are examined. The LSTM approach shows the best result overall, which confirms the development of NN in the literature. Besides, the quantitative evaluation other criteria can be taken into account like complexity and computational effort, NN approaches show good results here too. It is noticeable, that leaving out the standstill data leads to a more accurate replication of the physical sensor signal. The incorporation of additional data from the monitoring system like pressure and temperature values did not improve the VS approach, which were used to model operating conditions. The replication of a second sensor still shows acceptable agreement with the original data.

CONCLUSIONS

Different VS approaches – model-driven hybrid and data-driven approaches – were successfully applied to vibration data from an axial compressor test rig. The time-averaged RMS values were most suitable for this use case. The results indicate that the vibrational behaviour is not or weakly dependent on the operating point. Data-driven approaches have proven to be more efficient and provide a more accurate prediction of the physical sensor outputs. The complexity of the test stand led to poor results derived from the model purely based on theoretical mechanics principles. As a next step an evaluation of significance of the changes in predictive quality associated with AI methods will be pursued. This study represents a first step towards the application of VS to industrial machines with fewer installed sensors.

DYNAMIC RESPONSE OF FRACTIONALLY DAMPED MULTIPLATE SYSTEMS

Marina Shitikova*[1,2], Olga Zhavoronkova[1]
[1]Department of Structural and Theoretical Mechanics, Moscow University of Civil Engineering, Moscow, Russia

Summary In the present paper, a vertically inhomogeneous viscoelastic plate is modelled as a multiplate system, i.e. a set of thin plates interconnected with each other in terms of fractional derivative Kelvin-Voigt elements. The procedure allowing one to reduce the analysis of the dynamic response of such rather complex system to the solution of the characteristic equations of fractional oscillators with two retardation times and two fractional parameters has been proposed, that is to simplify significantly the solution of the problem under consideration.

INTRODUCTION

During the last three decades, fractional calculus entered the main stream of engineering analysis and has been widely applied to structural dynamic problems both in discrete and continuous equations, considering stationary and transient dynamic response of oscillators, beams, plates, cylindrical shells. The overview of recent publications could be found in [1,2]. The results obtained in the field have been critically estimated in the light of the present view of the place and role of the fractional calculus in engineering problems and practice.

In the present paper, the dynamic behaviour of a viscoelastic plate with nonhomogeneity varying with its width is considered utilizing the multilayered model involving different combinations of fractionally damped layers.

PROBLEM FORMULATION METHOD OF SOLUTION

One of the approaches for simulating multilayered structures is to consider a sandwich structure as a multibeam or multiplate system, in which deformable elastic or viscoelastic bodies (beams or plates) are interconnected by distributed light viscoelastic constrain elements which have the ability to resist axial deformation under static and dynamic conditions [3].

Let us consider a discrete-continuum inhomogeneous vertical chain system (Figure 1) involving a set of N thin viscoelastic plates with different material constants but with the same boundary contours and boundary conditions, which are interconnected with by N-1 viscoelastic constraint layers with equal material constants. The number of degrees of freedom of such a multilayered structure is equal to N-infinity, where N is a number of deformable plates in the chain, in so doing each Kirchhoff-Love plate admits the dynamic deflection $w_i(x,y,t)$. The plates may be subjected to transverse distributed external loads $q_i(x,y,t)$.

The dynamic response of such a viscoelastic plate with nonhomogeneity varying with its height, or a viscoelastic layer connected multiple plate system, could be described by the following system of the N governing coupled partial differential equations:

$$\tilde{D}_i \nabla^2 w_i + \rho_i h_i \ddot{w}_i = q_i + F_{i+1} - F_i \qquad (i = 1,2,...,N) \tag{1}$$

$$F_1 = \tilde{\lambda}_1 w_1, \qquad F_i = \tilde{\lambda}_i (w_i - w_{i-1}) \qquad (i = 2,3,...,N-1), \qquad F_N = \tilde{\lambda}_N w_N \tag{2}$$

formulated in terms of N unknown transverse displacements $w_i(x,y,t)$, where F_i is the reaction of the ith viscoelastic layer, $\tilde{D}_i$ is the cylindrical rigidity of the ith plate, Young's modulus $\tilde{E}_i$ of the ith plate and the coefficient of rigidity of the connecting viscoelastic layer $\tilde{\lambda}_i$ are the following Kelvin-Voigt-type operators of the fractional order

$$\tilde{D}_i = \frac{h_i^3 \tilde{E}_i}{12(1-\nu_i^2)}, \qquad \tilde{E}_i = E_{0(i)}(1+\tau_1^{\gamma_1} D^{\gamma_1}), \qquad \tilde{\lambda}_j = \lambda_{0(j)}(1+\tau_2^{\gamma_2} D^{\gamma_2}), \tag{3}$$

where $E_{0(i)}$ and $\lambda_{0(j)}$ are prolonged magnitudes of coefficients of rigidity for the ith plate and jth layer, respectively, τ_1, γ_1 and τ_2, γ_2 are the retardation time and fractional parameter for plates ans layers, respectively, D^γ is the Riemann-Liouville fractional derivative [1], and $0 < \gamma < 1$ is the order of the fractional derivative (fractional parameter).

Note that adding the Nth layer to this system allows one to consider the dynamic response of a multilayered plate on a viscoelastic foundation.

Supposing the solution of Eqs (1)-(3) in the modal form

$$w_i(x,y,t) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} W_{(1)mn}(x,y) x_{(i)mn}(t), \qquad i = 1,2,...,N \tag{4}$$

*Corresponding author. E-mail: mvs@vgasu.vrn.ru

dividing Eq. (1) by $\rho_i h_i$, substituting (2)-(4) in Eq. (1), multiplying each equation by $W_{(1)mn}(x,y)$, after integrating along the plates' length and width, and considering the orthogonality conditions and corresponding equal boundary conditions of the plates yield to the *mn*-family of systems containing coupled only *N*-ordinary fractional-order differential equations for the determination of unknown generalized displacement functions $x_{(i)mn}(t)$ $(i=1,2,....N, \quad m,n=1,2,...,\infty)$:

$$\ddot{x}_{(i)mn}+\Omega^2_{(i)mn}(1+\tau_1^{\gamma_1}D^{\gamma_1})x_{(i)mn}+\frac{\lambda_{0(i)}+\lambda_{0(i+1)}}{\rho_i h_i}(1+\tau_2^{\gamma_2}D^{\gamma_2})x_{(i)mn}-\frac{\lambda_{0(i+1)}}{\rho_i h_i}(1+\tau_2^{\gamma_2}D^{\gamma_2})x_{(i+1)mn}$$
$$-\frac{\lambda_{0(i)}}{\rho_i h_i}(1+\tau_2^{\gamma_2}D^{\gamma_2})x_{(i-1)mn}=P_{(i)mn}(t), \tag{5}$$

where

$$P_{(i)mn}(t)=\frac{\int_0^a\int_0^b q_i(x,y,t)W_{(1)mn}(x,y)dxdy}{\rho_i h_i\int_0^a\int_0^b[W_{(1)mn}(x,y)]^2dxdy}, \qquad \Omega^2_{(i)mn}=\frac{h_i^2\tilde{E}_i}{12\rho_i(1-\nu_i^2)}\nabla^2 W_{(1)mn}(x,y).$$

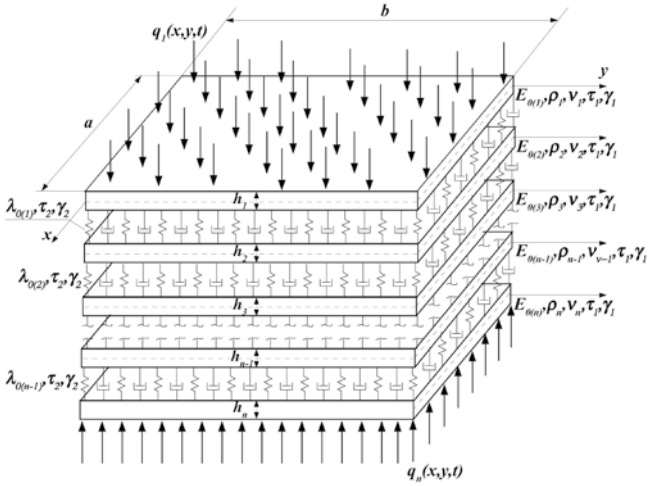

Figure 1. Scheme of a multiplate system.

Applying the Laplace transform to Eqs. (5), int to the sets of roducing the change of variables $\bar{x}^*_{(i)mn}=\bar{x}_{(i)mn}\sqrt{\rho_i h_i/\rho_1 h_1}$, and expanding the vectors $\bar{x}^*_{(i)mn}$ in terms of the eigenvectors, the governing equations in the Laplace domain could be reduced to the *n* sets of decoupled equations, each of which describes forced vibrations of an uncoupled Kelvin-Voigt fractional derivative oscillator with two retardation times and two fractional parameters. The solution of such characteristic equations was proposed in [4].

CONCLUSIONS

Thus, it has been shown how rather complex system modelling the dynamic response of the multilayered plate can be reduced to the sets of uncoupled fractionally damped oscillators characterized by two retardation times and two fractional parameters, what allows one to simplify significantly the solution of the problem under consideration.

The approach described above enables one to consider any number of elastic/viscoelastic plates interconnected by viscoelastic (or elastic) layers in the case when welded or sliding contact between the layers is ignored. For example, it could be applied with great success for finding an approximate solution of the dynamic problem of a simply supported elastic Kirchhoff-Love-type plane damped by a viscoelastic layer.

MULTI-SCALE INTERACTION WITH FLOWS OF KIRIGAMI STRUCTURES

Tom Marzin [1], Kerian Le Hay [1], Emmanuel de Langre [1], and Sophie Ramananarivo*[1]
[1]LadHyX, Department of Mechanics, Ecole polytechnique, Institut polytechnique de Paris, France

Summary We study the deformation of a kirigami- that is a sheet slit with a network of cuts- in a water flow. When stretched, the kirigami significantly opens up and thus acts as a poro-elastic surface that lets fluid through. We characterize experimentally and theoretically the relation between the cuts geometry and the resulting shape transformation. We show that macroscopic morphing is dictated by interactions with fluid at the scale of individual pores, whose geometry changes in turn with the sheet elongation. Understanding those multi-scale couplings provides a novel way to control and program shape-shifting in flows through the reverse-engineering of cut motifs.

INTRODUCTION

Lightweight compliant surfaces are commonly used as roofs (awnings), filtration systems or propulsive appendages, that operate in a fluid environment. Their flexibility allows for shape to change in fluid flows, to better endure harsh or fluctuating conditions. Alternatively, those passive deformations can be exploited for enhanced locomotion [1] or energy extraction from flows. The way the structure deforms is however key to fulfill its function, prompting the need for control levers.

Thin surfaces undergo primarily length-preserving deformations, which places severe restriction on accessible shapes. A way around such limitations is to add a network of cuts to the flat surface, a technique that is specific to kirigamis. The slits enable the material that remains to either rotate in plane or buckle out of plane (see Fig.1a), transforming the flat sheet into arbitrarily complex three-dimensional shapes. This technique has recently drawn the attention of scientists and engineers, as it also allows the design of tunable and predictable mechanical properties, such as extreme stretchability [2]. This enlarged design space offers exciting opportunities to control and program shape transformations under fluid loading.

An interesting feature of kirigamis from the perspective of fluid mechanics, is that stretching occurs through significant opening up of the material. It thus acts as an adaptive poro-elastic structure, where a flow deforms the kirigami and opens pores, which in turn alter the fluid loading. Local forces exerted by the fluid flowing through individual pores are then likely to condition the global behavior of the structure. The aim of this study is to understand those multi-scale fluid/structure interactions. We approach this problem on a first type of kirigami characterized by a pattern of parallel rows of slits (illustrated in Fig.1a).

EXPERIMENTAL SET-UP

The kirigami is made by laser cutting a 100 µm-thick mylar sheet. It is clamped at its two ends and placed in a cross flow generated by a water tunnel, where it occupies the whole test section of 15x15cm (see Fig.1b). A camera placed on top of the channel records the quasi-2D deformation induced by the fluid. Fig 1.c shows typical shapes extracted through image analysis, when regularly increasing the flow speed from 4 to 22 cm.s^{-1}. The amplitude of the deformation eventually tends to saturate for strong flows, and we note a surprising breaking of left-right symmetry that will be discussed later.

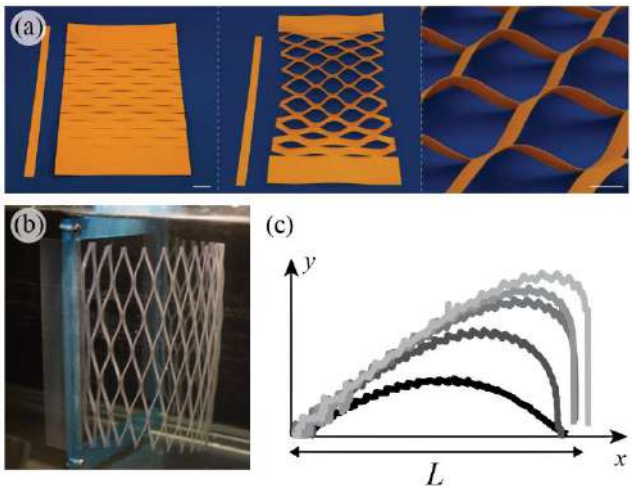

Figure 1. (a) Kirigami with a parallel arrangement of slits allowing for the struts in between to buckle out of plane [2]. (b) Deformation in a steady water cross-flow. (c) Typical shapes extracted from top-view pictures of the kirigami of length L, when increasing the flow speed (denoted by the grayscale).

Kirigamis with different elastic properties are tested, changing the length of the slits L_s, the distance between cuts within a row d_x, and the distance between rows d_y. Structural properties are characterized with an Instron, which records the force required to stretch the structure. We show that within the range of deformation explored in the experiments, the force-displacement curves are linear. An effective stiffness K is extracted from the slope, which scale as $K \sim \frac{Et^3 d_x}{(L_s - d_y)^3} \frac{N_y}{2N_x}$, with E the Young modulus, t the sheet thickness, and N_x and N_y the numbers of vertical and horizontal cut units. In the spirit of [3], this result is consistent with viewing the kirigami as a collection of plates that are bending, and act as spring assembled in parallel and in series. The three parameters L_s, d_x, and d_y effectively set the width and length of those plates, determining their 'stiffness'.

GLOBAL DEFORMATION OF THE PORO-ELASTIC SURFACE

We first characterize the fluid-induced shape changes by measuring the amplitude of the deformation y_{max} in the flow direction. This y_{max}, is nondimensionalized by the kirigami length L and shown in the inset of Fig.2a as a function of the flow speed U. The blue-to-yellow color gradient differentiates kirigamis with increasing slit length. Deformation increases with U, and is all the more pronounced for large L_s that correspond to smaller effective stiffness. A natural step is then to replot those data as a function of a Cauchy number $C_y = \rho H U^2 / K$. (with H the height of the kirigami and ρ the water density), that compares the fluid loading to elastic restoring forces. Fig.2a then shows a collapse of the data onto a single curve for the three series of kirigamis tested with varying L_s, d_x and d_y, respectively denoted by circle, triangle and square symbols. The competition between elastic and fluid opposing effects thus captures the amount of deformation of the kirigami. A finer study of coupling with flows is however required to interpret features such as the saturation of deformation observed for strong flows. This effect could in particular be attributed to the opening of porosity when stretching the surface, which tends to reduce the fluid loading. We thus set to investigate the detail of local interactions with flows at the individual pore level. Such information will also provide clues to understand the symmetry breaking in the shape transformation.

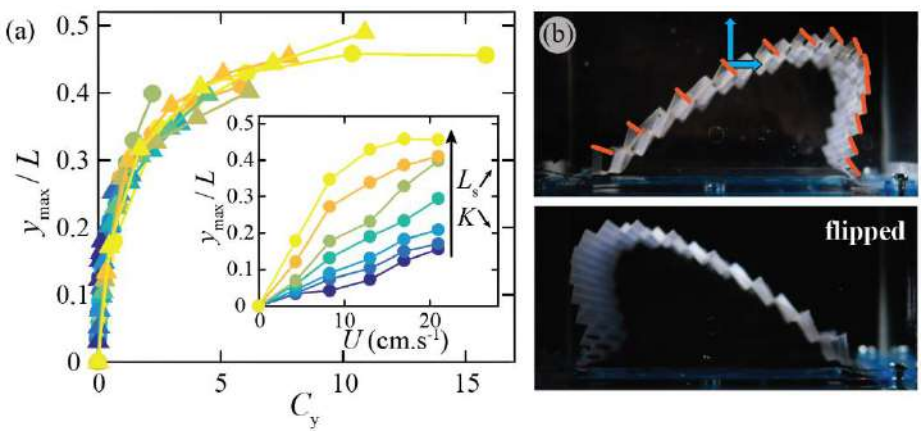

Figure 2. (a) [Inset] Dimensionless maximum deformation y_{max}/L as a function of flow speed U, for kirigamis with increasing slit length L_s and thus decreasing stiffness K (differentiated by a blue-to-yellow gradient). Results replotted as a function of a Cauchy number C_y (see main text) for different cut patterns. (b) The post-buckling tilting of the struts (outlined by orange lines) induces lateral forces, breaking the deformation symmetry. Flipping the kirigami upside down reverses the direction of the asymmetry.

LOCAL INTERACTIONS WITH FLOWS

The opening up of the kirigami with stretching can be characterized by measuring the evolution of the porosity Φ, that is the fraction of void area on the total area. Expectedly, porosity increases with the elongation ε, but the relation $\Phi(\varepsilon)$ also has the particularity of being independent of the slit length and inter-slit distances. This observation is directly explained by geometry arguments considering the out-of-plane tilting of strips within stretched kirigamis [3].

This out-of-plane buckling is also an important feature from a fluid dynamics viewpoint. Transverse lift forces are generated, and induce local tension leading to the observed assymetrical deformation (see top panel of Fig.2b). This asymmetry is prescribed by the strips orientation –which turns out to be highly biased by the fabrication process here-, but the direction spontaneously reverses upon flipping the kirigami upside down (bottom panel of Fig.2b).

To control and program shape shifting, local fluid forces need to be determined. Since those are difficult to measure in-situ, we devise a model system that reproduces the strip geometry and can be mounted on a force sensor. It consists of an assembly of 8 to 12 parallel blades, where the inter-blades spacing can be modified, as well as their orientation with respect to an incoming water flow. A six-axis force sensor measures forces both in the direction parallel and transverse to flow, to extract effective drag and lift coefficients. Those informations are used as input to model the two-dimensional deformation of the kirigami. The latter is modelled as an extensible thread –neglecting bending moments- and subjected to normal and transverse fluid forces that depend on local elongation. Model predictions show reasonable agreement with experimental results, providing clues to understand the feedback loop between local deformation and fluid forces.

Note that while the strips all buckle in the same direction in Fig.1a, it is not necessarily the case, and orientation could be varied throughout the sheet to access different deformations. It was shown in particular that buckling orientation can be controlled and programmed using notches in the material to guide the tilting [4]. Targeted macroscopic shape transformations could then be achieved through reverse-engineering of cut motif. This approach offers promising applications for intelligent structures for robotic and engineering, which passively adapt to changes in their fluid environment, such as filtration system with tunable filter mesh, or shape-shifting screens.

MEASURING LOCAL RATE-DEPENDENT PROPERTIES OF SOFT MATERIALS USING VOLUME CONTROLLED CAVITY EXPANSION

Christine Roth[1,2] and Tal Cohen[*1,3]
[1]Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA
[2]Institute of Mechanical Engineering, École Polytechnique Fédérale de Lausanne (EPFL), 1015 Lausanne, Switzerland
[3]Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

Summary. By manipulating the volume of an incompressible fluid droplet formed at the tip of a needle that is injected into a soft material, and measuring the resisting pressure, it is shown that a clear signature of the nonlinear rate-dependent properties of the subjected material can be captured. Comparison of theoretical predictions and experiments then allows for identification of an appropriate constitutive model and quantification of the material parameters.

INTRODUCTION/MOTIVATION

The ability to locally probe rate-dependent properties of soft and biological materials presents opportunities in various fields, from food science, biomechanics, and pharmaceuticals, to soft robotics, and medical diagnosis. However, while standard rheological methods are well suited to measure the response of homogeneous materials, they require the preparation of samples with particular shapes and sizes to be tested outside of their natural environment. Hence, if the material properties are heterogeneous, or when removal of the material from its natural environment can affect its mechanical response, these methods are limited. To address this challenge, recent advancements [1-3] that build on the methodology of Needle Induced Cavitation Rheology (NICR) [4,5], have been shown to capture the local nonlinear response of soft materials. There, by controlling the volume of a cavity formed at the tip of a needle, and measuring the resisting pressure, the pressure-volume response can be obtained (even beyond the fracture limit [3]). By comparison with theoretical predictions, the nonlinear constitutive model and fracture resistance is determined. This technique, which we refer to as Volume Controlled Cavity Expansion (VCCE), has been shown to produce repeatable measurements in both synthetic and biological materials, however it is limited to rate-independent properties. In this talk, I will present recent advancements in extending this technique to capture rate-dependent properties. I will discuss experimental challenges and will outline the theoretical model and constitutive relations that are used to characterize the large deformation rate dependent response of polymers with tuned properties.

DIMENSION REDUCTION FOR SOFT SLENDER STRUCTURES

Basile Audoly[1] and Claire Lestringant[1]
[1]Laboratoire de mécaniquedes solides,CNRS,Institut Polytechnique de Paris,Palaiseau,France
[2]Mechanics & Materials,Department of Mechanical and Process Engineering,ETH Zürich,8092 Zürich, Switzerland
[2]Structures Research Group, Department of Mechanical and Process Engineering, University of Cambridge, United Kingdom

Summary We propose a method for obtaining one-dimensional models for slender elastic structures. The method accounts for large changes in the shape of the cross-sections, as happens typically in structures undergoing finite strain. It yields an equivalent one-dimensional energy functional in terms of (apparent) macroscopic strain. The energy functional captures both the non-linear dependence on the local apparent strain, as well as the dependence on the strain gradient, and is suitable for the analysis of phenomena such as localization.

When applied to a slender elastic body in three dimensions, dimension reduction classically yields the celebrated Euler-Bernoulli rod model. The equivalent elastic moduli of the one-dimensional model can be expressed in terms of elastic and geometric properties of the cross-section. This classical approach to dimension reduction is limited to situations where all the cross-sections deform almost rigidly. In this case, the dimension reduction involves solving a problem of linear elasticity in every cross-section.

A number of slender structures deform in a way such that cross-sections do not deform rigidly at all. Consider the inflation of thin cylindrical balloon (*i.e.*, a cylindrical party balloon), for instance: the formation of localized bulges during inflation has been successfully described using membrane theory[2] but this inflation entails variations in the cross-sectional radius that are well beyond 100%, and the finite-strain version of the membrane theory is required[1]. Another example is the bending and twisting of thin elastic ribbons: when these ribbons are deformed with macroscopic bending and twisting strain comparable to the inverse of the width, the cross-sections deform into arcs of circle so as to preserve the inextensibility of the mid-surface. By treating the cross-sections as essentially rigid, the equivalent Navier-Bernoulli rod model misses important features of these slender structures, and provides a poor approximation to the essentially non-linear way in which these structures deform.

In this talk, we present an approach to dimension reduction for slender elastic structures that is applicable to slender structures possessing highly deformable cross-sections. The approach proceeds as follows. The deformed structure is parameterized in terms of a geometric center-line, and of local degrees of freedom. The strain energy is then worked out in terms of the geometric properties of the center-line and of the local degrees of freedom. A relaxation problem is considered, whereby the local degrees of freedom are relaxed while the geometry of the center-line is kept constant. A one-dimensional strain energy functional is defined as the strain energy of this relaxed configuration, seen as a function of the properties of the center-line. Next, we work out this one-dimensional strain energy functional in powers of the successive gradients of the apparent stretching, bending and twisting strain of the center-line[4]. At dominant order, we find a non-linear, possibly non-convex, energy functional depending on the local apparent strain of the center-line. To derive this energy, one has to analyze the homogeneous solutions in a non-linear setting, and this is how large changes in the cross-sections are resolved accurately. At the next order, we find a correction to the energy arising from the gradient of the apparent strain, in the form of a diffuse-interface model.

This general strategy is applied to derive accurate, explicit one-dimensional models for slender non-linear structures such as an inflated axisymmetric balloon[4], a hyper-elastic cylinder undergoing necking[3], a thin elastic ribbon, or a tape spring. The strain-gradient corrections, which are obtained systematically from the general procedure and are asymptotically exact, allow us to analyze various types of localization phenomena easily and accurately.

FINITE STRING RADIUS STRONGLY MODIFIES THE CLASSIC CAPSTAN PROBLEM

Harmeet Singh*[1] and John H. Maddocks[1]
[1]Institute of Mathematics, École Polytechnique Fédérale de Lausanne, Switzerland

Summary In the classic capstan problem the maximum possible tension in a flexible string wrapped around a rigid tube with frictional contact grows exponentially with the wrapping angle. This result relies only on force balance taken with two tacit assumptions: 1) The thickness of the string is negligible, and 2) there is a single contact line. Motivated by recent experimental work in modelling knots, we generalise the classic analysis to allow A) finite string thickness, and B) double contact lines, which can arise when the rigid tube is itself curved. Finite thickness requires that moment balance must be considered in addition to force balance. As a consequence the maximum tension growth is decreased. In contrast, double contact lines lead to an increase in the effective friction coefficient, and an associated increased maximal growth in tension.

THE PROBLEM

The classic capstan problem in mechanics entails determining the maximum possible increase in tension in a completely flexible string that is wrapped around a (planar, perpendicular, but possibly non-circular) cross-section of a rigid capstan with a frictional interaction governed by Coulomb's Static Inequality Law. This problem is treated in many places, e.g. [1]. Motivated by contemporaneous analytical and experimental work in modelling knots where neither of the two assumptions 1) and 2) above is a good approximation, we have generalised the classic capstan analysis to allow for A) finite string thickness, and B) double contact lines, which can arise when the capstan is itself a rigid, but curved, tubular surface.

RESULTS FOR FINITE THICKNESS WITH A SINGLE CONTACT LINE

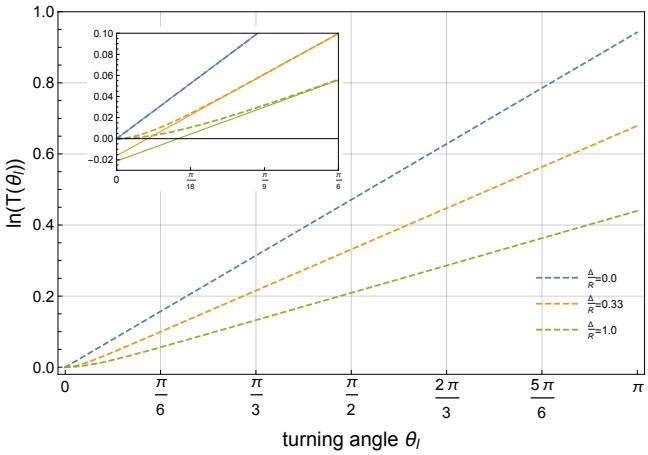

Figure 1: Natural log of maximal tension growth vs. wrapping/turning angle θ_l (scaled with unit tension at the initial zero turning angle, and in the case of a circular capstan cross-section). In all three cases shown, the asymptotic maximal growth rate is linear with slope $(1-\frac{\Delta}{R+\Delta})\mu$ where Δ and R are respectively the string and capstan radii, and $\mu = 0.3$ is the assumed Coulomb coefficient of static friction. For our generalisation to the case of non-zero string radius, there is also an initial layer with sub-exponential growth in the tension (cf. inset, where the straight line asymptotes are also shown).

We argue that finite string thickness implies that moment balance of the flexible string must be considered in addition to force balance, and as a consequence (whenever there is still a single, planar, contact line) the maximal asymptotic growth remains locally exponential, but with a significantly reduced growth constant involving a geometrical (possibly variable) pre-factor times the coefficient of friction (Figure 1). We also predict the existence of a non-exponential initial layer for the maximal tension at small wrapping/turning angles which further reduces (albeit only slightly) the maximal possible tension (Figure 1 inset).

The data of Figure 1 is obtained by considering the following ODE IVP which expresses balance of forces and moments on a planar configuration for a string that supports no internal bending moment

$$T' = (1-\kappa)f\,, \quad (\kappa f)' = T - \Lambda\,, \tag{1}$$

$$T(0) = 1\,, \quad f(0) = 0\,, \tag{2}$$

$$\text{subject to} \quad |f| \le \mu\Lambda\,. \tag{3}$$

Here T is the tension scaled by its initial value, and expressed as a function of turning angle θ_l, κ is the curvature of the string centreline scaled by the tube radius Δ ($\kappa = \frac{\Delta}{R+\Delta}$ a constant in the case when the capstan cross-section is an arc of a circle of radius R), f is the frictional contact force per unit turning angle, which is related to the normal contact pressure per unit turning angle $\Lambda \ge 0$ via the Coulomb inequality (for densities) with coefficient of friction μ. The initial condition $f(0) = 0$ arises as part of moment balance.

Consideration of the above system reveals that maximal tension growth arises for $f \ge 0$ and the largest possible value of $-\Lambda$ i.e. in the Coulomb friction inequality, the equality bound $\Lambda = \frac{f}{\mu}$ always holds. Then for maximal tension growth we eliminate Λ to arrive at the system

$$T' = (1-\kappa)f\,, \quad (\kappa f)' = T - \frac{f}{\mu}\,, \quad T(0) = 1\,, \quad f(0) = 0\,. \tag{4}$$

The classic capstan system arises in the singular limit $\kappa \equiv 0$, so that $T' = \mu T$, $T(0) = 1$, whose exponential solution is one curve in Figure 1. The two other curves are numerical solutions of the system (4) for two constant values of $\kappa = \frac{\Delta}{R+\Delta}$.

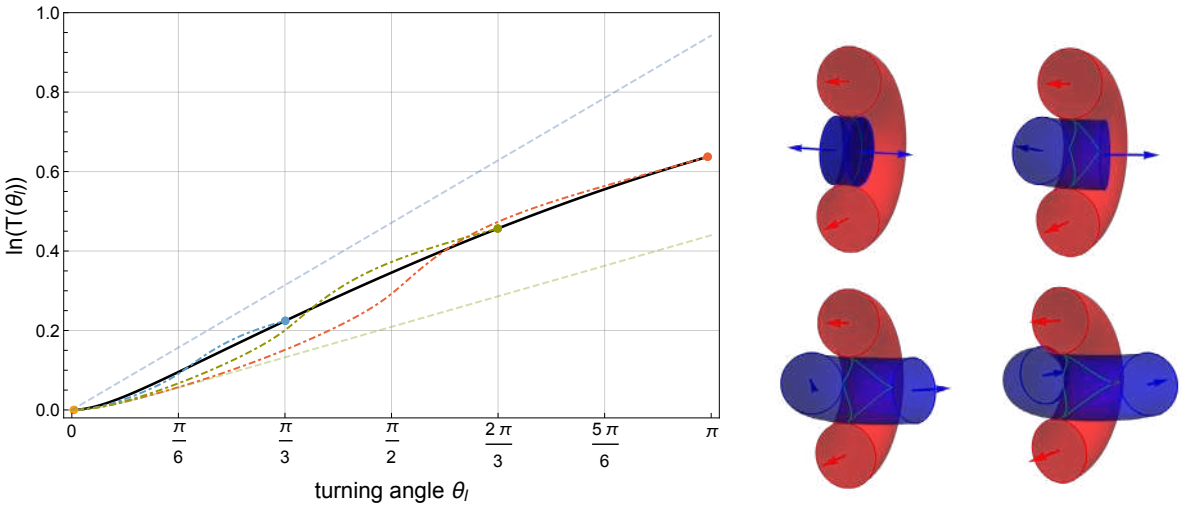
RESULTS FOR DOUBLE CONTACT LINES

Our motivation for this investigation is to obtain a mechanical analysis of knots. A typical situation in that context is two tubes, both flexible, with circular cross-sections of comparable radii, interacting with each other through mutual volume exclusion and with friction at the contact interface. Through a small generalisation of remarkable results of Starostin [2] for (the four-fold symmetric case of) the orthogonal clasp, we obtained one-parameter families of pairs of U-shaped planar tube configurations (red and blue in Figure 2b panel b)) that are in equilibrium for two flexible strings interacting without friction. We have shown four snapshots from a continuous family in which the opening angle of the red tubes is constant while the opening angle of the blue tube is varied. The main point of interest for us is that there are double contact lines (shown in green) between the pairs of tubes in each member of this family.

These tubular configurations with double contact lines are equally valid as configurations when we assume that the red tubes are entirely rigid, so that they can be taken as forming a capstan. Then we can solve the analogous versions of the balance laws above, but now in the case of double contact lines, in order to compute the maximal possible tension growth in the blue tubes in the presence of friction. The results are plotted in panel a). The four coloured dots are the maximal possible end tensions for each of the four cases, with the associated coloured dot-dashed lines being the internal distribution of tension on the maximal tension growth equilibria (where in the case of the shortest blue tube the internal tension distribution is not visible at this scale). The black solid line indicates the maximal end tension along the entire one-parameter family of double contact line equilibria as a function of the end opening angle for the blue tubes. It is this line that is comparable to the single contact line results presented in Figure 1 for various values of $\frac{\Delta}{R}$ and varying turning angle. In particular for the same value of friction coefficient μ, and for each overall opening angle, the possible maximal tension in the finite-radius $\frac{\Delta}{R} = 1$ double-contact case with a highly curved capstan tube, is less than for the classic idealised zero radius case $\frac{\Delta}{R} = 0$, but greater than for the comparable finite radius $\frac{\Delta}{R} = 1$ single contact line case, that arises for a right cylindrical capstan.



(a) (b)

Figure 2: (a) Natural log of the maximum tensions in the flexible string (blue) plotted against its turning angle θ_l around the red tube (assumed to be rigid). The end opening angle of the red tube/capstan is held fixed at π radians in the four cases. The dot-dashed curves represent tension profiles for the four cases $\theta_l = \{0, \frac{\pi}{3}, \frac{2\pi}{3}, \pi\}$ of end opening angles for the blue tube. The two dashed curves correspond to the single contact case for $\frac{\Delta}{R} = \{0, 1\}$ from Figure 1 shown here for comparison. (b) Equilibrium configurations showing the double contact lines (in green) between the two tubes corresponding to the four cases in (a).

CONCLUSIONS

We have shown that considering a finite tube radius as a generalisation of the classic capstan problem has two opposing effects. If the capstan has a geometry that still gives rise to single contact lines, then finite tube thickness decreases the maximal possible tensions, due to the necessity to balance moments. However if the rigid capstan is itself a sufficiently deformed tube, then finite radius geometry can also give rise to double contact lines, which in turn allow an increase in maximum tension distributions. In the classic case of $\frac{\Delta}{R} = 0$ the shape of the capstan outside its planar cross-section can play no role. For the examples shown here, the increases in maximal tension distributions due to double contact, do not approach the classic bounds that pertain in the singular limit of vanishing tube radius. We believe that to fully understand the mechanics of three-dimensional knots these competing consequences of finite tube radii need to be better understood.

EXPERIMENTS AND MODELING OF THE VISCOELASTIC BEHAVIOR OF POLYMERIC GELS

Nikola Bosnjak[1] and Shawn A. Chester *[1]
[1]Mechanical Engineering, New Jersey Institute of Technology, Newark, NJ USA

Summary A polymeric gel is a cross-linked polymer network swollen with a solvent. Also, as is well known many polymeric materials exhibit viscoelastic behavior in their mechanical response. In this work, we report on our recent experimental observations and theoretical modeling involving the change in the viscoelastic response of the polymeric material VHB caused by equilibrium swelling in multiple solvents. To characterize this change, we have developed an experimental procedure that includes mechanical testing when virgin, free swelling, mechanical testing when swollen, and mechanical testing after drying. A model is used to help interpret the experimental results. The key finding of this work is that our results indicate that the viscoelastic behavior of initially dry VHB, reversibly, becomes essentially hyperelastic when swollen to equilibrium in multiple solvents.

INTRODUCTION

When exposed to a suitable solvent, many polymeric materials will imbibe the solvent. During this process, the polymer network expands, and the fluid molecules migrate into the polymer microstructure, forming a solid-fluid continuum known as polymeric gel. And many polymeric gels are classified as active materials due to their ability to respond to various stimuli.

The goal of this project is to characterize the viscoelastic response of both dry and fully swollen polymeric gels through experimental observations and continuum level modeling. Towards our goal, we have developed an experimental procedure intended to capture the major aspects of the non-linear mechanical behavior of polymeric gels, including the viscoelastic response. To complement the experimental observations, we calibrate a constitutive model for viscoelastic polymeric gels. In what follows, we restrict our attention to the specific cases where the material is either completely dry, or fully swollen.

For our experiments we have chosen the commercially available material VHB 4910, since it is well known exhibit viscoelastic behavior in the absence of fluid. Also, we have observed that VHB 4910 swells when in contact with suitable solvents. Therefore all of our experiments make use of n-Pentane, o-Xylene, and Toluene, as solvents in conjunction with VHB 4910 to create our polymeric gels. The continuum-level constitutive model is mechanically incompressible, includes viscoelasticity, and does not explicitly take diffusion into account. That is to say we consider time dependence in the mechanical response, however not in the diffusive response of the solvent, which is taken to be at a known and fixed degree of swelling.

Readers are referred to [1] for full details related to this project.

EXPERIMENTAL RESULTS

We use dog-bone shaped specimens, and virgin samples are cut out from a roll of VHB 4910 tape using an ASTM D638-V cutting die. The nominal length, width, and thickness of the virgin gauge section are 9.49 mm, 3.18 mm, and 1 mm respectively. The results of some of our uniaxial tests on virgin specimens are shown in Figure 1. The dry virgin material exhibits pronounced rate-dependent behavior, which is observed in Figures 1b and 1a, and Figure 1b shows the measured stress relaxation behavior at an applied stretch of $\lambda = 2$. And in Figure 1c the large deformation quasi-static tension test results at a rate of 10^{-4}s^{-1} are plotted along with the long term creep and relaxation data at equilibrium. Since the large deformation quasi-static tensile response has some hysteresis, we interpolated the creep and relaxation data (utilizing the `smooth` function in MATLAB) to obtain the time-independent response of the material. Figure 2a shows a subset of our data with multiple stretch-stress curves all superimposed atop each other, and immediately the change in behavior is visible. The behavior of virgin samples shows clear viscoelastic effects. However, the fully swollen results show no signs of rate dependency, nor hysteresis, with load-unload stretch-stress curves obtained at different rates being almost completely on top of each other. Measurements of the hysteresis, stiffness, and stress-stretch behavior all lead toward the hypothesis that *the fully swollen material has lost nearly all viscoelasticity, and the fully swollen material behaves like a non-linear elastic material.* To assess if swelling causes irreversible changes to the mechanical behavior, we solvent cycle — freely swell, then freely dry — and then use those samples for uniaxial tests. For samples that have been solvent cycled five times, Figure 2b shows the reappearance of the viscoelastic response for uniaxial load-unload experiments. These results show that *prior solvent cycling has no significant residual effects on the overall response of the polymer, which we take as an indication of the reversibility of the process.*

Figure 2: a) A subset of the experimental results showing the load-unload response for moderate rates displaying the clear affect of equilibrium swelling on the behavior. b) Uniaxial load-unload tensile test results after solvent cycling 5 times with n-Pentane, o-Xylene and Toluene. For ease of comparison, we also show the virgin results.

CONTINUUM LEVEL MODEL

Our continuum-level constitutive model for polymeric gels is provided in detail in [1], it is only overviewed here. The large deformation time-independent response of the polymer is modeled employing a non-Gaussian statistical mechanics model, which takes into account the limited extensibility of polymer chains, as well as a scaling exponent on the swelling ratio to account for the change in effective stiffness. Viscous effects are modeled following a micromechanically motivated approach. Lastly, the mixing between the polymer network and solvent is accounted for by the Flory-Huggins model.

CONCLUSIONS

Using VHB 4910 along with three different solvents, n-Pentane, o-Xylene and Toluene, we have measured the mechanical response in (i) quasi-static uniaxial large deformation tension, (ii) uniaxial load-unload at multiple rates, and (iii) stress relaxation; when virgin, fully swollen, and solvent cycled. The most notable result of these experiments being the apparent loss of viscoelasticity in the response due to the uptake of solvent. Additionally, through solvent cycling, our measurements show the reappearance of viscoelasticity, suggesting the process is reversible. In addition, we have developed a continuum-level constitutive model for viscoelastic polymeric gels. Our model is successfully calibrated against the obtained experimental data, thus proving capable to replicate the major features of viscoelastic gel behavior observed in our experiments. The calibration of our constitutive model showed (i) low utilization of the time-dependent stress contribution for the samples fully swollen in n-Pentane; (ii) almost complete absence of the time-dependent stress contribution for samples fully swollen with o-Xylene and Toluene. Although not the aim of this study, we have found the failure of the material fully swollen with o-Xylene and Toluene to be occurring at the stretch at which the dry material (both virgin and solvent cycled) is still intact. That is a very interesting result that indicates there is more to learn, however we leave it for future work. Lastly, while we characterized the behavior of a viscoelastic gel when fully swollen, the mechanical response at intermediate degrees of swelling is yet to be determined and is the focus of our future work.

SHAPE-CHANGING ELASTOMER VIA LIQUID-GAS PHASE TRANSITION

Saint-Jean Maïka*[1], Etienne Reyssat[1], José Bico[1], Benoît Roman[1]
[1]PMMH, CNRS, ESPCI Paris, Université PSL, Sorbonne Université, Université de Paris, Paris, France

Summary: We use the liquid-gas transition of droplets dispersed in an elastomer matrix to design reversible shape changing materials. More specifically, we use droplets of alcohol trapped in silicone rubber. Upon heating, the liquid boils inside the cavities, leading to a rise of the inner pressure and to the global expansion of the material. Our goal is to design planar sheets that can evolve to controlled 3D structures. The strategy adopted here is to use an embedded structure to geometrically constrain the deformations of the material.

INRODUCTION

Shape changing materials is currently an active field of research, motivated by potential applications in minimally invasive surgery [1], tissue engineering [2], soft robotics [3] and, more generally, in smart materials [4]. One possible strategy consists in embedding a network of airways in plates made of an elastomeric matrix [5]. Upon inflation, the airways deform anisotropically, leading to local metric change through the plate. As a consequence, the plate buckles and adopts a 3D shape prescribed by the architecture of the airways. Following this work, we propose a different strategy where an embedded skeleton limits the extension of the material in certain directions, leading to programmed 3D shapes.

METHODS AND RESULTS

The growing matrix used in this study is inspired by the recent work of Miriyev *et al.* [6]. This technique is based on thermal actuation of an elastomer material in which ethanol droplets are dispersed. When heated, ethanol vaporizes, which increases the pressure inside the cavities and induces a large expansion of the material. This action is, in principle, reversible as the pressure is released when the ethanol goes back to its liquid state (although in practice we observe-some aging of the material due to the diffusion of ethanol through the matrix).

Our goal is to use this expanding material to design objects than can change shape upon heating. The strategy selected here is to control in-plane metric deformation by locally constraining the expansion along given directions. To this aim, custom meshes made out of thin ~~cut~~ Mylar sheets are embedded in the matrix.

Technically, two identical meshes are disposed symmetrically on both sides of a plate of elastomer to prevent spontaneous bending by bilayer effect. Each mesh is finally covered with a thin layer of raw elastomer to prevent alcohol leaks (Figure 1a).

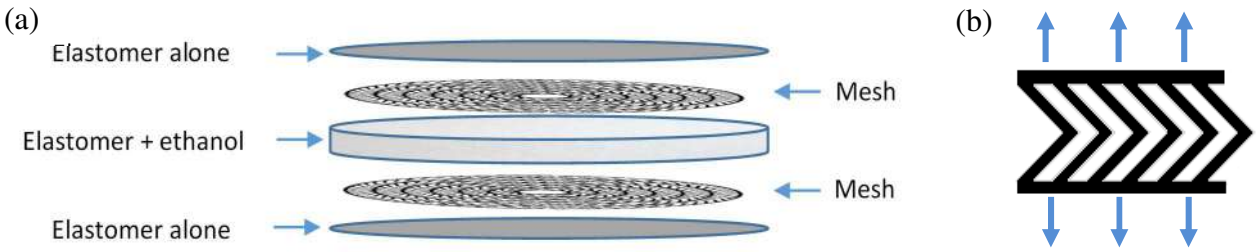

Figure 1: (a) Composition of the sample. Two identical thin meshes are placed on each side of a plate of active matrix (elastomer with alcohol droplets) and then covered with a layer of pure elastomer. (b) Typical chevron pattern of the mesh that permits an expansion in the vertical direction but blocks the horizontal direction.

The meshes used are designed differently according to the desired 3D shape. Different types of designs are developed: like chevrons (Figure 1.b). Depending on the pattern, both positive and negative Gaussian curvatures can be obtained from planar shapes. Having both negative and positive Gaussian curvatures allows us to potentially design any shape. The orientation and angle of the patterns of the mesh determine the final shape of the object (Figure 2). The kinematics of the embedded mesh can be rationalized with simplified designs that lead to uniaxial extension.
Under high extension the mesh reaches a maximum deformation dictated by geometry. Such finite extensibility stiffens the composite material. As a consequence, in addition to dictating the shape, the embedded meshes also tend to rigidify the final structure.

ON THE MECHANICS OF *E*-CONES

Souhayl Sadik*[1] and Marcelo Azevedo Dias †[1]
[1]Department of Engineering, Aarhus University, 8000 Aarhus C, Denmark

Summary In this work, we study the most basic and fundamental geometric building block of Kirigami: a thin sheet with a single cut. We consider the deformation of a circular thin plate with a radial slit following the opening of the slit by a given excess angle. In the isometric limit—as the thickness of the disk approaches zero—the elastic energy has no stretching contribution and the shape of the disk is governed by the bending energy as it approaches that of an *e*-cone: a conical solution where all the generators remain straight and intersect at a singularity at its apex. We solve the geometrically nonlinear boundary value problem for a Saint Venant-Kirchhoff constitutive plate model to find the geometry of the e-cone as well as the surface stresses and couple-stresses (moments). We further investigate the local singular behaviour of the slit near the crack tip by relaxing the inextensibility condition and discarding the conical ansatz in an attempt to access the stretching region around the apex.

KINEMATICS

Kirigami, the Japanese art of paper cutting, offers unexplored ways to tailor the morphology of thin elastic sheets. Indeed, by exploiting the fundamental principles of this art and carefully tuning the geometry and the topology of the cuts, it unlocks a great potential to control the structural and mechanical properties of thin sheets across multiple scales [1]. In order to generate predictable and adaptable patterns or motion control as well as regulate the multi-stable nature of these structures, one would need to understand the fundamental behaviour of such structures [2]. In this work, we explore the emergent local non-linear effects in Kirigami by focusing our attention on the study of the deformation of a single cut and the inherent interplay of geometry and mechanics.

We consider a reduced two-dimensional shell model $\mathcal{H}$ for a circular thin disk with a radial slit extending from its centre to its boundary. We assume an excess angle of ψ and look for a developable conical solution: the disk deforms in $\mathbb{R}^3$ such that all its radial generators remain straight and unstretched. In terms of the deformation embedding, it amounts to assuming the conical ansatz for the deformation mapping $\varphi(R,\Phi) = (R, \theta(\Phi), \phi(\Phi))$, where $\{R, \Phi\}$, $0 \leq \Phi \leq 2\pi$ is a polar coordinates system on $\mathcal{H}$ such that its origin sits at the center of $\mathcal{H}$ and $\Phi = 0$ and $\Phi = 2\pi$ arbitrarily correspond to the two lips of the slit, and $\{r, \theta, \phi\}$, $0 \leq \theta \leq \pi$, $0 \leq \phi < 2\pi$ is a spherical coordinate system in $\mathbb{R}^3$. We further assume the following boundary conditions to enforce the opening of the slit by an angle ψ and control the angles of rotation of its lips by η_1 and η_2 : $\theta(0) = \theta(2\pi) = \frac{\pi}{2}$, $\phi(0) = \frac{\psi}{2}$, $\phi(2\pi) = 2\pi - \frac{\psi}{2}$, $\theta'(0) = \eta_1$, and $\theta'(2\pi) = \eta_2$.

In the deformed configuration $\varphi(\mathcal{H}) \subset \mathbb{R}^3$, we denote the normal of the surface by $\boldsymbol{n}$ and its first and second fundamental forms by $\boldsymbol{g} = \bar{\boldsymbol{g}}_{|\varphi(\mathcal{H})}$ and $\boldsymbol{\beta} = -(\nabla^{\bar{\boldsymbol{g}}}\boldsymbol{n})^{\flat}$,[1] respectively. To quantify the strain, we define an intrinsic strain measure $\boldsymbol{C} = \varphi^*\boldsymbol{g}$ [2]—the right Cauchy-Green deformation tensor;[3] and an extrinsic strain measure $\boldsymbol{\Theta} = \varphi^*\boldsymbol{\beta}$. We denote by J the Jacobian of the deformation $J = \sqrt{\frac{\det \boldsymbol{C}}{\det \boldsymbol{G}}}$. We define the convected manifold $(\mathcal{H}, \boldsymbol{C}, \boldsymbol{\Theta})$ as the Riemannian manifold resulting from pulling-back the geometry of the deformed surface onto $\mathcal{H}$, i.e., taking $\boldsymbol{C}$ and $\boldsymbol{\Theta}$ to be the first and second fundamental forms of $\mathcal{H}$, respectively.

The inextensibility yields that $\phi(\Phi) = \frac{\psi}{2} + \int_0^{\Phi} \frac{\sqrt{1-\theta'^2(\eta)}}{\sin[\theta(\eta)]}\, d\eta$, and it follows that the deformed fundamental forms read

$$\boldsymbol{C} = \begin{pmatrix} 0 & 0 \\ 0 & R^2 \end{pmatrix}, \quad \boldsymbol{\Theta} = \begin{pmatrix} 0 & 0 \\ 0 & R\kappa(\Phi) \end{pmatrix},$$

where we introduce the normal curvature $\kappa(\Phi) := \frac{\cot[\theta(\Phi)]\left(1-\theta'^2(\Phi)\right) - \theta''(\Phi)}{\sqrt{1-\theta'^2(\Phi)}}$.

BALANCE LAWS

We assume that the disk is made of a material with a Saint Venant-Kirchhoff constitutive model. In the convected manifold $(\mathcal{H}, \boldsymbol{C}, \boldsymbol{\Theta})$, the strain energy density $\mathcal{W}$ of the material reads[4]

$$\mathcal{W} = \frac{h}{4}\left\{\mu \mathrm{tr}\left[(\boldsymbol{C}-\boldsymbol{G})^2\right] + \frac{\mu\lambda}{2\mu+\lambda}\left[\mathrm{tr}\,(\boldsymbol{C}-\boldsymbol{G})\right]^2\right\} - \boldsymbol{p}:(\boldsymbol{C}-\boldsymbol{G}) + \frac{h^3}{12}\left\{\mu \mathrm{tr}\left[(\boldsymbol{\Theta}-\boldsymbol{B})^2\right] + \frac{\mu\lambda}{2\mu+\lambda}\left[\mathrm{tr}\,(\boldsymbol{\Theta}-\boldsymbol{B})\right]^2\right\},$$

*E-mail: souhayl.sadik@eng.au.dk.
†E-mail: madias@eng.au.dk.

[1]The flat symbol in $(.)^{\flat}$ denotes the operator for lowering tensor indices.

[2]φ^* denotes the pullback by the diffeomorphism φ. As examples, the pullback of a $\binom{0}{2}$-rank tensor $\boldsymbol{w}$ reads in local coordinates $(\varphi^*\boldsymbol{w})_{AB} = \frac{\partial\varphi^a}{\partial X^A}\frac{\partial\varphi^b}{\partial X^B} w_{ab}$; and the pullback of a $\binom{2}{0}$-rank tensor $\boldsymbol{\omega}$ reads in local coordinates $(\varphi^*\boldsymbol{\omega})_{AB} = \frac{\partial\varphi^{-A}}{\partial x^a}\frac{\partial\varphi^{-B}}{\partial x^b}\omega^{ab}$.

[3]Note that the right Cauchy-Green deformation tensor is typically defined as $\boldsymbol{F}^{\mathsf{T}}\boldsymbol{F}$ where $^{\mathsf{T}}$ denotes the transpose operator. In our notation, we have $\boldsymbol{C} = \left(\boldsymbol{F}^{\mathsf{T}}\boldsymbol{F}\right)^{\flat}$.

[4]Note that in the convected manifold, one has $C^{AK}C_{KB} = \delta^A{}_B$ so that raising $((.)^{\sharp})$ and lowering $((.)^{\flat})$ tensor indices is performed using the convected metric $\boldsymbol{C}$, e.g., $T^A{}_B = C^{AK}T_{KB}$. Also, the trace of a tensor is computed by using the convected metric $\boldsymbol{C}$, e.g., $\mathrm{tr}\,(\boldsymbol{T}) = C^{AB}T_{AB}$ and $\mathrm{tr}\,(\boldsymbol{C}) = 3$.

where h is the thickness of the disk, μ and λ the Lamé coefficients, and $\boldsymbol{p}$ the $\binom{2}{0}$-rank tensor Lagrange multiplier enforcing the inextensiblity condition $\boldsymbol{C} = \boldsymbol{G}$. Without any loss of generality, we assume the following form for the Lagrange multiplier $\boldsymbol{p}$

$$\boldsymbol{p}(R,\Phi) = \begin{pmatrix} p_1(R,\Phi) & \frac{\tau(R,\Phi)}{R} \\ \frac{\tau(R,\Phi)}{R} & \frac{p_2(R,\Phi)}{R^2} \end{pmatrix}$$

In the convected manifold $(\mathcal{H}, \boldsymbol{C}, \boldsymbol{\Theta})$, the balance laws for the disk read

$$\mathrm{Div}_{\boldsymbol{C}} \left(\boldsymbol{\Sigma} + \boldsymbol{C}^\sharp \cdot \boldsymbol{\Theta} \cdot \boldsymbol{\Lambda} \right) + \boldsymbol{C}^\sharp \cdot \boldsymbol{\Theta} \cdot \mathrm{Div}_{\boldsymbol{C}} (\boldsymbol{\Lambda}) = \boldsymbol{0}\,, \tag{1a}$$

$$\left(\boldsymbol{\Sigma} + \boldsymbol{C}^\sharp \cdot \boldsymbol{\Theta} \cdot \boldsymbol{\Lambda} \right) : \boldsymbol{\Theta} - \Delta_{\boldsymbol{C}} (\boldsymbol{\Lambda}) = 0\,, \tag{1b}$$

where $\mathrm{Div}_{\boldsymbol{C}}$ and $\Delta_{\boldsymbol{C}}$ respectively denote the divergence and the Laplace operators in the convected manifold; they read as follow $\mathrm{Div}_{\boldsymbol{C}}\, \boldsymbol{\Sigma} = \Sigma^{AB}{}_{||B}$ and $\Delta_{\boldsymbol{C}} \boldsymbol{\Lambda} = \Lambda^{AB}{}_{||AB}$, where a subscript double stroke $||$ denote covariant differentiation with respect to $\boldsymbol{C}$ taken as a metric on $\mathcal{H}$. Reducing $\boldsymbol{p}$, the balance laws (1) reduce to a single equation governing the normal curvature κ and it reads

$$\kappa''(\Phi) + \frac{\kappa^3(\Phi)}{2} + \left(1 + \alpha - \frac{3(\lambda+2\mu)}{h^3 \mu(\lambda+\mu)} \int_0^\Phi b(\eta)\, d\eta \right) \kappa(\Phi) = 0\,. \tag{2}$$

Note that for $b = 0$, Cerda and Mahadevan [3], Guven and Müller [5], and Efrati et al [**?**] have all obtained the same elastica equation governing the normal curvature κ from a reduced conical model. Using the solution $\boldsymbol{p}$ of (1), we may write the radial and circumferential effective surface traction $\boldsymbol{f}$ and effective surface shear s as follow

$$\begin{aligned}
\bar{\boldsymbol{f}}_R &= \left[\frac{h^3\mu(\lambda+\mu)}{3(\lambda+2\mu)} \frac{\frac{1}{2}\kappa^2(\Phi)+\alpha}{R^2} - \frac{a'(\Phi) + (\ln(R)+1)b'(\Phi) + \int_0^\Phi b(\eta)d\eta}{R^2} - \frac{c(\Phi)}{R} \right] \boldsymbol{u} - \left[\frac{a(\Phi)+\ln(R)b(\Phi)}{R^2} \right] \boldsymbol{t}\,; \\
\bar{s}_R &= \frac{h^3\mu(\lambda+\mu)}{3(\lambda+2\mu)} \frac{\kappa(\Phi)}{R^2}\,; \quad \bar{\boldsymbol{m}}_R = \frac{h^3\mu\lambda}{6(\lambda+2\mu)} \frac{\kappa(\Phi)}{R}\, \boldsymbol{u}\,; \\
\bar{\boldsymbol{f}}_\Phi &= -\left[\frac{a(\Phi)+\ln(R)b(\Phi)}{R^2} \right] \boldsymbol{u} + \left[-\frac{h^3\mu(\lambda+\mu)}{3(\lambda+2\mu)} \frac{\frac{1}{2}\kappa^2(\Phi)+\alpha}{R^2} + \frac{\int_0^\Phi b(\eta)d\eta}{R^2} \right] \boldsymbol{t}\,; \\
\bar{s}_\Phi &= \frac{h^3\mu(\lambda+\mu)}{3(\lambda+2\mu)} \frac{\kappa'(\Phi)}{R^2}\,; \quad \bar{\boldsymbol{m}}_\Phi = \frac{h^3\mu(\lambda+\mu)}{3(\lambda+2\mu)} \frac{\kappa(\Phi)}{R}\, \boldsymbol{t}\,;
\end{aligned} \tag{3}$$

for some constant α and some functions a, b, and c of the angle Φ; where $\boldsymbol{t} = \varphi_* \partial_\Phi$ and $\boldsymbol{u} = \varphi_* \partial_R$. Note that $\boldsymbol{t}$ and $\boldsymbol{u}$ are respectively the tangent and the in-surface normal of any curve in the deformed configuration that resulted from the deformation of a circle centered at the origin in the reference configuration of the disk—the curve that is parametrized by the assumed conical ansatz for a fixed R. We have hereby obtained more general results on the state of stress in the *e*-cone which are nonetheless consistent with the results found by Cerda and Mahadevan [3] and Guven and Müller [5].

CONCLUSIONS

We have achieved a full description of the geometry and the mechanics of the *e*-cone. However, it is easy to see that the apex represent a singularity for the curvature, the stress, and the energy—it is indeed a singularity for all quantities. Indeed, for a small region near the apex, the deformation of the e-cone is regularised by an added contribution of the stretching energy on top of the bending energy. This resolves the singularity by eliminating the inexentensibility condition and the conical ansatz. As such, the local solution near the apex is no longer invariant under a radial dilation with respect to its centre. We are currently investigating this region and have so far obtained by rescaling the problem scaling laws in the apex area and consequently proven that the stretching and bending contributions are of the same order.

FROM BIFURCATION TO SNAP-THROUGH BUCKLING OF ELASTIC THIN SHELLS WITH LARGE AXISYMMETRIC IMPERFECTION

Chuan Qiao, Lu Liu, and Damiano Pasini*
Department of Mechanical Engineering, McGill University, Montreal, Canada

Summary Elastic thin shells are well-known for their highly unstable post-buckling response that exhausts their pressure bearing capacity and leads to catastrophic collapse. This paper examines elastic thin shells with a large axisymmetric imperfection that can escape the classical bifurcation of perfect spherical shells. The results show that the imperfect shell undergoes snap-through buckling followed by a stable post-buckling that offers increasing resistance to pressure over a large shell deformation. In addition, a sensitivity analysis on the role of defect geometry reveals the emergence of four buckling modes. The findings show that harnessing defect geometry can be effective in programming the post-buckling characteristics and transition between buckling modes, thus offering potential routes for the design of soft metamaterials.

INTRODUCTION

The post-buckling response of elastic thin shells subject to prescribed uniform external pressure is highly unstable [1]. This phenomenon deprives shell functionality and has two main features. First, prior to bifurcation, the shell deformation, in particular the displacement of the pole, is tiny compared to the shell radius thereby yielding almost no change in volume. Second, under a given pressure the shell is unstable for the entire post-buckling regime, showing the inability to resist any increase in pressure and spontaneous marching towards full eversion.

To escape the classical bifurcation of perfect spherical shells, this paper examines elastic thin shells with a large axisymmetric imperfection [2] and compares its buckling response with that of perfect shells subject to a uniform external pressure. We present a theoretical model that uses exact expressions of stretching and bending strains for axisymmetric deformations without any restrictions on the magnitude of displacements and rotations, along with a campaign of experiments on fabricated shell samples and a comprehensive computational study. The results can capture the defect sensitivity of imperfect shells to selected parameters of shell and defect geometry.

GEOMETRY OF THE IMPERFECT SHELL

We examine an imperfect shell (Figs. 1 a and b) with a large imperfection in the form of an axisymmetric circular-arc indentation that can vary in amplitude, angular width, and meridional angle. The arc can collapse to a line segment for a small amplitude or a semicircle for a large amplitude. The imperfection is also assumed to lie between the equator and the upper pole of the semi circumference. The slenderness of the shell is defined by the radius to thickness ratio.

COMPARISON BETWEEN THE BUCKLING OF THE PERFECT AND IMPERFECT SHELLS

Figure 1c shows three curves, one of which is obtained from a theoretical model that uses exact expressions of stretching and bending strains for axisymmetric deformations. The blue dashed line is for the perfect baseline hemispherical shell and represents the classical buckling response extensively investigated in literature [1]. Normalized

with the Zoelly's buckling pressure p_C [3], the pressure rapidly increases with tiny pole displacement up to unity. Post bifurcation, a monotonic plunge of pressure appears, followed by a gradually descending plateau (just below 0.1) that spans the entire range.

The purple and red curves in Figure 1c refer to the imperfect shell with uniform thickness. The former (purple dots) is the pressure provided by our theoretical model, which employs exact expressions of stretching and bending strains for axisymmetric deformations, and the latter (red solid line) that obtained by our numerical model (ABAQUS). The difference between the maximum pressure predicted by the theoretical and FEM models is below 1%. At the normalized pole displacement of $w_{pole} / R = 0.04$, the pressure of the imperfect shell enters a region of snap-through buckling, after which the pressure monotonically increases to reach a maximum value of $p / p_C = 0.33$ at $w_{pole} / R = 0.46$.

A number of differences emerge between the perfect and imperfect shell shown in Figure 1c. The main one is their buckling mode. The imperfect shell first undergoes snap-through buckling at a pressure lower than the maximum pressure, and then it regains stability as the pressure increases to the maximum, a phenomenon not observed in the perfect spherical counterpart. In contrast, the perfect shell undergoes bifurcation buckling for a tiny value (below 1%) of the normalized pole displacement, where the pressure reaches its maximum without undergoing snap-through instability. After the bifurcation point, the post-buckling pressure decreases monotonically until the shell is everted, thereby denying the chance for the shell to regain stability [1].

SENSITIVITY TO IMPERFECTION GEOMETRY

Figure 2 shows four possible modes for the imperfect shell to respond to pressure. Mode 1 resembles the classical instability of a perfect spherical, i.e. an inward dimple-like shape (Figure 2a) and it is governed by small values of the imperfection. Mode 2 identifies a post-buckling response with deformation localized within the imperfection region (Figure 2b). This mode indicates a transition from bifurcation to snap through buckling. It is governed by a larger imperfection size. Figure 2c illustrates mode 3, a snap-through buckling controlled by a localized deformation accrued below the imperfection. This response is caused by increasing values of the imperfection size. For all of the aforementioned buckling modes (1, 2, and 3), the shell collapses once the prescribed pressure exceeds the buckling pressure. Mode 4 (Figure 2d) describes a scenario where snap-through buckling with mode 2 arises before the attainment of the maximum pressure with mode 3. This behaviour is triggered by a large width and moderate amplitude of the imperfection.

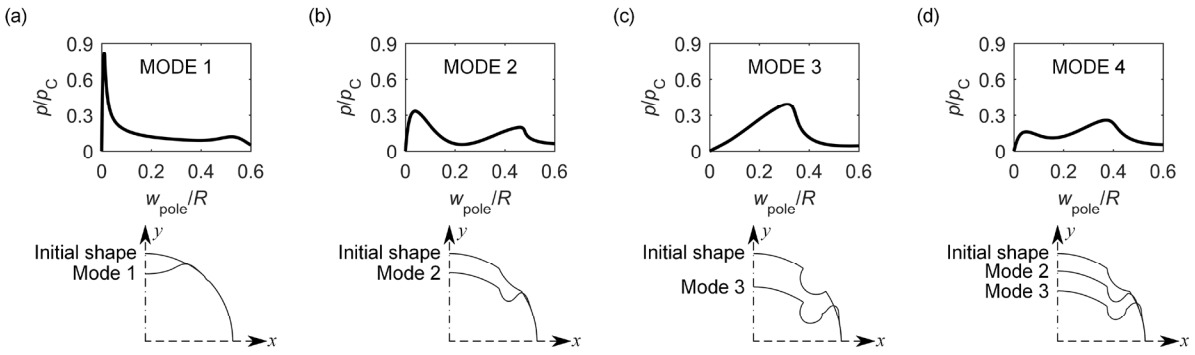

Figure 2. Possible deformation modes leading to shell collapse. (a) Bifurcation buckling. (b), (c), and (d) Snap-through buckling.

CONCLUSIONS

This paper has investigated the impact of a large axisymmetric imperfection on the buckling response of a thin elastic shell subject to uniform external pressure. A large axisymmetric imperfection can cause the shell response to depart from bifurcation buckling, i.e. the classical dimple-like shape of perfect shells typically triggered by a tiny pole displacement. Our shell theory formulation with exact stretching and bending strain measures shows quantitative agreement with FEM simulations for large shell displacements and rotations. Four modes have been identified: bifurcation instability caused by small sized imperfections, and three snap-through responses generated by large sized imperfections. These results highlight that a sizeable snap-through tunability could be exploited for the design of soft robots and morphing metamaterials.

SOFT ELASTICITY BY DOMAIN FORMATION IN MAGNETOACTIVE COMPOSITES

Pedro Ponte Castañeda*[1,2] and Joshua Furer[2]
[1]Department of Mechanical Engineering & Applied Mechanics, University of Pennsylvania, Philadelphia, USA
[2]Graduate Program in Applied Mathematics & Computational Sciences, University of Pennsylvania, Philadelphia, USA

Summary Reinforced elastomeric composites with periodic microstructures can undergo both microscopic and macroscopic instabilities. This paper is concerned with the post-bifurcation response of magneto-active elastomeric composites after the possible development of a macroscopic instability. By means of the relaxation or quasiconvexification of the principal solution for the homogenized energy function, it is shown that the response after the onset of a macroscopic instability corresponds to domain formation and is associated with soft modes of deformation that can be controlled by an externally applied magnetic field.

EXTENDED SUMMARY

This paper deals with the stability and post-bifurcation response of magneto-active elastomeric composites. In the purely mechanical context, it has been known for a long time [1, 2] that elastomeric composites with periodic microstructures can undergo both microscopic (short wavelength) and macroscopic (long wavelength) instabilities, which can be estimated from their incremental or *local* energy. In addition, it is also known that macroscopic instabilities can be detected by loss of strong ellipticity of the incremental homogenized response in both periodic and random systems [2, 3], but the behavior of the composites after the onset of such macroscopic instabilities is less well understood. Consistent with experimental observations in nanostructured thermoplastic elastomers [4], recent theoretical work [5, 6] indicates that, under appropriate loading conditions, it is possible for the "principal" solution, i.e. the solution before the onset of any instability, to bifurcate into a lower-energy solution by the formation of domains (see Fig. 1). These domains form on a scale much larger than that of the heterogeneity, but still small when compared to the original macroscopic scale, and are associated with "soft modes" of deformation. Mathematically, the post-bifurcation behavior after the onset of a macroscopic instability can be related to the relaxation or quasiconvexification of the principal solution for the homogenized energy function, which in turn can be estimated by means of the rank-1 convexification. As it turns out, this *global* approach provides estimates for the onset of macroscopic instabilities that can be different from those that can be generated by checking loss of ellipticity of the incremental or *local* response, but that are more consistent with the definition of the homogenized energy function [2, 3].

In the context of dielectric elastomer laminates with periodic microstructures, the onset of microscopic and macroscopic instabilities has also been investigated based on the incremental or local response [7]—and they have been found to depend on the magnitude and orientation of the applied electric field. Analogous results have been obtained for macroscopic instabilities in magneto-active elastomer with random distributions of aligned short fiber [8]. In this paper, we consider a different approach based on the global homogenized energy of magneto-elastic composites [5, 6] and investigate the post-bifurcation response after the development of macroscopic instabilities. For analytical ease, we consider a simple laminate consisting of two isotropic neo-Hookean phases with linear magnetic responses. Making use of generalized notions of quasiconvexification and rank-1 convexification in the magneto-elastic context, we obtain estimates for the relaxation of the magneto-active composites and find long wavelength instabilities and soft modes of deformation under appropriate loading conditions. In particular, we consider the application of a magnetic field parallel and perpendicular to the layers.

The first important conclusion drawn in this work is that, as in the purely mechanical context, in the generalized magneto-elastic setting, strict global rank-one convexity of the principal solution is generally lost prior to strong ellipticity, as measured by the generalized strong ellipticity condition making use of the incremental magneto-elastic moduli of the principal solution. In fact, only under pure shear loading with a magnetic field parallel and perpendicular to the layers (in the undeformed configuration) are strong ellipticity and strict rank-one convexity lost simultaneously. For more general loading, rank-one convexity can be lost significantly earlier than strong ellipticity.

While the relaxation can only be computed exactly for certain loading conditions, upper and lower bounds based on the rank-1 convexification and polyconvexity, respectively, remain rather tight so long as the alignment of the magnetic field with the layers is not too close. Even still, the difference between the bounds decreases as the magnetic field comes into alignment with the layers, whereby the upper bound can give an accurate prediction of the relaxation for all loading conditions.

In addition, and consistent with the incremental approach [8], a magnetic field perpendicular to the layers tends to destabilize the composite. It is therefore interesting that our knowledge of the relaxation is best in these destabilized states. In investigating the behavior of the laminate, we found that the mechanism of instability, namely sufficient compression along the layers, can either be promoted or inhibited, depending on the orientation of the applied magnetic field. In

Figure 1: (a) Domain formation in Oriented Lamellar Block Copolymer Films: TEM image of a "chevron" structure formed by perpendicular deformation to 300% strain [4]. (b) Rank-1 convexification construction for relaxation of neo-Hookean laminates.

particular, the application of a magnetic field perpendicular to the layers has the effect of reducing the value of the axial stretch (relative to the value in the purely mechanical case) necessary for an instability to develop. In fact, we found that a macroscopic instability can be triggered just by prescribing such a magnetic field, in the undeformed configuration. Such instabilities result in the formation of lamellar domains, and the construction is found to be similar to that in the purely mechanical case. In all cases, stability can be regained through the application of sufficient shear, and the relaxation not only induces mechanical softening, but can also lead to an increase or decrease in the macroscopic magnetic response, depending on the orientation of the magnetic field.

Summary We present a computational scheme for predicting whether addition of new modules to an existing modular robotic structure will mechanically overload the system, causing it to break or lose stability. The algorithm is executed by the modular robot itself in a distributed way, and relies on the iterative solution of mechanical equilibrium equations derived from a simple Finite Element model of the robot. In the model, inter-modular connections are represented as beams and the contact between modules and external supports is accounted for by a predictor-corrector scheme. The algorithm is verified through simulations in the Programmable Matter simulator *VisibleSim* and real-life experiments on the modular robotic system *Blinky Blocks*.

MOTIVATION

This work stems from investigations into self-reconfigurable modular robots with a view towards Programmable Matter [1]. Such systems are built of simple robotic units—modules—which can compute, exchange information, join, disjoin, and move over one another. If the modules were sufficiently small, numerous and well-powered, they could potentially form a highly-versatile active metamaterial, with shape- and microstructure-changing capabilities.

Much work on self-reconfigurable robots focuses on kinematics and is devoted to reconfiguration planning—designing such module movements which allow the entire ensemble to transition from one configuration into another [2]. The present work, by contrast, focuses on mechanics of modular structures [3] and is purely static. We consider the rarely-discussed problem of mechanical safety of a modular structure, which is crucial for the structure's functionality as a physical system and reconfiguration in particular [4].

PROBLEM STATEMENT

The modular structure rests on the ground, or is otherwise in contact with external supports, loaded by its own weight. If additional modules are attached to the system, two failure scenarios may occur. Either some inter-modular connection may become overloaded and break (Fig. 1) or the center of gravity of the system may shift insecurely causing the structure to topple (Fig. 2). The task is to predict if the structure will fail or not, knowing the strength of connectors and the places where new modules will be added to the system. The prognosis should be obtained by the modular system itself using its distributed MIMD computational structure with a mesh connection topology, as it was outlined in [4].

METHODS

We focus on cubic modules attached side to side, and thus on structures arranged over a cubic Cartesian grid (Figs. 1 and 2). Despite this narrow scope, the proposed methods are general and can be used with other setups as well.

In the algorithm, the modular structure is represented as a Finite Element (FE) model whose nodal values are stored by the modules in a distributed fashion. We use a simple FE model in which each module corresponds to a single node with 6 degrees of freedom (3 displacements and 3 rotations), while connections between modules are represented as elastic beams with respective nodes as endpoints [5]. Each module only stores its own 6 nodal values. The contact with external supports is also modeled using beams, but ones having variable elastic parameters—during the iterative solution, a predictor-corrector scheme is employed to emulate unilateral connections. Further, selected modules simulate the presence of the new modules which will be added to the system.

The solution is obtained using the weighted Jacobi iterative scheme [6]. The main advantage of this procedure is that computations can be done locally—each module computes its own nodal values at step $i+1$ using only the values at step i from its immediate neighborhood. After the iterations have converged to a desired tolerance, each module checks if any of its connections is overloaded by comparing the junction forces predicted by the beam model with the strength of connectors. This addresses the bond breakage problem. Modules also aggregate information about the active points of contact with external supports, and are able to predict if the structure will tip over or not. This addresses the stability problem.

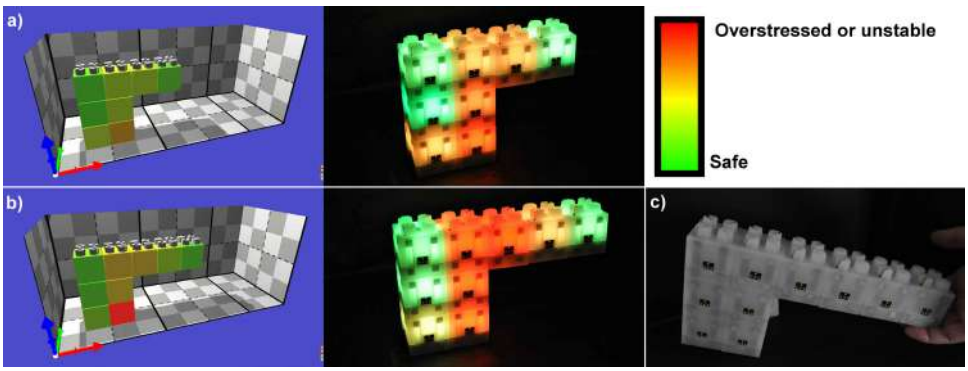

Figure 2: An example of stability loss. Adding successive modules moves the center of gravity of the cantilever beyond the supports and the structure tips over. Left—simulations in *VisibleSim*; center and right—experiments on *Blinky Blocks*.

RESULTS

Tests were performed in the dedicated simulator *VisibleSim* [7] and on the static robotic modules *Blinky Blocks* [8]. The attachment forces of Blinky Blocks were determined experimentally, while their elastic parameters assessed. Hardware experiments, like those presented in Figs. 1 and 2, revealed that the algorithm correctly predicts the mechanical behavior of small ensembles of modules, despite its crude FE representation of connected modules and the simple contact model. The weighted Jacobi solution scheme converges slowly, as expected, which will have to be addressed in the future by applying more complex alternatives like Krylov subspace methods or multigrid methods [6].

WRINKLING ANALYSIS OF THE FILM IN A SANDWICH SYSTEM UNDER BI-DIRECTIONAL PRESSURES

Guohua Nie*[1], and Guohang Shao [1]
[1]Institute of Applied Mechanics, School of Aerospace Engineering and Applied Mechanics, Tongji University, Shanghai 200092, China

Summary The 2D wrinkling of the film in a layer-film-layer sandwich system under the action of bi-directional uniform pressures is presented. The analytical relation between the pressure and wave number is derived based on classical thin-plate theory for the film and 3D elasticity theory for the two compliant layers, which is readily used to predict appearance of wrinkling and do a parametric analysis. Numerical examples are given to illustrate critical wave length and strain for various ratios of moduli of the system for the cases that both the layers are all fixed at their exterior surfaces or one layer is free while the other is fixed. The present results are compared with finite element simulation on equivalent thermal buckling by relating critical thermal strain to critical pressure. A comparison indicates that the present solution is valid and accurate enough in computation.

INTRODUCTION

A stiff thin film bonded to the surface of a compliant substrate can buckle to form periodic wrinkling patterns under compressive stresses [1]. The wrinkling patterns have a huge potential for various applications, e.g., wrinkles may be used as stretchable and foldable electronics, etc. In the fabrication of such electronic devices, a layer-film-layer sandwich system is of particular importance. To avoid delamination of the circuit (film-layer system) and/or fracture of metal interconnects (film) under high bending, an additional encapsulating layer is introduced on top of the circuit to improve adhesion and alleviate the strain level because such sandwich system shifts the neutral mechanical plane to the film plane [2]. For 1D sinusoidal interfacial wrinkling in a film-layer or sandwich system under unidirectional pressure, some theoretical solutions for critical pressure and wave number for the onset of interfacial wrinkles have been proposed by combination of thin-plate theory for the film with the solution for boundary value problem under plane strain condition for one layer or bi-layer materials [3,4]. However, the plane strain condition will no longer exist for the layers for two dimensional wrinkling of film (e.g., square checkerboard mode, etc.) induced by action of bi-directional pressures. This paper aims to present a theoretical solution for 2D wrinkling of the film in the sandwich system.

ANALYSIS AND RESULTS

As shown in Figure 1, a thin plate (film) of height h is assumed to be bonded to two corresponding surfaces of upper and lower compliant layers (substrates) with heights of H_u and H_l, respectively. When there exists 2D wrinkling in the sandwich system under combined uniform bi-directional pressures N, the governing equation for buckling of the film is $D_f\nabla^4 w=\Delta p-N\nabla^2 w$, where w and Δp are the deflection of the film and pressure difference from two substrates respectively and $D_f=E_f h^3/12\left(1-\mu_f^2\right)$ in which E_f,μ_f are elastic modulus and Poisson's ratio, respectively. It is assumed that the deflection takes the bi-directional (periodic) sinusoidal form of $w=A\cos(kx)\cos(ky)$ where A and k are amplitude and wave number, respectively. Due to a linear perturbation procedure [4], the relation between the pressure and wave number can be derived as $N=2D_f k^2-\left(\bar{g}_u\bar{E}_u-\bar{g}_l\bar{E}_l\right)/2k$, where $\bar{E}_{u,l}=E_{u,l}/(1-\mu_{u,l}^2)$ and $E_{u,l},\mu_{u,l}$ are elastic moduli and Poisson's ratios of the upper and lower substrates, respectively. The two unknown quantities, $\bar{g}_u,\bar{g}_l$, relate to wave number k and are determined by using a three dimensional elastic solution described below for the two compliant layers together with boundary conditions for the layers and continuous conditions between the film and layers. The critical wave number k_c can be obtained by condition of extremum, i.e., $\partial N/\partial k=0$, and the critical pressure N_c causing the 2D wrinkling of the film is thus evaluated as $N_c=N\big|_{k=k_c}$.

To deduce the 3D solution for the two compliant layers, the equilibrium equations can be expressed in terms of the displacement components u_i^s as $(1-2\mu_s)u_{i,jj}^s+u_{j,ji}^s=0\ (i,j=1,2,3)$, where $s=u,l$ stands for the upper and lower layers (substrates) respectively and u_1^s,u_2^s and u_3^s are three components in the x-, y-, and z-directions, respectively. The displacement fields can be taken the form of $u_1^s=u_x(z)\sin(kx)\cos(ky)$, $u_2^s=u_y(z)\cos(kx)\sin(ky)$, $u_3^s=u_z(z)\cos(kx)\cos(ky)$ where $u_x(z),u_y(z)$ and $u_z(z)$ are resulted from the above equilibrium equations as $u_x=\sum_{p=1}^{6}C_p^s f_p(z)$, $u_y=\sum_{p=1}^{6}C_p^s g_p(z)$ and $u_z=\sum_{p=1}^{6}C_p^s h_p(z)$ in which coefficients $C_p^s\ (p=1,2,...,6)$ are determined by specific boundary conditions for the lower and upper layers and continuous conditions between the film and layers while $f_p(z),g_p(z),h_p(z)$ are the resulting explicit functions of z and k. Here two cases for boundary conditions are considered: (a) Clamped Condition (CC), where a compliant layer is fixed at its exterior surface; and (b) Free Condition (FC), where the layer is free at its exterior surface. Based on the resulting displacement fields for the compliant layers,

*Corresponding author. E-mail: ghnie@tongji.edu.cn

the corresponding stress components can be determined. The above unknown quantities $\bar{g}_u, \bar{g}_l$ have the results of $\bar{g}_u = \sum_{p=1}^{6} C_p m_p(z)\big|_{z=h/2} / \bar{E}_u kA, \bar{g}_l = \sum_{p=1}^{6} C_p m_p(z)\big|_{z=-h/2} / \bar{E}_l kA,$ which results in an analytical expression for the pressure N.

To verify the present theoretical model a finite element simulation is performed by using ANSYS code. The 3D element (Solid70) is chosen for the sandwich system. The thermal buckling analysis is performed to simulate the corresponding wrinkling of the system under uniform pressures. Based on the Lanczos method is used to determine the critical strain ε_c by $\varepsilon_c = \alpha \times \Delta T_c$ where α and ΔT_c are thermal expansion coefficient and critical temperature, respectively. The critical temperature is determined by using Eigen Buckling in the code. Test of convergence of the finite element model is done by changing the numbers of elements of the film and substrates. The total number is around 300,000 for a valid finite element simulation. The critical wave length λ_c is thus obtained. The critical pressure N_c and wave number k_c for the finite element simulation can be determined by $\varepsilon_c = (1-\mu_f) N_c / h E_f$ and $\lambda_c = 2\pi / k_c$.

In computation for finite element model it is assumed that the thicknesses of substrates and film are $H_u = H_l = 10h$ and $h = 2.0\,\text{nm}$, respectively. The Poisson's ratios are $\mu_u = \mu_l = \mu_f = 0.3$, and the elastic moduli of upper and lower substrates are $E_u = E_l = E_s = 1.0\,\text{GPa}$ where E_s denotes the same value of the two moduli. The change in non-dimensional critical wave length $\lambda^* = \lambda_c / h$ and strain ε_c with non-dimensional modulus of the film E_f / E_s is shown in Figure 2 for two cases of CC-CC and CC-FC where the first shorthand notation (CC) represents boundary condition for the lower substrate layer while the second notation (CC or FC) stands for condition for the upper substrate layer. When the critical wave length increases substantially with the ratio of modulus when $E_f / E_s < 50.0$ and increases slowly with a larger ratio of modulus. In contrast, the critical strain presents an opposite trend, which indicates that a stiffer film causes easily wrinkling of the film. The comparison shows that the present theoretical results agree well with the data from finite element simulation.

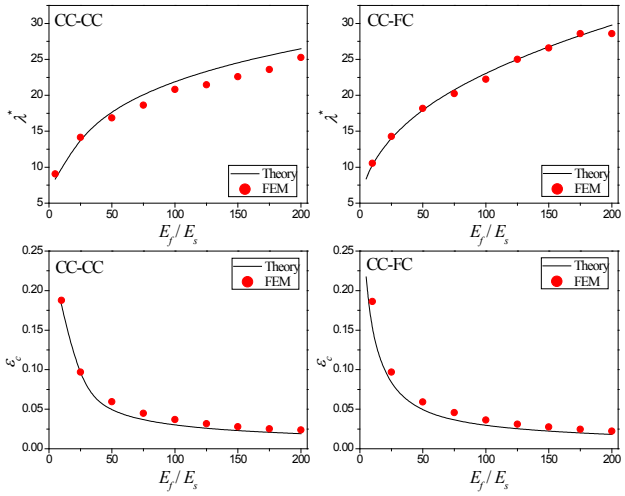

Figure 2. Comparison of critical wave length and strain for various ratios of moduli

CONCLUSIONS

A theoretical solution is proposed to predict two dimensional (periodic) sinusoidal wrinkling of the film in a layer-film-layer sandwich system under the action of bi-directional uniform pressures. The analytical relation between the pressure and wave number is derived based on classical thin-plate theory for the film and 3D elasticity theory for the two compliant layers (substrates) in connection with boundary conditions for the lower and upper layers and continuous conditions between the film and layers. Numerical examples are given to verify the present model. The resulting relation between the pressure and wave number can be readily used to predict and evaluate the appearance of wrinkling in the sandwich system.

ELASTO-ACTIVE INSTABILITIES OF SOLVENT-FILLED SPHERICAL MICROCAPSULES

Michele Curatolo[1] and Paola Nardinocchi*[1]
[1]Department of Structural and Geotechnical Engineering, Sapienza Università di Roma, Roma, Italy

Summary We investigated the occurrence of instability modes in water-filled microcapsules under drying through a multi-physics model. We show as a necessary condition to start instability is the occurrence of water-under-tension inside the cavity and as it is determined by some key geometrical and mechanical parameters of the structure.

INTRODUCTION

Instabilities of spherical shells have been largely studied starting from the major contribution by Koiter in the 1960s with specific reference to pressurized shells, as discussed in [1]. Typically, these shells were acted by an external pressure field and their instability modes have been studied in terms of pressure versus change in volume curves and pressure versus normal deflection curves, through exact formulations and differently approximated formulations.
Instabilities may also occur in solvent-filled spherical microcapsules due to solvent release processes, initiated by different causes, which determine critical loads on microcapsules walls. Nature delivers a few examples of soft capsules confining microscopic cavities undergoing a dehydration process; for example, in Fern Sporangium, it drives the conditions to realize spores dispersion [2, 3]. The working principles of these mechanisms in Nature have been classified and studied in terms of the specific functional demands that they fulfill [4]. On the contrary, analysing the possibility to reproduce them in soft polymers, which requires an accurate modeling and the identification of the determinants of the key mechanism, is still lacking.
Inspired by these observations, we investigated the occurrence of instability modes in water-filled microcapsules under drying through a multi-physics model which has been elaborated and successively tested in different situations by the Authors (see [5, 6] and references therein). A necessary condition to start instability is the occurrence of water-under-tension inside the cavity. It determines a negative pressure field on the inner walls of the microcapsules, also breaks the smooth drying process induced by water evaporation and drives a sharp change in pressure under constant volume within the confined cavity. The onset of the process has been shown to depend on geometrical and mechanical parameters and is realised through bending of the cavity's walls [6]. However, when spherical confined cavities are involved, bending is not realized due to the high geometric stiffness of the structure and it is the presence of small inhomogeneities of the microcapsule walls which breaks the symmetry and determine different instability modes.

ELASTO-ACTIVE SPHERICAL MICROCAPSULES

Spherical microcapsules are thin closed spherical shells which have a fixed geometrical size at the dry state $\mathcal{B}_d$ defined by the thickness h and the radius R of the middle surface. We describe their chemo-mechanical state by the displacement field $\mathbf{u}_d$ and the water concentration c_d, per unit dry volume, and discuss the hydration and de-hydration processes induced by different environmental conditions, as represented by the cartoons in figure 1. The hydration process corresponds to

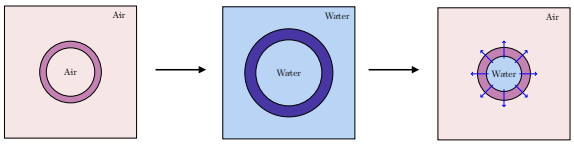

Figure 1: Cycle of hydration and de–hydration of a spherical capsule, from left to right.

embed the dry capsule (left cartoon in figure 1) into a bath until the walls are fully swollen and the cavity filled with water (middle cartoon in figure 1). The swelling-induced deformation which produces the fully swollen and stress-free state is a homothety whose value λ_o is determined from the following equation

$$\mathcal{R}\,T\Big(\log\frac{\lambda_o^3-1}{\lambda_o^3}+\frac{1}{\lambda_o^3}+\frac{\chi}{\lambda_o^6}\Big)+\frac{G_d}{\lambda_o}\Omega=\mu_e\,, \tag{.1}$$

with R, T, χ, G_d, Ω and μ_e the gas constant, the temperature, the Flory parameter, the shear modulus of the dry polymer, the water molar volume and the chemical potential of the bath. The successive de-hydration process, that is especially interesting with respect to the possible instability modes of the capsules, starts from the fully swollen state and proceeds by de-hydrating the body from the outside. It corresponds to pull out the swollen spherical shell, with its cavity filled with water, from the bath and to expose it to air. The dynamics of the process is based, as usual, on the standard equations of

*Corresponding author. E-mail: paola.nardinocchi@uniroma1.it

balance of forces and solvent mass; the dry-reference stress $\mathbf{S}_d$ and solvent flux $\mathbf{h}_d$ are constitutively prescribed within the context of Flory thermodynamics and the two state variables of the problem are coupled by the volumetric constraint $\det \mathbf{F}_d = 1 + \Omega c_d$, being $\mathbf{F}_d = \mathbf{I} + \nabla \mathbf{u}_d$, which forces the volume change $\det \mathbf{F}_d$ due to the displacement to be equal to the one due to solvent absorption or release.
Those standard equations are here joined with a new global volumetric constraint and distinguished boundary conditions, in the following explained. We assume that

$$\mathbf{S}_d\,\mathbf{m} = -p_e\,\mathbf{F}_d^{\star}\,\mathbf{m} \quad \text{and} \quad \mathbf{S}_d\,\mathbf{m} = -p_i\,\mathbf{F}_d^{\star}\,\mathbf{m} \tag{.2}$$

on the outer and inner boundary of the capsule, respectively. The internal pressure $p_i = p_i(t)$ is a key element in the analysis of the drying-driven suction effect, as already discussed [6]. It arises as reaction to the volumetric coupling $v_c(t) = v_w(t)$ between the water volume $v_w = v_w(t)$ and the cavity volume $v_c = v_c(t)$, and represents the pressure corresponding to the so-called suction effect. Finally, to break the spherical symmetry, we added two stiffer regions around the poles characterised by a *deepness* parameter $\bar{\theta}$ and a *stiffness amplifier* parameter α.
A first analysis of the problem has shown that the mechanical phenomenon resembles the buckling of pressurised spherical shells, largely studied in the Literature (see [1] and references therein) also in presence of softer regions around the poles. However, there are important differences between the two situations: (**i**) water fills cavity and constraints cavity volume; (**ii**) the pressure is not a control parameter of the process, which is a dynamical process driven by the de-hydration of the shell; (**iii**) the de-hydration process realises a differential swelling across the thickness of the shell so equipping the shell with a natural curvature which can play a role in the mechanical instability we observed. We found that, with these conditions, the de-hydration process can induced an instability mechanism whose characteristics are controlled by $\bar{\theta}$ and α. A first analysis of the problem in terms of dimensionless inner pressure p_i/G_d and change in volume v_c/v_{co} of the cavity with respect to the initial volume v_{co} shows a sharp change in pressure as identifier of the instability mechanism. Our conjecture is that different values of the α and $\bar{\theta}$ parameters produce different instability modes.

CONCLUSIONS

We presented the first results of a study focused on elasto-active instabilities in spherical microcapsules. Due to the complexities of the computational analysis, our next steps will be supported with semi-analytical methods which will start from the analysis presented in [7].

MODELING AND INSTABILITIES IN MAGNETICALLY HARD, VISCOELASTIC MAGNETORHEOLOGICAL ELASTOMERS

Dipayan Mukherjee*[1] and Kostas Danas[1]
[1]LMS, C.N.R.S, École Polytechnique, Institute Polytechnique de Paris, Palaiseau, 91128, France

Summary We present a family of unstable microstructural responses of hard magnetic particle-filled, viscoelastic magnetorheological elastomers. Energy dissipates in such two phase magneto-active composites primarily due to two distinct mechanisms, namely, (a) magnetic hysteresis in the hard-magnetic inclusions and (b) viscous dissipation in the mechanically soft elastomeric matrix. Full-field numerical computations are performed by employing an augmented incremental variational principle, which enables the computation of the effective magnetization and magnetostriction, without considering the effect of the background Maxwell stress. While the MREs with circular inclusions only exhibit particle rearrangements, the elliptical inclusions, in contrast, lead to instability via rotating rapidly to align themselves along the direction of applied magnetic fields.

INTRODUCTION

NdFeB particle-filled, mechanically soft magnetorheological elastomers (MREs) find application in a wide range of engineering devices ranging from smart sensors to soft robotic manipulators. In contrast to the traditional carbonyl iron particle (CIP)-filled MREs, the NdFeB particles in the composites exhibit magnetic hysteresis, leading to an overall hard-magnetic response of the composite. Thus, NdFeB particle-filled MREs are also referred to be hard MREs (or h-MREs in short).

Despite several analytical, numerical and experimental investigations for the modeling and instabilities in the CIP-filled MREs have been performed [1, 2, 3, 5], very few numerical and experimental investigations have been reported for this novel class of h-MREs. The present work employs an augmented, incremental variational principle to investigate the material and the microstructure dependence of the effective response of h-MREs. The following section lays down the choice of internal variables and the local constitutive models of the particle and matrix phases.

LOCAL CONSTITUTIVE BEHAVIOR

The hard magnetic NdFeB particles are also mechanically stiff. Thus, the energy dissipation in the particle phase is considered solely due to the magnetic hysteresis. The hysteretic constitutive response is modeled via first considering an additive decomposition of the magnetic h-field, such that $\mathbf{H} = \mathbf{H}_e + \mathbf{H}_r$, where $\mathbf{H}$ is the total h-field, while $\mathbf{H}_e$ and $\mathbf{H}_r$ are the energetic and remanent components of $\mathbf{H}$, respectively. Then we employ the evolving switching surface (ESS) model [4] that is developed in terms of the generalized standard materials (GSM) framework, which leads to thermodynamically consistent dissipation models, provided the associated dissipation potential remains strictly convex. The thermodynamic internal variable in the ESS model is considered to be $\mathbf{H}_r$. The resulting hysteretic magnetization response is shown in Fig. 1a.

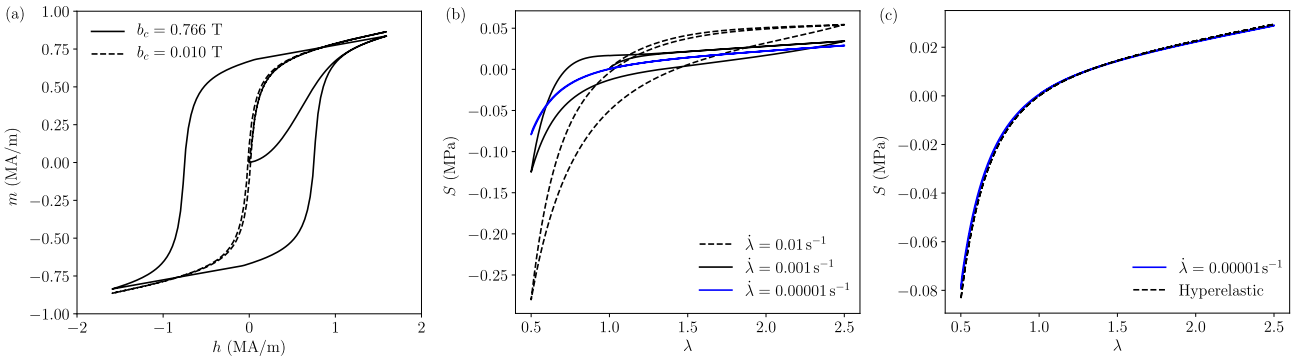

Figure 1: (a) Magnetic hysteresis loop obtained from the ESS model. (b) Rate-dependent, viscoelastic stretch-stress response of the matrix. (c) Hyperelastic stress-stretch response in the limit of quasi-static loading.

The elastomer matrix, on the other hand, is magnetically inert but mechanically viscous in nature. The viscoelastic response of the matrix is modeled via first considering a multiplicative decomposition of the total deformation gradient $\mathbf{F}$, such that $\mathbf{F} = \mathbf{F}_e\mathbf{F}_v$, where the subscripts e and v represents energetic and viscous part of $\mathbf{F}$, respectively. The GSM framework is also applied in this case, in order to obtain a thermodynamically consistent and objective viscoelastic model. Here the internal variable is considered to be $\mathbf{F}_v$. The local stretch-stress response of such viscous elastomers are shown in Fig. 1b. Notably, the dissipative viscoelastic model leads to the energetic hyperelastic model in the limit of quasi-static loading (see Fig. 1c).

EFFECT OF MAGNETIC HYSTERESIS AND VISCOELASTICITY ON PARTICLE ROTATIONS

Numerical computations are carried out via employing an augmented, incremental variational principle [2] that enables us to eliminate the effect of the background Maxwell stress while computing the effective magnetostriction and also facilitates the application of an Eulerian h-field across the periodic representative volume elements (RVEs). Two sets of 2-dimensional RVEs are considered for our investigations having (a) randomly distributed circular particles and (b) single elliptic inclusions with various volume fractions, aspect ratios and initial orientations.

A representative computed response for an elliptical inclusion in mechanically hard and soft matrices is shown in Fig. 2. Here we observe that a soft matrix — facilitating easy rotations — leads to microstructural instabilities. Thus, it is

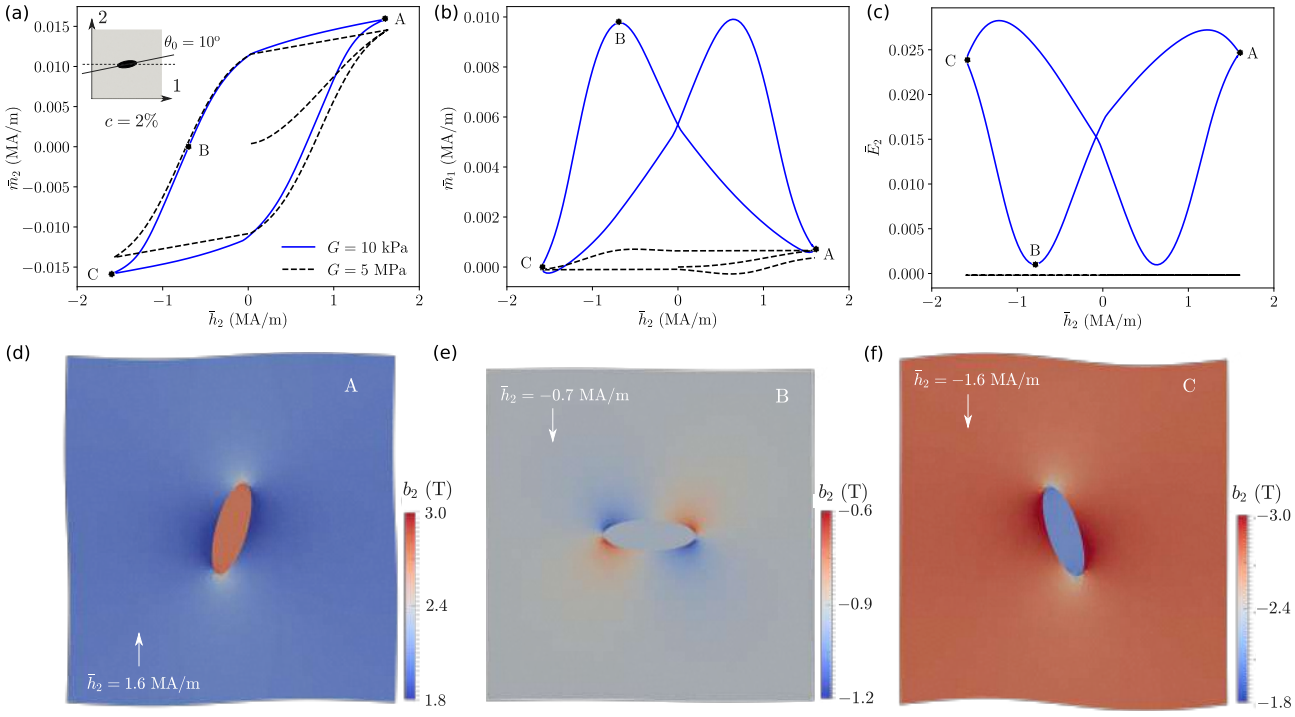

Figure 2: Effective (a) parallel and (b) transverse magnetization and (c) transverse magnetostriction of the MREs with a single elliptical inclusion in mechanically soft (solid lines) and hard (dashed lines) matrices. (a) (inset) Initial configuration of the elliptical inclusion. (d-f) Contours of the local parallel magnetic field in the RVE under different applied h-fields indicated by A,B and C on a-c.

noted that the magnetization in the particle never vanish, rather, the permanently magnetized particle becomes unstable via rotating rapidly to align itself along the reversed loading direction. By contrast, a standard magnetization-demagnetization response along with a negligibly small magnetostriction is observed in the MREs with a mechanically hard matrix, which, in turn, hinders the rotation of the elliptical inclusion.

CONCLUSIONS

The unstable magneto-mechanical response of magnetically hard but mechanically soft MREs are observed to be strongly dependent on the elastic modulus of the matrix for the elliptical inclusions. The circular inclusions, on the other hand, undergoes only particle rearrangements and thus, do not exhibit microstructural instabilities. However, the effective magnetostriction in the latter, in turn, depends strongly on the matrix elastic modulus and the rate of magnetic loading/unloading. Thus, the microstructural instabilities in the h-MREs are found to be strongly dependent on the morphology of the inclusions as well as on the elastic and viscous properties of the matrix.

ULTRA-SOFT ELASTIC CYLINDERS DEFORMED BY THEIR OWN WEIGHT

Summary Deformations of hanging elastic cylinders subjected to the Earth's gravity field are investigated. The specimens, made of polyacrylamide hydrogels, are attached from their top circular cross section to a rigid plate. An equilibrium configuration results from the interplay between gravity that tends to deform the cylinders downwards under their own weight, and elasticity that resists these distortions. The corresponding steady state exhibits fascinating shapes which are measured with lab-based micro-tomography. For any given initial radius to height ratio, the deformed cylinders are no longer axially symmetric beyond a critical value of a control parameter that depends on the volume force, the height and the elastic modulus: self-similar wrinkling hierarchies develop, and dimples appear at the bottom surface of the shallowest samples. We show that these patterns are the consequences of elastic instabilities.

INTRODUCTION

Many materials such as biological tissues can withstand huge elastic deformations over more than several hundred percent. Fascinating and puzzling shapes can result from these large deformations which have to be better understood in view of emerging applications as computer-assisted precision surgery involving human organs among which some are elastic and can undergo large deformations. A physical rationalization of these phenomena requires first to model materials subjected to basic external loads in simple geometries.

We present here an experimental study of the deformations of elastic cylinders attached to a rigid plate at the upper cross section, and submitted to a downwards constant volume force in the vertical direction. This minimal system is enough to exhibit intriguing shapes such as those encountered in more complex systems with practical applications.

MATERIALS AND METHODS

We use aqueous polyacrylamide gels, that can be considered as incompressible with a mass density ρ almost equal to that of water. They behave as elastic material for strains up to several hundreds percent, whose shear modulus μ can be tuned by varying the concentrations in monomers and cross-linkers.

In these experiments, the reagents generating the gels are first dissolved into ultra-pure water and poured into cylindrical dishes up to the brim. After the gel is cured into the dish, its top surface is attached by capillary action onto a rigid horizontal surface coated with a sheet of paper, and the dish is gently removed from below. This results in a hanging cylinder of gel attached from the top and deformed by the gravitational acceleration g. The radius of the dishes, R, and the height, h, are between $36\,\mathrm{mm}$ and $150\,\mathrm{mm}$ and between $8\,\mathrm{mm}$ and $40\,\mathrm{mm}$ respectively. The shear modulus of the gel lies between 10 and $160\,\mathrm{Pa}$, a value compared to modulus of tissues (as liver or brain).

The dimensionless gravity acceleration α is defined as the ratio of the characteristic gravitational stress, $\rho g h$, to the shear modulus: $\alpha = \rho g h/\mu$. α lies between 1 and 16 in the experiments reported here. Surface tension is not always negligible with soft solids [2], and the dimensionless parameter α has to be complemented with another one, namely $\beta = \gamma/(\mu h)$, with γ the surface energy per unit area. For polyacrylamide gels in air, $\gamma \simeq 70\,\mathrm{mN\,m^{-1}}$. Taking for instance $\mu \sim 35\,\mathrm{Pa}$ and $h \sim 20\,\mathrm{mm}$ as characteristic shear modulus and height, one gets $\beta \sim 0.1$.

CASCADE OF WRINKLES

The equilibrium shapes of the hanging cylinders are acquired using x-ray tomography. The observed deformed shapes are axially symmetric for the samples with $\alpha < 4.7$. For samples with $\alpha = 4.7$, wrinkles appear, and upon increasing α, a second generation in the wrinkles hierarchy of size appears for samples with $\alpha > 6.02$, leading to hierarchical structures (Fig. 1-(a-c)). The amplitude of the wrinkles as well as the degree of branching is the highest at the top of the shape decreasing downwards until vanishing at the bottom of the hanging cylinder.

These hierarchical wrinkles result from a Biot-like elastic instability [3] : once the surface deformation of the elastic gel reach a threshold, wrinkles develop, releasing a part of the accumulated stress. If the remaining surface strain is again larger than the threshold, a new generation of wrinkles develops [1].

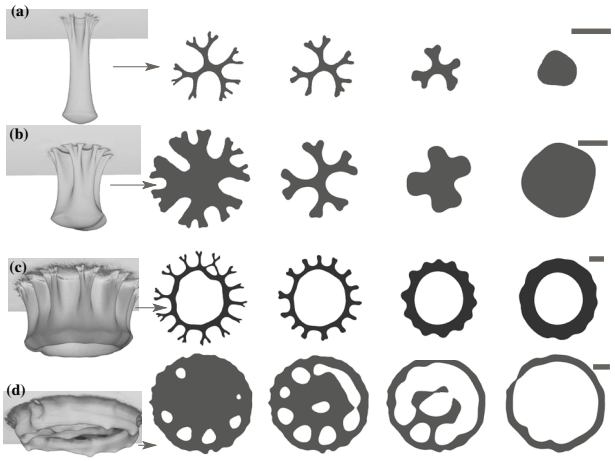

Figure 1: Three-dimensional views and horizontal slices at various heights (from the top to the bottom of the samples) of 4 hanging cylinders with initial dimensions ($R \times h$) and shear modulus: $22\,\mathrm{mm} \times 25\,\mathrm{mm}$, $\mu = 27.4 \pm 1.5\,\mathrm{Pa}$ (a); $37\,\mathrm{mm} \times 24\,\mathrm{mm}$, $\mu = 29.2\,\mathrm{Pa}$ (b); $69\,\mathrm{mm} \times 17\,\mathrm{mm}$, $\mu = 18.6\,\mathrm{Pa}$ (c); $72\,\mathrm{mm} \times 9\,\mathrm{mm}$, $\mu = 12.9\,\mathrm{Pa}$ (d). In the slices, the gel is in black; the white areas continuously surrounded by black areas correspond to the central depression (c,d) or to dimples (d). The dimensionless accelerations (α) and surface tensions (β) for these samples are respectively $(8.94,\ 0.1)$ for (a);$(8.05, 0.1)$ for (b); $(8.96\ , 0.2)$ for (c); and $(6.84\ , 0.6)$ for (d). Gray bar length is $2\,\mathrm{cm}$. From [1].

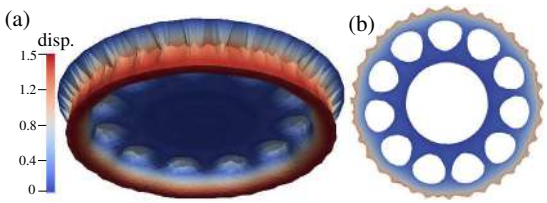

Figure 2: **(a)** Deformed shape computed with $R/h = 8$, $\alpha = 5.58$ and $\beta = 0$. Colors indicate the ratio of the total displacement to the initial height. **(b)** Horizontal slice of the previous deformed shape (a) at the distance h below the rigid plate. From [1].

DEPRESSIONS AS A RESULT OF A RAYLEIGH-TAYLOR MECHANISM

In addition to wrinkles, quasi-regular dimples appear at the lower surface of samples with large aspect ratios (see Fig. 1(d)). Finite element (FE) simulations consisting of minimizing the sum of gravity and neo-Hookean elastic energies of a hanging cylinder have been carried out, with a quantitative agreement with the experiments, indicating that the formation of the dimples are the consequence of the Elastic Rayleigh-Taylor instability [4, 5, 1]

CONCLUSIONS

X-ray micro-tomography has proved to be a powerful technique capable of capturing complex equilibrium shapes of hydrogels subjected to large deformations, whereas conventional optical methods are more difficult to handle with these transparent and folded samples.
Although the system consisting of a hanging elastic cylinder is probably one of the simplest in order to study the mechanical response of highly stretchable elastic material, the resulting deformations are manifold, whose underlying mechanisms have been unveiled in this paper.

NETWORK THEORY FOR MORPHOLOGICAL CONTROL OF SOFT ROBOTS

Edoardo Milana*[1], Joost Jennen[1,2], Giorgio Oliveri [2], Benjamin Gorissen[1,3], Johannes Overvelde[2]and Dominiek Reynaerts[1]
[1]Department of Mechanical Engineering, KU Leuven, Leuven, Belgium
[2]AMOLF, Amsterdam, The Netherlands
[3]John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts

Summary Simplified design of soft robots, featuring continuum actuators, conflicts with the opportunity of independently controlling different degrees of freedom associated with dedicated actuation. The use of nonlinearities can help bridging the gap. Indeed, nonlinearity can be an opportunity for morphological control, where groups of actuators are actuated using a single input signal and functionality emerges from the interplay of nonlinearities and environmental triggers. In this work we will detail on a framework to analyze and design this actuation behavior in a morphological setting, using electrical network theory. To demonstrate the strength of this approach, we demonstrate actuation sequencing using fluidic actuation technology where the order of sequence can be altered by varying the amplitude of the single input signal.

INTRODUCTION

Advances in polymer synthesis and their digital manufacturing processes paved the way for the rapid advancement of the field of soft robotics where materials are used with stiffness comparable to biological tissue [1]. Inherent safety, large deformations and adaptability to unstructured environments are few of the reasons why soft robots are outperforming conventional rigid robots in applications that necessitate interactions with unpredictable surroundings such as navigating uneven terrains or handling amorphous objects [2]. Instead of sensing the environment and adapting the actuator behavior in a feedback loop, soft robots can display the same functionality since the environment is able to directly influence the robot hardware. This concept is referred to as embodied intelligence which is in stark contrast to the central intelligence paradigm in conventional robotics. Instead of concentrating all computational power in the software, it was shown by Pfeifer and Bongard [3] that in nature intelligent behaviors are not simply encoded in the brain of a living agent, but they rather emerge due to body-environment interactions. Muscles and tendons, similarly to soft actuators, harness their elasticity to adapt their response to different tasks without being continuously controlled by the brain. This phenomenon in particular is referred to as morphological computation and underline the fact that complex and adaptable responses can be achieved with simple low-level software control in addition to morphological intelligence.

The field of soft robotics is highly compatible with the concept of embodied intelligence, which has been recently displayed in literature. In previous work, we were able to [4] harness the elastic snap-through instability of soft balloon-like actuators for event triggering in a network of such actuators. We used the same type of nonlinear inflatable actuators to drive ambulatory locomotion in a soft articulated robot [5] where 8 actuators were sequenced using only one pressure input. However, a general analysis tool that takes into account additional fluidic effects is missing, making it difficult to design the morphological response of a network of inflatable actuators. In this work we apply a modeling framework that uses an electrical circuit analogy to analyze the global behavior of such fluidic network [6], in particular we apply it to snap-through actuators. This tool will be applied to a fluidic network where the actuation sequence of a nonlinear 2-actuator system will be analyzed. We show that this sequence can be altered by changing the amplitude of the input signal, which directly follows from a parameter sensitivity analysis using the same tool.

NONLINEAR FLUIDIC NETWORKS

Inflatable soft robotic systems can be thought of as a network of inflatable actuators that are linked to each other using tubing as fluidic interconnections. Inflatable actuators are characterized by a pressure-volume relationship, and tubing by a pressure-flow relationship. As volume-pressure-flow are analogous to the electrical quantities of charge-voltage-current, it is possible to convert a network of inflatable actuators and tubing, to an equivalent electrical circuit if nonlinear impedances are used to mimic the nonlinear fluidic characteristics. A schematic of the fluidic-electric analogy can be seen in Fig. 1a. Distribution of charge over time is analogue to the fluid volume distribution in the system, which for inflatable actuators is directly linked to their deformation.

MORPHOLOGICAL CONTROL

In order to obtain a sequential response of the actuators in the system, nonlinearities need to be incorporated in the fluidic network. In this work we use inflatable actuators that exhibit an isochoric snap-through, where a rubber cavity is enclosed by a conically shaped membrane, similar to the actuators used in [7]. This membrane will go through an elastic structural instability and snaps out of the cavity with a sudden and significant deformation (fig. 1b). The nonlinear pressure-volume characteristic shows two local extrema (a peak and a valley, fig. 1c) corresponding to the snapping pressures. Extrema can be tuned by varying some geometrical parameters of the actuator such as membrane thickness and

*Corresponding author. E-mail: edoardo.milana@kuleuven.be

membrane angle. The highly nonlinear pressure-volume relationship of this actuator can be translated to an electrical analogue, by a stepwise linear interpolation of capacitors, as shown on figure 1c.

As case study of morphological control, we analyze the response of a network composed of two such nonlinear actuators having different pressure peaks and interconnected through flow restrictors (fig. 1d-e). The main goal is to obtain a sequential actuation with a single pressure input and to change the sequence by only acting on the input. Indeed, if the pressure input amplitude is low, pressure drops caused by flow restrictors can be neglected. In this case the actuators will move in the sequence prescribed by the pressure peaks locations of their characteristic (fig. 1f, dashed lines). In contrast, for high amplitude inputs, pressure drops play a significant role and according to the position of the flow restrictors in the network, the actuation sequence can change. If the actuator with the lowest pressure peak has the highest flow restrictor in series, it snaps after the motion of the other actuator (fig. 1f, continuous lines). Thanks to the electric circuit analogy, the system can be analyzed numerically through Simulink and compared against experiments.

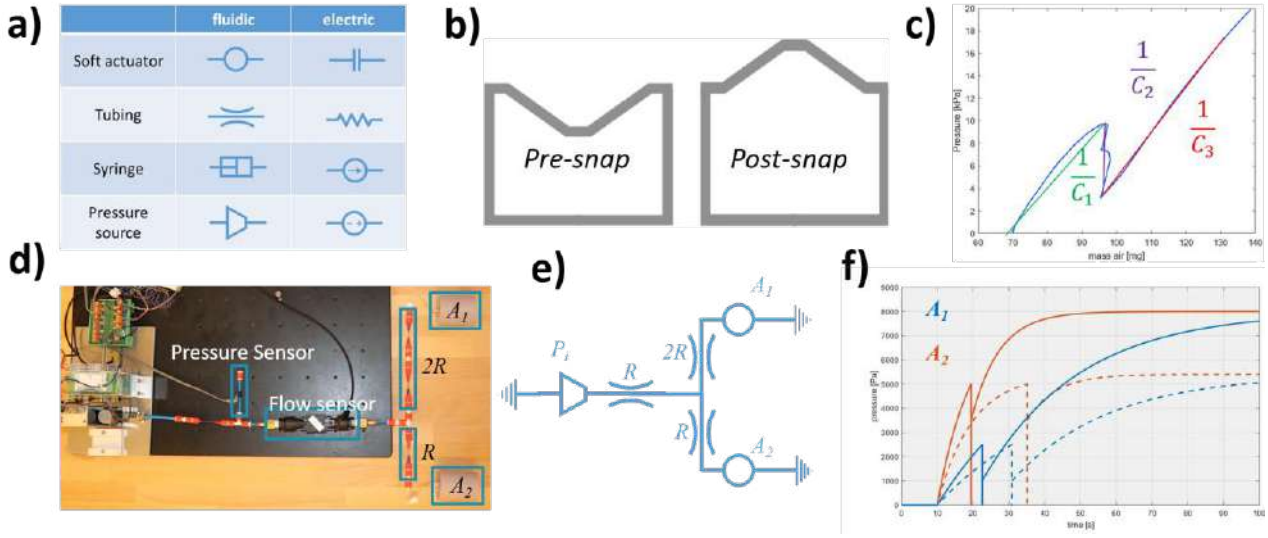

Figure 1. a) Impedance analogy for soft fluidic networks. b) Deformation sketch of the nonlinear snapping actuator. c) Nonlinear characteristics of the soft actuator and its stepwise linear approximation. d) Experimental setup comprising two nonlinear actuators and flow restrictors. e) Circuit scheme of the setup. f) Time response of the two actuators for an high pressure amplitude step (continuous line) and low amplitude (dashed line). Snapping times are different leading to a change of the actuation sequence.

CONCLUSIONS

A network of nonlinear inflatable actuators that are connected using fluidic tubes can be analyzed using electrical network theory as volume-pressure-flow is analogous to charge-voltage-current. With this technique, the response of an arbitrary network of nonlinear building blocks can be simulated in Simulink, which can be loaded by either a pressure or volume input. This has been done to analyze morphological control of 2-actuators nonlinear system, where we showed that the actuation sequence can be changed by varying the input amplitude thanks to their highly nonlinear response. This design strategy can further be used to develop highly complex soft robotic behaviors, emerging from the interaction of simple nonlinear building blocks, in an effort to simplify control schemes.

SNAP-SHAPING GROOVY SHEETS

Anne Meeussen*[1,2] and Martin L. van Hecke [1,2]
[1]Designer Matter Department, AMOLF, Amsterdam, The Netherlands
[2]Leiden Institute of Physics, Leiden University, Leiden, The Netherlands

Summary Thin sheets show unusual behaviour, from curve-stiffening [1] to crumpling [2]. These phenomena arise from a geometry-mediated competition between stretching and bending energies, which produces rich emergent effects. Here, we harness a thin sheet with a simple geometry—a *groovy sheet* with parallel undulations—to create a multistable structure with minimal preprogramming. We show that our groovy sheets exhibit rapid, easy-to-actuate, and reversible shape-switching between a large array of out-of-plane states via snap-through instabilities. Our work opens up new vistas for the design of shape-shifting materials, leveraging thin sheets' potential for large elastic deflections.

COMPLIANT ORIGAMI

Origami, the archetypical shape-shifting material, is often modelled as having stiff facets and perfectly soft hinges. However, real origami structures' facets and hinges may bend and stretch. Adding compliance to rigid origami models enriches their behaviour, leading especially to the creation of mechanically multistable structures [3]. Compliance thus opens up a new design space for shape-shifting structures, with the potential to formulate design rules for controlling a structure's stable configurations.

SNAPPING GROOVY SHEETS

We explore this new shape-design space using a compliant *groovy sheet*, consisting of thin, soft plates connected by parallel curved hinges (Fig. 1a, left). When point loads are applied to the sheet's edges (Fig. 1a, middle), the structure undergoes a rapid, elastic snap-through instability into a new stable configuration with a distinct curled shape (Fig. 1a, right).

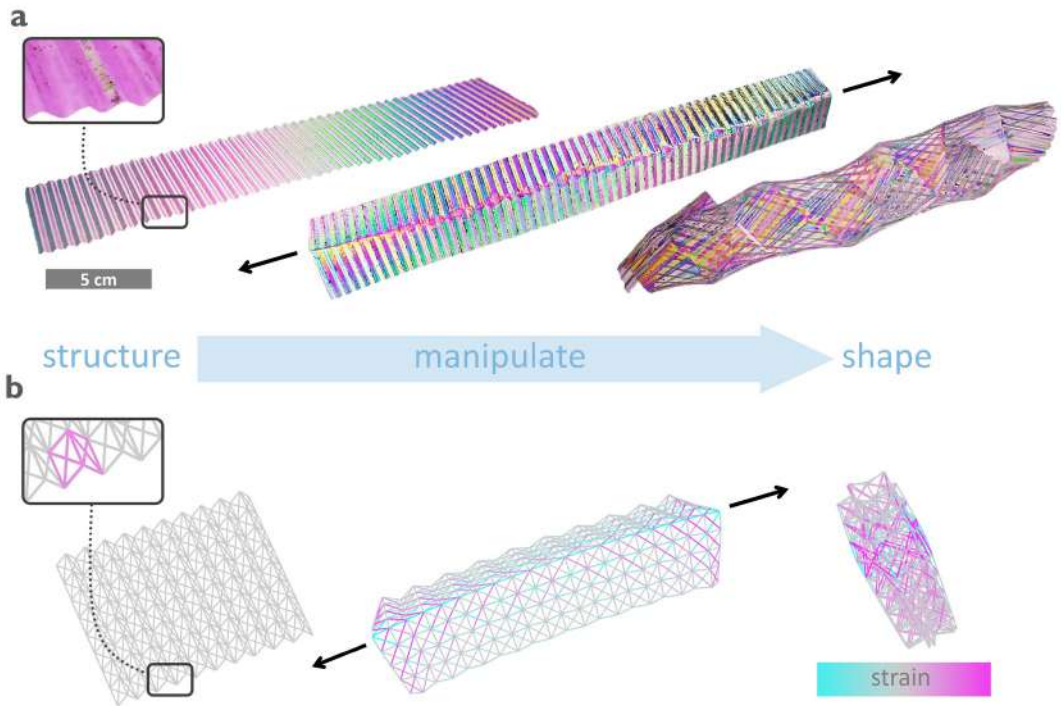

Figure 1: **A groovy sheet snaps through into a new, stable shape. a)** A sheet made of 15 μm thick PET film, consisting of soft plates and parallel hinges that form a series of grooves (inset) is shown. The colouring is obtained by photographing the strip between crossed polarisers. Under external point forces (dark arrows), the sheet snaps through into a new, stable, spiralling shape. **b)** The behaviour of the groovy sheet is simulated using a simplified network model, consisting of stiff linear springs connected by soft torsional springs (inset). Under external loading, the simulated network finds a new stable configuration that reproduces the rolling shape of the real sheet.

*Corresponding author. E-mail: a.meeussen@gmail.com

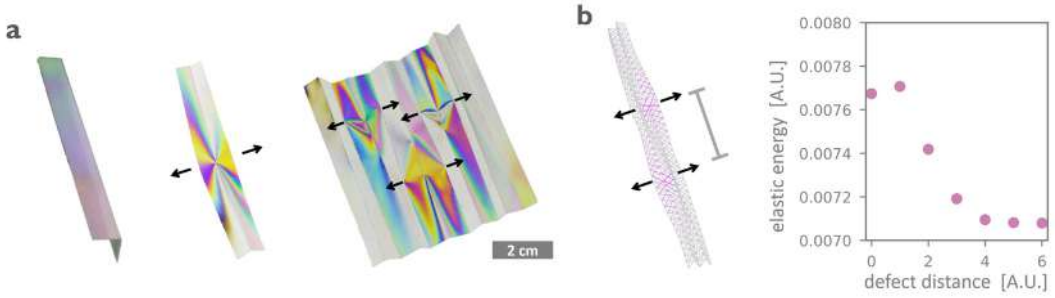

Figure 2: **Individual snap-through defects in each groove are responsible for the reshaping behaviour of the sheet. a)** A single PET film groove (23 μm thick) undergoes a snap-through instability into a new, stable state under external forcing. A stretched defect is created at the snap-through location. In a large groovy sheet, this local stretching leads to geometric interactions between defects. **b)** Defect interactions can be investigated using the discrete model shown in Fig. 1b, by calculating the network's elastic energy as a function of the distance between defects (indicated left). The results (shown right) indicate that defects created close together will stay that way to minimize their energy; conversely, defects created at a distance will repel.

Bistability from groove geometry

This reshaping is purely a result of the presence of compliance in the sheet's grooves, which produces a geometry-mediated energetic competition between stretching and bending in the underlying material of the sheet. We confirm that geometric coupling between stretching and bending in the groovy sheet leads to bistable behaviour via a simple computational model, illustrated in Fig. 1b.

Local defects shape the sheet

We further show that the reshaping capacity of the groovy sheet is contained in the snapping behaviour of its individual groove [4]: each groove may snap through into a configuration with a locally stretched defect (Fig. 2a, left). In a large sheet, adjacent local defects result in a geometrically incompatible structure- it is energetically costly to accommodate defect clusters. As a result, defects will interact and move to minimize geometric frustration (Fig. 2a, right). The interaction between defects depends on their mutual distance; our network model indicates that nearby defects will attract, while distant defects repel (Fig. 2b). A line of neighbouring defects in a groovy sheet will therefore be stable, minimizing the overall energy. The resulting geometry produces a characteristic spiralling shape.

CONCLUSIONS

In conclusion, we show that compliance of thin sheets—that is, their geometry-mediated competition between bending and stretching—leads to a rich design space of multistable structures. We show here that the range of available multistable shapes of a thin, groovy sheet can be explored and understood with straightforward experimental tools and minimal numerical models.

MECHANICS-INFORMED PROGRAMMING OF PASSIVELY CONTROLLED, UNTETHERED SOFT ROBOTS

Summary Most soft robots require a tether to rigid power and control systems to locomote. An alternative to this approach is to use soft active materials that exert work in response to various environmental stimuli. However, the creation of untethered, active matter-based robots presents challenges. Predicting the kinematics of these systems is not straightforward because they often operate in nonlinear elastic regimes, and programming the sequential actuation of different robotic components requires understanding the effect of chemistry and geometry on responses to stimuli. Here, we showcase the programming of a "rollbot" that morphs into a prism and self-propels when heated. To do so, we control the chemistry and geometry of liquid crystal elastomer bilayer hinges during 3D printing, informed by thermo-mechanical characterizations of the materials.

BACKGROUND

Untethered self-propulsion is a requirement for robotic systems that navigate large distances. Given that untethered operation often requires carrying power and control systems that add mass to the robot, active matter that self-actuates in response to external stimuli (e.g., temperature, light, chemical gradients, and electric fields) has been explored as an alternative to soft robotic systems that rely on pneumatics or onboard electronics [1].

Precisely controlling the kinematics of soft robots that rely on pneumatic systems or active matter can be challenging because of their operation in nonlinear elastic regimes [2]. Origami-based strategies address this challenge by localizing large, predictable shape changes of the overall structural frame to discrete creases [3]. Origami-inspired approaches become especially compelling when implemented with active materials that can be programmed to actuate creases in a desired sequence in response to an external stimulus, as this broadens the space of achievable geometries and enables multi-gait locomotion. However, many active materials lack energy density or the capability to deform reversibly [4]. These features are necessary for applications that involve bearing large loads or self-propelling over many actuation cycles.

Liquid crystal elastomers (LCEs) have recently emerged as a promising class of soft active matter because they generate large, powerful, and repeatable deformations upon heating above their nematic-to-isotropic transition temperature (T_{NI}), thus meeting the demands of soft robotic applications specified above. The direction of contractile strain (director) can be programmed by aligning rigid mesogens during fabrication [5].

SUMMARY OF RESULTS

Toward the objective of creating soft robots that can shape-morph and self-propel repeatedly in response to external stimuli, we 3D printed LCE in the form of active hinges that interconnect passive polymeric tiles. When heated above their actuation temperatures, the printed LCE hinges exhibit a large, reversible bending response. To achieve controlled bending, we fabricated each LCE hinge in a bilayer design in which the two halves have orthogonal directors. A spontaneous strain mismatch caused each hinge to bend when heated above their actuation temperature. Using this method, the folding orientation, hinge angles, torque output, and actuator geometry are fully programmable by adjusting the print path. By printing LCE inks with different T_{NI}, we created soft robotic matter with predetermined folding sequences upon heating. These materials generate torques capable of lifting objects that were more than two orders of magnitude heavier than the hinges themselves, and torque remained constant over multiple heating and cooling cycles, which is essential for repeatable propulsion in untethered robots.

We use a multi-material 3D printing approach to demonstrate simple embodiments of origami-inspired soft robots that are manufactured in a single step. Upon deployment, shape-morphing and self-propulsion were passively controlled via the constitutive response of the printed matter. Among the soft robotic structures created using this manufacturing approach, we highlight an initially flat structure that reconfigured to a pentagonal prism and propelled itself by rolling on a hot surface, which we refer to as a "rollbot." The thermo-mechanical characterization of bilayers of varied chemistry and printed geometry informed the programming of the hinge actuators so that they met the kinematic and torque requirements of the "rollbot," shown in the figure below.

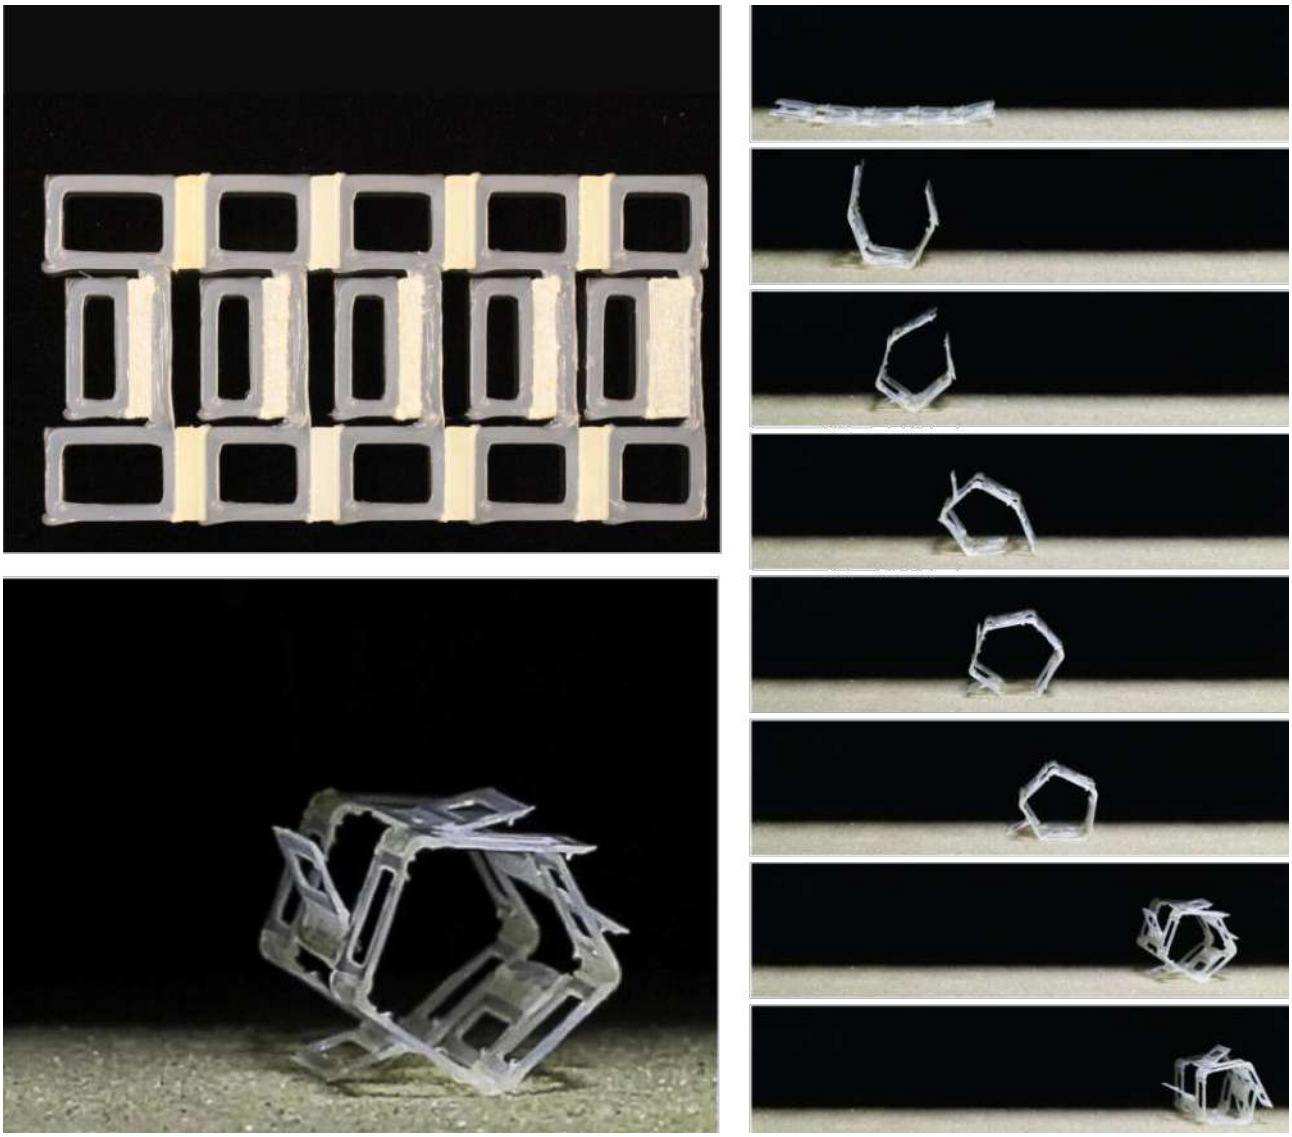

Figure 1. Passive control of self-assembly and propulsion in a rolling architecture (i.e., rollbot). The entire structure was printed flat (top left). The structural frame was composed of two outer rails that use low-T_{NI} LCE hinges to morph from a flat state to a pentagonal prism. These rails were connected by bridges that hold propelling high-T_{NI} LCE hinges. A hot plate and a convective environment were used to passively induce the desired assembly (bottom left) and rolling motion (right). In the assembled 3D configuration, the high-T_{NI} LCE hinges actuated when in contact with the hot plate, rolling the structure over the adjacent vertex and onto the next hinge, which carried out the same action. Both low-T_{NI} and high-T_{NI} LCE hinge dimensions were chosen based on thermo-mechanical characterizations of the materials. Because these hinges unfolded away from the hot surface, their repeated actuation was possible.

CONCLUSIONS

Using an additive manufacturing approach that enables us to program the response of active materials to external stimuli and integrate them with several materials, we have created passively controlled shape-morphing and self-propelling structures. This method enables programming the actuation temperature, folding angle and orientation, and torque output of LCE hinges. Importantly, these materials actuate reversibly and their torque outputs are large enough for self-propulsion and for lifting objects that are much heavier than the hinges themselves. Given the modular nature of the additive manufacturing approach, we envision incorporating LCEs that respond to other stimuli (e.g., light, pH, and humidity) within these printed architectures in the future.

A NUMERICAL MODEL FOR SOFT TWO-DIMENSIONAL MATERIALS

Daniele Liprandi[1], Federico Bosia[2], and Nicola Maria Pugno [*1,3]
[1]Department of Civil, Environmental and Mechanical Engineering, Università di Trento, Trento, Italy
[2]Department of Applied Science and Technology, Politecnico di Torino, Torino, Italy

Summary Many soft materials are implemented in devices that mechanically interact with other bodies. When a soft two-dimensional membrane touches another body or a substrate it becomes impossible to analytically predict its exact behaviour. Adhesion, friction, stress and fracture propagations are important rulers of the mechanical responses. In this work, we propose numerical models which are able to quickly calculate complex mechanical responses of soft membranes interacting with a substrate. The Lattice Spring Model is used to discretize the continuous membrane and allows the definition of heterogeneous materials. We show how this can be applied to soft biological membranes and how different parameters affect their mechanical responses.

INTRODUCTION

The term "soft materials" covers polymeric materials, such as rubbers, gels and self-adhesive materials, but also many biological and bio-inspired materials such as living tissues. Soft materials have now attracted high interest from the robotic and biomedical fields as they can be the elementary bricks for the development of new devices.
A common problem in the development of new devices is the need of thin materials able to interact and adhere to a surface, sustain large deformations before failing and having predetermined mechanical responses [1,2]. The interaction between surfaces is one of the major rulers of the behaviour of these adhesive membranes and has been intensively studied in the past years both theoretically and experimentally. Even so, the adhesive and frictional properties of two generic surfaces for three-dimensional problems are far to be understood. If we don't consider particular symmetries or homogeneous conditions, it is almost impossible to predict how stresses and strains will distribute during the adhesive interaction between the two materials. This is caused by the high number of interplaying parameters, which comprehend the geometrical and mechanical properties of the materials, the substrate properties and the adhesive potentials connecting them. The number of parameters further increases when composite, heterogeneous or hierarchical materials are considered. Nonhomogeneous materials are of particular interest for their tunability, often proved by the multiple instances which can be found in nature. To tackle these problems, we developed a theoretical-numerical approach to simulate the behaviour of a heterogeneous membrane-like soft structure interacting with a rigid substrate.

METHOD

We use two discretization techniques for both the soft membrane and the interface. We apply the framework method to discretize continuous surfaces using structured lattices. The lattice definition is based on the framework method and the Lattice Spring Model. The Lattice Spring Model allows us to simulate heterogeneous soft membranes as shown in Figure 1. The interaction between the structure and the rigid substrate is simulated by a fibrillar three-dimensional cohesive law. We have developed a hand-written C++ code, which allows our model to have both great portability and versatility.

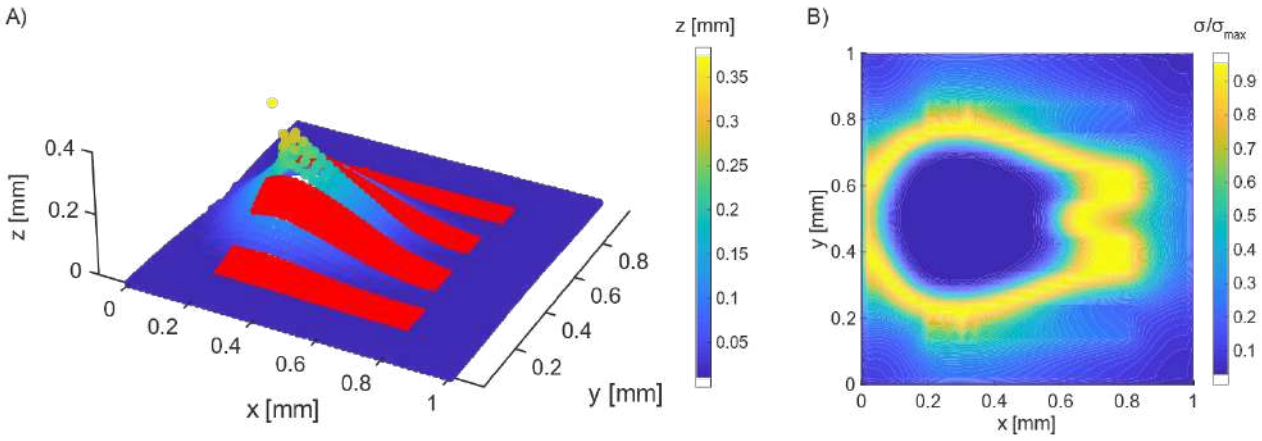

Figure 1. A) 3D Membrane displacement map of a composite membrane being pulled from a substrate in a single point at an angle $\theta = 60°$. The red parts of the membrane have a higher Young modulus. The colormap indicates the vertical displacement. B) Normalized interface stress map.

RESULTS

The results presented show how the stress and strain distributions are influenced by the system parameters. We apply the model to a spider disc attachment-like structure, explaining the evolutionary path of the geometrical parameters. We show how the geometrical properties of the membrane rule the maximal pull-off force and extensibility of the system, and how tearing phenomena and heterogeneous mechanical properties change the behaviour of the peeling process.

RIGOROUS NUMERICAL 1D MODEL FOR HYPERELASTIC SLENDER SOLIDS

Helen Liedtke*[1], Claire Lestringant[1,2], and Dennis Kochmann[1]
[1]Mechanics & Materials, Department of Mechanical and Process Engineering, ETH Zurich, Zurich, Switzerland
[2]Structures Research Group, Department of Engineering, University of Cambridge, Cambridge, United Kingdom

Summary We introduce a computational mechanics approach for the dimensional reduction of slender structures at finite strains with generic cross-sections and hyperelastic constitutive behaviour following a formal asymptotic approach. We validate our model with a suite of test cases.

Slender structures undergoing extreme deformations are of interest in many disciplines and applications such as biology [1], soft robotics [2] and 4D printing [3]. Finding efficient and accurate models for these structures at finite strains is an important challenge arising in all these different fields. In particular, when slender elements are combined with nonlinear and/or heterogeneous material behaviour and have complex cross-sectional shapes, classical 1D models often lose applicability. Recent efforts, see [4], propose a formal asymptotic dimension reduction approach that starts from a general, nonlinear 2D or 3D model. Following this approach, we propose to implement a systematic numerical method to define and solve accurate 1D models for hyperelastic slender solids at finite strains for a variety of cross-sectional geometries as well as constitutive behaviours.

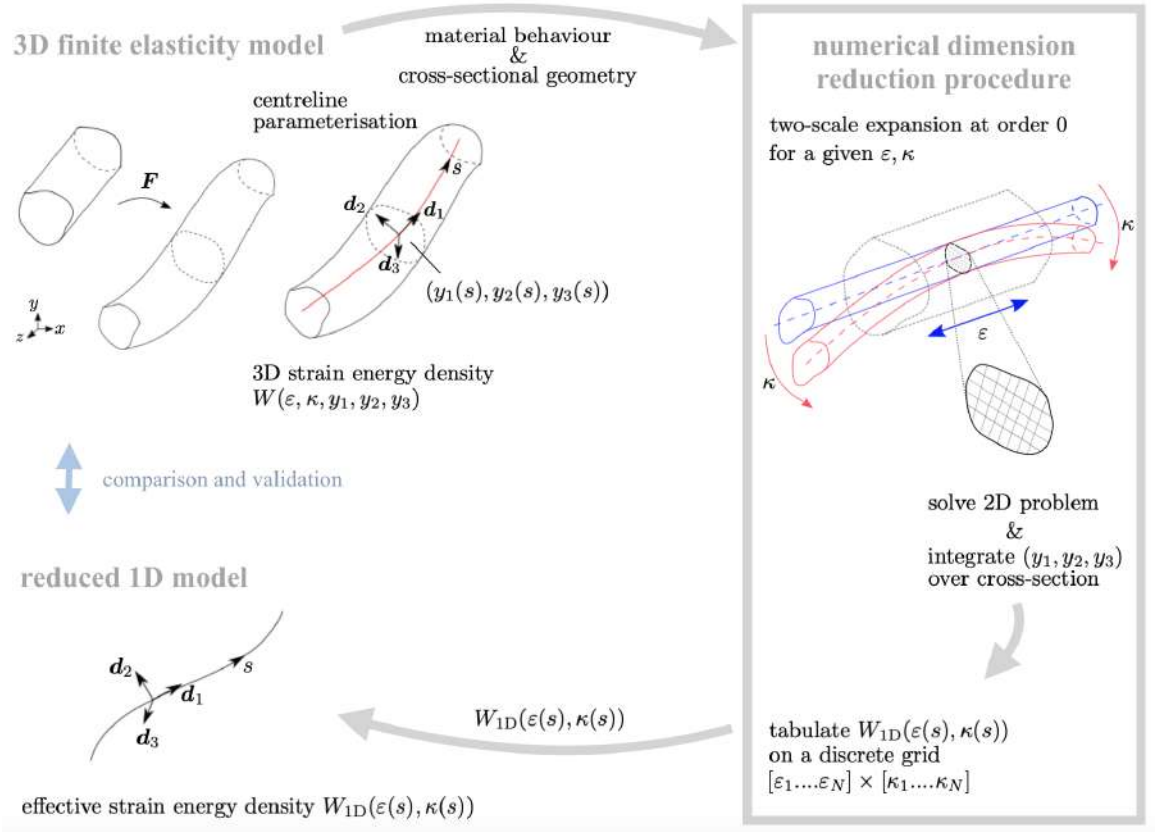

Figure 1: A flowchart showcasing the dimension reduction procedure.

Starting from a generic 3D slender structure, as shown in Figure 1, we parameterise the centreline as shown in red with the Lagrangian curvilinear coordinate s. At every s, an orthonormal set of material frame directors $(\boldsymbol{d}_1, \boldsymbol{d}_2, \boldsymbol{d}_3)$ defines the average orientation of the cross-section, while the coordinates (y_1, y_2, y_3), which depend on the position s, capture the geometry of the deformed cross-section. The information on the material behaviour and the cross-sectional geometry is passed to the numerical dimension reduction algorithm for a given load case, i.e. the axial strain ε and/or the curvature κ. Using a two-scale expansion, we rescale the longitudinal coordinate s by a small parameter η (typically of dimension of the cross-section over the length). Consequently, all axial gradients disappear at order 0 and the solution is homogeneous

*Corresponding author. E-mail: helen.liedtke@mavt.ethz.ch.

along the length. We are left with a 2D finite elasticity problem on a generic cross-section of the solid, that can be solved with standard FE. We then integrate the coordinates (y_1, y_2, y_3) over the cross-section, which yields the reduced 1D strain energy density, which is ultimately tabulated for a catalogue of different strains. The resulting reduced 1D energy allows us to define a 1D model that depends on the centerline's deformations ε and κ only (for 2D deformations). The latter is solved with an in-house nonlinear discrete beam framework [5].

We present the theoretical foundation, implementation and evaluate the accuracy of the reduced model by solving a set of test cases for which we solve both the original 3D problem and the reduced nonlinear 1D model. Our comparison includes hyperelastic models as well as cross-sectional shapes both in linear and nonlinear regimes, as well as a comparison of the efficiency of the two approaches.

PLAYING WITH A ROPE ON THE GROUND: A TOY-MODEL FOR DYNAMICAL ELASTIC CONTACTS.

Benoît Seron and Gregory Kozyreff*
Optique Non linéaire Théorique,Département de Physique,Université libre de Bruxelles(U.L.B.)CP231,Campus de la Plaine, Bruxelles, Belgium

Summary We study theoretically, numerically, and experimentally the dynamics of a rope laid on the ground when one end is lifted and harmonically vibrated vertically with a small amplitude around a given value. Intuitively, at small frequencies, only the part of the rope that is lifted should be set into motion, the rest of it remaining inert. Meanwhile, the location of the first contact with the ground, $x_c(t)$, should advance and recede, following the up and down motion at the lifted end of the rope. Next, a critical frequency is expected, above which waves are radiated along the rope away from the vibrated end. Our study confirms this intuition and yields the critical frequency of this transition. However, further investigation reveals that the dynamics is much richer than anticipated. Firstly, the location $x_c(t)$ tends to display a strongly anharmonic behaviour even well below the critical frequency. Secondly, we find that an infinity of secondary critical frequencies exist and that the stability diagram is actually covered by Arnold's tongues.

INTRODUCTION

Problems of contact between deformable bodies are among the most difficult ones in elasticity, and only a few are exactly solvable [1, 2, 3]. Aside from the fundamental interest of the subject, structures containing parts that enter in contact and transfer loads between each other abound in engineering. Hence, the study of elastic contact is of significant practical importance.

Here, we explore the physics of a slender body in dynamical contact with an obstacle: namely a rope laid on the ground with one of its ends vibrated vertically around a given altitude. Our motivation is primarily fundamental; we note, however, that some connection can be made with the dynamics of strands of hair making contact with the human body, the mechanics of rugs [4, 5] or the mechanical instabilities affecting rods injected in cylinders [6, 7], borehole drilling [8, 9] and ocean cable laying [10].

The system we consider is depicted in Fig. 1 and the simplest possible mathematical model for the elevation $w(x,t)$ of the rope is that of a nearly horizontal elastic beam [3]:

$$\rho\frac{\partial^2 w}{\partial t^2} = T\frac{\partial^2 w}{\partial x^2} - B\frac{\partial^4 w}{\partial x^4} - \rho g, \qquad w \geq 0, \tag{1}$$

$$w - Z(t) = \frac{\partial^2 w}{\partial x^2} = 0, \qquad x = 0, \tag{2}$$

$$w = \frac{\partial w}{\partial x} = \frac{\partial^2 w}{\partial x^2} = 0, \qquad x = x_c(t). \tag{3}$$

with ρ, T, B and g respectively the linear density, tension, bending stiffness and the acceleration of gravity. At $x = 0$, the rope is lifted to a height $Z(t)$ and the point of contact between the rope and the ground is located at $x_c(t)$, to be found as a functional of $Z(t)$. Although Eq. (1) is formally linear, the above differential problem is in fact strongly nonlinear, since $w(x,t)$ is nonlinearly coupled to the location $x_c(t)$ where Eq. (3) is imposed, and $x_c(t)$ is to be found as part of the solution.

Above, the tension T is difficult to predict and control, experimentally, as it is affected by the friction between the ground and the rope. Nevertheless, it greatly simplifies the analysis if we assume that it is constant and that it dominates bending: $B\partial^4 w/\partial x^4 \ll T\partial^2 w/\partial x^2$. In that limit, bending stiffness only manifests itself in boundary layers and can be neglected in first approximation. Finally, the excitation of the rope is given by

$$Z(t) = Z_0 + \epsilon z(t), \qquad z(t) = \cos(\omega t), \tag{4}$$

and we wish to establish a map of the possible dynamical behaviours in the (ω, ϵ) plane.

RESULTS

In the absence of harmonic excitation ($\epsilon = 0$) and in the limit of small bending stiffness, it is easy to find that

$$x_c = x_{c,0} = \left(\frac{2TZ_0}{\rho g}\right)^{1/2}\left[1 + O\left(\beta^{1/2}\right)\right], \qquad \beta = \frac{\rho g B}{2T^2 Z_0} \ll 1. \tag{5}$$

Next, in the limit $0 < \epsilon \ll 1$, we find that

$$x_c \sim x_{c,0}\left[1 + \frac{\epsilon}{2}\frac{\pi\omega/\omega_c}{\sin(\pi\omega/\omega_c)}\cos(\omega t) + O\left(\epsilon^2\right)\right], \qquad \omega_c = \left(\frac{\pi^2 g}{2Z_0}\right)^{1/2}. \tag{6}$$

*Corresponding author. E-mail: gkozyref@ulb.ac.be

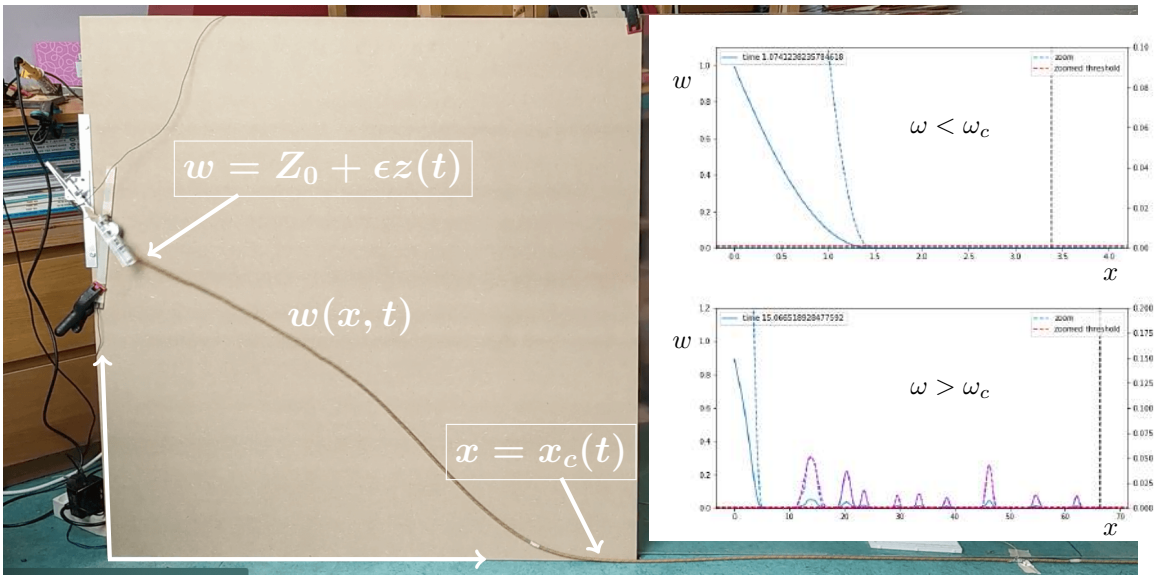

Figure 1: Experimental set-up. Top inset: snapshot of numerical simulation below instability threshold. Bottom inset: unstable regime. Full lines: $w(x,t)$, dotted lines: $10 \times w(x,t)$. Parameters: $Z_0 = 1$m, $\epsilon = 0.2$, $\beta = 0.1$.

The above result indicates that the response diverges as $\omega \to \omega_c$ and the expression for ω_c makes the rope appear as a pendulum of effective length $2Z_0/\pi^2$. Interestingly, the tension T does not appear in the expression for the resonant pulsation ω_c. This is because $x_{c,0}$ is naturally adjusted so that the propagation time of a disturbance between the vibrated end and the first contact point is independent of T.

As one approaches the resonant pulsation ω_c, the amplitude of vibration of the rope increases to such an extent that the rope can enter in contact with the ground at an intermediate location x^* between $x = 0$ and $x = x_c$. The region of the rope that is lifted in the range $x^* < x < x_c$ subsequently splits into one or more bumps that moves away from the origin. Thus, a dynamical transition is observed between a state of localised oscillations and a state of wave radiation along the rope. This dynamical scenario is confirmed both experimentally and by numerical simulations, performed with a code adapted from the work of Liakou *et al.* [8]. In Fig. 1, a close-up on the pulses in the radiation regime show that they are accurately given by fundamental travelling wave solutions of the beam equation [3].

A closer inspection of numerical simulations well below ω_c reveals that $x_c(t)$ can display quite an erratic behaviour, far from the simple harmonic form suggested by Eq. (6). This arises from the fact that the spectral response function actually contains a discrete infinity of resonances, at $\omega_n = n\omega_c$ ($n \geq 1$). These can easily be excited if special care is not taken to switch on the oscillations $z(t)$ sufficiently gradually. This infinite set of resonances indicates that the rope is a more complicated dynamical object than a simple pendulum: They are the signature of delayed interactions mediated by waves travelling up and down the rope.

A second surprise comes from carrying the perturbative analysis to higher orders in ϵ. At each new order, new harmonics are born due to the nonlinearity. For instance, at $O(\epsilon^2)$, the rope vibrates at a pulsation 2ω. As 2ω becomes close to ω_c the corresponding $O(\epsilon^2)$ amplitude diverges and a new region of instability is produced in the (ω, ϵ) plane. More generally, at $O(\epsilon^p)$ terms of frequency $p\omega$ are found and these are liable to diverge if they come close to $q\omega_c$. Therefore and infinity of nonlinear resonances actually exist, given by $(p/q)\omega$ with arbitrary integers p and q. Numerically, we have been able to observe regions of instability in the vicinity of $\omega_c/2$ and $2\omega_c/3$ in the form of Arnold's tongue.

DYNAMICS OF PHASE SEPARATION WITH NONLINEAR ELASTIC EFFECTS

Mrityunjay Kothari[1] and Tal Cohen [*1,2]
[1]Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA
[2]Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

Summary. Phase separation in binary liquid mixtures is arrested in the presence of elastic networks and leads to a nearly uniformly-sized distribution of the dilute-phase droplets. The droplets show a directional preference to migrate in presence of elastic property gradients. We model the dynamics of the resulting front propagation and discuss how elasticity controls the entire process.

INTRODUCTION

Phase separation is observed across the scales and in a variety of physical processes that range from the fields of biology to metallurgy. Liquid-liquid phase separation and subsequent species migration is understood to be a crucial mechanism for regulating the normal bodily functions of a cell. For instance, P-granule assembly is believed to employ phase separation as a mechanism to polarize the cell along its anterior-posterior axis as a precursor to cell differentiation [1]. The dynamics of this process is dependent on the cytoplasm and its properties. Similarly, phase separation phenomena are commonly observed in metals [2,3]. In the case of metals, elastic fields in the matrix are well known to affect the phase transitions; they can either inhibit or promote the growth of precipitates [4]. While important work has been carried out, both experimentally and theoretically, in understanding the elastic effects on phase separation and species migration in soft-material systems, understanding the dynamics of these processes still presents many challenges. In practical applications, the matrix properties are often heterogeneous, and the phase separation process is sensitive to these non-uniformities. In this talk, we will focus on 1D heterogeneity in elastic properties of the matrix and will examine the long-time dynamics of phase separation. In particular we explain through our model the observation of a propagating droplet dissolution front in a composite elastic sample made of stiff and soft materials [5]. We will discuss quantitatively how elasticity controls the speed of the front. We will also extend the model to analyse a graded elastic material and its effects on phase separation.

MECHANICAL RESPONSE OF WRINKLED STRUCTURES

Sijie Tong[1] and Andrej Košmrlj*[1]
[1]Department of Mechanical and Aerospace Engineering, Princeton University, Princeton, NJ, USA

Summary The wrinkling instability of compressed stiff thin films bound to soft substrates has been recently exploited to create structures with tunable drag, wetting and adhesion. While these studies successfully demonstrated the proofs of concepts, the quantitative understanding is still lacking, because we don't know how wrinkled surfaces deform in response to interactions with environment. To address this issue, we systematically study how wrinkled structures respond to infinitesimal surface forces both in the vertical and horizontal directions. We find that the linear response diverges near the onset of wrinkling instability and then decays away from this critical threshold. Our theory can be further used to study the response of wrinkled structures to more complicated distributions of external forces and can thus provide insights for the above-mentioned applications.

Wrinkling instability of compressed stiff thin films bound to soft substrates has been studied for many years and the formation and evolution of wrinkles is well understood [1, 2, 3]. In recent years, the wrinkling instability has been exploited to create structures with tunable drag [4], wetting [5], adhesion [6], and to create a template for DNA wire formation [7]. While these studies successfully demonstrated the proofs of concepts, the quantitative understanding is still lacking, because we don't know how wrinkled surfaces deform in response to interactions with environment. In this talk, I will discuss how we try to address this issue by systematically studying theoretically and numerically how wrinkled structures respond to infinitesimal surface forces both in the vertical and horizontal directions. We find that the linear response diverges near the onset of the wrinkling instability and then decays away from this critical compression threshold (see Fig. 1). The mechanical response near the critical compression threshold can be understood exclusively in terms of the dominant characteristic Fourier mode of wrinkles, which is decoupled from other modes. In analogy with the critical phenomena in ferromagnets, we can introduce the critical exponents for the response of the characteristic modes of wrinkles, which are consistent with the Landau theory [8] (see Fig. 1). However, away from the critical compression threshold, the coupling between different Fourier modes becomes significant and it affects the mechanical response. Our theory can be further used to study the response of wrinkled structures to more complicated distributions of external forces and can thus provide insights for the above-mentioned applications.

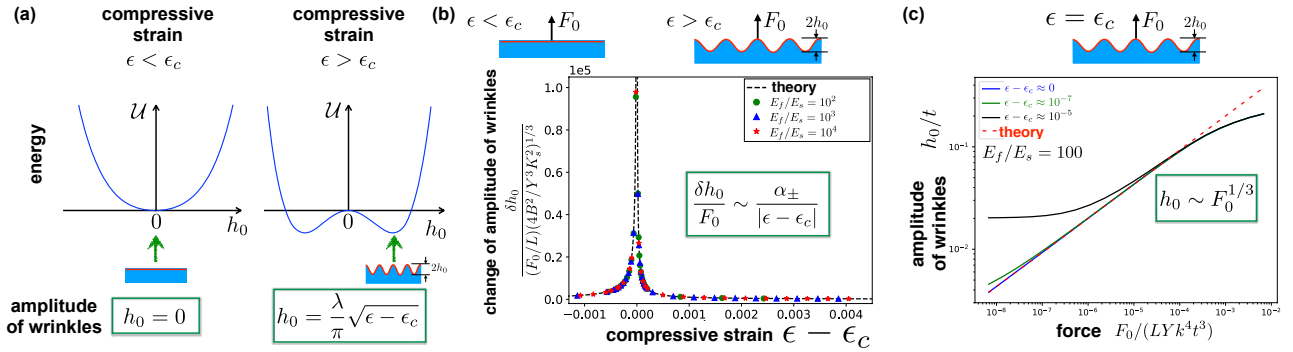

Figure 1: Relation between mechanical response of wrinkled structures and the Landau's theory of phase transition in ferromagnets, where the compressive strain ϵ, amplitude of wrinkles h_0 and external force F_0 are analogous to temperature, magnetization and magnetic field, respectively. (a) Energy landscape of wrinkled structures in the absence of external force as a function of compressive strain ϵ. Above the critical compressive strain ϵ_c the amplitude of wrinkles increases as $h_0 \propto \sqrt{\epsilon - \epsilon_c}$, which is analogous to spontaneous magnetization in ferromagnets below the critical temperature. (b) Linear response to vertical force diverges near the critical compressive strain as $\delta h_0/F_0 \sim |\epsilon - \epsilon_c|^{-1}$, which is analogous to the diverging susceptibility in ferromagnets near the critical temperature. (c) Exactly at the critical compressive strain ($\epsilon = \epsilon_c$) the amplitude of wrinkles grows nonlinearly with the applied force as $h_0 \sim F_0^{1/3}$, which is analogous to the nonlinear relation between magnetization and applied magnetic field in ferromagnets at the critical temperature.

ON THE DEFORMATION DEPENDENCE OF SURFACE STRESSES IN SOFT SOLIDS

Stefanie Heyden*[1], Robert W. Style[1], and Eric R. Dufresne[1]
[1]Department of Materials, ETH Zürich, 8093 Zürich, Switzerland

Summary Surface tension effects dominate the material behavior at scales below the elastocapillary length, which extends to the range of micrometers for increasingly soft materials such as hydrogels. Recent experiments using static wetting techniques suggest stretch-dependent surface stresses of soft solids [1, 2]. In this work, we present analytical solutions to the static wetting problem on stretched substrates. Following a Green's function approach, we extend the generalized Flamant-Cerruti problem, regularized by the addition of surface stresses, to furthermore account for uniaxial pre-stretches of the substrate. Symmetry breakage thereby allows us to gain insight into the intermediate-deformation regime between the two extreme cases of Youngs law for wetting on rigid substrates and Neumann's triangle for wetting on liquid substrates. Surface profiles and opening angles of wetting ridges are calculated and discussed in both frameworks of linearized and finite kinematics and compared to available experimental data [2].

OUTLINE OF THE PROBLEM

The analytical problem which originates from the static wetting framework is depicted in Figure 1. A liquid droplet is deposited on a soft substrate subjected to a finite pre-stretch λ. At the solid-vapor interface, forces originating from the liquid surface tension γ_l and the solid surface stresses γ_{sl} and γ_{sv} are balanced. Here, we focuse on the limiting case of large droplets, for which droplet curvature may be neglected and liquid surface tension acts along a straight contact line. The substrate is furthermore assumed to be neutrally-wetted. Due to pre-stretches applied to the solid substrate, the emergent surface stresses are rendered anisotropic. The fully three-dimensional surface profile upon static wetting is recovered by allowing solutions to account for varying in-plane angles between the applied pre-stretch and the in-plane direction perpendicular to the contact line.

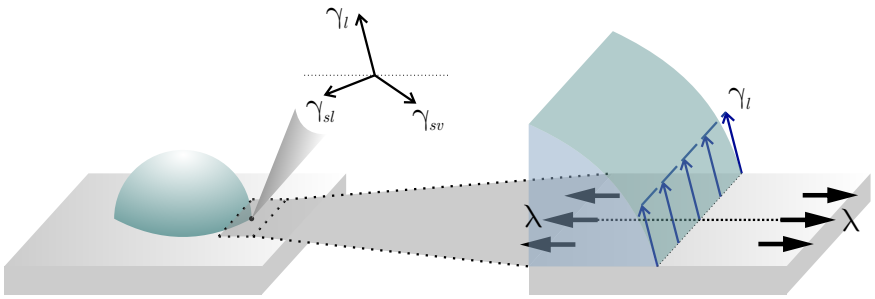

Figure 1: Sketch of the static wetting scenario: A liquid droplet is deposited on a soft substrate subjected to a finite pre-stretch λ. At the solid-vapor interface, forces originating from the liquid surface tension γ_l and the solid surface stresses γ_{sl} and γ_{sv} are balanced.

BULK ELASTICITY

To solve for the resulting substrate deformations due to the presence of the droplet within the framework of linearized kinematics, we follow a classical Green's function approach. The Navier–Lamé equations are simplified based on the assumption of plane strain conditions within the in-plane direction parallel to the contact line as prevalent in the large-droplet limit. Further, application of Fourier transforms results in a system of ordinary differential equations. Here, we aim to solve for substrate displacements at the surface only, for which tractions and displacements may be related via a generic spring constant $\hat{Q}_{ij}$.

SURFACE STRESSES

In order to take into account surface stresses counteracting the tractions applied at the substrate's surface, we start from a force balance at the surface. Surface stresses counteracting both normal- and in-plane tractions are derived, and the generic spring constant $\hat{Q}_{ij}$ is generalized to furthermore account for the additional action of surface stresses. To model anisotropic surface stresses based on an applied substrate pre-stretch, resultant surface stresses are calculated within the frameworks of both linearized kinematics and finite kinematics. In the latter case, we linearize about the configuration of an applied finite pre-stretch preceding droplet deposition.

*Corresponding author. E-mail: stefanie.heyden@mat.ethz.ch.

CONCLUSIONS

In this work, we present analytical solutions to the static wetting problem on an anisotropically stretched substrate. The generalized Flamant-Cerruti problem (regularized by the addition of surface stresses) is hence extended to furthermore account for anisotropic pre-stretches of the substrate. Moreover, solutions allow us to recover the full three-dimensional surface profile. By comparison to available experimental data, we show that a theoretical model of deformatio- dependent surface stresses predicts opening angles of the wetting ridge within experimental error measures.

THE ELASTIC CLASP: MECHANICS OF TWO DEFORMABLE FILAMENTS IN FRICTIONAL CONTACT

Paul Grandgeorge*[1], Changyeob Baek[1,2], Paul Johanns[1], Tomohiko Sano[1], and Pedro M. Reis[1]
[1]Flexible Structures Laboratory, Institute of Mechanical Engineering, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland
[2]Department of Mechanical Engineering, Massachusetts Institute of Technology, Boston, USA

Summary Knots, knits, weaves, and braids are but a few examples of intricate filaments in mechanical contact. Despite our broad empirical experience with such systems, there is a striking lack of fundamental understanding to predictively model their mechanical behavior. Indeed, the intricacy of entangled filaments coupled to the strong geometrical and material non-linearities involved make it challenging to develop high-fidelity quantitative models. Here, we adopt state-of-the-art 3D-imaging tools (X-ray tomography) combined with mechanical testing to investigate a canonical configuration of this class of problems; we focus on the frictional behavior of two elastic rods brought orthogonally into mechanical contact and made to slide against each other. We demonstrate how the frictional behavior between these two rods is closely related to the shape and size of their contact region.

MECHANICAL RESPONSE OF TWO ELASTIC RODS LOADED INTO FRICTIONAL CONTACT

Knotted filaments are ubiquitous across a wide range of length scales to moor ships to docks, secure adventurous climbers, or ensure the robustness of medical sutures. Yet, our understanding of the mechanical behavior of these intricate structures remains primarily empirical, gained through millennia of hands-on experience. This striking lack of fundamental understanding stems from the non-trivial coupling between topology, geometry, and mechanics in these systems. Past studies have either focused on ideal knots where no elasticity is taken into account [1] or on loose elastic knots [2, 3]. The latter are not representative of practical knots, which are usually tight. To gain a more in-depth mechanical insight into the primary mechanical ingredients underlying knotted structures, we investigate the mechanics of a minimal, yet representative, configuration of this class of problems: two elastic rods loaded into frictional contact.

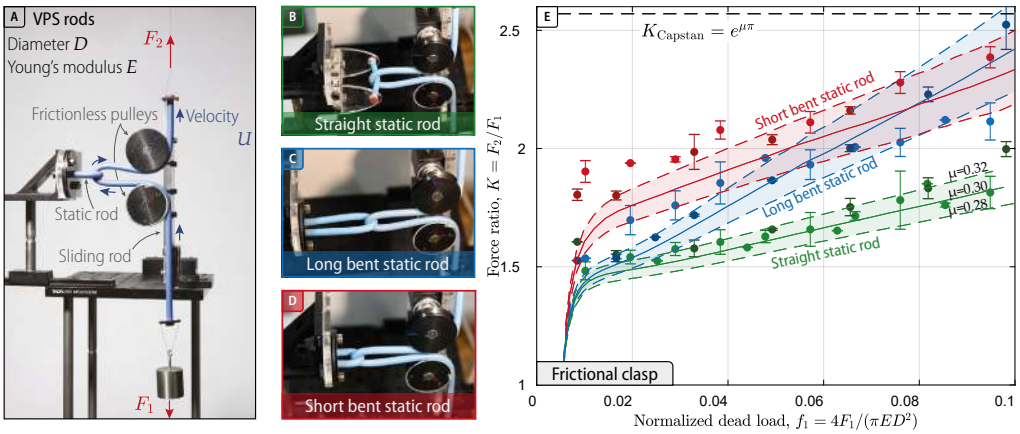

Figure 1: **Frictional clasp. A** – Experimental setup to quantify the force jump that an elastic rod is subjected to when sliding against another (static) elastic rod. A dead load F_1 is applied at one end of the sliding rod, and the stationary force F_2 required to achieve a constant upward velocity U of the upper end of the sliding rod is measured. The static rod configurations are shown in panels **B**, **C** and **D** and the experimental and numerical results of the force ratio $K = F_2/F_1$ as a function of the dimensionless dead load $f_1 = 4F_1/(\pi E D^2)$ a presented in panel **E**.

In Figure 1-**A**, we present our experimental apparatus comprising a long sliding *rod I* that is guided by two frictionless pulleys to thread through a second static *rod II* attached to a rigid frame. Rod II can be initially set to be either straight or pre-bent. We refer to this configuration of two elastic rods in crossing contact as the *elastic clasp*. The two rods composing this clasp are fabricated in-house out of Vinylpoly-Siloxane (VPS). Their Young's Modulus is varied using two different grades of VPS ($E = 0.52$ and 1.2 MPa). The sliding rod is weighted by a dead load F_1 attached to its lower extremity so as to study how this loading influences the mechanical response of the system. We focus on three different static rod configurations. In the first case (Figure 1-**B**), the static rod is set straight. In the two other configurations (Figure 1-**C** and **D**) the static is initially pre-bent by clamping its ends close to each other.

A typical experimental test involves using an Instron machine to impose the displacement of the upper end of the sliding rod that is loaded at the other end by the dead weight, F_1, and measuring the reaction force using a load cell.

*Corresponding author. E-mail: paul.grandgeorge@epfl.ch

This force first increases quickly before reaching a stationary plateau at F_2. In Figure 1-**E**, we plot the force ratio $K = F_2/F_1$ as a function of the normalized dead load $f_1 = 4F_1/(\pi ED^2)$ for the three static rods configurations. The experimental results (data points) are in good agreement with finite element (FEM) simulations (solid lines) using a friction coefficient of $\mu = 0.30 \pm 0.02$. The shaded region associated with the FEM results corresponds to the propagation of the uncertainty in μ. The friction coefficient was independently measured, and a value of μ =0.30 ±0.03 was obtained. Surprisingly, the force ratio K increases with f_1 for the three static rod configurations. By contrast, a classic *Capstan analysis* for an inextensible belt with no bending stiffness wrapped around a rigid cylinder, would predict a constant force ratio $K_C = e^{\mu\alpha} = 2.57$ for $\mu = 0.30$ and an imposed contact angle $\alpha = \pi$. The discrepancy between experimental (and FEM) results and the Capstan model is due to the elasticity of the rods (bending, torsion, and stretching). Elastic deformation plays a major role in setting the local geometry of the contact region by affecting both the global shape of the rods, as well as the local deformation of the cross-section near the region of contact between the two rods.

X-RAY TOMOGRAPHY TO CHARACTERIZE THE CONTACT REGION

To investigate the mechanics of the frictional elastic clasp in more detail, we first experimentally characterize its geometry in the frictionless case. In this set of experiments, two rods are clamped at both of their ends and brought into mechanical contact by increasing the distance between the two supporting walls. Using state-of-the-art X-ray micro computed tomography (μCT) and mechanical tensile testing, we experimentally assess the geometry of this system at different levels of loading. A 3D-image processing algorithm developed in-house then allows us to quantify relevant geometric properties of the clasp, including the Cosserat frame of the rod and the local opening angle $\theta_{\mathrm{I,II}}$. The latter is defined as the angle described by the tangents of the centerline at the first and last contact point along the arc-length of either rod (rod I or II, see Figure 2-**A**). In Figure 2-**B**, we plot the results for the measured opening angle of the orthogonal clasp as a function of the dimensionless force applied at its ends, $f_y = 4F_y/\pi ED^2$, for different configurations (similar to the ones analyzed in the frictional case). As the vertical force applied by the two walls ($2F_y$) to the rod ends increases, the opening angle decreases for the pre-bent rods. Moreover, the strongly heterogeneous contact pressure map, computed using FEM (Figure 2-**C**), encodes information on how this contact region will lead to non-trivial frictional behavior.

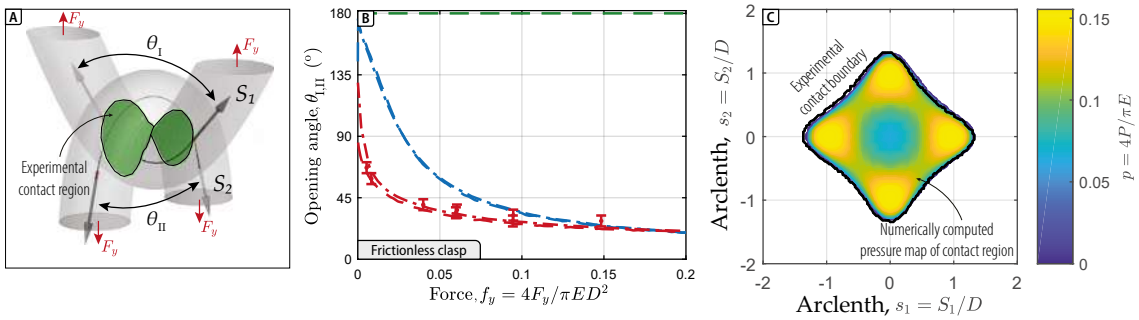

Figure 2: **Geometry of the contact region in an elastic clasp.** **A** – X-ray tomographic reconstruction of an experimental scan showing the centerline of the two rods (solid lines) and the contact surface (in green). **B** – Opening angle measured for different clasp configurations, the red (blue) curves correspond to rods of length $L = 60$ mm ($L = 160$ mm) clamped at their ends at a distance $W = 16$ mm, in contact with a rod either in this same configuration or with a rod whose ends are clamped further apart, at a distance $W = 0.7L$. The opening angle of one rod is almost unaffected by the configuration of the rod it is in contact with. Note that the green dashed line represents the opening angle of fiber kept straight (180°). **C** – FEM computed heterogeneous pressure map of a symmetric elastic clasp.

Modeling efforts are currently ongoing to study the influence of geometric reconfigurations of the contact region between two rods on the tension drop observed in this frictional clasp by adapting the modified capstan theory for elastic rods, as proposed by Jung *et al.* [4]. We believe such a fundamental understanding and characterization of the interplay between geometry, elasticity, and friction will help unravelling the behavior of more complex intricate filaments systems such as knots, knits, braids, and weaves.

ON THE ROLE OF THE INCOMPRESSIBILITY CONSTRAINT IN SOFT DIELECTRIC COMPOSITES

Valentina Volpini[1], Lorenzo Bardella*[2], and Massimiliano Gei†[3,4]

Summary In this work we demonstrate that the incompressibility constraint customarily adopted in literature to model soft dielectric composites may lead to incorrect predictions. In fact, although in these composites each phase may individually be assumed to be incompressible, for high-phase contrast in terms of elastic moduli the volumetric deformation of the softest phase can provide a non-negligible contribution to the effective behaviour. To reach our goal, we determine the effective electric response of a two-phase Dielectric Laminated Composite (DLC) actuator, whose softest phase is described by a constitutive law admitting volumetric deformation. Our results, discussed in the light of the limit case in which the softest phase consists of void, are expected to aid the design of high-performance hierarchical DLCs.

PROBLEM STATEMENT

We investigate the two-phase DLC actuator illustrated in Figure 1, which is built by repeating a unit cell constituted by an incompressible phase a and a considerably softer phase b, the latter being compressible. We describe the DLC effective behaviour in terms of the macroscopic deformation gradient $\mathbf{F}$ and the nominal electric field $\mathbf{E}$, along with their work-conjugate first Piola-Kirchhoff stress $\mathbf{S}$ and nominal electric displacement $\mathbf{D}$. All the microscopic fields and the material constants (such as the shear modulus μ and the electric permittivity ϵ) are indicated with the subscripts a and b, depending on the phase.

We assume the following free-energy density for the phase a, based on neo-Hookean hyperelasticity [1, 2]:

$$W_a = \frac{\mu_a}{2}\left[\mathrm{tr}(\mathbf{F}_a^{\mathrm{T}}\mathbf{F}_a) - 3\right] - \frac{\epsilon_a}{2}|\mathbf{F}_a^{-\mathrm{T}}\mathbf{E}_a|^2 \tag{1}$$

where tr and $^{\mathrm{T}}$ are the trace and transpose operators and $|\mathbf{v}|$ is the modulus of $\mathbf{v}$. For the phase b, we adopt the following *decoupled* free-energy density:

$$W_b = \frac{\mu_b}{2}\left(\frac{\mathrm{tr}(\mathbf{F}_b^{\mathrm{T}}\mathbf{F}_b)}{J_b^{2/3}} - 3\right) + \frac{K_b}{2}\left(\frac{J_b^2 - 1}{2} - \ln J_b\right) - \frac{\epsilon_b J_b}{2}|\mathbf{F}_b^{-\mathrm{T}}\mathbf{E}_b|^2 \tag{2}$$

in which $J_b = \det \mathbf{F}_b$ and K_b is the bulk modulus.

We consider a voltage-driven actuator subject to the following macroscopic boundary conditions. We apply increasing transverse nominal electric field $E_2 = \Delta\phi/h_0$ (see Figure 1), whereas we disregard edge effects, such that $E_1 = 0$. For what concerns the mechanics, we assume plane-strain and hamper macroscopic shear deformations, such that the sole non-vanishing components of $\mathbf{F}$ are the longitudinal stretch $F_{11} \equiv \lambda_1$, the transverse stretch F_{22}, and $F_{33} = 1$. Correspondingly, the effective direct stress components vanish, that is $S_{11} = 0$ and $S_{22} = 0$, while, in general, $S_{12} \neq 0$, $D_1 \neq 0$, $D_2 \neq 0$. We solve the problem by the homogenisation approach for hierarchical DLCs based on the continuity relationships holding at the interfaces [3, 1, 2, 4], assuming that the microscopic fields are spatially uniform in each phase.

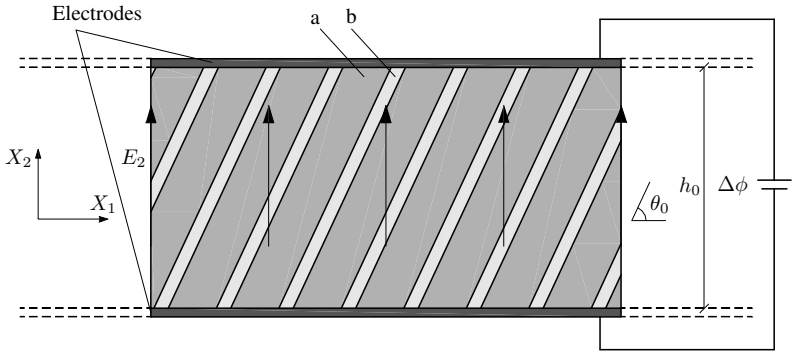

Figure 1: Geometric parameters of the DLC actuator consisting of incompressible phase a and compressible phase b. $\Delta\phi$ is the applied voltage drop across the electrodes, h_0 is the actuator thickness in the undeformed configuration, and θ_0 is the lamination angle.

†Corresponding author. E-mail: geim@cardiff.ac.uk.

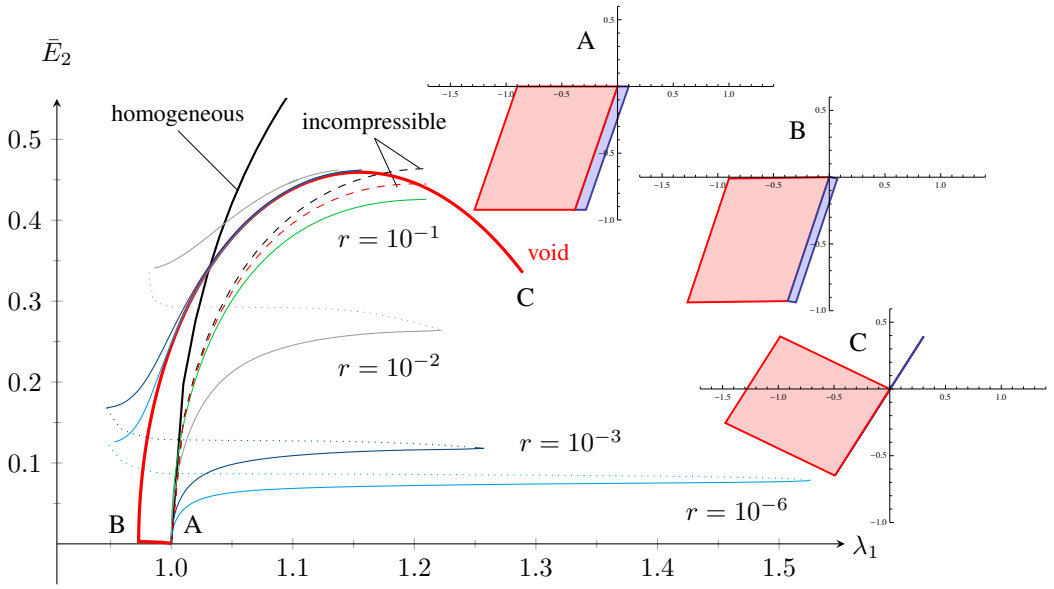

Figure 2: Performance of the compressible DLC actuator for varying $r = K_b/\mu_a$. Other parameters are $\theta_0 = 3\pi/8$, initial volume fraction of the compressible phase equal to 0.1, $\mu_a/\mu_b = 3 \times 10^3$, and $\epsilon_a/\epsilon_b = 10$. For the case in which phase b is void (red curves) we refer to $\mu_a = 10$ MPa and provide the configurations assumed by the two-phase unit cell at stages A (rest), B, and C.

RESULTS, DISCUSSION, AND PERSPECTIVES

Figure 2 illustrates the actuator response in terms of λ_1 as a function of the nondimensional electric field $\bar{E}_2 = E_2\sqrt{\epsilon_a/\mu_a}$, by varying the bulk modulus K_b through the ratio $r = K_b/\mu_a$. To discuss the results, we consider the case, referred to as the "limit case", in which the compressible phase b is void, for which the potential (2) has the electrostatic contribution only. In this case, we observe a behaviour characterised by three branches. The first branch (from A to B) is an initial *transient*, in which phase b suddenly shrinks whereas the continuity condition of stress at the interfaces cannot be properly satisfied. After this transient, a state of microscopically uniform *Cauchy* shear stress is reached all over the DLC. In this situation, holding up to the final stage C, all the electromechanical conditions are satisfied, as we can analytically prove. Our analysis also sets $\theta_0 = 3\pi/8$ as the lamination angle maximising J_b after the initial transient. After stage B, a second branch with increasing $\bar{E}_2$ follows, in which the DLC elongates as the result of local shear deformations and rotations. This branch ends with a maximum that we ascribe to the onset of a pull-in electromechanical instability. In the final branch $\bar{E}_2$ must decrease and the analysis ends when the phase b completely vanishes.

For a solid compressible phase b, the curves in Figure 2 share important features with the limit case, after an interesting high-performance branch. Then, in a transient response (dotted part of the curves), analogous to the first branch in the limit case, phase b largely shrinks while violating interface stress continuity. After this transient, the response approaches the limit case (from the left in Figure 2) for suitably small r. About the actuation response, for relative small r we observe an enhancement with respect to both the homogeneous DLC consisting of the sole phase a (black curve) and the incompressible DLC (black dashed curve), whose response is predicted through the effective potential obtained in [2]. Interestingly, the latter behaviour is very close to that of the incompressible DLC whose phase b is void (red dashed curve), which, in turn, is significantly different from the limit case, or any case with small r. This gives a clear indication that the incompressibility constraint in dielectric composites with large phase contrast should be cautiously adopted.

The foregoing results summarise those under publication in [5]. In this contribution we aim at further explaining the behaviour above by resorting to two strategies, towards relaxing the problem at hand and modelling actual hierarchical DLCs. First, we will consider imperfect interfaces. Second, we will allow the DLC to experience a non-vanishing macroscopic shear deformation F_{12}, to be constitutively related to the shear stress S_{12} through a linear law. Such a relation may, in fact, be particularised to both the case above and the case where one sets $S_{12} = 0$ to leave F_{12} free, for which, for any solid phase b, the obtained actuation responses continuously satisfy all the electromechanical conditions, being free from transients such as those reported above [5].

SHAPE MORPHING VIA INFLATABLE ZIGZAGS

Tian Gao*[1],Emmanuel Siéfert[1],José Bico[1],Etienne Reyssat[1],Benoît Roman[1],and Antonio De Simone[2,3]
[1]Physique et Mécanique des Milieux Hétérogènes (PMMH),ESPCI Paris,PSL University,CNRS,Sorbonne Universités,Université de Paris,75005Paris,France

[3]The Biorobotics Institute, Scuola Superiore Sant'Anna, 56127 Pisa, Italy

Summary Zigzags structures are found in a wide variety of fields. For instance, the future leaves of hornbeam are folded in the buds into zigzagging features that deploy as the leaves grow. This natural example has been the source of inspiration to develop origami designs. Here, we present a novel strategy where inextensible thin patches are sealed along zigzag paths to generate complex shape transformation under applied pressure. We investigate the change in metrics induced by the inflation of these paths and the consequent transformation of the initially flat patches into 3D structures. We also study the case of asymmetric zigzags, which leads to a rotation of the average deformation tensor and widens the routes for reverse-engineering. We finally propose a theoretical model based on zigzagging paths to program the deployment of flat sheets into 3D shapes.

INTRODUCTION

The concept of shape morphing has received great attention in a range of fields from dynamic optics, tissue engineering, aeronautics to soft robotics. Although inspired by biological morphogenesis, programming shapes from 2-dimensional (2D) to 3-dimensional (3D) is essentially a geometrical challenge. More specifically, one needs to control the metric tensor at every point to define the target Gaussian curvatures. From a physical standpoint, shape transformation requires materials to modify intrinsically their geometry in reponse to external stimuli, such as chemical swelling, dielectric elastomers, liquid crystal elastomers or magnetic responsive materials. In our previous research, we introduce **baromorph** [1] as a pneumatic shape-morphing structure made of stretchable material which encodes the target 3D shape by embedding a specific network of airways. Here, we provide a new platform by writing zigzags on quasi-inextensible thin sheets, along with an inverse problem model.

EXPERIMENT AND MECHANISM

This inflatable structure is primarily made of two superimposed thermoplastic sheets that are sealed together along a zigzag path. A soldering iron mounted on an XY-plotter or a CNC-machine directly "writes" heat-sealed zigzag seams on the two superimposed sheets (Fig.1(a)) [2]. Zigzags are characterized by their angle θ_0 at rest (Fig. 1(c)). Inflating these flat "zigzags" involves contraction of the material both along and perpendicular to the average zigzag direction (Fig. 1(b)(c)). Indeed, in the case $\theta_0 = 0$ (no zigzags),the contraction is purely perpendicular, whereas for large angles $\theta_0 \simeq \pi/2$, contraction occurs mostly along the zigzag direction. Fig.1(d) shows the quantitative agreement between the experimental measurements and the theoretical prediction for the typical contraction rate $\bar{\lambda} = 0.77$. It is interesting to notice that changing the angle of the zigzags does not impact the overall area contraction upon inflation, which remains equal to $\bar{\lambda}$.

INVERSE PROBLEM AND RESULTS

We are interested in inducing controlled changes of the shape of the material surface by generating changes of lengths and angles of its material fibers through actuation, described by changes of the metric tensor from its reference value g_0 to a new value g. The possibility of changing the curvature (morphing) of a surface by acting on its metric relies on a remarkable theorem by Gauss, the celebrated *theorema egregium*, stating that the Gaussian curvature K of a surface (the product of its principal curvatures) can be computed by differentiating the components of its metric tensor. The interpretation of Gauss' theorem as a morphing scheme has been suggested in the pioneering work of Klein et al. (2007) [3]. This approach has been exploited in Arroyo et al. (2012) [4]; Arroyo and DeSimone (2014) [5]; to model shape-shifting envelopes of unicellular organisms, and we follow the approach of these papers closely.

Let us consider a stretch with principal directions along the coordinate lines

$$g = \begin{bmatrix} \lambda^2 & 0 \\ 0 & \mu^2 \end{bmatrix} \tag{1}$$

where $\lambda = \lambda(u,v) \in (0,+\infty)$ and $\mu = \mu(u,v) \in (0,+\infty)$ are the stretches along the $u-$ and $v-$ coordinate lines, respectively. By setting $\lambda\mu = \bar{\lambda}$ (fixed area ratio), we obtain after some calculations

$$K = -\frac{1}{\bar{\lambda}^2}((\lambda\lambda_{,v})_{,v} + (\mu\mu_{,u})_{,u}) \quad (\lambda\mu = \bar{\lambda}) \tag{2}$$

Experimental realisations of structures of constant positive and constant negative GC may be found in Fig. 2.

PIERCING SOFT SOLIDS: A MECHANICAL THEORY FOR SURFACE RUPTURE

Stefano Fregonese[1], Mattia Bacca[1]
[1]Department of Mechanical Engineering, University of British Columbia, Vancouver, Canada

Summary The determination of the critical force to be applied to a needle in order to pierce a soft material is key in order to improve surgical technology (e.g. robotic surgery), manufacturing (food processing) and in-situ material characterization. Previous investigations unravelled the force required in order to deeply penetrate a soft rubber once the needle is already inserted but did not determine the critical force for needle insertion (the piercing force creating surface rupture). Recent investigations proposed a phenomenological analysis for the determination of such force based on experimental observations but without providing a quantitative mechanical theory to support their conclusions. We propose a mechanistic theory based on energetic analysis to finally obtain a quantitative prediction of the critical piercing force based on needle geometry and material behaviour.

INTRODUCTION

The deep penetration of a soft solid by a punch is of widespread technological importance, with application for robotic surgery, piercing the skin by needling and injection of liquid, penetration of rubber packaging and food processing. Despite the luck of standardization, there are many industries in which the mechanism of surface rupture plays an important role and affects not only the cutting process but often has a direct influence on human life. Applications such as measuring mechanical properties of biological tissue are of technological importance for remote robotic surgery, where the needs of having in situ measurements are fundamental. Robotic control of deformable objects is a topic of increasing importance in the textile, medical and food processing domains. However, the interaction with deformable materials remains unsolved issue principally due to the variability in mechanical behaviour. Previous attempts to solve this issue have generated some partially complete solutions [1-2] and empirical data [3]. We propose here a simple mechanical theory to finally calculate the critical force and depth to rupture a soft material via needle insertion.

MECHANICAL THEORY

We propose here an energetic approach to quantify the critical rupture force and penetration depth of a soft material by needle insertion. The method is based on an energetic comparison between two distinct configurations in the system: (i) Deep indentation and (ii) deep penetration. The former considers the needle to be pushed against the free surface of the material without any penetration, while the latter considers the needle is already inserted in the material. Take d to be the depth at which the needle is being pushed toward the free surface of the material from an initial state of zero force applied and the tip of the needle touching the free surface. Both configurations are characterized by a force applied to the back of the needle $F_i(d)$, and $F_{ii}(d)$ ($F(0) = 0$ in both cases), and the mechanical work required to reach the depth d in both configurations is $w_i(d) = \int_0^d F_i(d)\delta d$ and $w_{ii}(d) = \int_0^d F_{ii}(d)\delta d$.

Surface rupture occurs when d reaches the critical depth d_c. At $d < d_c$, we have $w_i(d) < w_{ii}(d)$, *i.e.* deep indentation requires less mechanical work, hence configuration (i) is favoured. Conversely, for $d \geq d_c$, we have $w_i(d) \geq w_{ii}(d)$, giving configuration (ii) to be energetically favoured, hence promptings surface rupture.

Our model system considers a needle of cylindrical shape with a spherical tip (Figure 1).

Deep indentation

We calculate the indentation energy via finite element analysis (FEA). The mechanical behaviour of the material is described with a single term Ogden strain energy density

$$u(\lambda_1, \lambda_2, \lambda_3) = \frac{\mu}{\alpha}(\lambda_1^\alpha + \lambda_2^\alpha + \lambda_3^\alpha - 3) \quad (1)$$

with λ_1, λ_2 and λ_3 the principal stretches, $2\mu = \alpha\mu$ the shear modulus of the material and α a dimensionless material parameter. $F_i(d)$ is expressed in dimensionless form as a Taylor expansion around the resting condition $F_i(0) = 0$, as

$$\frac{F_i(d)}{\mu R^2} = \sum_{k=1}^{n} a_k \left(\frac{d}{R}\right)^k \quad (2)$$

with R the radius of the needle (see Figure 1*a*), a_k the Taylor series coefficients, and n the number of terms of the series needed to fit the results obtained with FEA. From Eq. (2) the mechanical work due to deep penetration, in dimensionless form, is then

$$\frac{w_i(d)}{\mu R^3} = \sum_{k=1}^{n} \frac{a_k}{k+1} \left(\frac{d}{R}\right)^{k+1} \quad (3)$$

*Stefano Fregonese. E-mail: fregonese.stefano88@gmail.com.

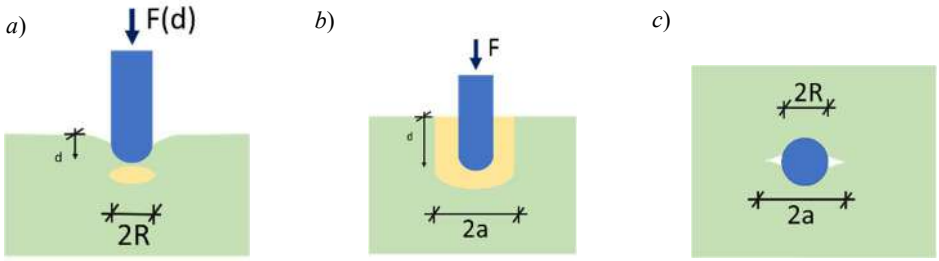

Figure 1: *a*) Deep indentation (i), side view; *b*) Deep penetration (ii), side view; *c*) Deep penetration (ii), top view

Deep penetration

The mechanical work due to deep penetration is calculated from two energetic contributions: (1) the work of fracture; (2) the work of spacing [1-2]. The former is the work done to the material to create a fracture-slit capable of allocating needle penetration and is done via rupture of molecular bonds in the material (see Figure 1*b*). The latter is the work done to the material to space it in order to accommodate the presence of the needle (see Figure 1c). We have then $w_{ii}(d) = w_{(1)}(d) + w_{(2)}(d)$, with

$$\frac{w_{(1)}(d)}{\mu R^3} = 2\left(\frac{G_c}{\mu R}\right)\left(\frac{a}{R}\right)\left(\frac{d}{R}\right) \qquad (4a)$$

$$\frac{w_{(2)}(d)}{\mu R^3} = h(a/R)\frac{d}{R} \qquad (4b)$$

where G_c is the toughness of the material, a is the size of the fracture-slit (Figure 1*b-c*) and $h(a/R)$ is a dimensionless spacing-function [1]. Both $h(a/R)$ and a are calculated from FEA as a function of the dimensionless term $G_c/\mu R$. The surface rupture condition $w_i(d_c) = w_{ii}(d_c)$ to obtain d_c and then the critical force $F_c = F_i(d_c)$ for surface rupture is finally calculated numerically from Eq. (2-4).

RESULTS

We adapted our theory to calculate the critical force F_c and depth d_c needed to puncture a gel ($\mu = 7{,}2kPa, G_{IC} = 25N/m$), and compared our predictions with experiments [3], as shown in Figure 2.

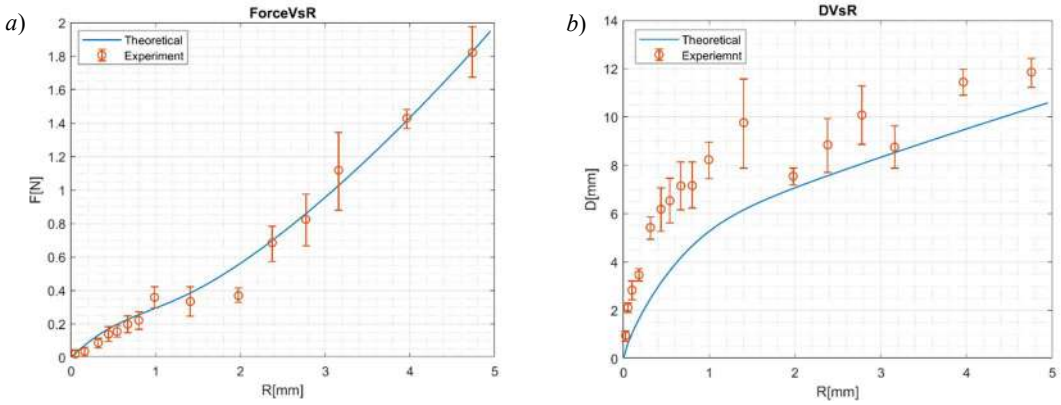

Figure 2: Surface rupture conditions, theory (blue lines) versus experiments (orange circles) [3]: *a*) Critical force for surface rupture F_c; *b*) Critical depth d_c

DISCUSSION AND CONCLUSIONS

From Figure 2, we can conclude that our theory provides quantitative agreement with the experiments in predicting the critical force, F_c, and qualitative agreement in predicting the critical depth, d_c. In Figure 2*b*, it can be seen that our model underestimates the experiments for smaller R, where d_c/R is larger. The material behavior is described with the simple Eq. (1), thus a loss of accuracy is expected for larger d_c/R. We expect an improvement in accuracy in Figure 2*b* from the use of more sophisticated models in replacement of Eq. (1).

SIMULATING COMPLIANT CREASES, CONTACT, AND THICKNESS IN ORIGAMI

Yi Zhu[1], and Evgueni Filipov[1]
[1]Department of Civil and Environmental Engineering, University of Michigan, Ann Arbor, MI

Summary This work presents a set of recent advancements in mechanical modelling of deformable origami structures. We use a bar and hinge model where bars represent in-plane stiffness of the thin sheet while rotational hinges represent bending stiffness of the sheet and the prescribed fold lines. First, we introduce a modification that allows the model to simulate compliant creases with a non-negligible width. This modification is important for capturing the true geometry of the origami system, and for better approximating the crease flexibility for extensional and torsional deformation modes. Next, we introduce a model that can detect contact within the origami, initiate and disengage contact interactions, prevent penetration of the thin sheet panels, and provide force continuity for the mechanical simulation. When combined with the compliant crease modification, this contact model can also mimic the effects of thickness in origami structures. These bar and hinge derived models use a sparse nodal representation of the origami which makes them computationally efficient and versatile for simulating a vast assortment of origami geometries. These advancements in mechanical modelling are important for simulating the geometry, self-assembly, bistability, contacts, and resulting mechanical behaviours in origami structures.

INTRODUCTION

The principles of folding thin sheets into origami have inspired a variety of practical engineering applications ranging from metamaterials and medical robotics, to deployable space structures and adaptable architectures. Advantages of these systems include self-assembly from flat sheets, compact stowing and deployment, geometric reconfiguration, tuneable mechanical properties, and more. Over the past decade, a bar and hinge based modelling approach emerged as a convenient, efficient, and versatile method for simulating the geometric, kinematic, and mechanical characteristics of origami structures [1-3]. In contrast to discretized finite element methods, each flat panel of the origami is approximated only with several bars and rotational hinges. This sparsity makes the model efficient and generally appropriate for estimating the global mechanics of the origami which are highly dependent on the system geometry. This work enhances the capability of bar and hinge models by enabling the simulation of compliant creases, contact and thickness.

COMPLIANT CREASE MODIFICATION

Many origami-inspired structures do not have a discrete hinge element (concentrated along a line), but instead have a flexible and compliant crease region where distributed folding occurs (Figure 1). These compliant regions, are especially common in micro fabricated structures, where the compliant crease also often acts as an active actuator that is used to accomplish the folding of the origami. This compliant crease region is important for the final folded geometry of the origami [4] and can be responsible for bistable behaviours in the system [5]. We discretize the compliant crease region by adding new bar and hinge elements as shown in Figure 1(a). The axial stiffness of the bar elements was derived based on plate theory, while the bending stiffness of the hinge elements was derived based on a pseudo-rigid-body model. These formulations were verified using a finite element simulation that captures the full mechanical behaviour of the origami [6-7]. The bar and hinge approximation performs well for tension, shear, bending (both small and large deformations), and torsion of the compliant crease. The proposed model produces the best estimate of structural stiffness when the crease aspect ratio is $\alpha \approx 0.1$ and the panel thickness ratio is $\beta \approx 3.0$. These ratios are representative of real origami systems with compliant creases. When the compliant creases are modeled appropriatley, the bar and hinge model can better approximate the final folding geometries and mechanical behaviors of the origami [6-7].

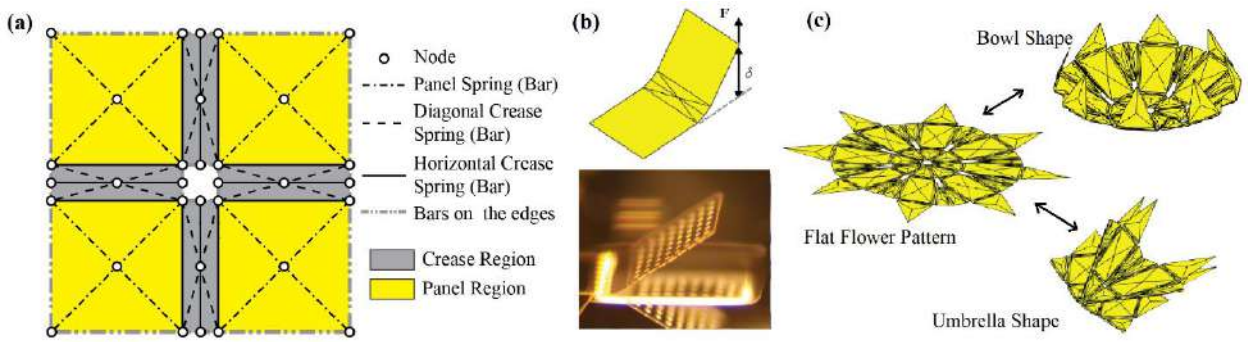

Figure 1. (a) An origami vertex discretized with compliant crease regions. Additional bars and rotational hinges can better capture the geometry and deformations of the crease. (b) A compliant crease model with a similar shape to electro-thermally activated micro-origami fabricated in our laboratory. (c) Possible folding of complex shapes with compliant hinges. All images are from [6].

CONTACT MODEL

The presence of self-contact within origami patterns has been difficult to simulate, yet it has significant implications on the foldability, kinematics and resulting mechanical properties of the final origami system. We present a contact model

that is based on the principle of stationary potential energy and assumes that the contact forces are conserved. The contact potential is formulated to approach infinity as the distance d between the contacting panel and node approaches zero:

$$\Pi(d(\boldsymbol{x})) = \begin{cases} k_e \left\{ \ln\left[\sec\left(\frac{\pi}{2} - \frac{\pi d}{2d_0}\right)\right] - \frac{1}{2}\left(\frac{\pi}{2} - \frac{\pi d}{2d_0}\right)^2 \right\}, & (d \le d_0) \\ 0 & (d > d_0) \end{cases},$$

where d_0 is the contact threshold distance, and k_e is a constant used to scale the magnitude of the potential. The corresponding internal force vector is calculated by taking the gradient of the potential, and the stiffness matrix is calculated from the Hessian of the potential. In our recent paper [8], we verified that this contact model (1) produces a continuous force field; (2) prevents penetration by giving infinite forces and stiffness as d approaches zero; and (3) has a piecewise formulation that allows initiation and disengagement of contact. To implement contact detection into the bar and hinge model we do a double loop over all flat panels and nodes, to determine the distances and initiate contact as necessary. Self-assembly or mechanical loading of the system is done incrementally [3], and the potential energy can successfully capture contact when it occurs (Figure 2). Contact within origami systems often leads to locking and stiffening of the structure, which is also approximated with the simplified bar and hinge model. When the contact model is implemented with compliant creases, we can set d_0 to be the thickness of the panels and k_e to be a relatively large value; as such the model effectively mimics the thickness of the origami panels as shown in Figure 3.

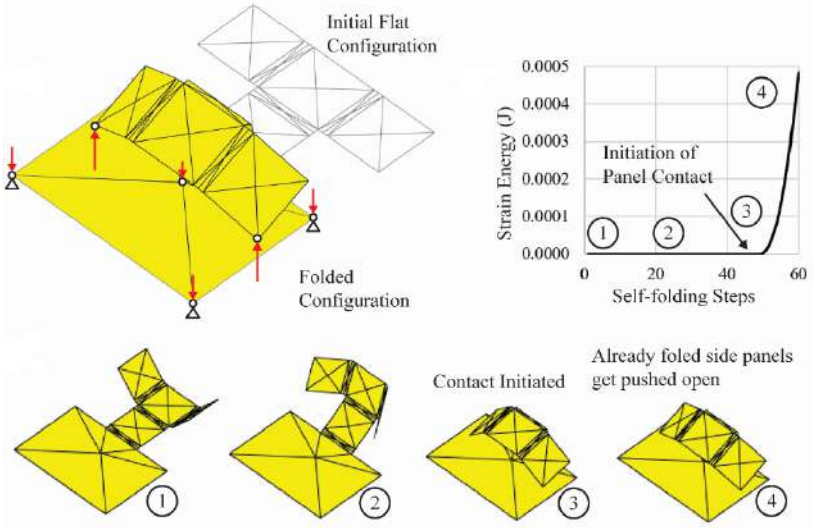

Figure 2. Self-assembly of an origami that experience self-contact during the folding sequence. This contact creates strain energy in the system. Images are from [8].

CONCLUDING REMARKS

This work presents a new method for simulating compliant creases, contact, and thickness in origami-inspired structures. Capturing these effects is important for better approximating the folded geometry, and predicting the mechanical characteristics of thin deformable sheets. The existence of compliant hinges can allow for bistable behaviours in the origami, and can allow for more complex geometries to be folded. The new contact model can evaluate if the folding of an origami pattern will be influenced by contact, and can capture relevant mechanical behaviours in the structure after contact occurs. These simulation approaches can enable the advanced study and design of new origami inspired structures and metamaterials with advanced mechanical properties and functionality.

A HIGHLY STRETCHABLE MAGNETIC DOUBLE-NETWORK COMPOSITE

Xiangchao Feng[1], Zhuo Ma[2], and Wei Hong[3]
[1]Qian Xuesen Laboratory of Space Technology, Beijing, China
[2]Department of Aerospace Engineering, Iowa State University, Ames,USA
[3]Department of Aerospace Engineering, Southern University of Science and Technology, Shenzhen,China

Summary This paper presents the manufacturing and testing results of a magnetic double network composite, consisting of permanent magnet chains and polymer matrix. The initially connected permanent magnet chains were used as sacrificial and reconnecting components in the composite. The strength of the composite was limited by the magnetic attractions while the maximum stretch was limit by the stretchability of the matrix. The composite was significantly tougher than either of the constituents. A one-dimensional model is developed to examine the mechanical and the damage distribution and energy dissipation process of DN magnetic composite. To further study the property and fracture toughness of the DN magnetic composite, a quasi-static, two-dimensional phase-field model of fracture are developed. Simulations have shown that an effective fracture energy one order of magnitude higher than the base polymer material.

INTRODUCTION

Double-network (DN) gels and elastomers have been of great interest to researchers in the last decades for their superior mechanical characteristics including both high strength and high toughness [1]. The desirable features endow DN gels and elastomers with applications in various areas[1-4]. Inspired by the salient self-healing capabilities of the ionic crosslinks in the tough gels, we designed and tested a magnetic DN composite capable of large and recoverable deformation in this work. In analogy to the reversible ionic crosslinks in self-healing hydrogels [5-6], permanent magnets were used as the sacrificial and reconnecting components in the composite. The strength of the composite was limited by the magnetic attractions while the maximum stretch was limit by the stretchability of the matrix. The composite was significantly tougher than either of the constituents. Upon unloading, the magnetic attraction between neighboring magnetics held them back again and the composite's stiffness and strength were fully recovered. To better understand the mechanical properties of the magnetic DN composite, a quasi-static continuum model is developed to study the damage distribution and energy dissipation process. The model predicts the stress-strain relation of the magnetic DN composite with various magnetic lattice compositions in the uniaxial tension test; the results agree well with experimental results.

EXPERIMENTATION

The magnetic DN composite samples were prepared by first pouring the well-mixed Polydimethylsiloxane (PDMS, WACKER SILICONES) precursor solution around the chains of cylindrical permanent magnets of two different sizes (φ4mm×10mm, φ2mm×1mm) inside rectangular molds. Once fully cured, the PDMS-magnet samples were removed from the molds for testing. The mechanical tests were carried out with an Instron 5960 dual column testing system. Each sample was held vertically by metallic grips with the magnetic chains aligned in the loading axis.

RESULTS AND DISCUSSION

A typical force–extension curve of a PDMS-magnetic DN composite subjected to uniaxial tension is shown in Fig.1(a), together with the reference curves measured from the base materials. Corresponding to the stress plateau in stage II was the coexistence of two phases: a partially damaged phase with separated magnet links and an intact phase with connected magnet links, as shown by the insets of Fig.1(a). Over the stress plateau, further stretch was manifested by the growth of the partially damaged zones at the expense of the intact magnetic links. Stage II continued until all the magnets were separated. In stage III, deformation was accompanied by further stretching of the matrix and sliding between the magnets and the matrix. The force needed to separate two magnets is much higher than the force two highly-separated magnets require to snap together. Such an asymmetry between loading and unloading results in a hysteresis over the stress-strain curve Fig.1(b). When reloaded, the nominal stress plateaued at the same level as in previous cycles， indicating that both the stiffness and the strength of the composite were recovered. The total free energy stored in the magnetic DN composite may be divided into two parts: the energy stored in the permanent magnets W_m and the energy stored in the polymer matrix W_e . The energy stored in the permanent magnets attenuates quickly as the inter-particle distance increases. The second network is stretchable and will hold the integrity of structure. We write the free energy density function to include three contributing terms:

$$W = W_{\mathrm{m}} + \mathrm{g}(\phi)W_e + W_d[1 - g(\phi)] + \frac{\kappa}{2}(\nabla\phi)^2 \qquad (1)$$

The third term on the right-hand side of Eq. (1) represents the energy associated with material damage. When the strain energy at a material particle exceeds the threshold W_d, the damaged state with $\phi = 0$ becomes energetically favorable. The gradient energy term is added to regulate the transition between the coexisting states.

In the fracture tests of pre-cracked sample, as shown by Fig.2., a large process zone formed near the crack tip by fragmenting the connected magnet chains to resist crack propagation. The local deformation and damage fields of representative results in 2D energy snapshots are shown in Fig.2. In the process zone, the initial damage pattern propagates in the shear band direction before reflected by boundary, the fracture process zone encompasses the entire

sample prior to the crack propagation. In the second stage, the crack tip in polymer matrix propagates, and the cracks advances.

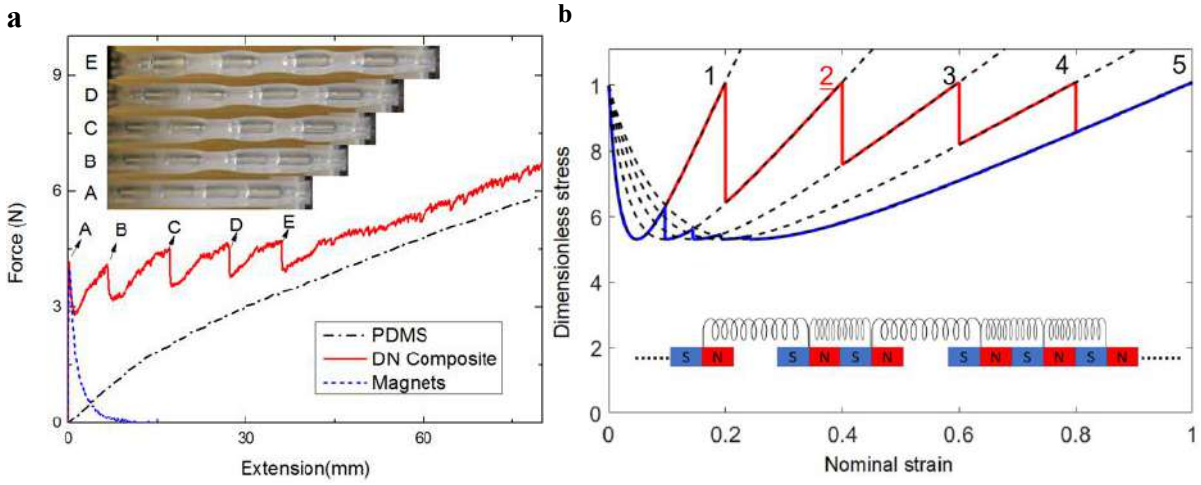

Figure 1. (a)Force-Extension curves of PDMS-Magnets composite, and DN composite with single chain of magnets. The insets A–E are the snapshots of the sample corresponding to the specific points along the loading curves. Over the stress plateau (A-E), partially damaged regions coexisted with the undamaged regions, and the extension was accompanied by the growth of the "damaged" regions. (b). Theoretical dimensionless stress-strain curves of one DN composite for case when 1,2,3,4 and 5 pairs of magnets are separated and reconnect. The sketch of magnets chain in bottom was indicate 2 unit cells are open.

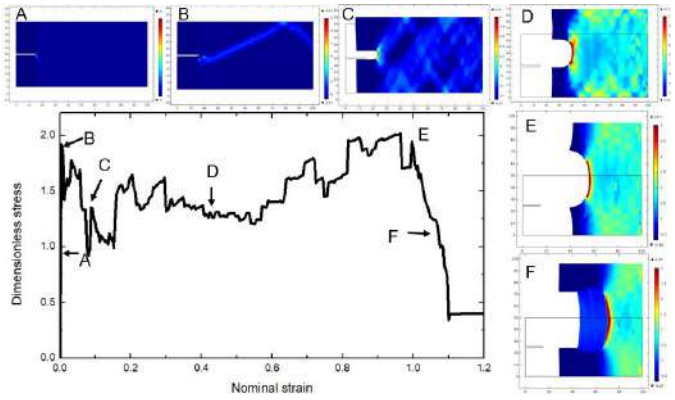

Figure 2. A typical dimensionless stress-strain curve of magnetic DN composites under fracture test. The insets A-F are the snapshots corresponding to the specific points along the loading curves. The color scale shows the nominal free energy density. Over the stress plateau (B-E), partially damaged regions coexisted with the undamaged regions, and the stretch was accompanied by the growth of the damaged regions. The snapshot E is taken at the moment before the crack starts to propagate. The snapshots F were captured during the crack propagation.

CONCLUSIONS

In analogy to the reversible ionic crosslinks in self-healing hydrogels, permanent magnets were used as the sacrificial and reconnecting components in the DN composite. We designed and tested a magnetic DN composite capable of large and recoverable deformation in this work. The theoretical model predicts the stress-strain relation of the magnetic DN composite with various magnetic lattice compositions in the uniaxial tension test; the results agree will with experimental results. Through visualizing the damage evolution, it may provide insights towards further understanding the toughening mechanism and optimizing of magnetic DN composites for enhanced properties.

THE INTRINSIC APPROACH IN LIQUID CRYSTALS: COMPATIBILITY, FRUSTRATED PHASES, AND INVERSE DESIGN PROBLEMS.

Efi Efrati[1]
[1]Department of Physics of Complex Systems, Weizmann Institute of Science, Rehovot, Israel

Summary :
Unlike Lego bricks that perfectly assemble next to one another, in many molecular assemblies and modern applications of responsive materials some misfit is almost always present. The constituents of such structures must distort in order to fit next to one another resulting in geometrically frustrated structures that possess no stress-free rest state. The elastic behavior of such structures is thus best described through local intrinsic geometric quantities such as their metric. In this talk, I will discuss the notion of compatibility, geometric frustration and the intrinsic approach as it arises in two-dimensional liquid crystals. I will show that the intrinsic approach does not only accurately describe frustrated states but also allows us to solve inverse design problems that were previously inaccessible analytically.

Geometrically Frustrated Assemblies

Geometrically frustrated assemblies are structures comprised of ill-fitting building blocks, typically possessing two or more mutually contradicting geometric tendencies.[1] Such structures lack a stress free rest state precluding the use of standard elastic treatments, which are based on the displacement vectors. The conformations such structures adopt are thus compromises between their mutually contradicting intrinsic geometric tendencies. This can give rise to elaborate conformations that arise from very simple input. Geometrically frustrated structures display super extensive elastic energy, a tendency for filamentation, and exotic response properties.[2]

Frustrated assemblies arise in a wide variety of systems in soft matter including chiral colloids[3], twisted molecular crystals[4], macromolecules, and commonly arises in plastic deformations, in viscoelastic solids and in hygro-morphing plants. The lack of a stress free configuration in these systems motivates a description that utilizes intrinsic geometric quantities such as the reference metric of the material manifold. Such descriptions were recently applied to molecular crystals revealing the gradual untwisting of twisted molecular crystal as the crystal's cross-section grows.[4] For uniform frustration in 2D the metric description predicts an elastic energy that scales like the area cubed for isotropic domains, while narrow ribbons show extensive elastic energy growing linearly with the area.[2] For thin elastic sheets the metric approach accurately predicts both the morphology and the non-trivial elastic response properties. Most recently, the metric approach was used to predict the future stability of viscoelastic structures.[5]

The key elements of a successful intrinsic description of a frustrated structure is the identification of the relevant intrinsic variables that fully characterise the system, and the common relations these quantities must obey to describe a viable structure. In what follows we do so for two-dimensional liquid crystals. We identify two scalar quantities that fully describe the phase, and one differential relation these quantities must satisfy. We conclude by demonstrating the power of this approach in solving the inverse problem of the nematic elastomers.

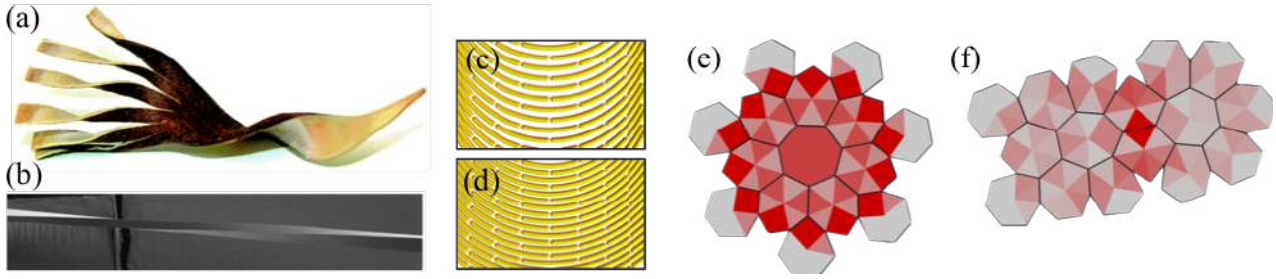

Figure 1. Frustrated assemblies. (a) Cutting a frustrated structure will cause it to deform to partially alleviate frustration. (b) SEM image of a twisted molecular crystal of Hippuric acid. (c) and (d) show a constant bend and zero splay planar arrangements of bent rods. However, the two cannot be simultaneously achieved. (e) and (f) show an isotropic and narrow assembly of 15 elastic heptagons in the plane colored by elastic energy. The filamentous structure shows much less elastic frustration. Panels (a), (b), (c) and (d) adapted from references 2,4 and 7.

The intrinsic approach for two dimensional liquid crystals

The simplest liquid crystalline phase is the simple nematic, in which molecules elongated along one axis orient on average to point in the same direction uniformly. Deviations of the orientations field, termed the director, from this uniform phase create gradients in the director both along the director, called bend deformations, and transversely giving rise to splay deformations. The bend and splay are given by $b = |(n \cdot \nabla)n|$ and $s = |(n_\perp \cdot \nabla)n|$ respectively, where n denotes the director unit field, and $n_\perp$denotes the director perpendicular direction. If two director fields share the same bend and splay functions they differ only by a rigid motion. The splay and bend uniquely characterize director fields, yet not every two scalar functions could constitute the splay and bend of a director field. It is well known that there is no director with zero splay and constant non-zero bend in the plane. Moreover, bend core liquid crystals, under the appropriate conditions, locally favour this inaccessible phase.

We next obtain the compatibility conditions for two-dimensional directors in arbitrarily curved surfaces. We begin with identifying the bend with the geodesic curvature of the director integral curves, and the splay with the geodesic curvature of the perpendicular integral curves. A careful implementation of the Gauss-Bonnet theorem yields

$$b^2 + s^2 + n \cdot \nabla s - n_\perp \cdot \nabla b = -K,$$

where K is the local Gaussian curvature of the surface in which the director is embedded. The above equation must hold at every point on the surface for b and s to be the bend and splay functions of a director on the surface. If the above equation holds one can find a director field n such that its splay and bend function read s and b respectively, unique up to rigid motions. Considering the case of uniform fields is particularly elucidating; the equation $b^2 + s^2 = -K$ implies that for the flat case where K=0 yields that only the trivial nematic with vanishing splay and bend is compatible. In positively curved spaces (like the surface of the sphere) where 0<K there are no compatible phases of uniform bend and splay. Last, for hyperbolic surface there are many such phases.

The compatibility condition above not only allows us to identify if an attempted phase is frustrated, but identifies the phases that are admissible. This replaces the elastic question of mechanical equilibrium with one of an optimal embedding, the cost function determined by materials constitutive relations. For the case of an attempted phase of vanishing splay and a constant bend in a domain of width W and length L the theory predicts an elastic energetic cost that scales as $E_{el} \propto W^3 L$.[6] For an Isotropic domain this implies a super-extensive elastic energy that scales with the area squared. For ribbons of constant width the energy becomes extensive. Thus, much like frustrated solids the ordered domains will tend to filament.

The nematic elastomer inverse design problem

The intrinsic approach to liquid crystals is not only useful for understanding frustrated states, but also allows solving analytically the inverse design problem of nematic elastomers. Nematic elastomers are elastomeric solids that possess an internal uniaxial orientational order. The locally preferred direction (director field) in the material can be externally prescribed during fabrication. Upon heating the orientational order is lost and the metrial shrinks by a factor λ along the director, and expands by a factor $\lambda^{-\nu}$ in the perpendicular direction. This in turn distorts the initially planar manifold to form a curved metric of Gaussian curvature

$$K = (\lambda^{2\nu} - \lambda^{-2}) \times \left(\cos(2\theta)[\left(\partial_y\theta\right)^2 - (\partial_x\theta)^2 + \partial_x\partial_y\theta] + \frac{1}{2}\sin(2\theta)\left[(\partial_x\theta)^2 - \left(\partial_y\theta\right)^2 - 4\partial_x\theta\,\partial_y\theta\right)\right).$$

The above equation is straightforward to implement if θ is known and we seek to learn what surface would be obtained upon actuation. However, recent advances in material science including programmable nematic elastomers, 4D printing applications and pneumatic soft actuators motivate the inverse problem: Given a desired surface with a prescribed K can we design a director that would realize it upon actuation. This amounts to finding a solution $\theta(x,y)$ in the plane to the above equation. There are two main impediments to reaching a solution. The first is that the Gaussian curvature is given on the distorted surface with respect to some intrinsic coordinates $K(u,v)$, whereas the unknown field and differential relation are in the (x,y) plane. The second impediment is the inaccessibility of the information that the initial state is flat. Setting $\lambda = 1$ above (which corresponds to the flat configuration before actuation) yields zero on both side of the equation and adds no information.

If we rewrite the equation above using the intrinsic approach we obtain $-K = \lambda^2(s^2 + n \cdot \nabla s) + \lambda^{2\nu}(b^2 - n_\perp \cdot \nabla b)$. Setting $\lambda = 1$ and $K = 0$ yields an independent equation. We may now solve for the splay and bend on the distorted surface, or equivalently on the plane solving simultaneously for $u(x,y), v(x,y), s(x,y)$ and $b(x,y)$. We perform this to produce the director field that would distort into the surface resembling a face, see figure 2. The initial data to the hyperbolic partial differential equations are given as two mutually perpendicular curves on the distorted surface which we interpret as integral curves of n and $n_\perp$.

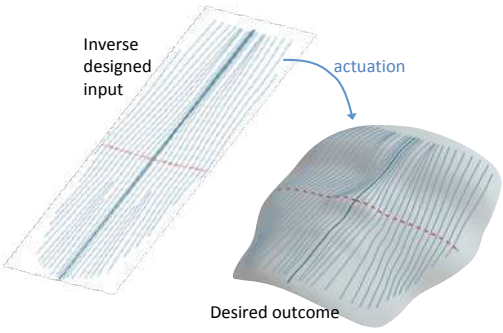

Figure 2. Solving the nematic elastomer inverse design. Adapted from 6.

CONCLUSIONS

We show that the splay and bend scalar fully describe a 2D director field, and provide the relation these fields must satisfy to describe a realizable field on arbitrary surfaces[7]. This intrinsic description allows us to solve the inverse design problem which is relevant to a variety of shaping mechanisms from nematic elastomers[6], to 4D printing and baromorphing[8].

MULTIFUNCTIONAL VISCOELASTIC COMBINATORIAL METAMATERIALS

David M.J. Dykstra*[1], Aleksi Bossart[1,2], Jop van der Laan[1], and Corentin Coulais[1]

Summary Mechanical metamaterials are structured forms of matter that can exhibit advanced functionalities such as non-reciprocity [1], shape-shifting [2, 3, 4], strain-rate dependency [5] and negative responses [6]. To date, most metamaterials only have a single functionality, underpinned by a single soft deformation mode or an uncontrollable extensive number of modes. Here, we introduce a novel class of combinatorial metamaterials that are multifunctional. We find a rich design space, which can host multiple yet a sub-extensive number of soft deformation modes. We demonstrate the multifunctional nature of such metamaterials using viscoelasticity. In particular, we realize a metamaterial that has a negative (positive) Poisson's ratio for low (high) compression rate. This makes our metamaterial an early example of multi-functional matter, thus paving the way for robust and adaptable devices.

BACKGROUND

Relating architectural details to emerging properties is a daunting challenge for the design of metamaterials. In particular, metamaterials so far exhibit either only a single deformation mode—which limit their functionality to a single shape-change or a single property— or exhibit a number of deformations modes or deformation branches that grow linearly or exponentially with the system size [2, 4], which are very difficult to actuate — in practice only one deformation mode or deformation branch can be actuated. To attack this challenge, we restrict our attention to combinatorial metamaterials [3], where the structural complexity is reduced to a discrete design space, typically by controlling the orientation of the constitutive unit cells. Such discreteness makes the design space much easier to explore and has been leveraged to create non-periodic metamaterials with shape-changing [3] and topological properties [7], yet, only for single mode metamamaterials so far.

COMBINATORIAL MODEL

Here, we introduce a novel unit cell with two soft deformation modes (Fig. 1a). In order to understand the structure and number of zero modes, we introduce a combinatorial model that maps out angle deformations onto a directed graph. To obtain it, we begin by linearizing the geometric constraints for a single cell at rest, which allows us to express three angles in terms of the other two. Conveniently, this relationship between small angle deformations has integer coefficients, allowing for a neat graphical representation of single-cell deformations (Fig. 1a) as arrows on a vertex with 5 edges (Fig. 1b). We can then construct a variety of tessellations of this unit cell. By construction, each edge corresponds to a hinge in real space, for which the sum of angles on either side remains constant (Fig. 1c). This makes it possible to draw only one group of arrows per edge; geometric constraints are easily propagated from one vertex to its neighbours. Hence, each configuration of arrows on this graph corresponds to a zero mode and provides an intuitive representation of the mechanical deformations it entails. This is reminescent of the integrable vertex models found in 2D statistical physics [8, 9], since it also amounts to counting arrow configurations that respect a set of local constraints, including the ice rule. Even though its algebraic structure remains a largely uncharted territory, this model provides a powerful graphical design tool that provides direct insight in the behaviour of combinatorial metamaterials.

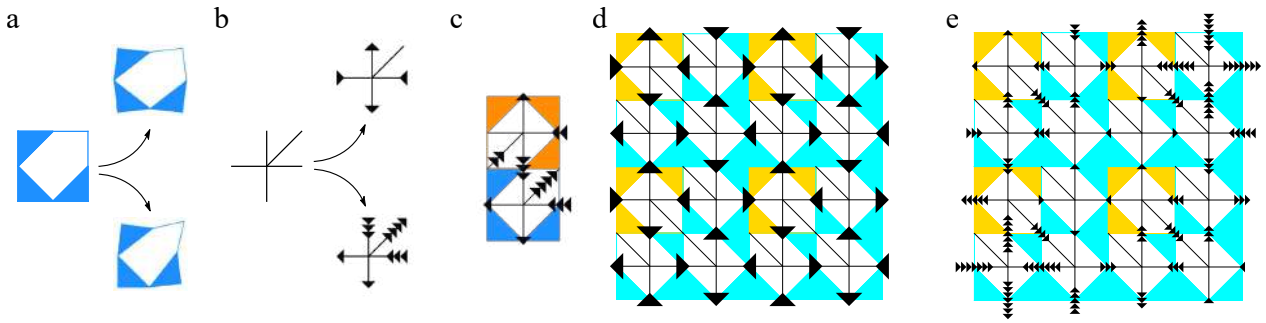

Figure 1: **Modes structure and vertex representation.** (a) Unit cell with two possible deformation modes (b) Vertex model representation. (c) Combinatorial index matching. (d) Counter-rotating squares in bimodal design. (e) Second bulk bi-domain mode.

Our new tool allows us to explore a variety of tessellations. An example of a periodic tessellation is shown in Fig. 1d, with a counter-rotating zero mode visualised using the vertex representation, which can be found for any rectangular

*Corresponding author. E-mail: d.m.j.dykstra@uva.nl

tessellation of our unit cell and has been studied extensively in the past [6]. What makes this specific tiling interesting is that it also features, regardless of system size, exactly one alternative bulk mode (Fig. 1e), which can be classified as a bi-domain mode, symmetric about the diagonal from north-west to south-east, increasing its deformation linearly when moving away from the symmetry axis. Other tesselations can offer a variety of zero mode counts, such as an extensive number of modes growing with system size, a finite number of modes larger than one or only the single mode of Fig. 1d.

MULTIFUNCTIONAL VISCOELASTICITY

In the following, we demonstrate that we can use these modes to generate multifunctional materials, harnessing strain-rate dependent viscoelasticity. To do so, we use a combination of additive manufacturing and casting to produce the architecture of Fig. 1d-e, resulting in the metamaterials of Fig. 2a. The sample of Fig. 2a features a hinge geometry that favours bending, with elastic hinges (green) and viscoelastic hinges (grey). For short time scales ($<$ 1sec) the viscoelastic material is stiffest and for long time scales ($>$ 1sec), it undergoes stress-relaxation and become softer than the elastic material. We compress the metamaterials at slow ($\dot{\varepsilon} = 9.3 \cdot 10^{-6} s^{-1}$) and fast ($\dot{\varepsilon} = 0.11 s^{-1}$) loading rates. We observe that the metamaterial responds in the counter-rotating mode when actuated slowly (Fig. 2c) and in the bi-domain mode when actuated rapidly (Fig. 2b). This can be explained as follows: for fast compression at short time scales, the elastic hinges are relatively softer and hence deform and lead to the bi-domain mode, while for slow compression at long time scales, the elastic hinges are relatively stiffer and hence not deform, thus leading to the the counter-rotating mode.

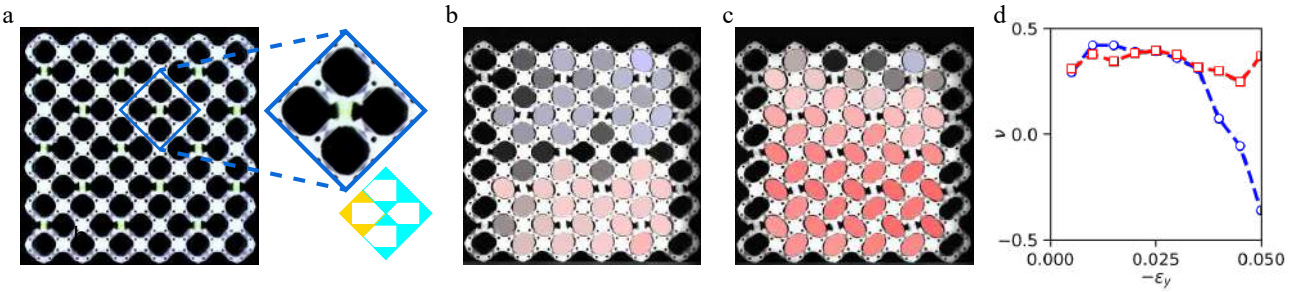

Figure 2: **Multifunctionality mediated by viscoelasticity** (a) Bimode metamaterial at rest and close up on a unit cell with schematic representation. (b-c) Snapshot of the metamaterial and reconstructed ellipses after a compression $\varepsilon = 0.056$ at a strain rate $\dot{\varepsilon} = 0.11 s^{-1}$ (b) and $\dot{\varepsilon} = 9.3 \cdot 10^{-6} s^{-1}$ (c). (d) Incremental Poisson's ratio vs. compressive strain ε for compression at a strain rate $\dot{\varepsilon} = 0.11 s^{-1}$ (blue circles) and $\dot{\varepsilon} = 9.3 \cdot 10^{-6} s^{-1}$ (red squares).

Interestingly, these two modes induce different Poisson's ratios (Fig. 2d). Namely, the counter-rotating deformation mode leads to a response with a negative Poisson's ratio while the bi-domain mode induces a positive Poisson's ratio. Therefore, our metamaterial is multifuntional, non-auxetic under fast compression rate and auxetic at slow compression rate.

CONCLUSIONS

To conclude, we have created a novel class of multifunctional metamaterials, that harness a combinatorial architecture to exhibit multiple modes, which we use to generate loading-rate dependent multifunctionality. Our work significantly advances the field of metamaterials and could be used to generate new kinds of multifunction materials.

PRESSURE-INDUCED COMPOSITION CHANGES IN A GEL FORCED TO MOVE BETWEEN TWO PLATES: THE ROLE OF ELASTIC AND OSMOTIC PROPERTIES

Fernando P. Duda*[1], Angela C. Souza[2], and Eliot Fried[3]

Summary We present a theory for the coupling between large deformation and fluid permeation in polymer gels that allows for the presence of sharp interfaces separating regions of high and low polymer volume fraction. The theory is specialized to study the problem of pressure driven fluid flow through a gel-filled channel, with the aim of investigating how the elastic and osmotic properties of the gel and the applied pressure gradient affect the composition, and hence the fluid flow, through the initially uniform gel under steady-state conditions. For a gel defined by Gent and Flory-Huggins models for elastic and mixing free energies, we demonstrate that the applied pressure gradient leads to a non-uniform polymer distribution across the channel which under appropriate circumstances is associated with the formation of regions of high and low polymer volume fraction separated by sharp interfaces.

PRELIMINARIES

Following Duda, Souza & Fried (2010), we present a theory for the coupling between large deformation and fluid permeation in polymer gels that allows for the presence of sharp interfaces separating regions of high and low polymer volume fraction. The main novelty here is the introduction of an extra force balance to account for the power expenditure associated with interface motion. Thus, by combining the basic balances of the theory, namely network content conservation, fluid content balance, mechanical force balance, and configurational force balance, with a constitutive theory compatible with thermodynamics, we derive the governing equations of the theory. Using the standard notation of continuum mechanics, we write the spatial version of these equations as follows:

- Bulk equations

$$\begin{aligned} &\phi \det \mathbf{F} = \phi_0, \\ &\operatorname{div}\,(\mathbf{T}_{\mathrm{n}} - p\mathbf{I}) = \mathbf{0}, \\ &\operatorname{div}\,(\upsilon \boldsymbol{\jmath} + \mathbf{v}) = 0, \end{aligned} \tag{1}$$

with the constitutive equations for network stress $\mathbf{T}_{\mathrm{n}}$ and fluid flux $\boldsymbol{\jmath}$ given by

$$\begin{aligned} &\mathbf{T}_{\mathrm{n}} = \frac{2}{\sqrt{I_3}}\left(\frac{\partial \tilde{\psi}_e(I_1,I_2)}{\partial I_1}\mathbf{B} + \frac{\partial \tilde{\psi}_e(I_1,I_2)}{\partial I_2}(I_1\mathbf{I}-\mathbf{B})\mathbf{B}\right) - \hat{\pi}(\phi)\mathbf{I}, \\ &\boldsymbol{\jmath} = -\upsilon\, \hat{m}(\phi)\operatorname{grad} p. \end{aligned} \tag{2}$$

Here and henceforth, $\mathbf{F}$ is the deformation gradient, ϕ and ϕ_0 the polymer volume fractions in the reference and actual configurations, p the interstitial fluid pressure, υ the volume occupied by an individual fluid molecule, $\mathbf{v}$ the network velocity, (I_1, I_2, I_3) the list of the principal invariants of the left Cauchy-Green tensor $\mathbf{B} = \mathbf{F}\mathbf{F}^{\top}$, $\hat{\psi}_e$ the elastic free energy response, $\hat{\pi}$ the osmotic pressure response, which is related to mixing free energy response $\hat{\psi}_m$ by the relation $\hat{\pi} = (\phi^2/\phi_0)\partial\hat{\psi}_m/\partial\phi$, and $\hat{m}$ the fluid mobility response. External body forces, inertial effects, and solvent supply are neglected here;

- Interface equations

$$\begin{aligned} &[\phi]u - [\phi\mathbf{v}]\cdot\mathbb{m} = 0, \\ &[\mathbf{T}_{\mathrm{n}}]\mathbb{m} = \mathbf{0}, \\ &[c]u - [c\mathbf{v}]\cdot\mathbb{m} = [\boldsymbol{\jmath}]\cdot\mathbb{m}, \\ &[\hat{\psi}_e(\mathbf{F}) + \hat{\psi}_m(\phi)] - |\mathbf{F}^*\mathbb{n}|^2\,\mathbf{T}_{\mathrm{n}}\mathbb{m}\cdot[\mathbf{F}]\,(\mathbf{F}^*)^{-1}\,\mathbb{m} = 0, \end{aligned} \tag{3}$$

where u is the interface speed, $\mathbb{m}$ ($\mathbb{n}$) the normal to the (referential) interface, c the fluid number density, and $\mathbf{F}^*$ the cofactor of $\mathbf{F}$. We have assumed a coherent interface across which the fluid pressure was continuous.

Next, we apply the foregoing theory to study the steady-state behavior of a gel of uniform composition placed between two flat plates and forced by a pressure gradient.

PRESSURE-DRIVEN FLOW THROUGH A GEL-FILLED CHANNEL

Consider the space between two infinitely long parallel plates separated by a gap d and completely filled by a gel which is fixed to and impermeable at the plates. We introduce a Cartesian coordinate system with the x-axis chosen parallel to the flow, the y-axis orthogonal to the plates, and z-axis orthogonal to the (x, y)-plane. We take the plates to be located at $y = 0$ and $y = d$. Initially, the gel is in a stress-free state with polymer volume fraction constant and equal to ϕ_0. Then, a pressure gradient a is applied causing the fluid to flow through the gel, which in turn deforms locally according to the deformation gradient

$$[\mathbf{F}] = \begin{bmatrix} 1 & \gamma & 0 \\ 0 & \eta & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{4}$$

This implies that that $\mathbf{F}$ is a superimposition of an uniaxial extension with stretch η on a simple shear with amount γ. These unknown quantities, which are functions y, are obtained by considering two distinct situations according to which interfaces are absent not.

In absence of interfaces, η and γ are smooth functions and must obey the set equations

$$\begin{aligned} &\hat{\tau}(\gamma(y), \eta(y)) = -a(y - d/2), \\ &\hat{\sigma}(\gamma(y), \eta(y)) = k, \\ &\int_0^d (1/\eta(y))\, dy = d, \end{aligned} \tag{5}$$

with k an unknown constant to be determined. The first two equations above follows from the combination of $(1)_2$, $(2)_1$, and (4), where $\hat{\tau}$ and $\hat{\sigma}$ are the constitutive for the shear and normal stresses acting in a plane normal to the y-direction.

We now consider the presence of two interfaces located symmetrically with respect to the central line between the two plates. In this case, η and γ are smooth away from and display jump discontinuity across the interfaces located at $y = w$ and $y = d - w$, with $w < d/2$. Thus, our problem reduces to the determination of γ and η for each y away from the interface, the corresponding limit values at the interfaces, and the location of the interfaces. Thus, we have to supplement $(5)_{1,2}$, which now hold only for points away from the interfaces, and $(5)_3$ with the following interface conditions obtained from (3):

$$\begin{aligned} &\hat{\tau}(\gamma_+, \eta_+) = -a(w - d/2), \qquad \hat{\sigma}(\gamma_+, \eta_+) = k, \\ &\hat{\tau}(\gamma_-, \eta_-) = -a(w - d/2), \qquad \hat{\sigma}(\gamma_-, \eta_-) = k, \\ &[\hat{\psi}_e(I_1, I_2) + \hat{\psi}_m(\eta)] + a(w - d/2)(\gamma_+ - \gamma_-) - k[\eta] = 0. \end{aligned} \tag{6}$$

These relations hold at $y = w$ and involves the limit values $\gamma_\pm$ and $\eta_\pm$ pf γ and η. The relations holding at $y = d - w$ are, by symmetry, redundant and for this reason are not displayed here.

We now consider a gel defined by Gent and Flory-Huggins models for $\hat{\psi}_e$ and $\hat{\psi}_m$, respectively. These models involves the following parameters: shear modulus G, finite extensibility parameter J_m, Boltzmann constant k_B , absolute temperature T, and the Flory-Huggins interaction parameter. Figure 1 plots the profile for $\phi/\phi_0 (= 1/\eta)$ for $\phi_0 = 0.1$, $J_m = 10.$, $k_BT/(\upsilon G) = 100.$, and two values of χ: (a) $\chi = 0.2$ (good solvent) and (b) $\chi = 1.$ (bad solvent). The same values of ad/G were adopted in both cases.

OSCILLATING CONFIGURATIONAL CONSTRAINTS AND NONLINEAR DYNAMICS OF EXTREMELY DEFORMABLE STRUCTURES

F. Dal Corso*[1], P. Koutsogiannakis[1], D. Misseroni[1], T. Papathanasiou[2], and Davide Bigoni[1]

Summary The motion of an elastic rod, constrained with a frictionless sliding sleeve periodically oscillating in time, is analyzed. Based on an analytical formulation and a numerical resolution, the resulting nonlinear dynamic response is shown to be heavily influenced by the configurational tangential reaction generated at the sliding sleeve constraint. More specifically, the system response features three characteristic motion patterns: (i.) the final complete injection, (ii.) the final complete transverse ejection, or (iii.) an initial ejection along the longitudinal direction (despite gravity) followed by an injection resulting to a steady small amplitude oscillation around a non-null external length value. Dynamic simulation of all characteristic motion patterns is achieved by means of an in-house Finite Element solver. The present results pave the way to longitudinal actuation by means of transverse non-periodic oscillations and control theory could be a powerful tool for optimal actuators.

Nonlinear structural dynamics breaks the limits of traditional linear elastic design, to create elements working beyond the realm of linearized kinematics, fully inside the nonlinear range, therefore meeting the strong requirements imposed by soft robotics, flexible locomotion devices, metastructures, architected structures for vibration mitigation, and morphable structures. Within this context, the influence of configurational (or 'Eshelby-like') forces on the nonlinear dynamics of structures is investigated in the presence of periodically oscillating sliding sleeves.

Configurational forces were introduced by Eshelby [10] to describe the motion of defects within solids and have been shown recently to act on elastic rods constrained by sliding sleeves [5]. In particular, the sliding of an elastic rod through a frictionless sleeve generates at the constraint exit an 'Eshelby-like' force with direction parallel to that of sliding. Recent studies have utilized the action of configurational forces to explain unexpected quasi-static response [4, 7, 8] of structures, analyze propulsion characteristics [6, 9], through a material force balance [11, 14], and investigate constrained buckling problems [12, 13]. Moreover, recent research on configurational forces in structural mechanics has eventually inspired a new interpretation of their action in solids [2].

The analysis of configurational forces acting on structures was recently extended to the dynamic framework [1] and developed in the special case of a moving mass m attached to an elastic rod of bending stiffness B and external length $\ell(t)$ varying in time t. Similar to the quasi-static case, the configurational force under dynamic conditions was found to be proportional to the square of the bending moment at the sliding sleeve entrance. Complex and often counterintuitive motion of the mass was also revealed, leading to complete rod injection and ejection from the sleeve constraint. In this study, the influence of the sliding sleeve constraint periodic transverse oscillation $\bar{u}_g \sin \omega t$ is considered (Fig. 1 (left)).

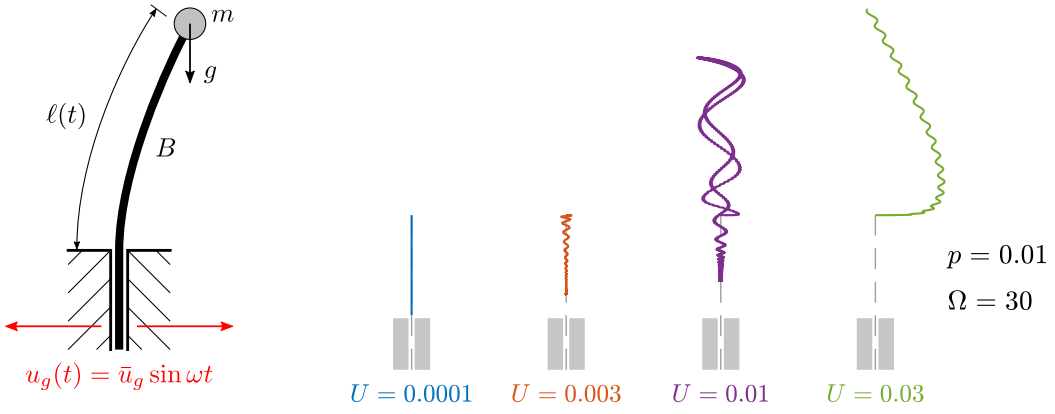

Figure 1: (Left) A lumped mass attached to an elastic rod slipping into a frictionless sliding sleeve parallel to the gravity direction and subject to an oscillatory transverse motion. The part of rod outside the configurational constraint has external length $\ell(t)$ varying in time. (Right) Theoretical predictions of the lumped mass trajectory for $p = 0.01$, $\Omega = 30$, and varying $U = \{0.0001,\ 0.003,\ 0.01,\ 0.03\}$, showing a final complete injection ($U = 0.0001$), an initial longitudinal ejection followed by an injection ending with a stationary motion at almost constant external length ($U = 0.003$ and 0.01), and a final complete transverse ejection ($U = 0.03$).

To numerically simulate this system, an in-house Finite Element (FE) code has been developed. The formulation extends a recently developed methodology [3] by including the effects of sliding sleeve constraints. The time response is computed assuming negligible elastic rod inertia by solving a nonlinear Differential-Algebraic Equation (DAE) system. In

*Corresponding author. E-mail: francesco.dalcorso@unitn.it

addition to possible dissipation sources, the time evolution is found to depend only on the following three dimensionless parameters

$$p = \frac{m\,g\,\ell_0^2}{B}, \qquad \Omega = \omega\sqrt{\frac{m\ell_0^3}{B}}, \qquad U = \frac{\overline{u}_g}{\ell_0},$$

where g is the gravity acceleration (acting parallel to the sliding direction) and ℓ_0 is the value of the external length $\ell(t)$ at the initial state ($t = 0$).

The structure response is observed to dramatically change with varying values of p, Ω, and U. More specifically, the system shows two limit states corresponding to complete injection or complete transverse ejection of the rod. Furthermore, a third, qualitatively different and intriguing motion, has been found. In this third case, the rod is initially ejected along the longitudinal direction (despite gravity) and then injected settling to a steady small oscillation around a non-null external length value. Theoretical predictions for the mass trajectory are reported in Fig. 1 (right), while the $\ell(t)$ values are depicted in Fig. 2 for a system with $p = 0.01$, and $\Omega = 30$, and $U = \{0.0001,\ 0.003,\ 0.01,\ 0.03\}$.

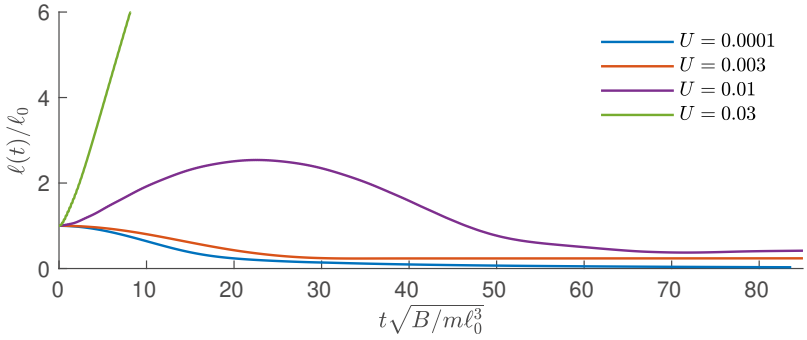

Figure 2: Evolution in time t of the external length ℓ for a system with $p = 0.01$ and $\Omega = 30$, with varying $U = \{0.0001,\ 0.003,\ 0.01,\ 0.03\}$.

The present results pave the way to longitudinal actuation by means of non-periodic transverse oscillations, where control theory could be employed for optimization purposes.

Summary It has been recently found that the lamellar structure of plant thylakoids and the endoplasmic reticulum are abundant with helical motifs connecting adjacent layers. In addition, both right- and left-handed motifs were observed in distributions suggesting total pitch balance. So far, the analytical treatment of such motifs embedded in minimal surfaces has been limited to the small-slope approximation, which breaks in the relevant biological regimes. Here, we provide a method for building exact and analytically tractable minimal surfaces containing any desired distribution of helical motifs. We then consider the fundamental structure and interaction between two motifs of either opposite or similar handedness. Finally, we use our new method to construct minimal surfaces with an arbitrary array of N helical motifs and show that local area minimization leads to global pitch balance.

INTRODUCTION

Minimal surfaces arise as the ground state of a variety of manmade and naturally occurring membranes and lamellar structures. They minimize area among all surfaces with a given boundary and should naturally appear when surface tension is the dominant effect. Minimal surfaces can also be relevant in systems dominated by membrane bending energy as they form a special class of critical points of the Helfrich free energy [4]. Recently, helical motifs were found in the lamellar structures of plant thylakoids [5] and the endoplasmic reticulum [6], where both right and left handed motifs were observed in stoichiometry suggesting total pitch balance [2, 6]. To better understand these structures we require the ability to build minimal surfaces in which the appropriate helical motifs are present.

In the modeling of endoplasmic reticulum, the inter-layer connections are arranged in a checkerboard array of oppositely handed helical motifs [6]. Despite that the modeled structures are not minimal surfaces, it was argued that they possess a low bending energy which in fact places an upper bound on the amount of bending the true smoothed texture is expected to display. In contrast, the helical motifs in thylakoids have distinct pitch and core radius distributions yet still display total pitch balance on average [2]. In trying to model these system analytically, Guven et al [3] considered the small slope approximation whose main advantage is that minimal surfaces are represented by the graph of harmonic functions and, consequently, it allows for the simple addition of helical motifs of arbitrary geometry and topology due to the additivity of harmonic functions. However, the resulting surfaces are not exactly minimal, what is exceptionally apparent in the immediate vicinity of the helical structures, i.e., within a distance of a few pitch lengths from the core of each motif. Unfortunately, this imposes limitations for this type of approach as in the biologically and physically relevant regimes the helical motifs are commonly separated by a distance comparable to the pitch, rendering the small slope approximation irrelevant for these structures [2, 6].

To address this issue, in this work we provide a recipe for constructing exact minimal surfaces with an arbitrary distribution of helical motifs. This is based on a representation of minimal surfaces known as *Enneper immersion* [1], from which follows that any harmonic graph can be deformed into an exact minimal surface through an explicit, yet non-local operation. In other words, we correct an approximate minimal surface given as a harmonic graph over the plane such that it becomes an exact minimal surface by only exploiting lateral displacements and not varying the height data.

CONCATENATING TWO HELICAL MOTIFS

Consider a surface given by a harmonic function h over a domain $\Omega \subset \mathbb{C}$: $\mathbf{r}(z = x + iy) = (z, h(z))$, $\partial_{\bar{z}}\partial_z h = 0$, where $\bar{z} = x - iy$, $\partial_z \equiv \frac{\partial}{\partial z}$ and $\partial_{\bar{z}} \equiv \frac{\partial}{\partial \bar{z}}$. The mean curvature satisfies $H \propto \mathcal{O}(\|\nabla h\|^2)$ and the surface is considered minimal within the small slope approximation, i.e., when terms of order $\mathcal{O}(\|\nabla h\|^2)$ are omitted. One can then "add" helical motifs due to the additivity of harmonic functions. Indeed, the surface $\mathbf{r}(z) = (z, p_0 \arg(z - z_0))$ yields a helicoid of pitch p_0 centered around z_0 which is exactly minimal. One can explicitly construct a surface which includes N helical motifs located at the points z_i and of corresponding pitches p_i through $\mathbf{r}(z) = (z, \sum_{i=1}^{N} p_i \arg(z - z_i))$. Its mean curvature, however, does not vanish identically. To fix this, we apply to an approximately minimal surface in the form of a harmonic graph lateral displacements leading to a new surface, the Enneper immersion of h, which is an exact minimal surface [1]: $\mathbf{r} = (z - \overline{P(z)}, h(z))$, where $P(z) = \int (\partial_z h)^2 \, dz$. This operation provides a conformal parameterization whose area element dA and Gaussian curvature K read $dA = (1 + \frac{1}{4}\|\nabla h\|^2)^2 dx\, dy$ and $K = -4\frac{|\partial_{zz} h|^2}{(1+|\partial_z h|^2)^4} = \frac{h_{xx}h_{yy} - h_{xy}^2}{[1+\frac{1}{4}(h_x^2+h_y^2)]^4}$.

We now come to analyze the fundamental problem of adding two helical motifs of similar and opposite handedness. Given two helical motifs of pitches p_1 and p_2 located at $z_1 = \frac{R}{2}$ and $z_2 = -\frac{R}{2}$, $R > 0$, the corresponding harmonic function is $h(z) = p_1 \arg(z - z_1) + p_2 \arg(z - z_2)$ whose graph is only minimal up to $\mathcal{O}(\|\nabla h\|^2)$. Integrating $(\partial_z h)^2$, we have

$$P(z) = \frac{p_1^2}{4(z - \frac{R}{2})} + \frac{p_2^2}{4(z + \frac{R}{2})} + \frac{p_1 p_2}{2R}\left[\ln(z + \frac{R}{2}) - \ln(z - \frac{R}{2})\right]. \quad (1)$$

*Corresponding author. E-mail: luiz.da-silva@weizmann.ac.il

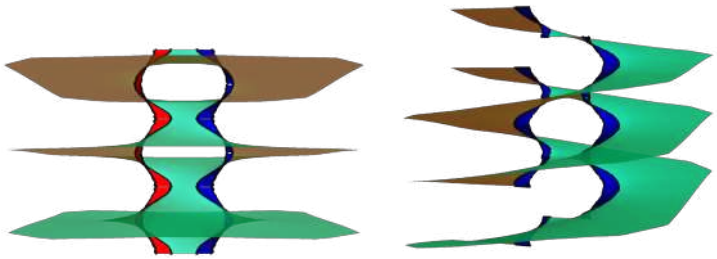

Figure 1: Layers of minimal dipole (left) and non-dipole (right) obtained by concatenating two helical motifs. (In the figures, $|p_1| = |p_2| = 0.15$ and $R = 1$.) The inner rims colored in red and blue emphasize the distinct handedness of the motifs.

The first two terms are the sum of $P_{\{z_1,p_1\}}(z)$ and $P_{\{z_2,p_2\}}(z)$ associated with two helicoids around $\pm\frac{R}{2}$, while the last term creates an interaction between them required to make the parameterization a conformal minimal immersion. In addition, since P decays as $1/|z|$, the harmonic graph of h is a good approximation for the corresponding Enneper immersion at large distances from the core. However, the approximated and exact minimal surfaces differ in the immediate vicinity of the helical core. The same reasoning equally applies for the addition of an arbitrary number of helical motifs since $P = \sum_i \frac{p_i^2}{4(z-z_i)} - \sum_{i<j} \frac{p_i p_j}{z_j - z_i}[\ln(z-z_j) - \ln(z-z_i)]$.

We start by considering the symmetric problem of gluing two identical motifs such that $p_1 = p_2 = p$. We next come to analyze a single leaf bearing in mind that the full structure is comprised of two such leaves repeated periodically. To describe the geometry of the helical core, we may compute the gradient and Hessian of $h(z) = p\arg(z+\frac{R}{2}) + p\arg(z-\frac{R}{2})$. The area of an annulus with radii $r_2 > r_1 \gg R$ is then $\int_{r_1}^{r_2} dA \approx \pi(r_2^2 - r_1^2) + 4\pi p^2 \ln(r_2/r_1) + \mathcal{O}((r/R)^{-2})$, $r = |z|$, while the Gaussian curvature is $K \approx -\frac{4}{R^2}\left(\frac{p}{R}\right)^2\left(\frac{r}{R}\right)^{-4}$, $r \gg R$. As expected, up to a small correction, the area of a minimal pair of identical motifs behaves for large distances as the area of two interlaced helicoids of pitch $p_0 = 2p$. The same is valid for the Gaussian curvature: $K \approx -4p^2/r^4$, which is precisely the asymptotic behavior for a helicoid of pitch $p_0 = 2p$.

For the case of a pair of oppositely handed motifs, $p = p_1 = -p_2$, the associated harmonic function is $h(z) = p\arg(z+\frac{R}{2}) - p\arg(z-\frac{R}{2})$. Here, we have $\int_{r_1}^{r_2} dA \approx \pi(r_2^2 - r_1^2) + \mathcal{O}((r/R)^{-2})$, $r_2 > r_1 \gg R$, whose non-trivial contribution is the area of a planar annulus. This confirms that for large distances, a minimal pair of opposite helical motifs is approximated by parallel stacked planes. The Gaussian curvature behaves as $K \approx -\frac{4}{R^2}\left(\frac{p}{R}\right)^2\left(\frac{r}{R}\right)^{-6}$, $r \gg R$. Notice that K decays faster than the Gaussian curvature of a minimal pair with $p_1 + p_2 \neq 0$.

CONCLUSIONS

We provided a recipe for constructing exact minimal surfaces with an arbitrary distribution of helical motifs, which in particular corrected the small slope approximation in the immediate vicinity of the helical structures. The process is described by the addition of helicoidal motifs but also taking into account an effective interaction between them necessary to guarantee minimality of the surface. Moreover, at large distances from the helical core, the corresponding exact minimal surface is well approximated by a helicoid whose pitch equals the total pitch of the helical structure. This implies that the boundary conditions at the far field regime is not altered by our deformation process. Our method can also be used for determining the attraction/repulsion between any two motifs, as well as to prove that strict area minimization favors global pitch balance.

CHARACTERIZINGHIGH-RATE, FINITE MATERIAL DEFORMATIONS OF SOFT MATERIALS IN INERTIAL MICROCAVITATION

Selda Buyukozturk[1,2], and Christian Franck [2]
[1]School of Engineering, Brown University, Providence, Rhode Island, USA
[2]Department of Mechanical Engineering, University of Wisconsin - Madison, Madison, Wisconsin, USA

Summary We recently developed a new method to characterize the constitutive behavior of soft materials undergoing high-strain rate deformations using laser-induced cavitation, called Inertial Microcavitation Rheometry. However, the current theoretical framework was developed with limited experimental modulation of bubble amplitude limiting the regime of accessible material deformations. The model also neglects to address inelastic material behavior at large material stretches. This study focuses on experimentally identifying critical material stretches during the transition from viscoelastic to inelastic behavior by systematically controlling bubble amplitude and material deformations over a large stretch range. This critical experimental data will lay the foundation for incorporating damage and failure mechanisms of inelastic behavior of soft materials undergoing high-strain rate deformations.

MOTIVATION

The motivation of this study is to develop a deeper understanding of inertial cavitation and its resulting bubble dynamics in soft materials, which has significant applications in the study of biological tissues, polymeric coatings, biofouling, composites and other synthetic materials. Laser-induced cavitation (LIC) is a thermally driven inertial process with the ability to characterize material behavior at high-strain rate ($10^3 - 10^8\ s^{-1}$) deformations. Through the integration of appropriate theoretical framework, material stresses and strains during cavitation can be estimated for homogeneous, isotropic materials through Inertial Microcavitation Rheometry (IMR), a tool we recently developed to characterize the non-linear viscoelastic properties of soft materials at high strain rates [1].

The previous development of IMR has considered only a limited material stretch ratio regime, neglecting to incorporate inelastic material behavior. This study aims to: (1) identify the critical material stretches exhibited at the transition from viscoelastic to inelastic material behavior and (2) develop new experimentation for the modulation of LIC bubble amplitudes. Experimental methods to achieve these aims include varying cavitation laser energy and using micron-sized heat sink particles to drive bubble nucleation. This characterization will pave the way to future work in the development and incorporation of damage and failure mechanisms into the theoretical framework.

BACKGROUND

LIC is a reliable and robust experimental method for generating spatially-controlled microns sized cavitation bubbles in soft materials. Complex nucleation physics generally results in the ionization and formation of a bubble consisting of an approximate two-phase vapor and gas mixture. The resulting oscillating bubble interacts with the surrounding material and is modelled to determine constitutive behavior to predict material stresses and strains at high-strain rates.

Inertial Microcavitation Rheometry (IMR)

IMR uses the experimentally obtained high-speed time-lapse data of bubble oscillations within the given material of interest, and for spherically symmetric bubbles computes the temporal evolution of the bubble radius, R(t) [1]. The normalized value $R(t) / R_{eq}$ is also defined to be the material stretch, $\lambda(t)$. Assuming spherical bubble symmetry and near-field material incompressibility, the 1D momentum balance and conservation of mass equations, with the incorporation of traction and kinematic boundary conditions of the bubble, present the Keller-Miksis equation,

$$(1-\frac{\dot{R}}{c})R\ddot{R}+\frac{3}{2}(1-\frac{\dot{R}}{3c})\dot{R}^2=\frac{1}{\rho}(1+\frac{\dot{R}}{c})(p_b-\frac{2\gamma}{R}+S-p_\infty)+\frac{1}{\rho}\frac{R}{c}\overline{(p_b-\frac{2\gamma}{R}+S)}^{\cdot} \quad (1)$$

R is bubble radius, c is material wave speed, ρ is mass density, p_b is bubble pressure, γ is surface tension, and p_∞ is far-field pressure. S describes the constitutive material behavior as a function of hoop and radial stress. IMR employs the least squares method to best fit material parameters across several constitutive models to determine the best material fit.

EXPERIMENTAL APPROACH

A Q-switched 532nm Nd:YAG laser (Amplitude) with 6ns pulse is aligned into the back port of a Ti2 Nikon Microscope. As shown in Figure 1a, a dichroic notch filter is used to path the laser into the back aperture of a microscope objective to focus the beam within the volume of a hydrogel to initiate cavitation. Bubble kinematics are imaged through the objective using a high-speed camera. Laser energy attenuation is controlled with Neutral Density (ND) filters placed in beam path and laser energy is measured with an EnergyMax Sensor (Coherent). Isotropic homogeneous polyacrylamide hydrogels are used for cavitation: “soft” and “stiff” gels with quasi-static shear moduli, $G_{\infty,soft}$=0.461 kPa and $G_{\infty,stiff}$=2.97 kPa. Separate polyacrylamide samples were made with 20μm polystyrene particles with conductive paramagnetic coating. These particles, hereto referred to as heat sink particles, are used to lower the bubble nucleation threshold in the gels.

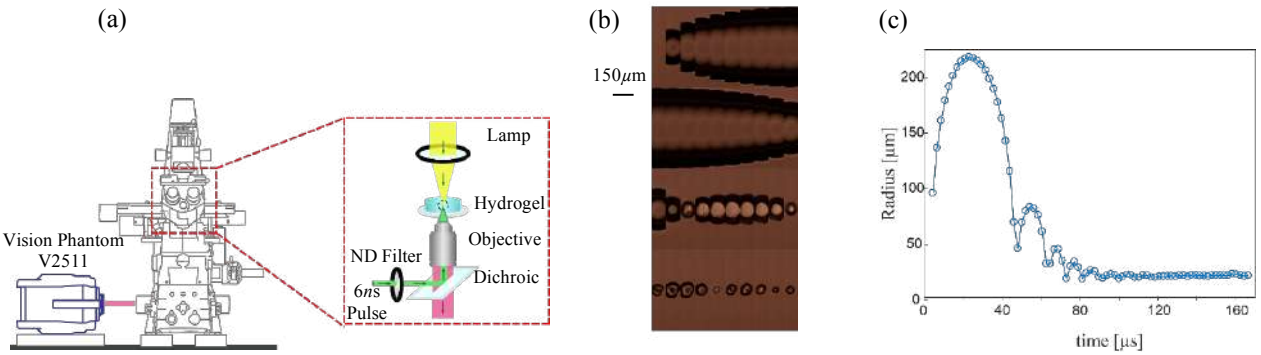

Figure 1. (a) LIC experimental setup on Ti2 Nikon Microscope (b) LIC bubble time-lapse (2-3μs per frame) in polyacrylamide (c) Radius vs. time of LIC bubble in polyacrylamide (sampled at 480k fps)

PRELIMINARY RESULTS & CONCLUSIONS

Polyacrylamide hydrogels undergoing large finite deformations at high strain-rates have been measured and fitted to a non-linear Kelvin-Voigt model, which extends the traditional quasi-static Neo-Hookean description of polyacrylamide to include dynamic shear viscosities [1]. However, at high laser energies, the model may fail to capture the complete bubble dynamics due to unaccounted inelastic material behavior. Experimentally, this is reflected in loss of bubble amplitude, as well as bubble asphericity. As schematically depicted in Figure 2a, experimental bubble radius vs. time is compared to its simulated IMR curve. The first peak consistently fits well, but there is a discrepancy for subsequent peaks unaccounted for by the current IMR nonlinear viscoelastic model.

In Figure 2b, bubbles in polyacrylamide were nucleated at relatively high laser energies. An increase in laser energy increased the maximum bubble radius, in line with other energetics studies performed in literature [2]. At the same laser energies, "soft" polyacrylamide exhibited a higher bubble amplitude than "stiff".

R_{max} and R_{eq} scale with laser energy and within this regime, the maximum material stretch ratio is relatively constant. For "soft" polyacrylamide for example, the maximum stretch ratio is approximately 9 across all energy levels. When laser energy is drastically decreased, the energy threshold may be too low to overcome the dielectric breakdown barrier required for bubble nucleation. In this presentation, we will show that when a lower energy laser is focused at a micron-sized heat sink particle, a bubble will not only successfully nucleate, but the material stretch ratio will drastically decrease. Preliminary results indicate the ability to change the material stretch experimentally to explore the complete finite deformation range of polyacrylamide.

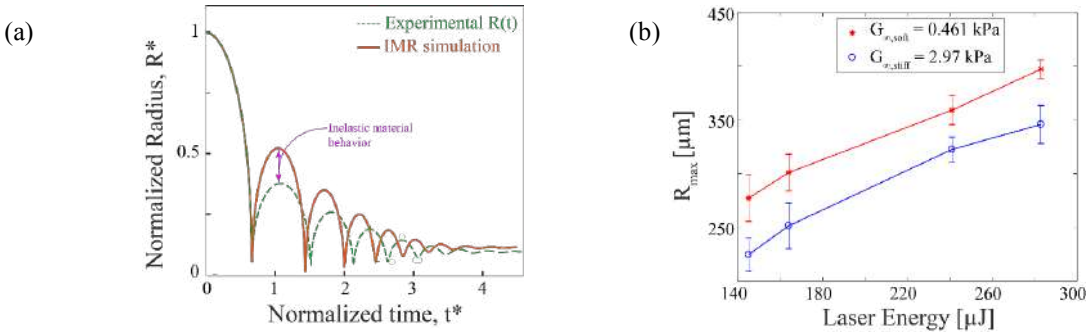

Figure 2. (a) Schematic showing IMR simulation at large material stretches and experimental discrepancy (b) R_{max} vs. laser energy

This study will test the limitations of current IMR model to identify critical stretches at the transition from viscoelastic to inelastic material behavior, as well as provide new experimental methods for controlled bubble amplitude modulation. The experimental acquisition of a full finite deformation regime will lay the foundation for the incorporation of inelastic material behavior into the theoretical framework. Studies such as energy loss through the material, asphericity, rupture, wrinkling, and more may be included ultimately improving our fundamental understanding of the high-rate deformation behavior of soft materials and improve our ability to predict constitutive material properties and material performance.

THE ONSET OF PLASTICITY THROUGH INFLATION OF THIN FILMS

Federico Bosi*[1] and Khurram Suleman[1]
[1] Department of Mechanical Engineering, University College London, London, UK

Summary We present a novel approach that enables a reliable characterisation of the yield strength through the sharp change in strain distribution that develops at the onset of plasticity when soft membranes are inflated. The method is based on a finite strain solution for the mechanical response of pressurised elastoplastic thin films, analytically obtained and numerically validated. Non-contact optical experiments are performed on different materials and prove the accuracy of the proposed technique, thus opening new perspectives for the prediction of the yield stress of structural membranes in a wide range of thermo-mechanical loading conditions.

INTRODUCTION

The use of thin films in lightweight structures is rapidly increasing, with applications ranging from soft robotics to advanced aerospace systems. Therefore, a comprehensive understanding of membranes governing deformation mechanisms is required to predict their complex time and temperature-dependent responses [1]. In particular, it is recognised that a reliable experimental method to assess the onset of plasticity in thin films is missing [2], and it limits the knowledge of the yield condition, thus preventing an optimal design of membrane structures. Currently, the experimental determination of the yield strength in structural thin sheets strongly depends on the methodology employed for its detection, leading to unacceptable variability in the results. In order to overcome the difficulty of a precise measurement of the (visco)elastoplastic threshold, an alternative material-independent imaging technique is here developed.

FINITE STRAIN ELASTOPLASTIC INFLATION OF SOFT MEMBRANES

The mechanics of pressurised membranes has been treated by several authors, who investigated the elastic, hyperelastic and perfectly plastic inflation of circular isotropic thin sheets [3, 4]. However, the mechanical response of an elastoplastic thin film has never been studied before, and it is presented here as the foundation of the proposed experimental technique to assess the onset of plasticity. A flat circular membrane of initial radius r_0 and thickness h_0 is subjected to a pressure p. Under the plane stress assumption, the finite strain formulation can be obtained by rearranging the equilibrium equations and compatibility conditions into a system of differential equations

$$\begin{cases} r\dfrac{d\epsilon_\theta}{dr} = e^{\epsilon_r-\epsilon_\theta}\sqrt{1-e^{-2\epsilon_r}\left(\dfrac{dw}{dr}\right)^2}-1 \\ \dfrac{2}{\sqrt{3}}re^{\epsilon_\theta}\left(\dfrac{d\bar{\sigma}}{dr}\cos\phi-\bar{\sigma}\sin\phi\dfrac{d\phi}{dr}+\bar{\sigma}\cos\phi\dfrac{d\epsilon_h}{dr}\right)+\bar{\sigma}\left(\dfrac{1}{\sqrt{3}}\cos\phi-\sin\phi\right)\sqrt{e^{2\epsilon_r}-\left(\dfrac{dw}{dr}\right)^2}=0 \\ \dfrac{dw}{dr} = -\dfrac{\sqrt{3}rp}{4h_0\bar{\sigma}\cos\phi}e^{\epsilon_r+\epsilon_\theta-\epsilon_h} \end{cases} \tag{1}$$

where w is the vertical displacement, $\bar{\sigma}$ and ϕ are introduced to parametrise the stress components σ_r and σ_θ and r, θ, h represent the radial, circumferential and thickness directions, respectively. The strain components $\epsilon_r, \epsilon_\theta, \epsilon_h$ are defined by an isotropic strain hardening bilinear constitutive model, characterised by the yield stress σ_y, Fig. 1a. Therefore, the unknowns $\bar{\sigma}, \phi, w$ can be obtained by numerically solving eq. (1) through the Euler method, iterating over the radial domain for different values of the pressure p until the boundary condition $w(r_0) = 0$ is satisfied.

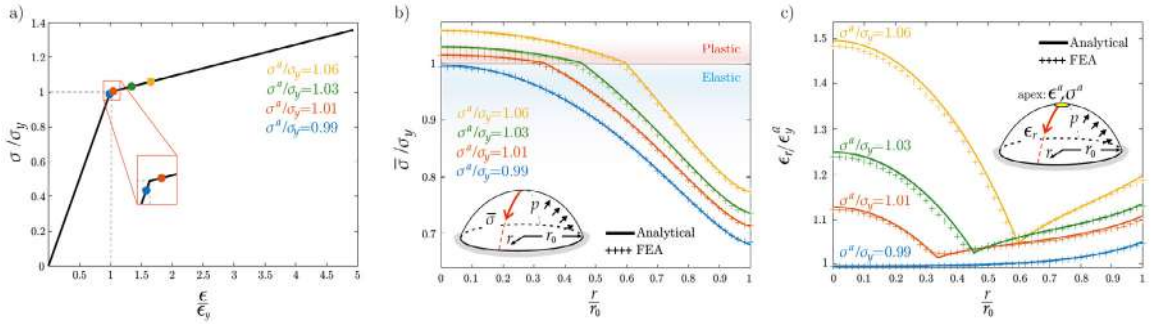

Figure 1: Inflation of circular elastoplastic membranes: (a) strain hardening bilinear constitutive relation; comparison between analytical and FEA solutions for the radial distribution of normalised equivalent stress $\bar{\sigma}/\sigma_y$ (b) and normalised radial strain ϵ_r/ϵ_y^a (c).

*Corresponding author. E-mail: f.bosi@ucl.ac.uk

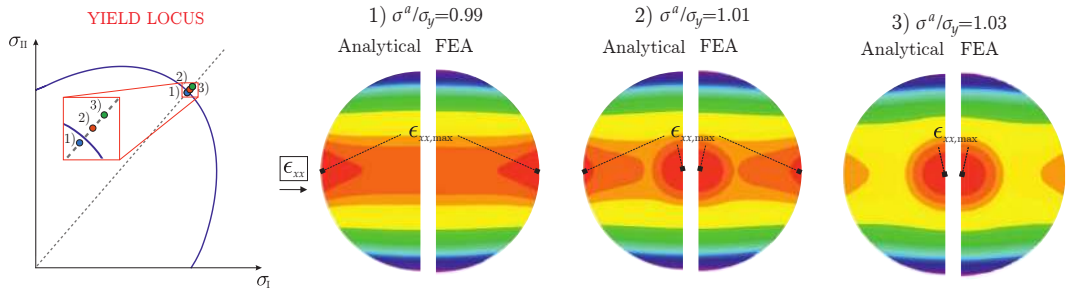

Figure 2: Yield domain and comparison between analytical and FEA contour plots of the horizontal strain ϵ_{xx} across the membrane, showing the sudden and distinct change in maximum strain distribution ($\epsilon_{xx,\text{max}}$) that characterises the onset of plasticity.

The obtained results are presented in Fig. 1b,c together with the finite element solution (Abaqus, Dassault Systèmes), which validates the theoretical approach. The dimensionless equivalent stress $\bar{\sigma}/\sigma_y$ and normalised radial strain ϵ_r/ϵ_y^a (ϵ_y^a is the yield strain at the apex) are reported for four different values of the dimensionless equibiaxial apex stress $\sigma^a/\sigma_y = [0.99, 1.01, 1.03, 1.06]$ in the proximity of the onset of plasticity. Fig. 1c shows the drastic change in strain distribution when plastic deformations develop from the centre of the thin film. In particular, when the membrane is in the elastic regime (blue curve, $\sigma^a/\sigma_y = 0.99$), the maximum radial strain lies at the edge of the membrane, while immediately after the onset of irreversible deformations (red curve, $\sigma^a/\sigma_y = 1.01$), the highest radial strain moves to the centre, which corresponds to the apex of the inflated membrane.

The rapidly developing strain localisation associated with the onset of plasticity is highlighted in Fig. 2, which reports the yield surface for J2 plasticity and the contour plots of the horizontal strain ϵ_{xx} for three subsequent normalised stress values at the membrane apex, corresponding to different inflation pressures. This phenomenon, demonstrated here for an elastoplastic bilinear model, can be proven for distinct constitutive relations and materials. Therefore, the observed localisation can be employed for the development of a novel imaging technique to assess the yield strength in thin films.

EXPERIMENTAL DETERMINATION OF THE ONSET OF PLASTICITY

The abrupt change in strain distribution that emerges at the onset of plasticity has been experimentally validated on a custom made setup, where the in-plane strains of LLDPE membranes were measured through digital image correlation (VIC3D, Correlated Solution). Fig. 3 reports the horizontal strain across the thin sheets, highlighting the localisation that suddenly develops when the yield domain is reached. Since the maximum horizontal (and radial) strain quickly change location when plasticity develops, moving from the edges to the centre, we can assume that yielding develops when $\epsilon_{xx,\text{edge}} = \epsilon_{xx,\text{centre}}$. Therefore, we were able to measure in real-time the yield strength of the viscoelastic material for a wide range of temperatures and strain rates, with a maximum relative error of 7% when compared with the time-consuming strain recovery procedure, considered the most reliable one [5]. The proposed experimental method has been further proven by applying it to aluminium foils and PEEK films, showing excellent results in the yield stress prediction.

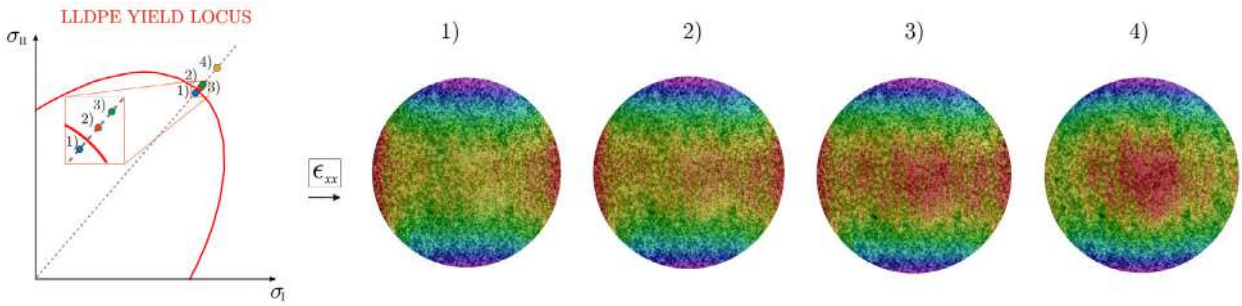

Figure 3: Experimental observation of strain localisation in LLDPE inflated membranes: yield surface and ϵ_{xx} strain contour plots. The abrupt change in strain distribution that develops at the onset of plasticity is employed for a reliable assessment of the yield stress.

FLUTTER OF ELASTIC RODS SUBJECT TO ZIEGLER AND REUT LOADS

Davide Bigoni[1]
[1]Department of Civil, Environmental and Mechanical Engineering, Università di Trento, Trento, Italy

Summary Flutter and divergence instabilities are theoretically and experimentally analysed in elastic structures subject to follower loads of the Ziegler type and to loads acting on a line of the Reut type. It is shown how these loads can be obtained through an exploitation of Coulomb friction. Computer simulations and experiments on scale models reveal how flutter and divergence develop and how they are influenced by dissipation.

INTRODUCTION

Non-conservative loads are advocated as sources of dynamic instabilities such as flutter and divergence. One of these loads is the tangential follower force considered by Ziegler [10] and another is a force constrained to act along a fixed straight line, as introduced by Reut [8], see also Bolotin [4].

The problem with these loads is their realization, which has been considered impossible during the last fifty years [5, 6].

REALIZATION OF THE NON-CONSERVATIVE FORCES

Following Bigoni and Noselli [3], Bigoni et al. [1] and Bigoni and Misseroni [2] it is shown, both theoretically and experimentally, how to obtain the Ziegler's (Fig. 1) and Reut's (Fig. 2) forces by exploiting contact with Coulomb friction.

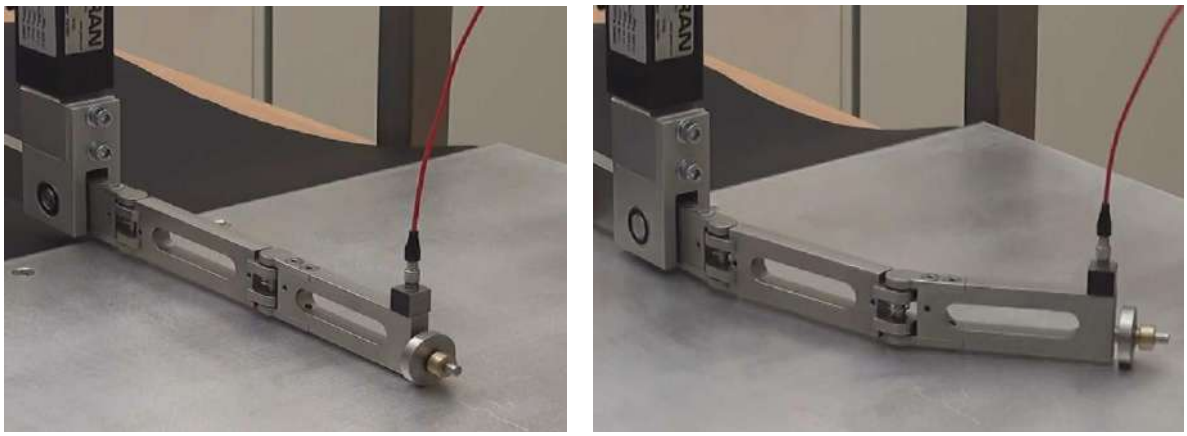

Figure 1. The realization via Coulomb friction of the follower load postulated by Ziegler.

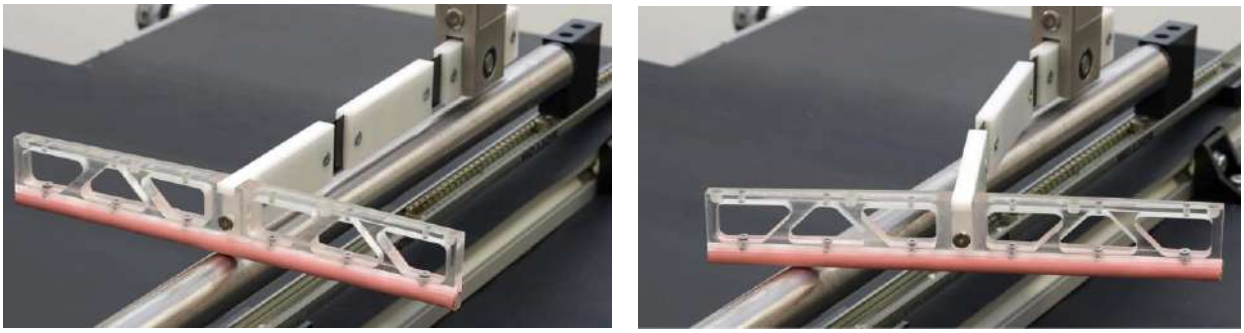

Figure 2. The realization via Coulomb friction of the follower load postulated by Reut.

FLUTTER & DISSIPATION-INDUCED INSTABILITIES

Viscosity was theoretically proven to have a detrimental effect on the stability with respect to flutter and Hopf bifurcations [7, 9]. In the limit of vanishing viscosity, the so-called Ziegler paradox was found, which corresponds to a discontinuity in the critical load occurring in the limit. Effects related to the viscosity remained so far not validated experimentally, so that an experimental campaign was performed to highlight these. Experiments are shown to provide positive evidence to the theoretical results.

CONCLUSIONS

Flutter and divergence instabilities, as well as the detrimental effect of viscosity on critical loads, are documented indisputably, thus bringing an end to a long debate and opening a new research area, with perspective applications to mechanical actuators, high-precision cutting tools, or energy harvesting devices.

INFLATABLES MAZES: FROM FLAT SHEETS TO 3D STRUCTURES.

Emmanuel Siéfert[1], Julian Panetta[2], Tian Gao[1], Étienne Reyssat[1], José Bico*[1], Mark Pauly[2], and Benoît Roman[1]
[1]Physique et Mécanique des Milieux hétérogènes, CNRS, ESPCI Paris, PSL Research University, Sorbonne Université and Université de Paris, France
[2]Computer Graphics and Geometry Laboratory, EPFL, Lausane, Switzerland

Summary We present a simple technique to encode 3D shapes on flat fabrics through metric changes. Our technique is inspired by curved folded and Miura-ori origami and is based on the inflation of a channel network obtained by heat-sealing two opposite pieces of fabric. Similarly to folds in origami, inflated channels induce a strongly anisotropic in-plane contraction which dictates the Gaussian curvature of the deployed structure. We present different strategies to control such differential contraction and discuss a numerical inverse model. In addition to shapes, we describe the mechanical properties of the inflated structure that involve both material properties and pressure.

INTRODUCTION: CHANGING METRICS TO CHANGE SHAPES

Cartographers have long been faced with the problem of deforming the continents in order to project the Earth on a flat map. Similarly, wrapping a ball with a sheet of paper induces wrinkles where the excess of paper is stored. Indeed, changing the Gaussian curvature of a surface (the product of both main curvatures) requires a change in metrics, i.e. the distances between material points along the surface. Many living structures, e.g. plant leaves, rely on differential growth to adopt complex 3D shapes [1]. Differential growth has been a source of inspiration for recent developments such as swelling hydrogels [2, 3, 4], liquid crystal elastomers [5, 6], dielectric elastomers [7, 8] or *baromorph* materials [9]. However, these systems are based on soft elastomers and large size structures tend to sag under their own weight.
Traditional origami is also an elegant way to transform an unstretchable flat sheet into a complex 3D structure. In this case, folds may accommodate the excess of surface resulting from a change in the apparent metric of the structure [10, 11]. As the sheet is locally simply bent, stiff materials may be used, e.g. polymers, metals or event graphene sheets [12]. However, folding flat origami outlines into shape can be complex.

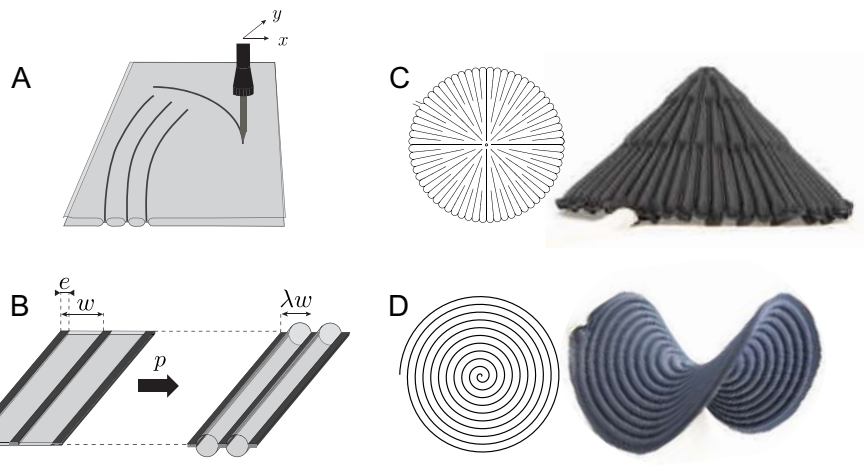

Figure 1: **A** Heal-sealing process: a network of channels is printed on two superimposed pieces of fabric coated with a thermoplastic layer. **B** Upon inflation, the section of the channels contracts while the length remains unchanged which induces differential metric change of the fabric. **C** Conical shape obtained with radial channels. **D** Saddle shape resulting from orthoradial channels.

INFLATING MAZES

We present here an alternative concept to transform initially flat sheets into stiff and lightweight inflatable shells (Fig.1A). Two flat superimposed sheets (typically made of thermoplastic coated fabric) are sealed together along a specific pattern of seam lines, defining a "maze" of channels. A soldering iron mounted on an XY-plotter directly prints the pattern [13]. Inflation induces in-plane contraction perpendicular to the channels through the local bending of the sheets. This contraction mechanism plays the same role as a fold in origami: the seam lines are equivalent to the positions of valley folds, with mountain folds in between (Fig. 1B). As a simple example, a structure with radial seams adopts a conical shape

*Corresponding author. E-mail: jose.bico@espci.fr

(Fig. 1C), as radial folds in a disk of paper would lead to a cone. Conversely, a disk with circular channels buckles into a saddle shape (Fig. 1D) equivalent to origami structures involving circular folds [14]. In contrast with standard origami, the deployment of the 3D structure is here spontaneous and does not require mechanical actuation of individual folds. Moreover, while rigidly-foldable origami tessellations may involve soft deployment modes, the effective folding angle of inflatable mazes is fixed by volume maximization. The shape is dictated by the design of the maze and does not rely on a complex assembly of flat patches, as in common inflatable structures [15]. We present and rationalize three different strategies (curved channels, seams of varying width, zig-zag seams) to distort the metrics and propose analytic ways to program simple geometric shapes ranging from domes to helices (Fig. 2). Such strategies are the source of an inverse model solved with numerical tools developed in the computer graphics community. We finally discuss the mechanical properties of the inflated structures. Internal pressure p provides stiffness to the resulting structure that is similar to other large scale inflatables, such as fabric air beams, stratospheric balloons or architectural buildings [16]. We show how the bending and stretching rigidity of these inflates mazes both depend on the applied pressure and on material stiffness.

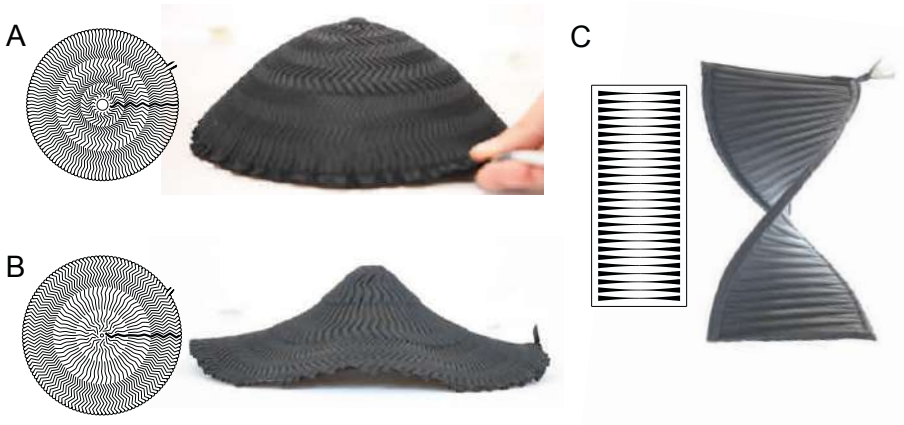

Figure 2: **A** and **B** Dome and hat obtained with a zig-zag pattern reminiscent of Miura-ori tesselation. **C** Helix obtained by tuning the width of the seam lines.

Summary Imparting elastic sheets with a controlled pattern enables the creation of materials with unusual characteristics. Herein, we analyse the tensile and shear response of laser cut rubber sheets featuring an auxetic pattern designed via topology optimization. A set of dedicated experimental and numerical tools are adapted for this purpose. Quasi-static mechanical tests up to 50% effective strain, associated with image processing techniques and a robust digital image correlation permit to detect the geometry contour and measure displacements and strains fields. The results are compared with a FE-analysis, undertaken using a hyper-elastic Mooney-Rivlin constitutive law. The numerical results remarkably grasp the experiments, and appear as a good indicator to assess the impact of the manufacturing process, geometry non-linearity and base material non-linearity on the final properties.

Keywords auxetic, rubber, digital image correlation, identification

Soft elastomers readily change their shapes in response to external stimuli, such as mechanical load or heat. Their high thoughness and capability to withstand large deformations have been harnessed in a wide range of emerging fields including stretchable electronics, soft robotics and biomimetics [9, 8, 10, 6]. Poisson's ratio is another key parameter to consider, as it determines the deformation shape of the material and has a major contribution to modulate shear modulus and bulk modulus from the solid mechanics background. Remarkably, the Poisson's ratio of elastomers is contained in a narrow range with a value close to 0.5, and nearly invariant in all directions [7]. Alternatively, the Poisson's ratio of a material can deviate from its inherent value by introducing cellular structures [4]. Additionally, in thin sheets, architectured cut patterns are easily fabricated via subtractive technologies. Auxetics are materials that expand transversely under an applied uniaxial stretch load and vice versa by means of a tailored structural mechanism. Classical embodiments enable the control over a small range of strains ($\sim 10\%$).

In this work, we investigate the evolving pattern transformation under uniaxial loading at finite strain of laser cut rubber sheets with a periodic pattern derived from a topology optimization procedure, through experiments and simulations. After introducing the experimental facility, testing method, material models and modelling strategy, we discuss the observed effective properties and compare them to the finite element simulations.

EXPERIMENTAL AND COMPUTATIONAL METHODOLOGY

More precisely, we analyze the deformation of rubber sheets patterned with an auxetic design proposed in [2]. The design of the elementary unit cell, illustrated in Figure 1(a-b), results from a topology optimization procedure combining the level set method and the asymptotic homogenization theory [3] with the objective of prescribing effective elasticity tensor and more specifically Poisson's ratio. The designed geometry resembles a typical re-entrant honeycomb structure, with trusses of varying width. The macroscopic behaviour of the periodic unit cell carries an orthotropic symmetry. To identify experimentally the complete two-dimensional constitutive behaviour, 3 sorts of specimen were devised (2 specimens for vertical and horizontal uniaxial tensile tests respectively, 1 specimen for a shear test) consisting of a periodical assembling from the optimal unit cell. The repetition of unit cell was adapted, such that the local constraints of the clamps cause minor deviations when evaluating the elastic properties at the center of the specimen. The specimen were laser cut from a 1.5mm-thick natural rubber sheet, then mechanically tested on a universal Instron 10kN tensile machine (mounted 50N load cell) up to 50% effective strain. For the shear test, a specific set-up consisting of 2 plexiglass plates was required to constrain the deformation in the focal plane, as shown in Figure 1(c). During the mechanical tests, a digital camera recorded images of the specimen surface to allow for displacement field measurements via digital image correlation. A black and white speckle pattern was applied on the specimen surface using sprayed paint to increase the image contrast. The mechanical properties of natural rubber were equally explored through uniaxial tensile tests on standard dog-bone specimens. A Mooney-Rivlin incompressible hyper-elastic model, acceptable for intermediate elongations (50-100%), was selected to fit the experimental stress–strain response and calibrate material parameters. Using the experimental data, local and global approaches to digital image correlation were employed to measure displacement and strain field. Elastic properties of the macroscopic continuum could be identified, and their evolution at finite strain could be tracked. Full-field measurements by means of digital image correlation (DIC) were carried out using an in house programming operating on MATLAB software. The experimental mesh was obtained using classical image processing on the reference image of the specimen surface. In complement to experiments, finite element computation were undertaken under the assumption of large transformations, plane stress using the finite element solver Cast3M 2018 [1]. The mesh was obtained using image processing from the binarized images of the optimal level set function, from Figure 1(a) and completed to the sample geometry. The material parameters of the hyper-elastic model were identified from the tensile curve of the base material.

(g) Stress-strain curve for horizontal tension, comparison with the numerical model (h) Evolution of the apparent Poisson's ratio with respect to the longitudinal strain.

RESULTS AND DISCUSSION

During both horizontal and vertical tensile extensions, a lateral expansion indicating a negative Poisson's ratio was clearly visible. A first local-DIC measurements was performed to comfort this visual observations. We measured the macroscopic displacement at each nodes of the honeycomb, and derived a strain field, as illustrated in Figure 1 (e). The ratio of the averaged strain components yields an effective Poisson's ratio. The displacements fields obtained using global-DIC measurements permit a further comparison with predictions and give an insight of the deformation mechanism of the samples, i.e. how the structure moves and deforms. The specimens exhibited a structural deformation at small strain, where different parts of the "lattice" behave as rigid struts and deformable hinges, in spite of the soft natural rubber. Regarding the Poisson's ratio, the results show that the initial measure was close to the predictions in the optimization process and was not degraded by the manufacturing process. Conversely, the stiffness of the honeycomb turned out to be extremely sensitive to the manufacturing uncertainties. A comparison between experimental results (in black) and the numerical simulation (in pink), depicted in Figure 1(g) reveals a significant gap in stiffness by looking at the effective stress strain curve. An observation under an optical microscope revealed that the trusses of the fabricated specimen were $\sim 100\,\mu m$ thinner than the model. The calculation gave a better prediction when using the experimental DIC mesh (curve in red). The good agreement between simulation and experiments further permits to estimate the stress distribution during shear, the experimental measures being biased by the frictions in the channel. At finite strains, the mechanical behaviour shifts rapidly, indicating in particular a decrease of the "auxeticity" of the specimen. Beyond 10% effective strain, the Poisson's ratio is no longer in agreement with the desired value. The evolution of the Poisson's ratio with applied strain has already been observed and discussed in [5] on polymeric filament structure. In complement, they arrived to correct the phenomenon up to 20% strain using a non-linear material behaviour in the optimization process. In the case of the design procedure used here, the extension to non-linear material behaviour is currently under investigation and will appear in subsequent work of the authors.

Summary We derive analytical design sensitivity analysis formulation using an adjoint variable method, based on an isogeometric finite element formulation of geometrically and materially nonlinear Timoshenko beams, which incorporates in-plane deformation of the cross-section described by two extensible directors [1], and frictionless beam-to-beam contact. Further, we present an optimal design in three-dimensional beam lattice structures undergoing large deformations with contact interactions of constituent ligaments. The developed gradient-based design optimization method is combined with a stochastic approach in order to avoid multiple local minima. Our application is to design an auxetic structure having an extremal and constant negative Poisson's ratio during large compressive deformations.

ABSTRACT

Periodic slender structures or lattice structures have been widely studied due to their low weight, outstanding structural performances, and possibility of tailoring effective mechanical properties. For design problems in material microstructures, mathematical optimization methods are often exploited to achieve a target mechanical property. However, an incorporation of contact interactions of constituent ligaments to the lattice structural design optimization framework is significantly challenging, and to the best of our knowledge, it still remains unexplored. In this research, we develop a gradient-based optimal design method for three-dimensional beam lattice structures considering contact constraints. A target application of the developed method is a lattice structure with enhanced impact energy-absorption properties like auxetic structures. We particularly deal with large deformations, where the effective Poisson's ratio strongly depends on the magnitude of applied loads. Choi et al. [2] obtained two- and three-dimensional beam lattice structures having a negative Poisson's ratio -2 along specific directions in both tension and compression loadings (see Fig. 1); however, due to the absence of contact condition in the simulations, the maximum load magnitude was limited to avoid unphysical overlap between ligaments. Fig. 2 shows an experimental verification of the two-dimensional auxetic structure.

Beam contact formulations have been successfully exploited in deformation analyses of slender bodies with contact interactions. For example, in Sauer and Mergel [3], a geometrically exact shear-deformable planar beam model with varying cross-section along the beam length was employed to describe adhesion and debonding of thin film. Also, a contact interaction in a biopolymer network was simulated in Meier et al. [4] using a Kirchhoff beam model with a unified contact formulation, which combines a point-to-point and a line-to-line contact formulations using a variationally consistent transition between those two formulations. However, in those previous works, no cross-section deformation was assumed, although local contact may lead to a significant influence on the deformation of cross-sections. In the present research, we employ the formulation of geometrically and materially nonlinear Timoshenko beams, which considers in-plane deformation of the cross-section described by two extensible directors [1]. This formulation allows direct application of nonlinear three-dimensional constitutive laws without zero stress conditions.

AN "ELASTICA ROBOT": TIP CONTROL IN TENDON-DRIVEN ELASTIC ARMS

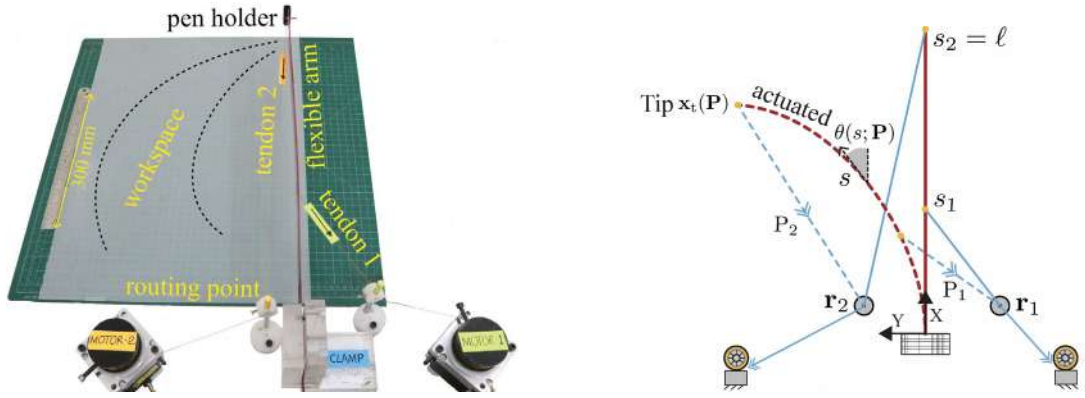
Ramsharan Rangarajan*[1] and Poornakanta Handral[1]
[1]Department of Mechanical Engineering, Indian Institute of Science Bangalore, India

Summary Various applications ranging from pipeline inspection to robot-assisted surgery require highly maneuverable devices with precisely controllable tips. In this contribution, we propose and experimentally validate a mechanics-based approach to quasistatically manipulate the tip location of a flexible arm by controlling the tensions in a pair of cables attached to its centerline. We show that by adopting a geometrically nonlinear elastica model for the arm, by carefully accounting for configuration-dependent tendon loadings, and by interpreting the problem of manipulating the arm as one of load optimization, it is possible to realize a high degree of accuracy. The resulting device functions as an energy-efficient robot that is well suited for miniaturization.

INTRODUCTION

An emerging class of robots is composed of flexible structures and function by exploiting the compliances of their constitutive elements. Such robots are aimed at applications that demand high maneuverability for navigation in closed or cluttered environments, that require interaction with compliant substrates, and at applications where energy-efficiency is critical. Their operating principle stands in stark contrast to traditional robots typically composed of networks of links with actuated joints whose compliances are generally considered to be a hindrance for controlled operation. Our work here is motivated by the observation that developments in strategies for controlling flexible elements in robots lags behind technologies for designing and fabricating them.

The arrangement in Fig. 1a shows of a slender flexible arm clamped at one end and loaded by a pair of cables. We demonstrate that by modeling the highly deformable arm as an elastica and by posing control as a problem of optimizing tensions in the cables, the tip of the arm can be accurately positioned within a feasible workspace. Our choice of tendon actuation is based on its simplicity, ease of experimental realization and its suitability for space applications.



(a) (b)

Figure 1: Illustration of the experimental setup in (a) and its idealization in (b). The arm is made of Polycarbonate and is about 600 mm long. The first tendon is attached at $s_1 = 200\,\mathrm{mm}$ and the second at $s_2 = 600\,\mathrm{mm}$. The total cost of the setup is about $255.

AN INVERSE PROBLEM FOR ELASTICA CONTROL

The schematic in Fig. 1b represents an idealization of the setup in Fig. 1a. A straight elastic arm of length ℓ is loaded by a pair of tendons attached at distances $s = s_1$ and $s = s_2$ along its centerline, where $s \in [0, \ell]$ denotes the arc-length parameter of the centerline measured from the clamped end and $0 < s_1 < s_2 = \ell$. For simplicity, we set $s_2 = \ell$ and assume actuation using two tendons. We presume the arm to be inextensible and its cross sections to be rigid and unshearable. The deformation of the arm that results from imposing tensions $\mathbf{P} = (\mathrm{P}_1, \mathrm{P}_2)$ in the two tendons can hence be parameterized by the inclination angle $s \mapsto \theta(s;\mathbf{P})$ of the tangent to the centerline. Referring to the Cartesian system indicated in the figure, coordinates of the deformed centerline follows as $s \mapsto \mathbf{x}(s;\mathbf{P}) = \int_{\xi=0}^{s} (\cos\theta(\xi;\mathbf{P}), \sin\theta(\xi;\mathbf{P}))\, d\xi$. In particular, $\mathbf{x}_1(\mathbf{P}) \triangleq \mathbf{x}(s_1;\mathbf{P})$ and $\mathbf{x}_2(\mathbf{P}) = \mathbf{x}(s_2;\mathbf{P})$ identify the points of attachment of the tendons in the deformed configuration. The second argument $\mathbf{P}$ of θ and $\mathbf{x}$ explicitly denote their dependence on the loading.

Presuming a linear relationship between the curvature $\theta' = d\theta/ds$ of the centerline and the moment, force balance in the arm is succinctly stated as

$$\mathrm{B}\theta''(s;\mathbf{P}) + \mathbf{x}'(s;\mathbf{P}) \times (\mathrm{H}(s_1 - s)\mathbf{F}_1(\mathbf{P}) + \mathbf{F}_2(\mathbf{P})) = 0, \tag{1}$$

(c) Cursive writing.

Figure 2: Demonstrating versatility and accuracy of experimentally realized tip control using the setup shown in Fig. 1. Deviations in distances and angles consistently remain smaller than $2\,\mathrm{mm}$ and 1°, respectively.

where B is the bending stiffness, H is the Heaviside function, $\mathbf{F}_i(\mathbf{P}) = \mathrm{P}_i(\mathbf{r}_i - \mathbf{x}_i(\mathbf{P}))/\|\mathbf{r}_i - \mathbf{x}_i(\mathbf{P})\|$ for $i = 1, 2$ are the tendon loadings resulting from the imposed tensions P_1 and P_2, and $\mathbf{r}_1, \mathbf{r}_2$ are the fixed routing points of the two cables. Equation (1) is supplemented with boundary conditions $\theta(0, \mathbf{P}) = \theta'(\ell, \mathbf{P}) = 0$ representing the clamped and moment-free ends. Nonlinearity in the model represented by eq. (1) is purely geometrical and stems from three sources—computing curvatures of the centerline exactly, measuring moment arms of loads without approximation, and accounting for the dependence of tendon inclinations on the deformation.

We formulate the control problem of placing the tip $\mathbf{x}_\mathrm{t}(\mathbf{P})$ of the flexible arm at a desired location $\mathbf{x}_\mathrm{d}$ as one of computing optimal cable tensions. Introducing the cost function $\mathrm{E}(\mathbf{P}) = \|\mathbf{x}_\mathrm{d} - \mathbf{x}_\mathrm{t}(\mathbf{P})\|^2/2$ to measure the deviation of the tip from the desired position, we pose tip-control as a parameter optimization problem for P_1 and P_2:

$$\text{Find } \mathbf{P} \in \arg \min_{\mathbf{P} \in [\mathbb{R}_{\geq 0}]^2} \{\mathrm{E}(\mathbf{P}) \,:\, \theta(s; \mathbf{P}) \text{ solves eq. (1)}\}. \tag{2}$$

In the talk, we will discuss key aspects of resolving the minimization problem in eq. (2) by explicitly computing the sensitivities of the state $\theta(s; \mathbf{P})$ to the tensions P_1 and P_2. These sensitivities reveal an innate coupling between the independent actuations arising from the configuration dependence of loading directions.

EXPERIMENTAL REALIZATION

Fig. 1a shows the experimental setup used. Small holes located along the centerline of the arm serve as attachment points for two stiff metal-reinforced cables. The length of the arm is short enough so that its centerline does not visibly sag due to gravity, and its width is large enough to reduce axial twisting caused by small deviations from idealized loading conditions. Each cable is routed through a fixed point to a motorized spool, which reels in/out the cable, thereby controlling its length and in turn the tension it bears. A light attachment holds a pen to trace the location of the tip as the arm deforms to monitor the accuracy of tip-control realized. Although it is possible to impose the computed optimal tensions $(\mathrm{P}_1, \mathrm{P}_2)$ by coupling each cable with a tension gauge, for the sake of simplicity and to avoid errors caused by friction between cables and their routing posts, we instead impose the computed cable lengths instead. Hence, actuating the arm simply requires prescribing the number of revolutions for each motor. Fig. 2 shows representative examples demonstrating the accuracy of tip control realized in the experiments.

More remarks in the talk. In the talk, we will discuss key aspects determining the workspace of the proposed robotic device. We will also discuss how the proposed framework can be easily adapted for shape control of the elastica. Such problems arise when manipulating surgical instruments or inspection devices in constrained environments. We will highlight interesting aspects of the tendon-controlled elastica problem, including the possibilities of and distinctions between instabilities in load and length-controlled settings.

AN EXPERIMENTAL INVESTIGATION OF MODELS FOR ELASTIC RIBBONS

Arun Kumar[1] and Ramsharan Rangarajan *[1]
[1]Department of Mechanical Engineering, Indian Institute of Science Bangalore, India

Summary Understanding the feature-rich buckling dominated behavior of thin elastic ribbons is ripe with opportunities for fundamental studies in exploring the nexus between geometry and mechanics. Predictive mechanical models play an instrumental role to this end. Here, we critically examine common modeling approaches for elastic ribbons using carefully designed experiments and detailed shape measurements. Specifically, we demonstrate simple and practically realizable ribbon deformations that easily contradict assumptions underlying nonlinear rod and von Karman plate models, resulting in large discrepancies between model predictions and experimental measurements. We identify and validate, seemingly for the first time, the applicability of the 1-director Cosserat plate model for elastic ribbons subject to a useful range of loading conditions. In the process, we discover interesting aspects of the behavior of annular ribbons. We also establish them to be prototypical systems with a tunable degree of geometric nonlinearity, making them well suited for (in)validation of dedicated ribbon models proposed in the literature.

INTRODUCTION

Ribbons are slender structures characterized by three disparate geometric dimensions— length ℓ, width w and thickness h, which are ordered such that $\ell \gg w \gg h$. The pair of slenderness ratios ℓ/w and w/h dictate its rich buckling-dominated mechanical behavior independently of the material constitution. In many ways, the growing body of literature on the mechanics of ribbons is exemplary of an evolving paradigm that considers buckling and related geometric nonlinearities as features to be exploited in applications ranging from flexible robotics to miniaturized electronic devices, rather than as modes of failure

Our goal in this contribution is to critically examine commonly used modeling approaches for ribbons by comparing their predictions with detailed measurements from quasi-static experiments. Specifically, we consider modeling elastic ribbons as nonlinear rods with highly anisotropic cross-sections, as Kirchhoff-Love plates, as von Karman plates, as 1-director Cosserat plates, and as developable surfaces. The theories examined span the gamut of linear, weakly nonlinear and fully nonlinear one/two dimensional models. Through carefully designed table-top experiments, we highlight the significance of geometric nonlinearities stemming from assumed strain-displacement relationships in these models.

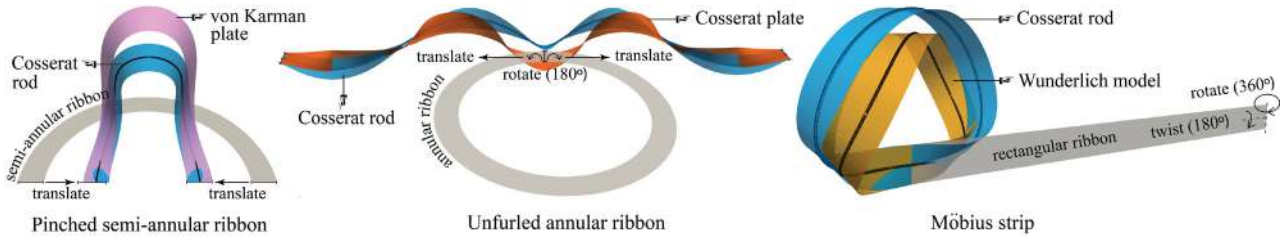

Figure 1: Simple experiments exposing unambiguous differences in the predictions of four models for elastic ribbons. Our primary goal in this contribution is to critically examine the accuracies of these predictions using simple experiments and detailed measurements.

NOT ALL RIBBON MODELS ARE CREATED EQUAL

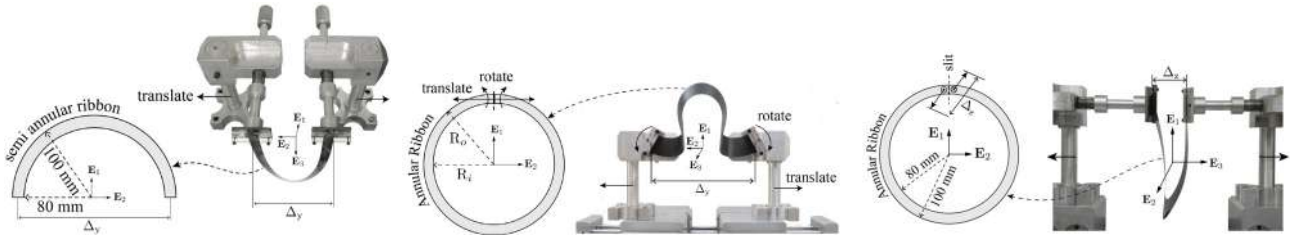
Figure 1 succinctly summarizes the motivation behind our investigation. The figure illustrates three simple virtual experiments that involve rotating and translating clamped ends of semi-annular, annular and rectangular ribbons. Therein, we show predictions of the Cosserat rod model alongside those of von Karman plate, Cosserat plate, and Wunderlich models. Each prediction represents a converged numerical simulation for the respective model. In each case, we find that a pair of models make drastically different predictions for the shape of the ribbon. The figure then evokes the obvious question— *which model is right?* Or, adopting a very skeptical point of view, could it be that all the predictions shown in the figure are inaccurate?

Experiments to settle the debate. We resort to simple physical realizations of the experiments depicted in fig. 1 along with detailed measurements to settle the debate. The setup used in our experiments is shown in Fig 2, and consists of a pair of translatable clamps to hold an annulus and semi-annulus shaped ribbon. The clamps are additionally rotatable about an axis perpendicular to the direction of translation. We use ribbon specimens cut from flat radiography sheets. The difference between the inner and outer radii defines the width w, while the circumference along the mean radius furnishes the length scale ℓ. The mean radius also endows the ribbon with a non zero geodesic curvature. Roughly speaking, when

*Corresponding author. E-mail: rram@iisc.ac.in

its ends are translated and rotated relative to each other, the ribbon responds to compression along its peripheries by assuming buckled three-dimensional configurations. The resulting deformations are reminiscent of undulations observed in fabrics, edges of leaves/petals, or in ripped plastic sheets as a result of growth, thermal expansion, plastic deformation or residual stresses. Our experiments exploit the difference in dimensions between the inner and outer circumferences of the ribbon to produce a similar effect.

For measuring shapes of deformed ribbons, we sample the exposed surfaces using a line laser scanner mounted on a portable coordinate measuring machine to determine a dense point cloud representation. We directly compare shapes digitized in this way, with configurations predicted by various models and compute quantitative measures of deviations. Using novel algorithmic techniques, we compute detailed differential geometric quantities including mean and Gaussian curvatures from the measured data, which facilitate detailed full field comparisons with strain invariants predicted by the different models.



(a) Pinched semi annular ribbon (b) Unfurled annular ribbon (c) Transversely displaced annular ribbon

Figure 2: Experimental setup showing a slit annular ribbon whose edges held in clamps. The three tests shown consist in rotating the edges about the $\mathbf{E}_3$ axis and linearly translating them along an orthogonal direction, causing the ribbon to deforms into complex three-dimensional shapes.

KEY FINDINGS

- Our experiments reveal annular ribbons to be prototypical systems which exhibit varying degrees of geometric nonlinearity in response to simple displacement and rotation boundary conditions. We demonstrate the existence of multiple stable equilibria, bifurcation phenomena that appear to be correlated with the number of zero crossings in the mean curvature of the ribbon, emergence of creases and localization of energy.

- By scrutinizing an obstacle course of test cases, we identify a set of simple experiments, including the ones shown in Figs. 1 and 2, that highlight the consequences of kinematic relations assumed in the Kirchhoff-Love plate, von Karman plate, Cosserat plate and nonlinear Cosserat rod theories. Measurements from these experiments enable us to decisively (in)validate the applicability of the various ribbon models considered. They highlight assumptions underlying that Kirchhoff rod and von Karman plate models that render them inadequate for modeling a seemingly practical range of deformations of elastic ribbons. These observations are not criticisms of the latter two models, but a reminder that their underlying kinematic assumptions are easily violated when considering deformations of ribbons.

- We find the 1-director Cosserat plate model to be in very good agreement with a broad range of experimental measurements. In particular, for the problem of predicting shapes of Möbius strips, both the Cosserat plate and Wunderlich model predict solutions that agree well with experimental measurements.

- Our study establishes a clear way to test dedicated one-dimensional ribbon models proposed in the literature. Specifically, simulations using 1-director Cosserat plates can serve as benchmark solutions against which to compare predictions of various ribbon models. The narrow width model of Sadowsky, the finite width model of Wunderlich, and the rod-based model of [2] are appealing candidates for such validations. Ribbon models derived by dimensional reduction from von Karman plate theories will benefit from such validations, especially in light of our observations concerning the von Karman plate model.

ANALYSIS OF SOFT SHELLS OF REVOLUTION AT LARGE DEFORMATIONS

Ekaterina Korovaytseva
Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary An algorithm of soft shells of revolution axisymmetric dynamic deformation problems solution is represented in the work. The algorithm imposes no restrictions on the form of meridian of the shell, values of deformation investigated or physical relations describing behavior of shell material. Features of software implementation of the algorithm are pointed out. Characteristics of calculation process which influence calculation stability, iteration process convergence and solution accuracy are specified. The result of test calculation of hemispherical shell made of Treloar material inflation is represented.

In a general case statements of geometrically and physically nonlinear problems concerning investigation of soft shells at large deformations behavior are quite complicated. Owing to this complexity reported studies on the dynamic problems of soft shells are quite scarce. In the works studied only solutions of concrete applied problems or specific problems of soft shells with the simplest meridian form deformation are represented.

In the work given an algorithm of axisymmetric dynamic deformation of unbranched soft shells of revolution with arbitrary meridian form calculation is suggested. The algorithm imposes no restrictions on values of deformation investigated or physical relations describing behavior of shell material. For the purpose of generalization of problem statement we use vector-matrix formalization of resolving equation system and subsequent transformations of vector functions of vector variables.

We suppose soft shell to be loaded by internal pressure. Let it stress state be biaxial in the general case. We construct the resolving equation system on the basis of general theory of soft shells [1]. This system includes two differential equations of motion, two differential geometrical equations, eight additional algebraic equations and two physical relations. In order to simplify mathematical manipulation we shall represent the resolving system of equations in vector-matrix form:

$$\frac{\partial \vec{y}_i}{\partial x_i} = f_i(x_i, y_i, z_i, \mu_i, q_i) + M_i \cdot \frac{\partial^2 \vec{y}_i}{\partial t^2}, \; i \in [1, N] \tag{1}$$

$$\varphi_i(x_i, y_i, z_i, \mu_i, q_i) = 0. \tag{2}$$

Boundary conditions have the form

$$\psi_1(x_{1,b}, y_{1,b}, z_{1,b}, \mu_{1,b}, q_{1,b}) = 0; \quad 1 \quad 2, \; x_{1,b} \quad x_{N,e}, \tag{3}$$

and conjunction conditions for the segments of the shell can be written as

$$y_j(x_{j,e}) = y_{j+1}(x_{j+1,b}), \; j \in [1, \; N-1]. \tag{4}$$

Here y_i is resolving variables vector, z_i is additional variables vector, q_i is vector of given surface loads; μ_i is vector of characteristic geometrical parameters; M_i is mass matrix of the *i*-th segment of the shell; ψ_1, ψ_2 are vector functions of given boundary conditions with the number of components p and s respectively, where $p + s = n$; $f_i(x_i, y_i, z_i, \mu_i, q_i)$ is vector function of n components of right-hand side of the resolving equation system; $\varphi_i(x_i, y_i, z_i, \mu_i, q_i)$ is vector function of nonlinear additional algebraic equations; N is a number of segments of the boundary problem, indices b and e denote beginning and end of a segment.

For the solution of nonlinear boundary problem (1)-(4) we use method of lines, replacing time derivatives by finite differences. Thus the system (1) turns into the system of ordinary nonlinear differential equations, for solution of which we use parameter differentiation method. According to the concept of parameter differentiation method, instead of given loads we introduce variable loads with the same meridian distribution, but depending on nonlinear boundary problem solution step process parameter α : $q_i^*(x_i) = \alpha \cdot q_i(x_i)$. As a result the problem (1)-(4) can be written at each time step $t = t_k$:

$$\frac{dy_{i,k}}{dx_i} = f_{i,k}^*(x_i, y_{i,k}, q_{i,k}^*, \mu_{i,k}); \quad i \in [1, N] \tag{5}$$

$$\varphi_{i,k}(x_i, y_{i,k}, z_{i,k}, \mu_{i,k}, q_{i,k}^*) = 0. \tag{6}$$

$$\psi_{1,k}(x_{1,b}, y_{1,b}, z_{1,b}, \mu_{1,b}, q_{1,b}) = 0; \quad 1 \quad 2, \; x_{1,b} \quad x_{N,e}, \tag{7}$$

$$y_{j,k}(x_{j,e}) = y_{j+1,k}(x_{j+1,b}), \; j \in [1, \; N-1]. \tag{8}$$

Solution of the problem (5)-(8) at $\alpha = 1$ corresponds to the solution of the problem (1-4).

According to the procedure of parameter differentiation method [2], we differentiate the relations (5)-(8) of the problem with respect to some chosen parameter T. Then, expressing the speed of additional variables vector $z_i = dz_i / dT$ from the differentiated algebraic relations (6), we obtain the following quasilinear boundary problem in speeds of vector variables:

$$\frac{dy_{i,k}}{dx_i} = A_{i,k}^{*}(x_i, \vec{y}_{i,k}, \vec{z}_{i,k}, \vec{\mu}_{i,k}, \vec{q}_{i,k}, \alpha)\vec{y}_{i,k} + \vec{a}_{i,k}^{*}(x_i, \vec{y}_{i,k}, \vec{z}_{i,k}, \vec{\mu}_{i,k}, \vec{q}_{i,k}, \alpha)\alpha; \quad i \in [1, N] \tag{9}$$

with boundary conditions

$$\frac{\partial \psi_{1,k}}{\partial \acute{o}_{1,k,b}} \acute{o}_{1,k,b} + \frac{\partial \psi_{1,k}}{\partial z_{1,k,b}} z_{1,k,b} + \frac{\partial \psi_{1,k}}{\partial q_{1,k,b}} q_{1,k,b}\alpha = 0; \quad 1 \quad 2; \quad 1,b \quad N,e \tag{10}$$

and conjunction conditions

$$y_{j,k}(x_{j,e}) = y_{j+1,k}(x_{j+1,b}), \ j \in [1, N-1]. \tag{11}$$

Here dots above the variables y_i, z_i, α denote derivative with respect to parameter T, and

$$A_{i,k}^{*}(x_i, y_{i,k}, z_{i,k}, \mu_{i,k}, q_{i,k}, \alpha) = \frac{\partial f_{i,k}^{*}}{\partial y_{i,k}} - \frac{\partial f_{i,k}^{*}}{\partial z_{i,k}} \left(\frac{\partial \varphi_{i,k}}{\partial z_{i,k}} \right)^{-1} \cdot \frac{\partial \varphi_{i,k}}{\partial y_{i,k}};$$

$$a_{i,k}^{*}(x_i, y_{i,k}, z_{i,k}, \mu_{i,k}, q_{i,k}, \alpha) = \frac{\partial f_{i,k}^{*}}{\partial q_{i,k}} q_{i,k} - \frac{\partial f_{i,k}^{*}}{\partial z_{i,k}} \left(\frac{\partial \varphi_{i,k}}{\partial z_{i,k}} \right)^{-1} \cdot \frac{\partial \varphi_{i,k}}{\partial q_{i,k}} q_{i,k}.$$

Solution of the problem (9)-(11) can be obtained using method of initial parameters. Initial problems of subsequent calculation of the variables themselves have the form

$$\begin{aligned} \frac{dy_{i,j}}{dT} &= y_{i,j}(y_{i\,j}\ z_{i\,j,}\ x_{i\,j}, T, \quad), \\ \frac{dz_{i,j}}{dT} &= z_{i,j}(y_{i\,j}\ z_{i\,j,}\ x_{i\,j}, T, \quad) \ j \in [\ N\ ]\ j \in [\ N_j\ ] \\ \frac{d\alpha}{dT} &= \alpha(y_{i,j}\ T\ ) \end{aligned} \tag{12}$$

Cauchy problem (12) is nonlinear, and the right-hand side of it is known only in discrete form. Besides, the value of parameter increment depends on iteration process convergence rate and cannot be predicted. That is why for the solution of the problem (12) we use specially developed methods of solution of Cauchy problems with right-hand side known at discrete values of variable step.

It should be mentioned that in the absence of prestress the matrix of partial derivatives $\frac{\partial \varphi_{i,k}}{\partial z_{i,k}}$ is singular, which makes the represented algorithm using difficult at the first step of the solution. So regularization of system (5)-(8) solution is required when starting calculation process. Regularization means constructing resolving equation system of soft shells theory with a solution close to the solution of the initial problem. But this new equation system must be well-conditioned.

The algorithm described was tested for the solution of problem of hemispherical shell dynamic inflation. We considered different boundary conditions for the shell. Nonlinear Treloar physical relations were taken to describe properties of soft shell material.

It was established that stability and convergence of calculation process realizing the algorithm represented depend on a number of factors: shell material type, prestress existence, value of pre-pressure, boundary conditions, value of initial increment of parameter T, number of steps for which solution regularization is carried out, number of integration points along the meridian of the shell, time step, way of acceleration finite-difference approximation. Recommendations concerning establishing values of calculation process parameters allowing obtaining correct solution were drawn up.

The reported study was funded by RFBR and Moscow city Government, according to the research project No. 19-38-70005 mol_a_mos.

MACROSCOPIC FRACTURE CRITERION OF LITHIUM-ION BATTERY ELECTRODE

Yoshinao Kishimoto*[1], Yukiyoshi Kobayashi[1], Toshihisa Ohtsuka[1], Kyohei Nakamura[1], Yuki Tsukagoshi[1], Shota Ono[1] and HiroshiYamazaki[1]
[1]Department of Mechanical Engineering, Tokyo City University, Tokyo, Japan

Summary Lithium-ion batteries are widely used as power sources for mechanical structures such as electric vehicles. Damages of electrodes cause performance deterioration and abnormal heating of lithium-ion batteries. This study has proposed a macroscopic fracture criterion of electrodes based on a mechanical model. The microscopic fracture of electrodes occurs when binder resins connecting active materials break. The mechanical model approximates alignment of particles as the body-centred cubic (bcc) and the face-centred cubic (fcc) which are the well-known crystal lattices. The tensile test results agreed with the tensile strength of electrodes calculated by the mechanical model. In the bending tests and the buckling tests, crack initiation of electrodes could be predicted by the macroscopic fracture criterion.

INTRODUCTION

Lithium-ion batteries (LIBs) which has high energy density is expected to be main power sources of electric vehicles. For application to automobiles, the reliability of LIBs should be guaranteed against various external loads. Damages of electrodes cause performance deterioration and abnormal heating of lithium-ion batteries [1], [2]. Most of the studies agree in that microscopic structure of electrodes is bridged structure in which particles of active material (AM) are bonded by binder, and fracture of electrodes is due to fracture of binder. Numerical simulations by the discrete element method seems to be the most exact approach to evaluate basic mechanical properties of electrodes [3]. However, actual alignment of particles of AM is random, and the high-cost simulations must be iterated for enormous numbers of alignment cases. This study has proposed a simple and macroscopic fracture criterion of electrodes based on a mechanical model.

MACROSCOPIC FRACTURE CRITERION

Figure 1 shows schematics of the microscopic model of electrode material. Although actual alignment of particles of AM is random, this study approximates the alignment as the body-centred cubic (bcc) and the face-centred cubic (fcc) which are the well-known crystal lattices. Then, the macroscopic stress σ on the bulk and the microscopic stress σ_t on each binder are related by the following equation.

$$\sigma = \frac{8\alpha_b}{\zeta N} \times \sigma_t \tag{1}$$

where α_b is volume ratio of binder. ζ is constant value (= 0.589 (bcc model), 0.438 (fcc model)) and N is coordination number (= 8 (bcc model), 12 (fcc model)). Therefore, $8 / \zeta N$ is set to 1.61 on average. Equation (1) gives a macroscopic fracture criterion of electrodes if tensile strength of binder is substituted into the stress σ_t.

SPECIMEN AND EXPERIMENT PROCEDURE

Specimens are prepared by pasting graphite powder and thermoplastic fluropolymer binder (polyvinylidene fluoride, PVDF) on copper foil by reference to negative electrodes for LIBs. The mean diameter of the graphite powder is d = 5 μm. The compounding weight ratio Graphite:PDVF is from 94:6 to 50:50. In the tensile tests, uniaxial tensile load is applied on the electrode material removed from the copper foil, and the tensile strength of the electrode material is measured. In the bending tests and the buckling tests, bending moment and uniaxial compressive load is respectively applied on the specimens by attaching both ends of the copper foil on the testing machines.

RESULTS AND DISCUSSION

Figure 2 shows results of the tensile tests. The macroscopic fracture of the electrode material is brittle fracture. Many marks of fractured binder are observed by SEM images. The tensile strength is proportional to the volume ratio of the binder, and the experimental values agree with the theoretical line. In this respect, the binder clearly supports the structure.

Figure 3 shows results of the bending tests and the buckling tests. A crack initiated in some of the specimens. The tensile stress on the surface of the specimen is estimated by the following equation.

$$\sigma = \frac{8\alpha_b}{\zeta N} \times \frac{E_b}{\zeta}\left(\varepsilon + \frac{t}{\rho}\right) \tag{2}$$

where E_b is Young's modulus of the electrode material (= 1 GPa). ζ is set to 0.5 on average. ε, t, ρ are measured strain of the surface of the copper foil, thickness of the electrode material and curvature radius of the specimens, respectively. As shown in Fig. 3, the estimated stress of most of the cracked specimens is equal to or more than the tensile strength of the electrode material. Therefore, the macroscopic fracture criterion can predict the crack initiation of the electrodes.

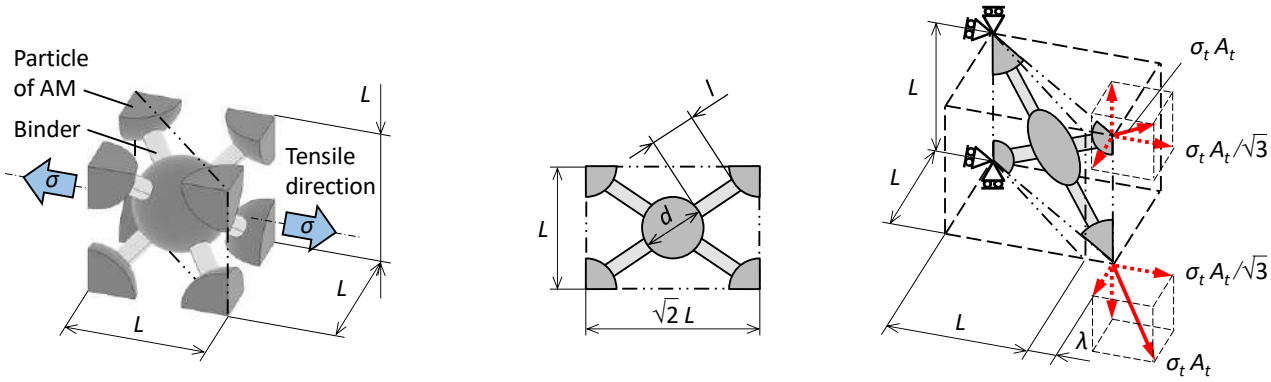

Figure 1. Microscopic model of electrode material (bcc model)

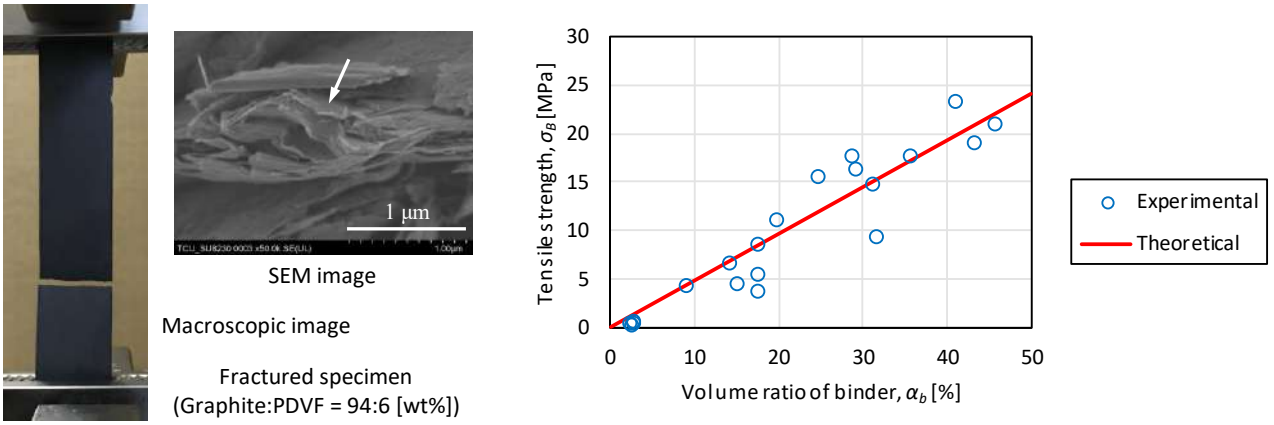

Figure 2. Results of tensile tests of electrode material

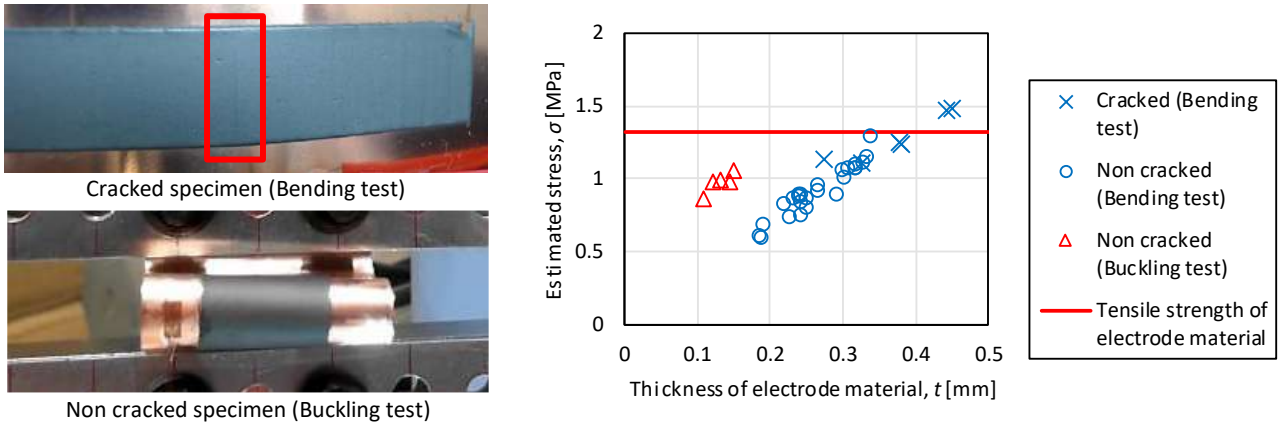

Figure 3. Results of bending tests and buckling tests (Compound weight ratio of specimen, Graphite:PVDF = 94:6 [wt%])

CONCLUSIONS

This study has proposed a simple and macroscopic fracture criterion of electrodes based on the bcc model and the fcc model. The tensile test results agreed with the tensile strength of electrodes calculated by the mechanical model. In the bending tests and the buckling tests, the macroscopic criterion could predict the crack initiation of the electrodes. ANALYTICAL METHOD OF HORIZONTAL RESISTANT MECHANISM OF STRUCTURAL PLYWOOD ON HYBRID STEEL-WOOD STRUCTURE

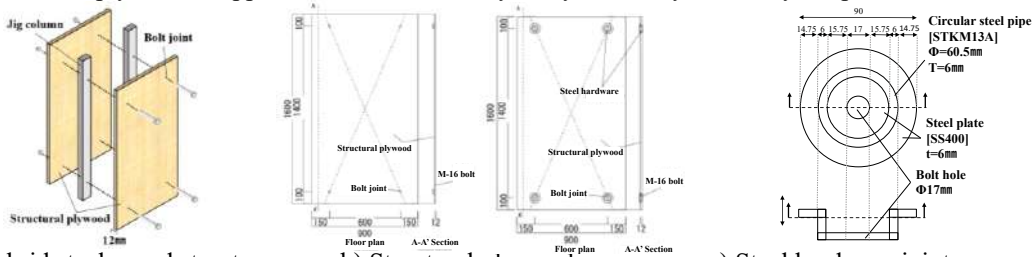
Haruka Kataoka*[1], Takumi Ito[1*], Tsubasa Saito [1*]
[1]Department of Architecture, Faculty of Engineering, Tokyo University of Science, Tokyo, Japan

Summary Authors has suggested a structural sandwich panel which a steel column is sandwiched by thick plywood connected by bolt joints. In this paper, the horizontal loading test of structural plywood is performed as parameter with bolt joint method, whether the steel hardware is installed or not. Also, based on the test study, the analytical method of horizontal resistant mechanism is proposed. From the comparison with test result, the proposed method can estimate the strength of the sandwich panel structure.

INTRODUCTION

Recently, in Japan, to promote the use of domestic wood in architectural engineering field such as Olympic Stadium 2020 Tokyo, a various kind of hybrid structural system using wood and steel has been proposed. Authors have proposed the composite structural panel system and joint method, which steel column is sandwiched by thick plywood connected by bolt joints and the steel hardware [1] (see Fig.1). Furthermore, from the past experimental study, the proposed sandwich panel presents the high strength and rigidity due to composite effect.

This study aims the application of this system for prefab low-rise steel frame which has narrow space, a composite of 12mm-thick structural plywood is applied. And the feasibility study and analytical study are performed.



a) Hybrid steel-wood structure b) Structural plywood c) Steel hardware joint

Fig.1 Conceptual diagram of hybrid steel-wood structure and steel hardware joint

OUTLINE OF EXPERIMENT STUDY

To investigate the resistant mechanism of structural plywood on hybrid steel-wood structure, the fundamental loading test is conducted only on structural plywood. Here, a steel member is assumed as rigid with pin-supported, and the two sheets of plywood are fastened with M-16 bolt on the steel pillar.

The test setup is presented on Fig.2, and the cyclic loading with incremental amplitude is done. The loading jack is set on the top of steel jig column, and the out-of-plane deformation is supported by linear-guide. The horizontal load is measured by load cell, and horizontal displacement is measured by displacement meter. The strain gauges are put on the surface of plywood.

The size of structural plywood of specimen is 910×1600×12mm. The horizontal loading test is performed as parameter with bolt joint method, whether the steel hardware is installed or not. The steel hardware is made by steel plate (SS400) and steel pipe (STKM13A) are welded. The clearance of joint hole is 2.5mm in case of the specimen not using steel hardware and 1mm in case of the specimen using steel hardware. The list of test specimens is summarized on Table.1.

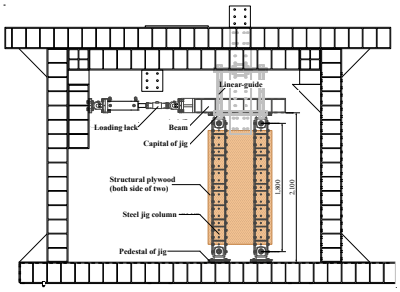


Fig.2 Test setup (unit: mm)

Table.1 List of test specimen

Specimen name	Steel hardware	Load method
N-C	Not	Cycle
S-C	Being	

N: not using the steel hardware, S: using the steel hardware
※Not→Not using, Being→Using, Load method→Load pattern, Cyclic→Cyclic by incremental amplitude

From the test study, the results of strength and rigidity are summarized on Table 2. And the ultimate state of test specimen is shown in Fig.3. From Table.2, the specimen with steel hardware presents high strength. From Fig.3, the end opening fracture and out-of-plane deformation are observed during cyclic loading. Also, from the test result of strain and inter deformation angle of bolt joint, it is predicted that the resistant mechanism as brace mechanism subjected to horizontal load is appeared as shown in Fig.4. Furthermore, the horizontal load on steel column is translated throw the bolt, and the bearing resistant mechanism is occurred between the bolt and plywood.

Table.2 Result of experiment

Specimen name	proportional limit [kN]	maximum bearing force [kN]	rigidity [kN/mm]
N-C	4.1	5.8	0.25
S-C	10.6	14.3	1.3

a)N-C b)S-C

Fig.3 Ultimate state of test specimen

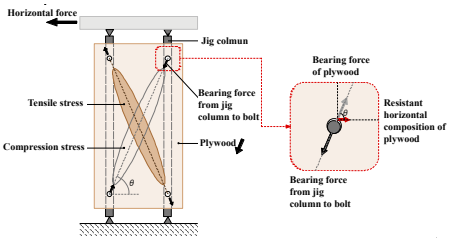

Fig.4 Conceptual diagram of brace resistant mechanism

ANALYTICAL METHOD AND CONSIDERATION

From the test results as previous mentioned, the resistant mechanism with diagonal brace on plywood is occurred, and the bearing force translates the horizontal load on steel member. Here, the analytical model of whole resistant mechanism of plywood (see Fig.5) and the bearing model on bolt joint (see Fig.6) are assumed to estimate the strength.

First, the horizontal force P as shown Fig.5 is evaluated as follows:

$$P = \frac{\mathrm{H}\times\mathrm{T}\times\cos\theta}{\mathrm{L}} \qquad \text{(Formula.1)}$$

Where, H: height of plywood, T: bearing force of bolt joint, L: distance between steel column.

The bearing force of bolt joint T_u (see Fig.6) are presented as follows:

$$Tu = \frac{2\times d\times\delta\times Fe}{\cos\theta} \qquad \text{(Formula.2)}$$

Where, d: thickness of plywood, δ: effective diameter on bearing, Fe: bearing strength of plywood (=19.4N/mm^2 (base bearing strength of 0° fiber direction)) [4]

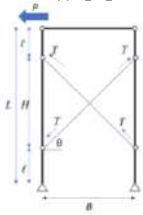

Fig.5 Analytical model of whole resistant mechanism of plywood

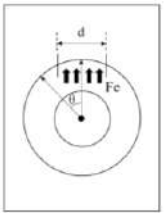

Fig.6 Bearing model on bolt joint

The size and material properties of plywood are summarized on Table.3, and the test result and analysis compare on Table.4. A direction of bearing force is assumed as 0°, and the bearing strength of bolt joint is calculated here.

From the comparison of Table 4, in case of N-C, the horizontal strength of experimental result shows 2 times comparing with analysis results. This error is derived from the strength of bearing of bolt joint, that is, the other resistant mechanism is predicted such as hardening, stress concentration. However, the whole resistant mechanism as shown in Fig.4 can chase the test result. Next, in case of S-C, the analysis result show good agreement of test result. It means that the bearing strength under wide area can be estimated by Formula 1.

Table.3 Size and material properties

Specimen name	maximum bearing force mechanism model				bearing force mechanism model			
	H [mm]	L [mm]	B [mm]	cosθ	d [mm]	δ [mm]	Fe [N/mm^2]	cosθ
N-C	1400	1800	910	0.55	12	16	19.4	1.1
S-C						61.2		

Table.4 Comparison of test results and analysis

Specimen name	bearing force [kN]		T/Tu	maximum bearing force [kN]		P/Pu
	experiment T	analysis Tu		experiment P	analysis Pu	
N-C	13.7	8.1	1.691358	5.8	3.4	1.7058824
S-C	33.7	31	1.0870968	14.3	13.1	1.0916031

CONCLUSIONS

From the test study, the specimen with steel hardware presents high strength, and the end opening fracture and out-of-plane deformation are observed during cyclic loading. Also, from the test result of strain and inter deformation angle of bolt joint, it is predicted that the resistant mechanism as brace mechanism. The analytical model of whole resistant mechanism of plywood and the bearing model on bolt joint are assumed to estimate the strength. The analysis result show that the bearing strength under wide area can be estimated.

Summary We are interested in the energy transfer between a throwing engine and slender elastic projectiles. We have recently shown that the deformation dynamics of a projectile plays a major role in tuning its throw efficiency [1]. Here we investigate the case of slender elastic objects that are subject to bending deformations, such as arrows and spears. Different kind of projectiles are designed to investigate this question. A bow-like throwing engine is built to accelerate projectiles up to 100 times the standard gravity. The deformation dynamics is of paramount importance for the energy transfer and a gain of 150% can be reached for an optimal projectile. A simple model determines the relevant dimensionless parameters and is in good agreement with the experimental data.

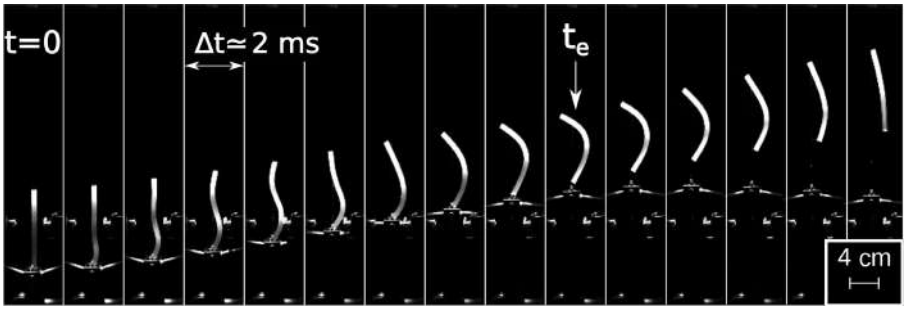

Figure 1: Image sequence displaying the deformation of a projectile while accelerated by the throwing engine. The projectile is made of a synthetic elastomer.

INTRODUCTION

Throwing objects is relevant for many natural processes [2] and is central to many technological innovations in human history. This is the case of bow-assisted shots in primitive societies or ejections by means of medieval catapults [3]. A recent study [1] has shown that elastic objects thrown by a catapult-like engine can obtain a 250% gain of kinetic energy as compared to a rigid projectile thrown in the same conditions. This phenomenon, called "superpropulsion", appears when the time scales of the object deformation and of the throwing engine acceleration are of the same order. While this phenomenon was characterized with longitudinal deformations, we investigate here the case of slender elastic projectiles that bend and exhibit transverse deformations.

EXPERIMENTAL SETUP

We perform experiments by throwing elastic beams. Several materials are tested, from soft elastomers to metallic rods (Fig. 1). The projectiles are vertically accelerated up to 100 times the standard gravity by a bow-inspired throwing engine. We vary numerous parameters systematically: mass (0.1 - 1 g), length L (1-10 cm), diameter (0.2-5 mm) and Young modulus of the projectile E (50 MPa-140 GPa), as well as the amplitude A (1-8 cm) and frequency f of the throwing engine (around 20 Hz). This engine has a harmonic motion described by $z(t) = A\,[1 - \cos(2\pi f t)]$ with a maximal velocity $V_p = 2\pi A f$. In order to have good time and space resolutions of our data, the experiments are imaged by a high-speed camera with a frame rate of 10^4 frames per second. We use an algorithm to track automatically the positions of the different parts of the system (masses and throwing engine). From these positions, we are able to measure the velocity of each object over time and particularly the ejection velocity of the projectile V_e at the time t_e as well as V_p, the velocity at which a rigid projectile would take off.

RESULTS

The efficiency is characterized by the energy transfer factor $\alpha = \left(\frac{V_e}{V_p}\right)^2$. We present results from four projectiles with same diameter, elastic modulus and mass but different lengths. The values obtained for α depend strongly on the

*Corresponding author. E-mail: guillaume.giombini@unice.fr

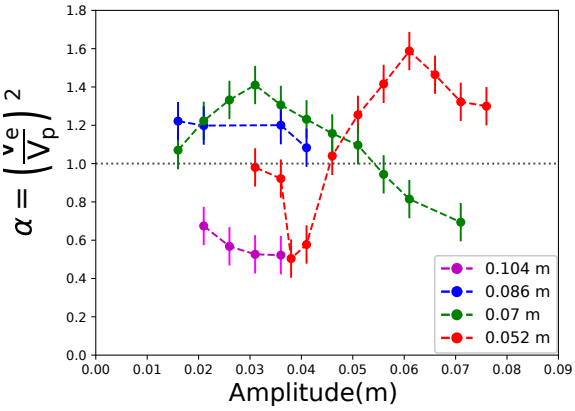

Figure 2: α as a function of the loading amplitude for four projectiles with the same diameter, mass and elastic modulus but different lengths. We see here a common behaviour: α increases, exhibits a maximum value and then decreases. The amplitude of the optimum depends on the length.

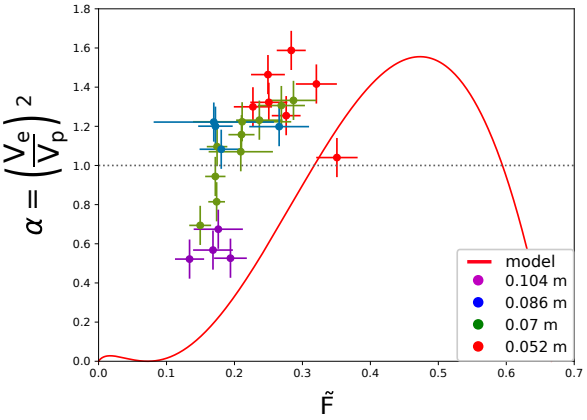

Figure 3: α as a function of the force ratio $\tilde{F}$ for the same lengths studied in Fig. 2. We see that the data align on a trend similar to the one predicted by the model (red solid line) with no free parameter, but slightly shifted towards the left.

amplitude (Fig. 2). At small ones, the projectile acts as a rigid object without any kinetic energy gain. For intermediate amplitudes, we observe transverse deformations that can lead to a kinetic energy gain of 150%. At large amplitudes, α decreases and the projectile exhibits very large deformations that can be irreversible and lead to failure of the beam. The effect of the amplitude emphasizes a nonlinear dynamics and the amplitude at optimal ejection is found to depend on the projectile length.

MODEL

We built a model to find the relevant dimensionless parameters. The projectiles are modeled by massless elastic beams with two point masses at the edges. In that case, the elastic beam pushes on the point masses with a constant force, equal to Euler's load, as soon as it bends. Within the frame of the model, the deformation dynamics can be calculated and the set of equations emphasizes two relevant parameters: the ratio of the amplitude to length and the ratio of the elastic force to the inertia force, which is a function of the amplitude and frequency of the throwing engine as well as the mass of the projectile. We find that the previous results are no longer disperse but follow a single trend when expressed as a function of the force ratio instead of the amplitude, in relative good agreement with the model (Fig. 3).

CONCLUSION

We have shown that the efficiency of a deformable beam can reach 150% the one of a rigid projectile thrown in the same conditions and that this effect is nonlinear since it depends on the amplitude of the throwing engine. A simple model gives the relevant dimensionless parameters, in good agreement with experiments. This study could be relevant for archery and the way arrows are shot from a bow: we expect a matching between bows and arrows to maximize the transfer of energy.

WRINKLING INSTABILITY OF MICROCAPSULES IN EXTENSIONAL FLOW

Revaz Chachanidze,Kaili Xie,Clément de Loubens*,and Marc Leonetti†
Univ. Grenoble Alpes, CNRS, Grenoble INP, LRP, 38000 Grenoble,France

Summary Soft microcapsules are core-shell particles, i.e viscous droplets bounded by a soft elastic membrane and embedded in another viscous fluid. If buckling of capsules under pressure or local indentation has been investigated in literature, this is certainly not the case in simple flows. Well-defined wrinkles and folds are experimentally first observed on the membrane of stretched capsules by extensional flow when the hydrodynamic stress is above a threshold. It depends on the membrane elastic properties and the capsule's size. A master curve for wrinkling bifurcation is demonstrated. The scaling of the wrinkle's wavelength with microcapsule's characteristics is determined in the limit of small wavelength compared to the capsule's size. The phase diagram is established.

INTRODUCTION

Microcapsules are droplets bounded by a solid membrane characterized by a Young modulus which can vary on several order of magnitudes, depending on the applications. They are used to protect internalized molecules of interest, to convey and to deliver their contents in food, cosmetics and medecine... Soft microcapsules in flow model also the behavior of biological cells in living fluids such as blood. Indeed, soft deformable particles such as vesicles, polymersomes and capsules exhibit analog spatiotemporal dynamics than Red Blood Cells in shear flow. These shape instabilities are more or less oscillations of the global shape, i.e without wrinkles for example.

However, in the 70s, [1] observed a shape modulation when RBCs are stiffened, a phenomenon explained by buckling. [2] studied large capsules of several millimeters moving inside channels. If the study is only focused on the curvature inversion at the rear as RBCs, wrinkles can be visualized (but not mentioned) on figures. Finally, [3] visualize also wrinkles at the membrane of one kind of small capsules in shear flow. However, if compressive domains due to fluid-structure coupling are expected at membrane [4, 5], neither scaling, nor phase diagram were established.

Here, we study experimentally the emergence of the wrinkling instability of capsules with well controlled mechanical properties in a planar extensional flow.

MATERIALS AND METHODS

Microcapsule fabrication

The microcapsule membrane is formed via electostatic complexation of chitosan (CAS 9012-76-4, Sigma-Aldrich) with phosphatidic acid [6]. Chitosan is dissolved in demineralized water at concentration 0.05 - 3.0 g/L (pH of water is adjusted to 3.0 by adding hydrochloric acid). Phosphatidic acid (AMP 4455, Palsgaard) is dissolved in rapeseed oil. Microfluidic generation of chitosan droplets in the oil phase allows to create uniform in size capsules (30 - 400 μm). The complexation time for membrane formation takes 2-30 minutes. After that in order to stop the reaction the capsules are washed in cyclohexane (CAS 110-82-7, purity 99.5%, Sigma Aldrich) an resuspended in silicon oil AP1000 (IMCD, viscosity 1.18 Pa·s - 22°C). The membrane thickness (20 nm - 1 μm) is estimated with atomic force microscopy (for the details see Xie *et al.*, [7]). Typically, the Young modulus E is 4 MPa.

Microfluidic chamber

The microfluidic chamber with a 1 x 1 mm^2 cross section is composed of two intersecting channels and is used to create a planar extensional flow [8, 9]. The capsule suspension is pushed through the chamber and visualised with a bright field microscope (Olympus IX-71) equiped with a 20x objective and a fast camera (Photron Fastcam SA3). The surface shear elastic modulus G_s is determined in the limit of small deformations by applying hydrodynamic stress to a capsule, where deformation is defined as the Taylor parameter $D = (L - S)/(L + S)$. Here, S and L are the small and big axes of the capsule respectively Figure 1.

RESULTS AND DISCUSSION

The microcapsules, initially spherical, deform into ellipsoids under hydrodynamic stress. Their membrane experiences the wrinkling instability when the stress surpasses a threshold which depends on membrane properties: figure 1-a,b. The wavelength changes strongly between both cases as the thickness. This trend is similar to the case of flat soft films under static extension [10]. Thicker membrane, larger critical hydrodynamic stress: figure 1-c.

†Corresponding author. E-mail: leonettm@univ-grenoble-alpes.fr.

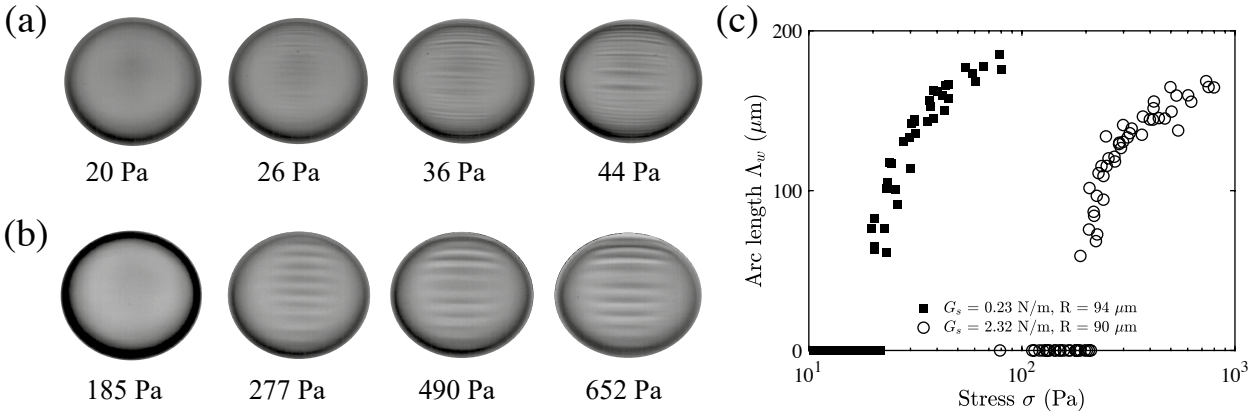

Figure 1: **(a, b)** : Development of the wrinkles on the capsules with 60 $\pm$ 8 nm **(a)** and 650 $\pm$ 80 nm **(b)** thick membrane. In the case a, focalized structures can be observed at 44 Pa. **(c)**: Wrinkling lenght Λ_w as a function of hydrodynamic stress σ,

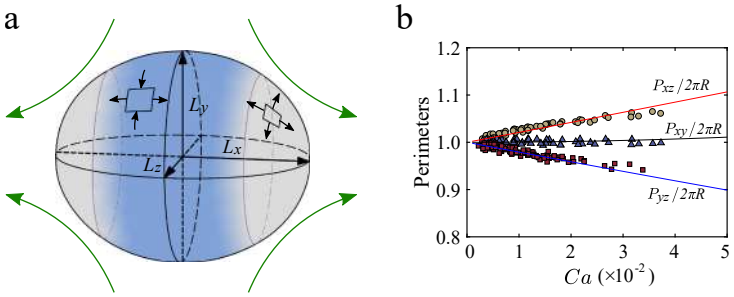

Figure 2: **(a)**: Schematic depiction of a capsule in an elongational flow. The blue zone corresponds to the domain under azimuthal compression. **(b)**: Evolution of a capsule perimeter in three principal planes of deformation

In this flow configuration, capsules are stretched in the direction flow (positive membre tension) while at the center, membranes become under compression even at small stress (negative membrane tension). See the compressive zone schematically depicted in blue color on the figure 2-a and is quantified with the decrease of the perimeter in the orthogonal plane (x-z) on the figure. 2-b.

We study the nature of this instability by quantifying the length of the wrinkles presented on the figure 1-c. We observe that the wrinkling threshold depends on the surface shear elastic modulus G_s of a capsule as well as on its radius R leading to recasting all the results on a master curve using the dimensionless elastic capillary number. Thus the critical capillary number is unique and does not depend on thickness contrary to the theory [11]. By an original optical set-up, the section is also visualized to determine accurately the scaling of the wavelength. A phase diagram is established.

CONCLUSION

In flow microcapsules can experience wrinkling instability which can be fully characterised experimentally.

PUMPING FLUID WITH A THIN-WALLED PNEUMATIC SOFT ACTUATOR

Maziar arfaee[1], Johannes T.B. Overvelde*[2], and Jolanda Kluin [1]
[1]Department of Cardiothoracic surgery, Academic medical centre, Amsterdam, Netherlands
[2]AMOLF, Amsterdam, Netherlands

Abstract: Soft actuators are becoming increasingly popular for application where adaptability is important, due to their embodied intelligence. They are typically light-weight, easy to process, safe in human-body interaction and also low cost in fabrication. In the following, we will introduce a thin-walled soft actuator made by heat sealing two thin layers of materials. Our system is actuated pneumatically and can have various motions based on the sealing pattern. We demonstrate our approach by fabricating a prototype of a soft pump that can be used as an artificial heart, and demonstrate promising results for this system in terms of efficiency.

BACKGROUND

Soft robotics is a recent field of robotics, in which intelligence is embodied in the robot by way of compliance of materials. Soft actuators are being developed to make motions in soft robots and can work as a part of industrial systems or medical devices, that can be safer than solid actuators in combination with a soft end effector. This is because both the actuator and end effector have the capability of adapting their shape to their environment. Moreover, soft actuators are getting popular to study due to their low manufacturing cost, safe human-machine interaction [1], light-weight and also ease of process. However, this comes at a cost of high precision [2]. Importantly, many motions can be embedded in soft actuators by manufacturing them in different shapes, such that simple outputs could potentially lead to various and complex outputs [3].

Soft actuators can be actuated pneumatically, hydraulically, by heat, chemical reactions, or electric fields [4][5]. Among these ways of actuating, soft pneumatic actuators have become popular as they are powerful and also relative easy to control. Several studies have been done on design and optimization of such soft pneumatic actuators during the last decade, with a main focus on: (i) Development of different geometrical designs to have various motions; (ii) increase power output; (iii) Try to find analytically model the actuators in order to predict and optimize the behavior before fabricating. Studies have shown geometrical design can affect the output motion significantly [1][6]. Also the behavior of the actuator can be changed by using different materials which have different properties. Finally, as it is possible to fabricate soft actuators with biocompatible materials, they can be utilized in devices aimed to interact with human body like rehabilitation devices, surgical devices for minimal invasive surgery and prosthesis [2].

THIN-WALLED SOFT ACTUATOR

In this study, we propose a thin-walled soft pneumatic actuator which can be made by any thin thermoplastic sheets, for example in this study we used thermoplastic polyurethane sheets with a thickness of 0.3 millimeters. The actuator is made of two layers which are sealed together using a custom heat sealer, in which particularly channels and chambers are embedded to program the actuator with certain behavior upon inflation. The pattern of sealing determines the channel arrangements and so the behavior. By inflating the actuator, the channels are inflated, which effectively reduces the distance between the sealing lines, such that the whole actuator shrinks perpendicular to the channel walls (i.e. sealing direction). Therefore, the shrinkage pattern can be modified by analyzing and designing different patterns of channels. The simplest motion of the thin-walled soft actuator is contraction in one direction which is similar to the motion needed for artificial muscles [7].

Here we demonstrate the actuators by building a prototype for a soft pump, in which we enclose a volume by our inflatable actuators. By inflating the walls we are able to reduce the enclosed volume, and pump a certain volume. In particular, we are interested in pumping a large amount of fluid, while only inflating the walls by a small amount. In other words, we would like to achieve transmission ratio higher than one. Moreover, we aim to achieve high transmission ratios with high efficiency of this pumping. Therefore, we have developed a measurement platform which allows us to determine both quantities accurately. Initial tests showed that the outflow can rise up to twice as the inflow regarding the inside pressure, with efficiencies up to 80 percent.

CONCLUSIONS

We have just started to explore the potential of these thin-walled pneumatic actuators, and initial results shown great potential. Our goal in the future will be to optimize the design of the actuators, to improve transmission ratios, while keeping high efficiencies, with the ultimate goal to develop a soft total artificial heart.

SOFT CELLULAR METAMATERIALS WITH PROGRAMMABLE DEFORMATION-CONTROLLED SHAPE

Zhaohang Zhang[1], Anastasiia O. Krushynska*[1]
[1]Engineering and Technology Institute Groningen, Faculty of Science and Engineering, University of Groningen, Groningen, The Netherlands

Summary Rich microstructure makes cellular metamaterials promising candidates for delivering programmable behaviour. In this paper, we develop a comprehensive method based on theoretical, numerical and experimental analysis aimed to program the shape of soft cylindrical structures subject to tensile deformation. The programmable response originates from a combination of auxetic and conventional honeycomb unit cells with different geometric parameters allowing to control the structural shape. First, we theoretically study the dependence of the mechanical properties on the geometric parameters of honeycomb unit cells. Then, we introduce a theory-driven design approach to program the structural shape. Further, we explore the possibilities of an experiment-driven optimization to find more complex programmable designs. For that, the cylindrical honeycomb structures are fabricated by means of additive manufacturing techniques and will be tested experimentally. The prescribed deformation of a complex shape has great application potential in the fields of medical equipment and intelligent structures, while further development of programmable and even automated design methods can facilitate their eventual use.

INTRODUCTION

Rapid advances in additive manufacturing, computational design and conceptual breakthroughs have allowed considering the material design not only as a means to solve practical problems, but also as a catalyst for unveiling novel material functionalities [1]. Rationally designed architectures give rise to unprecedented mechanical properties that can be exploited to create advanced materials with novel functionalities [2]. The recent paradigms of shape-morphing, topological and nonlinear metamaterials have opened roadmaps for the development of truly smart materials, e.g. those with a complex response to a single stimulus [3]. When realized in a two- or three-dimensional setting, these metamaterials can be used to switch, activate or regulate the mechanical structural response and associated functionalities. Specifically, they have a promising potential in flexible electronics and wearable devices, like prosthetics and orthotics [4].

Mechanical cellular metamaterials form an ideal platform for the development of novel smart and multi-functional materials thanks to their high-dimensional design space determined by a variety of geometric parameters and bulk material properties [5]. On the one hand, their architectural elements, including cell arrangement, corner angle, cell length, strut width, etc., provide sufficient degrees of freedom (DOFs) to design new functionalities [6]. On the other hand, an enormous amount of available DOFs makes it very challenging to find the most feasible solution. To address this challenge, it is promising to exploit computational design and optimization tools helping to avoid tedious trial-and-error procedures and excessive experimentation.

In this work, we focus on the design of soft cylindrical structures formed by a combination of auxetic and conventional honeycomb unit cells (e.g. star-shaped and octagon unit cells) and propose two techniques to achieve their programmable mechanical response driven by external deformation.

METHODS & RESULTS

To study the described structures and to implement their programmable behaviour, we use a combination of theoretical methods, numerical simulations, and experiments supplementing each other as described below.

Honeycomb unit cells analysis

Among different kinds of honeycomb unit cells, we consider star-shaped and octagon honeycomb configurations (SOH) with a biaxial symmetry (Fig. 1a) to facilitate their integration in a single structure when geometric parameters are varied. It is well-known that the mechanical properties of cellular materials are governed by their geometric parameters. For our SOH unit cells, these are the wall thickness and the inner angle between adjacent struts. As the angle changes from 10° to 180°, the unit-cell geometry is transformed from auxetic ($10° < \theta < 53°$) to conventional ($53° < \theta < 180°$) characterized by a positive and negative Poisson's ratio, respectively. The effective Young's modulus and Poisson's ratio of each unit cell were evaluated theoretically by means of the beam theory that accounts for tensile and bending deformations. The obtained results are approximate, though they can be used as a rough reference for programmable designs.

Programming of the honeycomb structures

One of the key parameters governing the deformation of the whole structure is the effective Poisson's ratio of a unit cell. Since its value was shown to be regulated by the inner angle and/or the wall thickness, the deformation and thus the final shape of the structure can be programmed by e.g. varying the inner angle. To achieve this, one can use different techniques, e.g. the theory-driven derivation or the experimental-driven optimization method.

The theory-driven derivation implies the use of 1D periodic unit cells in the 2D arrangement (Fig. 1b), where the inner angle of the unit cells is different along the y-direction and remains unchanged along the x-direction. In this case, the

*Corresponding author. E-mail: **a.o.krushynska@rug.nl**

linear-elastic strain in the y-direction, induced by forces on the left- and right-hand sides of the structure, will be inversely proportional to the effective Young's modulus of each column. The linear-elastic strain in the x-direction will be then proportional to the ratio of the effective Poisson's ratio and effective Young's modulus. The combination of these strains will influence the structural shape. We have verified this in numerous numerical simulations. Two of the pre-programmed structural shapes are shown in Figs.1c, d. However, soft materials are usually deformed in a nonlinear regime. Thus, to properly estimate the structural response, we are planning to consider large deformations as well.

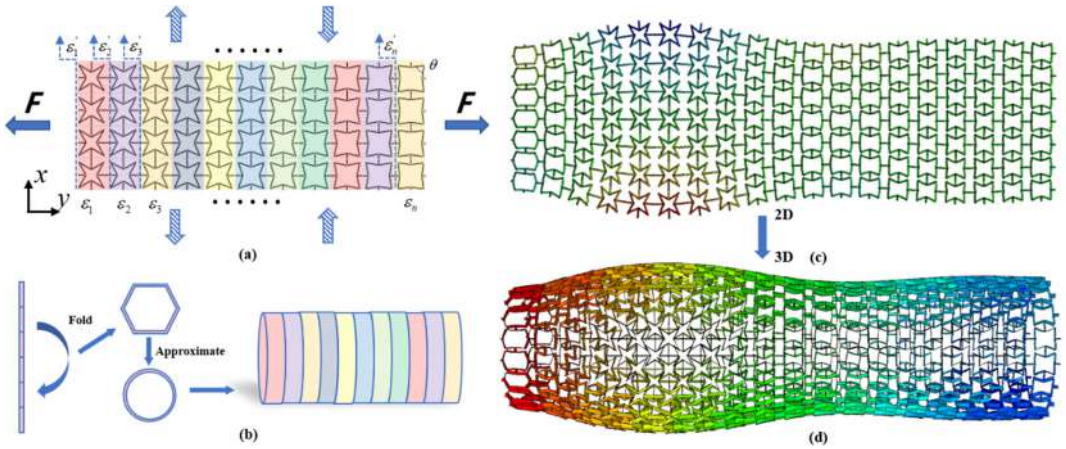

Figure 1. Schematic demonstration of (a) the deformation of 1D-periodic cellular metamaterial under tensile load and (b) the conversion of a flat honeycomb structure to a cylindrical one. Examples of (c) a flat honeycomb cellular meta-structure of pre-programmed shape and (d) a cylindrical cellular meta-structure of a pre-programmed shape.

The second, experiment-driven optimization technique allows considering a fully 2D arrangement of the unit cells. The main idea of this approach is that meta-structures can be fabricated, e.g. by additive manufacturing techniques, and tested experimentally to study the effect of the design parameters on the structural response. The experimental data supplemented by relevant numerical results form a benchmark for further optimization that can deliver more complex designs tailored to demand. To implement this approach, we have fabricated several samples by means of 3D-printers Form2 and Objet260 Connex3 from tough and soft resin, respectively. The experimental tests including tensile and compression analysis are underway.

CONCLUSIONS

We preliminary demonstrated that simple cellular honeycomb structures are excellent candidates for delivering a programmable mechanical response. The theory-driven derivation was shown to be an effective tool to program the shape of cylindrical honeycombs with a 1D-periodic arrangement of auxetic and conventional unit cells. The alternative experimental-based optimization will be used to design more complex arrangements, and, ultimately, to automate the design process to a certain degree. Therefore, we believe that the proposed techniques will be of use for the design of truly programmable metamaterials and will eventually facilitate their application in the fields of medical equipment and smart industry.

A FINITE STRAIN PLATE MODEL FOR WRINKLING IN ANISOTROPIC HYPERELASTIC FILMS

Yifan Yang and Fan Xu*
Institute of Mechanics and Computational Engineering, Department of Aeronautics and Astronautics, Fudan University, Shanghai, China

Summary Transverse wrinkles commonly occur in a uniaxially tensile elastic membrane and can vanish upon excess stretching. The wrinkling direction is usually perpendicular to the stretching direction under isotropic elasticity. Here, we show that wrinkles are orientable by material anisotropy, such as in fiber-reinforced or fibrous films, and the wrinkling orientation can be tuned by varying the stiffness and direction of fibers. To quantitatively describe large anisotropic deformations and predict morphological evolution, we develop a finite strain model by introducing anisotropic, hyperelastic constitutive law into the geometrically extended Föppl-von Kármán nonlinear plate theory. We find that the shear modulus ratio between fibers and matrix significantly affects the critical buckling threshold, restabilization point and wrinkling amplitude. The shear modulus ratio above a critical value prevents the appearance of wrinkles. Effects of the angle between fibers and stretching direction on the oblique wrinkling orientation are carefully examined. The findings could provide an effective way to design wrinkle-tunable surfaces for fiber-reinforced or biomimetic membranes.

INTRODUCTION

Surface wrinkling instability is widely used to realize multifunctional smart structures and devices, such as the measurement of material properties, controllable optical transmittance, topology optimization, synthetic camouflaging skins, reprogrammable Braille designing and bioinspired surface structured sensors. Most previous efforts were made on isotropic materials and little is known about wrinkling response of anisotropic films. Here, we fill this gap by developing a mathematical model through introducing anisotropic, hyperelastic constitution into the geometrically extended Föppl-von Kármán (FvK) nonlinear plate theory, to quantitatively explore fiber-related wrinkles and their morphological evolution. We derive a simple yet effective anisotropic finite strain plate model inspired by the classical Gent constitutive law [1], while it is not difficult to implement other types of anisotropic hyperelastic materials with multiple families of fibers. Based on our model, we find that shear modulus ratio between fibers and isotropic matrix significantly affects the critical buckling threshold, restabilization point and wrinkling amplitude. Moreover, the shear modulus ratio above a critical value can even resist wrinkles. We reveal that the orientation of oblique wrinkles strongly depends on the fibers stiffness and the angle between fibers and stretching direction.

EXTENDED FÖPPL-VON KÁRMÁN PLATE MODEL WITH ANISOTROPIC HYPERELASTICITY

Let us consider a simple case that a single family of fibers reinforces the isotropic matrix. Motivated by Gent model, Horgan [1] presented a three-parameter strain energy for neo-Hookean materials reinforced by a family of fibers. Taking the incompressibility condition $J = 1$ into account, the strain energy function can be expressed as

$$\Psi = \frac{\mu}{2}\left(I_1 - 3\right) + \frac{\mu_1}{2}\left(I_4 - 1\right)^2 - p\left(J - 1\right), \tag{1}$$

where p denotes a Lagrange multiplier that can be identified as hydrostatic pressure.

For thin films, the direction of fibers is usually restricted in plane and thus the unit vector of fibers can be expressed as $\boldsymbol{a}_{0s} = (\cos\varphi_0, \sin\varphi_0)^T$, in which $\varphi_0 \in [0, 90°]$ represents the angle between fibers and stretching direction in the initial reference configuration. Combining the Kirchhoff-Love hypothesis and plane stress condition, the in-plane second P-K stress tensor is written as

$$\mathbf{S}_s = \mu\mathbf{I}_s + 2\mu_1\left(I_4 - 1\right)\boldsymbol{a}_{0s} \otimes \boldsymbol{a}_{0s} - p\mathbf{C}_s^{-1}. \tag{2}$$

Based on the extended FvK nonlinear plate theory [2], the 2D membrane energy is given by

$$W_m\left(\mathbf{C}_s^{\circ}\right) = h\Psi\left(\mathbf{C}_s^{\circ}\right), \tag{3}$$

and the bending energy density $W_b\left(\mathbf{K}_s\right)$ can be written as the contributions of the matrix [2] and fibers [3]:

$$W_b\left(\mathbf{K}_s\right) = \frac{Eh^3}{24\left(1-\nu^2\right)}\left(\nu\mathrm{tr}(\mathbf{K}_s)^2 + (1-\nu)\mathbf{K}_s \cdot \mathbf{K}_s\right) + \frac{\mu_1 h^3}{6}\left(\boldsymbol{a}_{0s} \cdot \mathbf{K}_s \cdot \boldsymbol{a}_{0s}\right)^2, \tag{4}$$

in which E and ν represent the initial Young's modulus and Poisson's ratio in the linear elastic regime, respectively. The potential energy $\mathcal{P}$ of the membrane reads

$$\mathcal{P} = \int_{\Omega_{2D}} \left[W_m\left(\mathbf{C}_s\right) + W_b\left(\mathbf{K}_s\right)\right] \mathrm{d}\Omega. \tag{5}$$

*Corresponding author. E-mail: fanxu@fudan.edu.cn

The first variation of the potential energy (5) with respect to the components of displacement field yields the Euler-Lagrange equilibrium equations:

$$\nabla_s \cdot [(\mathbf{I}_s + \nabla_s \mathbf{u}) \cdot \mathbf{S}_s] = \mathbf{0}, \tag{6}$$

$$\nabla_s \cdot (\nabla_s \cdot \mathbf{M}_s) + h \nabla_s \cdot (\mathbf{S}_s \cdot \nabla_s w) = 0, \tag{7}$$

in which $\nabla_s \cdot (\nabla_s \cdot)$ denotes the surface divergence and $\mathbf{M}_s := \partial W_b(\mathbf{K}_s)/\partial \mathbf{K}_s$ represents bending moment.

RESULTS

We set the fiber direction along the stretching direction ($\varphi_0 = 0°$). An isola-center bifurcation phenomenon is observed in Fig. 1, where the instability boundary shrinks with increasing k, and the membrane remains flat when $k \geqslant 0.2$. This fact implies a promising way for wrinkle-free or wrinkle-resistant surface design.

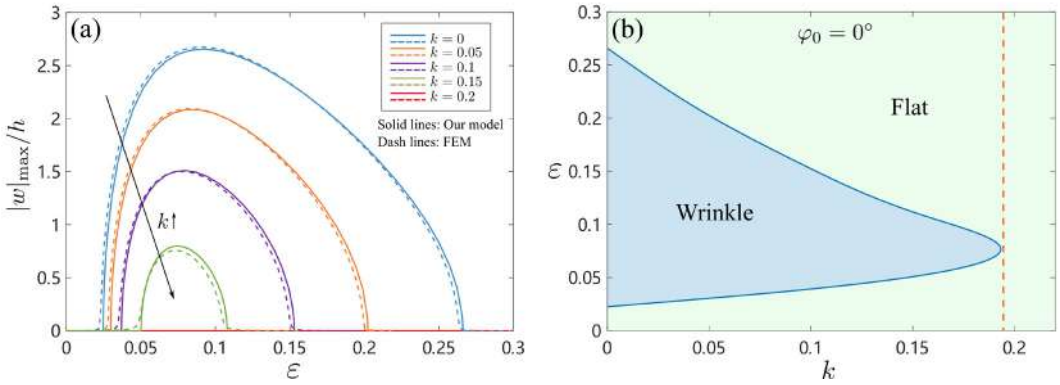

Figure 1: (a) Isola-center bifurcation diagram of uniaxially stretched membranes with varying shear modulus ratio ($k = \mu_1/\mu$). The solid lines represent predictions by our model, while the dash lines stand for those computed by FEM. With the increase of k, the isola-center bifurcation cycle dramatically shrinks. (b) Calculated phase diagrams on stability boundaries determined by the shear modulus ratio k and tensile strain ε. The anisotropic membranes wrinkle when their parameters are located in the blue region, while remain flat in the green region. Fiber angle $\varphi_0 = 0°$.

We find that the fiber direction determines the oblique angle of wrinkles, as shown in Fig. 2. The contours of compressive stresses in the pre-buckling stage of anisotropic membranes are drawn in the third line of Fig. 2. It can be seen that the compressive stress has the similar distribution as the wrinkling orientation (maximum compression parallel to wrinkling direction). Altering the material anisotropy, *i.e.*, the angle between fibers and stretching direction, is shown to be a feasible way for the formation of orientation-tunable wrinkling patterns.

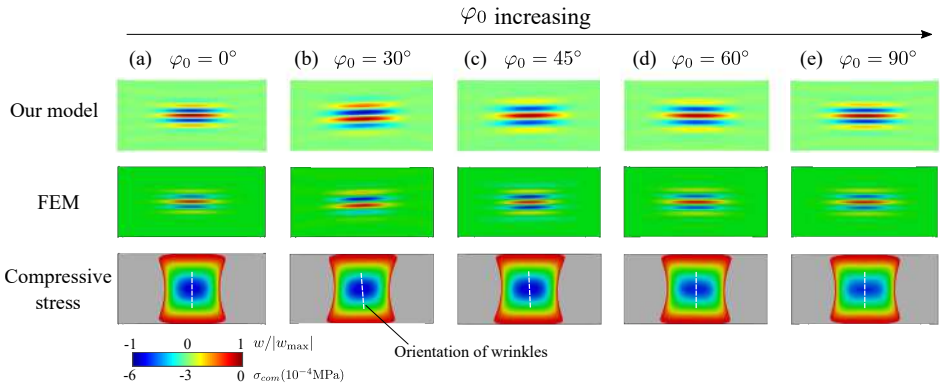

Figure 2: Oriented oblique wrinkles and contours of compressive stresses for various angles between material anisotropy and stretching direction. Shear modulus: $k = 0.15$.

A BI-SHELL VALVE UTILIZING SHELL SNAPPING INTERACTION FOR FAST ACTUATION OF PNEUMATIC SOFT ROBOTS

Chuan Qiao, Lu Liu, and Damiano Pasini*
Department of Mechanical Engineering, McGill University, Montreal, Canada

Summary Fast actuation of pneumatic soft robots is typically achieved through either pressure-controlled strategies involving a bulky system of pressure supply, or actuators engaging structural instabilities or chemical explosions. All these routes are not straightforward to realize and have their own challenges. In this paper, we introduce a bi-shell valve that can operate through the slow deflation of a syringe to produce a fast volume output for rapid actuation. The valve leverages the snapping and interaction of its constituent shells, whose geometry can be effectively tuned to maximize its volume change output. Our valve works through deflation, yet its architecture can be adapted to work as a rapid inflation valve or pneumatic volume fuse, hence offering additional routes for soft robot control and actuation.

INTRODUCTION

Rapid actuation is challenging to achieve for most pneumatic and hydraulic soft robots. The most widely used approach is to quickly inflate a soft actuator through a pressure controlled system. This requires a cumbersome setup f pressure supply, sensors, hard valves and a control algorithm. Alternative strategies exists, and propose fairly sophisticated modifications to the actuator which needs to be embedded in the soft robot. These mainly rely on the integration of structural instabilities in the actuator architecture [1] or on the use of explosive chemical reactions [2].

In this paper, we provide a volume-controlled solution, a bi-shell valve, that bypasses the requirements above [3]. Its operation needs only a slowly dispensed volume input to deliver fast volume output. The function this valve can deliver is unattainable by existing soft valves, which can either fully (on-off control) or partially (flux control) block a fluid flow. Its hallmarks are also distinct over current valve concepts: the architecture encompasses two shells (one spherical cap and one imperfect shell), and its physics is underpinned by the cooperative deformation and snap-through interaction of its constituent shells.

DESIGN OF THE BI-SHELL VALVE

The design of the bi-shell valve (Figure 1a) consists of two elastic shells, a shallow spherical cap and an imperfect hemispherical shell with a large indentation in the form of an axisymmetric elliptical arc. Both shells are mounted on a input chamber, which is used to deflate them by a slow volume-controlled input from the inlet. The spherical cap is also enclosed by an output chamber that capitalizes on its snapping to deliver a fast volume output.

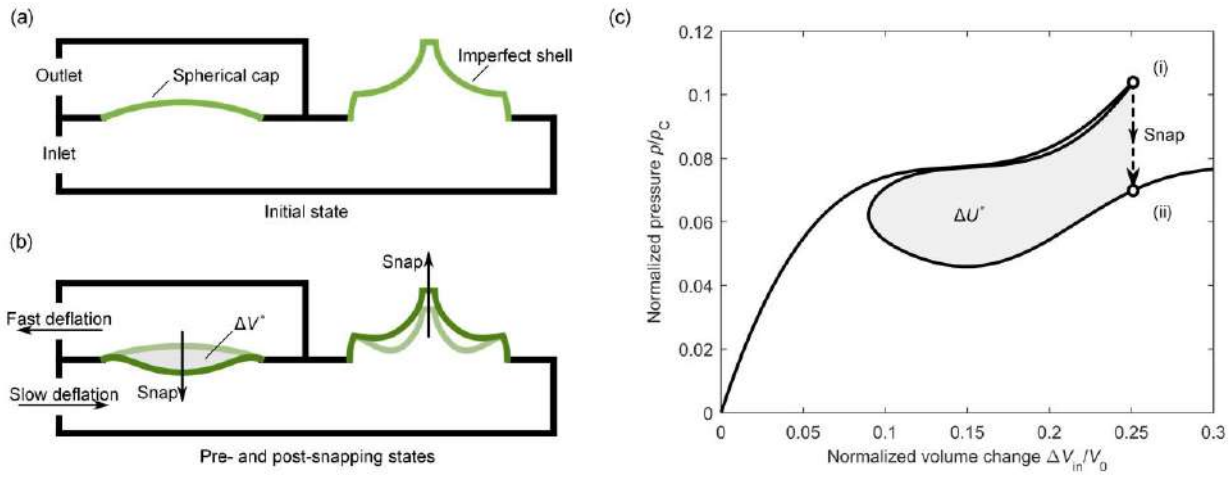

Figure 1. (a) Schematic of the bi-shell valve. (b) The configuration of the bi-shell valve in pre- and post-snapping states. (c) Pressure-volume response of the bi-shell valve.

Figure 1b shows the configuration of the bi-shell valve in its pre- and post-snapping states. When the input chamber of the bi-shell valve is slowly deflated from the inlet, the imperfect shell first deflates during the pre-snapping state (light green), while storing volume change and energy. During this phase, the spherical cap stays almost in its initial shape. After snapping (dark green), the imperfect shell springs up towards its undeformed state, releasing the volume change and energy stored during pre-snapping. The spherical cap, on the other hand, snaps downward to a fully everted state. The sudden collapse of the spherical cap generates a fast volume change ΔV^*, which is depicted by the grey area (Fig. 1c) bounded by the pre- and post-snapping states of the spherical cap. This volume change is captured by the output chamber and is made readily available to rapidly deflate any soft robots that is connected to the valve outlet.

*Corresponding author. E-mail: damiano.pasini@mcgill.ca.

Figure 1c shows the pressure volume response of the bi-shell valve obtained from our analysis. The pressure is normalized with the theoretical buckling pressure p_C of an elastic spherical shell with a radius identical to the radius of the imperfect shell, whereas the volume change is normalized with the volume of a hemisphere V_0. Upon deflation, the pressure gradually increases to the snapping pressure at the pre-snapping state (i), followed by an abrupt drop in pressure when the bi-shell valve snaps to the post-snapping state (ii). During snapping, the bi-shell valve releases the elastic energy ΔU^* (the grey area in Figure 1c), which can be used for rapid actuation of soft robots.

INDIVIDUAL RESPONSE AND INTERACTION OF THE CONSTITUENT SHELLS

Figure 2 shows the individual response (pressure-volume change) of the spherical cap (left - a) and the imperfect shell (right - b). The former exhibits a highly unstable response that is characteristic of elastic spherical thin shells. This is expressed by the quick escalation of pressure to a high critical value (state i) in response to a small volume change, followed by a drop to a lower plateau that spans a wide range of volume change before raising again. On the other hand, the latter shows a stable pressure response over a large volume change, with a buckling mode enabled by the type and geometry of the imperfection. In this case, the pressure-volume response displays three portions: an initial regime where the pressure increases quickly, followed first by a plateau with a mild increase in pressure, and finally by a rapid increase of pressure.

When the shells are connected through the input chamber of the valve, their concerted deformation is governed by the equilibrium of pressure and volume. This condition requires that their pressure must be equal, and that their total volume change should equal the input volume change. At the pre-snapping state (i), both shells share the identical value of pressure. With further deflation, the buckling of the spherical cap triggers a sudden decrease in the pressure resistance of the cap, which forces the bi-shell system to snap and regain the balance of pressure in a new stable state, i.e. the post-snapping state (ii). During snapping, the spherical cap is deflated by ΔV^*, while the imperfect shell is inflated by the same amount of volume change. The total energy released during snapping ΔU^* (Fig. 1c) is the difference between the energy released by the imperfect shell ΔU_2^* (Fig 2b) and the energy stored by the spherical cap ΔU_1^* (Fig 2a).

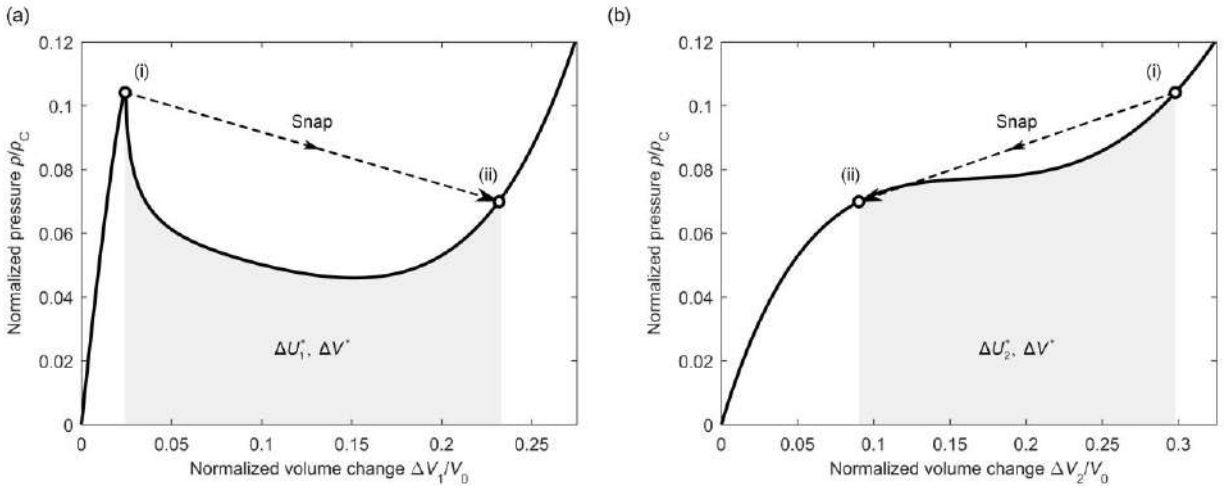

Figure 2. Pressure-volume change responses of the constituent shells. (a) The spherical cap. (b) The imperfect shell.

CONCLUSIONS

This work has introduced a bi-shell valve that harnesses the snapping and interaction of its constituent shells to convert a slow volume input into a fast volume output for fast actuation of soft robots. The valve can be directly connected to a soft robot without modifications to its design, and its performance can be controlled passively by simply tuning the shape of its constituent shells. The bi-shell valve concept introduced in this work along with its variational designs can offer new routes to provide actuation and control of soft pneumatic actuators.

NON-ORIENTABLE MECHANICS IN METAMATERIALS

Xiaofei Guo*[1,3], Marcelo Guzman[2], Denis Bartolo[2], David Carpentier[2], and Corentin Coulais[1]
[1]Institute of Physics, University of Amsterdam, Amsterdam, Netherlands

Summary Non-orientability is a topological property, which has potential to achieve novel and unusual mechanical behaviours. However, the complex geometry of non-orientable structures limits their applications in the real world. Here we show that it is possible to achieve non-orientable mechanics in an orientable metamaterial. This is achieved by geometrical frustration, which generates a single movable domain wall in periodic structures during loading. The moving path of the domain wall can be controlled by the loading sequence, which leads to different mechanical responses. In other words, the proposed metamaterial can break abelian rules and has a sequential memory. Based on the sequential memory, we build a mechanical sequential logic gate, which can achieve the same value table as a Set-Reset latch, one of the most basic sequential logic gates in electronic fields. The concept of non-orientable mechanics opens up a new avenue for new designs of metamaterials and mechanical logic gates.

BACKGROUND

Unlike avoiding imperfections in traditional metamaterials, flexible metamaterials harness instability, defect and frustration to achieve novel functionalities, such as pattern and shape transformations[1, 2], reprogrammable property[3] and multistability[4]. However, few studies have focused on the mechanics in non-orientable structures, which has potential to achieve new functionalities. But the non-orientability generally leads to complex geometries, which limits applications. Here we achieve non-orientable mechanics in an orientable structure using instability and frustration. The concept of non-orientable mechanics provides new ideas for metamaterials designs.

NON-ORIENTABLE MECHANICS

Orientability is a topological property of surfaces, which describes whether it is possible to make a consistent choice of surface normal vector at every point. A Mobius strip is the simplest non-orientable surface. Due to the non-orientability, Out-of-plane deformations or shear deformations must pass through zero in one round of a Mobius strip[5], which is robust and topologically protected. The topologically protected zero point is the characteristic of non-orientable mechanics.

Here we show that it is possible to achieve non-orientable mechanics in an orientable metamaterial: the rotating-square mechanism. The unit cell of rotating-square mechanisms includes up and down two squares and arranges along the horizontal direction (Fig.1(a)). In an open rotating-square chain, adjacent unit cells always trend to rotate in opposite directions like a mechanical antiferromagnet[6]. Once a rotating-square chain is closed by joining its ends together, the mechanism of a rotating-square ring depends on the parity of total number of unit cells. If the number of unit cells is even, it still can follow the compatible antiferromagnetic mechanism. If the number of unit cells is odd, the rotating-square ring forms a frustrated mechanism (Fig.1(a)). The frustration leads a conflict between two opposite rotating mechanisms. The junction between two rotating mechanisms is defined as a domain wall, at where the rotation is zero. Therefore, an odd number rotating-square system always has a zero deformation point, like the non-orientable mechanics in a Mobius strip.

NON-ABELIAN MECHANICS

Due to the single domain wall, rotating-square ring can achieve non-abelian mechanics under three compressive forces. Three forces applied on the rotating-square ring are marked as A, B and C. The response of the loading sequence as A→B→C is different from the response of the loading sequence as A→C→B (Fig.1(b)). Therefore, the proposed mechanism has a sequential memory. It also can be represented as non-abelian mechanics, i.e. $A+B+C \neq A+C+B$. The reason of realizing non-abelian mechanics includes the characteristic property of buckling and the move of the domain wall. Different loading sequences push the domain wall along different paths(Fig.1(b)), which leads to different responses of deformations and achieves non-abelian mechanics in statics.

SEQUENTIAL LOGIC GATES

The non-abelian property of non-orientable mechanics gives a system sequential memories, which enables it to achieve a mechanical sequential logic gate. Unlike combinatorial logic, the output of sequential logic not only depends on the current input, also its previous states. To achieve a mechanical logic gate by the rotating-square ring, input and output codes are defined as follows. Similar to the previous discussion, three forces A, B and C are applied. The force A is defined as a pre-load, which is not included in the input. Therefore, there are two inputs, force B and C, which are applied

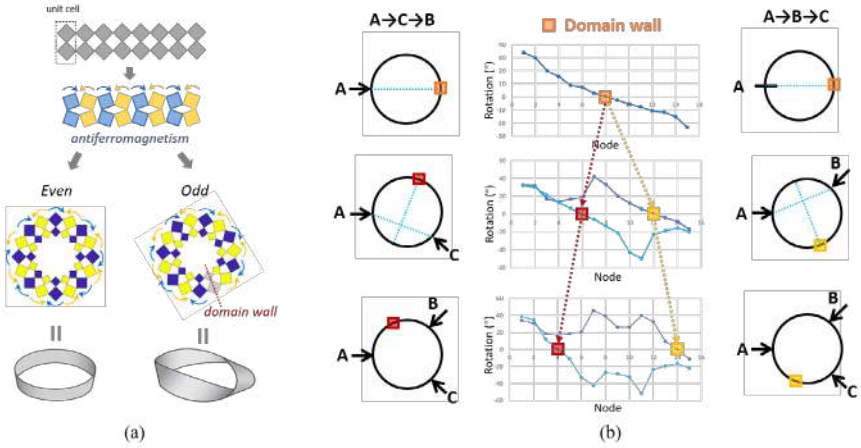

Figure 1: **Non-orientable mechanical metamterials.** (a) The antiferromagnetic rotating mechanism. If the number is odd(even), the rotating-square ring has the similar non-orientable(orientable) mechanics as a Mobius(cylinder) strip. (b) The moving path of the domain wall of the rotating-square ring depends on the loading sequences, which leads to different mechanical responses and achieves non-abelian mechanics, $A + B + C \neq A + C + B$.

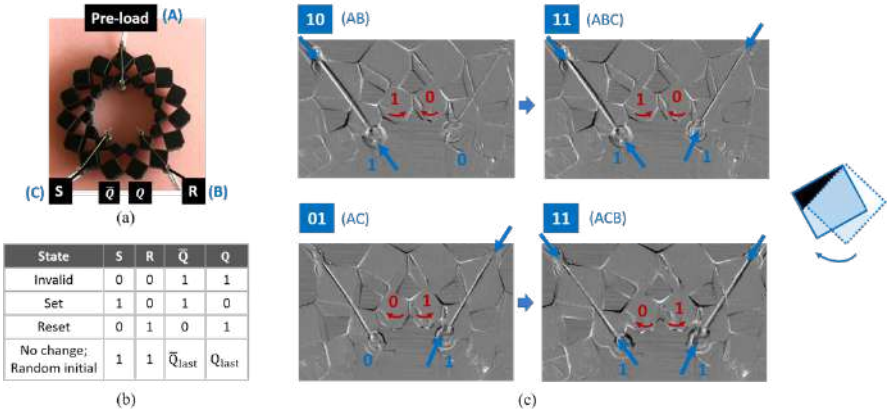
by actuators (Fig.2(a)). Their actuated states are respectively represented as R and S. If the actuator is on(off), S or R is coded as 1(0). The outputs are the deformations of two unit cells between two actuators. If the unit cell rotates anticlockwise(clockwise), it is coded as 1(0). Since the adjacent unit cells rotate in different direction, the two outputs are marked as Q and $\bar{Q}$. All responses of this mechanical logic gate exactly conform to the value table of a Set-Reset flip-flop (Fig.2(b)(c)), one of the most basic sequential logic gates.



State	S	R	$\bar{Q}$	Q
Invalid	0	0	1	1
Set	1	0	1	0
Reset	0	1	0	1
No change; Random initial	1	1	$\bar{Q}_{last}$	Q_{last}

(b)

Figure 2: **Mechanical sequential logic gates.** (a) The setup used to achieve a mechanical Set-Reset flip-flop, one of the most typical sequential logic gates. (b) The value table of a Set-Reset flip-flop. (c) The responses under different actuation states in experiments. The rotation direction of unit cells is marked by black and white triangles.

CONCLUSIONS

In summary, we proved that it is possible to achieve non-orientable mechanics in a flat orientable metamaterial. It is achieved by the antiferromagnetic rotating mechanism. When the number of unit cells is odd, the antiferromagnetic mechanism forms a frustration. The frustration automatically generates a domain wall, which is similar to the topologically protected zero point in a Mobius strip. The moving path of the domain wall depends on the loading sequences and achieves non-abelian property. A mechanical sequential logic gate was built using the sequential memory of the rotating-square ring. The concept of non-orientable mechanics opens up a new avenue for metamaterials designs.

A SIMPLE MACROSCALE MODEL OF THERMOMECHANICAL RESPONSE OF TCPF ACTUATORS

Miha Brojan*[1] and Jan Zavodnik[1]
[1]Laboratory for Nonlinear Mechanics, University of Ljubljana, Ljubljana, Slovenia

Summary The recent discovery of a negative effective thermal expansion in twisted and coiled polymer fibres (TCPFs), has opened new routes for development of systems that can mimic natural skeletal muscles. It was shown that TCPF actuators are a viable alternative to pneumatic, hydraulic and electric actuators due to their ability to develop a significant force per unit mass, low cost of manufacture and ease of operation. To optimize the development and functionality of TCPFs, a comprehensive modelling of thermal untwist and the TCPF shortening is of great importance. For this purpose, we present a concise and simple mathematical model capable of describing thermally induced deformation and additionally, elastic deformations caused by mechanical loads and residual torsion from the fabrication process. We show a remarkable match between the theory and experiments.

TCPF CONTRACTION MECHANISM

Twisted and coiled polymer fibres (TCPFs, shown in Fig. 1) have been proposed by Haines et al. [1]. Since then this system has attracted a lot of attention as it has found use in many applications, e.g. as pneumatic and hydraulic actuator alternatives, for residual energy harvesting, as limb actuators, robotic arms, self-regulating relayes, etc. The main advantages of the TCPF actuators are their low production cost, simplicity and the ability to perform large strokes.

The TCPFs are essentially twisted and then coiled crystalline polymeric fibres of nylon, polypropylene or some other polymers, which exhibit a thermal expansion anisotropy in the longitudinal/transverse fibre direction. The thermal expansion anisotropy is a direct consequence of the polymer chain orientation following the extrusion process. It is precisely this anisotropy that causes the twisted fibres to untwist during heating, resulting in a change of the helix angle and an effective shortening of the twisted and coiled polymer fibre. This large effective shortening of the TCPF is harvested in actuator applications, as large strokes are often required in various applications.

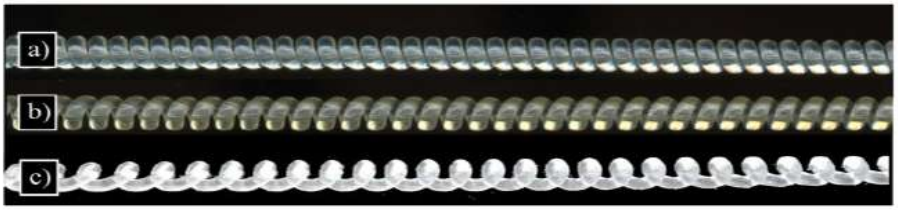

Figure 1. a) Coiled virgin TCPU b) Thermally treated TCPU c) Plastically deformed TCPF.

Several models that describe the TCPF behaviour have been proposed. The commonality between the models is that they are often either too simple to accurately describe the phenomenon or are way too convoluted to enable a deep understanding and rapid parametric analysis of the TCPF response. In our study we focused on understanding the TCPF mechanics via concise theoretical modelling and precise experiments. We therefore present a simple, concise, yet accurate mathematical model to predict and describe the mechanisms that govern the TCPF contraction and force production.

The first part of our model describes the temperature expansion fiber untwist with the use of a simple transverse anisotropic thermal expansion material model. The twisted fibre thermal expansion anisotropy is modelled in the local coordinate system that follows the rotation of polymer chains rather than in a global coordinate system that is fixed to the fibre. Therefore, we can more easily follow the untwist of the fibre. We find that a model reduction in terms of assuming axial symmetry of the polymer fibre, assuming that untwist is constant along the fibre and employing an averaging in the radial direction can significantly simplify the solution procedure while maintaining a remarkable accuracy of the problem within the performance limits of the TCPFs. This way we find that the temperature and axial loading cause an effective fibre untwist which can be written as

$$\Delta\phi^{\mathrm{eff}}(T,F)=\frac{4\varepsilon(\phi_0+\Delta\phi_F)}{\gamma_{l\phi,0}^4}\left(\gamma_{l\phi,0}^2-(1-2\varepsilon(T))\ln\left(1+\frac{\gamma_{l\phi,0}^2}{1-2\varepsilon(T)}\right)\right)+\Delta\phi_F(T,F).$$

Here ϕ_0 is the initial fibre twist, $\gamma_{l\phi,0}=\phi_0 r_0/l_0$ is the dimensionless initial fibre twist with r_0 as initial outer fibre radius, l_0 is the initial fibre length, ε labels the difference between the longitudinal and the circumferential/radial polymer thermal expansion, expression $\Delta\phi_F(T,F)$ is the axial force caused untwist that depends on the force F and the temperature dependent material parameters. This axial force caused untwist can be calculated e.g. from the principle of virtual work.

*Corresponding author. E-mail: miha.brojan@fs.uni-lj.si

The second part of our model describes the kinematic connection between the thermally caused untwist $\Delta\phi^{eff}$ and the TCPF effective shortening. Our kinematic relation between the fibre untwist and helix angle stems directly from the differential geometry where the change of twist is described as

$$\tau = |\frac{\partial^2 r}{\partial s^2}|^{-2}\left[\frac{\partial \boldsymbol{r}}{\partial s}, \frac{\partial^2 \boldsymbol{r}}{\partial s^2}, \frac{\partial^3 \boldsymbol{r}}{\partial s^3}\right].$$

Here $\boldsymbol{r}$ is the position vector describing the spatial curve and s is the arc-length parameter. The total twist can therefore be calculated as $\phi = \tau l + \Gamma$, where Γ is the residual twist emanating from fabrication. From here the kinematic relation for a helix is written as

$$\Delta\phi = 2\pi n(\cos\tilde{\theta} - \cos\theta),$$

where n is the number of coils, $\tilde{\theta}$ is the deformed helix angle and θ is the initial helix angle. This relation offers a direct insight into the behaviour of the TCPFs.

Furthermore, a simple, low-cost, but effective experimental setup (not shown here) that allows the study of TCPF fabrication mechanics and the validation of the theory was also developed. The fabrication process itself is not complex but requires at least a qualitative knowledge of the physical phenomena at play in order to successfully fabricate a high quality TCPF. With the use of our experimental setup, we explore and describe the good practice and underlying mechanism of the coiling process in order to successfully fabricate a high performance TCPF. An excellent agreement between our theoretical results and the results from the literature [2,3,4] is shown in Fig. 2.

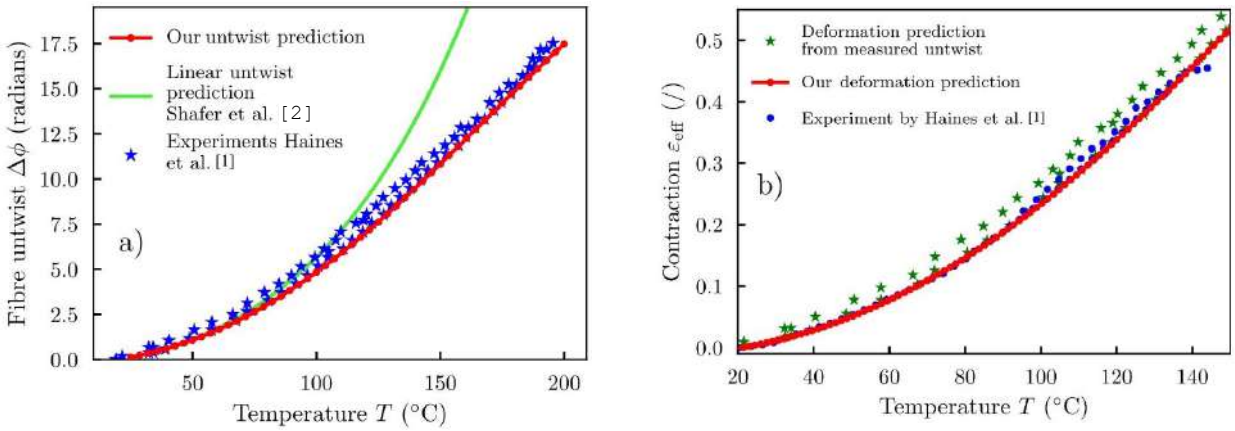

Figure 2: Comparison between our theoretical predictions, experiments by Haines et al. [1] and model by Shafer et al. [2]. a) Fibre untwist as a function of temperature. b) TCPF contraction as a function of temperature.

CONCLUSIONS

In our study we focused on understanding of the TCPF mechanics via concise theoretical modelling and precise experiments. We have developed a simple and accurate theoretical model to describe the behaviour of TCPFs in which we consider thermally induced deformation, elastic deformations caused by mechanical loads and residual torsion from the fabrication process. The proposed model describes the anisotropy without unnecessary complexity and is accurate within the performance limits of the TCPFs. With the use of our model and experimental setup we described the underlying mechanism of the coiling process to successfully fabricate a high performance TCPF. We show a very good match between the theory and experiments.

PIECEWISE VARIABLE STRAIN APPROACH FOR THE MODELING OF SOFT ROBOTS: THEORY AND APPLICATION

Costanza Armanini*[1], Frederic Boyer[2], and Federico Renda[1,3]
[1]Department of Mechanical Engineering, Khalifa University of Science and Technology, Abu Dhabi, UAE
[2]LS2N lab, Institut Mines Telecom Atlantique, 44307 Nantes, France.
[3]Khalifa University Center for Autonomous Robotic Systems (KUCARS), Khalifa University of Science and Technology, Abu Dhabi, UAE

Summary One of the main challenges in the soft robotics field is the development of mathematical models capable of describing the complex deformed configurations with both accuracy and simplicity. In an effort to develop models based on continuum mechanics and parametrized by a small set of relative, serial-link DOFs, the Piecewise-Constant-Strain (PCS) approach has been proposed [1] to efficiently model soft, rigid and hybrid multi-body systems within the same framework. Here, the PCS approach is generalized to the case of non-constant strains and applied to the static equilibrium of soft manipulators internally actuated by tendon and/or fluidic chambers with general routing [2]. Moreover, we present an example of application of the modeling approach for the design and development of a novel generation of macro-scale underwater propellers that draw their inspiration from flagellated organisms.

DISCRETE VARIABLE-STRAIN MODEL

Continuum kinematics and statics

A Cosserat rod is a continuous stack of rigid cross-sections parametrized by a material curvilinear abscissa $X \in [0, L]$ where L is the total length of the rod. Identifying each rigid cross-section with the moving frame rigidly attached to it, the configuration space of the rod is completely defined by a curve $\boldsymbol{g}(\cdot) : X \mapsto \boldsymbol{g}(X) \in SE(3)$ represented by the homogeneous matrix:

$$\boldsymbol{g} = \begin{pmatrix} \mathbf{R} & \mathbf{r} \\ \mathbf{0}^T & 1 \end{pmatrix}, \tag{1}$$

where $\mathbf{r}(X) \in \mathbb{R}^3$ is the position vector of the origin of the moving frame and $\mathbf{R}(X) \in SO(3)$ is the rotation matrix representing its orientation with respect to the spatial frame. Considering the Lie algebra $\mathfrak{se}(3)$ of $SE(3)$, the derivative of $\boldsymbol{g}$ with respect to X defines the strain state of the rod $\widehat{\boldsymbol{\xi}}(\cdot) : X \mapsto \widehat{\boldsymbol{\xi}}(X) \in \mathfrak{se}(3)$, while the equality of mixed partial derivatives of $\boldsymbol{g}$ with respect to space X and time t yields the velocity of the moving frame $\widehat{\boldsymbol{\eta}}(\cdot) : X \mapsto \widehat{\boldsymbol{\eta}}(X) \in \mathfrak{se}(3)$:

$$\boldsymbol{g}' = \boldsymbol{g}\widehat{\boldsymbol{\xi}}\,, \qquad\qquad \boldsymbol{\eta}' = \dot{\boldsymbol{\xi}} - \mathrm{ad}_{\boldsymbol{\xi}}\boldsymbol{\eta}\,, \tag{2}$$

where ad is the adjoint map. We consider now the static equilibrium of a Cosserat rod internally actuated by a distributed tendons and/or fluidic chambers. Taking the equilibrium of a section of an elastic rod and limiting the length of the section to zero, the static ordinary differential equation and its final value are obtained:

$$\begin{aligned} &(\boldsymbol{\mathcal{F}}_i - \boldsymbol{\mathcal{F}}_a)' + \mathrm{ad}^*_{\boldsymbol{\xi}}(\boldsymbol{\mathcal{F}}_i - \boldsymbol{\mathcal{F}}_a) = \mathbf{0}\,, \\ &\boldsymbol{\mathcal{F}}_i(L) = \boldsymbol{\mathcal{F}}_a(L)\,, \end{aligned} \tag{3}$$

Above, $\boldsymbol{\mathcal{F}}_i(X)$ and $\boldsymbol{\mathcal{F}}_a(X)$ represent the internal elastic and the actuation load respectively, given by:

$$\boldsymbol{\mathcal{F}}_i(X) = \boldsymbol{\Sigma}(X)\left(\boldsymbol{\xi}(X) - \boldsymbol{\xi}^*\right) \qquad \boldsymbol{\mathcal{F}}_a(X) = \begin{bmatrix} \tilde{\boldsymbol{d}}(X)\boldsymbol{t}(X) \\ \boldsymbol{t}(X) \end{bmatrix} \tau\,, \tag{4}$$

where $\boldsymbol{\Sigma}(X)$ is the elasticity tensor matrix, $\boldsymbol{d}(X)$ represents the distance from the mid-line to the internal actuator, $\boldsymbol{t}(X)$ is the unit vector tangent to the actuator path, and τ is the magnitude of the actuation force given by the tension of the tendon or by fluid pressure for a fluidic actuation.

Discrete model

The infinite dimensional strain field $\boldsymbol{\xi}$ can be discretized by selecting a set of vector functions to form a finite basis for the field. This can be represented as:

$$\boldsymbol{\xi}(X) = \boldsymbol{B}_q(X)\boldsymbol{q} + \boldsymbol{\xi}^*\,, \tag{5}$$

where $\boldsymbol{B}_q(X) \in \mathbb{R}^{6\times n}$ is a matrix function whose columns form the basis for the strain field $\boldsymbol{\xi}$ and $\boldsymbol{q} \in \mathbb{R}^n$ is the vector of coordinates in that basis, n being the number of degrees of freedom. Inserting the strain discretization, the velocity-strain equation can be analytically integrated:

$$\boldsymbol{\eta}(X) = \left[\mathrm{Ad}^{-1}_{\boldsymbol{g}} \int_0^X \mathrm{Ad}_{\boldsymbol{g}}\boldsymbol{B}_q ds\right]\dot{\boldsymbol{q}} = \boldsymbol{J}(\boldsymbol{q}, X)\dot{\boldsymbol{q}}\,, \tag{6}$$

*Corresponding author. E-mail: costanza.armanini@ku.ac.ae.

which defines the geometric Jacobian $\boldsymbol{J}(\boldsymbol{q}, X) \in \mathbb{R}^{6\times n}$ for a variable-strain soft manipulator. Finally, it is now possible to obtain the generalized static equation of the system by virtue of the D'Alembert's principle:

$$\int_0^L \boldsymbol{B}_q^T \boldsymbol{\mathcal{F}}_i dX = \int_0^L \boldsymbol{B}_q^T \boldsymbol{\mathcal{F}}_a dX \,, \qquad \boldsymbol{\mathcal{F}}_a(X) = \boldsymbol{B}_\tau(\boldsymbol{q}, X)\boldsymbol{\tau} \,, \tag{7}$$

where $\boldsymbol{B}_\tau(\boldsymbol{q}, X) \in \mathbb{R}^{6\times n_a}$ is a matrix function whose columns are given by vector functions and $\boldsymbol{\tau} \in \mathbb{R}^{n_a}$ is the vector of magnitude actuation forces. In Figure 1, we present the modeling of a conical arm, with linear and helical path actuators in the reference configuration, i.e.: the distance $\boldsymbol{d}(X)$ to the center-line has respectively linear and sinusoidal coordinates in the local frame.

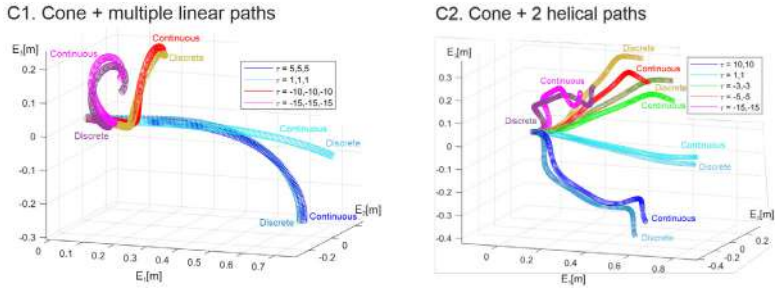

Figure 1: Example of a conycal manipulator with (left) linear and (right) helical path actuators.

A FLAGELLUM PROPELLER: MODELLING AND TESTING

The proposed model is employed to design a macro-scale aquatic soft robot propeller inspired by flagellated prokaryotic bacteria. Interacting with the surrounding fluid, the propeller exploits the compliance of its own body to passively attain a range of stable helical waves which are responsible for the generation of positive net thrust. We investigate the relationship between actuation frequency and material elasticity in determining the steady-state configuration of the system and its thrust output. Different experiments are performed and finally a complete robot is fabricated.

A THEORETICAL STUDY ON THE TRANSIENT MORPHING OF LINEAR POROELASTIC PLATES

Dario Andrini[1], Alessandro Lucantonio[2], and Giovanni Noselli[1]
[1]Department of Mathematics, SISSA–International School for Advanced Studies, Trieste, Italy
[2]Department of Excellence in Robotics & AI, The BioRobotics Institute, Scuola Superiore Sant'Anna, Pisa, Italy

Summary Based on their shape-shifting capabilities, soft active materials have enabled new possibilities for the engineering of sensing and actuation devices. While the relation between strains and equilibrium shapes has been fully characterized, the transient morphing of thin structures is rather unexplored. Here we focus on polymer gel plates and derive a reduced linear model to study their time-dependent response. We show that independent control of stretching and bending deformations in stress-free conditions allows to realize spherical shapes with prescribed geometry of the mid-plane. Further, we demonstrate that tensile (compressive) membrane stresses delay (accelerate) swelling-induced shape transitions, as compared to the stress-free evolution. We believe that these effects should be considered for the accurate design of smart systems and may contribute to explain the complexity of natural shapes.

A LINEAR MODEL FOR THIN POROELASTIC PLATES

Understanding the way natural systems control and exploit shape changes to achieve biological functions is currently the subject of intense research inspiring the realization of synthetic replicas of natural shape morphing mechanisms using smart materials. Particular attention has been devoted to thin structures, such as plates and shells and to the exploration of their final equilibrium configurations. However, very little is known about the transient processes of morphing, apart from mainly experimental reports [1].

In this work, we focus on the transient shape morphing of poroelastic plates made of swelling gels. Despite geometric non-linearities play a crucial role in determining the configurations of active plates, we employ a linearized theory that is amenable to explicit analytical treatments.

The system of evolution equations for Kirchhoff linear poroelastic plates was first derived by Taber [2] starting from the three-dimensional setting, and later justified in [3]. Here we proposed an alternative derivation, following a formal asymptotic expansion approach inspired by Miara [4].

Let $\mathcal{B} = \omega \times (-h/2, h/2) \subset \mathbb{R}^3$ be the undeformed equilibrium configuration of the plate (ω is the mid-surface whereas h denotes the thickness). We write $(\mathbf{x}, x_3) \in \omega \times (-h/2, h/2) \subset \mathbb{R}^3$ for a point of the plate. The state of the plate is determined by the in-plane and transverse displacement fields $\mathbf{u}$ and u_3 respectively and the chemical potential μ. We finally introduce the in-plane strain $\mathbf{E} = \operatorname{sym} \nabla \mathbf{u}$ and curvature $\mathbf{K} = -\nabla\nabla u_3$ tensors.

We will consider cases where a free standing poroelastic plate is immersed into a solvent bath: null tractions are imposed on $\partial\omega$ and Dirichlet conditions $\mu = \mu_\star^\pm$ on $\omega \times \{\pm h/2\} := \omega^\pm$.

The symmetries of the governing equations allow to establish the dependence of the solution on the boundary conditions. We have that $\mathbf{E} = \mathscr{P}[\mu_m]$ and $\mathbf{K} = \mathscr{Q}[\mu_d]$ where $\mathscr{P}$ and $\mathscr{Q}$ are two linear operators and $\mu_m = (\mu_\star^+ + \mu_\star^-)/2$, $\mu_d = (\mu_\star^+ - \mu_\star^-)/2$. As a consequence of this $\mu_\star^+$ and $\mu_\star^-$ can be chosen so as to select any of the admissible evolutions of in-plane strain and curvature corresponding to given values of μ_m and μ_d, respectively. Consequently, there is no mutual influence between strain and curvature dynamics, a feature of interest in the context of the shape control of thin structures. We remark that this decoupled response is not expected to occur in the context of non-linear theories.

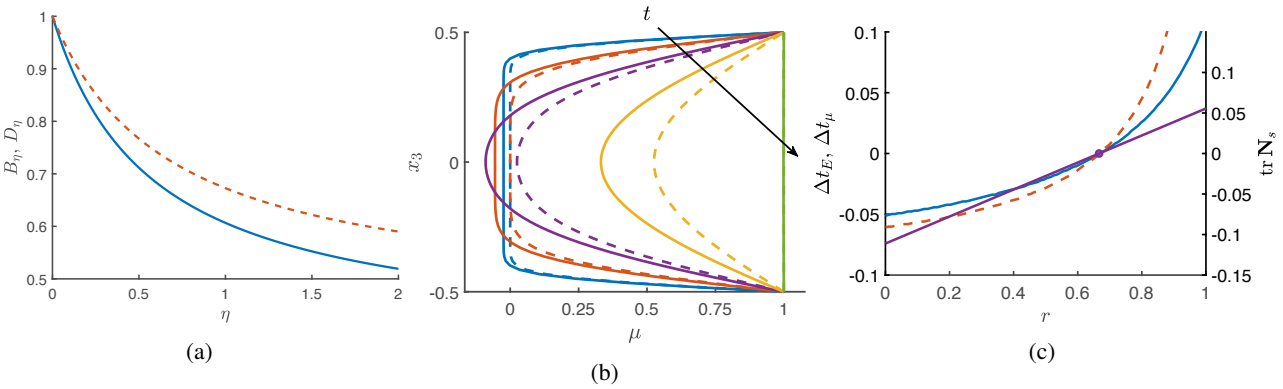
ANALYSIS OF THE STRESS-FREE PROBLEM

We now focus on a special class of solutions whose (thickness averaged) in-plane stress ($\mathbf{N}$) and bending moment ($\mathbf{M}$) are null everywhere in ω. We will refer to this problem as the stress-free problem.

First we derive necessary and sufficient conditions for the boundary conditions on μ to produce stress-free solutions. They need to satisfy $\Delta\mu_m = 0$ and $\nabla\mu_d = 0$ such that $\mu_\star^+$ and $\mu_\star^-$ are harmonic functions whose difference must be constant. As a consequence of that we conclude that stress-free configurations correspond to spherical shapes with any prescribed geometry of the mid-plane.

Next we obtain an analytical solution using the method proposed by Taber [2], in particular the procedure requires to take the Laplace transform of the governing equations in time. However the inverse transform cannot be analytically computed and so we present approximate solutions which are shown to be of significant accuracy. Interestingly these reveal an exponential decay through which the process reaches the stationary state. More specifically $\mathbf{u}$ and u_3 decay like $e^{-\pi^2 B_\eta t}$ and $e^{-4\pi^2 D_\eta t}$ respectively. The coefficients B_η and D_η have an explicit expression depending on the parameter $\eta = G/\lambda$ where G and λ are the shear and the bulk moduli respectively. Their dependence on η is depicted in Figure 1a. Notice that larger values of η correspond to slower shape changes.

We remark that, in general, the equation regulating solvent diffusion inside the gel is coupled to the displacement field through $\operatorname{tr}\mathbf{E}$ and $\operatorname{tr}\mathbf{K}$. This is not the case in the limit of $\eta \to 0$ where the governing equation for solvent diffusion



(a) (b) (c)

Figure 1: (a) Plots of B_η (solid blue line) and D_η (dashed red line) as functions of η. (b) Evolution in time for the chemical potential for $\mu_m = 1$, $\mu_d = 0$. Continuous line correspond to $\eta = 0.5$ while dashed lines to $\eta = 0$. (c) Time differences Δt_E (solid blue line) and Δt_μ (dashed red line) as functions of the radial coordinate. The purple line represents the trace of $\mathbf{N}$ at equilibrium. The crossover point of $\Delta t_E = \Delta t_\mu$ corresponds to the location where $\mathrm{tr}\,\mathbf{N}_s$ vanishes.

becomes a standard heat equation for μ. Hence Figure 1a shows that the weaker the coupling between diffusion and mechanics, the faster is the process. Finally we compared in Figure 1b the evolution of the profile for the chemical potential in the cases when $\eta = 0.5$ and $\eta = 0$.

EFFECT OF STRESSES ON THE SWELLING DYNAMICS: AN EXAMPLE

Differently from the stress-free case, where the time evolution of fields leading to stationarity is influenced only by mechanical parameters and is independent on the in-plane coordinate, the general fully coupled problem is sensitive to the internal stress distribution. To explore such sensitivity we computed a *semi-analytical* (numerical tools are used to invert the Laplace transform) solution of a specific problem where ω is the unit disk and $\mu_\star^\pm$ are taken with circular symmetry. In particular we chose $\mu_m(r) = 1 - r$ and $\mu_d(r) = 0$ where r is the radial coordinate. Observe that such a distribution of μ_m is not harmonic thus not allowing for a stress-free solution. Our analysis reveals how internal stresses affect pointwisely the process of shape change by swelling. As an average measure of swelling rate, we define the time $t_E(r)$ needed for $\mathrm{tr}\,\mathbf{E}$ to reach its steady state value within a tolerance of 0.1%. We notice that such a measure is conveniently a constant, t_{SF}, which only depends on η for any stress-free problem as already anticipated. Analogously, we introduce $t_\mu(r)$ for $N_\mu := \int_{-h/2}^{h/2} \mu \, \mathrm{d}x_3$. In Figure 1c we report results for $\Delta t_E = t_E/t_{SF} - 1$ and $\Delta t_\mu = t_\mu/t_{SF} - 1$, along with the steady state value of $\mathrm{tr}\,\mathbf{N}$. We notice that *compressive (tensile) stresses promote faster (slower) swelling with respect to the stress-free case*.

CONCLUSIONS

In this work, we have derived trough an asymptotic procedure a linear poroelastic plate model. First, we have studied a stress-free problem that has allowed us to obtain explicit, approximate solutions for the state fields. Then, we have presented a problem where elasticity and solvent transport are fully-coupled, namely, the planar swelling of a circular plate, which we have solved using a semi-analytical approach. We have found that tensile (compressive) membrane stresses delay (accelerate) swelling. Even though such an example concerns a specific choice of geometry and boundary conditions, our results highlight the impact of stresses on the dynamics of swelling of poroelastic plates. Given the theoretical nature of the present paper, we also plan to carry out experiments to validate our conclusions. Future works will be devoted to generalizing our findings, as well as extending the model to the non-linear regime.

THE NON-HERMITIAN PHYSICS OF NON-RECIPROCAL ROBOTIC METAMATERIALS

Corentin Coulais*[1]
[1]Institute of Physics, University of Amsterdam, the Netherlands

Summary We create 1D and 2D robotic mechanical metamaterials wherein we use local control loops to break reciprocity at the level of the interactions between the unit cells to probe a wide range of non-Hermitian phenomena, ranging from the non-Hermitian skin effect, to non-Hermitian topological bulk-edge correspondence and odd-elasticity.

INTRODUCTION

Non-reciprocal transmission of motion is potentially highly beneficial to a wide range of applications, ranging from wave guiding to shock and vibration damping and energy harvesting. To date, large levels of non-reciprocity have been realized using broken spatial or temporal symmetries, yet mostly in the vicinity of resonances, bandgaps or using non-linearities, thereby non-reciprocal transmission remains limited to narrow ranges of frequencies or input magnitudes and sensitive to attenuation. Here, we create 1D and 2D robotic mechanical metamaterials wherein we use local control loops to break reciprocity at the level of the interactions between the unit cells to probe a wide range of non-Hermitian phenomena.

In such systems, we first show theoretically and experimentally that first-of-their-kind spatially asymmetric standing waves at all frequencies and unidirectionally amplified propagating waves emerge. These findings realize the mechanical analogue of the non-Hermitian skin effect. Second, we use this platform to discover a novel form of topological bulk-edge correspondence in a purely non-Hermitian setting. Third, we extend our explorations to the non-linear regime and observe the emergence of non-reciprocal solitons. Finally, we generalise our robotic metamaterials in 2D to create non-reciprocal shape-changing structures that realize odd elasticity.

UNIDIRECTIONALLY AMPLIFIED WAVES

Inspired by recent developments in robotics and active metamaterials, we create a robotic mechanical metamaterial (Fig. 1a) that uses distributed active control to break reciprocity at the level of the interactions between the building blocks themselves (Fig. 1b) [1]. This work builds on the field of active metamaterials, yet with a key new twist: while active metamaterials only have actuating elements, robotic metamaterials include a combination of local sensing, computation, communication, and actuation. As a result, they feature unique wave phenomena, namely asymmetric modes at all frequencies and unidirectional amplification (Fig. 1cb), and in turn realize large, broadband, linear, and self-amplified nonreciprocal transmission of mechanical waves. These findings realize the classical counterpart of the so-called non-Hermitian skin effect, recently theoretically introduced in quantum mechanics. These findings can be further generalized in the nonlinear regime and can lead to the emergence of non-reciprocal dissipative solitons.

(f-g) Corresponding edge mode localized on the right (f) or left (g) for trivial and winding topology, respectively.

NON-HERMITIAN TOPOLOGY AND BULK-EDGE CORRESPONDENCE

In a second time, we endow our 1D robotic metamaterials with non-Hermitian topological properties [2]. In particular, by generalizing the quantum-to-classical analogy to a non-Hermitian setting (Fig. 2), we establish a bulk-edge correspondence for this new type of truly non-Hermitian topology. We find that a change in the non-Hermitian topological invariant is accompanied by a localization change in the zero-energy edge modes (Fig. 2ef). We establish this non-Hermitian bulk-edge correspondence experimentally by measuring both bulk-invariants and edge modes and observe that a change in the non-Hermitian topological invariant coincides with the localization change of the topological edge mode, thus proving the robustness of the theoretical prediction.

ODD-ELASTICITY

Finally, we extend our robotic metamaterial platform to 2D and implement a recent proposal to realize non-symmetric elastic tensors, termed odd-elasticity [3]. Combining experiments, numerics and theory, we demonstrate that 2D non-reciprocal robotic metamaterials can realize non-reciprocal shear-extension coupling, wherein extension induces shear but shear does not induce extension as well as wave propagation even in overdamped conditions. We further evidence peculiar nonlinear behavior, in the form of self-oscillations and multistable response.

CONCLUSIONS

We have shown that non-reciprocal robotic metamaterials can realize a number of intriguing non-Hermitian phenomena and as such are a prime platform to explore non-Hermitian physics. Exciting further works include miniaturization, other non-Hermitian approaches and generalization beyond mechanics.

PHYSICAL BASIS OF THE WILLI-FORM EQUATIONS AND SOME RELATED APPLICATIONS

Zhihai Xiang*[1], Hexuan Gao[1], Yixiao Sun[1], and Zhuyou Hu[1]
[1]Department of Engineering Mechanics, Tsinghua University, Beijing, China

Summary The form-invariant property of wave equations is essential to the success of using transformation methods to design metamaterials. It is well known that the classical elastodynamic equations are not form-invariant, but the Willis equations have this property. We have proved that the Willis-form equations with displacement coupling terms can be naturally obtained by using the transformation method in time domain. Here we show that these equations can also be obtained through energy approach and have clear physical meanings. Based on these understandings, at least three applications are possible. The first is developing a general method to design elastic metamaterials by minimizing the coupling terms. The second is proposing an efficient geometrically nonlinear finite element method with the help of the coupling terms. The third is identifying the distribution of residual stresses based on the coupling terms.

INTRODUCTION

Transformation methods have achieved great success in designing optic and acoustic metamaterials [1]. However, the development of elastic metamaterials is rather slow, because Milton et al. have proved that classical elastodynamic equations in frequency domain transform to the following new elastodynamic equations, which are form-invariant [2]:

$$\boldsymbol{\Sigma} = \boldsymbol{C} : \nabla \boldsymbol{U} + \boldsymbol{S} \cdot \boldsymbol{U} \tag{1a}$$

$$\nabla \cdot \boldsymbol{\Sigma} = \boldsymbol{S}^{\mathrm{T}} : \nabla \boldsymbol{U} - \omega^2 \overline{\boldsymbol{\rho}} \cdot \boldsymbol{U} \tag{1b}$$

where $\boldsymbol{\Sigma}$ and $\boldsymbol{U}$ are amplitudes of stresses and displacements, respectively; $\boldsymbol{C}$ is the elasticity tensor; $\boldsymbol{S}$ is a third-order tensor; $\overline{\boldsymbol{\rho}}$ is the effective mass density that is the function of angular frequency ω.

The unclear physical meaning of $\boldsymbol{S}$ impedes using Eq. (1) to design elastic metamaterials. However, it is interesting that Eq. (1) can be regarded as a special case of the Willis equations in time domain established several decades ago [3]:

$$\langle \boldsymbol{\sigma} \rangle = \boldsymbol{C}_{eff} \otimes \langle \boldsymbol{e} \rangle + \boldsymbol{S}_{eff} \circ \langle \dot{\boldsymbol{u}} \rangle \tag{2a}$$

$$\nabla \cdot \langle \boldsymbol{\sigma} \rangle + \boldsymbol{f} = \boldsymbol{S}_{eff}^{\dagger} \circ \langle \dot{\boldsymbol{e}} \rangle + \boldsymbol{\rho}_{eff} \odot \langle \ddot{\boldsymbol{u}} \rangle \tag{2b}$$

where $\boldsymbol{\sigma}$ is the stress; $\boldsymbol{u}$ is the displacement; $\boldsymbol{e}$ is the linear strain; $\boldsymbol{f}$ is the body force; $\langle\ \rangle$ denotes the ensemble average; the superposed dot denotes the differentiation with respect to time t; $\boldsymbol{C}_{eff}$, $\boldsymbol{S}_{eff}$ and $\boldsymbol{\rho}_{eff}$ are operators related with a dynamic Green's function; $\otimes$, $\circ$ and $\odot$ are non-local operators involving time and space convolutions [4].

However, if we apply transformation method in time domain, we can naturally obtain [5]:

$$\boldsymbol{\sigma} = \boldsymbol{C} : \boldsymbol{e} + \boldsymbol{S} \cdot \boldsymbol{u} \tag{3a}$$

$$\nabla \cdot \boldsymbol{\sigma} + \Delta \boldsymbol{f}_e = \boldsymbol{S}^{\mathrm{T}} : \boldsymbol{e} + \boldsymbol{K} \cdot \boldsymbol{u} + \boldsymbol{\rho} \cdot \ddot{\boldsymbol{u}} \tag{3b}$$

where $\Delta \boldsymbol{f}_e$ is the incremental external body force. When deformation gradient is adopted to connect the displacement before and after transformation, Eq. (3) in frequency domain are the same as Eq. (1). Later on, we proved that Eq. (3) has clear relations with the gradient of pre-stress $\boldsymbol{\sigma}^0$ through differential approach [6], i.e., $\boldsymbol{S} = \boldsymbol{\sigma}^0 \nabla$ and $\boldsymbol{K} = (\nabla \cdot \boldsymbol{\sigma}^0) \nabla$. They can be verified by an experiment of rotational spring [7], and can ensure time synchronization when only spatial transformation is applied [8]. By noticing the differential property of time convolution, Eq. (2) and Eq. (3) are mathematically equivalent [7]. In addition, since pre-stress gradients are explicitly involved, Eq. (3) is also non-local and could be regarded as a special case of Eq. (2), similar to its frequency counterparts of Eq. (1). In this sense, Eq. (3) is reasonably named *the Willis-form equations*.

In the following text, we will derive the Willis-form equations through energy approach, and show that they have solid physical basis. Then, some examples are briefly introduced to demonstrate some potential applications.

THE WILLIS-FORM EQUATIONS FROM ENERGY POINT OF VIEW

In an inhomogeneous media with initial configuration B^0, a material point locates at position $\boldsymbol{x}^0$ in the global Cartesian coordinate system with pre-stress $\boldsymbol{\sigma}^0$. This material point moves to position $\boldsymbol{x}^1$ in the deformed configuration B^1 after a small perturbation, corresponding to a small displacement $\boldsymbol{u} = \boldsymbol{x}^1 - \boldsymbol{x}^0$ and a linear strain $\boldsymbol{e}$. Since the media is inhomogeneous, the strain energy density of this material point is an explicit function of the spatial position [9, 10], which can be presented as:

$$W(\boldsymbol{x}^1, \boldsymbol{e}) \approx W(\boldsymbol{x}^0, \boldsymbol{0}) + \frac{\partial W(\boldsymbol{x}^0, \boldsymbol{0})}{\partial \boldsymbol{e}} : \boldsymbol{e} + \frac{\partial W(\boldsymbol{x}^0, \boldsymbol{0})}{\partial \boldsymbol{x}} \cdot \boldsymbol{u} + \frac{1}{2} \left(\boldsymbol{e} : \frac{\partial^2 W(\boldsymbol{x}^0, \boldsymbol{0})}{\partial \boldsymbol{e} \partial \boldsymbol{e}} : \boldsymbol{e} + \boldsymbol{u} \cdot \frac{\partial^2 W(\boldsymbol{x}^0, \boldsymbol{0})}{\partial \boldsymbol{x} \partial \boldsymbol{x}} \cdot \boldsymbol{u} + 2\boldsymbol{e} : \frac{\partial^2 W(\boldsymbol{x}^0, \boldsymbol{0})}{\partial \boldsymbol{e} \partial \boldsymbol{x}} \cdot \boldsymbol{u} \right) \tag{4}$$

According to the theory of thermodynamics, the stress of this material point in B^1 is $\partial W(\boldsymbol{x}^1, \boldsymbol{e}) / \partial \boldsymbol{e}$, which can be presented in configuration B^0 according to Eq. (4), i.e., the second Piola-Kirchhoff stress of this material point is:

*Corresponding author. E-mail: xiangzhihai@tsinghua.edu.cn.

$$\boldsymbol{\sigma}^1\left(\boldsymbol{x}^0\right) \approx \frac{\partial W\left(\boldsymbol{x}^0,\mathbf{0}\right)}{\partial \boldsymbol{e}} + \frac{\partial^2 W\left(\boldsymbol{x}^0,\mathbf{0}\right)}{\partial \boldsymbol{e}\partial \boldsymbol{e}} : \boldsymbol{e} + \frac{\partial^2 W\left(\boldsymbol{x}^0,\mathbf{0}\right)}{\partial \boldsymbol{e}\partial \boldsymbol{x}} \cdot \boldsymbol{u} = \boldsymbol{\sigma}^0\left(\boldsymbol{x}^0\right) + \boldsymbol{C}\left(\boldsymbol{x}^0\right) : \boldsymbol{e} + \left[\boldsymbol{\sigma}^0\left(\boldsymbol{x}^0\right)\nabla\right]\cdot\boldsymbol{u} \tag{5}$$

Thus, the incremental second Piola-Kirchhoff stress is $\boldsymbol{\sigma} = \boldsymbol{\sigma}^0 - \boldsymbol{\sigma}^0 = \boldsymbol{C}:\boldsymbol{e} + (\boldsymbol{\sigma}^0\nabla)\cdot\boldsymbol{u}$, which is the same as Eq. (3a).

To derive the equation of motion, we firstly establish the incremental Lagrangian function $\Delta L = \Delta W + \Delta V - \Delta T$, where $\Delta W = W(\boldsymbol{x}^1,\boldsymbol{e}) - W(\boldsymbol{x}^0,\boldsymbol{e})$ is the incremental strain energy density; $\Delta V = -\boldsymbol{f}_e^0\cdot\boldsymbol{u} - \boldsymbol{u}\cdot\left(\boldsymbol{f}_e^0\nabla\right)\cdot\boldsymbol{u}/2 - \Delta\boldsymbol{f}_e\cdot\boldsymbol{u}$ is the incremental potential density of external body force (denoted by subscript e); and $\Delta T = \dot{\boldsymbol{u}}\cdot\boldsymbol{\rho}\cdot\dot{\boldsymbol{u}}/2$ is the incremental kinetic energy density. Then, we can obtain the effective body force in configuration B^1 as $\boldsymbol{f}^1 = -\partial\left(\Delta W + \Delta V\right)/\partial\boldsymbol{u} = \boldsymbol{f}_e^0 + \Delta\boldsymbol{f}_e + \left(\boldsymbol{f}_e^0\nabla\right)\cdot\boldsymbol{u} - \left(\boldsymbol{\sigma}^0\nabla\right):\boldsymbol{e} - W^0\nabla - \left(W^0\nabla\nabla\right)\cdot\boldsymbol{u}$, where $W^0 = W(\boldsymbol{x}^0,\boldsymbol{e})$. Therefore, it is obvious that $\boldsymbol{f}^0 = \boldsymbol{f}_e^0 - W^0\nabla$. Here, we can see the extra body force $-W^0\nabla$ due to the inhomogeneous strain energy density and the extra body force $\left(\boldsymbol{f}_e^0\nabla\right)\cdot\boldsymbol{u} - \left(\boldsymbol{\sigma}^0\nabla\right):\boldsymbol{e} - \left(W^0\nabla\nabla\right)\cdot\boldsymbol{u}$ activated by deformation.

Noticing $\nabla\cdot\boldsymbol{\sigma}^0 + \boldsymbol{f}^0 = \mathbf{0}$ in B^0, the incremental equation of motion from B^0 to B^1 can be obtained by [10]:

$$\frac{\partial\left(\Delta L\right)}{\partial\boldsymbol{u}} - \frac{\mathrm{d}}{\mathrm{d}\boldsymbol{x}}\frac{\partial\left(\Delta L\right)}{\partial\boldsymbol{e}} - \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial\left(\Delta L\right)}{\partial\dot{\boldsymbol{u}}} = 0 \quad\Rightarrow\quad \nabla\cdot\boldsymbol{\sigma} + \Delta\boldsymbol{f}_e = \left(\boldsymbol{\sigma}^0\nabla\right)^{\mathrm{T}} : \boldsymbol{e} + \left[\left(\nabla\cdot\boldsymbol{\sigma}^0\right)\nabla\right]\cdot\boldsymbol{u} + \boldsymbol{\rho}\cdot\ddot{\boldsymbol{u}} \tag{6}$$

which is the same as Eq. (3b).

APPLICATIONS

Since the Willis-form equations have very clear physical meanings, it is possible to explore related applications.

The first application is based on the finding that the elastic potential energy is nearly form-invariant after conformal mappings, when the longitudinal wave velocity is much larger than the transverse wave velocity [11]. This means that it is possible to use the transformation method to design elastic metamaterials by minimizing the extra coupling term. Experimental results of a vibration isolator [11] and an elastic wave concentrator [12] designed in this way demonstrate that these metamaterials have good low frequency performances through wide frequency bandwidths.

Another application aims at utilizing pre-stress gradients to construct a natural secant stiffness matrix. In this way, we can accelerate the geometrically nonlinear finite element analyses, and introduce natural perturbations near the critical point [13]. Without assuming the form of imperfections, the obtained buckling loads are about 10% lower than those of perfect shells by using classical numerical methods and are very close to experimental results for nearly perfect shells.

Since the Willis-form equations contain the pre-stress gradients, they can be used to identify the distribution of residual stresses, especially around notches [14]. Experimental re • sults demonstrate that this identification method can achieve high accuracy if the residual stresses gradient is significant compared with material tangent stiffness.

CONCLUSIONS

Here we clarify the physical basis of the Willis-form equations. Since pre-stress gradients are explicitly included, these equations are intrinsically non-local and can be regarded as special cases of the original Willis equations. We can envisage that the potential applications of these equations are not limited to the examples given here.

NONLINEAR DYNAMICS OF MECHANICAL METAMATERIALS MADE OF SNAPPING SHALLOW ARCHES

Eleonora Tubaldi[*1], Gabriele Librandi[2], and Katia Bertoldi[*2]
[1]Department of Mechanical Engineering, University of Maryland, College Park, USA [2]School of Engineering and Applied Sciences, Harvard University, Cambridge, USA

Summary Classic snap-through buckling behavior of shallow arches represents a source of inspiration for engineering new nonlinear mechanical metamaterials. In this study, we realize snapping bistable nonlinear structures using arches as building block. The goal is to allow signal transmission by exploiting the sudden reconfiguration of a system of arches excited in one single element. To this end, two designs are proposed: (i) sequence of elastic shallow arches (i.e. buckled beams) with progressively decreasing rises, and (ii) sequence of elastically and plastically deformed shallow arches with the same rise. These nonlinear mechanical metamaterials are designed to manipulate the propagation of elastic pulses in unprecedented ways.

ANALYSES AND EXPERIMENTS

Dynamics of a single shallow arch has been studied for decades and snap-through instability has been investigated under several loading conditions [1-3]. Recent studies have focused even further on the snap-through instability of this structural element discovering new interesting features (critical slowing down [4]) and applications for jumping poppers [5]. Snap-through instability can also be exploited for mechanical signal transmission [6, 7].
A straight steel beam (Figure 1(a)) can be manufactured into a shallow arch by either plastically deform it (Figure 1(b)) or by elastically buckle it (Figure 1(c)). The elastic shallow arch (Figure 1(c)) is a symmetric element that can snap between two equilibrium conditions associated to the same potential energy wells. Thus, the snapping of a series of arches connected by rotating hinges is limited by the damping of the system that will eventually stop the snapping motion. We propose two strategies to overcome this issue and realize a chain of "energetic favorable" snap-through instabilities: (i) progressively decreasing the rise of a chain of arches reducing the energy barrier to overcome between the two stable equilibrium configurations (Figure 1(d,f)), (ii) introducing a plastically deformed shallow arch (Figure 1(b)) in its inverted configuration (Figure 1(e,g)).

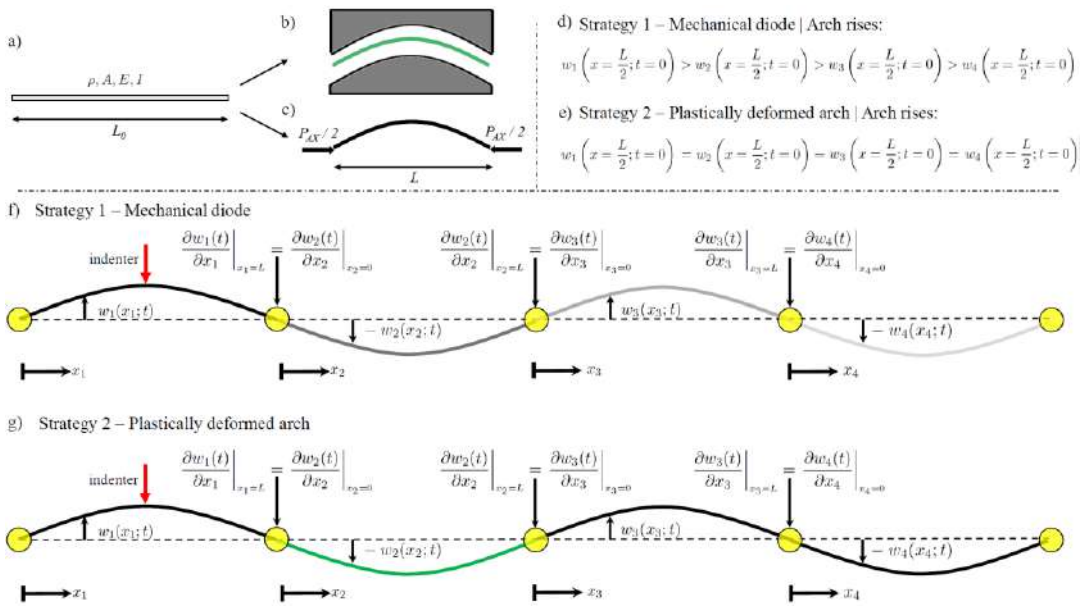

Figure 1. (a) A straight steel beam is manufactured into a shallow arch by (b) either plastically deform it or by (c) elastically buckle it. Both the plastically deformed arch and the buckled beam have an end-to-end distance equals to $L < L_0$. Arch rise sequence of (d) Strategy 1 and (e) Strategy 2. (f-g) Schematic of Strategy 1 and 2, respectively. All the arches are simply supported and the hinges are represented by the yellow circles. Hinges impose the rotation of two consecutive arches to be the same.

Thanks to the first strategy we can design a reversible and tunable mechanical diode that allows the propagation of incoming signals from one direction but blocks the ones propagating in the other one. The mechanical diode is also reversible because in the transmitting direction multiple signals can propagate. To propagate a signal in a sequence of arches with the same rise, the second strategy requires the introduction of an element that acts as a "battery" and it releases energy once activates. This element is represented by the plastically deformed shallow arch (green arch in Figure 1) which snaps between two asymmetric equilibrium conditions undergoing a large, nonlinear displacement. In its initial

*Corresponding authors. E-mail: etubaldi@umd.edu, bertoldi@seas.harvard.edu.

configuration, the plastic shallow arch is placed in its high energy well which is given by its inverted equilibrium condition. Then, the transition from its high energy well to the lower energy well is triggered by the snapping of the preceding elastic arch. This tailorable transition from high to low strain potential energy results in a release of energy that is exploited to propagate a stable signal in the "metastructure" of these bistable elements at an arbitrary distance.
We use a combination of experiments and analytical modelling to investigate both systems. Experiments have been performed on sequences of four shallows arches for both strategies. In Figure 2, experimental results for the Strategy 1 are showed. The rises of the four arches are slightly decreasing in such a way that the arch with the blue circle has a biggest rise and the last arch with the green circle has the smallest rise. The indenter pushes the first arch downwards and the arch is in contact with the indenter up to t = 0.85s. It is worth noticing that at t = 0.85s, while the hinge between the first and second arch has started to rotate inducing a motion to the second arch, the third and fourth arches still do not perceive the motion of the other arches. For t > 0.85s the first arch reaches an unstable configuration and quickly snap downwards to its stable and inverted state. At this point the entire chain is forced to snap generating a mechanical signal from left to right. At t = 1.10s the chain is found to be in a new and still stable configuration. A similar behaviour has been experienced with Strategy 2, but reversibility is lost.
A theoretical model is developed to accurately predict the snapping behaviour of both plastic and elastic shallow arches. The deformation of the arches has been tracked and reconstructed by placing markers on the structure and it has been compared with the theoretically predicted one showing an impressive agreement.

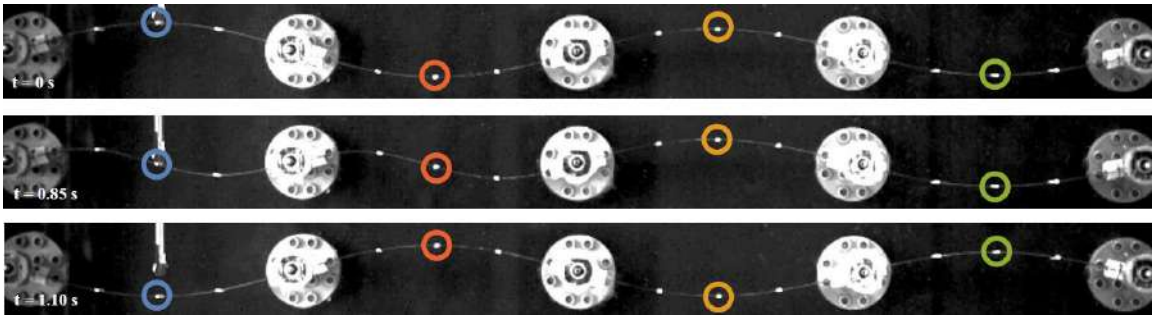

Figure 2. Snapshots of experimental representation of Strategy 1 with four arches.

CONCLUSIONS

We are able to harness the snapping of a series of shallow arches to achieve mechanical signal transmission. We propose two strategies to guarantee the robustness of the proposed design. In the first strategy, a reversible mechanical diode is obtained by carefully modulating the sequence of the rise of the arches. The second strategy counts on the introduction of "batteries" which snap between two stable configurations with different energy wells granting a surplus of energy which allows the chain reaction. This opens avenues to new applications of nonlinear mechanical metamaterials for signal transmission purposes.

Summary With an adequate scaling on the physical parameters, resonances are possible in the inclusions of a thin micro-structured medium. The homogenization of such media yields jump conditions that are non-local in time. Auxiliary variables are used to take into account the resonant behaviour and perform time domain simulations. These simulations are compared with simulations in the microstructured original medium to discuss the accuracy of the homogenized model obtained.

EFFECTIVE MODEL

The physical problem concerns the propagation of scalar waves within the framework of the linear anti-plane elasticity in 2D across a periodic row of inclusions $\cup_i \Omega_i$ embedded within a homogeneous matrix Ω_m, with both media being assumed to be isotropic. The thickness and the periodicity of the row are denoted by e and h respectively and we assume that $e = \mathcal{O}(h)$. The spatial coordinates are denoted by $\boldsymbol{X} = (X_1, X_2)$ respectively, with X_2 being the direction of periodicity of the inclusions as shown in Figure 1. The mass density ρ and the shear modulus μ are piecewise constant as:

$$(\rho, \mu)(\boldsymbol{x}) = \begin{cases} (\rho_m, \mu_m) & \text{in the matrix} \\ (\rho_i, \mu_i) & \text{in the inclusions.} \end{cases}$$

The wavelength λ within the matrix is assumed to be much larger than the spacing h between inclusions. Defining the wavenumber within the matrix as $k_m = 2\pi/\lambda$, we introduce the ratio $\eta = k_m h$ that satisfies $\eta \ll 1$ for the configurations of interest. This geometrical assumption allows to homogenize the microstructure in the long-wavelength regime [1]. However, these results do not apply to microstructures with high material contrast as the latter can be the seat of local resonances. In particular, they can occur for a low contrast in mass density $\rho_i/\rho_m = \mathcal{O}(1)$ and a high contrast in shear modulus $\mu_i/\mu_m = \mathcal{O}(\eta^2)$, a configuration which we consider in the present study.

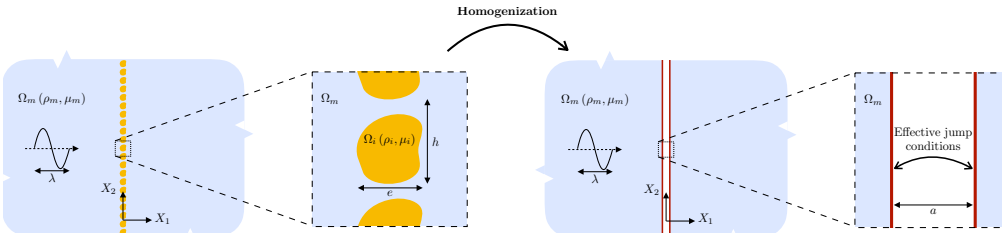

Figure 1: Homogenization process for a single periodic row of inclusions.

Under these asumptions, the microstructured problem can be replaced by an equivalent homogenized problem. It consists in solving the evolution equations around an enlarged interface of thickness a, and jump conditions on the velocity V and the normal stress vector Σ_1 across this enlarged interface. These jump conditions take into account the microstructure characteristics and read in the time-domain :

$$\begin{cases} [\![V]\!]_a &= B_1 \langle \partial_{X_1} V \rangle_a + B_2 \langle \partial_{X_2} V \rangle_a, \\ [\![\Sigma_1]\!]_a &= C_{11} \langle \partial_{X_1} \Sigma_1 \rangle_a + C_{12} \langle \partial_{X_2} \Sigma_1 \rangle_a + C_{22} \langle \partial_{X_2} \Sigma_2 \rangle_a + hD * \langle \boldsymbol{\nabla} \cdot \boldsymbol{\Sigma} \rangle_a, \end{cases} \tag{1}$$

where we have defined

$$[\![f]\!]_a (X_2) = f\left(\frac{a}{2}, X_2\right) - f\left(-\frac{a}{2}, X_2\right), \tag{2}$$

$$\langle f \rangle_a (X_2) = \frac{1}{2}\left(f\left(\frac{a}{2}, X_2\right) + f\left(-\frac{a}{2}, X_2\right)\right) \tag{3}$$

being the jump of f across the homogenized enlarged interface and the mean value of f, respectively. D encapsulates the resonant behaviour of the inclusions and its Fourier transform can be written as [2]:

$$\hat{D}(\omega) = \alpha_0 - \sum_{n \geq 1} \alpha_n^2 \frac{\omega^2}{\omega^2 - \omega_n^2}, \tag{4}$$

where the set of $\{\omega_n\}$ denote resonant frequencies, with $\{\omega_n^2\}$ linked to eigenvalues of the Laplacian in an inclusion. Stability of such system is linked to energy considerations and is guaranteed for a specific interface thickness $a \geq e$.

NUMERICAL MODELING

Formulating the system in the time domain with a convolution product is very costly numerically and would reduce the computational gains obtained from homogenization. To avoid this, auxiliary fields [3] are formally introduced in the frequency-domain formulation of the homogenized problem [2] due to the expression of $\hat{D}$ (4). We introduce the original variable set $\boldsymbol{u} = (V, \boldsymbol{\Sigma})^\top$ and the set $\boldsymbol{w}$ of auxiliary variables. The system in the time-domain now consists of first-order equations in time that are complemented by jump conditions that are local in time. Considering the complete set of variables $\tilde{\boldsymbol{u}} = (\boldsymbol{u}, \boldsymbol{w})^\top$ it can be written in a compact form for all $t > 0$ as:

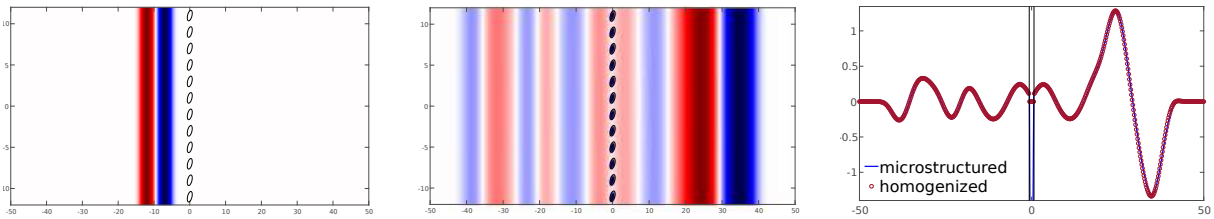
$$\begin{cases} \partial_t \boldsymbol{u} + \mathbb{A}_j \partial_j \boldsymbol{u} = \boldsymbol{0} & (|X_1| \geq a/2, X_2 \in \mathbb{R}), \\ \partial_t \boldsymbol{w} + \mathbb{B} \langle \partial_j^2 \partial_\ell \boldsymbol{u} \rangle_a + \mathbb{C} \boldsymbol{w} = \boldsymbol{0} & (X_2 \in \mathbb{R}), \\ [\![\boldsymbol{u}]\!]_a = \mathbb{D}_j \langle \partial_j \boldsymbol{u} \rangle_a + \mathbb{E} \boldsymbol{w} & (X_2 \in \mathbb{R}), \end{cases} \tag{5}$$

using the Einstein summation convention for repeated indices and where the matrices $\mathbb{A}_j$, $\mathbb{B}$, $\mathbb{C}$, $\mathbb{D}_j$ and $\mathbb{E}$ concatenate the parameters characterizing the resonant meta-interface model considered. This formulation is at price of handling $2N_R$ auxiliary variables, with N_R the number of resonances chosen to truncate the sum in (4), introduced only along the enlarged interface.

An explicit finite-difference scheme is used to solve numerically the homogenized problem (5). The scheme has to be adapted because the solution is not defined in the enlarged interface. This modification will take into account the jump conditions. A point M is called an irregular point if the stencil at M requires nodes that are in the enlarged interface where the solution is not defined. For these points, some phantom values values will be used in the enlarged interface, and direct numerical values will be used otherwhise. These phantom values are constructed as a smooth extension of the solution on the interfaces using the jump conditions. Their construction is detailed in [4] for the non-resonant case and is adapted here in the resonant case.

NUMERICAL EXPERIMENTS

For a plane wave and a plane or circulat resonant meta-interface, a semi-analytical solution of the homogenized problem can be computed. Comparisons of both semi-analytical and numerical solutions allow to validate the numerical method. After this validation, we can compare numerical solutions of time-domain simulations in the microstructured configuration and effective configuration. The numerical error measured will provide an estimation of the global modeling error and will be used to assess the validity of the homogenized model. Fields and profiles are presented in Figure 2 for $\eta = 0.4$. As expected, the solutions agree for a low value of η and deviate from one another as it goes to 1.



(a) Velocity field at the initial time

(b) Velocity field at the final time in the microstructured configuration

(c) Comparison of the profiles in the homogenized and microstructured configurations at the final time

Figure 2: Velocity fields in the microstructured configuration and corresponding profiles for both configurations.

CONCLUSIONS

Performing the homogenization process directly in the time-domain for this hightly contrasted inclusions leads to jump conditions that are stable for an enough enlarged interface but non-local in time. Introducing auxiliary variables allows to build a numerical approach to perform time-domain simulations in the effective medium and compare its solutions with simulations involving the original microstructure. It is discussed how it deteriorates as the frequency increases.

DYNAMICS OF TWO-DIMENSIONAL NON-HERMITIAN ELASTIC LATTICES WITH NON-LOCAL FEEEDBACK CONTROL INTERACTIONS

Massimo Ruzzene[1] and Matheus I. N. Rosa [1]
[1]Department of Mechanical Engineering, University of Colorado Boulder, Boulder, USA

Summary We investigate a family of elastic lattices where non-local feedback control interactions lead to a series of unconventional phenomena stemming from their non-Hermiticity. In two-dimensional lattices, the feedback interactions produce directional and non-reciprocal wave amplification, occurring in multiple frequency/wavenumber bands depending on the non-local nature of the control interactions. Moreover, the non-Hermitian skin effect manifests as modes localized at the boundaries of finite lattice strips, whose combined effect in two directions leads to the existence of bulk modes localized at corner of finite two-dimensional lattices. Our results describe fundamental properties of non-Hermitian elastic lattices, opening new possibilities for the design of active metamaterials with novel functionalities related to selective wave filtering, amplification and localization.

INTRODUCTION

Non-Hermitian systems are non-conservative systems where loss and/or gain are inherently present from interactions with the environment, and have been the focus of many research efforts by the physics and engineering communities. By carefully engineering the balance between gain and loss, unconventional phenomena such as unidirectional invisibility [1] and enhanced sensitivity to perturbations [2] have been demonstrated. Unique topological features have also been explored, such as the non-Hermitian skin effect [3], whereby all eigenstates of one-dimensional (1D) systems are localized at a boundary, in sharp contrast with the extended Bloch modes of Hermitian counterparts.

In this context, feedback control was recently introduced as a strategy to design mechanical metamaterials with non-reciprocal couplings [4,5], opening a new avenue for the exploration of the unique properties of non-Hermitian systems. Following such notable contributions, we study the dynamics of a family of one and two-dimensional elastic lattices with local and non-local feedback interactions [6], revealing a series of unconventional phenomena associated with their non-Hermiticity. Among the key results, we demonstrate non-reciprocity associated with attenuation and amplification for waves propagating along different directions in 1D and 2D lattices, illustrating that multiple non-reciprocal bands can be established by engineering the non-local nature of the control interactions. We also study the topological properties associated with the complex dispersion bands, resulting in localization of bulk modes at edges and corners according to the non-Hermitian skin effect. The talk will focus mostly on the properties of two-dimensional lattices, such as directional and non-reciprocal wave amplification, tunability, the effects of the non-local nature of the feedback interactions, and bulk modes localized at corners of finite two-dimensional lattices.

TWO-DIMENSIONAL ELASTIC LATTICES WITH FEEDBACK INTERACTIONS

We consider a 2D lattice of equal masses m connected by springs k, separated by a unit distance in both x and y directions (Fig. 1a). Each mass moves along the perpendicular z direction, so that the springs react with a force proportional to the relative vertical motion of neighboring masses. Feedback interactions are defined by an additional force applied to mass n,m proportional to the elongation of a spring a units behind in the x and y directions, which is expressed as $f_{n,m} = k_{c_x}\left(u_{n-a,m} - u_{n-(a+1),m}\right) + k_{c_y}\left(u_{n,m-a} - u_{n,m-(a+1)}\right)$, where k_{c_x} and k_{c_y} are the proportionality constants for elongations of springs aligned with the x and y directions, respectively. By imposing Bloch wave solutions of the form $u_{n.m} = Ue^{i(\omega t - \mu_x n - \mu_y m)}$, where ω denotes angular frequency while μ_x and μ_y are the wave vector components along x and y, the following dispersion relation can be obtained:

$$\Omega^2 = 2\left(2 - \cos\mu_x - \cos\mu_y\right) - \gamma_x e^{i\mu_x a}\left(1 - e^{i\mu_x}\right) - \gamma_y e^{i\mu_y a}\left(1 - e^{i\mu_y}\right),$$

where $\Omega = \omega/\omega_0$, with $\omega_0 = \sqrt{k/m}$, while $\gamma_x = k_{c_x}/k$ and $\gamma_y = k_{c_y}/k$. The feedback interaction makes the right-hand side of the dispersion relation generally complex, which results in complex frequencies $\Omega = \Omega_r + i\Omega_i$. The solutions are associated with a wave $u_{n,m} = Ue^{i(\Omega_r\tau - \mu_x n - \mu_y m)}e^{-\Omega_i\tau}$ that travels along the direction defined by the wave-vector components ($\theta = \tan^{-1}(\mu_y/\mu_x)$), and that is exponentially attenuated (amplified) in time when Ω_i is positive (negative).

Figures 1(b,c) display the real and imaginary iso-frequency contours of the dispersion surfaces for a representative case with $\gamma_x = \gamma_y = 0.1$ and local control interactions ($a = 0$). While the real part (Fig. 1b) closely resembles that of a passive 2D lattice, the imaginary part of the frequency contours (Fig. 1c) exhibits directional dependent attenuation and amplification zones. In particular, a region for which $\Omega_i < 0$ is identified in the third quadrant of the μ_x, μ_y plane, revealing a range of directions for wave amplification. This is further illustrated by considering a frequency of $\Omega = 0.7$, whose corresponding contour in the Ω_r map, highlighted by the thick black line in Fig. 1b, is approximately circular, possibly suggesting isotropic propagation. However, the wave vector components at this frequency (also highlighted by the thick black line in Fig. 1c), cross regions of positive and negative imaginary frequency. The angular dependence of

Ω_i is displayed in Fig. 1d, where it is plotted in polar form versus the propagation angle θ. In the figure, the thick blue lobe denotes amplification corresponding to $\Omega_i < 0$, while the thin red line defines the angular range associated with attenuation. The plot shows that maximum amplification is found for $\theta \approx 225^o$, which corresponds to waves traveling towards the left bottom corner of a square lattice. We illustrate this by considering a transient time domain simulation on a lattice with 100 x 100 masses, with a force consisting of a 5-cycle sinusoidal burst of frequency $\Omega = 0.7$ applied to the center mass of the lattice. Snapshots of the lattice motion at two subsequent time instants displayed in Figs. 1(e,f) confirm that waves are preferentially amplified as they travel towards the bottom left corner of the lattice.

The talk will describe further properties of the non-Hermitian lattices such as tunability based on anisotropic control parameters ($\gamma_x \neq \gamma_y$), multiple non-reciprocal frequency bands for lattices with non-local control ($a > 0$), topological properties of the complex dispersion bands in terms of winding numbers and their relation to skin modes localized at the edges of finite lattice strips, and bulk modes localized at corners of finite two-dimensional lattices. Multiple avenues for future work are suggested such as possibilities for experimental implementation, exploration of different geometries, modulations of control parameters, modification of control laws (*e.g.* derivative and integral controls), as well as the introduction of non-linearities.

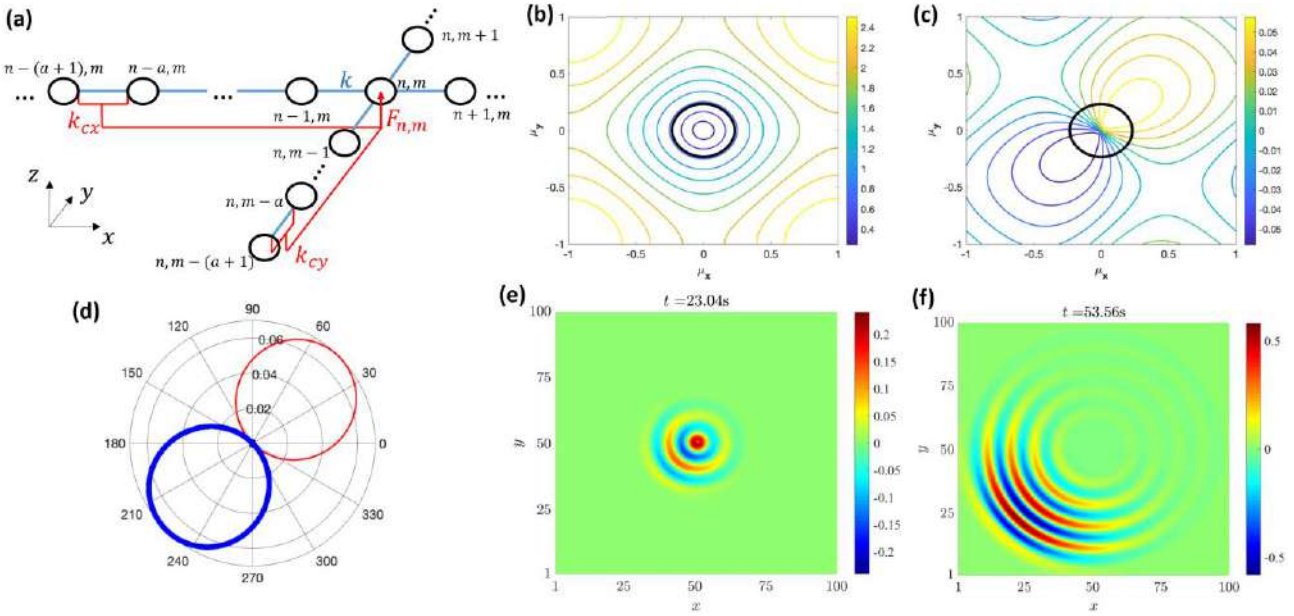

Figure 1. Non-reciprocal wave amplification in two-dimensional lattice with feedback interactions. (a) Schematic of 2D lattice where a feedback force is applied to each mass along the lattice, reacting proportionally to the strain of springs a units behind in the x and y directions. (b,c) Iso-frequency contours corresponding to the real part Ω_r (b), and imaginary part Ω_i (c) of the dispersion $\Omega(\mu_x, \mu_y)$. The thick black line outlines the contour for $\Omega_r = 0.7$, and defines the wave vector components governing propagation at the considered frequency. (d) Angular variation of Ω_i highlighting the angular range of amplification (thick blue line) and attenuation (thin red line). (e,f) Snapshots of transient response to a tone-burst excitation at $\Omega = 0.7$ applied to the center mass of the lattice, illustrating that waves traveling towards the bottom left corner are preferentially amplified.

BAND GAPS AND SIZE-EFFECTS IN A HETEROGENEOUS CAUCHY MATERIAL IN THE DYNAMIC FRAMEWORK

Gianluca Rizzi*[1], Patrizio Neff[2], and Angela Madeo[1]
[1]Laboratoire GEOMAS, INSA Lyon, Lyon, French
[2]Fakultät für Mathematik,Universität Duisburg-Essen,Essen,Germany

Summary The mechanical response of a heterogeneous Cauchy material (see Fig. 1) subjected to dynamic solicitations cannot always be adequately represented via a classic homogeneous model. To overcome this problem, it is possible to use an enriched continuum such as a *relaxed micromorphic model* to catch phenomenons like *band gaps* and *size-effect*.

INTRODUCTION

It is clear nowadays that both in statics and dynamics, the presence of heterogeneities or microstructures within a solid can cause micromechanical effects which can only be described through non local and higher-order models [1]-[2]. In particular, these effects are magnified for a finite-size domain when its dimensions are comparable to the size of its unit cell.

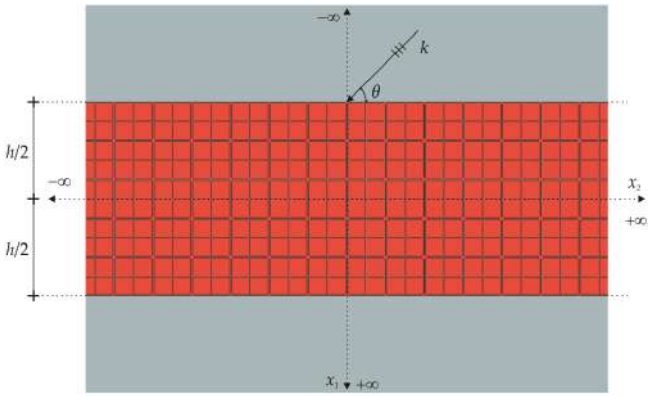

Figure 1: Inclusion of a microstructured Cauchy material embedded between two homogeneous media.

Two examples of micromechanical effects are the so called *size-effects* and *band gaps*. The *size-effect* consists in how the mechanical response of a solid changes when changing the ratio between the characteristic size of the macroscopic specimen and that of the unit cell (in dynamics it is also important the ratio between the wavelength of the incident wave and both the size of the unit cell and the size of the solid considered). On the other hand, *band gaps* are frequency ranges for which waves do not propagate due to scattering or local resonance phenomena at the level of the microstructure. In order to be able to replicate both these micromechanical effects in a continuum mechanics framework, a relaxed micromorphic model is here proposed [3]-[4].

The jump conditions at the interfaces consist in the continuity of the displacement and of the generalized traction for both the relaxed micromorphic and Cauchy continuum and, additionally, null double force for the relaxed micromorphic continuum (see [4] for more details).

We use this model to explore the scattering response of a finite-size metamaterial slab embedded between two homogenous media (see Fig. 2 and Fig. 3). The obtained response is than compared with that retrieved via a FEM simulation of the microstructured material.

RELAXED MICROMORPHIC MODEL

The expression of the kinetic energy density for a relaxed micromorphic continuum is:

$$\begin{aligned} J\left(u_{,t}, \nabla u_{,t}, P_{,t}\right) = \quad & \tfrac{1}{2}\rho\langle u_{,t}, u_{,t}\rangle + \tfrac{1}{2}\mathbb{J}_{micro}\langle \mathrm{sym}P_{,t}, \mathrm{sym}P_{,t}\rangle + \tfrac{1}{2}\mathbb{J}_{c}\langle \mathrm{skew}P_{,t}, \mathrm{skew}P_{,t}\rangle \\ & + \tfrac{1}{2}\mathbb{T}_{e}\langle \mathrm{sym}\nabla u_{,t}, \mathrm{sym}\nabla u_{,t}\rangle + \tfrac{1}{2}\mathbb{T}_{c}\langle \mathrm{skew}\nabla u_{,t}, \mathrm{skew}\nabla u_{,t}\rangle, \end{aligned} \tag{1}$$

where u is the macroscopic displacement field, $P \in \mathbb{R}^{3x3}$ is the non-symmetric micro-distortion tensor, ρ is the macroscopic apparent density, and $\mathbb{J}_{micro}$, $\mathbb{J}_c$, $\mathbb{T}_e$, $\mathbb{T}_c$ are 4th order micro-inertia tensors [4] whose coefficients are dynamic characteristic lengths (L_i, $\overline{L}_i$ with $i = 1, 2, 3, 4$).

*Corresponding author. E-mail: gianluca.rizzi@insa-lyon.fr

The expression of the strain energy density for a relaxed micromorphic continuum is:

$$W\left(\nabla u, P, \mathrm{Curl}P\right) = \begin{aligned} &\tfrac{1}{2}\mathbb{C}_e\langle \mathrm{sym}\left(\nabla u - P\right), \mathrm{sym}\left(\nabla u - P\right)\rangle + \tfrac{1}{2}\mathbb{C}_{micro}\langle \mathrm{sym}P, \mathrm{sym}P\rangle \\ &+\tfrac{1}{2}\mathbb{C}_c\langle \mathrm{skew}\left(\nabla u - P\right), \mathrm{skew}\left(\nabla u - P\right)\rangle + \tfrac{\mu_{micro}L_c^2}{2}\langle \mathrm{Curl}P, \mathrm{Curl}P\rangle, \end{aligned} \tag{2}$$

where $\mathbb{C}_e$, $\mathbb{C}_{micro}$, and $\mathbb{C}_c$ are 4th order tensors and μ_{micro} and $\mathbf{L_c}$ are scalar quantities [4]. The micro-inertia and the elastic parameter numerical values can be found in [4] and a the solution considered is time-harmonic.

RESULTS

The comparison in terms of reflection coefficient between the microstructured material (MM), the Cauchy material (CM) (Fig. 2), and the realxed micromorphic material (RMM) (Fig. 3) is here presented for the case of study of a slab (Fig. 1) of thickness 20 and 30 cells. For the sake of compactness, we only present the case of an in-plane pressure incident wave, but analogous conclusions can be drawn for the case of shear incident ones.

As it can be seen, the band gaps are captured very well by the relaxed micromorphic material while not at all by the correspondent Cauchy counterpart.

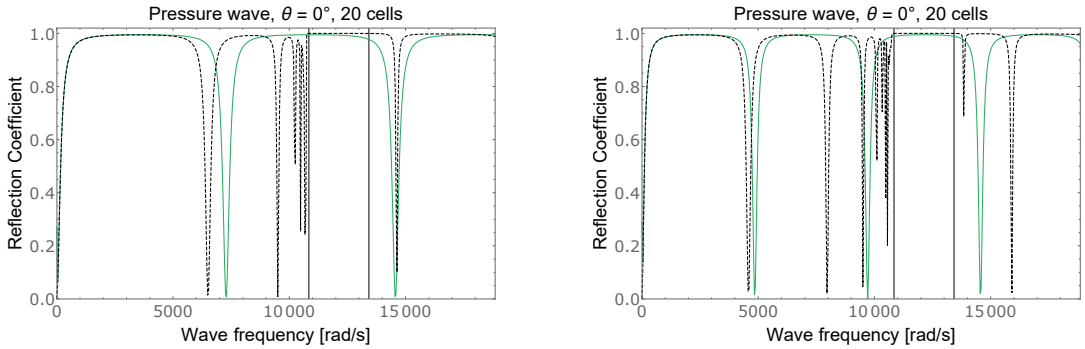

Figure 2: Comparison between the microstructured material (dashed black) and the effective Cauchy continuum (green) in terms of reflection coefficient for two slabs of 20 and 30 cells thick.

It is also important to underline that the position of the band gaps (Fig. 3) are due to the coefficient L_i and $\overline{L}_i$.

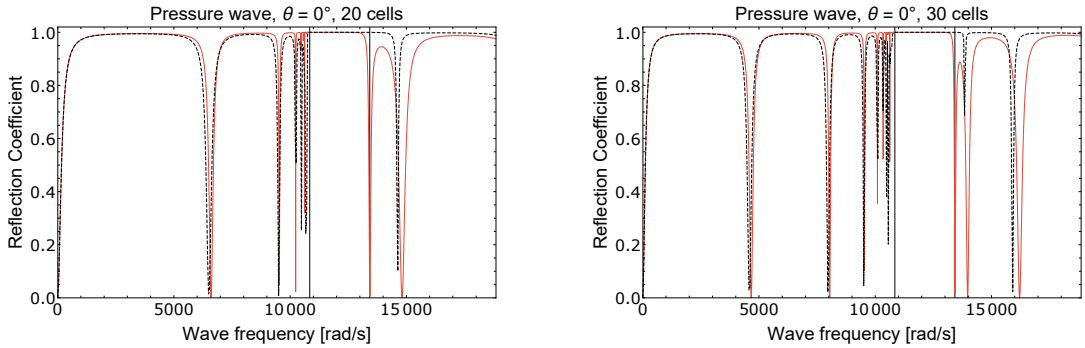

Figure 3: Comparison between the microstructured material (dashed black) and the effective relaxed micromorphic continuum (red) in terms of reflection coefficient for two slabs of 20 and 30 cells thick.

INVESTIGATING THE DYNAMICS OF SURFACE WAVES IN RESONANT HALF-SPACES

Antonio Palermo[1], Farhad Zeighami[1], and Alessandro Marzani *[1]
[1]Department of Civil, Chemical, Environmental and Materials Engineering, University of Bologna, Bologna,Italy

Summary We study the dynamics of vertically polarized surface waves propagating in elastic half-spaces patterned with locally resonant inclusions. By employing an effective medium description able to capture the low-frequency dynamics of the inclusions, we derive a closed-form dispersion relation of Rayleigh-like waves and discuss their dispersive features, including the formation of surface waves band gaps.

BACKGROUND

Elastic metamaterials are artificial composites with local resonant particles or structures of subwavelength dimensions hosted in an elastic medium [1]. When elastic waves propagate through a resonant medium, they hybridize with the local resonant modes of the inclusions, leading to frequency band gaps generated from the avoided crossing behavior between repelling modes. These band gaps arise in the narrow frequency range between the resonance and antiresonance mode of the inclusions. Homogenization techniques have been employed to model the dispersive properties of one-dimensional, two-dimensional, and bulk resonant media. Additionally, resonant boundary conditions have been used to describe the dynamics of resonant structures placed on the surface of elastic half-spaces, for Rayleigh and Love waves control [2]. Nonetheless, the dynamics of surface waves in a half-space equipped with resonant inclusions through its whole depth remains still unexplored. Hence, in what follows, we describe the dynamics of Rayleigh-like waves in a resonant half-space, summarizing and complementing with further numerical results, some of the analytical developments and numerical models presented in our earlier work [3].

ANALYTICAL MODEL AND RESULTS

We investigate the propagation of vertically polarized surface waves in a homogeneous elastic resonant half-space (see Fig. 1a). The resonant medium is formed by a periodic arrangement of hard cylindrical inclusions (i), covered by soft coating layers (c) and embedded in an elastic hosting matrix (h).

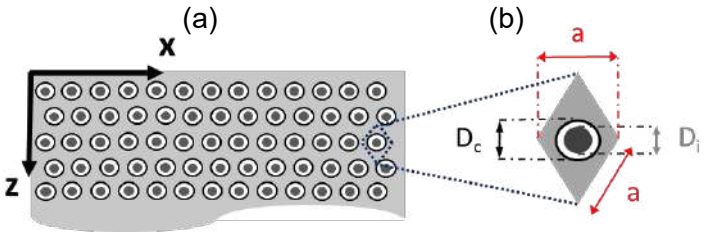

Figure 1: (a) Schematic of a two-dimensional (2D) resonant half-space. (b) Basic unit cell.

For the example of choice, the inclusions are arranged in a triangular lattice of spacing $a = 3\ cm$. We adopt an effective medium description to provide closed-form expression of the effective mass density ρ_{eff} and elastic moduli λ_{eff}, μ_{eff}, able to correctly capture the low-frequency dynamics of the composite medium. In detail, for the effective density, we adopt the closed-form expression provided by Liu [4]:

$$\rho_{eff}(\omega) = \phi_h \rho_h + (\phi_c + \phi_i)\rho_c \left[g_1(\omega) - g_2(\omega) \frac{g(\omega)}{R(\omega) - \frac{\rho_i}{\rho_c}} \right] \tag{1}$$

where ρ_h, ρ_c and ρ_i, are the mass densities, ϕ_h, ϕ_c, and ϕ_i are the filling fractions of the host, coating, and inclusion, respectively, and $g_1(\omega)$, $g_2(\omega)$, $g(\omega)$ and $R(\omega)$ are frequency-dependent functions given in Ref. [4].
Conversely, for the effective elastic moduli, we employ a two-step homogenization procedure, adapting the static approximation employed by Mei et al. [5] for a bi-phase composite. Hence, we first calculate the effective elastic parameters of the resonant inclusion, combining the hard cylindrical particle with its soft interface. The effective elastic moduli of such bi-composite, $\mu_{i,c}$ and $\lambda_{i,c}$, are obtained from the equations [5]:

$$\begin{aligned} \frac{\mu_{i,c} - \mu_c}{\mu_{i,c} + \mu_c} &= \phi_{i,c} \frac{\mu_i - \mu_c}{\mu_i + \mu_c}, \\ \frac{(\lambda_{i,c} + \mu_{i,c}) - (\lambda_c + \mu_c)}{\lambda_{i,c} + \mu_{i,c} + \mu_c} &= \phi_{i,c} \frac{(\lambda_i + \mu_i) - (\lambda_c + \mu_c)}{\lambda_i + \mu_i + \mu_c}, \end{aligned} \tag{2}$$

*Corresponding author. E-mail: alessandro.marzani@unibo.it

where $\phi_{i,c} = (D_i/D_c)^2$ is the filling ratio of the cylinder within the resonant inclusion.
The homogenization procedure is repeated by combining the homogenized resonant inclusion ($\mu_{i,c}$, and $\lambda_{i,c}$) and the host material to obtain the effective parameters μ_{eff} and λ_{eff}. Equipped with effective density and elastic moduli of the composite medium, we obtain the dispersive longitudinal $c_{L,eff}(\omega)$ and shear $c_{T,eff}(\omega)$ effective bulk velocities as:

$$c_{T,eff}(\omega) = \sqrt{\frac{\mu_{eff}}{\rho_{eff}(\omega)}},\ c_{L,eff}(\omega) = \sqrt{\frac{\lambda_{eff} + 2\mu_{eff}}{\rho_{eff}(\omega)}} \tag{3}$$

At this stage, the dispersive properties of Rayleigh waves in a resonant half-space are calculated by adopting the expressions in Eqs. (2) and (3) in the standard Rayleigh wave dispersion law [6].

$$\left(2 - \left(\frac{\omega}{kc_{T,eff}}\right)^2\right)^2 - 4\sqrt{1 - \left(\frac{\omega}{kc_{T,eff}}\right)^2}\sqrt{1 - \left(\frac{\omega}{kc_{L,eff}}\right)^2} = 0 \tag{4}$$

Fig. 2 shows (in continuous black lines) the complex wavenumber ($k = k_r + ik_i$) of Eq. (4) calculated for a composite medium consisting of aluminum inclusions ($\rho = 2.7 \times 10^3 kg/m^3$, $\mu = 2.59 \times 10^{10} N/m^2$ and $\lambda = 6.05 \times 10^{10} N/m^2$), coated with rubber ($\rho = 1.3 \times 10^3 kg/m^3$, $\mu = 5 \times 10^5 N/m^2$ and $\lambda = 5 \times 10^6 N/m^2$), and embedded in epoxy matrix ($\rho = 1.18 \times 10^3 kg/m^3$, $\mu = 1.59 \times 10^9 N/m^2$ and $\lambda = 4.43 \times 10^9 N/m^2$). Analytical solutions, provided in terms of non-dimensional complex wavenumber $k' = ka/\pi$ vs. non-dimensional angular frequency $\omega' = \omega/\omega_r$, where ω_r is the angular resonance frequency of the resonant system, agree well with numerical solutions obtained via finite element modelling of the composite material. The dispersion curve highlights the existence of a band gap where the propagation of Rayleigh waves is forbidden. The gap occurs in the same frequency region where bulk waves are hindered.

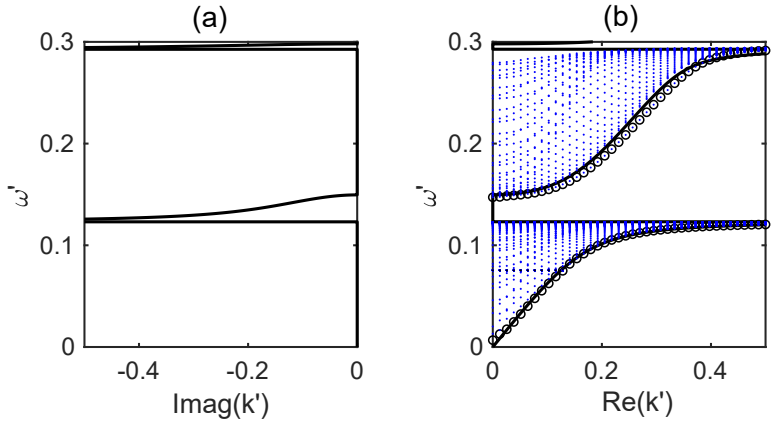

Figure 2: (a) Imaginary and (b) real wavenumbers of vertically polarized surface waves in the resonant half-space. Blue dots and black circles mark bulk and surface modes predicted by FE simulations, respectively.

CONCLUSIONS

In this work, we investigate the propagation of vertically polarized surface waves in resonant half-spaces. We derive effective parameters of the resonant medium via homogenization approaches and develop an analytical dispersion law for the interaction of Rayleigh waves existing in the resonant half-space. According to our model, band gaps exist around the resonance frequencies of the inclusions. An in-depth analysis on the band gap frequency width as well as on its dependence on the depth of the resonant inclusions will be presented at the conference.

CANONICAL QUASICRYSTALLINE MULTILAYERED METAMATERIALS

Lorenzo Morini*[1], Zhijiang Chen[1], and Massimiliano Gei[1,2]
[1]School of Engineering, Cardiff University, Cardiff, UK
[2]Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy

Summary A new class of two-phase periodic laminates with a *quasicrystalline* structure (generated by the Fibonacci substitution rule) is introduced. Recently, we found that the Floquet-Bloch spectrum of antiplane waves propagating in this particular type of layered composite has a self-similar layout which can be characterized through an invariant function of the frequency, the so-called Kohmoto invariant. Moreover, for particular ratios between the geometrical and constitutive parameters of the two constituent phases (*canonical* ratios), the spectra are periodic. We illustrate how these two unique properties can be used to design quasicrystalline lamitates providing negative refraction of an antiplane wave obliquely incident at the interface with an elastic substrate. It is shown that, beyond a certain frequency threshold, high order Fibonacci laminates allow negative refraction of a single transmitted mode at lower frequencies with respect to a periodic classical bilayer. The attained results represent an important advancement towards the realisation of multilayered quasicrystalline metamaterials with the aim to control negatively refracted elastic waves.

QUASICRYSTALLINE-GENERATED LAMINATES

We define a class of two-dimensional, two-phase quasicrystalline laminates with layering direction parallel to the axis y (see Fig. 1/(A)). Each of its elements is composed of a repeated elementary cell $\mathcal{F}_i$ where the two basic components, A and B, are arranged in series according to the standard Fibonacci sequence, which is based on the following substitution rule $A \to AB,\ B \to A$. The repetition of the fundamental cells assures global periodicity along axis x and the possibility of applying the Floquet-Bloch technique in order to study harmonic wave propagation in these systems.

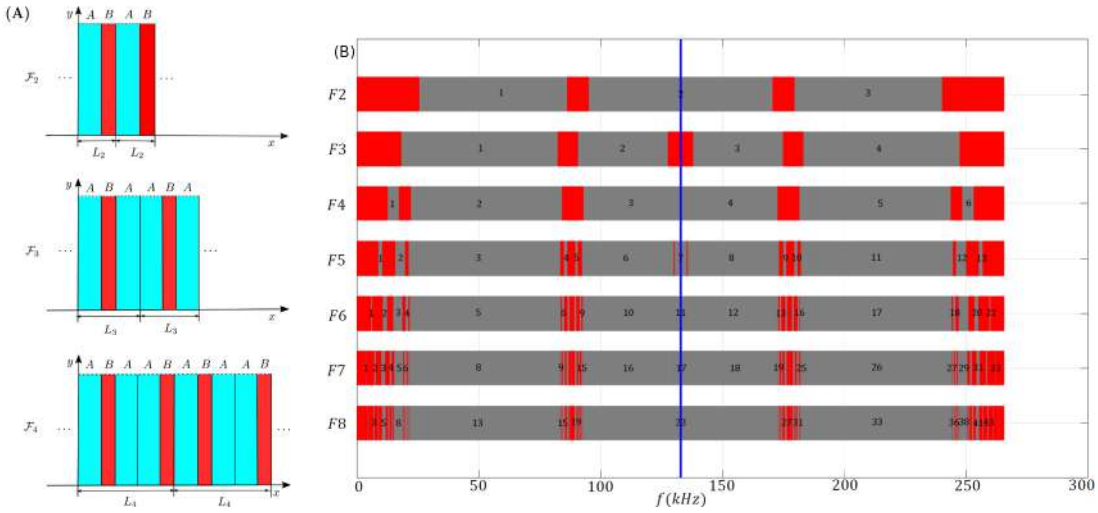

Figure 1: (A): two-dimensional laminates assembled according to $\mathcal{F}_2$, $\mathcal{F}_3$ and $\mathcal{F}_4$ Fibonacci cells. (B): Diagram reporting, in the grey zones, the number N_i^f of real solutions K_y of the dispersion relation for cells $\mathcal{F}_2$ to $\mathcal{F}_8$ as a function of the frequency. Transition zones are highlighted in red.

The dispersion relation for Floquet-Bloch harmonic antiplane waves propagating in Fibonacci laminates as those illustrated in Fig. 1/(A) assumes the form

$$\cos\left(K_x L_i\right) = \frac{1}{2}\mathrm{tr}\mathbf{M}_i(f, K_y), \tag{1}$$

where $\mathbf{M}_i$ is the trasmission matrix of the ith-order cell $\mathcal{F}_i$, L_i is the total length of the cell, $f = \omega/2\pi$ is the wave frequency, K_x and K_y are the components of the wave vector directed along $x-$ and $y-$ axis, respectively. $\mathbf{M}_i$ is unimodular, i.e. $\det\mathbf{M}_i = 1$, and follows the recursion rule $\mathbf{M}_{i+1} = \mathbf{M}_{i-1}\mathbf{M}_i$, with $\mathbf{M}_0 = \mathbf{M}_B$ and $\mathbf{M}_1 = \mathbf{M}_A$ [1]. Assuming a given wave frequency f, for any real value of K_x we found a finite number N_i^f of real and an infinite number of imaginary solutions K_y of the dispersion relation (1) [2]. This means that for any real K_x we have N_i^f propogating waves and infinite evanescent modes along the $y-$direction. The numerical solution of (1), obtained for a determinate set of frequencies by varying K_x along the intervals $0 \le K_x \le m\pi/L_i$, $m \in \mathbb{N}$ (*Brillouin zones*), shows that: i) assuming given values of f and K_x, N_i^f increases for high order Fibonacci cells $\mathcal{F}_i$ [3]; ii) if f belongs to some particular frequency ranges, N_i^f depends on the value of K_x and we have $N_i^f = t-1$ for $0 \le K_x \le \overline{K}_x$ and $N_i^f = t$ for $\overline{K}_x \le K_x \le m\pi/L_i$. We denote these frequency ranges as *transition zones*. The t-th transition zone is that where N_i^f switches from $t-1$ to t.

SELF-SIMILAR TRANSITION ZONE LAYOUT AND CANONICAL RATIO

An example of transition zone layout for laminates designed according to cells $\mathcal{F}_2$ to $\mathcal{F}_8$ is reported in Fig. 1/(B) as a function of the frequency. We note that they are disposed according to a self-similar pattern. The analysis of the dispersion curves obtained assuming $K_y = 0$ (transverse wave propagation in the laminate) reveals that for any cell $\mathcal{F}_i$ the position of pass bands coincide with that of transition zones. In this specific case, the transfer matrix $\mathbf{M}_i$ and the dispersion relation (1) become identical to those defined in [1] and [5]. Consequently, the self similarity is governed by a local scaling whose factor is analogous to that used in those papers for studying the spectrum of quasicrystalline-generated structural waveguides:

$$\kappa_0^+(f) = \frac{1}{4}\left(\sqrt{4+(4+I_0(f))^2}+(4+I_0(f))\right)^2, \tag{2}$$

where $I_0(f)$ is the so-called Kohmoto's invariant [4]. A transition zone $f_i^B - f_i^A$ of the cell $\mathcal{F}_i$ centred at a frequency f^* is related to the transition zone $f_{i+6}^B - f_{i+6}^A$ of $\mathcal{F}_{i+6}$ centred almost about the same value f^* by the scaling law $f_{i+6}^B - f_{i+6}^A \approx (f_i^B - f_i^A)/\kappa$, where $\kappa = \kappa_0^+(f^*)$. Similarly, $f_{i+3}^B - f_{i+3}^A \approx (f_i^B - f_i^A)/\lambda$, with $\lambda = \sqrt{\kappa}$.
By observing Fig. 1/(B), we also note that for any cell $\mathcal{F}_i$, the arrangement of the transition zones is periodic. This is achieved for rational values of the ratio $\beta = c_A h_B / c_B h_A$, where h_A and h_B are the thicknesses of phases A and B, c_A and c_B the shear wave speed in materials A and B, respectively. We denote β as *canonical ratio*, and the laminates characterized by $\beta \in \mathbb{Q}$ as *canonical laminates* (for the case shown in Fig.1/(B), $\beta = 2$).

NEGATIVE REFRACTION USING QUASICRYSTALLINE LAMINATES

We now use the quasicrystalline laminates to obtain negative refraction of an antiplane wave across an interface with an elastic substrate (schematic of the problem reported in Fig.2/(A)). For each value of K_x corresponding to a given frequency and an arbitrary angle of incidence in the interval $0 \leq \theta \leq \pi/2$, we have N_i^f real solutions of the dispersion relation (1). These real solutions correspond to propagating modes transmitted at the interface. In order to have only one single negatively refracted mode (*pure negative refraction*), the incident wave frequency should belong to the interval $f_i^{min} \leq f \leq \tilde{f}_i$ [3], where $f_i^{min} = \sqrt{\mu_0}/(2L_i\rho_0)$ (with μ_0 and ρ_0 shear modulus and mass density of the substrate, respectively), and $\tilde{f}_i$ is the highest frequency of the second transition zone. Remembering the spectrum analysis reported in the first section, we can calculate $\tilde{f}_i$ for any Fibonacci cell $\mathcal{F}_i$. Moreover, using the scaling factor (2) together with the associated scaling relationships and the condition of periodicity $\beta \in \mathbb{Q}$, we can design canonical laminates providing pure negative refraction in several ranges of frequencies considering different elastic substrates. The results illustrated in Fig.2/(B) for a PMMA-steel laminate bonded to a polyethylene substrate show that, by considering the same angle of incidence ($\theta = 20°$) high-order Fibonacci cells yield single negatively refracted modes at lower frequencies with respect to standard two-phase periodic laminates (represented by cell $\mathcal{F}_2$).

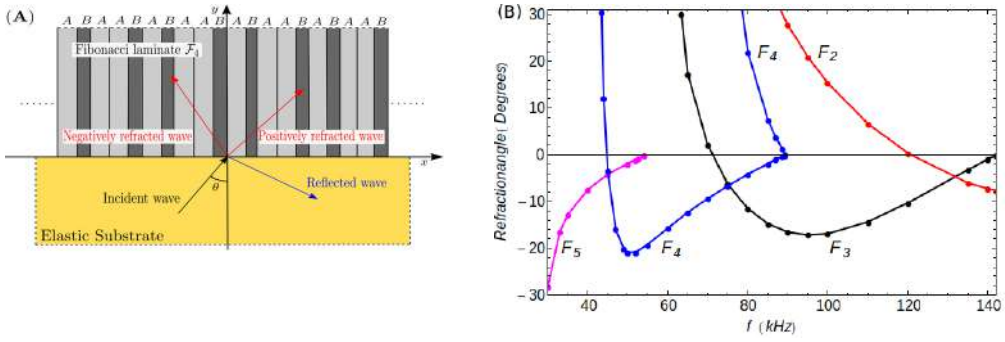

Figure 2: (A): Schematic of the problem of an antiplane wave approaching the interface between an elastic substrate and a Fibonacci laminate $\mathcal{F}_4$. (B): Angles of refraction corresponding to an incident angle $\theta = 20°$ plotted versus the frequency for cells $\mathcal{F}_2$ to $\mathcal{F}_5$.

CONCLUSIONS

The propagation of antiplane shear waves in two-phase periodic quasicrystalline-generated laminates following the Fibonacci substitution rules has been studied. The Floquet-Bloch analysis reveals that particular ranges of frequencies, called transition zones, are disposed in the dispersion diagrams according to a self-similar pattern. Numerical results show that these self-similarity properties together with the condition for the periodicity of the spectrum can be used to design high order Fibonacci laminates allowing negative wave refraction of a single transmitted mode at lower frequencies with respect to a classical periodic bilayer.

CLOAKING OF MULTIPLE INTERACTING VOIDS

Diego Misseroni*[1]
[1]Department of Civil, Environmental and Mechanical Engineering, Università di Trento, Trento, Italy

Summary A new approach, based on the concept of the redistribution of the mass and the stiffening of the boundary, is proposed for the cloaking of multiple interacting voids embedded into an elastic plate. This new method is validated via both numerical simulations and experiments. This technique, very simple in principle, produces invisibility of the randomly located voids to flexural waves over a wide range of frequencies. The proposed design can find applications in mechanical problems ranging from the micro-scale to the macro-scale.

THE CLOAKING DESIGN

In elasticity, the invisibility of a defect (such as a void or an inclusion) embedded into a vibrating plate is achieved when the vibration propagating within the medium is not perturbed by its presence. In the last decades, several methods have been proposed in the attempt to make an object invisible to flexural vibrations. Usually, they are based on the so-called *cloaking transformation*, a concept originally developed in electromagnetism and optics [1, 2, 3, 4]. The 'perfect cloak' of an object implies omnidirectional and total scattering elimination over a wide frequency range, a goal that should be achieved with a sufficiently thin coating, of simple design and realization.

A radically new design concept is introduced to make voids invisible within an extremely broad range of frequencies, never challenged so far. Without recurring to the concept of cloaking transformation, a simple procedure to strongly reduce scattering is proposed, based on mass and moment of inertia conservation and elastic stiffening averaging along the boundary of the void, as shown schematically in Fig. 1. Such a cloaking design is introduced regarding an elastic plate perforated with several voids, randomly located and inclined.

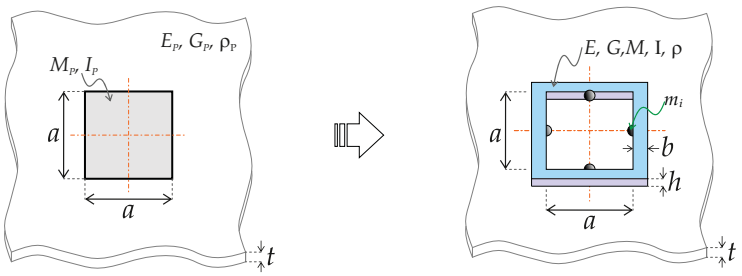

Figure 1: Sketch of the cloaking design. (left) A void of dimension $a \times a$ has to be cloaked in an elastic plate. (right) A stiffer and heavy frame is placed along the boundary of the void to maintain the same mass, the same moment of inertia around the axes of the void and the same bending stiffness eliminated by the void.

NUMERICAL VALIDATION

Numerical simulations were performed in Abaqus to demonstrate omnidirectionality of the cloak and multiple invisibility for several voids randomly located and inclined. An out-of-plane vibration is applied at one end of three different plates: i) an intact plate, ii) a plate with reinforced voids and iii) a plate with unreinforced voids. The frequency of the excitation is continuously varied until resonance, to show that the eigenmodes of the intact plate and the plate with cloaked voids are the same, while the resonance modes of the perforated plate with uncloaked voids are different. In Fig. 2 the modes associated with three frequencies for which the cloak works exceptionally well so that multiple and omnidirectional invisibility is almost perfect) are reported. The plate with cloaked voids is shown to behave almost identically with the intact plate, while it strongly differs from the perforated plate, which remains almost undeformed (because it vibrates far from resonance).

EXPERIMENTAL PROOF

In addition to the numerical simulations, resonance experiments were carried out to validate the efficiency of the proposed method exploiting the experimental setup shown in Fig 3. The resonance is detected using a stroboscopic light and the experiments exactly confirm the expectation (a set of photos is shown in Fig. 4) and show coincidence up to the fourth mode of vibration for the intact plate and the perforated plate with cloaked voids, while the plate with the unreinforced voids vibrates far from its resonance frequency and thus appears only slightly deformed.

*Corresponding author. E-mail: diego.misseroni@unitn.it

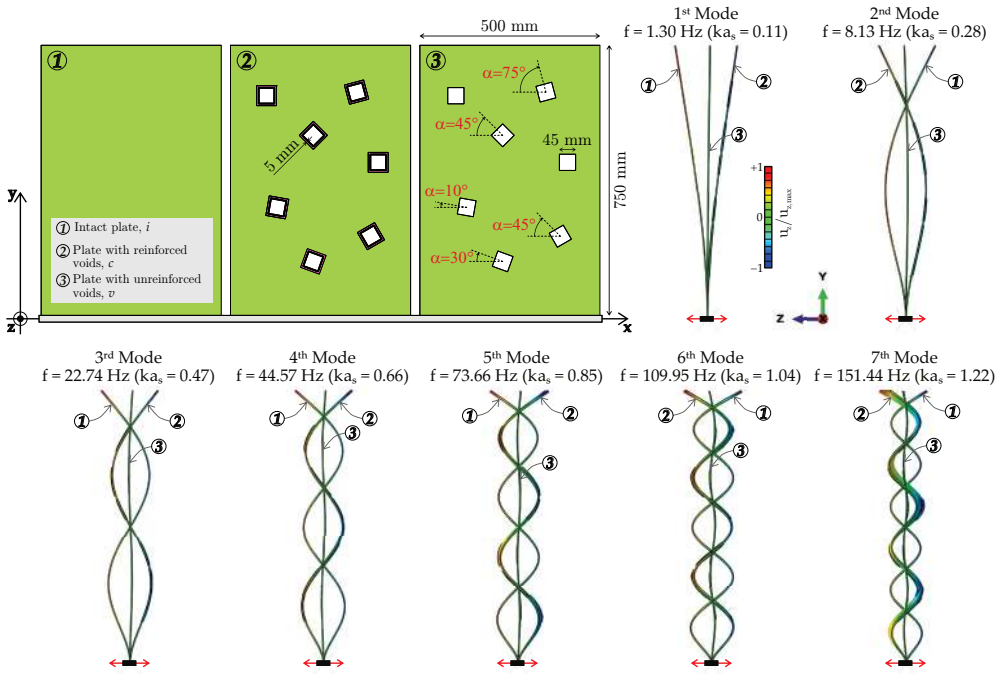

Figure 2: Omnidirectional cloak and multiple invisibility of 7 randomly located and inclined voids. The eigenmodes of the intact plate and the plate with cloaked voids coincide up to (and beyond) the 7^{th} mode and are different from those of the plate with unreinforced voids.

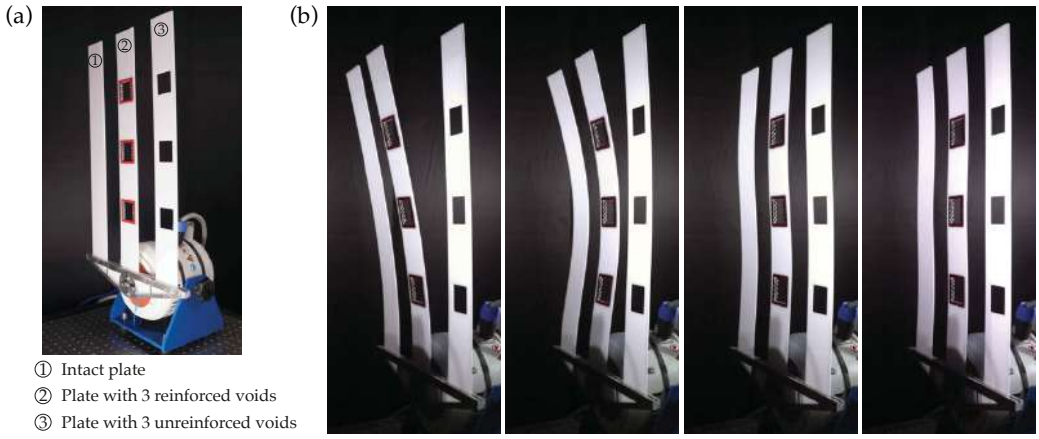

Figure 3: (a) Experimental setup employed to impose the flexural vibration at one end of the elastic plates. (b) Stroboscopic snapshots taken during the resonance experiments. The intact plate behaves the same as the plate with the reinforced voids. The plate with unreinforced voids remains almost undeformed because it vibrates at a frequency far from its resonance.

CONCLUSIONS

A new method, based on the mass redistribution and the stiffening of the boundary, is proposed to obtain the invisibility of square voids embedded in elastic plates. The efficiency of the method was tested through both numerical simulations and real experiments performed on a proof-of-concept cloaking model. The obtained outcomes fully confirm the goodness of the method and pave the wave to the achievement of an 'ideal' cloak.

Summary Nature has engineered complex designs to achieve advanced properties and functionalities over hundreds of thousands of years. For instance, a hierarchical organization over multiple length scales allows enhanced quasistatic mechanical properties (such as high specific strength, stiffness, and toughness). While largely investigated in the quasistatic domain, the role of hierarchy in the dynamic behaviour of metamaterials remains largely unexplored. Here we numerically and experimentally investigate the influence of bio-inspired hierarchical organization on the wave dispersion diagram in metamaterials with self-similar structures at various spatial scales. The study reveals that the hierarchical architecture provides advantages for the dynamic performance with respect to conventional metamaterials.

INTRODUCTION

Hierarchical structures with constituents over multiple length scales are found in various natural materials like bones, shells, spider silk and others, all of which display enhanced quasi-static mechanical properties, such as high specific strength, stiffness and toughness, attributed to hierarchy [1-3]. However, the role of hierarchy in the dynamic behaviour of metamaterials remains largely unexplored. This work assesses the effect of bio-inspired hierarchical organization on the band structure of continuous mechanical metamaterials [4].

Although optimized conventional metamaterial configurations have recently been proposed [5, 6], elementary unit cells comprising single inclusions or cavities often provide limited frequency band gaps (BGs), so that lightweight, practically oriented meta-structures with multi-scale wave attenuation remain to be achieved.

MODELS AND METHODS

One way to potentially overcome the mentioned limitations is to exploit bio-inspired structural hierarchy. Structural hierarchy is here understood in the sense that a representative metamaterial unit cell comprises multiple arrangements of inhomogeneities at various size scales. If the same arrangement occurs at every scale, the pattern is called self-similar. We consider single-phase metamaterials formed by self-similar unit cells with different hierarchical levels, as schematically shown in Figure 1A.

We consider small-amplitude waves. In the case of a linear elastic medium, in the absence of external forces, the wave field is described by standard wave equations for two-dimensional displacements. The analysis is restricted to harmonic waves and forms a necessary basis for studying other types of wave motions. Due to the structural periodicity of the metamaterials, the displacements are also periodic in space and thus can be represented using the Floquet-Bloch expansion theorem. This allows to restrict the analysis of an infinite periodic medium to that of a representative unit cell only (Figure 1A) with Bloch periodic conditions at the unit cell boundaries [7].

RESULTS

The dispersion diagrams for the hierarchical cross-like metamaterial with regular and external hierarchical organization is shown in Figures 1B-D. It clearly appears that the wide band gap ranging from approximately 42 kHz to 96 kHz is almost preserved. Pass bands located inside the latter band gap are represented by mostly flat lines corresponding to localized modes. These modes do not couple with external field in realistic structures, which always have a certain level of energy dissipation.

Also, the introduction of hierarchy allows to shift the band gap corresponding to the ordinary unit cell to an approximately 3 times lower frequency. Several other band gaps appear at the band gap frequencies of the regular structure [4].

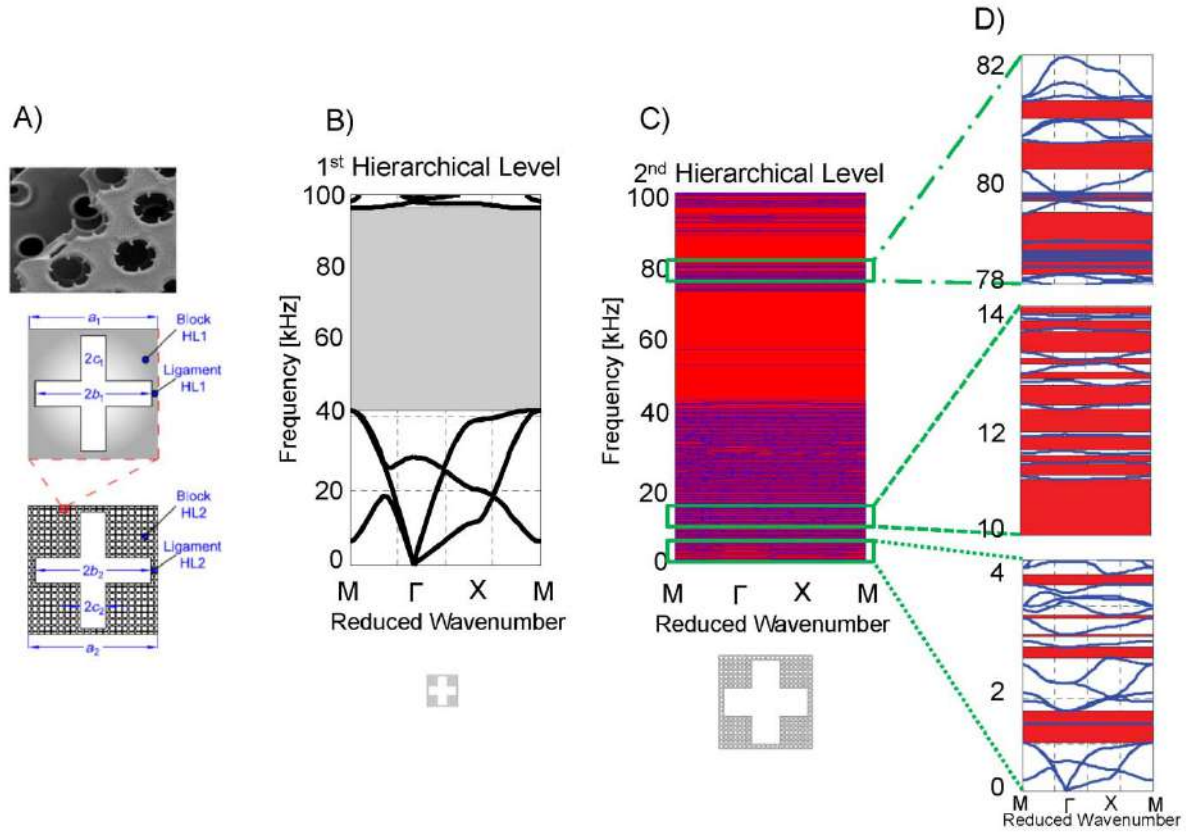

Figure 1. (A) Hierarchical structures found in natural materials, diatom cell walls (top) presenting holes at different spatial scales and the corresponding bio-inspired hierarchical metamaterial unit cells (bottom). The structure is made of cross-like cavities repeated over multiple scales. Dispersion diagrams for the regular cross-like metamaterial with (B) regular and (C) hierarchical organization. (D) Zoomed regions of the dispersion diagram. The hierarchical organization at different spatial scales allows preserving the BG originating from a smaller constitutive geometry and opening frequency band gaps at lower frequencies.

CONCLUSIONS

We have numerically and experimentally investigated the influence of bio-inspired hierarchical organization on wave dispersion in metamaterials with self-similar constituents at various spatial scales. Various advantages are found and here summarized:
(1) partial conservation of the band gaps induced by the constitutive regular geometries;
(2) nucleation of additional hierarchically induced band gaps;
(3) similar wave dynamics at low frequencies for hierarchical and corresponding regular structures;
(4) shift of band gaps to lower frequencies due to the effective mass and stiffness reduction.

DAMPING IN PHONONIC AND ACOUSTIC METAMATERIALS: FROM UNDERSTANDING TO TAILORABLE BEHAVIOR

Anastasiia O. Krushynska[1]
[1]Engineering and Technology Institute Groningen (ENTEG), Faculty of Science and Engineering, University of Groningen, Groningen, the Netherlands

Summary This work is focused on establishing fundamental relations between architecture-driven dynamics of phononic & acoustic metamaterials and material properties of their constituents. First, by considering acoustic waves in thermoset and thermoplastic polymers, we summarize two key structure-driven mechanisms for wave manipulation and investigate the effects of material viscosity on them. Then we introduce a particle wave damping for 3D-printed metamaterials and prove that it has a strong potential for achieving controllable wave dissipation. All the reported results are verified experimentally on full-scale polymeric and metallic samples.

INTRODUCTION

Phononic and acoustic metamaterials are known for their superior abilities to control acoustic and ultrasonic waves at various frequency ranges. During the last three decades, a plethora of fascinating experimental works demonstrated intriguing dynamic phenomena, including wave attenuation at extremely low frequencies, subwavelength focusing and imaging, cloaking, scattering-free and one-way wave propagation, etc. [1]. These and other functionalities arise due to a tailored metamaterial architecture, rather than constituent materials. However, for acoustic waves in solids, material properties can significantly influence wave propagation in metamaterials and even cancel wave manipulation mechanisms induced by architecture. Prominent examples are frequency band gaps in polymeric phononic meta-structures, where material viscosity can shift the band gaps or even completely wash them out [2, 3]. In other cases, wave energy dissipation in a constituent material can be of advantage, as e.g. in metallic phononic structures with Bragg's scattering mechanism, when dissipation losses could be used to decrease a large number of the metamaterial unit cells necessary to reach a certain attenuation level [4].

Proper understanding of the influence of viscoelastic and other nonlinear material properties on the wave dynamics in metamaterials requires a rigorous theoretical treatment, thorough experimental testing and accurate data for all relevant material parameters. In the first part of this talk, we show how this problem can be tackled for phononic structures made of thermoset and thermoplastic polymers.

On the other hand, it is highly desirable to be able to control the level of material damping with the aim to enable even more advanced manipulation of elastic waves in metamaterials. As the material viscosity governed by complex molecular interactions might be very challenging to manipulate (if possible at all), we propose to harness a particle-driven damping widely used in vibration and noise reduction technologies. This mechanism can be easily employed due to recent advances in additive manufacturing techniques allowing to manufacture structures of arbitrary complex shapes. The working principle and potential of the particle-driven damping will be discussed in the second part of this talk.

WAVE DYNAMICS OF VISCOELASTIC POLYMERIC PHONONIC MATERIALS

As the dynamics of elastic waves in phononic and acoustic metamaterials is mainly governed by their tailored architecture, rather than constituents, it is common, in the first approximation, to model the material response as linear elastic neglecting any possible nonlinearities [1]. This approach, however, often fails in case of polymeric materials characterized by frequency-dependent viscoelastic losses [2,3]. Simplified viscoelastic models with a few viscous parameters cannot always capture related viscoelastic effects due to a broad frequency content of the material relaxation moduli commonly expanded over several orders of frequency magnitude, while the use of multi-mode models is restricted either by a lack of experimentally measured relaxation data or limitations of commercial finite-element software packages to deal with complex-valued dynamic characteristics [5]. In overall, it is unclear which material models should be used to correctly describe wave propagation in viscoelastic phononic and acoustic metamaterials.

Here, we present a thorough study of viscoelastic effects in thermoset and thermoplastic polymers on wave attenuation in phononic materials with the Bragg and local resonance wave manipulation mechanisms. The theoretical analysis is based on the in-house numerical framework developed previously to investigate wave dispersion in dissipative phononic meta-structures, which is capable of dealing with arbitrary complex linear viscoelastic models [6], and finite-element transmission simulations performed by means of the COMSOL Multiphysics. The material response is represented by the relaxation moduli accurately measured over the frequency range from 10^{-2} to 10^{7} Hz that distinguishes this study from other works using approximate or limited (in frequencies) data. Based on the obtained results, we derive clear guidelines on the validity of the commonly used simplified viscoelastic models depending on the working frequency ranges of a phononic material and suggest how the structural response can be analysed in the cases when the simplified models are inapplicable. The obtained results are verified in experimental tests on PMMA phononic plates exhibiting band gaps at various frequency scales (see Fig. 1). More details on the experimental measurements are given below.

PARTICLE-DRIVEN WAVE DISSIPATION IN 3D-PRINTED METAMATERIALS

Particle damping is a technique allowing to achieve energy dissipation in a vibrating cavity filled with particles. The damping mechanism, governed by collisions and friction between particles and the cavity walls, is widely used for reduction of vibrations in compressors, gears, and even rocket engines. With the advances in additive manufacturing techniques, the particle-driven damping can easily be implemented in phononic and acoustic metamaterials.

This work introduces the concept of phononic materials with architectural units partially or completely filled with particles. We first design simple solid 3D phononic configurations with the Bragg scattering and local resonance mechanisms and then analyse how the particle-driven damping implemented in various parts of these structures influences their wave attenuation abilities at band-gap frequencies. Careful analysis of the metamaterial microstructure filled with particles allows us to derive useful effective characteristics in order to correctly describe the particle damping at the macroscopic scale. The obtained results, confirmed by experimental measurements on metallic samples, reveal that the designed meta-structures are characterized by enhanced wave dissipation and can also exhibit tailorable energy dissipation by simply varying the volume of cavities filled by particles. Hence, the particle-driven damping opens promising avenues for further improving the control over wave dynamics in phononic metamaterials and their exploitation in multiple engineering applications.

EXPERIMENTAL TESTING

The theoretically derived results on wave dissipation in metamaterials are verified by performing transmission pitch-catch tests on polymeric phononic plates and 3D-printed metallic metamaterial samples (Fig. 2). The specimens are made with a milling machine from pristine PMMA thermoplastic plates and by means of SLM 3D-printing technique from 316L stainless steel, respectively. The wave propagation is excited using either a frequency sweep in a target frequency range by means of an amplified vibration exciter (TIRA, Shaker 51110) glued to the specimen surface, or broadband piezo-transducers at higher frequencies. The measured data are in an excellent agreement with the numerical predictions.

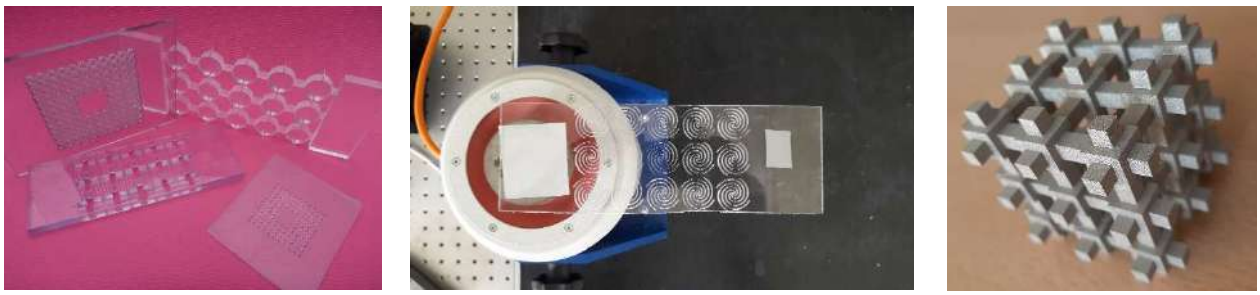

Figure 1. (*from left to right*) Polymeric (PMMA) phononic plates for experimental validation of viscoelastic effects on the dynamics of elastic waves controlled by the Bragg scattering and local resonance mechanisms; a part of the experimental setup for the transmission pitch-catch experiments in a low-frequency sonic frequency range; a metallic (stainless steel 316L) phononic crystal with particle-driven wave attenuation mechanism.

ACKNOWLEDGEMENT

The author would like to thank Profs. F. Bosia, A.S. Gliozzi and M. Scalerandi (Polytechnic University of Turin, Italy) and Dr. S. Ghio and Prof. N.M. Pugno (University of Trento, Italy) for their indispensable contribution in manufacturing of the polymeric samples, experimental testing and their continuous support of this project. Special appreciation goes to Dr. M. Acuautla Meneses, M. Stokroos (Discrete Technology and Production Automation Group, University of Groningen, the Netherlands), and Dr. T. Pijper (Phillips, Innovation cluster Drachten, the Netherlands) for the experimental measurements and manufacturing of the 3D-printed metallic samples.

Summary We present a three-dimensional model describing the propagation of elastic waves in a soil substrate supporting an array of cylindrical beams with flexural and compressional resonances. The resulting surface waves are of two types : hybridized Rayleigh waves in the sagittal plane with bandgaps resulting from an interplay between flexural and compressional resonances, and a surface wave with displacements perpendicular to the sagittal plane; this latter wave is the elastic analog of electromagnetic spoof plasmons and it is sensitive to flexural resonances only. Similar, yet quantitatively different, physics is reported in a two-dimensional setting involving resonances of plates.

We consider an array of beams atop a semi-infinite soil substrate $z \in (-\infty, 0)$. The beams are slender bodies, which means that their radius r_b is much smaller than their height h_b and we denote $(\rho_\mathrm{b}, E_\mathrm{b}, \nu_\mathrm{b})$ their mass density, Young's modulus and Poisson ratio. For the soil, $(\rho_\mathrm{s}, \lambda_\mathrm{s}, \mu_\mathrm{s})$ are the mass density and the two Lamé's coefficients. We have shown in [1] that the presence of an array of beams or plates can be encapsulated in effective boundary conditions on the soil surface which read

$$\sigma_{x\alpha}(\boldsymbol{x}, 0) = \mu_\mathrm{s} k_\mathrm{T} \varepsilon \, f_\mathrm{F}(\Omega) \, u_\alpha(\boldsymbol{x}, 0), \quad \alpha = x, y \quad \text{and} \quad \sigma_{zz}(\boldsymbol{x}, 0) = \mu_\mathrm{s} k_\mathrm{T} \varepsilon \, f_\mathrm{C}(\Omega) \, u_z(\boldsymbol{x}, 0), \tag{1}$$

where ω is the frequency, $k_\mathrm{T} = \omega\sqrt{\rho_\mathrm{s}/\mu_\mathrm{s}}$, $\Omega = \omega/\omega_0$ a dimensionless frequency with $\omega_0 = \frac{1}{\mathcal{S} h_\mathrm{b}}\sqrt{\frac{E_\mathrm{b}}{\rho_\mathrm{b}}}$, $\varepsilon = \frac{\theta}{\mathcal{S}}\sqrt{\frac{\rho_\mathrm{b} E_\mathrm{b}}{\rho_\mathrm{s}\mu_\mathrm{s}}}$ a coupling parameter with : for beams (3D) $\mathcal{S} = 2h_\mathrm{b}/r_\mathrm{b}$, $\theta = \pi r_\mathrm{b}^2/a^2$ and for plates (2D) $\mathcal{S} = \sqrt{3(1-\nu_\mathrm{b}^2)}h_\mathrm{b}/r_\mathrm{b}$, $\theta = 2r_\mathrm{b}/a$. The displacements associated to surface waves are written in terms of the elastic potentials $(\varphi, \boldsymbol{\psi})$, with

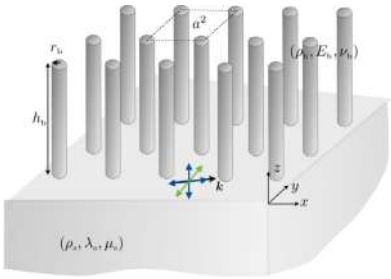

Figure 1: Soil substrate supporting an array of beams with flexural and compressional resonances. Hybridized Rayleigh waves with motions in the sagittal plane (blue arrows) and out-of-plane elastic SPPs (green arrows).

$\boldsymbol{u} = \Re\left[\boldsymbol{\nabla}\varphi + \boldsymbol{\nabla} \times \boldsymbol{\psi}\right]$ and $\boldsymbol{\nabla} \cdot \boldsymbol{\psi} = 0$. Making use of the isotropy of the medium, we define

$$\varphi(\boldsymbol{x}, z) = -\frac{iA}{k} \, e^{k\alpha_\mathrm{L} z + i\boldsymbol{k}\cdot\boldsymbol{x}}, \quad \boldsymbol{\psi}(\boldsymbol{x}, z) = \frac{1}{k}\left(B_n \boldsymbol{n} + B_t \boldsymbol{t} + iB_z \boldsymbol{e}_z\right) e^{k\alpha_\mathrm{T} z + i\boldsymbol{k}\cdot\boldsymbol{x}}, \tag{2}$$

with $B_n + \alpha_\mathrm{T} B_z = 0$, and where $\boldsymbol{k} = k\boldsymbol{n}$ and $\boldsymbol{t} \cdot \boldsymbol{n} = 0$. With β the ratio of the celerities of the Rayleigh wave c and of the bulk shear wave c_T, we have $\beta = \frac{k_\mathrm{T}}{k}$, $\quad 1 - \alpha_\mathrm{T}^2 = \beta^2$, $\quad 1 - \alpha_\mathrm{L}^2 = \xi\beta^2$, where $\xi = \mu_\mathrm{s}/(\lambda_\mathrm{s} + 2\mu_\mathrm{s})$. Doing so provides two families of surface waves. In the sagittal plane, hybridized Rayleigh waves have a dispersion of the form

$$\left(1 + \alpha_\mathrm{T}^2\right)^2 - 4\alpha_\mathrm{T}\alpha_\mathrm{L} + C_\varepsilon(\beta, \Omega) = 0, \quad \text{with} \quad C_\varepsilon(\beta, \Omega) = \varepsilon\beta^3 \left[f_\mathrm{C}\alpha_\mathrm{L} + f_\mathrm{F}\alpha_\mathrm{T}\right] + \varepsilon^2\beta^2 f_\mathrm{C} f_\mathrm{F}\left(\alpha_\mathrm{L}\alpha_\mathrm{T} - 1\right). \tag{3}$$

(where f stands for $f(\Omega)$). Next, displacement perpendicular to the sagittal plane is associated with a surface wave whose dispersion $\beta = \frac{1}{\sqrt{1+\varepsilon^2 f_\mathrm{F}^2(\Omega)}}$, $f_\mathrm{F}(\Omega) \geq 0$, is the elastic analog of electromagnetic spoof plasmons. As one would expect for $\varepsilon = 0$, the classical Rayleigh waves is recovered, and the elastic SPP disappears (with $k = k_\mathrm{T}$). Typical exemples of the dispersion of hybridized Rayleigh waves are reported in Fig. 2 for beams and plates (numerical validations are provided in this case). For plates, the overall agreement between direct numerics and our model is good. In particular, the coexistence of two branches in frequency ranges below the flexural resonances is confirmed. Next, as expected, the dispersion observed for an array of beams significantly differs from that observed for an array of plates.

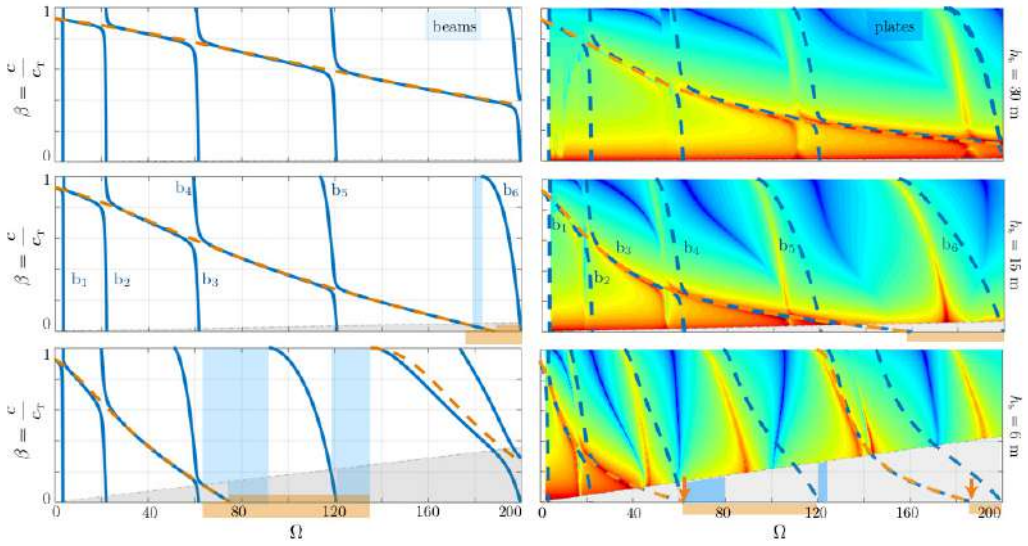

Figure 2: Dispersion of the hybridized Rayleigh wave for 3D beams and 2D plates – dimensionless velocity c/c_T versus $\Omega = \omega/\omega_0$ (blue lines). Dashed red lines show the dispersion produced by the compressional resonances on their own ($f_F = 0$). Bandgaps can be opened by periodicity (light blue region in the Brillouin zone) or they can be intrinsic (light blue region outside of the Brillouin zone, independent of a) and enlarged by periodicity.

The ellipticity χ of surface waves of the Rayleigh type (horizontal to vertical displacement ratio) characterizes the displacements at the soil surface. In the absence of out-of-plane displacements, from (3), it reads

$$\chi = \frac{\alpha_T\beta^2 + \varepsilon\beta f_C(\alpha_L\alpha_T - 1)}{2\alpha_L\alpha_T - (1+\alpha_T^2)} = \frac{2\alpha_L\alpha_T - (1+\alpha_T^2)}{\beta^2\alpha_L + \varepsilon\beta f_F(\alpha_L\alpha_T - 1)}, \tag{4}$$

whose variations versus Ω are reported in Fig. 3 for $h_b = 15$ m (middle panels in Fig. 2). In the reported cases, the branches b_n, $n = 1$ to 5, are below the first compressional resonance. From (4) and (3), these branches have 3 typical points: (i) the starting point ($\beta = 1$) for which $\chi = \varepsilon f_C$ which increases when $n = 1, \cdots, 5$ increases as f_C does; (ii) the frequency at which the wave motion transitions from prograde to retrograde with $\chi = 0$ when $f_F \to \infty$ and this is consistent with (1) which predicts $u_n = 0$ at the flexural resonances, (iii) the ending point for $\beta \to 0$ resulting in $\chi = -1/\xi$ for any branch. Next the branch b_6 appears just before the longitudinal resonance where $f_C \to \infty$ imposes $u_z = 0$. It results high values of χ in the neighbourhood of the singularity and it is worth noting that this affects a branch which is dictated by the interplay of flexural and compressional resonances.

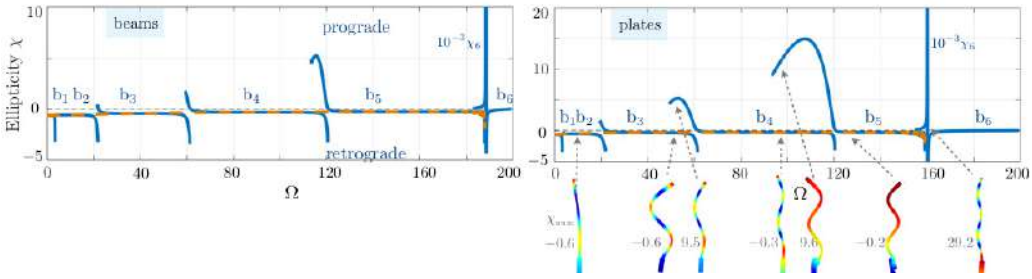

Figure 3: Ellipticity χ of the hybridized Rayleigh waves versus Ω – Blue lines show χ from (4), dashed red lines neglecting the flexion. Insets show the deformations in the plates atop the soil in a single cell.

We shall discuss the following points (i) The hybridized Rayleigh waves have an important part of their spectrum associated with celerities larger than that of the classical Rayleigh waves; (ii) These waves are associated with prograde or retrograde motion at the soil interface with large variations of the ellipticity; (iii) The existence of an out-of-plane surface wave, with infinite ellipticity on its own. This should be useful for the analysis of the displacement components in particular on records of the ambient noise for which the horizontal displacement is the sum of the two contributions [2, 3].

Summary Advances in shape-morphing materials, such as hydrogels, shape memory polymers and light-responsive polymers have enabled prescribing self-directed deformations of initially flat geometries. However, most proposed solutions evolve towards a target geometry without considering time-dependent actuation paths. To achieve more complex geometries and avoid self-collisions, it is critical to encode a spatial and temporal shape evolution within the initially flat shell. Recent realizations of time-dependent morphing are limited to the actuation of few, discrete hinges and cannot form doubly curved surfaces. Here, we demonstrate a method for encoding temporal shape evolution in architected shells that assume complex shapes and doubly curved geometries. The shells are non-periodic tessellations of pre-stressed contractile unit cells that soften in water at rates prescribed locally by mesostructure geometry. The ensuing midplane contraction is coupled to the formation of encoded curvatures. We propose an inverse design tool based on a data-driven model for unit cells' temporal responses.

INTRODUCTION

Morphing flat sheets into complex, three-dimensional geometries is a challenge that has been pursued for centuries by artists, and more recently by mathematicians and scientists. In engineering, the search for materials suitable for such transformations has been motivated by the ease of two-dimensional fabrication, which relies on subtractive processes, such as punching, machining, water jetting or laser cutting. Flat objects can be stacked in volumetrically efficient arrangements, which simplifies transportation and storage. While flat sheets are easy to fabricate and store, many structural and functional applications across scales rely on changing surface curvatures (e.g., tunable mirrors [1, 2] and parabolic antennae [3]). Morphing between flat geometries and desired curved surfaces requires methods for prescribing local deformations.

Here, we show that spatio-temporal information can be embedded in the geometry of architected shells that morph from flat to smooth three-dimensional shapes. This programmed temporal evolution enables reaching target geometries that would be impeded by collisions if shells actuated with uniform or unplanned deformation rates. Furthermore, our shells use polymers that actuate when the temperature in their environment is set to a critical value. At room temperature, they remain flat, storing the energy necessary to drive the deformation.

SPATIO-TEMPORAL PROGRAMMING OF SELF-ACTUATED SHELL MECHANISMS

We propose an inverse design algorithm for shell architectures and the temporal evolution of their shapes (Fig. 1). The algorithm collects user inputs at two stages: the first input is the desired 3D target surface, and the second is the specification of local deformation rates. We term this temporal map input an *actuation time landscape*. The algorithm outputs the mesostructure for initially flat shells that we fabricate and test. These shells have three layers, with a ~ 4.6 mm total thickness. The two outer layers are 3D-printed tessellations of non-uniform unit cells, made of Vero PureWhite (Stratasys). The middle layer is a 0.5 mm thick pre-stretched elastic membrane, which stores the energy required to drive the morphing process. Actuation from the flat to the curved profile is triggered by immersing the shells into $56°$ C water, which causes the outer layers to soften over the course of approximately 30 to 80 s.

The unit cells have a grid spacing of $\sim$ 10 mm, and are composed of cylindrical bases connected at the external shell surfaces by pairs of V-shaped brackets (Fig. 2). The bases serve as attachment points to the elastic membrane and as mounting points for the brackets. The brackets serve as nonlinear springs: they hold the structure flat prior to being placed in water, and then they guide the temporal morphing process, softening at rates determined by their geometric parameters when heated (thicker brackets soften at slower rates). There are also bumpers attached to the bases in the space between the brackets, which collide when the local contraction reaches the target magnitude and control the contact angle between adjacent unit cells. The membrane provides energy for actuation, compressing the brackets as they soften. All of these components play an important role for reaching targeted geometries through spatio-temporal programming. For example, the petalled structure shown in Fig. 3 has been programmed so that the petals reach their target shape sequentially, actuating from smallest to largest. If all petals deformed at the same rate, they would collide and would not reach the target geometry.

We incorporated a discretized mechanical model of our shells in an inverse design algorithm for obtaining desired temporal morphing. Given a target geometry and a smooth time landscape, the algorithm automatically generates the flat shell mesostructure that will produce the corresponding morphing process. The selection of bracket thicknesses is governed by the designer's specification of the actuation time landscape. Thicker brackets soften at a slower rate than

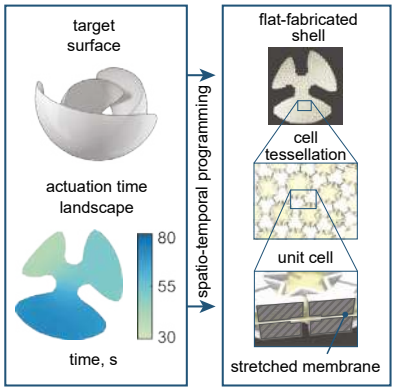

Fig. 1. A user-specified target surface and actuation time landscape are inputs to an inverse design procedure that defines the mesostructure of flat-fabricated shells that morph into the target geometries

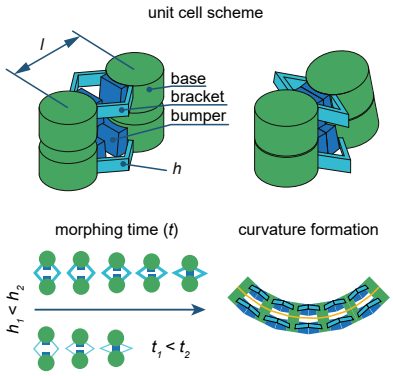

Fig. 2. Each unit cell has an initial central length *l*. Brackets control actuation time through their softening rate, which is controlled by their thickness, *h*, and a set of bumpers prescribe final local curvatures upon collision.

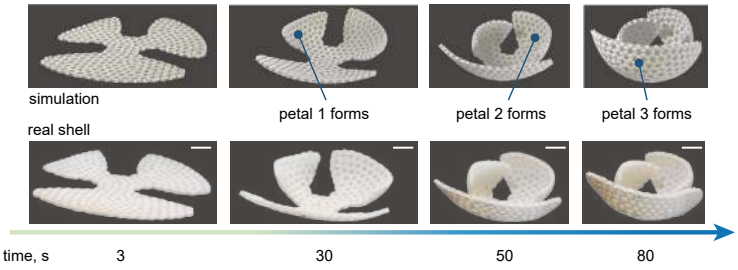

Fig. 3. Morphing of a petalled structure with an actuation time landscape ensuring that larger petals cover their smaller neighbors avoiding collisions on the way. Simulation and experiments are compared at 3, 30, 50, and 80 seconds in water. The structure replicates the encoded actuation time landscape shown in Fig. 1. Scale bars, 3 cm.

Fig. 4. A self-interweaving shell. Scale bar, 3 cm.

narrower ones, enabling distinct target deformation times to be realized in each region of the shell for collision avoidance, visual impression or other desired functionalities. Given that there can be a broad range of morphing sequences that yield certain target geometries, the morphing process can be designed according to the designer's goals by iterating through actuation time landscapes and observing their effect.

We showcase the complexity of achievable shapes through a set of examples, the most challenging of which is the self-interweaving structure shown in Fig. 4.

CONCLUSION

The significance of this method is that it enables collision-avoidance during deformations from flat shapes to curved geometries. We built a design system based on a data-driven mechanical model of mesostructures to predict shape evolution in time, enabling temporal morphing design. Applications of self-actuating shells to biomedical and construction industries are close to becoming reality with the fast advances in this field of study. Further generalizations of our approach to other materials such as liquid-crystal elastomers, bio-compatible polymers, and conventional engineering materials whose properties evolve in time due to other stimuli such as temperature, humidity, light, pH, etc., could enable rapid manufacturing of load-bearing structures that can only assume desired geometries through temporally planned deformations upon deployment as well as robotic materials temporally programmed for a broader range of functionalities.

DYNAMIC FLOPPY EDGE MODES AND ASYMMETRIC TRANSMISSION IN TOPOLOGICAL LATTICES

Jihong Ma[1], Di Zhou[2], Kai Sun[3], Xiaoming Mao[3], and Stefano Gonella*[4]

Summary Topological Maxwell lattices are known to support floppy edge modes on selected boundaries according to their polarization vector. For ideal lattices consisting of links connected by perfect hinges, the edge modes occur at zero frequency. For realistic lattices, whose hinges are ligaments with finite bending stiffness, the floppy modes morph into low-frequency edge phonons that coexist with the acoustic bulk modes. In this work, we experimentally document the existence of these modes, we investigate their dependence upon the hinge parameters and we exploit them to realize configurations with low-frequency asymmetric wave transport capabilities.

BACKGROUND INFORMATION

In recent years, substantial efforts have been devoted to applying the conceptual framework of topological states of matter, initially introduced for electronic and quantum systems, to classical mechanical systems. It has been shown that mechanical systems can acquire unconventional mechanical behaviors, such as one-way wave transport characteristics, that are rooted in the topological states of their phonon band structures. An especially interesting family of systems is represented by the so-called *Maxwell lattices* [1], i.e., lattices that contain an equal number of degrees of freedom and constraints in the bulk and, for this reason, are *on the verge of mechanical instability*. For an ideal system consisting of point masses connected by harmonic springs and forming a periodic lattice in d-dimensional space, the condition for a Maxwell lattice is $\langle z \rangle = 2d$, where $\langle z \rangle$ is the mean coordination number. This condition comes from balancing the degrees of freedom per site, d, with the average number of constraints per site, $\langle z \rangle / 2$.

These systems are known to feature topologically protected *floppy modes* (i.e., states of deformation that do not cause stresses in the ligaments and do not cost any energy) [2] and *states of self stress* (i.e., states of stress that are self equilibrated without external forces). These modes can be established either at the lattice *edges* (or boundaries) or at internal *domain walls* (or interfaces) between lattice sub-domains.

A topological invariant $\boldsymbol{R}_{\mathrm{T}}$, called *topological polarization vector*, was introduced by Kane and Lubensky in [3] to characterize the localization of floppy modes and states of self stress. Interestingly, $\boldsymbol{R}_{\mathrm{T}}$ can be constructed using information of the lattice unit cell and can therefore be seen as a *property of the bulk*. Nevertheless, it controls phenomena (e.g., the manifestation of floppy edge modes) *that manifest at the edges*. This fact can be seen as a clear example of the so-called *bulk-edge correspondence*, which is a fundamental principle underpinning many phenomena in topological mechanics, according to which certain classes of phenomena, despite being intimately controlled by the bulk, ultimately manifest at the edges. *Reconfigurable kagome lattices* have also been studied in which, by rotating the triangular elements about the hinges, it is possible to change not only the lattice geometry, but also the polarization vector, turning on/off floppy edge modes as well as dynamically deciding on which edge these modes will be observed.

The static behavior of ideal topological lattices has been extensively studied using ball-and-spring models. In contrast, experimental validations addressing the dynamic behavior of realistic lattices with finite hinges have been much sparser. In this work, we report on computational and experimental work that attempts to fill this gap in the literature.

RESULTS OF NUMERICAL AND EXPERIMENTAL ANALYSIS

We consider a strip of twisted and deformed kagome lattice, as shown in Fig. 1(a). The triangles in the unit cell are connected through thin, yet finite, ligaments, as shown in the inset. For the corresponding ideal lattice, the polarization vector points to the top edge, deeming it as the floppy edge and leaving the bottom edge as the non-floppy, or stiff, boundary. To verify whether the polarization is preserved even in the presence of ligaments at the hinges, we perform a supercell analysis. To this end, we consider a strip of cells spanning from top to bottom edge and we impose Bloch conditions in the direction of the arrow. The super cell band diagram reveals the existence of two low-frequency branches in the frequency range of the non-dispersive region of the canonical bulk acoustic modes. Since these modes do not appear in the band diagram of the unit cell, they cannot be bulk modes. Inspection of the mode shapes for these new branches confirms that they correspond to deformation mechanisms that localize at the edges, deeming them as *edge modes*. Two mode shapes associated with short-wavelength excitations ($\xi \to \pi$, where ξ is the non-dimensional wavenumber) of the lowest edge mode are reported in Fig. 1(b). *In essence, the observed edge modes are the dynamical counterparts of the zero-frequency floppy edge modes of ideal polarized Maxwell lattices, which have "migrated" towards finite frequencies.*

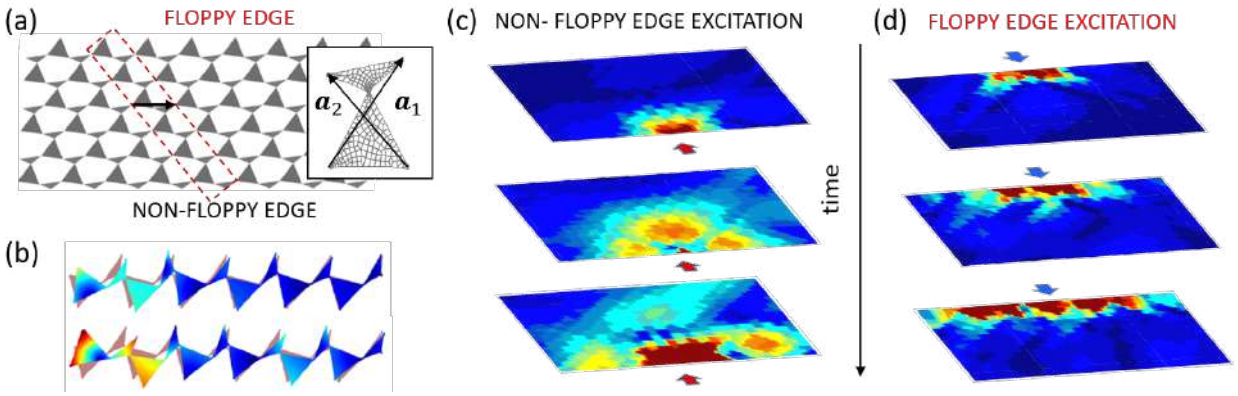

Figure 1: Dynamical behavior of topologically polarized Maxwell lattice. (a) Lattice geometry with unit cell featuring finite-thickness ligament hinge highlighted in the inset, super-cell encapsulated by dashed box, and floppy and non-floppy edges marked. (b) Two short-wavelength mode shapes for the first edge mode, revealing localization of deformation at the floppy edge. (c) Snapshots of wavefield for excitation at the non-floppy edge showing long-wavelength wave propagation in the bulk. (d) Snapshots of wavefield for excitation at the floppy edge, featuring localization at the excited edge.

To confirm the polarized behavior, we conduct dynamical experiments on a lattice specimen obtained from a sheet of acrylonitrile butadiene styrene (ABS) using water-jet cutting [4]. In this physical realization, the ligaments connecting the triangular elements of the kagome cell are slender elements endowed with finite thickness which can deform both axially and flexurally in the plane of the lattice. We excite the specimen with burst excitations in the frequency band of the edge mode. We conduct two separate tests in which we excite the structure from the non-floppy and from the floppy edge, respectively. The in-plane response of the lattice is captured using a 3D Scanning Laser Doppler Vibrometer. When we excite from the non-floppy edge, we mostly activate long-wavelength bulk waves that rapidly transport signal across the specimen, as shown in Fig. 1(c). In contrast, when we prescribe excitation a the floppy edge, we observe an edge wave in which the energy remains localized within a thin strip of lattice at the excited edge, as shown in Fig. 1(d). This behavior can be explained by recalling that, while in both cases the excitation frequency lives in the band of the edge mode, only an excitation prescribed at the floppy edge can directly activate the mechanisms associated with the edge modes.

To show that the asymmetric wave transport is frequency-dependent and confined to low frequencies, we perform a sweep of the carrier frequency in which, for each value of ω, we measure the displacement transmissibility between the excitation edge and the opposite edge. Again, we compare excitations prescribed at the floppy edge against excitations imposed at the non-floppy one. The results suggest that a significant difference in transmissibility between the two scenarios is observed over the entire frequency interval of the edge mode. Above the cut-off of the edge mode branch, the trasmissibility behavior is instead insensitive to the excitation edge selection. To further understand the effect of the bending stiffness of the hinges, we conduct FEM simulations for lattices with identical lattice vectors and connectivity but featuring ligaments with different thickness. The simulations reveal that, with thicker hinges, the polarization is further diluted and considerable leakage is observed in the bulk, where a mixture of bulk and edge phonons is observed.

By means of simulations, we also study the behavior of topologically polarized Maxwell lattices on elastic foundations operating in the nonlinear regime. We show that the simultaneous availability of nonlinearity (from large deformations) and asymmetry in the response (here guaranteed by the asymmetric behavior of the edges) can be leveraged to realize non-reciprocal phonon transmission. The non-reciprocal wave transmission can be switched on/off via topological phase transitions, paving the way to the design of metamaterials that can serve as tunable topologically protected phonon diodes.

CONCLUSIONS

In conclusion, we experimentally demonstrate that the topological characteristics of Maxwell lattices are overall preserved at finite frequencies when the non-ideality of their hinges is relaxed. However, with thicker ligaments, the behavior starts to deviate from that of an ideal topological lattice, as the polarization predicted for ideal lattices becomes progressively less adequate to capture the actual conditions established with continuum elasticity.

NON-LOCAL DYNAMIC CONTINUALIZATION OF DISCRETE PERIODIC MATERIALS VIA INTEGRAL TRANSFORM

Andrea Bacigalupo[1], Luigi Gambarotta[*1], Marco Lepidi[1] and Francesca Vadalà[1]
[1]Department of Civil, Chemical and Environmental Engineering, University of Genoa, Genoa, Italy

Summary A continualization of lattice-like materials based on a non-local integral down-scaling law is proposed. The difference equation of motion of the Lagrangian system is transformed into an integro-differential equation or a partial differential equation of infinite order. The resulting integral non-local continuum presents a Floquet-Bloch spectrum coinciding with the actual Lagrangian one. By a multi-variate expansion of the kernels of the integro-differential equation and retaining a prescribed number of higher-order terms, the governing equations of the higher order continuum are obtained, which are characterized by non-local constitutive and inertial tensors. Moreover, it is shown that the equivalent continuum governed by this field equations exhibit frequency band structures which are convergent to the actual Lagrangian one in the first Brillouin zone.

INTRODUCTION

The characterization of non-local continua to approximate the dynamic behavior of lattice-like materials presents some critical points regarding the energetic consistency of the equivalent continuum (see for reference [1-4]). To overcome these drawbacks, an energetically consistent continualization scheme has been proposed for beam-lattice materials for the optimal design of hyper-performance wave guides [5]. This approach resulted in a good approximation in simulating both the boundary layer effects and the frequency band structure of 1D beam lattices with lumped mass. In the present work a generalization of the previous formulation [5] is proposed and extended to 2D lattice-like materials.

DISCRETE AND CONTINUUM MODELS

Let us consider the pre-stressed cable net shown in Figure 1.a. The net is made of N pre-stressed massless strings of equal length ℓ connected at the nodes. Each node having mass m undergoes transverse motion and may be subjected to transverse forces. The resulting lattice-like material is characterized by the coordination number n representing the number of strings departing from the reference node $(i_1,...,i_{n/2})$ whose non-dimensional displacement $\psi_{i_1,...,i_{n/2}} = v_{i_1,...,i_{n/2}}/\ell$ is involved in the its dynamic balance equation

$$\begin{aligned}&\alpha_{i_1-1,...,i_{n/2}}\psi_{i_1-1,...,i_{n/2}} + \alpha_{i_1+1,...,i_{n/2}}\psi_{i_1+1,...,i_{n/2}} + \alpha_{i_1,...,i_{n/2}}\psi_{i_1,...,i_{n/2}} + ... + \\ &+\alpha_{i_1,...,i_{n/2}-1}\psi_{i_1,...,i_{n/2}-1} + \alpha_{i_1,...,i_{n/2}+1}\psi_{i_1,...,i_{n/2}+1} + f_{i_1,...,i_{n/2}} = I_\psi \ddot{\psi}_{i_1,...,i_{n/2}}\end{aligned} \quad (1)$$

being $f_{i_1,...,i_{n/2}} = \mathrm{f}_{i_1,...,i_{n/2}}/N$, $I_\psi = m\ell/N$ and $\alpha_{i_1,...,i_{n/2}}$ coefficients depending on the topology of the cable net.

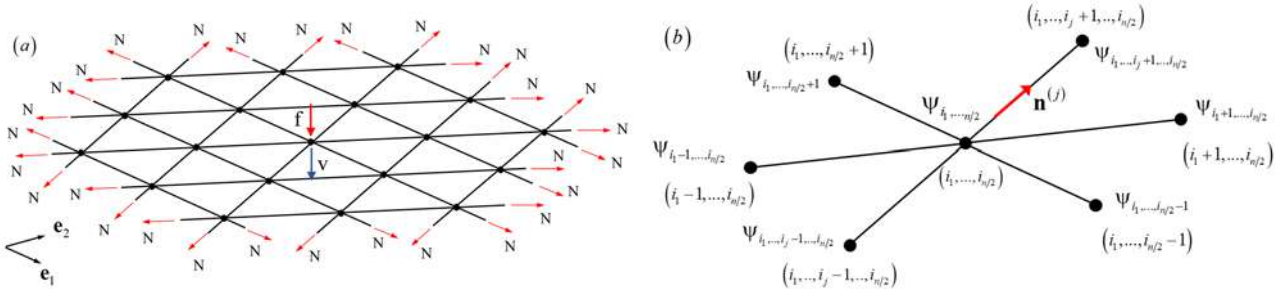

Figure 1. (a) Triangular prestressed cable net; (b) the reference node and the adjacent nodes with the connecting strings.

By introducing the multi-dimensional Z-transform $\hat{\psi}(z_1,..,z_{n/2},t) = Z\left[\psi_{i_1,...,i_{n/2}}\right] = \sum_{-\infty}^{+\infty}\cdots\sum_{-\infty}^{+\infty}\psi_{i_1,...,i_{n/2}}(t)\,z_1^{-i_1}\cdots z_{n/2}^{-i_{n/2}}$, with $z_j \in \mathbb{C}$, equation (1) may be reformulated as follows

$$\begin{pmatrix}\alpha_{i_1-1,...,i_{n/2}}z_1^{-1} + \alpha_{i_1+1,...,i_{n/2}}z_1 + \alpha_{i_1,...,i_{n/2}} + ...\\ ..... + \alpha_{i_1,...,i_{n/2}-1}z_{n/2}^{-1} + \alpha_{i_1,...,i_{n/2}+1}z_{n/2}\end{pmatrix}\hat{\psi}(z_1,..,z_{n/2},t) + \hat{f}(z_1,..,z_{n/2},t) = I\ddot{\hat{\psi}}(z_1,..,z_{n/2},t). \quad (2)$$

Let us consider the mapping $z_j = \exp\left(I\, n_r^{(j)} k_r \ell\right)$ on the unit circle (with $j = 1,..,n/2$ and $r = 1,2$) together with a continuum field $\Psi(x_1,x_2,t)$ in the physical space related through its Fourier transform $\mathcal{F}\left[\Psi(x_1,x_2,t)\right]$ to the Z-transformed nodal displacements defined as

*Corresponding author. E-mail: luigi.gambarotta@unige.it

$$\hat{\psi}\left(k_1,k_2,t\right) = Z\left[\psi_{i_1,\ldots,i_{n/2}}\right]\Big|_{z_j=\exp\left(In_r^{(j)}k_r\ell\right)} \doteq \mathcal{F}\left[\Psi\left(x_1,x_2,t\right)\right] = \hat{\Psi}\left(k_1,k_2,t\right) \quad . \tag{3}$$

As a consequence, equation (2) takes the form of governing equation of an integral non-local continuum as follows

$$\begin{aligned}&\mathcal{F}^{-1}\left[\begin{pmatrix}\alpha_{i_1-1,\ldots,i_{n/2}}\exp\left(-I\,n_r^{(1)}k_r\ell\right)+\alpha_{i_1+1,\ldots,i_{n/2}}\exp\left(I\,n_r^{(1)}k_r\ell\right)+\alpha_{i_1,\ldots,i_{n/2}}+\ldots\ldots+\\ +\alpha_{i_1,\ldots,i_{n/2}-1}\exp\left(-I\,n_r^{(n/2)}k_r\ell\right)+\alpha_{i_1,\ldots,i_{n/2}+1}\exp\left(I\,n_r^{(n/2)}k_r\ell\right)\end{pmatrix}\hat{\Psi}\left(k_1,k_2,t\right)\right]+\\ &+\mathcal{F}^{-1}\left[\hat{F}\left(k_1,k_2,t\right)\right]=I_\psi\mathcal{F}^{-1}\left[\ddot{\hat{\Psi}}\left(k_1,k_2,t\right)\right] \quad .\end{aligned} \tag{4}$$

The dispersion function associated to equation (4) is coincident by definition with the corresponding one of the Lagrangian model. By expanding the kernel in Taylor series and after truncation at the *H* order, a differential equation in terms of the continuum displacement field $\Psi\left(x_1,x_2,t\right)$ is obtained to which corresponds to a Lagrangian function having constitutive potential energy density not positive defined (*standard continualization*). Moreover, such equation presents only local/standard inertial terms. These problems may be circumvented by introducing a proper defined mapping of the transformed displacements $\hat{\Psi}\left(k_1,k_2,t\right)$ in the Fourier space into a new auxiliary regularizing continuum field $\hat{\Psi}^R\left(k_1,k_2,t\right)$ in the same space as follows

$$\hat{\Psi}^R\left(k_1,k_2,t\right) \doteq \prod_{j=1}^{n/2}\frac{\exp\left(In_r^{(j)}k_r\ell\right)-\exp\left(-In_r^{(j)}k_r\ell\right)}{2I\,n_r^{(j)}k_r\ell}\;\hat{\Psi}\left(k_1,k_2,t\right) \quad . \tag{5}$$

In this case a new integro-differential equation is obtained, which involves two kernels: the constitutive and the inertial ones. By expanding the kernels in Taylor series and after truncation at the *H* order, a differential equation in terms of the continuum displacement field $\hat{\Psi}^R\left(k_1,k_2,t\right)$ is obtained to which a Lagrangian function corresponds having both the constitutive potential energy and the kinetic energy density positive defined. In this case also inertial non-locality is consistently obtained (*enhanced continualization*). The frequency dispersive functions in the first Brillouin zone are represented in Figure 2 for the discrete Lagrangian model and the continuum models obtained via *standard* and *enhanced continualization*.

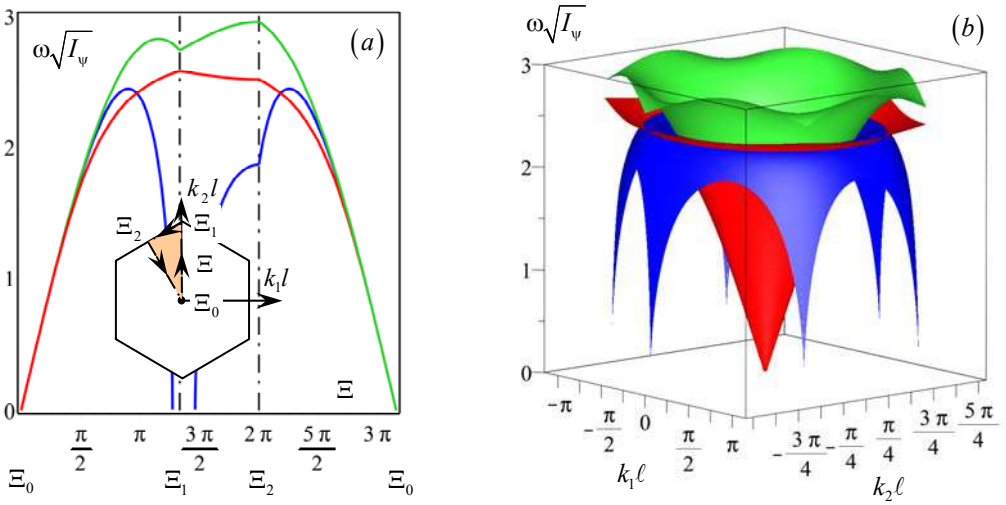

Figure 2. Frequency dispersive functions of the triangular pre-stressed cable net: Lagrangian model (green); 4th order standard continualization (blue); 4th order enhanced continualization (red).

MICROSCALE BISTABLE TENSEGRITY STRUCTURES

Zacharias Vangelatos[1], Andrea Micheletti[2], Costas Grigoropoulos[1], and Fernando Fraternali[3]

[3]Department of Civil Engineering, University of Salerno, Fisciano (Salerno), Italy

Summary We design and fabricate through multiphoton lithography microscale tensegrity lattices that exhibit bistable mechanical response. The examined structures tesselate tensegrity prisms in the three-dimensional space. Such units undergo a snapping twisting transformation between two stable configurations under compression loading. In situ indentation tests show the activation of the snapping event at the end of a primary softening response branch in the examined lattices, and the repetition of such a transition under loading-unloading cycles. The presented numerical and experimental results lead us to conclude that multiphoton lithography offers an accurate procedure to fabricate multi-cell tensegrity lattices with multi-stable response, which may feature unconventional static and dynamic responses, energy absorption capacity and solitary wave dynamics.

FABRICATION OF MICROSCALE TENSEGRITIES

The structures examined in the present study were fabricated by multiphoton lithography [1] using the experimental setup shown in Fig. 1. The employed material is a hybrid organic-inorganic material Zr-DMAEMA consisting of 70 wt% zirconium propoxide, 10 wt% (2-dimethylaminoethyl) methacrylate (DMAEMA) (Sigma-Aldrich), and 20 wt% ASTM type II deionized, distilled water. Briefly, 1.4 ml of 3-(trimethoxysilyl)propyl methacrylate (MAPTMS) (Sigma-Aldrich) were first mixed with 0.14 gr of hydrochloric acid in a vial. Then, in another vial, 137.7 μl of DMAEMA were mixed with 0.66 ml of zirconium (IV) propoxide solution containing 70 wt% 1-propanol. After intermixing the two mixtures, they were placed in a vial diluted with 0.2 ml of distilled water and 0.016 gr of photoinitiator consisting of 4,4′-bis(diethylamino)benzophenone (Sigma-Aldrich). Before the fabrication, the experimental material was placed on glass substrates and heated at 40 ºC for 2 hr in vacuum. Details about the material synthesis and experimental setup have also been reported elsewhere [1]. It should be noted that multiphoton lithography is the only fabrication technique with the resolution needed to construct the structures examined in this study. The only challenge with this technique is the perception of the 3D space when designing these geometries. All of the metamaterial structures were fabricated several times to ensure repeatability. The unit cells height was 10 μm and the beam diameter was 0.5 μm. The structures were fabricated with constant cross sections, since variance of the thickness at the hinges resulted in inept photopolymerization of the structure. Figure 2 illustrates the fabricated structures.

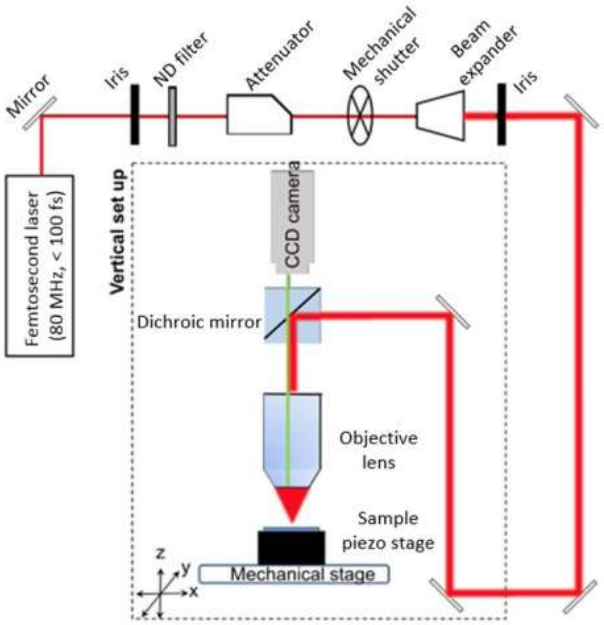

Figure 1. Schematic of the multiphoton lithography experimental setup.

MECHANICAL TESTING

In situ indentation tests were performed with a nanoindentation apparatus (PI 85 SEM PicoIndenter, Hysitron) placed inside a scanning electron microscope (FEI Quanta 3D FEG), thus enabling high-precision nanomechanical testing and real-time recording of the deformation. The molybdenum tip (Model # 72SC-D3/035 (407A-M)) was cut to a diameter of

75 μm by a femtosecond laser and was finished with a Focused Ion Beam (FIB) to be flat. The maximum tip displacement was set at 10 μm. A triangular force function with loading and unloading rates both set at 0.2 μm/s was used in all the tests. To ensure the repeatability of the measurements, each experiment was repeated at least three times. The force-displacement plots of 3D assemblies of bistable tensegrity prisms reveal a softening behavior during loading form the first stable configuration, up to a snapping event that drives the structure into a second stable configuration (Fig. 3). The twisting mechanism that characterizes such a transition is preserved after unloading and during repeated loading-unloading cycles.

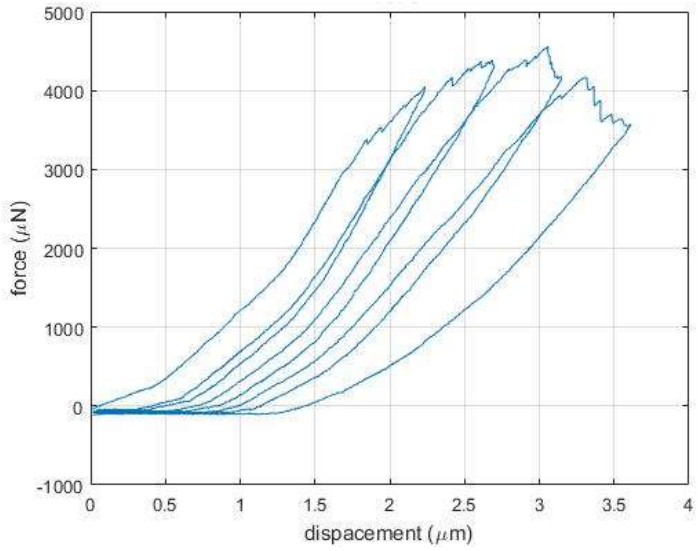

Figure 3. Force-displacement plot of an in-situ indentation test.

CONCLUSIONS

The results of the present study demonstrate that fabrication of multistable tensegrity lattices is highly feasible via multiphoton lithography, and pave the way to the fabrication of multi-cell tensegrity metamaterials with unprecedented static and dynamic responses [3-5] at the microscale.

SELF-LOCKING ORIGAMI MECHANICAL METAMATERIALS: PROGRAMMABLE STIFFNESS AND PARAMETER IDENTIFICATION

Hongbin Fang*[1], Zuolin Liu[2], and Jian Xu[2]
[1]Institute of AI and Robotics, Fudan University, Shanghai, China
[2]School of Aerospace Engineering and Applied Mechanics, Tongji University, Shanghai, China

Summary Origami has been recognized as an important resource for designing mechanical metamaterials. Based on the single-collinear degree-4 vertex origami tessellation, it is found that each unit cell can self-lock at a non-flat configuration. Experiments and numerical analyses show that by switching the deformation modes of the constituent cell from pre-locking folding to post-locking pressing, its stiffness experiences a sudden jump. Such a stiffness jump is generalized to a multi-segment piecewise stiffness profile in a multilayer mechanical metamaterial. Note that for a given self-locking origami metamaterial, the constitutive relation (including the model and the parameters) is always completely opaque and unmeasurable. Hence, based on the piecewise linear assumption, a *physically-interpretable* neural-fuzzy network is built to construct the model and identify the unknown parameters.

INTRODUCTION

Single-collinear degree-4 vertex origami unit would self-lock at a non-flat configuration owing to the collision of facets. This property can be utilized to develop self-locking origami mechanical metamaterials. We show that kinematically, self-locking origami mechanical metamaterials possess wide design space to adjust its foldability and relative density [1,2]. Experiments and finite element analyses are combined to demonstrate that by switching the deformation modes of the constituent cell from pre-locking folding to post-locking pressing, which essentially, is a phase change, its stiffness would experience a sudden jump. By tessellating multiple layers into an n-layer metamaterial, an n-segment piecewise stiffness profile can be achieved. Furthermore, by strategically switching the constituent cells' deformation modes through active methods, the n-layer metamaterial's stiffness is controllable among $2n$ target stiffness values [2].

Note that practically, for a finished self-locking origami mechanical metamaterial, the number of locking points, the positions of locking points, and the stiffness value in each deformation stage are always difficult to be accurately obtained a priori through simple measurements, which makes the constitutive relation (i.e., the force-deformation profile) completely or partly opaque. This arouses interests in adopting inverse approaches, i.e., dynamic identification methods, to precisely estimate the parameters and build the model. Aiming at this specific problem, the piecewise linear constitutive relation is determined using a physically-interpretable neural-fuzzy network [3].

LOCKING-INDUCED PROGRAMMABLE PIECEWISE STIFFNESS

A single self-locking origami cell would experience two deformation modes that are qualitatively different when being compressed: the pre-locking folding mode and the post-locking pressing mode (Fig. 1(a)). In the folding mode, the cell exhibits relatively low stiffness that originates from the rotational stiffness of the creases; while in the pressing mode, the cell receives a significant increase in stiffness that comes from the bending or twisting of the origami facets. By connecting n origami cells in series by assuming force balance at the connections, a self-locking origami structure can be obtained (Fig. 1(b)).

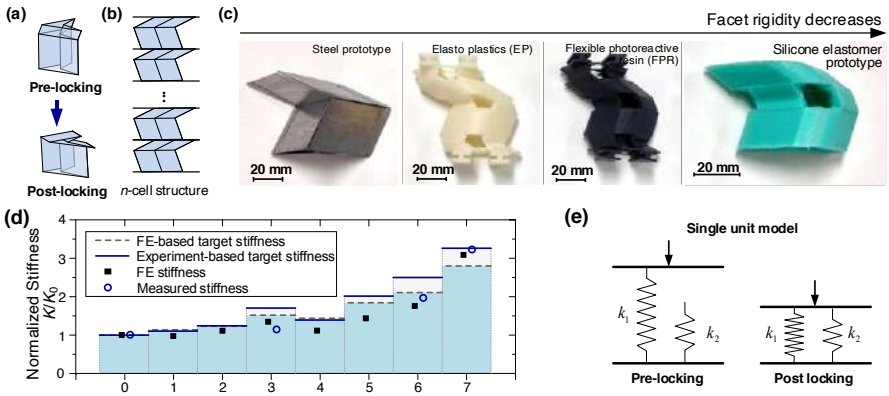

Figure 1. Self-locking origami mechanical metamaterials. (a) A single unit at the pre-locking and the post-locking modes; (b) a n-cell self-locking origami structure; (c) experimental prototypes made of different materials; (d) FE and experimental results; (e) equivalent lumped mass model of a single unit.

Theoretically, if without any internal actuation or control to individually deform the constituent cells, the overall structure can exhibit n+1 stiffness values in a passive compression/tension process. Each time when a constituent cell reaches or leaves its self-locking configuration, the overall stiffness of the structure will undergo a jump. On the other

* Corresponding author. E-mail: fanghongbin@fudan.edu.cn.

hand, if internal actuations are applied, each constituent cell's folding and locking can be actively controlled. In such a scenario, the overall structure is capable of reaching 2^n stiffness values by strategically switching the constituent cells' deformation modes between pre-locking folding and post-locking compressing.

Based on different materials and via different methods, proof-of-concept unit prototypes are fabricated (Fig. 1(c)). Particularly, quasi-static tests and finite element analyses are performed on a 3-layer prototype made of flexible photoreactive resin (FPR) via 3D printing. The predicted 4 (n+1=4) stiffness segments in a passive compression process and the predicted 8(2^n=8) stiffness segments in an active folding process are verified (Fig. 1(d)). Moreover, to quantify such piecewise stiffness profile, an equivalent spring model is also developed (Fig. 1(e)).

IDENTIFICATION OF THE PIECEWISE LINEAR CONSTITUTIVE RELATION USING A PHYSICALLY-INTERPRETABLE NEURAL-FUZZY NETWORK

The self-locking origami metamaterial can be utilized as nonlinear damper, where the load mass may be subjected to force excitation. In such a scenario, the number and positions of the non-smooth points and the linear parameters of each segment of the piecewise-linear constitutive relation is completely unknown; they need to be determined via dynamic identifications.

In this research, after processing the data based on B-Spline Galerkin finite element and integration by parts, a local linear neural-fuzzy network (LLNFN) is built (Figure2). The LLNFN consists of three layers: the input layer, the hidden layer that symbolizes the fuzzy rules, and the output layer. Numerical experiments show that the built network could effectively determine the form and the parameters of the piecewise-liner constitutive relation. Moreover, unlike conventional neural network that the components are not physically interpretable, here, the constructed neural network possesses specific physical meaning of its components: the number of neurons relates to the number of piecewise segments (i.e., the number of self-locking origami cells), the coefficients of the local linear models relate to the parameters of the constitutive relation in each segment (i.e., the pre-locking and post-locking stiffness of each self-locking origami cell), and the validity functions relate to the positions of non-smooth points (i.e., locking position of the origami cell).

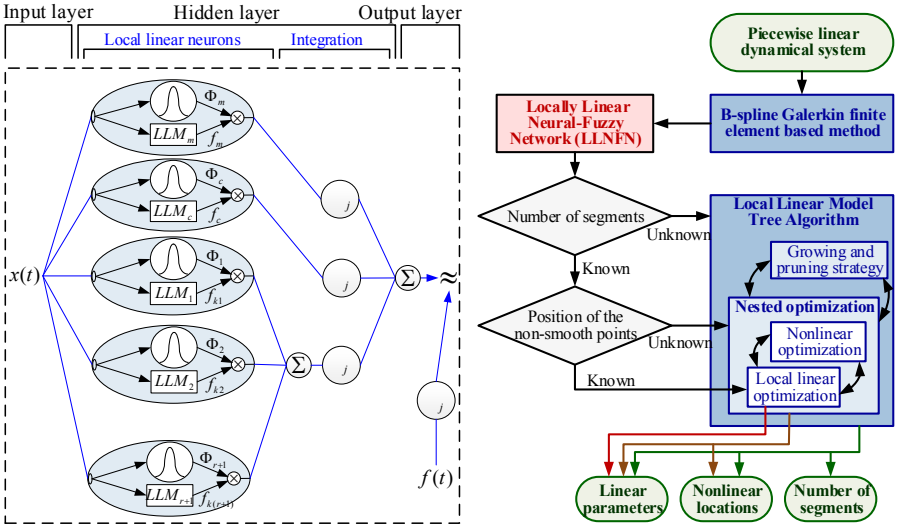

Figure 2. The constructed neural-fuzzy network used for identifying the unknown piecewise linear constitutive relation of the self-locking origami structure.

CONCLUSIONS

Through experimental and numerical efforts, we demonstrate that the self-locking degree-4 vertex origamis provide a new platform for the design of metamaterials with programmable kinematic and mechanical properties, including programmable deformability, programmable density, and programmable stiffness. The programmability originates from the locking and the locking-induced stiffness jump of the non-flat-foldable origami. On the other hand, acquiring the constitutive force-deformation relations of the self-locking origami structures is of practical importance for applying them into engineering systems, especially for dynamic applications. This is achieved in this research through a physically-interpretable neural-fuzzy network. This research would therefore establish a solid foundation for exploring the mechanical and dynamical properties of the self-locking origami metamaterials, and meanwhile, significantly advance their engineering applications [4].

Summary Precise control of elastic waves along surfaces is a challenge for many applications in the field of mechanical vibrations, ultrasonic inspection and energy harvesting. Graded arrays of rods on elastic substrates recently revealed superior performances for broadband wave trapping and mode conversion. In this study, we present elastic metasurfaces able to govern waves at different scales and to increase energy harvesting using the Rainbow effect. The efficiency of the proposed metasurfaces is supported by analytical, numerical and experimental results, demonstrating the energy harvesting advantages of such designs.

INTRODUCTION

Metamaterials concepts are receiving increasing popularity for wave control across much of physics and engineering in electromagnetism, optics, acoustics and elasticity. While the momentum initially focused on the subwavelength bandgaps generated by the resonance, the research has delivered new forms of control, encompassing tailored graded designs to obtain spatially varying refractive index, wide bandgaps and mode conversion [1-3]. To capitalize on recent elastic metamaterial designs, energy harvesting is an attractive application [4] useful to self-power small electronic components, avoiding periodic battery replacement and chemical waste.

RESULTS

Starting from the seminal work on the resonant metawedge that supports both conversion and broadband reflection [2], we have restricted the problem to the case of a plate with graded rod-like resonators. Because each rod has a different resonance frequency, trapping varies spatially according to the frequency content of the incident wave, giving rise to the Rainbow effect [5]. By grading the array from short to tall resonators the group velocity tends to zero at the turning point

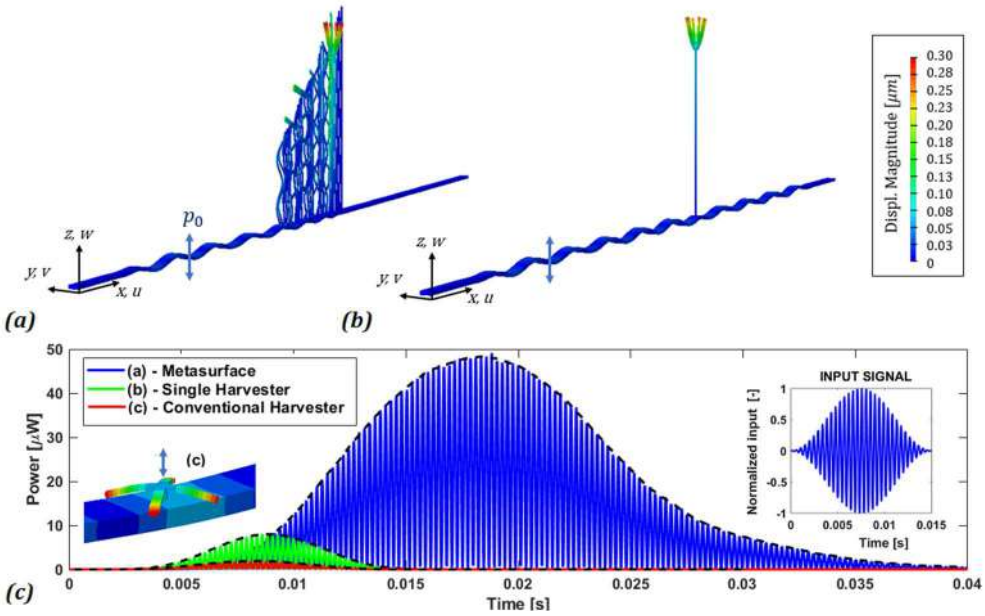

Figure 1. Harvester on a plate strip with (a), and without (b), the metasurface at time t = 10 ms. Electrical power for a maximum input acceleration of 1g at 2.15 kHz with, and without, the metasurface and compared to conventional cantilever beam scheme (c).

and the wave slows down and therefore spends time in the vicinity of the resonator feeding energy into it. Introducing in the array a properly designed piezo-augmented resonator is it possible to increase harvesting efficiency with respect to

*Corresponding author. E-mail: jacopomaria.deponti@polimi.it

conventional solutions (Figure 1) [6].
A similar effect can be obtained with horizontal beams directly attached on the plate strip, obtaining a device easy to manufacture also at microscale (Figure 2).

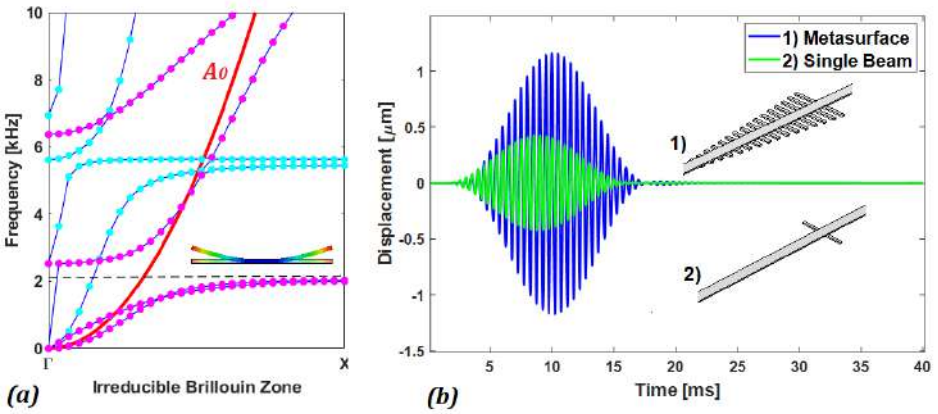

Figure 2. Rainbow trapping with horizontal beams directly attached on a plate strip. Dispersion curves (colors represent wave polarization: purple vertical, light blue horizontal) for a unit cell with a beam at right and left side (a). Tip displacement of the same beam inside 1) and outside 2) the metasurface (b) at 2.15 kHz.

After an introduction of the control capacity of graded elastic metasurface, the talk will present the numerical optimization of the trapping capacity and the results from an experiment in the kHz range. The experimental setup will be discussed in detail, showing the importance of a correct realization of Absorbing boundaries using the Acoustic Black Hole effect (Figure 3) [7].

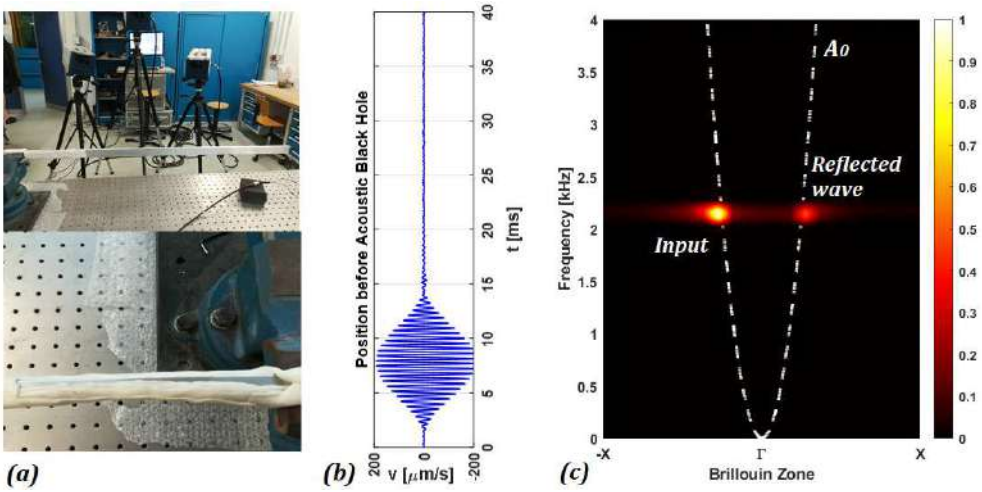

Figure 3. Experimental results on the Acoustic Black Hole. Experimental setup and Acoustic Black hole at the edge of the plate strip (a), velocity field before the Black Hole (b) and experimental dispersion showing the reflected wave reduction (c)

CONCLUSIONS

Efficient wave manipulation for enhanced energy harvesting is demonstrated using graded metasurfaces with different configurations. Energy is trapped in the position of the harvester, providing strong amplification. Broadband behavior can be achieved placing more than one harvester or exploiting nonlinear effects.

Summary This talk will provide an overview of elastic metasurfaces in the context of phononic crystals, gradient index lenses, transformation optics and resonant graded surface arrays and will draws upon analogies in the field of optics, photonic crystals and electromagnetism.

INTRODUCTION

Elastic metasurfaces can be constructed in several different ways, some of which bear more relation to phononic crystals than to metamaterials based upon resonances. I will cover both and discuss their relative merits, as shown in Fig. 1, and discussed in [1], it is possible to use surface resonance to tune and manipulate Rayleigh waves.

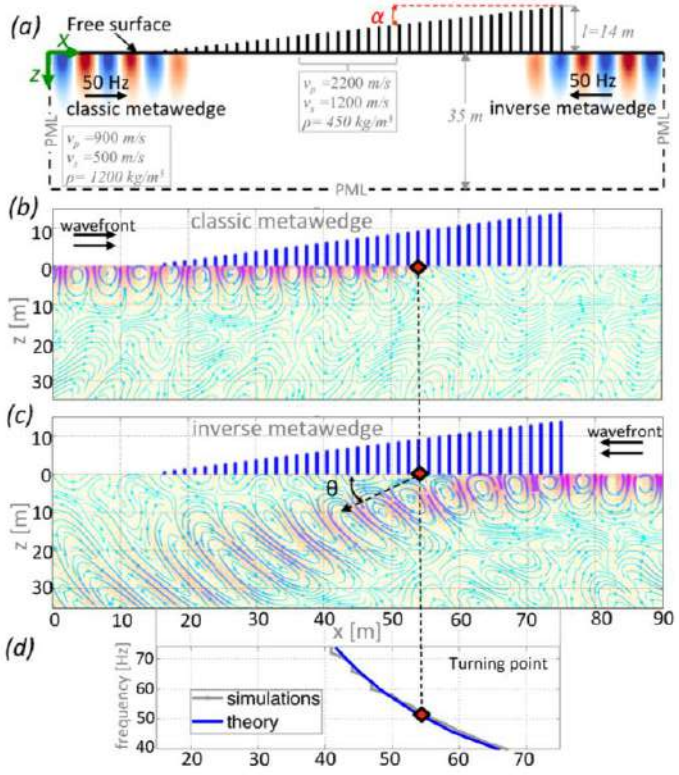

Figure 1. The metawedge from [1] is shown in (a)-(d) showing the effect of grading a surface array of rods that have resonances. In particular (b) shows frequency spatial selection and the ability to separate out frequency, panel (c) shows conversion from surface Rayleigh wave into bulk shear waves.

It is also possible to manipulate surface Rayleigh waves using ideas from transformation optics, this is an approach that has several merits. An initial attempt to steer surface waves using Luneburg lenses is in [2] and one aim of this talk is to discuss this approach in more detail.

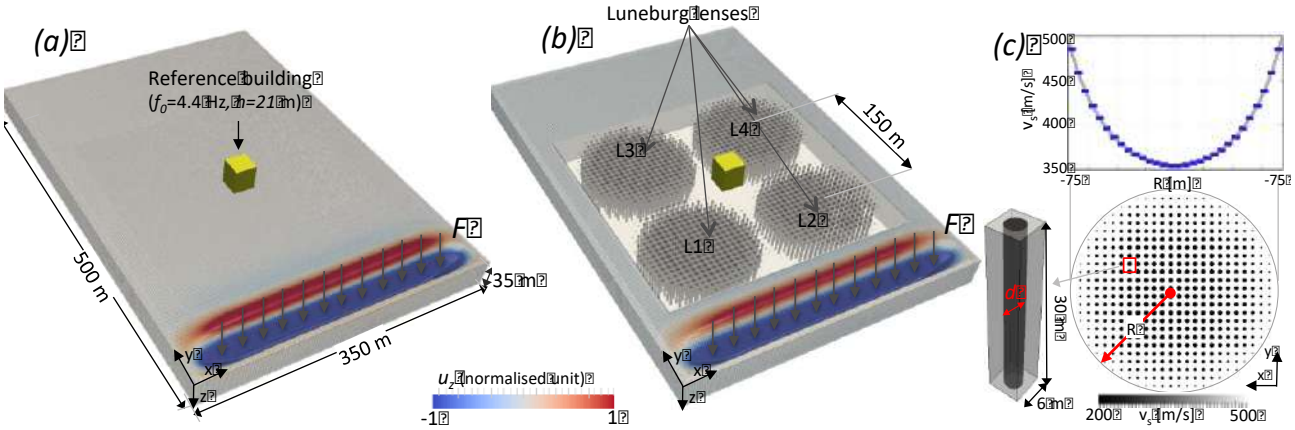

Figure 2. Using an arrangement of Luneburg lenses to steer surface elastic Rayleigh waves.

A TRULY RE-PROGRAMMABLE MECHANICAL METAMATERIAL USING MAGNETIC ACTUATION

Tian Chen*[1,2], Mark Pauly[2], and Pedro Reis[1]
[1]Flexible Structures Laboratory,Ecole Polytechnique Fédérale de Lausanne,Switzerland
[2]Computer Graphics and Geometry Laboratory,École Polytechnique Fédérale de Lausanne,Switzerland

Summary Mechanical metamaterials are engineered systems that exhibit physical properties that may not exist in conventional bulk materials. The periodicity or the internal unit structure of a mechanical metamaterial is often optimized for specific mechanical behavior. During fabrication, such architected materials are effectively "programmed" once and for all, and their functionality cannot be altered *a posteriori*. Here, we show a truly programmable metamaterial with fixed periodicity and internal structure, but each unit cell can be independently and reversely programmed on-demand. Programming of individual cells is achieved by switching between the equilibrium states of a bistable elastic shell using magnetic actuation. A tiled sheet of such unit cells exhibits tunable mechanical properties, including its stiffness, and yield strength and ultimate strength.

MAGNETIC PROGRAMMING OF UNIT CELLS

We propose a novel concept for a mechanical metamaterial that combines the versatility of a standard metamaterial (*i.e.*, periodicity and identical internal structure) with the targeted functionality of an architected structure [1], and with the novelty of repurposing after fabrication. In our system, each unit cell be switched to undergo a state change independently of the nearby cells, which we refer to as *programming*. Similar to a computer function, once programmed, the metamaterial maps the input (*e.g.*, quasi-static compression) to a set of desired outputs (*e.g.*, effective properties such as stiffness, yield strength, and ultimate strength). For a different set of desired outputs, the our metamaterial can be reprogrammed, reversibly, and on demand.

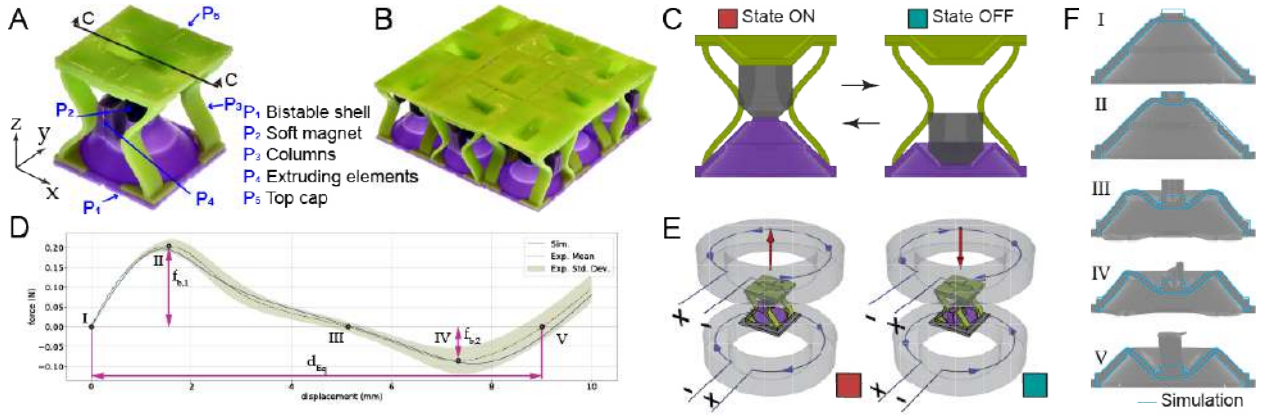

Figure 1: Design of one unit cell and its programming procedure. A: Fabricated and assembled unit cell using VPS. B: An tiled array of the unit cell. C: Geometry of the two equilibrium states. D: Force displacement behavior of the elastic bistable shell. E: Programming method using electromagnetic coils. F: CT imagery and simulation of the bistable shell under increasing displacement.

The unit cell of our elastic system (Fig. 1A) comprises a bistable elastic shell P_1, a soft magnet P_2, two set of naturally-curved columns P_3, two extruding elements P_4 and the top cap P_5. All parts are cast using Vinyl Polysiloxane (VPS) with the molds printed using Stereolithography. Each unit cell is cubic in shape and has an edge length of $30\,\mathrm{mm}$. Multiple cells can be tiled in a square lattice configuration (Fig. 1B). Each unit cell has two stable equilibrium states (Fig. 1C). The ON state is the state at which the unit cell is fabricated. In this state, the soft magnet is in contact with the top cap, and the columns are in contact with the extruding side elements. In the OFF state, the bistable shell snaps to a second equilibrium configuration, and both contacts are lost. Magnetic interactions are leveraged to switch between the ON and the OFF states, thereby enabling programming[2].

Programming is performed by moving the entire array on the x-y plane so that the intended unit cell is positioned at the center of the two electromagnetic coils of radius R and a separation distance of $\sqrt{3}R$. This is referred to as the Maxwell configuration. With equal current in the two coils, a constant gradient field ∇B is created. Consequently, a constant force f_m is experienced by the soft magnet. Hence, the behavior is analogous to a force boundary condition, *i.e.*, when the force at the apex of the shell reaches $f_{\mathrm{b},1}$, it will snap beyond the second equilibrium position. When the field is turned off, the shell will return to the second equilibrium (Fig. 1D). By reversing the polarity, the opposite effect is achieved. Since the

*Corresponding author. E-mail: tian.chen@epfl.ch

absolute value of $f_{b,1}$ is higher than that of $f_{b,2}$ and ∇B is constant within the predicted movement of the soft magnet, the magnetic field only needs to deliver a force greater than $f_{b,1}$ to enable programming and reprogramming. The dimensions of the elastic shell are optimized to maximize $f_{b,1}$ so long as it is lower than f_m. The optimized design allows for the ratio $f_{b,2}/f_{b,1}$ to be increased so that the stability of the second equilibrium state is maximized and to maximize d_{Eq} to widen the difference in mechanical behavior. X-ray micro computed tomography (μCT) is used to obtain a volumetric scan of the sample and help validate Finite Element Modeling (FEM) predictions (Fig. 1F).

MECHANICAL BEHAVIOR OF THE METAMATERIAL

Both a single unit cell and the assembled square array of 3×3 unit cells are tested under quasi-static cyclic compression from 0 to a strain of 0.26 at a rate of $1\,\mathrm{mm\,s^{-1}}$. Our results show a significant difference between the mechanical behavior of the two states in the quantities of interest, namely, stiffness, yield, and ultimate strength (Fig. 2A). Two topological changes contribute to this difference. Firstly, the switchable contact of the center (soft magnet and the bistable shell) to the top cap allows for the load to be carried axially, instead of only through bending of the columns (Fig. 2B, LP_1). Secondly, the confinement of the extruding elements exerted by the two columns again creates an axial load path (Fig. 2B, LP_2). Note that boundaries of the unit cell do not experience significant strain, and remain compatible with neighboring cells.

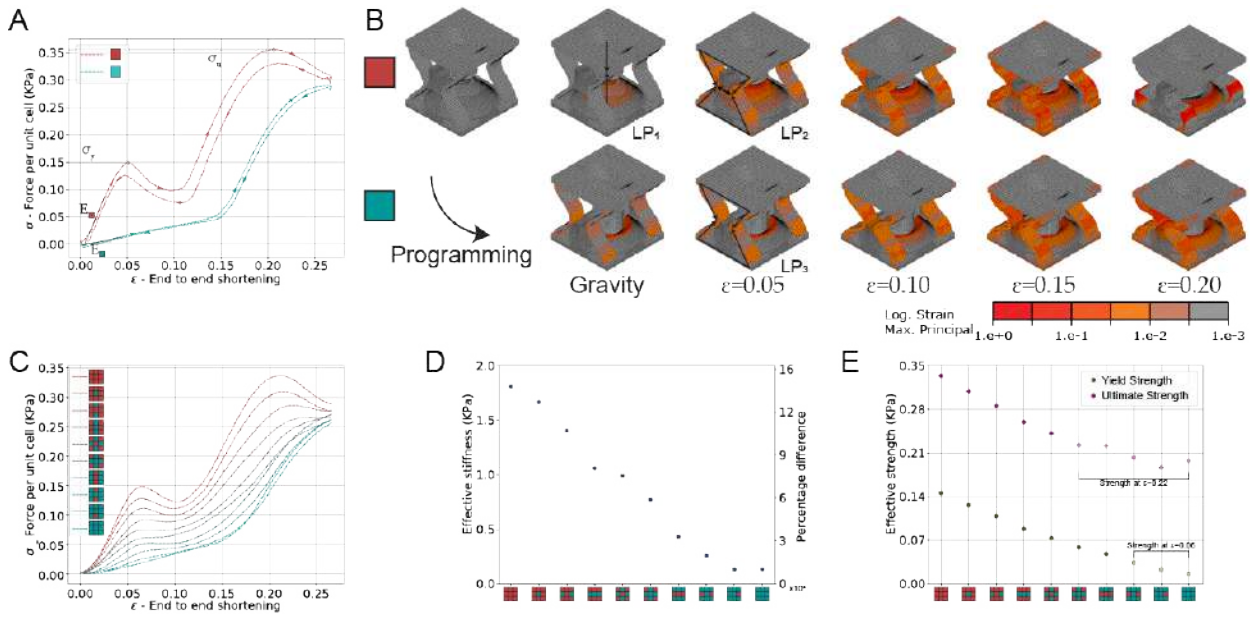

Figure 2: Mechanical response of the metamaterial under a compressive displacement. A. Behavior of one unit cell in both ON and OFF states. B. Corresponding simulation of a single unit cell, showing principal strains at different compression. C. Behavior of a 3×3 array in all possible combinations. D. Effective stiffness of each combination. E. Effective yield and ultimate strength of each combination.

As in a computer program, the execution of a function should not change the function itself, *i.e.* the programming should not be undone under compression. In our system, the programming procedure also involves a compressive load on the bistable shell. Nonetheless, due to the interaction between the buckled columns and the extruding element upon compression of the entire unit cell, these two processes are decoupled. Load and unloading of a unit cell in either state show a reversible stress-strain behavior with small loss due to viscoelasticity (Fig. 2A).

The loading part of the behavior of a 3 by 3 array (Fig. 2C) show interpolations between the two states of ON and OFF, thereby enabling a finer tunability of properties. All 9 combinations of the states are tested, with programming done with coils installed on the Instron testing machine. The stiffness is calculated by finding the maximum gradient prior to the yield. A near linear increase is observed as more unit cells are switched from the OFF to the ON state (Fig. 2D). The maximum increase is approximately $1500\,\%$. Similar tunability is exhibited with yield and ultimate strength. Note that these quantities cannot be unambiguously defined if most unit cells are in the OFF state. Therefore end-to-end shortening strain of 0.06 and 0.22 are used to provide a measure of the yield and ultimate strength respectively.

ONE-WAY FLEXURAL WAVES IN PLATES WITH CHIRAL RESONATORS

Giorgio Carta*[1], Daniel J. Colquitt[2], Alexander B. Movchan[2], Natasha V. Movchan[2], and Ian S. Jones[3]
[1]Department of Mechanical, Chemical and Materials Engineering, University of Cagliari, Cagliari, Italy

Summary In this contribution, we show how flexural waves can be forced to propagate in a single preferential direction within a thin elastic plate. This phenomenon is attained by introducing a periodic system of chiral resonators, consisting of elastic beams connected to gyroscopic spinners. The junction conditions between the beams and the plate are derived analytically by means of asymptotic techniques and employing the new concept of "logarithmic rotational spring". One-way wave propagation is generated by a time-harmonic force at the interface between two sub-domains of the structure, where the gyroscopic spinners rotate in opposite directions. The proposed system is versatile, as the direction of propagation and the frequency at which the phenomenon is observed can be varied by changing the rotations of the gyroscopic spinners.

INTRODUCTION

Phononic crystals and elastic metamaterials have received increasing attention from the scientific community in recent years [1]. In this context, chirality (the property of an object that cannot be superimposed onto its mirror image) has been used to design auxetic media [2] and alter the dispersive features of discrete systems [3]. Generally, these structures are geometrically chiral. In this paper, we consider an active chiral system, where chirality is induced by the mechanical action of gyroscopic spinners.

The aim of the present paper is to show the possibility of generating flexural waves in an elastic plate that propagate in one direction only. One-way edge modes immune to backscattering were firstly observed in photonic crystals and associated with the quantum Hall effect [4]. In elasticity, topologically protected edge and interfacial modes have been realised, for example, in plates [5, 6, 7, 8, 9] and lattices [10, 11, 12, 13]. Here, we exploit the preferential directionality conferred by gyroscopic spinners to create one-way interfacial waves in an elastic plate.

MODEL DESCRIPTION: PERIODIC ARRAY OF CHIRAL RESONATORS CONNECTED TO A PLATE

The system under consideration is illustrated in Fig. 1a. It consists of an elastic plate, connected to a doubly-periodic array of chiral resonators, represented by elastic beams whose tips are attached to gyroscopic spinners. The latter are solids of revolution characterised by mass m, moments of inertia I_1 and I_0 (about the axis of revolution and about the two perpendicular axes passing through the spinner's base, respectively) and gyricity Ω, representing the sum of the spinner's initial precession and spin rates. In [14] it is proved that the gyricity remains constant during the spinner's motion. The junction conditions between the beam and the plate are derived analytically in [15].

The elementary cell of the periodic system is assumed to be square. The band diagram of the system is determined for the case when the gyricity is uniform throughout the structure. Fig. 1b shows the band diagram when $\Omega = 100$ rad/s along the path Γ X M Y Γ, drawn in the inset. In the computations, the side length of the elementary cell is taken as $L = 2$ m. The plate has thickness $h = 0.01$ m, Young's modulus $E_\mathrm{p} = 70$ GPa, Poisson's ratio $\nu_\mathrm{p} = 0.3$ and density $\rho_\mathrm{p} = 2700$ kg/m^3. The beams have length $l = 1$ m, circular cross-section of radius $a = 0.02$ m, and the same elastic constants and density as the plate. The gyroscopic spinners are characterised by $m = 1$ kg, $I_0 = 4$ kg m^2 and $I_1 = 2$ kg m^2.

From Fig. 1b, it can be noticed that a narrow stop-band appears at low frequencies. The eigenmodes of the periodic cell for a given wave vector and frequency exhibit rotation of the beam around the z-axis. In addition, we note that the directions of rotation of the beam for two eigenmodes above and below the stop-band are opposite. This behaviour is exploited to create unidirectional waves, as discussed in the following.

ONE-WAY LOCALISED WAVES PRODUCED BY A TIME-HARMONIC FORCE

We consider a plate divided into two sub-domains, where the gyroscopic spinners rotate in opposite directions (see Fig. 1a). The system is excited by a time-harmonic force, applied at the upper end of a beam close to the interface between the two sub-domains. If the frequency of the force is taken inside the stop-band, for instance $\omega = \omega^* = 19.8$ rad/s (refer to Fig. 1b), waves are likely to propagate along the interface, in one specific direction.

In the numerical simulations, performed in the finite element software *Comsol Multiphysics*, the plate is made of 50×50 elementary cells. In order to avoid reflections of waves at the boundaries, PML (*Perfectly Matched Layers*) are inserted near the edges of the computational model. Fig. 1c presents the colour map of the plate's transverse displacement amplitude W_p due to a force of amplitude 1 N. It is apparent that waves propagate only to the left of the force and are localised at the interface.

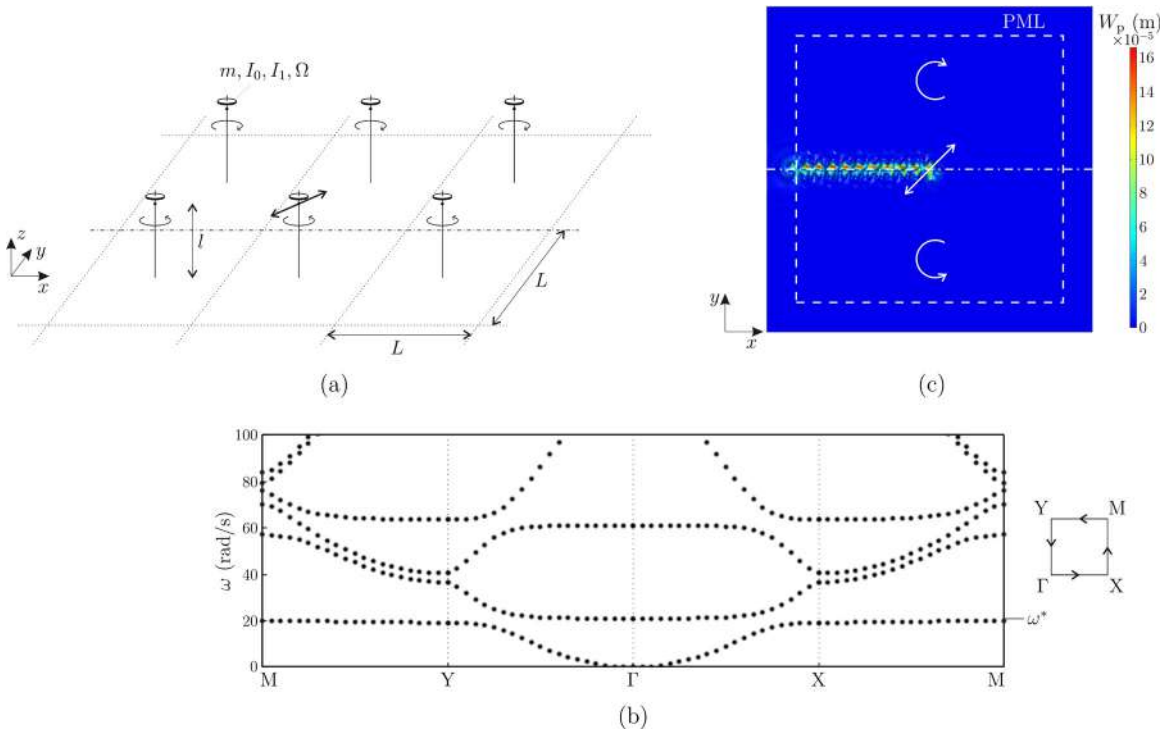

Figure 1: (a) Plate connected to a doubly-periodic array of beams with gyroscopic spinners; (b) band diagram of the periodic system along the path Γ X M Y Γ; (c) displacement amplitude field produced by a time-harmonic force with frequency ω^*, indicated in (b).

CONCLUSIONS

The results of Fig. 1 demonstrate that the proposed system, consisting of a plate attached to a doubly-periodic array of chiral resonators, is capable of supporting one-way interfacial waves. The model is flexible in that the same phenomenon can be replicated at different frequencies and with opposite direction of propagation by changing the value or the sign of the gyricity Ω. More sophisticated models can be designed and constructed, such as the system described in [16], incorporating double resonators made of two beams and two gyroscopic spinners.

We envisage that the chiral structure described here can have important applications in mechanical and civil engineering, for the control of vibrations in structural systems and mechanical elements.

PERIODIC GEOMETRIC TRANSFOMATION FOR OUT-OF-PLANE SHEAR WAVES

Bibinur Meirbekova[1,2] and Michele Brun*[1]
[1]Department of Mechanical, Chemical and Material Engineering, University of Cagliari, Cagliari 09123, Italy
[2]Department of Mechanics and Mathematics, Al-Farabi Kazakh National University, Almaty 050040, Kazakhstan

Summary A two-dimensional periodic geometric transformation is considered for the problem of out-of-plane shear wave propagation in an elastic media. The transformation leads to the design of a doubly periodic particulate medium with a system of anisotropic and inhomogeneous interfaces surrounding the void or rigid inclusions. The dynamic properties of the system are determined comparing the dispersion properties before and after the geometric transformation.

The analysis of dispersive properties reveals the invariance of the dynamic behavior for a "regular" transformation, but also the possibility to obtain new effects for "overlapping" and "unfolding" transformations.

Due to periodicity, it is possible to cloak an arbitrarily large region with multiple large holes, or to obtain a highly reflective interface in presence of holes of negligible size.

DOUBLY PERIODIC GEOMETRIC TRANSFORMATIONS

Geometric transformation techniques have been extensively applied to design cloaking system capable to hide defects. The basic idea is that a simply connected region, most often a circle, is mapped into a multiply connected one (an annulus). Greenleaf, Lassas and Uhlmann [1] showed that singular transformations lead to cloaking for conductivity, while [2, 3] applied this technique to achieve cloaking for electromagnetic waves. In vector elasticity, the wave equations are not invariant under a general mapping [4, 5, 6], while the biharmonic equation for flexural wave propagation in Kirchhoff plates is transformed into an equation of an inhomogeneous and anisotropic plate in presence of in-plane stress [7, 8]. Extended reviews on transformation optics in metamaterials in different fields, with a focus on experimental results, can be found in [9, 10].

Here, a doubly periodic geometric transformation is considered, as shown in Figure 1. In each cell, the non singular local radial transformation from the original local coordinate R to the transformed one r is

$$r = g(R) = R_0 + \frac{R_0 - R_2}{R_0 - R_1}(R - R_0), \tag{1}$$

where the homogeneous isotropic interface in $R \in [R_1, R_0]$ is mapped into the inhomogeneous anisotropic interface in $r \in [R_2, R_0]$.

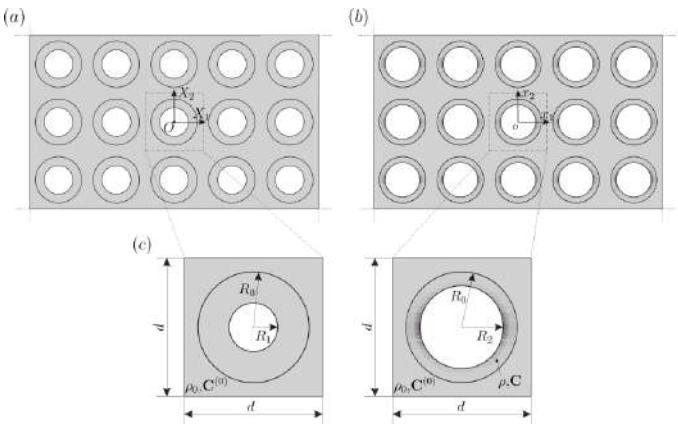

Figure 1: Double periodic geometric transformation of the perforated medium. Each homogeneous interface (a,c) of internal and external radii R_1 and R_0, respectively, is transformed into an interface (b,c) of internal and external radii R_2 and R_0, respectively.

*Corresponding author. E-mail: mbrun@unica.it

Filtering properties

Thanks to the periodicity of the transformation, it is possible to cloak multiple inclusions in an arbitrary large region, also in the case of relatively large defects. Additionally, by taking advantage of periodicity, it is possible to design a grating interface, with voids of negligible size, that shows extremely high reflection in a broad frequency and angle of incidence interval.

In Figure 2, the particular case of an interface in a waveguide is reported. An interface made of five void inclusions is present. In the upper part of the figure, in presence of relatively large voids ($2R_2/d = 0.8$), the incident wave

$$u_I = e^{ik_1 x_1 \cos\left(\frac{\pi x_2}{d}\right)} \tag{2}$$

is practically totally transmitted.

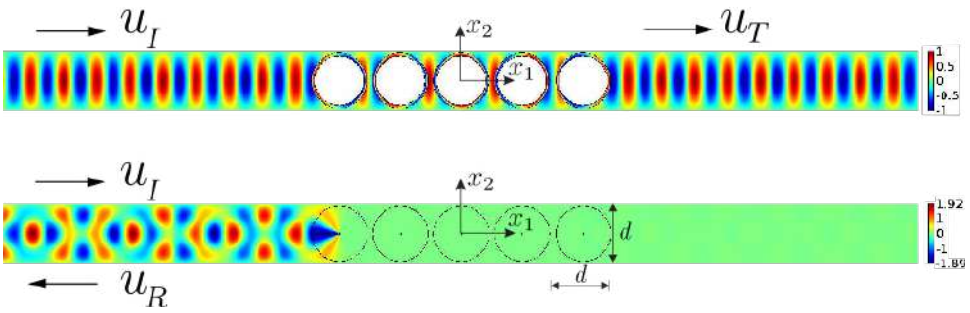

Figure 2: Wave transmission in a waveguide throughout an interface made of five void inclusions. Extremely high transmission and reflection in presence of, respectively, large and small holes are shown.

In the second case, while the size of the voids is relatively small ($2R_2/d = 0.01$), the incident wave is practically totally reflected. Such response is present in the all frequency interval that has been analysed with except of some peaks of transmission associated to the classical Fabry-Perot resonance.

CONCLUSIONS

The proposed elastic phononic crystal combines the properties of single inclusion cloaks with those of periodic systems in order to cloak multiple inclusion in a wide region or to reflect the incident energy. The filtering system is passive and does not need any active control.

BAYESIAN MACHINE LEARNING IN METAMATERIAL DESIGN: FRAGILE BECOMES SUPER-COMPRESSIBLE

Miguel A. Bessa*[1], P. Glowacki [1], and M. Houlder[1]
[1]Materials Science and Engineering, Delft University of Technology, Delft, The Netherlands

Summary We present the data-driven discovery of a metamaterial exhibiting recoverable super-compressibility. Unlike the usual materials design process that is guided by trial-and-error experimentation, we follow a unique computational data-driven approach where Bayesian machine learning guides the design process while experimentation is used for validation, not discovery. This enabled the design and additive manufacturing of a lightweight, recoverable and super-compressible metamaterial achieving more than 90% compressive strain without damage, despite using brittle base materials (fracture strain $\varepsilon_f < 4\%$). More importantly, within minutes, the machine learning model can be optimized to adapt the designs to different base materials, length-scales and manufacturing processes. The complete article has been published recently [1], and the computer code is released as open-source to promote future data-driven discoveries in multiple fields: https://github.com/mabessa/F3DAS

INTRODUCTION

Our data-driven exploration follows a framework that is opening new avenues in the design of materials and structures [2, 3, 4]. This modular framework integrates (1) design of experiments to sample the input variables, (2) efficient predictive analyses to generate the output database, (3) machine learning to establish input-output relationships from the database, and (4) optimization to determine optimum designs from the machine learning model. Different methods can be chosen for each module depending on the problem's dimensionality, size of database needed for the learning process, and whether the phenomena of interest is probabilistic or deterministic. Here, we focus on designing a new metamaterial based on a concept design introduced in the aerospace literature: the deployable mast [5]. Since our mechanical metamaterial undergoes probabilistic responses due to buckling/postbuckling mechanisms, and involves a moderate number of design parameters, we used a recent Bayesian machine learning method called sparse Gaussian processes [6] to fulfill these requirements while being sufficiently scalable.

DATA-DRIVEN DISCOVERY OF METAMATERIAL

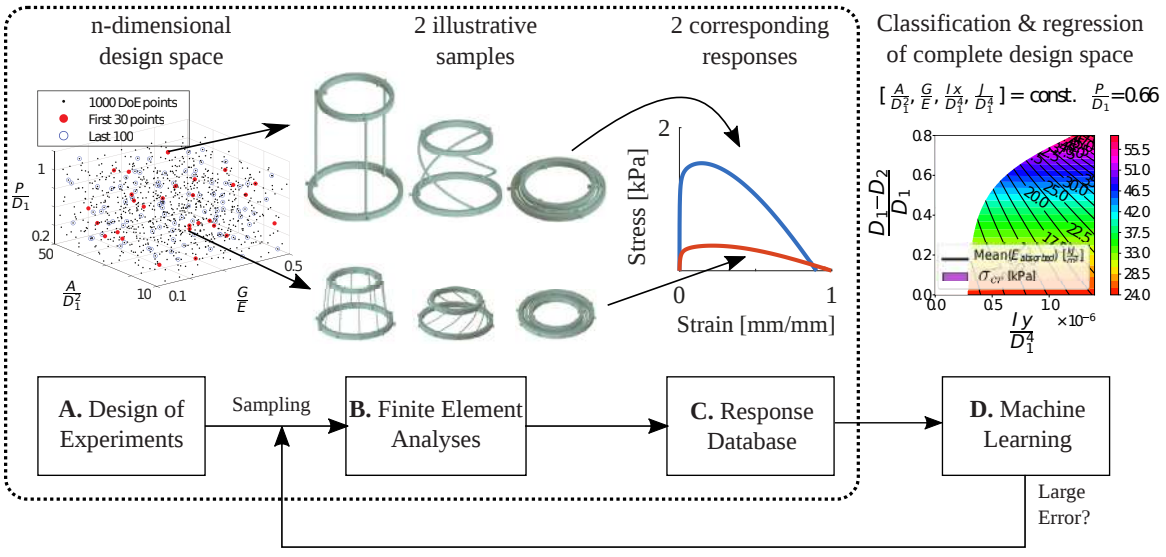

Figure 1: Data-driven design of super-compressible metamaterial building block using 7 design variables. [1]

Figure 1 summarizes the data-driven design of the metamaterial concept. First, the metamaterial is parameterized according to the design variables that define the geometry (top and bottom base diameters, D_1 and D_2, height P, and four parameters that define the cross-section of the vertical elements (longerons): the cross-sectional area A, moments of inertia I_x and I_y, and torsional constant J_τ). In addition, since the metamaterial is targeted to be reversibly deformable, any chosen base material is defined by its elastic constants: the Young's modulus E and the shear modulus G. Given that this is a nonlinear elastic mechanics problem we know *a priori* that the geometric variables can be scaled by one of the dimensions, chosen here as D_1, and that we can consider the ratio of elastic constants G/E. These seven input variables are then sampled according to a Sobol sequence (Figure 1A), finite element simulations for each sampling point (Figure

*Corresponding author. E-mail: M.A.Bessa@tudelft.nl

1B) create a database (Figure 1C), that is then evaluated by Bayesian machine learning to classify and regress the design space (Figure 1D).

The obtained machine learning model provides the relationship between the input design variables and the output quantities of interest: buckling strength and toughness of the metamaterial. This machine learning model can then be used as a surrogate model on which sensitivity analysis, dimensionality reduction or gradient based optimization techniques can be used. This has enabled us to predict viable designs of the super-compressible metamaterial and 3D print them at different length-scales. Figure 2 shows the microscopic design after being tested with a nanomechanical testing device. As shown in the figure, the metamaterial recovers from multiple cyclic loads and achieves unprecedented compressibility and strength. The macroscopic example (not shown for conciseness) achieves over 95% compressibility.

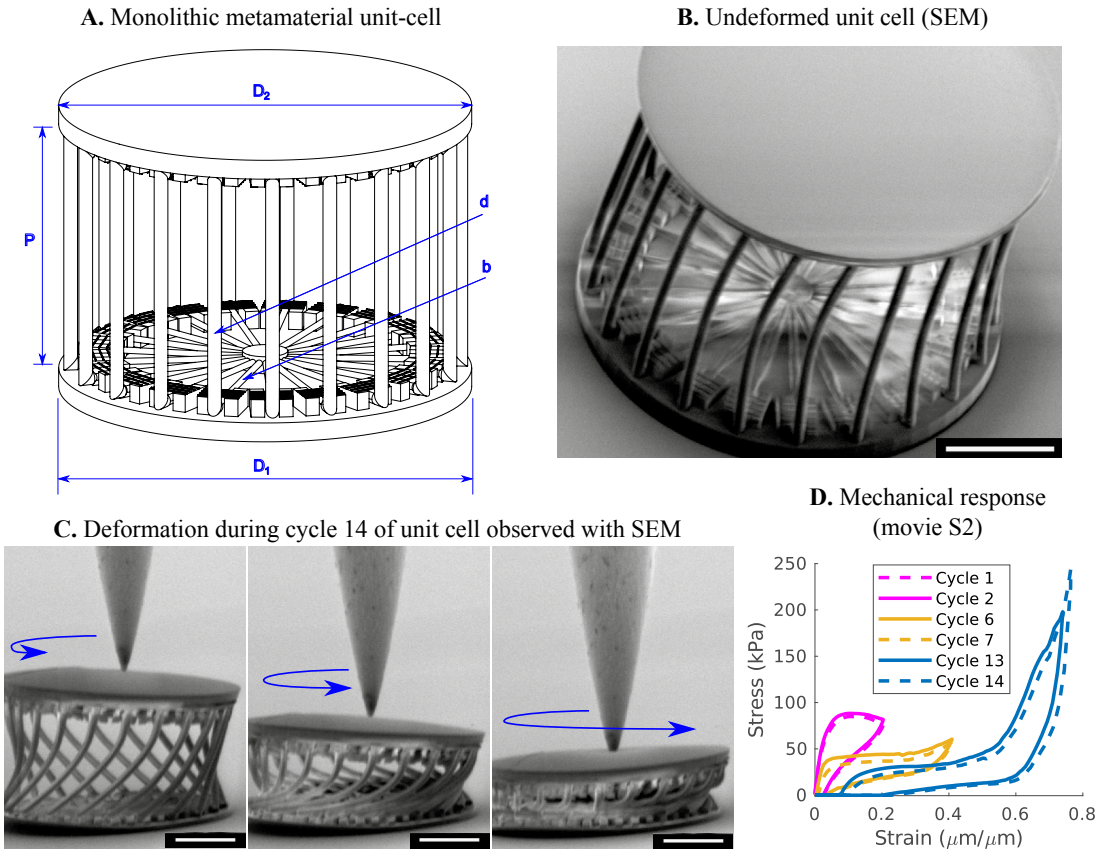

Figure 2: Monolithic metamaterial obtained with two-photon nanolithography. [1]

CONCLUSIONS

We demonstrate that inverting the design process from experimentally-guided to data-driven is possible and advantageous even when computational models are missing some information. This approach is widely applicable to design and analyze different materials and structures. The essential requisites are that "enough" data about the problem of interest is available, and that the data is sufficiently accurate. This data does not need to be exclusively computational, as it could also be analytical or experimental. Therefore, we believe that machine learning will play an ever-increasing role in the quest for the best materials, but it is in tuning them for unforeseen scenarios where it may be most attractive to use it.

BROADBAND CONTROL OF WATER WAVE ENERGY AMPLIFICATION IN CHIRPED ARRAYS

Aidan Archer[1], Hugh Wolgamot[1], Jana Orszaghova[1], Luke Bennetts*[2], Malte Peter[3], and Richard Craster[4]
[1]Wave Energy Research Centre, University of Western Australia, Australia
[2]School of Mathematical Sciences, University of Adelaide, Australia
[3]Institute of Mathematics, University of Augsburg, Germany
[4]Department of Mathematics, Imperial College London, UK

Summary Water waves in natural environments are typically broadband, nonlinear and dynamic phenomena. Taking concepts developed for slow light in optics, we address the challenge of designing arrays to control the spatial distribution of wave energy, and amplify target frequencies at specified locations. Experiments on incident waves interacting with a chirped array of eight vertical cylinders demonstrate significant amplifications, as predicted numerically, providing motivation for application to energy harvesting.

The ability of chirped (or graded) arrays to create slow light or sound waves, confine them, and filter them spatially according to frequency is attractive for wave control. There is a comprehensive body of work, primarily in optics, plasmonics and electromagnetism, which forms a paradigm for the control of waves more broadly, and has been extended to the field of elasticity [1], where it is used to generate mode conversion devices that hybridise surface waves to body waves. A feature less often exploited is that energy can accumulate in regions where the group velocity tends to zero [2]. Assuming the local behaviour in the array is dominated by neighbouring elements enables the implied local periodicity to predict band-gaps (or forbidden frequencies), and the band-gap edges determine a relation between local array properties and frequencies at which group velocities are zero.

In a seemingly disparate branch of ocean engineering, there has been intense activity on methods to harvest the vast quantity of renewable energy carried by ocean waves. Many wave energy converter (WEC) designs have been proposed [3], and a very large class of WECs are tuned to resonate with the dominant frequencies in a sea-state, but suffer from having small bandwidth compared to the bandwidth of the (random) incident waves [4]. In any practical application, multiple interacting WECs will be present, and much research has focussed on regular arrangements of these [5].

We address the pressing question of whether it is possible to take advantage of generic chirped-array concepts from optics in a (potentially nonlinear and dissipative) water wave system, to yield amplification of chosen frequencies at different locations, where (in an absorbing array) the energy could conceivably be captured by suitably tuned WECs. We do so through careful experimentation on waves of length order metres, interacting with an array of eight identical fixed bottom-mounted cylinders arranged along the centreline of a wave flume, and with chirped spacing (Fig. 1 left).

Guided by band-gap theory of doubly-periodic infinite arrays, we probe the resonant modes using regular incident waves of angular frequency $\omega = 6.50\,\mathrm{rad\,s^{-1}}$ and amplitude $a_{\mathrm{inc}} = 0.01\,\mathrm{m}$. Eulerian point measurements of the free surface elevation, η, are recorded at the centre of each of the first six spacings. Linear time-series responses show large amplifications in spacing 3, and minimal transmission farther along the array (Fig. 1 middle), consistent with theoretical predictions. Further, similar mode shapes to those predicted by linear theory were observed, as indicated by the wetted surface of the cylinders (Fig. 1 right).

Focussed incident wave packets are used to investigate the overall spectral structure of the response. The transfer function

$$\mathcal{A}(\omega) = \frac{\mathcal{F}(\eta)}{\mathcal{F}(\eta_{\mathrm{inc}})} \quad \text{where} \quad \mathcal{F} \text{ denotes the Fourier transform,}$$

Figure 1: Left: Experimental set-up. Figure 2: (a) Experimental and (b) numerical amplitude transfer functions, at wave probe locations along the array (shown as constant in each spacing). Grey strips represent spatial locations of cylinders 1–7.

is used to quantify amplitude amplifications over the frequency spectrum. Fig. 2 shows the amplitude transfer function calculated from a linear numerical model (right) and from focussed wave group experiments (left). The experimental and numerical transfer functions are in excellent agreement, notwithstanding the expected larger and sharper amplifications in the numerical model. Amplifications on the first and second bands are evident, along with the spectral downshift along the array.

We have presented results from wave-flume experiments that demonstrate localisation and amplification of water waves along a chirped array of bottom-mounted cylinders, despite the challenges of working with highly resonant systems in a finite-length flume. Linear theory was shown to predict the amplification spectrum accurately in frequency–distance space, including peak resonance locations and spectral downshifts along the array. Moreover, even for the rather small array of eight cylinders used, the amplification locations, at which the group velocity slows to zero, were shown to be consistent with the band structure of infinite periodic arrays using local cylinder spacings. The outcomes suggest future strategies for ocean wave energy harvesting should consider taking advantage of the broadband response and precise control demonstrated here. We have not attempted a parametric study to optimise such an array; this will be a future undertaking.

TUNING EFFECTIVE DYNAMICAL PROPERTIES OF PERIODIC MEDIA BY FFT-ACCELERATED TOPOLOGICAL OPTIMIZATION

Rémi Cornaggia [1] and Cédric Bellis*[1]
[1]Aix-Marseille Univ, CNRS, Centrale Marseille, LMA UMR 7031, Marseille, France

Summary In the context of waves in periodic media, we propose an iterative algorithm that determines an optimal material distribution to reach target effective dispersive properties. It relies on an homogenized model of this medium, an update procedure based on the topological derivative concept, and on an efficient FFT-accelerated method to solve cell problems.

INTRODUCTION

We are interested in standing waves in unbounded two-dimensional domains filled with a periodic medium, *e.g.* antiplane elastic shear waves. The material is made of cells $Y_\ell = \ell Y$, where Y is the reference unit cell and ℓ the characteristic periodicity length (Fig. 1). At circular frequency ω, the wave amplitude u_ℓ obeys the equation:

$$\boldsymbol{\nabla} \cdot \left(\mu_\ell \boldsymbol{\nabla} u_\ell\right) + \rho_\ell \omega^2 u_\ell = 0, \tag{1}$$

where μ_ℓ and ρ_ℓ are the Y_ℓ-periodic shear modulus and density of the medium.

In the long wavelength regime ($\lambda > \ell$), the motion can be described approximatively by the superposition of a slowly varying mean field U and higher-order (in $\varepsilon = \ell/\lambda$) oscillating correctors. Given an effective (homogenized) model satisfied by U, the effective dispersion of the medium is characterized by the variations of the phase velocity $c(k, \boldsymbol{d}) = \omega(k, \boldsymbol{d})/k$ of a plane wave $U(\boldsymbol{x}) = \exp(\mathrm{i}k\boldsymbol{d} \cdot \boldsymbol{x})$ when the wavenumber k and direction $\boldsymbol{d}$ vary. Here we adopt the following direction-dependant dispersion indicator:

$$\gamma(\boldsymbol{d}) := \left.\frac{\partial^2 c^2(k, \boldsymbol{d})}{\partial k^2}\right|_{k=0}. \tag{2}$$

In this work, the goal is to optimize the material distribution within the unit cell Y to reach some target effective dispersive properties, in particular to maximize their anisotropy. The proposed method relies on four main components: a second-order homogenized effective model, the topological derivatives of the model's coefficients, an iterative topological optimization algorithm for the unit cell, and an efficient fixed-point FFT method to evaluate these topological derivatives at each iteration. These components are now described in more details.

SECOND-ORDER HOMOGENIZED MODEL

The two-scale asymptotic homogenization method [1, 3] is a popular way to derive an effective model from the equation (1). One obtains a fourth-order wave equation for the mean field U:

$$\boldsymbol{\mu}^0 : \boldsymbol{\nabla}^2 U + \omega^2 \varrho^0 U + \ell^2 \left[\boldsymbol{\mu}^2 :: \boldsymbol{\nabla}^4 U + \omega^2 \boldsymbol{\varrho}^2 : \boldsymbol{\nabla}^2 U\right] = 0, \tag{3}$$

where $(\boldsymbol{\mu}^0, \varrho^0, \boldsymbol{\mu}^2, \boldsymbol{\varrho}^2)$ are constant tensors computed by solving cell problems over Y [3], ":" and "::" indicate inner products between second- and fourth-order tensors, and $\boldsymbol{\nabla}^j = \boldsymbol{\nabla}(\boldsymbol{\nabla}^{j-1})$. Moreover, this model coincides with the one obtained by the Bloch-Floquet wave method (see [1, Sect. 3] for the case $\rho_\ell = 1$). The dispersion indicator γ defined by (2) is then simply given by:

$$\gamma(\boldsymbol{d}) = 2\ell^2 \left[\frac{\boldsymbol{\varrho}^2 \otimes \boldsymbol{\mu}^0 - \varrho^0 \boldsymbol{\mu}^2}{(\varrho^0)^2}\right] :: (\boldsymbol{d} \otimes \boldsymbol{d} \otimes \boldsymbol{d} \otimes \boldsymbol{d}). \tag{4}$$

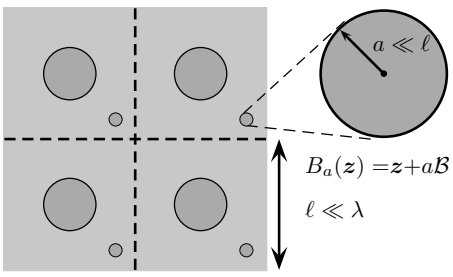

Figure 1: Periodic material and small phase change

TOPOLOGICAL OPTIMIZATION OF THE UNIT CELL

To reach a target dispersive behavior, one first defines a cost functional to be minimized, *e.g.*

$$J(Y;\boldsymbol{d}_1,\boldsymbol{d}_2,\ldots,\boldsymbol{d}_{N_d}) = \frac{1}{2}\left(\sum_{j=1}^{N_d} w_j \left[\gamma(\boldsymbol{d}_j)\right]^{\alpha_j}\right), \tag{5}$$

where each exponent α_j is fixed to 2 (resp -2) to minimize (resp. maximize) the dispersion in direction $\boldsymbol{d}_j$ and the positive constants w_j are user-defined weights that balance the contribution of each term in the cost functional. This cost functional depends on the cell Y implicitely through the homogenized coefficients that intervene in the expression (4) of γ.

An iterative topological optimization algorithm, already used in microstructural optimization of static properties [2], is then adapted to the present situation. We restrain ourselves to two-phase cells, which are described thanks to a level-set function ψ. At each iteration, the update of this function is based on the concept of topological sensitivity (TS) of the cost functional to an infinitesimal phase change at point $\boldsymbol{z}$, supported by a small disc B_a of size $a \ll \ell$, as depicted in Figure 1. This TS, denoted $\mathcal{D}J$, is the leading-order coefficient of the following expansion of the perturbed cost functional J_a:

$$J_a = J + (a/\ell)^2 \mathcal{D}J(\boldsymbol{z}) + o\left((a/\ell)^2\right).$$

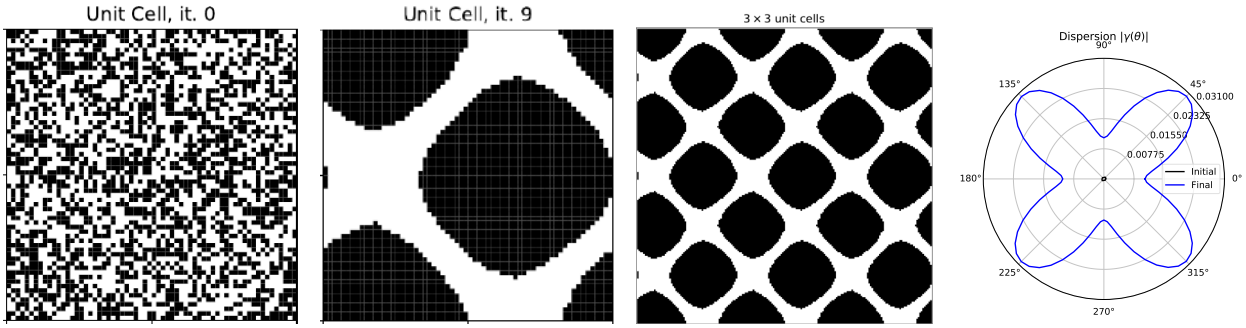
The negative minima of the map $\boldsymbol{z} \mapsto \mathcal{D}J(\boldsymbol{z})$ thus indicates the locations in Y where a small phase change would decrease J the most. Following [2], the level-set update $\psi_n \to \psi_{n+1}$ is done by partial projections of ψ_n onto the TS $\mathcal{D}J$. The algorithm stops when the optimality condition $\mathcal{D}J > 0$ is reached, indicating a local minimum of J.

COMPUTATIONAL CONSIDERATIONS

At each iteration, the TS $\mathcal{D}J$ is computed by simple algebraic combinations of the TSs of the four coefficients $(\boldsymbol{\mu}^0, \varrho^0, \boldsymbol{\mu}^2, \boldsymbol{\varrho}^2)$ whose evaluation requires the resolution of 12 direct and adjoint scalar potential problems on the current material configuration of the cell Y, as specified in [3].

To solve these problems, we adopted the FFT-accelerated algorithm proposed by Moulinec and Suquet in the 90's (see *e.g.* the introduction of [4]), that permits (i) a meshless representation of the unit cell as an image, (ii) a very simple implementation of the whole procedure and (iii) good computational performances.

An example of microstructure obtained with the proposed procedure is presented in Fig. 2. We also note that a similar study is conducted in [1], using the shape derivative of the homogenized coefficients rather than their topological derivative to update the level-set.



(a) Initial unit cell (b) Final unit cell (c) Resulting microstructure (3×3 unit cells) (d) Final dispersion indicator γ

Figure 2: Microstructure optimization to maximize the dispersion in the directions $\theta = \pm\pi/4$ and minimize it in the directions $\theta = 0,\ \pi/2$ ($N_d = 4$ in the definition (5) of J). The unit cell is discretized into 128×128 pixels and initialized with a random distribution of materials 1 (white pixels) and 2 (black pixels). The material ratios are $\mu_2/\mu_1 = 6$ and $\rho_2/\rho_1 = 1.5$. The optimality condition was reached after 9 iterations.

A PHONONIC CRYSTAL FOR RADIAL TORSIONAL WAVES

Ignacio Arretche[1], and Kathryn H. Matlack [1]
[1]Department of Mechanical Science and Engineering, University of Illinois Urbana-Champaign, Illinois, USA

Summary: We present a phononic crystal that exhibits periodic behavior in terms of radial torsional waves, even though its unit cells are geometrically different. The phononic crystal is motivated by a lumped parameter model and consists of a series of alternating steel and rubber rings of different thicknesses that provides unit cells with constant effective properties even though they have different dimensions. The system exhibits the typical stop band of a monoatomic lattice, paving the way for vibration suppression of radially propagating torsional waves.

INTODUCTION

Torsional vibrations in rotating and reciprocating machinery are one of the main reasons for their failure and rapid wear [1]. Current solutions to reduce torsional vibration usually involve addition of mass or complex mechanisms. On the other hand, architected metamaterials and phononic crystals have shown promise in terms of reducing vibrations [2]. Proposed metamaterials for torsional vibration suppression have been limited to one-dimensional chains of ring resonators attached to a central shaft [3]. These systems deal with the propagation of plane torsional waves in the axial direction and require long chains of rings that may be impractical where space is limited. An alternative approach is to attenuate vibrations as they propagate radially outward from the center of a ring, such as in a gearbox. However, this presents additional challenges, mainly due to difficulties in achieving periodic coefficients when the wave equation is expressed in cylindrical coordinates, which inhibits the application of Floquet theory for analysis. In fact, most work in metamaterials and phononic crystals deals with Cartesian plane waves and only a few studies have considered cylindrical wave fronts [4,5]. For example, radial propagation of torsional vibrations through finite metamaterials made of equal alternating radial rings have been studied using a localization factor method [4]. However, vibration transmission of these metamaterials is strongly dependent on where the infinite system is truncated to make the finite metamaterial. Other solutions involve anisotropic mass density to achieve invariance to radial translation in the equations of motion [5], but these material properties may be hard to achieve. Here, we instead impose periodicity by starting with an infinite lumped parameter model that exhibits invariance to radial translation. We then construct a numerical model of the system using alternating non-periodic layers of rubber and steel of different thicknesses. The outcome is a phononic crystal that behaves as a periodic media although is not geometrically periodic.

PHONONIC CRYSTAL MODEL AND RESULTS

We first analyze a lumped parameter model consisting of an infinite chain of rigid rings of equal mass moment of inertia and torsional springs of equal torsional stiffness (Fig. 1a). We define the unit cell as one rigid ring and one torsional spring. Note that this definition is based on equal effective properties (i.e. inertia of the rigid rings and torsional stiffness of torsional springs) and not geometry. The infinite lumped parameter model is a radial tessellation of unit cells and the equation of motion of the n^{th} unit cell can be expressed as:

$$I\ddot{\theta}_n = \beta_T\theta_{n-1} + \beta_T\theta_{n+1} - 2\beta_T\theta_n \tag{1}$$

where θ_n is the angular displacement of the rigid ring of the n^{th} unit cell, I is the mass moment of inertia of the rigid rings and β_T is the torsional stiffness of the torsional springs. The equation of motion is invariant to radial translations of the form $r = r + n\Delta r$. Thus, we seek Bloch plane wave solutions:

$$\theta_n = Ae^{i(kn\Delta r - \omega t)} \tag{2}$$

where k is the wavenumber and Δr is the lattice constant (Fig. 1a). Introducing equation (2) into equation (1), we obtain the dispersion relation, which is equivalent to that of a monoatomic one dimensional phononic crystal (Fig. 1c):

$$\omega(k) = 2\sqrt{\frac{\beta_T}{I}}\left|\sin\left(\frac{k\Delta r}{2}\right)\right| \tag{3}$$

Like the monoatomic phononic crystal, this model shows a cut-off frequency above which no propagating solution exists, i.e. there is attenuation of radially propagating torsional waves above such frequency.

The main challenge with this simple lumped parameter system is translating it to a phononic crystal geometry, as the dimensions must be carefully chosen to obtain equal rotational inertia and torsional stiffness in each unit cell (equations (4) and (5) below). We propose a unit cell made of one steel and one rubber ring (Fig. 1b). The rubber rings, which have low density and low stiffness, approximate the torsional springs, and the steel rings, which have high density and high stiffness, represent the rigid rings. The torsional stiffness of each rubber ring (β_T) [6] and rotational inertia of each steel ring (I) can be calculated as:

*Corresponding author. E-mail: ia6@illinois.edu

$$\beta_T = \frac{4\pi r_{r2n}^2 r_{r1n}^2 h_r}{r_{r2n}^2 - r_{r1n}^2}\mu_r \tag{4}$$

$$I = \frac{\rho_s \pi h_{sn}}{2}(r_{s2n}^4 - r_{s1n}^4) \tag{5}$$

where r_2 is the external radius of each ring, r_1 is the internal radius of each ring, h is the height of the ring, ρ is the material density, μ is the material shear modulus, and subscripts s, r, and n represent steel, rubber, and unit cell number, respectively. Equations (4) and (5) show that in order to keep the effective torsional stiffness and inertia the same for all unit cells, the thicknesses of both steel and rubber rings must be different for each unit cell. In addition, for equation (3) to be valid the lattice constant (Δr) must also be kept constant, thus the sum of the steel and rubber ring thicknesses of each unit must be equal for all unit cells. To satisfy this, we use different steel ring heights in each unit cell.

To analyze the validity of this approach we model a 4-unit cell phononic crystal (Fig. 1b). We choose dimensions of each unit cell such that they all have the same moment of inertia of the steel ring, the same torsional stiffness of the rubber ring, and the same lattice constant. We use finite element methods to simulate a frequency sweep analysis by applying an angular harmonic displacement on the internal boundary of the inner ring and fixing the external boundary of the external ring. We calculate transmission as the ratio of reaction moment on the external ring to reaction moment on the internal ring. Comparison between transmission curves (Fig. 1d) and the stop band predicted by the lumped parameter model (Fig. 1c) indicates that the finite phononic crystal behaves as the infinite lumped parameter model. Furthermore, analysis of 3 phononic crystals with different internal radius (r_0), different lattice constant, and equal predicted cut-off frequency shows the response of the finite phononic crystal is independent of where we truncate the infinite chain. This is further proof that the finite phononic crystal behaves as an infinitely periodic system. Most importantly, the proposed system behaves as a periodic system to radially propagating torsional vibrations solely due to the periodicity of its effective material properties. The novelty of this analysis and design lies in introducing a phononic crystal that exhibits behavior of typical periodic media even though all of its unit cells are geometrically different.

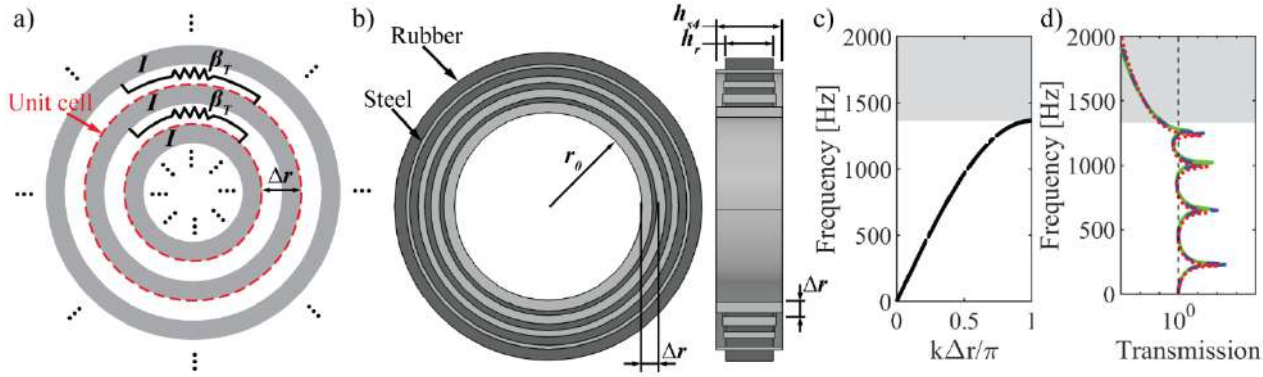

Figure 1. a) Infinitely periodic lumped parameter model (red-dashed lines show the unit cell). b) Phononic crystal for radial torsional waves. Rubber and steel rings are shown in dark and light grey, respectively. c) Dispersion relation obtained from periodic lumped parameter model. Shaded region shows stop band. d) Finite element transmission curves of phononic crystal for $r_0 = 10mm, \Delta r/r_0 = 0.36$ (green-solid), $r_0 = 25mm, \Delta r/r_0 = 0.16$ (blue-dashed), and $r_0 = 100mm, \Delta r/r_0 = 0.04$ (red-dotted).

CONCLUSION

We presented a phononic crystal for radially propagating torsional waves. The design is developed from a simple lumped parameter system that shows radial translational invariance of its equations of motion. We model the phononic crystal by using series of concentric rings of steel and rubber of different thicknesses. We show that even though the phononic crystal is not geometrically periodic (i.e. each unit cell is geometrically different), it behaves as a periodic system to radially propagating torsional waves. The capability of torsional wave attenuation above a cut-off frequency makes the design applicable for torsional vibration suppression.

ELASTIC WAVE TRANSMISSION IN LOCALLY RESONANT MATERIALS WITH VARIABLE RESONATORS

Jacopo Maria De Ponti[1], Stefano Iannaccio[1], and Raffaele Ardito[*1]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary A special case of locally resonant material (LRM) is considered, with unit cells constituted of a frame-like 3D structure and resonating cantilevers attached to each node. The resonators can be suitably tuned in order to have low-frequency, complete and wide band gaps. The present study deals mainly with the wave transmission through non-periodic assemblies, given by the juxtaposition of cells endowed with different resonators. The transmission plots are obtained by means of finite element analyses and shows the presence of band gaps also for the non-periodic media, even though the performances are not comparable to the periodic cases. Remarkably, the transmission is highly affected by the sense of wave propagation.

INTRODUCTION

Locally resonant materials (LRMs) are engineered materials, typically represented by a periodic repetition of a unit cell, with special effective properties that, in some specific situations, may lead to the presence of frequency ranges in which wave propagation is prohibited (band gaps). Such a property can be used in many different ambits, with the purpose of controlling and manipulating elastic wave propagation. As an example, LRMs can be adopted for the elimination of machine vibrations, see e.g. [1, 2]. The vibration suppression is achieved if the leading frequency of the input vibration that, for the case of rotating machinery, is relatively low (about 50 Hz), lies within the band gap. LRMs are based on the local vibrations of its components, thus it is possible to obtain band gaps with a central frequency which is well below the frequency of the wave associated to the cell dimension of the metamaterial [3,4].

The present paper deals with a frame-like 3D structure with resonant cantilevers attached to the nodes, as originally proposed in [5]. Such a design is endowed with some specific advantages: an extremely lightweight structure is obtained, with global stiffness regulated by the dimensions of the frame and low-frequency bandgap governed by the features of the resonators. The LRM is made of a single material, so that the manufacturing process is highly simplified. The main purpose of the present paper is the numeric analysis of the LRM, both in terms of wave dispersion diagram for an infinite periodic medium and for the wave transmission behaviour of finite assemblies. More specifically, transmission analyses are referred to the presence of different unit cells, with the same frame structure but different resonators. The effects of such a non-periodic arrangement are studied from a computational point of view.

METHODS

The considered metamaterial is given by the three-dimensional assembly of unit cells, endowed with cubic symmetry (see Fig. 1). The cell is constituted of a regular frame, with three mutually perpendicular beams (square cross-section, side w) whose span is equal to the unit cell size a. A set of cantilever resonators is attached in correspondence of the nodal points of the frame. Each resonator is given by a cylindrical beam (diameter w_{res}) and a spherical tip mass (radius R_{res}). The theoretical analysis of LRM shows that the band gap width is increased if the mass of the resonator m_R is large with respect to the non-resonating mass m (namely, the mass of the frame plus the part of the resonator that is not excited). Therefore, the design of the unit cell is studied to maximize the tip mass and the number of resonators.

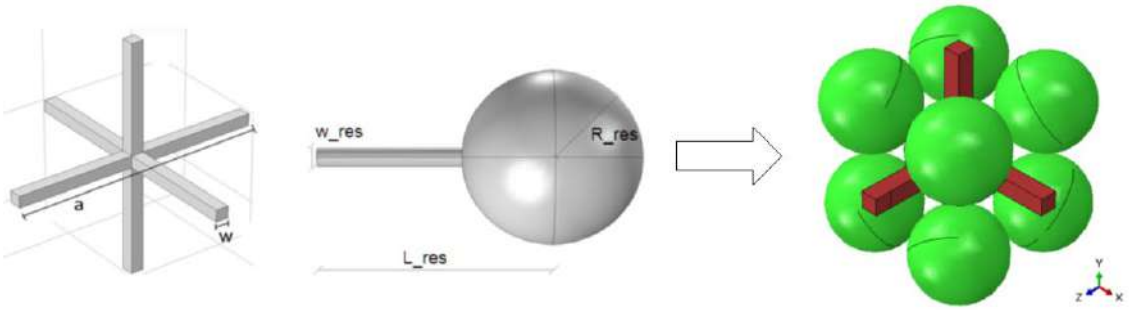

Figure 1 – Design of the unit cell of the considered LRM

To investigate the performance of the LRM as a filter for elastic waves, two types of analyses are executed: wave dispersion analysis on the unit cell, provided that suitable Bloch-Foquet boundary conditions are introduced for periodicity; wave transmission, in the frequency domain, on a finite 3D assembly of a certain number of unit cells. The analyses are carried out via the Finite Element Method, using the software ABAQUS with ad hoc user subroutines to implement Bloch-Floquet conditions. The transmission through finite realizations is computed via a frequency response

*Corresponding author. E-mail: raffaele.ardito@polimi.it

analysis, with input acceleration on one side of the structure. The convergence is achieved for a quite refined mesh, so that the analyses are burdensome.

RESULTS

The results are referred to a specific material, i.e. Nylon PA12, since a set of prototype is realized via additive manufacturing (Selective Laser Sintering [6]) for future experimental tests. The geometric features are selected with the purpose of having band gaps around the frequency of interest for machine vibration. The size of the unit cell is $a = 50$ mm, and the width of the frame element is $w = 4$ mm. Three different unit cells are considered, with resonators tuned at $f_1 = 38$ Hz, $f_2 = 45$ Hz, $f_3 = 50$ Hz. The finite structure is constituted of three layers, 2x2 cells each, with the sequence of the above mentioned resonators. The dispersion plot is represented in Figure 2 and it is compared to the three cases of homogeneous cells (periodic structures). It is possible to notice that the non-periodic structure is still endowed with band gaps, but their width is smaller than the periodic case. Indeed, the largest band gap for the non-periodic material starts in correspondence of f_3, but the closing point is characterised by a frequency much lower than the case of periodic LRM. Similar results are obtained for other cases, with a large number of cells with resonating frequency varying according to a predefined law. An interesting result is represented by non-reciprocity of the band gap: the transmission plot in one sense is by far different if the opposite propagation verse is considered. More specifically, the band gap regions are modified, so that for some frequencies an elastic wave is strongly attenuated in one sense and amplified in the opposite one. Such a property, not shown for paucity of space, is reproduced for different non-periodic arrangements.

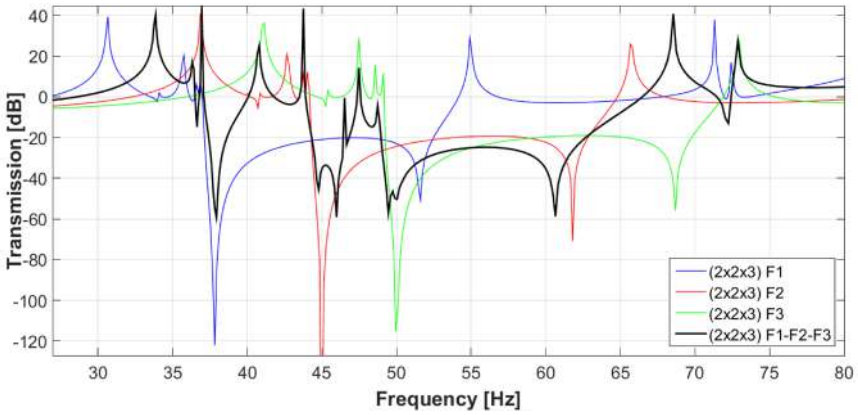

Figure 2 – Transmission plot for the periodic LRMs (blue, red, green lines, with resonators tuned at $f_1 = 38$ Hz, $f_2 = 45$ Hz, $f_3 = 50$ Hz) and the non-periodic arrangement of the three layers (black line).

CONCLUSIONS

The present study is referred to the performance assessment of an innovative LRM, via computational analysis. Focus is on the wave transmission through non-periodic LRMs, with a progressive variation of the resonating frequency in the different layers. The results show that non-periodic LRMs are still endowed with low-frequency band gap, even though it is not possible to merge the overlapped gaps for different resonators. It is worth noting that wave transmission is very different if the verse if propagation is changed. Such a feature could be of interest for the development of innovative metamaterials in the elastic field and deserves future research, also by means of the execution of experimental tests on prototypes realized via additive manufacturing.

ON THE SMOOTHNESS OF BOUNDARIES FOR THE COMPUTATIONAL DESIGN OF PHONONIC CRYSTALS

Sanne J. van den Boom[1], Fredvan Keulen[1], and Alejandro M. Aragón*[1]
[1]Precision and Microsystems Engineering, Delft University of Technology, Delft, the Netherlands

Summary Acoustic/elastic metamaterials and phononic crystals (PnCs) have received increased attention in recent years due to the presence of bandgaps. Their computational design has relied to a great extent on topology optimization (TO), a technique that combines finite element analysis (FEA) with a gradient-based optimizer. However, standard density-based and Ersatz material level-set-based TO schemes use a diffuse representation of the geometry that does not accurately capture material boundaries. In this presentation we show the effect of boundary representation on the design of PnCs. We also introduce an enriched TO technique that greatly reduces the computational cost of design by improving the accuracy of the field at boundaries. The technique shows great potential for the design of PnCs and other metamaterials that interact with waves, whose optimal geometry is expected to be smooth.

INTRODUCTION

Metamaterials (MMs) obtain peculiar functionality by means of an engineered structure. MMs are usually created from a building block—a periodic unit cell (PUC)—that is replicated in space to amplify the desired behavior. Although initially developed in electro-magnetism, mechanical MMs have showed incredible potential in other realms of physics. Acoustic/elastic MMs and phononic crystals (PnCs), which are engineered to interact with waves, are of particular interest because of the presence of bandgaps, *i.e.*, ranges of mechanical wave frequencies that do not propagate through the metamaterial. These MMs are currently being considered for energy harvesting, communication, thermal barriers, elastic/acoustic filters, vibrationless environments for high-precision equipment, improved transducers, waveguides, acoustic lasers (phasers), sound protection devices, and earthquake shields.

Given a target functionality, it is not straightforward to obtain an optimal PnC design because of the complexity of the periodic structural configuration; therefore, the ineffective empirical trial-and-error approach to design has to be replaced by adequate numerical tools to obtain the most out of the metamaterial. The design of PnCs is extremely challenging not only because it has to be tailored to a particular application, but also because current design tools demand for vast computational resources. Standard TO or Ersatz level-set-based TO have limited applicability in PnC design due to a poor topological representation caused by the use of structured meshes, which can reproduce at best *pixelized* or *staircase* boundaries with density properties that do not correspond to void nor material. In this talk we show that this geometry representation and modeling is detrimental for the design of materials whose geometry is expected to be smooth, as is the case with MMs that interact with waves. We compare the results with diffuse interfaces commonly used in density-based TO with those obtained by enriched FEA that captures the geometry smoothly. We also introduce an enriched TO framework and discuss its performance for maximizing PnCs' bandgaps.

METHODS

The band structure of a PnC is commonly obtained by analyzing its periodic unit cell (PUC). We first consider a PUC with a simple geometry: a square domain containing a circular inclusion with contrasting material properties. In both material phases the behavior is governed by the elastodynamic wave equation, whose variational form is discretized straightforwardly by following standard finite element procedures. With $\boldsymbol{u}^h$ denoting the finite element approximation, which is a function of both coordinate $\boldsymbol{x}$ and time t, we prescribe Bloch-Floquet periodic boundary conditions $\boldsymbol{u}^h(\boldsymbol{x}+\boldsymbol{a},t) = e^{i(\boldsymbol{k}\cdot\boldsymbol{a})}\boldsymbol{u}^h(\boldsymbol{x},t)$, where $\boldsymbol{a}$ is the lattice vector between two periodic edges and $\boldsymbol{k} \in \mathcal{K}$ is a wave vector of a finite set $\mathcal{K}$ along the edge of the irreducible Brillouin zone. The band structure is then obtained by solving an eigenvalue analysis for each wave vector $\boldsymbol{k} \in \mathcal{K}$ along the edge of the irreducible Brillouin zone:

$$\left[\tilde{\boldsymbol{K}} - \omega_j^2 \tilde{\boldsymbol{M}}\right] \tilde{\boldsymbol{V}}_j = \boldsymbol{0}, \qquad j = 1, \ldots, N, \qquad \forall \boldsymbol{k} \in \mathcal{K}, \tag{1}$$

where ω_j is jth numerical frequency out of N bands considered, $\tilde{\boldsymbol{V}}_j$ the corresponding eigenvector, $\tilde{\boldsymbol{K}} = \boldsymbol{T}^{\mathsf{H}}\boldsymbol{K}\boldsymbol{T}$ and $\tilde{\boldsymbol{M}} = \boldsymbol{T}^{\mathsf{H}}\boldsymbol{M}\boldsymbol{T}$, $\boldsymbol{T}$ is complex valued and depends on $\boldsymbol{k}$, and $\boldsymbol{K}$, $\boldsymbol{M}$ are the global stiffness and mass matrices, respectively.

Both standard and enriched finite element spaces are considered. For the latter, the approximation is given by [1, 2]

$$\boldsymbol{u}^h(\boldsymbol{x}) = \underbrace{\sum_{i \in \iota_h} N_i(\boldsymbol{x})\, \boldsymbol{U}_i}_{\text{standard FEM}} + \underbrace{\sum_{i \in \iota_w} \psi_i(\boldsymbol{x})\, \boldsymbol{\alpha}_i}_{\text{enrichment}}, \tag{2}$$

where the standard FE term—comprised of Lagrange shape functions N_i and corresponding degrees of freedom (DOFs) $\boldsymbol{U}_i$—is augmented by an enrichment term that captures, by means of enrichment functions ψ_i and corresponding enrichment DOFs $\boldsymbol{\alpha}_i$, a smoother (piecewise linear) description of the circular inclusion. As a result, the enriched finite element solution captures more accurately the field along material interfaces and boundaries.

EFFECT OF GEOMETRY DESCRIPTION FOR BANDGAP ANALYSIS

We conduct band structure analysis focusing on the first five bands ($N = 5$), and compare the results obtained by standard and enriched FEA. While enriched FEA captures smooth boundaries by means of enrichment functions, standard FEA uses the pixelized representation commonly used in standard TO. We quantify the error in the band structure by:

$$\epsilon = \sqrt{\frac{1}{|\mathcal{K}|\,N}\frac{\sum_{\boldsymbol{k}\in\mathcal{K}}\sum_{j=1}^{N}(\omega_j-\omega_j^\star)^2}{\sum_{\boldsymbol{k}\in\mathcal{K}}\sum_{j=1}^{N}\omega_j^{\star 2}}}, \tag{3}$$

where $|\cdot|$ denotes set cardinality, $\omega_j^\star$ is the *reference* jth frequency for wave vector $\boldsymbol{k}$, obtained by an *overkill* FE analysis.

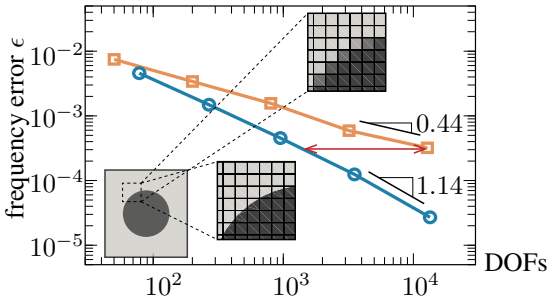

Figure 1: Error given by (3), showing the adverse effect of the pixelized boundary.

Figure 1 shows the mesh convergence analysis, where (3) is plotted against the total number of DOFs—which is proportional to the cost of solving the problem and increases with finer FE meshes. The results reveal that using a pixelized representation is detrimental to band structure analysis, as it has a considerable error in predicting the bandgap. The enriched FEA has not only higher accuracy but also a higher convergence rate (1.44 vs. 0.44).

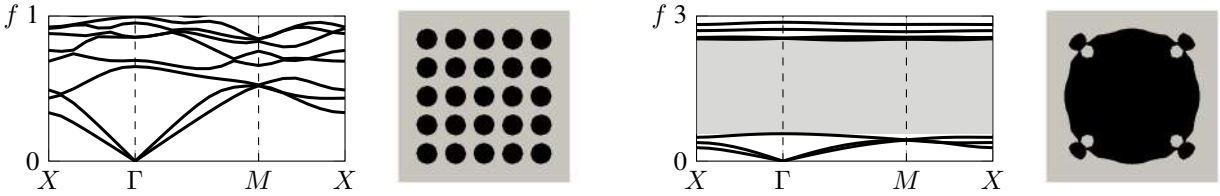
COMPUTATIONAL DESIGN VIA ENRICHED TOPOLOGY OPTIMIZATION

Topology optimization (TO) was introduced in the late 80s as a means to find optimal structural designs. In a nutshell, in TO an optimal structure is obtained through an iterative procedure that performs FEA and uses sensitivity information to improve topology for the next iteration. Building on the aforementioned advantages of enriched FEA, we propose an enriched TO approach to design a PnC. The objective of the optimization is to maximize the width of the bandgap, which is expressed mathematically as

$$\begin{aligned}\boldsymbol{\phi}^\star &= \arg\max_{\boldsymbol{\phi}\in\mathcal{D}} \mathcal{F} = \min\left(\omega_4^2\right) - \max\left(\omega_3^2\right)\\ &\text{such that } \left[\tilde{\boldsymbol{K}}\left(\boldsymbol{\phi}\right) - \omega_j^2\tilde{\boldsymbol{M}}\left(\boldsymbol{\phi}\right)\right]\tilde{\boldsymbol{V}}_j = \boldsymbol{0} \quad \forall \boldsymbol{k}\in\mathcal{K}, \quad V_{\Omega_i}\le V_c, \quad \phi_{\min}\le\phi_i\le\phi_{\max},\end{aligned} \tag{4}$$

where ω_3 and ω_4 denote the frequencies corresponding to the bands that define the first bandgap, $\boldsymbol{\phi}$ is a vector of design variables, restricted to minimum and maximum values, and we place a constraint on the target volume of inclusion V_{Ω_i}.

Figure 2 shows the results of the enriched TO applied to a PUC composed by two materials. Figure 2a shows the dispersion diagram for an initial PUC design seeded with 25 inclusions—for which there is no bandgap—and Figure 2b shows the band structure obtained after just 50 iterations.



(a) (b)

Figure 2: (a) Band structure obtained for the initial bimaterial design shown; and (b) wide bandgap obtained at the 50th iteration of topology optimization that uses enriched FEA.

CONCLUSIONS

The bandgap mesh convergence results of Figure 1 illustrate that enriched FEA has a clear edge over standard FEA for band structure analysis. About an order of magnitude less DOFs is required for the same level of accuracy, and because DOFs are directly proportional to the cost of solving the problem, for a given accuracy enriched FEA can save considerably on computational costs. Because optimization is essentially a loop over FEA, the cost advantages discussed for bandgap analysis carry over to TO. As a proof of concept, the enriched TO technique was used to design of a phononic crystal composed of two materials for maximizing bandgap. The proposed technique shows tremendous potential for the design of this and other metamaterials that interact with waves.

AMPLITUDE DEPENDENT EDGE STATES AND DISCRETE BREATHERS IN NON- LINEAR SPATIALLY MODULATED ELASTIC LATTICES

Matheus I. N. Rosa[1], Michael J. Leamy[2] and Massimo Ruzzene [1]
[1]Department of Mechanical Engineering, University of Colorado Boulder, Boulder, USA
[2]School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, USA

Summary We investigate the amplitude dependent behaviour of the spectral properties of elastic lattices with spatial stiffness modulation and cubic non-linearities via a harmonic balance approach. We demonstrate that edge states localized at the boundaries of finite lattices, whose existence are attributed to non-trivial topological properties defined in the linear regime, are robust with non-linearities within a certain amplitude range, although some reduction in the degree of localization may occur. We also demonstrate that bulk modes may experience transitions to discrete breathers localized in the interior of the domain as a function of amplitude. The predicted spectral behaviour is confirmed by forced response computations and direct time domain simulations, and possibilities for future work such as amplitude-driven mode transitions are discussed.

INTRODUCTION

In this work we investigate the role of weak non-linearities on the dynamics of spatially modulated one-dimensional (1D) elastic lattices. In the linear regime, the spatial stiffness modulation was shown to produce non-trivial topological properties characterized by integer-valued Chern numbers [1]. As a result, edge states localized at the boundaries of finite lattices are found to span the spectral gaps as a function of the phase of the stiffness modulation. A transition of the edge states can be exploited for topological pumping by smoothly modulating the stiffness phase along a second dimension, resulting in a robust edge-to-edge transport of energy. This phenomenon may be useful in technological applications and devices that rely on manipulating information through elastic waves.

When it comes to the effects of non-linearities in topological states, previous work has demonstrated amplitude dependent behaviour of topological interface states and 2D edge modes in discrete lattices with cubic non-linearities, suggesting potential for tunable devices based on amplitude-dependent localization and wave transport [2]. A more recent study has demonstrated, numerically and experimentally, an edge-to-bulk transition of 1D interface states using fidget spinners with magnetic interactions [3]. These results suggest that non-linear interactions may lead to amplitude-dependent tunable devices, but also that possible limitations related to the loss of topological protection may need to be considered.

Motivated by these works, we here consider the effects of non-linearities on the edge states of spatially modulated elastic lattices [1]. Seeking to understand the limitations of topological protection, our results indicate that the edge states maintain robustness within a certain amplitude range, but the degree of localization may decrease when their branch tangentially approximates the bulk. We also explore mode transitions experienced by the bulk modes as they become localized in the interior of the lattice for increasing amplitudes, in a manner reminiscent of discrete breathers [4]. Our results are obtained through a harmonic balance approach and confirmed by forced response computations and direct time domain simulations.

NON-LINEAR SPATIALLY MODULATED ELASTIC LATTICES

We consider one-dimensional (1D) lattices of equal masses m connected by springs whose constant k_n is defined by the sampling of a sinusoidal function (Fig. 1a), *i.e.* $k_n = k_0[1 + \alpha\cos(\frac{2\pi np}{q} + \phi)]$. By fixing $\frac{p}{q} = 1/3$, we define a periodic lattice with 3 masses per unit cell (since $k_{n+3} = k_n$), whose topological properties are interpreted based on variations of the phase ϕ [1]. Non-linearities of the cubic type are introduced by considering restoring forces of the from $F = k_n(\Delta x + \epsilon\Delta x^3)$, where ϵ is a small parameter. The governing equation of motion for a mass with index n is expressed as

$$m\ddot{u}_n + k_n(u_n - u_{n+1}) + k_{n-1}(u_n - u_{n-1}) + \epsilon k_n(u_n - u_{n+1})^3 + \epsilon k_{n-1}(u_n - u_{n-1})^3 = 0.$$

We investigate the behaviour of a free-free finite lattice comprising $N = 42$ masses with parameters $m = k_0 = 1, \alpha = 0.6, \phi = 0.35\pi,$ and $\epsilon = 0.01$ via a Harmonic Balance (HB) approach, resulting in the amplitude dependent spectrum of Fig. 1b. In the figure, blue dots correspond to frequencies ω that numerically solve a set of non-linear algebraic equations (resulting from the HB approach) when a certain amplitude level is imposed, here corresponding to the L_2 norm of the displacements of all masses along the lattice. Shaded grey areas correspond to the limits of the dispersion bands, also estimated as a function of amplitude via a Multiple Time Scales analysis [5]. For very low amplitudes ($A \approx 0$), the linear analysis predicts the existence of a left-localized edge state (branch a) and a right-localized edge state (branch c) inside the gaps [1], while bulk modes within shaded grey regions are non-localized, globally spanning modes. As amplitude increases, the frequencies of the finite lattice modes tend to shift to the right, representing the typical hardening behaviour associated with positive cubic non-linearities. The evolution of the mode shapes of the edge states with amplitude (first harmonic) are displayed in Figs. 1(c,d), while the behaviour of two bulk modes (branches

d and e) are also tracked as a function of amplitude and are reported in Figs. 1(e,f). We note that the branch of the first edge state (branch a) remains within the gap for the considered amplitude range, and as a result it maintains its left-localized nature (Fig. 1c). However, the branch of the second edge state (branch c) slowly approaches a region populated by bulk modes, and as a result its degree of localization decreases (Fig. 1d). The branch of this edge state remains tangential with the bulk, and does not cross or enter the bulk region, which suggests that topological protection is maintained even though resulting in a lower degree of localization. Finally, we observe that a few bulk modes (such as branches d and e) detach from the bulk regions as a function of amplitude, resulting in a transition of their mode shapes to localized at one or more regions in the interior of the lattice, which is reminiscent of discrete breathers. This behaviour is aligned with observations in the literature of discrete breathers where modes of this kind are formed through bifurcations of band edge plane waves in monoatomic lattices [4].

In the talk we also show results for forced response computations to confirm the amplitude dependent behaviour of the finite lattice spectrum, in addition to direct time domain simulations. We discuss further possibilities associated with amplitude-driven mode transitions, such as edge-to-edge transitions (topological pumping) or even edge-to-interior localization transitions by exploiting the discrete breathers.

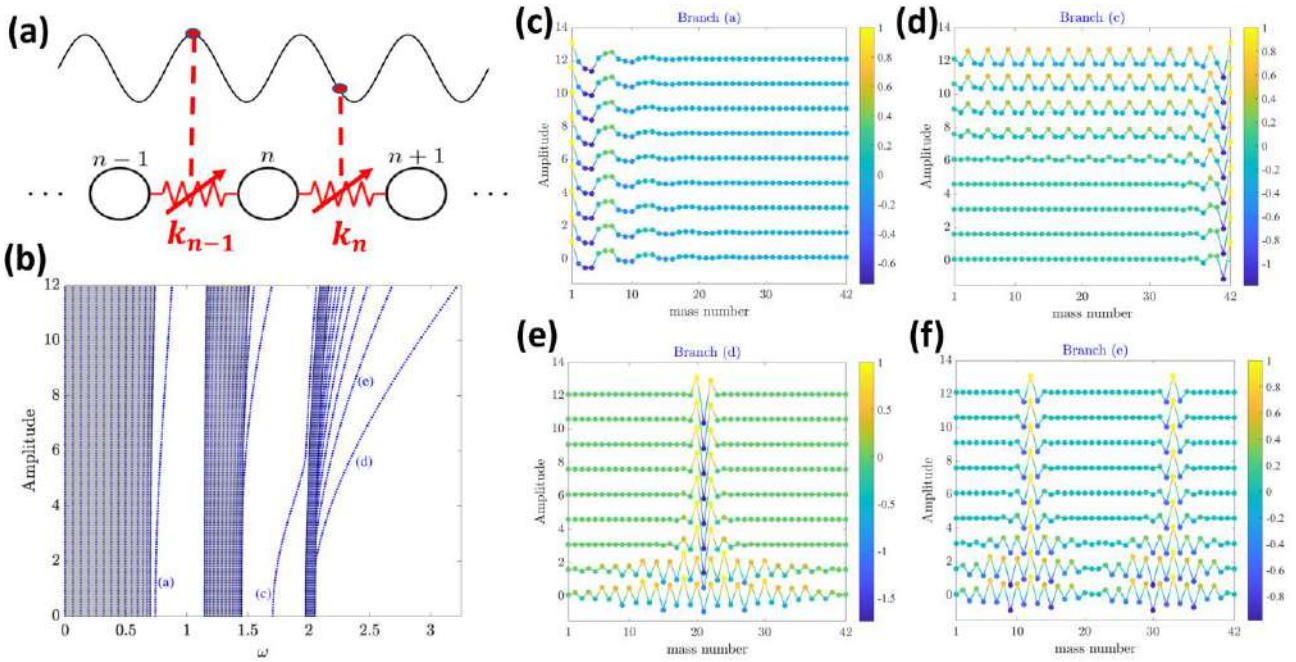

Figure 1. Amplitude dependent behaviour of non-linear spatially modulated elastic lattices. (a) Schematic of 1D lattice of masses connected by non-linear springs that provide a restoring force $F = k_n(\Delta x + \epsilon \Delta x^3)$, whose constant k_n is defined by the sampling of a sinusoidal function, *i.e.* $k_n = k_0[1 + \alpha \cos(2\pi np/q + \phi)]$. (b) Amplitude dependent spectrum of finite lattice with N=42 masses with free-free boundary conditions and parameters $m = k_0 = 1, \alpha = 0.6, \phi = 0.35\pi,$ and $\epsilon = 0.01$. Blue dots correspond to modes of the finite lattice as a function of amplitude, while shaded grey areas denote the limits of the dispersion bands as a function of amplitude. The variation of the mode shape of the edge states (branches a,c) with amplitude are displayed in (c,d), while transitions from globally spanning to discrete breather experienced by bulk modes (branches d and e) are illustrated in (e,f).

NEGATIVE REFLECTION AND POLARIZATION CONTROL OF ELASTIC WAVE VIA BROADBAND METAMATERIAL

Rui Zhu*[1], Zhou Hu [1], Mingye Zheng [1]and Gengkai Hu [1]
[1]School of Aerospace Engineering, Beijing Institute of Technology, Beijing, China

Summary In this work, a non-resonant metamaterial supporting single polarized elastic wave is designed, which provides an excellent solution for broadband wave mode control and can lead to novel elastic wave phenomena. Particularly, total polarization separation, conversion and negative reflection are demonstrated in this presentation by using the so-called singly polarized solid (SPS). Furthermore, by delicate design, the Littrow configuration of elastic wave is demonstrated for the first time. Noting that the extraordinary wave phenomena only depend on the engineered elasticity tensor of the solid metamaterial and therefore, are intrinsically broadband, which can be beneficial for various elastic wave applications.

Introduction

Elastic waves possess various polarization characteristics that are absent in its acoustic and electromagnetic counterparts. Due to the complex polarization nature, achieving broadband control of elastic waves has been proved to be more difficult [1]. Resonance-based elastic metamaterials have been harnessed for peculiar elastic wave manipulations [2,3], but unfortunately, only in a narrow band near the resonant frequency of the metamaterial's microstructure. Recently, phase shifting via metasurfaces demonstrates the capability to separate different polarized waves, which, however, still suffers the narrow-band problem [4]. On the other hand, pentamode metamaterials supporting only one stress state offer a non-resonant way to manipulate elastic wave in a much wider frequency range [5]. In this presentation, a non-resonant metamaterial supporting only one elastic wave mode, called singly polarized solid (SPS), is proposed. Three interesting and potentially useful elastic wave phenomena including polarization separation, mode conversion and negative reflection are demonstrated.

Results

Different from the ordinary solids that support two polarized waves, for example isotropic solids support both longitudinal and transverse waves, the proposed SPS can only support singly polarized wave due to its engineered elastic tensor as

$$C=\begin{bmatrix} C_{11} & \gamma\sqrt{C_{11}C_{22}} & 0 \\ \gamma\sqrt{C_{11}C_{22}} & C_{22} & 0 \\ 0 & 0 & 0 \end{bmatrix}, \tag{1}$$

where $\gamma=\pm1$. For $\gamma=1$, the SPS can only support quasi-longitudinal wave. Especially, under the condition of $C_{11}=C_{12}$, it supports longitudinal wave omnidirectionally as a fluid-like solid. For $\gamma=-1$, the SPS can support longitudinal wave along its principal axis and transvers wave along a particular direction of $\varphi=\tan^{-1}\sqrt[4]{C_{11}/C_{22}}$. Here, we focus on the SPS with $\gamma=-1$ which has richer controllability on wave polarizations.

First, the elastic wave transmission in an ultrathin SPS layer sandwiched between semi-infinite isotropic solids is explored with the parameters running over the full material anisotropy and principal orientation. Selective wave mode filtering is observed in a broad frequency range by only changing the principal orientation of the ultrathin metamaterial layer, as shown in Figure 1 (a) and (b), respectively. Furthermore, by conducting transient elastic wave simulations in the non-resonant metamaterial layer, longitudinal and shear waves can be controlled independently to enable total wave transmission as well as total wave isolation, as shown in Figure 1 (c) and (d), respectively.

Then, mode converting and negative reflection in anisotropic SPS are demonstrated. The equi-frequency curve (EFC) of the SPS is shown in Fig. 2(a), which indicates the unique singly polarized wave supportability. The negative reflection region is marked with yellow colour, which means that the energy flux of reflected wave and incident wave locate in the same side of the surface normal of the traction free boundary. Fig. 2(b) shows that negative reflection occurs after a longitudinal incident wave interacting with the traction free boundary of the anisotropic SPS. Finally, by carefully designing the negative reflection angle and the microstructure of the SPS, a Littrow configuration of elastic wave is achieved for the first time, as shown in Fig. 2(c).

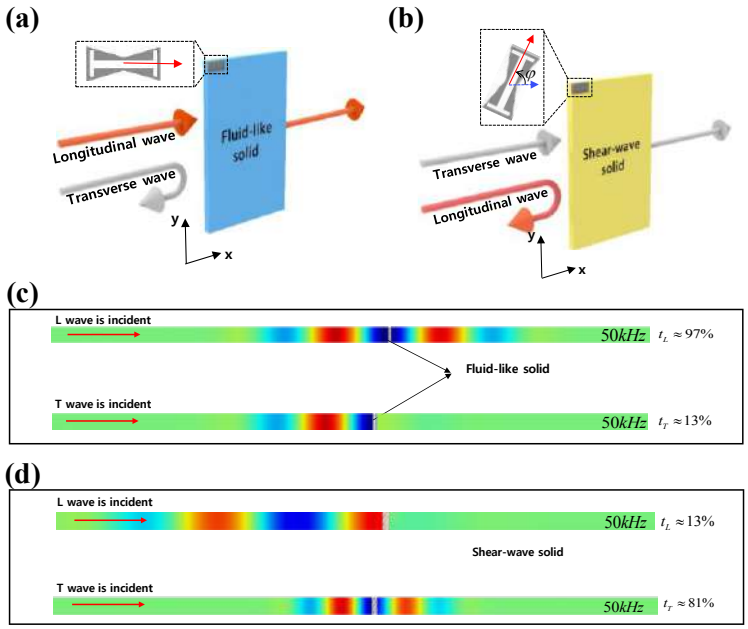

Figure 1. Mode separation in the negative SPS layer (a) without or (b) with rotation of the principal axis of the microstructure, respectively.

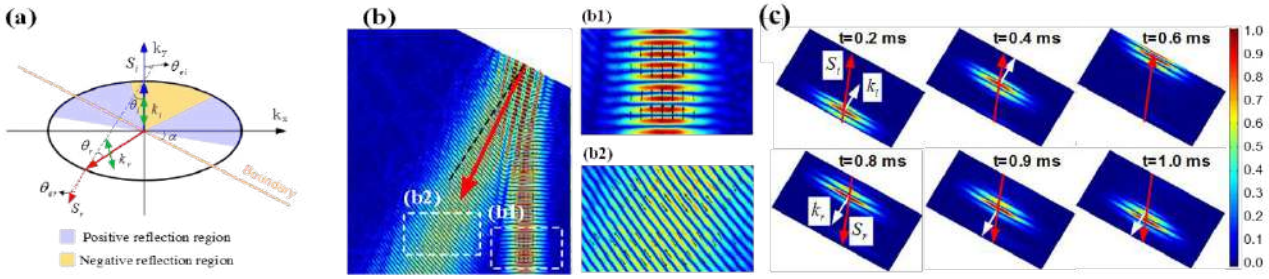

Figure 2. Total mode conversion and negative reflection of elastic wave in an anisotropic SPS.

CONCLUSIONS

In this presentation, the non-resonant metamaterial called SPS is investigated and peculiar elastic wave manipulations are demonstrated. By harnessing the engineered wave properties in SPSs, three interesting and potentially useful elastic wave phenomena including total wave mode separation and conversion, complete negative reflection are theoretically predicted as well as numerically demonstrated. More importantly, unlike other metamaterial-based wave control, those extraordinary wave phenomena do not rely on any resonance and therefore, are intrinsically broadband.

PROGRAMMING MECHANICAL METAMATERIALS BY PERMANENT MAGNETS

Viacheslav Slesarenko*[1,2]
[1]Freiburg Institute for Advanced Studies, Freiburg, Germany
[2]Cluster of Excellence livMatS @ FIT, University of Freiburg, Freiburg, Germany

Summary The enrichment of the design space of mechanical metamaterials by harnessing non-mechanical interactions is in the scope of this research. In particular, it is revealed that the energy landscape of the mechanical metamaterials can be tuned through the embedment of the permanent magnets into the architecture of the metamaterial. The control over the mechanical behavior of the metamaterials consisting of rotating squares through embedment of the modified elementary cells with attractive and repulsive configurations of the magnets is demonstrated experimentally and numerically. Moreover, this approach is shown to be effective in introducing multistability into the materials with initially single equilibrium state. The capacity to manipulate the energy landscape on the global and local scales provides powerful means for the design of advanced mechanical metamaterials.

Nowadays, mechanical metamaterials are mostly treated as functional materials rather than structural, so there is an ongoing quest to add new functionalities and make metamaterials responsive, adaptive, or programmable. One of the ways to achieve these goals is to go beyond mechanical interaction between elements of the metamaterial and harness other physical phenomena. Among a wide variety of the designs, stimuli-responsive metamaterials capable of reacting to the external magnetic field were demonstrated [1]. Unfortunately, a high magnetic field is required for the successful activation, making such metamaterials unfeasible for the practical applications. At the same time, there is another potential approach to harness magnetic interaction by employing permanent magnets embedded into the architecture of the metamaterial. Recently, it was shown in practice that the permanent magnets could provide powerful means to adjust the behavior of the mechanical metamaterials [2], origami structures [3], and energy harvesters [4]. In this study, a new way to program the performance of the metamaterials by modifying their energy landscape through embedment of the permanent magnets in the different configurations is proposed and studied both experimentally and numerically [5].

A classical design of the metamaterial consisting of the rotating squares connected by the soft hinges was adopted for this study (Figure 1e). Under biaxial compression, this particular metamaterial undergoes a buckling-driven transformation from the initial open state to the closed state, as shown in Figures 1a,b for the elementary cell consisting of four rotating squares. In order to program the behavior of the metamaterial, some elementary cells were modified through the embedment of the cubic permanent magnets inside of each rotating square. For the permanent magnets with magnetic moments perpendicular to the metamaterial, each of the modified elementary cells can exist in three configurations: neutral (no embedded magnets) (a), repulsive (c), and attractive (d) (see Figure 1). To study the contribution of the magnetic interaction, the numerical simulations of the infinite structure using FEA software COMSOL 5.4 were performed. The unit cell of the studied metamaterial with the embedded magnets is shown by a dashed square in Figure 1e. The unit cell was subjected to biaxial compression with lateral displacement D_b, while the maximal rotation of the squares was limited by 45° to prevent the contact between squares. The magnetic interaction between two out-of-plane magnets was treated as dipole-dipole interaction with the total force exerted on the second magnet

calculated as $\boldsymbol{F} = s\frac{3\mu_0 m^2}{4\pi|\boldsymbol{r}|^5}\boldsymbol{r}$, where $\mu_0 = 4\pi \times 10^{-7}$ H/m is the permeability of the vacuum, $\boldsymbol{r}$ is the vector connecting centers of the first and second magnets, m is the value of a magnetic moment, and $s = +1$ for co-directed (repulsive) configuration or $s = -1$ otherwise. Therefore, the magnetic energy of the elementary cell is equal to $U = \frac{\mu_0}{4\pi}\sum_{ij}\frac{s_{ij}m^2}{|\boldsymbol{r}_{ij}|^3}$, where the sum is taken for all pairwise combinations of magnets. The magnetic interaction between different elementary cells was neglected. The magnetic moment $m = 0.105$ Am^2 was used in simulations due to the good approximation of the magnetic behavior of cubic $5 \times 5 \times 5$ mm Nd-magnets of N42 grade used in the experimental study. The rotating squares were treated as rigid bodies, while the soft hinges were considered as neo-Hookean solids with shear modulus $\mu = 1.1$ MPa and Poisson's ratio of $\nu = 0.46$. For comparison reasons, the biaxial displacement D_b and corresponding force F_b were recalculated for the metamaterial with 16x16 rotating elements.

Figure 1g shows the force-displacement curves obtained for the mechanical metamaterial with a periodic distribution of the modified elementary cells in a neutral (black), repulsive (red), and attractive (blue) configurations. Dashed lines are obtained for metamaterial with weaker magnets ($m = 0.075$ Am^2). Being subjected to equibiaxial compression, the metamaterial with a neutral configuration of the modified elementary cells undergoes buckling which leads to the drastic drop in the effective elastic modulus due to the replacement of initially compressive state of the hinges by the bending in the post-buckling regime. The metamaterials with non-neutral configurations of the modified cells also undergo similar buckling; however, the embedment of the repulsive configuration leads to the increase in the critical buckling force. Moreover, the increase in the magnetic moment for this configuration leads to an increase in the slope of the force-displacement curve in the post-buckling regime, making metamaterial less compliant. In contrast, for the metamaterial with attractive configuration, the slope of the curve becomes negative. Moreover, when the decreasing force reaches zero during loading (red circle on the blue curve), the snap-through to the closed state of the metamaterial rapidly occurs. This instability-driven transition can be explained by examining the total energy of the metamaterial calculated as a sum of magnetic and elastic components (Figure 1h). The energy of the metamaterial with repulsive configuration is a convex function with only one minimum corresponding to the open state. At the same time, the reduction of the distance between attractive magnets leads to a significant decrease in magnetic energy during compression. As a result, the energy function becomes concave, and for large enough m, it has a maximum that corresponds to zero force and leads to subsequent realization of snap-through instability during compression. Therefore, modified metamaterial has two stable equilibrium states, proving that the embedment of attractive magnets can be employed for modification of the energy landscape.

To verify the predicted behavior of the metamaterial with modified elementary cells, 3D-printed mechanical metamaterials with the same design were tested experimentally (Figure 1f). The voids in the interior of the rotating squares enable the quick reconfiguration of the metamaterial to reprogram its behavior through the embedment of the permanent magnets in various configurations. The samples with two various arrangements of the modified elementary cells (blue squares and white circles in Figure 1e) were subjected to the equibiaxial compression in the special transparent fixtures preventing out-of-plane deformation. The force-displacement curves for the displacement D_b and force F_b are shown in Figure 1i. As in the numerical study, for both studied arrangements of the magnets, the repulsive configuration leads to the increase in the buckling strain, and the positive slope of the curve is observed in the post-buckling regime. While the numerical results show that the value of the magnetic moment affects the observed behavior, by experimentally comparing the mechanical performances for two arrangements, a similar role can be assigned to the density of the modified elementary cells in the mechanical metamaterial. The increase in the number of the modified elementary cells amplifies the contribution of the magnetic energy. The snap-through behavior is also captured experimentally for the metamaterials with attractive configurations, as marked by red circles in Figure 1i. Upon reaching the critical strain, the metamaterial rapidly switches to the closed configuration by rotating all square elements until their contact and remains in the closed state even after removal of the external load.

Therefore, it is shown both experimentally and numerically that the rational embedment of the interacting permanent magnets inside the structure of the mechanical metamaterials enables the enhanced control over their performance and can be exploited to introduce multistability to the systems with initially single equilibrium state. In general, this approach can be applied to manipulate the energy landscape of mechanical metamaterials on the global and local scales by harnessing the intricate interplay between elastic and magnetic energies. It can provide a powerful means to design advanced mechanical metamaterials with programmable behavior.

The research leading to these results has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie-Sklodowska-Curie grant agreement №754340. The research received support by the Deutsche Forschungsgemeinschaft (DFG) under Germany's Excellence Strategy – EXC-2193/1-390951807.

Summary Recently, the topological interface/surface states are of great interest as they are robust against the local defects and immune from the back-scattering. In this paper, the topological properties of the engineered metamaterial SSH lattices are studied. The metamaterial lattices are formed by locating the metamaterial cavities in desired positions. By varying the coupling strengths between these cavities the topological interface and edge states obtained, which are robust to the local disorder. Based on the topological states, we propose the piezoelectric energy harvester.

INTRODUCTION

In recent years, the field of topological matters is growing rapidly in condensed matter physics. The topological interface/surface states are robust against the local defects and immune from the back-scattering. Recently, the concept of topological matters was extended to classical waves in artificial periodic structures, for example, electromagnetic waves in electromagnetic metamaterials and acoustic/elastic waves in acoustic/elastic metamaterials [1, 2]. Piezoelectric energy harvesting by converting ambient vibrations into low-power electricity is of interest as the rapid development of the electronic industry [3]. As the topological states are usually highly confined at interfaces or edges, these topological states show potential applications in energy harvesting.

RESULTS AND DISCUSSION

It is known that cavities (or the so-called point defects) can be introduced into a perfect elastic metamaterial by breaking the lattice periodicity at desired positions. Since the displacement fields are usually confined in the cavities, the interactions between these cavities can be described by the tight binging model, which is widely used for predicting the band structures of electronic materials. Thus, the cavities can be arranged into any specific lattice, such as the Su-Schrieffer-Heeger (SSH) model, and then the topological characteristics of the elastic waves in such an elastic metamaterial lattice can be mapped to the classic electronic system with the same lattice.

The unit-cell of a two-dimensional (2D) elastic metamaterial slab is illustrated in the inset of Fig. 1(a). The elastic pillars are periodically deposited on a homogeneous slab. The band structure of the unit-cell is shown in Fig. 1(a), where the results are calculated by the finite element method (FEM). It is seen that an absolute phononic band gap (the yellow shadow in Fig. 1(a)) can be obtained in such an elastic metamaterial, which is fundamental for the cavities (the cavity modes). The cavity is formed by removing a pillar from the perfect elastic metamaterial. A metamaterial cavity can support several cavity modes with frequencies inside the phononic band gap. The displacement distribution of the 1st cavity mode is shown in Fig. 1(b). It is clearly observed that the elastic energy is highly confined inside the cavity region. Then various forms of metamaterial lattices can be constructed by using the cavity modes.

We construct the one-dimensional (1D) SSH lattice by the metamaterial cavities. The classic SSH model is given in Fig. 2, where the unit-cell (in the dashed rectangle) is composed of two atoms A and B with the nearest-neighbor coupling. The intra- and inter-coupling strengths are denoted by γ_{a} and γ_{b}, respectively. The super-cell (in the dashed rectangle) of the metamaterial lattice which contains two cavities is shown in Fig. 3(a). The coupling strength between the neighboring cavities can be tuned by altering the distances between the cavities. The wave characteristics of the metamaterial SSH lattices are analyzed by both the FEM and tight binding model. The effective Hamiltonian is derived from the analytic model, and the topological phase of the phononic band gaps can be characterized by the winding number. The results show that when the intra-coupling strength is larger (smaller) than the inter-coupling strength, the phononic band gap is topologically trivial (non-trivial).

The topological interface state can be achieved by connecting the metamaterial lattices with different topological phases, as shown in Fig. 3(b). From the modal distribution one can observe that the elastic waves are highly localized in near the interface. Notably, such topological interface state is robust to the local disorder. Moreover, the topological edge states can be found at the edge of metamaterial lattice with the topological non-trivial phase. In addition, the topological interface and edge states are verified in the fabricated samples. Finally, the mechanical energy of the topological states is collected by utilizing the piezoelectric patches. Compared with the reference slab, the output electric power of the topological metamaterial lattice is significantly increased.

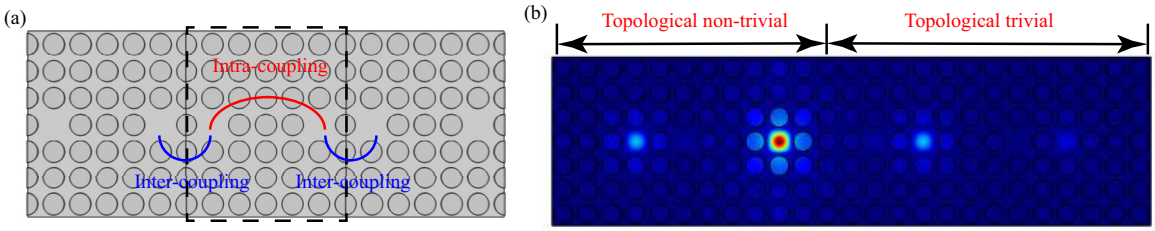

Figure 3: (a) Schematic diagram of the super-cell of the metamaterial SSH lattice. (b) Displacement field distribution of the topological interface state, where the interface is formed by connecting the metamaterial lattices with topological non-trivial and trivial phases.

CONCLUSIONS

The topological properties of the engineered metamaterial SSH lattices are studied. The topological interface and edge states obtained, which are robust to the local disorder. Additionally, the piezoelectric energy harvester is proposed by utilizing the topological states. Note that various phenomena in electronic or quantum systems may be realized in the elastic or acoustic systems using the engineered material lattices.

A KIND OF SINGLE-PHASE FULL BANDGAPS PHONONIC CRYSTALS AND EXPERIMENTAL EVIDENCE

Tianyan Liu*[1], Pengzhou Li [1], and Kun Zhang[1]
[1]Reactor Engineering Sub-institute, Nuclear Power Institute of China, Chengdu, China

Summary Based on understanding of the dynamical explanation of locally resonant phononic crystals, a one-dimensional simple mechanical model is established based on the mass-spring chain model, which can accurately and easily predict the lower and upper frequencies of the first bandgap in locally resonant phononic crystals. In addition, the dynamic model can explain the modal and vibration response of locally resonant phononic crystals. On the basis of the model, a kind of single-phase PCs structure with full-bandgaps is designed, which can omnidirectionally obtain locally resonant bandgaps in a very low frequency range by using the cantilever beam, which have great potential in the field of large-scale mechanical vibration isolation. As a verification, we also made steel samples of this kind of PCs, and the existence of full-bandgaps is confirmed in the experiment.

INTRODUCTION

The phononic crystals make the propagation of vibrations forbidden (infinite structure) or greatly suppressed (finite structure) within the band gap. This characteristic of phononic crystals enables them to be applied in the field of vibration isolation of large mechanical devices[1–3]. However, in some special environments, such as the nuclear island environment, the traditional phonon crystal structure cannot work efficiently. Thus, it is necessary to design a phononic crystals vibration isolation structure composed mainly of steel materials. In this paper, a dynamic model for predicting the upper and lower bandgap edge of locally resonant phononic crystals is proposed. On this basis, a kind of single-phase locally resonant phononic crystals with full bandgap is designed, and its energy band structure and transmission are analyzed. In additional, a steel PCs sample was made, and the existence of full-bandgaps is confirmed in the experiment.

MECHANICAL MODEL

In the reference[4], the modal at the bandgap boundary is divided into two vibrational forms, the one is the natural mode of the resonator structure, and the other is one that the free vibration between the resonator and the matrix. Thus, a mass-spring chain model, shown in the fig.1, is proposed.

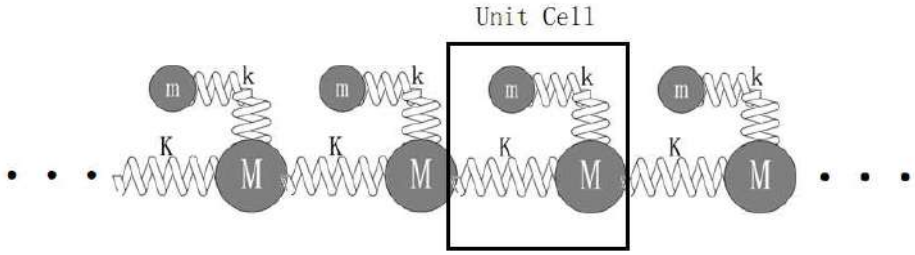

Figure 1. Mass-spring chain schematic diagram. As an one-dimensional infinite model of locally resonant PCs, there are four units' cells (one of them is enclosed by a solid box), which repeat indefinitely on both sides, shown in the figure.

The one-dimensional PCs has periodicity in the direction between left and right, based on Bloch Theorem, both U_L and U_R are demanded to satisfy the constrain determined by the following equation,

$$U_R = U_L e^{ik(-r_R+r_L)} = U_L e^{-ik_p a}. \quad (1)$$

According to the relationship of U_L and U_R determined in Eq. (1), we define k_p as the wave vector in the propagation direction, and introduce a new variable stiffness K',

$$K' = (e^{ik_p\frac{a}{2}} - e^{-ik_p\frac{a}{2}})^2 K. \quad (2)$$

By employing variable K', the unit cell model can be changed to the two-degree-of-freedom model. This 2-DOF model has two eigenvalue branches, which describe two coupled vibration modes of the locally resonant PCs in physics. Fig. 2(a) depicts the vibration mode of upper edge and Fig. 2(b) depicts the vibration mode of lower edge. These two diametrically opposite modes of vibration cut off the vibration transmission. There will be no vibration modes between these vibration modes frequency, which is the first forbidden band of the locally resonant PCs.

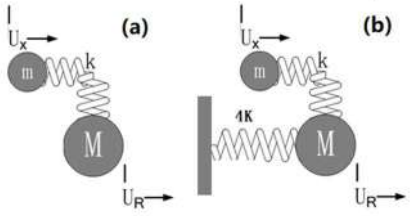

Figure 2. Vibration mode of unit cell.

GEOMETRIC DESIGN AND EXPERIMENTAL EVIDENCE

*Corresponding author. E-mail: rexroi@hotmail.com.

In order to apply it in the vibration isolation structure of the common device, the unit cell size is limited to 10 cm, the thickness of phononic crystal plate is 3 cm, and the lower edge frequency of first band gap generated by the phononic crystal plate should be less than 600 Hz, which covered most pump electromagnetic vibration frequency. According to the requirements, as shown in Fig. 3, it is designed the phononic crystal unit cell structure in this work.

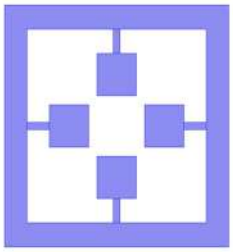

Figure 3. Schematic view of unit cell

The band structure of this PCs is fully discussed in Fig. 4, including isotropic and anisotropic situation. Furthermore, as a validation, the numerical simulation results are compared with the experimental results. Similar transmission is obtained in FIG. 5, which prove the existence of low-frequency bandgaps of single-phase locally resonant PCs.

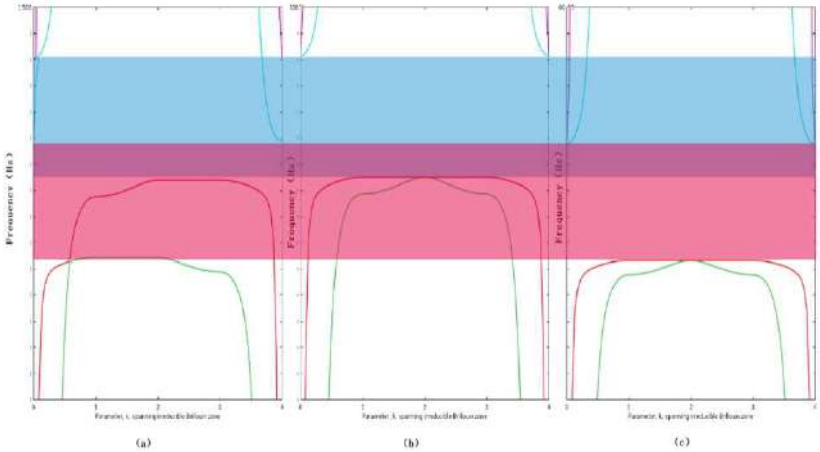

Figure 4. The band structure of designed PCs.

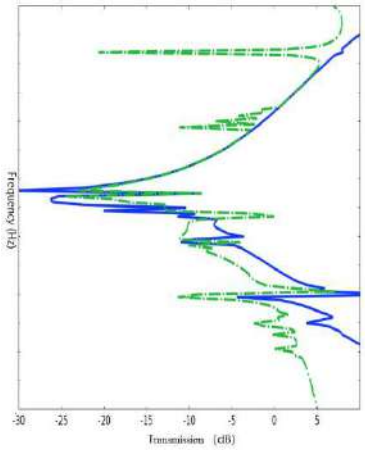

Figure 5. Transmission spectra.

CONCLUSIONS

Through lucubration of the proposed dynamic model, a kind of single-phase locally resonant phononic crystals with very low frequency bandgaps was designed and experimentally verified.These PCs have guiding significance to the design of vibration isolation structures of nuclear devices.

A NOVEL HIERARCHAL METAMATERIAL WITH TUNABLE BANDGAPS

Hamid Jafari, Soroush Sepehri, Mahmoud Mosavi Mashhadi, Mohammad Reza Hairi Yazdi, and Mir Masoud Seyyed Fakhrabadi *
School of Mechanical Engineering, College of Engineering, University of Tehran, Tehran, Iran

Summary Designing an acoustic/elastic metamaterial with wide and tunable band gaps has been one of the significant fields of study for structural engineers and scholars, and applying hierarchy is one of the latest developed methods to tune the attenuation zones of an elastic metamaterial. In this manuscript, a novel hierarchal concept structure able to exhibit tunable bandgaps is presented. Aside from the geometrical changes occurred in the structure due to the hierarchy, the effect of the change in the elastic modulus and density of the inner structure of the proposed geometry on the dispersion curves of the hierarchal structure is studied numerically using the finite element method and applying Bloch's theorem. The results of the present study can pave the way for designing elastic metamaterials with the ability to present wider and more tunable band gaps in the future.

BACKGROUND

Due to their exceptional mechanical, vibrational, and thermal characteristics, periodic lattice materials have been the subject of numerous studies in the past 20 years. One of the most notable features of such structures is their ability to attenuate specific ranges of frequency in the dispersion curve. In such ranges, which are called bandgaps by many researchers, the wave motion stops, and thus it cannot propagate any further. This phenomenon serves as the main principle in designing the vibration, acoustic and elastic filters. Recently, Jafari et al. [1] studied the wave propagation behavior of architected microtubule-based nano-bio-filters of various topologies and concluded that the geometry and relative density of an architected structure plays a vital role in the wave propagation characteristics of periodic architected structures.

The performance of a filter is evaluated by the location and width of the occurring bandgaps and how it can serve a specific need. In order to be able to engineer and design tunable elastic/acoustic metamaterial, one has to understand the underlying mechanisms of forming bandgaps fully. Typically, two different mechanisms are noted as the main reasons for forming the bandgaps, namely the Bragg scattering [2] and local resonance [3]. While the bandgaps induced by the Bragg scattering phenomenon are typically formed in the wavelengths in the order of the lattice constant, energy localization of the propagating waves is the reason behind the locally resonant bandgaps, which are formed in lower frequencies. Hence, aside from the geometry, mechanical parameters such as the elastic modulus and density may affect the band diagram of the system and lead to the formation of new bandgaps in different regions.

In the present study, a concept hierarchal lattice structure is presented with the ability to exhibit tunable bandgaps. Aside from the topological changes made in the structure by introducing hierarchy, different materials are used in different levels of hierarchy to measure the material effects of the bandgap formation and behavior. Further, the concept of functionally graded thickness is introduced in the structure for various levels of hierarchy, and its effects on the performance of the periodic lattice metamaterials are studied. The structures are modeled using the finite element method, and the wave propagation analysis is carried out by implementing the Bloch's theorem on the provided 2-D hierarchal structures.

FORMULATION

By applying Bloch's theorem, the wave propagation behavior of a periodic structure can be studied by analyzing a single unit cell, thus saving us a lot of time and processing power. According to this theorem, the following equation can be written to describe the deformation of specific point with position vector $q(\vec{R})$ to its corresponding position vector in the reference unit cell $q(\vec{R}_i)$ [4]:

$$q(\vec{R}) = q(\vec{R}_i)e^{\vec{\kappa}.(\vec{R}-\vec{R}_i)} = q(\vec{R}_i)e^{\vec{\kappa}.(m_1\vec{a}_1+m_2\vec{a}_2)} = q(\vec{R}_i)e^{(k_1m_1+k_2m_2)} \quad (1)$$

In the previous equations, $\vec{\kappa}$ is the wave vector with components κ_1 and κ_2 in the direction of $\vec{a}_1$ and $\vec{a}_2$, respectively. Further, the components κ_1 and κ_2 are in a complex form with real part (δ) and an imaginary part (ϵ), serving as the attenuation and phase constants, respectively. Since in the present study, the waves are propagating without attenuation, the real parts are assumed to be zero; hence, the description of the wave vectors components can be reduced to $\kappa_1 = i\epsilon_1$ and $\kappa_2 = i\epsilon_2$.

The schematics of a hierarchal lattice structure of proposed topology are depicted in Figure 1 along with its reciprocal lattice and Brillouin zones. Implementing the finite element method to model the structure, the following eigenvalue problem can be solved to find the dispersion curves of the present structures in the reduced coordinates:

$$\left(\tilde{K}(k_1,k_2) - \omega^2\tilde{K}(k_1,k_2)\right)\begin{bmatrix}q_1\\q_2\\q_i\end{bmatrix} = 0 \quad (2)$$

THEMATIC SESSION SM

Figure 1. Periodic tunable architected structure a) Base model b) First order of hierarchy (unit cell as red one) c) FBZ and IBZ

RESULTS AND DISCUSSIONS

The dispersion curves of the rectangular periodic architecture are depicted in Figure 2 along with the band diagram of a hierarchal unit cell. It is observed that increasing the connectivity number of nodes via adding including hierarchy leads to opening new locally resonant bandgaps. The local resonance nature of this bandgap is designated by the flat lower band. Further, since the plotted frequencies are normalized against the first natural frequency of the lateral vibration of a clamped-clamped beam with the same length as that of the rectangular structure, the occurrence of local resonance at points close to the normal frequency $\omega = 2$ proves that the added hierarchy is responsible for the energy localization in the structure. Performing a careful parameter study on the length and mechanical properties of the added hierarchal levels, one can tune this local resonance (and possible other resonances), leading to designing a periodic lattice structure with the ability to exhibit bandgaps in desired frequency ranges.

Another effect of changing the topology of the structure by introducing hierarchy is the widening of the directional band gaps as a result of adding stiffer elements to the structure. This phenomenon can also be tuned by changing the material composition of the whole structure by using different materials for different levels of hierarchy.

Figure 2. dispersion curves of a) rectangular lattice b) hierarchal rectangular lattice

CONCLUSION

In the present manuscript, a novel hierarchal architected structure, capable of exhibiting tunable bandgaps, is presented and its wave propagation behavior is studied using the finite element method and Bloch's theorem. In addition to the geometrical changes made to the structure by adding hierarchy, the effect of the elastic modulus ratio on the dispersion curves is illustrated and further, the implementation of functionally graded thickness in different levels of hierarchy is further scrutinized. The results of the current study prove that by adding different levels of hierarchy to the structure, it can exhibit bandgaps induced by local resonance. This phenomenon opens ways to tune the bandgap position by changing geometrical and material properties of the hierarchal periodic lattice structure.

INTEGRATED DESIGN OF MECHANICAL REINFORCEMENT AND MICROWAVE ABSORPTION FOR LIGHTWEIGHT METASTRUCTURE

Yixing Huang[1], Mingji Chen[2]and Daining Fang*[1,2]
[1]State Key Laboratory for Turbulence & Complex Systems, College of Engineering, Peking University, Beijing 100871, P. R. China
[2]Institute of Advanced Structure Technology, Beijing Institute of Technology, Beijing 100081, P. R. China

Summary Poor mechanical properties of microwave absorbing materials which are widely used to protect aircrafts and vessels from radar detection limit seriously their further applications. A metastructure with integrated design of mechanical reinforcement and broadband microwave absorption is optimized and fabricated with nano lossy composites. Theoretical stress solution is given to improve structural parameters with better stress distribution. Lightweight design is achieved by internal cavity carving in the metastructure. The improved flexural strength and absorption performance exhibit effective coordination of multi-scale mechanical strengthening and electromagnetic resonance with small thickness.

INTRODUCTION

Covering microwave absorbing (MA) materials on metallic surfaces is the major way to reduce radar cross section and protect targets from radar detection, which is seriously significant for unit survival in battle fields. However, poor mechanical properties of MA coatings, which is used dominantly in current situation, limit their further application to a great extent[1, 2]. MA Coating peeling, crush and smash are inevitable in the short-term usage period because of mechanical impact and loading in working conditions. Thus, mechanical reinforcement is essential to improve working efficiency and reduce cost of MA materials in engineering sense. In recent years, proposal of metastructure concept makes it possible to integrate spatial mechanical lattice and microwave absorbers into one practical structure, which is promising to enhance the structural mechanical strength of the metastructure for broadband microwave absorption. Typical microwave metastructure is designed with lattice to generate spatial electromagnetic resonance so that more microwave energy in broader frequency bands can be dissipated. The lattice for microwave absorption is often fabricated with polymer embedded with metallic resonant circuit, which is of poor load bearing, while mechanical lattice is usually fabricated with aluminium or steel which is complete microwave reflectors. Thus, combining the function of microwave absorption and mechanical resistance is challenging. In this paper, the metastructure fabricated by nano lossy lattice and carbon/glass fibres with microwave dissipation and mechanical reinforcement is presented, which is promising to solve the conflict between mechanical and electromagnetic designs.

THEORETICAL STRESS DISTRIBUTION

The proposed metastructure is composed of glass fibre reinforced composite (GFRC), carbon fibre reinforced composite (CFRC) and nano lossy lattice made of epoxy resin (ER), multiwall carbon nanotube (MWCNT) and spherical carbonyl iron particles (CI) as shown in Figure 1 (a). In order to enhance the mechanical strength of the metastructure and achieve lightweight properties, the stress should be reduced by optimizing the lattice structural parameters under the same load. The three-point bending model of the metastructure is shown in Figure 1 (a). Five dangerous points that are supposed to be subject to the maximum stress are marked as a_1, a_2, a_3, a_4 and a_5 respectively. Under the circumstances of three-point bending working condition, point a_1 is subject to the maximum compressive stress on the top of the GFRC, point a_2 is subject to shear stress on the interface between the lattice core and the GFRC, point a_3 is subject to shear stress that may tear the rib and the substrate apart in the lattice, point a_4 is subject to shear stress on the interface between the lattice and the CFRC, and point a_5 is subject to the maximum tensile stress at the bottom of the CFRC. According to Euler–Bernoulli beam theory and assumption of plane cross section, the normal stress of GFRC and CFRC in the metastructure under three-point bending can be written as

$$\sigma_{GF}=\frac{MyE_{GF}}{E_{GF}I_{GFz}+E_LI_{Lz}+E_{CF}I_{CFz}}\ (1)\quad \sigma_{CF}=\frac{MyE_{CF}}{E_{GF}I_{GFz}+E_LI_{Lz}+E_{CF}I_{CFz}}\ (2),$$

where E_{GF} (16.43GPa), E_L (4.15GPa) and E_{CF} (21.73GPa) are the measured elastic modulus of the GFRC, lattice core and CFRC respectively, I_{GFz}, I_{Lz} and I_{CFz} are the inertia moment of the GFRC, lattice core and CFRC with respect to the cross section, and M is the moment applied to the metastructure, y is the vertical coordinate. The shear stress of the metastructure can be written as

$$\tau_{xy}=\begin{cases}-\dfrac{F_S\left[E_{CF}S^*_{CF1z}+E_LS^*_{L1z}\right]}{2(P-L)\left(E_{GF}I_{GFz}+E_LI_{Lz}+E_{CF}I_{CFz}\right)}, & (0<y\le A_1+A_3-y_{C1})\\ \dfrac{F_S\left[E_{GF}S^*_{GF1z}+E_LS^*_{L2z}\right]}{2(P-L)\left(E_{GF}I_{GFz}+E_LI_{Lz}+E_{CF}I_{CFz}\right)}, & (A_3-y_{C1}\le y\le 0)\end{cases}\quad (3),$$

where

$$I_{GFz}=\frac{PA_3^3}{6}+2PA_3\cdot\left(y_{C1}-\frac{A_3}{2}\right)^2\ (4)\quad I_{CFz}=\frac{PA_4^3}{6}+2PA_4\cdot\left(H-\frac{A_4}{2}-y_{C1}\right)^2\ (5)\quad I_{Lz}=\frac{(P-L)A_1^3}{6}+2\left(y_{C1}-A_3-\frac{A_1}{2}\right)^2(P-L)A_1+\frac{PA_2^3}{6}+2\left(A_1+A_3+\frac{A_2}{2}-y_{C1}\right)^2PA_2\ (6)$$

$$S^*_{CF1z}=(2H-A_4-2y_{C1})PA_4\ (7)\quad S^*_{L1z}=PA_2\left(2A_1+2A_3+A_2-2y_{C1}\right)+\left(A_1+A_3-y_{C1}+y\right)\left(A_1+A_3-y_{C1}-y\right)(P-L)\ (8)$$

* Corresponding author. E-mail: fangdn@pku.edu.cn

$$S^*_{GF1z}=(A_3-2y_{C1})PA_3 \text{ (9)} \quad S^*_{L2z}=-(y_{C1}-A_3+y)(y_{C1}-A_3-y)(P-L) \text{ (10)} \quad y_{C1}=\frac{PA_3^2+(2H-A_4)PA_4+(2A_3+A_1)(P-L)A_1+(2A_1+2A_3+A_2)PA_2}{2P(A_2+A_3+A_4)+2(P-L)A_1} \text{ (11).}$$

S^*_{CF1z} and S^*_{GF1z} are the inertia moment of the CFRC and the GFRC with respect to the neutral surface, S^*_{L1z} and S^*_{L2z} are the inertia moment of the lattice part which is below or above the calculated point's y coordinate with respect to the neutral surface, and $H=A_1+A_2+A_3+A_4$. Since the shear stress condition above and below the neutral surface is different, the shear stress distribution is in a different pattern when coordinate y is larger or smaller than zero. The designed load is 1100N.

When increasing the height of the lattice rib A_1 from 0.1mm to 5mm, the normal stress in point a_1 and a_5 decreases dramatically from 1200MPa to 200MPa, while the normal stress in point a_2 and a_4 changes slightly (Figure 1 (b)). Thus the design dimension A_1 is essential for dangerous point a_1 and a_5. Shear stress in point a_2 and a_3 also decreases from -70MPa to -20MPa with A_1 increased (Figure 1 (c)). However, when increasing the cavity side length L from 3mm to 20mm, the shear stress in point a_2 and a_3 increases drastically from -20MPa to -150MPa. Considering the stress level, the final parameters are optimized as P=20mm, L=17.5mm, A_1=2mm, A_2=1mm, A_3=0.5mm.

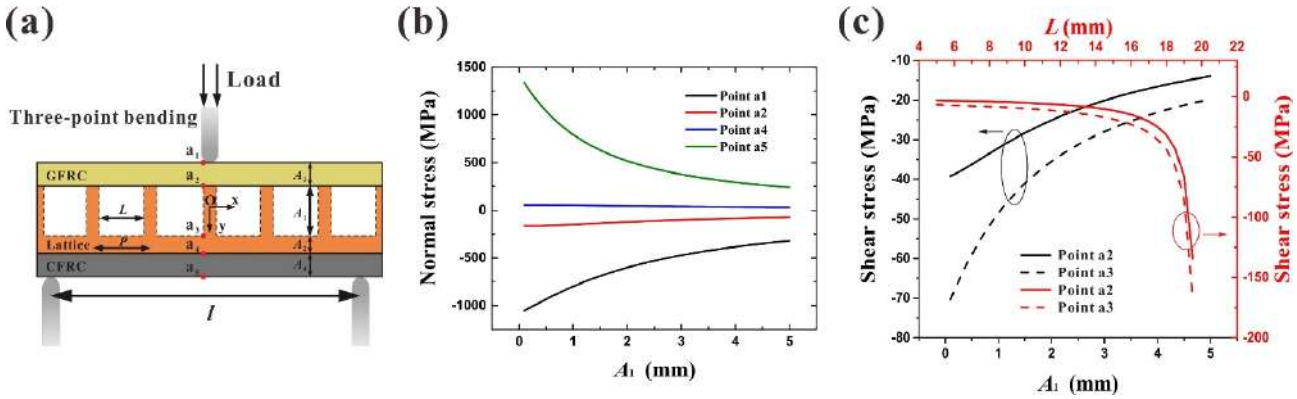

Figure 1: (a) The three-point bending model of the metastructure and dangerous points. (b) The normal stress in the dangerous points in the metastructure when varying A_1. (c) The shear stress in the dangerous points in the metastructure when varying A_1 and L.

MECHANICAL-MICROWAVE ABSORPTION PERFORMANCE

The nano lossy lattice reinforced by MWCNT and CI (ER:MWCNT:CI=48vol%:2vol%:50vol%) in micro-scale and meso-scale and by CFRC and GFRC in macro-scale is the essential way to replace steel-made lattice for broadband microwave absorption (Figure 2 (a)). The measured load-deflection curve in three-point bending test and experimental reflectivity measured by NRL arch method exhibit effective load bearing with maximum load of 1111N and broadband microwave absorption with -9dB bandwidth from 2.54GHz to 22.81GHz crossing the S, C, X, Ku and K bands (Figure 2 (b)). The metastructure is able to resist loading from the deflection of 3mm to 12mm even after the fracture of GFRC (the maximum load), indicating the reliable mechanical reinforcement. Compared with structures reported in previous typical studies[1, 2], the proposed metastructure improves both the flexural strength and the -10dB effective bandwidth-thickness ratio up to 126.2MPa and 2.99GHz/mm, which suggests that the structural design is reasonable to maintain microwave absorption and mechanical resistance in one structure (Figure 2 (c)). With cavity design, the areal density of the metastructure is only 4.11kg/m^2, one-third of the plate form with the same thickness. The combined design methodology of mechanics-electromagnetics is promising for multifunctional structure development.

NON-RECIPROCAL SOLITONS IN ROBOTIC METAMATERIALS

Martin Brandenbourger*[1], Hans Dekker[1], and Corentin Coulais[1]
[1]Institute of Physics, University of Amsterdam, Amsterdam, the Netherlands

Summary The recent development of robotic metamaterials, which are assemblies of building blocks integrating sensors and actuators, enables the implementation of non-conservative interactions within mechanical systems. This opens the way to the emergence of unique large scale mechanical properties. Here, we use this new platform to generate soliton waves that indefinitely propagate in only one direction. We show that these waves emerge from a balance between mechanical non-linearities and linear non-reciprocal interactions, namely, which preferably transmit motion in one direction. We rationalize the conditions of existence of these solitons and demonstrate that they exist even in the presence of friction. These results establish new ways to reliably transport mechanical energy.

INTRODUCTION

Over the last few years, there has been an explosion of activity on non-reciprocal metamaterials [1, 2, 3], namely, which transmit motion in one direction, but block it in the other. However, to date, non-reciprocal transmission has only been achieved for a limited range of frequencies and input magnitudes. The recent development of robotic metamaterials, which are assemblies of building blocks integrating sensors and actuators, enables the implementation of non-conservative interactions within mechanical systems. Using this approach, recent research [1] have created robotic mechanical metamaterials that break reciprocity at the linear level and have shown that first-of-their-kind unidirectionally amplified waves emerge. This first observation opens the way to new wave manipulations in active metamaterials. Here, we show that the same platform can generate soliton waves that indefinitely propagate in only one direction. We rationalize the conditions of existence of these solitons and demonstrate that they exist even in the presence of friction, which qualifies them as dissipative solitons [4, 5, 6, 7]. These results establish new ways to reliably transport mechanical energy and to store mechanical waves.

OBSERVATION OF A SOLITON

Our metamaterial consists of 20 robotic building block with rotational degrees of freedom (Fig. 1A). Each robotic unit cell consists of a mechanical rotor with a rotational moment of inertia J, of a local control system, and is mechanically coupled to its neighbors via pre-stretched elastic beams with a torsional stiffness C (Fig. 1B). The rotors are made out of a 3D printed pieces mounted on a rotor shaft, and are housed in units that are placed equidistantly in a circle. The local control system takes as input the signals from the angular sensors of neighboring building blocks, and computes an output torque which the motor applies to the rotor. The output torque on a building block i, τ_i, is computed using the non-reciprocal feedback rule $\tau_i = \epsilon(-\phi_{i-1} + \phi_{i+1})$. The parameter ϵ is a feedback parameter indicating the strength of the non reciprocal interaction and ϕ_{i-1} (ϕ_{i+1}) is the angular displacement of the rotor $i-1$ ($i+1$). Once the robotic metamaterial excited with a pulse, a solitary wave packet propagates through the system in only one direction (Fig. 1C). By analyzing this wave, we verify that it is characterized by a constant shape and velocity over time, which qualifies it as a soliton.

REGIME OF EXISTENCE

In Hamiltonian systems, classical soliton theory applies and the soliton stability is only governed by the balance between dispersion and non-linearity. For a given system, a range of solitons shapes and velocities exist, depending on the initial conditions. However, energy is constantly injected in our system via the robotic parts and the viscous friction of each rotor dissipates energy. Therefore, the unidirectional wave observed in our system has to be described by dissipative soliton theory [4, 5, 6, 7], where the balance between dispersion and non-linearity is complemented with a balance between dissipation and driving. These solitary waves are characteristic of active systems and are found in semiconductors, nonlinear optical systems and chemical systems. In this growing field of research, the complexity of the experiments often makes difficult the control of each parameter, in particular the balance between dissipation and driving. This robotic mechanical metamaterial, with its unique control over the driving via the parameter ϵ, enables a fine tuning of this balance. Therefore, we generated a diagram of soliton stability, where the feedback parameter ϵ and the initial velocity of the pulse ω_0 have been varied. The stability of the solitary wave is described by a characteristic exponential time decay α. The experimental phase diagram (Fig. 1D) shows a soliton region (black crosses) that starts at high initial pulses and expands toward lower initial pulses for higher feedback parameters ϵ. As expected, solitons are not observed for low feedback parameters, in which case the wave slowly decreases in amplitude over time, and for high feedback parameters, in which case the wave amplitude self-amplifies and explodes as it propagates. According

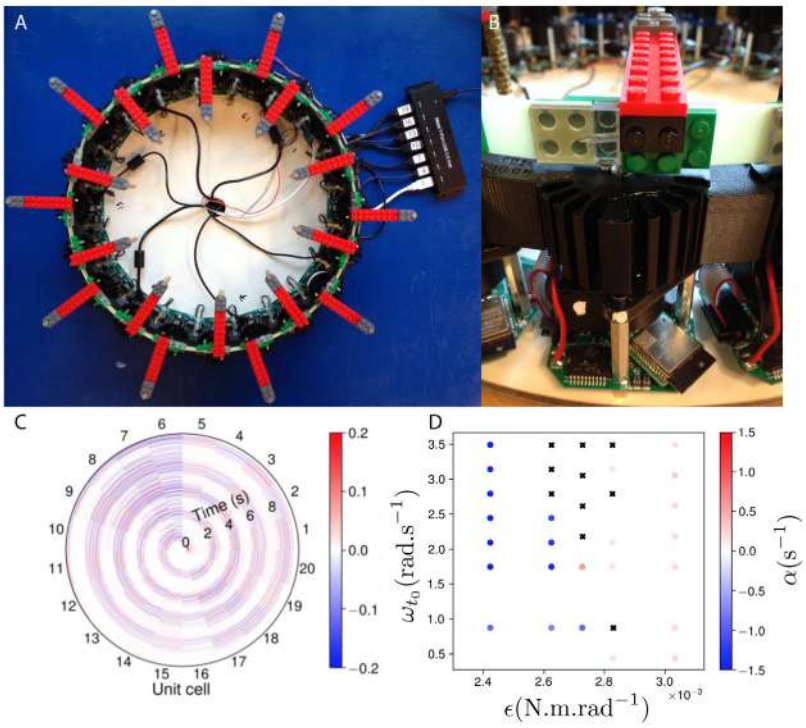

Figure 1: (A) Top view of the mechanical metamaterial constituted of 20 building blocks connected to each other via green elastic rubber bands. (B) Side view of one building block, where the bottom part corresponds to the local control system enabling linear non-reciprocity. (C) Measurement of a solitary wave propagating along the robotic metamaterial. The unit cells are numbered from 1 to 20. The color scale corresponds to the amplitude of oscillation of an oscillator in radians. (D) Phase diagram describing the region of existence of dissipative solitons (black crosses) as a function of the initial speed of the pulse ω_{t_0} and the feedback parameter ϵ. The parameter α describes the characteristic decay time of the propagating waves.

to dissipative soliton theory, for every value of driving, there should be a distinct soliton in terms of its velocity and wave form, irrespectively of the initial conditions. This is confirmed experimentally as we observe that the soliton speed increases linearly a function of the balance between driving and dissipation. Furthermore, for specific initial conditions, we observe breathing solitons, where the wave form of the soliton oscillates between two shapes. This phenomenon has been observed in other discrete systems, such as photonics crystals [5], Josephson junctions [6] and Bose-Einstein condensates [7] and has been referenced as localized breathers. The simplicity of the present mechanical systems brings unique opportunities to study in details the breathing behavior of solitons.

CONCLUSION

By adding nonlinear interactions in a linearly non-reciprocal metamaterial, we observed for the first time a unidirectional dissipative soliton. Its existence is governed by the balance between both dispersion versus non-linearity and driving versus friction. The robotic nature of this metamaterial enables easy exploration of the influence of driving on the active system via a feedback parameter. We show that the dissipative soliton exists for a fixed range of feedback parameters and input velocities. For specific initial conditions, we observe breathing solitons, where the wave form of the soliton oscillates between two shapes. The constant nature of the soliton wave and the fine control that we have over its properties opens new ways of creating materials that act as tunable, non-reciprocal waveguides.

MACHINE LEARNING OF MECHANISMS IN COMBINATORIAL METAMATERIALS

Ryan van Mastrigt*[1,2], Corentin Coulais[1], Martin van Hecke[2,3], and Marjolein Dijkstra[4]

[3]Leiden Institute of Physics, Leiden University, Leiden, the Netherlands
[4]Debye Institute, Utrecht University, Utrecht, the Netherlands

Summary Combinatorial metamaterials are metamaterials designed by combining unit cells picked from a discrete set. This discretised design space allows us to explore the limitless structural complexity of metamaterials in a controlled manner. However, analytical and conventional numerical approaches have difficulty in efficiently navigating large design spaces, which grow exponentially with system size. Here we employ machine learning techniques to explore combinatorial metamaterial design. We show that trained convolutional neural networks are able to classify never before seen configurations near perfectly. To study the scalability of this long-correlation classification problem, we investigate the relation between network complexity and configuration size. Our work provides insight into application and scaling of neural networks to complex discrete structure-property maps.

BACKGROUND

Most mechanical metamaterials are designed by tiling a unit cell on a particular grid. The zero-energy deformations, or floppy modes, of such a material depend strongly on how the adjacent unit cells interact with each other, i.e. if they allow for compatible zero-energy deformations. By varying the grid or the design of them, it is possible to design materials with a wide range of exotic properties[1].
More complex metamaterial designs can be explored in a controlled manner by expanding the design space to designs composed by selecting unit cells from a finite set, which allows for exotic material behaviour such as specific deformation response[2], strain rate selectable modes[3], or control of defects[4]. However, for large configuration sizes the design space increases exponentially, which hinders analytic and numeric exploration of the full design space.

RULES FOR LINE MODES

Here, we focus on the design of 2D metamaterials composed by periodic tiling of $n \times n$ super cells on a square grid, where the latter are in turn composed by tiling of $k \times k$ unit cells selected from a finite set. This set consists of a singular bimodal fundamental unit cell and its three 90°rotations, the unit cell and its two deformation modes are shown in figure 1**a**. The complete metamaterial thus consists of a $nk \times nk$ grid of unit cells as is shown in figure 1**b**.
Depending on the precise configuration of the super cell, the metamaterial is able to host a number of floppy modes M_n^k. As n increases, for some super cell configurations M_n^k increases linearly with n. This is due to the configuration supporting line modes - deformations that span the whole material along one spatial direction. It turns out that all super cell configurations can be classified as either having a line mode (class B) or not (class A).
For a super cell to allow for a line mode to exist in the horizontal (vertical) direction, a set of adjacent rows (columns) of unit cells must allow for compatible periodic deformations in the horizontal (vertical) direction while inducing no or the counter-rotating squares mode in the unit cells outside of the set. Thus recognising line modes in super cell configurations means recognising compatible local deformations throughout the whole material, i.e. a set of abstract rules to be followed throughout the material.

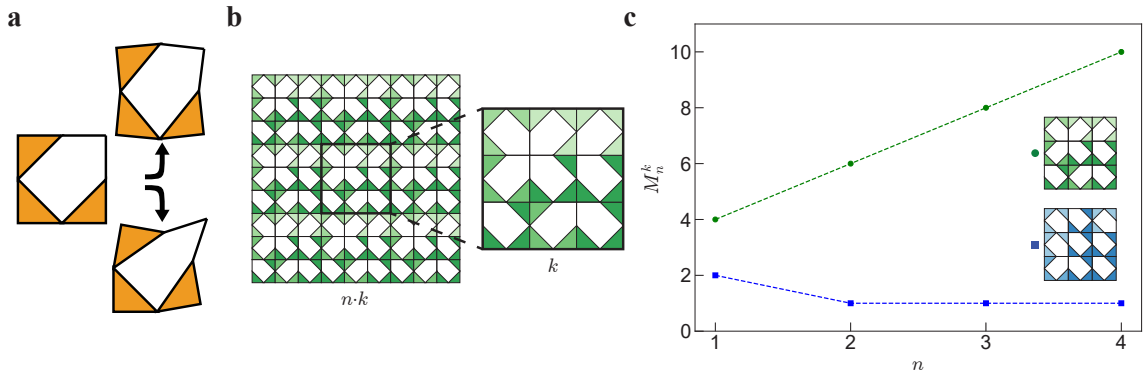

Figure 1: **Material hierarchy and mode scaling. a.** Unit cell with two possible deformation modes. **b.** Super cell (right) tiled periodically in the metamaterial (left). **c.** Number of floppy modes with obc M_n^k as a function of n for two $k = 3$ super cells shown in the legend.

MACHINE LEARNING LINE MODES

However, in general it may be difficult to define such rules, especially for complex unit cells. In the following, we study the application of machine learning to reduce the combinatorial search space for line modes.
A large number of very simple, minimal convolutional neural networks (CNNs) are trained and assessed over training and test sets respectively for a range of super cell sizes. Each CNN consists of a single convolutional layer of n_f filters, a single hidden layer of n_h neurons, and an output layer of two neurons.
In order to fairly assess the performance of the trained nets over the different configuration sizes, recall is used as the performance measure. The recall is defined as the ratio of correctly classified class B configurations over all class B configurations, which is invariant to the class balance of the test set.
The recall as a function of the hyperparameters n_f and n_h is shown in figure 2. Clearly, for sufficiently large neural networks the recall is very high and the performance of the networks are excellent. However, when the network has a relatively small number of parameters, the performance worsens. The difference between the configuration sizes is striking, indicating that non-trivial scaling between line mode complexity and neural network performance is present.

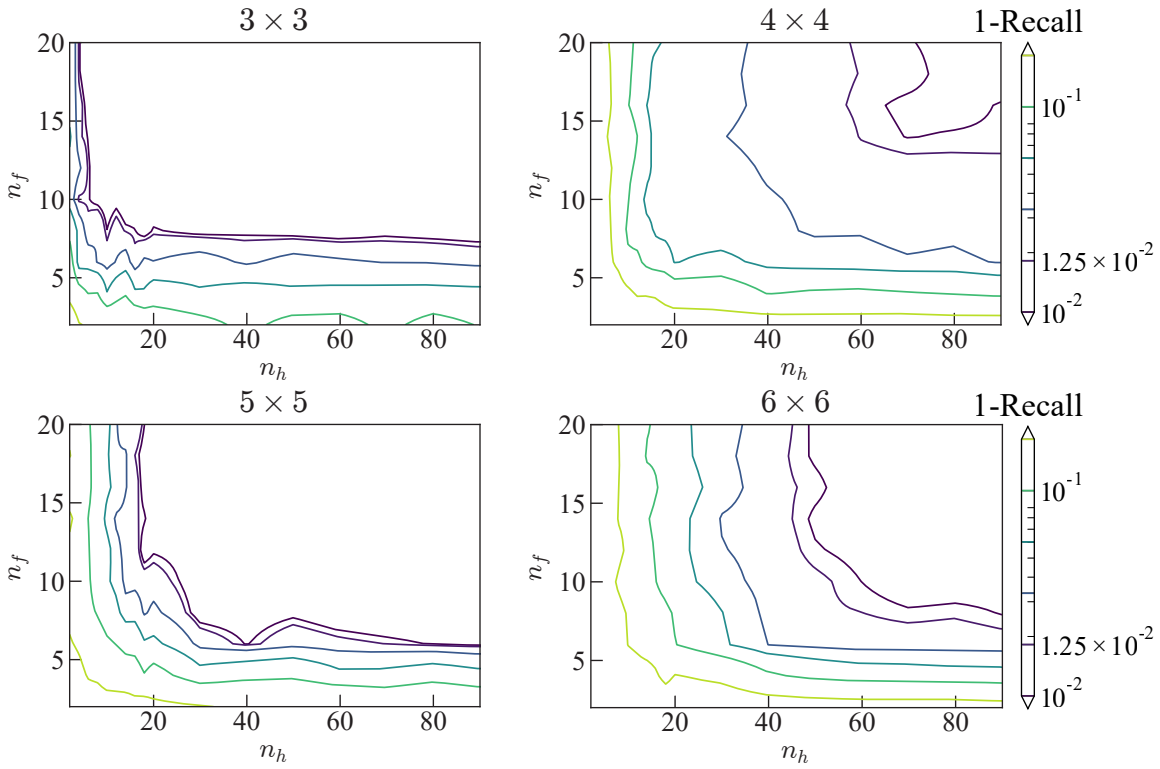

Figure 2: **Trained CNN performance.** The recall as a function of the number of filters n_f and hidden neurons n_h for neural networks trained on different configuration sizes $k \times k$.

CONCLUSIONS

To conclude, we have created a metamaterial that is capable of deforming periodically along a spatial direction, given that the super cell configuration supports such a mode. We have shown that with convolutional neural networks, we are able to classify - with high accuracy - super cells that are able to do this, over a range of super cell sizes. Further analysis of underparameterised neural networks trained on this problem, has shown the presence of a non-trivial scaling relation between super cell size and neural network performance. We intent to explore this scaling further, through rescaling of the recall and in depth analysis of size effects on line modes. Understanding how size effects in metamaterial design propagate through neural network learning is key in further application of neural networks to material design problems.

CONSTRUCTION OF DISPERSION CURVE BY PARTS THROUGH ASYMPTOTIC MULTI-SCALE METHOD

Antoine Rallu*[1], Claude Boutin[1], and Stéphane Hans[1]
[1] LTDS CNRS UMR 5513 ENTPE, Vaulx-en-Velin, France

Summary Dynamics at low frequencies of periodic heterogeneous media is conventionally described by the method of homogenization of periodic media, when it exists a scale separation between displacements and the characteristic size of a cell irreducible from the media. At higher frequency, this separation of scales is lost and the homogenization method becomes obsolete. To cross this barrier, a multi-scale method is propose to consider periodic modes over a period composed of several irreducible cells. Around the eigenfrequencies of these multicells periods with periodic boundary conditions, large evolution situations emerge. A new separation of scales is therefore defined between the amplitude of the mode and the characteristic size of the period. The equations governing the modulation are thus obtained, and their nature differs if the mode considered is single or multiple. From the macroscopic modulation equations we can extract an approximation of the fundamental dispersion curve, in the vicinity of the periodic eigenmodes of the multi-cells period. Consequently, a construction by parts of the fundamental dispersion curve is provided.

INTRODUCTION

The goal of this paper is to describe the methodology of construction of parts of the dispersion curve of periodic elastic networks. This process is full and clearly described on a periodic network of elastic resonators : First, a multi-cells approach is presented in order to identify the situation of large scale evolutions, which correspond to the frequency ranges around the eigenfrequencies of the multi-cells period Ω_p, that is a period constituted by p irreducible cells Ω, with periodic boundary conditions. Then, in these situations, the framekork of asymptotic analysis of high-frequency modulation [Rallu *et al.*, 2018] in periodic systems is a applied and yields the equations governing the large scale modulations. This method is illustrated on the case of periodic framed beams, that is periodic structures made of the 1D-repetition of a frame, see Figure 1.

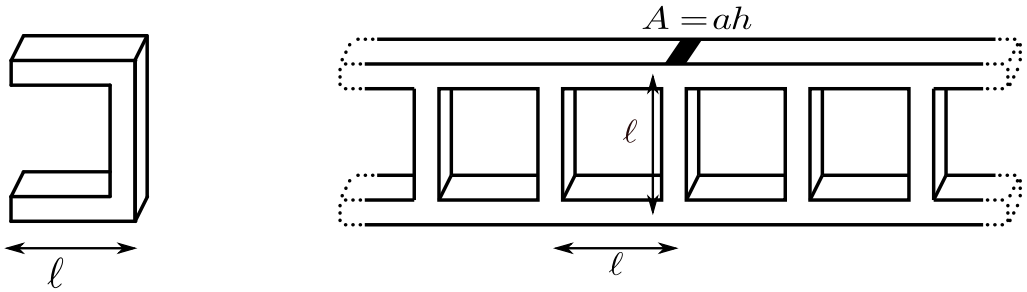

Figure 1: Left : Cell Ω of the reticulated beam. Right : periodic framed beam.

METHODOLOGY

This asymptotic approach is closely related to the HPDM method [Caillerie *et al.*, 1989] and to the modulation analysis of elastic composites [Craster *et al.*, 2010], [Boutin *et al.*, 2012]. At first, one focuses on p-cells period Ω_p, whose angular eigenfrequencies for periodic boundary conditions are denoted ω_J. For frequencies close to ω_J, the modal amplitude envelop varies at a large scale L compared to the length $\ell_p = p\,\ell$ of Ω_p. This assumption of scale separation allows us to define the small parameter $\varepsilon_p = \ell_p/L = p\,\ell/L \ll 1$.

Then the procedure is splitted into the following key steps. 1. Reduce the studied structure to an equivalent discrete model. This is obtained by condensing the balance equations of the beam elements within the period at the nodes of the period. 2. Establish an exact recurrence equation by expressing the balance of the edges nodes of the considered (multi-)cells period. 3. Identify the periodic eigenmodes and eigenfrequencies of the (multi-)cell. 4. Consider frequencies close to a given eigenfrequency and assume a large scale modulation. Then rewrite the recurrence equation in terms of Taylor expansions of the continuous variables that describe the amplitude of the eigenmode. 5. Introduce the asymptotic expansions of the variables and rescale the physical parameters of the element constituting the period. Here, all the local frames are identical, and we consider a slenderness contrast of the local frame as $\ell/a = O(\varepsilon_p^{-1})$. 6. Deduce the various envelope models that apply close to the eigenfrequencies of the considered (multi-)cells.

This approach applied on the transversal kinematics allows to extract the approximation of dispersion curve around the periodic eigenmodes of periods made of one, two and three irreducible cells. All the equations are detailed in [Rallu *et al.*, 2018]. These approximations are given in dashed lines on Figure 2.

*Corresponding author. E-mail: antoine.rallu@entpe.fr

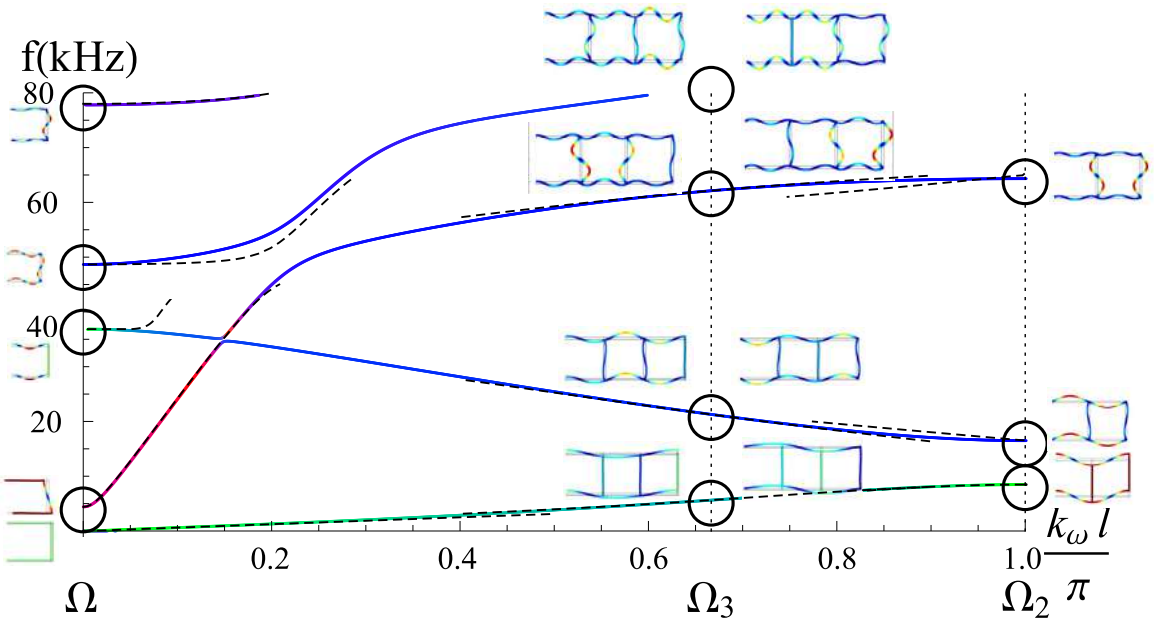

Figure 2: Dispersion curve in the half on the first Brillouin zone for the transversal kinematics. Black circles correspond to the Bloch modes for periods made of one cell (Ω), two cells (Ω_2) and three cells (Ω_3). In dashed lines the asymptotic description of the dispersion curves derived by modulation analysis.

NUMERICAL RESOLUTION

From the finite difference relation established on the first step of the previous methodology, the dispersion tensor of the system can be reached, whose the null determinant yields the dispersion relations. Their numerical resolutions are performed point by point by sampling half of the first Brillouin zone for a sufficiently large number of points. Furthermore, for each solution, the kernel of the dispersion tensor is calculated to identify the associated kinematics. As an illustration the dispersion of the transversal waves of a framed beam whose wall and floor elements are identical is studied. In addition, the kernel kinematics is also depicted, in attributing a given color for each component namely the color of the dot being the linear combination of the three colors weighted by the proportion of each component.

CONCLUSIONS

At low frequencies, the modulation approach matches the classical homogenization method. But at higher frequencies, the nature of the descriptions departs from the usual macroscopic formulation : (i) the macroscopic operator is applied on the amplitude of the periodic eigenmodes, (ii) instead of an unique equivalent model, a family of descriptions is derived for modulation phenomena; this family is associated to the modes of the irreducible or the multiple cells, (iii) the nature of the modulation equations is different whether the mode is simple or multiple. Thanks to these macroscopic descriptions, a piecewise built of the dispersion curve is possible in the vicinity of the periodic eigenfrequencies of Ω_p. Finally, compared to Floquet-Bloch theory, the specificity of the modulation approach is to extract the frequency bands where the large scale modulations are allowed and to determine their governing equations. As an illustration, we applied this methodology to reticulated beams, whose the enriched kinematics and the continuous distribution of mass and stiffness involve wave dispersion curves with several branches. The main outcomes are (i) a given dispersion branch may involves different kinematics, (ii) the modulation analysis performed on multi-cell around rational Bloch number allows to build by parts the dispersion curves and to relate them to an effective analytical description, (iii) these approximations are reliable in a range such that the kinematics do not significantly changed. These results established on a particular beam lattices may be extended to more complexe periodic structures and clarify the physics behind the dispersion curves.

ACOUSTICS OF WHISTLING KETTLES, MATING MICE AND DRIPPING TAPS

Anurag Agarwal* [1]
[1]Department of Engineering, University of Cambridge, Cambridge, United Kingdom

Summary In this talk, we will explore the sound generation mechanisms from three everyday phenomena.

WHISTLING KETTLES

The whistle in a steam kettle provides a good example of a hole tone system, in which two orifice plates are held a short distance apart in a cylindrical duct. This setup leads to distinct audible tones for a large range of flow rates. In this talk we will see that the whistle's behaviour is divided into two regions of operation Reynolds numbers (based on orifice diameter and jet velocity). Below a critical Reynolds number the whistle exhibits a near-constant frequency behaviour. A mathematical model based on a Helmholtz resonator explains this behaviour well. Above the critical Reynolds number, the whistle exhibits a constant Strouhal number behaviour. We will see that in this regime the resonant modes of the upstream duct are coupled with the vortex shedding at the jet exit.

MATING MICE

Mice produce ultrasonic mating calls in the form of a whistle. Our experimental results show that the whistle is not caused by a hole tone mechanism or superficial vocal fold vibrations as previously thought. We will see that mice use a wall/edge-jet based resonance mechanism to produce robust ultrasonic whistles.

DRIPPING TAPS

A leaky dripping tap produces a distinctive and irritating plink. The plink is caused by a small drop falling into a larger body of liquid and has been the subject of scientific curiosity for more than a century. Previous investigators have determined that the source of the sound is a pulsating air bubble trapped under the surface of the water during the drop impact. However, it was not clear just how the underwater bubble produces the plink heard above water by the human ear. Through a series of synchronised high-speed video and audio measurements we will see that the airborne sound field is not simply the underwater field propagating through the water-air interface, as had previously been assumed. We propose an alternative hypothesis that the oscillating bubble induces oscillations of the water surface itself, giving a more efficient mechanism by which the underwater bubble drives the airborne sound field. A model for this new hypothesis produces good agreement with experimental data.

ACKNOWLEDGEMENT

The work presented in this talk was made possible through collaborations with Ross Henrywood, Elena Mahrt, Coen Elemans, Sam Phillips, and Peter Jordan.

EDUCING NOZZLE REFLECTION-COEFFICIENTS FROM TURBULENT JET DATA

Robin Prinja* [1], Eduardo Martini[2], Peter Jordan[1], Aaron Towne[3], and André V. G. Cavalieri[2]
[1]Département Fluides, Thermique et Combustion, Institut Pprime, Université de Poitiers, Poitiers, France
[2]Instituto Tecnológico de Aeronáutica, São José dos Campos/SP, Brazil
[3]Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI 48109, USA

Summary This work studies resonance mechanisms that underpin tones that occur in high Mach-number subsonic jets due to resonance between upstream and downstream traveling waves that are coupled by reflection in the nozzle plane and at downstream turning points. Local stability analysis is used based on mean velocity profiles near the nozzle exit plane. Projection of Large Eddy Simulation (LES) data on the eigenbasis shows that Kelvin-Helmholtz (KH) and a small selection of upstream and downstream traveling guided modes have substantial amplitudes, and they accurately reconstruct the LES data illustrating the low-rank nature of the resonance. Following the eduction of mode amplitudes, a procedure is implemented in order to compute reflection-coefficients in the nozzle plane, which are necessary for developing predictive resonance models.

INTRODUCTION

Acoustic tones observed in Mach 0.9 jet have been shown to be associated with a family of linear waves that resonate in the jet between the nozzle exit plane and downstream turning points ([1] and [2]). The same waves have been shown to be responsible for jet-flap interaction tones [3]. At the end locations, the resonance models ([3]) require knowledge of reflection-coefficients. The goal of this work is to educe these coefficients using LES data.

METHODOLOGY

It has been shown that waves in turbulent jets can be modelled using linear stability theory ([1] and [2]), where stability analysis is done on the time-averaged mean flow. We perform a local analysis at $0.3D$ downstream from the nozzle exit. Mean flow from LES is fitted with $tanh$ analytical profile. We consider azimuthal mode, $m = 0$ and Strouhal number, $St = fD/U_{jet} = 0.39$, which corresponds to the resonance mode. The normal mode ansatz is,

$$q = q(r)e^{i\alpha x}e^{-i2\pi ft} \tag{1}$$

where, α is the axial wavenumber and $q(r)$ is the radial structure of the fluctuation. Formulating the system as an eigenvalue problem ($Aq = i\alpha Bq$), we get the eigenspectrum as shown in Fig. 1(a). The modes of interest are marked with crosses (for details about other modes, see [4]). The only unstable mode is KH ($\times$, k^+_{KH} mode). The resonating modes are indicated by green, blue and red crosses: ($\times$, k_2^+), ($\times$, k_1^-) & ($\times$, k_3^-), where the superscripts - and + refer to the generalised group velocity.

Biorthogonal projections

Instability wave amplitudes, undetermined in linear analysis, are obtained by biorthogonal projections. Prior to projection, the eigenfunctions are normalised such that they have (i) $\int_0^\infty [\mid u'_x \mid^2 + \mid u'_r \mid^2] r\, dr = 1$ (ii) $\angle u'_x = 0^o$ at $r = 0$, where u'_x and u'_r are axial and radial fluctuations respectively, and r is the radial coordinate. The LES data is then projected on to 4 modes of interest as follows:

$$\mathbf{a}_i(n) = (q_i^{ad})^H\ B\ q_n^{LES} \tag{2}$$

where, q_i^{ad} is the adjoint eigenfunction of the i^{th} mode, H is the hermitian transpose and q_n^{LES} is the LES fluctuation data from n^{th} LES realization (we have 153 realizations) and $\mathbf{a}_i$ is the vector of projection coefficients for the i^{th} mode. A rank-4 reconstruction of the LES data, using these modes, is shown by plotting u'_x PSD in Fig.1(b).

Reflection-coefficient evaluation

In the nozzle exit plane, we compute reflection-coefficients for 2 pairs of modes (k_2^+/k_1^- and k_2^+/k_3^-). Each pair involves a k^- wave that reflects at the nozzle exit plane. As we have projection coefficients at $x/D = 0.3$, we shift them to $x/D = 0$ using the ansatz (equation 1). From here onwards, we refer to the projections coefficient vector at $x/D = 0$ as $\mathbf{a}$.

The amplitude of a k_2^+ wave is related to the amplitudes of k^- waves through the reflection-coefficients as,

$$\mathbf{a}_2^+ = R_2^1\ \mathbf{a}_1^- + R_2^3\ \mathbf{a}_3^- + R_2^o\ \mathbf{a}_o \tag{3}$$

*Corresponding author. E-mail: robin.prinja@univ-poitiers.fr.

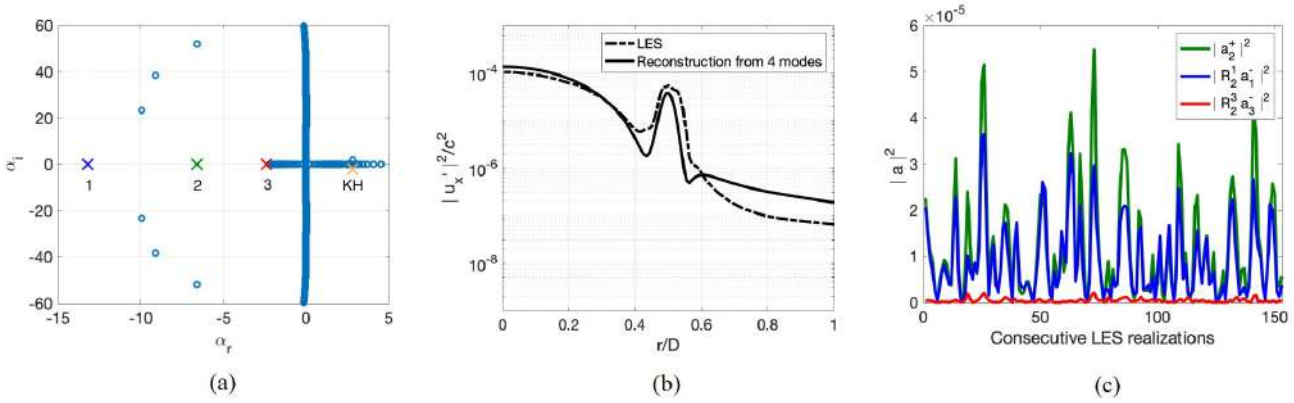

Figure 1: $St = 0.39$, $m = 0$. **(a)** Eigenspectrum. **(b)** Rank-4 reconstruction of u_x' PSD (here, c is the sound speed). **(c)** $\mid \mathbf{a}_2^+ \mid^2$, $\mid R_2^1\, \mathbf{a}_1^- \mid^2$ and $\mid R_2^3\, \mathbf{a}_3^- \mid^2$ (see equation 3 for reference) are plotted against consecutive LES realizations.

The last term on the R.H.S. accounts for reflections from other upstream traveling waves and transmissions from nozzle boundary layer fluctuations. Taking the dot product of equation 3 with $\mathbf{a}_1^{-H}$ leads to,

$$\mathbf{a}_2^+ \cdot \mathbf{a}_1^{-H} = R_2^1\, \mathbf{a}_1^- \cdot \mathbf{a}_1^{-H} + R_2^3\, \mathbf{a}_3^- \cdot \mathbf{a}_1^{-H} \tag{4}$$

where we have assumed that all other waves are uncorrelated with the k_1^- wave (i.e. $\mathbf{a}_o \cdot \mathbf{a}_1^{-H} = 0$). This assumption is supported by the negligible projection coefficients obtained for all other modes and by the accurate reconstruction of the LES by the rank-4 model. Similarly, taking the dot product of equation 3 with $\mathbf{a}_3^{-H}$ and using $\mathbf{a}_o \cdot \mathbf{a}_3^{-H} = 0$, we get,

$$\mathbf{a}_2^+ \cdot \mathbf{a}_3^{-H} = R_2^1\, \mathbf{a}_1^- \cdot \mathbf{a}_3^{-H} + R_2^3\, \mathbf{a}_3^- \cdot \mathbf{a}_3^{-H} \tag{5}$$

We can solve the equations 4 and 5 together to obtain the reflection-coefficients.

RESULTS

A coherence analysis is performed using the educed wave amplitudes to establish which modes are resonating at a given frequency. The mode pairs identified by this analysis are consistent with the scenarios proposed by [1]. Reflection-coefficients (RC) are then computed using the approach described above, giving the following results for the RC magnitudes,

$$\mid R_2^1 \mid = 0.62\ (k_2^+/k_1^-\ \text{pair})\ \&\ \mid R_2^3 \mid = 0.89\ (k_2^+/k_3^-\ \text{pair}).$$

The respective contribution of k_1^- and k_3^- modes to the k_2^+ considered can be appreciated in Fig. 1(c), where the square magnitude of projection coefficients for k_2^+, and the contributions of k_1^- and k_3^- modes are plotted w.r.t FFT realisations. Fig. 1(c) shows that k_2^+ sharply follows the k_1^- demonstrating that k_2^+ is primarily driven by the reflection of k_1^- in the nozzle plane, consistent with the scenario proposed in [1].

A similar approach was implemented for other frequencies and will be shown at the conference.

CONCLUSIONS

Reflection-coefficients in the nozzle plane of a turbulent jet of Mach 0.9 were educed from LES data. The approach involved: (i) the eduction of wave amplitudes from the turbulent data by its projection on the eigenbasis of a local stability analysis in the vicinity of the nozzle plane, and (ii) the calculation of RC via consideration of a low-rank model of the resonance dynamics.

Summary We present a linear stability-based, mode-matching approach for the evaluation of reflection and transmission coefficients associated with waves generated by interaction between a Kelvin-Helmholtz instability wave and a normal shock. We use vortex-sheet and finite-thickness linear-stability models to compute the initial amplitudes of the upstream-travelling guided jet modes generated by the said interaction, which are now known to close the feedback loop that underpins screech in imperfectly expanded supersonic jets.

INTRODUCTION

The problem we consider is motivated by the sound generated by under-expanded, supersonic jets, and, in particular, the phenomenon known as screech, a mechanistic explanation for which was first provided by Powell [4]. The mechanism involves turbulence structures that convect through the shock-cell pattern; this Shock-Turbulence Interaction (STI) results in the generation of upstream-travelling waves. When the phases of the upstream-travelling waves and downstream-travelling turbulence structures are suitably matched, at the jet exit plane and at the STI locations, resonance may occur. The turbulence structures considered important for screech are what are often referred to as coherent structures. Downstream-travelling coherent structures can be modelled using linear theory and are largely underpinned by Kelvin-Helmholtz (K-H) instability of the mean flow [1]. The upstream-travelling waves important for screech were considered by Powell [4] to be free-stream sound waves. This approach has been questioned by Shen & Tam [5], who suggested that the upstream-travelling disturbance might comprise a family of guided jet modes that can be described using linear stability theory. A simplified screech-tone prediction model based on this idea has been developed and validated by Mancinelli *et al.* [2]. In this model, the spatial growth of the K-H instability is ignored, and a phase-matching criterion is sufficient to provide a reasonable prediction of screech-tone frequencies. In a more complete model [3], where the spatial growth rates of the upstream- and downstream-travelling waves are included, knowledge of the reflection coefficient in the jet exit plane and at the location of STI is required.

It is this that motivates the study we report. We use linear theory to consider the interaction between a downstream-travelling K-H wave and a normal shock. We consider the transmitted and reflected waves, and employ a mode-matching procedure to determine the reflection coefficient at the STI location that determines the initial amplitude of the upstream-travelling guided jet waves active in the screech loop. We consider vortex-sheet and finite-thickness flow models.

MODELLING FRAMEWORK

We consider an axisymmetric shock-containing supersonic jet. The shock is assumed to be normal. We assume an incident K-H wave on the shock with unitary amplitude, $I = 1$. The interaction of the incoming wave with the shock generates a collection of reflected (R) and transmitted (T) modes. A mode is identified as (i) reflected, if upstream of the shock (subscript 1) and upstream-travelling, (ii) transmitted, if downstream of the shock (subscript 2) and downstream-travelling. The propagation direction of waves is determined using the Briggs-Bers criterion.

The shock discontinuity is divided along the radial distance r into infinitesimal control volumes $\mathrm{d}V$ and conservation equations are applied on these. Performing Reynolds decomposition and assuming a normal-mode ansatz, the linearised jump equations for normal shock can be written in a compact form as follows,

$$\mathbf{A}_1 \left(I\hat{\mathbf{q}}_{1I} + \sum_{n=1}^{\infty} R_n \hat{\mathbf{q}}_{1R,n} \right) = \mathbf{A}_2 \sum_{n=1}^{\infty} T_n \hat{\mathbf{q}}_{2T,n}, \tag{1}$$

where $\mathbf{A}_1$ and $\mathbf{A}_2$ are operators depending on the mean flow upstream and downstream of the shock, respectively. The vectors of eigenfunctions $\hat{\mathbf{q}}_n = \left\{ \hat{\rho}, \hat{u}_x, \hat{u}_r, \hat{u}_\theta, \hat{T}, \hat{p} \right\}$ are computed using either a vortex-sheet (V-S) model or a finite-thickness linear-stability model based on the Rayleigh Equation (RE). For the latter, we use for the mean flow the following hyperbolic-tangent velocity profile: $\overline{u}_x(r) = \frac{1}{2} M_a \left(1 + \tanh\left(\frac{R}{4\theta_R} \left(\frac{R}{r} - \frac{r}{R} \right) \right) \right)$, with $R/\theta_R = 30$, where R is the radius, θ_R the shear-layer momentum thickness and M_a the acoustic Mach number.

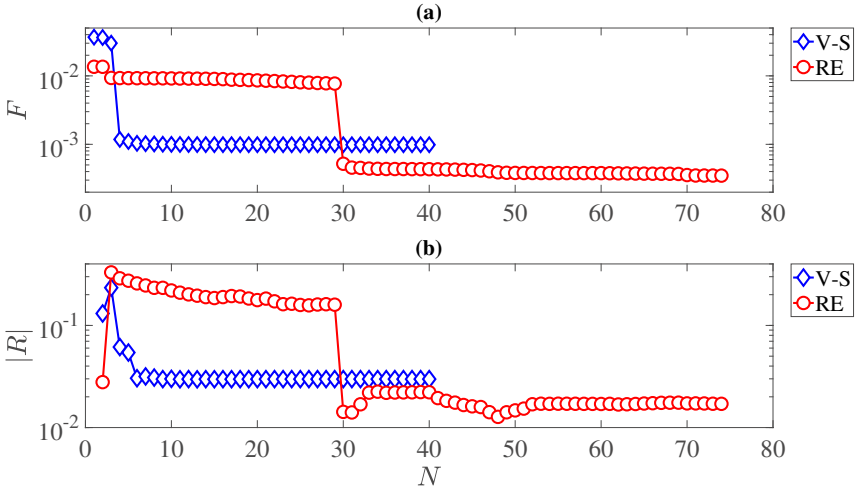

Figure 1: Evolution of the solution as a function of the number of modes considered: (a) objective function to minimise, (b) reflection-coefficient amplitude. ◇ refer to results obtained using a vortex-sheet model, ○ to Rayleigh equation.

Reflection-coefficient calculation

Equation (1) is exact if all jet modes are considered. If we truncate the sum to a finite number of modes N, an error $\epsilon\,(r)$ is introduced for each conservation equation. Equation (1) can thus be written as follows,

$$\mathbf{A}_1\left(I\hat{\mathbf{q}}_{1I}+\sum_{n=1}^{N}R_n\hat{\mathbf{q}}_{1R,n}\right)-\mathbf{A}_2\sum_{n=1}^{N}T_n\hat{\mathbf{q}}_{2T,n}=\boldsymbol{\epsilon}, \tag{2}$$

where $\boldsymbol{\epsilon}\,(r)$ is the vector of errors associated with each conservation equation. It is clear that $\boldsymbol{\epsilon}\to 0$ if the number of modes $N\to\infty$. The reflection and transmission coefficients associated with each mode R_n and T_n, respectively, can be computed by a least-mean-square minimization of the errors:

$$[R_{opt,n},T_{opt,n}]=\min_{R_n,T_n\in\mathcal{C}}\underbrace{\int_0^{\infty}|\boldsymbol{\epsilon}^2\,(r)\,|\,\mathrm{d}r}_{F} \tag{3}$$

where F is the objective function to minimise. The minimization problem is solved using the Nelder-Mead algorithm, which is a heuristic direct-search algorithm based on the simplex method. A convergence analysis is carried out by increasing the number of modes N.

RESULTS

Figure 1 shows the evolution of the objective function and the reflection-coefficient amplitude associated with the upstream-travelling guided jet mode as a function of the number of modes considered. Results obtained using both V-S model and Rayleigh equation to describe the jet wave dynamics are reported. We note that the solution appears to have converged for both flow models. The effect of the shear-layer thickness results in a reduction of $|R|$ of about 40% when free-stream acoustic modes of the continuous branches and critical-layer modes are included in the computation.

CONCLUSIONS

We present a linear stability-based, mode-matching approach to calculate the reflection coefficient associated with an upstream-travelling guided jet mode generated by the interaction between a K-H instability wave and a normal shock. The jet wave dynamics are modelled using a cylindrical vortex-sheet model as well as the compressible Rayleigh equation, in order to highlight the role played by the shear-layer thickness.

ACOUSTICS OF CEREBRAL ANEURYSMS

Amélie Lamarquette * [1] and Anurag Agarwal[1]
[1]Department of Engineering, University of Cambridge, Cambridge, United Kingdom

Summary Cerebral aneurysms are common lesions that can be life threatening. They are known to generate a narrowband sound, the mechanism of which remains poorly understood. Previous studies suggest that the lesions act as resonators in a self-excited system. However, this hypothesis has never been validated, partly because of a lack of experimental evidence. This paper presents an experimental study in which aneurysms are modelled by flexible bulbs. The results reveal the presence of two different sources of vibrations: periodic flow structures and structural vibrations. When the frequencies associated with these two sources coincide, resonance can occur that can help explain the observed sound from aneurysms.

INTRODUCTION

Brain aneurysms are localised expansions of a blood vessel that carry a significant risk of bursting. These lesions occur in about 3.2% of the population [11]. While most of them are asymptomatic and will remain harmless [10], ruptured cerebral aneurysms are the primary cause of spontaneous subarachnoid haemorrhage, a devastating type of stroke. Unfortunately, the mechanics of the rupture of an aneurysm is still not fully understood. For instance, even though bigger aneurysms are thought of as having a higher chance of bursting, small ruptured aneurysms are encountered more often than large ruptured aneurysms (van Gijn et al. [8]). Hence, a better understanding on the rupture of aneurysms is needed to distinguish between benign and life-threatening lesions.

In 1970, during exposed surgeries, Ferguson [4] recorded musical sound, or *bruits*, from 10 out of 17 aneurysms. The mechanism behind bruit generation remains unexplained. However, the main hypotheses include the presence of flow turbulence in the lesion [4], as well as self-excited vibrations in which aneurysms act as resonators [5]. Arterial wall vibrations and turbulence are known to affect the wall integrity [2, 3]. Therefore, understanding the generation of aneurysmal sound may reveal important phenomena behind ruptured aneurysms.

Recent studies to explain the sound have been based on CFD and have focused on the high-frequencies present in the flow using CFD [6, 9]. They have ignored the possibility of the resonance of aneurysms. This loss of interest is likely caused by earlier research that suggested that aneurysms are stable [7, 1]. However, these studies did not include the possibility of high-frequency flow structures able to excite aneurysm vibration, and thus the possibility of self-excited oscillations cannot be disregarded. This paper presents an experimental study that investigates the vibrations of a model aneurysm arising from the interaction of fluid flow and structural vibrations.

EXPERIMENTAL SET-UP AND RESULTS

In the experiments carried out, the blood vessels are modelled by a rigid structure and aneurysms by flexible bulbs immersed in water. Blood was replaced with a mixture of water and glycerol, which was pumped through the rig at a constant velocity. Figure 1 presents the design used and highlights the important geometrical parameters. Additional parameters include flow speed U, fluid viscosity ν, Young modulus E, fluid density ρ_f and bulb material density ρ_s. For a typical Reynolds number ($Re = UD/\nu$) at the systole phase of the cardiac cycle, other non-dimensional numbers were identified to scale the system to a convenient size. Their values are outlined in table 1. The sound from the system was recorded with a hydrophone.

Non-dimensional numbers	Physiological	Model 1	Model 2
Re	1220	1077	1088
$E/\rho_f U^2$	811	954	58
ρ_f/ρ_s	1.06	1.15	0.92
d/D	0.70	0.67	0.71
a/D	1.1	1.1	0.52-1.1
a_0/D	1.9	2.7	2.9
h/D	0.12	0.20-0.40	0.15-0.22
α	100°	100°	100°

Table 1: Typical physiological and experimental values of the parameters.

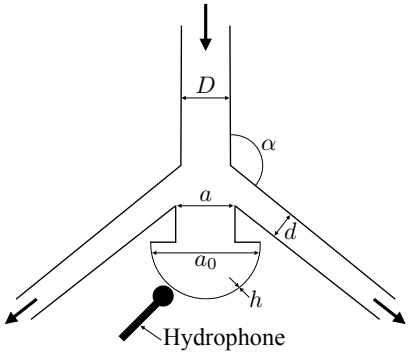

Figure 1: Design of the aneurysm model

*Corresponding author. E-mail: al858@cam.ac.uk.

Figure 2 displays spectra obtained from the hydrophone recordings for different Reynolds numbers. For each Reynolds number, it is possible to identify two frequencies of interest in the spectrum. One corresponds to the natural vibrations of the bulb (dashed line in figure 2), which is fixed with the flow rate, the other is a peak that increases in frequency with increasing Reynolds numbers (arrows in figure 2). At a Reynolds number of about 484 (red curve), the two frequencies coincide resulting in a larger amplitude indicative of resonance. Past that value (blue curve), the peak related to the flow moves to the right of the resonance frequency. Similar results have been found for different bulb thicknesses and artery geometry. The resonance frequency seems to be independent of the artery geometry but increases with bulb thickness and decreases with bulb size. The frequency of the flow is however related to the diameter of the incoming tube. To compare the results from all of the geometries investigated here, the Strouhal number $St = fD/U$ was analysed as a function of the Reynolds number (figure 3). The experimental data collapse well around a fitted curve using a power law.

The results are representative of a self-excited system, in which the bulbs are excited by periodic flow features. However, to the authors' knowledge, there is no theoretical model available in the literature that can accurately predict the resonance frequency of the system.

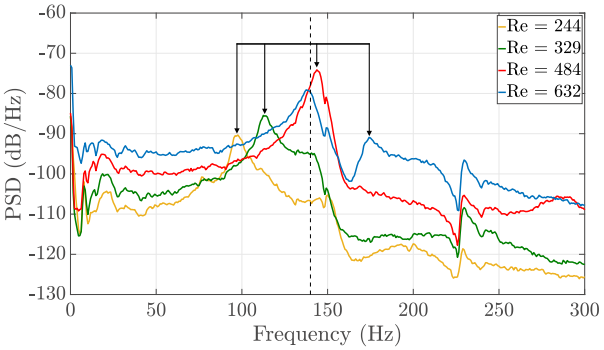

Figure 2: Power spectra for various Reynolds numbers

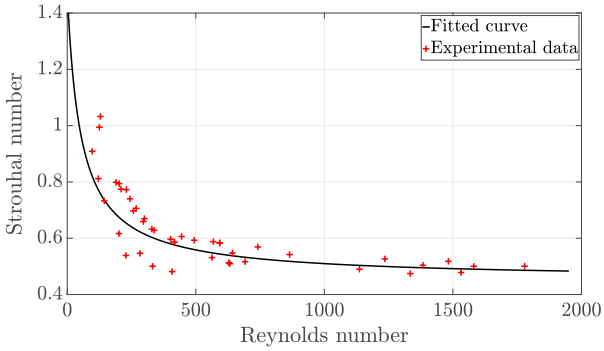

Figure 3: Strouhal number as a function of the Reynolds number

CONCLUSIONS

Our experiments show the presence of two separate frequencies, one related to the flow and the other to the bulb (the aneurysm). As the flow frequency increases with the Reynolds number and the bulb frequency remains constant, there is a critical flow speed at which the two frequencies coincide, leading to the resonance of the system. The results are indicative of a self-excited oscillation mechanism, and suggest that previous studies that concluded that the lesions are not subject to resonance may have overlooked the importance of flow-structure interactions.

We are currently developing a theoretical model to predict the resonance frequency of such systems. In parallel, a flow visualisation study is being carried out to understand the onset of the periodic flow structures, which will help us understand the conditions necessary for the onset of self-excited oscillations.

EXPERIMENTAL INVESTIGATION OF UAV ROTOR NOISE

Romain Gojon* [1], Hélène Parisot-Dupuis[1], Thierry Jardin[1], and Jean-Marc Moschetta[1]
[1]ISAE-SUPAERO, Université de Toulouse, Toulouse, France

Summary The present work outlines efforts at ISAE-SUPAERO to reduce the aeroacoustic footprint of rotors operating at low Reynolds and low Mach numbers typical of small and medium scale Unmanned Air Vehicles (UAVs). An experimental campaign is presented that serves as a basis for the validation of several numerical approaches, from high fidelity LES to low order models like BEMT and NVLM coupled with a FW-H formulation. Two off-the-shelf rotors and four rotors of canonical shape are considered. Aerodynamic and acoustic results from the two first rotors allow to validate the experimental setup. The four canonical rotors are printed at the laboratory using stereolithography, and corresponding results help unravel the physics behind UAV rotor noise.

EXPERIMENTAL SETUP

An experimental campaign that aims at investigating rotor noise is conducted in an anechoic chamber whose wedge-tip to wedge-tip dimensions are $5.02 \times 5.24 \times 5.34$ m^3 and anechoicity is validated between 80 Hz and 16,000 Hz. The rotor is located at the acoustic center of the chamber, at the top of a 2.8 m height pylon visible in figure 1. Just under the rotor, a Faulhaber 327-024 BP4 electric motor is mounted. This motor is expected to radiate less noise than conventional off-the-shelf small scale motors [1].

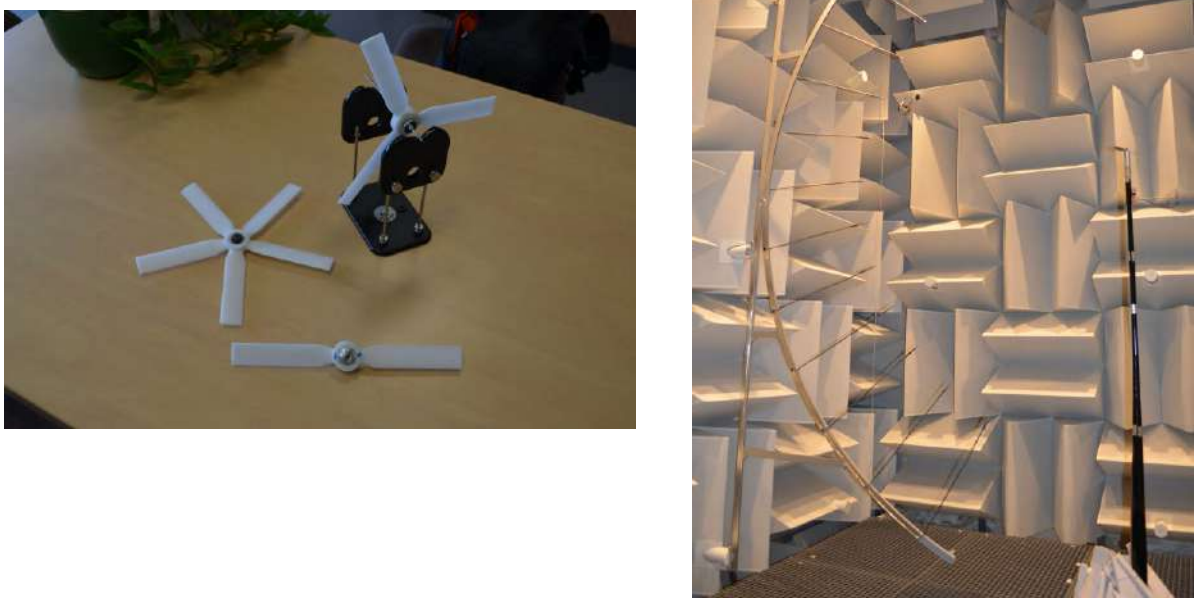

Figure 1: Canonical rotors printed by stereolithography (left) and experimental setup (right).

A six-axis ATI load-cell is positioned directly underneath the motor to measure aerodynamic loads. Moreover, a three-axis accelerometer from DJB Instruments is mounted on the pylon, 25 cm below the rotor plane, to monitor possible vibrations transmitted to the pylon. Acoustic measurements are performed using 1/4" GRAS 40PH microphones of sensitivity 50 mv.Pa^{-1}. In order to study the far-field noise, a directivity antenna is used with 13 microphones, located at a constant distance of 162.0 cm from the rotor center each 10 degrees from 30 to 150 degrees (90 degrees being the rotor plane). A near-field microphone is also placed 25 cm below the rotor plane and 25 cm away in the radial direction. The numerical setup is visible in figure 1.

Two rotors from the literature (APC 9x6 SF and 11x4.7 SF) and four rotors of canonical shape are considered. Aerodynamic and acoustic results from the two first rotors allow to validate the experimental setup against other experimental results from the litterature [2, 1]. The four canonical rotors are printed at the laboratory using stereolithography, some of which are visible in figure 1. They have a NACA0012 profile with a uniform chord length and a constant pitch angle of 10 degrees. The diameter and the chord are 12.5 cm and 2.5 cm respectively. Cases with two blades, three blades, four blades and five blades are considered. They are presented in table 1. Note that the simulation of those rotors using a NVLM approach coupled to a FW-H formulation has been performed recently [3].

*Corresponding author. E-mail: romain.gojon@isae-supaero.fr

Table 1: Canonical rotors geometries and operating conditions

	Value
Number of blades (N_B)	$2, 3, 4, 5$
Radius (R)	12.5 [cm]
Chord length (c)	2.5 [cm]
Advance ratio (J)	0
Free-stream velocity (v_∞)	0 [m/s]
Rotating speed (Ω)	$1,000 \rightarrow 10,000$ [RPM]
Reynolds number (chord-based, at the tip)	$\rightarrow 220,000$
Mach number (at the tip)	$\rightarrow 0.38$

RESULTS

Acoustic spectra are calculated from pressure signals whose sampling rate and total duration are $25,600$ Hz and 16 s. The Fourier transform is applied on 100 blocks with a 50% overlap and the frequency resolution is 3.125 Hz. Far-filed spectra in the rotor plane obtained for the APC 9X6 SF rotor are depicted in figure 2.

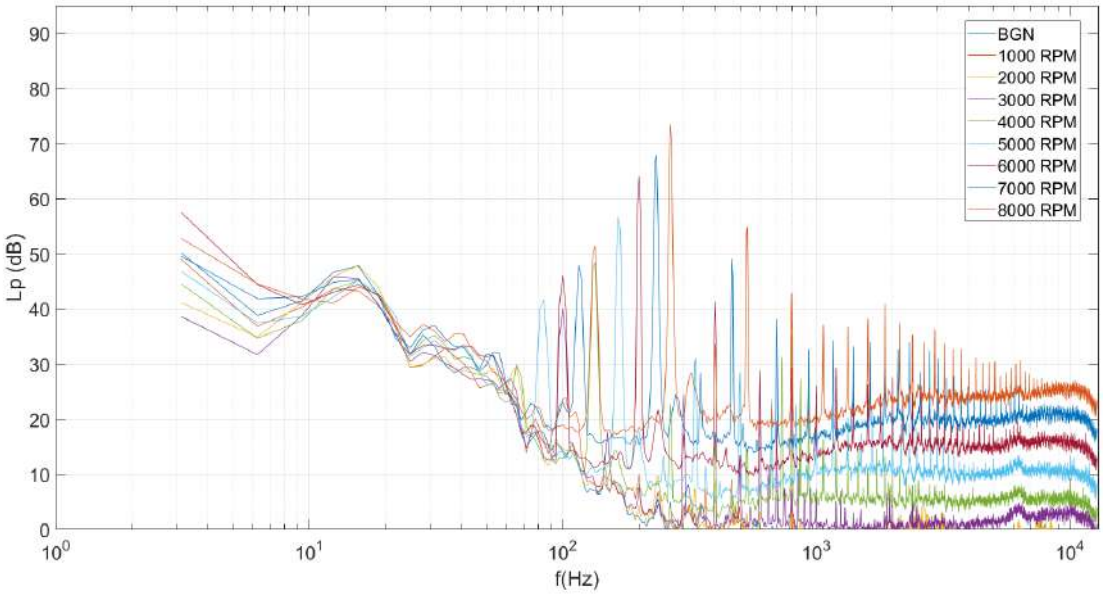

Figure 2: Acoustic spectra in the far-field in the rotor plane for the rotor APC 9X6 SF.

A background noise is presented to compare with. Data obtained for various rotation speeds are plotted, from $1,000$ to $8,000$ RPM. The dominant tone corresponds to the blade passing frequency in all cases, as expected. Its amplitude is increasing with the rotation speed. A high frequency broadband noise is also observed with an amplitude increasing with the rotation speed and with a dipole-like directivity pattern (not shown here).

CONCLUSIONS

An experimental campaign is conducted to study UAV rotor noise. The numerical setup is validated using data from the literature. Then canonical rotors are tested in order to unravel the noise source mechanisms.

ACTIVE CONTROL OF INSTABILITY WAVES IN JET SHEAR LAYER IN VIEW OF JETWING INTERACTION NOISE REDUCTION

Victor Kopiev[1], Georgy Faranosov*[1], Oleg Bychkov[1], Vladimir Kopiev[1], Ivan Moralev[2] and Pavel Kazansky[2]
[1]Central Aerohydrodynamic Institute (TsAGI), Moscow, Russia
[2]Joint Institute of High Temperature RAS, Moscow, Russia

Summary This work demonstrates the possibility of active control of low-frequency jet-wing interaction noise when the wing is close to the jet shear layer. The main idea of the proposed approach is connected with the reduction of the amplitude of instability waves developing in the jet shear layer in the form of wave packets. Jet-wing interaction noise is related to the scattering of jet near-field pressure pulsations, which are footprints of instability waves, by the wing trailing edge. Therefore, mitigation of instability waves should directly lead to noise reduction. Active control system is developed and tested in experiments. Control action is provided by a dielectric barrier discharge plasma actuator mounted inside the nozzle. It is shown for a subsonic jet that the system is capable to reduce jet-wing interaction noise at the target frequency by about 3 dB.

INTRODUCTION

Application of turbofan engines with high and very high bypass ratio implies that nozzle diameter increases. Corresponding reduction of jet velocity leads to a significant reduction of jet noise. However, larger engines have to be more integrated into airframe. In case of such a tight engine-airframe integration, the jet issuing from the engine's nozzle may pass rather close to the wing so that intensive jet-wing interaction noise arises. This effect was studied in a number of publications [1-5]. It was demonstrated that additional low-frequency hump in noise spectrum is related to the scattering of the jet near-field hydrodynamic pulsations by the wing trailing edge [3-5]. These near-field pulsations can be considered as footprints of coherent structures evolving in the jet shear layer in the form of instability wave-packets of different azimuthal numbers [3, 5]. Thus, jet-wing interaction noise reduction strategy can be formulated in terms of instability wave control [6] as it is sketched in Figure 1.

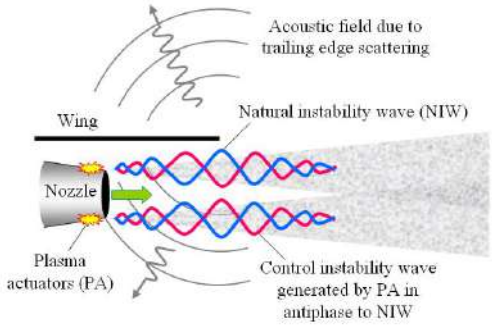

Figure 1. Control strategy for jet-wing interaction noise reduction.

Plasma actuators are widely used for realization of control action in flow control applications [7], including attempts of flow/noise control of standalone jets [8-10]. Current work continues our previous studies [10] where it was demonstrated the possibility of control of artificially excited instability waves in the jet shear layer by means of high-frequency dielectric barrier discharge (HF DBD) plasma actuators. The main idea of control in [10] was based on the generation by the plasma actuator of an instability wave which is of the same amplitude but in antiphase to the instability wave artificially excited in the jet shear layer. In this study, we extend the concept tested for tone excited jets [10] for the case of natural unexcited jets in accordance with the control strategy described in [6]. It is shown that the proposed approach makes it possible to reduce instability wave intensity in unexcited jet (and hence jet-wing interaction noise) in the narrow band around the target frequency.

EXPERIMENTAL SETUP AND MAIN RESULTS

Small-scale model that simulates jet-wing configuration was studied experimentally in the anechoic chamber AC-2 at TsAGI. The diameter of the nozzle was $D = 50$ mm and the wing was simulated by a flat plate of dimensions 1.2m x 0.35m x 0.003m (Figure 2). The trailing edge of the plate was shifted downstream from the nozzle exit plane by $1.7D$, the distance between the jet axis and the plate was $0.9D$. Several jet Mach numbers in the range 0.4-0.9 were considered.

As shown in [4, 5], only the first two near-field azimuthal modes significantly contribute to the low-frequency jet-wing interaction noise. Therefore, in the current work the control system were designed with the aim to reduce axisymmetric part of the near-field pressure pulsations. It was realized by HF DBD plasma actuator with a ring-like electrode mounted inside the nozzle near the nozzle edge (3-5 mm from the nozzle exit) as shown in Figure 2. Generally, the configuration of the actuator is similar to that used for the case of artificially excited instability wave control [10] with the difference that metal nozzle covered by a dielectric (using the technique of detonation deposition of a dielectric barrier), rather than the fully dielectric nozzle [10], is used in the current study. The control strategy, proposed in [6], is implemented as follows. It consists in the narrowband sliding filtration of the original signal measured by the reference microphone flush-mounted on the plate near its trailing edge and the formation of a narrowband control action. Signal filtration is realized by the AD/DA converter integrating a digital signal processor (DSP). The signal is processed in real time by the DSP. The code of the module driver is modified to include digital

*Corresponding author. E-mail: georgefalt@rambler.ru

filtering of the signal from the reference microphone and correct phase and amplitude distortions. The processed signal is then used for modulating the voltage at the discharge on the actuator in order to generate instability wave of proper amplitude in antiphase to that measured by the reference microphone. The control system and experimental setup are shown in Figure 2. To reduce jet installation noise, the signal amplification and phase delay were manually adjusted step-by-step by the DSP reprogramming and analyzing of the spectrum on the reference microphone. To monitor the response of the system to the control action, several microphones were distributed in the near and far field of the jet: five microphones in the far field (Bruel & Kjaer, ½'', type 4189, at an arc of 30*D* radius) and six microphones in the near field (Bruel & Kjaer, ¼'', type 4935) as shown in Figure 2 (right).

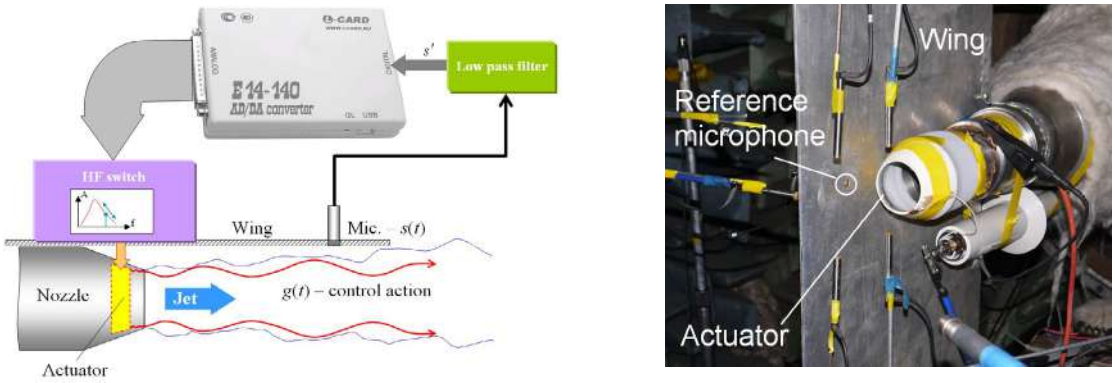

Figure 2. Sketch of the control system.

As soon as the proper parameters of the transfer function were defined, the effect of noise reduction in the far-field could be observed in a narrow band around the target frequency with minor penalties at both sides of the filter band. Corresponding results for Mach 0.4 jet are shown in Figure 3. It can be seen that the value of noise reduction reaches 3 dB. The effect of noise reduction becomes less pronounced for the microphones located downstream due to the cardioid-like directivity of the jet-wing interaction noise. At these observation angles the signal is dominated by the jet noise and less sensitive to the control.

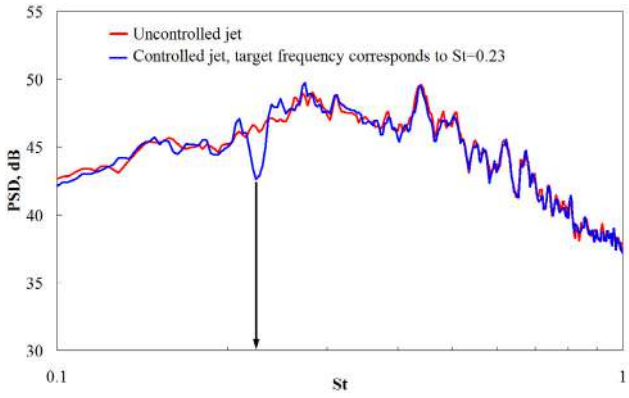

Figure 3. Acoustic spectra on the "under-the-wing" microphone in the far field. Jet Mach number 0.4. Target control frequency corresponds to Strouhal number St ≈ 0.23.

JET NOISE SOURCE ESTIMATION USING RESOLVENT ANALYSIS

Filipe R. Amaral* [1] and André V. G. Cavalieri[1]
[1]Divisão de Engenharia Aeroespacial, Instituto Tecnológico de Aeronáutica, 12228-900 São José dos Campos, Brazil

Summary A resolvent-based method is applied to estimate the flow state and the noise source statistics from a small number of measurements of both a synthetic line wavepacket source model and a large eddy simulation database of a Mach 0.4 fully turbulent jet. Good agreement is observed for both cases with near exact match for the synthetic case. The results highlight the pertinence of resolvent-based estimation in aeroacoustics, as the method avoids the compact-source assumption used in beamforming frameworks and is thus suitable for the estimation of source statistics using microphone arrays, which can also be placed in the near pressure field of the source. Future work will include a more complete formulation of the Lighthill's tensor to improve the accuracy of source estimation.

INTRODUCTION AND METHODS

The estimation of aeroacoustic noise sources is an important step for the understanding of physical mechanisms behind the sound generation and for further development of noise control strategies. Acoustic beamforming [1] is a well-established technique aimed at noise source estimation employing a limited number of probes. Such a technique assumes a distribution of uncorrelated monopole point sources as a premise, which is not an adequate hypothesis for jet noise source estimation, since the presence of organized large-scale structures, modeled as wavepackets, are not taken into account.

In this work, the recently developed resolvent-based methodology estimation [5] is thus applied to estimate the source forcing cross-spectral density (CSD) and consequently the flow state. Such a method employes the Lighthill's acoustic analogy written in operator notation, casting the problem in the input (source distribution, $P_{ff} = \mathcal{E}(\mathbf{f}\mathbf{f}^*)$, where $\mathbf{f}$ is the source term, * indicates the Hermitian transpose and $\mathcal{E}$ is the expected-value operator) / output (radiated pressure, $P_{qq} = \mathcal{E}(\mathbf{q}\mathbf{q}^*)$) framework [4]. For the Lighthill's acoustic analogy, the resolvent operator $\mathbf{R}$ can be obtained using the analytical free-field Green's function with integration weights. Hence, the pressure field (flow response) is related to the source distribution (forcing) by $P_{qq} = \mathbf{R}\, P_{ff}\, \mathbf{R}^*$. In most situations, one has limited information on the flow state at an array of sensors $\mathbf{y}$ distributed along a few positions. In this case, the resolvent operator may be used to estimate source statistics from sensor data and, subsequently, obtain the radiated sound in other locations [5].

In order to verify if the resolvent-based methodology is suitable to estimate the source statistics from a limited set of know data, two test cases were employed. The first case consists of a line source modeled as a wavepacket of amplitude-envelope length scale L, coherence decay characteristic length L_c and hydrodynamic wavenumber k_h [3]. The values of $L_c = L$ and $k_h L = 5$ where chosen in order to obtain a source that is both partially desynchronized regarding to the spatially evolving wavepacket fluctuations and an extended wavepacket, mimicking the main features of sound radiation by a Mach 0.6 jet. The second case comprises a large eddy simulation (LES) database of an isothermal Mach 0.4 turbulent jet [2], from which the axisymmetric pressure fluctuations were taken.

PRELIMINARY RESULTS

The analytical pressure CSD [4] was sampled, or measured, with a 38-probe array distributed along a line. Such a line of equally-spaced probes is centered on the source origin $x/L = 0$, distant of $h/L = 1$ regarding the source vertical position h and extends between $-4 \leq x/L \leq 4$ (closed circles near the source origin in Fig. 1a). The probes thus mimic a near-field array of microphones. Figure 1b shows the source CSD (P_{ff}) estimated from the near-field array, clearly recovering the signature of a jittering wavepacket [4]. The Power Spectral Density (PSD) of the estimated state $\mathbf{q}$ is shown in Fig. 1c, given by the P_{qq} line. A remarkable agreement with the probe PSD, $P_{yy,nf}$, is observed, which confirms that the identified source matches nearly exactly the fluctuations at the probe array. The identified source of Fig. 1b is then propagated to a far-field array (closed triangles in Fig. 1a). The PSDs of both far-field data ($P_{yy,ff}$ line) and propagated pressure field from the identified source ($RP_{ff}R^\dagger$ line) are shown in Fig. 1c. An excellent agreement is obtained up to a polar angle of $120°$ measured from the downstream axis.

Figure 2a exhibits a 100-probe array employed to acquire pressure data from the LES. The array was positioned along a $7°$-inclined line, extending between $0 \leq x/D \leq 30$. Such probes, displayed in the figure as closed circles, were equally-spaced and the first array probe is positioned at the jet lip line. The LES jet noise estimated line-source CSD (P_{ff}) is shown in Fig. 2b for Strouhal number $St = 0.2$, whereas the PSD of the estimated state is displayed in Fig. 2c. The measured and the estimated noise spectra, given by $P_{yy,nf}$ and P_{qq} lines in Fig. 2c show good agreement, although the estimated state P_{qq} underestimate the measured PSD $P_{yy,nf}$ by approximately 5 dB for $x/D \geq 15$. Figure 2c also displays the jet noise P_{ff} propagated to a 30-probes array positioned in the acoustic field (shown as closed triangles in Fig. 2a). The overall levels are predicted by the source, but with discrepancies likely due to the line-source simplification and the consideration of only longitudinal quadrupoles in Lighthill's analogy.

CONCLUSIONS

In this extended abstract we have shown results of a resolvent-based estimation applied to jet noise obtained with limited number of probes. An analytical wavepacket line source model, mimicking jet noise source features, and an LES jet database were employed as test cases. The method successfully estimated the forcing source P_{ff} and the state P_{qq}, particularly for the analytical source, which was tailored for the simplifications used here (line distribution of longitudinal quadrupoles). Nonetheless, the method is a viable alternative to acoustic beamforming, particularly for non-compact sources typical in aeroacoustics, whose wavepacket features are accurately identified in both cases. We are currently developing a formulation of the Lighthill's stress tensor in order to achieve better accuracy for the LES database and further improve our estimations.

STRATEGIES FOR THE EVALUATION OF THE FLUID-DYNAMIC ACOUSTIC POWER PRODUCED BY AN ORIFICE

Luca Fenini[1], Luca Nicola Quaroni* [2], Gabriele Mazzaro[3], and Stefano Malavasi[4]
[1,2,4]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
[3]Engineering department, Pibiviesse S.r.l., Nerviano (MI), Italy

Summary A novel approach to numerically estimating the acoustic power produced by gas flow through control devices is presented. The procedure is based on the simulation of stationary fluid flow by means of the Reynolds Averaged Navier-Stokes (RANS) equations employing Computational Fluid Dynamics (CFD) techniques. An appropriate expression for the acoustic power density as defined by existing literature allows to obtain the acoustic power by integrating over an aptly-defined source region. A discussion of the results obtained for a single-hole orifice plate through the proposed and the reference international standards' procedure follows.

INTRODUCTION

Several fluid-dynamic processes in industrial settings are managed by means of flow-control devices, either fixed (e.g. orifice plates) or mobile (e.g. valves). The working principle of such devices is the conversion of part of the mechanical energy of the flow into turbulent kinetic energy. While most of such energy is dissipated into heat, a small portion escapes the flow as acoustic pressure fluctuations which are then transmitted to the medium surrounding the pipe though the vibration of its walls [1]. This phenomenon is particularly important for gas flows, where it may result in sound pressure levels dangerously high for the health and wellbeing of the work personnel. The international standard regulating the acoustic emissions of gas flow-control devices and reference for this short paper is the IEC 60534-8-3 [2]. Such standard provides a procedure for estimating the sound pressure level of a control device based on the definition of an acoustical efficiency for the conversion of mechanical power into acoustic power. A major drawback for the provided approach is however that such acoustical efficiency only indirectly takes into consideration the specific flow characteristics of a given type of device, as it's dependent on a factor which is constant for any given flow-control device category (e.g. orifice plates, gate valves...). In the present work, an approach developed by Fenini [3] based on the computation of the acoustic power density as defined by Proudman [4] is applied to a single-orifice plate. The acoustical power is estimated directly from the flow field, leading to a more case-dependent computation of the acoustic emissions of the device. The choice of the single-hole orifice plate is justified by the relative simplicity of its flow field and by the possibility of using the results as a starting point for the more complex geometries relevant to the industrial world.

MODEL FORMULATION

Computational model of the plate

The single-hole orifice plate subject of the present manuscript is characterized by an orifice-to-line diameter ratio $\beta = d/D$ of 0.4 and sharp edges. The diameter of the test line D and the thickness of the plate t are respectively set equal to 24.3 mm and 10 mm. A computational domain of $10D$ upstream and $15D$ downstream of the device is chosen so as to guarantee that the upstream and downstream boundaries' velocity profiles don't influence the results. The symmetric domain allows for a reduction of the required computational resources by simulating only a quarter of the pipe's section.

The flow simulations were performed using the finite-volume-based code *ANSYS Fluent 19.1*. An hexahedral mesh was built and through a sensitivity analysis a ratio of $2 \cdot 10^{-2}$ between the cell's size in the proximity of the orifice and the line's diameter was found to provide results independent of the grid. The chosen working fluid is dry air, whose equation of state is set as the ideal gas law; its viscosity is instead kept constant and independent of temperature. The effects of turbulence on the mean flow are accounted for through the choice of the RNG $k-\varepsilon$ model. Due to the moderate compressibility of the flow, the implicit *coupled* pressure-based algorithm is chosen as solver. As for the boundary conditions, an inlet absolute pressure of 6 bar and progressively decreasing static pressures at the outlet are imposed. Temperature is set equal to 293 K at both inlet and outlet.

Acoustic power estimation

The following approach for computing the acoustic power W_a of the flow was developed by Fenini [3]. The *acoustic power density* P is calculated at every cell's centroid employing the definition given by Proudman [4]:

$$P(\mathbf{x}) = \alpha_P \rho \varepsilon \left(\frac{\sqrt{2k/3}}{c} \right)^5 \tag{1}$$

where ρ is the fluid density, ε is the turbulent dissipation rate, k is the turbulent kinetic energy, c is the local speed of sound and α_P is a numerical constant set equal to 3.804 in this study [5]. The acoustic power can be computed by integrating P over an aptly-defined source region S:

$$W_a = \int_S P(\mathbf{x}) d\mathbf{x} \tag{2}$$

*Corresponding author. E-mail: lucanicola.quaroni@mail.polimi.it

where S is defined in this study as the fluid volume for which the turbulent kinetic energy k is greater than 20% of the maximum value reached in the domain. For comparison, the expression for W_a as provided by the international standard has the shape:

$$W_a = 10^{A_\eta} \cdot f\,(regime) \tag{3}$$

where A_η is the *valve correction factor for acoustical efficiency* and f is an expression dependent on the flow regime, which is itself defined based on the value of the relative pressure drop $x = (p_1 - p_2)/p_1$ (p_1 and p_2 respectively the static pressure measured at $2D$ upstream and $6D$ downstream of the device, see [2]). None of the quantities in eq. (3) directly takes into account the characteristics of the flow field developed at the control device. In particular the value for A_η is provided as constant for each specific device typology (e.g. -4.8 for orifice plates, -4 for a generic dipole source) thus neglecting the substantial differences in geometry which may be present within the same category (e.g. round- v.s. sharp-edged orifices).

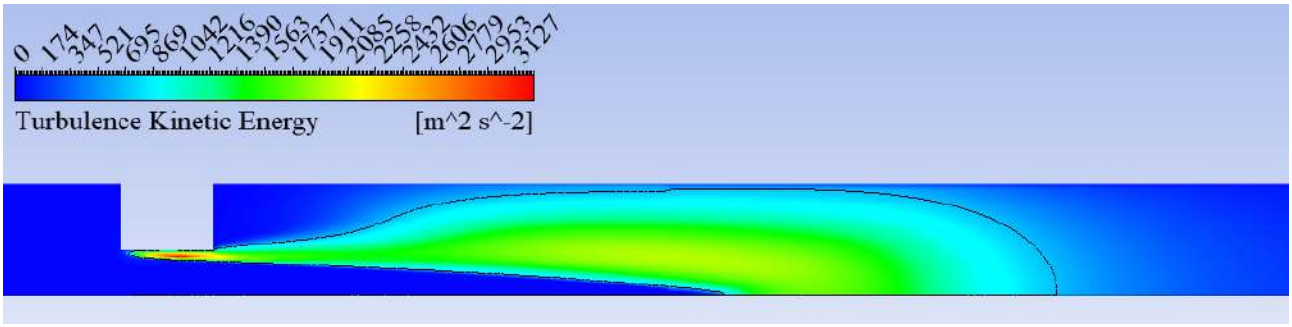

Figure 1: Turbulent kinetic energy and acoustic source region S (enclosed by the black contour line) for $x = 0.2$. Threshold value for $k = 0.2 \cdot k_{max} \approx 627\, m^2/s^2$. Flow is from left to right.

RESULTS

The acoustic power for varying x computed through the proposed approach and the international standard's procedure (for A_η equal to -4.8 and - 4) is reported in fig. (2). The A_η factor for varying x obtained by inverting eq. (3) once the acoustic power was known from eq. (2) is also reported.

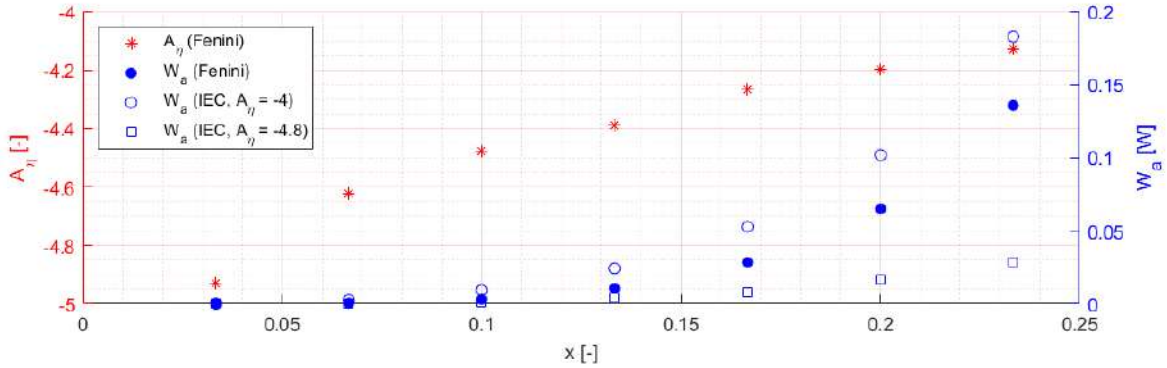

Figure 2: Acoustic power W_a and valve correction factor for acoustical efficiency A_η for varying x as computed through Fenini's procedure. The acoustic power calculated using the international standards' procedure is also displayed for comparison.

The acoustic power W_a shows a qualitatively similar behaviour between the two approaches. More quantitatively however, as x increases, the acoustic power computed through eq. (2) tends to the values obtained using the standard's procedure with $A_\eta = -4$. Such a behaviour can be better appreciated by looking at the A_η obtained through the proposed approach, which tends to the value the international standard suggests for general dipole sources. This indicates that the procedure outlined in [2] may underestimate the acoustic power emissions, and therefore the resulting sound pressure level produced by flow-control devices. An experimental plant is under construction at the "G. Fantoli" Hydraulics' Laboratory of Politecnico di Milano. Once completed, the above findings will be validated experimentally and further tests will be carried out on more complex geometries.

STREAMING IN A KUNDT'S TUBE OF AN ARBITRARY DIAMETER

Alen Pavlic[1] and Jürg Dual [1]
[1]Institute for Mechanical Systems, ETH Zurich, Zurich, Switzerland

We solve an axisymmetric streaming problem in a Kundt's tube that follows from the perturbation expansion of the governing equations for a compressible Newtonian fluid. No restriction is imposed on the diameter of the rigid tube with respect to the viscous boundary layer thickness and acoustic wavelength. We show that the streaming torus bounded by the wall expands towards the center of the tube with the increase of the relative thickness of the viscous boundary layer. An additional (Rayleigh) streaming torus is bounded by the aforementioned streaming and is gradually reduced as the viscous boundary layer expands. Furthermore, we analyse cases exceeding the critical viscous boundary layer thickness relative to the tube radius, at which the Rayleigh streaming disappears.

INTRODUCTION

Kundt's tube is a well-known experiment for measuring the speed of sound in fluids [1]. In 1876, Dvorak [2] observed a steady fluid flow in a Kundt's tube, i.e. the acoustic streaming, and ever since, the challenge of analytically modelling such flows exists. In 1884, Rayleigh derived the first analytical solution [3], which assumes a 2D channel geometry, and a small viscous boundary layer. Rayleigh's solution predicts that the fluid flows from a velocity antinode to the node along the middle of the channel, and in the opposite direction near the wall. The direction of the flow was later validated experimentally by Andrade [4].

Here, we present an analytical solution for the streaming in a Kundt's tube without restrictions on the tube diameter with regards to the viscous boundary layer thickness and acoustic wavelength. The solution is used to numerically investigate the streaming patterns in some cases that are beyond the scope of Rayleigh's theory.

We show that when the viscous boundary layer thickness becomes comparable to the tube diameter, Rayleigh streaming disappears, and only the oppositely directed Schlichting streaming remains. This transition is invariant of the material properties when the acoustic wavelength is large compared to the tube radius. When the acoustic wavelength is comparable to the tube radius, a large-scale Eckart-like streaming supersedes the Rayleigh streaming.

PROBLEM STATEMENT

The viscous fluid is, initially at rest, placed in an infinite rigid tube with an inner diameter of $2a$. Two counterpropagating harmonic weakly decaying travelling waves are assumed in the fluid, oriented along the axis of the tube (pseudo-standing wave). Thermal effects are neglected, and the fluid motion is therefore governed by the Navier-Stokes equations, the continuity equation, and the equation of state, namely,

$$\rho \frac{\partial \boldsymbol{v}}{\partial t} + \rho(\boldsymbol{v}\cdot\boldsymbol{\nabla})\boldsymbol{v} = -\boldsymbol{\nabla}p + \eta\nabla^2\boldsymbol{v} + \left(\eta_\mathrm{B} + \frac{\eta}{3}\right)\boldsymbol{\nabla}(\boldsymbol{\nabla}\cdot\boldsymbol{v})\,,$$

$$\frac{\partial \rho}{\partial t} + \boldsymbol{\nabla}\cdot(\rho\boldsymbol{v}) = 0\,,$$

$$p = p(\rho) \quad (p_1 = c_\mathrm{f}^2\rho_1 \rightarrow \text{at the first order}).$$

The three variables in the governing equations are the velocity $\boldsymbol{v}$, pressure p, and density ρ. Material constants defining the viscous fluid are the equilibrium density ρ_0, the speed of sound c_f, and the dynamic and bulk viscosity, η and η_B, respectively. The problem is constrained by the no-slip boundary condition at the wall.

By applying a regular perturbation technique, the problem can be solved in successive steps of increasing order in terms of small Mach number. The perturbed variables can then be written in a series form, namely, $(\,) = (\,)_0 + (\,)_1 + (\,)_2 + \cdots$, where the subscript denotes the order in the perturbation expansion, and where $(\,)_1 \gg (\,)_2$.

RESULTS

The defined problem has been divided onto the first- and second-order problems, and solved in two consecutive steps. The procedure of solving the problem analytically is described in detail by Pavlic and Dual [5]. The solution has no restriction on the thickness of the viscous boundary layer δ. Here, we use the derived expression for the Eulerian streaming velocity $\langle\boldsymbol{v}_2\rangle$ and for the average mass transport velocity, defined as $\langle\boldsymbol{v}_2\rangle^\mathrm{M} = \langle\boldsymbol{v}_2\rangle + \langle\rho_1\boldsymbol{v}_1\rangle/\rho_0$, for numerical analysis of the evolution of streaming patterns inside the tube.

The analysis revealed, as indicated in Figure 1, three distinct regimes of streaming possible within a Kundt's tube. When the ratio $\Xi = a/\delta$ is larger than the critical ratio Ξ_S, we observe coexistence of the Rayleigh and the oppositely directed Schlichting streaming. Rayleigh streaming being the flow from the velocity node towards the antinode along the center of the tube, and in the opposite direction near the wall. If the radius is decreased below Ξ_S, only the Schlichting streaming remains.

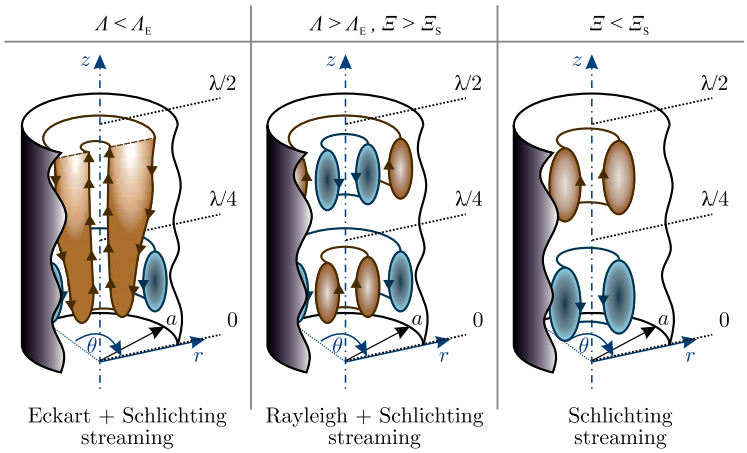

Figure 1. Different streaming regimes that depend on the ratios $\Xi = a/\delta$ and $\Lambda = \lambda/a$ relative to the critical ratios Ξ_S and Λ_E.

Critical ratio Ξ_S, at which the transition between streaming regimes appears, was found to be invariant of material properties when the acoustic wavelength $\lambda = c_f/f$ is large compared to the tube radius. The distinct values appear to be $\Xi_S = 5.6$ and $\Xi_S^M = 6.2$, for the Eulerian streaming velocity and for the average mass transport velocity, respectively. When the acoustic wavelength is smaller than $\sim 10a$, the streaming becomes qualitatively affected by the ratio $\Lambda = \lambda/a$. For glycerol, at $\Xi = 22.5$, the transition between Rayleigh and Eckart-like streaming appears at critical ratio $\Lambda_E = 3.1$ for $\langle \boldsymbol{v}_2 \rangle$ and at $\Lambda_E^M = 3.5$ for $\langle \boldsymbol{v}_2 \rangle^M$. Some exemplary streaming patterns for an oil are depicted in Figure 2. The frequency of the standing wave with a pressure amplitude (at $z = 0$) of 100 kPa is 100 kHz. The oil used for the analysis has the dynamic viscosity of $\delta = 41.5$ mPa s, the bulk viscosity of $\delta = 89.3$ mPa s, the density of $\rho_0 = 922.6$ kg m^{-3}, and the speed of sound of $c_f = 1445$ m s^{-1}.

The average mass transport velocity patterns shown in Figure 2 indicate the reversal of the direction of the streaming as the relative radius Ξ is decreased from 22.5 to 3.33 ($< \Xi_S$). Furthermore, a non-periodicity of the streaming pattern along the axis of the tube (z) appears due to the decoupling of the exponential amplitude dependency of the first-order solution to the sum of exponential and sinusoidal parts at the second order. The magnitude of the streaming velocity at the center of the tube was found to approach the simplified solution by Schuster and Matz [7], provided that $\Xi \geq 20$.

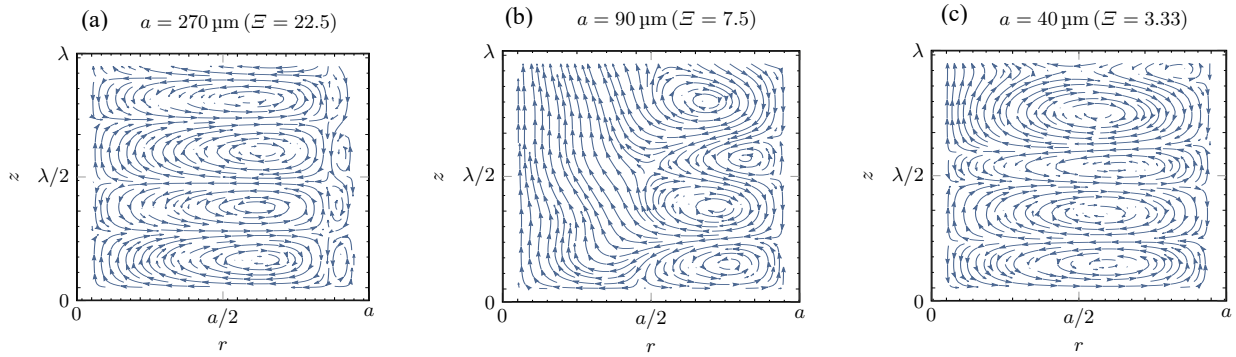

Figure 2. Average mass transport velocity patterns inside oil, at 100 kHz and with a pressure amplitude of 100 kPa. The arrows indicate the direction of the flow, and reveal the reversal of the streaming direction as Ξ is decreased (a) 22.5 to (c) 3.33.

CONCLUSIONS

The patterns that result from the analytical solution for the streaming in a Kundt's tube reveal an interesting and complex steady behaviour in such systems. This could be relevant for the design of acoustofluidic devices for manipulation of microparticles and cells.

MULTI PHYSICAL MODELLING OF COMPOSITE CELLULAR PIEZOCRYSTALLINE WAVEGUIDES

Ara S. Avetisyan* [1] and Vazgen M. Khachatryan[1]
[1]Department of Deformable Systems Dynamic and Coupled Fields, Institute of Mechanics of National Academy of Sciences of Armenia, Yerevan, Armenia

Summary Some possible variants of elastic multipartial waves formation and propagation in three-layer reticular waveguide with canonical rectangular cells of different piezo-crystals are considered. The cells are in acoustic contact. In neighboring cells of different piezo-materials, four-partial electroelastic wave of anti-plane strain and six-partial electroelastic wave of plane stress-strain state are formed simultaneously. The composite waveguide is modelled as a periodic structure of longitudinally inhomogeneous columns. The formation of electroelastic wave over the thickness of the composite waveguide is studied, and dispersion equations for electroelastic wave signal frequency filtration along the waveguide are obtained. It is shown that, by a proper choice of material pairs and relative thicknesses of layers, it is possible to achieve diverse schemes of wave formation and frequency filtration in the composite waveguide.

STRUCTURE OF THE WAVEGUIDE AND MATHEMATICAL BOUNDARY-VALUE PROBLEM

Consider a piezoelectric waveguide with reticular inner structure (see Figure 1(a)), which allows propagation of multiportional high-frequency electroelastic wave signal. The rectangular cells are in non-acoustic contact. The piezoelectric materials and the sagittal sections of the cells are chosen in such a way that, in neighbouring cells "B" and "R", two-partial electroelastic wave of anti-plane strain state of SH type and three-partial electroelastic wave of plane stress-strain state of P& SV type, respectively, occur simultaneously [1]. The three-layer waveguide is represented as a one-layer periodically-inhomogeneous waveguide with elastic composite columns (see Figure 1(b)).

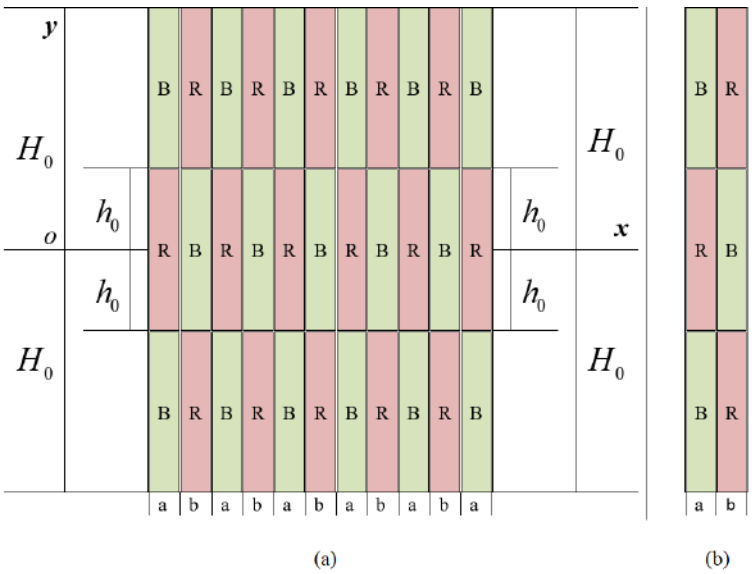

Figure 1: Structure of the waveguide. (a) Schematic representation of longitudinal section, (b) Periodically repeated unit.

The mathematical boundary-value problem consists of a system of equations for the two-partial and three-partial electroelastic waves of anti-plane strain state and plane stress-strain state in respective piezoelectric cells of the composite waveguide, of boundary conditions on surfaces of non-acoustic contact of "B" and "R" cells, as well as of boundary conditions on external shielded surfaces of the waveguide.

PROPAGATION OF NORMAL WAVE SIGNAL IN RETICULAR WAVEGUIDE

Electroelastic wave signal $\{f^{(j)} \cdot \exp(-i\omega t)\}$ forms two-partial and three-partial vibrations in respective cells of the reticular waveguide. The longitudinally periodic structure of the waveguide (see Figure 1(b)), allows propagation of periodic Floquet-type wave modes [2, 3].

*Corresponding author. E-mail: ara.serg.avetisyan@gmail.com.

In the case when electroacoustic signal occurs, in cells of "B" type, four-partial electroelastic shear wave occurs. Anti-plane elastic shear displacements $W_{mn}(x,y,t)$ and vibrations of electric field $\Phi_{mn}(x,y,t)$ in each cell of "B" type of the waveguide read as

$$f_m^{(B)}(x,y) = \sum_{n=1}^{4} Y_{mn}^{(B)}[y, k_m(\omega)\cdot p_{mn}^{(B)}(k_m(\omega))]\cdot X_{mn}^{(B)}[x, k_m(\omega)].$$

In cells of "R" type, six-partial electroelastic wave of plane stress state occurs. Elastic displacements $U_{mn}(x,y,t)$ and $V_{mn}(x,y,t)$, as well as the corresponding vibrations of electric field $\Phi_{mn}(x,y,t)$ in each cell of "B" type of the waveguide read as

$$f_m^{(R)}(x,y) = \sum_{n=1}^{6} Y_{mn}^{(R)}[y, k_m(\omega)\cdot p_{mn}^{(R)}(k_m(\omega))]\cdot X_{mn}^{(R)}[x, k_m(\omega)]$$

The coefficient of the solution periodicity in the waveguide, $\mu = \exp[(a+b)\cdot k_m^*(\omega)]$, the step of wave-forms in sub-layers, $\lambda_m(\omega) = 2\pi/k_m(\omega)$, and the coefficients of wave-forms formation in each cell, $p_{mn}^{(B)}(k_m(\omega))$ and $p_{mn}^{(R)}(k_m(\omega))$, are defined in terms of geometry material characteristics of the cells and frequency of the incoming wave signal.

When high-frequency electroacoustic signal is propagating, hybrid electroacoustic waves occur in the waveguide. Then, in cells of "B" type, localization of wave energy of Blustein-Gulyaev type occur near the surface. In cells of "R" type, localization of wave energy of Rayleigh type occur near the surface. Localization of energy of electro-active elastic vibrations occur also near the mechanically free, shielded surfaces $y = \pm H_0$, and near internal surfaces $y = \pm h_0$ of non-acoustic contact of the cells.

Near-surface localizations of wave energy near two different surfaces of each cell are qualitatively similar, but differ quantitatively. The distributions of electromechanical characteristics in neighboring composite sub-layers of "B-R-B" and "R-B-R" (see Figure 1(b)) types also differ.

The waveguide is represented as a three-channel waveguide with corresponding domains of admissible (forbidden) wave lengths

$$\lambda_m^*(\omega) = \frac{2\pi(a+b)}{\arccos\left[C_{Bt}, C_{Rt}, C_{Rl}, k_m(\omega), k_{m+1}(\omega), p_{m\alpha}^{(B)}(k_m(\omega)), p_{m\pm1\alpha}^{(R)}(k_m(\omega))\right]}, \quad \alpha = 1,2,3, \quad m = 1,2.$$

Obviously, the domains of admissible wave lengths of the external layers coincide, i.e., $\{\lambda_1^*(\omega)\} = \{\lambda_2^*(\omega)\}$. When $\{\lambda_0^*(\omega)\}\cap\{\lambda_2^*(\omega)\} \neq \varnothing$, i.e., the corresponding domains of admissible wave lengths have common points, the waveguide will be three-channel with two similar channels (for the given frequency). When $\{\lambda_0^*(\omega)\}\cap\{\lambda_2^*(\omega)\} = \varnothing$, the hybrid wave will propagate through one of the waveguide layers.

CONCLUSIONS

It is possible to generate electroactive hybrid elastic wave with cycle of transformation of anti-plane strain state to plane stress-strain state in reticular piezoelectric waveguide.

In the case of high-frequency electroacoustic signal, near the mechanically free shielded surfaces of a three-layer waveguide and near the inner surfaces of non-acoustic contact between the waveguide cells, localization of wave energy of hybrid electroacoustic waves of Blustein-Gulyaev and Rayleigh types occurs.

The reticular waveguide may functionate as in single-channel, as well as in multi-channel of wave modes transfer. By a proper choice of material characteristics and geometry of cells, the composite waveguide may serve as filter and resonator of electroelastic waves.

COUPLING FLEXIBLE STRUCTURE AND VISCOUS, COMPRESSIBLE FLUID: A CASE FOR MODEL ORDER REDUCTION

Florian Toth* [1], Hamideh Hassanpour[1], and Manfred Kaltenbacher[1,2]
[1]Institute of Mechanics and Mechatronics, TU Wien, Vienna, Austria
[2]Institute of Fundamentals and Theory in Electrical Engineering (IGTE), Graz University of Technology, Graz, Austria

Summary We present a finite element formulation for the coupled modeling of a flexible structure and a viscous, compressible fluid. The coupling is realized using a non-conforming grid technique based on Nitsche's method. Employing the reduced basis method the typically very large system of equations resulting from the finite element discretisation is reduced dramatically using only a few natural modes as generalized degrees of freedom in a reduced-order model. Finally, the accuracy and computational performance of the reduced and full model are compared.

INTRODUCTION

In classical acoustics where the acoustic wave equation is employed, the fluid is often assumed as inviscid. This assumption is justified in cases where the relevant problem dimensions are large compared to the viscous boundary layer thickness, which depends on the viscosity of the medium and the frequency of interest. Especially on small scales, e.g. in MEMS applications, viscous effects should be considered. A similar reasoning applies to thermal effects (i.e. thermal conductivity in the fluid). Both can be modeled very efficiently by employing the finite element method (FEM) for the acoustic wave equation and modeling the acoustic and thermal boundary layer effects by impedance type boundary conditions [1]. Another common approach is to use a linearisation of the compressible flow equations, and use FEM to solve for pressure, velocity, and temperature field [2]. Coupling between fluid and flexible structure can be done using non-conforming grids [3, 4, 5], enforcing the interface conditions in the weak sense, and removing the need for a conforming mesh on the fluid-structure interface. Since the computational effort for the described method is rather high, we employ model order reduction based on the eigenmodes of the coupled system.

PHYSICAL MODEL

For the sake of simplicity, we disregard thermal effects, allowing us to treat the fluid problem using balance of mass and momentum only. To obtain the governing equations in linearised form, one first employs a perturbation ansatz for the fluid pressure, i.e. $\bar{p}(\boldsymbol{x},t) = p_\mathrm{f}(\boldsymbol{x}) + p(\boldsymbol{x},t)$, density $\bar{\rho}_\mathrm{f}(\boldsymbol{x},t) = \rho_\mathrm{f}(\boldsymbol{x}) + \rho(\boldsymbol{x},t)$ and velocity $\bar{\boldsymbol{v}}_\mathrm{f}(\boldsymbol{x},t) = \boldsymbol{v}(\boldsymbol{x},t)$, where the background fluid is assumed at rest and fulfilling the equilibrium condition. Furthermore, we assume a linearised equation of state relating pressure and density variation by $p\rho_\mathrm{f} = K_\mathrm{f}\rho$ where K denotes the bulk modulus. Using above assumptions one obtains the linearised version of the compressible flow equations describing the fluid by

$$\frac{\rho_\mathrm{f}}{K_\mathrm{f}}\frac{\partial p}{\partial t} + \nabla\cdot(\rho_\mathrm{f}\boldsymbol{v}) = 0, \quad \text{and} \quad \rho_\mathrm{f}\frac{\partial \boldsymbol{v}}{\partial t} - \nabla\cdot\boldsymbol{\sigma}_\mathrm{f} = \boldsymbol{0}, \quad \text{in } \Omega_\mathrm{f}. \tag{1}$$

The fluid is assumed as isotropic and Newtonian, i.e. the fluid stress tensor is written as

$$\boldsymbol{\sigma}_\mathrm{f} = -p\boldsymbol{I} + \big(\nabla\boldsymbol{v} + (\nabla\boldsymbol{v})^T\big) - \big(\frac{2}{3}\mu - \eta\big)\boldsymbol{I}\nabla\cdot\boldsymbol{v}, \tag{2}$$

where the parameters μ and η denote the shear and bulk viscosity, respectively, and $\boldsymbol{I}$ is the unit tensor.

The behavior of the elastic structure is described by the balance of momentum written in terms of the displacement $\boldsymbol{u}$ as

$$\rho_\mathrm{s}\frac{\partial^2\boldsymbol{u}}{\partial t^2} - \nabla\cdot\boldsymbol{\sigma} = \boldsymbol{0} \quad \text{in } \Omega_\mathrm{s}. \tag{3}$$

Assuming a linear elastic material and small stains the stress tensor is described as

$$\boldsymbol{\sigma} = \boldsymbol{C} : \boldsymbol{\mathcal{B}}(\boldsymbol{u}), \quad \text{with} \quad \boldsymbol{\mathcal{B}}(\boldsymbol{u}) = \frac{1}{2}\big(\nabla\boldsymbol{u} + (\nabla\boldsymbol{u})^T\big), \tag{4}$$

where $\boldsymbol{C}$ denotes the stiffness tensor, and $\boldsymbol{\mathcal{B}}$ the strain tensor.

Finally fluid and solid domains are coupled by enforcing the kinematic and dynamic interface conditions

$$\frac{\partial \boldsymbol{u}}{\partial t} = \boldsymbol{v}, \quad \text{and} \quad \boldsymbol{\sigma}_\mathrm{f}\cdot\boldsymbol{n} = \boldsymbol{\sigma}_\mathrm{s}\cdot\boldsymbol{n}, \quad \text{on } \Gamma_\mathrm{i}. \tag{5}$$

*Corresponding author. E-mail: florian.toth@tuwien.ac.at.

FINITE ELEMENT FORMULATION

The corresponding weak form is derived in the standard procedure by introducing suitable test functions, denoted by $()'$, assuming homogeneous Neumann boundary conditions in the integration by parts for the sake of simplicity. Coupling of solid and fluid domain based on Nitsche's method is done by summing the respective momentum balance equations, using the dynamic interface condition and introducing a penalty term to enforce the kinematic interface condition, yielding

$$\int_{\Omega_\mathrm{f}} p' \nabla \cdot \boldsymbol{v} \,\mathrm{d}\Omega + \int_{\Omega_\mathrm{f}} p' \frac{\rho_\mathrm{f}}{K_\mathrm{f}} \frac{\partial p}{\partial t} \,\mathrm{d}\Omega = 0, \tag{6}$$

$$\int_{\Omega_\mathrm{f}} \rho_\mathrm{f} \boldsymbol{v}' \cdot \frac{\partial \boldsymbol{v}}{\partial t} \,\mathrm{d}\Omega + \int_{\Omega_\mathrm{f}} \nabla \boldsymbol{v}' : \boldsymbol{\sigma}_\mathrm{f} \,\mathrm{d}\Omega + \int_{\Omega_\mathrm{s}} \boldsymbol{u}' \cdot \rho_\mathrm{s} \frac{\partial^2 \boldsymbol{u}}{\partial t^2} \,\mathrm{d}\Omega + \int_{\Omega_\mathrm{s}} \nabla \boldsymbol{u}' : \boldsymbol{\sigma}_\mathrm{f} \,\mathrm{d}\Omega$$
$$- \int_{\Gamma_\mathrm{i}} (\boldsymbol{u}' - \boldsymbol{v}') \cdot \boldsymbol{\sigma}_\mathrm{s} \cdot \boldsymbol{n} \,\mathrm{d}\Gamma + \beta \int_{\Gamma_\mathrm{i}} (\boldsymbol{u}' - \boldsymbol{v}') \cdot (\frac{\partial \boldsymbol{u}}{\partial t} - \boldsymbol{v}) \,\mathrm{d}\Gamma = \boldsymbol{0}, \tag{7}$$

where the penalty factor β was introduced. Above mixed formulation contains pressure, velocity and displacement degrees and can be discretised using nodal finite elements. Ensuring the order of the ansatz functions for the pressure degrees of freedom is one lower than for the velocity results in a stable formulation.

MODEL ORDER REDUCTION

Introducing the ansatz $\boldsymbol{w}(t) = \hat{\boldsymbol{w}} e^{\lambda t}$ for the vector of unknowns, the discretised system can be written in the form

$$\boldsymbol{M}\lambda^2 \hat{\boldsymbol{w}} + \boldsymbol{D}\lambda \hat{\boldsymbol{w}} + \boldsymbol{K}\hat{\boldsymbol{w}} = \boldsymbol{0}, \tag{8}$$

representing a quadratic eigenvalue problem. Computing a set of eigenvalues and corresponding modes enables us to obtain a reduced order system by projecting onto the modal basis. Since the mass matrix $\boldsymbol{M}$ has no full rank and the damping and stiffness matrices $\boldsymbol{C}$ and $\boldsymbol{K}$ are not symmetric, the projection to the modal system needs left and right eigenvectors.

CONCLUSION

The finite element formulation was implemented in the open source code openCFS [6]. The reduced basis method offers an attractive option to speed up the solution of systems where a small number of modes are of interest. This is usually the case in fluid-solid coupled systems where the structural modes usually dominate the behaviors of the system, and the fluid is responsible for the damping effect, which can be accurately modeled by the presented strategy.

EFFICIENT "MATRIX-FREE" PARTIAL-ASSEMBLY ALGORITHMS FOR HIGH-ORDER ALE HYDRODYNAMICS ON GPUS

Robert N. Rieben[1], Arturo Vargas *[1]
[1]Weapons and Complex Integration, Lawrence Livermore National Laboratory, Livermore, USA

Summary In this talk, we present our two-fold approach in tailoring Blast, an arbitrary Lagrangian-Eulerian (ALE) multi-material hydrodynamics code developed at LLNL, for advanced architectures. A distinguishing feature of Blast is the choice of high order finite element methods leading to higher arithmetic intensity per data access; a trait favored by modern computing processors. Our first approach leverages partial assembly techniques and exploits the tensor product structure of quad/hex elements. Through this approach, the action of global operators only requires values at quadrature points enabling reduced storage and on the fly calculations. Second, to remain portable across computing platforms, our implementation builds on the RAJA programming model and Umpire resource manager. Together RAJA and Umpire enable maintaining a single source code suitable for heterogenous computing systems.

With the introduction of advanced architectures such as GPUs, a major effort has been set forth to develop algorithms and implementations for hydrodynamics codes which can realize performance on next gen computer systems. MARBL is a next generation Multiphysics code for modelling ICF/pulsed power experiments and is being developed at LLNL as part of the Exascale Computing Project. A core component of MARBL is the high-order, multi-material, arbitrary Lagrangian-Eulerian (ALE) module based on high-order finite elements, called BLAST [1]. A distinguishing feature of BLAST is the choice of high order finite element methods leading to higher arithmetic intensity per data access; a trait favored by modern computing processors. In this talk, we discuss our two-fold strategy for achieving high-performance on advanced architectures like GPUs which includes adoption of efficient "matrix-free" methods and use of the RAJA performance portability abstraction layer [2] for on-node parallelism.

The core of BLAST is the Lagrange phase where we solve the time dependent Euler equations of compressible gas dynamics on a moving mesh with explicit high order time-stepping. This algorithm requires the solution of a global linear system for solving the momentum conservation equation, involving both a "mass" and a rectangular "force" matrix. In our standard solution approach, we fully assemble global, sparse, parallel distributed matrices for the momentum solve. This approach has poor scaling characteristics as a function of the polynomial degree of the finite elements used for discretization. In addition, solution of the global linear system for momentum requires parallel matrix-vector multiplies which is a bandwidth limited computational kernel.

The first component of our approach for achieving high-performance on advanced architectures refactors the Lagrange phase of BLAST to bypass the assembly of global operators and only assemble data at quadrature points. This partial assembly strategy enables us to decompose the action of global matrices into a set of element wise operator evaluations (i.e. computing the action of the operator per element). At high finite element orders, this results in a compute bound algorithm that is well suited for GPU acceleration. In addition, it enables us to exploit the tensor product structure of finite element basis functions on quadrilateral/hexahedral elements leading to a reduction in required operations. To explore the properties of this approach, we have developed a miniapp, called LAGHOS [3], which captures the key properties of the Lagrange phase of BLAST. LAGHOS supports both full and partial assembly methods.

The second component of our high-performance strategy is the use of the RAJA abstraction layer to support on node threading along with the Umpire resource manager developed at LLNL. Together, RAJA and Umpire enable maintaining a single source code suitable for heterogenous computing systems. We report on performance characteristics of both LAGHOS and BLAST using the partial assembly approach combined with RAJA and discuss the code changes that were required to enable this.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344, LLNL-ABS- 800797.

Summary High-resolution direct numerical simulations of Rayleigh-Bénard convection have contributed significantly to our better understanding of structure formation and transport processes in turbulent convection flows which are driven by buoyancy forces. In this presentation two particular applications of supercomputing to turbulent Rayleigh-Bénard convection are discussed in more detail: (1) convection in slender cells for very high Rayleigh numbers up to $\mathrm{Ra} = 10^{15}$ at a Prandtl number $\mathrm{Pr} = 1$, and (2) convection in horizontally extended domains at a very low Prandtl number $\mathrm{Pr} = 10^{-3}$ for Rayleigh numbers up to $\mathrm{Ra} = 10^{6}$. It is explained why both cases are important in view to applications of convection and why they require massively parallel simulations.

INTRODUCTION

Turbulent Rayleigh-Bénard convection (RBC), triggered in a fluid layer which is uniformly heated from below and cooled from above, is considered the paradigm for many examples of buoyancy-driven turbulence reaching from stellar convection via atmospheric and oceanic turbulence to cooling blankets in nuclear engineering or the storage of renewable energy in liquid metal batteries (see e.g. [1, 2] for more details). Central questions in RBC are related (1) to the fundamental law governing the global turbulent transport of heat and momentum across the convection layer and (2) the characteristic scales and times of large-scale convection patterns in extended layers as a function of dimensionless parameters characterizing the flow . These parameters are the Rayleigh number $\mathrm{Ra} = g\alpha\Delta T H^3/(\nu\kappa)$, which quantifies the relative magnitude of the thermal driving to the viscous and diffusive forces of the fluid motion and is directly proportional to the temperature difference $\Delta T = T_{\mathrm{bottom}} - T_{\mathrm{top}}$ maintained between the top and bottom plates, and the Prandtl number $\mathrm{Pr} = \nu/\kappa$, which is the ratio of momentum and thermal diffusivities denoted by ν and κ, respectively. Here, g, α, and H are the acceleration due to gravity, the isobaric thermal expansion coefficient, and the fluid layer height H, respectively. A third parameter is the aspect ratio Γ that relates a horizontal scale of the setup, such as a diameter d of the closed (cylindrical) cell or the horizontal length L to the height H.

Direct numerical simulations (DNS) which resolve all scales face significant challenges to advance towards parameter regimes of realistic convection flows in nature. Figure 1 illustrates this circumstance for the example of solar convection. Turbulent convection inside the Sun operates at Prandtl numbers $\mathrm{Pr} \sim 10^{-6}$ and (local) Rayleigh numbers $\mathrm{Ra} \sim 10^{22}$ and should be considered in domains $\Gamma \gg 1$. Despite the fact that a RBC model neglects additional important physical processes which interact in solar convection, the values of Ra and Pr will not be accessible in foreseeable future. Some progress can be made however along two lines, either for small aspect ratio cells in order to advance to the highest accessible Rayleigh numbers or for moderate Rayleigh number in order to advance to the lowest accessible Prandtl numbers in horizontally extended domains. Both routes are followed in supercomputer simulations of RBC which apply the spectral element code nek5000 [3] or a finite difference method [4] and will be discussed here. See again figure 1 for the accessible range of both simulation series which we denote as DNS 1 and DNS 2 in the following.

CONVECTION IN SLENDER CELL AT VERY HIGH RAYLEIGH NUMBER

The global transport of heat and momentum in turbulent convection is constrained by thin thermal and viscous boundary layers at the heated and cooled boundaries of the system. This bottleneck is thought to be lifted once the boundary layers themselves become fully turbulent at very high values of the Rayleigh number Ra. Laboratory experiments in cylindrical cells for $\mathrm{Ra} \geq 10^{12}$ have reported different outcomes on the existence of the transition to such an "ultimate" state of turbulent convection. We showed by series DNS 1 of three-dimensional RBC in a slender cylindrical cell with $\Gamma = 1/10$ that the ultimate state does not occur even at $\mathrm{Ra} = 10^{15}$, and relate the result to the flow structure, in particular inside the boundary layers [5]. Figure 1 displays a temperature snapshot close to the heated bottom plate. We find that the Nusselt number — the dimensionless measure of heat transport — follows the power law of $\mathrm{Nu} = (0.055 \pm 0.010) \times \mathrm{Ra}^{0.33\pm0.01}$, which is almost identical to the classical prediction based on marginally stable boundary layers. Intermittent fluctuations in the wall stress, a blueprint of turbulence in the vicinity of the boundaries, manifest at all Ra considered here, increase with increasing Ra, and demonstrate that no abrupt transition of the boundary layer to turbulence is likely. The largest direct numerical simulations at $\mathrm{Ra} = 10^{15}$ were conducted with more than 17 million spectral elements and used 524,288 Message Passing Interface (MPI) processes on the Blue Gene/Q supercomputer Mira at the Argonne National Laboratory that alone required more than 100 million core-hours.

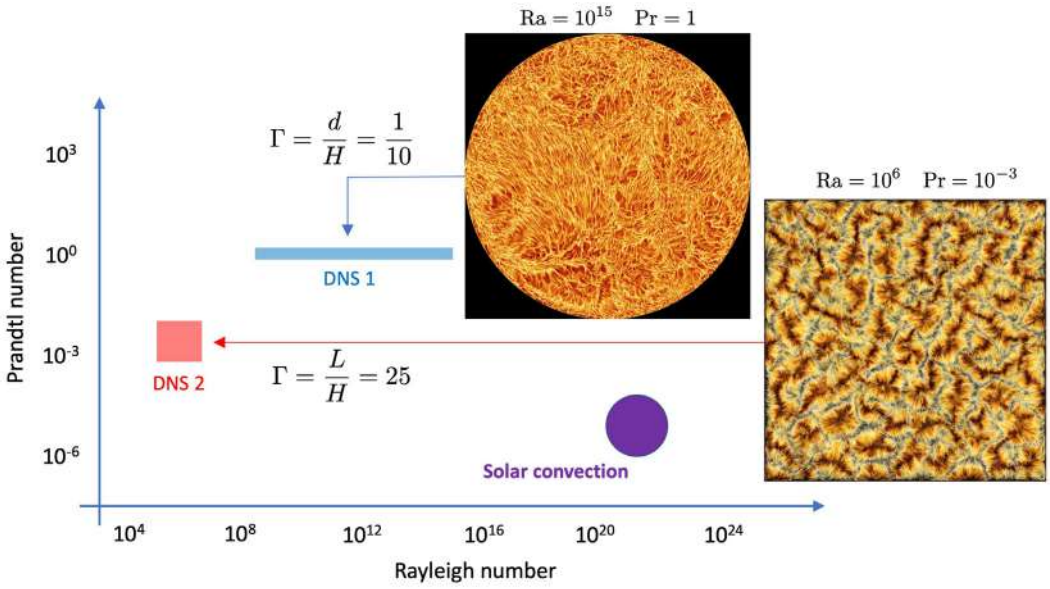

Figure 1: The parameter plane, which is spanned by the Rayleigh number Ra and the Prandtl number Pr, is shown together with the two series of DNS of turbulent Rayleigh-Bénard convection. For both series, a snapshot picture is added. DNS 1: contours of the temperature field close to the heated bottom plate of the slender cylindrical cell. DNS 2: Top view on the convection domain with streamlines of the velocity field colored by velocity magnitude. Also indicated is the typical range of Rayleigh and Prandtl number in solar convection.

CONVECTION IN EXTENDED LAYER AT VERY LOW PRANDTL NUMBER

RBC flows in horizontally extended domains show an organisation into regular large-scale patterns which are termed *turbulent superstructures* of convection [6]. They are reminiscent to the patterns in the weakly nonlinear regime of thermal convection for Rayleigh numbers right above the linear instability threshold. We have studied these patterns as a function of Rayleigh and Prandtl numbers in rectangular simulation domains with a large aspect ratio of $\Gamma = 25$ and obtained characteristic spatial and time scales as a function of $(\mathrm{Ra}, \mathrm{Pr})$. The analysis of these large-scale computations require a strong data reduction, e.g., to reveal the role of turbulent superstructures for the global heat transfer across the layer. Therefore, we applied deep convolutional neural networks to reduce the raw 3d simulation data to a planar dynamic ridge network and to quantify the turbulent heat transfer that is connected with this structure [7]. A particular challenge are RBC simulations at very low Prandtl number in this setting (see DNS 2 in figure 1 again). The reason is that the fluid turbulence becomes highly inertial at low Prandtl numbers. This requires very fine computational grids, both, in the boundary layers and in the bulk. The largest DNS, which was conducted at $\mathrm{Ra} = 10^6$ and $\mathrm{Pr} = 10^{-3}$ on the SuperMUC NG computer at the Leibniz Rechenzentrum Garching, used a non-uniform finite-difference Cartesian grid with a resolution of $N_x : N_y : N_z = 12800 : 12800 : 800$ points that sum up to more than 131 billion grid points.

Acknowledgements. The present DNS 1 were enabled by an award of computer time provided by the Innovative and Novel Computational Impact on Theory and Experiment (INCITE) program, and used resources of the Argonne Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC02-06CH11357. DNS 2 were enabled by Grant No. HIL12 of the John von Neumann Institute for Computing in Jülich (Germany) and Grant No. pr62se of the Gauss Centre for Supercomputing (Germany). UNCERTAINTY QUANTIFICATION TECHNIQUES FOR SCALE-RESOLVING SIMULATIONS OF WALL-BOUNDED TURBULENCE

Saleh Rezaeiravesh[1,2], Narges Tabatabaei[1,2], Ricardo Vinuesa[1,2], and Philipp Schlatter * [1,2]
[1]Linné FLOW Centre, KTH Mechanics, Royal Institute of Technology, Stockholm, Sweden
[2]Swedish e-Science Research Centre (SeRC), Stockholm, Sweden

Summary Scale-resolving simulations of wall-bounded turbulent flows can be very expensive and, on the other hand, their performance depends on various numerical and modeling parameters. Dealing with these challenges can be facilitated by making use of novel techniques from the field of uncertainty quantification (UQ). In this regard, two connected paths of research are pursued here. First, using a combination of stochastic collocation and polynomial chaos expansion (PCE) methods with global sensitivity analysis, a framework is developed to efficiently assess accuracy, sensitivity, and robustness of scale-resolving simulations when different numerical parameters are allowed to vary. In the second path, multifidelity models are developed which are beneficial for constructing predictive models over the input space of high-fidelity flow simulations. Such models provide the possibility of conducting robust optimization and uncertainty quantification studies involving wall-resolving simulations. The frameworks in this study are software-independent, however, the main focus is on Nek5000 [1] that is an open-source high-order highly-scalable spectral-element flow solver. The presented UQ techniques are particularly relevant in the view of large-scale (exascale) computing.

INTERFACES BETWEEN UQ AND TURBULENCE SIMULATIONS

Assessment of Numerical Uncertainties

Numerical solutions of the Navier–Stokes equations for turbulent flows can be contaminated by some level of uncertainties and errors originating from different sources, including the followings: the projection, discretization of spatial and temporal derivatives, velocity-pressure coupling, imposing initial and boundary conditions, meshing, bugs in the code, limited sampling time, etc. A part of this study aims at investigating how the accuracy and certainty of the quantities of interest (QoIs) of canonical wall-bounded turbulent flows are sensitive to various numerical parameters and time averaging. Assume $\varphi_h(\mathbf{x},t)$ represents a discrete flow quantity obtained by direct numercal simulation (DNS) or large-eddy simulation (LES), where $\mathbf{x}$ is the position vector and t is time. The averaged value of $\varphi_h(\mathbf{x},t)$ over statistically homogeneous directions and finite time T is considered to be a QoI and represented by $\langle\varphi_h(\mathbf{x},t)\rangle_T$. Given a reference true data, $\langle\varphi_h^\circ(\mathbf{x},t)\rangle$, we can write,

$$\|\langle\varphi_h(\mathbf{x},t)\rangle_T - \langle\varphi_h^\circ(\mathbf{x},t)\rangle\| \leq \|\langle\varphi_h(\mathbf{x},t)\rangle - \langle\varphi_h(\mathbf{x},t)\rangle_T\| + \|\langle\varphi_h(\mathbf{x},t)\rangle - \langle\varphi_h^\circ(\mathbf{x},t)\rangle\| \,.$$

On the right-hand side, the first and second terms represent the uncertainties due to finite time-averaging (sampling error), $\mathcal{E}_T$, and the combination of all other numerical and modeling errors (excluding the projection error), $\mathcal{E}_n$, respectively. To estimate the uncertainty in the QoIs due to time averaging, $\mathcal{E}_T$, the use of different techniques such as classical, batch-based and autoregressive methods is discussed, see e.g. [2] and the references therein. Due to the dominant non-linearity of the Navier–Stokes equations and the fact that various numerical and modeling errors are intertwined, deriving accurate a-posteriori estimates for $\mathcal{E}_n$ in turbulent flows is not feasible. Here, the strategy is to study the sensitivity and behavior of the $\mathcal{E}_n$ of different QoIs with respect to several sources of uncertainty through systematic flow simulations, see *e.g.*[3, 4]. Therefore, a UQ forward problem is formulated in which the numerical parameters, such as grid resolution and filtering parameters, are considered to be uncertain. The associated uncertainties in these parameters (hereafter shown by $\mathbf{q}$) are propagated into the responses or quantities of interest $\mathcal{R}$. The parameters $\mathbf{q}$ are allowed to vary over the presumed admissible space Q. Using polynomial chaos expansion (PCE) [5] with stochastic collocation samples in a non-intrusive way, surrogates are constructed for $\mathcal{R} = \tilde{f}(\mathbf{q})$. Employing the surrogates, the portraits of the errors in the QoIs are obtained over the whole space Q and stochastic moments of QoIs are estimated. Moreover, the Sobol indices [6] provide a quantitative basis to compare the global sensitivity of different errors with respect to variation of $\mathbf{q}$.

Figure 1 shows a set of described analysis for wall-resolved simulations of channel flow at $\mathrm{Re}_\tau = 300$, where Re_τ is based on friction velocity and channel half-height. The uncertain parameters $\mathbf{q}$ are Δx^+ and Δz^+, the inner-scaled average distance between collocation points in the streamwise and spanwise directions, respectively. Variation of the error in mean streamwise velocity, $\langle u\rangle$, in the admissible space of parameters $\mathbf{q}$, sensitivity indices of the errors in different QoIs with respect to these parameters, and robustness of the QoIs when $\mathbf{q}$ vary over Q are illustrated in Figure 1. The study also investigates the impact of filtering approach and associated parameters in addition to grid resolution controllers.

Multifidelity Models

Uncertainty quantification, prediction and robust optimization for problems involving wall-bounded turbulent flows can be very expensive, since exploration of the input space demands several realizations. Therefore accurate yet cost-effective models are required for such purposes. The present study reports our recent progress on further developing and exploiting multifidelity models which rely on Gaussian processes [7]. Following Goh et al. [8], at each hierarchical level

*Corresponding author. E-mail: pschlatt@mech.kth.se.

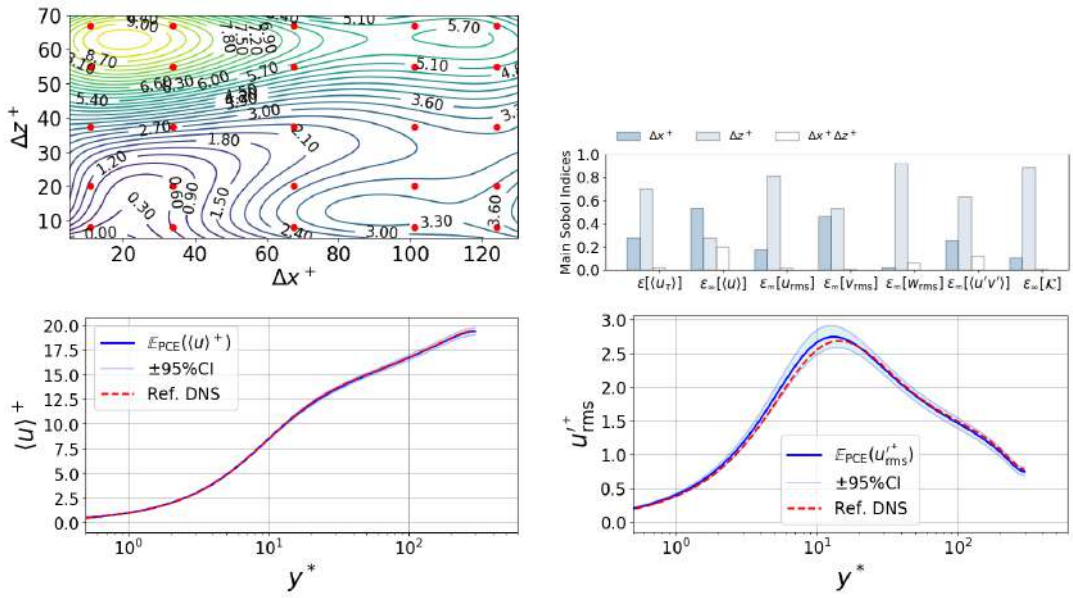

Figure 1: UQ study of turbulent channel flow at $\mathrm{Re}_\tau = 300$ when inner-scaled grid resolutions in wall-parallel plane are allowed to vary: variation of error in $\langle u \rangle$ in Δx^+-Δz^+ plane (top-left), Sobol sensitivity indices for different QoIs with respect to Δx^+ and Δz^+ which are varying over $[5, 50]$ and $[5, 30]$, respectively (top-right) with resulting propagation of uncertainty in the inner-scaled mean and rms streamwise velocities (bottom).

in our multifidelity model, the Kennedy-O'Hagan model [9] is used which allows for considering both model inadequacy and aleatoric uncertainties in the process of data fusion. Using a limited number of realizations (mostly by running low-fidelity simulations), the calibration parameters and hyperparameters appearing in the multifidelity model are estimated within a Bayesian framework. The constructed model can then be employed for uncertainty propagation and prediction over the whole input space. In particular, the turbulent flow around a standard NACA airfoil is considered with time-averaged aerodynamic characteristics as QoIs. The input variables (uncertain and controlled parameters) include the angle of attack, Reynolds number, and specific locations on the airfoil. To construct the multifidelity model, data from wall-resolved LES, Reynolds-averaged Navier-Stokes (RANS) simulations, and panel method are employed. Upon availability, new experimental measurements are also considered. The accuracy and credibility of the model predictions and their sensitivity with respect to various influential factors will be discussed.

CONCLUSIONS

It is shown how UQ techniques can be extremely helpful in studies involving simulations of wall turbulence. Such techniques make it possible to rank the parameters which influence the accuracy, sensitivity and robustness of the numerical simulations. Moreover, they can be used for development of a framework for quantitative comparison between different flow solvers. Multifidelity models can be utilized as an efficient surrogate for actual wall-resolving simulations in problems where exploration of a parameter/input space is required. The insights gained from this study will pave the way for the further development of the multifidelity models for wall-bounded turbulent flows, and will also allow us to design future high-fidelity simulation campaigns for airfoils and wings. This project is in the context of the Excellerat EU Centre of Excellence.

LARGE EDDY SIMULATION OF FLOWS OVER POROUS STRUCTURES WITH A MASSIVELY PARALLEL ADAPTIVE LATTICE BOLTZMANN METHOD

Ralf Deiterding and Mikaël P. Grondeau
Aerodynamics and Flight Mechanics Research Group, University of Southampton
Boldrewood Innovation Campus, Southampton, SO16 7QF, United Kingdom

Summary We discuss the construction and parallel performance of our self-developed parallel and dynamically adaptive lattice Boltzmann software AMROC-LBM. We apply the code to large eddy simulations of turbulent boundary layer flows over rough and permeable surfaces. Beside the fluid mechanical results, the computational performance of AMROC-LBM in dynamically adaptive as well as in unigrid mode on large-scale and massively parallel supercomputer systems is discussed.

INTRODUCTION

Predicting turbulent boundary layer flows over complex porous surfaces accurately requires a low-dissipation computational approach with high temporal and spatial fidelity. While compressible large eddy simulation (LES) in the transonic or supersonic regime is best accomplished with high-order finite volume schemes, the lattice Boltzmann method (LBM) has emerged as a particularly powerful alternative for LES or direct numerical simulation of subsonic flows.

Being a type of immersed boundary method, the LBM is well suited for modelling porous structures. A unique capability of our LBM implementation is the seamless integration into a fully parallelized block-structured adaptive mesh refinement algorithm implemented in our generic massively parallel framework AMROC [1], thereby allowing local resolution increases on-the-fly and depending on the local flow field. Here, we sketch the inner workings of AMROC-LBM [2,3] and report on first LES results of boundary layer development over a prototypical rough wall scenario consisting of regularly arranged spheres of identical size [4]. Parallel performance of our implementation on dynamically evolving as well as on static uniform grids is discussed.

METHODS

The LBM is based on solving a simplified Boltzmann equation with a time-explicit streaming and collision algorithm on a Cartesian lattice. The streaming step is exact, and the scheme exhibits very low numerical dissipation. Here, we employ the single-relaxation-time (SRT) collision operator, for which it is mandatory to apply a turbulence model in high Reynolds number situations. We adopt an LES approach with eddy viscosity model [3], which can easily be considered in the LBM by adding a turbulent eddy viscosity, evaluated locally in each cell, to the kinematic viscosity of the gas. Here, we have used the constant coefficient Smagorinsky model.

Our LBM is implemented on finite volume type meshes and considers geometrically complex boundaries with a level-set-based ghost-fluid-type approach. Dynamic mesh adaptation can be applied in addition in order to increase the local resolution based on the level set function and features detected in the flow field, as provided by out MPI-parallelized structured adaptive mesh refinement (SAMR) software system AMROC. In the SAMR approach, cells are clustered with a special algorithm into non-overlapping rectangular grids. Refinement levels are integrated recursively. See [1] for details. Distributions streaming across refinement boundaries are fully considered in AMROC-LBM by a specially designed correction algorithm [2,3]. For mesh partitioning, AMROC uses a space filling curve algorithm.

RESULTS

An adaptive LBM-based LES of the boundary layer flow over a prototype porous surface using AMROC is shown in Fig. 1. Two levels of dynamic mesh resolution have been used in this preliminary computation. Inspired by a case studied by Stoesser et al. [4], flow of air imposed by a flume at velocity of U=8m/s, modelled as a surface sliding in the x-direction at the top domain boundary, passes over two layers of 18x10 regularly positioned spheres of D=12mm diameter on top of a flat fixed wall bottom (x-y-plane). The distance of the flume is H=41mm above the sphere surfaces, giving a Reynolds number of the bulk channel flow of $\mathrm{Re}=UH/\nu=20372$. Figure 1 is depicting the instantaneous velocity in the x-direction after approximately 12 flow periods through the domain, when the boundary layer is reasonable well formed. Figure 2 shows the averaged x-velocity above the spheres in locations of minimal and maximal porosity compared to the reference data by Stoesser et al. While the resolution of the LBM computation is still coarser, convergence can be clearly by inferred.

Strong scalability benchmarks on the Archer system of AMROC-LBM have been also been carried out for the prototype setup. Starting from a 360x240x108 base grid and adding dynamically up to 2 additional levels refined in all spatial directions by factors 2 and 4, respectively, the benchmark computation corresponds to a uniform mesh of 2880x1920x864 = 4.78e9 cells. The benchmark computed 80 timesteps on the finest grid level and included 4 complete parallel mesh redistributions. 24,844,504 cells where used at the end of this test on the first refinement level and 10,838,016 on the second. The left plot of Fig. 2 displays the speedup of the parallel computation with increasing core count compared to the ideal linear line. Since the LBM is computationally rather inexpensive, parallel scalability on very large processor

number is difficult to achieve when mesh adaptation is employed. At least until 1536 cores the performance gains from using more processors are quite acceptable for our implementation. For comparison, the right plot of Fig. 2 shows the speedup for the initial 80 timesteps for this case when using a uniform and static mesh of 1440x1920x432 = 1.19e9 cells.

CONCLUSIONS

LES of turbulent boundary layer flow over a generic prototype rough and permeable surface have been carried out with our self-developed parallel and dynamically adaptive lattice Boltzmann code AMROC-LBM. Good agreement with available reference data is achieved and verifies the correctness of the adaptive LBM and LES implementation.

While scalability of the explicit AMROC-LBM code when running in static uniform grid mode is up to O(10,000) cores, first benchmark computations have confirmed good scalability of AMROC-LBM on hierarchical, self-adapting meshes on O(1000) cores for a prototype surface. At the conference significantly higher resolved simulations of LES over technically relevant surface geometries will be presented. The preliminary studies discussed here have confirmed the suitability of our overall approach.

ULTRA HIGH RESOLUTION TOPOLOGY OPTIMIZATION FOR SHELL STRUCTURES

Erik A. Träff[1], Niels Aage[1], and Ole Sigmund[1]
[1]Department of Mechanical Engineering, Technical University of Denmark, Lyngby, Denmark

Summary Topology optimization for shell structures has numerous applications, such as optimizing shell thickness, shell reinforcement, and fiber orientation. Performing high resolution topology optimization on shell structures remains challenging due to high condition numbers of the resulting stiffness matrices, which stems both from the shell geometry and from the material heterogeneity. The proposed design methodology consists of a novel combination of methods to perform topology optimization in extreme resolutions for shell structures. The approach is showcased on an aircraft fuselage which is resolved with 4.2 million shell elements, which is a factor of 50 times larger than the current state-of-the-art for shell topology optimization.

INTRODUCTION

A range of structural optimization problems can be solved by applying topology optimization to shell structures, including thickness optimization, reinforcement placement, and fiber orientation. All such problem formulations have potential uses in larger structures such as wind turbine blades, ship hulls, and aircrafts. To be successful, this requires efficient methods to perform topology optimization with shell formulations. The use of shells in high resolution models is complicated by the high condition numbers which usually accompany thin walled structures [1], decreasing the rate of convergence in iterative solvers.

SHELL ELEMENT

The shell element used here is a linearised version of the solid shell formulation presented in [2]. The shell is modelled as a hexahedral element, with three displacement degrees of freedom at each node. In order to increase accuracy, the element is modelled using several alternate strain interpolations to alleviate locking phenomena. The formulation also supports integrating multiple material layers throughout the thickness, which is used to implement passive regions in the optimization. In order to reduce the increased condition number associated with thin shells the Scaled Thickness Conditioning (STC) [3] is applied to the formulation. The accuracy of the resulting linear element is validated against a set of test cases and found to be sufficiently accurate.

MULTIGRID FOR SHELLS

In order to solve the resulting system of equations a geometric multigrid precondtioner is employed. The used multigrid interpolation corresponds to the method presented in [4] applied to a solid shell element. A standard V-cycle multigrid scheme is used with Galerkin projections. The prolongation is constructed by projecting a query point onto the quadrilateral mid-plane of the coarse element, where the interpolation is obtained using quadrilateral shape-functions. An algebraic multigrid preconditioned conjugate gradient method is finally used to approximate the coarse space correction in the multigrid scheme, as also done in [5].

ULTRA FINE RESOLUTION EXAMPLE

To show the efficiency of the presented method, an example using the aircraft fuselage from the NASA common research model is presented [6]. The model consists of 4.2 million shell elements, or 19 million degrees of freedom. The shell is modelled with a passive outer shell of thickness 0.025mm, and an interior support layer of 2.4975cm which is optimized using SIMP and a PDE based filter with filter radius of 5cm [7, 8]. At this point the mesh is refined to an extent where the average element side-length of 1cm is smaller than the modelled shell thickness of 2.5cm. As the number of shells only quadruples every time the average element size is halved, very fine resolutions can be obtained using only

Figure 1: Side view of aircraft fuselage after 200 iterations of optimization. The mesh consists of 4.3 million shell elements, resulting in an average element side length of 1 cm. Red colour indicates the existence of supporting 2.4975cm of material, while blue indicates the absence of support resulting in only the passive shell of thickness 0.025mm.

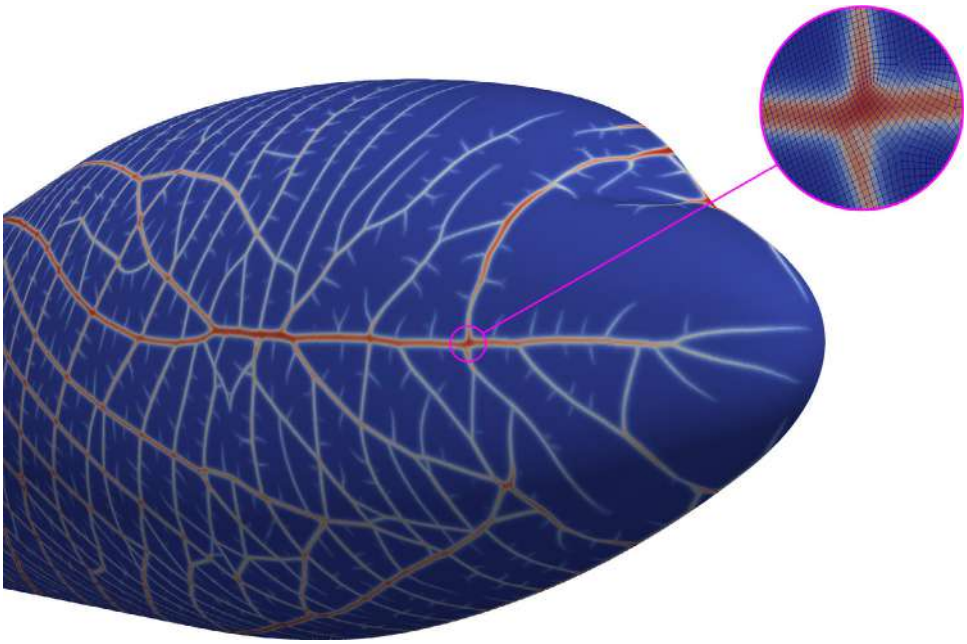

Figure 2: Close up on aircraft fuselage mesh, in order to visualize the element size. Red colour indicates the existence of supporting 2.4975cm of material, while blue indicates the absence of support resulting in only the passive shell of thickness 0.025mm.

millions of elements. The fuselage is modelled without an interior structure and with simplified boundary conditions and loading. Therefore the resulting structure should not be considered in itself, but rather as a showcase of the efficiency of the presented approach. The presented solution was computed on 15 nodes, each with two Intel Xeon E5-2680v2 CPUs, totalling in 300 cores. Finally, it should be noted that the computational obstacle in achieving higher resolution is no longer solving the state equation, but rather constructing the unstructured mesh, as this is a sequential process.

CONCLUSION

The presented approach using linear shell elements is demonstrated to be able to solve extremely finely resolved systems, where the shell thickness becomes larger than the element sizes. This is considered sufficient for most practical applications, although the mesh only consists of millions of elements, in comparison with the billion elements required in similar three-dimensional solid cases [5].

LARGE-SCALE SPECTRAL-ELEMENT SIMULATIONS OF COMPLEX TURBULENT FLOWS THROUGH ADAPTIVE MESH REFINEMENT

Daniele Massaro* [1], Nicolas Offermans[1], Adam Peplinski[1], and Philipp Schlatter[1]
[1]Linné FLOW Centre, KTH Mechanics, Royal Institute of Technology, Stockholm, Sweden

Summary The present investigation focuses on the adaptive mesh refinement technique applied in fully turbulent flows. In particular for large-scale problem, where the solution behaviour is in general not a-priori known, such adaptive techniques are necessary to assess the committed error. In that regard, the strive towards exascale calculations needs to go along with appropriate control of errors in the full domain. In the present study, a number of direct numerical simulations of three-dimensional incompressible flow in relatively complex geometries, *e.g.* the flow in a constricted periodic channel or around a stepped cylinder, have been performed. Results are aimed to assess the efficacy of different error indicators and eventually contribute to the understanding of the complex physics involved in such flows.

MOTIVATION

The study of fluid dynamics appears to be fundamental in most human activities, such as predicting weather patterns or transportation by car, bicycle, plane and so on. In most situations the flow is transitional or turbulent, in which special attention needs to be paid to the proper resolution of the small scales, in particular in DNS and (high-resolution) LES. In complex geometries understanding in advance where a refine mesh is required and where a coarse is enough is far from trivial. The experience and intuition may give us good guesses, but a-priori knowledge of the flow physics is generally not available. This is even more important of large-scale simulations on forthcoming computer systems, where more and more of the complex physics is incorporated into the simulation. In these situations, it is absoutely necessary to control the arising errors, and adapt the meshes adequately. This work is in the context of the Excellerat Centre of Excellence, where the simulation fidelity has been identified as one of the relevant points towards exascale.

The adaptive-mesh-refinement (AMR) technique allows to automatically refine or coarsen the mesh based on the characteristics of the flow, avoiding a long-standing issue in Computational Fluid Dynamics (CFD) [1, 2]. The objective of AMR is to increase the accuracy of the solution at a lower computational cost than what was achievable with a fixed mesh. The two main ingredients of AMR are computational tools to adapt the mesh, and to efficient and accurately estimate the local error. Obviously the choice of these two affects the entire simulation.

When it comes to high-order methods such as the spectral element method, a previous study was carried out on a steady and unsteady flow around two-dimensional cylinder in a sub and super-critical Reynolds regime [4, 3]. We have also considered more complex geometries, *e.g.* the turbulent boundary layer on a wing [6], and the fully turbulent three-dimensional flow in a constricted periodic channel (periodic hill, [3]). In this contribution we would like to focus on a case with intermediate complexity, but yet the clear need for AMR: The turbulent flow around a stepped cylinder, which consists of two attached cylinders with different diameters.

METHOD AND PRELIMINARY RESULTS

A number of direct numerical simulations (DNS) have been performed in three-dimensional turbulent incompressible flows, *i.e.* the periodic hill and the stepped cylinder. The implementation is carried out in Nek5000, an open-source, highly scalable and portable code based on the spectral-element method (SEM). Initially, we define a coarse mesh with the aim to refine only those regions pointed out by the chosen error indicator. The three possible strategies consist in moving the existing grid points (r-refinement), locally increasing the number of grid points (h-refinement) or locally increasing the polynomial order (p-refinement). The h-refinement has been used in our study for its flexibility and relative ease of implementation. For the future, in particular p-refinement in the proximity of wall appears as another promising approach.

The committed error has been defined and measured in an appropriate and numerically efficient way. Indeed errors resulting from the discretization and resolution of partial differential equations with SEM arise from different sources. In practice, we assumed the mathematical model to be consistent and the adequate finite accuracy of computers sufficient. We are left with the truncation error, which arises because the solution is approximated by a finite spectral expansion, and the quadrature error, related to the discrete integration. In order to estimate these errors we employ two methods used in our study: The spectral error indicator, developed by [7], relies on the local properties of the solution. For simplicity we introduce here the formulation for a 1D solution $u(x)$ and its spectral transformation $u(x) = \sum_{k=0}^{\infty} \hat{u}_k L_k(x)$, where L_k is the Legendre polynomial at order k, which is the polynomial basis implemented in Nek5000, and $\hat{u}_k$ is the k-th spectral coefficient. Looking at the N–order of the polynomial expansion, we obtain the spectral element solution $[\mathbf{u}_N, p_N]$ and the error indicator, which is $\epsilon_{ind} \approx \|u - u_N\|_{L^2}$, reads:

$$\epsilon_{ind} = \left(\int_N^{\infty} \frac{\hat{u}(k)^2}{\frac{2k+1}{2}} dk + \frac{\hat{u}_N^2}{\frac{2N+1}{2}} \right)^{\frac{1}{2}} \tag{1}$$

*Corresponding author. E-mail: dmassaro@kth.se

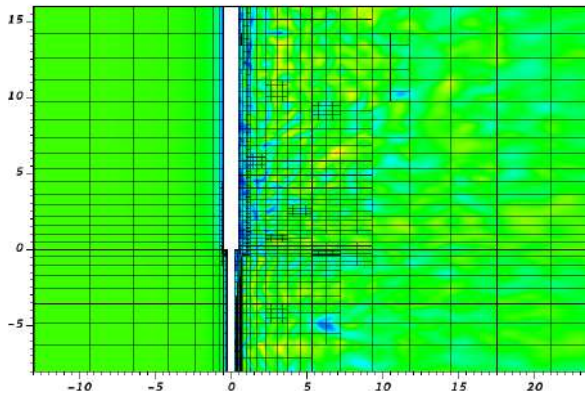

Figure 1: Velocity field of the external 3D flow around a stepped cylinder where the mesh has been refined few times. The simulation is carried out at $Re = 1000$. Individual shed vortices can be tracked, leading to refinement and de-refinment as the simulation proceeds. Alternatively, a static (non-conformal) mesh can be defined based on the sensitivity of turbulence statistics.

where the decay of the spectral element coefficients is assumed to be $\hat{u}_k \sim \hat{u} = cexp(-\sigma k)$. Previous works ([3]) pointed out that this estimator is the best to track the error in flow with high gradients and aims to uniformly reducing the error on the solution.

On the other hand we have implemented the adjoint error estimator. This kind of error estimators are goal-oriented and generate an estimation of the committed error based on a functional of interest. In this case we used the method of the adjoint-weighted residuals by [8], which combines local info in the form of strong residuals and the global sensitivity given by the computation of the dual problem. Firstly we need to define the functional of interest J. In an unsteady turbulent flow, the functional of physical interest is commonly a time-averaged quantity, *e.g.* stresses, mean fluxes, drag or lift coefficients. The averaging time T is chosen long enough for the statistics to convergence. An estimation of the error on the functional is computed as:

$$\begin{aligned}
\delta J &= |J(\mathbf{u}, p) - J(\mathbf{u}_N, p_N)| = \\
&< \sum_{e=1}^{E} \frac{1}{T} \int_O^T \Big[|R_1(\mathbf{u}_N, p_N)|_{L^2(\Omega_e)} \cdot |\mathbf{u}^+ - \mathbf{u}_N^+|_{L^2(\Omega_e)} + \\
&+ |R_2(\mathbf{u}_N, p_N)|_{\Gamma_e} \cdot |\mathbf{u}^+ - \mathbf{u}_N^+|_{\Gamma_e} + \\
&+ \|R_3(\mathbf{u}_N, p_N)\|_{L^2(\Omega_e)} \cdot \|p^+ - p_N^+\|_{L^2(\Omega_e)} \Big] \mathrm{d}t
\end{aligned} \tag{2}$$

where R_1 and R_3 are the strong residuals of the momentum and continuity equations, R_2 correspond to the jump in the stresses at the interface between elements (usually neglected). The terms $|\mathbf{u}^+ - \mathbf{u}_N^+|$ and $\|p^+ - p_N^+\|$ represent the interpolation error on the adjoint field and are estimated with the spectral error indicator [5]. The adjoint error estimators are analytically elegant, but suffer from the problem of the stability of the adjoint equation in the context of turbulent (chaotic) flows.

Figure 1 shows a snapshot of the velocity field around a stepped cylinder, which represents a fully three-dimensional case with curved elements. In the final contribution, we compare the various error estimators on this case, and provide a physical description of the flow physics based on refined meshes. Some perspectives, related to the savings in grid points and gains in accuracy, are given, motivated also by flow cases relevant to aeronautics [6].

IMPROVING STRONG SCALABILITY LIMITS OF ENGINEERING SIMULATIONS

Niclas Jansson * [1] and Rahul Bale[2]
[1]PDC Center for High Performance Computing, KTH Royal Institute of Technology, Stockholm, Sweden
[2]RIKEN Center for Computational Science, Kobe, Japan

Summary Engineering simulations based on finite volume codes scale reasonably well as long as each core has sufficient amount of local work that can balance communication costs. However, achieving efficient performance at exascale will require unreasonable large problem sizes, in particular for low-order methods, where the small amount of work per grid point already is a limiting factor on current post petascale machines. For multi-block Cartesian based methods, one of the key bottlenecks is the halo-exchange, where communication latency starts to limit performance as the number of cores increases. We present our work on improving strong scalability of the multiphysics code CUBE using multithreaded halo-exchange algorithms based on lightweight one-sided communication. A description of these new communication kernels is given, and we present a detailed performance analysis.

INTRODUCTION

To strongly scale finite volume codes on future exascale systems will require either unreasonable large problem sizes to balance communication costs, or algorithmic developments need to be achieved which retain strong scalability even for very few grid points per core. This is in particular the case for low-order methods, where the small amount of work per grid points already is a limiting factor on current post petascale machines. One of the key bottlenecks is halo-exchange, where communication costs starts to limit performance as the number of cores increases.

The message passing paradigm has been the dominating programming model for writing highly scalable scientific applications for decades. Among several implementations, the Message Passing Interface (MPI) has over the years come out as the de facto standard. Based upon a two-sided communication schematics, it is a challenge to handle large amount of fine-grained parallelism. A common optimization is to use non blocking communication, which allows overlapping computation and communication. However, with very few grid points per core, even overlapping techniques will fail, and both latency and synchronization costs of communication will severely limits the strong scalability of an application.

Today at the dawn of exascale computing, some concerns have been raised whether current parallel programming models are capable of delivering the needed performance on future systems. Therefore a large investment has been made in various exascale computing projects worldwide to provide novel programming models, suitable for expressing the massive parallelism that exascale computing will offer. Another key aspect of these new models is their lower latency and synchronization costs, allowing for good performance even for very small problem sizes per core.

ENSURING STRONG SCALABILITY VIA NOVEL PROGRAMMING MODELS

We present our work on improving strong scalability for for Complex Unified Building cubE (CUBE) [1], a multiphysics framework for solving complex engineering problems with moving geometries. The framework is based on a block-structured Cartesian meshing technique called Building Cube method (BCM) [2], with a constraint based immersed boundary method, based upon Lagrangian particles, to represent the complex geometries encountered in industrial applications. The halo-exchange kernel in CUBE is based on a multithreaded two-sided message passage implementation, which overlaps the communication and computation on both a intra- and inter-node level.

To improve the performance of our communication kernels, we replace the two-sided MPI with lightweight, low latency one-sided communication offered by the Partitioned Global Address Space (PGAS) extensions of Fortran 2008 (co-arrays). Using co-arrays we observe an improved strong scalability limit due to the low-latency of PGAS. This allows good performance even with very few grid points and improves exascale readiness of CUBE.

FAST IN-SITU TOMOGRAPHY OF MECHANICAL TESTS

Clément Jailin* [1] and Stéphane Rouxy[1]
[1]Université Paris-Saclay, ENS Paris-Saclay, CNRS, Laboratoire de Mécanique et Technologie, Cachan, France

Summary In situ mechanical tests in a tomograph may provide a remarkable wealth of information resolving both microstructure and 4D (space and time) displacement fields from Digital Volume Correlation (DVC). The limiting point of this technique is the duration of tomographic acquisitions. Projection-based DVC (P-DVC) breaks this barrier and opens up the possibility to complete a mechanical test, which can be quantitatively exploited for identification of mechanical quantities of interest, *in about one minute*. Two examples of application will be discussed, namely, the identification of an elastoplastic constitutive law and a fracture test.

INTRODUCTION

Successive tomographic scans of a mechanically loaded specimen at different levels of load brings an extraordinarily rich amount of information. Not only from the microstructure, and its changes (e.g., pores in ductile fracture, microcracks for damaging materials) but also from complete 3D displacement fields within the specimen as can be retrieved from the use of Digital Volume Correlation (DVC) [1].

However, lab-scale tomographs usually require a rather lengthy acquisition time (typically from several tens of minutes to a few hours) during which the specimen has to remain perfectly motionless. As a consequence, in situ mechanical testing in a tomograph appears as intrinsically limited to quasistatic loadings, unless one resorts to synchrotron facilities where high-rate tomography can be achieved [2, 3]. Moreover, each 3D image usually displays the very same microstructure up to its warping due to mechanical deformations. Hence, the long duration of the acquisition is needed to resolve small details of the microstructure that do not convey a very rich information for the kinematics. But, when a subvoxel displacement resolution is sought, it is necessary to have a highly resolved image and therefore one cannot be satisfied with a coarse resolution in spite of its faster acquisition. This limitation may seem impossible to overcome.

One way out is not to perform a reconstruction of the microstructure, but rather to only address the kinematics from radiographs (or equivalently projections) acquired on-the-fly as the mechanical test is performed, together with the same sample rotation as classically used in tomography. The only requirement then becomes that the specimen should not move significantly during the exposure time of *one radiograph*, which is typically 1,000 times less demanding than for a full scan. However, a single projection cannot allow for the inversion of the full 3D displacement field at each instant of time, as motions along the X-ray beam do not influence the projection, thereby making the problem severely ill-posed. One key ingredient to make the problem well-posed is to introduce a parameterization in time that couples different projection angles. Dealing with a nonlocal in time measurement of the kinematics only requires a smooth temporal evolution, a requirement that is expected to hold true most of the time in the course of mechanical tests. The resulting technique is called Projection-based DVC or P-DVC [4].

PROJECTION-BASED DIGITAL VOLUME CORRELATION

It is assumed that prior to the mechanical test, a full tomography of the specimen has been acquired, following a standard acquisition and reconstruction. The resulting 3D image is denoted as $f(\boldsymbol{x}, t_0)$, giving the coefficient of absorption f at voxel position $\boldsymbol{x}$. Time t_0 is used to refer to the initial state. This 3D image is reconstructed from the projection data, $p(\boldsymbol{r}, \theta)$, which is computed from the radiograph $I(\boldsymbol{r}, \theta)$ acquired when the specimen has been rotated by an angle θ, and the flat field $I_0(\boldsymbol{r})$ radiograph acquired without specimen, $p(r, \theta) = -\log(I(\boldsymbol{r}, \theta)/I_0(\boldsymbol{r}))$. The linear projection operator is denoted Π_θ so that the reconstruction is obtained from the inversion of the set of equations

$$\Pi_\theta[f(\boldsymbol{x}, t_0)] = p(\boldsymbol{r}, \theta) \tag{1}$$

where Π sums up all absorption coefficients $f(\boldsymbol{x}, t_0)$ encountered along the X-ray hitting the detector at position $\boldsymbol{r}$.

In the proposed approach, $f(\boldsymbol{x}, t_0)$ being known, projections $p(\boldsymbol{r}, t, \theta(t))$ are acquired at different instants of time t with varying load and rotation angle $\theta(t)$. P-DVC then consists in solving

$$\Pi_\theta[f(\boldsymbol{x} - \boldsymbol{u}(\boldsymbol{x}, t), t_0)] = p(\boldsymbol{r}, t, \theta(t)) \tag{2}$$

for the *Eulerian* displacement field, $\boldsymbol{u}(\boldsymbol{x}, t)$, which is parameterized as

$$\boldsymbol{u}(\boldsymbol{x}, t) = \sum_i a_i \boldsymbol{\chi}_i(\boldsymbol{x}, t) \tag{3}$$

To make the problem better conditioned, a reduced kinematic basis may be considered. As earlier mentioned, having an extended support is needed to make the problem well-posed. For kinematic basis reduction, different routes may be followed:

- One possibility consists in exploiting prior knowledge on the studied material or its constitutive law. Here a finite-element (FE) modeling may be used where the degrees of freedom become the unknowns of the model, which are the boundary conditions and possibly one or several constitutive parameters. The basis functions $\boldsymbol{\chi}_i(\boldsymbol{x},t)$ are thus computed from the FE modeling, which itself involves a mesh that is tailored to the studied domain.
- An alternative comes from a more agnostic reduced-basis representation of the kinematics. For instance, a separated representation $\boldsymbol{\chi}_i(\boldsymbol{x},t) = \phi_{i_1}(t)\boldsymbol{\psi}_{i_2}(\boldsymbol{x})$ is known to be quite efficient at extracting a reduced basis. Here, the scalar functions $\phi_j(t)$ or vector fields $\boldsymbol{\psi}_k(\boldsymbol{x})$ can be computed to be the most suited to hierarchically account for most of the signal. Depending on the norm used to evaluate these "modes," this approach can be termed differently, namely, Proper Orthogonal Decomposition (POD) for an Euclidian metric or Proper Generalized Decomposition (PGD) if a more physically motivated variational principle is used to weight the modes. For P-DVC, the PGD norm may originate from the minimization of the quadratic differences between left and right members of Equation (2), or it may come from the mechanical model itself.

Let us emphasize that the second strategy leaves more freedom to account from deviations from an a priori postulated model. Likewise, it also receives less guidance from such a modeling and hence may generate poorer conditioning. Thus, there is nothing like a unique optimal way to proceed, the best choice has to rely on the degree of confidence that one has on the proposed model. It is also important to stress that, in the end, a given choice of strategy will lead to a solution, with which a residual (i.e., difference between acquired and modeled projections) should be computed. The compatibility of the residual with the statistical characteristics of noise will finally validate or not the choice, and possibly invite one to revisit the modeling.

EXAMPLES

Elastoplastic calibration

In the first example, detailed in Refs. [5, 6], a slender dog-done specimen was used in a uniaxial tensile test. The studied material was chosen to be nodular graphite cast iron loaded until fracture. The test was performed in less than 5 minutes, and was interrupted by a sudden localization leading to the initiation of a crack that broke the specimen into two pieces. For this test, a first parameterization was used in the same spirit as beam theory where each section along the specimen axis z was considered to be essentially rigid-body motions, parameterized by z [5]. A second version involving an elastoplastic law was further used to calibrate the constitutive parameters [6].

Fracture test

In the second example, a refractory material was used and the goal of the test was to determine its toughness [7]. The duration of the test was less than 30 seconds. In spite of the fact that the sample geometry was adjusted in order to stabilize crack propagation, the crack fractured the sample into two blocks as soon as it initiated. However, the last load level that the specimen could withstand and the first one where it could not resist provides a bounding interval for toughness.

CONCLUSION

The possibility of performing fast mechanical tests in a tomograph offers a novel playground for studying viscoelastic materials (e.g., elastomers, gels, polymer matrix composites). If combined with the ultra-fast tomographic devices available at synchrotron facilities, even higher time resolutions are envisioned. Yet, the rotation rate of the specimen is likely to be the ultimate limiting factor!

As a side result, let us also note that the underlying mathematical problem of dealing with highly lacunar data for PGD or POD is addressed in the above approaches through an original algorithm [8] that outperforms classical "Gappy-POD" procedures in terms of convergence speed and noise robustness.

ON A VOLUMETRIC TEMPERATURE AND VELOCITY MEASUREMENT TECHNIQUE FOR SUB-MILLIMETER SCALES

Christian Cierpka
Institute of Thermodynamics and Fluid Mechanics, Technische Universität Ilmenau, Ilmenau, Germany

Summary The development and the validation of a volumetric measurement technique for the simultaneous determination of temperature and velocity in small geometries will be presented. The technique is based on the so-called astigmatism particle tracking velocimetry which uses the defocus effect including an additional cylindrical lens in the system. Particle images appear elliptically distorted on the camera sensor depending on their three-dimensional position within the measurement volume. Using classical image processing or neural networks the volumetric particle position can be determined reliably. In order to measure the temperature two fluorescent dyes (EuTTA and Perylen) are incorporated in the particles. The luminescence lifetime and intensity of the Europium-complex is temperature sensitive. Thus either evaluating the lifetime using a high speed camera, or evaluating the intensity of the particle images by a monochrome or color camera will enable the estimation of the particle temperature. Within the presentation an overview of the various approaches will be given, advantages and drawbacks as well as examples of applications will be discussed.

Introduction of the measurement technique

Heat and mass transfer is important in many engineering applications. Especially in microfluidic devices where the surface to volume ratio is largely increased and the velocity field is always three-dimensional, measurements are often the only tool to evaluate the flow as boundary conditions may be unknown. A measurement technique that allows for three-dimensional velocity field measurements with only one optical access is the astigmatism particle tracking velocimetry (APTV) [1]. The images of small tracer particles in the flow are used to determine their displacement between two successive time instants. In order to measure the out-of-plane position an additional cylindrical lens is introduced in the system and the particle images appear as ellipses on the camera sensor. The size of the major axes depend on their depth position in the volume. Using particle tracking the volumetric trajectories of the particles can be determined. Using fast cameras that allow for time resolved measurements Lagrangian velocities and acceleration can be estimated precisely with a higher spatial accuracy than typically achieved in correlation based techniques like µPIV. If the flow is steady the spatial resolution can also be much higher than for µPIV. One of the main advantages of APTV is the ability of volumetric measurements using standard equipment with only one optical access and the addition of one low cost cylindrical lens.
However, very often also scalar fields like temperature, concentration or pH are of interest. Therefore the particles were incorporated with two temperature sensitive fluorescent dyes, an Europium-complex (EuTTA) and perylen [2]. EuTTA shows a significant change in the luminescence intensity and lifetime with temperature, whereas perylen is insensitive to temperature variations when illuminated with ultraviolet light. The use of the two dyes allows to correct for variations in light source intensity. A big advantage of this combination is, that the emission spectra of perylene (~420–550 nm) and EuTTA (~575–635 nm) are far apart from each other and do not overlap. This makes it easy to filter the respective signals with corresponding wavelength filters using two cameras. A drawback of such a procedure is that the images of both cameras have to be overlapped for data evaluation. However, also a single color camera using a Bayer mosaic can be used as the cross talk for the different color pixels is quite low. To test both approaches a heated flow in a microchannel was used. The setups are shown in Fig. 1. Both approaches are generally well suited. The one camera approach is much simpler to use but smaller uncertainties could be reached by the two camera setup if a high signal to noise ratio (>10) can be achieved [3].

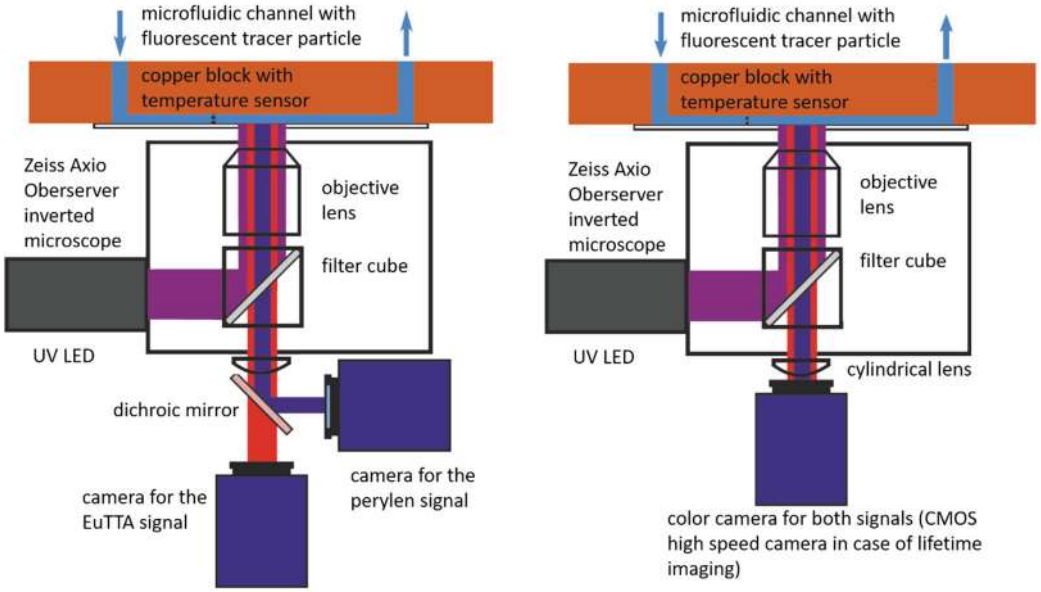

Figure 1. Setup for the different temperature measurement approaches (two color intensity – left, color camera intensity of lifetime imaging - right) adopted from [3].

If a high speed camera is available also the luminescent lifetime can be evaluated with a similar setup as for the color camera (see Fig. 1, right). Although the timing scheme is much more complex to decouple the velocity estimation from the temperature measurement, the uncertainty was shown to be lower especially in the case of varying illumination intensity as for example in multi-phase flows or complex geometries [4].

Results

The developed technique was applied to measure the Marangoni flow and the temperature field around an electrochemically produced hydrogen bubble on a microelectrode. The results helped to clarify the origin of the gradients in surface tension [5]. In Fig. 2 (top - left) the velocity field in the close vicinity of the bubble foot is shown. A vertical structure can clearly be seen. The origin of this flow is the surface tension that varies with temperature. Since Joule heating causes a higher temperature the electrode (as can be seen on Fig. 2 top-right) the surface tension at the electrode is lower which causes the Marangoni flow to evolve. Furthermore, the application of the technique to investigate a heating system for a fast start-up of a direct methanol fuel cell (see Fig. 2 bottom) will be discussed in the talk [6].

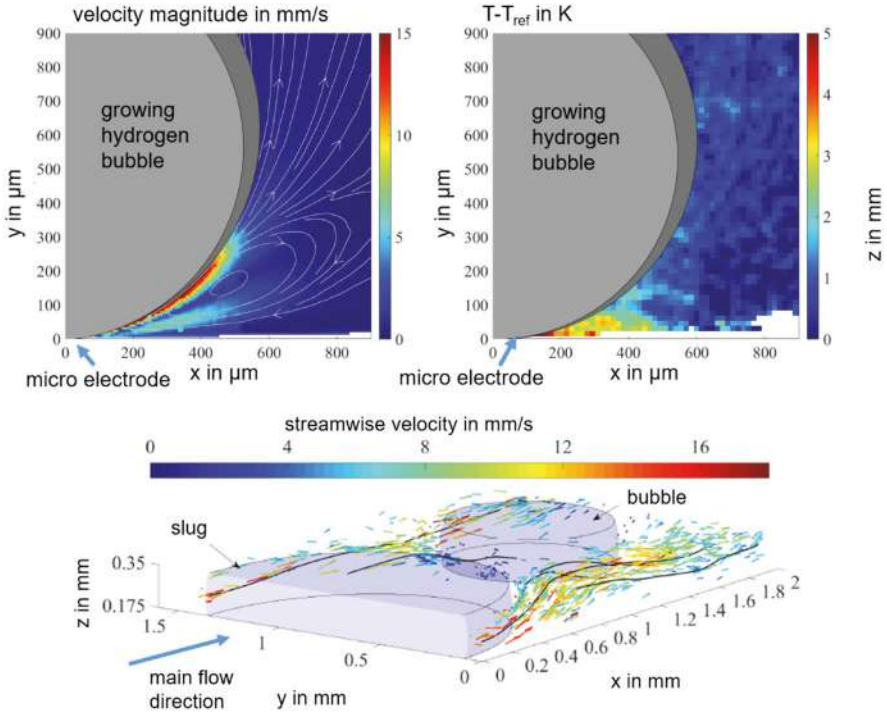

Figure 2. Velocity in the close vicinity of a hydrogen bubble generated by electrolysis at a micro electrode (top-left) and corresponding temperature field measured by lifetime imaging (top-right) adopted from [5]. Flow field around a gas bubble in a direct methanol flue cell (bottom) adopted from [6].

Conclusion and Outlook

It was shown that the measurement technique allows for reliable measurements in complex geometries including multi-phase flows. Either intensity of lifetime of the luminescence of the particles can be used for the additional temperature determination. Using the lifetime evaluation for the temperature shows lower uncertainties for the sake of higher equipment costs and higher timing complexity to have the temperature and velocity measurement independent of each other. This allows for a high flexibility of the system. Further improvements of the technique will be the application of deep neural networks to determine the particle position, temperature and eventually also classify particles. This would be advantageous for systems with multi-disperse particle mixtures, as typically in process engineering and biological applications. Since neural networks are also more robust using different shaped for the particles mono-disperse high cost particles are not anymore necessary.

EXPLORATION OF DYNAMICAL PROPERTIES OF TURBULENT NEAR WAKES FOR DRAG REDUCTION

Y. Haffner[1], J. Boreé[1], A. Spohn[1], T. Castelain[2]

Summary A fascinating aspect of turbulent aerodynamics of bluff bodies at large Reynolds number is the wide range of length and time scales that one has to explore in order to understand the flow dynamics. Based on a long-standing experience obtained in our large scale subsonic wind-tunnel, our goal is here to illustrate on two typical examples the temporal and spatial resolution requirements for coupled pressure and velocity measurements. A short physical analysis and details on experimental techniques are provided below for this invited contribution in the thematic session on Experimental Methods in Mechanics. Research supported by the French Agence Nationale pour la Recherche (ANR) through the project Activ_ROAD (ID ANR-15-CE22-0002) and the CPER Feder program Transport.

Drag reduction of ground vehicles has become a major challenge for the transport industry due to increasing need for reducing fuel consumption and carbon pollution. Flows around such bluff bodies contain massively separated flow regions which lead to wake flows. Our aim is to understand the origins of wake flow changes and associated drag variations by developing wake control strategies. A fascinating aspect of these turbulent aerodynamics at large Reynolds number ($\approx 10^6$) is the interaction between a wide range of length and time scales. At the length scale of the body, an absolute instability leading to periodic vortex shedding is responsible for self-sustained oscillations. Reflectional symmetry breaking, leading to random switching with a long time dynamic, is also observed. Specific flow structures, namely turbulent shear layers surrounding the near wake and, in case of slanted geometries, 3D conical vortices of trailing type, interact producing significant drag contributions.
Modifications of these wakes can be obtained using so called "wake pressure control" devices which change the orientation of mean streamlines at separation using fixed geometrical tapering, moving flaps [1] or steady blowing [2]. Another way, named here "turbulence control", is to modify the dynamical state of the separating shear layers by altering mass and momentum exchanges as well as interactions between shear layers in order to change the mean near wake and to reduce the drag [3]. High frequency pulsed jets interacting with control surfaces [4, 5] combine both strategies. Capturing the dynamics of the unsteady jets, their interactions with small control surfaces and with the turbulent shear layers is thereby of utmost importance.
Experimental and numerical approaches are very complementary. Large Eddy Simulation [6] provide a wealth of information. However, it remains out of reach to compute the long-time dynamics for such a large range of space and time scales in particular when resolving actuations at small scale. Experiments are therefore needed and must be performed on models having a noticeable size (of order 1 meter) in order to reach Reynolds numbers of order 10^6. Recent experimental research has focused on resolving tri-dimensional (3D) characteristics using a scan of particle image velocimetry (PIV) [7], stereo-PIV fields [8] or tomo-PIV [9]. Our goal is here to discuss temporal and spatial resolution requirements for coupled pressure and velocity measurements obtained with typical flow geometries.

Analysis of transient near wake reversals and their consequences on drag [10].
The main objective is here to illustrate the reduction in base drag observed during wake reversals. Indeed, we will show that the flow structure for transient symmetric states explored during the reversals differ from those of static symmetry-breaking states. During the wake reversals, the disorganization of the recirculating flow leads to a transient symmetric state with a reduced interaction between opposed shear layers. A transient drag reduction of 8 % is measured when compared to asymmetric states.
In such a situation, one has to capture spatial and temporal dynamics not only at the scale of separating shear layers but also at the scale of the body because one needs to analyse the interaction of the shear layers. The experiments are performed inside the working section of a subsonic wind-tunnel of 2,4m width and 2,6m height. The turbulence intensity of the upstream flow is of the order of 0.3 % with flow homogeneity better than 0.5 %. The model with height H = 0,3 m, width W = 0,36m and length L = 1m (aspect ratio H/W = 0,83) is fixed on a raised false floor with a ground clearance G = 0,05m which corresponds to about five times the thickness of the turbulent boundary layer upstream of the model. Experiments discussed are performed at $U_0 = 25m/s$ or $Re_H = HU_0/\nu = 5310^5$ where ν is the kinematic viscosity of the air at operating temperature. The boundary layer at separation along the rear edges of the model is fully turbulent with a characteristic momentum thickness of $\theta_0 = 2.2310^{-3}m$ measured using hot-wire anemometry. "Time Resolved" particle image velocimetry (TR-PIV) is performed in the near-wake of the model to gain insight in the flow structure. The setup is associated to a large field of view (FOV) spanning the whole recirculating wake (approx. 1,8H X 1,3H) in the horizontal plane of symmetry of the model. A Phantom VEO4K 990 camera (sensor of 4096 X 2300 px) coupled to a Sigma DG Macro 105 mm objective captures this FOV in a double-frame mode at a frequency of 500 Hz. In order to ensure sufficient illumination of the PIV plane, two lasers Continuum Terra PIV 2 x 30 mJ and Quantronix Darwin Duo 18 mJ are synchronously fired from each side of the test section. The flow is seeded with 1µm-diameter particles. Multi-pass cross-correlation is performed using Davis 10.1 with a final interrogation window of 12 x 12 pixels and overlap of 50 %. For this setup, care is taken to resolve both temporally and spatially all relevant scales in the wake. The frame rate is sufficient to resolve the smallest time-scales associated to the initial shear layer instability after separation of the

turbulent boundary layer. This frequency-scale is estimated to be $f_\theta = St_{\theta_0} U_0/\theta_0 \approx 230Hz$ where $St_{\theta_0} = 0{,}022$ is the initial most amplified time-scale in a turbulent shear layer according to [11]. Similarly the spatial resolution of the velocity measurements is around 1mm which is less than half of θ_0.

Analysis of Unsteady Coanda effect for drag reduction.

The second example is a situation where a noticeable drag decrease is obtained by fluidic boat tailing in combination with the unsteady Coanda effect [4, 5]. Our results point to the need of a careful matching between the jet forcing frequency and the size of the curved surfaces to gain the maximum potential out of the unsteady Coanda effect for drag reduction. Indeed for high frequencies of order $O(U_0/r)$ where r is the size of the flap, strong vortical coherent structures produced by the interaction of the pulsed jets and the separating shear layer not only delay the separation of the boundary layer but also induce a favourable curvature of the shear layer immediately downstream separation. This leads to drag reductions up to 12%. Therefore, in such a problem, one has not only to resolve statistical properties of the wake at a large scale but also scales imposed by actuation. To this end, two planar two-component setups are used. A large field of view (FOV) covering the whole recirculation region in the wake in the vertical plane of symmetry of the model and a smaller FOV localized in the same plane covering the beginning of the top shear layer. Both FOV are captured by a LaVision Imager LX 16Mpx equipped with respectively a a Zeiss Makro-Planar ZF 50 mm lens and a Nikon AF Micro-Nikkor 400 mm lens. A laser light sheet of 1 mm thickness is provided by a Quantel EverGreen 2 x 200 mJ laser. For the small FOV, although the pulsed jets are not directly seeded, the aspiration phase of the forcing still allows for a weak presence of particles in the laminar flow coming from the jets, which leads to satisfactory seeding of the flow. For each configuration studied, the acquisition of 1000 image pairs with an acquisition rate of 4 Hz led to satisfactory convergence of the second order statistics. Image pairs are processed by Davis 8.4 software with a final interrogation window of 16x16 pixels and overlap of 50% leading to a velocity vector each 1.2mm and 0.15mm respectively for both types of field of view. Additional phase-locked measurements using as reference the command signal of the forcing system are performed for the small FOV. In this case, between 500 and 1000 images are acquired for each phase, and each pulsing period is split into 7 to 13 phases. For the small FOV, specific surface treatment is applied on the curved surfaces in order to limit the laser light reflexions. Two additional steps are used in the processing of image pairs: a sliding minimum subtraction in order to eliminate residual laser light reflexions near the curved surface, and an image translation to correct for the small displacements of the model due to relative flexibility of the aerodynamic balance which can result in 1-2 pixels displacement for this PIV setup with high magnification factor.

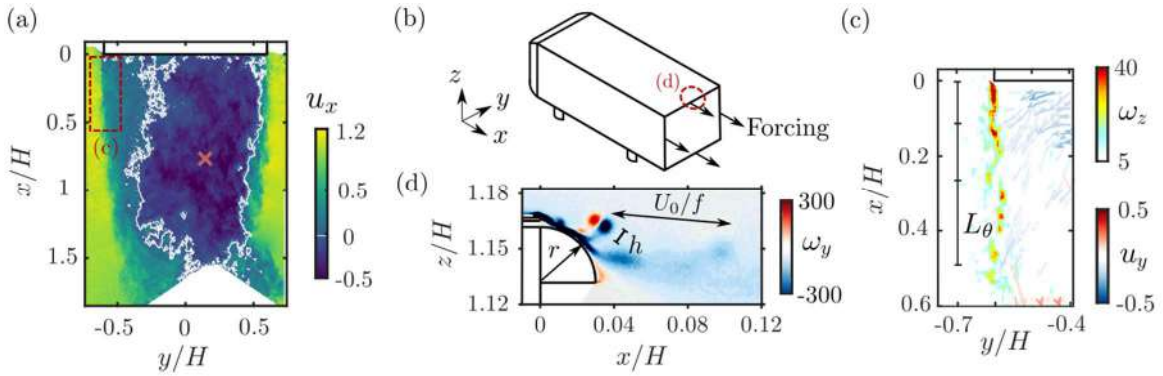

Figure 1. Various length scales of the turbulent near wake. (a) Wake flow in the horizontal symmetry plane of the model with reflectional symmetry-breaking at a scale H. (b) Bluff body. (c) Zoom on shear layer surrounding the recirculation region (red rectangle in (a)). The vorticity sheet rolls-up at length scales of order $L_\theta = T_\theta\, U_0/2 \approx 0.1H$. (d) Flow around an edge of the base (red circle in (b)) forced periodically at frequency f. The forcing produces coherent vortical structures at a scale$3h \approx 0.01H$ periodically repeated at a scale$3U_0/f$. All quantities are made non-dimensional with U_0 and H.

FROM UNSTEADY INFLOW TO DEFORMATION - AN EXPERIMENTAL STUDY ON THE AERODYNAMICS AND STRUCTURAL BEHAVIOR OF A ROTOR BLADE

Tom T. B. Wester* [1], Lars Kröger[1], Apostolos Langidis[1], Martina Göring[2], Simon Nietiedt[2], Thomas Luhmann[2], Joachim Peinke[1], and Gerd Gülker[1]
[1]University of Oldenburg, ForWind and Institute of Physics, Küpkersweg 70, 26129 Oldenburg, Germany
[2]Jade University of Applied Sciences, Institute of Applied Photogrammetry and Geoinformatics (IAPG), Ofener Str. 16/19, 26121 Oldenburg, Germany

Summary The aim of the present study is the investigation of the flow field around a wind turbine rotor blade under periodic changes of the angle of inflow. Additionally, also the resulting deformation of the blade is tracked to examine the impact of such inflow on the structure itself. For this purpose wind tunnel experiments are carried out on a clamped rotor blade of the Oldenburg wind turbine model called MoWiTO 1.8. During the experiment the global forces as well as the local flow around the blade are measured. In addition to this also a photogrammetry system for measuring the blade deformation is used. A 2D active grid is used to create customized flow conditions based on real flow situations at a rotating turbine. For the measurement of the respective span, the wind speed of the wind tunnel was also adapted to the rotating case.

INTRODUCTION

In free field operation wind turbines face a broad range of inflow conditions. In most cases the inflow is of turbulent nature resulting in changes of the incoming wind velocities and direction. Such changes result in angle of attack (AoA) variations for the rotating turbine blade and as a result fast fluctuations of lift and drag force take place. These recurring fluctuations can then lead to wear and tear of the system, which means that the planned service life cannot be achieved. To build more durable turbines it is therefore essential to understand the influence of turbulent flow on the aerodynamics of the rotor blade. Furthermore, the resulting material and torsional behavior due to turbulent inflow need to be understood to adapt the blades to the given flow situation.
This study will present a novel setup with a combination of two state of the art measurement systems. For resolving the flow field around the blade at different spans a high-speed PIV system is used. This techniques allow the investigation of the direct influence of the imposed flow on the rotor blade aerodynamics. In addition, a synchronized photogrammetry multi-camera system is used, which can measure the global deflections of the blade. By simultaneous measurement it is possible to draw direct conclusions about the interaction between inflow, aerodynamics and structural deformations.
The long term objective of the experiment are measurements on a rotating wind energy system. Therefore, it shall also be tested whether the effects on a rotating and pitching system can be simulated with the setup presented here.

EXPERIMENT

The experiment is performed in a wind tunnel of the University of Oldenburg. A schematic sketch of the used setup is shown in figure 1 including all used measurement equipment. The wind tunnel itself has an outlet of 0.8×1.0 m^2 and a test section length of 1.8 m. During the experiments the wind tunnel is operated in open test section configuration. A 2D active grid [1] is attached to the outlet of the nozzle to generate sinusoidal angle of inflow (AoI) changes with a frequency of 8 Hz corresponding to the rotational frequency of the model wind turbine. The experiment focuses on a single wind turbine blade of the Oldenburg model wind turbine called MoWiTO 1.8 [2]. The blade is attached to force and torque sensors 1.1 m behind the 2D active grid. The force and torque sensors are used to measure the global acting forces with a sampling frequency of 1 kHz. To investigate the local flow field a high-speed stereoscopic PIV system is used, which is represented in the figure 1 by grey cameras. For illumination a double pulsed laser with a repetition rate of 1 kHz is used, which is coupled into the wind tunnel from downstream. Since it is only possible to investigate the flow field in discrete planes, the flow fields at 25%, 30%, 35% and 70% of the blade span are investigated during the experiment. To adapt the flow fields to the rotating system, the wind speed of the tunnel is adjusted to the respective span. The generated flow field is based on the rotating and pitching system presented at the wind energy science conference 2019 and shall be compared with the presented results.
In addition to the investigation of the flow field, this study also investigates the deformation and deflection of the rotor blade itself. A photogrammetry system consisting of four high-speed cameras and high power pulsed LEDs [3]. These are represented in the figure 1 by the blue cameras. In contrast to the PIV measurement system, the photogrammetry system is able to record the deformation of the entire rotor blade in all three dimensions. The measured data of both systems are transformed into a common 3D coordinate system. This combination of force, flow and deformation measurements can then be used to analyze the fluid structure interaction (FSI), which was previously only possible in computational fluid dynamics (CFD) in such high temporal resolution and combination.

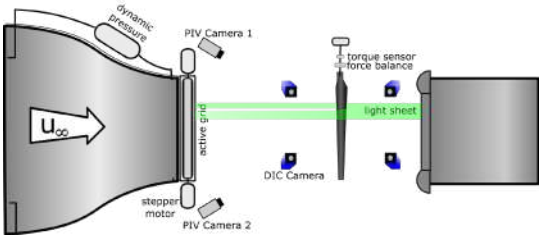

Figure 1: Sketch of the used experimental setup. Shown is the PIV Setup consisting of the two grey cameras and the green light sheet as well as the photogrammetry setup represented by the blue cameras.

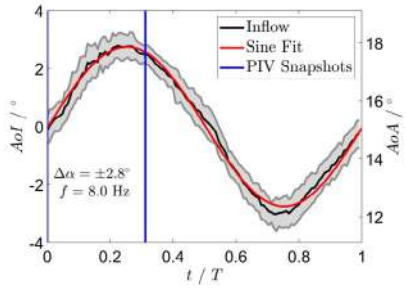

Figure 2: Generated angle of inflow (AoI) and resulting angle of attack (AoA) variations during the measurement at 25% span. Added to the phase averaged measurement in black is a sinusoidal fit in red and the vertical lines in blue represent the times of the PIV Snapshots in figure 3.

AERODYNAMIC RESULTS

As an example, the abstract here will only deal with the case of the 25% span, focusing on aerodynamics. Further comparisons as well as the integration of the deflection will be postponed to the presentation.
Figure 2 shows the generated sinusoidal inflow with an angle of inflow (AoI) amplitude of $\pm 2.8°$ and a frequency of 8 Hz resulting in an angle of attack (AoA) change for the blade from $12.3°$ up to $17.9°$. The wind tunnel velocity during the experiment is set to $u_\infty = 15.9\frac{m}{s}$. With the corresponding chord length c this results in a reduced frequency of $k = \frac{\pi c f}{u} = 0.13$, which is highly unsteady [4].
Figure 3 shows on the left side the vorticity field at an AoI of $0°$. In the figure it is easy to see that the shear layer between wing and free flow is very small here. In comparison, the right side of the figure shows the vorticity field near the maximum of the AoI. Here, a much more pronounced shear layer is visible, which indicates that the flow here is no longer fully attached. This is in agreement with the findings from the measurements from the rotating system and the pitching airfoil.
Besides the flow measurements, other cases of the measurement campaign with focus on the blade deflection have already been presented in [3]. The results were very promising and showed a deformation well correlated with the given flow field.

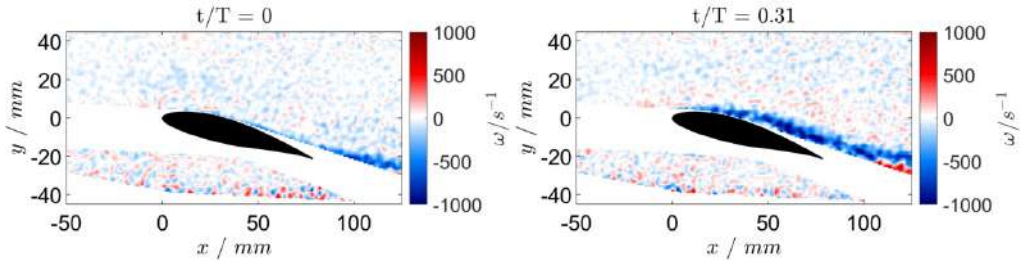

Figure 3: Phase averaged vorticity field for an AoI of $0°$ on the left side and near the maximum AoI on the right side.

CONCLUSION

In the presented study an innovative setup was tested, in which two powerful and non-intrusive optical measurement systems were combined to get new insights into the complex fluid structure interaction. The results that can be achieved by this setup will enable future investigations of FSI in the rotating system under turbulent inflow. Furthermore, the results from the non-rotating system are in good agreement with those from the rotating system, indicating that the flow modulation with the 2D active grid can reflect the real conditions of a rotating system very well. This could significantly reduce the complexity of some investigations in the future.

MEASUREMENTS WITH A NEW STEREO-DUAL-PIV SYSTEM IN A FORWARD-FACING STEP FLOW

Christopher J. Schauerte[1], Deepak Prem Ramaswamy * [1], and Anne-Marie Schreyer[1]
[1]Institute of Aerodynamics and Chair of Fluid Dynamics, RWTH Aachen University, Aachen, Germany

Summary A new stereo-dual-PIV system to analyze turbulent flows with unsteady effects has been developed. Our particular interest is the investigation of complex high-speed flows; the associated conditions thus define the design parameters of the system. After system validation, first measurements were performed in a low-speed forward-facing step flow, featuring multiple instances of flow separation and reattachment, enclosing recirculation zones. The design of the measurement system will be presented, along with results and a detailed discussion of the turbulence and unsteady flow patterns in the fully turbulent flow over a forward-facing step geometry at 10 m/s. Based on measurements of all three components of the mean and turbulent velocity vector throughout the flow field along with the temporal auto-correlation coefficient for several small time delays, we will analyze the flow topology.

MOTIVATION AND APPROACH

To be able to analyze the turbulence and spatio-temporal links in complex high-speed flows, we developed a stereo-dual-particle image velocimetry (Stereo-Dual-PIV) system. In particular, the system was designed to analyze shock wave/turbulent boundary layer interactions (SWTBLI) with separation, a type of flow with major impact and relevance for numerous aerospace-transportation and -propulsion applications [1]. These three-dimensional and highly unsteady flows impose demanding requirements on a measurement system: a very large range of characteristic frequencies, ranging from O(100 Hz) for the low-frequency unsteadiness of the separation bubble/shock system, over O(10 kHz) for large-scale coherent turbulent structures to O(100 kHz) for small-scale boundary-layer turbulence [2], needs to be resolved. High spatial and temporal resolutions are required for accurate measurements of the turbulent quantities in wall-bound flows. To be able to analyze space-time links across the interaction, which is required to better understand the underlying mechanisms in the flow, we need a relatively large field of view that covers the entire interaction flow field and thus allows simultaneous measurements across the field. Due to the three-dimensionality of the flow field, we desired measurements of all three velocity components. Furthermore, a high laser-pulse energy is needed to provide sufficient illumination for the small tracer particles required in high-speed flows. Existing PIV systems cannot provide the temporal and spatial resolutions required in high-speed flows at the same time. Classic PIV measurement systems typically feature high-resolution CCD sensors, allowing for a sufficiently high spatial resolution, but no temporal resolution. On the other hand, high-speed PIV systems using CMOS sensors can provide reasonable temporal resolutions up to O(50 kHz) [5] but cannot provide the required spatial resolution.

Therefore, a carefully synchronized multi-frame approach was chosen for our system: two Stereo-PIV systems, each of them delivering all three components of the velocity vector in the measurement plane, are arranged such that they observe the exact same field of view. Two sets of PIV-image pairs at a preselected, arbitrarily small temporal delays can thus be recorded. With measurements at a number of time delays, temporal and thus also spectral information becomes available.

The validation of the PIV system was performed based on the subsonic flow across a forward-facing step measured in a continuously running subsonic wind tunnel. The large installation space and continuous run times at the low-speed facility have proven advantageous to validate different systems against each other. Care was taken to choose appropriate validation parameters that are transferable to the high-speed flows of interest. This flow topology is well suited to show the capabilities of the new measurement system and is also of inherent scientific interest for multiple reasons: the flow configuration forming at a two-dimensional forward-facing step is of highly dynamic behavior and complexity, featuring several closed separation zones and an unsteadiness of the separation bubble [4], which is typically similar to the unsteadiness occurring in shock-induced separation [2]. The prevailing flow features, namely two distinct separation regions [3], recirculation zones, and reattachment events are of immense importance and interest, also taking into consideration the actually targeted supersonic flow pattern. The results presented on this flow field will therefore help understand high-speed flows with separation, especially the influential phenomenon of the low-frequency unsteadiness, and also demonstrate the capabilities of the Stereo-Dual-PIV system.

EXPERIMENTAL SETUP

Experimental facility and model

The experiments for this study were performed in the closed-circuit low-speed wind tunnel at the Institute of Aerodynamics, RWTH Aachen University. The open test-section has a total length of 1.8 m and a cross section of 1.2 m x 1.2 m. The turbulence intensity based on the freestream velocity fluctuation of the wind tunnel is below 0.3%.

*Corresponding author. E-mail: a.schreyer@aia.rwth-aachen.de.

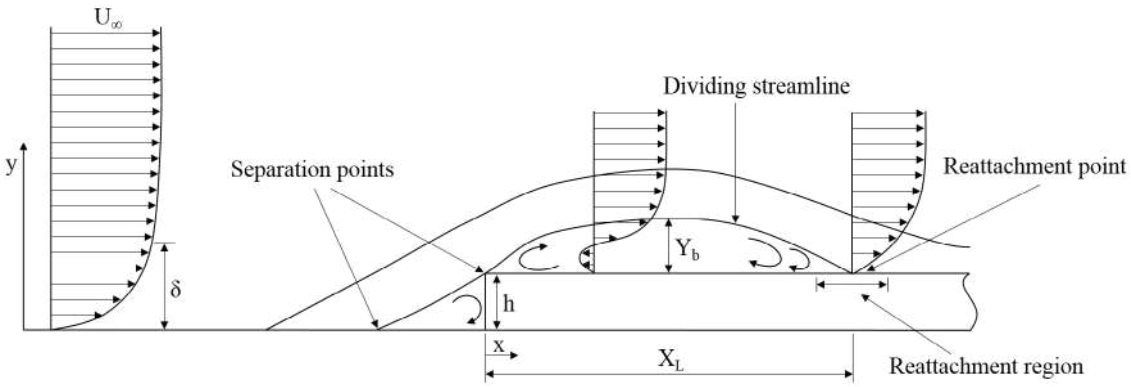

Figure 1: Schematic of the flow topology in the flow across a forward-facing step. Figure from Sherry et al. [6]

The experimental model consisted of a flat plate of 1350×2030 mm (width x length) mounted horizontally in the test section. A rectangular forward-facing step was installed onto the flat plate. The leading edge of the flat plane was a half ellipse, and a tripping wire with a diameter of 0.5 mm installed downstream of the leading edge was used to ensure a fully developed turbulent boundary layer at the measurement region. The step induces large-scale separation, a schematic of the establishing flow topology is shown in Figure 1.

The Stereo-Dual-PIV system

The PIV system is a further development of the Dual-PIV system described by Schreyer et al. [5]. The setup is composed of two separate, but synchronized Stereo-PIV systems, each of them including a double-pulse PIV laser and two 11 megapixel CCD cameras, corresponding to a sensor resolution of 4008 x 2672 pixels. Consequently, each subsystem provides access to all three spatial components of the velocity vector in the measurement plane. Both systems are carefully aligned, such that image sequences of the identical section of the flow field are captured. The temporal delay between the systems is precisely adjustable and can be chosen arbitrarily small. Measurements at a preselected set of time delays thus make the desired temporal and thus spectral information accessible. Frequency-based image separation, which is based on the application of two lasers emitting at slightly distinct wavelengths, combined with high-quality color filters installed in front of the cameras, allows to separate the recorded images of the subsystems. This allows the choice of lasers with similar characteristics and an equally large laser pulse energy of 200 mJ/pulse, enabling a high signal-to-noise ratio that is equally large for both subsystems.

CONCLUSIONS

The high accuracy in the system alignment and the high-quality image separation that can be obtained with the presented setup allow measurement data of very high quality, suitable for turbulence measurements in wall-bound flows. Furthermore, the setup provides a very low measurement noise level. Based on measurements of all three components of the mean and turbulent velocity vector throughout the flow field along with the temporal auto-correlation coefficient for several small time delays, the flow topology and dynamics in complex unsteady three-dimensional flows in both high- and low-speed flows can be assessed and analyzed.

DEEP RECURRENT NETWORKS FOR PARTICLE IMAGE VELOCIMETRY

Christian Lagemann* [1], Kai Lagemann [2], Michael Klaas[1], and Wolfgang Schröder[1]
[1]RWTH Aachen University, Chair of Fluid Mechanics and Institute of Aerodynamics, Aachen, Germany
[2]German Center for Neurodegenerative Diseases, Bonn, Germany

Summary For many years, convolutional neural networks have successfully been used in a variety of tasks, e.g., image classification, object detection, and pattern recognition, and have been recently adapted to improve post-processing steps in Particle-Image Velocimetry (PIV), one of the most important measurement techniques in experimental fluid dynamics. These supervised and unsupervised learning based approaches show promising results but often fail to generalize well to real-world applications. Changing light and diverse particle conditions are still major challenges for achieving high robustness in end-to-end learning based PIV processing. To tackle these challenges in general PIV applications, we apply a novel deep neural network architecture for optical flow estimation called Recurrent All-Pairs Field Transforms (RAFT) [1]. Using RAFT as an optical flow estimation backbone achieves a new state-of-the-art accuracy on public PIV datasets, generalizes well to unknown real-world experimental data, and allows for a significantly higher spatial resolution compared to state-of-the-art PIV algorithms based on cross-correlation methods.

INTRODUCTION

In recent years, common tasks of computer vision, e.g., object detection and recognition, have improved dramatically due to significant advances in the field of machine learning. Low-cost high performance processing units in combination with a higher amount of reasonable training data led to outstanding breakthroughs in deep learning and convolutional neural networks (CNNs). Deep learning methods have shown to side-step the problem of explicitly formulating an optimization pipeline and directly adjust the parameters of an end-to-end network in a general fashion to estimate optical flow. Motivated by the successes of end-to-end deep learning, CNNs have been suggested for addressing current challenges in PIV processing and started to match or even outperform state-of-the-art algorithms in terms of efficiency, accuracy, or spatial resolution. Cai et al. [3] formulated a first dense optical flow estimator for PIV problems achieving decent accuracy while significantly improving the spatial resolution compared to cross-correlation based methods. Adapting a lighter network architecture like LiteFlowNet [2] further increased accuracy and reduced the number of trainable parameters. The major task of current research is to identify network architectures that perform better, train more easily, and achieve good robustness to changing light and particle conditions in novel scenes.

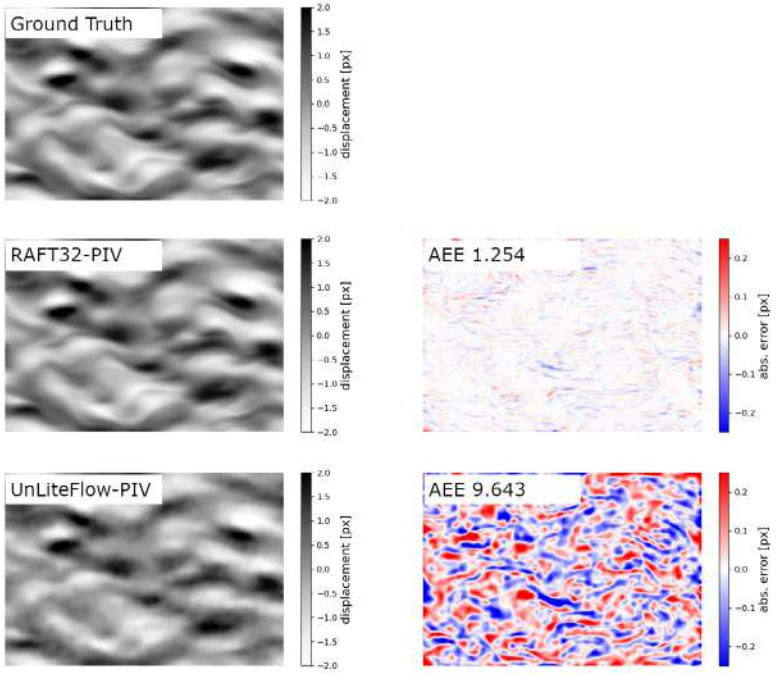

Figure 1: Optical flow prediction of different network architectures (left) and absolute error between ground truth flow and network predictions in vertical flow direction (right: lighter is better).

To tackle these challenges, we apply a novel deep neural architecture for optical flow estimation called Recurrent All-Pairs Field Transforms (RAFT) [1] to general PIV applications. RAFT extracts per-pixel features, computes a 4 level multi-scale correlation volume for all pairs of pixels, and iteratively updates a flow field using a convolutional gated recurrent unit. Compared to other optical flow networks, it is unique in the sense that it operates at a single resolution using a large number of lightweight, recurrent update operators. Using RAFT as optical flow backbone achieves state-of-the-art

*Corresponding author. E-mail: c.lagemann@aia.rwth-aachen.de

accuracy on synthetic PIV datasets, generalizes well to unknown real-world experimental data, and opens the door for further self-supervised or unsupervised learning approaches. We trained our RAFT model on a publicly available synthetic PIV image dataset and further designed more challenging datasets increasing the maximum particle shift to a maximum of $\pm 20px$ while significantly decreasing the number of particles within an image domain at the same time. Finally, we applied our trained model to experimental data performing on pair with state-of-the-art PIV algorithms.

RESULTS

Fig. 1 depicts the predefined reference displacement data of a direct numerical simulation of isotropic turbulence together with the computed estimates of our RAFT based method and a state-of-the-art unsupervised PIV network. Analyzing the absolute error distribution clearly reveals that our RAFT based method outperforms state-of-the-art PIV networks. In addition, RAFT provides a second major benefit over traditional cross-correlation PIV algorithms, the high spatial resolution, since it computes per-pixel flow estimates. In our test cases, the RAFT based flow predictions have a 64 times higher resolution compared to our cross-correlation based PIV approach. Especially in turbulent flows characterized by strong fluctuations and gradients, a higher spatial resolution allows to resolve finer flow structures. We evaluate this benefit for a transitional turbulent boundary layer of an incompressible flow over a flat plate with an elliptical leading edge. These results are provided in the final manuscript.
Finally, we applied our models to real-world experimental PIV data. The test case is taken from a measurement dealing with a turbulent wavy channel flow as described in [4]. The PIV images are analyzed using our in-house code PascalPIV. Fig. 2 clearly depicts that our RAFT approach performs on pair with available cross-correlation PIV methods while significantly increasing the spatial resolution. Furthermore, RAFT outperforms state-of-the-art PIV networks and shows less noisy results due to its iterative nature. These results as well as the findings of various synthetic and experimental data will thoroughly be discussed in the final manuscript.

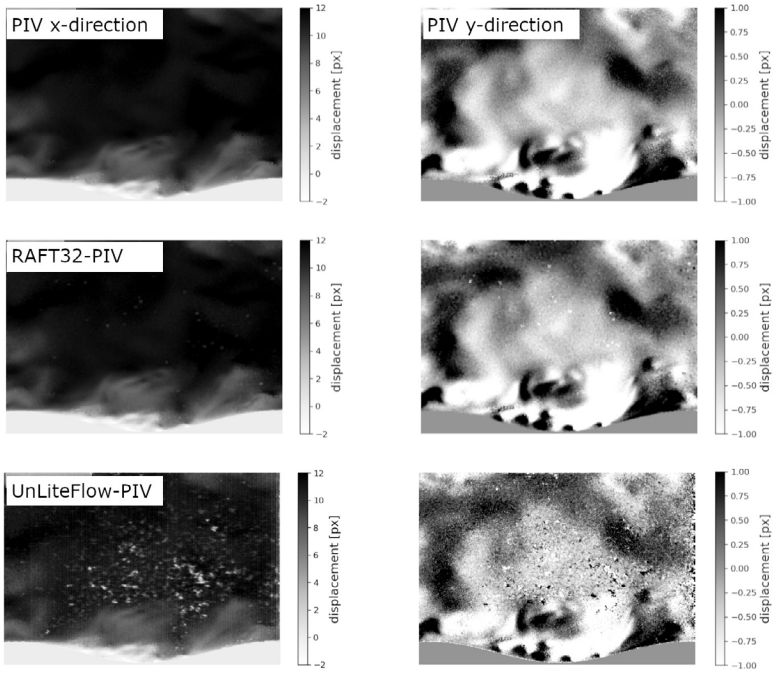

Figure 2: Visual comparison of our RAFT models and state-of-the-art PIV algorithms as well as PIV networks.

CONCLUSIONS

Several deep neural network architectures used for PIV processing were evaluated. Our RAFT based models achieve a new state-of-the-art accuracy on a public PIV image dataset and outperform available supervised and unsupervised learning based approaches. We demonstrate that our RAFT models also perform well in significantly more challenging flow field and image conditions, e.g., low particle density and changing light conditions, again outperforming available PIV networks. Furthermore, we apply our RAFT models to real-world experimental PIV data performing on pair with sophisticated state-of-the-art PIV algorithms while significantly improving the spatial resolution.

3D STRAIN FIELD EVOLUTION DURING TENSILE LOADING OF PAPERBOARD

Sara Johansson[1]*, Stephen Hall[1], Jonas Engqvist[1], and Johan Tryding[1]
[1]Division of Solid Mechanics, Lund University, Lund, Sweden

Summary Paperboard is subject to a range of mechanical deformations during package processing and there is a need for an increased understanding of deformation mechanisms to optimize these processes. In this study, the 3D strain field evolution of single-ply paperboard samples were investigated during in-plane uniaxial tension tests using X-ray tomography and digital volume correlation. The loading was applied in two directions; along and across the main fibre direction. Full 3D strain tensor fields were analysed in an incremental manner across four consecutive load steps before material failure. The strain field patterns differed between samples loaded along and across the main fibre direction. However, for both types of samples, strain localization occurred early and the established patterns intensified with further loading.

INTRODUCTION: DAMAGE MECHANISMS IN PAPERBOARD

Paperboard is an essential component to many food and beverage products. During the package processing the paperboard is subject to a range of mechanical deformations that are necessary for the forming of the package, but could also compromise the overall product performance. Numerical modelling has become an important tool towards optimising the package forming processes[1], but more detailed models require more detailed experimental support in terms of the material structure and deformation mechanisms. In this work we investigate the 3D evolution of paperboard microstructures based on 4D x-ray tomography imaging and Digital Volume Correlation (DVC) to quantify the development of the 3D tensor strain fields leading to damage. Furthermore, as paperboard is a highly anisotropic material, we investigate how the direction of loading with respect to the material microstructure affects the development of strain fields and damage in the lead up to material failure.

MATERIAL AND METHODS: X-RAY TOMOGRAPHY AND DIGITAL VOLUME CORRELATION

The material studied here is a single-ply paperboard consisting of bleached fibres and coated with two layers of clay/latex on one side. Notched samples from this paperboard (see sketch in Figure 1, left) were subjected to in-plane uniaxial tension tests in two different material directions; the Machine Direction (MD) and the Cross machine Direction (CD). The tensile loading was performed using a small custom-built tensile test device designed to be used within an x-ray tomograph. Loading was carried out in load steps with x-ray tomography acquisitions after each step to image the internal microstructures in the material. The MD and CD samples were loaded in load steps of 15N and 8N, respectively, resulting in four load steps before the peak force was reached and failure occurred in the samples.

X-ray tomography imaging was performed using a Zeiss Xradia XRM520, at the 4D Imaging Lab at Lund University. The x-ray source parameters were set to 110kV and 10W. 1601 projections were collected during 360º rotation, which resulted in scanning times of around 1 hour and 10 minutes. The final 3D images had cubic voxels of side length 4 µm.

To obtain the full tensor strain fields in 3D, the x-ray tomography images were analysed by DVC. DVC was performed in an incremental manner (comparing strain evolution across each consecutive load step) using the tomography volumes corresponding to these loading steps. The open source Python code Spam 0.4.3[2] was used for the DVC analysis. After an initial registration of rigid body motions, a node spacing 20 voxels and a correlation window size of 21 voxels was chosen for the DVC, as it resulted in relatively high resolution of the strain fields and reasonable computation times.

RESULTS AND DISCUSSION: STRAIN FIELD EVOLUTION

The macroscopic stress-displacement curves for the MD and CD samples are shown in Figure 1 (middle), where the loading steps are marked with red circles. Stress relaxation occurring during the x-ray tomography data collection can be observed for all load steps. The sample loaded in the MD experienced a relatively steep increase in stress up to around 60 MPa, followed by a rapid drop to 10 MPa when the sample failed. The stress/strain curve measured on the CD sample has a wider shape and becomes significantly nonlinear as the maximum stress around 40 MPa is approached. After the failure, the stress drops to around 10 MPa and continues to decrease gradually with further material separation.

Also shown in Figure 1 (right) are 2D visualizations of the samples after failure (load step 06, central plane). In the MD sample, the fracture (as indicated by the zone with low fibre density) extends from the upper parts of both notches and approximately diagonally towards the centre of the sample. The central part contains slightly higher amounts of fibres compared to the edges. The fracture in the CD sample runs roughly diagonally from the upper part of the left notch towards the lower part of the right notch. On average, the sample looks more damaged close to the right notch compared to the left.

Although the full strain tensor is obtained from the DVC analysis, we focus on the volumetric strain field here. Figure 2 shows, for both samples, 3 orthogonal sections through the volumetric strain field volumes and for three loading increments before material failure. In both cases, patterns of elevated strain developed already at early load increments and increased in magnitude with further loading, but the patterns remained similar throughout the loading. The areas of

*Corresponding author. E-mail: sara.johansson@solid.lth.se.

elevated strain also extend further to neighbouring parts of the sample at later load increments. The patterns differ between the MD and CD samples in both plane view and the thickness directions. In MD, the strain localisation starts at the notches and extend towards the centre in apparently diagonal directions (at least partly). The strain is, on average, high close to the notches compared to the centre; a pattern that can be recognized from the fracture at load step 06 in Figure 1. In the thickness directions, the strain is localized in the central parts of the sample which indicates that the sample started to delaminate and increase in thickness. The CD strain field developed mainly from the right notch (where the major fracture zone appeared after failure, Figure 1) and extended in a roughly horizontal direction towards the left notch. The diagonal or vertical patterns observed in the MD strain fields cannot be distinguished in the CD strain fields. In the last loading increment, high strains developed throughout the sample width.

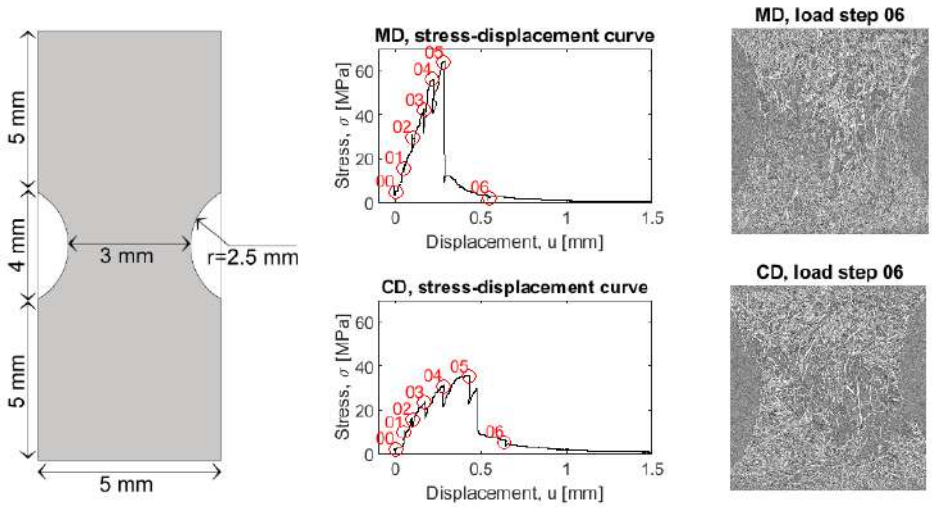

Figure 1. Left: Sketch and dimensions of the samples. Middle: Macroscopic stress-displacement curves. Right: Visualisation of the fractured samples at loading step 06 (centre of the image stacks).

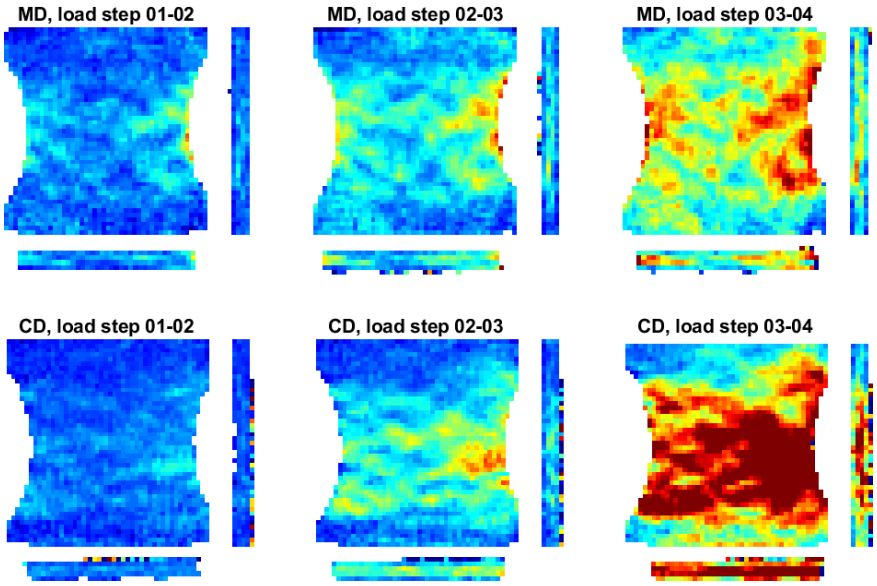

Figure 2. Volumetric strain fields (colour scale -1-8%). The 2D visualisations represent the centre of the volume in each direction.

The difference between MD and CD in terms of strain field evolution and fracture patterns is interpreted as a consequence of the main fibre direction, i.e. vertical in MD and horizontal in CD. A possible explanation is that the CD sample failure results from separation of fibres, while in the MD sample, vertically aligned fibres might break or elongate. More analysis at the resolution of single fibre behaviour is needed to verify these hypotheses and to fully understand the processes underlying the strain field evolution and fracture processes.

A TRANSIENT THERMAL ANALYSIS OF A FAST RESPONSE HEAT FLUX SENSOR

Konstantin Huber* [1] and Tim Rödiger † [1]
[1]Department of Mechanical Engineering, University of Applied Sciences Landshut, Landshut, Germany

Summary The measurement principle of heat flux sensors based on the transversal Seebeck effect (TSE) require homogeneous temperature differences across their active layers. A transient thermal analysis using 3D FEA is applied to investigate the TSE-based Atomic Layer Thermopile (ALTP) sensor in combustion environments. Studying the location depending temperature difference of the top and bottom side of the active layer while applying highly transient thermal engine loads shows a homogeneous distribution over the active surface. The results indicate that the presented sensor design leads only to small thermal disturbance effects within the active layer and make it applicable to engine diagnostics.

SENSOR DESIGN

The active layers of TSE-based ALTP sensors have a thin tilted layer structure made out of Yittrium-Barium-Copperoxid (YBCO) and Copperdioxide ($Cu0_2$) with approx. $500 - 700\,\mathrm{nm}$ thickness and an active surface of $1 - 6\,\mathrm{mm}^2$ fabricated on top of a strontium titanate substrate ($SrTiO_3$). The induced output voltage U_{ALTP} is calculated by

$$U_{ALTP} = 0.5\, l\, \sin 2\gamma\, \Delta S\, \Delta T\, d^{-1} \tag{1}$$

and directly proportional to the incident heat flux density, when a constant temperature difference over the sensor's active layer (top vs. bottom side) is present (γ is the tilt angle, d is the thickness and l the length of the active film, ΔS is the difference of the Seebeck coefficients of the two materials) [1]. Previous studies concerning measurements in supersonic wind tunnels demonstrated the accuracy and time constant in the microsecond range in short-duration measurements based on a semi-infinite wall assumption for the substrate [2].

However, long duration measurements like combustion applications violate the semi-infinite wall assumption and lead to significant changes in the boundary conditions of the active layer. This study investigates therefore changes in the temperature distribution leading to resulting voltage and calibration assumptions. The electrical signal connection to the active layer is made via a thin gold layer, an electric conductive adhesive and copper cables (Figure 1a).

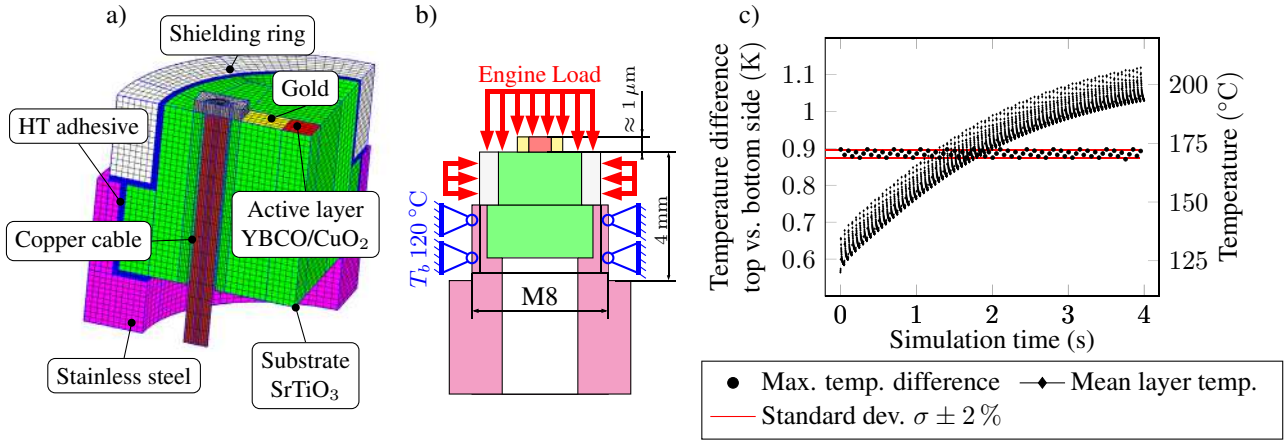

Figure 1: a) Schematic view of the discretized ALTP module, b) sectional view of the module and its thermal boundary conditions, c) time progression diagram of the temperature difference and the mean temperature of the active layer.

SIMULATION SETUP AND RESULTS

The sensor module is discretized using micrometer scaled hexahedron second order elements (C3D20). Making use of symmetry characteristics in two directions lead to a quarter model (Figure 1a). The active layer and the gold contact are modeled with 10 layers and an overall thickness of $1\,\mu\mathrm{m}$ with increasing discretization fineness towards their contact region. The anisotropic active film (nm-layered) was modeled like the rest of the sensor module as homogeneous isotropic structure with thermal parameters proposed by Zeuner [3]. Due to fast changing thermal loads on the front surface, the time step is chosen to $0.7\,\mathrm{ms}$.

*Corresponding author. E-mail: konstantin.huber@haw-landshut.de
†E-mail: tim.roediger@haw-landshut.de

It should be noted that this study constitutes an ideal situation with regard to disturbing effects like location depending thermal loads, contact resistances (neglected) or differences in the manufacturing process of the active layer. As thermal boundary conditions a constant thread temperature of $T_b = 120\,°\mathrm{C}$ is assumed (Figure 1b). The thermal load on the front side is discretized in $10\,°\mathrm{CA} - 0.7\,\mathrm{ms}$ steps, measured for a single cylinder 4-stroke engine with a cylinder volume of $485\,\mathrm{cc}$ and manifold injection operating at $2400\,\mathrm{rpm}$ and $4.4\,\mathrm{bar}$ mean effective pressure [4].

In order to investigate possible temporal variation in the temperature difference of the active layer, the mean nodal temperature values of the top- and bottom side are subtracted from one another and displayed in Figure 1c. Despite slightly varying maximum values ($\sigma \pm 2\,\%$) for each load peak the temperature difference stays constant over time although the mean layer temperature illustrated in diamonds rises by approx. $80\,\mathrm{K}$ and highly transient loads are present.

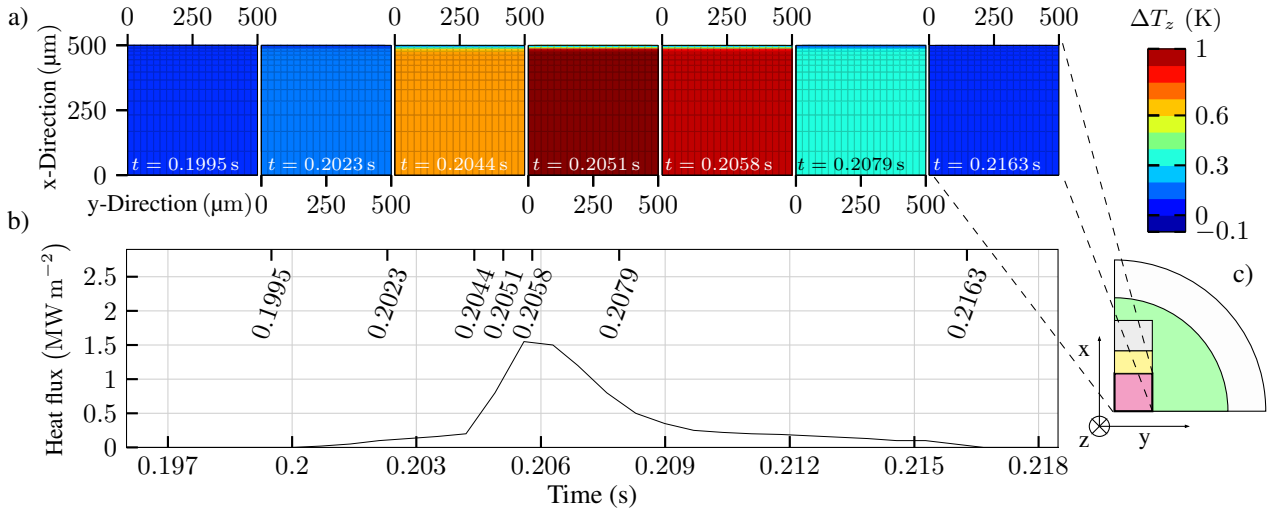

Figure 2: The time and location depending 2D-temperature difference distribution (Fig. 2a) of the active layer for one load cycle (Fig. 2b) is shown. Fig. 2c displays a top view schematic of the considered active film area for better orientation.

Figure 2a shows the temperature difference distributions of the active layer for selected time steps along the load cycle. The temperature difference rises and reaches a maximum of approx. $1\,\mathrm{K}$ for $t = 0.2051\,\mathrm{s}$ shortly before the maximum heat load in the cycle. Afterwards the temperature difference decays again and reaches around $0\,\mathrm{K}$ as at the beginning of the cycle.

The temperature distribution is homogeneous over the active surface along the entire cycle, only for $x > 490\,\mu\mathrm{m}$ a trend towards reduced local temperature differences can be observed when thermal loads are present. This reduction can be explained by the adjacent gold layer for $x > 500\,\mu\mathrm{m}$ (not displayed in Fig. 2a) with a much higher thermal product as the active layer that acts as heat sink. In the immediate vicinity of the gold layer the temperature difference is reduced to approx. one hundredth of the difference in the unaffected area. This reduction could lead to measurement errors of the heat flux sensor and different boundary discretizations varying in their fineness are used to estimate the affected active sensor area. The discretization study shows that the affected area for which $\Delta T < 0.9 \cdot \Delta T_{\mathrm{unaffected}}$ is rather small and makes up only $2\,\%$ of the overall active surface area.

CONCLUSION

FEA analysis can be used for the design and layout of heat flux sensors based on TSE. It is possible to estimate local and time-dependent temperature difference disturbances of the active layer that can lead to systematic errors of their working principle. The FEA investigation of a specific ALTP-sensor in a combustion induced load cycle shows a fairly constant temperature difference distribution over the top and bottom side of the active layer and a homogeneous temperature distribution over the surface. The studied design seems promising for the use in long duration and highly transient scenarios like combustion engine measurements.

Summary The deformation of a metamaterial (i.e., millimetric pantograph) in a bias extension test is measured via digital image correlation (DIC) performed at different scales. Thanks to the gray level residuals, the microscale results are found to be in better agreement with the experiment than mesoscale and macroscale analyses. Fine analyses around the hinges show that relative displacements occur between the two beam layers of the pantograph.

INTRODUCTION

Pantographic structures are characterized by two families of equally spaced beams interconnected at their intersection points via cylindrical pivots. These structures, realized by using standard devices in additive manufacturing (3D printing), can be described as metamaterials since they have been designed upon the basis of 2nd gradient theories of continuum mechanics [1, 2]. Such material systems are peculiar due to their ability to undergo large deformation (> 50 % stretch) while remaining elastic. The present effort is motivated by the requirement to characterize the detailed deformation of pantographic unit cells formed of two orthogonal sets of 3 beams. They are subjected to tensile experiment and digital image correlation (DIC) will be applied to extract the details of their deformation.

DIC consists in registering images acquired during mechanical tests [3]. From such analyses, displacement, strain and residual fields are obtained. For the experiment reported herein, FE-based DIC will be applied at three different scales. Hencky-type regularization (i.e., incremental elastic regularization) is implemented [4]. Thanks to such type of regularization, large strains can be achieved without penalizing too much the registration scheme. Further, focused analyses about the hinges will also be carried out via global DIC at the microscale.

DIC ANALYSES OF BIAS EXTENSION TEST

The specimen considered in this analysis was designed to represent the unit cell behavior of pantographic structures. The sample was fabricated using a 3D printer using the SLS (selective laser sintering) technology with polyamide powder (PA2200) with average grain size of 56 μm. The pantographic unit cell specimen was subjected to tensile loading in step-by-step quasi-static conditions in displacement control mode. The grips connecting the specimen to the loading machine are designed to apply an axial tensile action and resist the overall specimen rotation about the loading axis. For measurements of displacement fields, the specimen grips were sprayed on their surface to make a black speckle pattern prior to the testing. However, the surface of the beams was just marked by a set of crosses whose distance is about 30 pixels. Such situation required the regularization to be adapted and a size of $\ell_{reg} = 150$ pixels enabled all DIC calculations reported herein to converge.

Multiscale Meshes

Each of the following meshes is made of 3-noded triangles (T3). First, a macroscopic mesh encompassing the pantographic structure is considered (Figure 1(a)). The sought kinematics then corresponds to the macroscopic response of such materials. The average element size ℓ, which is defined as the square root of the mean element surface, is equal to 12 pixels.

Second, T3-based DIC registrations are also performed at the mesoscale. The external geometry of the pantographic structure is explicitly accounted for, but the kinematics is that of an underlying FE mesh in which the hinges are not explicitly described (Figure 1(b)). The mesh is tailored to the pantograph surface via simple morphological operations [2]. The average element size ℓ is equal to 10 pixels.

To account for the 11 hinges, a third (i.e., microscopic) mesh is constructed. Each beam of the pantograph is individually meshed (Figure 1(c)) with a mean element size $\ell = 11$ pixels. Consequently, the two meshes overlap in the intersection areas about each hinge. An additional operation was needed, namely backtracking the mesh constructed on the nominal geometry of the pantograph [4]. The hinges can then be recreated by using Lagrange multipliers prescribing the corresponding kinematic constraints (in terms of nodal displacements) in the registration systems to solve, or the kinematics of two beam systems can be left free. The beams were therefore allowed at least to rotate about each hinge, which was not possible in the mesoscopic analyses. The two supports of the pantograph were also meshed with two triangular elements and connected to the corresponding hinges of the pantograph.

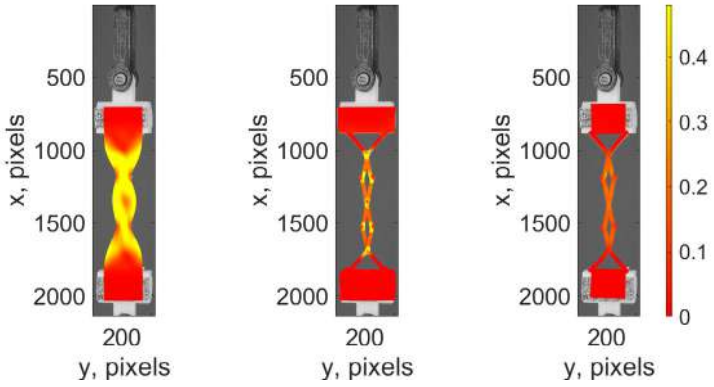
Figure 1: Different meshes used in DIC analyses at (a) macroscopic, (b) mesoscopic, and (c) microscopic scales

Comparison of Different Kinematic Hypotheses

In the following analyses, only the state corresponding to the maximum stretch will be reported. From the measured displacement field, the strain field is computed by exact differentiation of the shape functions of T3 elements. In the present case, the Green-Lagrange strain measure will be reported. The maximum level of the color bar corresponds to 1.5 times the overall Green-Lagrange strain (i.e., computed from the length variation between the two supports). Figure 2 shows the maximum principal strain fields for global DIC analyses at different scales. For the macroscopic mesh (Figure 2(a)), the strains are very high in most of the sample. For the mesoscopic mesh (Figure 2(b)), the strains concentrate in the vicinity of the hinges, but the beams also experience significant elongations, except those that are connected to the two supports. For the microscopic mesh, the strains remain lower everywhere and do not concentrate around hinges (Figure 2(c)). However, the strains in the beams do not vanish, which indicates that some strain energy was stored in the pantograph.



(a) Macro (b) meso (c) µicro

Figure 2: Maximum principal strain for DIC analyses at various scales

Table 1: RMS residuals (expressed in gray levels) corresponding to the analyses shown in Figure 2

Scale	RMS(ρ)
Macro	30 GL
meso	15 GL
µicro	8 GL

The choice of any discretization is probed by computing the correlation residual field ρ and its RMS level. The lower the latter, the more trustworthy the measured displacement field. Table 1 shows that the macroscopic kinematics leads to an RMS level that is twice as high as that at the mesoscale, itself twice as high as that at the microscale when no kinematic constraint is applied to the hinges. Such results are very useful for devising models that can be written at various scales.

SPATIALLY DISTRIBUTED TRANSVERSE ISOTROPY AROUND A HOLE: FROM PARAMETER IDENTIFICATION TO VALIDATION

Stefan Hartmann* [1], Rose Rogin Gilbert[1], and Ali Kheiri Marghzar[1]
[1]Institute of Applied Mechanics, Clausthal University of Technology, Clausthal-Zellerfeld, Germany

Summary Usually fiber-reinforced composite sheets are drilled to join them together with rivets. In this case, the fibers are cut and the load cannot be transferred directly via the fibers. Alternatively, the fibers can be bypassed around the holes leading to a different stress-strain state. To investigate the structural behavior, we have to model the spatially distributed anisotropy, where we draw on a model of transverse isotropy, and to determine the material parameters. Thus, a detailed discussion of both the spatially distributed fiber orientation as well as material parameter identification has to be held, especially if the parameters should be addressed uniquely. Experiments for the purposes of both parameter identification as well as validation are proposed.

INTRODUCTION

We follow a question in composite technology to avoid the drilling of fibers to obtain holes inside a composite plate, see sketch 1. In this case, the fibers are placed around the hole leading to a different stress and strain state. Here, we restrict

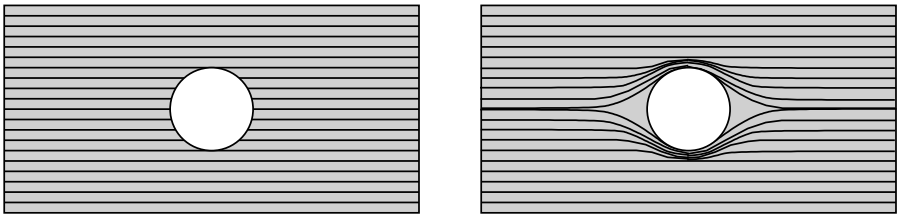

Figure 1: Comparison of two fiber orientation samples (left: uniform, unidirectional fiber orientation – classical technology, where the fibers are drilled; right: fibers bypassing a hole)

ourselves to unidirectional fiber orientations. The classical approach, we call it *uniform, unidirectional fiber orientation*, the material properties are assumed to be constant over the specimen. The case where the fibers are placed around the hole is called the *bypassing case*. From the perspective of modeling, we need the material parameters for transverse isotropy, where we assume small strains and linear elasticity. Even this seemingly simple approach reveals some challenges: first, the modeling of the fiber orientation, and, second, the unique determination of the material parameters.

B-SPLINE APPROACH FOR FIBER ORIENTATION

A common approach in finite element simulations is to assign an estimated but constant fiber orientation to a small region. This yields discontinuities in the stress-strain behavior. In [1] a first continuous approach using streamlines around a circular region is proposed. Although this leads to reasonable results, it does not reflect the real fiber orientation. Therefore, digital images were taken during the manufacturing process of the composite plates, where the fiber orientation could be seen. Afterwards, the images are evaluated and B-splines are chosen to interpolate the coordinates assigned to the fibers. One of the two coordinate lines of the B-splines "surfaces" represent the fiber line, and the orientation can be determined by the tangent vectors, see [2]. Consequently, a continuously spatial representation of the fiber orientation is available so that individual fiber orientations at each Gauss-point within a finite element can be assigned.

PARAMETER IDENTIFICATION OF TRANSVERSE ISOTROPY

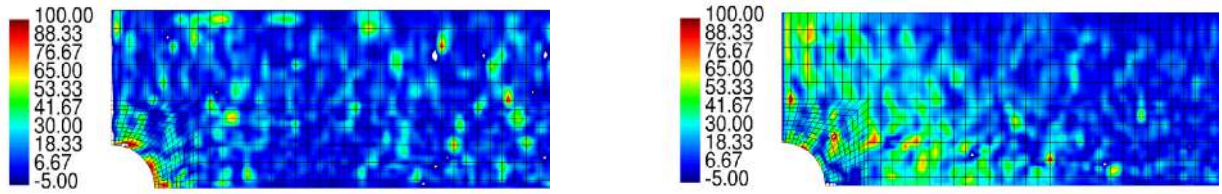
The second question to be addressed is the issue of unique parameter identification to determine the five material parameters of linear elastic, transverse isotropy. A current approach is the application of digital image correlation systems (DIC-system) and to evaluate three different orientations of the fibers in an uniaxial tensile test (e.g. fiber angles relative to loading direction $\gamma = 0°, 45°, 90°$) and compare it to finite element solution. However, it turns out that this does not address all parameters. A concept to obtain a hint whether the parameters are identifiable is given by [3]. In this case, the Hessian of a quadratic Taylor-series in the solution of the optimizer is drawn on and its determinant is investigated. If it is singular, the parameters cannot be identified uniquely. This, however, has to be done with the same experimental process, but with a re-identification step using purely numerical results, see [4]. Alternatively, a detailed study using analytical results is provided in [5] showing that various experiments are required, tension for $\gamma = 0°, 90°$, shear, and a particular compression test. This compression test requires either a new (and very sensitive) experimental device or

*Corresponding author. E-mail: stefan.hartmann@tu-clausthal.de.

using a numerical representative volume element, where at the pure matrix material the elastic parameters have to be determined as well. We combine the DIC/FEM-approach with the necessary experiments as well as the evaluation of identifiability leading to reliable parameters. Accordingly, we require four tests for the composite plus one test at the pure matrix material times five repetitions for reproducibility aspects. The whole concept and the experiments are shown in detail.

VALIDATION

After the determination of the parameters, the comparison of plates with a hole where the fibers are cut, and where the fibers bypass the holes is performed both experimentally and numerically. For this purpose, experiments for the different samples are performed and the surface strains are determined using a DIC-system. To circumvent the critical approach of comparing only optically resulting images, the surface strains of the DIC-system and those of the finite element simulations are evaluated numerically. Consequently, we obtain real errors between the finite element simulation and the DIC results, see Fig. 2. In this context, it must be mentioned that the evaluation of displacements implies the



(a) Unidirectional fiber orientation (b) Bypass approach

Figure 2: Relative strain error of maximum principal strain. Comparison of unidirectional fiber orientation and bypassing approach. Here, only one-eighth of the sample and the DIC-region is shown (modeled with 20-noded hexahedral elements).

consideration of the rigid body motion of the experimental device, which is very difficult to avoid. Thus, the strain determination concept in [6] is drawn on, where the strain data of one program (e.g. DIC) can be projected to the other system (e.g. FEM).

CONCLUSIONS

A detailed study to obtain both the continuous fiber distribution as well as unique material parameters for linear elastic, transverse isotropic material is provided using a DIC/FEM approach. Particularly, identifiability is a specific challenge. Moreover, the continuous representation of the spatially inhomogeneous fiber orientation is a further issue, where one possibility is the application of B-splines. Various experimental tests are performed to identify the parameters and to validate plates with a hole, where, on the one hand, uniform fiber directions are chosen and the holes are drilled, and, where, on the other hand, the fibers bypass the holes. The validation examples provided show direct numerical errors, and not a statement of a visual comparison whether the simulation is good or bad.

DELAMINATION TESTS ON CFRP-REINFORCED MASONRY PILLARS: EXPERIMENTS, OPTICAL MONITORING AND FINITE ELEMENT MODELLING

Roberto Fedele[1], Gianpaolo Rosati[1], Marco Scaioni[2], Gabriele Milani[2]
[1]Department of Civil and Environmental Engineering (DICA), Politecnico di Milano, Milano, Italy
[2]Department of Architecture, Built Environment and Construction Engineering (ABC), Politecnico di Milano, Milano, Italy

Summary Masonry pillars constituted of historical bricks and mortar joints, externally reinforced by CFRP strips, were subjected to 1-tonn delamination tests to investigate their mechanical response up to failure. The experiments were monitored by conventional point gauges and by no contact, full field 2D Digital Image Correlation technique. Recourse was made to a three dimensional, heterogeneous finite element model with isotropic damage, under the simplifying assumption of perfect adhesion of the reinforcement sheet, to simulate the macroscopic behaviour of the reinforced pillar as a function of complex dissipative mechanisms which develop inside the quasi-brittle bulk.

RETROFITTING AND REPAIRING INTERVENTIONS

For the historical heritage and monumental buildings, possibly affected by chemical–physical ageing processes and deteriorated by past accidental events (such as earthquakes), there is a special need for sustainable retrofitting and repairing interventions, to increase the in-plane shear resistance, to provide out-of-plane bearing capacity, or also to reduce seismic vulnerability, see e.g. [1-2]. Fiber-Reinforced-Polymers (FRP), and especially those made of carbon fibers (CFRP), are available as stiff sheets ready to be glued to the support, or alternatively as multi-directional tissue to be embedded into grout and adhesive layers. Since one decade at least, such reinforcements have been widely used in rehabilitation works for several reasons: (i) they do not increase the structural mass, due to their excellent "specific" stiffness and strength; (ii) they are extremely simple to apply and can adhere to differently shaped surfaces such as arches and vaults [3], even irregular or very rough; (iii) they turn out to be non-intrusive and non-destructive since exhibit low impact on the pre-existing scenario. Due also to the technical progress in high strength adhesives, the CFRP/masonry interface has to be considered no longer as the weakest element of the system, and complex damage mechanisms are expected to develop within the bulk of quasi-brittle masonry when loaded up to failure.

SINGLE-LAP SHEAR TESTS

The effectiveness of the glued reinforcement on the overall behaviour of the structural element was assessed by single-lap shear tests, see [1]. An ad hoc steel frame, with additional stiffening rods, was realized to prevent rigid body motion of the pillar during the 1-tonn experiments, whilst prescribing a tangential slip between the reinforcement and the support, see Figure 1. The experiments were performed under closed loop control, with feedback signal provided by a clip gauge located at the anchor of the strip. This provision allowed a stable control of the tests also along the post peak branch, which would result in a snap back behavior if referred not only to the stroke but even to the LVDTs located closely to the notch. The clip gauge measured the tangential slip of the reinforcement with respect to the substrate, disregarding the overall deformation of the pillar and a large part of the initial, elastic deformation of the FRP strip itself. A single camera was utilized to monitor in real time the reinforced surface (average pixel footprint on the object was about 84 μm), exploiting the natural texture of the masonry, and picture sequence was processed by 2D Digital Image Correlation (DIC), see [4-8]. Sources of inaccuracies for the kinematic measurements by a single camera were carefully assessed by comparative benchmark tests, and corrective provisions were implemented including camera calibration by Brown's model and homography registration [1]. Full field measurements allowed us to detect local slips of the reinforcement with respect to the underlying masonry substrate. In the present scenario, data from DIC were especially useful to estimate the "actual" history of relative displacements at the notch of the reinforcement, to be prescribed to the finite element model as boundary conditions. Moreover, kinematic measurements were utilized to calibrate the effective elastic properties of the reinforcement, resulting from the superposition of several layers (primer, grout and epoxy adhesive). In fact, Young's modulus of the CFRP strip turned out to be markedly different from the nominal value corresponding to the carbon fibers, and in agreement with a basic mixture rule. As expected, the nonlinear response up to failure of the reinforced pillar was dominated by the strength of the substrate, namely by damage mechanisms occurring within the masonry bulk: this circumstance was confirmed by post-mortem inspection of the debonded material, including thick layers of the substrate.

FINITE ELEMENT MODELLING

A three dimensional, heterogeneous model of the pillar was developed in Abaqus® environment [9], enriched by a VUmat Fortran routine [10] for user defined constitutive relationships. Brick and mortar were described as elastic damageable phases by an isotropic damage model, see [1-2,11]: their different parameters were estimated on the basis of compressive tests, when necessary integrated by literature suggestions. The FRP reinforcement was assumed to behave elastically and to perfectly adhere to the substrate, without the need of intermediate layers closely to the interface. A strategy for fracture energy regularization based on a characteristic length was implemented at the level of element routine,

leading to a satisfactory objectivity of the overall response, resulting almost independent of the adopted discretization. In the presence of severe damage, recourse was made to an explicit integration scheme for the simulation of the quasi-static tests. Small time steps (corresponding to about 10^{-6} of the final prescribed displacement) were required for the conditional stability of the analyses, confirmed by an amount of kinematic energy not increasing along time and negligible with respect to cumulated internal energy. To decrease the computational effort (up to 120,000 elements were included within the finest discretization), 8-node brick elements with reduced integration were utilized. Moreover, when local value of damage variable exceeded a suitable threshold (close to unity), elements were deleted from the analysis ("erosion" strategy). Model predictions indicated, along the initial branch, damage propagating within a thick region close to the reinforcement: at approaching the overall peak, a wide, spoon shaped damaged region developed starting from the strip anchor, see [11]. This scenario was in satisfactory agreement with post mortem analyses of debonded material.

IN-SITU KINEMATIC TRACKING VIA RUGGED MULTI-SENSOR MEMS UNITS

Andrin Caviezel * [1], Adrian Ringenbach[1], Miguel Sanchez[1], Marc Christen[1], Philipp Mayer[2], Michele Magno[2], Luca Benini[2], and Perry Bartelt[1]
[1]WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland
[2]ETH Zurich, Integrated Systems Lab IIS, Zurich, Switzerland

Summary The development in miniaturised microelectronic mechanical systems (MEMS) sensors during the last decade driven by growing needs for autonomous driving and unmanned aerial vehicle navigation lead to a giant performance increase. Here, we present data acquired via rugged low-power multi-sensor nodes, that have been designed to acquire and log accurate inertial sensor measurements during induced in-field experiments with falling rocks and moving avalanches. Field experiments have been carried out with several differently shaped rocks on typical terrain in the Swiss alpine region. The sensor streams are integral part of an excessive experimental campaign, studying influence of rock shape and mass. Using equally shaped rocks with masses up to 2670 kg offers for the first time systematic insights on rock kinematics and its dependence on the rock mass.

INTRODUCTION

Rockfall hazard engineers face the erratic problem of predicting runout distances, jump heights and lateral dispersion of falling rocks. The better the accuracy of this information the more reliable are the design of danger maps and the higher the cost-efficiency of protection methods such as rockfall dams and nets. With the advent of affordable and available computer power such risk assessments rely on three-dimensional rockfall modelling as standard technology. The calibration and refinement of any used model pose a challenging task and to date relies heavily on case study back calculations. Experimental trajectory analysis paired with in-situ MEMS data can help to calibrate constitutive models and/or numerical model input parameters [1]. Here, we present for the first time in-situ acceleration and gyroscope data streams covering the a mass range from 45 kg up to 2670 kg used at the experimental campaign *Chant Sura* [2] gathered over the last three summer seasons.

INERTIAL MEASUREMENT UNIT DEDICATED TO HIGH IMPACT KINEMATICS

The hardware platform used in the presented work has been under development since 2016 and has been steadily upgraded and improved. Selection of suitable MEMS is of upmost importance for a reliable and functional design of a sensor node dedicated to high impact and high speed motions. In the fast evolving electronic world, consumer grade chips in the range up to ± 16 g and ± 2000 °/s are succumbed to even shorter support times and decommissioning cycles. The used, specialised InvenSense ITG-3701 full scale range 3-axis gyroscope for high impact wearable, high speed motion applications with maximum measurment range of ± 4000 °/s as well as the STM accelerometer H3LIS331DL with its maximal range of ± 400 g have been active and supported for new designs over the last years. Both sensors allow for a sampling rate of 1 kHz, resolving the short duration impact kinematics in rock-ground or rock-net interactions. The so-called *StoneNode v4.0* is the upgraded version of an earlier design presented in Ref. [3]. The most recent layout is shown in Fig. 1a with its three- jaw fixation chuck used to place at the centre of mass of any given test block in induced rockfall experiments shown in Fig. 1b. Upgrades for extended pressure measurement options are the Bosch Sensortec BMP3870 and the STM LSPS22HH targeting consumer drone applications and therefore rather high sampling rates of 200 Hz included in redundant design in the *SnowNode* option (see Fig. 1c).

RESULTS

Figure 2 shows the gyroscope and accelerometer sensor stream for selected runs for cubic EOTA rocks (norm rock of the European Organisation for Technical Assessment used in standardised rock fence testing procedures in official European Technical Approval Guidelines) with masses between 46 and 2670 kg collected at the *Chant Sura* test site [2]. Sensor failure prevents the acceleration data of the 2670 kg block to be present. The gyroscope plots feature a maximum ordinate range of 4000°/s, the maximum measurement range. The decrease in rotational speed owing to an ever growing moment of inertia is nicely visible. While the rotational velocity pattern of the EOTA_{45kg} and EOTA_{2670kg} feature a rather continuous increase and decrease - the pattern of a rock speeding up in a homogeneous slope and continuously rolling out due to flatter terrain - the EOTA_{220kg} and EOTA_{840kg} resultant angular velocity features sharp drops signifying heavily energy dissipating impacts. The individual nature of such an impact needs detailed analysis as such pattern can arise due to a heavily scarring impact into soft, compactable soil or due to opposing faces of rigid objects alike.

CONCLUSIONS

We present novel data from *StoneNode* IMUs a rugged low-power sensor device dedicated to the acquisition of rockfall dynamics in induced experiments. Such real scale tests are vital ingredients for the development and refinement of constitutive laws for accurate simulation models. The selected approach to deploy equally shaped rocks in different masses strives towards coming up with generic rock-terrain contact models that are independent of rock size and shape. The presented in-situ data allows do gain direct insights into the different impact behaviour caused by varying boundary conditions and configurations. The acting forces act over very short time periods and are impossible to average or linearize. Further analysis will allow to come up with empirically based laws for the rock-terrain contact and reconstruct and forecast acting forces for varying impact conditions. Future application might feature trajectory reconstruction via sensor fusion approaches complementing existing techniques based on external surveying techniques.

SIMULTANEOUS STRAIN AND TEMPERATURE FIELD MEASUREMENT TECHNIQUE BASED ON DIGITAL IMAGE CORRELATION AND THERMOGRAPHIC PHOSPHOR THERMOMETRY

Tao Cai[1], Taekyung Lee[1], Yoon Seong Park[1], Kyung Chun Kim*,[1]
[1] School of Mechanical Engineering, Pusan National University, Busan 46241, Korea

Summary: A two-dimensional (2D) phosphorescence-based strain and temperature simultaneous measurement technology is presented in this study. Here, 6 μm size MFG phosphor particles was sprayed to the surface of test target as sensor. A measurement system was established which included a high-speed camera, a 385nm LED, and a signal generator. The signal generator controls the LED to output a 100 Hz pulse light to excite the phosphor. The phosphorescence was then detected by the high-speed camera with a frequency of 10 kHz. The temperature information was obtained by the phosphorescent decay rate using lifetime method. The digital image correlation (DIC) method was then used with the random markings formed by spraying. A 100 Hz temperature and strain measurement technology is implemented based on the current experimental conditions. The measurement procedure was used for measurements of temperature and deformation of aluminum plate with pulsed current. The results from experiments showed the possibility of 2D measuring surface temperature and strain in a harsh environment with a non-invasive method.

INTRODUCTION

Temperature and strain/stress are usually highly coupled in many areas such as electronics package[1], electricity transportation[2], aerospace engine[3], new type battery[4], and so on. The acquisition of accurate temperature and stress-strain fields will help optimize the product and improve the engineering quality. Besides, an important capability is to measure both temperatue and strain/stress at the same time, which could continue to further the understanding of mechanics, suhc as thermal stress/strain. However, in many cases, the measurement environment is very harsh (high temperature, high voltage, high magnetic field), which limited access to these parameters. Therefore, a non-contact or semi-contact optical technology for multi-physics measurement of temperature and strain/stress is need to meet the needs.

DIC is an importantand widely used non-contact technique for measuring material strain[5]. It can obtain the strain information by calculating the displacement of the feature points of the two images. At present, it has been developed into two-dimensional or even three-dimensional measurement technology. Although it has been highly developed, the only access to strain information limits its application. Thermographic phosphor thermometry (TPT) is a temperature measurement technique based on the thermal dependence of phosphor luminescence[6]. Due to its non-intrusiveness, high accuracy, and high spatial resolution, TPT has clear advantages over traditional techniques, such as thermocouples, pyrometry, and infrared thermography. During the application of TP, the phosphor particles usually be sprayed onto the surface of the object to be measured. Uneven spraying will create random speckles on the surface.

Based on the speckles created by the spray, it is possible to achieve a simultaneous measurement of temperature and strain combined with DIC technique. In the present work, the lifetime method has been used to measure a two-dimensional temperature distribution. Simultaneously, the DIC will be used to caculated the strain during the temperature changes.

METHOLODLOGY

In current measurement technique, a signal generator was used to control the excitation and high-speed camera. The timing chart of excitation light (here is a UV LED) and camrea is shown in figure 1. The LED will output a f_{Ex}=100 Hz pulse light to excite the phosphor. At the same time, the high-speed camera will record the excitation and decay of the phosphorescent signal at a frequency of f_{Ca}=10 kHz. Figure 2 shows the excitation and decay of phosphorescence over two cycles using the high-speed camera. As shown in Figure 2, the temperature information could be obtained by the decay of phosphorescence. Simultaneously, using the random speckles (shown in Figure 3, right) as feature points, strain

*Corresponding author: Kyung Chun KIM. E-mail: kckim@pusan.ac.kr

information could be obtained by DIC technique. Both of the frequency of temperature and strain acquisition is 100 Hz.

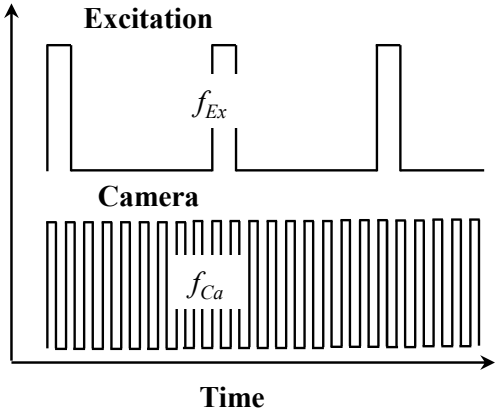

Figure 1 Timing chart

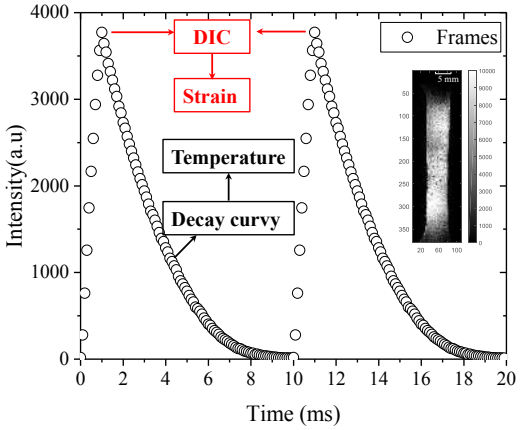

Figure 2 Schematic diagram of obtaining temperature and strain

The technique was applied in the measurement of heating and thermal strain of a aluminum strip during a high voltage current passing through it. The experimental setup was shown in figure 3. A pulse current of up to 1000 A will pass through the aluminum strip. Due to the self-existing resistance, the aluminum strip will instantly be heated up and deformed. Figure 4 shows the measured temperature and strain fields.

A TRIBOLOGICAL SCALE DOWN FROM RIG TEST TO LAB TEST: ANALYSIS ON SRV EXPERIMENTAL RESULTS AS A SCREENING FOR FZG RIG TEST

Davide Massocchi[1]*, Marco Lattuada[2], Paolo Pennacchi[1], Steven Chatterton[1]
[1]Department of Mechanical Engineering, Politecnico di Milano, Milano, Italy [2] Eni SpA, Downstream product R&D, Milano, Italy

Summary Governments and institutions have sustainable development goals: the improvement of energy efficiency and the reduction of CO_2 emissions, in a "green economy" approach, currently become the fundamental drivers that push research and development activity towards the optimization of rotating machines components, in the industrial sector, with special focus on lubrication systems too. In order to face the numerous challenges of the future, Eni and PoliMI (Politecnico di Milano) have decided to support a doctoral research activity on the specific topic of Tribological Methodologies [1] to support the development of innovative lubricating oils. Basically, the activity is directed towards the optimization of tribological testing methods and equipment for better discriminate the performance of lubricants in operating conditions as much predictive as possible of real applications. In this context, the present paper describes the results of an experimental campaign based on the use of a well selected SRV* tribometer procedure as a screening of a rig test, the FZG** test, leading to concrete benefits as saving time and operative costs. Four cases for the determination of failure load stage of SRV have been defined and, in many cases, a good correlation with FZG rig test has been found. A very good repeatability of this method has been proven too. The aim of the authors is to continue the experimentation, thus providing a more robust evaluation also considering the impact of lubricant formulation.

Keywords: Tribological test, energy efficiency, rig test, screening

1. Method setup

A widely used test method to evaluate load carrying capacity in industrial oils is the FZG test A/8.3/90. A-type gears, wheel and pinion, are loaded stepwise in 12 load step stages from a Hertzian stress of 146 to 1841 N/mm^2. The step time duration is 15 minutes and the starting oil temperature is 90 ± 3 °C, under conditions of dip lubrication without cooling. Gear flanks are inspected after each load stage for scuffing marks. Failure load stage is indicated when the wear area detected on all pinion teeth exceeds the area of a single tooth. The Optimol method[3] aims to screen and reproduce the scuffing rig test using the SRV tribometer. The concept is to reproduce the Hertzian contact pressure used in the FGZ test rig using the cylinder on disk contact for the SRV test: the load steps for the SRV EP procedure are presented in Table 1.

FZG load step	1	2	4	6	8	10	12	14	16	18
Hertzian surface pressure [N/mm²]	146	295	621	929	1223	1539	1841	2170	2465	2777
SRV® normal force [N]	7	28	126	282	489	774	1107	1538	1985	2520

Table 1 Loads of SRV procedure according to Hertzian contact pressure in FZG loads steps[2]

The duration of each step is 217 seconds, which is a result of prior investigations [5]. The conditions for the step test are the following: the temperature is 98°C, stroke is 2 mm and frequency is 50 Hz. We have defined threshold values of some parameters for test execution, the so-called cut-off values. In particular, for this experimental campaign we set the following cut-off values of COF and stroke: 0.3 as maximum COF and a stroke deviation of maximum 55%. We fixed these values for two main reasons: on one hand for safety operation, as to quickly block test run while high seizure occurs; on the other, the above limits selected allow us to detect also microseizures and seizure (of limited intensity) helping in the qualitative analysis of COF profile. The SRV (Fig. 1) is a very versatile device for measuring the coefficient of friction and the wear and EP characteristics of lubricating oils and greases under various operating conditions. In addition to the standard tests this equipment is very well suitable for in-house tests in order to simulate, on a laboratory scale, operating conditions that often occur in operation of machinery/components/circuits. For the evaluation criteria of oil performances and failure load stage assignment, in our experimental campaign we defined four cases described in the third section.

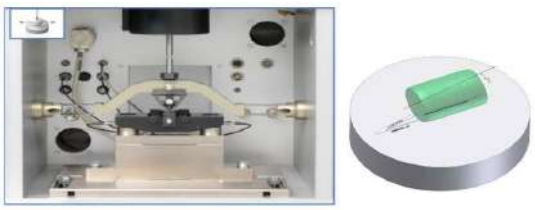

Fig. 1 SRV tribometer & Cylinder on disk[3]

2. Experimental campaign

The coupling selected, for the experimental campaign, is cylinder on disk. The lower specimen is a disk Ø 24 x 7.9 mm, made of hardened rolling bearing steel AISI 52100 / 100Cr6. The upper surface is polished and aligned at 10° to the direction of movement along its longitudinal axis (cf. Fig. 1). The lubricants tested are commercial gear oils, turbine oils and circulating oils. Specimens' surfaces were ultrasonically cleaned in ethanol for 5 min; after mounted and locked with a torque wrench with a load of 30N. We use the SRV EP procedure with the only difference of temperature (T = 90°C instead of 98°C). A very small amount of oil sample is needed and the operator should dry both the upper and lower specimens during the setting phase. The procedure is done for each oil for a minimum of three repetitions and is defined as good repeatability a difference of ± 1 stage.

*SRV stands for Schwingung (Oscillating), Reibung (Friction), Verschleiž (Wear)
* *FZG stands for "Forschungsstelle fur Zahnrader und Getriebebau", the Technical Institute for the Study of Gears and Drive Mechanisms

3. Experimental results discussion and conclusion

In this section we present in detail some experimental results and we discuss the relationship between rig test and laboratory test. Fig. 2 shows the simplest case: during the test we detect the presence of a net COF peak; in correspondence of this the tested oil reaches the failure load stage. In Fig. 3, in the last steps, we see an increase in the COF profile without huge peak or multiple small peaks and any thickening of the curve; for this reason, we can conclude that the oil has passed all steps of the procedure. In our campaign we assign to this oil an SRV failure load stage >12, even if the stages of SRV procedure are 17. In fact, in order to be comparable to FZG, it is enough for us that it exceeds the 12th SRV stage (so that, if the SRV failure load stage is greater than 15th or reaches the end, it would not be so relevant). In Fig. 4 we see a lot peaks attributable to microseizures phenomena in the final steps; after the first microseizure, the COF curve presents other peaks of higher intensity. In our analysis we assign the failure load stage at the stage where a series of microseizures occurs and continues for at least few seconds. In Fig.5 we see a special and unique case in our experimentation. At the middle of the test, COF profile changes, becoming flat and reaching high values as in the first steps. This behavior has occurred quite exactly in all the test repetitions. We categorize this report as Case 4.

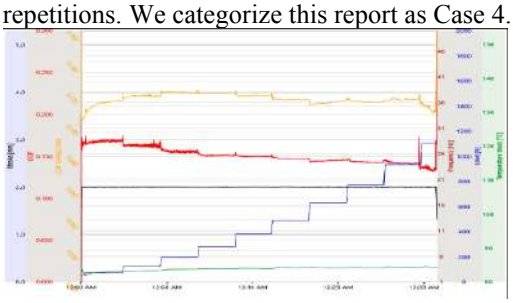

Fig.2 Case 1: example

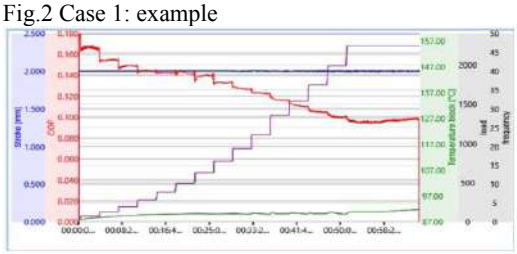

Fig.3 Case 2: example

Oil type	Viscosity grade	SRV failure load stage	FZG failure load stage
gas turbine oil	ISO VG 15	11	12
gas turbine oil	ISO VG 32	11	12
gas turbine oil	ISO VG 46	12	12
turbine oil	ISO VG 46	8	9
gear oil	ISO VG 320	>12	>12
gear oil	ISO VG 460	>12	>12
circulating oil	ISO VG 68	>12	>12
circulating oil	ISO VG 68	n.d.	12
circulating oil	ISO VG 68	>12	n.a.
circulating oil	ISO VG 68	>12	12

Table 2 Experimental results: tribo and rig tests

In Table 2 we report the results of SRV test, as an average value between the repetitions we carried out for each oil and in the last column FZG data to easily compare both machines tests. For only one product we do not have FZG data and for one oil we do not assign the SRV failure load stage (it belongs to case 4). For the others we notice a difference of only ± 1 stage and based on this, a good correlation between SRV and FZG tests has been found, appropriately distinguished in the cases previously identified (the oils tested mainly belong to case 1 and 2).

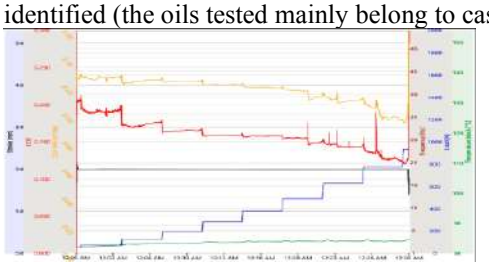

Fig.4 Case 3: example

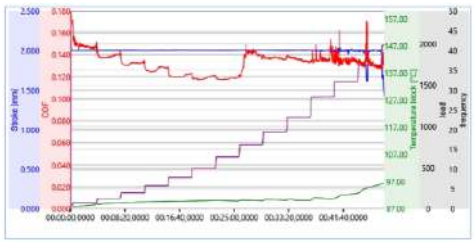

Fig.5 Case 4: example

The aim of the authors is to continue the experimentation by using other procedures and investigate the impact of lubricant formulation: to predict, estimate or determine synergistic/antagonistic effect of oil components. The results obtained and those that we are going to collect in the next experimental activity provide useful preliminary indications on the behavior of the lubricant thus helping a formulator in a lubricating oil development. Finally, from the work carried out, the importance of optimizing tribological test methods really emerges: advantages from the point of view of product development and final machine performance, being an extremely useful tool for the constant improvement of the energy efficiency of modern industrial systems.

FABRICATION OF 2D DENSE SUSPENSIONS OF SOFT PARTICLES IN MICROFLUIDIC CHANNELS

Lars Kool[1], K. Lawrence Galloway[2], Paulo Arratia[2], and Anke Lindner*[1]
[1]Laboratoire de Physique et Méchanique des Milieux Hétérogènes, ESPCI, Paris, France
[2]Department of Mechanical Engineering and Applied Mechanics, University of Pennsylvania, Philadelphia, PA, USA

Summary To properly understand the macroscopic response of soft particle glasses to stress/strain, an understanding of the material microstructure and its dynamics upon exposure to stresses is required. Here, we present a versatile experimental system to study the microstructure and dynamics of 2D hydrogel ensembles as function of the applied stress. This system is based on the in-situ fabrication of PEGDA hydrogel particles by UV-crosslinking. When a stress is applied, by flowing uncured solution over and under the particles, the packing compresses. We were able to extract several microstructural quantities, such as inter-particle forces and excess entropy, as well as several dynamical quantities, such as D^2_{min} and visco-elastic timescales. This experimental model system could give key insights in the connection between the microstructure and dynamics of soft particle glasses.

INTRODUCTION

Soft particle glasses (SPG's) are ubiquitous, from emulsions and foams, to pastes and dry food products, and are therefore of great industrial relevance. Over the last decades, our knowledge on SPG's has increased significantly, thanks to both numerical and experimental studies. However, experimental studies focus mainly on the macroscopic response of the SPG's to stress/strain, whereas microscopic studies have received much less attention, as they have proven to be difficult or require expensive equipment, like X-ray or NMR machines. But, for a proper interpretation of the macroscopic measurements, an understanding of the material microstructure and its response to forces and stresses is required. Another problem that arises while studying the effects of particle softness, is that it is complicated to isolate the effects of just the particle softness. As changing the Young's modulus often requires to change the material, which inevitably lead to changes in properties like friction coefficient, surface roughness, and/or interparticle interactions. Here, we present an experimental system with an unprecedented degree of control. By fabricating hydrogel particles inside a microfluidic channel, we can control shape and size of the system, as well as the size, shape, and Young's modulus of the particles with little to no additional effort. This method will allow us to isolate the effects of particle softness on the response of SPG's to compressive stress.

METHOD

Experimental sytem

In our experiments, the particles are contained inside a microfluidic device, made by casting poly-dimethylsiloxane (PDMS) over a positive master mould. The casted PDMS is then bonded to a PDMS coated glass slide to form the final microfluidic device (Figure 1A). As PDMS is porous to gases, our microfluidic devices allow for the diffusion of oxygen into the PEGDA solution. This locally inhibits the UV-polymerization reaction, causing the particles to not stick to the channel walls. By placing a wall with small perforations near the outlet of the microfluidic channel, we created a uni-axial compression system (Figure 1B). However, this wall can also easily be fitted with an orifice to form a silo, or angled to form a hopper (Figure 1C)

Figure 1: A) Schematic representation of the hydrogel particle fabrication (Adapted from Bechert et al. 2019 [2]). B) Example of a channel that can be used for compressional experiments. C) Example of a 2D hopper in a microfluidic channel. D) Typical packing of bidisperse particles.

Soft particles

The soft hydrogel particles were fabricated in-situ by UV-crosslinking polyethylene glycol diacrylate (PEGDA) (Figure 1A). The UV-light first passes through a shutter, to control the exposure of the solution to UV-light. Then, the light passes through the field-stop position. By placing a mask in the field stop position of the microscope, we are able to give the particle the desired size (ranging from as small as $\sim 10\ \mu m$ to several mm), as well as shape (Figure 2C) [1]. Finally, the light passes through the objective of the microscope, which focusses the UV-light on the desired spot in the channel. The Young's modulus of the particles can be controlled over 3 orders of magnitude (between $\sim$ 10 kPa and $\sim$ 10 MPa), by either changing UV-exposure time and/or by diluting the PEGDA solution with polyethylene glycol (PEG) [3]. By moving the focal spot through the channel using an automated stage, we fabricated large ensembles ($\sim$ 2000 particles) of these particles, with initial configuration obtained from DEM or MD simulations (Figure 1D).

RESULTS & OUTLOOK

We are able to impose a hydrodynamic compressive force on the packing, by imposing a flow of uncured PEGDA solution over and under the particles using a pressure controller, allowing for step stress and oscillatory compression experiments. An add advantage of our system is that one can interrogate the material microstructure, as a function of the applied forc. This allows us to obtain microstructural quantities such as the force network (calculated using Hertzian contact theory, Figure 2A-C) and excess entropy (calculated from the pair correlation function), and link them to dynamical quantities such as local rearrangements (quantified by the local non-affine deformation D^2_{min}, Figure 2D) and relaxation timescales (obtained from step-stress/relaxation experiments, Figure 2E). For example, we observed an anisotropy in the average interparticle force (a microstructural quantity, Figure 2C), which is not expected in the quasi-static regime. We hope to be able to link this dynamical quantities, such as the difference in visco-elastic time-scales or a possible anisotropy in the number of local rearrangements during compression and decompression.

We envision that this technique could play a key role in determining the development of an (empirical) microstructural model to describe the behavior of granular materials and the influence of particle softness and particle shape, on the behavior of granular materials, by linking material microstructure to its dynamics.

DETERMINING COMPLEX SPATIAL PATTERNS DURING CRYSTALLISATION OF SOFT MATTER

Priya Subramanian * [1] and Alastair Rucklidge[2]
[1]Mathematical Institute, University of Oxford, Oxford UK
[2]School of Mathematics, University of Leeds, Leeds UK

Summary Soft matter systems display a wide range of spatial patterns as asymptotic states during crystallisation and can be modelled as a pattern forming system governed by a conserved dynamics. Traditional first tools for analysis of such pattern forming systems include linear stability analysis and a weakly nonlinear analysis. In addition, numerical continuation and direct simulations can be employed to determine invariant solutions. In this work, we show that combining equivariant bifurcation theory and numerical continuation with numerical algebraic geometry allows us to determine all solutions with a chosen symmetry subgroup. We explore the advantages of this method in identifying co-existing metastable states, unearthing invariant solutions with reduced symmetry and in identifying parameter regimes with multiple solutions.

Soft matter such as polymers crystallise when cooled from a melt and can self-assemble into a variety of spatially complex patterns [1]. Phase field crystal (PFC) models that include information about small length scales and operate over diffusive time scales have been employed to model the crystallisation of soft matter [2]. This PFC model is also known as the conserved Swift-Hohenberg equation. When analysing this model beyond linear stability thresholds using a weakly nonlinear analysis, the resulting normal form equations are usually in the form of coupled ordinary differential equations (ODEs) for the amplitudes of the active modes, i.e., modes that are growing or neutrally stable.

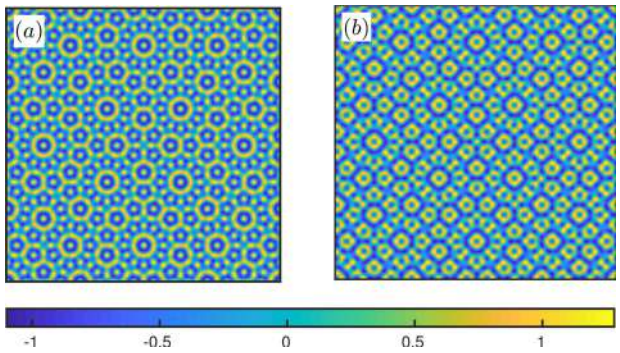

Figure 1: Figure 1: Variation of scalar density in a 2D soft matter system modelled using in a PFC model showing co-existing dynamically stable dodecagonal quasicrystal states.

We use homotopy methods from numerical algebraic geometry to solve for all solutions of the chosen amplitude equations in a non-iterative method [3]. Solutions obtained this way are used as initial guesses for numerical continuation to determine invariant solutions to the full model. Starting with dodecagonal symmetry in 2D, we discover multiple co-existing metastable states at the same parameters with the same symmetry as shown in Figure 1 (a) and (b).

Effects of broken symmetry can also be investigated robustly by solving amplitude equations corresponding to reduced symmetry subgroups. In Figure 2, we show results obtained from starting with full 3D icosahedral symmetry and relaxing constraints to investigate states with different reduced symmetries. We obtain four different metastable states: two different periodic stackings of 2D decagonal QCs, an aperiodic stacking of 2D decagonal QC and the globally stable fully symmetric 3D icosahedral QC at the same parameter combination.

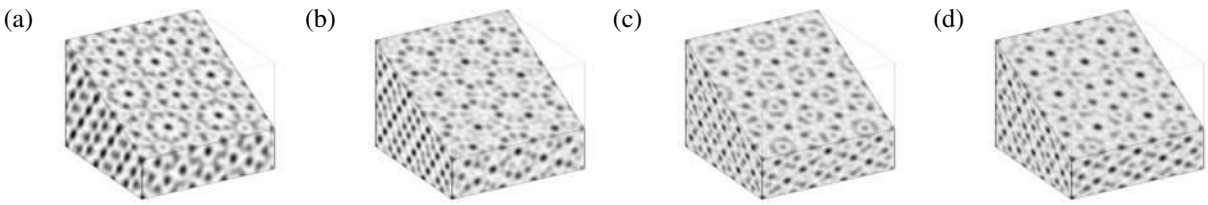

Figure 2: Variation of scalar density in a 3D soft matter system modelled using in a PFC model, sliced along the plane (1.618, 0, 1) for extended dynamically stable states of (a) a periodic stacking of 2D decagonal QC with large stacking wavelength, (b) a periodic stacking of 2D decagonal QC with small stacking wavelength and (c) an aperiodic stacking of 2D decagonal QC and (d) a fully symmetric icosahedral QC.

Combining equivariant bifurcation theory along with numerical algebraic geometry allows us to obtain multiple co-existing metastable states with same symmetry properties, obtain solutions for reduced symmetry subgroups and makes it feasible to probe multi-parameter ranges in pattern forming system to identify interesting parameter regimes with multiple invariant solutions.

INVARIANT SOLUTIONS UNDERLYING LOCALIZED BURSTING SPOTS IN INCLINED CONVECTION

Florian Reetz[1] and Tobias M. Schneider * [1]
[1]Emergent Complexity in Physical Systems Laboratory (ECPS), École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Summary Convection in a fluid layer inclined against gravity exhibits a large variety of flow patterns including intermittent bursting spots. Here localized regions of strong convection spontaneously emerge in a regularly patterned background and subsequently decay. We identify exact invariant solutions of the nonlinear flow equations underlying the transiently emerging bursting spots and thereby rationalize both temporal and spatial properties of the observed convection pattern. This work highlights the power of nonlinear dynamical systems approaches for explaining patterns in driven dissipative systems well above the onset of linear instability.

INTRODUCTION

Thermal convection in a fluid layer inclined against gravity shows a large variety of self-organized flow patterns. As a function of the externally controlled temperature difference or Rayleigh number Ra, the inclination angle γ and the material dependent Prandtl number Pr patterns of various complexity ranging from unpatterned laminar flow and spatially periodic stationary convection rolls to spatio-temporal chaos and turbulence are observed in experiments and simulations [1].

For $\mathrm{Pr} = 1.07$ (compressed CO_2) and an inclination of $\gamma = 78°$, the laminar base flow loses stability to two types of stationary convection rolls, longitudinal rolls (LR) aligned with the incline and transverse roles (TR) oriented in perpendicular direction, at almost identical critical values of $\mathrm{Ra}_c = 8078$. Above the critical threshold, for $0 < \epsilon < 0.1$ with $\epsilon = \mathrm{Ra}/\mathrm{Ra}_c - 1$, a spatio-temporally intermittent convection pattern is observed, previously termed 'transverse bursts' [2]. The bursting phenomenon is characterised by spatially localized spots of intense convection that transiently emerge and decay within a background of weak longitudinal rolls. The aim of the present study is to explain these *bursting spots* including their two key features: (i) Intermittent time evolution of spontaneously arising and decaying bursts of convection and (ii) spatial localization of a chevron-like convection pattern within a background of longitudinal rolls.

INTERMITTENT TIME EVOLUTION

Following the recent identification of exact invariant solutions of the three-dimensional Oberbeck-Boussinesq equations underlying less complex spatially periodic patterns at other values of the control parameters [3, 4], we here describe two unstable equilibrium solutions whose dynamical connection supports the temporal dynamics of bursting spots. A chevron equilibrium (CH) is identified that captures the internal structure of the spots and coexists with the longitudinal roll equilibrium (LR) in the state space of the system. In a doubly periodic domain of extent $[L_x, L_y, H] = [4.5, 4, 1]$,

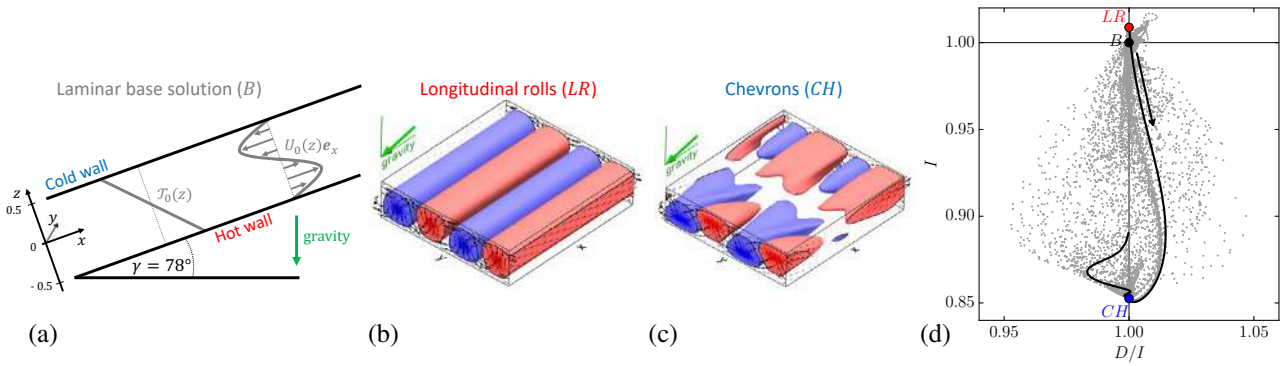

Figure 1: The intermittent temporal dynamics of bursting spots in ILC at $\epsilon = 0.05$ transiently visits three unstable equilibrium solutions: (a) the schematically shown laminar base solution, B, (b) longitudinal rolls, LR, (c) a previously unknown chevron equilibrium solution, CH, resembling the core pattern of bursting spots. The 3D contours illustrate temperature fluctuations around B. In panel (d), a two-dimensional state space projection (I: energy input, D: dissipation) of a simulated state vector trajectory reveals intermittent dynamics shadowing a dominant dynamical connection $LR \to CH$ (black curve). Since CH is a saddle point, the dynamics departs from CH following a decaying chaotic trajectory (only the initial part of the trajectory is shown). The background point cloud, extracted from a long simulation over 10 000 free fall time units, illustrates the chaotic attractor. Equilibrium solutions and time evolution are computed using the open-source spectral code *Channelflow-ILC* [5] at control parameters $[\gamma, \mathrm{Pr}, \epsilon] = [78°, 1.07, 0.05]$ in a doubly periodic domain of extent $[L_x, L_y, H] = [4.5, 4, 1]$.

*Corresponding author. E-mail: tobias.schneider@epfl.ch.

both equilibria are dynamically unstable. State space projections of the simulated time evolution indicate that the chaotic trajectory shadows a dominant rapidly traced dynamical connection $LR \rightarrow CH$. The trajectory than slowly departs from the unstable chevron equilibrium along a complex trajectory and decays towards LR from where the next burst $LR \rightarrow CH$ is triggered (Figure 1). Thus, both unstable equilibrium solutions together with their dynamical connection support the observed intermittent temporal dynamics of the bursting spots.

LOCALIZATION IN SPACE

To explain the dynamics of *spatially localized* bursting spots, invariant solutions must capture the spatial coexistence of the chevron pattern and the longitudinal rolls. We construct localized variants of the chevron equilibrium by extending the lateral size of the numerical domain, first in the spanwise direction and then in both, spanwise and streamwise direction. The constructed collection of spanwise and doubly localized invariant solutions includes equilibrium solutions, traveling waves and periodic orbits that all capture the localized pattern of bursting spots. Numerical continuation of these unstable invariant solutions in ϵ traces their solution branches and reveals their subcritical bifurcations from the spatially periodic CH solution. Moreover, the solutions branches continue to control parameters where laminar ILC is linearly stable, $\epsilon < 0$. There, the branches undergo homoclinic snaking which changes the number of localized chevron structures and leads to spot patterns of arbitrary size (Figure 2). Consequently, pattern forming bifurcations create localized invariant solutions capturing the spatial coexistence of two types of convection patterns as observed within bursting spots.

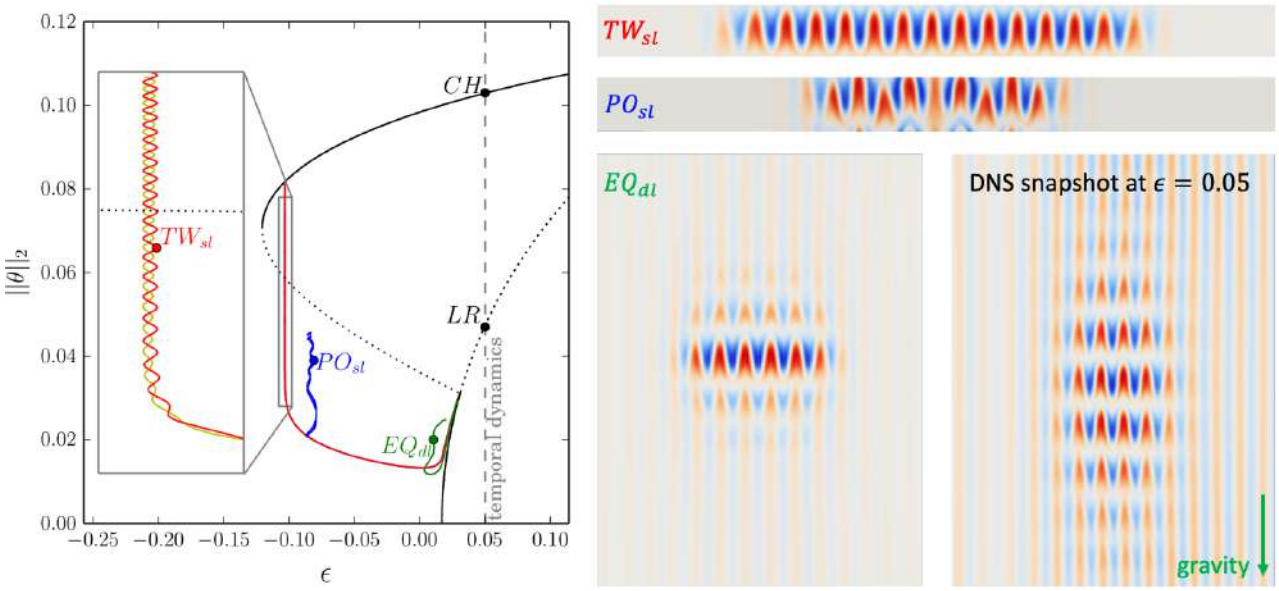

Figure 2: Subcritical bifurcations give rise to spatially periodic, spanwise localized (sl), and doubly localized (dl) variants of the chevron equilibrium, CH. Localized invariant solutions include equilibria (EQ), traveling waves (TW) and periodic orbits (PO). Selected invariant solutions along the branches are visualized in terms of midplane temperature contours and compared to a snapshot from a direct numerical simulation (DNS) in a large domain. While TW_{sl} undergoes regular snaking bifurcations, the spanwise localized periodic orbit, PO_{sl}, and the doubly localized equilibrium EQ_{dl} undergo irregular snaking bifurcations. $||\theta||_2$ is the norm of the temperature fluctuations around B.

CONCLUSIONS

The discussed exact invariant solutions of the nonlinear flow equations capture both temporal and spatial properties of bursting spots in inclined layer convection. This work highlights the power of fully nonlinear dynamical systems approaches for explaining patterns in driven dissipative systems well above the onset of linear instability.

FARADAY PILOT WAVES IN A CAVITY: A HYDRODYNAMIC CORRAL

Paul A. Milewski * [1] and Matthew Durey[2]
[1]Department of Mathematical Sciences, University of Bath, Bath, UK
[2]Department of Mathematics, MIT, Cambridge, USA

Summary Millimetric droplets may bounce periodically on the surface of a vertically vibrating bath of the same fluid, each impact exciting a wave-field subcritical Faraday waves. The cumulative generated wavefield can then guide the droplet's horizontal motion, providing the system with memory of both the past path and the geometry of the fluid domain. In particular, the droplet may be confined by a submarine "corral" which modulates the Faraday waves. Experiments show that this configuration can lead to dynamics bearing striking resemblance to quantum mechanical corrals. We describe a framework for understanding the fluid dynamical problem that is derived from first principles, and is simple enough for mathematical and efficient numerical treatment.

EXTENDED ABSTRACT

A millimetric droplet may bounce periodically on the surface of a vertically vibrating bath of the same fluid; the thin air layer separating the droplet from the bath during impact prevents coalescence. Each impact excites a wave-field consisting primarily of subcritical temporally decaying (due to viscous effects) Faraday waves, whose longevity depends inversely on the closeness of the shaking strength to the Faraday instability threshold (Couder et. al. 2005). As the shaking strength increases, and due to the generated wavefield, the bouncing destabilizes to horizontal "walking" across the bath, whereby the droplet is propelled at each impact by the slope of its associated Faraday wave field generated at previous impacts. In the walking regime the droplet may then be confined by either an external field or by submarine "corral" topography that modulate the Faraday wavefield and hence modify the path of the drop (Harris et. al. 2013). In this context, the decay time of the Faraday waves result in a "path-memory" of previous impacts, which encode the topographical information of the domain (Fort et. al. 2010).

The resulting non-Markovian dynamics are similar in many respects to the pilot-wave dynamics envisaged by de Broglie as a physical framework for understanding quantum mechanics (Bush 2015).

We have developed a hydrodynamic pilot-wave model, formulated from first principles, that exhibits the behaviour observed in the laboratory experiments. In describing the wave field, our approach is a linear quasi-potential flow description inspired by the inviscid theory of Benjamin & Ursell (1954), with viscous damping being incorporated in the manner outlined by Lamb (1932). The droplet-bath interaction, in its simplest form, is modelled with a periodic, instantaneous and localised impact on the surface. These allow for an elegant reduction of the full hydrodynamic coupled system to period map to account for the fluid evolution followed by jump conditions at each impact that generate the new waves and guide the horizontal trajectory of the particle (see Durey & Milewski 2017). The model is sufficiently simple for a mathematical study of the bifurcations and stability of the system.

This model can be simulated very efficiently and is therefore appropriate for elucidating certain statistical long-time behaviour inaccessible to more detailed computations of impact wave generation such as those of Milewski et. al. (2015) or Galeano-Rios et. al (2017, 2019). For example, we can show that in confined states and near the Faraday threshold, a mean hydrodynamic pilot wave field arises from the stationary distribution of droplet positions. We prove a relation between the droplet position distributions and this mean wave-field, rationalising aspects of the dynamics at high memory (Durey et. al. 2018). All prior realistic fluid dynamical simulations of this system were based on a fluid domain without underlying geometry where the droplet was trapped by an external potential instead.

Herein we present the first model capable of the capturing the dynamics in a corral that confines the droplet. The corral consists of a cavity with a deep cylindrical region surrounded by shallow region which prevents the particle and waves to propagate into it (see Figure 1). We use a domain decomposition method to compute the Dirichlet to Neumann map for the velocity potential at the surface, which allows us to compute the cavity wave modes of the system. We can then apply the above-described discrete methods to generate waves at each impact and evolve the pilot wave system achieving efficient simulation speeds. We find all the states described experimentally and some new ones: centre and off-centre

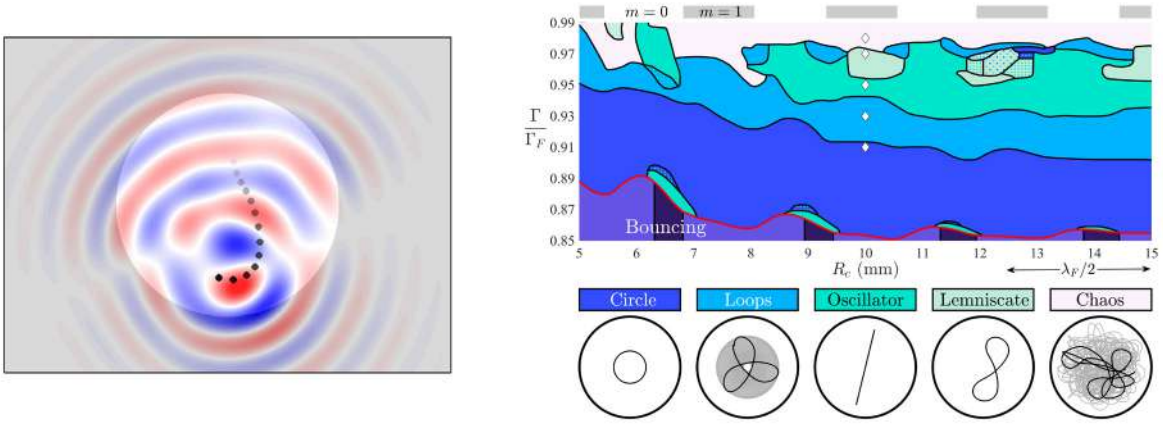

Figure 2: Left: Typical trajectory at intermediate memory showing droplet path and Faraday pilot waves. Right: Diagram indicating various observed dynamics as a function of corral radius and forcing strength.

bouncers, circular orbits, oscillators, lemniscates, n-foils and chaotic motion. A typical trajectory and wave-structure, together with a summary of the behaviour of the system for varying corral radii and forcing is shown in Figure 2. We deduce the stability of the trajectories, compare these trajectories to experimental works, and rationalise the observations, in particular we highlight the importance of whether the most unstable mode is axisymmetric. We compare some features of the dynamics to the case without topography, but instead with an external potential. Finally, in the chaotic regime, we obtain droplet distributions that have some spatial structure but do not reproduce the "cavity mode" feature seen in experiments. We postulate that the differences between our model and experimental results arise from the assumption of periodic impacts and discuss how to remove this assumption in the model.

SURFACTANTS DRIVEN OUT OF EQUILIBRIUM BY A FLOW

Shreyas Mandre* [1]
[1]Mathematics Institute, University of Warwick, Coventry UK

Summary The description of the flow driven only by a point source of surfactant is complicated by the multitude of the surfactant's physico-chemical parameters. The value of these parameters in practice depends on the local surfactant concentrations, which in turn depends on the flow. For flow driven by a point source of surfactant, the radial velocity decays as r^n, where two values of n, $-3/5$ and -1, are experimentally observed. Previous work (J. Fluid Mech., 832, 777-792, 2017; Phys. Rev. Lett, 119, 26501, 2017) has explained the exponents through two different surfactant models, without the knowledge or estimation of any of the surfactant physico-chemical parameter. Here we present a unified model for the surfactant, where the two exponents are realized as two asymptotic limits.

INTRODUCTION TO SURFACTANTS

Surfactants are chemical compounds, which by virtue of its molecular structure adsorbs onto a fluid-fluid interface and reduces its surface tension. In equilibrium, the dissolved and adsorbed concentrations of the surfactant are uniform, and the Gibbs adsorption isotherm relates them to each other and to the surface tension of the interface. For dilute solutions of the surfactant, the adsorbed concentration increases linearly with the dissolved concentration, and so does the reduction in surface tension. As the solution gets more concentrated, the adsorbed concentration saturates owing to overcrowding of molecules on the interface and the surface tension also levels out.

The picture is richer when the system is out of equilibrium, in which case the surfactant distribution need not be uniform. A gradient of surface tension due to a non-uniform distribution of surfactants, known as the Marangoni stress, drives a flow, which in turn transports the surfactant. Mathematical models of surfactant-driven flows couple the Navier-Stokes equations with the surfactant dynamics. The surfactant dynamics themselves consist of the chemical kinetics between and the transport of the adsorbed and the dissolved phases. However, the plethora of surfactant physico-chemical parameters poses a challenge for use of such models for prediction in experimental systems. It is so especially because the values of these parameters changes with surfactant concentration. These concentrations themselves are also difficult to measure *in situ*.

Here we consider the case of a point source of surfactant on a liquid interface, which drives an axisymmetric flow away from the source (see Figure 1). Such a flow is inspired by two experiments on the air-water interface: (i) the flow due to a static disc of camphoric acid [1], and (ii) the flow due to the injection of surfactant from a narrow tube [2]. Experiments revealed that the velocity away from the source decayed with distance either as r^{-1} or as $r^{-3/5}$, depending on the nature of the source. A theoretical explanation of the resulting flow has been sought before [3], but the flow could only be explained recently [4] in terms of the dynamics being dominated by either the dissolved or adsorbed surfactant phases. Remarkably, this conclusion could be reached without the explicit knowledge or estimation of the surfactant's physico-chemical parameters.

Here starting from the general surfactant dynamics model, we derive two asymptotic limits under which the two power-laws for the decay of velocity are observed.

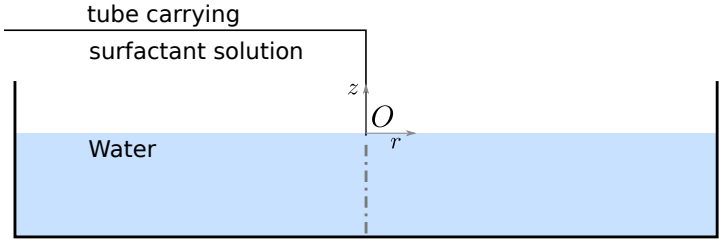

Figure 1: Schematic of a flow driven by a point source of surfactant. The experimental setup consists of a pool of water several centimeters in depth. The surfactant is released at point O on the air-water interface. The resulting gradients in surface tension drive a flow, which inturn also transport the surfactant.

ASYMPTOTICS OF SURFACTANT DYNAMICS

The general surfactant dynamics model invokes the concentration of the dissolved phase c and that of the adsorbed phase Γ. The dissolved concentration follows the transport equation

$$c_t + \boldsymbol{u} \cdot \boldsymbol{\nabla} c = D\nabla^2 c \quad \text{in the fluid,} \tag{1}$$

and the adsorbed concentration follows

$$\Gamma_t + \boldsymbol{\nabla} \cdot (\boldsymbol{u}_s \Gamma) = D_s \nabla_s^2 \Gamma + j \quad \text{on the interface.} \tag{2}$$

The exchange flux, j, between the two depends on the degree of departure from equilibrium and for dilute concentrations may be written as

$$j = -\boldsymbol{\nabla} c \cdot \hat{\boldsymbol{n}} = k_a c - k_d \Gamma, \tag{3}$$

where k_a and k_d are reaction rate constants for the adsorption and desorption process. The surface tension σ decreases linearly with Γ, i.e. $\sigma - \sigma_0 = -K\Gamma$, where σ_0 is the surface tension of pure water. Note that the diffusion term in (2) can be neglected because the advection term dominates over it, but the one in (1), while also small, must be retained because the formation of a boundary layer of thickness $\delta = \sqrt{DL/T}$ perpendicular to the interface.

Two timescales of relevance to the dynamics are the hydrodynamic timescale L/U, where L is the characteristic radial length scale for the flow and U the characteristic speed in the radial direction, and the kinetic timescale $1/k_d$. When the hydrodynamic timescale is much faster than the kinetic (i.e. when the reaction is much slower than the time the flow takes the transport the chemicals), the exchange flux j can be neglected and the equation (2) governing Γ decouples from (1). In other words, the terms Γ_t balances $\boldsymbol{u}_s \cdot \boldsymbol{\nabla}\Gamma$, whilst j is an order $k_d L/U$ smaller. The surface tension depends only on Γ and, therefore, only on (2). The dissolved concentration evolves independently according to (1), but with a no-flux condition on the interface. This limit is dominated by adsorbed surfactant, in which case previous work [4, 1] showed that the radial velocity decays as $r^{-3/5}$.

The other asymptotic limit is the one where the adsorption-desorption kinetics are much faster than the hydrodynamics, so that the exchange flux saturates the interface to equilibrium, i.e., $k_a c = k_d \Gamma$. In this case, $\Gamma = (k_a/k_d)c$ and c is governed by (1), while (2) becomes $j \approx 0$. The adsorbed surfactant dynamics are thus eliminated. This is the limit dominated by dissolved surfactant, in which case previous work [4, 1] showed that the radial velocity decays as r^{-1}.

CONCLUSION

I showed in a previous article [4] that in the case dominated by adsorbed surfactant, the radial velocity decays as $r^{-3/5}$, and in the case dominated by dissolved surfactant the velocity decays as r^{-1}. The agreement of the power-law decay of velocity is not a coincidence but a direct consequence of the two limits of surfactant dynamics is demonstrated by comparing the three-dimensional profile of radial velocity [1]. Here we have shown that the two possibilities arise from a unified model of surfactant dynamics.

MODEL SELECTION OF PDES FOR PATTERN FORMATION

Natsuhiko Yoshinaga * [1,2] and Satoru Tokuda[2,3]
[1]WPI - Advanced Institute for Materials Research, Tohoku University, Sendai 980-8577, Japan
[2]MathAM-OIL, AIST,Sendai 980-8577, Japan

Summary We propose an inverse problem of partial differential equations (PDEs) for pattern formation[1]. From one snapshot of a target pattern, we successfully estimate the best model and its parameters using Bayesian model selection. The success of our method is achieved by (i) making a family of the models from which we select the best, (ii) defining an order parameter which characterises features of a ordered pattern, and (iii) efficient sampling of posterior distribution in the parameter space by using the replica exchange Monte Carlo method. We demonstrate our method for a two-dimensional dodecagonal quasi crystal.

INTRODUCTION

Partial differential equations (PDE) have been widely used to reproduce patterns in nature. To understand the mechanism of pattern formation, nonlinear PDEs have been employed for fluid convection[2], microphase separation of block copolymers[3], and crystals[4]. Despite a number of PDE models have been proposed, they rely on pre-request knowledge of physical laws and symmetries, and it requires significant efforts to develop a model reproducing a desired pattern. The challenge is quantitative and physically interpretable modelling of a complex phenomenon, which demands both developing a model and parameter estimation. The identification of a model equation is a recent key topic of machine leaning and data science. Several methods have been proposed to derive PDEs from time series data[5].

In this study, we propose the method to select a PDE model and its parameters to reproduce a given snapshot of a pattern, and from that, to get a physical insight of the target pattern[1]. We apply our method to two-dimensional nontrivial patterns, namely quasi-crystal with twelve-fold symmetry reproduced by using a family of phase-field crystal models. Our method not only estimates the parameters to reproduce these patterns but also gives an insight on the appropriate number of characteristic length scales hidden in the patterns.

MODEL SELECTION OF PDE

We consider a pattern that is expressed by the scalar density field $\psi(\mathbf{x})$. An example of a dodecagonal quasicrystal is shown in Fig. 1(a). We explorer a model to reproduce a target pattern $\hat{\psi}(\mathbf{x})$ at the steady state of an unknown model described by nonlinear PDEs, $\partial_t \psi(\mathbf{x}) = f_\mu[\psi(\mathbf{x})]$ with parameters μ. Our target pattern is ordered and has many invariants under translation, rotation, and also the action of symmetry group that the pattern has. In order to extract these features of the pattern $\psi(\mathbf{x})$, we define the order parameter $\Psi[\psi(\mathbf{x})]$. The model is specified by the functional form of $f[\psi(\mathbf{x})]$. We consider a family of the models based on a phase-field crystal (PFC) model in which each model has m length scales. For a given target pattern, we estimate the appropriate number of length scales by estimating the best model, and also estimate the parameters in the model. The estimation is performed by the Bayesian model selection in which we compute posterior distribution of parameters and marginal likelihood using the replica exchange Monte Carlo (REMC) sampling[6].

Order Parameter

To quantify the similarity between a target pattern $\hat{\psi}(\mathbf{x})$ and a pattern $\psi(\mathbf{x})$ that we get from the candidate model, we consider the cost function, which is zero when the two patterns are identical while it is larger when the obtained pattern is far from the target pattern. We define the order parameter, $\mathbf{\Psi}[\psi(\mathbf{x})] = (\Psi_1, \Psi_2, \ldots, \Psi_l)$, and the cost function, $E = \frac{1}{2}\sum_{l=1}^{l_0} \left|\Psi_l[\psi] - \hat{\Psi}_l\right|^2$ where l denotes a mode of the order parameter and l_0 is the maximum mode number. Here, $\hat{\Psi}_l = \Psi_l[\hat{\psi}]$ is the order parameter for the target pattern. The order parameter is rotational invariant form of the quantity A_l. This is given in two dimensions, by $A_l[\psi] = \int |\psi(\mathbf{k})| e^{il\theta_k} d\mathbf{k}^2$ where θ_k is a polar angle in the Fourier space. We consider appropriate norm that is invariant under rotation, $\Psi_l = |A_l|$.

Family of models

We consider a pattern described by a scalar density field $\psi(\mathbf{x})$ in a box with a periodic boundary condition. The density field $\psi(\mathbf{x})$ is obtained by a candidate model of a PDE. We focus on a family of the PFC models given by $\partial_t \psi = \mathcal{L}\psi + \Delta\psi^3$ with the linear operator is denoted by $\mathcal{L}$. The family is constructed by modifying the linear operator $\mathcal{L}$ so that the system has one or more characteristic length scales. The simplest PFC model is nothing but a conserved version of the Swift-Hohenberg (SH) equation. The SH equation reproduces a stripe and hexagonal patterns in two dimensions.

The conventional PFC equation has a single characteristic length at which a real part of the eigenvalue is positive.In order to consider the arbitrary number of length scales, we use m characteristic wave numbers, $q_0, q_1, \cdots, q_{m-1}$, and the values of the spectral, $a_0, a_1, \cdots, a_{m-1}$, at the wave number $k = q_i$. A family of our models is described in the Fourier transformation of the density field $\psi(\mathbf{k}) = \mathcal{F}[\psi(\mathbf{x})]$ with $\mathcal{L}_k = a_0 S_0(k) + \cdots + a_m S_m(k) + k^2\left(1-k^2\right)^2 \cdots \left(q_m^2 - k^2\right)^2$.

(d,e) Histograms of the cost function, E, for $m = 2$ (d) and $m = 1$ (e). (f) The estimated parameter in $m = 2$. The vertical lines show the true parameter value to reproduce the target pattern.

RESULTS

In REMC, we perform parallel MC sampling for various inverse temperature, β, chracterising the likelihood ($P[\mu|\psi] \propto e^{-\beta E}$)[6]. Efficient search in the parameter space μ is capable by this method. At the low temperature (large β), we obtain the pattern very similar to the target pattern as demonstrated in Fig. 1(c,d). The estimated parameters are also well agree to the parameters that we used to generate the target pattern (Fig.1(f)). The estimate length scale is $q_1 = 0.52$ with the second length scale $q_0 = 1$. The ratio between them is agree to $q_0/q_1 = 2\cos(\pi/12) \approx 1.9319$, which is necessary value to generate this pattern[7]. Our method automatically estimates this ratio. The estimation works also for other parameters.

The model with two length scales ($m = 2$) can reproduce the quasicrystal pattern whereas the model $m = 1$ cannot. This is demonstrated by the histogram of the cost function (Fig. 1(d,e)). The latter model $m = 1$ has hexagonal patterns and higher E. From the marginal likelihood, we may conclude that the model with two length scales is indeed likely.

Our method is not restricted to estimation of parameters that numerically generates the target pattern. A target pattern is produced by properly superposing plane waves. The simplest case is a stripe pattern, which is expressed by one wave in one direction in two-dimensional space. This target pattern is not necessarily a steady solution of one of the candidate models. Nevertheless, we may estimate approximated parameters and the best model that can reproduce the pattern.

We demonstrate this idea using a two-dimensional dodecagonal quasi-crystal, which is generated by $\psi = \sum_{i=1}^{12} \cos(\mathbf{k}_i \cdot \mathbf{x})$ in which the wave vectors $\mathbf{k}_i$ are appropriately chosen[7]. The pattern is similar to numerically generated quasi-crystal, but in the current case there is no true parameters $\hat{\mu}$ and model. Using the pattern generated by analytic function, our method estimates quasi-crystal patterns, and both in two-length-scale and three-length-scale models reproduce quasi-crystal patterns. The estimated parameters reproduce the inherent ratio of the length scales $q_0/q_1 = 1.948 \approx 2\cos(\pi/12)$.

CONCLUSIONS

We demonstrated that the method can not only estimate the parameters that reproduces a target pattern, but also estimate the most likely model. The success of our approach relies on the order parameters, Bayesian model selection, and a family of models. The order parameters can extract symmetries of the pattern, and distinguish two visually similar patterns produced with different number of characteristic length scales. In order to perform model selection, we use REMC, which efficiently compute posterior probability distribution. This enables us to evaluate marginal likelihood of each model. Our approach can be applied to other family of models as well as three dimensional patterns[1].

NUMERICAL SIMULATION OF WAVY MODULATION OF FARADAY WAVES

Laurette S. Tuckerman * [1] and Rahul Agrawal[2]
[1]Physique et Mécanique des Milieux Hétérogènes (PMMH), ESPCI Paris, CNRS, PSL Research University, Sorbonne Université, Université de Paris, F-75005 Paris, France
[2]Department of Mechanical Engineering, Indian Institute of Technology Bombay, Maharashtra, India 400076

Summary Numerical simulations are carried out of an experimentally observed modulational instability of Faraday waves [1] in which the regular pattern of square waves acquires a large-scale low-frequency spatio-temporal waviness.

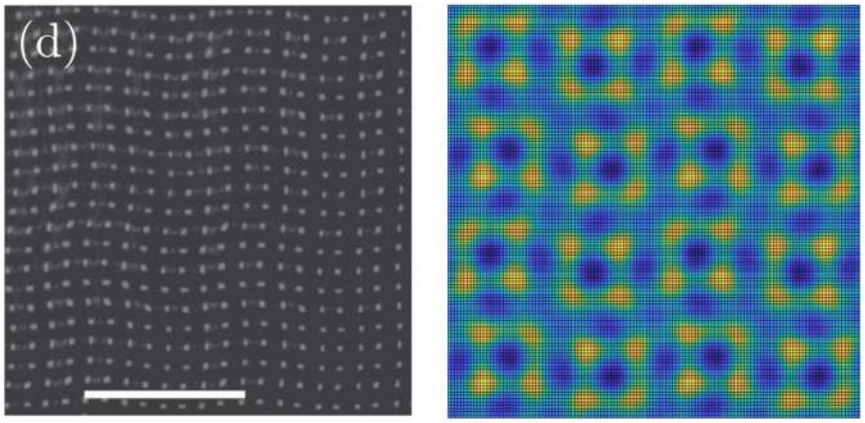

Figure 1: Faraday pattern with wavy large-wavelength modulation. Left: experiments [1]. Right: Initial condition for our simulations.

When a fluid layer is subjected to vertical vibrations of sufficient amplitude, standing waves appear at the surface via the classic Faraday instability. The pattern often forms a square grid, and at a higher oscillation amplitude, these regular squares may rearrange themselves into larger structures. In our group, Périnet et al. [2] produced the first numerical simulations of Faraday waves. For vibration amplitudes in a small range approximately twice the Faraday threshold, Domino et al [1] observed experimentally a wavy large-wavelength modulation of a square pattern of Faraday waves, shown in figure 1 (right). The spatial wavelength of the wavy modulation is four times that of the basic square pattern, while the temporal period is about 20 times as long.

We have investigated this pattern numerically using the massively parallel code `BLUE` written by Shin et al. [4]. This multiphase code BLUE is based on recently developed hybrid front-tracking/level-set interface methods. Both the fluid layer and the air above it are represented by a single field, with a density and viscosity which take on different values in the two phases. A 3D Cartesian mesh is used to represent the field, while the free surface is represented by triangles on a Lagrangian interface mesh. Kahouadji et al. [3] have previously used this code to study supersquares, a different variant of a regular square pattern, in which the grid of standing waves spontaneously partitions itself into two-by-two blocks, with the diagonal blocks in phase with one another.

To simulate the pattern in [1], we use an initial condition which is constructed to resemble the large-scale pattern; see the right portion of figure 2. The pattern appears persists for several long oscillation periods but eventually reverts to a basic square pattern, in contrast to the permanent waviness in the experiments; see figure 2. Domino et al [1] proposed an interpretation of the wavy instability in terms of the theory of elasticity. Numerical simulations produce accurate global quantities such as the kinetic energy and the total surface area as a function of time, as well as the complete velocity field and position of the surface. We analyze this detailed information to learn more about the secondary pattern and the mechanism responsible for its instability.

SHORT-TERM PREDICTION OF A BUOYANCY-DRIVEN TURBULENT FIRE UNDER LOW-GRAVITY ENVIRONMENT

[1]Department of Mechanical Engineering, Tokyo University of Science, Tokyo, Japan
[2]Department of Mechanical Engineering, Ritsumeikan University, Shiga, Japan

Summary We numerically study the spatiotemporal dynamics and short-term predictability of a buoyancy-driven turbulent fire under low-gravity environment. We observe a significant transition from order to disorder structures in the degree in the spatial horizontal visibility graph. The entropy transport from temperature to streamwise flow velocity fluctuations is predominant near the interface between hot combustion products and cold surrounding air. The transfer entropy is an important measure for determining the predictability of the flow velocity fluctuations in the near-field.

The complex coupling of hydrodynamic flow, heat/mass diffusion, and a rapid chemical reaction gives rise to a rich variety of flame front instabilities. Buoyancy-driven flame puffing is an important class of flame front instabilities in diffusion flames. Our recent study [1] using a large-eddy simulation has shown the existence of two important dynamical states in a mid-scale buoyancy-driven turbulent fire: low-dimensional deterministic chaos in the near-field and high-dimensional deterministic chaos in the far-field. These dynamical states have been reasonably identified by the advanced analyses based on symbolic dynamics and statistical complexity [2]. In this study, we clarify the mutual interaction between flow velocity and temperature fluctuations in a buoyancy-driven turbulent fire under low-gravity environment using the symbolic recurrence plots (SRPs) [3] and the transfer entropy [4]. In addition, we examine the predictability of streamwise flow velocity fluctuations using the echo state networks as one of promising machine learning technologies.

We obtain the numerical data of a spatiotemporal structure in a buoyancy-driven turbulent fire under low-gravity environment from large-eddy simulation [1,2]. The governing equations, the discretization method of the governing equations, and the boundary conditions are all the same as those in the previous studies [1,2]. In this study, the computational domains in the x, y, and z directions are set to 2.0 m, 2.0 m, and 5.0 m. Methane gas is supplied from a square central area with dimensions of 1 m × 1 m. The gravity level G (= g_a/g, where g is the gravitational acceleration under normal-gravity and g_a is the gravitational acceleration under low-gravity) is set to 0.8. Similarly to in the previous studies [1, 2], we analyse the streamwise flow velocity and temperature fluctuations for a sufficient interval of 28 s during a turbulent fire.

Recurrence plots [3] enable us to capture the dynamical changes to chaos via bifurcations. They are constructed by computing the distances between all sets of points in a phase space. Symbolic recurrence plots (SRPs), which are an extended version of the recurrence plots, incorporate the rank order patterns in time series [5], and are effective for capturing the similarity of two dynamical states [6]. In this study, we use SRPs to evaluate the similarity of streamwise flow velocity and temperature fluctuations. The adjacency matrix of SRPs is obtained as Eq. (1).

$$R_{ij} = \begin{cases} 1 & \pi^D_{w'}(t_i) = \pi^D_{T'}(t_j) \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

Here, $\pi^D_{w'}(t_i)$ and $\pi^D_{T'}(t_j)$ are the rank order patterns of the streamwise flow velocity fluctuations w' and the temperature fluctuations T', and D is the embedding dimension. In this study, we estimate the recurrence rate S_{RR} to quantify the similarity of w' and T'.

$$S_{RR} = \frac{1}{N-(D-1)-|\tau|} \sum_{i=1}^{N-(D-1)-|\tau|} R_{ij} \tag{2}$$

S_{RR} represents the density on the diagonal in SRPs, and approaches to unity as w' and T' reach a similar dynamical state. Note j is set to $i+\tau$.

Transfer entropy is one of the useful measures to estimate the causality between two time series [4]. In this study, we estimate the transfer entropy defined as Eq. (3) to clarify the mutual interaction of the streamwise flow velocity and temperature fluctuations.

$$S_{E,T'\to w'} = \sum_{i=1}^{N-\tau} p(w'(t_{i+\tau}), \mathbf{w}_i^k, \mathbf{T}_i^l) \log \frac{p(w'(t_{i+\tau}) \mid \mathbf{w}_i^k, \mathbf{T}_i^l)}{p(w'(t_{i+\tau}) \mid \mathbf{w}_i^k)} \tag{3}$$

A machine learning called reservoir computing is an effective model-free predictor [7]. Reservoir computing has been applied to chaotic time series (e.g., Lorentz equation and Kuramoto-Sivashinsky equation) [7,8]. In this study, we consider the echo state networks and use T' as the input data to obtain the future state of w' as the output data.

Figure 1(A) shows the variation in S_{RR} as a function of τ_a for different z at G = 0.8. Note that τ_a is set to the actual delay time (=$\tau\Delta t$, where Δt is the time resolution). S_{RR} takes high values at $z \sim 1.0$ m, indicating that T' and w' are synchronized each other. S_{RR} periodically changes in terms of τ_a, indicating the strong periodicity of both fluctuations. S_{RR} reaches to approximately 0.3 and the periodic dynamical structure disappears in the far-field. In the previous studies

[1,2], we have reported that high randomness of the streamwise flow velocity and temperature fluctuations in the far-field is attributed to the formation of high-dimensional chaos. This leads to the formation of non-synchronized state in the far-field. Figure 1(B) shows the spatial distribution of ΔS_E ($= S_{E,T'\to w'} - S_{E,w'\to T'}$). ΔS_E takes high positive values near the shear layer region between hot combustion products and cold surrounding air. This means that the temperature fluctuations strongly affect the streamwise flow velocity fluctuations at this region. These suggest that the transfer entropy is useful for extracting the driving region of a buoyancy-driven turbulent fire. Figure 2 shows the variation in the ΔS_E and correlation coefficient C between the predicted values and the corresponding reference values of w' as a function of x for different z at $G = 0.8$. The spatial distribution of ΔS_E reasonably corresponds to that of C in the near-field. This means that ΔS_E has a significant impact on the predictability of the streamwise flow velocity fluctuations in the near-field. These results show that the transfer entropy is an important measure for determining the predictability of the streamwise flow velocity fluctuations in the near-field under low gravity environment.

FARADAY INSTABILITY IN 1D CAVITIES : TIME CRYSTALS AND MODE SELECTION

Guillaume d'Hardemare [1], Antonin Eddi *[2] and Emmanuel Fort [1]
[1] Institut Langevin, ESPCI Paris, CNRS, PSL University, 1 rue Jussieu, F-75005 Paris, France
[2] PMMH, CNRS, ESPCI Paris, Universit PSL, Sorbonne Université, Universit de Paris, F-75005, Paris,France

Summary Faraday instability is equivalent to a time crystal, where the parametric amplification leads to the apparition of k-gaps, formally analogous to the energy band gap is solid-state physics. As energy is not conserved, this results in an unstable domain in k-space where modes grow. Here, we investigate experimentally Faraday instability in 1D cavities, where we can tune the excited mode by changing the cavity length. This allows us to probe the amplification band of the instability. Abruptly changing the phase of the excitation further allows us to observe the overdamped modes of the instability, measuring for the first time their decay rate predicted theoretically but never observed so far.

FARADAY INSTABILITY AS A TIME CRYSTAL

Faraday instability is observed when a liquid bath is vertically shaken above a certain threshold [1]. It has been extensively studied experimentally and theoretically as an instability in the stationary regime, with focus on the forcing threshold, pattern formation and the various dissipation processes or the hydrodynamic associated phenomena. This parametric instability can be revisited within the framework of Floquet time crystals. For an inviscid fluid in a bath submitted to vertical acceleration $a_0\cos(2\omega_f t)$, the modes are given by a Mathieu equation [2]. The free surface elevation $\xi(\mathbf{r},t)$ at position $\mathbf{r}$ and time t can be decomposed in Fourier modes $\hat{\xi}(\mathbf{k},t)$ of wavevector $\mathbf{k}$ following:
$\frac{\partial^2\hat{\xi}(\mathbf{k},t)}{\partial t^2} + \omega_0^2(\boldsymbol{k})\hat{\xi}(\mathbf{k},t) = -a_0 \mathrm{k}\cos(2\omega_f t)\,\hat{\xi}(\mathbf{k},t)$ with $\omega_0(\mathrm{k})$, the angular frequency given by the dispersion relation for gravity-capillary waves and k, the wavenumber. This equation describes the modes in a medium with a gravity modulation. The variation of the effective gravity induces a speed modulation of the gravito-capillary waves which can be seen as a modulation of the refractive index [4,5]. The solutions of the Mathieu equation are given by the Bloch-Floquet theorem while in the case of liquid with a small viscosity ν, a damping term $-2\gamma\partial\hat{\xi}/\partial t$ should be added to the Mathieu equation, γ being the damping rate related to the fluid viscosity by $\gamma = 2\nu\mathrm{k}^2$ [3]. Figure 1 shows a typical complex dispersion curve obtained with a small viscosity, with vertical k-gaps (in momentum). These k-gaps are the analog of the horizontal energy gaps observed in spatial crystals in which the waves cannot propagate. Within the k-gaps, the vertical excitation of the bath leads to two possible solutions: one being overdamped compared to a bath at rest, the other being underdamped. For sufficient forcing, the Faraday instability is observed and a standing wave at half the excitation frequency appears on the surface.

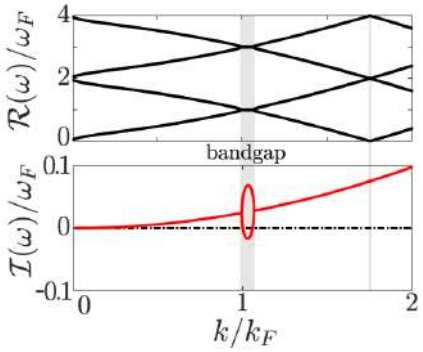

Figure 1: Dispersion relation showing the band structure of the Faraday instability as a water wave time crystal. Top: real part $\Re(\omega)$ of the angular frequency ω versus the normalized wavenumber k/k_F with k_F being the Faraday wavenumber Bottom: Imaginary part $\Im(\omega)$ of the angular frequency as a function of k/k_F. The small parabolic variation corresponds to the viscous damping

EXPERIMENTS

We now focus on a versatile implementation of a 1D time crystal based on Faraday instability. It consists in a 1D wave cavity whose length L can be tuned that is submitted to vertical harmonic vibrations. Faraday waves are excited at half the forcing frequency Ω_F. The associated wavelength λ_F is given by the capillary-gravity dispersion relation for water-waves and is chosen so that it equals twice the width of the tank to excite the first transverse mode of the cavity. We measure the exponential growth rate of the waves which corresponds to the imaginary part of the Floquet exponent $\Im(\omega)$ as well as the wavelength λ inside the cavity. The growth rates (Fig. 2a) exhibit peaks separated by half a Faraday wavelength λ_F. These peaks correspond to matching between a mode associated to the Faraday instability and a resonant mode of the cavity which wavelength satisfies $\lambda = 2L_{\mathrm{eff}}/n$, n being the mode number and L_{eff}, the effective cavity length taking into account the boundary conditions. Varying the cavity length results in scanning the k-gap associated to the Faraday instability (Fig. 2b). The curve of the growth rate thus corresponds to a periodic scanning of the k-gap with maxima obtained for cavity lengths satisfying $L_{\mathrm{eff}} = n\lambda_F/2$.
Last, we introduce a topological defect in the time crystal by suddenly π-shifting the excitation period which results in concatenating two time crystals with opposite phase. At the interface, the existing mode is turned into the overdamped one. By extracting the damping rate, we are thus able to measure the entire complex dispersion inside the k-gap of the Faraday time crystal.

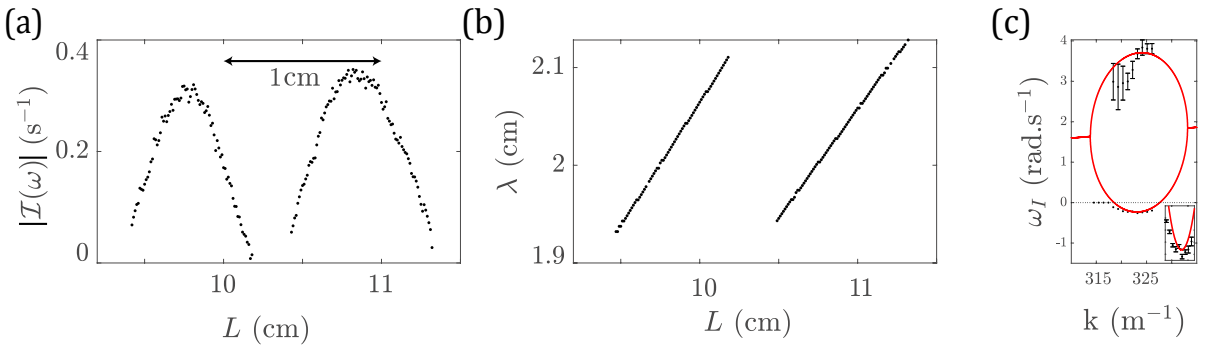

Figure 2: (a) Growth rate of the amplitude $|\Im(\omega)|$ and (b) wavelength λ of the mode in the cavity as a function of the cavity size L. The peaks are associated to the matching between the Faraday instability k-gap modes and the ones of the cavity. (c) Measurement of growth and decay rates inside the k-gap. The solid red curves give the result of the computation based on a damped Mathieu equation using experimental values of the viscosity. The inset provides a zoom on the lower part of the curve.

GROWTH AND DECAY OF ISOLATED TURBULENT BAND IN PLANE-COUETTE FLOW

Jianzhou Lu, Jianjun Tao *, and Weitao Zhou
SKLTCS, Department of Mechanics and Engineering Science, College of Engineering, Peking University, Beijing, P.R. China

Summary The transition of plane Couette flow is numerically investigated in a large computational domain. It is found that the averaged period of the transient growth reduces slowly with the decrease of the Reynolds number (Re) except when Re is close to a threshold value of 286. During the decay process, the band contracts from its both ends with a statistical constant velocity, but keeps its center, width, and tilt angle statistically unchanged. For self-sustained turbulent band, three growth styles are observed. At moderate Re, the isolated band extends obliquely as what happens in plane Poiseuille flow. With the increase of Re, transverse split occurs and the band breaks into several attached segments, forming a shape of 'F'. Further increasing Re leads to a longitudinal split, i.e. the isolated band becomes wider at first and then splits into two parallel bands.

INTRODUCTION

It is known that plane Couette flow (PCF) is always linearly stable, but may turn to be turbulent at moderate Reynolds numbers by the subcritical transition. Leutheusser and Chu [1] studied the flow between a moving water surface and an upper flat stationary plate, and determined the transitional Reynolds number as 280. It should be noted that the spanwise aspect ratio of the experimental channel was small and the water flow was turbulent, suggesting that the water surface was rough. From then on, substantial progresses have been made and the localized turbulent band or stripe is found to be a key structure for the transition in channel flows [2]. The band growth and decay processes have been simulated in large domains with under-resolution simulations [3, 4], and it was mentioned that the low resolution lowered the threshold for sustained turbulence from 325 to 210 [3] and impeded reliable predictions for fully resolved cases. Therefore, the spatio-temporal evolution of the isolated turbulent bands still requires fully-resolved numerical investigations.

METHODS AND RESULTS

We conduct numerical simulations on the PCF in a large domain of the size $800h \times 2h \times 712h$, and a spectral code [5] is used to solve the incompressible Navier-Stokes equations, where the velocity field is expanded in a basis of Fourier modes (in the streamwise x- and spanwise z-directions) and Chebyshev polynomials (in the wall-normal direction y). The numerical resolution is 2048 spectral modes in x, 33 in y, and 2048 in z. The boundary conditions are periodic in the x- and z-directions and there is no-slip at the walls ($y = \pm h$). The half of the velocity difference between the boundaries U and the half channel gap h are chosen as the characteristic velocity and the length scale, respectively. In the following simulations, an isolated turbulent band, i.e., a unique straight band whose length is several times smaller than the domain size, is used as the initial perturbation.

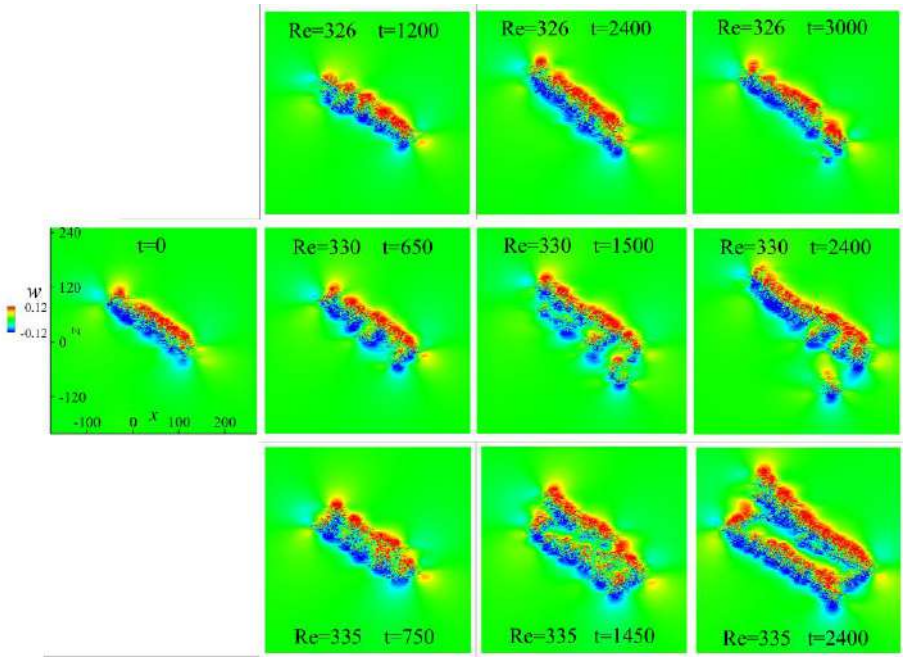

Figure 1: Iso-contours of the spanwise velocity in the mid-plane. The initial fields are the same for all three cases.

*Corresponding author. E-mail: jjtao@pku.edu.cn

As shown in Fig. 1, there are three different growth styles for localized turbulence. For moderate Re, e.g. Re=326, the isolated band extends obliquely with time as what occurs in plane Poiseuille flow but with a much lower extension velocity. When Re increases to 330, transverse split occurs and the band breaks into attached segments, forming a shape of 'F'. It seems that the transverse split may lead to the lateral branching observed in the previous under-resolution simulations [4]. A longitudinal split happens when Re is further increased, e.g. Re=335 as shown in Fig. 1, the isolated band becomes wider at first and then splits into two parallel bands. In fact, the later growth style includes the former one(s), and hence the turbulence spreads more and more efficiently with the increase of Re.

Since the disturbance kinetic energy of the main body of the isolated band is statistically uniform and the band is straight with a finite width, its shape may be simplified as a tilted rectangle. The center, width, length, and tilt angle of the rectangle can be determined based on the disturbance kinetic energy of the band in the midplane with the method proposed for plane Poiseuille flow [6]. According to the simulations for Re=314, 317, and 318, the position of the band center varies stochastically but does not move much during a period more than 3000 time units, reflecting that the convective velocity of such a localized structure is nearly zero. After an initial period of adjustment, the band contracts longitudinally, i.e. its length decreases generally while its width and tilt angle remain statistically constants. The temporal variation of the band length may be fitted linearly, suggesting a constant contraction velocity. A similar contraction phenomenon was observed before in an under-resolved simulation, where the position of the band center and the shape parameters (e.g., the tilt angle) were not analyzed quantitatively [3]. For the present decaying isolated band, the tilt angle is $(27 \pm 3)^\circ$ when Re is between 314 and 318.

In order to study the statistical properties of the decay process (Fig. 2a), ten samples are calculated for each Reynolds number, and the initial flow fields are composed by the same band and different random disturbances in the whole fields. We define a parameter, the transient-growth time T_{grow}, which is the ensemble average of the mean periods obtained from different samples when the growth rate of E_{k} is positive, and draw it in Fig. 2(b). It is shown that T_{grow} decreases monotonically by lowering Re, and there is a drastic decline of T_{grow} as Re reduces to 286, indicating a threshold for the transient growth of the turbulent band. When Re<286, the probability of the transient growth is very small, implying that the turbulent band can hardly be formed from the transient growth of any initial disturbances.

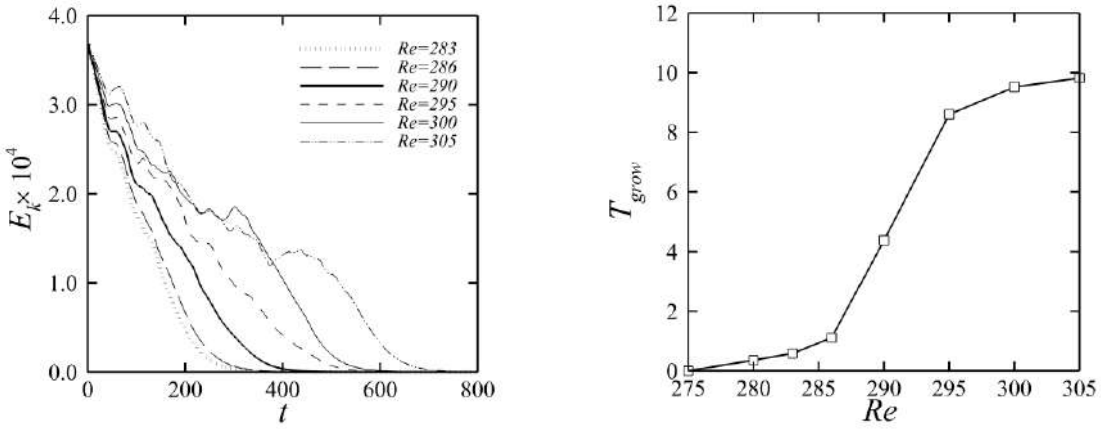

Figure 2: Time series of the volume-averaged disturbance kinetic energy E_{k} at different Reynolds numbers obtained with the same initial turbulent band; (b) transient-growth time T_{grow} as a function of Re

CONCLUSIONS

Direct numerical simulations are carried out to study the subcritical transition of plane Couette flow in a large computational domain. It is found that the isolated turbulent band decays in a style of longitudinal contraction at low Reynolds numbers, and the lower bound Reynolds number of the transient-growth regime is defined as 286. In addition, three different growth styles of the isolated turbulent band are illustrated, i.e. the oblique extension, transverse split, and the longitudinal split. It is believed that their joint action leads to the formation of labyrinthine patterns observed in simulations and experiments.

BISPECTRAL MODE DECOMPOSITION FOR DISCOVERY OF TRIADIC INTERACTIONS FROM FLOW DATA

Oliver T. Schmidt * [1]
[1]Department of Mechanical and Aerospace Engineering, University of California San Diego, La Jolla, CA, USA

Summary Bispectral mode decomposition is introduced as a mean of detecting triadic nonlinear interactions in flow data. The method leverages the fact that triadic interactions are characterized by quadratic phase coupling. The proposed decomposition computes modes that optimally represents the data in terms of an integral measure of the bispectral density, which in turn detects quadratic phase coupling in deterministic signals. The two main outputs of the method are the mode bispectrum and the corresponding bispectral modes. The mode bispectrum indicates triadically interacting frequency triplets and the corresponding modes reveal the coherent flow structures generated by the interaction. We demonstrate the method on direct numerical simulation data of planar cylinder flow at $Re = 500$ and particle image velocimetry data of massively separated turbulent flow behind a flat plate at high angle of attack.

INTRODUCTION

Triadic interactions are the fundamental mechanism of energy transfer in fluid flows. They result from the quadratic nonlinearity of the Navier-Stokes equations and manifest as triads,

$$\mathbf{k}_j \pm \mathbf{k}_k \pm \mathbf{k}_l = \mathbf{0}, \quad f_j \pm f_k \pm f_l = 0,$$

in Fourier space, i.e., triplets of three wavenumber vectors, $(\mathbf{k}_j, \mathbf{k}_k, \mathbf{k}_l)$, or frequencies, (f_j, f_k, f_l), that sum to zero. The latter condition implies that triads of wavenumber vectors and frequencies form triangles in their respective spaces. The turbulent cascade of energy, from large to small scales, is a well-known result of triadic interactions (see, e.g., Kraichnan, 1967).

As the Fourier transform of the third statistical moment, the bispectrum is a direct measure of non-Gaussianity of a stochastic signal. Most important in the context of three-wave interactions is the observation that the bispectrum correlates two frequency components with the frequency component corresponding to the sum of these two frequencies. This can be seen from its definition in terms of the expectation operator,

$$S_{qqq}(f_1, f_2) = \lim_{T\to\infty} \frac{1}{T} E[\hat{q}(f_1)^* \hat{q}(f_2)^* \hat{q}(f_1 + f_2)]. \tag{1}$$

The goal of this work is to devise a modal decomposition that reveals the presence of triadic nonlinear interactions from multidimensional data. Since quadratic phase coupling is characteristic of these interactions, the bispectrum defined in equation (1) can be used to detect them. To compute modes that exhibit quadratic phase coupling over extended portions of the flow field, we require the decomposition to optimally represent the data in terms of an integral measure of the bispectral density. These requirements translate into the problem of finding the vector that maximizes the Rayleigh quotient of a non-Hermitian matrix. We solve this problem using a slightly modified version of the algorithm by He and Watson (1997) for the computation of the numerical radius of a general complex matrix.

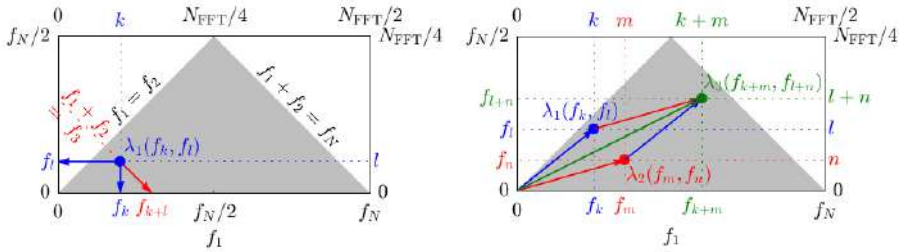

Figure 1: Frequency triads in the principal region of the mode bispectrum. Left: a local maximum $\lambda_1(f_k, f_l)$ indicates phase-coupling between the components of the triad (f_k, f_l, f_{k+l}) due to quadratic nonlinearity. Harmonics and the mean flow distortion (not shown) are generated by self-interactions like (f_k, f_k, f_{2k}) and $(f_k, f_{-k}, 0)$, respectively. Right: two triads (f_k, f_l, f_{k+l}) and (f_m, f_n, f_{m+n}) can interact to generate a new wave component (f_{k+m}, f_{l+n}).

The resulting decomposition may be understood as the extension of the analysis of time signals using higher-order spectra to multidimensional datasets, or *vice versa*, as an extension of spectral proper orthogonal decomposition to higher-order spectra. The two main results of this bispectral mode decomposition are the mode bispectrum and bispectral modes. As an estimator for the mode bispectrum we adapt Welch's method (Welch, 1967), which is an asymptotically consistent spectral estimator for the power spectral density that may equally be used to converge third-order statistics.

*Corresponding author. E-mail: oschmidt@ucsd.edu.

Figure 1 shows a schematic of the principal region of the mode bispectrum. All other regions contain redundant information or lie outside of the Nyquist limit. It hence suffices to plot this region. For brevity, we will use integer frequency index doublets (k, l) instead of physical frequency doublets (f_k, f_l) or triplets (f_k, f_l, f_{k+l}) to represent triads. Also discussed in figure 1 is the generation of new wave components through triad interactions.

Database						Spectral estimation		
Case	Variables	N_x	N_y, N_r	N_t	Δt	N_{FFT}	N_{ovlp}	N_{blk}
Cylinder DNS	u, v	250	125	4096	0.06	1024	512	7
Plate PIV	u, v	120	69	$2.5 \cdot 10^4$	$0.002s$	5000	0	50

Table 1: Parameters of the example databases and spectral estimation parameters. The DNS data are non-dimensionalized by the cylinder diameter and freestream velocity and the PIV data are given in SI units.

To demonstrate the method, we investigate the two flows summarized in table 1. The direct numerical simulation data of planar cylinder flow at $Re = 500$ is a canonical example of a laminar flow with strong nonlinear dynamics. The second example is that of particle image velocimetry (PIV) data of a flat plate at a high angle of attack. It is characterized not only by nonlinear dynamics at a wide range of scales down to turbulence, but also high levels of measurement noise. Figure 2 shows a flow visualization and of the PIV data, as well as the mode bispectrum and two examples of modes obtained from bispectral mode decomposition. In this example, the triad corresponding to the self-interaction of the fundamental bluff body vortex shedding is analyzed. The bispectral mode (11,0) shown in figure 2d corresponds to this fundamental instability evolving on the mean flow. By comparing the fundamental mode with its self-interaction, i.e., mode (11,11) shown in 2e, it becomes evident that the fundamental self-interaction occurs for a phase angle of 90° and generates a structure of twice the fundamental streamwise wavenumber (and frequency). As anticipated, the mode bispectrum shown in figure 2c confirms that the fundamental self-interaction is the dominant nonlinear triad in this flow, i.e. it attains its maximum at (11,11). This can be seen more clearly in the insert, in which the fundamental and its self-interaction triad are marked by circles. The cylinder flow example will be presented in the talk. Furthermore, we will introduce the summed mode bispectrum and the bispectral interaction map. The summed mode bispectrum is a compact representation of the mode bispectrum that permits comparison with classical spectra. The bispectral interaction map indicates where in physical space triadic interactions are active.

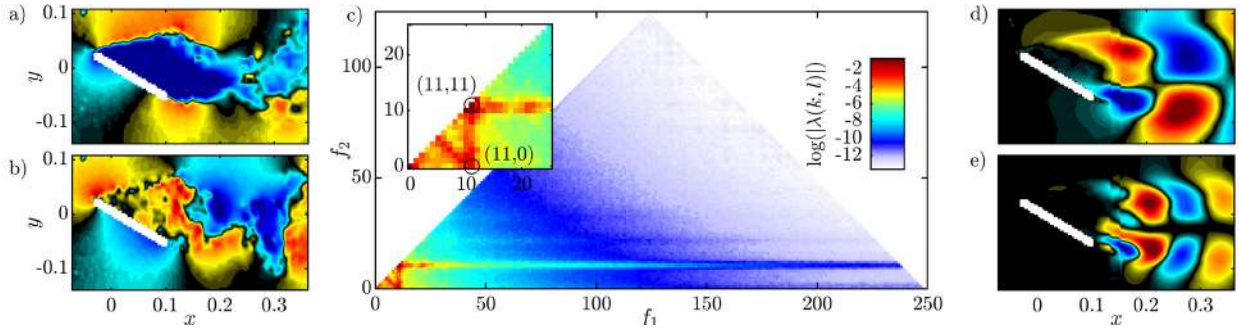

Figure 2: Bispectral mode analysis of PIV data of a flat plate at high angle of attack: (a,b) instantaneous streamwise and transverse velocity field; (c) mode bispectrum; (d) bispectral mode (11,0) corresponding to the fundamental bluff body vortex shedding frequency; (e) bispectral mode (11,11) resulting from the self-interaction of the fundamental mode. The streamwise velocity component is shown in (d,e). PIV data courtesy of Karen Mulleners, EPFL.

AN ADJOINT PRECURSOR OF EXTREME EVENTS IN CHAOTIC SYSTEMS

Alberto Racca * [1] and Luca Magri[1,2]
[1]Department of Engineering, University of Cambridge, Cambridge, United Kingdom
2Institute of Advanced Studies, Technische Universität München, Munich, Germany (visiting)

Summary We propose an *adjoint precursor* for real-time prediction of extreme events in chaotic systems. The precursor is calculated in the adjoint tangent space, which is decomposed by Covariant Lyapunov Vectors (CLVs) analysis. To quantify the performance of the adjoint precursor, we introduce a figure of merit in the time domain, which is compared with the traditional statistical figures of merits. We test the formulation on a variety of chaotic fluid systems: Rayleigh-Bénard convection, turbulent shear flow, and electrodissolution. In this abstract, we report the results for the electrodissolution system.

INTRODUCTION

Extreme events, which are sudden and violent changes of a state or an observable, arise in a large spectrum of fluid mechanics systems such as oceanic rogue waves, weather patterns, electrodissolution, combustion instabilities and turbulence. Because extreme events are typically undesirable in engineering systems, robust statistical methods for their prediction have been proposed recently [1, 2]. In this work, we use covariant Lyapunov vector (CLV) analysis combined with an adjoint method to propose a new precursor in a chaotic system. Covariant Lyapunov Vectors provide a basis of the tangent space of a chaotic attractor, which is split into unstable, stable and neutral subspaces. The CLVs determine the directions along which an infinitesimal perturbation to the system evolves exponentially with rates given by the Lyapunov Exponents [3]. In stability analysis, [4] mathematically and numerically showed that CLV analysis is a generalization of eigenvalue and Floquet theory to chaotic systems. Only recently a stable numerical algorithm for computing CLVs has been proposed [5]. This algorithm was employed to investigate chaotic fluid systems such intermittency in turbulence [6] and acoustics [4]. We employ CLV analysis to find a basis of the adjoint space, which is necessary to design the proposed precursors.

METHODS

We consider a fluid system that can be described as a nonlinear dynamical system $\dot{\mathbf{q}} = \mathbf{F}(\mathbf{q})$. The tangent equation $\dot{\mathbf{y}} = \mathbf{J}\mathbf{y}$, where $\mathbf{J} \equiv d\mathbf{F}/d\mathbf{q}$ is the Jacobian, governs the dynamics of an infinitesimal perturbation $\mathbf{y}$ to the solution $\mathbf{q}$. We consider the adjoint equation, $\dot{\mathbf{y}}^+ = -\mathbf{J}^T\mathbf{y}^+$, in which the adjoint variables are denoted by the superscript +. We express the adjoint solutions with the mapping $\mathbf{M}^+(t_0, t^*)$, which is defined as $\mathbf{y}^+(t^*) = \mathbf{M}^+(t_0, t^*)\mathbf{y}^+(t_0)$. We define the adjoint precursor

$$\lambda^{+(i)}_{\Delta T}(t) = \frac{1}{\Delta T}\ln\left(\frac{||\mathbf{M}^+(t-\Delta T, t)\mathbf{y}^+_{\mathbf{v}^+_i}(t-\Delta T)||}{||\mathbf{y}^+_{\mathbf{v}^+_i}(t-\Delta T)||}\right), \tag{1}$$

where $\mathbf{v}^+_i$ is the i-th adjoint CLV associated with the i-th adjoint Lyapunov exponent. We introduce the quantity $x_{max}(t) = \max_{t' \in (t+\tau)}(x(t'))$ [1] to assess the causality relation between a precursor ν and an observable x, where $\tau = [t_i, t_f]$ is the time interval in which the precursor spikes to foretell the occurrence of an extreme event. We compare the entire time series of the candidate precursor with x_{max} to evaluate the correlation between the earlier spike of ν with a future burst in x. The threshold that defines an extreme event is $x > x_{ee}$, whereas the threshold that defines a precursor for an extreme event is $\nu > \nu^*$. While the former is set a priori, the latter is chosen a posteriori depending on which predictive capability we want to maximize. To assess the performance of any pair (ν^*, x_{ee}), we compute statistical metrics for the classification of imbalanced data sets such as precision, recall and the F_1 score [7], which are based on the probability density functions (PDFs) $\mathcal{P}(\nu, x_{max})$, $\mathcal{P}(\nu)$ and $\mathcal{P}(x_{max})$. Statistical metrics are informative, but they cannot quantify the precursor's capability of correctly predicting an extreme event in the time domain. This is because statistical metrics are computed from the continuous overlapping of the two time series, but we are interested in correlating the spike of the precursor with the burst of the observable (rather than comparing the entire set of values in the interval τ). Therefore, we also assess the performance by evaluating the discrete matching between the two peaks in the time domain. We consider that an extreme event is correctly predicted if, during τ prior to the event, the precursor takes a value $\nu > \nu^*$ during a maximum. Subsequently, we define the Percentage of Predicted Peaks (POPP) as the number of correctly predicted extreme events over the total number of extreme events in the time series. With the POPP and the percentage of true positives over the total number of predictions (TPP), in a similar fashion to the F_1 score, we define a quantity F_{ee} to quantify the performance of the precursor in the time domain

$$F_{ee} = \frac{2}{\text{POPP}^{-1} + \text{TPP}^{-1}}. \tag{2}$$

RESULTS AND DISCUSSION

We test the formulation on a variety of chaotic fluid systems: Rayleigh-Bénard convection [8], turbulent shear flow [9], and electrodissolution [2]. Here, we report the results for an electrodissolution system, which displays homoclinic chaos. We time integrate the three nonlinear ordinary differential equations for 4×10^4 time units. The left panel of Fig. 1 shows the extreme events of the observable x, which phisycally is a current, preceded by spikes in the adjoint precursor associated with the unstable CLV direction, $\nu(t) = 1/\tau_{avg} \int_{t-\tau_{avg}}^{t} \lambda_{0.01}^{+(1)}(t')dt'$, $\tau_{avg} = 1.5$. The average over τ_{avg} is performed to filter out high amplitude and frequency oscillations that are related to the fast dynamics of the bursts. We set $x_{ee} = 15.0$, which is a threshold such that EE% $= 2.2\%$ of the total time is covered by extreme events (755 spikes). In the right panel of Fig. 1, we plot the figures of merit as a function of ν^* for a selected range of the threshold and prediction interval $\tau = [3.3, 4.0]$ along with the statistical False Positive Rate (FPR). The value $\nu_1^* = 1.336$ that maximizes the conventional statistical score, $F_1 = 0.603$, is not suitable for assessing extreme event prediction in the time domain because of the large number of false positives (POPP = 1, TPP = 0.616, FPR/EE% = 0.276 and $F_{ee} = 0.763$). On the other hand, the choice $\nu_2^* = 1.619$, which maximizes the proposed time-domain metric, $F_{ee} = 0.964$, is able to predict 97.5% extreme events with a low rate of false positives of 3.6% (POPP = 0.975, TPP = 0.964, FPR/EE% $= 0.023$). (Note that the intermediate value $\nu_3^* = 1.563$ ensures POPP $= 1$, but it provides more false positives: TPP $= 0.883$, FPR/EE% $= 0.044$ and $F_{ee} = 0.939$ (right panel of Fig. 1).)

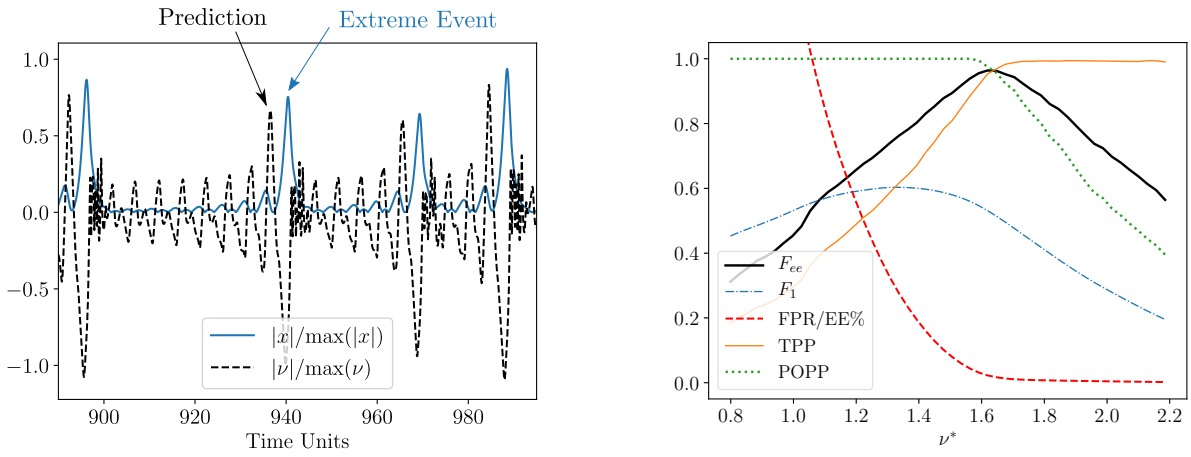

Figure 1: Left: Observable with extreme events and adjoint precursor. Right: different figures of merit as a function of the precursor threshold ν^*.

In conclusion, we propose an adjoint precursor for predicting the onset of extreme events in chaotic systems. We test the precursor in chaotic fluids systems, showing the results for an electrodissolution problem. We quantify the performance of the adjoint precursor with both statistical and time-domain figures of merit. The adjoint precursor performs well against both figures of merits. This work opens up new possibilities for the prediction of extreme events in deterministic systems. Current work is devoted to scaling this method up to high-dimensional turbulent flows.

ODE TO AN ICICLE: ON THE GROWTH MECHANISM OF RIPPLED ICICLES

John Ladan * [1] and Stephen W. Morris[1]
[1]Department of Physics, University of Toronto, 60 St George St.,Toronto, Ontario, Canada, M5S 1A7.

Summary Icicles are familiar ice formations with a distinctive morphology. Icicles form when water drips from a point of support into sub-freezing air. Liquid water flows over the icicle's evolving shape, onto which some of the water freezes, while the remaining water drips from the tip. Icicles often have a rippled shape, which has been traced to an instability triggered by the presence of small amounts of impurities in the water. We grew rippled icicles under controlled laboratory conditions using a dye as the impurity. The dye allowed the exterior flow of the water over the icicle surface to be visualized. In addition, we examined cross sectioned icicles and used the pattern of inclusions observed to study the concentration dependence of the ripple wavelength. Both these studies shed new light on the unexplained mechanism of the rippling instability.

Introduction

Icicles are deceptively simple-looking natural ice formations. They are an example of "wet" ice growth [1], in which a gravity-driven thin-film flow of the liquid phase control the ice growth mechanism. While ordinary icicles are obviously mostly harmless, similar wet ice build-up processes can be a significant hazard if they occur on power lines [2] or aircraft wings [3]. Accounting for the shape of such ice formations is a difficult free-boundary growth problem with a natural time scale separation between the slowly evolving shape that forms the substrate for the relatively fast flow of the liquid water. This flow in turn determines the availability of water for ice formation as well as controlling the flux of latent heat away from the freezing surface and into the surrounding cold air. The emergent shape of an icicle is thus the result of a highly non-equilibrium growth process [4].

Rippled icicles

It is commonly observed that some natural icicles exhibit a rippled shape, while others are smooth. The wavelength of the ripple pattern is remarkably constant, close to 1 cm, independent of the growing conditions. This suggests that icicle growth is subject to a strongly wavelength-selective morphological instability. In the first detailed laboratory study of icicle formation and morphology, Chen *et. al* [5] showed that the presence of impurities in the water is responsible for this instability. The growth rate of the ripple pattern was roughly logarithmic in the impurity concentration. No threshold concentration was observed for the onset of the instability, which is apparent even at very low concentrations (around 20 ppm of NaCl), however icicles grown from distilled water are smooth. For concentrations below 300ppm, ripples travel slowly and consistently upward during growth. Previous theories of the rippling instability [6, 7, 8] assumed pure water and thus completely fail to account for the dependence of the instability on impurities.

In the present study, we extend and improve upon the experimental results of Chen *et. al* [5], using an updated version of the same apparatus. In addition to using NaCl, we employed a strong dye (sodium fluorescein) as an impurity, and take sections of the icicle to observe the interior. The dye allowed tracking of the impurities visually — appearing orange when trapped inside the ice, but fluorescing green when in liquid on the surface. We propose that the mixed-phase nature of the ice and the rivulet pattern on the surface are intrinsic to the mechanism of ripple formation.

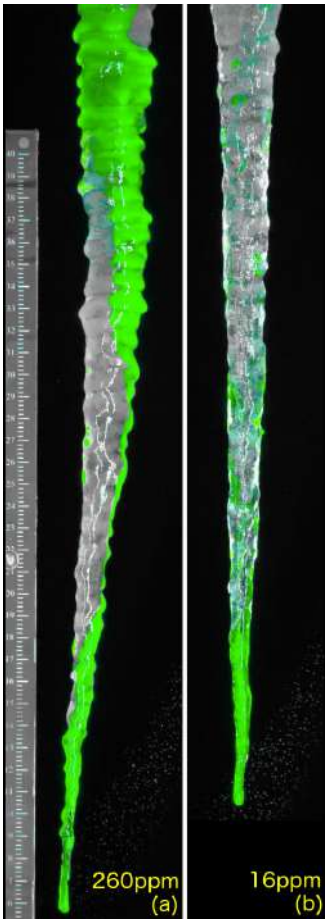

Figure 1: False-colour images of two icicles. The liquid on the surface is highlighted green. The 260ppm icicle (a) has significant ripples and much more liquid covering the surface than the 16ppm icicle (b).

Surface coverage of liquid

Sodium fluorescein only emits green light when in liquid, providing a visualization of the rather complex pattern of water flow over the surface of the growing icicle (Figure 1). The fluorescence shows that the surface flow is entirely different than the full-coverage thin shear flow assumed by existing models of the rippling instability [6, 7, 8]. This flow turns out not to wet the entire surface of the icicle, but rather is confined to rivulets. The complex and shifting pattern of rivulets interacts with the topography of the ripples.

Isolating the liquid covered parts of the icicle, we observe that the amount of surface covered increases with concentration, and the liquid tends to sit atop the ripples. The location of the water appears to coincide with regions of higher growth, consistent with the upward travel direction of the ripples.

*Corresponding author. E-mail: jladan@physics.utoronto.ca.

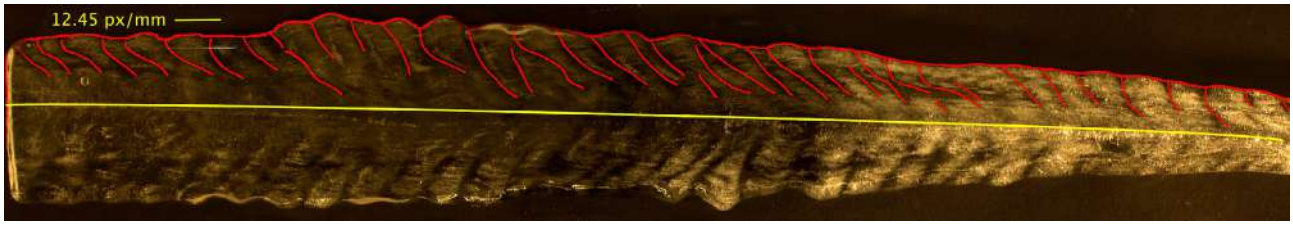

Figure 2: A longitudinal section of an icicle grown with 80ppm NaCl with clear sections of ice highlighted above the centreline. Down is to the right. The upward angle of the inclusions matches the upward growth direction of the ripples, and the median distance between lines matches the wavelength of the ripples. Near the middle of the icicle, there is evidence of wavelength selection where a band of inclusions is edged out by its neighbours.

Trapped impurities

When rippled icicles are cross-sectioned, a chevron pattern of inclusions within the ice is observed [4], which is correlated with the exterior rippled shape. We made the first systematic study of the pattern of inclusions, which contain much more information about the rippling instability than is available from the exterior topography alone. When viewed closely, inclusions appear to be small bubbles inside of the ice. However, when a dye (sodium fluorescein) is used, we can observe that the inclusions are actually filled with the instability-driving impurities.

Longitudinal sections give a view of the growth of the icicle over time. The inclusions have a chevron-shape (Figure 2), with a median centre-to-centre distance between bands matching the wavelength of the ripples (typically 7-10 mm). The upward slope of the inclusions matches what we expect from the ascending ripples observed in past experiments [5]. The concentration dependence of the spacing between bands of inclusions is weak, as shown in Figure 3.

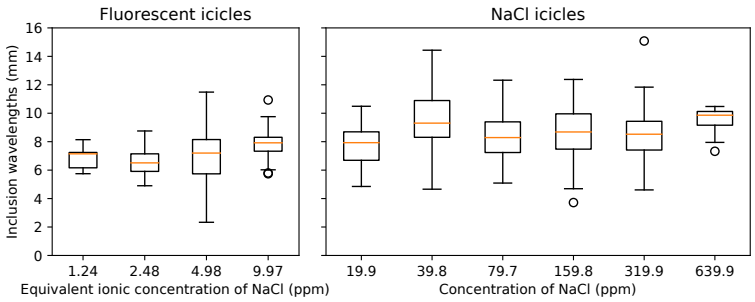

Figure 3: Measured centre-to-centre distances of inclusion bands in icicles. The values match previous measurements of the ripple wavelength [5]. The slight increasing trend with concentration is not statistically significant with this number of measurements.

Unsurprisingly, the amount of the inclusions increases with salt concentration. At the lowest concentrations (less than 20ppm NaCl), the ice is nearly pure. When ripples are visible on the icicle (between 20ppm and 200ppm NaCl) the chevron pattern is clear in the interior. At higher concentrations in this range, there are also signs of wavelength selection, as some bands of inclusions are squeezed out by their neighbours. Above roughly 300ppm NaCl (one tenth the concentration of sea water), there is no longer a chevron pattern and the entire interior appears to be mixed-phase even though ripples are still present. This is also the concentration above which the phase-speed of the ripples (up or down the icicle) is unpredictable, which suggests the bands of pure ice may control the travel of the ripples.

Conclusions

There exists no complete theory of icicle growth which includes impurity effects and the rippling instability. Our observations suggest that the instability is not simply due to freezing point depression or the complete rejection of impurities from the ice. A complete theory needs to account for the pattern of trapped inclusions, as well as for the incomplete surface coverage due to the varying surface properties of the ice.

LIFE AND FATE OF A BUBBLE IN A CONSTRICTED HELESHAW CHANNEL

Antoine Gaillard[1], Jack S. Keeler[2], Alice B. Thompson[2], Andrew L. Hazel[2], and Anne Juel *[1]
[1]MCND and Department of Physics & Astronomy, University of Manchester, UK
[2]Department of Mathematics and MCND, University of Manchester, UK

Summary We study experimentally a geometrically-perturbed Hele-Shaw channel which supports several stable invariant modes of bubble propagation. We investigate the evolution of a centred bubble of fixed volume as a function of flow rate and initial shape. We find that the bubble frequently changes topology through the exploration of multiple-tipped modes and that in the long term, either a single bubble may be recovered or multiple bubbles remain, whose relative distance increases with time. We find numerically that these dynamics are orchestrated by weakly-unstable, two-bubble edge states of the system. We also study how the bubble becomes increasingly sensitive to initial conditions and exhibits long and disordered transients as the flow rate increases.

INTRODUCTION

Two-phase displacement flow in a confined geometry is a fundamental problem in fluid mechanics with applications in biomechanics, geophysics and industry. A canonical example is the viscous fingering instability which occurs when air displaces a viscous fluid in a Hele-Shaw channel of width much greater than its depth. A single finger of air, symmetric about the centreline of the channel, is formed following the destabilisation of an initially flat interface [1]. Beyond a threshold value of the driving parameter that depends on the roughness of the channel, this finger becomes unstable to tip-splitting leading to the emergence of complex patterns [2]. As the steady solution is found to be linearly stable for all computed flow rates [3], any further instabilities observed must arise subcritically; that is, they result from finite amplitude perturbations which drive the system away from equilibrium. In addition, the depth-averaged model of this two-phase flow contains alternative families of multiple-tipped symmetric solutions and asymmetric solutions, which are weakly unstable [4].

Recent experiments and numerical simulations [4] have shown that with the introduction of a depth-perturbation to the bottom of the channel henceforth referred to as a rail (Fig. 1a,b), the system retains similar modes of finger or bubble propagation as in the Hele-Shaw channel of rectangular cross-section, but their stability is altered so that several stable invariant solutions occur for the same imposed flow rates, as indicated by the solid lines in the numerical bifurcation diagram of Fig. 1c.

Hence, several long-term invariant outcomes are possible for a bubble propagating from a centred initial position but the bubble may also undergo changes in topology by breaking up into multiple bubbles [5]. In this talk, we characterise the transient evolution of propagating bubbles from controlled initial conditions. We compare our results with numerical simulations which indicate that when the flow-rate is large enough the bubble evolution is guided by transient exploration of the stable manifolds of weakly unstable two-bubble edge states of the system [5].

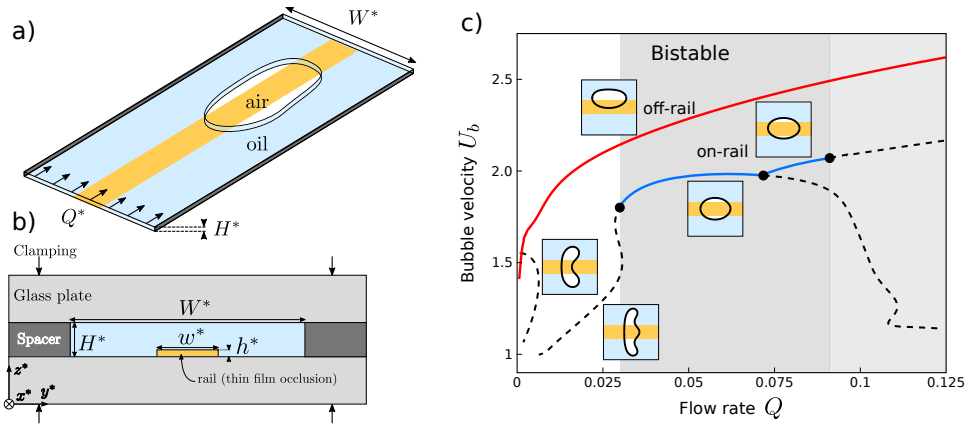

Figure 1: (a) Top-view of the experimental channel with an axially uniform, centred rail. (b) Cross-section of the channel. (c) Numerical bifurcation diagram depicting the steady modes of bubble propagation in terms of the bubble velocity as a function of the flow rate [5]. Stable and unstable modes are indicated by solid and dashed lines, respectively. The red line corresponds to stable off-rail solutions, which are asymmetric about the centreline of the channel and the blue lines to stable on-rail symmetric and asymmetric solutions.

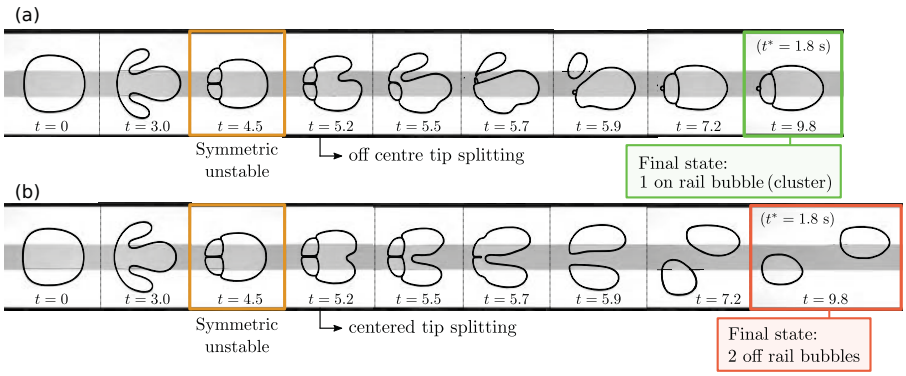

Figure 2: Sensitivity to initial conditions. (a) and (b) show different bubble evolutions starting from bubbles of similar shapes with initial bubble width $b = 0.58$ at relatively large flow rate $Q = 0.10$.

EXPERIMENT

The experimental channel is shown schematically in Fig.1a,b. The channel aspect ratio is fixed at 40, and the rail occupies 25% of the channel width and 2.4% of its height. An air bubble of controlled volume is injected at one end of the channel and propagated by infusing silicone oil at a constant flow rate with a non-dimensional flow rate $Q = \mu Q^* / (W^* H^* \sigma)$, where μ is the dynamic viscosity of the oil, σ the surface tension, $W^* H^*$ the cross-section of the unoccluded channel and Q^* the dimensional flow rate. We impose controlled initial conditions by deforming a centred bubble to a width $b = b^* / W^*$, and propagating it from rest. We track its evolution in top-view with a camera that moves with the bubble.

RESULTS

We find that depending on the initial bubble shape and the value of the flow rate, an initially centred bubble may evolve towards the on-rail or off-rail invariant modes (see Fig. 1c) or undergo a change in topology by breaking up into two bubbles, whose relative distance increases as they propagate. There is a rich variety of transient evolution scenarios leading to these long-term outcomes, which each occurs in well-defined regions of the parameter plane spanning flow rate and initial bubble width.

Above a threshold flow rate, initially slender bubbles tend to evolve towards on-rail invariant modes, often through a complex transient evolution involving break-up and recombination events. By contrast, initially wide bubbles break up into two separating bubbles. Examples of these long-term outcomes are shown in the images of the final states in Fig. 2.

For initially wide bubbles, the early-time evolution leads to a double-tipped bubble reminiscent of the weakly unstable state shown in Fig. 1c. As the bubble propagates, the two tips elongate until break-up into two bubbles on either side of the rail. These two newly formed bubbles may either remain on separate sides of the rail or one may migrate over the rail to recombine with the other. Numerical simulations of this process indicate that the evolution of this newly formed two-bubble system is orchestrated by weakly unstable two-bubble steady solutions whose existence depends on the flow rate and the relative bubble sizes.

For more slender bubbles, the early-time evolution is to a triple-tipped bubble similar to the unstable steady solution in Fig. 1c. The triple-tipped bubble breaks up into three bubbles which recombine into a compound bubble, as illustrated by the first three snapshots in Fig. 2(a-b). This symmetric bubble then breaks up into two bubbles which either recombine into an on-rail asymmetric compound bubble (a) or separate indefinitely (b). Fig. 2 also illustrates the sensitivity of the system at high flow rate since both figures correspond to the same initial condition within experimental resolution. In fact, as the flow rate is increased, the evolution becomes increasingly disordered and the bubble can break up into multiple parts, some of which are sufficiently small to rapidly separate from the larger bubbles as they propagate, resulting in a loss of volume of the remaining parts.

LOCALISED RADIAL PATTERNS ON THE FREE SURFACE OF A FERROFLUID

D. J. Hill *[1], D. J. B. Lloyd[1], and M. R. Turner[1]
[1]Department of Mathematics, University of Surrey, Guildford, Surrey GU2 7XH, UK

Summary This paper investigates the existence of localised axisymmetric (radial) patterns on the surface of a ferrofluid; smooth, bounded solutions which decay exponentially away from the pattern's centre (core). Results are shown for an unbounded cylinder of ferrofluid equipped with a linear magnetisation law, where a uniform magnetic field is applied vertically through the fluid. For a critical applied field strength, three classes of stationary radial solutions are found: spots A & B which have a larger magnitude at the core, and rings which have algebraic decay towards the core. These correspond exactly to the classes of radial solutions found for the Swift-Hohenberg equation [1, 2]. The values of the linear magnetisation μ and depth D of the ferrofluid are investigated and parameter regions in which localised radial solutions emerge are identified.

INTRODUCTION

Localised patterns appear in many physical and biological settings; vegetation in arid-climates [3] and crime hotspot modelling [4] to name but a few. Studying the Rosensweig instability, a normal-field instability where peaks spontaneously emerge from the free surface of a ferrofluid when a supercritical vertical magnetic field is applied, allows analytical investigations to be motivated by experimental results. Localised radial peaks (spots) have been observed by Richter (2005) [5] for local perturbations of the applied magnetic field, which persist when the perturbation is removed.

By setting up the problem as a free-surface variational problem, the ferrohydrostatic equations greatly resemble the equations for the emergence of gravity-capillary waves, which have been studied in great detail. There are also ample examples of using invariant manifold theory to find radial localised solutions for ODEs. However, three significant problems arise for the radial ferrohydrostatic case:

1. The ferrohydrostatic equations include non-autonomous terms, meaning that standard water waves techniques might not apply.
2. The localised radial patterns observed in [5] are dominated by the dynamics near the core, so techniques to find homoclinic solutions, such as in the one-dimensional ferrohydrostatic problem [6], are no longer sufficient.
3. The ferrohydrostatic equations form a quasilinear PDE system, where invariant manifold theory is not currently established, except for periodic solutions [7].

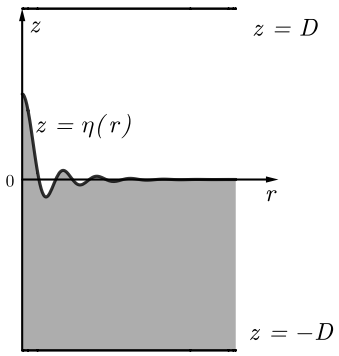

Figure 1: The domain of the problem; a ferrofluid (shaded) below air (white).

This work establishes a formal-analytic approach to finding the existence of radial solutions for the ferrohydrostatic problem, providing a framework for a rigorous proof at a later time. It also contributes techniques for future investigations of localised solutions to a PDE system.

THEORY & RESULTS

The domain is defined as two immiscible fluids from $-D < z < \eta(r)$ and $\eta(r) < z < D$, respectively, separated by a free surface at $z = \eta(r)$, see Fig. 1. The ferrohydrostatic system consists of solving Maxwell's equations in both fluids with a linear magnetisation law $\mathbf{B} = \mu_0\mu\mathbf{H}$ for respective induction and magnetizing fields $\mathbf{B}$ and $\mathbf{H}$ in the ferrofluid, as well as solving the Bernoulli equation at the interface. Applying standard transformations, as seen in [6], the full problem can be reduced to a six-dimensional PDE system of the form

$$\frac{\mathrm{d}}{\mathrm{d}r}\mathbf{u}(r,z) = \mathbf{L}(r)\mathbf{u} + \mathcal{F}(\mathbf{u},\varepsilon,r), \tag{1}$$

where ε is the bifurcation parameter such that $\varepsilon = 0$ is the bifurcation point, $\mathbf{L}(r)$ is a linear non-autonomous differential operator containing ∂_{zz} terms, and $\mathcal{F}$ is the collection of all nonlinear terms. In order to reduce this PDE system to an ODE system, an r-independent basis is required. The operator $\mathbf{L}_0 := \lim_{r\to\infty}\mathbf{L}(r)$ has eigenvalues $\pm ik$ with double multiplicity and $\pm\lambda_j \in \mathbb{R}$ for $j \in \mathbb{N}$, with respective eigenvectors $\{\mathbf{e}, \mathbf{f}, \overline{\mathbf{e}}, \overline{\mathbf{f}}\}$ and $\{\mathbf{e}_j, \mathbf{e}_{-j}\}$ for $j \in \mathbb{N}$. This is a complete basis, and so we can write

$$\mathbf{u}(r,z) = a(r)\,\mathbf{e} + b(r)\,\mathbf{f} + \overline{a}(r)\,\overline{\mathbf{e}} + \overline{b}(r)\,\overline{\mathbf{f}} + \sum_{n=1}^{\infty}\left\{a_n(r)\,\mathbf{e}_n + a_{-n}(r)\,\mathbf{e}_{-n}\right\}. \tag{2}$$

Projecting onto each respective eigenvector, the system reduces to an infinite number of nonlinear, non-autonomous amplitude equations for $a(r), b(r), a_j(r)$.

*Corresponding author. E-mail: d.j.hill@surrey.ac.uk

For $|\varepsilon| \ll 1$, we calculate solutions to the linear amplitude system and construct a fixed-point equation, parametrising the core manifold $\mathcal{W}^{cu}_{-}$, containing all small amplitude solutions that are bounded as $r \to 0$, for all $r \in [0, r_0]$. Next, the far-field manifold $\mathcal{W}^{s}_{+}$, containing all small amplitude solutions that exponentially decay to zero as $r \to \infty$, is parametrised. Stable foliations are constructed such that $\mathcal{W}^{s}_{+}$ can be written as a small perturbation from the stable part of a centre manifold $\mathcal{W}^{c}_{+}$, as seen in Fig. 2. In order to parametrise coordinates on $\mathcal{W}^{c}_{+}$ that decay to zero as $r \to \infty$, it is prudent to introduce geometric blow-up coordinates.

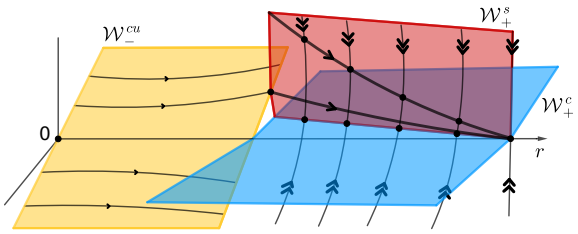

Figure 2: Schematic of the parametrisation of $\mathcal{W}^{s}_{+}$ and matching core & far-field manifolds.

By rescaling the variable $r \to s := \sqrt{\varepsilon} r$, the far-field equations restricted to $\mathcal{W}^{c}_{+}$ reduce to the nonautonomous real Ginzburg-Landau equation

$$\frac{\mathrm{d}^2}{\mathrm{d}s^2}\widetilde{a} = -\frac{1}{s}\frac{\mathrm{d}}{\mathrm{d}s}\widetilde{a} + \frac{1}{4s^2}\widetilde{a} + c_0\widetilde{a} + c_3\widetilde{a}^3, \qquad \widetilde{a} \in \mathbb{R},\ s \in \mathbb{R}^+, \tag{3}$$

where $\widetilde{a} := a/\sqrt{\varepsilon}$, c_0 and c_3 are both constants, $c_0 > 0$ and $c_3 < 0$ for particular values of parameters D, μ and the spatial wavenumber k. This has unique nontrivial decaying solutions that are defined for $\delta_0 < s < \infty$, where $\delta_0 > 0$ is a constant. However, as $\varepsilon \to 0$, control of the point $r = s/\sqrt{\varepsilon} = \delta_0/\sqrt{\varepsilon}$ is lost. Thus, a second change of coordinates must be introduced to control the transition from $r = \delta_0/\sqrt{\varepsilon}$ to the matching point $r = r_0$, see [2]. Having parametrised $\mathcal{W}^{s}_{+}$ at the matching point $r = r_0$, three distinct classes of solutions are found; spot A, spot B, and ring solutions. The spot A solution exists for all $0 < k \neq k_c$, for some critical wave number $k_c > 0$. These solutions remain close to the trivial state and have a free surface profile of the form

$$\eta_A(r) = C_A \varepsilon^{\frac{1}{2}} J_0(kr) + \mathrm{O}(\varepsilon), \qquad 0 \leq r \leq r_0, \tag{4}$$

where $C_A \neq 0$ is a constant, $\mathrm{sgn}(C_A) = \mathrm{sgn}(k - k_c)$, and J_ν is the ν-th order standard Bessel function of the first kind.

The spot B & ring solutions both require the coefficient c_3 in (3) to be negative in order to emerge, see Fig. 4. These solutions remain close to the trivial state and have profiles of the form

$$\eta^{\pm}_B(r) = \pm C_B \varepsilon^{\frac{3}{8}} J_0(kr) + \mathrm{O}(\varepsilon^{\frac{1}{2}}) \qquad 0 \leq r \leq r_0,$$
$$\eta^{\pm}_R(r) = \pm C_R \varepsilon^{\frac{3}{4}} \left[r J_1(kr) + b J_0(kr) \right] + \mathrm{O}(\varepsilon),$$

respectively, where $C_B, C_R, b > 0$ are all constants.

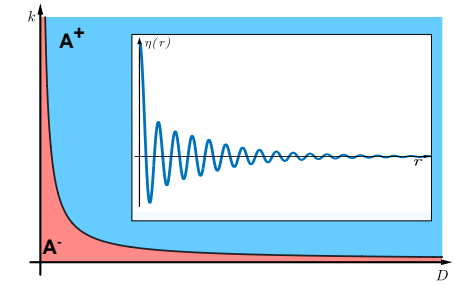

Figure 3: Plot of k in terms of D; spot A solutions have an elevation the blue region (A^+) and a depression in the red region (A^-).

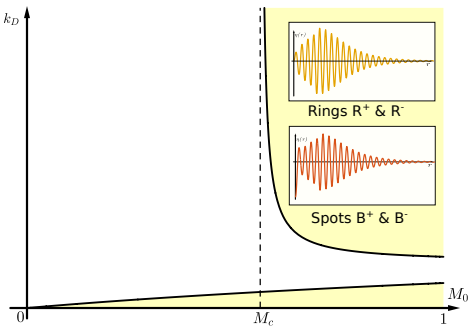

Figure 4: Plot of $k_D := kD$ in terms of $M_0 := \frac{\mu-1}{\mu+1}$; ring & spot B solutions emerge in the yellow regions.

CONCLUSIONS

For the radial ferrohydrostatic problem, one can formally show the existence of three classes of solutions; spot A, spot B, and rings. These solutions scale with the bifurcation parameter ε by $\varepsilon^{1/2}$, $\varepsilon^{3/8}$, and $\varepsilon^{3/4}$, respectively. Given a fixed depth D, localised patterns emerge for a sufficiently large magnetisation M_0. There is a critical spatial wave number k_c such that, for all $k > k_c$, spot A solutions exhibit an elevation at their core. Spot B and ring solutions require a magnetisation M_0 larger than a critical M_c in order to emerge. Existence regions of these localised radial patterns in (M_0, D) parameter space can be seen in Fig. 5.

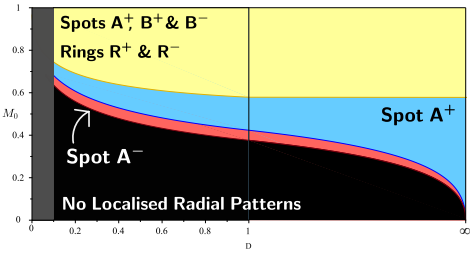

Figure 5: Existence regions of localised radial patterns for varying depth D and magnetisation M_0.

DYNAMICS OF MULTIPLE BUBBLES IN A CONSTRICTED HELE-SHAW CHANNEL

Jack S. Keeler[1], Antoine Gaillard[2], Alice B. Thompson[1], Anne Juel[2], and Andrew Hazel * [1]
[1]MCND and Department of Mathematics, University of Manchester, UK
[2]Department of Physics & Astronomy and MCND, University of Manchester, UK

Summary We study the dynamics of multiple air bubbles driven by the motion of a suspending viscous fluid within a constricted Hele-Shaw channel via numerical simulation of a depth-averaged model. Despite its apparent complexity the bubbles' transient behaviour is organised by a number of weakly unstable invariant solutions, so-called edge states. An unusual feature of the system is that changes in topology due to bubble break up or coalescence lead to changes in the invariant-solution structure during temporal evolution. Families of two-bubble and single-bubble invariant solutions can be related in the sense that their propagation speeds are identical, but there are two-bubble solutions that do not have single-bubble equivalents.

INTRODUCTION

The motion of one or more bubbles through confined rigid geometries otherwise filled by a viscous fluid is a fundamental problem in fluid mechanics. Recent work has shown that propagation of a single bubble through a Hele-Shaw channel containing a centred, depth-perturbation exhibits a rich and complex dynamics with regions of bistability, symmetry-breaking and evidence of stable and unstable time-periodic solutions [1, 2]. Despite its non-trivial dynamics, the system remains sufficiently simple to be effectively modelled using a depth-averaged theory [2]. Another important feature is that for a sufficiently viscous suspending fluid, the only nonlinearity arises due to the presence of the interface between the two fluids and hence different solutions can be distinguished using only the interfacial morphology. Based on the morphologic similarities between transient interface shapes and known unstable solutions of bubbles in Hele-Shaw cells, Franco-Gómez *et al.*[1] conjectured that the dynamics is organised by weakly unstable invariant solutions of the system. Here, we investigate this conjecture by directly relating the transient dynamics to invariant solutions of the depth-averaged model system. A complicating factor is that the bubble often breaks up into two or more bubbles during its evolution. In some cases, the resulting bubbles will coalesce to recover a single bubble state; in others the bubbles remain separate. Given the prevalence of bubble break up into two smaller bubbles, here we concentrate on two-bubble dynamics.

MODEL

We consider the propagation of two bubbles, each assumed to be a fixed volume of inviscid fluid at constant pressure, through a rectangular (Hele-Shaw) channel of geometry chosen to match that of our experimental studies [1]. The cross-sectional aspect ratio, width (W^*) / height (H^*), is fixed at 40 and the base of the channel contains a centred depth-perturbation, see Fig. 1, occupying 25% of the channel width and 2.4% of the channel height. The bubbles are surrounded by a viscous oil that is extracted at a constant flow rate Q^* from one end of the channel.

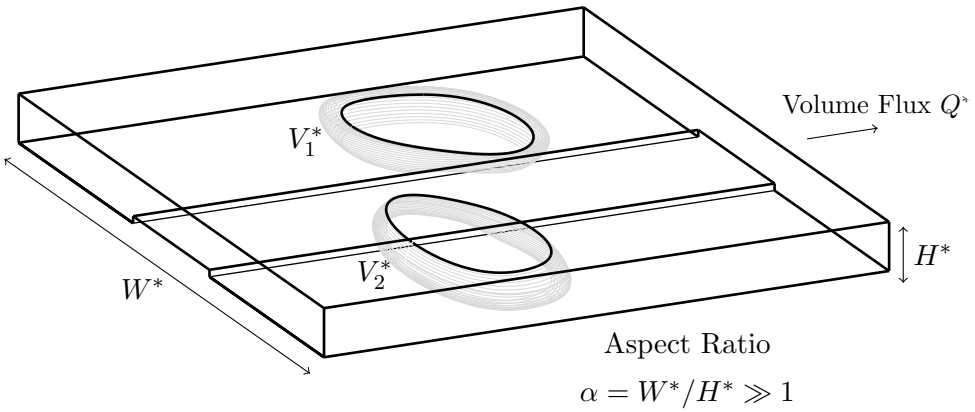

Figure 1: Two bubbles of volumes V_1^* and V_2^* propagate through an axially-uniform channel that contains a small centred geometric perturbation on its base. The suspending viscous fluid is extracted at a constant flow rate of Q^*.

The depth-averaged model system has been previously described [2] and the weak form of the governing equations is solved numerically using a finite element method implemented in the software library `oomph-lib` [4]. The library allows us to compute invariant solutions, determine their stability and perform time simulations all within the same framework. The key governing parameters are the dimensionless flow rate $Q = \mu Q^*/(W^* H^* \sigma)$ and dimensionless volumes of the two bubbles. Here, μ is the dynamic viscosity of the suspending fluid and σ is the constant surface tension at the bubble interface.

RESULTS

In order to identify invariant solutions we use edge tracking techniques [3] combined with time simulations. For the case of two unequal bubbles with a volume ratio of 2:1 illustrative results are shown in Fig. 2 by plotting the trajectories of the centre of mass (x_1, y_1) of the larger bubble.

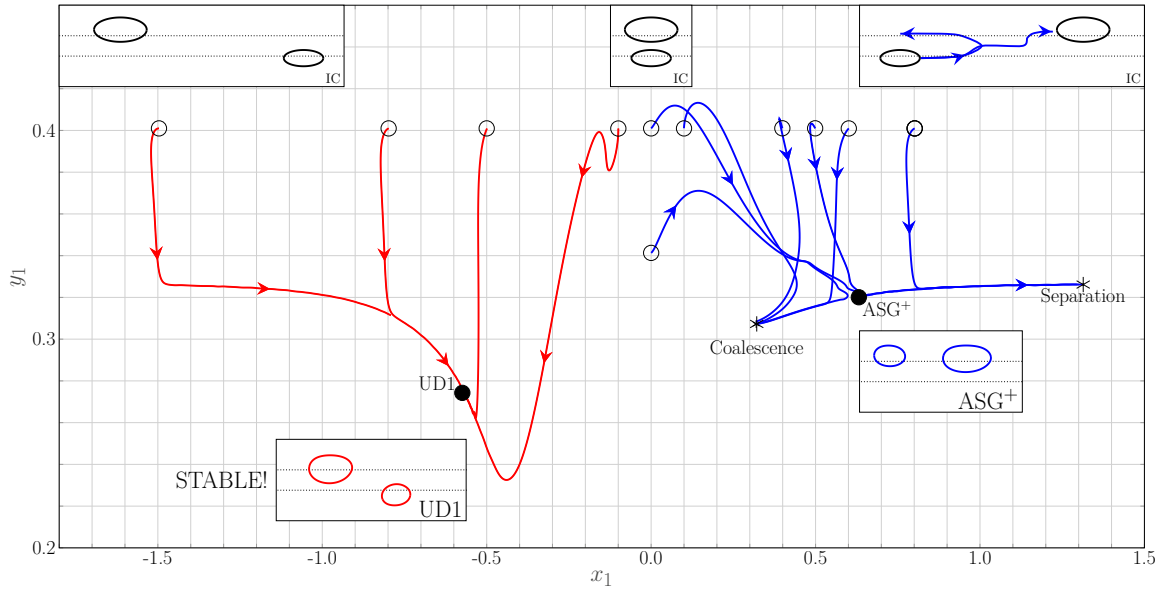

Figure 2: The temporal evolution of a system of two unequal bubbles at $Q = 0.04$ is represented by the trajectories of the centre of mass of the larger bubble: x_1 is the axial distance from the overall centre of mass of the two bubbles and y_1 is the cross-channel distance from the centreline. Initial conditions are shown as open circles and top-view snapshots of three initial conditions are shown as insets labelled IC. The evolution of the system is governed by steadily propagating invariant solutions indicated by filled circles with corresponding snapshots shown as insets labelled UD1 and ASG$^+$.

At the chosen flow rate, $Q = 0.04$, the larger bubble in isolation moves at a greater speed than the smaller bubble. Hence, the larger bubble will move towards the smaller if it is initially upstream ($x_1 < 0$) and the system evolves towards a stable two-bubble state, marked as UD1 in Fig. 2 (red trajectories). If the larger bubble is initially downstream ($x_1 > 0$) the system is instead influenced by a weakly unstable two-bubble state, ASG$^+$ (blue trajectories). If the bubbles are sufficiently close to each other they will eventually coalesce, but otherwise they separate. Thus ASG$^+$ acts as an edge state whose stable manifold divides the initial conditions leading to coalescence from those leading to separation. We use continuation methods to track the location of two-bubble invariant solutions under variations in the flow rate and bubble volumes. The weakly unstable state ASG$^+$ is equivalent to a single-bubble asymmetric solution in the sense that a single bubble of the same volume as the larger of the two bubbles propagates at the same speed for a given flow rate. The stable state UD1 does not have a single bubble equivalent. We find a variety of additional two-bubble invariant solutions not all of which have single-bubble equivalents and conjecture that the number of invariant solution branches increases with the number of bubbles.

CONCLUSIONS

We find considerable evidence that the transient dynamics of two bubbles moving in a constricted Hele-Shaw channel is organised by the many invariant solutions of the system. The propensity of the bubbles to split and coalesce leads to dynamic changes in the invariant solution structure and the number of invariant solutions increases with the number of bubbles, leading to increased complexity. There appears to be a direct correspondence between certain multiple-bubble solutions and single-bubble states, which may explain why the system is able to transition so readily between different bubble topologies.

THE ROLE OF A CAPILLARY MENISCUS ON THE FARADAY INSTABILITY

Alessandro Bongarzone[1], Francesco Viola[2], Simone Camarri[3], and François Gallaire*[1]

Summary The Faraday instability has been classically studied under the assumption of a free surface intersecting orthogonally the rigid container sidewalls. Here, the full system of equations, in both the inviscid and viscous cases, is solved asymptotically via a weakly nonlinear analysis using the multiple scale method; the resulting amplitude equation enables us to introduce the meniscus effects and to investigate how its presence disturbs the stability of the interface associated with the fundamental sub-harmonic parametric resonance. Two extreme cases of free slip and a pinned contact line are considered. Under certain combinations of external control parameters, the static meniscus may strongly modify the transition curves, commonly known as Faraday tongues; furthermore, when viscous dissipation is introduced, the meniscus also influences the instability thresholds.

INTRODUCTION

When a vessel containing liquid undergoes periodic vertical oscillations, the free liquid surface may be parametrically excited, emitting standing waves, depending on the combination of oscillation amplitude and frequency. This instability was first studied by [7], who observed experimentally that the frequency of the fluid oscillations was typically equal to half of the external frequency. Faraday waves have been often studied in analogy with the parametric excitation of systems having one degree of freedom, i.e. a pendulum whose length varies in time, that is governed by Mathieu's equation [5] with the fundamental, sub-harmonic, parametric resonance. Nevertheless, while the natural frequency of the simple parametric pendulum is unique, the fluid system has a countable infinity of eigenfrequencies (and associated eigenmodes) in a finite-size container.

Using the linear dispersion of gravito-capillary waves, [1] determined that the linear stability of the flat free surface of an ideal fluid is governed by a system of Mathieu's equations, whose solutions confirm Faraday's observation that the fundamental free surface response is sub-harmonic. With the exception of [2], the effect of viscous dissipation has been usually introduced a posteriori in the inviscid solution as a linear damping term. These linear analyses have been complemented by weakly nonlinear analysis in a sequence of papers over the last forty years [5, 3, 4].

All these studies, however, are based on the fundamental assumption that the free liquid surface is initially flat, which is necessary for an analytical solution of the problem. This assumption is reasonable in a large container (with respect to the capillary length) but is unrealistic for smaller containers where capillary effects at the meniscus are expected. Under vertical oscillations of arbitrary frequency and amplitude, any non horizontal meniscus emits surface waves that are synchronized with the excitation frequency. Indeed, in a non-inertial reference framework, the vertical periodic oscillations reduce to a modulation of the gravitational acceleration resulting in an oscillating capillary length. As explained by [3], these harmonic waves are not originated by the parametric resonance, but they are always present, even below the instability threshold. Hence, when the conditions for the Faraday instability are met, the Faraday waves evolve on the top of meniscus waves that behave as an unsteady base state, possibly perturbing the classical parametric instability analysis.

INVISCID CASE

We consider a planar (2D) container of height H, width $2L$ and aspect ratio L/H. The importance of the capillary effects is characterized by a Bond number $Bo = \frac{\rho g L^2}{\gamma}$ where ρ is the density, g the gravitational acceleration and γ the surface tension. In addition the wetting angle is denoted by θ_s.

In essence, the multiple scale approach proceeds by considering an order parameter ϵ and expanding the flow oscillation into an $\mathcal{O}(\epsilon)$ response at an eigenfrequency ω_n of amplitude A, and three contributions at order $\mathcal{O}(\epsilon^2)$: (i) the linear meniscus wave response to the vertical forcing $\epsilon^2 F \exp(i\Omega t)$ of small amplitude $\epsilon^2 F$ and frequency $\Omega = (2\omega_n + \epsilon^2 \Lambda)$ slightly detuned (by an order ϵ^2 difference in frequency) from the second harmonic of the considered sloshing wave, and (ii)-(iii) terms stemming from the inviscid flow nonlinearities, oscillating respectively at $2\omega_n$ and 0 frequency.

A very classical weakly nonlinear amplitude equation is obtained at order $\mathcal{O}(\epsilon^3)$ as a solvability condition. However its coefficients intrinsically account for the linear flow response at the forcing frequency, i.e. for the

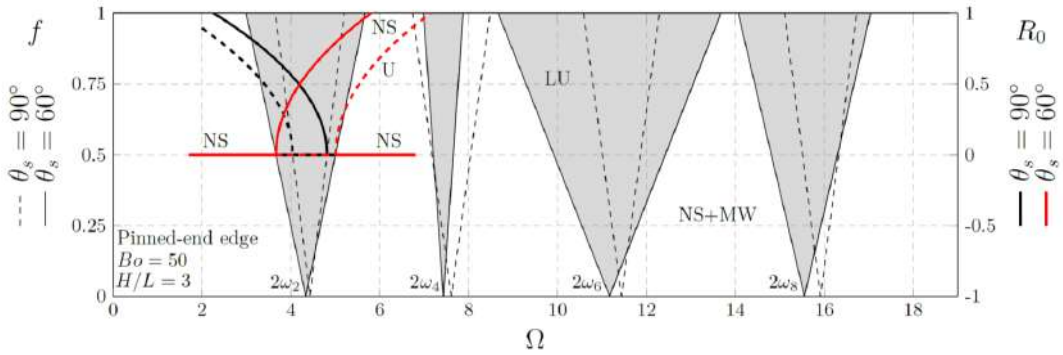

Figure 1: Thin lines: sub-harmonic Faraday tongues for the first four symmetric sloshing modes and pinned-end edge contact line. The unstable regions associated with the antisymmetric modes are not represented; dashed and solid lines are referred to $\theta_s = 90°$ and $\theta_s = 60°$ respectively; thick lines: nonlinear wave amplitude saturation associated with the first symmetric inviscid sloshing mode; black and red lines refers to $\theta_s = 90°$ and $\theta_s = 60°$; here the dashed lines mean the unstable branches, $Bo = 50$.

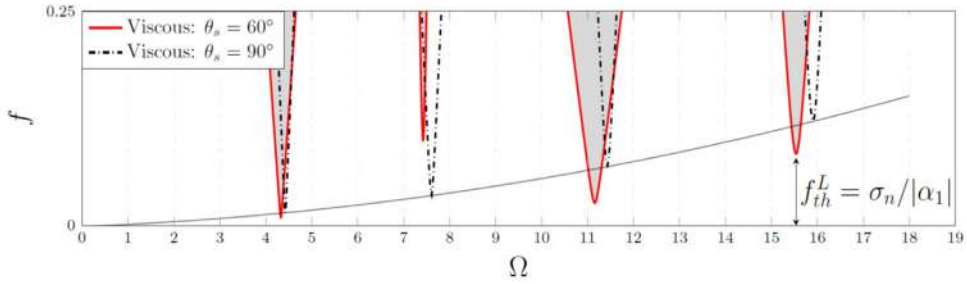

Figure 2: Viscous Faraday tongues for $\theta_s = 60°$ compared with their flat surface analogous case: the effect of the static meniscus on the instability threshold is markedly visible. $Re = 7363$, $Bo = 50$, $L/H = 3$.

meniscus waves. As seen in figure 1, for the a pinned contact line, an aspect ratio of the vessel of $L/H = 3$ (already in the deep water limit) and a Bond number $Bo = 50$, the presence of meniscus waves considerably alters the opening of the different Faraday tongues pertaining to the first four sloshing eigenfrequencies. In addition, they can even reverse the direction of hysteresis in the nonlinear response [3].

VISCOUS CASE

A very similar strategy can be followed including a finite viscosity μ, as long as the Reynolds number is large enough $Re = \frac{\rho g^{1/2} L^{3/2}}{\mu} \sim \epsilon^{-2}$, however to the price of increasingly complex algebraic calculations. Results are reported in figure 2, for $H/L = 3$, $Re = 7363$ and $Bo = 50$. It is seen that the meniscus waves also significantly affect the instability thresholds pertaining to the different tongues.

CONCLUSIONS

We have demonstrated that including the linear response of the flow in presence of a capillary meniscus has significant effects on the sub-harmonic instability tongues of invisicid and viscous Faraday instabilities. The generalization of this approach to higher order resonances hinges on the algebraic complexity of the asymptotic calculations.

STRONGLY NONLINEAR PATTERNS IN SLOW–FAST QUASI-LINEAR SYSTEMS

Gregory P. Chini * [1], Guillaume Michel[2], Alessia Ferraro[3], and Colm-cille Caulfield[4]

Summary The quasilinear (QL) reduction provides an effective starting point for the construction of pattern formation theories of certain strongly nonlinear and even ostensibly turbulent phenomena. The QL approximation can be asymptotically justified in the limit that suitably-defined fluctuations evolve rapidly relative to the mean fields about which their dynamics is linearized. Here, a new multiscale pattern formation formalism is developed for slow–fast QL systems susceptible to fast instabilities. A slaving relation for the fluctuation amplitude is derived that obviates the need to temporally resolve the fast dynamics by exploiting the tendency of these systems to self-organize on a *marginal-stability manifold*.

THE QUASI-LINEAR REDUCTION

The quasilinear (QL) or mean-field reduction [1] has proved surprisingly useful in the investigation of a wide variety of forced–dissipative pattern-forming fluid systems. The QL approximation involves parsing flow variables into suitable mean and fluctuation fields and then retaining fluctuation-fluctuation nonlinearities only where they feed back onto the mean fields through Reynolds stress divergences. Here, *quasilinear* should not be conflated with 'weakly nonlinear': indeed, the QL fluctuation fields are sufficiently strong to induce $O(1)$ changes in the mean fields, to which they are two-way coupled. Although increasingly invoked as a useful but *ad hoc* approximation, the QL reduction is asymptotically exact when the mean and fluctuation dynamics are scale separated in time. In particular, the approximation can be justified even for certain constrained or anisotropically-forced systems exhibiting fast *instabilities*, making it a potentially useful framework for the reduced description of strongly nonlinear patterns – the aim of the present work. Noteworthy examples include QL models of strongly-stratified free shear flows [2] (see below) and of various exact coherent states (ECS), e.g. equilibria, traveling waves, and periodic orbits, arising in constant-density wall-bounded flows [3].

A NEW MULTISCALE FORMALISM FOR SLOW–FAST QUASI-LINEAR SYSTEMS

A vexing attribute of slow–fast QL systems is that when the slow mean fields are locally frozen in time, exponential growth of the fluctuations is possible, invalidating the asymptotic reduction. To overcome this difficulty, a new multiscale formalism recently has been introduced [4], which is illustrated here by analyzing the following system of 1D PDEs:

$$\partial_t U = P(z,t) - U - \eta^2, \tag{1}$$
$$\epsilon\partial_t \eta = U\eta + \partial_z^2\eta - \epsilon\eta^3. \tag{2}$$

$P(z,t)$ is a specified inhomogeneous forcing, z is a spatial coordinate, and t is the time variable. As the parameter $\epsilon \to 0$, $U(z,t;\epsilon)$ and $\eta(z,t;\epsilon)$ are slow and fast fields, respectively. Indeed, formally introducing two time scales, $\tau \equiv t/\epsilon$ and $T \equiv t$, so that $U(z,t;\epsilon) \to U(z,\tau,T;\epsilon)$ and $\eta(z,t) \to \eta(z,\tau,T;\epsilon)$, and expanding U and η in an asymptotic power series in ϵ, the following leading-order system is obtained:

$$\partial_T \overline{U}_0 = P - \nu\overline{U}_0 - \overline{\eta_0^2}, \tag{3}$$
$$\partial_\tau \eta_0 = \overline{U}_0\eta_0 + \partial_z^2\eta_0. \tag{4}$$

Here, $\overline{(\cdot)}$ denotes a fast-time average. Unlike (1)–(2), the system (3)–(4) is quasilinear. Exploiting the separation in time scales between the mean and fluctuation dynamics enables the fluctuation equation to be treated as an eigenvalue (rather than initial-value) problem upon substituting the ansatz $\eta_0 = A(T)\hat{\eta}_0(z,T)e^{\sigma(T)\tau}$ into (4). For bounded solutions on the slow time scale, the only acceptable possibilities are that (real) leading eigenvalue $\sigma < 0$, in which case the amplitude $A(T)$ is set to zero, or $\sigma = 0$, in which case the resulting 'Reynolds stress' feedback $\overline{\eta_0^2} = |A|^2|\hat{\eta}_0|^2$ in (3).

For a given mean field, the eigenvalue problem for $\hat{\eta}_0$ is linear. The standard approach for deriving a slow-time (and potentially a slow-space) evolution equation for A – namely, by ensuring that the equations for higher-order fluctuations are solvable – fails to close. Instead, for slow–fast QL systems, $A(T)$ is constrained by the requirement that, once $\sigma = 0$, the fluctuation amplitude must self-consistently adjust to ensure the continued *emergent* marginal stability of the slowly-evolving mean field. Accordingly, a slow-time evolution equation for the growth rate rather than the amplitude is sought by taking the T derivative of the leading-order eigenvalue problem. The associated solvability condition requires

$$\frac{d\sigma}{dT} = \alpha - \beta|A|^2, \tag{5}$$

*Corresponding author. E-mail: greg.chini@unh.edu

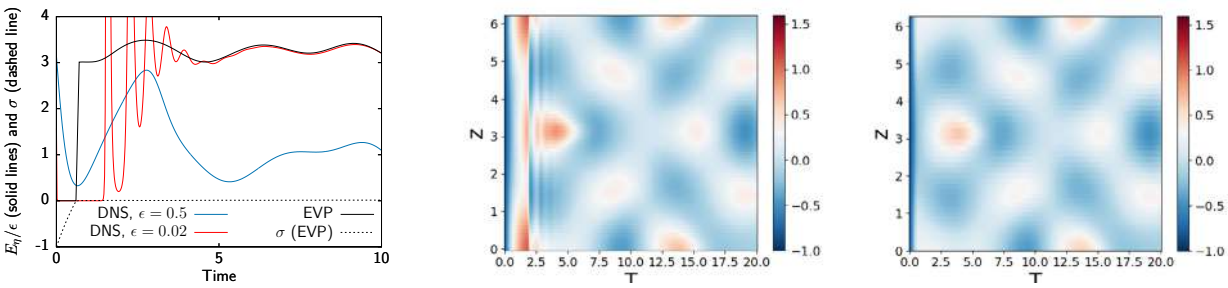

Figure 1: Comparison of the reduced model, in which (4) is treated as an eigenvalue problem (EVP) and solved at each slow-time step of (3) and A is prescribed according to (6), with DNS of (1)–(2). E_η is the fluctuation energy averaged over the fast-time scale. The right-hand plots show the space-time evolution of the slow field U from DNS (middle) and the multiscale algorithm (far right).

where $\alpha = \int_0^L \left(P - \nu \overline{U}_0^2\right) |\hat{\eta}_0|^2 \, dx$ and $\beta = \int_0^L |\hat{\eta}_0|^4 \, dx$ [4]. Recognizing that if $\sigma = 0$ at some slow time instant then $\mathrm{d}\sigma/\mathrm{d}T = 0$ must be enforced to preclude exponential fluctuation growth on the fast time scale (at least for $\alpha > 0$), the slow evolution of the amplitude is determined according to the following algorithm:

$$A(T) = \begin{cases} 0 & \text{if } \sigma < 0 \\ \sqrt{\alpha/\beta} & \text{if } \sigma = 0 \text{ and } (\alpha, \beta) \geq 0. \end{cases} \tag{6}$$

In figure 1 (left), the slow evolution of the fluctuation energy E_η (proportional to $|A|^2$) obtained from the mutiscale QL algorithm (EVP) is compared to that computed via direct numerical simulation (DNS) of the original system (1)–(2) for $\epsilon = 0.02$. The evolution of the leading eigenvalue also is shown, confirming that the algorithm succeeds in locking onto a marginal stability manifold. The right-hand plots provide a comparison of the space-time evolution of the mean field [5].

CONCLUSIONS AND FUTURE WORK

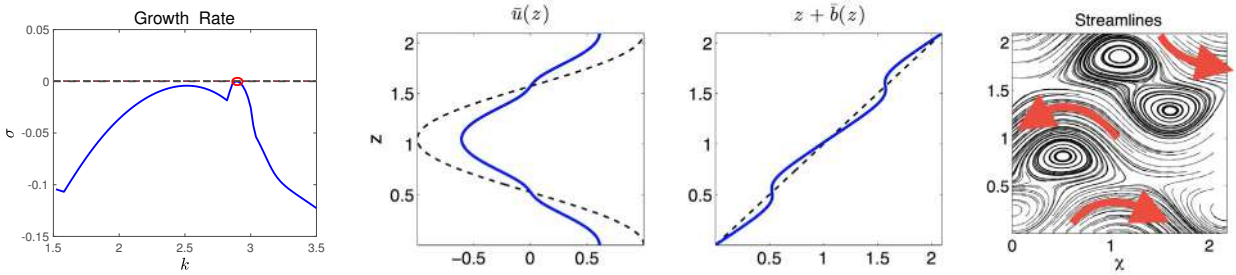

Figure 2: Computation of exact coherent states (ECS) in density-stratified Kolmogorov flow. In the absence of instabilities, the laminar state consists of a sinusoidal shear flow $\bar{u}(z)$ and linear buoyancy profile $z + \bar{b}(z)$, as shown by the dashed curves in the middle plots. In the dual asymptotic limits of large Reynolds number and strong stratification, a slow–fast QL reduction of the governing (2D) Boussinesq equations is possible. Application of the new multiscale formalism has enabled ECS to be obtained in this extreme parameter regime (as depicted by the solid profiles in middle plots and streamline pattern on the far right). For this 2D system, the algorithm ensures that the maximum growth rate $\sigma \leq 0$ over all 'fast' horizontal (χ) wavenumbers k (left-hand plot).

A new, multiscale formalism for slow-fast QL systems has been derived. The approach exploits the tendency of these systems to tune toward a marginal stability manifold, a manifestation of self-organized criticality. The slow evolution of the amplitude is determined via a slaving relationship to the mean field. Interestingly, this slaving is not associated with the usual strong dissipative contraction to a slow manifold but rather is effected by the Reynolds stress feedback from the fluctuations onto the mean field. In ongoing work, the new multiscale formalism is being used to compute ECS in strongly stratified shear flows (figure 2). Since the fluctuation fields are 2D, a further challenge arises [5]: predicting the slow temporal evolution of the 'fast' horizontal wavenumber k of the marginal mode(s) (figure 2, left). Future efforts will aim to incorporate a slow horizontal spatial coordinate (X) in addition to the fast horizontal coordinate (χ), yielding a systematically-reduced description of strongly nonlinear pattern formation in extended domains.

THE EDGE OF CHAOS AS A LAGRANGIAN COHERENT STRUCTURE

Miguel Beneitez * [1], Yohann Duguet[2], Philipp Schlatter[1], and Dan S. Henningson[1]
[1]Linné FLOW Centre and SeRC, KTH Engineering Mechanics, Royal Institute of Technology, Stockholm, Sweden
[2]LIMSI, University Paris-Saclay, Orsay, France

Summary Subcritical transition to turbulence in shear flows rests on a dividing manifold called the edge, delimiting trajectories approaching the laminar state from those approaching the turbulent state, in an appropriate state space. We apply here concepts and tools from Lagrangian analysis of material barriers, applied to investigate the edge manifold directly in the state space of autonomous arbitrary high-dimensional dissipative system, in which it is re-interpreted as a Lagrangian Coherent Structure (LCS). Two different diagnostics, Finite-time Lyapunov exponents and Lagrangian Descriptors, are used and compared with respect to their ability to identify the edge and their properties. They are illustrated on several low-order models of hard transition of increasing dimension and complexity, as well on well-resolved simulations of the Navier-Stokes equations in the case of plane Couette flow.

INTRODUCTION

A stimulating breakthrough occurred in the research on transition to turbulence, when researchers started adopting tools from deterministic chaos theory and dynamical systems, supported by the on-going progress of computer simulations. Among these recent developments, a central idea is that of "edge states": nonlinear flow structures living at the dynamical border between laminar and turbulent flow [1]. Being saddles of the system, they guide the evolution of the flow going towards turbulence [2]. Their stable manifold, called the edge of chaos, is of codimension one. Although the numerical bisection method used to identify such states is now classical, its limitations were pointed out in the case of spatially boundary layer flows [3]. In a radically different framework, there was recent progress in Lagrangian studies of tracers. The concept of Lagrangian Coherent Structure (LCS), i.e. sets of specific trajectories structuring the volume-preserving state space of the tracers, has gained maturity [4]. In particular the edge manifold mentioned above can be described efficiently as a hyperbolic repelling LCS of infinite dimension [5].

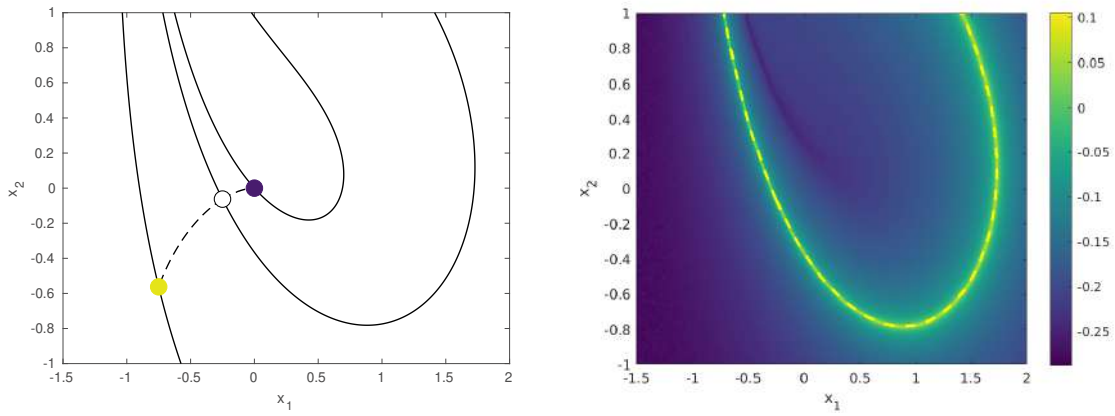

Figure 1: Left: state space for the two-dimensional Dauchot-Manneville system [7], solid points are stable fixed points and the empty point is a saddle node edge state. Solid lines are the stable or superstable manifolds of the fixed points and the dashed line is the unstable manifold of the edge state. Right: Stable manifold of the edge state visualised using isocontours of Finite-time Lyapunov exponents (FTLEs) for T=60. The ridge in the FTLEs captures efficiently the stable manifold of the edge state displayed in the left figure.

NEW INDICATORS TO LOCATE THE EDGE MANIFOLD

The main idea of this contribution is to use tools used in the study of LCSs, usually restrained to fields such as oceanography, to investigate the high-dimensional state space associated with transitioning flows. The main scalar indicator used in LCS studies is the finite-time Lyapunov exponent (FTLE), defined from the the leading eigenvalue of the right Cauchy-Green tensor. FTLEs measure a rate of divergence around a given finite-time trajectory defined between two times t and $t+T$. The challenge is to transfer a concept stemming from low-dimensional volume-preserving systems to arbitrary-dimensional dissipative systems. In autonomous systems, repelling hyperbolic LCSs can be well identified by ridges of FTLEs [4]. Being barriers to transport in state space, they nicely correspond to the notion of a dividing manifold except that they can be defined from finite-time data.

*Corresponding author. E-mail: beneitez@kth.se

An alternative to FTLEs consists of the Lagrangian Descriptors (LDs) described in Ref. [6]. Forward LDs measure a norm akin to the arclength along a finite-time trajectory between two times t and $t+T$. Their advantage is their ease of computation, their scalabilty and their ability to identify stable manifolds in the dissipative context.

Both indicators (FTLEs/LDs) have been tested to highlight the edge manifold in a series of low-dimensional models of increasing dimension. This is illustrated here in Fig. 1 for the case of the two-dimensional Dauchot-Manneville model [7], in which the edge is simply the stable manifold of the edge state, in this case the only saddle point of the system. This example is visually striking since the whole state space can be understood in one look.

EDGE TRACKING REVISITED

Incorporating ideas from the LCS community and extending them to arbitrary dimension makes it possible to revisit the edge tracking algorithm and make it more efficient computationally speaking. Since LCS can be identified by ridges of the FTLEs, the numerical optimisation of the FTLEs can be used to land exactly on the edge manifold. The same strategy has been used for LDs to detect edge trajectories and the related edge states in an almost infinite-dimensional case: a well-resolved direct numerical simulation plane Couette flow in a periodic cell. The associated state space has a dimension of $O(10^5)$. For both descriptors the algorithm finds the edge state fast and with arbitrary accuracy. While both methods outperform the classical bisection in terms of numerical efficiency, the revised bisection method based on LDs (which does not rely on an estimations of the Chauchy-Green tensor) has proved to be one order of magnitude faster for the studied cases, and relies on smaller values for the time horizon T.

CONCLUSIONS

In this conference contribution, we generalise here the popular notion of LCS to high-dimensional dissipative systems. The concept of edge manifold nicely corresponds to a subset of the repelling LCSs that can be identified using such descriptors as FTLEs or LDs. The advantage is not only a revised and more rigorous definition of the edge, but also faster algorithms for the numerical identification of edge states.

FLOW REVERSALS IN THE SPHERICAL RAYLEIGH-BÉNARD PROBLEM

Philippe Beltrame * [1]
[1]Avignon Université, INRAE, UMR EMMAH, Avignon, France

Summary The aim of the paper is to find and analyze flow reversals in the spherical Rayleigh-Bénard problem. The (3,4) mode interaction near the onset of convection is studied using amplitude equations by the center manifold reduction. We showed the existence of aperiodic flow reversals involving non-axisymmetric state-states, namely with octahedral symmetry. These dynamics are related to the existence of heteroclinic cycles of steady-states. The spherical symmetry plays a crucial role in their existence. The heteroclinic cycles may be not stable and intermittencies between flow reversals and chaotic dynamics are observed. Our results differ from the existing models of reversals in the geophysical context.

INTRODUCTION

Initially motivated by geophysical experiments (GEOFLOW project [1]), this study investigates numerically and theoretically the flow reversals of thermal convection in a spherical shell under a central force field. The problem is invariant by the $O(3)$ spherical symmetry and the case of a small rotation is studied as a perturbation. Since Friedrich and Haken [2] it is known that flow reversals between axisymmetric steady-states may occur when the spherical modes $\ell = 1$ and 2 are in competition. Chossat and Guyard [3] have shown the existence of heteroclinic cycles due to the spherical symmetry for the $(\ell, \ell + 1)$ mode interaction. These cycles induce reversals between axi-symmetric steady-states. Recently, we showed for the (3,4) mode interaction the existence of heteroclinic cycles involving steady-states with octahedral symmetry [4]. The dynamics is much more complex than for the reversals between axi-symmetry solutions. After a recall of the method and theoretical tools, we focus on the existence of flow reversals for the (3,4) mode interaction.

MODELING AND THEORETICAL TOOLS

The Rayleigh-Bénard convection is studied considering an incompressible Newtonian fluid under the Boussinesq approximation. The fluid is confined between two concentric spheres of radii R_{in} and R_{out} ($R_{in} < R_{out}$). A radial force field proportional to $g(r)$ acts on the fluid. When the inner sphere is heated uniformly at T_{in} and the outer sphere is cooled uniformly at $T_{out} < T_{in}$ a temperature gradient appears. The gravity field $g(r)$ encountered in the geophysical context for low-density fluid surrounding a high-density ball (like the Earth's inner core) is mainly proportional to $1/r^2$. In the laboratory, the dielectrophoretic central force field is $1/r^5$-dependent field as for the GEOFLOW experiment. In this work we focused on force fields due either to gravity or dielectrophoretic effect. The thermal convective flow depends on three non-dimensional parameters: the aspect ratio $\eta = \frac{R_{in}}{R_{out}}$, the Prandtl number Pr (ratio of kinematic viscosity to thermal diffusivity) and the Rayleigh number Ra measuring the buoyancy force. The resulting equations with no-slip boundary conditions can be found for instance in [5].
For a critical Rayleigh number and aspect ratio, the marginal modes of the linear problem span the space V of eigenmodes with the spherical modes $\ell = 3$ and 4. It is a well-established fact that the Rayleigh-Bénard problem satisfies the hypothesis of the center manifold reduction theorem, which allows to reducing the system of Partial Differential Equations (PDE) to an Ordinary Differential Equations (ODE) defined in the space V. The spherical symmetry is responsible for the high dimension of the center manifold, i.e. $\dim V = 16$ for the (3,4) mode interaction. The use of concepts and techniques of Equivariant Bifurcation Theory [6] is of crucial importance in the bifurcation analysis. For instance, the isotropy subgroups lattice identifies the possible bifurcated steady-states and their symmetry and helps to find possible heteroclinic cycles. According to [4], the onset of convection has to be a codimension 3 bifurcation in order to obtain complex time-dependent dynamics as intermittent-like behaviours. In the next section, we focus to flow reversals dynamics and their link with the structure of heteroclinic cycles of steady-states or rotating waves.

FLOW REVERSALS

Intermittent like behavior appears for specific parameter domains: long periods of quasi steady-states (axisymmetric or octahedral patterns) followed by sudden excursions to regimes far from equilibrium and relamination to another steady-state. Some of these dynamics result from a cycle of heteroclinic connections between steady-states. An example of this dynamics is displayed in Fig. 1(a). The plateaux displayed in the time evolution correspond to long duration near the steady-states with octahedral symmetry. The short transition between reversed steady-states appears with the sudden wake-up of the mode 3. The symmetry of steady-states is broken during the transitions between equilibria: the first transition corresponds to the di-hedral symmetry of order 6 and the back transition has the tetrahedral symmetry (see snapshots in Fig. 1).

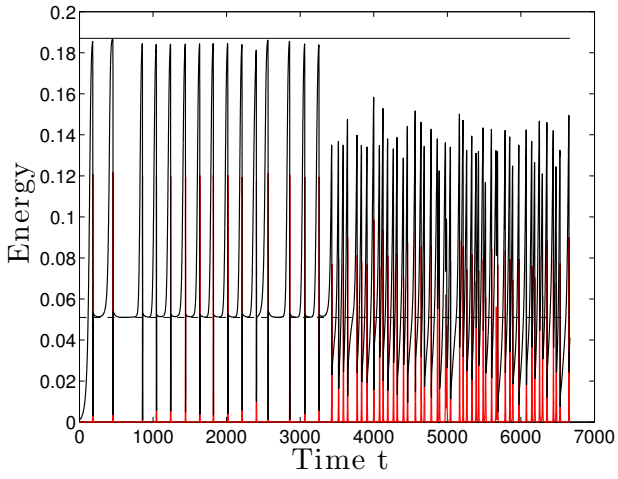
(a)



(b)

Figure 1: (a) [Top] Time evolution of the energy of the modes 3 and 4 (red and blue lines respectively) during the heteroclinic cycle. [Bottom] Evolution of the temperature field during the heteroclinic cycle. Large snapshots represent steady-states with octahedral symmetry and smaller snapshots represent a state during flow reversals. (b) Time evolution of the energy of the mode 3 [red] and mode 4 [black]. Firstly, the dynamics is close to a heteroclinic cycle similar to the one in Fig. 1 and suddenly ($t > 3500$) a chaotic dynamics takes place.

The heteroclinic cycles are not asymptotically stable in the usual sense [8]: the phase-space trajectories remain in the vicinity of heteroclinic connections but do not converge to the steady-states. As a consequence, the duration near the steady-states do not increase cycle by cycle. Indeed, the heteroclinic cycle may be unstable leading to intermittencies between the reversal and chaotic dynamics. In Fig. 1b the time evolution of the (3,4) modes lets appear a dozen of reversals disrupted by an irregular dynamics for which no steady-state is observed during for a long time. The heteroclinic cycle is in competition with a chaotic set which has repellent manifolds.
These reversals differ from the mechanism proposed in literature. The transitions between reversals are not identical as in [7]. Moreover, the noise is not required to escape from the steady-states in contrast to [7] and [8] .

These complex dynamics may remain in the rotating case. The equilibria become rotating waves (see for instance [9]) and the axis of these rotating waves coincides with the rotation axis. The consequence of this prevailed axis is that a part of the dynamics complexity vanishes but not the phenomenon of flow reversals.

CONCLUSION

We showed the existence complex aperiodic flow reversals between octahedral equilibria. The spherical symmetry plays a key role in their existence. The reversal mechanisms differ from the literature regarding the dynamo problem. The persistence of flow reversals in the rotating case spurs to study the case of higher rate rotation that is relevant in the geophysical context.

A PROBABILISTIC PROTOCOL TO ASSESS THE CONTROL OF FINITE-AMPLITUDE INSTABILITIES: APPLICATION TO TRANSITIONAL FLOWS

Cédric Beaume * [1], Anton Pershin[1], and Steve Tobias[1]
[1]School of Mathematics, University of Leeds, Leeds LS2 9JT, United Kingdom

Summary Transition to turbulence is an instability in which a laminar flow becomes chaotic. In most canonical flow setups, this occurs due a finite-amplitude instability: a perturbation of sufficient energy is necessary to trigger transition. Assessing the robustness of the laminar flow and, thus, the likelihood of observing transition to turbulence, is not straightforward: perturbations of different amplitude, but also of different shapes, behave differently. To reliably quantify the laminar flow robustness, we determine the probability that random perturbations decay as a function of their amplitude. We apply the same protocol in the presence of a well-known control strategy aimed at suppressing transition to quantify its efficiency. The protocol introduced here is versatile and can be used to study any finite-amplitude instability.

INTRODUCTION

In a large number of applications involving fluid transport, it is critical to maintain the flow in its laminar state, where it is associated with a relatively low dissipation rate. If left uncontrolled, the flow might transition to turbulence and yield substantial energy losses and increased wall-friction. Such an instability does not necessitate any additional physics than that of a sheared flow and is thus determined entirely by one parameter, the Reynolds number (hereafter Re). As a result of its simplicity, it has been studied for more than a century [1] in simple wall-bounded flows driven only by a pressure gradient (e.g. pipe flow) or by wall motion (e.g. plane Couette flow).

We focus here on plane Couette flow, the viscous incompressible flow confined between two parallel walls moving in opposite directions. The last decade saw substantial progress in the description of this flow as a dynamical system. In particular, the complexity of the edge of chaos, the separatrix between the basins of attraction of the laminar and turbulent flows, has been characterised [2], the local attractor on the edge has been computed in small [3] and large domains [4], the smallest perturbation to transition, or minimal seed, has been found [5]. Further to these findings, the instability has been characterised statistically and related to directed percolation [6, 7].

The most natural way to determine the success or failure of a control strategy in suppressing transition to turbulence is to verify whether or not it increases the robustness of the laminar flow to perturbations. This is not easily achieved: the statistical threshold for transition [6] does not inform on how sensitive the flow is in the subcritical regime; and the minimal seed [5] and the edge states [3] only represent single points on the edge. In this Paper, we propose a probabilistic protocol to quantify the robustness of the laminar flow to perturbations and extend it to quantify the efficiency of control strategies.

RESULTS

In plane Couette flow, the laminar flow is linearly stable and turbulence can be thought of as a statistically persistent state for $Re > 325$ [6]. The edge of chaos then corresponds to the separatrix between the basin of attraction of the laminar flow and that of turbulence. To completely understand the robustness of the laminar flow, one would ideally require knowledge of the full structure of the edge of chaos. Unfortunately, the edge is an intricate manifold [2] and an exhaustive characterisation seems out of reach. Instead of fully determining the location of the edge, we proceed by approximating the probability of being on either side of it for a given value of the perturbation energy.

We consider plane Couette flow in a domain of (nondimensional) size 4π in the streamwise direction, 2 in the wall-normal direction and $32\pi/15$ in the spanwise direction and fix the Reynolds number to a value larger than required to observe turbulence: $Re = 500$. We generate a set of random perturbations at 40 equidistributed kinetic energy levels between $E = 0$ and $E = 0.04$. The perturbations are expressed in the following way: $\mathbf{u} = A\mathbf{u}_\perp + B\mathbf{U}_{\mathbf{lam}}$, where $\mathbf{U}_{\mathbf{lam}}$ is the laminar flow, $\mathbf{u}_\perp$ is the projection of the perturbation in the space orthogonal to the laminar flow and A and B are coefficients. To generate $\mathbf{u}$, we first choose B and $\mathbf{u}_\perp$ randomly, then compute A so that the perturbation has the prescribed kinetic energy E. We then time-integrate the initial conditions $\mathbf{u_0} = \mathbf{U_{lam}} + \mathbf{u}$ until transition or laminarisation is observed according to the following rules: transition is observed if the flow kinetic energy exceeds E_{turb}, the average turbulence kinetic energy, and does not laminarize within 400 time units; laminarisation is observed when the kinetic energy of the flow decays below $E_{turb}/100$.

We show in the left panel of figure 1 the results obtained for 200 perturbation per energy levels in plane Couette flow and expressed via the laminarisation probability P_{lam}. The laminarisation probability can be fitted by a lower incomplete gamma function (more details in [8]) to exhibit similar behavior to the data and particularly its monotonic decay from $P_{lam} = 1$ to a non-zero value. At sufficiently large perturbation energy, the laminarisation probability can be seen to

*Corresponding author. E-mail: c.m.l.beaume@leeds.ac.uk.

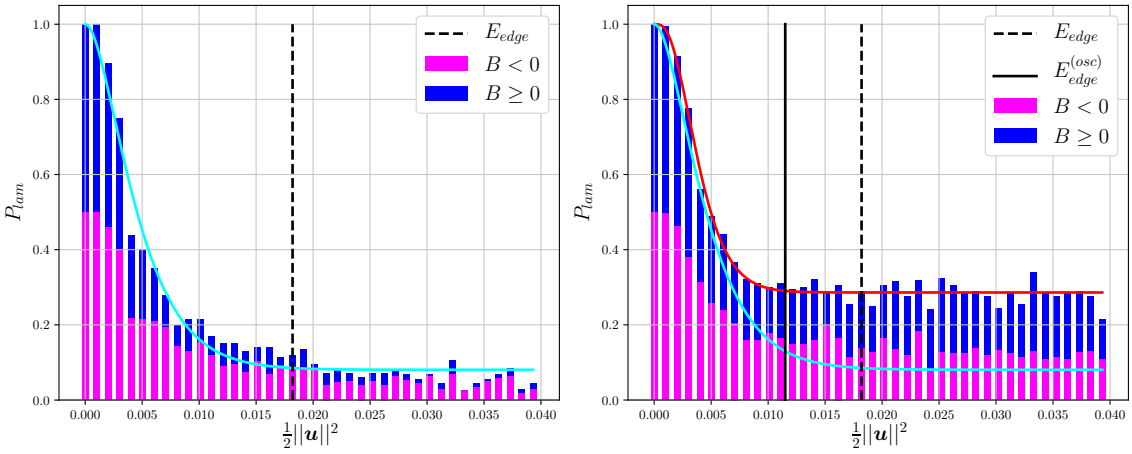

Figure 1: Laminarization probability P_{lam} for 40 perturbation energy $||\mathbf{u}||^2/2$ levels in plane Couette flow. The results are shown in the absence of control (left panel) and in the presence of control via wall oscillation (right panel, see text for details). In both cases, the contribution of shear enhancing perturbations is shown in blue while that of shear weakening ones is shown in pink. The solid blue (resp. red) curve corresponds to a fitting function in the absence (resp. presence) of control as explained in the text. The vertical dashed (resp. solid) line corresponds to the kinetic energy of the edge state in the absence (resp. presence) of control.

reach a plateau where virtually no shear enhancing perturbation ($B \geq 0$) laminarizes but where a non-negligible fraction of shear weakening perturbations ($B < 0$) laminarizes.

We reproduced the same study in the presence of control via wall oscillation: in addition to moving in the streamwise direction at constant (but opposite) speeds, the walls are oscillating in phase in the spanwise direction, a technique known to reduce turbulent drag [9] and increase the energy of the minimal seed [10]. We chose a control setup close to optimal according to [10]: the oscillation frequency is set to $1/16$ and the amplitude to 0.3. We chose the phase of oscillation randomly as part of the perturbation generation procedure. The results are shown on the right panel of figure 1. The control is successful: oscillating the walls increased the fraction of laminarizing perturbations at virtually all energy levels, and most noticeably for $E > 0.005$. The laminarization probability plateaux at values around 29% against 8% in the absence of control. Although wall oscillation stabilized approximately 10% of the shear weakening perturbations, its major effect is to stabilize a large number of shear enhancing perturbations, most of which would have triggered transition in the absence of control. Lastly, the energy of the edge state is lower in the presence of control than in its absence, a fact that might be misinterpreted as negative control without knowledge of the laminarization probability.

DISCUSSION

In this paper, we have introduced a protocol to characterise the robustness of the laminar flow to perturbations in plane Couette flow. The underpinning problem is that of transition to turbulence and the protocol used to quantify the efficiency of a control strategy based on wall oscillations. Given the nature of the protocol described here, it is clear that it has the potential to be a useful tool to assist the investigation of other finite-amplitude instabilities.

EXTENDING BARKLEY'S PIPE FLOW MODEL TO PLANE COUETTE FLOW

Cristóbal Arratia *
Nordita, KTH Royal Institute of Technology and Stockholm University Roslagstullsbacken 23, SE-106 91 Stockholm, Sweden

Summary We present our attempt at developing an extension of Barkley's pipe-flow model to plane Couette flow. Drawing a connection between amplitude equations and large-scale flows around turbulent spots, we propose an effective local model which presents a bifurcation scenario that is consistent with the phenomenology observed in small domains. We also find that the obliqueness of the laminar-turbulent patterns cannot be described purely as a Turing instability. We will discuss some additional elements that can be included and describe how the resulting spatiotemporal dynamics compares with transitional plane Couette flow in large domains.

INTRODUCTION

The coexistence between laminar and turbulent regions is generic to the subcritical transition to turbulence of wall-bounded shear flows. Relevant examples are laminar-turbulent patterns in plane Couette and other two-dimensionally extended flows [1, 2], and turbulent puffs and slugs in pipe flow [3]. An effective description of such structures in terms of a single bistable variable $q(\boldsymbol{x}, t)$, a 'turbulent intensity' representing a competition between laminar and turbulent states as a phase transition [4], provides a helpful but incomplete conceptual picture [5]; such a simplified reaction-diffusion model does not capture much of the distinctive dynamics of the laminar-turbulent interfaces.

The ability to mimic the evolution of laminar-turbulent interfaces throughout the transitional regime is a central aspect of the success of Barkley's pipe-flow model [3, 5], which he accomplished by adding an extra variable field $u(x, t)$. Physically, the new variable $u(x, t)$ plays a double role in modelling the effects of (i) the mean shear relevant to inhibit/promote the presence of turbulence in a certain region, and (ii) the large-scale advection of the laminar/turbulent interfaces.

EXTENSION TO TWO DIMENSIONS

While the use of an effective variable describing (i) the local retroaction between the mean shear and the turbulence intensity $q(x, z, t)$ can be directly transferred to the 2D case, the impossibility of describing (ii) the large-scale advection with a scalar variable in 2D is an important obstacle. Accordingly, we use $s(x, z, t)$ instead of $u(\boldsymbol{x}, t)$ to represent the mean shear only. The large scale advection, however, has been the object of much attention and cannot be dismissed since the large scale flows around turbulent patches are important to their evolution [2]. We propose to effectively describe this large scale advection from spatial gradients of the model variables. In particular, the quadrupolar flow structure observed around turbulent spots could be described, at the laminar-turbulent interfaces, roughly as $(v_x, v_z) = (\partial_x q, -\partial_z q)$. As a consequence, terms that one may expect in the form $\beta \boldsymbol{v} \cdot \nabla q$ and $\gamma(\nabla \cdot \boldsymbol{v})q$, for some constants β and γ, become

$$\beta(\partial_x q)^2 - \beta(\partial_z q)^2 + \gamma q \partial_x^2 q - \gamma q \partial_z^2 q. \tag{1}$$

These terms, which represent nonlinear advection and nonlinear diffusion, appear in a non-variational extension of the Swift-Hohenberg equation known to display complex spatiotemporal behaviour and patterns. Remarkably, this non-variational amplitude equation has been shown to generically govern the order parameter around bifurcations of codimension-3 involving the appearance of bi-stability together with the onset of a long wave Turing instability [6]. Note that a Turing instability was proposed by Manneville as a possible mechanism to explain the appearance of the laminar-turbulent patterns in the framework of effective reaction-diffusion models [7].

These considerations provide some promising ingredients in view of developing an effective model for transitional shear flow with two extended dimensions. The terms (1) are consistently generated in multiscale expansions used for deriving amplitude equations around a specific type of bifurcation [6]. This gives a specific clue for constructing an extension of Barkley's model with a local dynamics that generate the nonlinear advection and diffusion terms in (1). The extension, however, is not straightforward, since the 'nascent bistability' [6] of the codimension-3 bifurcation cannot physically correspond to the bistability between laminar and turbulent states of shear-flow transition, which are from the onset at a finite distance in state-space. Still, we can construct a local model with a similar bifurcation, and whose dynamics is qualitatively consistent with transition to turbulence of plane Couette flow in small domains.

A model of local dynamics

Consider the temporal dynamics given by

$$\frac{\mathrm{d}q}{\mathrm{d}t} = f(q, s) f_\infty(q, s) = q\left(-\delta + r + s + \alpha q - r q^2\right) f_\infty(q, s), \tag{2a}$$

$$\frac{\mathrm{d}s}{\mathrm{d}t} = g(q, s) g_\infty(q, s) = \left[1 - s - \alpha\rho q^2 + \frac{\alpha}{3} q^3\right] g_\infty(q, s), \tag{2b}$$

*E-mail: cristobal.arratia@gmail.com.

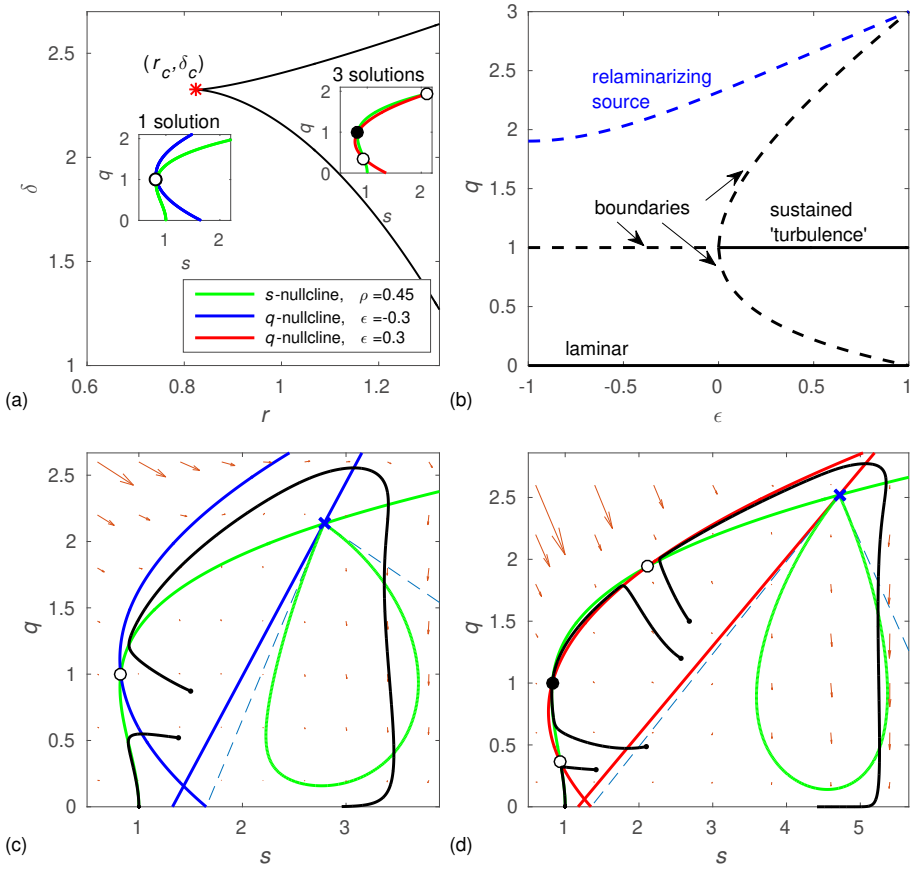

Figure 1: Qualitative properties of the local model for transitional turbulence in plane Couette flow. (a) Regions of the parameter space (r, δ) with different number of solutions. In addition to the laminar and the *ad-hoc* relaminarizing solutions, one or three other solutions exist to the left or right of the cusped line, respectively. The insets show the configuration of the nullclines. (b) Bifurcation diagram with control parameter $\epsilon = 3(r - r_c)/\alpha$ and fixed $\delta = \delta_c$. A state of (locally) sustained 'turbulence' appears at $\epsilon = 0$ through a subcritical pitchfork (local) bifurcation. (c,d) Temporal dynamics of the local model (2) in the (q, s)-plane. Black lines show sample trajectories, red arrows the state-space flow field, and coloured lines are nullclines as given in the legend of (a).

where q and s are the effective turbulent intensity and mean shear variables, and δ and r are control parameters with r the main bifurcation parameter (a 'Reynolds number'). $\alpha > 0$ and $0 \leq \rho \leq 2/3$ are free parameters at this stage. Stationary solutions given by $f(q, s) = g(q, s) = 0$ (defined implicitly by the second equalities in (2)) include a laminar state $(q, s) = (0, 1)$ and a 'turbulent' state where $q \equiv q_t$ is finite.

The main characteristics of the local model are described in Figure 1. There is a cusp in the (r, δ)-plane (point (r_c, δ_c) in Fig. 1(a)), for which three solutions $q_t = 1$ coincide. When increasing r with $\delta = \delta_c$ fixed, the saddle $q_t = 1$ is stabilized through a subcritical pitchfork bifurcation at $r_c = \alpha(1-\rho)$ (Fig. 1(b)). The functions $f_\infty(q, s)$ and $g_\infty(q, s)$ add a straight line and a 3-ellipse as q- and s-nullclines, respectively, whereby an *ad-hoc* solution is added that prevents the blow-up of the model by enforcing 'relaminarization'. Similar to plane Couette flow in small domains, there is a subcritical region with 'turbulent transients' (Fig. 1(c)) and a supercritical one where 'turbulence' is locally stable (Fig. 1(d)).

Spatial effects

Different diffusivities for $q(x, z, t)$ and $s(x, z, t)$ together with anisotropies along x and z is the first element considered when dealing with the spatiotemporal setting. A relevant observation is that, regardless of the anisotropy, the onset of the Turing instability develops always parallel to one of the axes. This implies that the obliqueness of the laminar turbulent bands cannot be described purely as a Turing instability of a reaction-diffusion model which satisfies the reflection symmetries around the x- and z-axes that are externally imposed. Further aspects of these developments will be discussed.

EFFECTS OF AN IMPOSED AXIAL FLOW ON A FERROFLUIDIC TAYLOR-COUETTE FLOW

Sebastian Altmeyer* [1] and Younghae Do[2]
[1]Castelldefels School of Telecom and Aerospace Engineering, Universitat Politcnica de Catalunya, Barcelona, 08034, Spain
[2]Department of Mathematics, KNU-Center for Nonlinear Dynamics, Kyungpook National University, Daegu 41566, South Korea

Summary We investigate the effects of an externally imposed axial mass flux [1, 2] (axial pressure gradient, axial through flow) on ferrofluidic Taylor-Couette flow under the influence of either an axial or a transverse magnetic field [3]. Without imposed axial through flow, due to the symmetry-conserving axial field and the symmetry-breaking transverse field, it gives rise to various vortex flows in ferrofluidic Taylor-Couette flow such as wavy Taylor vortex flow (wTVF), wavy spiral vortex flow (wSPI) and wavy vortex flows (wTVFHx and wSPIHx), which are typically produced by a non-linear interaction of *rotational, shear* and *magnetic instabilities*. In addition, when an axial through flow is imposed to a ferrofluidic Taylor-Couette flow in the presence of such a magnetic field, new helical vortex structures are born. In particular, we uncover *'modulated Mixed-Cross-Spirals'* with a combination of at least *three different* dominant azimuthal wavenumbers.

FIXED TRANSVERSAL MAGNETIC FIELD.

To investigate the effects of an externally imposed axial through flow Re, for a fixed transversal magnetic field ($s_x = 0.6$), examine dynamics of flow states by varying Re, specially focusing on bifurcation phenomenon for two fixed inner Reynold numbers, $Re_i = 110$ and 270. Due to a transversal magnetic field, all flow states are *inherently* $3D$ and wavy-like modulated flow [4] containing specific higher modes $m \pm 2$.

BIFURCATION SCENARIO

For $Re_i = 110$ and $Re = 0$ the system shows *multistability* having three stable states, $L1 - wSPI_{H_x}$, $R1 - wSPI_{H_x}$ and $wTVF_{H_x}$. By increasing Re, both flow states $R1 - wSPI_{H_x}$ and $wTVF_{H_x}$ move to $L1 - wSPI_{H_x}$, and then follow the destiny of $L1 - wSPI_{H_x}$ (Fig. 1(a)).

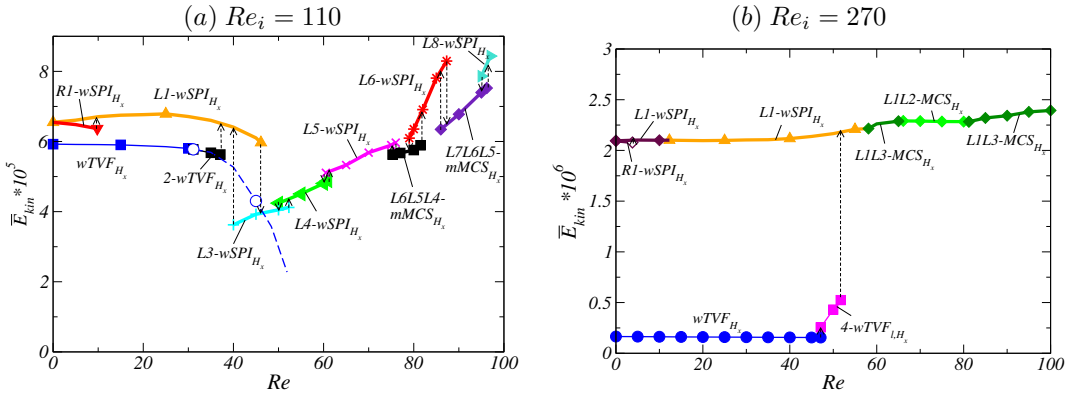

Figure 1: Bifurcation scenarios vs. imposed axial through flow Re. Bifurcation scenarios for (a) $Re_i = 110$ and (b) $Re_i = 270$, respectively. Shown is the total (time-averaged) modal kinetic energy E_{kin}. Different flow structures are labeled. Vertical arrows illustrate the transition direction to another stable state, when a flow state loses its stability. Thin [thick] lines correspond to toroidally closed [helical] flow states.

Increasing Re the state $wTVF_{H_x}$ becomes unstable at $Re \approx 35$, where a wavy flow state $2 - wTVF_{H_x}$ with dominant mode amplitudes $(2, \pm 1)$ bifurcates. At $Re \approx 38$, $2 - wTVF_{H_x}$ finally loses its stability, and moves towards a modulated helical spiral state $L1 - wSPI_{H_x}$. The helical downward propagating state $R1 - wSPI_{H_x}$ becomes unstable at $Re \approx 10$, and then moves toward a stable helical upward propagating state $L1 - wSPI_{H_x}$. Starting with $L1 - wSPI_{H_x}$, one obtains the following sequence of flow states (Fig. 1(a)):

$$\begin{aligned} L1 - wSPI_{H_x} \rightarrow L3 - wSPI_{H_x} \rightarrow L4 - wSPI_{H_x} \quad &\rightarrow \quad L5 - wSPI_{H_x} \rightarrow \\ L6L5L4 - mMCS_{H_x} \rightarrow L6 - wSPI_{H_x} \quad &\rightarrow \quad L7L6L5 - mMCS_{H_x} \rightarrow L8 - wSPI_{H_x}. \end{aligned}$$

While most steps in this scenario can be anticipated, i.e. increasing the helicity - larger azimuthal modes m with increasing Re one eventually finds a *new* type of *mixed mode states* as non-linear interaction. We will call this states *modulated Mixed-Cross-Spirals* ($mMCS_{H_x}$)[5] as they appear with *three* dominant azimuthal wavenumbers. For instance, $L6L5L4 - mMCS_{H_x}$ and $L7L6L5 - mMCS_{H_x}$.

*Corresponding author. E-mail: sebastian.andreas.altmeyer@upc.edu.

At larger $Re_i = 270$ (Fig. 1(b)) the sequence of flow state appearing out of $wTVF_{H_x}$ with increasing Re is quite different: $wTVF_{H_x} \rightarrow 4 - wTVF_{l,H_x} \rightarrow L1 - wSPI_{H_x}$.
At $Re \approx 47.6$, $wTVF_{H_x}$ bifurcates to $4 - wTVF_{l,H_x}$ with dominant azimuthal wavenumber $m = 4$. However flow states with lower azimuthal wavenumber m, as $2 - wTVF_{l,H_x}$ and $3 - wTVF_{l,H_x}$ were temporarily observed as *unstable* and only *transient* states. Further, at $Re \approx 52$, $4 - wTVF_{l,H_x}$ loses its stability, and then moves towards the helical $L1 - wSPI_{H_x}$. As before, within this transition process, $5 - wTVF_{l,H_x}$ and $6 - wTVF_{l,H_x}$ appear as *unstable transient* states. Interestingly we could not observe any other stable $wTVF_{l,H_x}$ with larger azimuthal wavenumber $m \geq 7$.

MODULATED MIXED-CROSS-SPIRALS

The spatial structure of a *stable* $L6L5L4 - mMCS_{H_x}$ (Fig. 2), which exists between $L5 - wSPI_{H_x}$ and $L6 - wSPI_{H_x}$ clearly illustrates the dominance of the largest mode $m = 6$ while at the same time the influence and modulation of *both* other dominant modes $m = 5$ and $m = 4$ are visible. The dominant azimuthal wavenumber m is decreasing from the inner towards the outer cylinder (Fig. 2(4)). Due to the symmetry-breaking effect of a transversal magnetic field,

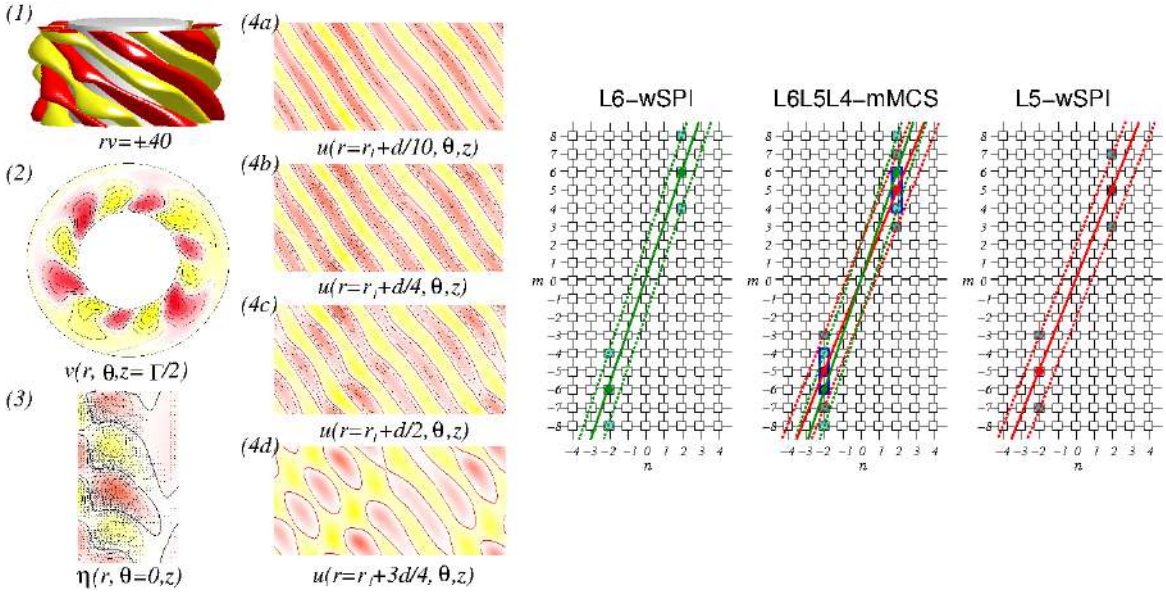

Figure 2: *Left:* Flow visualization of flow states L6L5L4-mMCS$_{H_x}$ at $s_x = 0.6$ & $s_z = 0.0$, $Re_i = 110$ and fixed axial through flow $Re = 82$. (1) Isosurface of rv; (2) The azimuthal velocity $v(r, \theta)$ at mid-plane; (3) Vector plot $[u(r, z), w(r, z)]$ of the radial and axial velocity components including color-coded azimuthal vorticity $\eta(r, \theta = 0, z)$). $(4a - d)$ The radial velocity $u(r, \theta, z)$ at different radial positions as indicated. *Right:* Dominant excited modes (colored squares) of the different solutions in the two-dimensional Fourier mode space (m, n). Filled circles denote linearly driven modes and linear Fourier mode subspaces are indicated by thick lines. They represent $L5 - wSPI_{H_x}(5n \pm 2, n)$, $L6 - wSPI_{H_x}(6n \pm 2, n)$, and a combination of both in $L6L5L4 - mMCS_{H_x}$.

the helical state $L5 - wSPI_{H_x}$ [$L6 - wSPI_{H_x}$] has its dominant mode $m = 5$ [$m = 6$] and an additionally stimulated modes $m \pm 2 = \{3, 7\}$ [$m \pm 2 = \{4, 8\}$] [4], respectively. When the states $L5 - wSPI_{H_x}$ and $L6 - wSPI_{H_x}$ come *close* in Re, they stimulate one of these additional modes (here $m = 4$) as a *nonlinear interaction* of dominant modes and thus a new state with *three* dominant modes is born. The correspondingmode space of $L6L5L4 - mMCS_{H_x}$ can be (linearly) constituted as a combination of two mode spaces of $L5 - wSPI_{H_x}$ and $L6 - wSPI_{H_x}$ [$(5n \pm 2, n)$ and $(6n \pm 2, n)$].

CONCLUSIONS

When an axial mass flux is applied to a ferrofludic system, the dynamics of a system can be described by results of competition of the *three* different instabilities; *centrifugal instability* due to rotation, *shear instability* due to axial mass flux and *magnetic instability* due to applied magnetic fields. Due to competition of these instabilities, previously unknown *new* flow states appear. These are *localized wavy Taylor vortices* ($wTVF_l$ and $wTVF_{l,H_x}$) and *modulated Mixed-Cross-Spirals* ($mMCS_{H_x}$). $mMCS_{H_x}$ appear as a byproduct of an interaction of an axial through flow and a transversal magnetic field. In fact the symmetry breaking nature of a transverse magnetic field is responsible for the appearance of $mMCS_{H_x}$ due to its additionally stimulated modes $m \pm 2$.

FARADAY INSTABILITY IN 1D CAVITIES : TIME CRYSTALS AND MODE SELECTION

Guillaume d'Hardemare [1], Antonin Eddi*[2] and Emmanuel Fort [1]
[1] Institut Langevin, ESPCI Paris, CNRS, PSL University, [1] rue Jussieu, F-75005 Paris, France
[2] PMMH, CNRS, ESPCI Paris, Université PSL, Sorbonne Université, Université de Paris, F-75005, Paris, France

Summary Faraday instability is equivalent to a time crystal, where the parametric amplification leads to the apparition of k-gaps, formally analogous to the energy band gap is solid-state physics. As energy is not conserved, this results in an unstable domain in k-space where modes grow. Here, we investigate experimentally Faraday instability in 1D cavities, where we can tune the excited mode by changing the cavity length. This allows us to probe the amplification band of the instability. Abruptly changing the phase of the excitation further allows us to observe the overdamped modes of the instability, measuring for the first time their decay rate predicted theoretically but never observed so far.

FARADAY INSTABILITY AS A TIME CRYSTAL

Faraday instability is observed when a liquid bath is vertically shaken above a certain threshold [1]. It has been extensively studied experimentally and theoretically as an instability in the stationary regime, with focus on the forcing threshold, pattern formation and the various dissipation processes or the hydrodynamic associated phenomena. This parametric instability can be revisited within the framework of Floquet time crystals. For an inviscid fluid in a bath submitted to vertical acceleration $a_0\cos(2\omega_f t)$, the modes are given by a Mathieu equation [2]. The free surface elevation $\xi(\mathbf{r},t)$ at position $\mathbf{r}$ and time t can be decomposed in Fourier modes $\hat{\xi}(\mathbf{k},t)$ of wavevector $\mathbf{k}$ following:
$\frac{\partial^2\hat{\xi}(\mathbf{k},t)}{\partial t^2} + \omega_0^2(\boldsymbol{k})\hat{\xi}(\mathbf{k},t) = -a_0 \mathrm{k}\cos\left(2\omega_f t\right)\hat{\xi}(\mathbf{k},t)$ with $\omega_0(\mathrm{k})$, the angular frequency given by the dispersion relation for gravity-capillary waves and k, the wavenumber. This equation describes the modes in a medium with a gravity modulation. The variation of the effective gravity induces a speed modulation of the gravito-capillary waves which can be seen as a modulation of the refractive index [4,5]. The solutions of the Mathieu equation are given by the Bloch-Floquet theorem while in the case of liquid with a small viscosity ν, a damping term $-2\gamma\partial\hat{\xi}/\partial t$ should be added to the Mathieu equation, γ being the damping rate related to the fluid viscosity by $\gamma = 2\nu\mathrm{k}^2$ [3]. Figure 1 shows a typical complex dispersion curve obtained with a small viscosity, with vertical k-gaps (in momentum). These k-gaps are the analog of the horizontal energy gaps observed in spatial crystals in which the waves cannot propagate. Within the k-gaps, the vertical excitation of the bath leads to two possible solutions: one being overdamped compared to a bath at rest, the other being underdamped. For sufficient forcing, the Faraday instability is observed and a standing wave at half the excitation frequency appears on the surface.

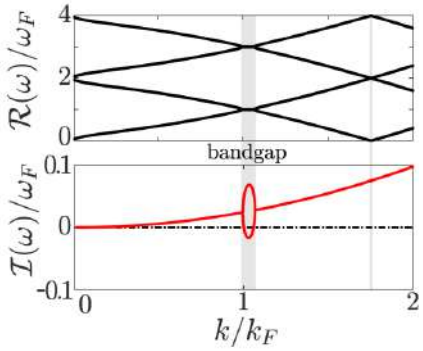

Figure 1: Dispersion relation showing the band structure of the Faraday instability as a water wave time crystal. Top: real part $\Re(\omega)$ of the angular frequency ω versus the normalized wavenumber k/k_F with k_F being the Faraday wavenumber Bottom: Imaginary part $\Im(\omega)$ of the angular frequency as a function of k/k_F. The small parabolic variation corresponds to the viscous damping

EXPERIMENTS

We now focus on a versatile implementation of a 1D time crystal based on Faraday instability. It consists in a 1D wave cavity whose length L can be tuned that is submitted to vertical harmonic vibrations. Faraday waves are excited at half the forcing frequency Ω_F. The associated wavelength λ_F is given by the capillary-gravity dispersion relation for water-waves and is chosen so that it equals twice the width of the tank to excite the first transverse mode of the cavity. We measure the exponential growth rate of the waves which corresponds to the imaginary part of the Floquet exponent $\Im(\omega)$ as well as the wavelength λ inside the cavity. The growth rates (Fig. 2a) exhibit peaks separated by half a Faraday wavelength λ_F. These peaks correspond to matching between a mode associated to the Faraday instability and a resonant mode of the cavity which wavelength satisfies $\lambda = 2L_{\mathrm{eff}}/n$, n being the mode number and L_{eff}, the effective cavity length taking into account the boundary conditions. Varying the cavity length results in scanning the k-gap associated to the Faraday instability (Fig. 2b). The curve of the growth rate thus corresponds to a periodic scanning of the k-gap with maxima obtained for cavity lengths satisfying $L_{\mathrm{eff}} = n\lambda_F/2$.
Last, we introduce a topological defect in the time crystal by suddenly π-shifting the excitation period which results in concatenating two time crystals with opposite phase. At the interface, the existing mode is turned into the overdamped one. By extracting the damping rate, we are thus able to measure the entire complex dispersion inside the k-gap of the Faraday time crystal.

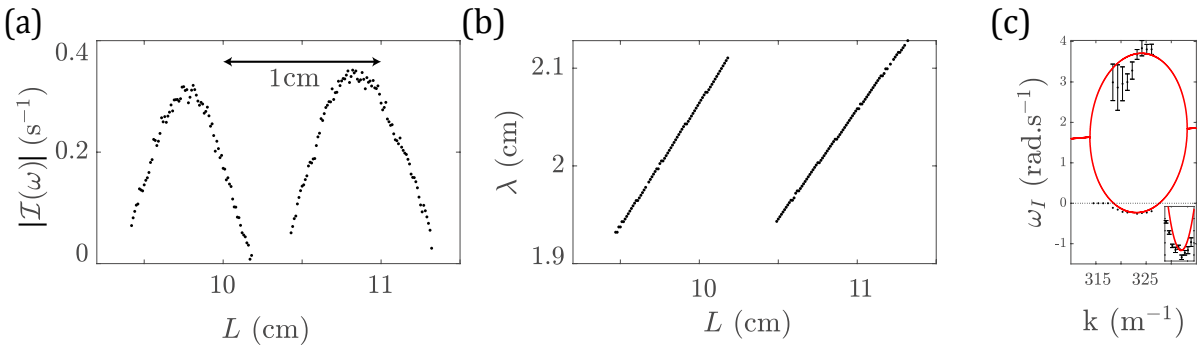

Figure 2: (a) Growth rate of the amplitude $|\Im(\omega)|$ and (b) wavelength λ of the mode in the cavity as a function of the cavity size L. The peaks are associated to the matching between the Faraday instability k-gap modes and the ones of the cavity. (c) Measurement of growth and decay rates inside the k-gap. The solid red curves give the result of the computation based on a damped Mathieu equation using experimental values of the viscosity. The inset provides a zoom on the lower part of the curve.

NON-LINEAR PRE AND POST BUCKLING BEHAVIOUR OF A TIMOSHENKO BEAM

Marwan Hariz* [1], Loïc Le Marrec † [1], and Jean Lerbet ‡ [2]
[1]Univ Rennes, CNRS, IRMAR - UMR 6625, F-35000 Rennes, France.
[2]Université d'Evry, CNRS, LaMME - UMR 8071, F-91037, Evry, France.

Summary Plane bending of a Timoshenko beam is derived using Cosserat formulation by the mean of a material curve and a moving director frame. Equilibrium relations are derived in the case of linear stress-strain relations and for both large strains and large displacements. Beam bending is controlled by magnitude and direction of a force and a bending moment. By a series of transformations, equilibrium equations are rearranged where pre and post buckling solutions are given in terms of Jacobi elliptic functions. From our knowledge this is the first attempt where such solution are derived by taking account a control of the bending moment.

KINEMATICS AND INTERNAL FORCES UNDER COSSERAT FORMULATION

We consider a Timoshenko model for plane motion of an homogeneous straight beam of length L. In a Cartesian frame, the beam axis is oriented along $\boldsymbol{e_z}$ in the stress-free configuration, and the motion lies in the $(\boldsymbol{e_x}, \boldsymbol{e_z})$-plane. However, for such a Cosserat-like structure it is justified to use a moving director frame $(\boldsymbol{d_1}, \boldsymbol{d_2}, \boldsymbol{d_3})$ for which $\boldsymbol{d_2} = \boldsymbol{e_y}$ and $\boldsymbol{d_3}$ is normal to the cross-section, because this basis is orthonormal $\boldsymbol{d_1} = \boldsymbol{d_3} \wedge \boldsymbol{d_2}$. In the stress-free configuration this basis coincide with the Cartesian frame, however during motion, the orientation of the section is not uniform, $\{\boldsymbol{d_i}(S)\}$ depends on the curvilinear abscissa S of the beam. $\boldsymbol{d_3}$ is not tangent to the center line as in the Euler-Bernoulli model.
Kinematics of the beam are governed by the placement $\boldsymbol{\varphi}(S)$ of the center line and rotation $\theta(S)$ of the section around $\boldsymbol{d_2}$. Following [6], deformation are described thanks to the curvature $\boldsymbol{\kappa}(S)$ and generalized strains $\widetilde{\boldsymbol{\varepsilon}}(S)$ with

$$\boldsymbol{\kappa} := \frac{\partial \theta}{\partial S}\,\boldsymbol{d_2} = \kappa_2 \boldsymbol{d_2}\,, \qquad \widetilde{\boldsymbol{\varepsilon}} := \frac{\partial \boldsymbol{\varphi}}{\partial S} - \boldsymbol{d_3} = \varepsilon_1 \mathbf{d_1} + (\varepsilon_3 - 1)\boldsymbol{d_3}\,. \tag{1}$$

Hereafter the kinematical variables are the component $\kappa_2(S)$ of the curvature and components $\varepsilon_1(S)$ and $\varepsilon_3(S)$ of the deformation $\frac{\partial \boldsymbol{\varphi}}{\partial S}$ of the center-line. In particular ε_1 is the shear strain and $\varepsilon_3 - 1$ is the longitudinal strain. Internal force acting on a section is $\boldsymbol{N} = N_1 \boldsymbol{d_1} + N_3 \boldsymbol{d_3}$ where N_1 and N_3 are the shear and normal components respectively. Internal moment is $\boldsymbol{M} = M_2 \boldsymbol{d_2}$ where M_2 is the bending moment.
Linear constitutive law is assumed : $N_1 = GA\varepsilon_1$, $N_3 = EA(\varepsilon_3 - 1)$ and $M_2 = EI\kappa_2$ where A and I are the area and the quadratic moment of the section, E and G are the Young modulus and shear modulus (including eventually a shear correction factor) of the beam material.

EQUILIBRIUM RELATIONS

Equilibrium relations for this static problem states [1, 2] :

$$\frac{\partial \boldsymbol{N}}{\partial S} = 0\,, \qquad \frac{\partial \boldsymbol{M}}{\partial S} + \frac{\partial \boldsymbol{\varphi}}{\partial S} \wedge \boldsymbol{N} = 0\,. \tag{2}$$

Non-dimensional kinematical variables are given thanks to the gyration radius $\varrho = \sqrt{I/A}$:

$$s = \frac{S}{\varrho}, \quad \ell = \frac{L}{\varrho}\,, \quad \varepsilon_i(s) = \varepsilon_i(S)\,, \quad \kappa_2(s) = \varrho\,\kappa_2(S)\,, \qquad i = 1, 3\,. \tag{3}$$

Last, a material parameter $g = E/G$ is introduced. Note that $g \simeq 2(1+\nu)$ where ν is the Poisson's ratio, then $2 \lesssim g \lesssim 3$. Hence (2) become in a non-dimensional form (the prime stands for derivation over s) :

$$\varepsilon_1' + g(\varepsilon_3 - 1)\kappa_2 = 0 \tag{4}$$
$$g\,\varepsilon_3' - \varepsilon_1 \kappa_2 = 0 \tag{5}$$
$$g\,\kappa_2' + \varepsilon_1 \varepsilon_3 - g\,\varepsilon_1(\varepsilon_3 - 1) = 0 \tag{6}$$

In order to prevent rigid motion $\theta(0)$ and $\boldsymbol{\varphi}(0)$ are set to zero. In this work boundary conditions are fixed by imposing force and moment at $s = \ell$. Let us denote $\boldsymbol{N_\ell} := \boldsymbol{N}(\ell)$ and $\boldsymbol{M_\ell} := \boldsymbol{M}(\ell)$. In terms of force, either orientation ϕ_ℓ and magnitude N_ℓ or equivalently shear and longitudinal components $N_{1\ell}$ and $N_{3\ell}$ may be prescribed. Here ϕ_ℓ is measured from the opposite normal of the section, then $N_{1\ell} = -N_\ell \sin(\phi_\ell)$ and $N_{3\ell} = -N_\ell \cos(\phi_\ell)$.

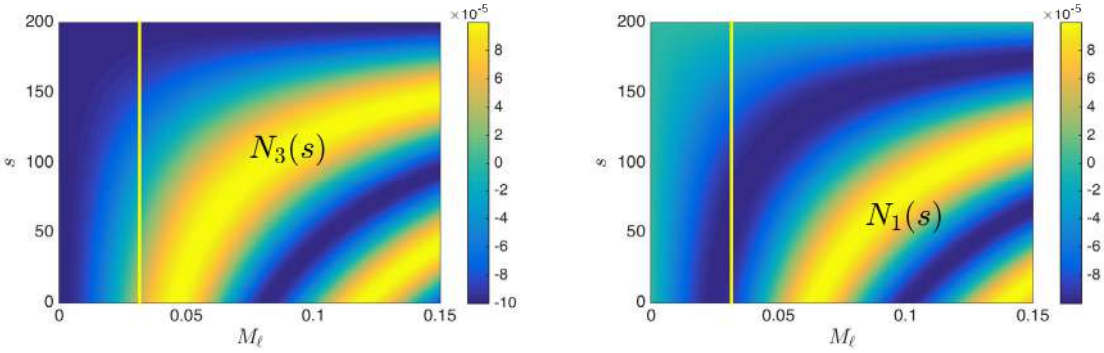

Figure 1: Internal longitudinal force $N_3(s)$ and shear force $N_1(s)$ for various bending moments at boundary $M_2(\ell) = M_\ell$. Here $\ell = 200$, $g = 2.5$ and the external load $N_\ell = 10^{-4}$ is fixed and purely longitudinal ($\phi_\ell = 0$ then $N_{1\ell} = 0$). Note that for such material the Euler critical buckling is $P_e = g\pi^2/\ell^2 \sim 6 \cdot 10^{-4}$ then a priori $|N_{3\ell}| < P_e$. The yellow line $M_\ell = 2\sqrt{gN_\ell} \sim 0.03$ splits the M_ℓ domain where $a < 0$ (left) and $a > 0$ (right).

PRE AND POST BUCKLING SOLUTIONS

From the first relation of (2), the force is uniform $\boldsymbol{N}(s) = \boldsymbol{N}_\ell$. This motivate us to introduce $\phi(s) \in]-\pi;\pi[$ such that $N_1(s) = -N_\ell \sin(\phi(s))$ and $N_3(s) = -N_\ell \cos(\phi(s))$ with $\phi(\ell) = \phi_\ell$. According to (4) or (5) it is straight forward to obtain $\phi' = -\kappa_2$. Injecting this relation into (6) we obtain after integration

$$-(g\phi')^2 + 2gN_\ell \cos\phi + (g-1)N_\ell^2 \cos^2\phi = \mu_\ell\,. \tag{7}$$

The constant of integration μ_ℓ is imposed by boundary conditions as $\mu_\ell = -M_{2\ell}^2 - 2gN_{3\ell} + (g-1)N_{3\ell}^2$. With the change of variable $t(s) = \tan(\phi(s)/2)$, (7) may be written as

$$(t')^2 = a(t^2-\alpha_-)(t^2-\alpha_+) \quad \text{with} \quad a = \frac{(g-1)N_\ell^2 - 2gN_\ell - \mu_\ell}{4g^2} \quad \alpha_\mp = \frac{(g-1)N_\ell^2 + \mu_\ell \mp 2N_\ell\sqrt{g^2+(g-1)\mu_\ell}}{(g-1)N_\ell^2 - 2gN_\ell - \mu_\ell}$$

that is completely determined by μ_ℓ and magnitude N_ℓ. Let us note $\omega_\mp = |\alpha_\mp|$. For practical application $\alpha_+ < 0$ but sign of α_- and a may vary according to the set $\{\mu_\ell, N_\ell\}$. This would strongly affect the solution of the differential equation:

If $a < 0$ and $\alpha_- < 0$ no real-valued solution

If $a < 0$ and $\alpha_- > 0$ $t(s) = \pm\sqrt{\omega_-}\,\mathrm{sn}\Big(\sqrt{|a|\omega_+}(s-s_0)\,\Big|\,-\dfrac{\omega_-}{\omega_+}\Big)$ or $t(s) = \pm\sqrt{\alpha_-}$

If $a > 0$ and $\alpha_- < 0$ $t(s) = \pm\sqrt{\omega_-}\,\mathrm{sc}\Big(\sqrt{|a|\omega_+}(s-s_0)\,\Big|\,1-\dfrac{\omega_-}{\omega_+}\Big)$

where s_0 is a constant choosen in order to satisfy boundary conditions. Jacobian functions $\mathrm{sn}(z\,|\,m)$ and $\mathrm{sc}(z\,|\,m)$ are defined according to [3].
An illustration is given for a practical application in Fig.1. It must be emphasized that for moderates bending momentum at the boundary, some homogeneous solutions may appears in addition to the non-homogenous ones depicted in the figures. Hence three equilibrium positions are possible for moderate bending boundary condition. The non-homogeneous solution observed for moderate bending moment corresponds to solution observed after such iterative process (i) impose a large external load in order to reach buckling (ii) reduce progressively the external load.
It is then interesting to investigate the stability of all these solutions in order to complete the analysis.

Summary An overview of the nonlinear dynamics of the magnetised spherical Couette flow is presented. This problem is fundamental for understanding magnetohydrodynamic MHD instabilities occurring when a liquid metal flow, driven by the rotation of the inner boundary in a spherical shell, is subjected to an axial magnetic field. The analysis, at a moderate rotation rate and applied magnetic fields, is based on direct numerical simulations and numerical tools from dynamical systems and chaos theory, as well as laboratory experiments. Several type of MHD waves are classified and a reasonable agreement between simulations and experiments is obtained.

THE MAGNETISED SPHERICAL COUETTE MODEL

The magnetized spherical Couette (MSC) system models the HEDGEHOG experiment (Hydromagnetic Experiment with Differentially Gyrating sphEres HOlding GaInSn) at the Helmholtz-Zentrum Dresden-Rossendorf. The set-up consists of a liquid metal (GaInSn), filling the gap between two differentially rotating spheres, subjected to an axial magnetic field. This model gives rise to a rich variety of nonaxisymmetric induction-free instabilities related to the hydrodynamic jet instability, a return flow instability and the Kelvin-Helmholtz-like Shercliff layer instability, and thus its study is fundamental in MHD. Indeed, MSC is important from an astrophysical point of view: MHD flows measured in previous sodium experiments [10] were interpreted as magnetorotational instability (MRI) on a background of a fully turbulent flow. However, the observed fluctuations were attributed in [6, 5] to the turbulent analogues of the above mentioned MSC instabilities.

Previous nonlinear studies [6] and the references therein, are build on a basis of few direct numerical simulations (DNS). Very recently the authors of [7] compared DNS with experimental data obtaining reasonable agreement. The latter studies motivated recent work [4, 3] for a deep analysis of the nonlinear dynamics, by means of continuation and bifurcation methods, of each MHD instability, providing a classification of rotating and modulated waves (periodic and quasiperiodic flows) bifurcated from the basic flow.

The inductionless approximation of the Navier-Stokes and induction equations, which is valid for liquid metals as GaInSn, give rise to

$$\begin{aligned} \partial_t \mathbf{v} + \mathrm{Re}\,(\mathbf{v}\cdot\nabla)\,\mathbf{v} &= -\nabla p^* + \nabla^2\mathbf{v} + \mathrm{Ha}^2(\nabla\times\mathbf{b})\times\hat{\mathbf{e}}_z, \\ 0 &= \nabla\times(\mathbf{v}\times\hat{\mathbf{e}}_z) + \nabla^2\mathbf{b}, \end{aligned}$$

where p^* is the dimensionless pressure containing all the potential forces, $\mathbf{v}$ the velocity field and $\mathbf{b}$ the magnetic field perturbation. The system is governed by 3 non-dimensional numbers:

$$\mathrm{Re} = \frac{\Omega_i r_i L}{\nu}, \quad \mathrm{Ha} = B_0 L\sqrt{\frac{\sigma}{\rho\nu}}, \quad \eta = \frac{r_i}{r_o},$$

with $\sigma = 1$ the electrical conductivity of the fluid, ν the kinematic viscosity, $L = r_o - r_i$ the gap width, Ω_i the rotation rate of the inner sphere and B_0 the strength of the applied (axial) magnetic field. The simulation of the system is performed with a modified version of the pseudospectral code described in [2] that uses high order (up to 5) time integration IMEX-BDF methods.

The HEDGEHOG experiment can operate with two different aspect ratios $\eta = 0.35, 0.5$ and is designed to run in a quasi-laminar regime ($\mathrm{Re} \in [10^3, 10^4]$ and $\mathrm{Ha} < 10^3$) rather than the previous experiments of turbulent liquid sodium [10]. This regime is also suitable for studying helical [11] and azimuthal [9] MRIs.

NONLINEAR WAVES

The MSC system is $\mathbf{SO}(2)\times\mathbf{Z}_2$-equivariant, i. e., invariant by azimuthal rotations and reflections with respect to the equatorial plane. In this class of dynamical systems the type of solutions appearing at successive bifurcations from the base state is theoretically known [8, 1]. From a primary Hopf bifurcation of the basic Couette flow, several branches of periodic rotating waves (RW) appear [4], which in turn give rise to quasiperiodic modulated rotating waves (MRW) at a secondary Hopf bifurcations [3]. Continuation methods [4] allow to obtain the curves of rotating waves to study the dependence of the rotating frequency upon the Hartman number. Comprehensive explorations of the parameter space by means of DNS of flows bifurcated from these rotating waves allows to find regions of multistability of flows with quasiperiodic

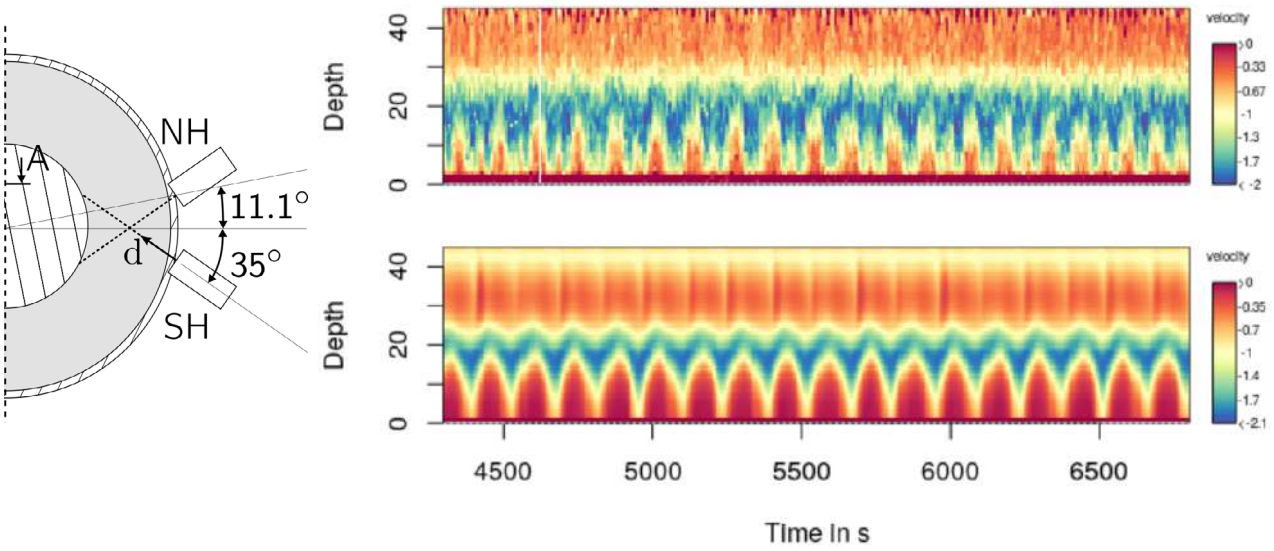

Figure 1: Left: Meridional section displaying the position of the ultrasonic Doppler velocimeter (UDV) DOP3010 probes. For each sensor the velocity along the dashed line is measured. Right: Experimental measurements (top) taken at one sensor on the north hemisphere (NH) and the corresponding numerical simulation (bottom). This radial jet instability corresponds to a modulated rotating wave at $\mathrm{Re} = 10^3$ and $\mathrm{Ha} = 2.5$.

and complex dependence [3]. The understanding and classification of the different types of azimuthal symmetries and temporal dependence of multistable flows is crucial for a successful comparison with experimental measurements.

Figure 1 illustrates the comparison of numerical and experimental velocities (mms^{-1}), along a line contained in a meridional plane (see figure caption), at $\mathrm{Re} = 10^3$ and $\mathrm{Ha} = 2.5$. According to the numerical simulations at these parameters several type of flows with azimuthal symmetry $m = 1$ are stable. The main difference between them is the azimuthal wave number, m_{max}, which mostly contributes to the flow kinetic energy. Concretely, two modulated rotating waves with $m_{\mathrm{max}} = 2$ and $m_{\mathrm{max}} = 3$ are found numerically and are stable at $\mathrm{Ha} = 2.5$. Because the experimental set-up consist of 6 UDV measuring sensors evenly displayed in the azimuthal direction, the $m = 2$ and $m = 3$ components of the flow can be estimated. In the case of Fig. 1 the main contribution to the kinetic energy of the experimental flow comes from the mode $m = 2$, and thus is compared with the simulated modulated wave with $m_{\mathrm{max}} = 2$. As displayed in Fig. 1 the amplitude and time dependence of the numerical solution and the experimental measurements are in good agreement.

CONCLUSIONS

A clear picture of complex nonlinear dynamics appearing in differentially rotating MHD flows in spherical geometry is revealed when analysing the system in terms of dynamical systems and bifurcations theory. In particular, the presence of different symmetry classes of rotating and modulated waves and their importance in the development of more complex flows can be understood. Indeed, regions of multistability can be determined with reasonable accuracy. This is of special relevance for understanding the origin of experimental flows and thus for the proper design of measurement techniques to capture flow symmetries.

RESOLVING SIMULATED SEQUENCES OF EARTHQUAKES AND FAULT INTERACTIONS

Valère Lambert[1]*, and Nadia Lapusta [1,2]
[1]Seismological Laboratory, California Institute of Technology, Pasadena, USA
[2] Department of Mechanical and Civil Engineering, California Institute of Technology, Pasadena, USA

Summary We examine the sensitivity of fault interactions in numerical simulations of sequences of earthquakes and aseismic slip (SEAS) to choices in numerical discretization and physical approximations of inertial effects, using a rate-and-state crustal fault model with two co-planar segments separated by a strong creeping barrier. We find that some physical fault and earthquake rupture quantities can be reliably determined from adequately resolved numerical models, however other quantities, such as the probability of a rupture jumping from one fault segment to another, are highly sensitive to modeling choices. Our findings suggest that some hazard parameters, such as the probability of multi-fault ruptures, may be extremely sensitive to both numerical and physical perturbations, and thus may be impractical to estimate in a reliable manner for natural faults.

Physics-based numerical modeling of earthquake source processes aims to combine available real-world data and physical principles to improve our understanding of fault behavior. There is growing interest in using numerical earthquake models of fault networks to directly determine quantities of interest for seismic hazard, such as the probability of an earthquake rupture jumping from one fault segment to another. However, the outcomes of numerical simulations can be subject to choices in numerical procedures and physical approximations, and assessing the predictive power of numerical models remains a topic of active research.

We investigate the sensitivity of numerical simulations of long-term sequences of earthquakes and aseismic slip to choices in numerical discretization and approximations for inertial (wave-mediated) effects, using a simplified 2-D elastodynamic continuum model of a crustal fault with two co-planar segments separated by a relatively strong creeping barrier (Figure 1A). Our simulations demonstrate that the frequency of two-segment ruptures and the complexity of the resulting earthquake sequences significantly depend on the modeling assumptions. In part, simulations with different numerical discretization (including insufficient discretization) and treatments of inertial effects may produce similar complexity of earthquake sequences but have very different probabilities of multi-segment ruptures.

Even among simulations that are well-resolved by standard considerations, some properties of simulated events are similar and some are not, when the fault is long enough compared to the nucleation size. That parameter regime promotes a wider distribution of rupture sizes and results in long-term differences in the simulated sequences of events. Typically, the most constraining discretization condition has been the need to resolve the cohesive zone, i.e., the region at the rupture front where shear resistance breaks down and all variables rapidly evolve, by more than 3 cells (Figure 1B; Day et al., 2005; Lapusta and Liu, 2009). While earthquake sequence behavior is virtually indistinguishable for some initial period of adequately resolved simulated sequences, the sequences of slip events eventually begin to diverge due to the subtle accumulation of numerical differences interacting with the highly nonlinear nature of the problem (Figure 1C-D).

In our models, we find that some relationships among physical properties, such as average slip, average static stress drop, and the history of average shear stress on the fault, are generally stable among adequately resolved simulations, suggesting that they may be reliably estimated from well-formulated numerical models (Figure 2). However, others properties, such as the probability of an earthquake rupture jumping from one fault segment to another, are highly sensitive to physical assumptions and numerical discretization, and hence vary even among well-resolved simulations and cannot be reliably inferred from such numerical studies (Figure 1C-D).

Our results emphasize the general need to examine the potential procedural dependence of simulation outcomes, including to resolution, particularly when assessing their predictive value for seismic hazard assessment. In addition, the significant sensitivity of some hazard parameters, such as the rate of multi-segment ruptures, to small perturbations in numerical models implies that the hazard parameters may also be extremely sensitive to physical perturbations on natural faults, suggesting that such hazard parameters are highly unstable and may be impractical to estimate in a reliable manner. This motivates the exploration of more meaningful metrics for constraining long-term fault behavior and assessing seismic hazard.

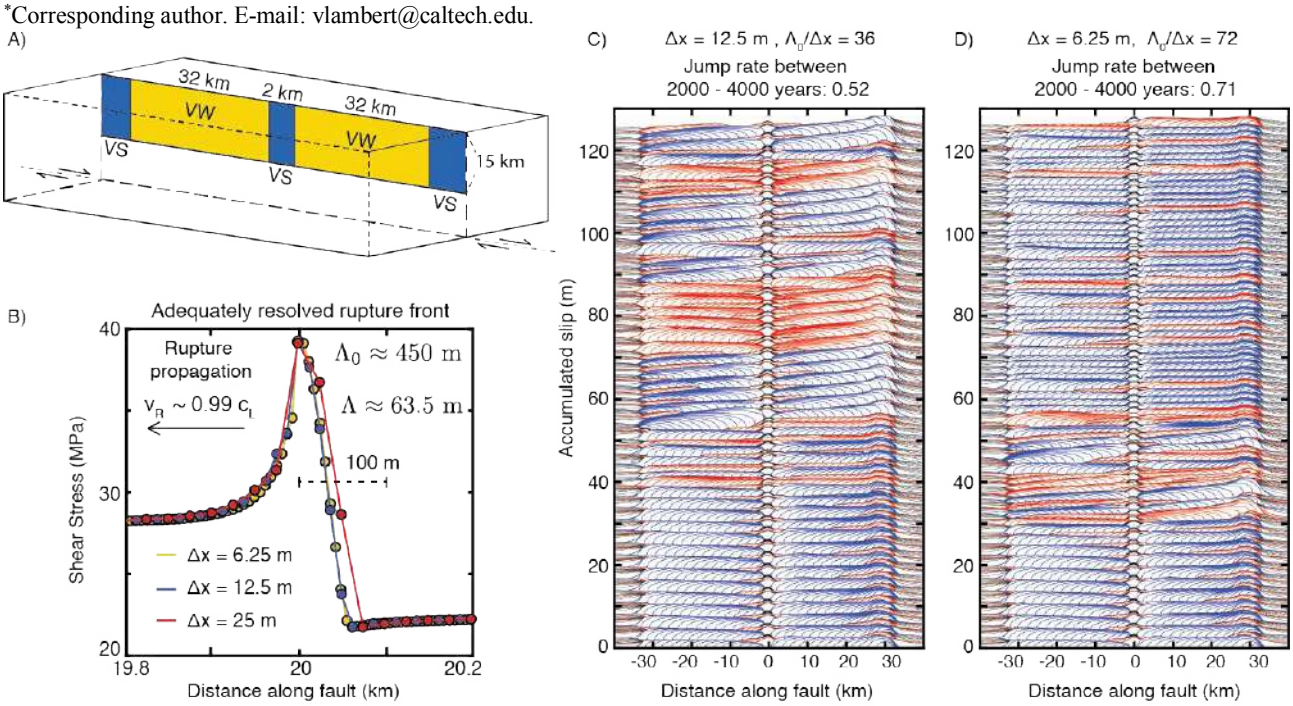

Figure 1. Sensitivity of simulated long-term interactions between two fault segments to numerical discretization even for well-resolved simulations. A) Schematic for a 2D plane-strain problem of a fault with two velocity-weakening segments separated by a velocity-strengthening barrier. B) Standard discretization considerations suggest the need to resolve the quasi-static cohesive zone size Λ_0 by at least 3 cells. During dynamic rupture the actual cohesive zone Λ shrinks as the rupture speed increases towards the limited wave speed (Day et al., 2005; Lapusta and Liu, 2009). (C-D) Slip history over 4000 years in two well-resolved simulations of earthquake sequences; e.g., the quasi-static cohesive zone size Λ_0 is resolved by 36 and 72 cells, respectively. The first 1000 years of simulated time are virtually indistinguishable. However, the long-term response, including the rate of two-segment ruptures, eventually begins to differ due to the compounded effects of small numerical differences and high nonlinearity of the problem, despite the simulations being well-resolved by any standard considerations. D)

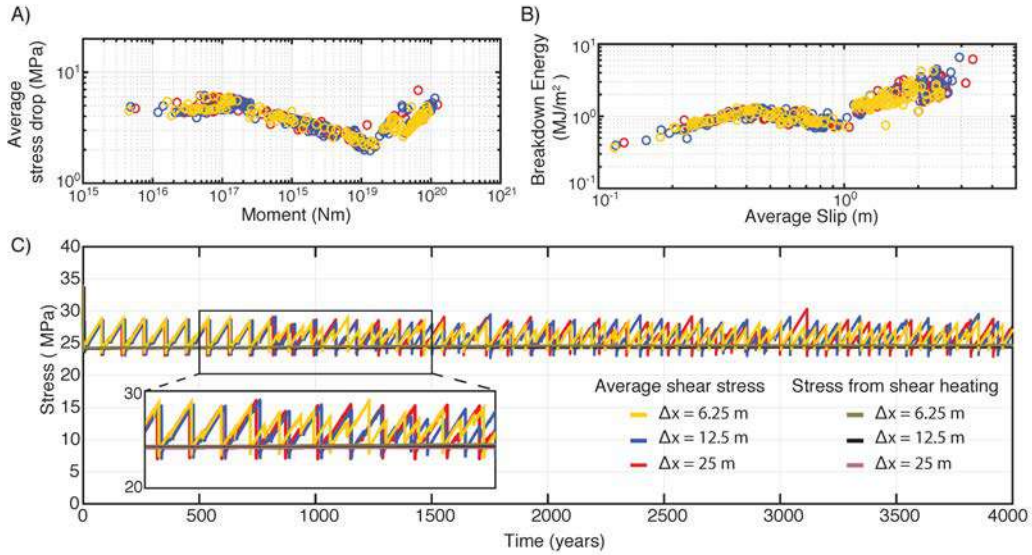

Figure 2. Consistent earthquake and fault properties among adequately resolved simulations. Despite differences in the simulated earthquake sequences, some simulated rupture and fault properties, such as the A) scaling of average static stress drop with seismic moment, B) scaling of average breakdown energy with slip, and C) evolution of average shear stress on the fault, are consistent among adequately-resolved simulations, suggesting that they may be reliably inferred from well-formulated numerical models.

MODERN PERSPECTIVES TO STATISTICAL CHARACTERIZATION OF HETEROGENEOUS POROUS MEDIA

Alberto Guadagnini
Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary Characterization of the spatial variability of attributes of natural porous media is critical in several environmental settings. Quantities such as, e.g., permeability, porosity, or geochemical parameters of natural systems typically exhibit spatial variations, their heterogeneous pattern being linked to the size of observation/measurement/support scale. As the latter becomes coarser, the system is seemingly associated with a decreased degree of heterogeneity. As such, sets of data linked to differing support scales provide diverse amounts of information. Here, we address the way stochastic representations of multiscale heterogeneity can be employed to assess documented manifestations of scaling of statistics of hydrological and soil science variables. We focus on perspectives associated with modern interpretive approaches to scaling of the main statistical descriptors of heterogeneity observed at diverse scales. We also include an appraisal of the potential of embedding elements of information theory in the analysis, as applied to the quantification of the information content related to data collected at differing measurement scales within a porous domain.

INTRODUCTION

Geostatistical approaches considered for the analysis of the major features associated with the spatial heterogeneity of quantities related to subsurface flow and transport processes assume that available observations of a target variable are sampled from a random field with a given distribution. The main statistics inferred from datasets of hydrogeological properties, including, e.g., hydraulic conductivity [1, 2, 3], electrical resistivity [2], log-permeability [4, 5, 6, 7], and neutron porosity [8] observations are characterized by distinct features. Spatial (or temporal) increments, $\Delta Y(\mathbf{s}) = Y(\mathbf{x}+\mathbf{s}) - Y(\mathbf{x})$, evaluated over the separation distance (or lag) $\mathbf{s}$, of a quantity $Y(\mathbf{x})$ ($\mathbf{x}$ denoting a position vector) display distributions characterized by peaks that become sharper and tails that tend to become heavier with decreasing lag. Distributions transitioning from heavy tailed at small lags to seemingly-Gaussian at increased lags are documented for a variety of spatial and/or temporal increments of environmental data, including sediment transport processes (e.g., [9]) and fully developed turbulence [10] as well as datasets of Earth, environmental and several other variables. Such a scale dependence is directly imprinted to the associated (statistical) moments of increment distributions, these and other aspects of statistical scaling being manifest in porous as well as fractured media characterized by either one or a hierarchy of spatial correlation scales.

In this broad context, several studies clarify that values of variables such as permeability and their associated statistics depend on a multiplicity of scales. These include the data support (or measurement scale), the size of the observation domain, and typical length scales describing spatial correlation (see e.g., [11, 12, 13, 14 and references therein]). As an example, we focus here on the length scale characterizing data sampling (i.e., the support or measurement scale). Laboratory- and field-scale evidences indicate that the mean value and the correlation length of a permeability field tend to increase with the size of the data support, the opposite behavior being displayed by the variance of data samples.

All of the above mentioned patterns suggest that the spatial distribution of permeability and other quantities tends to display an increased degree of homogeneity (as given by a decreased variance and an increased spatial correlation) with increasing support/measurement scale. These findings are also typically associated with the intuition that upscaling (here corresponding to data associated with increasing measurement/support scale) leads to a loss of information about the degree of spatial organization of the system property, corresponding to a loss of details.

THEORETICAL ELEMENTS AND SHOWCASES

The scale-dependent behavior of the probability density function (pdf) of incremental quantities can be captured through a Generalized Sub-Gaussian (GSG) model [8]. Such a theoretical framework describes the random field $Y(\mathbf{x}) = \langle Y \rangle + Y'(\mathbf{x})$, $\langle Y \rangle$ and $Y'(\mathbf{x})$ being the ensemble mean and a local zero-mean fluctuation, respectively, can be interpreted as $Y'(\mathbf{x}) = U(\mathbf{x})G(\mathbf{x})$, where $G(\mathbf{x})$ is a zero-mean, generally (but not necessarily) multi-scale Gaussian random field and $U(\mathbf{x})$ is a *subordinator*. The latter is independent of G and consists of statistically independent identically distributed non-negative random variables. The underlying Gaussian random field generally (but not necessarily) displays a multi-scale (statistical) nature. The latter can be captured, for example, through a geostatistical description based on a Truncated Power Variogram (TPV) model (e.g., [14] and references therein).

Here, we show how the original GSG model formulation can be generalized to include alternative distributional forms of the subordinator and present the ensuing analytical formulations. We then demonstrate the applicability of the theoretical framework by analyzing two datasets associated with differing processes and observation scales: (*i*) a dataset collecting measurements of surface topography of a (millimeter-scale) calcite sample resulting from induced mineral dissolution and (*ii*) a set of neutron porosity data sampled from a (kilometer-scale) deep vertical borehole in a reservoir.

We then rely on numerical simulations of conservative transport in a three-dimensional bounded porous medium and Quadratic Discriminant Analysis to document how different conservative transport observables might help in the non-univocal discrimination of model and parameters, thus translating into uncertain model outcomes. Our results document how the (ensemble averaged) longitudinal dispersion of a solute plume is scaled down in Sub-Gaussian fields with respect to their Gaussian counterparts after the solute has migrated across distances corresponding to a few integral scales of the conductivity field. This aspect is not clearly inferred from the analysis of individual realizations. We also find that the action of local dispersion tends to increase difficulties in the delineation of the influence of Sub-Gaussianity on transport. This reveals that one may not be able to discriminate between non-Gaussian and Gaussian conductivity fields relying solely on observations of the behavior of solutes migrating within the domain.

We then widen the scope of the analysis by relying on the unique datasets provided by Tidwell and Wilson [12, 13] and collecting the results of measurement campaigns targeted at the evaluation of air permeability data across the faces of a Berea Sandstone and a Topopah Spring Tuff blocks, considering different support/measurement scales. We leverage on such a truly multiscale datasets to address research questions such as "How much information is lost as the support scale increases?" and "How informative are data taken at a coarser support scale(s) with respect to those associated with a finer support scale?". The genuinely multi-scale nature of the data is analyzed through elements of Information Theory and enables us to quantify the way information is shared across measurement scales. On these bases, one can clearly identify information losses and/or redundancies that can be associated with the joint use of data sampled at differing scales.

We finally merge all of the above mentioned elements within a geostatistical interpretation of the system based on the GSG approach where a Truncated Power Variogram (TPV) model is employed to represent the underlying correlation structure. By doing so, we propose a way in which these models allow conditioning the spatial statistics of such fields on multiscale measurements via multiscale co-kriging.

CONCLUSIONS

This work is keyed to an appraisal of a variety of approaches aiming at the characterization of subsurface heterogeneity and focusing on the way statistical descriptors of the system transition across scales. We rely on interpretations based on geostatistical concepts, as integrated within a Generalized Sub-Gaussian model depicting the spatially correlated attributes of porous media at multiple scales. We then discuss the way elements of Information Theory can contribute to quantify the degree of information shared by data collected across differing scales and suggest an approach according to employ these to effectively yield a description of the main statistics of a given field at a desired scale.

The nature of the approaches makes these potentially amenable to be transferred to analyze settings involving other kinds of datasets associated with diverse hydrogeological quantities or considering joint assessment of data stemming from measurement/sampling devices of diverse designs. Future developments could also include exploring the possibility of embedding the approach within the workflow of optimal experimental design and/or data-worth analysis strategies.

WHAT WE CAN LEARN ABOUT INTERNAL TRANSFER MECHANISMS IN POROUS MEDIA (IMBIBITION, DRYING, COLLOID TRANSPORT, PHASE CHANGES) FROM MAGNETIC RESONANCE IMAGING AND OTHER NMR TECHNIQUES

Philippe Coussot
Université Paris-Est, Laboratoire Navier (ENPC-CNRS-IFSTTAR), Champs sur Marne, France

Summary Transport or transfers in porous media are often studied or described from global characteristics such as the amount of some quantity (liquid or particle mass) entering or exiting the sample, which precludes a deep understanding of local processes in time. Beyond the basic (non-quantitative) MRI technique, various techniques relying on NMR allow to provide a wide set of information on the quantitative evolution of the local liquid, porous structure, or solid-liquid interaction characteristics in time. We review several applications of these techniques and how they provided new information on the internal transfer mechanisms in porous media.

INTRODUCTION

Transport or transfers in porous media are often studied or described from global characteristics such as the amount of some quantity (liquid or particle mass) entering or exiting the sample, which precludes a deep understanding of local processes in time. Various more or less sophisticated techniques (confocal microscopy in transparent medium [1], neutron radiography or X-ray μ-CT [2], etc) allow to get some insight on the internal mechanisms. Here we focus on techniques relying on NMR (Nuclear Magnetic Resonance) which provide a wide set of information on the evolution of the local liquid or structure characteristics in time. NMR is based on the measure of the signal resulting from the resonance on the proton spins. For applications in porous media essentially the atoms in the liquid state are of interest. The basic MRI (Magnetic Resonance Imaging) technique relies on the distinction of the density of resonant spins at different places, but this approach is not quantitative and it resolution is generally not sufficient to get a precise information on the process characteristics at the pore scale. However, for processes homogeneous in the (cylindrical) sample cross-section, which may be checked from basic 2D MRI, it is possible to acquire the total signal in a thin cross-sectional layer and draw the distribution profile of liquid along the sample axis with an improved spatial resolution. Moreover, the NMR signal is not only sensitive to the spin density but also to its relaxation time which, roughly speaking, varies with the local solid-liquid interactions, and, under a field gradient, to its displacement. Coupling these characteristics with basic MRI widely opens the field of possibilities of measurements.

For sufficiently slow transient liquid transport processes such as imbibition, drying, phase changes, etc, following the liquid distribution in time provides a precise view of the internal processes. The sensitivity to displacement allows to measure the local velocity field or, alternatively but more precise as it does not suffer from resolution limitations, the probability density function of the velocity. The sensitivity to the solid-liquid interactions allows to measure the local concentration of suspended colloid particles, the local pore size, the water amount in the different possible states (e.g. free of bounded, in either large or small pores), etc. Such measurements make it possible to significantly progress in the knowledge of the transfer mechanisms in porous media. Here we review a series of examples of such approaches.

DRYING AND IMBIBITION

The evolution of the liquid distribution profile in a drying sample makes it possible to have a direct view of the liquid transport processes. This for example made it possible to show that, as long as gravity effects are negligible, from the very first times of drying the liquid fraction in a simple porous medium decreases homogeneously in time [3-4], a process which often lasts until a saturation of the order of 10%. Such an effect is due to capillary re-equilibration processes. However MRI also allowed to show that an almost homogeneous desaturation also occurs in porous materials with nanometric pores, whereas in such cases standard capillary effects cannot take place [4].

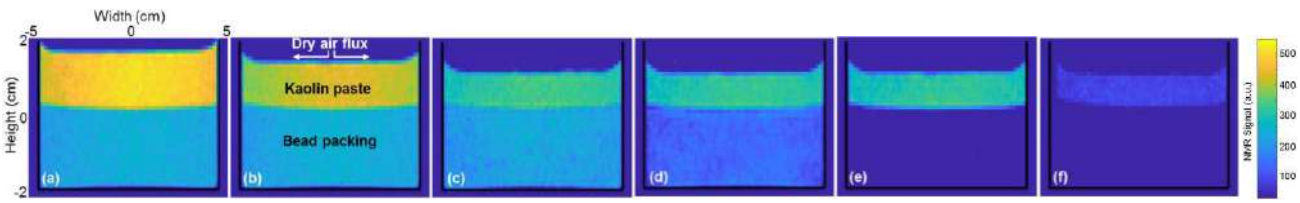

Figure 1: Qualitative (T2-weighted) 2D MRI Images of the kaolin paste (top) - bead packing (bottom) system at different times during drying: (a) 0, (b) 16 h, (c) 34 h, (d) 52 h, (e) 75 h, (f) 100 h. The NMR signal on the color scale is for each phase an increasing, but non-linear, function of the local water amount. Data from [5].

This technique appeared particularly useful for studying "composite" systems, made of layers of different types of porous materials, as it allows to quantify the liquid transfers between the layers. For example, it was shown that during the drying of a composite system made of a bead packing (substrate) covered by a clay paste, the substrate still undergoes a long homogeneous desaturation while the paste remains saturated (see Fig.1) [5]. The inverse situation of imbibition from a paste in a bead packing could also be studied [6] with this technique.

The power of NMR remarkably appears for the study of the imbibition or drying of complex porous systems containing several types of pores. For example, for hardwood, which contains free water inside long large vessels and small fibers, and bound water in the cell-walls, it was possible to distinguish the progression of the bound water and that of the free water, from which it appeared that the bound water surprisingly progresses faster (although by diffusion through the cell-walls) than the free water, an effect correlated to the strongly damped dynamics of imbibition as compared to the standard Washburn prediction [7]. At last the transfers between two phases can be followed by analysing the distribution of relaxation times when the relaxation times in the two phases are sufficiently different. This allows to follow the transfers between the different phases of a homogeneous system such as a hemp concrete or a cement paste containing aggregates.

TRANSPORT, DEPOSIT OR DISPERSION OF COLLOIDAL PARTICLES

In a saturated flow, the deposited fraction of colloid particles in a porous medium may be directly determined from the local liquid fraction with regards to liquid fraction before any deposit. This made it possible to observe the progressive deposition of non-colloidal particles by geometrical exclusion effects inside a 3D model porous medium, and to show that their concentration decreases exponentially with the distance from the entrance, which can described by a simple probabilistic model [8]. In general the NMR relaxation time of the liquid phase decreases with the ratio of the liquid volume to the area of the solid-liquid interface. This in particular implies that it will be smaller when the liquid is in smaller pores or the aspect ratio of the liquid volume is larger (e.g. films). This also implies that the relaxation time will be smaller for larger concentration of suspended solid particles. This made it possible to carry out relaxation-weighted measurements on pulses of suspensions of superparamagnetic colloidal particles injected in a granular packing and directly determine the dispersion coefficient from a straightforward analysis of the time evolution of the concentration profiles inside the sample (see Fig.2) [9]. The values obtained for this (directly observed) dispersion coefficient appeared to almost ten times lower than the commonly accepted values. This technique also made it possible to determine the local concentration in the flowing suspension in a different situation, if a fraction of particles is adsorbed onto the walls [10].

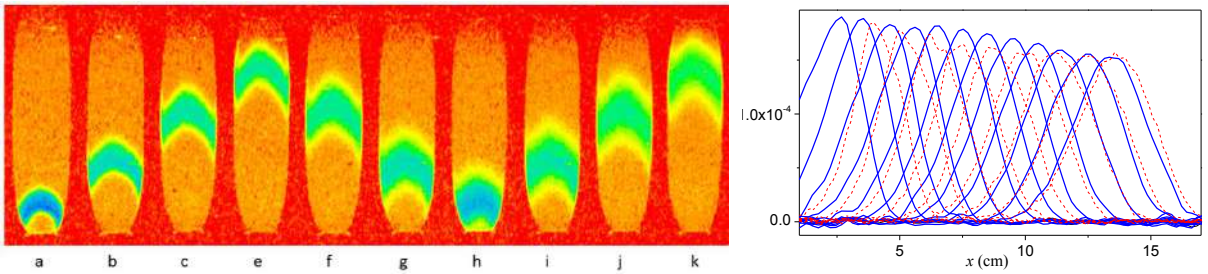

Figure 2: Left: Images of the particle distribution along longitudinal cross-sections at successive times during the flow through a bead packing (570 µm) with a pulse of colloid suspension : first upstream flow (a, b, c, d), downstream flow (e, f, g), second upstream flow (h, i, j). Color scale from maximum concentration to zero: blue-green-yellow-orange. Right: 1D quantitative profiles measured with another NMR technique. Data from [10].

NON-NEWTONIAN FLOWS IN POROUS MEDIA

Since yield stress fluids such as foams, emulsions, concentrated suspensions, exhibit a strongly non-linear constitutive equation, i.e. they behave as liquids above a critical stress and as solids otherwise, one expects that for such materials the Darcy's law will be strongly non-linear, which appeared to be effectively the case [11], but the question of the physical origin of such a law and of its coefficients remains open. It was suggested that such flows exhibit two original trends [12]: as the pressure drop increases a wider region of fluid starts to flow, an effect occurring at a local scale; at a macroscopic scale the flow starts only along a specific path throughout the porous medium and as the pressure drop is increased more flowing paths progressively form within the porous medium. However, with a simple porous medium (granular packing), from measurements using a NMR technique (pulsed-gradient spin echo (PGSE)), it was shown [13] that the probability density function of the velocity is similar to that for a Newtonian fluid, which suggests that this is the same for the local velocity field, while the stress needed to impose such a flow is non-linear.

A TALE OF X-RAY IMAGING AND MINIMAL SURFACES: REALIZING THE REVOLUTION IN ROCK CHARACTERIZATION

Martin J. Blunt, Branko Bijeljic, Qingyang Lin, Ali Raeini and Ying Gao
Department of Earth Science and Engineering, Imperial College, London, UK

Summary Recent developments in pore-scale modelling and imaging are reviewed, with an emphasis on three-dimensional X-ray visualizations of multiphase flow and reaction at reservoir conditions of temperature and pressure. Fundamental properties, such as contact angle, interfacial curvature, and pore-scale fluid distributions may be derived directly from these images, providing a powerful test for numerical models. We show how these pore-scale observations can be combined with measurements of pressure differential, which allow relative permeability and capillary pressure to be found simultaneously. We demonstrate how the morphology and curvature of the fluid interfaces impacts recovery. Modelling approaches are briefly reviewed, emphasizing that a hierarchy of methods are required to characterize flow.

OVERVIEW AND MOTIVATION

The understanding of multiphase flow in porous media is vital to address several important societal challenges, namely improved hydrocarbon production from underground reservoirs and the storage of the carbon dioxide produced from the burning of these fossil fuels [1]. Indeed, without widespread implementation of large-scale carbon capture and subsurface storage, underpinned by a fundamental understanding of subsurface flow processes, we are likely condemned to dangerous climate change combined with energy shortages.

We study the pore-scale fluid dynamics relevant for oil recovery and carbon dioxide storage, using high-resolution X-ray imaging and modelling calibrated to match the results of the experiments. Pore network modelling is introduced as a flexible upscaled formulation which uses experiments and direct numerical simulation to inform the pore-averaged properties used in the model.

MINIMAL SURFACES AND MODELLING

Figure 1 shows images highlighting the oil/water interfaces in a water-wet and a mixed-wet sandstone during waterflooding [2]. In a water-wet medium, the interfacial curvature is positive – oil bulges into water – which allows oil to be trapped. In the mixed-wet system, we see, remarkably, an approximately zero curvature, but where in one direction oil bulges into water and in the other water bulges into oil. The interfaces are approximately minimal surfaces, representing interfaces that minimize surface energy while being pinned at contact points. These minimal surfaces provide connectivity for oil and water and provide a topological explanation for the high oil recovery observed.

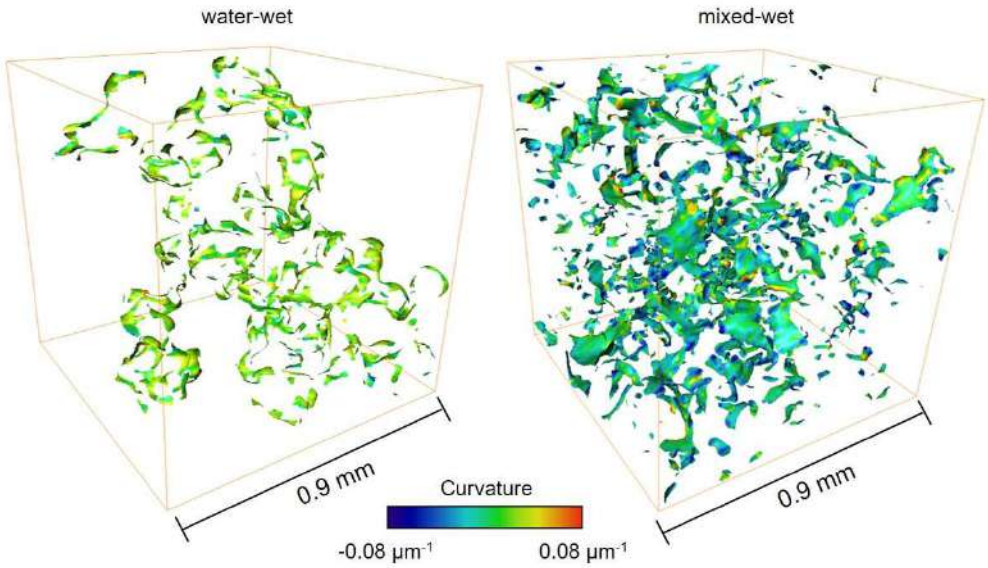

Figure 1. An illustration of the oil/water interface imaged in a water-wet (left) and mixed-wet (right) sandstone. The interfacial curvature is shown.

Figure 2 shows measured steady-state waterflood relative permeability on a mixed-wet reservoir carbonate from a producing reservoir in the Middle East where the pore-scale distribution of fluid has also been imaged [3]. The water connectivity is also shown – water preferentially fills water-wet pores and larger oil-wet pores throughout the sample, but this water is poorly connected, resulting in a low water relative permeability until a high saturation is reached and the

water clusters percolate in the macroscopic pore space. This leads to favourable local displacement efficiency, as the water is held back in the pore space.

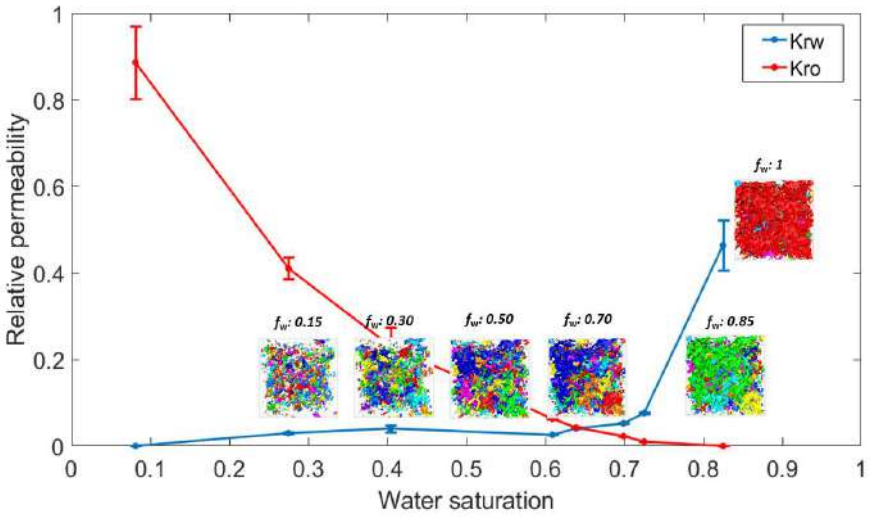

Figure 2. The waterflood relative permeability measured on a mixed-wet reservoir carbonate. Clusters of the water in macro-porosity are shown in different colours, indicating that water only percolates through the large pores at a high saturation, which explains the shape of the relative permeability function.

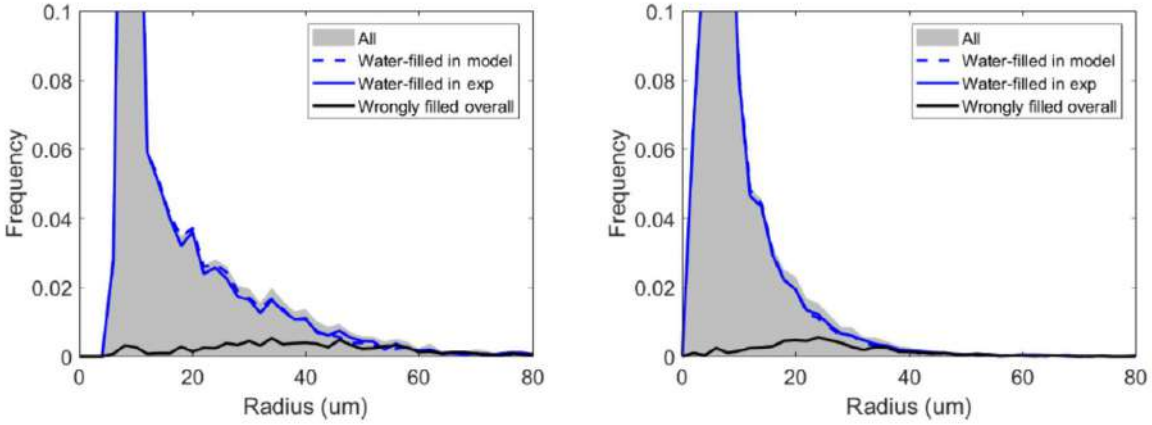

Figure 3. Pore-scale modelling results showing how the predictions of occupancy compares to direct imaging experiments. It is possible to almost exactly reproduce the correct sequence of filling with an appropriate assignment of wettability.

Figure 3 shows the results of pore-network modelling studies. If we assign wettability on a pore-by-pore basis we can reproduce almost exactly the sequence of displacement observed in the experiments. This provide a validated methodology to predict multiphase flow processes.

Further work will involve the combination of imaging, analysis and modelling to predict and interpret displacement processes for different porous materials and displacement processes.

A FRAMEWORK FOR THE EXACT RECONSTRUCTION OF DEVELOPED MACRO-SCALE FLOW IN MICRO-CHANNELS WITH LARGE ARRAYS OF PERIODIC SOLID STRUCTURES

[3]EnergyVille, Thor Park, 3600 Genk, Belgium

Summary A modelling framework is presented for the exact reconstruction of the developed macro-scale flow in micro-channels with arrays of periodic solid structures. Here, the macro-scale velocity and pressure are obtained from the Navier-Stokes equations by a double volume-averaging operator. That way, the constant macro-scale pressure gradient in the developed core region can be correlated to the macro-scale velocity by solving the periodically developed flow equations on a unit cell. For an exact reconstruction of the developed macro-scale velocity in the near-wall region, the equations are solved on an extended unit cell, containing part of the side walls. The channel's overall pressure drop and mass flow rate can then be related by a macro-scale velocity coefficient and coefficients for the macro-scale pressure drop over the in- and outlet region, as for channels without solid structures.

INTRODUCTION

For the characterisation of the incompressible laminar flow in micro-channels with large arrays of periodic solid structures, direct numerical simulation requires an enormous amount of computational resources. For this reason, generally, only a unit cell of the array is considered, and the bulk average flow variables of the entire channel are extracted under the assumption of periodically developed flow. By using this approach, friction factors for the pressure drop can be correlated to the bulk average velocity and thus to the fluid mass flow rate [1, 2]. For the exact calculation of the pressure drop over the entire channel, also the entrance and exit lengths as well as the pressure losses over the in- and outlet region of the channel need to be determined. In the literature, these lengths and loss coefficients are solely available for pipes or plate-channels without solid structures [3, 4].

For channels with solid structures, however, a macro-scale description based on bulk average quantities is not always appropriate. In our previous work [5, 6], it has been shown that an exact macro-scale description of the periodically developed flow and heat transfer regimes requires a double volume-averaging operation, as was first described by Quintard and Whitaker [7]. This filtering operation yields a spatially constant macro-scale pressure gradient and velocity, as well as a spatially constant heat transfer coefficient in the developed core region of the channel, whose relationship can be correlated through a flow simulation on a unit cell. At present, such closure correlations are only known for a few types of solid structures, and yet incompletely. Furthermore, it is not clear how the entrance and exit effects can be consistently incorporated in the context of a macro-scale description based on the double volume-averaging filter. Therefore, in this work, the macro-scale framework of [5, 6] is extended with more complete closure correlations for offset strip fins and square pin fins. In addition, the latter framework is used to formulate well-defined pressure-drop coefficients for the channel's in- and outlet regions, analogous to those for channels without solid structures. It is shown that in this framework, a macro-scale velocity coefficient can be derived, which incorporates the influence of the side walls of the channel.

EXACT RECONSTRUCTION OF THE MACRO-SCALE FLOW

Provided that the macro-scale velocity $\langle \mathbf{u} \rangle_m$ and pressure gradient $\nabla \langle p \rangle_m^f$ are computed through a double volume-averaging operator, these variables become constant in the periodically developed core region of the channel, as shown in figure 1a. In this region, the macro-scale velocity then equals the volume-averaged velocity over the unit cell $\langle \mathbf{u} \rangle$, and the macro-scale pressure gradient equals the pressure gradient over the unit cell $\nabla \mathrm{P}$:

$$\langle \mathbf{u} \rangle_m = \langle \mathbf{u} \rangle, \text{ and } \nabla \langle p \rangle_m^f = \nabla \mathrm{P}. \tag{1}$$

As a consequence, the relation between $\langle \mathbf{u} \rangle_m$ and $\nabla \langle p \rangle_m^f$ can be determined by solving the Navier-Stokes equations for periodically developed flow in a single unit cell. For an array of offset strip fins, the latter relationship can be represented in the form of the closure equation:

$$\nabla \mathrm{P} = -7.5 \cdot 10^5 \left(\frac{\mu}{l^2}\right) \frac{(1-e)^2}{e^3} \langle \mathbf{u} \rangle - 8.0 \left(\frac{\rho}{l}\right) \frac{(1-e)}{e^3} \|\langle \mathbf{u} \rangle\| \langle \mathbf{u} \rangle, \text{ with } e = \left(1 - \frac{t}{s}\right)^{0.18} \left(1 - \frac{t}{h+t}\right)^{0.18}, \tag{2}$$

where the geometry is characterised by the fin thickness t, height h, lateral spacing s, and length l [1, 2]. The closure equation (2) has been calculated numerically for $t/l = 0.02$ over the ranges $Re_l = \rho \|\langle \mathbf{u} \rangle\| l/\mu = 10 - 300$, $h/l = 0.12 - 1.00$, and $s/l = 0.12 - 0.48$, and has been fitted in analogy to the Ergun equation [8].

As schematically depicted in figure 1a, the macro-scale velocity and pressure gradient are not spatially constant over the in- and outlet region of a channel, but depend on the coordinate perpendicular to the main stream direction (dashed

(a) Macro-scale velocity and pressure as a function of the streamwise channel position

(b) Macro-scale velocity profile contraction in the near-wall region

(c) Extended unit cell (within red outline) in near-wall region (Ω_s: solid domain, Ω_f: fluid domain)

Figure 1: Schematics for the reconstruction of the macro-scale flow

lines). On the other hand, the bulk averaged pressures $p_{b,in}$ and $p_{b,out}$, which are obtained by integration over the channel inlet and outlet respectively and which determine the pumping power for the flow, do not depend on the position in the channel. Therefore, in order to include inlet and outlet pressure drops into the macro-scale description of [5, 6] by means of spatially constant loss coefficients K_{in} and K_{out}, the following relations are defined:

$$K_{in} = \frac{p_{b,in} - \langle p \rangle_m^f|_{\mathbf{x}_0} - \nabla \mathrm{P} \cdot (\mathbf{x}_{in} - \mathbf{x}_0)}{\frac{1}{2}\rho \|\langle \mathbf{u} \rangle\|^2}, \text{ and } K_{out} = \frac{-p_{b,out} + \langle p \rangle_m^f|_{\mathbf{x}_l} + \nabla \mathrm{P} \cdot (\mathbf{x}_{out} - \mathbf{x}_l)}{\frac{1}{2}\rho \|\langle \mathbf{u} \rangle\|^2}, \tag{3}$$

where $\mathbf{x}_0$ and $\mathbf{x}_l$ correspond to the onset point and end point of the periodically developed flow region. In accordance with equation (3), the entrance and exit length are thus respectively defined as $l_0 = \|(\mathbf{x}_0 - \mathbf{x}_{in})\|$ and $l_l = \|(\mathbf{x}_{out} - \mathbf{x}_l)\|$, as $\mathbf{x}_{in}$ and $\mathbf{x}_{out}$ denote the coordinate of the inlet and outlet sections. In absence of solid structures, the definitions (3) become equivalent to the loss coefficients which are used for channels without solid structures. Table 1 shows by way of illustration the entrance and exit lengths for an array of square pin fins, with a porosity of 0.75, as a function of the Reynolds number Re_l. It is clear that the entrance length increases with Re_l, while the exit length remains nearly constant over the entire range of Reynolds numbers.

Table 1: Entrance and exit lengths for a square pin fin array with a porosity of 0.75

Re_l	25	50	75	100	125	150	200
l_0/l	6.1	10.1	12.6	14.5	16.3	17.2	18.4
l_l/l	3.00	3.14	3.00	3.00	3.00	3.00	3.60

The macro-scale velocity $\langle \mathbf{u} \rangle_m$ varies over space in the near-wall region of the channel and hence differs from the constant value $\langle \mathbf{u} \rangle$ in the core. Therefore, for the inclusion of these effects on the mass flow rate, a macro-scale velocity coefficient α can be defined, which is the ratio of the macro-scale velocity in the core region of the array $\|\langle \mathbf{u} \rangle\|$ and the bulk averaged velocity $\|\mathbf{u}_b\|$. The coefficient α depends on the nature of the macro-scale velocity profile in the near-wall region (figure 1b) and hence on the macro-scale slip velocity at the side wall $\mathbf{u}_{slip}$. This macro-scale velocity profile can be determined by solving the flow equations on an extended unit cell, which contains a part of the channel's side walls (figure 1c). In this extended unit cell, the flow velocity satisfies periodicity between the boundaries Γ_1 and Γ_2, and Γ_3 and Γ_4, as well as the no-slip condition on the channel side wall Γ. For the studied arrays of offset strip fins and square pin fins, the width of the extended unit cell β has been found to equal twice the lateral geometry period l_2.

CONCLUSION

This work has presented a framework for the exact reconstruction of the macro-scale flow, defined through a double volume-averaging operation, in a micro-channel with arrays of periodic solid structures. A correlation between the macro-scale velocity and pressure gradient in the developed core region of the channel has been derived for offset strip fin arrays. Consistent definitions of loss coefficients for the channel's in- and outlet, analogous to definitions for channels without solid structures, have been proposed. Additionally, the effect of the channel's side walls on the macro-scale velocity has been taken into account by means of a velocity coefficient.

Summary Upon their drying, porous media mostly shrink. Depending on its pore size distribution and on the relative humidity, the porous medium can be deformed by the water in its pores through different physical processes, in particular through capillary effects and through surface adsorption effects. In porous media with a wide pore size distribution, such as cement-based materials, clay-based rocks, or wood, those 2 effects occur concomitantly: both contribute to drying shrinkage. Here we derive and validate a model of drying shrinkage that takes into account both capillary and surface adsorption effects, thus providing a model relevant over a large range of relative humidity. The derivation is performed by relying extensively on thermodynamics. The validation is performed based on shrinkage and adsorption data obtained on different materials (i.e., cement, concrete, and Vycor glass).

INTRODUCTION

Porous media are ubiquitous: e.g., wood, bones, sponges, concrete, soils are all porous. When such porous media are dried, they mostly shrink, as can be observed with a sponge. Such shrinkage is called drying shrinkage. One reason why drying induces a shrinkage is capillary effects: upon drying, surface tension and the curvature of the air-water meniscus in the pores makes that the pore water is more and more in tension and pulls more and more on the pore walls. Several poromechanical models (e.g., the Biot-Bishop model, the Coussy et al. model… all compared in [1]) consider this capillary effect as the main driving force for drying. However, for cement-based materials, such models have been shown [1] to fail at low relative humidity (i.e., below ~40%). One reason for such failure is that those models neglect the fact that, when a pore has lost most of its water and is filled with air, a layer of adsorbed water remains at the surface of the pores. Such adsorption of water at the pore surface contributes to the deformation, which is called the Bangham effect.

Presently, no thermodynamically-derived model of drying shrinkage exists, that considers both capillary and surface adsorption effects concomitantly. There is only one model [2] that does consider those two effects, but it was proposed based on a phenomenological approach. However, such thermodynamically-sound model is needed. Indeed, many materials, such as cement-based materials, clay-based rocks, wood… exhibit a very large pore size distribution (from macropores down to nanometer-sized pores), so that, at a generic relative humidity, part of the porosity (the finer one) is filled with liquid water subjected to capillary effects, while the other part of the porosity (the larger one) is unsaturated (i.e., filled with gas (i.e., air)) but sees its pore walls covered with a layer of adsorbed water whose thickness depends on relative humidity (see Fig. 1).

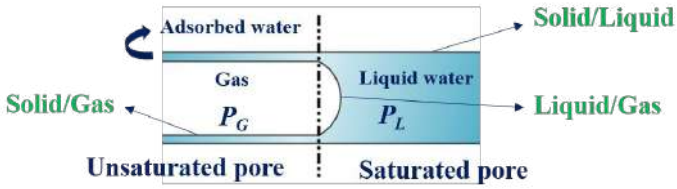

Figure 1. Schematics of a partially saturated pore system. The various interfaces at stake are indicated in green.

In this work we derive and validate a poromechanical model of drying shrinkage that takes into account both capillary and surface adsorption effects. First, we introduce the assumptions made in the derivation and discuss the resulting model. The model validation is then presented on 2 materials (namely a Vycor glass and a cement paste) and the insight that the model provides on the drying shrinkage process is briefly discussed.

DERIVATION AND DISCUSSION OF MODEL

The spirit of the model is to make it possible to predict drying shrinkage strains based on properties of the porous medium measured with classical techniques. We hence consider that the pore size distribution is measured with an adsorption isotherm analyzed with the BJH method, which assumes that pores are cylindrical. In accordance with the spirit with which we derive our model, we thus assume that pores are cylindrical. The model is derived for a linear elastic isotropic porous medium of bulk modulus K, Biot coefficient b, porosity ϕ_0, specific surface area A_0 per unit volume. The porous medium is partially filled with gas (i.e., air) at pressure P_G and liquid water (of density ρ_w and molar mass M_w) at pressure P_L. The relation $P_c(S_L)$, which relates the capillary pressure $P_c = P_G - P_L$ with the Lagrangian saturation S_L of the saturated pores in free water (and is therefore slightly different from the usual retention curve, which considers all water in the sample, not only the free one), is a characteristic of the pore size distribution. Likewise, we introduce a relation $\omega_G(S_L)$, which is the Lagrangian surface fraction of the walls of the unsaturated pores in the porous body and is also a characteristic of the pore size distribution. The capillary pressure P_c is related to the relative humidity

h_R through Kelvin's equation. The thickness $t(h_R)$ of adsorbed water on the walls of the unsaturated pores depends on the relative humidity h_R (or on its chemical potential μ): here we consider this dependence to be given by Badmann's equation. We finally assume that the amount of water adsorbed on the surface of the walls of the unsaturated pores does not depend on the surface strain of those walls.

After an extensive use of thermodynamics, we find that the variation $\Delta\varepsilon$ of volume strain of the porous solid during the drying process is given by $\Delta\varepsilon = b \cdot \Delta\pi/K$, where $\Delta\pi$ is the variation of a hydric stress π whose expression is:

$$\pi = P_L \cdot S_L + P_G \cdot (1 - S_L) + \frac{2}{3}\int_1^{S_L} P_c(S_L) \cdot dS_L + \frac{2}{3}(A_0/\phi_0) \cdot \left(\int_0^{\mu} \omega_G \cdot \frac{\rho^w}{M^w} \cdot t(h_R) d\mu - \left(\frac{\partial\gamma}{\partial\varepsilon}\right)\Big|_{\mu} \cdot \omega_G\right) \qquad (1)$$

where $\partial\gamma/\partial\varepsilon|_{\mu}$ is a parameter (assumed independent of relative humidity) that we call Shuttleworth parameter. In this expression, the first three terms capture the capillary effects. The fourth term captures the Bangham effect. The last term stems from the fact that, on solid surfaces, surface stress and surface tension are two different thermodynamic entities, as identified first by Shuttleworth. In the model derived phenomenologically in [2], this last term was missing.

VALIDATION OF MODEL

The model is validated on shrinkage data measured on Vycor glass, on cement paste, and on concrete. On those materials, on top of some basic properties (porosity ϕ_0, bulk modulus K…) and of the shrinkage upon drying, adsorption isotherms were also measured. By analyzing those isotherms with the BJH method, pore size distributions and hence the functions $P_c(S_L)$ and $\omega_G(S_L)$ are known, so that the only unknown parameters are the Biot coefficient b and the Shuttleworth parameter $\partial\gamma/\partial\varepsilon|_{\mu}$.

Figure 2 displays the predicted shrinkage strains for the Vycor glass and the cement paste upon their drying, for 2 reasonable Biot coefficients, by fitting the Shuttleworth parameter or setting it to zero. From this figure, it is clear that the model predicts the drying shrinkage strains satisfactorily on the full range of relative humidities. In particular, the model correctly captures the fact that, when relative humidity is decreased, the strain of the cement paste sample (Figure 2b) plateaus around h_R=0.35 and the strain of the Vycor glass (Figure 2a) even increases back (which is quite a counterintuitive phenomenon) around h_R=0.7.

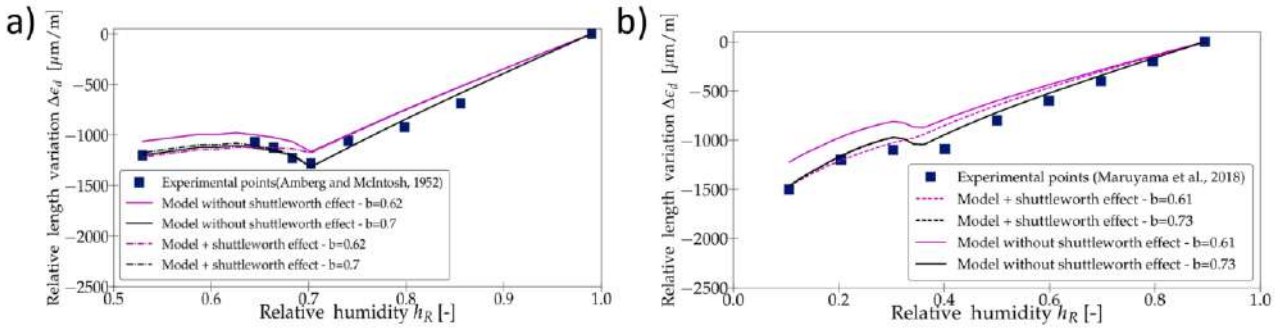

Figure 2. Predictions of drying shrinkage strains for (a) a Vycor glass and (b) a cement paste. Data are from [3] and [4], respectively.

An application of the model to those data also makes it possible to calculate the contribution of the various terms that intervene in Eq. (1). This application shows that the relative humidity at which the strain plateaus or even increases back (i.e., h_R=0.35 for the cement paste sample (Figure 2b) and h_R=0.7 for the Vycor glass (Figure 2a)) corresponds to a critical relative humidity above which capillary effects dominate and below which surface adsorption effects dominate.

CONCLUSIONS

In this work, we derived a model that predicts drying shrinkage by taking into account both capillary effects and surface adsorption effects. Most inputs to the model are rather simple properties of the porous medium (i.e., porosity, bulk modulus…) or can be obtained through the analysis of an adsorption isotherm. The model was validated on several materials over a large range of relative humidities. Using this model makes it possible to quantify, at a given relative humidity, the relative contribution of capillary effects and surface adsorption effects to the drying shrinkage strain.

STOKES FLOW COUPLED WITH NON HOMOGENEOUS POROELASTICITY

Matteo Taffetani * [1], Ricardo Ruiz Baier[2], and Sarah Waters[1]
[1]Mathematical Institute, University of Oxford, Oxford, United Kingdom
[2]School of Mathematics, Monash University, Clayton, Australia

Summary To engineer artificial tissue, a poroelastic biomaterial scaffold seeded with cells may be cultured within a perfusion bioreactor. Cells are mechanosensitive entities so the local mechanical environment may be tuned by controlling the spatial distribution of the porosity of the two phase poroelastic scaffold. To determine the impact of the heterogeneity on the kinematic variables and on the associated load distribution, we describe the porous domain using the equations of linear poroelasticity with the permeability and the shear modulus dependent upon the initial porosity field. We first show how the pressure and the strain fields are related to the permeability and the elastic properties solving the proper one dimensional problem and evaluating their asymptotic structure in the lubrication limit. Then we compute the full 2D fields by means of finite element simulations.

INTRODUCTION

The mechanical behaviour of the poroelastic domain in bioreactors for tissue growth is affected by a large variety of features including large deformations, growth of the cellular phase, remodelling of the solid phases, inhomogeneous and anisotropic description of the material properties. Often, as in the case of the perfusion system where the fluid is continuously force to flow through it, the porous domain is surrounded by a single phase fluid domain, and the interface mechanics is markedly different from the bulk mechanics.

To make quantitative advancements in the understanding of such fluid-poroelastic systems, we consider the problem of two domains, one fluid and one porous, that interface with each others through a single boundary, as in a perfusion bioreactor [1]. In addition to the presence of the interface, within the approach proposed here we retain the heterogeneous distribution of the material properties in the poroelastic domain, contrarily to [2] for example, and evaluate their effect on pressures, strains and velocities.

THEORETICAL FRAMEWORK

In the fluid domain we consider an incompressible Newtonian fluid whose flow is governed by the Stokes and the continuity equations.

Inertial effect are neglected also in the poroelastic domain and we consider a biphasic mixture of two intrinsically incompressible constituents. We let the permeability K and the solid shear modulus μ_s to be isotropic but inhomogeneous, depending on the spatial coordinate $\mathbf{x}$ through the porosity distribution $\theta(\mathbf{x})$: the function K is described through a Kozeny-Carman law [4] while the function μ_s through a linear dependence in $\theta(\mathbf{x})$. Under these assumptions, the non-linear description of the porous domain is given by a system of three equations in three unknowns (solid displacement, fluid pressure and variation of porosity). Linearising in the limit of small strain, the problem reduces to the classic pressure-displacement formulation [3], in which the equation for the variation of the fluid content decouples and with the initial porosity distribution $\theta_0(\mathbf{x})$ entering the expressions for K and μ_s.

To close the system we provide suitable initial data and boundary conditions related to the specific cases investigated. At the interface we follow [6] and we account for the continuity of normal fluxes, the continuity of the traction, the balance of the normal components of the stress in the fluid phase with the pressure in the porous domain, and the so-called Beavers-Joseph-Saffman condition.

NUMERICAL IMPLEMENTATION

We rewrite the poroelasticity equations using a three fields approach [7] (displacement, fluid pressure and total pressure), and note that since fluid pressure in the poroelastic domain has sufficient regularity, we do not require a Lagrange multiplier to enforce the coupling conditions. Another advantage of the present approach, inherited from [7] is that the formulation is robust with respect to the Lamé constants of the poroelastic structure, which is of particular importance when we test variations of the flow response to changes in the material properties of the skeleton and when the effective bulk modulus is large. All routines have been implemented using the open source finite element library FEniCS [8].

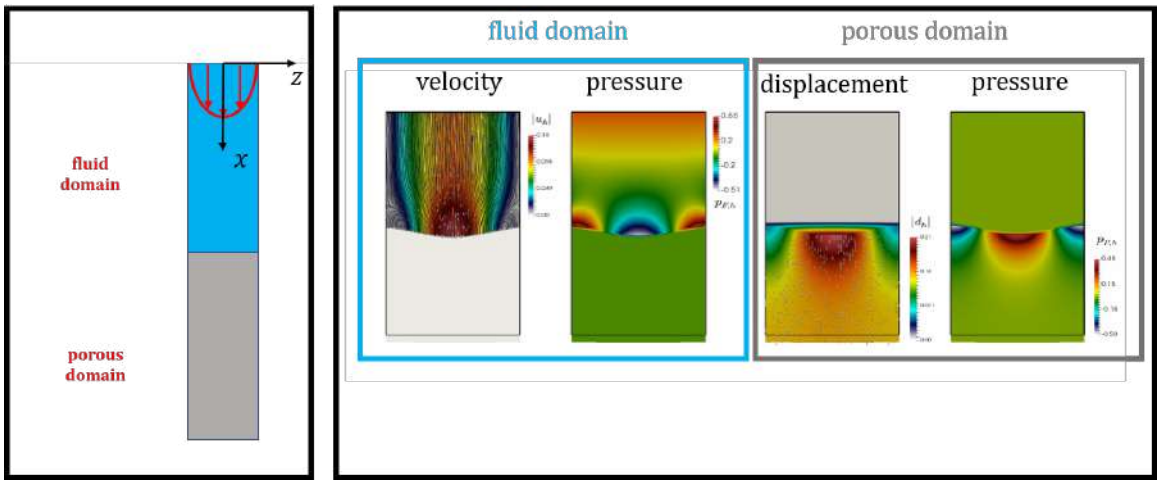

Figure 1: (left panel) Geometry under consideration. (right panel) Example of the velocity and pressure profiles in the fluid domain (blue panel) and the solid displacement and fluid pressure profiles in the porous domain (grey panel) as a response of an imposed Poiseuille profile for the velocity in the fluid domain on the top boundary.

RESULTS

We utilize this framework to consider the perfusion within a model bioreactor whose geometry is shown in figure 1 (left panel); fluid pressure and radial displacement are set to zero on the bottom edge of the porous domain while a prescribed flux is imposed at the inlet.

In the proper one dimensional reduction along the x direction and when a stationary flux is imposed, the fluid velocity throughout is constant while, in the porous domain, the pressure is described by $\int 1/K(\theta_0(x))$ and the longitudinal strain in term of $\int 1/\left(K(\theta_0(x))\left(2\mu_s(\theta_0(x))+\tilde{\lambda}\right)\right)$, where $\tilde{\lambda}$ is related to the effective compressibility of the porous domain. In the lubrication limit, where the aspect ratio of the channel is assumed to be small, we extend part of results in [2], being able to characterize the asymptotic behaviour of the deformation field in the deformable porous domain. An example of the full two dimensional fluid velocity, solid displacement and pressures maps obtained from finite element simulations is show in figure 1 (right panel).

CONCLUSION

Here we study the behaviour of a model perfusion bioreactor where the poroelastic domain is interfaced with the fluid domain. In the former, we employ the equations of linear poroelasticity when the material properties are kept inhomogeneous depending on a given prescribed initial porosity field. We first characterize the kinematic variables and compute the stress distributions when considering the proper one dimensional reduction and the lubrication limits: that allows to derive analytical relations useful to understand how these variables are related to the varying material properties. Then we compute the full two dimensional maps using finite element simulations.

This study opens toward the design of patterned porous scaffold for tissue growth, showing the possibility to compute *a priori* the local heterogeneous stress/strain distribution that a cell culture would sense.

INTERFACE CONDITIONS BETWEEN A FREE-FLUID REGION AND A POROUS MEDIUM

Sahrish B. Naqvi and Alessandro Bottaro *
Department of Civil, Chemical and Environmental Engineering, University of Genoa, Genoa, Italy

Summary Interfacial conditions at the dividing surface between a free-fluid and a porous region are of utmost importance when a two-domain approach is used to treat a coupled problem. Such conditions are here derived on the basis of adjoint homogenization [3] and the arising coefficients computed for the case of isotropic porous media. The conditions are then successfully tested for the case of a stagnation-point flow over a porous bed.

BACKGROUND

The problem of the interface coupling between a free-fluid region and a porous domain has been widely discussed analytically, numerically and experimentally (see e.g. [1]-[3]), most often with reference to simple uni-directional flows of the Poiseuille type. Recently, [2] approached the problem on the basis of homogenization theory, and derived conditions for both the slip velocity and the pressure jump across the dividing surface. Such conditions are derived here on the basis of adjoint homogenization [3], and a validation is provided against feature-resolving simulations for a flow with significant velocity components both tangent and normal to the interface.

THE MODEL

The microscopic domain (a *unit cell*) which crosses the dividing surface is illustrated in figure 1 (red lines). Small letters represent the variables for the microscopic problem while capital letters are used for the macroscopic one. The parameter used to expand the variables is $\epsilon = l/L$, ratio of small to large characteristic scales. The unit cell is periodic along the directions parallel to the dividing surface (x and z); along the interface-normal direction (y) the cell extends from the porous layer, assumed isotropic far from boundaries, to the free-fluid region. If l is the characteristic size of a unit cell

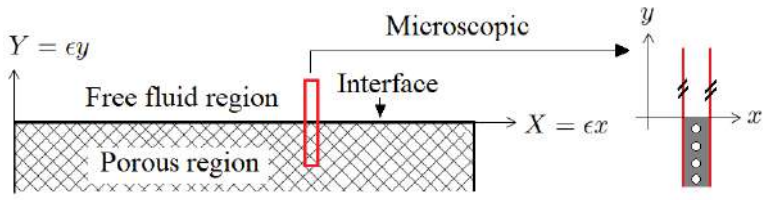

Figure 1: Sketch of the flat plate with overlaying porous bed (micro- and macro-scopic view).

deep within the porous layer, the interface-normal extent of the domain is typically four-times-l, both above and below the dividing surface (which we place in $y = 0$). It has been verified that such a y-length is adequate to produce results which are independent of the unit-cell size. Deep within the porous layer the fluid flow is induced by a macroscopic pressure gradient $\frac{\partial \bar{P}}{\partial X_i}$, whereas macroscopic shear ($\mu \frac{\partial U}{\partial Y}$) drives the flow in the free-fluid region. Assuming slow flow, the microscopic equations in the unit cell are:

$$\frac{\partial u_i}{\partial x_i} = 0, \quad -\frac{\partial p}{\partial x_i} + \mu \frac{\partial^2 u_i}{\partial x_j^2} = H(-y)\frac{\partial \bar{P}}{\partial X_i}, \tag{1}$$

with $H(y)$ the Heaviside function. At the lower end of the microscopic cell we assume periodicity to hold; on the upper boundary we enforce

$$\frac{\partial u}{\partial y} = \frac{\partial U}{\partial Y}, v = 0, \frac{\partial w}{\partial y} = \frac{\partial W}{\partial Y}. \tag{2}$$

The variables u_i and p are expanded in power series of ϵ; developing the problem at leading order it is found that the macroscale velocity components at the interface are

$$U|_{Y=0} = \epsilon \lambda \frac{\partial U}{\partial Y} - \epsilon^2 \mathcal{K}^{itf} \frac{\partial P}{\partial X}, \tag{3}$$

and likewise for W, whereas V (component of the velocity across the interface) is simply given by Darcy's law (and thus relies on a scalar permeability, denoted by $\mathcal{K}$), because of mass conservation.
There is also a pressure condition to be enforced; if we call P^+ and P^- the values of the pressure sufficiently above and sufficiently below the dividing surface in $Y = 0$, it is found that $P^+ - P^- = -a_j \frac{\partial P}{\partial X_j} + b_j \frac{\partial U_j}{\partial Y}$. The resolution of

*Corresponding author. E-mail: naqvi.sehrish@yahoo.com

the macroscopic problem proceeds iteratively, by first solving for the flow in the free-fluid region subject to no-slip and no-transpiration conditions at $Y = 0$; once the interface pressure is computed it is used as a boundary condition for the subsequent resolution of the flow in the porous domain. The solution of this problem is turn permits to correct the slip and transpiration velocities for the problem in the free-fluid region. The equations need to be iterated a few times between the two domains before convergence is reached. Of course, the accuracy of the whole procedure relies on the accuracy of the coefficients, $\mathcal{K}, \mathcal{K}^{itf}, \lambda, a_j$ and b_j, which are available from the numerical resolution of auxiliary problems in the unit cell.

MICRO- AND MACRO-SCOPIC RESULTS

The numerical simulation of the microscale problem (1)-(2) over a unit cell is done using circular or spherical grains; the results are displayed in figure 2 in terms of $\mathcal{K}, \mathcal{K}^{itf}$ and λ. These coefficients are then used in the slip condition (3) to simulate the macroscopic coupled flow between the free-fluid and the porous regions. The pressure coefficients a_j and b_j for isotropic porous inclusions vanish, i.e. there is no pressure jump at the dividing surface.

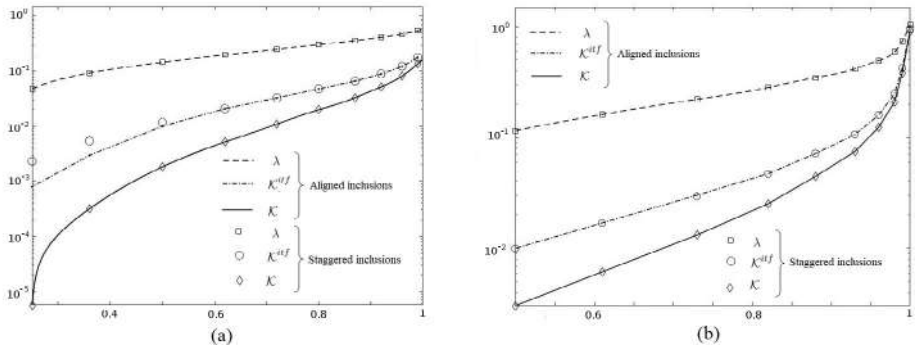

Figure 2: Macroscopic coefficients for (a) 2D (b) 3D isotropic grains, as function of porosity.

In the solution of the macroscale problem, a domain of size $15L$ and $Y = 5L$ in the X and Y direction, respectively, is considered. The situation considered is that of a stagnation point flow at $Re = 50$. Figure 3 shows the longitudinal velocity as function of Y, across the whole domain, both obtained from the model simulation (solid lines) and from a feature-resolved simulation (symbols) which captures the motion through the pores. The observed agreement is good.

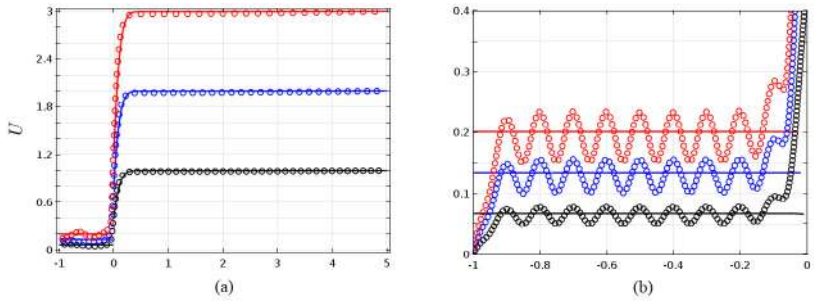

Figure 3: (a) Wall tangent velocity as a function of Y at three values of X (b) Close up of the flow field in the porous domain.

CONCLUSIONS

The interface conditions arising from homogenization theory at the dividing surface between a free-fluid and a porous region have been derived by homogenization, and the coefficients have been computed for some isotropic porous media as function of the porosity. The use of such conditions, which require no empirical coefficients, permits to reduce the computational resources needed in solving flow configurations where an interface of this kind appears. The stagnation point flow above a flat plate, covered by a porous bed, has been used as a test case. It is demonstrated that the derived conditions and coefficients yield very good results, againt fully-resolved simulations, at a fraction of the cost.

VISCOELASTIC FLOW PAST A BIPERIODIC ARRAY OF CYLINDERS

Omar Mokhtari[1], Yohan Davit*[1], Jean Claude Latché[2], Romain de Loubens[3], and Michel Quintard[1]

Summary We investigate numerically two and three-dimensional creeping viscoelastic flow past a biperiodic array of cylinders. The viscoelastic fluid is modeled using both the Oldroyd-B and FENE-CR constitutive models of dilute polymer solutions. The space discretization is based on the so-called Rannacher-Turek (RT) scheme. The time discretization uses a fractional-step algorithm where the solution of the Navier-Stokes equations is first obtained by a projection method and then the transport-reaction equation for the conformation tensor is solved by a finite-volume scheme. We show that vortices are generated upstream of the cylinder and study their evolution with the Weissenberg number. We also analyze the evolution of the permeability with the different regimes.

INTRODUCTION

Dilute and semi-dilute polymer solutions used in engineering applications, such as bioremediation or enhanced oil recovery, typically exhibit viscoelastic behaviors [1]. Understanding the complex interplay between the nonlinear rheology of the fluid and the porous structure [2] is of great importance to enhance macroscale models and to understand the connection between pore-scale phenomena and macroscale behavior. Here, we explore this problem using computational fluid dynamics and solve the flow problem at pore-scale to understand fundamental aspects of the physics.

CONSTITUTIVE MODEL

Here, we consider viscoelastic models for polymeric incompressible liquids governed by the following system of equations:

$$\rho(\partial_t \mathbf{u} + \xi \mathbf{u}\cdot\boldsymbol{\nabla}\mathbf{u}) = -\boldsymbol{\nabla} p + \operatorname{div}\boldsymbol{\tau}_s(\mathbf{u}) + \operatorname{div}\boldsymbol{\tau}_p + \mathbf{F}, \quad \boldsymbol{\tau}_p = \frac{\eta_p}{\lambda}\mathbf{f}(\mathbf{c})(\mathbf{c}-\mathbf{I_d}), \tag{1a}$$

$$\operatorname{div}\mathbf{u} = 0, \tag{1b}$$

$$\partial_t \mathbf{c} + \mathbf{u}\cdot\boldsymbol{\nabla}\mathbf{c} - (\boldsymbol{\nabla}\mathbf{u})\,\mathbf{c} - \mathbf{c}\,(\boldsymbol{\nabla}\mathbf{u})^t + \frac{1}{\lambda}\mathbf{g}(\mathbf{c})(\mathbf{c}-\mathbf{I_d}) = 0, \tag{1c}$$

where the constant coefficients ρ, η_s, η_p and λ are the fluid density, the solvent viscosity, the polymer viscosity and the polymer retardation time. The vector-valued function $\mathbf{u}$ is the velocity of the fluid, p is the pressure and $\boldsymbol{\tau}_s = \eta_s(\boldsymbol{\nabla}\mathbf{u} + (\boldsymbol{\nabla}\mathbf{u})^t)$ is the Newtonian stress tensor for the solvent. The tensor $\boldsymbol{\tau}_p$ is the part of the stress accounting for the presence of polymers and $\mathbf{c}$ is the conformation tensor. The vector $\mathbf{F}$ corresponds to a given body force. The coefficient ξ is zero for unsteady Stokes equations and $\xi = 1$ for Navier-Stokes equations. The functions $\mathbf{f}(\mathbf{c})$ and $\mathbf{g}(\mathbf{c})$ depend on the model. For example (see [3] for a review), the Oldroyd-B model is given by $\mathbf{f}(\mathbf{c}) = \mathbf{g}(\mathbf{c}) = \mathbf{I_d}$, and the Fene-CR model corresponds to $\mathbf{f}(\mathbf{c}) = \mathbf{g}(\mathbf{c}) = \frac{b}{b-\operatorname{tr}(\mathbf{c})}\mathbf{I_d}$, with b a real number greater than the space dimension. This system must be complemented by initial conditions for the velocity and the conformation tensor, and by suitable boundary conditions.

NUMERICAL METHOD

We developed a numerical scheme for the solution of System (1) based on the following technology. The space discretization is based on the so-called Rannacher-Turek (RT) scheme (see [5]). The time discretization uses a fractional-step algorithm where the solution of the Navier-Stokes equations (1a)-(1b) is first obtained by a standard projection method and then the transport-reaction equation for the conformation tensor (1c) is solved by a finite-volume scheme. The development of this scheme faces two essential difficulties. Firstly, we use a weak formulation of (1a) for the discretization of the term $\operatorname{div}\boldsymbol{\tau}_p$, which yields an essential ingredient for the scheme stability and a built-in Lax-Wendroff weak consistency property. Secondly, the solution of Equation (1c) requires special care due to the stiffness of the term $(\boldsymbol{\nabla}\mathbf{u})\,\mathbf{c} + \mathbf{c}\,(\boldsymbol{\nabla}\mathbf{u})^t$. In the spirit of [6], solution of Equation (1c) is split in pure convection steps, with a change of variable from $\mathbf{c}$ to $\log(\mathbf{c})$, and a reaction step, which consists in solving one ODE per cell thanks to the piecewise constant discretization of $\mathbf{c}$. In contrast with [6], ODEs are solved directly for $\mathbf{c}$, and not $\log(\mathbf{c})$, so as to avoid any artificial introduction of nonlinearities. We further use a local time step for each cell, which ensures scheme stability and prevents from a blow-up of the CPU cost. Computations are run (in parallel) with a dedicated module of the IRSN open-source CALIF3S software [4] developped at IMFT.

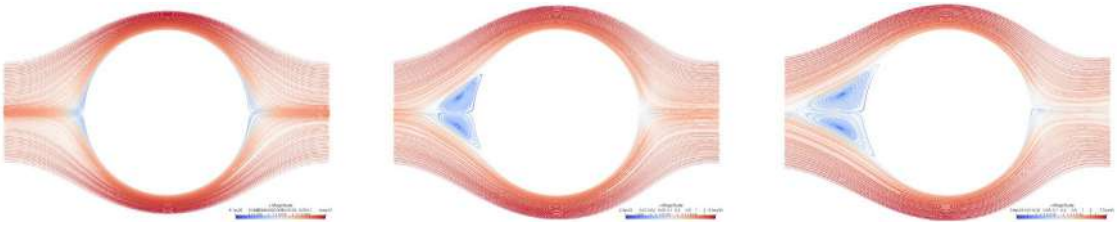

Figure 2: Streamlines with corresponding velocity magnitude in log scale. Two-dimensional case with $L = W = 2d$. From left to right: $W_i = 0.03$, 3.2 and 4.7. The flow is imposed from left to right.

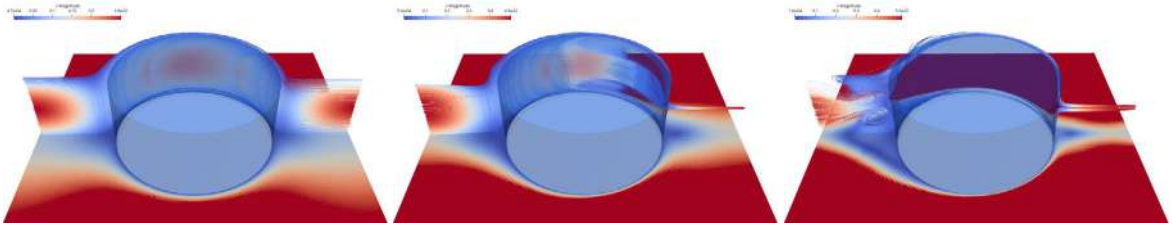

Figure 3: Streamlines and map of velocity magnitude. Three-dimensional case with $L = W = 2d$ and $H = d/2$. From left to right: $W_i = 0.5$, 1.5 and 2.5. The flow is imposed from left to right.

RESULTS

We consider the flow through a biperiodic array of cylinders. The flow length (x-direction) and width (y-direction) are L and W respectively. The cylindrical obstacle has diameter d. In the three-dimensional case, the height of the cylinder is H, see Figure 1. At the cylinder surface and the two horizontal planes (3D case), no-slip conditions are imposed and periodic boundary conditions are prescribed on vertical surfaces. The flow, is driven by a body force $\mathbf{F} \geq 0$ exerted on the fluid in the x-direction. We measure the resulting flowrate Q, defined as the constant integral of the normal velocity accross a plane normal to O_x. We then determine the corresponding Weissenberg number defined here as $W_i = \lambda U/d$, based on the cylinder diameter and the mean flow velocity U. The Reynolds number Re is set to zero ($\xi = 0$). We study the variation of the flow structure with the Weissenberg number. By increasing the Weissenberg number in the range 0.001 to 5, we first observe a Newtonian regime in the limit $W_i \to 0$ and then the appearance of stationary vortices upstream of the cylinder. For the 2D case (see Figure 2), the two vortices are counter-rotating on each side of the symmetry line. The same 2D structure of the upstream vortices have been observed experimentally [8]. In the 3D case, the vortices are 3D structures and at $W_i = 2.5$ we observe a complex structure with helically coiled streamlines (see Figure 3).

For porous media applications, we are also interested in characterizing the permeability, defined by

$$< \mathbf{u} >= \frac{K}{(\eta_s + \eta_p)}\mathbf{F} \tag{2}$$

as a function of the Weissenberg number. We observe first an increase of the permeability, followed by a sharp decrease with a minimum for Weissenberg numbers of about 0.4. This apparent thickening effect is known experimentally and has already been captured numerically (see [7]). Here, we observe that this permeability downturn corresponds to the appearance of the stationary vortices upstream of the cylinder and we study the phenomenon through energetic considerations.

CATCH AND RELEASE OF BUBBLES IN A SOFT GRANULAR MEDIUM

Summary A liquid-saturated packing of soft particles can behave like a complex fluid or like a porous solid, depending on the solid fraction. In the fluid-like state, invading gas bubbles will rise through the packing due to buoyancy with a rise velocity that decreases as the solid fraction increases. In the solid-like state, invading gas bubbles cannot rise unless their buoyancy overcomes the capillary entry pressure between the particles, in which case they will rise by migrating through the pore space of the packing. Here, we combine quasi-2D and 3D laboratory experiments with discrete-element simulations to show that the motion of gas bubbles through such a packing can be controlled by exploiting this dichotomy: Active manipulation of the solid fraction in a soft granular medium can be used for the on-demand catch and release of individual gas bubbles.

INTRODUCTION

The buoyancy-driven migration of gas bubbles through a liquid-saturated granular medium is important for a variety of natural and industrial processes, including the venting of biogenic gases from lakebed and seabed sediments [*e.g.*, Scandella et al., 2011], the venting of gases from industrial waste ponds [*e.g.*, Johnson et al., 2018], the venting of volatile gases from magma [*e.g.* Parmigiani et al., 2016], and the operation of many biological and chemical reactors.

There are several different mechanisms by which buoyant gas bubbles can migrate upward through and escape from a saturated granular medium, depending on bubble size, grain properties (*i.e.*, grain size, cohesion, and contact friction), and confining stress. In most applications, gas is unlikely to invade the pore space between the grains because of the large capillary entry pressure (*i.e.*, small grain size). Instead, for weak cohesion and low confining stress, sufficiently large gas bubbles will yield the medium and rise upward by fluidising the surrounding liquid-grain mixture. For stronger cohesion and/or higher confining stress, sufficiently large gas bubbles will instead "fracture" the medium by opening and then venting upward through a narrow pathway between the grains [*e.g.*, Lee et al.].

An important but ultimately unsurprising observation from field measurements of methane venting from lakes is that the venting rate varies inversely with fluctuations in confining stress [*e.g.*, Scandella et al., 2011]. A sudden decrease in confining stress tends to mobilise gas bubbles by weakening the sediment, making it easier for bubbles to displace the grains; a sudden increase in confining stress tends to arrest the motion of rising gas bubbles by strengthening the sediment, making it more difficult for gas bubbles to displace the grains. Here, inspired by this natural phenomenon, we study the impact of variations in confining stress on the motion of buoyant gas bubbles in a soft granular medium.

EXPERIMENTAL SYSTEM

We study this problem using quasi-2D and fully 3D experiments, as well as 3D discrete-element simulations. Our experimental system is a water-saturated packing of polyacrylamide hydrogel spheres with a mean diameter of $\sim 2\,\mathrm{mm}$. We pack these particles into a rigid container with a semi-permeable lid that constrains the particles but not the fluids, and which can be raised or lowered on-demand via a computer-controlled actuator. Lowering the lid increases the mean solid fraction in the container (*i.e.*, the mean density of the packing), which is analogous to increasing the confining stress; raising the lid does the opposite. We inject individual air bubbles into this system from below and record their motion with a digital camera.

RESULTS & DISCUSSION

We study this problem in three parts. We begin by studying the impact of different fixed initial solid fractions ϕ_s on the motion of bubbles through the packing, showing that the typical rise velocity decreases strongly as ϕ_s increases, and vanishes at a critical value $\phi_s^\star$ that depends weakly on bubble size. For $\phi_s > \phi_s^\star$, bubbles are unable to rise through the packing. We also measure the deformation of the packing as bubbles rise, finding that a rising bubble is surrounded by a fluidised zone in which particles flow around the bubble; particles outside of this zone are nearly stationary. The characteristic size of the rearrangement zone decreases as ϕ_s increases and vanishes at $\phi_s^\star$ (Figure 1).

We next study the transient response of the packing to sudden motions of the lid in the absense of bubbles. Specifically, we suddenly compress the packing by lowering the lid by an amount δ, and then subsequently allow the packing to relax by raising the lid by the same amount. We show that lowering the lid results in a poromechanical compaction front that propagates relatively quickly through the medium as the lid actively squeezes liquid out of the packing; in contrast,

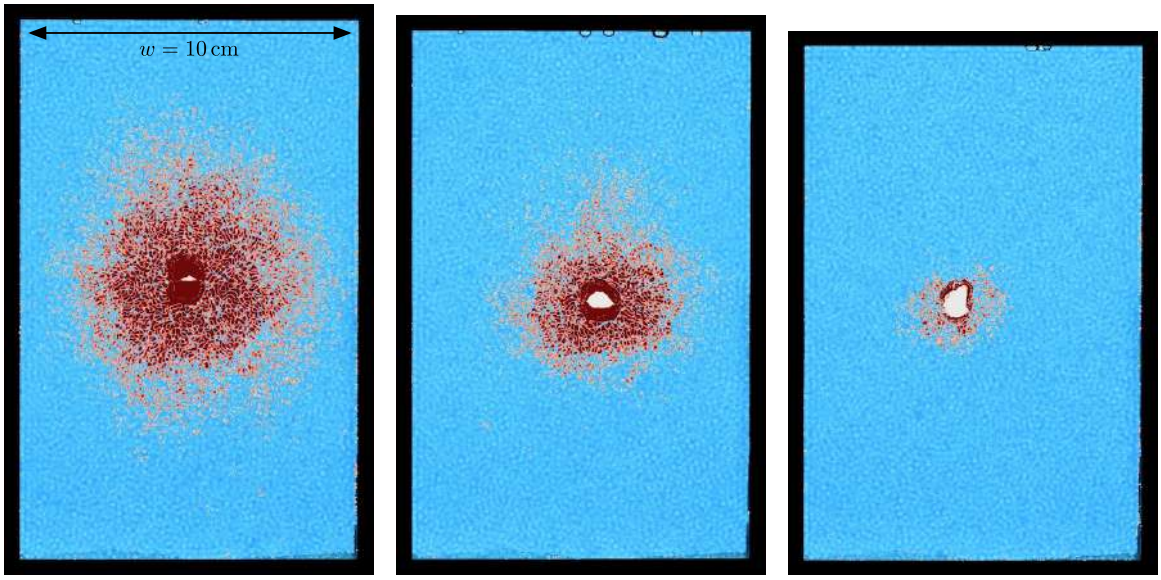

Figure 1: Snapshots of individual gas bubbles as they rise through a quasi-2D packing of soft particles for three different fixed mean solid fractions ϕ_s (increasing from left to right). We increase ϕ_s by lowering the lid, thus decreasing the height of the packing h. The red color indicates the fluidised zone around the bubble, as calculated from the motion of the particles. The size of this zone decreases strongly as ϕ_s increases (h decreases), as does the bubble velocity (not visible here). The bubble itself is partially obscured by the red color, but it is about the same size in all three cases.

raising the lid results in a poromechanical relaxation front that propagates relatively slowly through the medium as elastic expansion of the packing gradually sucks liquid back in. We also compare our experimental and simulation results with the predictions of a uniaxial model based on large-deformation poromechanics.

Finally, we study the consequences of raising or lowering the lid as a bubble actively rises through the packing. Specifically, we inject an air bubble into a packing for which $\phi_s < \phi_s^\star$ and then show that this rising bubble can be immobilised and re-mobilised on-demand by manipulating ϕ_s above and below $\phi_s^\star$ by lowering and raising the lid. We characterise this process by drawing on our earlier results for bubble migration at fixed ϕ_s and compaction and relaxation in the absense of a bubble.

CONCLUSIONS

We show here that active manipulation of the confining stress and/or the solid fraction in a soft granular medium can be used for the on-demand catch and release of individual gas bubbles. The physical insight developed in this study will contribute to our understanding of a variety of natural and industrial processes involving bubble migration in saturated granular media. In addition, we expect the active manipulation of confinement to be a useful tool for controlling bubble migration.

MULTISCALE POROMECHANICAL MODEL FOR CO_2-ENHANCED COALBED METHANE RECOVERY INCLUDING GAS ADSORPTION EFFECTS

Tien Dung Le*[1], Quoc Dat Ha[1], Christian Moyne[1]
[1]Laboratoire Energies et Mécanique Théorique et Appliquée (Nancy, France)

Summary: In this work we develop a three-scale poromechanical model for CO_2-enhanced coalbed methane recovery. Coal seam is composed of two levels of porosity associated with nanopores and fracture network (cleats). Adsorption isotherms in the nanopores are computed by using the Density Functional Theory for calculating gas mixture density profiles and solvation force in complex geometries, showing a much more pronounced adsorption potential of CO_2 compared to CH_4. At the microscale, a modified form of the effective stress principle is derived incorporating the solvation force effects. The poromechanics of the matrix is then homogenized with the cleat network giving rise to a macroscopic model ruled by the effective stress and Lagrangian porosity. Numerical simulations illustrate the cleat closure phenomena experimentally observed.

INTRODUCTION

CO_2-Enhanced CoalBed Methane Recovery consists of unconventional gas resource which combines CH_4 production with CO_2 sequestration. Coal seam is composed of a coal matrix containing pores of several nanometers with adsorbed CH_4 and a natural fracture network (cleats) with high permeability filled by water. Production of gas consists simply in reducing the pressure in the coal seam which first produces water from the cleats and subsequently gas desorbed from the matrix. The enhanced coalbed methane recovery consists of a CO_2 injection process into the reservoir taking advantage of its huge adsorption potential. However, unsuitable injection pressure may cause cleat closure near the injection well and shut down the injection process. In this work we propose a three-scale poromechanical model to describe the matrix swelling and cleat closure phenomena during CO_2 injection. Particular attention is paid to describe the gas mixture adsorption problem in the nanopores and its influence on the mechanics at the macroscale. To accomplish this task, in the framework of the Density Functional Theory (DFT), a novel numerical method is proposed to compute the gas density profiles and the solvation force for complex pore geometries. Since the solvation force is much higher than the bulk pressure, this force modifies considerably the mechanical properties of the matrix. Macroscopic governing equations are then derived by the homogenization method [1] where we upscale the anomalous behavior of the binary gas mixture in the nanopores. Finally, a 2D reservoir simulation of methane production enhanced by CO_2 injection is presented to illustrate the potential of the multiscale model.

GAS MIXTURE ADSORPTION AND SOLVATION FORCE

The Density Functional Theory (DFT) is applied to describe precisely the gas mixture adsorption phenomena in nanopores [2,3,4]. The adsorbed gas density profiles and the pressure exerted on the solid wall by the fluid (or solvation force) are numerically computed for an oblate spheroidal pore with two semi-major axes $a=b=4{,}5d_{CH4}$ and semi-minor axis $c=3d_{CH4}$, d_{CH4} is the CH_4 diameter. Fig. 1(a) displays the gas density profiles of CH_4 (blue curve) and CO_2 (red curve) according to the small axis Oz. We can observe much higher adsorption peaks of CO_2 compared to CH_4 with the same bulk gas densities. Fig. 1(b) displays the solvation force profile according to the small axis Oz. We can observe that the solvation force is negative, not uniform in the case of an ellipsoid and much higher in absolute order of magnitude than the bulk pressure P_b=8 MPa. Fig. 1(c) shows the dependence of the solvation force on the partial bulk pressure for a spherical pore of diameter $D=6d_{CH4}$. For high CO_2 bulk pressure, the solvation force decreases with CO_2 bulk pressure which may cause the matrix swelling.

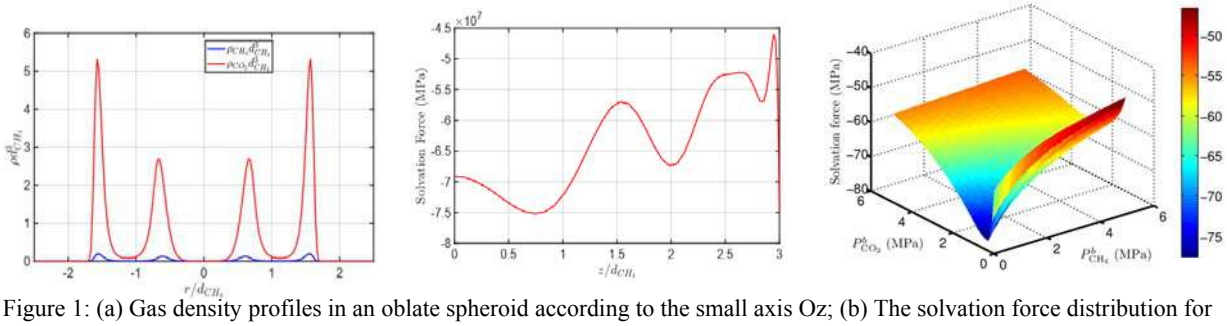

Figure 1: (a) Gas density profiles in an oblate spheroid according to the small axis Oz; (b) The solvation force distribution for an oblate spheroidal pore according to the small axis Oz (c) Dependence of the solvation force on the partial bulk pressures

MACROSCOPIC MODEL DERIVED FROM HOMOGENIZATION

At the microscale, a modified form of the effective stress principle is derived incorporating the solvation force effects. By linearizing the poromechanics around a reference state, the microscopic governing equations are rephrased with new coefficients strongly dependent on the solvation force. In Fig. 2(a), we can observe that the modified Biot-Willis coefficients of the matrix depending on the bulk pressure for each gas component can be larger than one in contrast to the classical poroelasticity due to the gas confinement effects, in particular for CO_2 (here i=1,2 correspond to CH_4 and CO_2 respectively). The poromechanics of the matrix is then homogenized with the cleat network giving rise to a three-scale model ruled by the effective stress, Lagrangian cleat porosity and permeability. The macroscopic laws of the effective stress tensor and Lagrangian cleat porosity are reconstructed in incremental forms where the effective coefficients are taken constant over each time interval and then updated to compute the next time interval. It should be noted that the proposed three-scale poromechanical model can be coupled with a multiscale transient model for flow and transport problems developed in other work in order to simulate the CO_2 injection process, the change of permeability and to predict the gas production curve.

Numerical simulations of the proposed poromechanical model coupled with the multiscale transient model are carried out in COMSOL Multiphysics software. Fig. 2(b) illustrates the ratio between the cleat permeability and its initial value. Near the injection well (lower left corner), the cleat permeability decreases significantly due to a matrix swelling induced by CO_2 adsorption. As observed at the nanoscale by the DFT approach, the adsorption potential of CO_2 is higher than CH_4. Therefore, CO_2 can replace CH_4 in the nanopores inducing a less attractive force which swells the matrix. Particular attention must be paid to the injection pressure to avoid total cleat closure near the injection well.

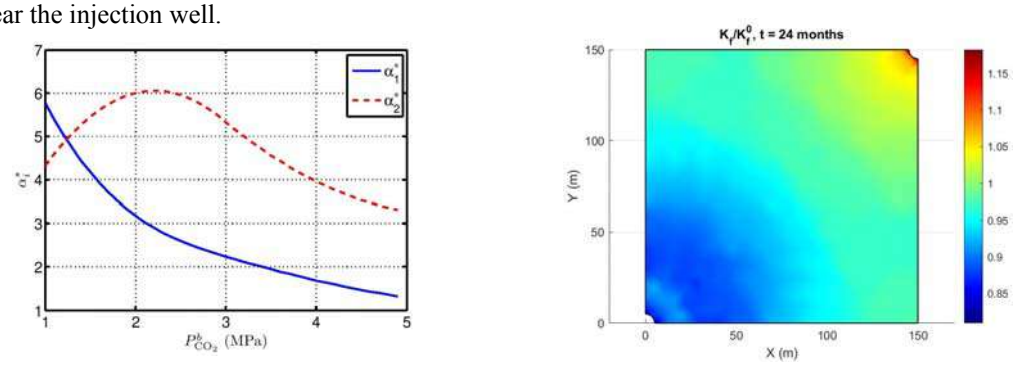

Figure 2: (a) Dependence of modified Biot-Willis coefficient on bulk pressure; (b) Ratio between the cleat permeability and its initial value after 24 months of gas production, P injection = 5 MPa

CONCLUSIONS

In this work we have constructed a three-scale model to describe the poromechanics of swelling porous media incorporating the deformation induced by solvation forces. A novel numerical method for solving the DFT equations allowed reconstructing numerically the fluid density profiles and the solvation force in complex pore geometry. After a first homogenization procedure to obtain the modified effective stress principle for the homogenized matrix including the contribution of solvation force, we highlight the magnitude of the Biot-Willis coefficient of the matrix which under adsorption effects can be greater than one. A second homogenization procedure was applied to construct the three-scale poromechanical model incorporating the cleat network. Such an approach was capable of incorporating the influence of solvation forces on the effective stress principle and the macroscopic nonlinear poroelastic coefficients. The proposed model can explain the experimentally observed cleat closure phenomena during CO_2 injection. Such a remarkable result illustrates the potential of the proposed approach in bridging highly complex adsorption phenomena at the nanoscale and the homogenized poromechanical behavior at the reservoir scale.

UPSCALED MODEL FOR NON-STEADY INERTIAL FLOW IN HOMOGENEOUS POROUS MEDIA

Didier Lasseux* [1], Francisco J. Valdés-Parada[2], and Fabien Bellet[3]
[1]CNRS, UMR 5295, Univ. Bordeaux, Talence, France
[2]Universidad Autónoma Metropolitana-Iztapalapa, Mexico City, Mexico
[3]CNRS, CentraleSupélec, Univ. Paris-Saclay, France

Summary A macroscopic model for non-steady and inertial one-phase incompressible flow in rigid porous media is presented using an upscaling technique. The resulting model is non-local in time and involves two effective coefficients, namely, a dynamic apparent permeability tensor and a vector accounting for the time-decaying influence of the flow initial condition. Ancillary closure problems are provided, which allow computing the effective coefficients. Symmetry and positiveness analyses of the apparent permeability are carried out. The performance of the macroscopic model for different macroscopic forcing is examined along with validation with direct numerical simulations. It is shown that the purely heuristic classical model, consisting in a Darcy-like model complemented with an accumulation term on the filtration velocity, is not appropriate.

MICROSCALE EQUATIONS AND UPSCALING

The commonly employed model to described non-steady one phase incompressible and creeping flow in homogeneous porous media is a heuristic Darcy equation to which an accumulation term on the filtration velocity is added [1, 2]. This empirical macroscale momentum equation has never been established on a theoretical basis. The purpose of this work is hence to formally derive a macroscopic non-steady model for one-phase flow (including inertia) in rigid and periodic porous media. The procedure starts with the classical Navier-Stokes equations at the pore-scale considering a no-slip boundary condition at the solid-fluid interface together with the velocity initial condition. An upscaling procedure, based on a short-cut version of the volume averaging method [3], is then applied to the pore-scale equations. Due to the non-linear character of the Navier-Stokes equation, a pseudo-linearization is applied considering Reynolds numbers smaller than the critical value corresponding to the first Hopf bifurcation. Nevertheles, this pseudo-linearization does not introduce any approximation [4].

MACROSCOPIC MODEL

The macroscopic mass and momentum equations, valid in the homogeneous part of the porous medium and obtained from upscaling, are given by

$$\nabla \cdot \langle \mathbf{v} \rangle = 0, \quad t > 0 \tag{1a}$$

$$\langle \mathbf{v} \rangle = -\frac{1}{\mu} \int_{t_0=0}^{t_0=t} \left. \frac{\partial \mathbf{H}_t}{\partial t} \right|_{t-t_0} \cdot \left(\nabla \langle p \rangle^\beta - \rho \mathbf{b} \right)\Big|_{t_0} + \boldsymbol{\alpha}, \quad t > 0 \tag{1b}$$

Here, $\langle \psi \rangle$ and $\langle \psi \rangle^\beta$ denote the superficial and fluid-phase (β) intrinsic averages of ψ. In addition, $\mathbf{v}$, p and t are the velocity, pressure and time whereas μ and ρ are the dynamic viscosity and density, both being constant. In the macroscopic momentum equation, $\rho\mathbf{b}$ is the body force per unit volume, $\mathbf{b}$ being space-independent (but eventually time-varying). In equation (1b), which is non-local in time, $\mathbf{H}_t$ is the dynamic apparent permeability tensor (it is apparent due to the inertial effects) whereas $\boldsymbol{\alpha}$ is an effective coefficient which only contains a source due to the initial velocity field, $\mathbf{v}_0$, and is zero when $\mathbf{v}_0 = \mathbf{0}$. The tensor $\mathbf{H}_t$ depends on $\mathbf{v}_0$ and on the macroscopic forcing. These two effective coefficients are determined from the solution of two closure problems [4]. In the long time limit, $\mathbf{H}_t \to \mathbf{H}$, $\mathbf{H}$ being the steady apparent permeability tensor introduced earlier [5]. The final value theorem applied to equation (1b) conveniently yields the steady form of the macroscopic inertial momentum equation also reported in [5]. Moreover, using a formalism reported in [6], it can be shown that $\mathbf{H}_t$ is non-symmetric, the skew symmetric part being only due to inertial effects. In the frequency domain, the dynamic apparent permeability is shown to be a positive definite tensor. Clearly, the macroscopic momentum equation (1b) contrasts with the classical heuristic model given by $\frac{\rho}{\varepsilon}\rho\frac{\partial\langle\mathbf{v}\rangle}{\partial t} = -\left(\nabla\langle p\rangle^\beta - \rho\mathbf{b}\right) - \mu\mathbf{H}^{-1}\cdot\langle\mathbf{v}\rangle, \quad t > 0.$

RESULTS

To illustrate the relevance and accuracy of the macroscopic model reported above, its predictions are compared to the results of direct numerical simulations (DNS) of the initial pore-scale equations. To do so, a two-dimensional model pore-structure made of a square pattern of parallel cylinders of square cross section is considered. Periodicity is applied in the vertical (y-) direction allowing to consider a single row of n cylinders ($n = 21$) in the horizontal (x-) direction.

*Corresponding author. E-mail: didier.lasseux@u-bordeaux.fr

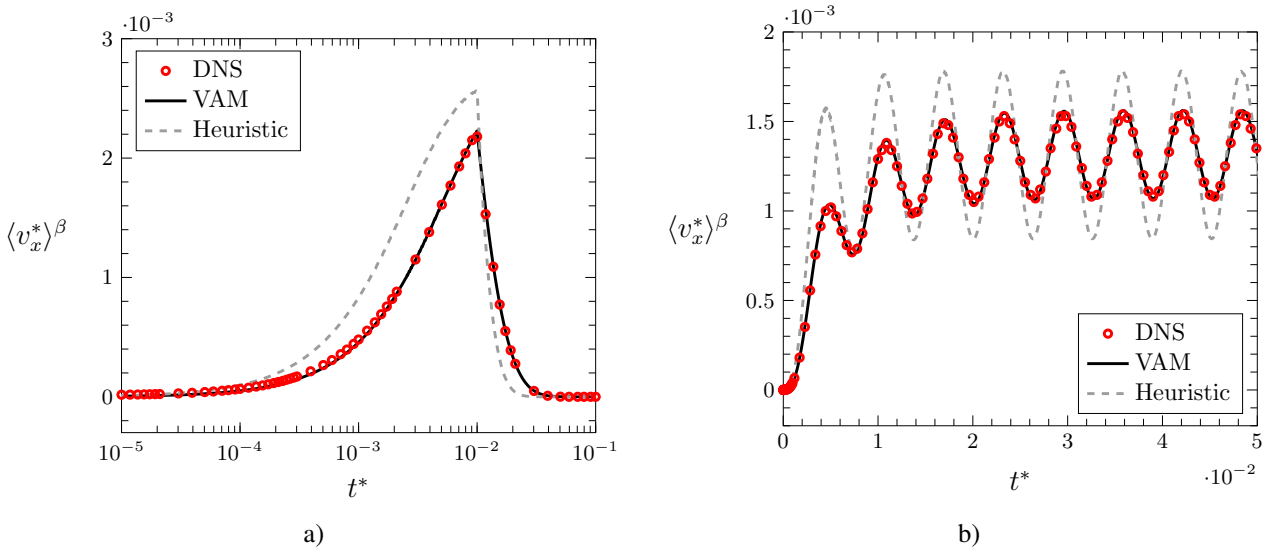

Figure 1: Dynamics of the x-component of the macroscale velocity as a response to a) a macroscopic pressure gradient pulse and b) an oscillatory macroscopic pressure gradient (see text for their expressions). Results from direct numerical simulations, from the solution of the macroscale model obtained by the volume averaging method (VAM) and from the heuristic model. In both cases, fluid is at rest at $t^\star = 0$. The porosity of the medium is 0.4 and the Reynolds number is $Re = 10^3$.

For the DNS, a pressure signal is imposed at the entrance of the medium ($x = 0$) while, at the exit, a zero pressure is maintained. For comparison with the macroscopic model, results are averaged over the central unit cell (*i.e.* far from the macroscopic boundaries where the medium is reasonnably homogeneous). For the macroscopic model, which reduces to 1D, a macroscopic pressure gradient, corresponding to that at the microscale, is applied in the x-direction.

Two different forms of the dynamic macroscopic pressure gradient were considered. The first one is a pulse given by $-\partial\langle p^\star\rangle^\beta/\partial x^\star = a$ with $a = 0,\ t^\star \leq 0;\ a = 1,\ 0 < t^\star < 10^{-2};\ a = 0,\ t^\star \geq 10^{-2}$. The second one corresponds to an oscillatory dimensionless pressure gradient given by $-\partial\langle p^\star\rangle^\beta/\partial x^\star = 0.5\,(1 - \cos(1000t^\star))$. In both cases, the initial velocity is $\mathbf{v}_0 = \mathbf{0}$.

Results on the dynamics of the dimensionless x-component of the intrinsic average velocity, $\langle v_x^\star\rangle^\beta$, are represented for the two cases in figure 1. The results from the macroscpoic model obtained with the volume averaging method (VAM) are compared to the DNS results and to the prediction of the heuristic model. This figure clearly shows that, in both cases, the dynamics of the velocity is perfectly predicted by the macroscopic model as it coincides with the DNS results. Moreover, the results obtained from the heuristic model poorly perform, proving the inadequacy of this model.

CONCLUSIONS

A macroscopic model for non-steady (inertial) one-phase Newtonian flow in a rigid homogeneous porous medium was formally derived in this work by upscaling the pore-scale mass conservation and Navier-Stokes equations. This macroscopic model is non local in time and involves a dynamic apparent permeability tensor together with an effective coefficient which accounts for the initial condition effects. Both effective parameters can be computed from the solution of two time-dependent closure problems. The macroscopic model contrasts with the heuristic model classically employed in the literature for which the macroscopic momentum equation is a Darcy-like equation to which an accumulation term on the filtration velocity is added. Numerical simulations on model test cases show that the macroscopic model derived here accurately predicts the velocity dynamics and is validated by comparison with direct numerical simulation of the pore-scale problem. The comparison also indicates that the prediction of the heuristic model poorly performs, making this model inadequate in the general case.

Apart from the fundamental interest in this formal macroscopic model, this represents an important step for further upscaling. Among many applications, it is also of major concern for the interpretation of non-steady experiments in which inertial effects and the influence of the initial condition are to be considered.

STRUCTURE GENERATED TURBULENCE IN STOCHATIC POROUS MEDIA

Kyung Chun Kim[1]*, Chanhee Moon[1], and Youngwoo Kim [1]
[1]School of Mechanical Engineering, Pusan National University, Busan, Korea

Summary This study investigates turbulence characteristics of flow inside a stochastic metal foam. Using micro-tomography and stereo-lithography, a transparent stochastic foam was printed. Quantitative flow visualization was performed using refractive index matching technique and time-resolved particle image velocimetry. Mixing and turbulence characteristics were discussed with various length scales. The structure generated turbulence is compared to the grid generated turbulence.

INTRODUCTION

Metal foam is a metallic sponge which consists of many struts and nodes interconnect the struts. The struts are the product of plateau borders and they form irregular cellular configurations. This metal foam structures have been of interest because their geometrical characteristics are theoretically desirable to many applications such as heat exchanger, chemical reactor, filter, etc. Metal foam geometry provides high porosity ($\varepsilon > 0.9$), high specific surface area, and complex flow path. Although the annual publication rate on the metal foam is constantly increasing, most of them have only considered lump parameters like pressure drop and Nusselt number based on the inlet/outlet data. In order to observe the flow structure inside the metal foams, the numerical methods mostly have been used. To the authors' knowledge, only Onstad et al. [1] experimentally observed the flow characteristics inside a 4x scaled opaque metal foam replica through magnetic resonance velocimetry under a turbulent flow condition. The reason for the low number of papers on the flow inside the metal foam is because the fabrication of a transparent metal foam replica was practically impossible. Current 3-D printing technology supports the fabrication of a transparent metal foam replica.

Cellular structures like metal foams can make jet flows inside themselves and these jets cause flow instability. A comprehensive study of the effects of the structure on the flow behavior should be conducted based on instantaneous and time-averaged data. In this study, flow characteristics through a 10 PPI (pores per inch) transparent metal foam replica have been investigated under laminar flow condition.

EXPERIMENTAL METHOD

A 10 PPI aluminum foam was prepared for the metal foam sample. An X-ray computed tomography system was used to obtain a 3-D CAD (Computer-aided design) file. Under 200 kV, 200μA and 267ms condition, 743 x 740 x 459 voxels were generated with a spatial resolution of 0.032 mm. The voxels were converted to a 3-D CAD file. In CAD software, a part of the metal foam replica CAD file is cropped into a perfect hexagon that has a size of 10 mm x 10 mm x 25 mm. Because of the resolution of the 3-D printer, the size of the cropped model was doubled. Therefore, the final size of the metal foam replica file is 20 mm x 20 mm x 50 mm. The metal foam replica was printed by Polyjet type 3-D printer (Objet Eden260VS, Stratasys Ltd.). Vero Clear resin and water-soluble support material (SUP707) were selected as printing materials.

The refractive index of Vero Clear material is 1.515 for 532 nm. Refractive index matched (RIM) solution based on NaI was prepared. As shown in Fig. 1., an acrylic square duct, which has size of 20 mm x 20 mm x 500 mm, was manufactured. That duct has one inlet and one outlet, and they are positioned above the duct to observe the flow in the spanwise plane. 3-D printed metal foam replica is placed 15 D away from the inlet. A test loop has been configured to circulate the RIM solution through the test section. As shown in Fig. 1., it consists of a RIM solution container, a gear pump, a flowmeter, a bubble trap, a test section, and a traverse to move the test section. The RIM solution container is partially immersed in water bath. A constant temperature hot plate with 25°C was placed bottom of the water bath to maintain the temperature of RIM solution. The RIM solution is transported by the gear pump. Flowrate was measured by a turbine type flowmeter.

One CMOS high-speed camera (1k x 1k resolution) and one continuous wave laser (532 nm, 5 W) power were used to conduct time-resolved 2-D PIV experiment. Because equivalent diameter of struts is 0.8±0.06 mm, the thickness of laser sheets was set to 0.5 mm. Rhodamine B coated fluorescence polymer particle (1-20 μm) was used as tracer.

RESULTS AND DISCUSSION

Figure 2 shows the flow characteristics through the metal foam replica. The two graphs on the left side of Figure 2 show turbulent kinetic energy and Reynolds stress components on the streamwise center plane. Each value is normalized by the square of the mean bulk velocity, and the range of the y-axis is -0.1 to 0.5. When a flow with a turbulence intensity close to zero is introduced, it can be seen that the turbulent intensity increases while passing through the metal foam replica. The turbulence decays after passing through the replica, all the values recover to zero again. This characteristic can also be confirmed by the vorticity shown on the right side of Figure 2. Up to a and the metal foam inlet b show no vortical structures, but a large number of vortex structures are generated from c. These vortices decay downstream of the

*Corresponding author. E-mail: kckim@pusan.ac.kr

metal foam. In this study, the decay exponent for decay power law is -0.6 to -2.1, and the spatial mean value is -1.4, which is similar to grid-generated turbulence. This represents there is no turbulence production downstream. The integral length scale was investigated to determine the streamwise jet coherence length. The length is indicated as about 7 mm, similar to the size of one cell. This is different from the result reported by Onstad et al. [1], but this is because the shape of the metal foam and the investigated Reynolds number are different.

We call this turbulence generated by metal foam structure as structure generated turbulence. The irregularly arranged pore network of the metal foam interacts with the flow to generate transverse flow motion [2]. Flow separation from the metal foam struts can increase flow fluctuations, and this effect should be investigated. Further investigation will be performed at various Reynolds numbers.

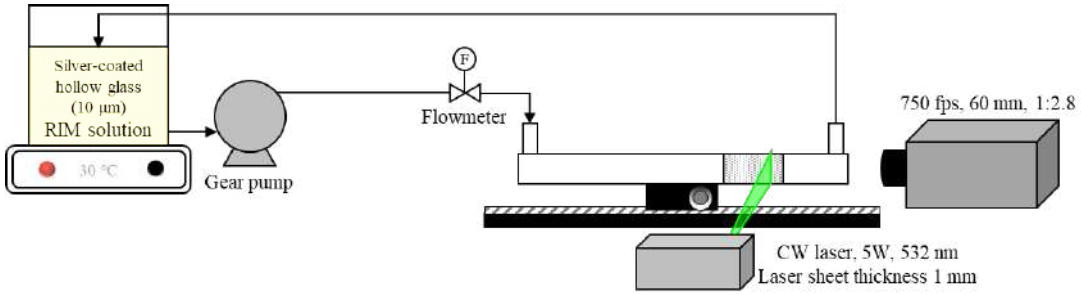

Figure 1. Experimental setup

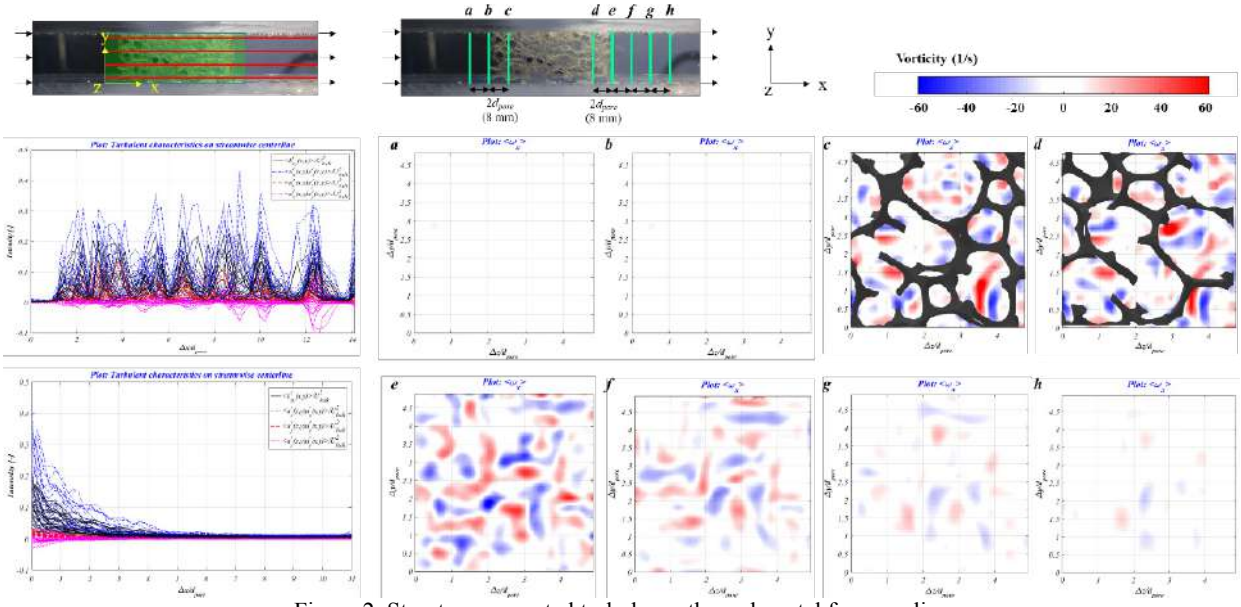

Figure 2. Structure generated turbulence through metal foam replica

CONCLUSIONS

Fluid flow entering the metal foam structure shows turbulent features. Jet-like flows are generated by the pore network, and the flow is furcated and interflowed successively. Shear layers generated by a jet are disturbed by interflowing jets. Strong transverse velocity was generated by 23% of U_b, and this was consistent with Onstad et al. [1]'s prediction that the strong transverse motion in a metal foam may occur even in laminar flow condition. Evolution of the spanwise vorticity in the metal foam structure was presented. Spanwise vorticity shows considerable fluctuation due to the complexity of flow motion in the metal foam structure. These turbulent characteristics were generated by the irregular metal foam structure: Structure generated turbulence. However, in this study, the investigation was conducted only for a single Reynolds number and single metal foam geometry. Present channel size is also not large enough to avoid wall effect. It is necessary to study the flow characteristics under the various Reynolds number and metal foam structures.

IMPACT OF WETTABILITY ON MULTIPHASE FLOW AND GRANULAR MECHANICS

Yue Meng[1], Bauyrzhan K. Primkulov[1], Zhibing Yang[2], Chung Yee Kwok[3], and Ruben Juanes*[1]

Summary. We study fluid-induced deformation of granular media, and the fundamental role of capillarity and wettability on the emergence of fracture patterns. We develop a hydromechanical computational model, coupling a "moving capacitor" dynamic network model of two-phase flow at the pore scale with a discrete element model of grain mechanics. We simulate the slow injection of a less viscous fluid into a frictional granular pack initially saturated with a more viscous, immiscible fluid. We study the impact of wettability and initial packing density, and find four different regimes of the fluid invasion: cavity expansion and fracturing, frictional fingers, capillary invasion, and capillary compaction. We explain fracture initiation as emerging from a jamming transition, and synthesize the system's behavior in the form of a novel phase diagram of jamming for wet granular media.

INTRODUCTION AND METHODS

As one of the factors that influences multiphase flow in porous media, wettability (the relative affinity of the substrate to each of the fluids, and measured by the contact angle θ) has been studied for decades. While much is now known about the role of wettability on multiphase displacements in porous media, fundamental gaps remain in the context of grain-scale mechanisms and their macroscale consequences. Given the importance of capillarity on fracture of granular packs [1,2], here we focus on the impact of wetting properties on the emergence of such fracture patterns. We also adopt packing density as a control parameter, since it can lead to a transition from Saffman–Taylor instability to dendritic (or ramified) fingering patterns, or from frictional fingering to stick-slip bubbles [1].

In this work, we uncover four fluid-invasion morphological regimes under different initial packing densities and substrate wettabilities: cavity expansion and fracturing, frictional fingers, capillary invasion, and capillary compaction. To rationalize these simulation outputs, we propose to analyze the evolution of the system as one approaching a jamming transition, which provides new insights that allow us to map the wealth of behavior onto a novel phase diagram of jamming for wet granular media.

We adopt a recently developed "moving capacitor" dynamic network model to simulate fluid-fluid displacement at the pore level [3]. The model employs an analog of the pore network geometry, where resistors, batteries and capacitors are responsible for viscous, out-of-plane, and in-plane Laplace pressure drops, respectively. The fluid-fluid interface is represented as a moving capacitor—when the interface advances, the Laplace pressure increases until it encounters a burst (equivalent to a Haines jump), touch (touches the nearest particle), or overlap event (coalesces with a neighboring interface) [4,5]. These events determine how the interface advances, enlisting one or more new particles when a node on the interface reaches its filling capacity and becomes unstable. This model reproduces both the displacement pattern and the injection pressure signal under a wide range of capillary numbers and substrate wettabilities [4–6].

To capture particle motion, we couple the dynamic flow network model with a discrete element model (DEM), PFC2D® [7]. Hydromechanical two-way coupling is achieved from three perspectives: (1) the fluid pressures calculated from the moving-capacitor flow model exert forces on particles, and lead to particle rearrangement and deformation; (2) particle movements change the geometric configuration of the granular pack, which in turn changes the pore network topology and throat conductances and capillary entry pressures; and (3) expansion of the central cavity around the injection port "consumes" injected fluid, which decreases the flow of fluid permeating through the granular pack.

RESULTS AND DISCUSSION

We simulate immiscible fluid-fluid displacement through a granular pack confined in a circular flow cell, by setting a constant injection rate at the center, and constant pressure at the perimeter. The invading and defending fluid viscosities are set to $\eta_{\text{inv}} = 8.9 \times 10^{-4}$ Pa · s for water, and $\eta_{\text{def}} = 0.34$ Pa · s for oil, respectively, and the interfacial tension is set to $\gamma = 13 \times 10^{-3}$ N · m^{-1}. These parameters are chosen to mimic the experiments of [6]. The granular pack has an outer and inner radius of $R_{\text{out}} = 13.25$ mm, $R_{\text{in}} = 0.5$ mm, and a height $h = 330$ μm. We adopt a simplified Hertz–Mindlin contact model [7] for particles in the granular pack, with the following properties: shear modulus $G = 50$ MPa, Poisson ratio $\nu = 0.5$ (quasi-incompressible), coefficient of friction $\mu = 0.3$, fluid density $\rho = 1040$ kg · m^{-3}, and mean grain diameter $d = 300$ μm with 10% standard deviation. We choose an injection rate $Q_{\text{inj}} = 4.3 \times 10^{-11}$ m^3 · s^{-1}, corresponding to a modified capillary number $\text{Ca}^* = \eta_{\text{def}} Q_{\text{inj}} / (\gamma h d^2) = 0.5$ [2], for which viscous pressure gradients have time to relax between front movements, and capillary effects govern the displacement. We conduct simulations in which we fix these parameters, and we vary the contact angle θ from 140° (drainage) to 46° (imbibition),

*Corresponding author. E-mail: juanes@mit.edu

and the initial packing density ϕ_0 from 0.68 (loose pack) to 0.84 (dense pack). In Figure 1, we show the fluid invasion morphologies that result from injection in the form of a visual phase diagram for different values of θ and ϕ_0. The collection of patterns at breakthrough—when the invading fluid first reaches the outer boundary—exhibits four different regimes:

1. *Regime I: Cavity expansion and fracturing.* When the injection pressure from fluid injection is sufficient to push particles outwards, the cavity keeps expanding until the energy input becomes insufficient to compact the granular pack further; the point at which fractures emerge.
2. *Regime II: Frictional fingers.* At only weakly-wetting conditions, the injection pressure is positive but smaller than in drainage. In this case, the injected fluid pushes away particles in certain directions, preferably those with loosely packed particles, and develops frictional fingers.
3. *Regime III: Capillary invasion.* When particles have been densely packed initially, a small injection pressure (either positive or negative) is insufficient to overcome the established chains of contact forces, and thus particles do not move. In this case, we observe patterns of capillary fluid invasion in rigid media.
4. *Regime IV: Capillary compaction.* In strong imbibition the injection pressure is negative, and for sufficiently loose granular packs, particles are dragged into the invading fluid under the out-of-plane curvature effect, leading to capillary compaction.

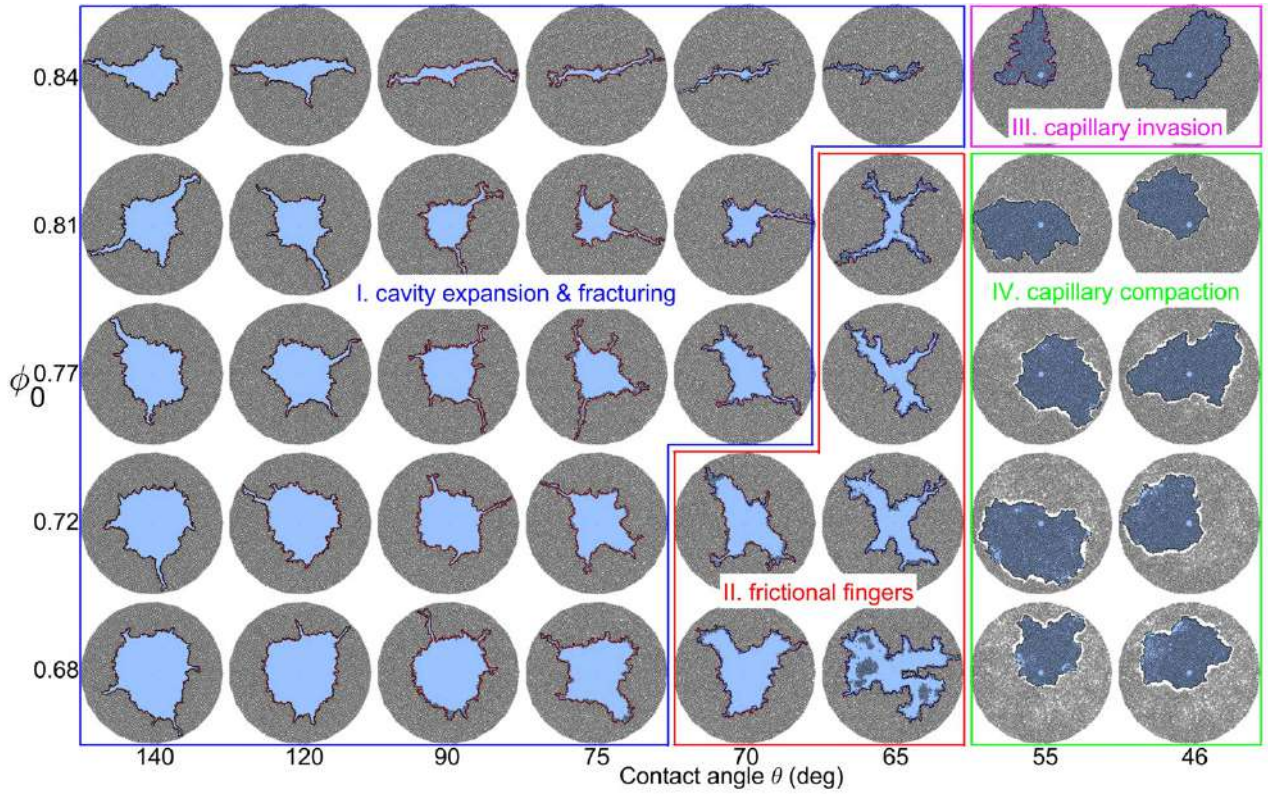

Figure 1. Visual phase diagram of the invading fluid morphology at breakthrough corresponding to different substrate wettabilities (contact angle θ) and initial packing densities ϕ_0.

CONCLUSIONS

In summary, we have studied morphological transitions in granular packs as a result of capillary-dominated fluid-fluid displacement via a novel, fully-coupled model of two-phase flow and grain mechanics. Simulations of fluid injection into a granular pack with different initial packing densities and substrate wettabilities have led to uncovering four invasion regimes: cavity expansion and fracturing, frictional fingers, capillary invasion, and capillary compaction. In particular, we have identified the emergence of fracture, and its surprising and unexplored dependence on the system's wettability.

DIFFERENTIAL DIFFUSIVITY EFFECTS ON REACTIVE CONVECTIVE DISSOLUTION IN A POROUS MEDIUM

Mamta Jotkar*[1], Laurence Rongy[1], and Anne De Wit [1]
[1]Nonlinear Physical Chemistry Unit, Université libre de Bruxelles, Brussels, Belgium

Summary Dissolution-driven convection is relevant in the context of CO_2 capture and sequestration and occurs in a host phase, initially separated from the dissolving species A, when a buoyantly unstable stratification develops upon dissolution. When all species diffuse equally, an A+B→C reaction is known to accelerate or decelerate the convective dynamics when C is denser or less dense than B, respectively. However, in practice, most species diffuse at different rates and alter the dynamics entirely. We observe that when B diffuses faster than C, the density profiles contain a local minimum below the reaction front and a double-diffusive instability occurs below the reaction front. When B diffuses slower than C, the density profiles contain a local minimum at the reaction front followed by a local maximum below, giving rise to diffusive-layer convection below the reaction front.

INTRODUCTION

Dissolution-driven convection, occurring in a host phase initially separated from the dissolving species A, when a buoyantly unstable stratification develops upon dissolution, has received significant attention due to its relevance in CO_2 capture and sequestration (CCS). In this technique, CO_2 is captured at production sites, transported through pipelines and injected into geological storage sites, such as saline aquifers for its long-term isolated storage. When CO_2 (phase A) is injected into an aquifer, it rises above the brine (host phase) up to an impermeable cap rock and a two-layer stratification develops. The two phases are partially miscible and initially separated by an interface. The subsequent dissolution of CO_2 in brine leads to a buoyantly unstable stratification due to the CO_2-rich brine being denser than the resident brine. This triggers a fingering instability and the resultant convective pattern is favourable to the sequestration technique since it accelerates the transfer of CO_2 towards the trapping host phase.

In the recent years, it has been demonstrated that chemical reactions have a strong impact on the convective dynamics. For example, when all species diffuse equally, an A+B→C reaction can accelerate or slow down the dissolution rate of species A, depending on the relative contribution to density of the reactant B and product C [1]. More precisely, when C is denser than B, the monotonically decreasing density profiles give rise to strong convective motion and accelerates the dissolution of A into the host phase. Conversely, when C is less dense than B, the density profiles are non-monotonic with a local minimum that acts as a barrier and prohibits the progression of the fingers. Consequently, the convective dynamics and dissolution rate is slowed down. So far, most of the studies in the literature have considered that all the species diffuse at equal rates. However, in practice, it is most likely that the species diffuse differently, as suggested by experiments and field investigations.

Following this motivation, we numerically study dissolution-driven convection in two partially miscible phases when the dissolving phase A, upon dissolution into the host phase reacts with a reactant B initially present in the host phase to produce C via an A+B→C type of reaction. Since all three species contribute to the density of the host phase and diffuse at different rates, it is possible to alter the buoyancy-driven instability by selecting the properties of B for a given A. In particular, we consider the impact of differential diffusivities δ_B and δ_C of B and C, respectively on the convective dynamics when C is denser or less dense than B. We quantify the dissolution flux, onset time for convection and asymptotic fluxes, which are essential in predicting the efficiency of a given sequestration technique.

PROBLEM FORMULATION

We consider a homogeneous, isotropic, isothermal porous medium, in which two partially miscible aqueous phases are initially separated in space by a horizontal interface. The gravitational field **g** points downwards along the vertical z-axis and is perpendicular to the horizontal x-axis. The phase A dissolves from above into the host phase containing a reactant B with an initial concentration B_0 to generate the product C via a second order reaction of the type A+B→C. All species contribute to the density stratification and diffuse at different rates. We assume a local chemical equilibrium such that the concentration of A at the interface (z = 0) remains constant in time, and is equal to its finite solubility A_0 in the host phase. The host phase extends from x = 0 to x = L in the horizontal direction and from z = 0 to z = H in the vertical direction.

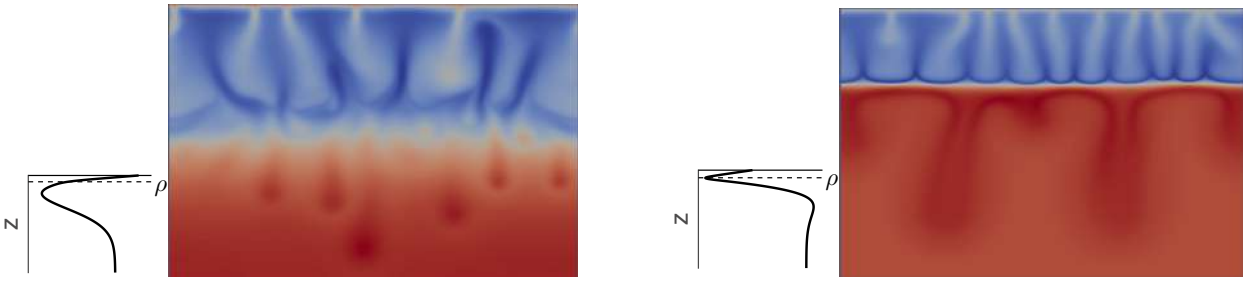
The reaction-diffusion-convection equations govern the temporal evolution of the solutal concentration of the species A, B and C. These equations are complemented by Darcy's equation for an incompressible flow in a porous medium and a linear equation of state for the density. Periodic boundary conditions are imposed at x = 0 and x = L, no vertical flow and no flux conditions are used for A, B and C at z = H (bottom boundary) while at z = 0 (interface), no vertical flow and no flux conditions are used for B and C along with A = 1. Since we focus on the differential diffusivity effects, the relevant parameters are the Rayleigh numbers, determining the contribution to density of species B and C, R_B and R_C

*Corresponding author. E-mail: mmtjotkar@gmail.com, mjotkar@ulb.ac.be.

and the diffusivities of B and C, δ_B and δ_C, respectively. We maintain Rayleigh number of A as $R_A = 1$ and the ratio of initial concentration B_0 of B with respective to solubility A_0 as $\beta = B_0/A_0 = 1$. For numerical simulations, we have used YALES2 software with the DARCY_module.

RESULTS

We classify the reaction-diffusion density profiles in the δ_B/δ_C versus R_B/R_C parameter space, consistent with the literature [2]. When B diffuses sufficiently faster than C, we observe that the density profiles contain a local minimum below the reaction front. Conversely, when B diffuses sufficiently slower than C, the density profiles contain a local minimum at the reaction front followed by a local maximum below it. We observe that an addition convection zone develops below the reaction front when all the species diffuse differentially due to a local stratification consisting of less dense fluid lying on top of a denser one. When B diffuses sufficiently faster than C, the stratification consisting of denser fluid layer rich in A lying above the less dense one at the reaction front containing A and C, develops primary fingers due to Rayleigh-Taylor (RT) instability. Below the reaction front, the slow-diffusing less dense fluid layer rich in B and C overlies fast-diffusing denser fluid containing B, which leads to double-diffusive (DD) instability with secondary fingers at the tips of the primary ones (figure 1, left). Conversely, when B diffuses sufficiently slower than C, we observe two zones of convection: above the reaction front, the primary fingering is due to RT instability and below the reaction front, a secondary convective pattern marked by antenna-like structures arises due to the less dense fast-diffusing fluid layer rich in B and C overlying a denser slow-diffusing fluid one consisting of B (figure 1, right). This is diffusive-layer convection (DLC) instability [3]. We then study the impact of these mechanisms on the temporal evolution of the dissolution flux of species A into the host phase and the onset time for convection.



(a) DD-RT (b) DLC-RT

Figure 1. (a) Reaction-diffusion (RD) density profile (*left*) and density field (*right*) when reactant B diffuses faster than product C. Double diffusive (DD) convection influencing Rayleigh-Taylor (RT) instability has a destabilizing effect on the nonlinear dynamics. Density scale varies between 3 (red) and 1.4 (blue). (b) RD density profile (*left*) and density field (*right*) when reactant B diffuses slower than product C. Diffusive-layer convection (DLC) influencing RT instability has a stabilizing effect. Density scale varies between 3.26 (red) and 1.243 (blue).

CONCLUSIONS

We have shown that differential diffusivities of the species have a significant impact on the convective dynamics including the presence of an additional zone of convection below the reaction front and the occurrence of double-diffusive convection. In general, when B diffuses faster than C, the effect is destabilizing and the onset time is reduced and conversely, when B diffuses slower than C, it has a stabilizing effect and the onset time is larger; for both C denser and less dense than B. Our results are crucial in the context of CO_2 capture and sequestration (CCS) technique for predicting its efficiency, since it is most likely that all species diffuse differentially and alter the dynamics.

THE IMPACT OF FLOW CONDITIONS ON THE CLOGGING OF A PORE BY COLLOIDAL PARTICLES

Delouche Nolwenn[1]*, Tabuteau Hervé [1]
[1]Institut de Physique de Rennes, Université de Rennes, France

Summary We use particle tracking to determine the hydrodynamical conditions of the abrupt flux decline during the clogging process of a pore by colloidal particles. We can detect every deposition event during the clogging with the measure of the average particle velocity and volume fraction of the particle accumulation behind the clog. Thanks to the Kozeny-Carman relation, we connect particles velocity and permeability of the clog. This approach helps us to determine the impact of the variation of the hydrodynamic conditions on the clogging process.

INTRODUCTION

The transport of dilute colloidal suspension through a porous medium like a filter or a soil, leads to the formation of clogs. This process is quite complex and results from a coupling between hydrodynamics and physicochemical parameters. Thanks to microfluidics, transparent porous media have been designed and allow monitoring the clogging process at the pore scale. Experimental studies have explored the geometry parameters promoting the fouling, like curvature at the pore entrance, shape and dimensions of the pore or confinement [1,3]. The investigation of the role of particle-wall or particle-particle interactions have also improved the understanding of the partial or total clogging conditions [2,4].
During such experiments there is an abrupt flux decline which corresponds to the clogging transition. Up to now, no quantitative link has been made between those two phenomena. Our experimental work helps to understand the dynamics of clog formation at the particle scale, relating each particle capture event to the corresponding decreases of the average variation of the particle velocity within the pore, using particle tracking. This approach also provides direct measurement of the volume fraction of both the flowing suspension and within the clog. Here we first determine the features of the clog transition and then we investigate the impact of the flow conditions on this transition as well on the subsequent growth of the clog.

MATERIALS AND METHODS

We flow a diluted suspension of polystyrene particles ($\phi = 5.10^{-3}$) under fixed pressure (fig.1a) through a constriction (fig.1b). A camera provides pictures at 100 frames/s that allows us using an algorithm sufficiently sensitive to track particles and get the spatial evolution of their velocity as they flow around the constriction.

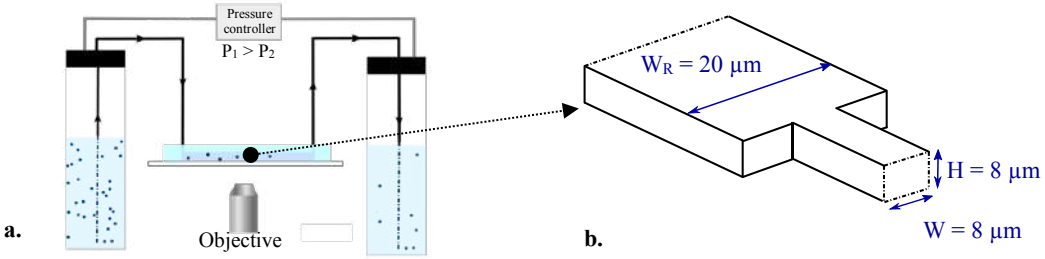

Figure 1: a. Schematic of the setup. b. Zoom in the central part of the channel in the constriction zone

RESULTS

We observe two significant steps during the clogging process. First, a partial clogging where the progressive particle deposition leads to a limited particle velocity decline (fig.2: a-f and plot). These deposits reduce the pore section until its complete clogging. At the very end of this process, an object is responsible of the final clogging which result in the most abrupt increase of the hydraulic resistance (image e to f). Later on, particles just pile up at the clog front leading to a slower increase of the channel resistance (fig.2 from image g up to l). The corresponding decrease of the velocity is also less abrupt since particle accumulation takes place into a wider part of the channel just upstream of the constriction zone, which thus has a lower hydraulic resistance.
We observe that the variation of the flow conditions has a direct consequence on particle deposition, while at high pressure the flow detaches some particles, in the lower range it limits their attachment. One may wonder if these erosion-deposition processes have also an impact of the structure of the clog and thus also on its hydraulic resistance. We investigate this by varying the pressure so that we get a large variation of the average particles velocity at the beginning of the experiment. The temporal evolution of the average particle velocity is reported in figure 3a. All the curves collapsed onto a master curve (insert figure 3b) indicating that the clogs formed for each applied pressure have the same permeability since the flow decline is identical.

*Corresponding author. E-mail: nolwenn.delouche@univ-rennes1.fr

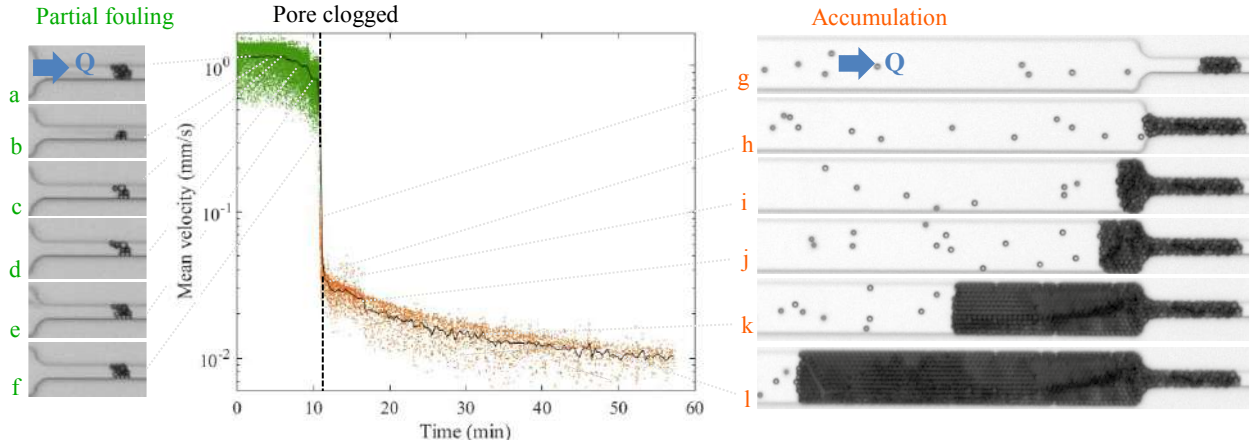

Figure 2: The two steps of the clog formation in a constriction: the partial clogging (a-f) followed by the particle accumulation (g-l). The plot is the temporal evolution of all the particle velocity that flow through the pore during the clogging process, with the continuous and the dotted lines corresponding respectively to the average velocity and the moment when the pore is clogged, i.e. when particle pile up at the clog front.

We use the Kozeny-Carman equation to determine the hydraulic resistance and the permeability of the packing of spherical particle from the constriction. From this equation we deduce that the fluid and also the particle velocity V vary as the inverse of the clog length L_c with a prefactor involving permeability. Based on independent measurement, made from image analysis we obtain a constant volume fraction $\phi_{exp} = 0.60 \pm 0.025$ for all pressures, which helps us to calculate the hydraulic resistance from the Kozeny-Carman equation. By plotting the average particle velocity against the clog length (fig.3b) we confirm that $V = A/L_c$, A being a constant irrespective of applied pressure. Therefore, we conclude that the hydraulic resistance of a colloidal clog does not depend on its dynamics of formation obtained with various flow conditions.

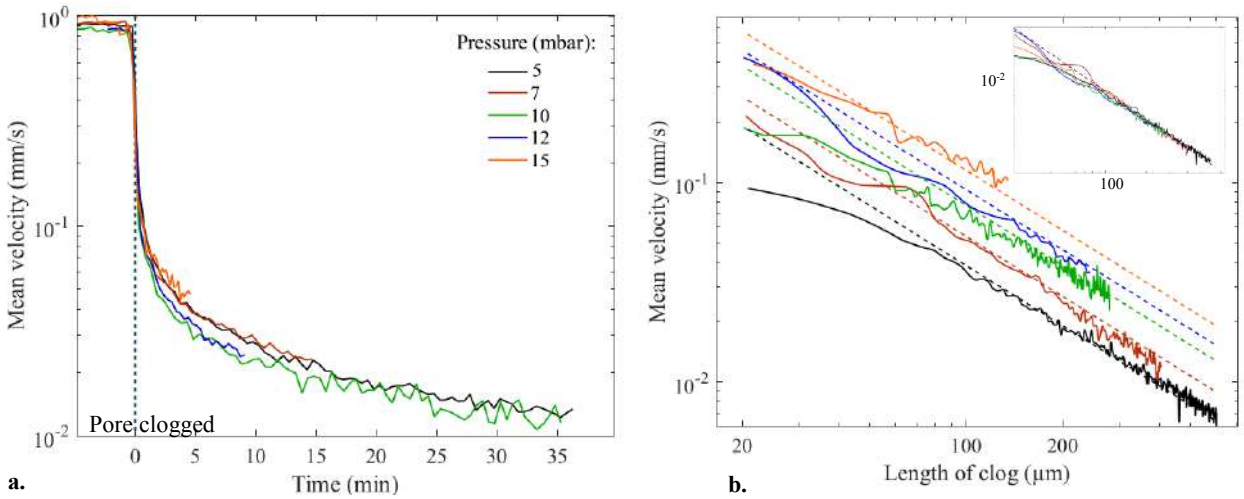

Figure 3: a. Temporal evolution of the average scaled velocity. The time is rescaled such that particle accumulation starts at zero for each applied pressure. b. Hydraulic resistance for a spherical packed bed, for different pressures. The continuous lines correspond to the experimental data while the dotted lines are fit by the Kozeny-Carman equation. Insert: master curve.

CONCLUSION

Coupling image analysis of the forming clog and tracking of flowing particles inside a pore help us to determine the dynamics of the clogging transition and also of the subsequent growth of the clog. We get a good estimate of the volume fraction of the clog which helps us to determine the hydraulic resistance of the clog. We show that this resistance does not change when we form clogs with different applied pressure. This new methodology can be easily implemented in order to study the evolution of hydraulic resistance of interconnected 2D porous media fouled by colloidal particles.

Summary Geological storage of CO_2 in deep saline aquifers is a promising measure to mitigate global warming by removing this greenhouse gas from the atmosphere and trapping it into such subsurface formations. When CO_2 is injected in these porous media, it dissolves in the interstitial brine rendering it denser than the resident brine below, which creates a convective instability. This instability contributes to accelerating CO_2 sequestration but remains poorly understood. In this paper, we demonstrate a combination of experimental techniques which makes it possible to measure for the first time the characteristics of this instability in a 3-D porous medium, using both Refractive Index Matching and Planar Laser Induced Fluorescence. The measured characteristics of the instability will be compared to the theoretical and numerical models available in the literature.

INTRODUCTION

Nowadays, about 32 gigatonnes of carbon dioxide (CO_2) are released annually into the atmosphere due to human activities [1]. As CO_2 is a greenhouse gas, this leads to a global warming of our planet representing a potentially disastrous global problem. One solution to mitigate this issue is to capture and store CO_2 in deep saline aquifers and depleted oil reservoirs, which are typically porous structures filled with brine. Once the CO_2 is injected into such formations, its motion through the reservoir is controlled by fluid mechanics. Being supercritical, it first rises to the top of the reservoir, displacing the brine and positioning itself above it. By dissolving into the brine, CO_2 then densifies it locally which creates a convective instability, thus increasing storage efficiency [2].

This instability is characterised by the Rayleigh and Darcy numbers

$$\mathrm{Ra} = \frac{K\Delta\rho g H}{\mu\phi D} \text{ and } \mathrm{Da} = \frac{K}{H^2}, \tag{1}$$

where K, H and ϕ are the permeability, the height and the porosity of the porous medium, g the gravity acceleration, μ the viscosity of the fluid, and D the diffusion coefficient of CO_2 in water. $\Delta\rho$ is the density difference between the CO_2-laden brine and that devoid of CO_2. Several theoretical and numerical studies have already discussed the typical characteristics of the instability (wavelength, growth rate, and onset time) as a function of the Rayleigh number [3, 4], assuming that Darcy's law is valid in the porous media they consider. Recently, experiments performed in a Hele-Shaw cell mimicking a two-dimensional porous medium have validated the theoretical and numerical results at low Rayleigh numbers [5]. However, to our knowledge, no experimental studies of this instability in a real porous medium have been reported yet. It is the goal of this paper to demonstrate the experimental technique we develop to study convective dissolution in a 3-D porous medium. In particular, the question of whether the description based on Darcy's law is relevant, when the wavelengh of the instability is on the order of the grain size, remains open. By varying the Rayleigh number in our experiments, we can change the wavelength of the instability and see how far the theory based on Darcy's law holds.

EXPERIMENTAL SETUP

The experimental setup consists in a 30 cm large, 1.5 cm thick, 30 cm high, closed and transparent tank. The bottom half is filled with a porous medium and salt water while the top half contains air at atmospheric pressure and a CO_2 sensor. The z-direction points downward and its origin $z = 0$ is set at the interface between the porous medium and the air. At time $t = 0$, part of the air in the top half of the tank is removed and replaced by CO_2, leading to a sudden increase of the CO_2 partial pressure above the porous medium. In this configuration, the density difference $\Delta\rho$ is therefore proportional to that partial pressure. In order to visualise the instability inside the granular medium, we use the combination of two different techniques: Refractive Index Matching to see through the porous medium and Planar Laser Induced Fluorescence to detect the presence of CO_2 in the interstitial fluid.

Refractive Index Matching and porous medium

Refractive Index Matching is known to allow optical access to the bulk of dense suspensions and porous media [6], by matching the optical indices of the fluid and solid phases. Therefore, these two phases have to be carefully chosen. In our experiments, we use FEP (fluorinated ethylene propylene) transparent particules, with an optical index close to water that can be matched with salt water at a density $\rho \approx 1.060$ g/cm^3. These particles have a typical size of 2 to 3 mm, and resemble flatten spheres or oblate spheroids. Their shape is not classical but relatively regular over the different particles. They provide us with a porosity $\phi \approx 40\%$ and a permeability $K \approx 2 \times 10^{-9}$ m^2. The thickness of the tank, about 5 to 7 particles, is small compared to the two other dimensions ensuring that the instability remains two-dimensional but is large enough so that the flow is fully three-dimensional in the bulk of the porous medium.

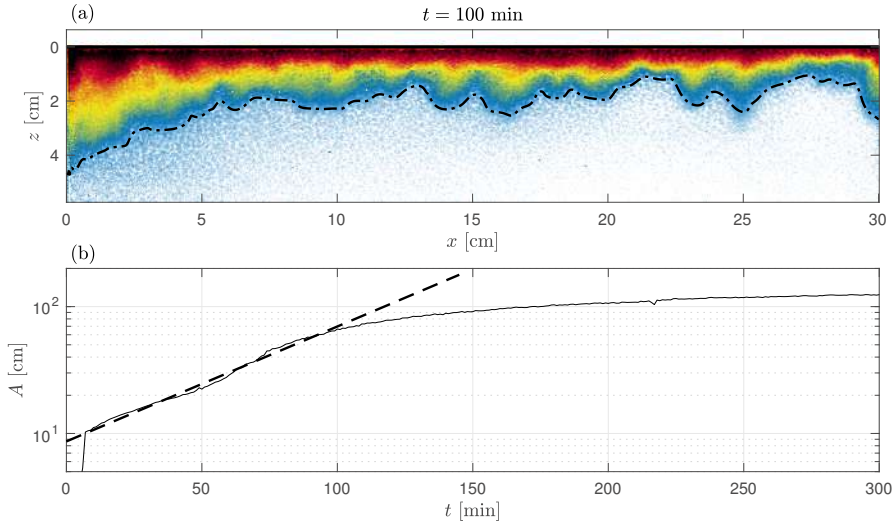

Figure 1: (a) Visualisation of the instability in a granular porous medium using Refractive Index Matching and Planar Laser Induced Fluorescence. The colors correspond qualitatively to different pH, correlated to CO_2 concentrations inside the porous medium. The detected front is shown with a dashed-dotted black line. (b) Lin-log plot of the front corrugation amplitude A as a function of time. The dashed thick line shows the slope from which the growth rate is measured.

Planar Laser Induced Fluorescence and instability characterization

The interstitial fluid, i.e. salt water, contains fluorescein at a given concentration of 10^{-6} mol/l. The tank is illuminated from the top, using a laser sheet obtained with a Powell lens to insure a homogeneous intensity along the sheet. The tank is filmed from its largest side using a camera equipped with a green light filter centred around the fluorescein emission wavelength. As the development of the instability is relatively slow, the frame rate is set to 1 image per minute. The presence of dissolved CO_2 acidifies the interstitial fluid and decreases the pH locally. As fluorescein light emission is pH-dependent [7], the emitted intensity at a position in the tank is correlated to the pH and therefore to the CO_2 concentration at that position. It is therefore possible to observe the instability by normalising the image at time t by the image at time $t = 0$, as shown in Figure 1(a). It allows us to detect the front of the instability $z_F(x, t)$, shown with a dashed-dotted black line in the figure. Using this quantity, one can measure the growth rate, the wavelength and non-linear time of the instability [5]. Indeed, the growth rate is measured by plotting the front corrugation amplitude $A(t)$, defined as the standard deviation of the front $z_F(x, t)$ along x, as a function of time. An example is shown in Figure 1(b), exhibiting a clear exponential growth of the amplitude at the beginning of the experiment. The time where the curve deviates from the exponential growth is defined as the non-linear time and the wavelength can be deduced from a Fourier transform of the front at that time.

ONGOING WORK TOWARDS FULL CHARACTERIZATION OF THE CONVECTIVE DISSOLUTION

We are currently performing experiments to measure the evolution of the characteristics of the instability (namely growth rate, non-linear time and wavelength) as a function of the Rayleigh number. This parameter is mainly changed by varying the CO_2 partial pressure above the porous medium. The experimental results will be compared to the theoretical and numerical results reported previously [3, 4] in order to evaluate over which range of Rayleigh numbers the predictions obtained with models based on Darcy's law remain valid. Moreover, by doing a careful calibration of fluorescein emitted light versus pH, it will be possible to obtain the CO_2 concentration from the images, and therefore the CO_2 flux in the experiments, which is crucial to estimate the characteristic time scale of CO2 storage, in particular towards industrial applications [1]. These investigations are ongoing and the results will be reported at the conference.

HOMOGENIZATION-INFORMED CONVOLUTIONAL NEURAL NETWORKS FOR QUANTIFICATION OF EFFECTIVE PROPERTIES OF POROUS MEDIA IN ENERGY STORAGE DEVICES

Ross Weber[1], Svyatoslav Korneev * [2], and Ilenia Battiato[1]
[1]Department of Energy Resources Engineering, Stanford University, Stanford, USA
[2]Palo Alto Research Center (PARC), Palo Alto, USA

Summary Lithium-ion battery modeling remains a challenge due to multiple physical phenomena occurring at multiple length and time scales. A multiscale model is derived via homogenization, where effective properties are determined by solving a closure problem on a representative unit cell at the particle scale. The closure problem, however, still requires solving a partial differential equation (PDE) in a 3D space, which is computationally expensive. We develop a Convolutional Neural Network (CNN) to determine effective parameters of porous media from pore-scale images of the microstructure. The CNN is trained from PDE solutions of the closure problem on randomly generated images of porous electrodes that have varying topological properties. Results demonstrate that the CNN is significantly more accurate than the frequently-used porosity-conductivity relation, also known as Bruggeman equation.

INTRODUCTION

Lithium-ion batteries (LIBs) have become the dominant energy storage for consumer electronics due to their extraordinary energy and power density. Upscaling them for electric vehicles and grid storage, however, remains a challenge in part due to the complexity and computational cost of modeling with pore-scale resolution. A major challenge is that microscale information is needed to describe macroscopic responses. The goal of present work is to create a mechanism to incorporate particle-scale physics in a macroscopic model through effective transport parameters while keeping computational costs contained. The baseline macroscale electrochemical model for LIBs is known as the Doyle-Fuller-Newman (DFN) model and has been widely applied to model charge/discharge behavior. The DFN assumes each electrode is composed of equally-sized spherical particles and resolves radial diffusion within these particles, as well as ion diffusion and electromigration across the electrolyte. In this technique, effective parameters Ψ_{eff}, such as diffusion and conductivity, are often obtained from their intrinsic counterparts Ψ by the Bruggeman relation $\Psi_{\text{eff}} = \eta\tau^{-1}\Psi$ with $\tau = \gamma\eta^{-\alpha}$, where τ is tortuosity and η is the electrode porosity. The constants α and γ are fitting parameters that can be determined analytically for idealized geometries or empirically. The Bruggeman equation is useful as it defines crucial dynamic properties as a function of porosity alone, but it has multiple drawbacks. First, it assumes isotropy and thus cannot account for direction-dependent phenomena, which are very pronounced in certain LIB electrodes, especially graphite, the most common anode material. Additionally, electrodes of the same porosity can exhibit very different transport behavior, as the specific morphology and orientation of the particles plays a significant role. As a result, the Bruggeman relation can lead to significant errors in estimating effective parameters.

ELECTROCHEMICAL MODEL AND CLOSURE PROBLEM

The homogenized model describes the macroscopic response of a LIB to input current and temperatures, which informs crucial metrics such as state-of-charge (SOC) and state-of-health (SOH) [1]. The macroscale mass and charge transport equations are obtained by upscaling the pore-scale Possion-Nernst-Planck equations, as described by Arunachalam *et al.* [2]. The electrode of length L is assumed to be composed of periodic unit cells of length ℓ, and a scale separation parameter is defined as $\epsilon = \ell/L \ll 1$. Averaged electrode and electrolyte concentration and potential $(\bar{c}_s, \bar{c}_e, \bar{\phi}_s, \bar{\phi}_e)$ in each cell are resolved by the macroscopic model. Within the unit cell, a closure variable χ is computed to determine effective transport parameters. This process is schematically indicated in Figure 1(Left), where the closure problem and the effective parameters are defined in terms of χ.

CONVOLUTIONAL NEURAL NETWORK

The aim of this work is to train a CNN to estimate the solutions of the closure problem presented in Figure 1(Left), and thus reduce the computational cost of parameter estimation. The input for the network is chosen to be a $60x60$ pixel binary image. To obtain sufficient training data, images were computer-generated to mimic porous electrodes. The image generation algorithm consisted of placing a *random* number of *randomly* shaped circle-like particles in *random* positions throughout an originally empty canvas. Example images generated are shown in Figure 1. The input images are a binary grid with $1s$ (white pixels) representing the electrolyte and $0s$ (black pixels) to denote active particles. $100,000$ images were generated of which $90,000$ were randomly selected as the training set, $5,000$ were used as the development set to tune hyperparameters, and $5,000$ were set aside as the test set to evaluate the performance of the CNN on unseen data.

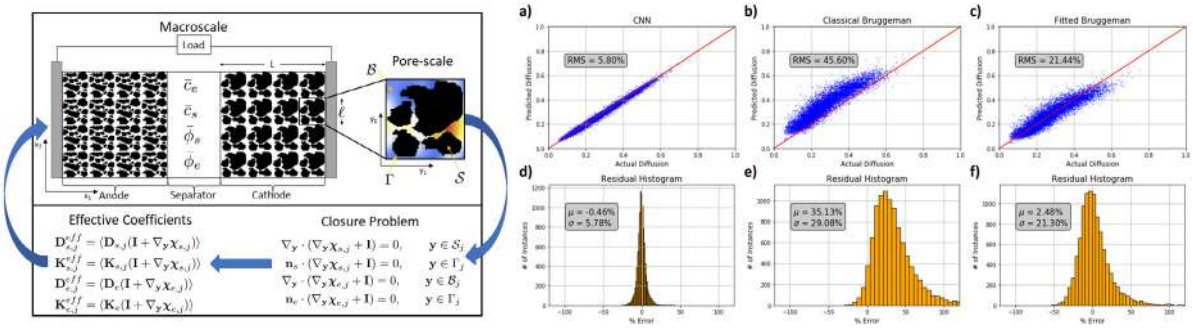

Figure 1: (**Left**) Schematic representation of the homogenization model and closure problem. The resolved χ variables are used to determine the effective dispersion and conductivity tensors from the solution of a closure problem on a pore-scale structure of arbitrary complexity. (**Right**) Top row: predicted dispersion coefficient vs actual for (a) CNN, (b) Classical Bruggeman, and (c) Fitted Bruggeman. Bottom row: histogram of the normalized error for each model. The solution to the closure problem is considered the actual dispersion coefficient because that is what the network was trained on.

Scatter plots showing the fit of the CNN, classical Bruggeman, and fitted Bruggeman model are shown in the top row of Figure 1(Right), where the "true" dispersion coefficients are taken as the closure problem solution because that is how the network was trained. The overall RMS error of the validation set was 6.26%. Using the classical and fitted Bruggeman resulted in RMS errors of 45.60% and 21.44% respectively, so the CNN made more than a $3x$ improvement.

RESULTS AND CONCLUSIONS

A preliminary investigation of the CNN on real images is performed in this section. The two real images considered were an SEM of a Lithium Cobalt Oxide ($LiCoO_2$) cathode from Hutzenlaub *et al.* [3], commonly used in LIBs for portable electronics, and of a Ni-yttria stabilized zirconia (Ni-YSZ) anode from Iwai *et al.* [4], a popular fuel cell anode. Each image is first processed to be consistent with the CNN input requirement by resizing to $60x60$ pixels and binarizing so that solid materials appear black and the electrolyte is white. Each transformed image is then put through the CNN from this work. The original and transformed images for each material are shown in the bottom-left corner of Figure 2a-b, which displays boxplots of the distribution of CNN predictions for each direction and their mean. The reference-provided effective coefficients are shown in green, and the fitted Bruggeman coefficients are shown in red. The classical Bruggeman predictions of 0.196 for $LiCoO_2$ and 0.327 for Ni-YSZ are not shown because they are well above the top of the plot. The results demonstrate that the mean CNN prediction is superior to the Bruggeman models. Furthermore, the shape of the boxplots suggests that the network consistently makes reliable predictions on real images.

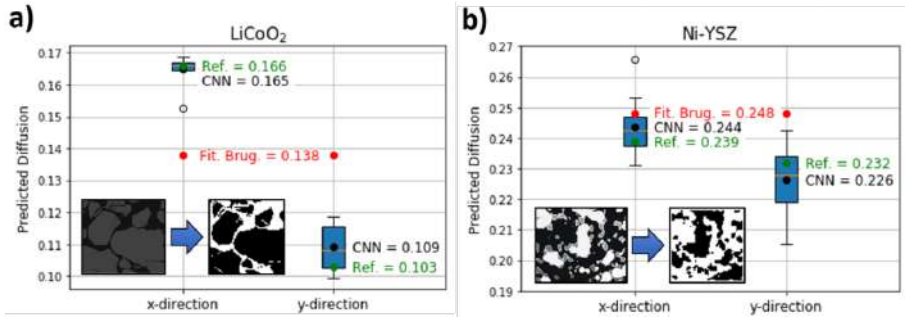

Figure 2: Box plots showing the x and y-components of the CNN-predicted transport tensors from real SEM images of (a) $LiCoO_2$ [3] and (b) Ni-YSZ [4]. The mean prediction is shown in black, the reference-provided coefficient is green, and the fitted Bruggeman output is in red. In the bottom-left of each subfigure, the original and transformed images are shown.

MODELLING TRANSFER OF MASS MOMENTUM INTO A POROUS MEDIA FROM OVERLYING FLOWS

Ugis Lacis[1] and Shervin Bagheri * [1]
[1]Department of Engineering Mechanics, KTH, Stockholm, Sweden

Summary Today, effective models of single-phase fluid flow inside dense porous materials (such as Darcy's law) are well established. However, much less is known on how to couple such models to a domain where the fluid flows unobstructed. This is despite the importance in many applications of characterising how entrainment, mixing and dispersion inside a porous material depends on the external fluid environment. Here, we present effective coupling conditions between free flows and porous media that takes into account the microstructure of porous material both in the bulk and at the interface. Our model consists of slip velocity, transpiration velocity and pressure jump condition for coupling Navier-Stokes equations to Darcy's law. These conditions are derived from conservation of mass and momentum and linear theory and constitute a subset of high-order boundary conditions that can be derived from a formal asymptotic expansion. Using a number of rather complicated 2D and 3D flow configurations, we will show that our model constitutes a practical approach to model the transfer mass and momentum between free flows and porous media, with no free empirical parameters and direct link to the pore microstructure.

INTRODUCTION

Models of free flows over porous surfaces would be valuable in a range of problems, including predicting the mixing of fresh water with groundwater in hyperheic zone in rivers, estimating the supply of nutrients and bioactive agents to porous scaffolds to stimulate tissue growth and for enhancing removal of water in gas-diffusion layers in fuel cells by imposing external gas flow. In these applications, the microstructure of the porous skeleton plays a central role in determining the entrainment of heat, mass, nutrients, ions, proteins and other particles from the external environment into the porous medium. Therefore, effective models with predictive capabilities need to take into account the microstructure of porous material both in the bulk and at interfaces with their external environment.

The challenge in modelling the interface between an unobstructed unsteady shear flow and a complex anisotropic porous bed is twofold. First, the form of boundary conditions that couple Navier-Stokes equations for the external flow with effective models of porous materials (such as Darcy's or Brinkman equations) is still unclear. Different combinations of velocity and pressure conditions have been suggested, but there has yet emerged a complete set of conditions as a clear winner. Second, given a particular form of coupling conditions, it unclear on how to determine the constitutive parameters appearing in the conditions. Different approaches to determine constitutive parameters of varying complexity have been suggested, but a few of them are practical from an engineering viewpoint.

Similar to bulk porous media, where Darcy's law is unquestioned for creeping single-phase flows and the components of the permeability tensor can be determined either from experiments or from unit-cell computations, we aim to establish a complete set of coupling conditions and an accompanying practical procedure to determine the associated constitutive parameters.

BACKGROUND

Let us provide a familiar example of a set of coupling boundary conditions using a two-dimensional configuration. We denote the streamwise and wall-normal coordinates by x and z and impose the effective boundary conditions at an interface plane at coordinate $z = z_i$. For rigid porous surfaces with a pore size l, one may impose the following effective velocity boundary conditions,

$$u_x = -\frac{K}{\mu}\frac{\partial p^-}{\partial x} + L\frac{\partial u_x}{\partial z}, \qquad u_z = -\frac{K}{\mu}\frac{\partial p^-}{\partial z} \qquad \text{on} \qquad z = z_i. \tag{1}$$

In the above expression, u_x is the tangential velocity component at the interface, u_z is the wall-normal velocity component and p^- is the pore pressure. Moreover, μ is the fluid viscosity, and $K \sim l^2$ is the interior permeability of the porous substrate, $L \sim l$ is the slip length. The first condition in the expression above was suggested by Beaver and Joseph [3]. Here, the slip length is the distance that the relative velocity at the interface has to be linearly extrapolated to reach zero value. The second condition for the penetration velocity imposes a continuity with the interior Darcy flow in the normal direction. An additional boundary condition for pore pressure p^- at the interface is required to solve for the interior Darcy flow. Until relatively recently pressure continuity was imposed $p^- = p$, where p is the pressure of the overlying free fluid. However, current state-of-the-art [4] is a jump in pressure given by

$$p^- - p = -\mu C_\pi \frac{\partial u_x}{\partial z} - 2\mu\frac{\partial u_z}{\partial z}.$$

Here, C_π (which is non-zero only for anisotropic porous surfaces) is a stabilisation parameter derived from matching boundary layer solutions with exterior solutions.

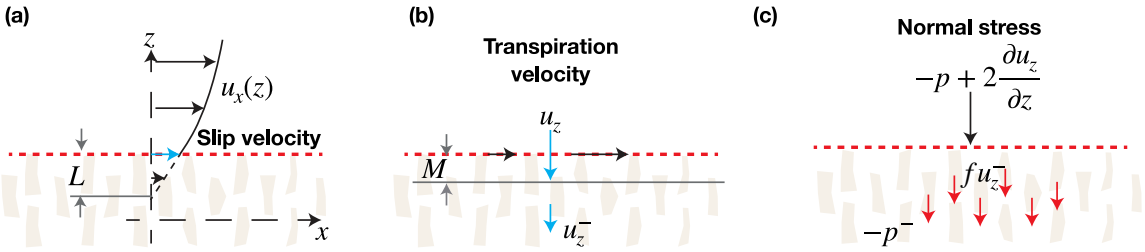

Figure 1: Schematics of the slip length L (a), the transpiration length M (b) and the resistance coefficient f (c).

RESULTS

In this talk, we aim to present a simple physical model for coupling Stokes equations to Darcy's law. The model, called Transpiration-Resistance Model (TRM), can be derived from assuming linearity and scale separation. The TR model captures the transport of interface tangential momentum as well as the transport of mass and interface normal momentum. It consists of the slip boundary condition given in equation (1) for the interface tangential velocity. The penetration velocity is extended with an additional term,

$$u_z = -\frac{K}{\mu}\frac{\partial p^-}{\partial y} - M\frac{\partial u_x}{\partial x} = u_z^- - M\frac{\partial u_x}{\partial x} \qquad \text{on} \qquad z = z_i \tag{2}$$

The new term quantifies how much a surface texture allows exchange of mass with the surrounding fluid due to a streamwise variation of the slip velocity. Geometrically (figure 1b), the transpiration length M is the distance below the interface for which a non-zero transpiration velocity u_z can exist due to fluctuating overlying shear flow. In the TRM, for a porous surface, the pressure condition reads,

$$-p + 2\mu\frac{\partial u_z}{\partial z} = -p^- + fu_z^-.$$

Here, the left-hand side is the normal stress of the outside free flow on the interface plane, and the right-hand side is the normal stress from the porous material. The resistance coefficient f quantifies the friction force that the Darcy seepage velocity generates while passing through the interface.

Figure 1 shows the interpretation of slip length L, transpiration coefficient M and resistance coefficient f. The TRM can be derived from linear theory by assuming; i) creeping flow assumption $Re < 1$; ii) scale separation assumption between system scale (H) and pore scale $\epsilon = l/H \ll 1$ and that iii) the surface is homogeneous i.e. it consists of repeating geometric entities or elements. Under these assumptions, the slip length, the transpiration length and the resistance coefficients are properties of the surface texture only, and can be computed by solving five fundamental Stokes problems. For a given texture, the knowledge of these effective coefficients provides important information on the diffusive/advective transport into the material as well as the ability of the solid skeleton to resist an externally imposed shear stress.

In this talk, we aim to present

- the validation of the suggested TRM by making use of pore-resolved two and three dimensional numerical simulations of shear flows over anisotropic porous media. Examples include a lid-driven cavity and separated backward-facing step with porous/textured surfaces. It will be shown that compared to other existing techniques, the transfer of mass and momentum is improved, allowing for better prediction of transport mechanisms across porous interfaces [1].
- an outline a mathematical derivation of high-order homogenized coupling conditions between Stokes equations and Darcy's law. These conditions, which are derived from asymptotic expansion, constitute a generalization of the TRM model [2].
- provide a simple and practical (numerically cheap) procedure to determine the constitutive parameters appearing in the coupling boundary conditions for TRM given a sample of periodic unit of the porous material.

STEAM-WATER RELATIVE PERMEABILITY AND THERMAL CONDUCTIVITY IN FRACTAL TREE-LIKE NETWORKS

Pengliang Yu[1] and Rosalind Archer [1]
[1]Department of Engineering Science, University of Auckland, Auckland, New Zealand

Summary This paper derives new expressions for steam-water relative permeability and thermal conductivity in fractal tree-like networks. The work was motivated by the need to enhance these properties in enhanced geothermal systems, where fractures are created in the reservoir rock to enhance its permeability. The derivation combines Darcy's law and the Young-Lapace equation (to handle capillarity) to model two-phase laminar flow in a branching network of cylindrical flow paths. The overall behaviour of the network is considered by equating the flow/thermal performance to a equivalent single flow path. The results are likely to be useful for interpreting tests from enhanced geothermal wells, and for establishing parameters in numerical models of these systems.

INTRODUCTION

Two-phase flow (steam and water) in enhanced geothermal systems occurs in networks on fracture in the rock that this work models as a fractal tree like network. The network can be described as:

$$l_k = l_0\alpha^k = l_m\alpha^{k-m} \tag{1}$$

$$d_k = d_0\beta^k = d_m\beta^{k-m} \tag{2}$$

$$N = \alpha^{-D_l} = \beta^{-D_d} \tag{3}$$

Where l_0 and d_0 are the length and diameter of the 0^{th} branching level, respectively, D_l is the fractal dimension of channel length distribution, and D_d is the fractal dimension for diameter distribution.

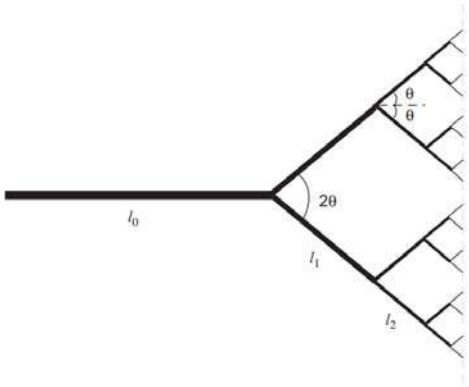

Figure 1. Fractal-like tree network model

The model assumes the flow through each channel is laminar and fully developed, thermally and hydrodynamically. In the case of an interface between steam and water phases (with saturations S_g and S_w) in a channel the Young-Laplace equation is used to model the relationship between the pressures in each phase. The channel is assumed to be water-wet with a connate water saturation (S_{wc}). Relative permeability for each phase compares the flow rate of that phase, to the flow rate which would exist in single phase flow. Flow rates are modelled using Darcy's law, so the length of the flow path is relevant. This work develops expressions for steam and water flow relative permeability in branched tree-like networks by equating the network to an equivalent single flow path (an approach taken by Xu et al. (2006) for hydraulic conductivity). Space constraints mean the full derivation is not presented, however one pivotal part of the derivation is equation (4) which defines the length of the total flow path in the network.

$$L_0 = l_0 + \sum_{k=1}^{m} l_k \cos\theta = l_0\left[1 + \frac{\alpha\left(1-\alpha^m\right)}{1-\alpha}\cos\theta\right] \tag{4}$$

The thermal conductivity of the network is considered using electrical engineering analogues (of resistance in series and parallel).

RESULTS

The effective (i.e. single phase) permeability (K) in the channel of 0th level (which has a diameter d_0) can be expressed by Equation 5.

$$K_{e\_0} = \frac{d_0^2}{32}\left(1 - S_{wc}\right)^2 \tag{5}$$

The relative permeability for water and steam in the network is derived (when taking into account capillary pressure effects, s and viscosity, m) to be:

$$k_{rw}^{+} = \frac{K_w}{K_{e\_0}} = \frac{S_w\left(S_w - S_{wc}\right)^2}{\left(1 - S_{wc}\right)^2}\left[\frac{1-\alpha}{1-\alpha^{m+1}}\frac{1-\alpha/N\beta^4}{1-\left(\alpha/N\beta^4\right)^{m+1}}\right]^{1/2}\left[1 + \frac{\alpha\left(1-\alpha^m\right)}{1-\alpha}\cos\theta\right] \tag{6}$$

$$k_{rg}^{+} = \frac{\sigma_1}{2\sigma_2 - \sigma_1}\left[\frac{\mu_w\left(1-S_w\right)^3 + 2\mu_g\left(1-S_w\right)^2\left(S_w - S_{wc}\right)}{\mu_w\left(1-S_{wc}\right)^2}\right]\left[\frac{1-\alpha}{1-\alpha^{m+1}}\frac{1-\alpha/N\beta^4}{1-\left(\alpha/N\beta^4\right)^{m+1}}\right]^{1/2}\left[1 + \frac{\alpha\left(1-\alpha^m\right)}{1-\alpha}\cos\theta\right] \tag{7}$$

The effective (e) thermal conductivity (k) of the network can be also be derived to be:

$$k_e = \left(k_w S_w + k_g S_g\right)\left(\frac{1 - N^{-(m+1)/D_l}}{1 - N^{-1/D_l}}\right)^2 \frac{1 - N^{1-\frac{2}{D_d}-\frac{1}{D_l}}}{1 - N^{(m+1)\left(1-\frac{2}{D_d}-\frac{1}{D_l}\right)}} \frac{1 - N^{\frac{2}{D_d}-\frac{1}{D_l}-1}}{1 - N^{(m+1)\left(\frac{2}{D_d}-\frac{1}{D_l}-1\right)}} \tag{8}$$

CONCLUSIONS

These results give fundamental insight into the flow and thermal behaviour of fractured porous media. The derivations were done with a view to using these results in an inverse modelling sense, i.e. in the interpretation of the response (pressure, temperature, flowrate) of wells in enhanced geothermal systems to infer the nature of the fracture networks in the reservoir. The results are also useful in establishing parameter values for numerical models of these systems which often use effective values to represent more complex porous medium properties.

FINITE ANALYTIC METHOD FOR SINGLE AND MULTI-PHASE FLOWS IN HETEROGENEOUS POROUS MEDIA

Xiao-Hong Wang* and Zhi-Feng Liu
Department of Thermal Science and Energy Engineering, University of Science and Technology of China, Hefei, Anhui 230026, P.R. China

Summary It is a challenge and long-standing problem to numerically describe fluid flows in porous media with permeability variations. With the traditional numerical scheme, the refinement ratio for the grid cell needs to be increasing dramatically to get an accurate result. We find out that this difficulty is caused by the singularities the problems. The finite analytic numerical scheme is proposed to solve the single-phase and multi-phase fluid flows in heterogeneous porous media to avoid the difficulty of the singularities.

Natural reservoirs exhibit wide permeability variations. In this case, the nodal flow effects will lead the flow fingering to the high permeability region (see figure 1). It is a challenge problem to numerically describe the nodal fingering effects. With the traditional numerical scheme, refining the coarse grid enough is the only manner to describe the flow pattern accurately.

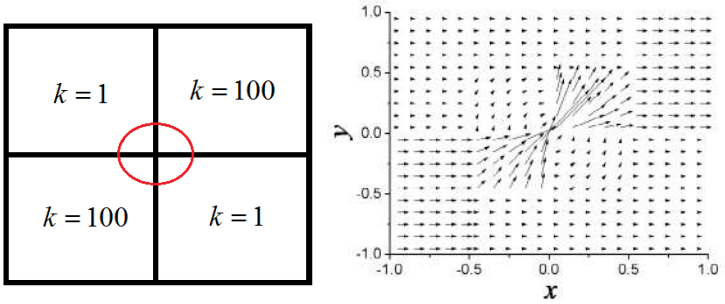

Figure 1. Velocity vector field on the 2×2 checkerboard for permeability ratio k_2/k_1=100.

For 2D problem with the heterogeneous scalar permeability distribution, enlightened from the numerical calculations on the flow pattern in the canonical 2×2 block with checkerboard geometry, which show that the pressure and its spatial gradient exhibit the power-law behaviors and especially the pressure gradient will tend to infinity when approaching the node joining different permeability domains, a local analytical nodal solution is derived. Based upon the analytical nodal solution, a finite analytic scheme is formulated for solving the fluid flows in 2D heterogeneous porous media. Numerical examples show that the detailed flow pattern can be reconstructed with the proposed numerical scheme under few grid refinements. Especially, only with 2×2 or 3×3 subdivisions, the proposed numerical scheme can provide rather accurate solutions. The convergent speed of the numerical scheme is independent of the permeability heterogeneity (see figure 2). In contrast, when using he traditional numerical schemes to simulate flow through a strong heterogeneous porous medium, the refinement ratio for the grid cell needs to be increasing dramatically to get an accurate result [1,2].

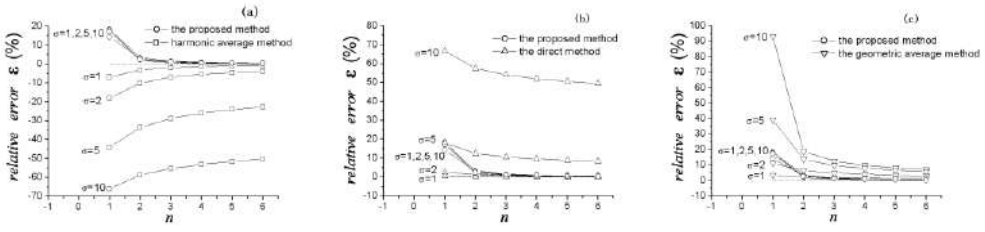

Figure 2. Plot of the relative errors of the equivalent permeabilities as a function of the grid refinement parameter n, calculated from different numerical schemes.

For 3D problem with the heterogeneous scalar permeability distribution, it is pointed out that the 3D flow will reduce to the 2D one in the neighborhood around each edge. Based upon the quasi-2D hypothesis, the 3D finite analytical numerical scheme can be constructed. Only with 2×2×2 or 3×3×3 subdivisions, the proposed numerical scheme can provide rather accurate solutions. The convergent speed of the numerical scheme is independent of the permeability heterogeneity (see figure.3). In contrast, when using the traditional numerical schemes to simulate flow through a strong heterogeneous porous medium, the refinement ratio for the grid cell needs to be increasing dramatically to get an accurate result [3].

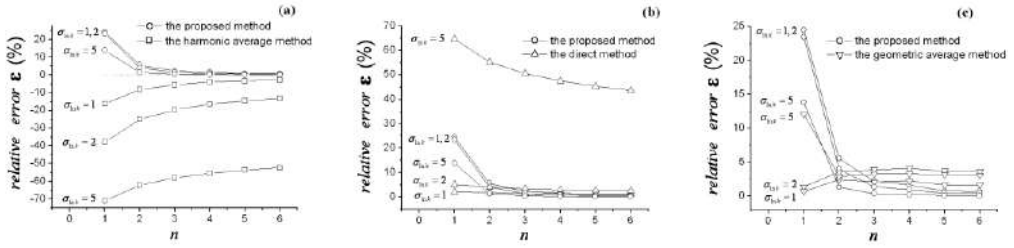

Figure 3. Plot of the relative errors of the equivalent permeabilities as a function of the grid refinement parameter n, calculated from different numerical schemes.

The finite analytic method is also developed to solve the 2D and 3D fluid flow in heterogeneous porous media with permeability in tensor form [4,5]. For the unstructured grids, a finite analytic scheme is constructed based upon the power-law analytic nodal solution in the angular domain with arbitrary shape. When approaching the grid node joining the subdomains, three different flow patterns may exist: power-law flow, linear flow or the stagnant flow. Numerical examples show that the proposed numerical scheme makes the convergences much quickly than the traditional methods [6].

For multi-phase flow in porous media, we construct a finite analytic numerical scheme [7]. Numerical examples show that the proposed scheme makes the convergences much faster as the refinement parameter increases, and the accuracy is independent of the heterogeneity. In contrast, when using the traditional numerical schemes to simulate flow through a strong heterogeneous porous medium, the refinement ratio for the grid cell needs to increase dramatically to get an accurate result (See figure. 4).

MISCIBLE RADIAL VISCOUS FINGERING WITH FINITENESS

Vandita Sharma* [1], Yuichiro Nagatsu[2], and Manoranjan Mishra[1]
[1]Department of Mathematics, Indian Institute of Technology Ropar, Punjab, India
[2]Department of Chemical Engineering, Tokyo University of Agriculture and Technology, Tokyo, Japan

Summary Finiteness in the porous medium flows may result from the oil trapped in the porous reservoirs after oil recovery or in the contaminant transport in aquifers. We focus on numerically understanding the effect of finiteness on the miscible viscous fingering. We consider the more viscous fluid occupying a fixed area and surrounded by the less viscous fluid. Further injection of the less viscous fluid results in a finite layer of the more viscous fluid, whose affect on the VF dynamics is explored. Depending upon the initial area, different fingering dynamics are reported. It is observed that there exists a critical area occupied by more viscous fluid for the fingering to occur. The numerical results are in good agreement with the existing experiments.

INTRODUCTION

Viscous fingering (VF) is a hydrodynamic instability ubiquitous in various porous media flows like enhanced oil recovery, CO_2 sequestration, contaminant transport in aquifers, to name a few [1]. The mobility gradient during the displacement of a more viscous fluid by a less viscous one results in finger like patterns, termed as VF. The displacement is broadly classified as rectilinear and radial displacement depending upon whether one fluid displaces the other linearly or radially and we term the VF in the corresponding geometry as rectilinear VF or radial VF. The rectilinear displacement is characterised by a uniform flow velocity while a non-uniform, spatially varying velocity is observed in the radial displacement. Consequently the VF dynamics are known to be affected by the kind of displacement [2]. In this work, we focus on the radial VF when more viscous fluid exists in finiteness between the layers of the less viscous fluid as commonly observed during enhanced oil recovery. We mathematically model the flow problem using COMSOL Multiphysics® [3] to examine the effect of finiteness of the more viscous fluid on VF dynamics. The finite element based COMSOL Multiphysics® helps to model the radial source flow by considering a disconnected domain to include the hole used for injection of the fluids as utilised in the VF experiments using Hele-Shaw cell [4, 5].

MATHEMATICAL MODELLING

We use the *two phase Darcy law (tpdl)* module of COMSOL Multiphysics® to model the flow of miscible, non-reactive, incompressible, Newtonian fluids through a two dimensional porous medium. The governing equations in the *tpdl* module are

$$\frac{\partial \epsilon_p \rho}{\partial t} + \vec{\nabla} \cdot (\rho \vec{u}) = 0, \tag{1}$$

$$\vec{u} = -\frac{\kappa}{\mu} \vec{\nabla} p, \tag{2}$$

$$\rho = \rho_1 s_1 + \rho_2 s_2, \tag{3}$$

$$\frac{1}{\mu} = s_1 \frac{\kappa_{r_1}}{\mu_1} + s_2 \frac{\kappa_{r_2}}{\mu_2}, \tag{4}$$

$$s_1 + s_2 = 1, \tag{5}$$

$$\frac{\partial \epsilon_p c_1}{\partial t} + \vec{\nabla} \cdot c_1 \vec{u} = \vec{\nabla} \cdot (D_c \vec{\nabla} c_1), c_1 = s_1 \rho_1, \tag{6}$$

where ϵ_p, κ are the porosity and the permeability of the porous medium. s_i, ρ_i and $\mu_i, i = 1, 2$ are respectively the saturation, density and viscosity of the two fluids ($i = 1$ denotes more viscous fluid and $i = 2$ denotes less viscous fluid). Equation (1) is the equation for the conservation of mass which reduces to the continuity equation for incompressible fluids for a constant ϵ_p and ρ. The conservation of momentum for flow through porous medium is given by the Darcy's law (equation (2)), where $\vec{u}$ is the Darcy velocity and p is the fluid pressure. The viscosity is specified as $\mu_1 = \mu_2 = \mu_{ref} \exp(R s_1)$, where $R = \ln(\mu_1/\mu_2)$ is a non-dimensonal parameter dealing with the viscosity contrast between the fluids and $\mu_{ref} = 1$ mPas. Further, the equation (6) is associated with the following initial condition in order to incorporate the effect of finiteness

$$s_1(x, y, t = 0) = \begin{cases} 1, & 0 < x^2 + y^2 \leq r_1^2 \\ 0, & \text{Otherwise} \end{cases} \tag{7}$$

Here r_1 is the radius of the circle occupied by more viscous fluid. The less viscous fluid is injected from the source using the inlet condition with an injection velocity U_0. Thus there exist three layers of fluids; first of the continuously injected less viscous followed by the finite layer of more viscous fluid which is further surrounded by the less viscous fluid as shown in figure 1. The width of the middle layer is modified by varying r_1 and various values of r_1 result in the different area occupied by the more viscous fluid.
A customised free traingular mesh of fluid dynamics is used for all the simulations.

*Corresponding author. E-mail: vandita.sharma@iitrpr.ac.in

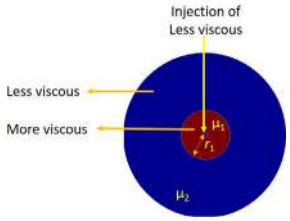

Figure 1: Schematic of the flow problem with an injection hole in the centre, showing the more viscous fluid surrounded by less viscous fluid. Injection of less viscous fluid results in finiteness of the more viscous fluid.

RESULTS AND DISCUSSION

The finiteness results in two interfaces, an *inward* interface where injected less viscous fluid displaces the more viscous fluid and an *outward* interface initially at a distance r_1 from the source, where more viscous fluid displaces the less viscous one. We show the density plots of saturation in figure 2 for different area occupied by more viscous fluid denoted by r_1. Depending upon the area occupied by the more viscous fluid, the two interfaces interact affecting VF dynamics. For a smaller area, the two interfaces are close enough for the diffusion to smear out concentration and hence viscosity gradient. Thus the unfavourable viscosity gradient at the *inward* interface may not be sufficient to trigger instability for smaller r_1. We perform a series of numerical simulations and observe that there exists a critical area occupied by more viscous fluid for the fingering to occur, which depends on R and U_0. The effect of finiteness is evident in figure 2 (a), b)) in which the *inward* interface is stable for $r_1 = 5$ mm while unstable for $r_1 = 30$ mm at $t = 180$ s for $R = 1, U_0 = 1.5$ mm/s. These results are consistent with the experimental results [5]. Further, if we increase R, intrinsic VF patterns are observed independent of the finiteness up to the time when the two interfaces are far apart (see figure 2c)). Once the two interfaces come in contact, the *outward* interface acts as a barrier preventing the fingers from growing further as evident in figure 2d).

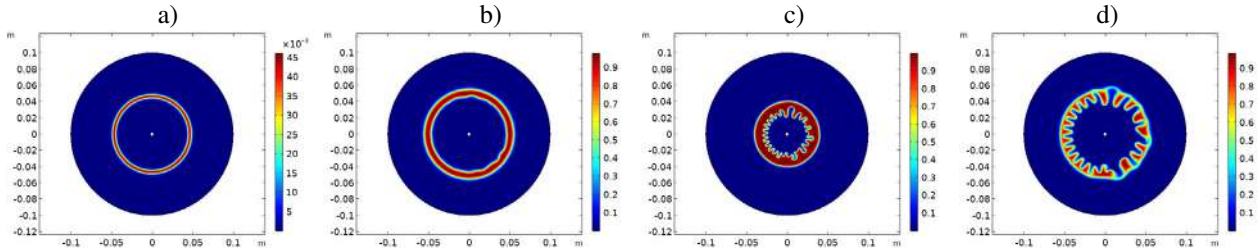

Figure 2: Density plots of saturation for a) $R = 1, U_0 = 1.5$ mm/s at $t = 180$ s for a) $r_1 = 5$ mm, b) $r_1 = 30$ mm, $R = 2, U_0 = 1.5$ mm/s, $r_1 = 30$ mm at c) $t = 60$ s, d) $t = 180$ s.

CONCLUSIONS

Finite element based COMSOL Multiphysics® is used to numerically capture the effect of finiteness under the similar experimental conditions utilised by Hamirul [5]. It is observed that the finiteness can result in a stable displacement despite an unfavourable viscosity gradient. In fact depending upon R, U_0, there exists a critical area for the fingering to occur, which is in agreement with the experiments. The effect of R is explored and it is found that the *outward* interface hinders growth of fingers resulting in the backward fingers.

OPTIMAL WETTABILITY DURING WATERFLOODING: DEPENDENCE ON STRUCTURAL FACTORS

Fanli Liu[1], Moran Wang *[1]
[1]Department of Engineering Mechanics, Tsinghua University, Beijing, China

Summary Oil recovery by waterflooding is known to heavily rely on the wetting condition of the reservoir. However, the common belief in low salinity waterflooding studies that a more water-wet condition is better seems to be in contradiction with many coreflooding experiments, where the maximum in oil recovery was found at near-neutral wettability.
This work offers an insight that the optimal wettability can be dependent on the structure of porous media. Theoretical derivations are done for simple geometries to show that modifying the structure can shift the optimal wettability. The rules are then applied in porous media and numerical simulations are carried out to validate the theoretical prediction. Finally, the dependence of the optimal wettability on several structural factors is studied and summarized and certain parameters are proposed to describe the relation.

INTRODUCTION

Waterflooding is a vastly applied oil recovery technique, during which water is injected from the injection well to displace oil inside porous rock towards the production well. The wetting condition of the reservoir is known to have a big impact on the displacing process and thus on the oil recovery by waterflooding. Moreover, wettability alteration has been recognized as the major mechanism of low salinity waterflooding or modified salinity waterflooding, a promising enhanced oil recovery technique where the ionic compositions are modified in the injected brine compared with traditional waterflooding. It is generally believed that, during low salinity waterflooding, altering the rock to a more water-wet condition leads to higher oil recovery.

However, there has been contradictory findings in terms of the optimal wettability for oil recovery. Jadhunandan and Morrow conducted more than 50 coreflooding experiments and found that the maximum in oil recovery occurred at close-to-neutral wettability, not strongly water-wet as many believed. They proposed that this was due to the snap-off mechanism which tended to happen in strongly water-wet condition and led to more trapped oil. A few follow-up experiments observed the same trend that weakly water-wet or neutrally wet was best for oil recovery. Simulation studies, on the other hand, has obtained various results where the optimal wettability could be strongly water-wet, neutrally wet or even oil-wet. So far there has been a lack of explanation for such contradictions.

This work offers a new insight in terms of what wetting condition is better for oil recovery by proposing that the optimal wettability can be dependent on the structure of the porous media. First, it is theoretically derived that for simple structures, how the change in structure can lead to the change in the optimal wettability and general rules are obtained. Then the rules are applied in porous media to predict the optimal wettability and two-dimensional simulations of waterflooding are conducted to validate the predictions. Finally, discussions are made on the impact of structural factors and how it can shed light on studies and applications of waterflooding.

THEORETICAL DERIVATION

In this section, it is theoretically derived that for some simple geometries weakly water-wet condition leads to the best oil recovery instead of strongly water-wet one. In addition, a minor change in the structure can reverse the trend and make strongly water-wet the best, indicating how the optimal wettability can be dependent on the structure. Some general rules are obtained in the derivation.

The derivation is done in the following manner. Consider a waterflooding process in the structure where the inlet boundary provides constant flux and the outlet boundary keeps constant pressure. The flow resistance in all possible flow paths from the inlet to the outlet is each calculated and the progress of flow is predicted as it should favour the path with the lowest resistance. Note that the resistance consists of the viscous term, the capillary term and the structural term due to the momentum loss where there is a sudden change of structure. As the flow advances, the configuration changes and the flow resistance is updated, which in term determines the flow path in the next step. By repeating such analysis, the overall flow path and thus oil recovery are obtained.

SIMULATION RESULTS

The rules obtained in the previous section on simple geometries can be extended to porous media. In this section, two-dimension numerical simulations of waterflooding are conducted to study the impact of structural factors on the optimal wettability and to validate the prediction by theory. The color-gradient two-phase lattice Boltzmann model is adopted. The porous media are first reconstructed from micro-CT images of sandstone, then modified in different manners in order to achieve different optimal wettability based on the theory.

Results show that the rules from simple geometries still apply for porous media to some extent. By modifying the porous structure, the optimal wettability can shift from strongly water-wet to weakly water-wet, as illustrated in Figure 1.

*Corresponding author. E-mail: mrwang@tsinghua.edu.cn.

DISCUSSION

In this section, the impact of structural factors on the optimal wettability is discussed based on the theoretical derivation and simulation results, with certain parameters proposed to describe such impact. It is also discussed how the findings can explain some contradictions in the previous studies.

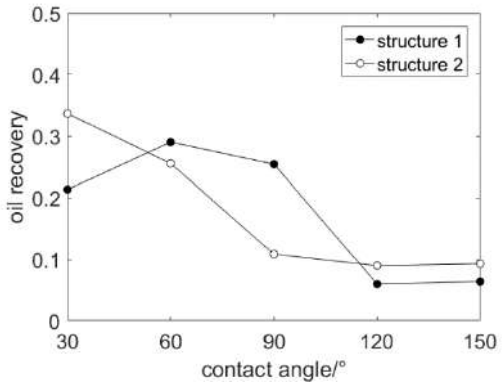

Figure 1. Oil recovery by waterflooding in different wetting conditions. Structure 1 and 2 are modified from the same micro-CT image of sandstone in different manners.

CONCLUSIONS

This work studies the dependence of the optimal wettability on structure factors by theoretical analyses and numerical simulation. It is found that weakly water-wet can be the optimal wettability instead of the commonly believed strongly water-wet, but changes in the structure can shift the optimal wettability towards more water-wet conditions. Certain parameters are proposed to describe the dependence and it is discussed how the findings can help further waterflooding studies.

NUMERICAL SIMULATION OF THERMO-HYDRO-MECHANICAL EFFECTS OF STEAM INJECTION IN POROUS MEDIA

Anastasiia Kostina *, Maxim Zhelnin and Oleg Plekhov
Laboratory of Solid Thermomechanics, Institute of Continuous Media Mechanics of the Ural Branch of Russian Academy of Science, Perm, Russia

Summary The work is devoted to the development and computer implementation of a coupled three-dimensional mathematical model of steam-assisted gravity drainage. The model describes filtration of the three-phase fluid in porous media, convective heat transfer, evaporation of water and steam condensation, effect of pore pressure on stress-strain state of a reservoir and porosity evolution. The developed model takes into account specific data on location and number of wells, structural features of oil reservoirs as well as all stages of steam chamber initiation and evolution. The obtained results are in a good agreement with the experimental data of Yarega oil field.

INTRODUCTION

Steam-assisted gravity drainage (SAGD) is one of the most effective ways to enhance heavy oil recovery. The aim of this method is to decrease oil viscosity by injection of hot steam into reservoir. Temperature rise reduces oil viscosity and increases oil mobility. Application of this technique is accompanied by complex interaction between thermal, mechanical and hydrodynamic processes occurring in a fluid-saturated media. As a result, permeability and porosity of the reservoir undergo substantial changes which have significant effect on oil recovery.

The aim of this work is to develop three-dimensional mathematical model of SAGD and propose algorithm for its computer realization. The model describes following effects: change in thermophysical and hydrodynamic properties of multiphase flow; convective heat transfer; phase change due to condensation and evaporation of water; effect of pore pressure on stress-strain state of the reservoir; thermal expansion of solid grains; evolution of porosity due to the volumetric strains and pore pressure.

MATHEMATICAL MODEL

The developed mathematical model is based on the assumption that pore fluid consists of three immiscible components (water, steam and oil) [1]. The mathematical formulation includes mass balance equations for water, oil and steam saturations. Filtration of each component is described Darcy's law. The energy balance equation incorporates convective heat transfer term and additional source term [2] describing phase change process. The mechanical part of the model includes momentum balance equation, geometric relation and Hook's law for effective stresses. Evolution of the porosity due to the thermal and mechanical loading of the reservoir is determined according to the model proposed in [3].

RESULTS OF NUMERICAL SIMULATION

Numerical algorithm was based on the pressure-saturation formulation using total flow velocity [4]. Spurious oscillations caused by convection were stabilized by artificial diffusion. The obtained system of equations was solved in finite-element software Comsol Multiphysics® using Weak Form PDE Interface, Heat Transfer and Structural Mechanics modules.

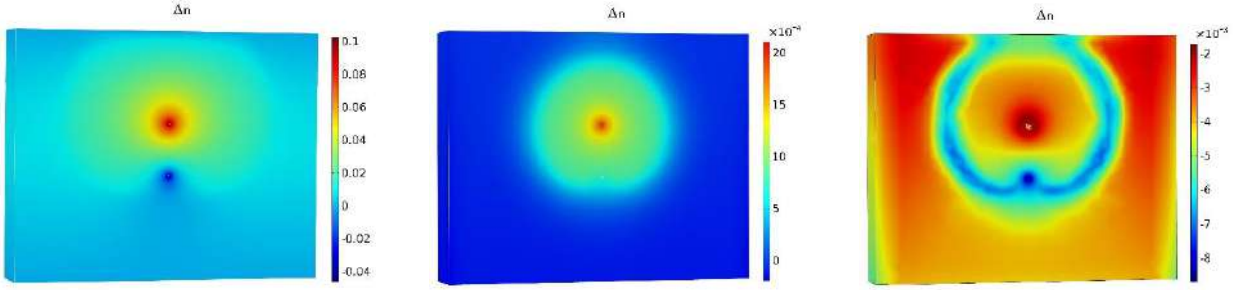
Analysis of porosity models has shown that there are three qualitatively different pictures of porosity distribution near the wells (Fig.1). If the pore pressure is a prevailing mechanism of porosity evolution (Fig 1 (a)) then the high-porous area and low-porous area are formed. Influence of the thermal expansion leads to the increase in porosity (Fig. 1 (b)). If the prevailing mechanism is compression of the reservoir due to the steam injection (Fig.1 (c)) then the "ring-shaped" low-porous area corresponding to the thermal front is formed. The obtained results have shown that accurate description of steam chamber shape and sizes and, as a consequence, of oil production rate in arbitrary reservoir requires identification of the prevailing mechanism of porosity evolution.

The developed model was applied to simulation of oil recovery by SAGD in Yarega oil deposit (Russian crude oil deposit in Komi Republic). This type of reservoir is characterized by porosity rise of 1%-3%. Therefore, the porosity equation in the proposed model combines two mechanisms of porosity increase (pore pressure and thermal expansion). Figure 2 shows results of the steam chamber formation in Yarega oil deposit using the proposed model. Homogeneous initial porosity (Fig. 2 (a)) gives the shape of the steam chamber close to the inverted triangle which is similar to the assumptions made in analytical models [5]. Heterogeneous initial distributions (Fig. 2 (b)-(c)) lead to the qualitatively different steam chamber shapes. Initial porosity with the predominant spatial orientation (Fig. 2 (c)) shows the difference in merging time of the neighboring wells. These results are confirmed by experimental studies of the steam chamber evolution in the reservoir which has different permeability in horizontal direction [6].

*Corresponding author. E-mail: kostina@icmm.ru.

Verification of the proposed model is based on the thermal monitoring data obtained by the observation well which is located on the distance of 134 m from the utmost pair of wells. Comparison between the calculated and experimentally measured temperature in the depth interval from 194 to 204 m has shown that the proposed model can predict the temperature with an accuracy of 0.5^0C.

The work was supported by Russian Science Foundation [grant No. 19-77-30008].



(a) (b) (c)

Figure 2. Steam chamber after 20 days of steam injection: homogeneous initial porosity (a), initial porosity with random distribution (b), initial porosity with the given predominant distribution (c).

CONCLUSIONS

The work is devoted to three-dimensional numerical simulation of fully coupled thermo-hydro-mechanical processes occurring in porous media during oil recovery by steam-assisted gravity drainage method. The developed model takes into account specific data on location and number of wells, structural features of oil reservoirs as well as all stages of steam chamber initiation and evolution. Verification of the model has shown good agreement with the field thermometry data of Yarega oil deposit.

SLOSHING IN HIGHLY PERMEABLE POROUS MEDIA

Xiaoning Di*[1], Yohan Davit[1], Michel Quintard[1]
[1]Institut de Mécanique des Fluides de Toulouse (IMFT), Université de Toulouse, CNRS, Toulouse, France

Summary Sloshing in highly permeable porous media is an interesting research topic that has received little attention in the literature. Here, we use the numerical models based on the Volume of Fluid method to investigate sloshing dynamics in highly permeable porous structures. At first, sloshing is studied at pore-scale for a two-dimensional tank with several fixed particles, the size of which is typical of highly permeable porous media. Then, we develop a macro-scale model based on the VOF method, corresponding to a thin saturation front. The model effective properties are calculated for a Unit-Cell representative of the medium. A comparison between the pore-scale and the macro-scale results shows that the macro-scale model accurately predicts the transient location of the sloshing surface. Results also emphasize that inertia correction may play an important quantitative role.

PORE-SCALE MODELLING OF SLOSHING

Pore-scale numerical results based on VOF modelling were obtained using the OpenFOAM® implementation for a 2D tank cavity filled with a staggered array of discs. Results, presented Figure 1, show that the porous medium filling cavity yields more dissipation and modifies significantly the sloshing dynamics. Results for the column on the left correspond to a pure-fluid cavity and results on the right are for a porous cavity. As observed in [1], the amplitude of the surface movement is more important for pure-fluid sloshing than in the presence of a porous filled cavity because of the resistance produced by the particles. Results also indicate that the sloshing surface is not spread locally over more than one Unit-Cell for such a high permeability medium, and this is in favour of the development of a macro-scale VOF model.

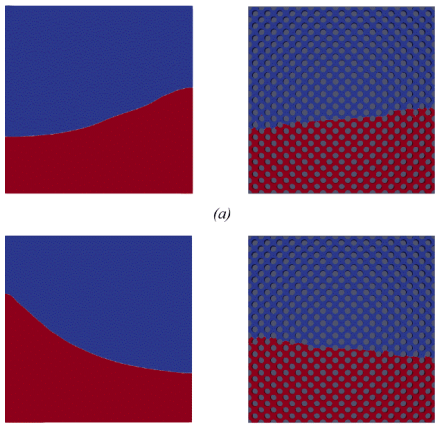

Figure 1. Comparison between pure fluid cavity and porous medium cavity sloshing (roll angle A=5°, sloshing period T=0.5 s, the length and height of cavity L=H=0.15 m, the diameter of particles d=0.5 cm, depth of cavity h=0.06 m). (a): t=0.5 s (b): t=0.75 s.

MACRO-SCALE MODELLING OF SLOSHING

A macro-scale model was established based on a VOF method and following the guidelines of a volume average method [2, 3]. The model takes into account the solid phase movement, a full anisotropic permeability tensor and a generalized term accounting for inertial effects. The macro-scale momentum equation reads

$$\rho\left(\frac{\partial \mathbf{U}}{\partial t}+\mathbf{U}\cdot\nabla\mathbf{U}\right)=-\nabla p+\rho\mathbf{g}+\nabla^2\mathbf{U}+k\sigma\nabla\alpha-\varepsilon\mu\mathbf{K_{app}}^{-1}\cdot\left(\mathbf{U}-\mathbf{U_{moving}}\right) \quad (1)$$

The last term on the right-hand side represents the resistance for flow in a moving porous medium. In this term, $\mathbf{U}$ is the intrinsic average velocity, α is the fluid volume fraction, $\mathbf{U_{moving}}$ is the local velocity of the moving porous medium and $\mathbf{K_{app}}$ is the apparent permeability taking into account all friction effects including inertia. In this study, we wrote $\mathbf{K_{app}}$ in the following form based on the work in [2, 3]

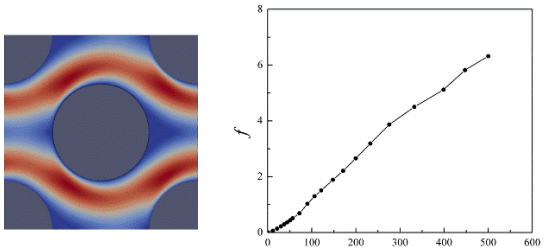
$$\mathbf{K_{app}}=\left(1+f(\mathrm{Re},\theta)\right)^{-1}\mathbf{P}\cdot\mathbf{K_0} \quad (2)$$

*Corresponding author. E-mail: xiaoning.di@toulouse-inp.fr.

where f is a non-linear inertia correction term, $\mathbf{K_0}$ the intrinsic permeability, $\mathbf{P}$ a rotation tensor that handles the additional anisotropic effects due to inertia. Therein, f and $\mathbf{P}$ depend on the Reynolds number Re and the orientation of the macro-scale pressure gradient, θ, with

$$\mathbf{P} = \begin{pmatrix} cos\left(\beta(\mathrm{Re},\theta)\right) & -sin\left(\beta(\mathrm{Re},\theta)\right) \\ sin\left(\beta(\mathrm{Re},\theta)\right) & cos\left(\beta(\mathrm{Re},\theta)\right) \end{pmatrix} \tag{3}$$

Further, β is also a function of θ and Re and it represents the angle between the orientations of macro-scale actual velocity and the macro-scale Darcy velocity that would be induced by the applied pressure gradient. Figure 2 shows an example of REV and the f - Re relationship in the situation $\theta = 0$ °.



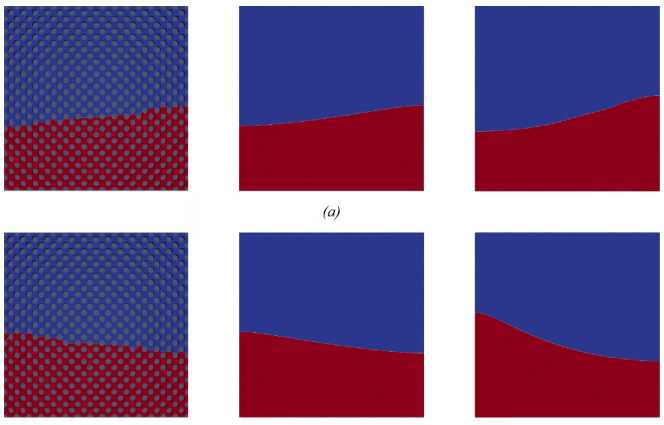
REV

(a) (b)

Figure 2. (*a*) Velocity field in the REV (Re = 56.73, $\theta = 0$ °); (*b*) The inertial correction f versus Re ($\theta = 0$ °).

All the equations presented above were implemented into a VOF solver in the computational fluid dynamics software OpenFOAM®.

Figure 3 shows the comparison between macro-scale and pore-scale sloshing at the same moments. It can be seen that the free surfaces are quite similar, indicating the ability of the macro-scale VOF model to reproduce the sloshing phenomena for highly permeable porous media. Further, through the comparison between the macro-scale results with and without inertia correction, it is obvious that the inertia correction plays an important role, particular for sloshing with short period which causes a high Re number. Without an inertia correction, the porous medium resistance is accordingly decreased inducing a movement of the free surface with larger amplitude.



(a)

(b)

Figure 3. Comparison between porous medium cavity sloshing, macro-scale sloshing with and without inertia correction (roll angle A=5°, sloshing period T=0.5 s, the length and height of cavity L=H=0.15 m, the diameter of particles d=0.5 cm, depth of cavity h=0.06 m). (*a*): t=0.5 s (*b*): t=0.75 s.

CONCLUSIONS

In this study, we have established a macro-scale VOF model for describing sloshing situations in highly permeable porous media. A comparison with direct numerical simulation at the pore-scale showed the ability of the macro-scale model to reproduce the observed results. The investigation also emphasized the need for a correct estimate of effective properties, including inertia correction.

ON THE ACCURACY OF DEVELOPED CLOSURE CORRELATIONS FOR MODELLING THE LAMINAR MACRO-SCALE FLOW IN CHANNELS WITH LARGE ARRAYS OF SOLID STRUCTURES.

Summary In this work, laminar flow through channels with large arrays of solid structures is modelled from a macro-scale viewpoint, through spatially averaged Navier-Stokes equations which take account of the presence of porosity gradients and channel boundaries. The accuracy of employing a double-volume-averaging operator in combination with closure correlations that are exact for the periodically developed regime, is evaluated for parallel-plate channels with arrays of square pin fins. It is shown that a fairly good agreement with direct numerical simulation can be obtained, when the macro-scale velocity profile in the near-wall region is known a priori.

INTRODUCTION

For the modelling of laminar incompressible flow through channels with large arrays of periodic solid structures, direct numerical simulation (DNS) of the Navier-Stokes equations is usually infeasible, as it necessitates supercomputing infrastructure. Therefore, macro-scale models have been proposed in the literature, which offer an approximative description of the average flow in such channels, while requiring significantly less computational resources. In essence, these macro-scale models enable us to restrict our analysis of the detailed flow to just one unit cell of the array.

Although the majority of macro-scale models for laminar channel flows have been formulated on empirical grounds, e.g. [1], most of the theoretical framework is adapted from the volume-averaged flow equations that describe the macro-scale flow through porous media [2]. As a consequence, the available macro-scale flow models incorporate different assumptions and approximations which have been verified for some classes of porous media, yet not for channel flows.

First, the volume-averaged flow equations for porous media neglect the spatial moments of the array of solid structures [3, 4]. For that reason, they do not recover a constant macro-scale pressure gradient when the flow in the array is periodically developed, like it has been assumed in the literature. As a result, the developed flow regime in channels cannot be reconstructed in exact agreement with results from DNS, unless the volume-averaged flow equations are replaced by spatially filtered flow equations [4]. The latter filtered flow equations are derived from the Navier-Stokes equations by applying a double-volume-averaging operator, or filter, which was originally proposed by Quintard and Whitaker [3].

Secondly, the volume-averaged flow equations presented in the literature rarely if ever take porosity gradients or domain boundaries into account. As such, they lose their validity near the inlet and outlet of the channel, as well as near the channel walls.

In order to circumvent the previous modelling inaccuracies, this work explores a macro-scale description of laminar channel flow which is based on a double-volume-averaging operator and closure correlations that are (nearly) exact for the periodically developed regime. The presented macro-scale flow equations take porosity gradients and domain boundaries into account. Furthermore, the accuracy of this macro-scale modelling approach is compared with DNS for arrays of square pin fins.

MACRO-SCALE FLOW EQUATIONS WITH DEVELOPED CLOSURE CORRELATIONS

When gradients of the porosity ϵ_{fm} and the presence of domain boundaries are taken into account, the macro-scale velocity $\langle \boldsymbol{u} \rangle_m$ and macro-scale pressure $\langle p \rangle_m$ are the solution of the following filtered Navier-Stokes equations:

$$\nabla \cdot \langle \boldsymbol{u} \rangle_m = 0 \,, \tag{1}$$

$$\rho_f \nabla \cdot \left(\epsilon_{fm}^{-1} \langle \boldsymbol{u} \rangle_m \langle \boldsymbol{u} \rangle_m \right) = -\nabla \langle p \rangle_m + \mu_f \nabla^2 \langle \boldsymbol{u} \rangle_m + \boldsymbol{b} + \langle \boldsymbol{f} \rangle_m \,. \tag{2}$$

Here, $\langle\ \rangle_m$ denotes the double-volume-averaging operator, so $\langle \boldsymbol{f} \rangle_m$ corresponds to the spatially averaged body force.

The closure force $\boldsymbol{b}$ in the macro-scale momentum equation (2) contains in good approximation only contributions from the viscous forces and pressure at the fluid-solid interface and the channel walls, as we can show that macro-scale momentum dispersion is negligible for (quasi-developed) laminar channel flows.

In the core of the channel, where the flow through the array of solid structures is periodically developed, the closure force is a spatially constant vector, $\boldsymbol{b}_{\text{dev}}$, which can be correlated to the macro-scale velocity in an exact manner by solving the periodic flow equations on a unit cell of the array [4]. For an array of square pin fins of width w, whose inter-fin spacing ℓ is equal to the channel height, this correlation takes the form

$$\boldsymbol{b}_{\text{dev}}(\epsilon_{fm}, \langle \boldsymbol{u} \rangle_m) \simeq -75 \frac{\mu_f}{\ell^2} \frac{(1-\epsilon_{fm})^{1/3}}{\epsilon_{fm}^3} \langle \boldsymbol{u} \rangle_m - 0.006 \frac{\rho_f}{\ell} \frac{(1-\epsilon_{fm})^{0.5}}{\epsilon_{fm}^3} \| \langle \boldsymbol{u} \rangle_m \| \langle \boldsymbol{u} \rangle_m \,. \tag{3}$$

*Corresponding author. E-mail: geert.buckinx@kuleuven.be

The latter correlation has been fitted numerically over a wide range of Reynolds numbers $Re_{\text{unit}} \triangleq \rho_f \|\langle \boldsymbol{u} \rangle_m\| \ell / \mu_f \in [0, 200]$ and porosities $\epsilon_{fm} = 1 - (w/\ell)^2 \in [0.5, 1]$, and holds as long as the directions of $\boldsymbol{b}_{\text{dev}}$ and $\langle \boldsymbol{u} \rangle_m$ are more or less aligned.

In the regions of the channel where porosity gradients are present, the closure force can be approximated in agreement with the closure mapping from [2, 3], which leads to

$$\boldsymbol{b}(\epsilon_{fm}, \langle \boldsymbol{u} \rangle_m, \langle p \rangle_m) \simeq \epsilon_{fm}^{-1} \langle p \rangle_m \nabla \epsilon_{fm} + \mu_f \nabla \epsilon_{fm} \cdot \nabla \left(\epsilon_{fm} \langle \boldsymbol{u} \rangle_m \right) + \boldsymbol{b}_{\text{dev}}(\epsilon_{fm}, \boldsymbol{G} \cdot \langle \boldsymbol{u} \rangle_m) \,, \tag{4}$$

where $\boldsymbol{G}$ equals the identity tensor $\boldsymbol{I}$ inside the core of the channel.

In the near-wall region, the tensor $\boldsymbol{G}$ maps the local macro-scale velocity to the (nearly) spatially constant macro-scale velocity in the core. This tensor can be constructed from the macro-scale velocity profile in the wall region, which is approximately linear when the distance between the array and the channels walls is less than the characteristic size ℓ of the unit cell. Therefore, $\boldsymbol{G}$ can be constructed from the slip-length l_{slip} of the macro-scale velocity at the channel wall, by solving the periodically developed flow equations on a unit cell in the near-wall region.

VALIDATION THROUGH COMPARISON WITH DNS

In order to validate the accuracy of the filtered flow equations (1)-(2) and developed closure correlations (3)-(4), a series of DNS experiments has been carried out for parallel-plate channels containing arrays of square pin fins. In these numerical experiments, the Reynolds number based on the bulk velocity was varied over the range $Re \triangleq \rho_f u_b \ell / \mu_f \in [25, 250]$, while the width of the fins was chosen as $w/\ell \in \left\{ \frac{1}{2}, \frac{1}{3}, \frac{1}{4} \right\}$.

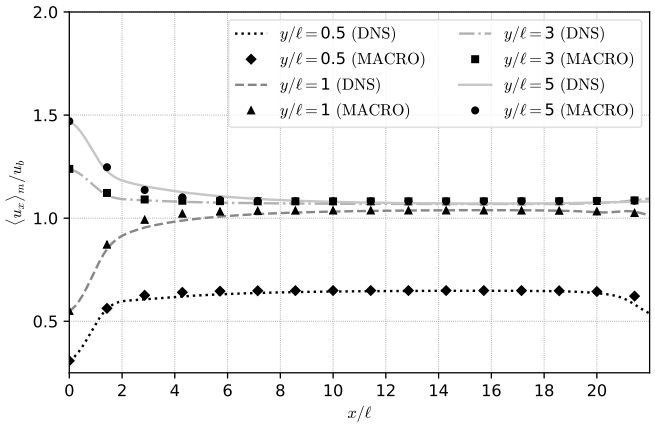

Figure 1: Macro-scale velocity $\langle u_x \rangle_m$ in the main flow direction x of a channel with an array of 20×10 pin fins, at different positions y along the width of the channel. ($w/\ell = 0.5$, $Re = 25$)

An example of the outcome of these DNS experiments is given in Figure 1, which shows the macro-scale velocity component $\langle u_x \rangle_m$ along the main flow direction x in a channel with an array of 20×10 pin fins with $w/\ell = 0.5$, for $Re = 25$. As it can be observed from Figure 1, the developed closure correlations (3)-(4) are capable of reproducing the macro-scale velocity in qualitatively good agreement with DNS at different positions y along the width of the channel, when the slip length is known a priori: $l_{\text{slip}}/\ell \simeq 0.25$ in this case. The relative point-wise difference between the results of the macro-scale model and DNS in terms of $\langle u_x \rangle_m$ is less than 5% in the core of the channel ($1 < y/\ell < 9$) and less than 15% in the near-wall region ($y/\ell \leq 1$ or $y/\ell \geq 9$) in this case. A comparable accuracy has been observed for the higher Reynolds numbers and higher porosities, as well as for larger arrays (for instance, of 60×10 pin fins).

CONCLUSIONS

By employing a double-volume-averaging operator and closure correlations that are exact for the periodically developed regime, the laminar macro-scale flow in simple parallel-plate channels can be reconstructed with point-wise differences of less than 15 to 20% with respect to direct numerical simulation, provided that the slip-length is known.

MULTISCALE SIMULATION OF GAS TRANSPORT IN POROUS MEDIA

Wei Su*[1], Minh Tuan Ho[1], Yonghao Zhang[1], and Lei Wu[2]
[1]School of Engineering, The University of Edinburgh, Edinburgh, UK
[2]Department of Mechanics and Aerospace Engineering, Southern University of Science and Technology, Shenzhen, China

Summary The general synthetic iterative scheme is proposed to solve gas kinetic equations for multiscale gas dynamics with the Knudsen number spanning a wide range, where the traditional Navier-Stokes equations fail. Macroscopic equations of conservative laws are solved alongside the mesoscopic equations to guide the evolution of molecular velocity distribution functions. Constitutive relations to close the macro equations are strictly derived from the gas kinetic equations. The scheme can accurately obtain steady-state solutions within dozens of iterations at any Knudsen number and asymptotically preserve the Navier-Stokes limit on coarse meshes. The advantages make the scheme a promising tool to model gas transport in porous media. As an example, we quantify the apparent gas permeability of porous media and try to find a universal slop in the Klinkenberg's correlation.

INTRODUCTION

Gas flows through porous media is found in a variety of engineering applications, such as the next-generation technologies of carbon capture and utilization, productions of unconventional gas to offset the decline of conventional fossil fuels, membrane oxygenation for extracorporeal life support, and fast-responding pressure-sensitive paint for flow-field measurement. The development of the new technologies requires research advances in not only new materials and industrial processes but also improved knowledge about the underlying physics of gas transport. However, the latter has largely been neglected due to lack of experimental and computational capabilities.

The characteristic length of the gas flows in the above applications is usually multiscale, e.g. gas evolution and production in shale sediments contain flows in fine-grained formation at the nano/microscale, through fracturing networks at the mesoscale and from reservoirs to wellbores at the macroscale. As a consequence, the flow can span over a wide range of the Knudsen numbers (*Kn*, the ratio of the mean free path of gas molecules to the characteristic flow length), where the traditional Navier-Stokes equations fail to model the flows while the gas kinetic theory is required. So far, very few numerical methods are designed to efficiently solve multiscale gas dynamics. Particularly, the conventional iterative scheme (CIS) in solving the gas kinetic equations suffers difficulties as the Knudsen number approaches to the continuum limit: it requires the cell size of the spatial grid to be smaller than the molecular mean free path, in order to suppress numerical dissipations; it costs hundreds of thousands iterations to obtain steady-state solutions because information propagation becomes very inefficient when molecular collisions dominate. Therefore, the scheme is prohibitively expensive for realistic engineering problems.

In this work, we introduce a novel iterative scheme to solve gas kinetic equations, which is proven to be a promising tool for efficient and accurate simulation of multiscale gas dynamics. Then, as an application, we use this tool to find a universal slip factor in the Klinkenberg's correlation of apparent gas permeability in porous media.

GENERAL SYNTHETIC ITERATIVE SCHEME FOR MULTISCALE SIMULATION

To tackle the difficulties of CIS in simulating small-Kn flows, we have proposed the general synthetic iterative scheme (GSIS) [1,2]. The key of GSIS is that the macroscopic equations of conservative laws are simultaneously solved alongside the gas kinetic equations, from which the macroscopic flow properties are obtained to guide the evolution of molecular velocity distribution functions. The constitutive relations of the stress tensor and the heat flux for the closure of the macro equations are strictly derived from the kinetic equations, which explicitly contain the Newtonian and Fourier's laws as well as the high-order terms beyond the Navier-Stokes limit. Therefore, GSIS can obtain steady-state solutions within dozens of iterations at any Knudsen number while predicting accurate results when the rarefied effects intensify.

Rigorous analyses of Fourier stability and Chapman-Enskog expansion show that [3]: the residue of solutions between two successive iterative steps can be reduced by at least three orders of magnitude only after 10 iterations, allowing the scheme to achieve fast convergence over the whole flow regime; the macro synthetic equations are reduced to the Navier-Stokes equations when the Knudsen number approaches zero, guaranteeing the scheme to obtain accurate solution in the near-continuum region on a spatial grid with cell size much larger than the molecular mean free path. These advantages make the GSIS a particularly promising tool in simulating multiscale gas transport through porous media.

ON SLIP FACTOR IN THE KLINKENBERG'S CORRELATION

The apparent gas permeability (AGP) of a porous medium is an important parameter to predict the production of unconventional gas. Due to the gaseous slippage at solid surfaces, AGP can be much larger than the intrinsic permeability. One of the most popular empirical estimation to quantify AGP is the Klinkenberg's correlation, which states that the ratio of AGP to the intrinsic permeability of a porous medium is approximately a linear function of reciprocal mean gas

*Corresponding author. E-mail: wei.su@ed.ac.uk.

pressure. Significant efforts have been made to construct a universal expression for the slope in the correlation. However, the major challenges remain: it is difficult to define the effective flow length in the Knudsen number for complex porous geometries; thus the slop in the Klinkenberg's correlation may significantly vary for different geometries such that a universal expression seems nearly impossible.

Using the developed GSIS, we solve the linearized Boltzmann kinetic equation to evaluate AGPs in simplified porous media represented by the two-dimensional Sierpinski fractal model, see Figure 1(a) and a pore body/throat system. Figure 1(b, c) compares the number of iteration steps and the obtained AGP between the GSIS and CIS, where it is found the GSIS can obtain the same results as the CIS but with significantly smaller computational effort, especially when Kn becomes small. Finally, a new definition of the characteristic flow length in porous media is proposed, which is a function of the porosity, tortuosity and intrinsic permeability. A unique slop of about 7 in the Klinkenberg's correlation can be found for the geometries considered, when the Knudsen number characterized by the new flow length (Kn*) is within the slip flow regime, see Figure 1(d). Note that the GSIS is also used to find the intrinsic permeability in the continuum region with $Kn = 10^{-5}$, which just needs no more than 20 steps and a few minutes of CPU time on a single processor to obtain the converged solutions. Compared with the solutions from lattice Boltzmann calculations, the GSIS can predict accurate results on the coarse meshes even with the maximum cell size being 6000 times the mean free path length of gas molecules, due to its asymptotic preserving.

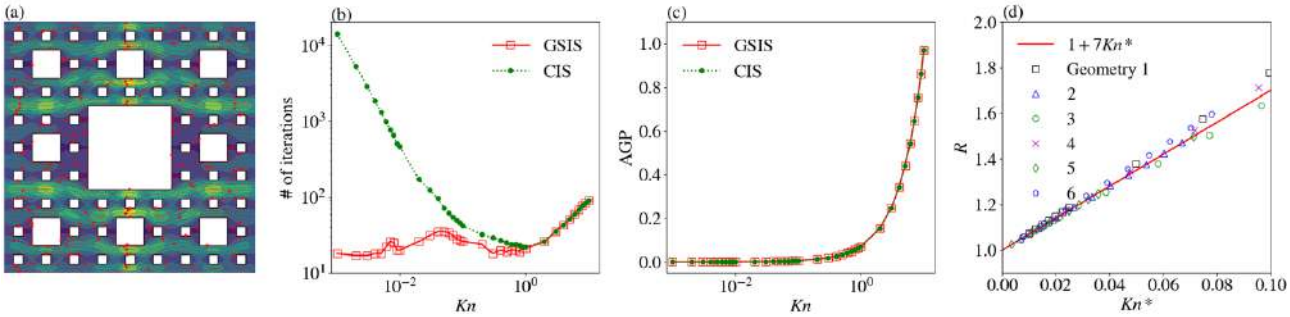

Figure 1: (a) Gas flow through Sierpinski fractal model; (b) Number of the iteration steps to obtain steady-state solutions; (c) Apparent gas permeability; (d) Ratio of AGP to intrinsic permeability (R) against Kn* using the new definition.

DEFORMATION-DRIVEN SOLUTE TRANSPORT IN SOFT POROUS MEDIA

Matilde Fiori*[1], Satyajit Pramanik [2], and Christopher W. MacMinn[1]
[1]Department of Engineering Science, University of Oxford, Oxford, UK
[2]Discipline of Mathematics, Indian Institute of Technology Gandhinagar, Gandhinagar, India

Summary Solute transport plays an important role in many soft porous materials, including the movement of contaminants in soils and the movement of nutrients and waste in living tissues and tissue-engineering scaffolds. These systems are also often exposed to large, periodic loading and deformation, which drives nontrivial fluid motion and changes in pore structure. Here, we study the strong coupling between fluid flow and mechanical stimulation during periodic deformations using a 1D continuum model based on large-deformation poroelasticity. We show that these reversible deformations lead to non-reversible spreading and mixing, even in a homogeneous medium. We analyse the three primary mechanisms of solute transport (advection, molecular diffusion, and mechanical dispersion) and study their separate impacts on the solute distribution. We also identify the key dimensionless parameters that govern deformation-driven transport, and we study their qualitative and quantitative impacts on solute spreading and mixing.

INTRODUCTION

Soft porous media are characterized by a highly deformable porous solid skeleton in which the pore space is occupied by a fluid phase. These materials can experience large volume changes, due to influx or efflux of the fluid. Internal fluid flow and external mechanical deformation are therefore highly coupled, through rearrangements of the pore structure [1].

The transport and mixing of solutes can be crucial in some soft porous media, from contaminants in soils to nutrients in biological tissues. In many cases, these materials are exposed to periodic deformations, which influence the resultant fluid flow and consequently impact on solute movements. In general, solute transport in soft porous media is driven by three main mechanisms – advection, molecular diffusion, and hydrodynamic dispersion. [2, 3]. Deformations affect these three phenomena by modifying the pore space – and, therefore, the fluid fraction in the domain at each time-step. Moreover, periodic deformations continuously alter the fluid and solid velocities, thus directly influencing advection and mechanical dispersion.

Here, by considering a simple one-dimensional model, we aim to describe the fundamental physics regulating the problem. We hence perform simulations to observe how a certain initial concentration profile is affected by changing some relevant parameters. Furthermore, we focus on the individual role of the three main transport mechanisms to fully characterise the effects of large periodic deformations on solute transport and mixing

PROBLEM FORMULATION AND THEORETICAL MODEL

Domain

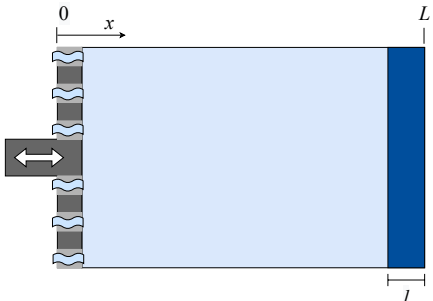

Figure 1: Scheme of the considered domain.

A schematic representation of the considered domain is shown in figure 1. We consider a soft porous medium of length L, subject to a periodic loading. The deformation is applied at the left boundary, which is, therefore, a moving boundary. Moreover, the left boundary is permeable, thus allowing fluid movement due to the applied stimulation. The right boundary is instead assumed to be fixed and impermeable. The solute is initially localised against the right boundary in a strip of width l. This formulation allows a one-dimensional analysis along the loading axis (x).

Theoretical Model

Our model comprehends a mechanical formulation – describing the coupling between deformation and fluid flow – and a transport formulation – providing the effects of fluid flow on the solute movements.

For the mechanical aspects, we formulate an evolution equation for the porosity field following the model developed by MacMinn *et al.* [1], through a rigorous nonlinear kinematic approach. We therefore apply the conservation of mass

*Corresponding author. E-mail: matilde.fiori@eng.ox.ac.uk

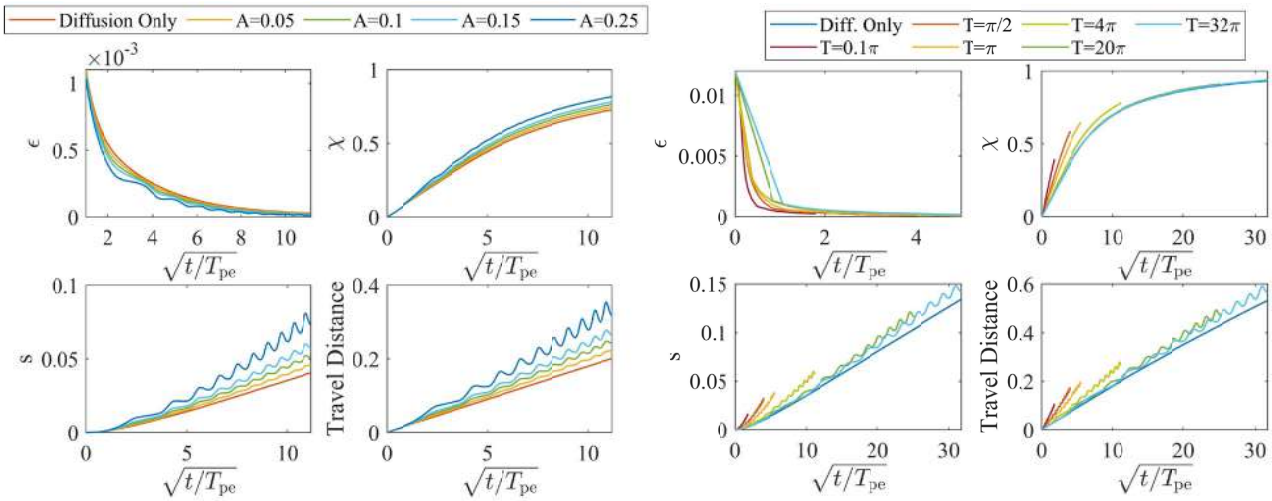

Figure 2: Results of varying the loading amplitude A (left) and the loading period T (right). In both cases, from left top to right bottom, the mixing rate ϵ, degree of mixing χ, spread s and travel distance are reported.

and Darcy's law, coupled with mechanical equilibrium through Terzaghi's effective stress. For the constitutive behaviour of the solid, we assume a deformation-dependent permeability and Hencky elasticity.

The evolution equation regulating solute transport is again formulated in terms of the evolving porosity field – weighted by the solute concentration – and includes contributions from advection, molecular diffusion and hydrodynamic dispersion, through the relevant coefficients.

RESULTS AND DISCUSSION

Isolation of transport mechanisms

In the first part of the study, we are able to isolate and examine the effects on the initial concentration profile of the transport phenomena by showing how each mechanism is individually responsible for a specific change in the shape and spread of the concentration profile. Moreover, we demonstrate that spread and contraction of the profiles are due the periodic changes in the pore space and fluid velocity. This analysis allows us to understand how the transport mechanisms are regulated by the evolving porosity and by the complex coupling between deformation and velocity fields.

Parameter Exploration

Next, we observe the effects on solute mixing and transport due to several parameters, like the loading amplitude, period and number of cycles, the values of the diffusion and dispersion coefficients, the amount of fluid and the amount of solute initially in the domain. In figure 2 we show two examples: in the first plot, we compare how mixing and transport of solutes are affected by different loading amplitude, while in the second plot we analyse different loading periods, keeping the amplitude fixed. From these examples, we can conclude that higher amplitudes lead to higher mixing and travelling of the solutes, as advection and hydrodynamic dispersion are enhanced. When considering different stimulation frequencies, instead, we show that longer periods behave more like pure molecular diffusion, while shorter periods highly enhance advection and hydrodynamic dispersion.

Overall, we observe that a periodic and reversible deformation for the material does not lead to reversible solute profiles. Furthermore, solute transport and mixing are highly dependent on several parameters describing the load applied and the material properties.

CONCLUSIONS

We provide a computational analysis to describe solute transport and mixing in soft porous media subject to large periodic deformation.

Overall, our results can have two main applications: first, they can be useful to predict solute transport and mixing given a certain set of fixed parameters; on the other hand, they can be used to control the final solute distribution by tuning the relative conditions. In the future, we will need to validate the model experimentally.

INTERMITTENT WATER TRANSFER: A WETTABILITY MODEL FOR POROUS MEDIA

Florian Cajot*[1] and Philippe Beltrame †[2]
[1]INRAE, UMR EMMAH, Avignon, France
[2]Avignon Université, INRAE, UMR EMMAH, Avignon, France

Summary We simulate water transfer in partial wetting porous media especially hydrophobic. A variant of Darcy-Richards model is considered by taking into account interactions between free surface of water and the porous matrix surface. These interactions lead to introduce new terms in the capillary pressure : effective repellent interaction and effective surface tension. The summation of the capillary pressure and the repellent pressure allows to represent partial wetting phenomena as the dis- and con-joining pressures for thin film on substrate. Using a 1D Finite Elemental code, we observe numerically a finite water spreading in the porous medium and we capture intermittent-like behavior at the interface of a stratified medium with two different grain sizes.

INTRODUCTION

Water transfer in unsaturated porous media displays phenomena still poorly understood as the fingering instability of the wetting front, water pinning and depinning in heterogeneous media. These phenomena are enhanced in the presence of hydrophobicity due, for instance, to organic matter. In the Darcy-Richards equation, the wetting property is defined via the capillary rise and the pressure head. In such a model, the water content diffuses towards the dryer region and thus cannot reproduce the water trapping. To take into account the front hysteresis, models based on the analogy of the contact angle of a water front on the surface are found in literature, for instance in [4].
In contrast, in the present study, we aim at describing the wettability via surface energy at interfaces. An effective term of short-range repulsion is introduced modeling the interaction between the porous matrix and thin water films. According to [1], this term is non negligible at low saturation. The sum of this repulsive term with the capillary pressure constitutes the analogous of con- and dis-joining pressures describing the interaction of partial wetting liquid [6]. An effective surface tension proposed in [3] is also taken into account. After detailing the model, we apply the model for stratified media with different porosity. The 1D simulation is performed using Finite Element Method.

MODEL

Our model is a generalization of Darcy-Richards equation of a porous medium with saturation s. Initially the Darcy-Richards equation only takes into account the hydraulic conductivity $K(s)$, the gravity $g_r\vec{x}$ and the capillary pressure $P_c(s)$ given by the Genutchen Mualem model [7]. Partial wetting or hydrophobicity are modeled by adding a repellent pressure $P_r(s)$ with opposite sign to the capillary pressure. Note that for hydrophilic media as sand, this term exists as reported by the experiments in [1] pointing out the hydrophobic behavior for low saturation in the sand. Therefore, we note the disjoining pressure of the porous medium $\Pi(s) = P_c - P_r$. The graph of the variation of Π and P_c w.r.t. the saturation s are displayed (Fig. 1a). The disjoining pressure differs from the capillary pressure only for low saturation.
Finally, we introduce a macroscopic surface tension T as described in [3] which takes into account the additional surface energy due to the water free surface. This term has also proved crucial in regularising instabilities generated by repulsive pressure. Thus, the generalized Darcy-Richards equation reads in dimensionless form:

$$\frac{\partial s}{\partial t} + \nabla \cdot \left[K(s)\nabla\left(\Pi(s) + g_r x + T\Delta s\right)\right] = 0. \tag{1}$$

where Δs is the Laplacian operator applied to s and according to [3] it represents the pressure contribution due to the effective surface tension.
Eq. (1) is a fourth order and nonlinear Partial Differential Equations (PDE). This equation is reminiscent of the lubrication equation with wettability in the thin film theory [6]. We expect then front instability and intermittent flow as shown in [2].

RESULTS

We mainly focus on 1D stratified media consisting of a silica sand layers alternating fine and coarse grains as presented in [5]. The experiment of this reference shows that when the wetting front arrives from fine-grain to a coarse-grain layer, the front progress stops. This stage is followed by the development of protrusions, which rapidly grow into fully fledged finger structures.
To model the stratified medium, we consider a variable conductivity $K(s, x)$ depending on the depth x and also a variable disjoining pressure $\Pi(s, x)$. Indeed, when the grain size increases surface area of the grains per unit volume decreases

(a) (b)

Figure 1: (a) Disjoining pressure [red] in Darcy-Richards model and [blue] in the variant form. (b) Saturation time evolution in depth x, in a stratified porous medium. [black] boundary of the different layers : coarse and fine, [red] initial saturation s_0 and [blue] intermittent like behavior. The conductivity contrast $C_K = 0.048$ and the wettability contrast is $C_W = 5$.

leading to lower amplitude of the disjoining pressure. Then, we define the wettability contrast C_W by the ratio of the disjoining amplitude in the fine-grain layer over the amplitude in the coarse-grain layer. In a similar way, we define the conductivity contrast C_K.

The time integration of Eq. (1) shows that the profile $s(x,t)$ converges to a stationary state where the water saturation is larger in the fine grain than in the coarse grain layer. However, for specific parameters the flow can be intermittent (Fig.1b). We identify two main parameters providing intermittent flow. Firstly, the wettability contrast should be large enough, in the simulation (Fig. 1b), the wettability amplitude decreases by 80%. Secondly, the coarse-grain layer has to be dry, i.e. the saturation has to be about 5%. This value of saturation points out the key role of the repellent pressure $P_r(s)$.

Note that the effective surface tension is not the cause of the intermittent behavior but it plays a role on the quantitative properties of the intermittent dynamics.

CONCLUSION

Taking account to surface energies especially wettability by a disjoining pressure into a variant model of Darcy-Richards equation, we capture intermittent-like behavior in a stratified medium. This study showed that the relevance of a repellent contribution in the interaction at low saturation, even if the medium is hydrophilic.

The results suggests that the front can be unstable, in coming works, we will develop a 2D code to study fingering phenomenon.

Finally, This model could be applied to hydrophobic porous media such as soils in the presence of organic matter.

NON-STATIONARY LIMIT CYCLE OSCILLATIONS OF A RESTRAINED SLENDER POINTED BODY WITH A BLUNT ELLIPTICAL BASE AT HIGH INCIDENCE

Oded Gottlieb, Mark Ishay, and David Degani
Department of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary: The response of a restrained slender pointed body with a blunt elliptical base is investigated numerically at high incidence in uniform flow. The flow is three-dimensional and laminar (with 30,000 Reynolds and 0.2 Mach numbers), whereas the body is restrained to rotate in the yaw direction only. The solutions are determined after removal of an initial disturbance and loss of periodicity is determined via Poincare' sampling of the upward zero-crossing side force. The resulting yaw response exhibits an intricate bifurcation structure that includes bi-stable periodic (finite amplitude) and non-stationary (small amplitude) limit cycles for moderate angles of attack, and non-stationary (finite amplitude) oscillations for high angles of attack. Investigation of the restraint torsion stiffness reveals an amazing resonant lock-in phenomena with quasiperiodic solutions for a 40° angle of attack.

INTRODUCTION

The flow around a pointed slender body of revolution at high incidence can generate significant side forces. The flow field can be so unstable that even upcoming turbulence or a small upstream disturbance can change the flow abruptly. It has been shown that these side forces can be altered by placing small irregularities near the body tip. Thus, when such a slender-body model is mounted on a balance in a wind tunnel, the nonlinear interaction between the flow and the structure can play a significant role on the configuration stability, and therefore, on the measurements. A numerical investigation of the fluid-structure interaction taking into account the elastic effects of the restraint has revealed existence of periodic and nonstationary oscillations for moderate and large angles of attack [1] culminating with an intricate bifurcation structure that included coexisting quasiperiodic tori and chaotic solutions foliated with periodic ultra-subharmonics [2]. Furthermore, a numerical investigation of a free-to-roll slender rigid-body of revolution placed in a wind tunnel at a high angle of attack (where the resistance to roll moment and bearing friction were represented by a linear viscoelastic torsion spring) revealed bi-stable periodic limit-cycle oscillations, which lost their periodicity with increasing stiffness of the restraining spring [3]. To date, the effect of the body's end on flow instabilities has not been systematically investigated and most research has focused on the effect of the pointed forebody as the body was very long and the base flow had little effect on the flow at the front of the body. Thus, in order to investigate the influence of a blunt elliptical base on the fluid-structure interaction of a slender pointed body, we consider a short inclined rigid tangent ogive-cylindrical body mounted on a viscoelastic torsion spring that is restrained to yaw (see Fig.1-left where spring is located at the coordinate system origin) and represents the resistance to a side-force induced moment and bearing friction. We focus on the self-excited limit cycle oscillations describing the restrained yaw response and the resulting wake pattern. The body is subjected to three-dimensional, compressible, laminar flow with a body diameter based Reynolds number of 30,000 and Mach number of 0.2. The second-order implicit Beam-Warming finite-difference scheme is employed to numerically solve the full Navier-Stokes equations, whereas the coupled structural equation is solved by an explicit 4th-order Runge-Kutta method. We employ a sub-iteration procedure for the flow-structure coupling and investigate the response after removal of an initial disturbance located near the ogive point.

RESULTS

We summarize the behaviour of the restrained yaw limit cycles for a fixed value of torsion stiffness in a bifurcation diagram (see Fig.1-right) which depicts four distinct regions of maximal limit cycle amplitude vs angle of attack (α): i) unique finite amplitude periodic oscillations [0°<α<20°], ii) coexisting bi-stable periodic finite amplitude and non-stationary small amplitude oscillations, [20°<α<35°], i) unique finite amplitude periodic oscillations [35°<α<45°], and iv) non-stationary finite amplitude oscillations, [α>45°].

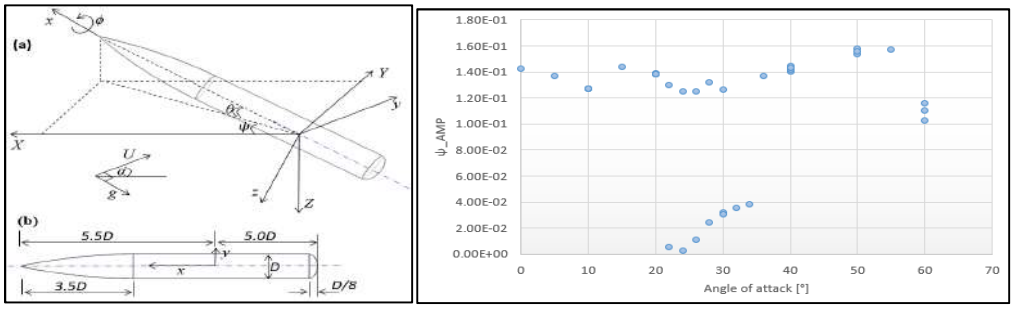

Figure 1. Body and coordinate system (left), and bifurcation diagram of yaw amplitude (right).

A comparison of the yaw phase planes with overlaid Poincare' maps and span-wise helicity contours between the moderate (α=30°) and high (α=50°) angles of attack (see Fig.2) clearly demonstrates the transition from a periodic structure with regular shedding of a fluctuating wake along the body (Fig.2-top) to a non-stationary structure with an irregular fluctuating wake (Fig.2-bottom). We note that limit cycle periodicity was determined by the yaw power spectra (not shown) the Poincare' map sampled every upward zero-crossing of the corresponding side force [2].

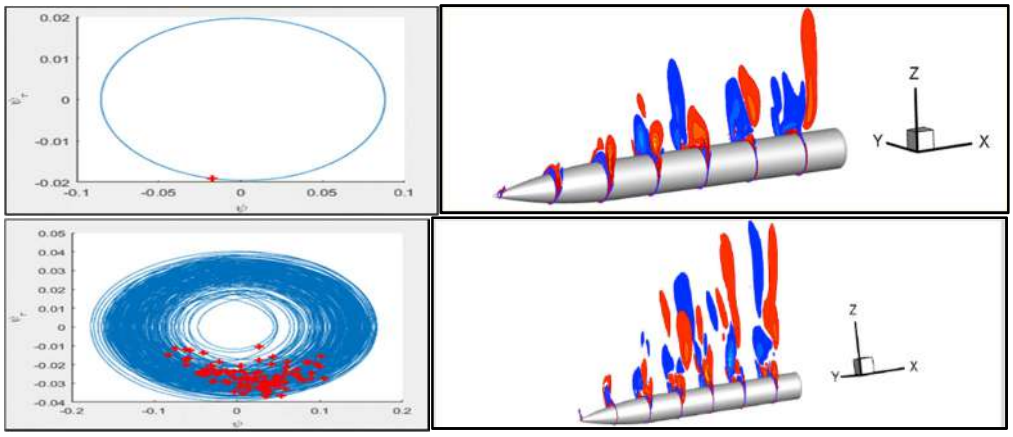

Figure 2. Yaw phase plane overlaid with Poincare' map (left) and span-wise helicity contours (right) for a finite amplitude periodic and nonstationary responses for moderate (top - α=30°) and high (bottom - α=50°) angles of attack respectively.

We also summarize the effect of the torsion spring stiffness on the yaw amplitude (see Fig.3-left) for a moderate angle of attack (α=40°) via the system reduced velocity (U*) defined here by the ratio of Mach number and the square root of the system torsional stiffness [$U^*=(U_\infty/Df_n)=(2\pi Ma/\sqrt{k_\psi})$]. The results reveal a distinct region of synchronization [4<U*<12] where the governing limit cycle frequency was very close to the system natural frequency and two desynchronized regions below and above the synchronized region. This phenomena represents resonant or lock-in behaviour found for both restrained circular cylinders [4] and tethered spheres [5] in uniform laminar flow but for significantly lower Reynolds numbers. A striking difference between the response here and results in literature for cylinders and spheres (where the synchronized response is periodic), is the appearance of synchronized quasiperiodic yaw in the resonant lock-in range (see Fig.3-midle) possibly due to the high Reynolds number of this work.

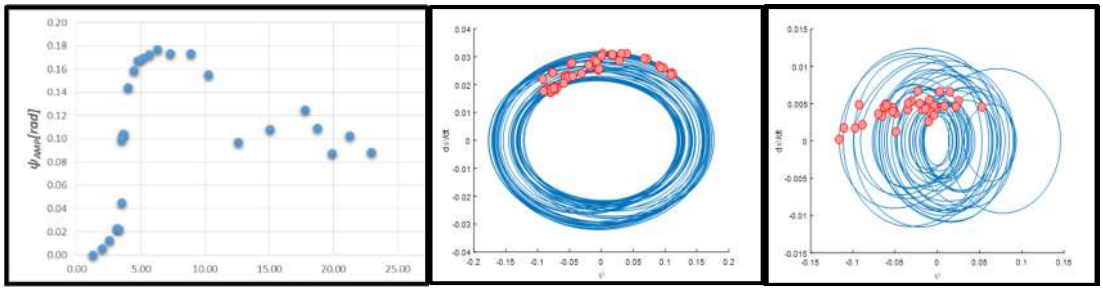

Figure 3. Maximal yaw angle amplitude (ψ_{AMP}) vs reduced velocity (U*) for α=40° (left) and phase planes overlaid with Poincare' maps for reduced velocities in the resonant lock-in range (middle- U*=6.3) and in the desynchronized range (right- U*=21.2).

CLOSING REMARKS

A numerical investigation of a pointed slender body of revolution restrained to yaw reveals an intricate bifurcation structure that includes: (i) periodic limit cycles for small angles of attack, (ii) bi-stable periodic (finite amplitude) and non-stationary (small amplitude) limit cycles for moderate angles of attack and (iii) non-stationary oscillations for large angles of attack. We note that the effect of the blunt elliptical base on the response of the short ogive-cylinder is to modify the classical supercritical bifurcation structure [2] where no restrained body motion was observed below a specific threshold whereas the response here (Fig.1-left) is reminiscent of a galloping like structure augmented by finite amplitude periodic limit cycles below the threshold for small amplitude oscillations.

FLEXIBLE FSI: FROM CARDIOVASCULAR MODELING TO AIR BLAST

Yuri Bazilevs*[1]
[1]School of Engineering, Brown University, Providence, RI, USA

Summary A general, flexible FSI framework is developed to accommodate a variety of applications of contemporary interest and importance in engineering and sciences. The framework is specialized to a set of concrete applications, and its veracity and potential are shown for cardiovascular mechanics, wind energy, and air blast applications.

FLEXIBLE FSI FRAMEWORK

Fluid–structure interaction (FSI) simulations at full scale are essential for accurate modeling in engineering and sciences. The motion and deformation of the solid/structure depends on the flow of the surrounding fluid, and the fluid flow patterns depend on the motion and deformation of the solid/structure. In order to simulate the coupled problem, the equations governing the fluid and structural mechanics need to be solved simultaneously, with proper kinematic and dynamic conditions coupling the two physical systems. Without that the modeling cannot be realistic.

To obtain high-fidelity predictive simulation of science and engineering systems of interest, 3D modeling is essential. However, such simulations engender a number of challenges that need to be addressed. The flow is often fully turbulent or transitional, requiring accurate and robust approaches to modeling turbulence, as well as the use of increased grid resolution. The presence of fluid boundary layers, where turbulence is created, complicates the situation further. Structures are often geometrically complex and slender, while solids often exhibit nearly incompressible behavior and localization of deformation due to strain softening constitutive behavior, all of which requires numerical approaches that are geometrically flexible, and avoid locking and other instabilities. FSI of structural systems often involves moving and stationary components, which require special treatment. Finally, algorithms for FSI coupling must be accurate, efficient and robust to preclude divergence of the computations.

To address the aforementioned challenges, in [1], we developed a framework for (FSI) modeling and simulation with emphasis on non-matching fluid–structure interface discretizations. We take the augmented Lagrangian approach to FSI as a point of departure. Here the Lagrange multiplier field is defined on the fluid–structure interface and is responsible for coupling of the two subsystems. Thus the FSI formulation does not rely on the continuity of the underlying function spaces across the fluid–structure interface in order to produce the correct coupling conditions between the fluid and structural subdomains. However, in deriving the final FSI formulation the interface Lagrange multiplier is formally eliminated and the formulation is written purely in terms of primal variables. Avoiding the use of Lagrange multipliers adds efficiency to the proposed formulation. As an added benefit, the ability to employ non-matching grids for multi-physics simulations leads to significantly relaxed requirements that are placed on the geometry modeling and meshing tools.

APPLICATIONS

Cardiovascular FSI Modeling

In patient-specific cardiovascular FSI, the vascular wall motion, in many cases, is relatively modest. The motion occurs largely due to the global pressure variations in the blood vessel during the heart beat cycle, and it does not produce a significant effects on the global features of the blood flow. The influence of vascular wall elasticity is most pronounced when it comes to predicting wall quantities, such as the wall shear stress (WSS) and oscillating shear index (OSI), which

are well known key factors that influence the onset and progression of atherosclerosis. As a result, staggered or block-iterative solution strategies for FSI [2], which essentially involve a sequence of standalone fluid and structural mechanics solves, present an efficient way of dealing with this problem class. When it comes to the simulation of cardiovascular devices, such as pulsatile ventricular assist devices (PVADs, see Figure 1 and [3]) or prosthetic heart valves [4], the underlying structural motions are complex, often times exhibiting topology change (or near topology change). The structure added mass is often high, requiring the use of quasi-direct FSI solution strategies [2] in order to make the computation converge. We focus on FSI of PVADs [3] and simulate the Berlin Heart, a pediatric pump that is known to cause a large number of thrombolytic events. To address the blood clotting issue, we developed a technique that allows us to assess the pump efficiency on terms of average particle residence time in the blood chamber, which is known to correlate with blood clotting. A formal shape optimization framework is deployed in conjunction with FSI modeling and particle-residence-time computation to obtain a new pump design that minimizes average particle residence time in the blood chamber.

Wind-Turbine FSI Modeling

We make use of the flexible FSI framework developed to target more advanced FSI simulations of wind turbines. For this, we illustrate how the recent advances in Isogeometric Analysis (IGA) [5] of thin structures may be used for efficient structural mechanics modeling of full wind turbine structures, including tower, nacelle, and blades. We consider both horizontal axis and vertical axis wind turbine designs. We enhance the sliding–interface formulation of aerodynamics [6], to handle flows about mechanical components in relative motion such as rotor–tower interaction to allow nonstationary sliding interfaces. To accommodate the nonstationary sliding interfaces, we developed a new mesh moving technique and present its mathematical formulation. The numerical examples include structural mechanics verification for the new offshore wind turbine blade design, FSI simulation of a horizontal axis wind turbine undergoing yawing motion as it turns into the wind and FSI simulation of a vertical axis wind turbine. The FSI simulations are performed at full scale and using realistic wind conditions and rotor speeds. We conclude by presenting the FSI simulation of two 5MW wind turbines operating in a thermally-stratified atmospheric boundary-layer (ABL) flow (see Figure 1(b)).

Air-Blast FSI Modeling

The flexible FSI methodology is more recently extended to develop a computational framework for air-blast FSI applications that combines the attractive features of both Eulerian- and Lagrangian-frame based methods [7,8]. The underlying numerical formulation makes use of two meshes – background and foreground – to discretize, in the variational (e.g., Galerkin) framework, the governing equations of the coupled FSI problem. The foreground mesh is "immersed" in the background mesh, and thus the proposed methodology belongs to a class of immersed methods. The background mesh basis functions approximate the kinematic and field variables (i.e., velocity, temperature, etc.) of the coupled problem in the variational framework. The foreground mesh, which is moving with the material-particle velocity computed on a background mesh, is used to track the material interfaces, to carry out the numerical quadrature of the solid domain, to perform the stress update, and to solve auxiliary ordinary or partial differential equations (PDEs) employed in the modeling framework in order to represent additional phenomena. Figure 1(c) shows a 3D simulation of cone blast near a concrete block. Interaction of air, detonation gas products, and concrete is simulated. Mushroom cloud of the detonation gas products (blue) is immersed into the air domain. Concrete particles (red) separate from the block forming a crater on the top surface.

STABILITY BOUNDARIES AND FLUID DAMPING OF ELASTICALLY-MOUNTED PITCHING SWEPT WINGS

Yuanhang Zhu* , Yunxing Su, and Kenneth Breuer
School of Engineering, Brown University, Providence, RI 02912, USA

Summary We experimentally study the nonlinear stability characteristics and the role of fluid damping for elastically-mounted pitching swept wings using a cyber-physical system. We show that the onset of large-amplitude limit-cycle oscillations (LCOs) depends on the static characteristics of the wing. The non-monotonic variation of the stability boundary for different sweep angles is conjectured to be the competition between two mechanisms: (*a*) the stabilization of leading-edge vortices (LEVs) by wing sweep, which promotes LCOs and thus destabilizes the system, and (*b*) fluid damping, which damps out LCOs and thus stabilizes the system. We characterize the fluid damping by performing 'ring down' experiments in quiescent water and show that fluid damping increases with sweep angles.

INTRODUCTION AND EXPERIMENTAL SETUP

Fluid-structure interactions of elastically mounted pitching wings is central in many applications. Recent works explored the effect of different parameters on the dynamics and flow physics of such systems. Menon and Mittal [1] numerically investigated the effects of structural damping, initial angle of attach (AOA) and the location of pivot axis on the flow-induced oscillations of passively pitching two-dimensional wings. Zhu *et al.* [2] experimentally studied the effect of inertia and stiffness on the stability boundaries of a cyber-physical pitching two-dimensional wing and reported super- and sub-critical transitions to large-amplitude LCOs for low- and high-inertia wings respectively. However, the effect of wing sweep on the stability characteristics of elastically mounted pitching wings remains unclear. We address this problem in the present study.

A schematic of the experimental setup is shown in Figure 1(*a*). Five NACA 0012 wings with sweep angle $\Lambda = 0°, 10°, 15°, 20°, 25°$ are tested in the present study. All the wings have a chord length of $c = 0.1$ m and a span of $s = 0.3$ m. The pivot (elastic) axis is a vertical line passing through the mid-chord point on the mid-span plane. A side view of the five wings is shown in Figure 1(*b*). The wing is mounted vertically in a water tunnel with a zero initial AOA. An endplate is added to the top of the wing to eliminate tip vortices at wing root. The structural properties of the wing are controlled by a cyber-physical system. The non-dimensional parameters used in the present study are inertia, I^*, damping, b^*, stiffness, k^*, and the fluid force (moment coefficient), τ_f^*. The inverse of k^* is the Cauchy number Ca, which defines the ratio between the fluid inertia force and the elastic restoring force. The Reynolds number, Re, is kept at 50,000 for all the stability boundary tests and static force measurements (Figure 1(*b*)(*c*)). For all the experiments testing the fluid damping (Figure 2), the water is quiescent. Detailed description and validation of the cyber-physical system and the definition of non-dimensional parameters can be found in [2].

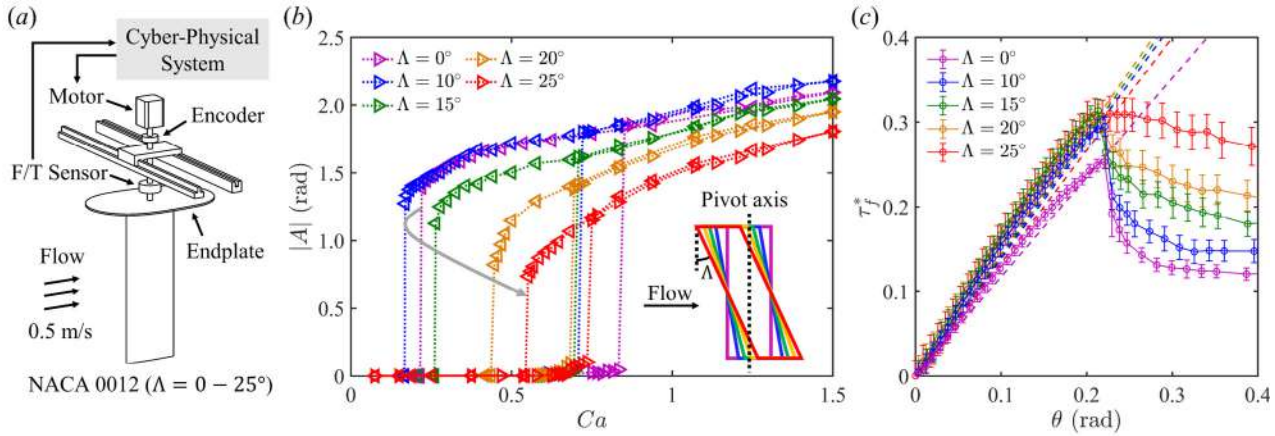

Figure 1: (*a*) A schematic of the experimental setup. (*b*) Bifurcation diagram at $I^* = 10.6$ and $b^* = 0.13$ for five wings ($\Lambda = 0°, 10°, 15°, 20°, 25°$). ▷: increasing Ca, ◁: decreasing Ca. (*c*) Static moment measurements.

RESULTS AND DISCUSSION

Stability boundaries of elastically mounted pitching swept wings

In the experiments, we fix $I^* = 10.6$ and $b^* = 0.13$, and incrementally vary Ca to define the stability boundaries of five wings with different sweep angles. Figure 1(*b*) shows the bifurcation diagram, in which the system response is represented by the pitching amplitude $|A|$. For all the wings, as Ca is increased, the system undergoes a subcritical bifurcation to large-amplitude LCOs, evidenced by an abrupt amplitude jump and a region of hysteretic bistability [2]. It is shown that both the onset and extinction of large-amplitude LCOs vary with the sweep angle. We attribute the difference in the onset point to the different static characteristics of the wings. Figure 1(*c*) shows that the static moment coefficient of the five wings can be divided into two groups, because the $\Lambda = 0°$ wing experiences lower static fluid force compared to the other four wings. This grouping is also evident in the results presented in Figure 1(*b*), where large-amplitude LCOs

*Corresponding author. E-mail: yuanhang_zhu@brown.edu

are seen to occur at a higher critical Ca for the $\Lambda = 0°$ wing. The critical elastic restoring force, $k_c^*\theta$, where k_c^* is the critical wing stiffness, is plotted using dashed lines in Figure 1(c) for all the five wings. It can be observed that all of the dashed lines coincide with the static stall point, which further suggests that the onset of large-amplitude LCOs is related the static characteristics of the wing.

As shown by the gray arrow in Figure 1(b), the extinction point (i.e. the saddle-node (SN) point) of the large-amplitude LCOs changes non-monotonically with the sweep angle. We conjecture that this non-monotonic behavior is due to the competition between two mechanisms, the destabilizing effect brought by the wing sweep and the stabilizing effect caused by the fluid damping. For $\Lambda = 0° - 10°$, the SN point extends to lower Ca, indicating that the system becomes more unstable. Previous studies [1, 2] have shown that large-amplitude LCOs are associated with the formation and shedding of strong LEVs. The persistence of LCOs at lower Ca for $\Lambda = 10°$ indicates that LEVs become more stable as compared to $\Lambda = 0°$. This agrees with previous findings [3, 4] that the wing sweep has a stabilization effect on LEVs by strengthening spanwise vorticity transport. For higher sweep angles ($\Lambda = 10° - 25°$), the large-amplitude LCOs die down at higher Ca, suggesting that a stabilizing mechanism comes into play. We think this stabilizing mechanism is fluid damping, because under the same pitching amplitude, wings with a higher sweep angle move more fluid due to larger tip motion. Due to high fluid damping, the pitching amplitude also decreases with Λ.

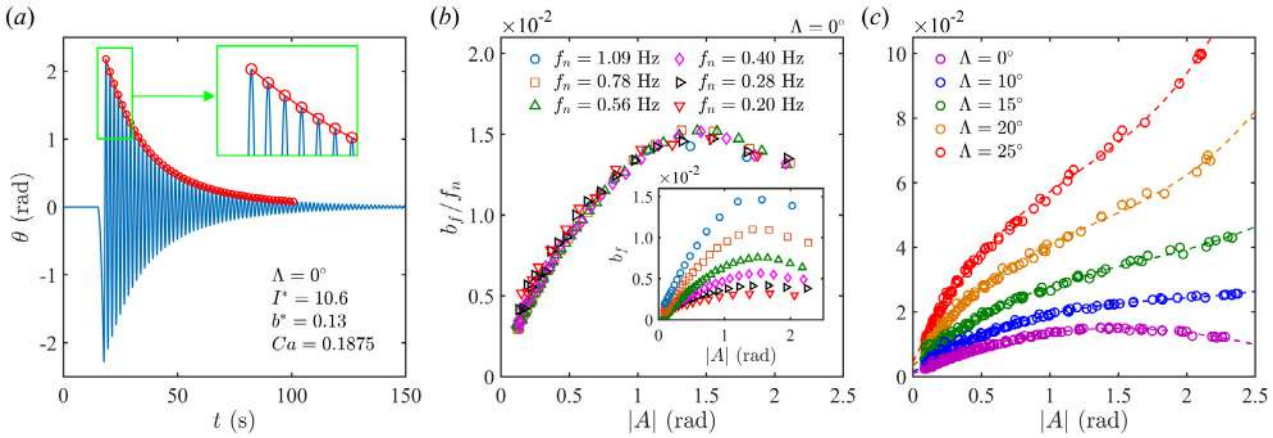

Figure 2: (a) An example of free damped oscillations. (b) Fluid damping scaling for the $\Lambda = 0°$ wing. Inset: Fluid damping versus pitching amplitude. (c) Fluid damping scaling for different wings. Note that (b) and (c) share the same y-axis label.

Fluid damping of swept wings in quiescent water

To characterize the fluid damping, we perform 'ring down' experiments in quiescent water, where we perturb the elastically mounted wing and analyze the amplitude evolution of the free oscillation. Figure 2(a) shows the result from a typical 'ring down' experiment. As shown in the zoom-in inset, for every two adjacent peaks (one cycle), we calculate the total cycle-averaged damping of the system by fitting an damped exponential to the two peaks. The structural damping is then subtracted from the total damping to get the cycle-averaged fluid damping, b_f. The corresponding pitching amplitude, $|A|$, is calculated to be the average amplitude of the two peaks. By changing the combination of I^* and k^*, we repeat the 'ring down' experiments for six different natural frequencies (f_n) and plot the result in the inset of Figure 2(b). It is seen that b_f increases non-monotonically with $|A|$ for a fixed f_n, and monotonically with f_n for a fixed $|A|$. When b_f is divided by f_n (Figure 2(b)), all the data points for different f_n collapse into one curve, indicating b_f/f_n is a good scaling parameter for the fluid damping. The 'ring down' experiments are repeated for the other four swept wings ($\Lambda = 10° - 25°$) and for each Λ, we are able to collapse the data points for different f_n using b_f/f_n, as shown in Figure 1(c). We observe that for a fixed $|A|$, b_f indeed increases with Λ. The b_f/f_n for each Λ can be accurately fit by a 3rd-order polynomial curve (dashed lines), and when Λ is high, b_f/f_n increases sharply, indicating the strengthening of nonlinear effects.

CONCLUSIONS AND FUTURE WORK

The onset of large-amplitude LCOs has been shown to depend on the static characteristics of the wing. The non-monotonic variation of the SN point has been attributed to the competition between a destabilizing mechanism brought by the stabilization of LEVs and a stabilizing mechanism caused by fluid damping. We have characterized the fluid damping for swept wings in quiescent water. A fluid damping scaling has been proposed and it has been shown that wings with higher sweep angles experience higher fluid damping. Our hypothesis that the system becomes more unstable because LEVs are stabilized by the wing sweep requires more experimental evidence and the next step is to characterize the effect of wing sweep on the LEV stability using 3D PIV experiments.

DEFORMATION OF FLEXIBLE MICRO HELICES UNDER FLOW-INDUCED VISCOUS FORCES

[1]Laboratoire de Physique et Mécanique des Milieux Hétérog`enes (PMMH), UMR7636 CNRS, ESPCI Paris, PSL Research University, Sorbonne Université, Université de Paris, Paris, France
[2]Polymer Science and Engineering Department, University of Massachusetts, Amherst, MA, USA

Summary The study of fluid structure interactions between helix-shaped particles and viscous flows is of importance for both fundamental science and technological applications. The constitutive chirality of such particles indeed induces breaking of the time-reversal symmetry associated with viscous flows. This effect is exploited by microorganisms, such as E. coli bacteria, to propel themselves through viscous media by rotating helically shaped flagella. In this work, we fabricate flexible micro-helices with vanishing pitch and report use of material creep under stress to modify in a controlled way the helical pitch. We study experimentally the deformation of helical ribbons under flow-induced viscous forces and quantify the influence of the pitch. We report an effective stiffening of the helix as the helix pitch increases.

CONTEXT

In parallel to theoretical studies, biological flagella have been used to understand the viscous flow-helix interactions, highlighting effects such as drifting in simple shear flows [1] or flagella polymorphic transition under high-stress [2]. But the use of these biological systems is intrinsically limited, as their mechanical and geometrical properties (notably chirality) are biologically determined and thus scarcely tunable. As a consequence, numerous methods have been proposed to fabricate tunable artificial helical structure to serve as model systems. Such artificial systems have allowed quantification of the influence of bacterial head size [3] or helix pitch angle [4] on swimming efficiency. These systems open up numerous technological applications such as micro robots for targeted drug delivery [5] or flow sensors. But the influence of the helix elasticity has been so far mostly neglected, as it heavily complexifies both theoretical and experimental approaches. The fabrication of flexible chiral structure at the micro-scale is indeed a challenge.

HELIX FABRICATION AND PITCH CONTROL

In this work, we use ribbons fabricated through an evaporative assembly technique called flow coating [6]. Two different materials were used: poly(methyl methacrylate) (PMMA) and modified poly(2-dimethylaminoethyl methacrylate) (dPDMAEMA). As a result of the asymmetric cross section of the ribbons, ribbons spontaneously coil when immersed into liquids, forming helices. The preferred helix radius is given by a balance between surface tension and elasticity and can be controlled by the ribbon thickness [7]. The preferred helix pitch is zero but a small pitch is observed nonetheless due non-overlap of the ribbon.

We demonstrate that, by taking advantage of the creeping of the material under stress, it is possible to obtain a permanent non-vanishing pitch. This effect is reported for both materials (PMMA and dPDMAEMA). The stress is induced by immersing the helix in a uniform flow, which extends the helix. When the flow is stopped, we observe a persistent non-homogeneous increase of the helix pitch as seen in Figure 1. The pitch change can be controlled by tuning the duration or the intensity of the flow. The stress can also be induced by an end-point force, *i.e.* pulling on both sides of the helix. In this case, preliminary experiments show a uniform increase of the pitch. These observations are consistent with the fact that for viscous forces, the resulting stress is distributed along the helix whereas for end-point forces, the stress is uniform. We note that as a side effect of the applied forces, the helix radius is also modified. Similarly, the subsequent radius change is non-homogeneous for flow-induced stress and homogeneous for stress induced by end-point forces.

HELIX DEFORMATION IN FLOW

This fabrication technique allows us to obtain helical ribbons of controllable pitch. But more importantly, it allows us to vary the pitch of a given helix in a controlled way, all other parameters being unaffected (notably material modulus and ribbon cross-section). We use this effect to isolate and probe the influence of the helical pitch on the deformation of helices in flow. Experiments are conducted as follows: a given flow rate is applied in a microfluidic channel of known dimension, in which a helix is held by a glass capillary. The subsequent helix deformation is tracked by measuring the helix axial length H. The flow is parabolic in the channel but as typical helical radii are small compared to the channel size, we consider that the helix is immersed in a locally uniform flow. The velocity of this flow V is estimated from the computed velocity field and the position of the helix within the channel.

We define a *flow cycle* as a series of flow steps imposed upon a helix at increasing flow rate. A typical flow cycle is shown in Figure 2.(a) along with the measured helix axial extension. For each flow cycle, a velocity-extension curve $\Delta H(V)$ is obtained and the slope α of the linear regime is extracted, as shown in Figure 2.(b). The so-called flow stiffness α quantifies how much a helix is stretched for a given flow velocity. This work-flow is repeated on the same helix for different values of the pitch, which is modified using the procedure described in the previous section. As shown in Figure 2.(c), data suggest that an increase in the helix pitch angle is associated with a smooth decrease in the flow stiffness *i.e.* an effective stiffening of the helix. Possible aging effects were discarded by letting helices sit in water for $24\,\mathrm{h}$ prior to experiments.

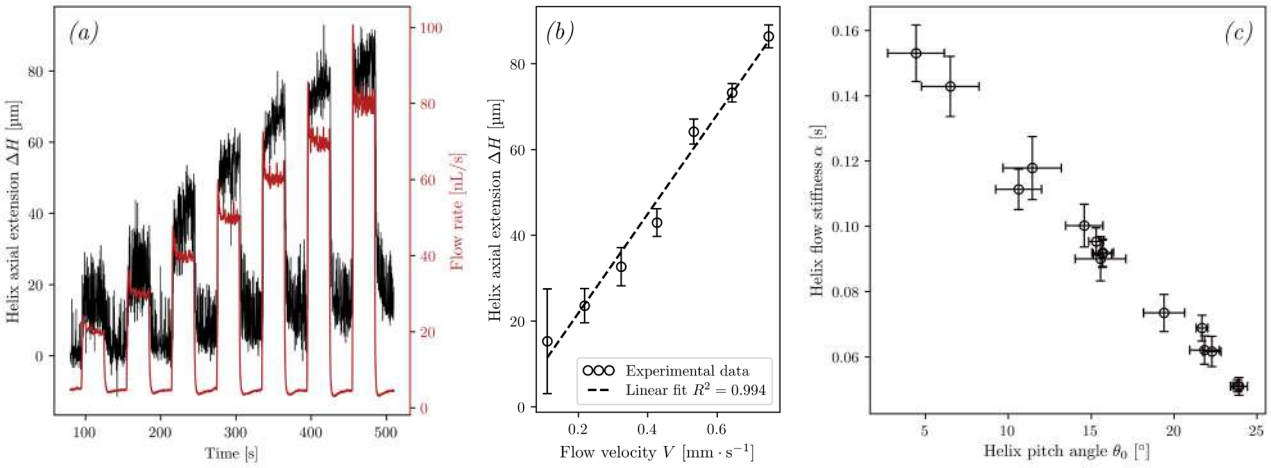

Figure 2: (a) Typical flow cycle applied upon a dPDMAEMA-made helix: the applied water flow rate (in red) and measured axial extension (in black) are plotted as a function of time. (b) Velocity-extension curve obtained from (a) and linear fitting to extract the helix flow stiffness. (c) Helix flow stiffness as a function of the helix pitch angle θ_0, defined as the angle subtended between a circumferential line and the pitch of the helix *i.e.* $\tan\theta_0 = p/2\pi R$.

CONCLUSION AND PERSPECTIVES

We have shown how to fabricate flexible micro helices of controllable radius and pitch. This fabrication method has allowed us to probe the influence of the helical pitch on the helix flow stiffness. We have acquired data suggesting an effective stiffening of the helix as the pitch increases. These experimental findings need to be confronted to recent theoretical modelings [8] to link the helix behavior to material and ribbon properties. A fine understanding of this link can allow characterization of the material, such as measurement of the Young's modulus [9]. Finally these micro-helices can be used to address more complicated problems, such as dynamics of freely transported helically shaped objects.

UNDERACTUATED FLUIDIC CONTROL OF A CONTINUOUS MULTISTABLE MEMBRANE

Ofek Peretz[1], Anand Kumar Mishra[2] , Robert F. Shepherd[2] , and Amir D. Gat[1]

Summary This work addresses the challenge of underactuated pattern generation in continuous multistable structures. The examined configuration is a slender membrane which can concurrently sustain two different equilibria states, separated by transition regions, and is actuated by a viscous fluid. We first demonstrate the formation and motion of a single transition region and then sequencing of several such moving transition regions to achieve arbitrary patterns by controlling the inlet pressure of the actuating fluid. Finally, we show that non-uniform membrane properties, along with transient dynamics of the fluid, can be leveraged to directly snap-through any segment of the membrane.

INTRODUCTION

Pressurization of confined fluids is a leading method for the actuation of such bistable elements, yielding governing dynamics involving both viscous and elastic effects. While the interaction of fluids bounded by elastic structures was extensively studied in recent years (see [1-3] as well as discussion in [4]), only a few researchers examined viscous flow interacting with bi-stable elasticity (e.g., [5-7]). So far, all previous works examined the actuation dynamics of either a single bi-stable element [8,9] or multistable structures [10,11], which are an assembly of discrete bistable elements. In this work, we present, for the first time, analysis and demonstration of fluidic-control of a continuous multistable structure. In contrast with discrete multistable configurations, such continuous structures inherently have infinite possible stable patterns. Importantly, in many of these works, each element has its own control input for inducing transitions between its bi-stable states [13,14]. Therefore, generating complex deformation patterns of such a multistable structure, typically requires control of multiple inputs, which greatly complicates the systems operation. We thus focus on achieving underactuated fluidic control, enabling to arbitrarily pattern such continuous structures by a single pressure inlet.

THEORETICAL AND EXPERIMENTAL RESULTS

The configuration studied in this work is presented in Fig. 1a, showing the experimental setup, including the membrane and a transition region separating between the two different equilibria states. The x coordinate denotes the streamwise direction, where the inlet is located at x = 0. The location of the transition region is denoted by $x_s^-(t) < x < x_s^+$. Initially, the entire membrane is at the snapped-up state. A sudden decrease in inlet pressure initiates snap-down near the inlet (Fig. 1a, region 1). A transition region (Fig. 1a, region 2) then starts propagating, separating the snapped-down region from the membrane segment which remained at the initial snapped-up state (Fig. 1a, region 3). To achieve two stable equilibria states at rest (meaning fluidic gauge pressure $p = 0$), we require both $p_s^{down} < 0$ and $p_s^{down} > 0$. Using this setup, in Fig. 2a we demonstrate the propagation of a single transition region in the channel. The initial state of the membrane is at a snapped-up state, and then we apply a Heaviside inlet pressure function of $p_{in} = -10\,kPa$ at $t = 0\,sec$. The negative inlet pressure creates transition to snap-down near the inlet as well as a transition region separating the snapped-up state far from the inlet. As time progresses, the transition region propagates along the flow direction, and the membrane gradually changes its state from snapped-up to snapped-down. The shape of the membrane at different time intervals is presented in Fig. 2a, where the blue and black lines represent the theoretical and experimental location of the transition region x_s vs. time t. To obtain insight regarding these results, we derived a theoretical model for the propagation of a single transition region in a multi-stable channel (Fig. 2a, black line denotes experimental results, blue line denotes theoretical results and red line denotes inlet pressure profile).

Above, we analytically analyzed and experimentally demonstrated the emergence and motion of a single transition region, and showed that when the inlet pressure returns to its nominal value, the membrane's shape remains nearly unchanged. Thus, by sequencing several inlet pressures, any pattern of a snapped-down and snapped-up regions along the channel can be created. Figure 2b shows the evolution of the membrane shape and presents the location of the transition regions, vs. time, as well as snapshots of the membrane shape at different time intervals. Initially, the channel is entirely at the snapped-up state. Then we applied alternating positive and negative gauge inlet pressures (see red line in Fig. 2b, denoting inlet pressure) to generate moving snap-down and snap-up transition regions, thus patterning the equilibrium state of the continuously multistable membrane.

CONCLUSIONS

To conclude, in this work we addressed the challenge of underactuated control of continuous multistable structures, which could play a vital role in the fields of soft robotics, MEMS, and meta-materials. We focused our study on a simple illustrative configuration composed of an slender elastic membrane, which is actuated by a viscous fluid. The membrane is able to concurrently sustain two different modes of stable cross-section shapes at different segments of the membrane. These different segments are shown to be separated by transition regions, and the location of these regions sets the stable equilibrium shape of the membrane. We theoretically analyzed and experimentally demonstrated the formation and motion of a single, and multiple, transition regions due to manipulation of the fluidic inlet pressure. We showed that sequencing of multiple transition regions enables to achieve underactuated control of the membrane equilibria shape.

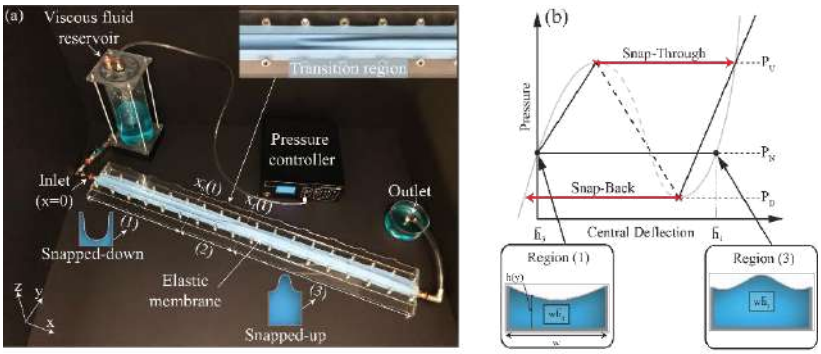

Figure 1: Panel (a) presents an illustration of a bi-stable behavior of a clamped-clamped curved elastic membrane. At the initial state (A), the configuration is at a stable deformation pattern. When pressure is applied on the bottom surface of the membrane, the component deforms gradually until a critical value of the pressure (denoted by p_s^{up}). At this point, the component snaps-through a region of unstable deformation shapes (B) until reaching a second stable deformation pattern (C). At state (C), decreasing the pressure below p_s^{up} will not bring the membrane back to state (A), due to hysteresis effect of the bi-stable dynamics. Snapping back to state (A) requires reaching a different lower critical value (denoted by p_s^{down}), associated with state (C). Panel (b) presents the experimental setup.

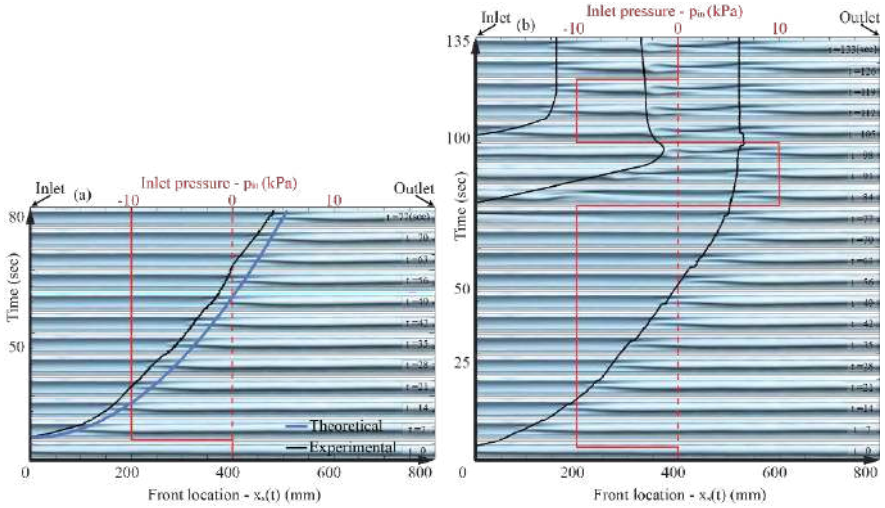

Figure 2: Panel (a) presents experimental and analytical results for a single transition region propagation and the location of the transition region at different time intervals (from 0-80 sec) and at varying inlet pressure ($p_{in} = 0\ to\ -10kPa$). Panel (b) presents experimental results of patterning using multiple transition regions propagation. Initially, the channel is at snapped-up state. Then we applied varying inlet pressures between negative and positive gauge values (red line, denoting inlet pressure) to generate moving snap-down and snap-up transition regions, which allow patterning of the continuously multistable membrane. After sequencing three transition regions (denoted in black line), separating four different stability states are obtained, we removed pressure actuation and the membrane pattern remained stable (see $t = 133\ sec$).

EFFECT OF CHORDWISE FLEXIBILITY ON PROPULSIVE PERFORMANCE OF HIGH INERTIA OSCILLATING FOILS

Summary This work studies the effects of chordwise flexibility and inertia on propulsive performance of an oscillating foil. The foil was undergoing pitch and heave motions in a uniform flow at Re = 80000. Forces exerted on the foil were directly measured using a load cell and were used to calculate the thrust and efficiency values. The phase-averaged quantitative flow patterns in the wake of the foil were obtained using particle image velocimetry. The circulation in the wake was related to the loading on the foil by calculating the moments of vorticity with respect to the pitching axis of the foil. Inertial and pressure forces were responsible for foil deformation at the different phases of the oscillating cycle. The deformation of the foil resulted in an increased wake width, leading to increases in amplitudes of the instantaneous loading on the foil and in the generated thrust coefficient.

INTRODUCTION

The prevalence of oscillating wings found in nature warrants research into the associated biomimetic technologies that could be developed from these principles. When acting as a thrust generator, oscillating-foil designs propose an elegant alternative to conventional rotary propellers, which have limited ranges of operational speeds where efficiency is maximum [1]. Advances in numerical and experimental capabilities in recent years has renewed interest in the subject and facilitated many novel studies including those on flexible foils. It was highlighted that passive chordwise flexibility of the wing or foil can improve propulsive efficiency at the expense of small decreases in net thrust [2]. Research into the effect of inertial properties and its relation to performance of flexible foils has been mainly limited to numerical campaigns, in which this structural property may be varied readily [3], [4]. The present work analyzes flexible foils with high inertia values in a wide parametric space of pitch amplitude and oscillating frequency combinations.

EXPERIMENTAL SYSTEM AND TECHNIQUES

The experiments were performed in a recirculating water channel with a test section that had a length of 250 cm and a cross section of 45x45 cm. The ambient turbulence intensity of the flow was less than 1% for the range of velocities used in the current study. A schematic of the experimental apparatus is shown in Fig. 1a. The foil was centered in the cross section of the flow channel. Heave and pitch motions were controlled independently by separate servo motors. The heave motor was rigidly mounted onto the water channel frame and connected to a linear carriage that generated the heave motion. The pitch motor was mounted onto the heave carriage, to which a loadcell and the test foil were attached. Both heave and pitch motion profiles were sinusoidal, with a phase difference of 90° between them, as shown in Fig. 1b.

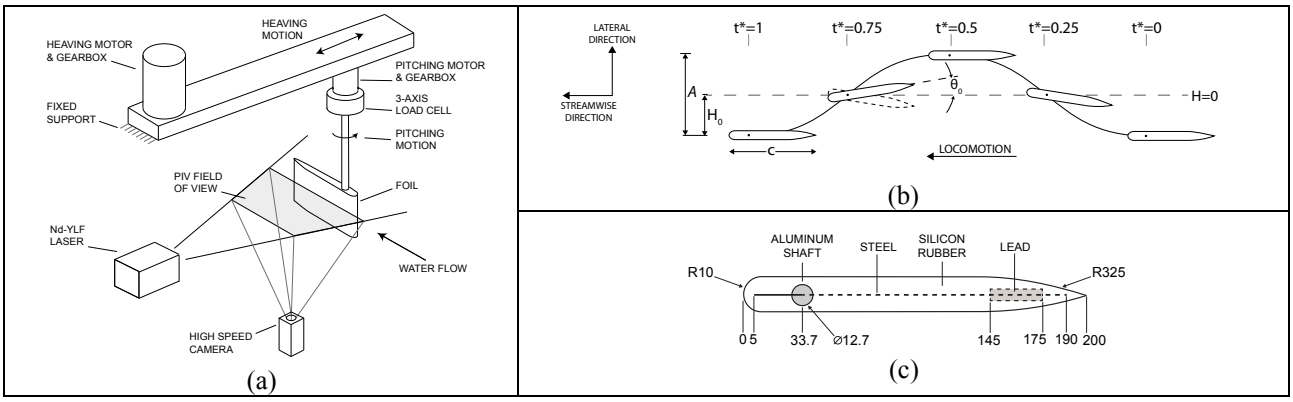

Figure 1. Schematics of the fully-passive turbine (a) and the PIV system (b).

Three foils of identical shape, but with different structural parameters, were used in experiments. All foils had a chord length of c = 200 mm and a span length of b = 140 mm. The cross-section of the foils is shown in Fig. 1c. This geometry was created to allow a weight to be embedded near the trailing edge of one of the foils, positioned at a distance 0.8c from the leading edge. The foil 'R', was constructed of plastic that is from a practical standpoint assumed to be fully rigid. The other two foils were constructed of a flexible silicon rubber. Flexible foil 'A' had a mass of 140 g embedded at the trailing edge location, and was reinforced in the chordwise direction by a stainless steel sheet. The second flexible foil, 'B', was constructed without the steel sheet or lead mass, and consequently was 34% less stiff than foil 'A'.

*Corresponding author. E-mail: poshkai@uvic.ca.

Fluid velocity was measured using high-speed particle image velocimetry (PIV) as shown schematically in Fig. 1a. The flow was seeded with tracer particles with a mean diameter of 10 μm that were illuminated by a pulsed laser. The images were processed with Davis LaVision 8.3 software using a multipass cross correlation technique. The smallest interrogation windows used were 12 pixels x 12 pixels, yielding a resolution of 0.26 vectors/mm.

RESULTS

All experiments were performed at $Re_c = 80000$ and with a heave amplitude $H_0 = 0.188c$. The recorded measurements for cycle-averaged thrust production $\overline{C_T}$ and efficiency η are presented in Fig. 2 for each of the three foils. The generated thrust values monotonically increased as a function of St for any given pitch angle, for all foils. Large positive pitch angles were necessary for high thrust production by the rigid foil, but they were not needed for high thrust production by both flexible foils. Moreover, the flexible foils showed significant increases in efficiency compared to their rigid counterpart.

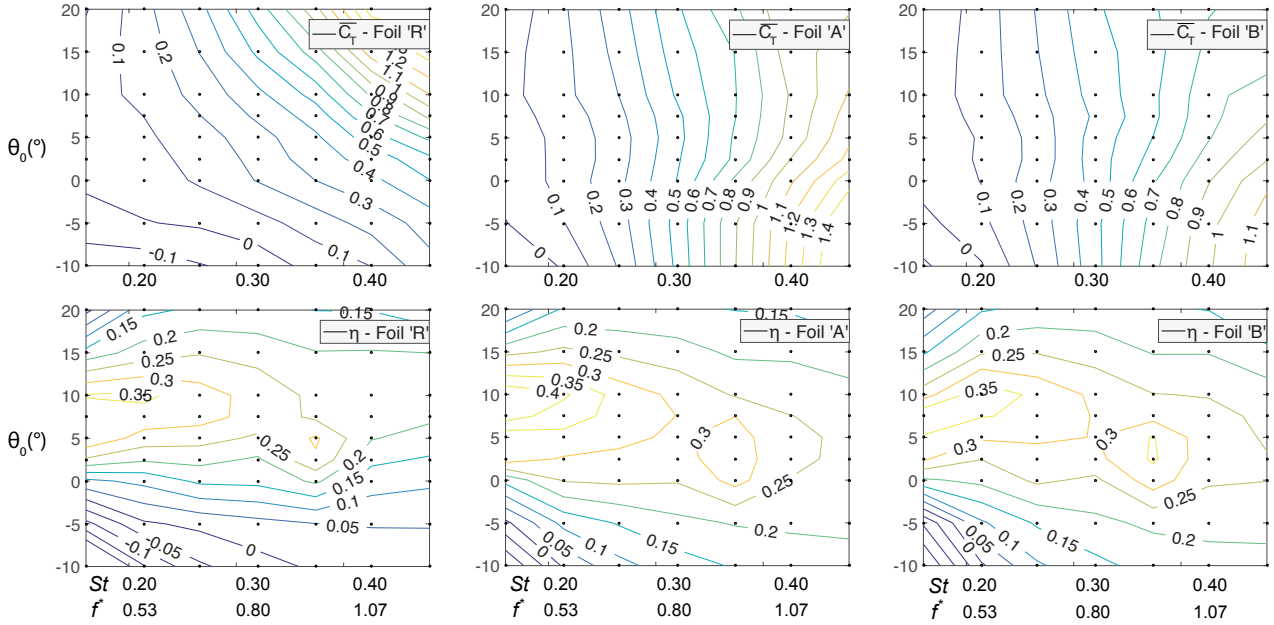

Figure 2. Thrust coefficient (top row) and efficiency (bottom row) as function of pitch angle and Strouhal number for foil 'R' (left column), foil 'A' (middle column) and foil 'B' (right column).

The PIV measurements (not shown herein) indicate that the transverse deflection of the trailing edge, which defined the effective instantaneous angle of attack, determined the timing of the trailing edge vortex shedding and, in turn, the generated thrust and efficiency.

CONCLUSIONS

The trends of propulsive performance observed for rigid and flexible foils differed in terms of response to pitch angles. Inertial forces were the dominant mechanism producing foil deformation at the beginning and at the end of a heave cycle. At the midstroke of the heaving motion, pressure forces were responsible for the majority of deformation. There appears to exist an optimal stiffness level that would result in maximum thrust and efficiency at all St in the considered range. In this scenario, the trailing edge would deform to ~15° when prescribed a pitch angle of ~5°.

LOCK-IN IN FLOW-INDUCED VIBRATION OF SPLITTER PLATES AND MEMBRANES

Mohd Furquan *[1], Tulsi Ram Sahu[1], and Sanjay Mittal[1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Kanpur, Kanpur, India

Summary The phenomenon of lock-in is investigated for flow-induced vibration of flexible structures at low Reynolds numbers. The structures considered are flexible plate attached to cylinder(s), a sail modelled by a flexible membrane mounted normal to the incoming flow, and inflation of a balloon. For the splitter plate, various configurations of the cylinder(s) are considered: a stationary cylinder, a freely vibrating cylinder on elastic support and two stationary side-by-side cylinders. The effect of varying the flexibility of the splitter plates is studied. Lock-in is found to occur with the first two Euler-Bernoulli modes of the splitter plate. The cylinder on elastic support vibrates out-of-phase with the tip of the plate when the plate is very flexible, and in-phase when the plate is stiff. This reversal in phase is explored by examining the normal modes of the structure.

INTRODUCTION

Flow-induced vibration (FIV) of flexible structures exhibit a number of interesting dynamical phenomena. Some of them, such as lock-in and hysteresis, have been extensively studied in the context of FIV of rigid bodies mounted on elastic support. Lock-in is said to occur when the frequency of FIV attains a value close to the natural frequency of the structure. Large amplitude of vibration is observed during lock-in. Its onset is dependent on whether the state is approached by increasing or decreasing the control parameter, generally Reynolds number or inverse of (non-dimensionalized) natural frequency. This dependence of lock-in/no lock-in on initial condition is called hysteresis.

The vibration of flexible structures is, however, far more complex. In addition to the modification of the lock-in regimes, these systems exhibit phase reversal and appearance of chaos even at low Re. We investigate some of these phenomena for vibration of splitter plates behind bluff bodies, flutter of a sail like body and ovalling oscillation of an inflating balloon.

COMPUTATIONAL METHOD

All computations are done via an in-house fluid-structure-interaction (FSI) set-up based on a partitioned approach. Incompressible Navier-Stokes equations are solved using space-time SUPG/PSPG stabilized FEM [1]. Three different structure models are used: nonlinear elastic model [1], Timoshenko beam model [2] and nonlinear membrane model [3]. All three are solved using semi-discrete Galerkin FEM. Fluid mesh is deformed to conform the fluid-solid interface by modeling it as a linear elastic pseudo-solid [1].

RESULTS AND DISCUSSION

The effect of flexibility of a splitter plate behind a circular cylinder on FIV is studied for three different configurations. Flexibility of the plate is characterized using the reduced speed U_p^*, defined as the inverse of first natural frequency of the plate non-dimensionalized by freestream speed and cylinder diameter (D). The Reynolds number, mass-ratio and length of the splitter plate are fixed at 150, 10 and $3.5D$, respectively. First, flow past a fixed cylinder with flexible plate is considered. Figures 1(a) and (b) show the time history of tip displacement and instantaneous vorticity fields at $U_p^* = 5$ and 60, respectively. These values of U_p^* correspond to the peaks of the first two, amongst the several, lock-in regions observed. The first lock-in has a smaller peak amplitude with frequency close to the first natural frequency of the plate. Plate deformation during first lock-in is accounted completely by the first Euler-Bernoulli bending mode. The second lock-in corresponds to a mix of the first two bending modes and a much larger peak amplitude. The frequency of vibration stays close to the second natural frequency of the plate. The two lock-in regions are separated by a range of U_p^* in which very small amplitude vibration at a frequency close to that for a rigid plate is observed. This region is analogous to the desynchronization region for VIV of an isolated cylinder. The second configuration consists of a cylinder vibrating freely on a spring with compliance $U_s^* = 6$. U_s^* is defined as the inverse of natural frequency of the spring-mass system when the plate is taken to be rigid. In case both cylinder and plate are free to vibrate, the structure is characterized by the pair (U_s^*, U_p^*). Figures 1(c) and (d) correspond to $(U_s^*, U_p^*) = (6, 5.36)$ and $(6, 12)$, respectively. The cylinder and the plate vibrate in-phase in the first case and out-of-phase in the second. However, in either case the plate shape resembles the first Euler-Bernoulli mode. Normal mode analysis of the structure reveals that such behaviour is a representative of the first two eigenmodes of an elastically mounted cylinder with flexible plate. A parametric study of the FIV further shows that the transition between these two modes, as U_p^* increases, is sudden in nature. Transition from in-phase (figure 1(e)) to out-of-phase vibration (figure 1(f)), with U_p^*, is also observed between flexible plates behind two fixed cylinders. However, there are no underlying structure modes responsible for this transition. In fact, the switch in phase relation occurs purely due to hydrodynamic coupling between identical bending modes of the two plates.

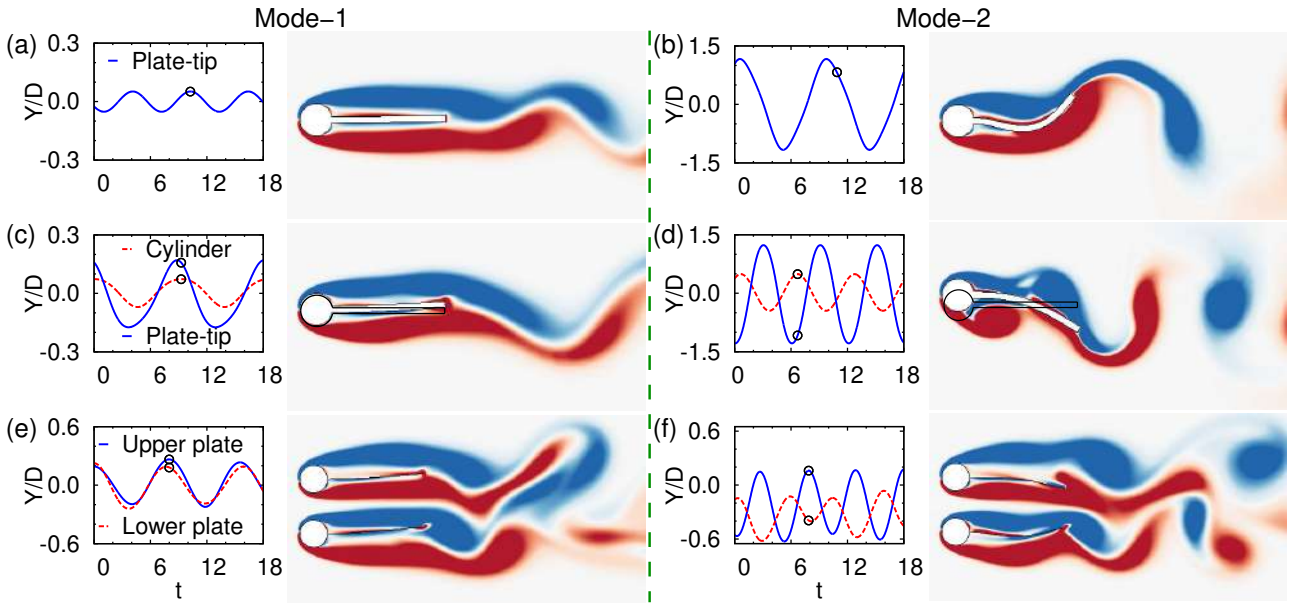

Figure 1: Flow past different configurations of circular cylinder(s) with flexible splitter plate(s) at $Re = 150$. Time history of tip displacement and instantaneous vorticity field for: fixed single cylinder at (a) $U_p^* = 5$ and (b) $U_p^* = 60$; elastically mounted cylinder at (c) $(U_s^*, U_p^*) = (6, 5.36)$ and (d) $(U_s^*, U_p^*) = (6, 12.8)$; two fixed cylinders at (e) $U_p^* = 4$ and (f) $U_p^* = 16$.

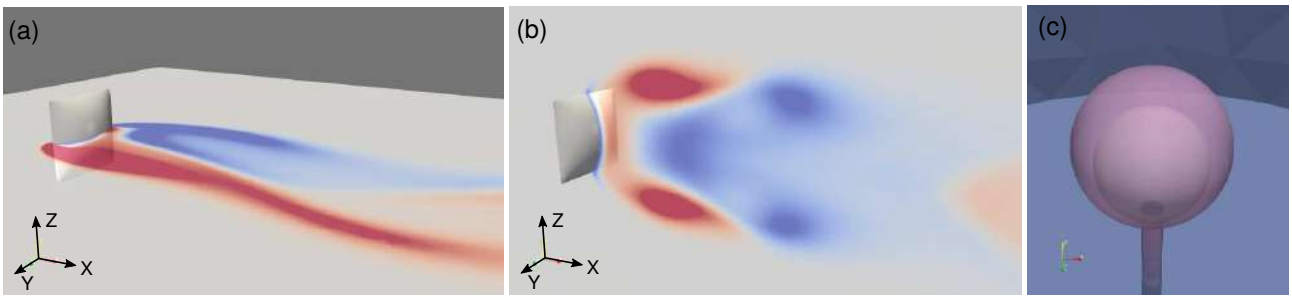

Figure 2: (a,b) Flow past a flexible square membrane sheet at $Re = 150$, $Ae = 5$ and $m^* = 10$: (a) Z-voriticty and (b) Y-vorticity fields along sectional planes through the center. (c) An inflated balloon undergoing ovalling oscillations for $Re = 500$, $Ae = 0.025$ and $m^* = 5$. Also shown for reference is the original un-inflated balloon.

FIV of membrane structures is studied. The membrane is characterized by stiffness $Ae = E/\rho_f U^2 L$ and mass-ratio $m^* = \rho_s/\rho_f L$, where E is Young's modulus, U is the characteristic speed, L is the characteristic length and ρ_f and ρ_s are the fluid and the membrane density. We first study the flow past a rectangular membrane held normal to an incoming uniform stream (along X axis). Figure 2(a) and (b) show the deformed membrane shape and Z and Y vorticity fields in two mid-sectional planes. The shape of the membrane resembles the first eigenmode of the structure. The vortex shedding is symmetric in the XZ plane and alternate in the XY plane. Figure 2(c) shows an initially spherical balloon undergoing ovalling oscillations as it inflates due to an applied pressure gradient in the inlet.

CONCLUSIONS

FIV of different structures is studied by varying flexibility. For a fixed cylinder with flexible plate, lock-in is observed with first, for $3 \lesssim U_p^* \lesssim 10$, and second, for $U_p^* \gtrsim 25$, Euler-Bernoulli modes. where the exact value of U_p^* for the onset of a lock-in is dependent on the initial condition used for computations. A stiff splitter plate, $U_p^* \lesssim 6$, vibrates in-phase with a freely oscillating cylinder due to lock-in with the first eigenmode of a vibrating cylinder with non-rigid plate. For $U_p^* \gtrsim 6$, the response is dominated by the second mode, leading to a reversal of the phase relation. Phase reversal, by increasing U_p^*, is also observed for two fixed cylinders with flexible plates.

FLOW-INDUCED DEFORMATION OF A BISTABLE ORIGAMI PATTERN

Tom Marzin[1], Emmanuel de Langre[1], and Sophie Ramananarivo* [1]
[1]LadHyX, Department of Mechanics, Ecole polytechnique, Institut polytechnique de Paris, France

Summary We experimentally investigate the elastic deformation of a 'waterbomb' folding unit in a controlled air flow. This fundamental origami base is selected for its large shape changes as well as its bistable properties. We measure the drag force experienced by the system as it reconfigures in the flow, and show an atypical drag-versus-flow speed curve, with abrupt changes in fluid loading. An analytical model is developed to corroborate our experimental results based on an energy balance between the elastic potential energy of the folds and the work of fluid forces. Understanding the behavior of such architected surfaces paves the way to control and program passive elastic response in flows.

INTRODUCTION

Flexibility allows for a structure to change shape in a flow and passively adapt to a varying fluid environment. Such reconfiguration offers a strategy for drag reduction through the combined effect of streamlining and reduction of frontal area [1]. The way the structure bends is determined by its elastic properties and its geometry: for example, a circular sheet cut along a radius rolls up into a cone when immersed in a flow [2]. Origamis, which recently emerged as a tool to engineer mechanical properties, represents an interesting opportunity to broaden the framework of flow-induced reconfigurations.

Origamis are sheets folded along crease patterns. Those patterns condition the morphing, allowing for extreme shape changes that can be exploited to deploy solar sails or foldable antenna. Targeted mechanical properties can also be implemented, such as auxetic behavior or multistability. Those features are interesting from the perspective of fluid/structure interaction as fluid loading is highly sensitive to large variations in area or shape.

Here, we study the behavior of origami in a controlled flow, starting with a single folding unit. We selected the so-called 'waterbomb' motif as one of the fundamental origami bases, that consists in an alternation of mountain or valley folds radiating from a single vertex (see Fig.1a). In the approximation of rigid faces, the kinematics is entirely prescribed by the motion of the folds [4]. The waterbomb motif then deforms along a single degree of freedom (DOF), but presents two stable equilibriums [3] (see Fig.1a). It would allow the structure to deploy in an incoming flow, before snapping past a critical speed.

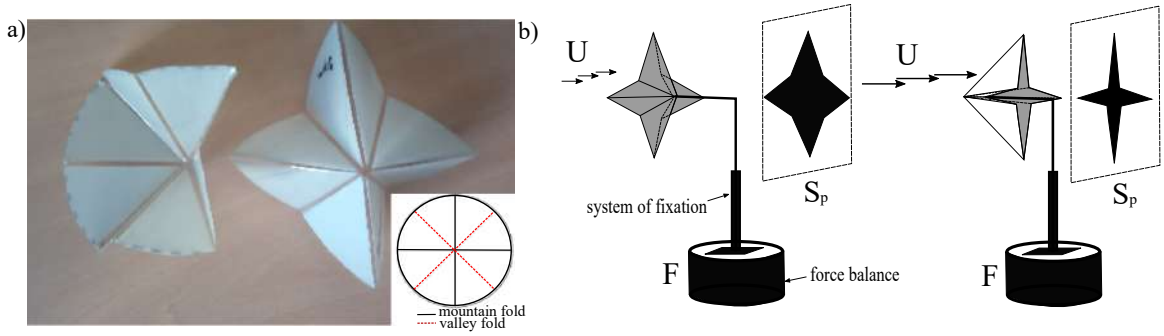

Figure 1: (a) 'Waterbomb' origami with rigid faces, assembled out of superposed mylar sheet. This base fold presents two stable states [Inset : crease pattern in the unfolded state]. (b) Experimental setup of a waterbomb base placed in an incoming flow of speed U. Past a critical speed, the structure snap-through. This reconfiguration leads to large changes of the projected surface S_p and the drag force F measured by a force balance.

EXPERIMENTAL SET UP AND RESULTS

The origami with rigid faces is implemented experimentally by superposing two mylar sheets of different thickness (Fig.1a), a thin one for the folds and a thicker one for the faces. The structure is placed in an open wind tunnel, that generates a controlled flow with velocity $U \sim 0 - 18\,m.s^{-1}$, with Reynolds numbers $Re \sim 10^3 - 10^4$. The drag force F experienced by the origami is measured by a precision balance, while we simultaneously record shape changes with a camera placed downstream of the air flow that extracts the projected surface S_p (Fig.1b). The origami is initially positioned with its concave side facing the flow, in order to study both its opening and closing. We vary the radius of the origami R, the stiffness of the folds κ as well as the opening angle in the unstrained state, and the number of folds N.

Fig.2a-b respectively show the projected surface S_p nondimensionalized by the unfolded surface S_0, and the drag force F, as a function of U wind velocity for the different parameters. The origami first deploys in the incoming flow and the increase in frontal area leads to a drag increase. Past a critical velocity, the deployed origami undergoes a snapping

*Corresponding author. E-mail: sophie.ramananarivo@ladhyx.polytechnique.fr

transition leading to an abrupt change in S_p and F. Past this point, the structure closes up in the flow and we observe the presence a force plateau, where drag no longer depends on the flow speed. As expected, larger the origamis (dark red curves, with $*$ symbols) tend to snap at lower critical wind velocity, with fluid forces acting on a greater area. Conversely, rigid origamis (dark red curves, with square symbols) require a higher U.

To capture the physical behavior of the system we define a Cauchy number $C_Y = \rho U^2 S_0/\kappa$ (with ρ the air density), that compares the fluid loading and the rigidity. The insets of Fig.2a-b show the results replotted in a non-dimensional form with $C_d = F/\rho U^2 S_0$ the drag coefficient as a a function of C_Y. The collapse of the curves shows that the behavior of the origami is set by the competition between the elastic restoring force of the folds and fluid forces. Note that C_Y however does not capture the effect of the number of folds or of changing the rest angle of the waterbomb, whose results are not shown in Fig.2.

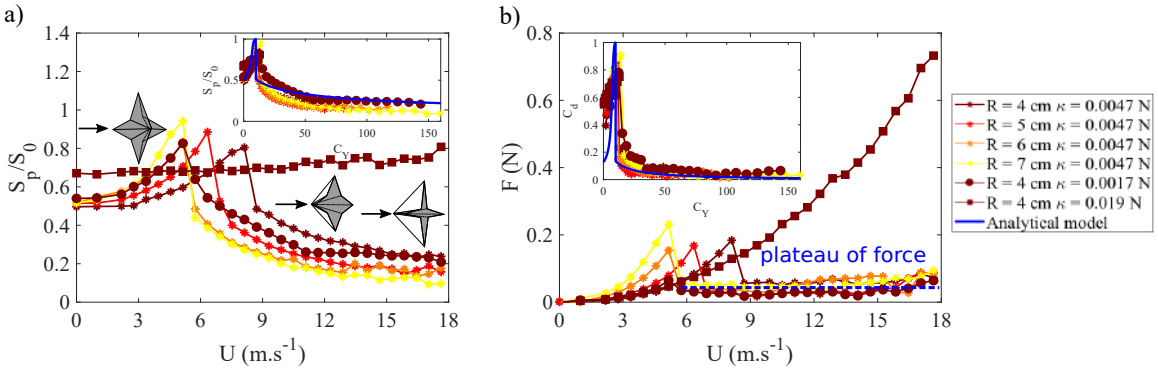

Figure 2: (a) Evolution of the relative projected surface S_p/S_o as a function of the flow speed U [Inset : data replotted as a function of the Cauchy number C_Y (see text), and compared to the model predictions]. (b) Drag force F as function of U, exhibiting a plateau at high speeds [Inset : Drag coefficient C_d vs. C_Y, with model predictions].

ANALYTICAL MODEL AND DISCUSSION

To rationalize our experimental results, we devise a simplified model to predict the static equilibrium of the waterbomb base structure under fluid loading. Our analytical model considers the energy of the origami that is the sum of two terms $E = E_{el} + W$, where E_{el} is the elastic potential energy obtained by modeling each fold as a torsional spring of linear rigidity κ and length R [3]. The second term W corresponds to the work done by fluid pressure forces acting on each face. Similarly to [1], we assume that the flow encountered by the origami is the far field one of speed $\underline{U}$, which exerts on each face a force $\underline{F_n}$ proportional to the momentum carried in the direction normal to the face $\underline{n}$: $\underline{F_n} = 1/2\rho S_0(\underline{U}.\underline{n})^2\underline{n}$. The energy of the structure that is to be minimized then writes :

$$E = \frac{N\kappa R}{4}[(\gamma_m - \gamma_m^0)^2 + (\gamma_v - \gamma_v^0)^2] - N\int \underline{F_n}.\underline{\delta r}, \tag{1}$$

Where $\underline{\delta r}$ is the trajectory of the face, and γ_m and γ_v are the mountain and valley folds angles respectively (the ^{0} denote the initial unstrained angles). It should be noted that E only depends on one variable as the origami deforms along a single DOF. This equation is solved numerically and the obtained predictions are compared to experimental data in the insets of Fig.2a-b. Despite strong hypothesis on the fluid, the opening and reconfiguration phases as well as the reversal threshold (critical Cauchy) are well predicted by our analytical model.

We showed that the extreme shape changes and bistable properties of the studied origami allow for an atypical non-monotonic drag-vs-speed curve. In strong flows, the fluid force experienced by the system also no longer depend on speed. This unusual behavior could be attributed to the localisation of deformation in the folds, an intrinsic feature of origamis. In the limit case of large deformation, the faces of the origami align with the flow, so that its radius R becomes irrelevant for the pressure drag. In the absence of any other lengthscale, dimensional analysis then suggests that fluid forces only scale with the rigidity of the folds. Finally, this system represents an interesting strategy for passive valves or hydraulic diode, that would expand in a water pipe and obstruct it, and eventually snap past a given threshold velocity to let fluid through. To control and program the pressure/flow rate curve of such system, it is then key to understand the fluid-elastic response of the origami, as well as effects of confinement.

COUPLED DYNAMICS AND SELF-INDUCED VIBRATION OF FLEXIBLE MEMBRANE WINGS AT MODERATE REYNOLDS NUMBER

Guojun Li* [1], Boo Cheong Khoo[1], and Rajeev Kumar Jaiman[2]
[1]Department of Mechanical Engineering, National University of Singapore, Singapore, Singapore

Summary The aeroelastic interaction between a flexible membrane structure and the surrounding unsteady flow is ubiquitous in nature and engineering systems. The present study aims to investigate the synchronized coupling between the vortex shedding and the flexible membrane at moderate Reynolds number. In particular, we examine the self-induced vibration and the lock-in phenomena during nonlinear unsteady fluid-membrane interaction. With the aid of the Global Fourier Mode Decomposition (GFMD) method, the most energetic aeroelastic modes are identified from the coupled fluid-elastic fields and the mode migration between different states is explored as functions of aeroelastic parameters. Based on the coupled modal analysis, we propose a feedback loop between the vortex shedding, the induced pressure fluctuations and the multimodal membrane vibration.

INTRODUCTION

During the past decades, morphing wings with elastic membrane components have received substantial attention from the aerospace engineering community in the context of bio-inspired flying vehicles. As demonstrated in [1, 2], the elastic membrane wings may possess superior aerodynamic performance with improved lift-to-drag ratio, delayed stall and enhanced flight stability while maintaining light-weight structures, compared to conventional aircraft wings. In previous studies on the membrane dynamics [3, 4], it was found that the coupled dynamics of the flexible membrane wings are strongly influenced by the aeroelastic parameters namely, the angle of attack, Reynolds number, mass ratio and the aeroelastic number. Specifically, the migration of the membrane modes [3] and the transition from thrust to drag [5] were observed in the coupled aeroelastic system with different parameters. Furthermore, the aerodynamic performance and the flow dynamics of flexible membranes are related to vibration modes. It is necessary to fully understand the coupling mechanism between multiple excited modes and their corresponding flow patterns when designing efficient flying vehicles. The intertwined modes of the unsteady flow and the membrane deformation pose serious challenges from a physical analysis standpoint. In particular, the lock-in mechanism and the structural mode migration related to the vortex-membrane interaction require further investigation.

In the current study, we consider a three-dimensional rectangular membrane wing and analyze the nonlinear fluid-membrane interaction as functions of the aeroelastic parameters. We focus on the four key questions: (i) Which types of membrane vibrations and wake patterns are dominant in the fluid-membrane interaction and how do we identify these dominant aeroelastic modes? (ii) What is the intrinsic relationship between the flow features and the flow-induced structural modes? (iii) How do the aeroelastic parameters influence the fluid-membrane interaction? (iv) What is the trigger factor of the structural mode migration and the membrane lock-in at various flow conditions? A global mode decomposition method based on the Fourier transform is employed to identify the dominant aeroelastic modes from the overlapped fields by estimating the contribution of the dominant mode and its harmonics to the overall membrane dynamics quantitatively. A series of numerical simulation is performed to investigate the evolution of the coupled dynamics of the flexible membrane wing and the trigger factor of the structural mode migration and the membrane lock-in phenomena.

HIGH-FIDELITY AEROELASTICITY FRAMEWORK

A recently developed high-fidelity aeroelasticity framework [2] is employed for the current study. The incompressible Navier-Stokes equations and the flexible multibody structural equations are integrated in a partitioned manner and the aeroelastic governing equations are solved based on a typical predictor-corrector scheme. An efficient and energy-conserving method based on the radial basis function (RBF) is employed to transfer the aerodynamic forces and the structural displacements along the fluid-structure interface with non-matching meshes. The extended RBF method is used to update the fluid meshes in the fluid domain by following the deformation of the flexible membrane wings. A nonlinear iterative force correction (NIFC) scheme [6] is implemented to address the numerical stability caused by the strong inertia effects during fluid-membrane interaction.

RESULTS AND DISCUSSION

A two-dimensional flexible membrane wing with fixed leading and trailing edges and a three-dimensional rectangular membrane wing with all fixed edges conducted by Rojratsirikul et al. [1] are simulated by the high-fidelity aeroelastic framework to study the fluid-membrane coupling dynamics and mechanism with various aeroelastic parameters. The

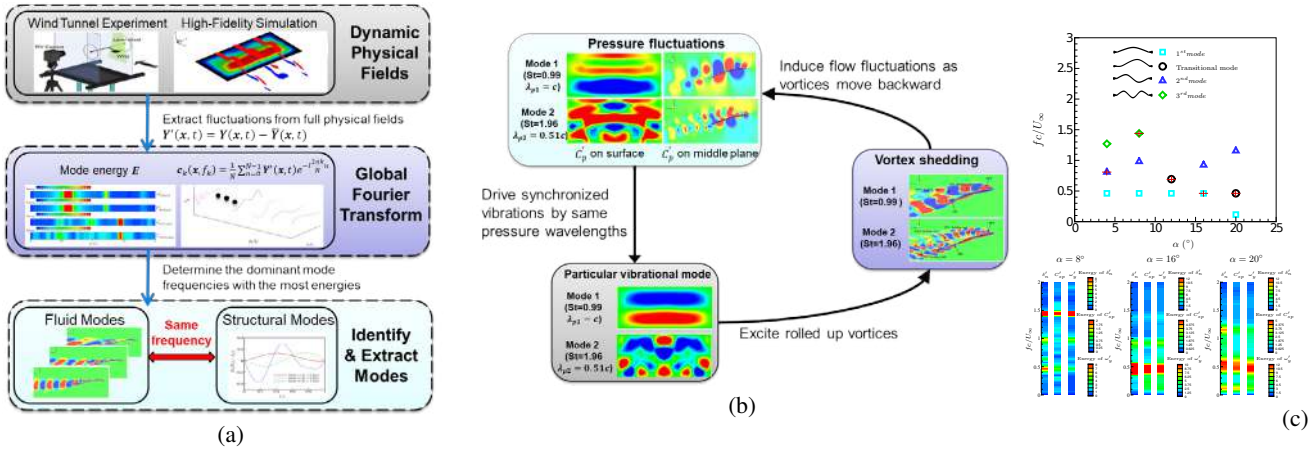

Figure 1: Flow-induced vibration of a flexible membrane wing: (a) a graphical illustration of Global Fourier Mode Decomposition (GFMD), including data pre-processing, mode decomposition and aeroelastic mode identification, (b) an illustration of fluid-membrane coupling mechanism at $Re = 24300$ and $\alpha = 15°$, and (c) mode migration map and global spatial mode energy spectra by decomposing the membrane deflection fluctuation, the surface pressure coefficient fluctuation and the spatial Y-vorticity fluctuation as a function of angle of attack α for a two-dimensional membrane wing at $Re = 2500$.

Global Fourier Mode Decomposition (GFMD) method is employed to decompose the full physical fields into particular aeroelastic mode ranked in frequency. A graphical illustration and the procedure of GFMD is presented in figure 1a.

With the aid of the GFMD method, we build a direct connection between the particular vibration modes and the induced flow patterns. We study how the flexible membrane interacts with the unsteady viscous flow to sustain the free vibration of a flexible membrane wing. Figure 1b illustrates a schematic of the fluid-membrane coupling mechanism for a three-dimensional flexible membrane wing. The flow-induced membrane vibration excites rolled up vortices near the leading edge. Subsequently, a chain of vortices moves backward resulting in the flow fluctuations in the flow domain as well as on the membrane surface. The induced pressure fluctuations drive the synchronized membrane vibrations by the same pressure wavelength. This feedback loop between the membrane vibration, the wake instability and the pressure fluctuations reveals how the structural mode is selected for the unsteady flow past the flexible membrane. The mode migration map and the global mode energy spectra are presented in figure 1c. As the angle of attack increases, the dominant mode migrates from 2^{nd} to 3^{rd} at $\alpha = 8°$, then it transits to the lower mode. Furthermore, it can be inferred from the energy spectra that the frequency of leading-edge vortex shedding synchronizes with the selected membrane mode. With regard to the relative inertial coupling, we consider a range of mass ratio $m^* \in [0.72, 14.4]$ at $\alpha = 15°$ and $Re = 24300$. Four distinctive membrane dynamic states are identified as a function of m^*, namely (i) deformed steady state, (ii) antisymmetry mode, (iii) transitional mode and (iv) symmetry mode. As the inertia effect becomes stronger, the 1^{st} mode turns to be the dominant mode when its mode energy exceeds that of the 2^{nd} mode.

CONCLUSIONS

We presented a series of aeroelastic simulations to investigate the coupled dynamics and self-induced vibration of the flexible membrane wings immersed in the incompressible unsteady viscous flow as functions of the angle of attack, Reynolds number and mass ratio. GFMD method was employed to isolate the dominant aeroelastic modes from the overlapped physical fields to connect the unsteady flow and the flow-excited vibration via the same mode frequency. A feedback loop between the membrane vibration, the wake instability and the induced pressure fluctuations was proposed for the coupled dynamics and self-induced vibration during fluid-membrane interaction. We found that the mode migration is triggered through the synchronized mode coupling between the multiple flow-excited modes.

RELIABILITY STUDY OF A FULLY-PASSIVE OSCILLATING-FOIL TURBINE CONCEPT

Dylan Iverson[1], Waltfred Lee[1], Guy Dumas [2], and Peter Oshkai*[1]
[1]Department of Mechanical Engineering, University of Victoria, Victoria, Canada
[2]Department of Mechanical Engineering, Laval University, Quebec City, Canada

Summary A fully-passive flapping-foil hydrokinetic turbine prototype was subjected to flow at Re = 21000 in a water channel. The prototype was exposed to symmetric vortices shed from an oscillating foil placed upstream, boundary layer tripping by distributed roughness on its surface and freestream turbulence introduced via fractal grid turbulence generator. The potential of power extraction of the foil undergoing elastically constrained oscillations in heave and pitch under these nonideal, unsteady flow conditions was quantified by implementing an eddy current brake. When placed in the wake of an upstream oscillating foil, the turbine was sensitive to the frequency of the shed vortices in the incoming flow. An overall increase in power extraction was observed when the turbine was subjected to high freestream turbulence, while the surface roughness had insignificant effect on turbine performance.

INTRODUCTION

The use of oscillating foils for hydrokinetic energy harvesting has received much interest in recent years. These systems consist of a foil that translates and rotates in a cyclic and periodic manner. These lift-based devices have been shown to reach energy extraction efficiencies competitive with their conventional rotary counterparts [1].

In the present study, a self-sustained fully-passive flapping-foil hydrokinetic turbine prototype [2] that is able to achieve efficiency of power extraction up to 31% with a NACA 0015 foil is investigated experimentally. This fully-passive turbine concept inherently relies on a two-way coupled fluid-structure interaction to develop motion responses leading to useful energy extraction. This feature leads to the question of how sensitive this design may be to disturbances in the flow field, where certain flow perturbations may significantly alter the passive response of the foil. The current study aims at qualifying this potential sensitivity.

EXPERIMENTAL SYSTEM AND TECHNIQUES

The experiments were performed in a recirculating water channel with a test section that has a length of 250 cm and a cross section of 45x45 cm. The ambient turbulence intensity of the flow was less than 1% for the range of velocities used in the current study.

A schematic of the two-degree-of-freedom turbine system is shown in Fig. 1a. The NACA 0015 foil of chord length c was constrained to move only in a linear heave motion $h(t)$, and a rotational pitch motion $\theta(t)$ about its pitching axis, located a distance x_p from the leading edge. Both degrees-of-freedom were elastically mounted, and a linear damping was applied independently to the heave degree-of-freedom. The blade positions in heave and in pitch were recorded at a sampling frequency of 83.3 Hz and during 120 s, which roughly corresponds to 100 oscillations of the blade, with two rotary encoders generating10000 pulses per revolution.

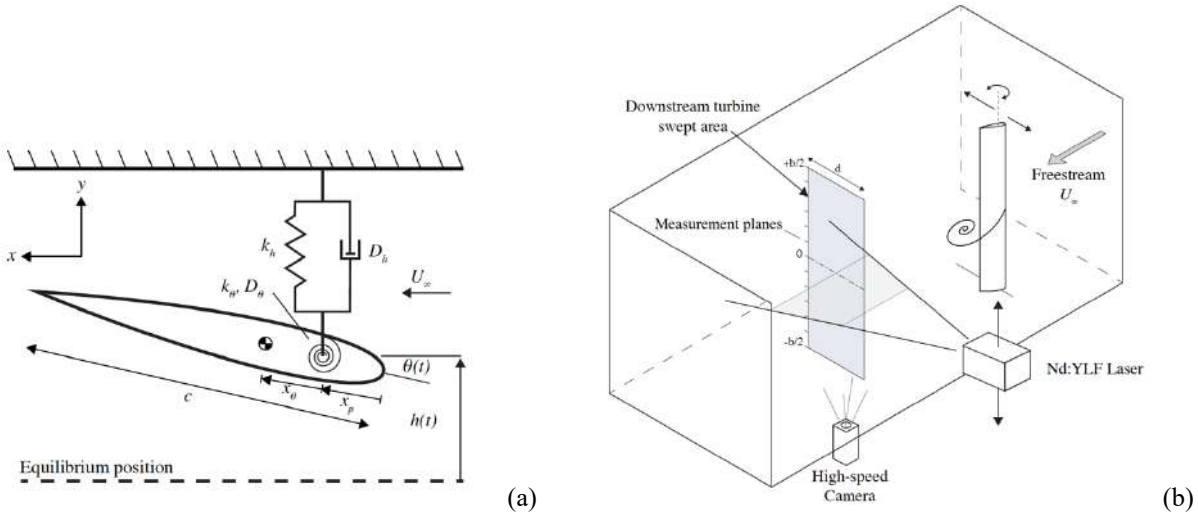

Figure 1. Schematics of the fully-passive turbine (a) and the PIV system (b).

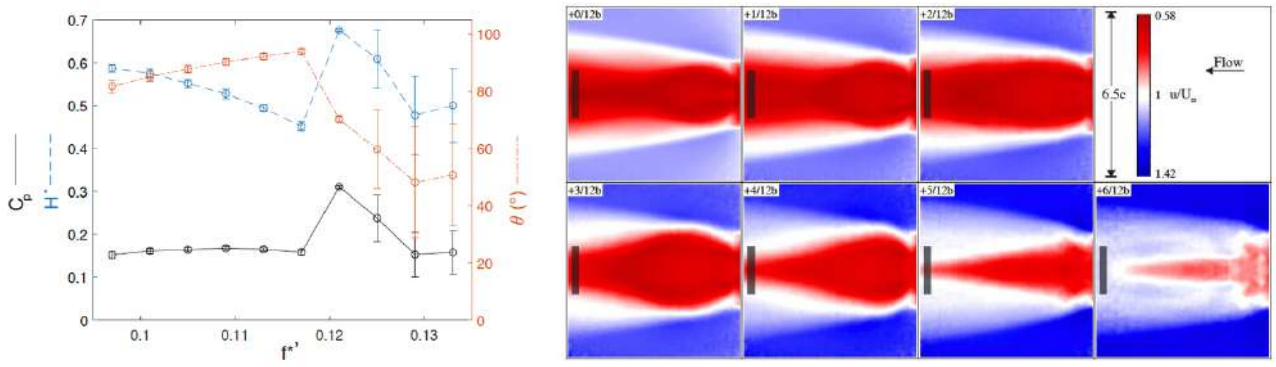
Fluid velocity was measured using high-speed particle image velocimetry (PIV) as shown schematically in Fig. 1b. The flow was seeded with tracer particles with a mean diameter of 10 μm that were illuminated by a pulsed laser. The

*Corresponding author. E-mail: poshkai@uvic.ca.

images were processed with Davis LaVision 8.3 software using a multipass cross correlation technique. The smallest interrogation windows used were 12 pixels x 12 pixels, yielding a resolution of 0.26 vectors/mm.

RESULTS

As shown in Fig. 2a, when the turbine was placed in the wake (6.5*c* downstream) of a similar foil undergoing prescribed periodic motions, the power extraction was significantly lower than that of the baseline case without an upstream foil, which had a value of power coefficient $C_p = 0.62$. This result is not unexpected, considering the momentum deficit in which the turbine operated as shown by the streamwise velocity fields of Fig. 2b. The spanwise structure of the wake of the upstream foil is also shown through the different vertical planes of Fig. 2b. Moreover, stable oscillations of the fully-passive foil were observed in a relatively narrow range of reduced frequencies of the upstream foil corresponding to $f^{*\prime} < 0.125$, as illustrated in Fig. 3.



(a) (b)

Figure 2. (a) Averaged power coefficient, heave amplitude, and pitch amplitude of the fully-passive turbine. $f^{*\prime}$ is the reduced frequency of the upstream foil. (b) Time-averaged PIV images of normalized streamwise velocity in the wake of the upstream foil. Grey bars represent location of the downstream turbine.

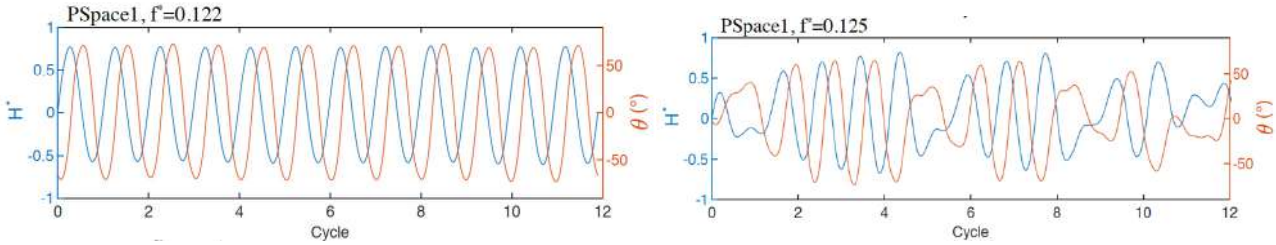


Figure 3. Heave and pitch amplitudes as functions of time over twelve cycles of turbine oscillation for two values of reduced frequency of the upstream foil.

When the boundary layer of the turbine was tripped by applying a strip of distributed roughness elements along the span of the blade, no significant improvement of turbine performance was observed presumably due to predominant stall condition that existed for a large portion of the oscillation cycle or ineffectiveness of the trip due to the relatively low Reynolds number.

On the other hand, when the turbulence level of the inflow was increased to 10% by installing a fractal grid upstream of the test section in the water channel, the power extraction increased by 5% - 13% relative to the baseline case of ambient turbulence. The heave amplitude also increased. It is hypothesized that the incoming turbulence delayed the stall by stimulating boundary layers transition or by increasing momentum transfer into the boundary layer or by reducing the coherence of the primary stall vortex.

CONCLUSIONS

When the fully-passive oscillating-foil turbine was placed in the wake of another foil undergoing a prescribed motion, the turbine performance was sensitive to the frequency of the generated vortices in the incoming flow. Regular oscillations were observed only in a narrow range of upstream kinematics. However, the prototype exhibited stable, and sometimes improved, performance when it was subjected to unstructured disturbances in the form of high freestream turbulence.

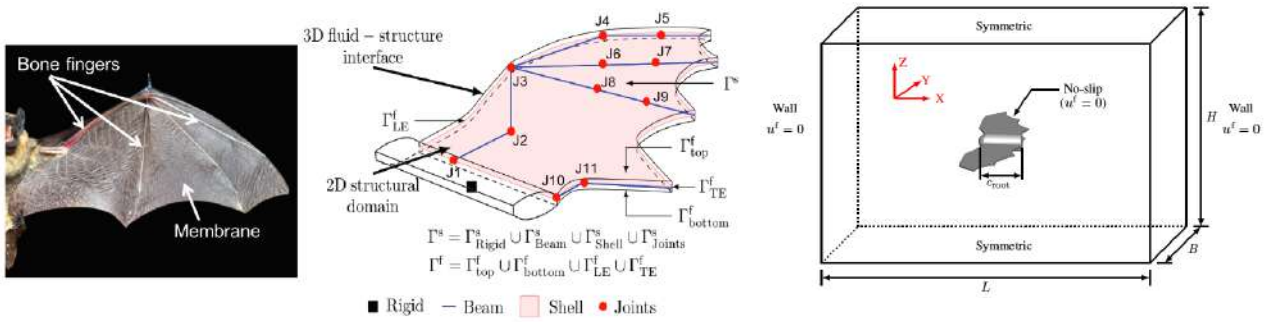
AEROELASTICITY OF HOVERING AND FLYING BATS

Vaibhav Joshi* [1] and Rajeev Kumar Jaiman[1]
[1]Department of Mechanical Engineering, University of British Columbia, Vancouver, Canada

Summary Wings of natural flyers such as bats have evolved over millions of years to adapt and articulate the flexibility of the wings for better flight performance, maneuverability and agility. With aim to understand this flapping phenomenon of bats, we investigate the aeroelastic effects of articulated membrane flexibility on the flow structures and their relation with the aerodynamic performance. We find that the flexibility increases the unsteady lift generation as well as reduces the mean drag due to the large deformation of the flexible wing compared to the rigid counterpart, as a result of larger downwash.

INTRODUCTION

Biologically inspired flying vehicles based on flapping motion of wings have gained recent attention in the aerodynamics community due to their characteristics of high agility and hovering capabilities, flexible and soft material wings and lower frequency of wing motion. Compared to the flying vehicles or drones such as Quadcopters which employ the rotary motion of wings, such bio-inspired vehicles made from flexible materials could be much safer and energy-efficient alternative. Of particular interest is the bat-inspired wing design which allows for better control of the wing motion and a simpler design from manufacturing point of view than a bird-inspired wing. According to the quasi-steady state aerodynamics, a bat flying at slow speed or hovering should not be able to generate sufficient lift to balance its weight. Therefore, an unsteady lift generation mechanism was proposed in [1] by studying the vortex generated by a bat via digital particle image velocimetry. It was found that the unsteady lift is generated by the articulated flexibility of the wing membranes which led to attached leading-edge vortices and the phenomenon of delayed stall. A recent study of mimicing the kinematics of bat flight using a robot [2] demonstrated the capability of better flight control by dynamically changing the wing conformations by adjustment of the bone fingers and joint actuator in the robot (Fig. 1(a)). Therefore, the multibody nature of the bat wing design allows for (i) wing membrane articulated flexibility giving the advantage of delayed stall, (ii) evolving wing span based on the aerodynamic requirements and (iii) better control of the wing kinematics by adaptive adjustment of the bone fingers and joints.



(a) (b)

Figure 1: (a) Flexible multibody nature of the bat wing and (b) problem setup for the numerical study.

The current numerical work aims to understand this relation between the articulated flexibility and the mechanism of unsteady lift generation. We employ a flexible multibody aeroelastic numerical framework to simulate the wing kinematics of a bat and understand the physical mechanisms of unsteady lift generation in various flight regimes. We intend to answer the following key questions in this work: (i) Does the flexibility in the membranes during passive flapping of the wing increase aerodynamic efficiency? (ii) How does the change in the wing deformation transform the flow structures around the bat wing? (iii) Can we optimize the articulated flexibility for maximizing the aerodynamic performance?

FLEXIBLE MULTIBODY AEROELASTIC FRAMEWORK

A generic flexible multibody wing of a bat is shown in Fig. 1(a) where the wing consists of bone fingers, membranes and joints which can be modeled as beam, thin shell element and revolute joints respectively. We employ a co-rotational transformation for the components of the multibody system where the rotation matrix is parametrized by conformal rotation vectors. The joints in the multibody system are solved as constraint to the structural equations. The structural domain is coupled with a three-dimensional incompressible Navier-Stokes variational framework by satisfying the kinematic and dynamic continuity along the fluid-structure interface. This is carried out with the help of an interpolation matrix which is formed by radial basis function approximation. A recent work on the formulation and the radial basis coupling can be found in [3].

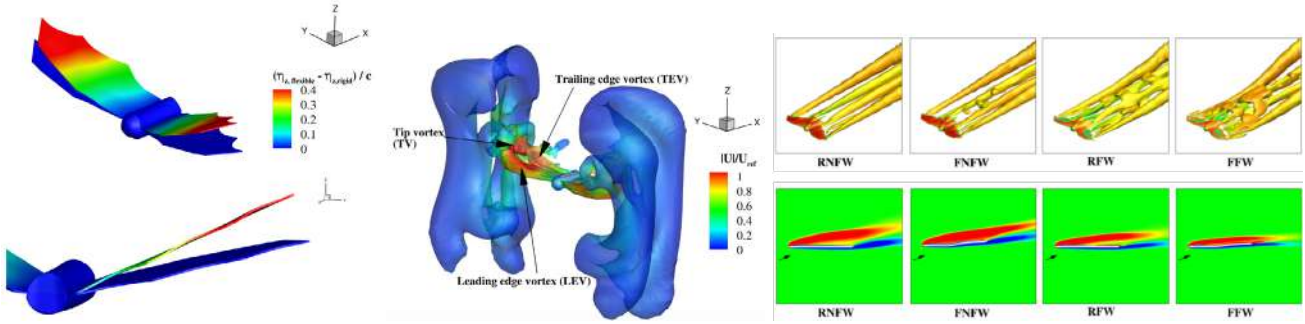
RESULTS AND DISCUSSION

To understand the effect of membrane flexibility on the aerodynamic performance, we perform two-sets of high-fidelity aeroelastic simulations for passive flapping of wings in a bat flight. The first set of studies correspond to hovering flight by considering two wing flapping configurations (Fig. 1(b)) with anisotropic structural properties: (1) rigid flapping wing (RFW) and (2) flexible flapping wing (FFW). The Reynolds number is defined based on the maximum wing-tip velocity U_{tip} of the rigid wing ($Re = \rho^{\text{f}} U_{\text{tip}} c/\mu^{\text{f}} = 574$), ρ^{f} and μ^{f} being the density and dynamic viscosity of air and c is the mean chord of the bat wing. The Aeroelastic number is defined as the ratio of the structural stiffness to the inertia of the flow ($Ae = Eh/(1/2\rho^{\text{f}} U_{\text{tip}}^2 c)$), where E and h are the Young's modulus and thickness of the structure respectively. It is in the range of $10^4 - 10^9$ for the FFW and 10^{16} for the rigid wing. The mass ratio is given as $m^* = \rho^{\text{s}} h/(\rho^{\text{f}} c)$, ρ^{s} being the density of the structure. It ranges from $1 - 46$ for FFW and is at a constant value of 116 for RFW. The observed vortex structures agree with the proposed model in [1] where the trailing edge vortex is connected to the leading edge vortex via the tip vortices, forming one vortex loop per wing (Fig. 2(a)). These vortices evolve and form a rectangular vortex ring near the wing tip with vorticity being supplied in each stroke of the wing. The size of the vortex ring is found to be comparatively larger for FFW suggesting a relatively larger circulation. It was observed that the large wing tip deformation for the FFW (Fig. 2(a)) leads to high wing tip velocity which induces more effective downwash leading to larger circulation and unsteady lift (41% higher), compared to the RFW. The flapping efficiency is also quantified with the help of the lift force F_z^{s}, wing tip velocity $u_{z,\text{tip}}^{\text{s}}$ and the swept area of the wing A_s as $\eta = (F_z^{\text{s}} u_{z,\text{tip}}^{\text{s}})_{\max}/(1/2\rho^{\text{f}} U_{\text{tip}}^3 A_s)$, and is found to be 38% higher for the flexible wing.



(a) (b)

Figure 2: (a) Comparison of the deformation of the FFW and the RFW for hovering flight. The large displacement of the FFW generates rectangular vortex rings with relatively larger circulation near the wing tip during hovering flight, and (b) vortex structures as well as streamwise vorticity during forward flight at 10° angle of attack at different wing configurations show the deformation of the flexible wing leading to delayed stall and reduced drag.

The second set of preliminary studies correspond to forward flight at 10° angle of attack with the following additional wing configurations than: rigid non-flapping wing (RNFW) and flexible non-flapping wing (FNFW). In this case, the Reynolds number, $Re = 12,000$ and is defined based on the incoming free-stream velocity; $Ae = 120 - 9 \times 10^6$ and $m^* = 4 - 30$ for the flexible wing and 9×10^6 and 30 for the rigid case respectively. The computations show that the mean drag is reduced by about 13% due to the adaptive alignment of the flexible wing with the flow. Furthermore, an 80% increase in the maximum unsteady lift is observed for the FFW compared to the RNFW. The vortex structures depict a delayed stall due to the attachment of the leading edge vortex as a consequence of the large deformation of the flexible wing (Fig. 2(b)).

CONCLUSIONS

Numerical studies are carried out to investigate the effects of membrane flexibility of the wing in bat flight on the aerodynamic performance with the help of a flexible multibody aeroelastic framework. It is observed that for both the flight regimes (hovering and forward flight), the unsteady lift is much higher for the flexible wings compared to the rigid counterpart. The efficiency for the flexible wing is found to be 38% higher than the rigid wing. The unsteady lift is generated due to the large wing tip displacement for the flexible wing leading to higher downwash velocity and circulation. In the forward flight regime, the flexible membrane deforms substantially leading to the attachment of the leading edge vortex as well as reduced drag, thus changing the vortex pattern so as to improve C_L/C_D by 10%.

COLLECTING MIST WITH A FIBROUS NET

Adèle Moncuquet[1], Romain Labbé[1], Alexander Mitranescu[1], Ana Rewakowicz[1], Xavier Amandolese[1,2], Sophie Ramananarivo[1], and Camille Duprat*[1]

[2]LMSSC, Conservatoire National des Arts et Métiers, Paris, France

Summary Capturing droplets from a stream with a fibrous material is a well-known and well-used process, from coalescence filters to fog harvesting. Here, we report experimental measurements of collection efficiency using a simple net arrangement consisting in an array of vertical fibres. Accounting for the growth of drops on fibres in a simple inertial impaction model allows predictive and quantitative comparisons with experiments, and we propose a simple structural change based on an elastocapillary effect in order to suppress drop growth and improve the collection efficiency. We then report drag force measurements on a fibrous net, and look for an optimal design of wind-resistant collecting nets.

INTRODUCTION

The filtration, or collection, of liquid droplets from mist is generally done by placing a fibrous structure in the path of the mist. In particular, coalescence filters are used to remove liquid from aerosols [1] and for a couple of decades, fog harvesting, i.e. the collection of fresh water from fog, has been developed for domestic use or for agriculture/livestock, as well as for reforestation projects [2]. The fog droplets are captured as they impact the wires of the fibrous nets; the water is then collected as drops fall along the mesh. Here, we focus on the collection of mist using a model system of parallel fibres. In particular, we identify the key role played by the drop distribution on the fibres on the collection efficiency of a single fibre, and propose a simple structural change to suppress drop growth thus overcoming this limitation. We then investigate the efficiency of a fibrous net, and report measurements of the drag on a fibrous panel, as a route toward the optimization of collecting nets.

CAPTURING DROPLETS WITH A FIBER

Using a custom made environmental wind tunnel, we produce an homogenous, laminar and well controlled flow of fog, composed of micron-sized droplets with a narrow size distribution and a mean droplet radius $r_d = 3.9\mu m$, carried at varying velocities $2 < U < 10$ m.s^{-1} with a constant water flow Q_w. We place a model net of surface S_f, composed of N_f fibers of diameter d_f, at the exit of the tunnel (of cross section S_{wt}) and measure the collected water volume as a function of time. We first focus on widely spaced fibers, i.e. with a spacing between fibres e_f sufficiently large to avoid interactions (typically $e_f = 10d_f$). As the mist passes through the mesh, fog droplets starts collecting on the fiber; drops appear on the fiber, grow, coalesce and fall periodically. The volume of collected water increases linearly with time, i.e. the collection rate Q_c is constant. We define the collection efficiency E as the ratio of the collected flow of water to the flow of water passing through the net $E = Q_c S_{wt}/(Q_w S_f)$. The main mechanism for the collection is the inertial impact of droplets on the fibres: a droplet carried in the flow can either follow the streamlines, and avoid the obstacle, or impact the fiber provided it has enough inertia [3]. The trajectory of the droplet, and thus the condition for impact and

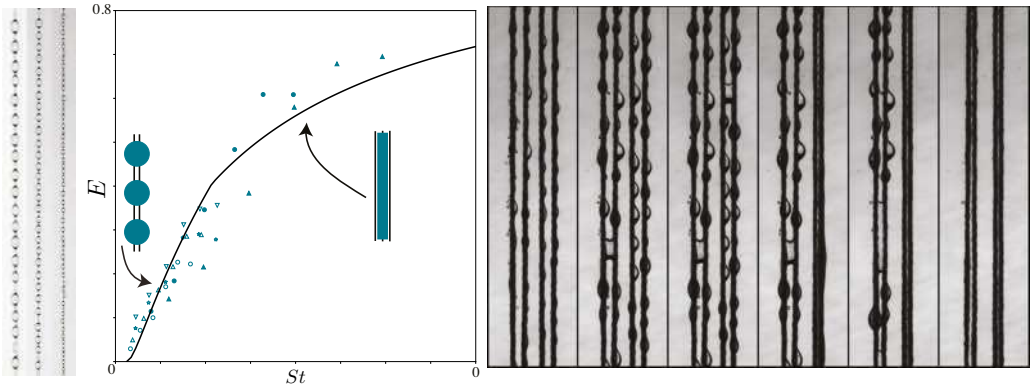

Figure 1: (a) Uniform drop distribution observed on fibres of different diameter during fog collection. (b) Evolution of the collection efficiency as a function of Stokes number, for individual fibres (open symbols corresponding to various diameter and wind velocities), and for liquid columns (filled symbols). Line corresponds to the inertial impaction model; here the definition of efficiency and Stokes is modified to take into account the presence of drops on fibers (open symbols) or to consider a perfectly hydrophilic fibre without drop growth (filled symbols). (c) Formation of liquid columns between two adjacent flexible fibres.

the collection rate, depends on a single dimensionless parameter given by the ratio of inertial force to viscous drag, i.e. the Stokes number $St = \frac{4\rho_d r_d^2 U}{9\mu d_f}$ (where ρ_d is the density of the liquid drop and μ the viscosity of air). A first solution to this problem was given in [3] and is widely used in filtration models [1]. We report precise measurements of collection efficiency over a large range of parameters, and observe that the collection mostly occurs on the drops growing on the fibres, and thus strongly depends on the drop distribution. Due to a growth and coalescence process, this drop distribution evolves toward a regular pattern of uniformly distributed drops, and a balance between capillarity and gravity sets an average drop size (Fig. 1 (a)) [4]. Accounting for these effects in the simple inertial impaction model allows predictive and quantitative comparisons with experiments (Fig. 1 (b)). The collection is thus limited by the growth of drops on the fibres; a small change in the structure of the net allows to create super- hydrophilic fibers, i.e. suppress drop growth, by simply bringing adjacent fibers closer in order to form continuous liquid columns (Fig. 1 (c)). This may be easily induced by using flexible fibers that collapse under the capillary forces generated by the drops [5]. Incoming droplets immediately coalesce with these wet columns, and the overall efficiency is significantly increased (Fig. 1 (b)).

FIBROUS NETWORKS: TOWARDS AN OPTIMAL NET

In order to define the efficiency of a net, we evaluate the collection rate of an assembly of fibers, of overall width L, with varying inter-fiber distances e_f, i.e. different solidities $s = N_f d_f / L$ (solidity is inversely proportional to the inter-fibre distance e_f). We extend our model to take into account the interactions between fibers. In particular, as the flow passes through the net, its velocity is modified as the permeability decreases, and thus the collection rate is modified. We measure the drag force exerted on a porous net of surface S, composed of parallel fibers, using a close wind tunnel. We report the evolution of the pressure loss coefficient $C_o = \Delta p/(0.5\rho U^2)$, or equivalently the drag force $D = \Delta p S$, as a function of the solidity of the net for fibers either spanning the entire width of the wind tunnel, or smaller fibrous panels around which flow deviations may occur (Fig. 2(a)). In the latter case, the collection efficiency should decrease with increasing solidity, i.e. for smaller interfibre distances, due to a blockage effect and thus a decrease of the water flow passing through the net. However, decreasing the distance between adjacent fibers also increases the number of fibers per unit area, and thus increase the overall collection of the net, i.e. the collection per unit area. There is thus an optimal value for collection, independent of the velocity, corresponding to the maximal number of fibers that can be placed in the net without a decrease in single fiber collection rate (Fig. 2(b)). Using our previous result, the efficiency can be further increased by forming super-hydrophilic liquid columns between adjacent fibres (inset in Fig. 2(b)), which also avoids clogging of the net with drops and thus ensures a constant solidity. Using our drag measurements and collection model, we look for the optimal solidity, i.e. the optimal arrangement for collection. Measurements of the efficiency of several nets with different structures/arrangements, fibre diameters and flexibilities, along with aerodynamic and aeroelastic characterizations are on going in order to design an optimal net.

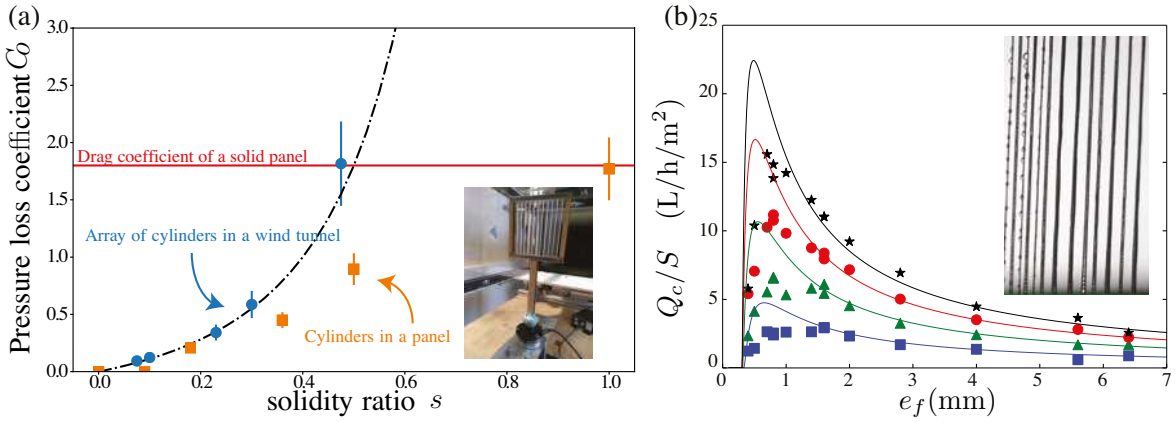

Figure 2: (a) Evolution of the pressure loss coefficient C_o as a function of the net solidity for an array of cylinders (blue circles) or a finite fibrous panel (orange squares). Dashed line corresponds to the theoretical model for a porous net. (b) Evolution of the net efficiency Q_c/S for a given surface S and fibre diameter d_f as a function of the spacing between fibres e_f for different incoming velocities U (from 1 to 4 m/s). Inset: a net composed of "super-hydrophilic" liquid columns between adjacent fibres.

A LAGRANGIAN APPROACH FOR FLUID-STRUCTURE INTERACTION VIA PARTICLE FINITE ELEMENT (PFEM) MODELING

Massimiliano Cremonesi* [1], Simone Meduri[2], and Umberto Perego[1]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
[2] Phononic Vibes, Milano, Italy

Summary A Lagrangian fully explicit approach for the co-simulation of 3D Fluid-Structure Interaction (FSI) problems is here presented. The fluid domain is modelled as a weakly compressible material through an explicit version of the Particle Finite Element Method (PFEM) while the structure is modelled with standard FEM. The strong coupling of the partitioned approach is ensured by a domain decomposition algorithm allowing an incompatible space-time discretizations in the two subdomains. A novel and efficient mesh smoothing procedure is proposed to remove bad quality elements that may arise due to frequent remeshing in the PFEM. The fully Lagrangian description of the present method is particularly effective in problems characterized by strong variations in the fluid boundaries and in the fluid-structure interface. Moreover, the highly parallelizable and fully explicit nature of the equations of the global solver is appealing for real-scale engineering applications.

INTRODUCTION

In many fields of engineering and technology, the numerical simulation of large scale three-dimensional Fluid-Structure Interaction (FSI) problems is of growing interest. A possibility to efficiently deal with these problems is to use partitioned approaches because they allow for the use of existing software. The present work presents a partitioned approach coupling an explicit version of the Lagrangian Particle Finite Element Method (PFEM) [1, 2] for the fluid sub-problem and a standard commercial FEM (SIMULIA Abaqus/Explicit) for the structural one. A domain decomposition approach based on the Gravouil and Combescure (GC) algorithm [3] is here employed for fluid-structure coupling. The key features of this approach are the possibility of different time-steps in the two subdomains and the use of non-conforming meshes at their interface [4].

Moreover, the fully Lagrangian nature of this coupled approach is particularly suited for the description of free surface flows and FSI problems with large structural displacements. The position of the fluid mesh nodes defines automatically the boundaries with no need for interface tracking algorithms. Unfortunately, the Lagrangian motion of the fluid nodes can lead to overly distorted meshes. This issue can be overcome generating a new mesh when the current one gets too distorted. The PFEM makes use of a Delaunay Tassellation coupled with a distortion criterion to efficiently generate a new connectivity for the mesh nodes. Unlucky, in 3D the Delaunay Tassellation may generate bad tetrahedra which, following an explicit approach, can lead to a vanishing stable time step size. To overcome the problem, a novel efficient smoothing technique has been developed to produce a regular mesh, with a reasonably large stable time increment for the explicit solver. This smoothing algorithm is fully explicit and parallelizable, because it exploits the same architecture of the fluid solver thanks to an elastic analogy [5].

The proposed approach is validated through test cases proposed in the literature and used to solve real-scale engineering problems. The comparison with the available solutions confirms the accuracy of the partitioned solver and the effectiveness of the smoothing technique.

COUPLING SCHEME

In the present approach, a partitioned strategy is employed to solve the FSI problem: the explicit version of the PFEM [2] is used for the fluid subdomain, while the commercial software SIMULIA Abaqus/Explicit is used for the structural subdomain. The two solvers are coupled at the interface with the Gravouil and Combescure (GC) algorithm [3], which is a Domain Decomposition method initially proposed for structural dynamics problems and then extended to FSI problems, e.g. in [6]. The key idea behind the algorithm is to split the kinematic solution of each subdomains into two terms, denoted as *free* and *link* solutions, respectively. The former is related to the free motion of each subdomain as if they were not interacting with each other. The latter evaluates the correction to this solution. This is done applying boundary tractions at the fluid-structure interface that play the role of Lagrange multipliers for the imposition of the kinematic constraint. These tractions restore the compatibility at the interface and ensure the strong coupling of the partitioned approach.

The GC algorithm allows for the use of different time steps in the two subdomains, as well as non-conforming meshes at the interface. The resulting interface problem consists of a system of fully decoupled equations, in the case of conforming meshes, and of only weakly coupled equations otherwise, leading to an efficient global explicit solver. The explicit time integration can be an appealing choice for many engineering applications where the time step size is intrinsically small, namely in large scale real applications with fast dynamics, high degree of non-linearity and in extremely large scale problems, where implicit methods may become computationally ineffective. A more detailed description of the proposed approach can be found in [4].

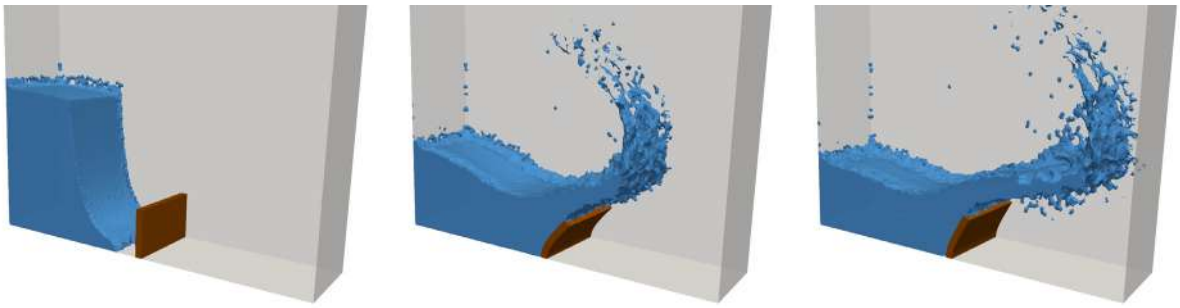
ELASTIC ANALOGY FOR 3D MESH SMOOTHING

The problem of mesh distortion related to the adoption of a Lagrangian description for viscous fluid flows is solved in the PFEM through the introduction of a new mesh when the current one gets too distorted. This is done exploiting the Delaunay Tassellation, combined with a distortion criterion, the α-shape method, to recover the correct domain boundaries. However, while in 2D the Delaunay algorithm ensures excellent mesh quality, in 3D bad elements may be generated. This represents a strong limitation for the use of explicit solvers because it leads to vanishing stable time step size. For this reason, a novel efficient mesh smoothing approach based on an elastic analogy has been developed to improve the worst elements insphere radii, with a computational cost compatible with the frequent remeshing procedure required by the PFEM. The mesh regularization is the result of the deformation produced in a fictitious elastic problem under the action of a suitable distribution fictitious pressures in highly distorted tetrahedra.

The resulting final smoothing algorithm is explicit and highly parallelizable and exploits the same algorithmic structure of the fluid solver. Its efficiency allows to obtain remarkable improvements on the stable time steps of the explicit fluid solver in a reasonable computational time that is compatible with its frequent application due to the remeshing procedure of the PFEM approach. A detailed description of the smoothing algorithm can be found in [5].

EXAMPLE

The proposed approach has been tested and validated on different test cases. Here, to show the potential of the proposed technique, a dam break with deformable obstacle is presented. On the left side of a tank, a column of water is initially sustained by a rigid wall that is instantaneously removed at the beginning of the analysis, letting the water flow inside the tank and hit an elastic deformable body clamped in the middle of the tank. The impact bends the obstacle, while the resulting long wave hits the right rigid wall of the tank (see Figure 1).



(a) $t = 0.10\ s$ (b) $t = 0.25\ s$ (c) $t = 0.30\ s$

Figure 1: Dam Break with elastic obstacle. Snapshot of the simulation at different time steps

CONCLUSIONS

This work presents a fully Lagrangian explicit partitioned approach for FSI problems, coupling the Particle Finite Element Method for the fluid subdomain and the commercial FEM software Abaqus/Explicit for the structural subdomain. The Lagrangian description of the Particle Finite Element Method for the fluid subdomain is particularly effective for free surface flows and large structural displacements. The coupling is achieved by means of the GC algorithm, which ensures strong coupling as well as the possibility to use incompatible space-time discretizations in the two subdomains. In the 3D framework, a novel efficient smoothing techique based on an elastic analogy has been presented. The considered numerical tests confirm the accuracy of the coupled approach, as well as the effectiveness of the smoothing procedure.

FLUID-STRUCTURE INTERACTION OF A CYLINDER IN A STRATIFIED FLUID

Sarah Christin*[1], Patrice Meunier [1], and Stéphane Le Dizès [1]
[1] Aix Marseille Univ, CNRS, Centrale Marseille, IRPHE

Summary This experimental study focuses on the flow induced vibrations of a circular cylinder horizontally translated at a constant speed in a stratified fluid. A mode analogous to vortex induced vibrations of the cylinder is observed as in a homogeneous fluid, but for a different frequency range, due to the additional restoring force of the stratification. Furthermore, a large amplitude galloping mode has been observed in contrast to a homogeneous circular cylinder wake where this type of oscillations cannot occur.

INTRODUCTION

Fluid-structure interactions have been widely studied in the past century, mainly under the angle of Vortex Induced Vibration (VIV) where the structure oscillates when the vortex shedding frequency induced by the flow is close to the structure natural frequency. This is a crucial problem in the design of civil engineering structures such as bridges or marine cables because this resonance phenomenon could lead to the breaking of the structure if the induced motion is too large. However, although most geophysical fluids are stratified, this kind of study has never been carried out in a non-homogeneous fluid. The goal is here to characterize the influence of a continuous stratification on flow induced vibrations.

A STRATIFIED VIV EXPERIMENT

The classical experiment of a spring-mounted cylinder is adapted to the case of a stratified fluid. The flowing water channel is replaced by a 4m-long towing tank, filled with stratified salted water (see figure 1). Cylinders of various diameters D (3, 4 and 6 cm) are towed horizontally at a velocity U using flat blade-shaped arms of length L (of 15, 30 or 50cm). The arms are free to rotate around their end thanks to ball bearings, thus allowing vertical oscillations of the cylinder. The drag creates a restoring force which mimics the action of a spring in classical VIV experiments. The mass ratio m* is finely adjusted to 1 such that the arms remain nearly horizontal.

The oscillations are studied as a function of non-dimensional parameters: the Reynolds number Re=UL/ν, the Froude number Fr=U/ND and the ratio L/D (N being the buoyancy frequency and ν the kinematic viscosity).

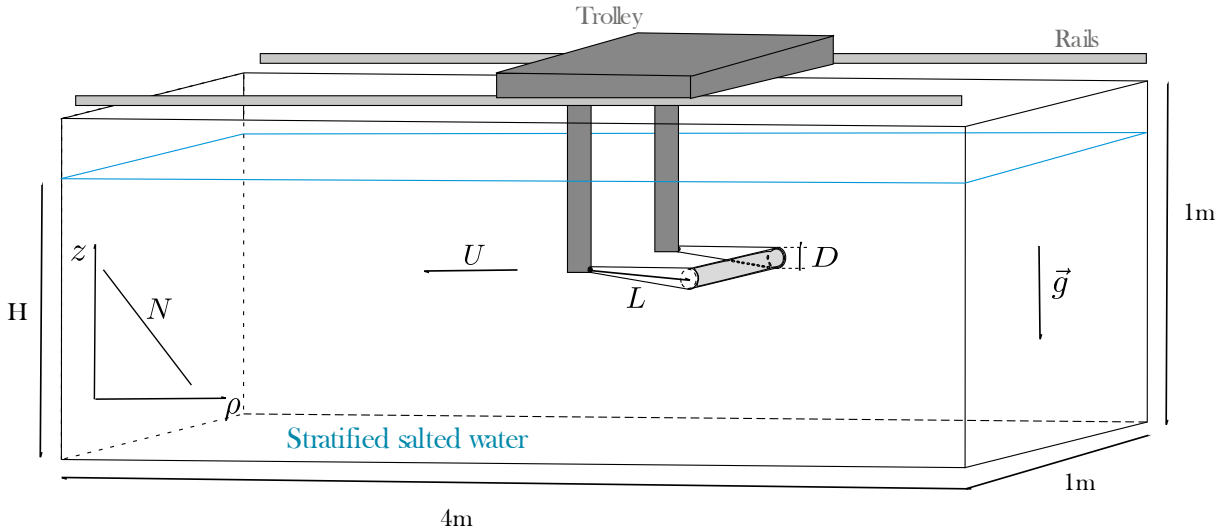

Figure 1. Sketch of the experimental setup

LARGE AMPLITUDE VIBRATIONS OF THE CYLINDER

Figure 2(a) shows the vertical position of the cylinder as a function of time in both the stratified and homogeneous cases for a specific Reynolds number as an example. Two things can be concluded: first, oscillations caused by a coupling between a structure and a flow also occur in a stratified fluid; second, the amplitude of these oscillations are far greater (more than a factor 10) in the stratified case than in the homogeneous case for the same parameters.

* E-mail: sarah.christin@univ-amu.fr.

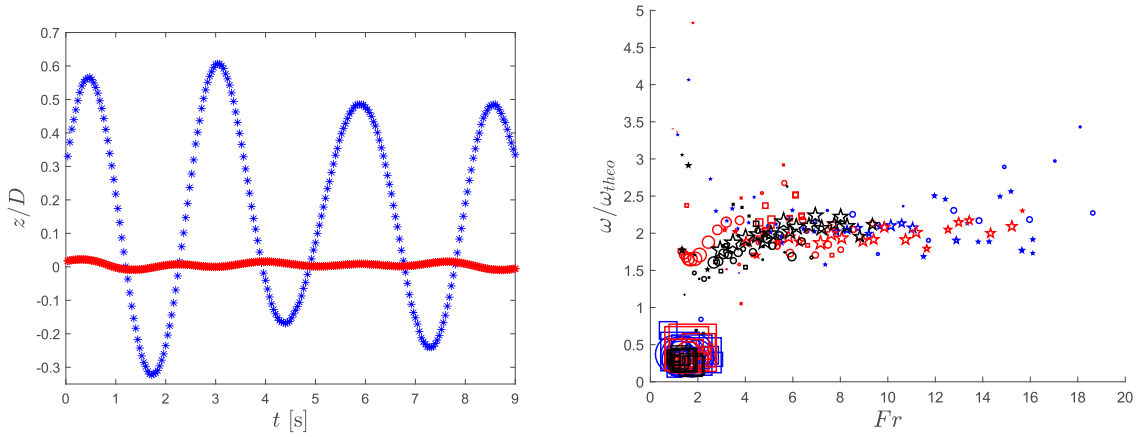

Figure 2. (a) Vertical position of the cylinder in a homogeneous fluid (red stars) and in a stratified fluid with Fr = 9.25 (blue stars). Here, L/D = 3.75 and Re = 6361. (b) Measured frequency ω as a function of the Froude number. The symbol's size is proportional to the oscillation's amplitude. Blue, red and black symbols stand for D=3, 4 and 6 cm, respectively, while squares, circles and stars stand for L= 50, 30 and 15 cm, respectively.

By varying the main parameters D, L and U, different Re, Fr and L/D are explored. A compilation of measures in all these cases is plotted in Figure 2(b), showing the existence of two modes of oscillations. The first one has low frequencies, is localized at small Fr and is favoured by a large L/D ratio. The second one has higher frequencies, can be observed for larger Fr and is favoured by low L/D ratio.

The VIV-like mode

The mode with higher frequencies is analogous to a classical VIV mode. Indeed, the natural frequency of the oscillator can be derived by summing the restoring forces on the cylinder due to the drag and to the stratification. It is equal to : $\omega_{theo} = \sqrt{\frac{N^2}{2} + \frac{C_D U^2}{\pi L D}}$, (where C_D, set to 1, is the drag coefficient of the cylinder). Figure 2(b) shows that the lock-in frequency is close to $2\omega_{theo}$, in good agreement with the VIV predictions for weak reduced mass m* (see Khalak and Williamson 1999 [1]). The stratification does not modify the physical origin of this oscillation. It simply increases the natural frequency, thus shifting the resonant band to larger ratios L/D. In a homogeneous fluid the oscillations would be locked for L/D smaller than 1. In our stratified experiment, they can be locked for L/D as large as 10.

The galloping mode

At lower Fr, and especially for large L/D ratio, a vibration mode comparable to a galloping mode is observed: oscillations with low frequencies and very high amplitudes (up to 2D) occur. In a homogeneous fluid, galloping is obtained when a symmetry is broken in the system (e.g. for a rectangular cylinder, see Bokaian and Geoola 1984 [2]) but is not observed with a circular cylinder. In the presence of stratification, the top/bottom symmetry is automatically broken. We show numerically that a weak tilt of the cylinder trajectory with respect to the horizontal creates a destabilizing lift. We argue that this effect is responsible of the galloping instability that is observed.

CONCLUSIONS

This study shows that stratification has a strong influence on the flow induced vibration phenomena affecting a moving cylinder. The stratification enhances a VIV-like mode: it leads to high amplitude oscillations even outside the classical band of resonance. It also induces new instabilities such as galloping.

THE ROLE OF FREE-SURFACE ON VORTEX-INDUCED VIBRATION OF A SPHERE

Amir Chizfahm[1], Vaibhav Joshi [1], and Rajeev Jaiman* [1]
[1]Department of Mechanical Engineering, The University of British Columbia, Vancouver, Canada

Summary Fluid-structure interaction (FSI) of submerged or floating spherical bodies has various applications in marine and offshore engineering. In this study, we aim to understand the dynamics of vortex-shedding modes and the free-surface effects on the flow-induced vibration (FIV) response of a freely vibrating sphere with fully and partially submerged configurations. To analyze the vortex synchronization regimes and the wake patterns, We systematically examine the mode transitions and the motion trajectories for a range of Reynolds number $Re \in [2000 - 15000]$. we find that the mode transition is strongly sensitive to the Reynolds number. Finally, we look into the effect of free surface on the FIV response of the sphere piercing the free surface. The maximum amplitude response of $\sim 2D$ is observed for the sphere at lock-in state which is greater than all the submerged cases studied.

INTRODUCTION

Flow-induced vibrations (FIV) of floating spheres can be useful for power generation and wave energy harvesting while such vibrations could be undesirable for spherical marine/offshore structures such as low-aspect-ratio escort tug-boats. Unlike a vast amount of literature available on two-dimensional geometry of elastically-mounted circular cylinders, there are limited studies on a three-dimensional geometry of a sphere undergoing flow-induced vibration. Besides, most of the studies on the FIV of the sphere performed for the flow past a fully submerged structural body with no free surface, to identify the modes of vibrations and motion trajectories [1]. Furthermore, there are only limited experimental studies considered the hydrodynamic effects of free-surface on FIV of the three-dimensional geometry of a sphere. The recent experimental study by [2] investigated the effect of proximity to the free surface on VIV of a fully and semi-submerged configurations of the sphere. Various regimes based on the amplitude response and the immersion ratio for the fully submerged and piercing sphere configurations were discussed. They observed that the sphere amplitude response is increased while it is piercing the free-surface for a range of immersion ratios $h^* = h/D$, where h is the distance from the top of the sphere to the free-surface and D is the sphere diameter. However, no specific wake mode was identified for the cases of piercing spheres in the study performed in [2].

In the current study, for the first time, successful validation of the 1-DOF vibrating sphere by considering the effect of the free-surface is established through detailed quantitative and qualitative comparisons with the experiments. We systematically explore the effect of Reynolds number on the mode transitions at VIV regime for a freely vibrating sphere, and its substantial effect on the coupled dynamical behavior and motion trajectories. The insight gained is used for identifying the wake modes and coupled dynamical interactions that lead to vortex-induced motion (VIM) with a large amplitude response for the sphere configuration piercing the free-surface.

HIGH-FIDELITY FSI NUMERICAL FRAMEWORK

The present study employs a first-principle based fully-coupled continuum mechanics formulation for solving a multi-phase fluid-structure interaction at high Reynolds number. The underlying formulation combines the fluid flow, structure, turbulence, two-phases and the mesh movement in an efficient and robust manner. The incompressible multiphase Navier-Stokes equations are solved via a stabilized variational framework which is coupled with a nonlinear elastic structural solver to solve the fluid-structure interaction problem. The free-surface effects are taken into account by modeling the air-water interface with the help of phase-field based Allen-Cahn equation and the turbulence is modeled via dynamic large eddy simulation (LES). The flow equations are solved in an arbitrary Lagrangian-Eulerian (ALE) framework for the mesh movement. For the stability and robustness purpose, these multi-fields are solved in an implicit manner [3].

RESULTS AND DISCUSSION

A representative schematic and the associated boundary conditions of the problem domain are shown in Fig. 1a. The root-mean-squared values of the amplitude response are compared with the recent experimental data of [2]. Our VIV results show a good agreement with the experimental data. Fig. 1b shows the trajectory response at the lock-in regime for two different Reynolds numbers. The motion trajectories for the cases in the range of $Re \in [2000 - 6000]$ are showing circular-type motion at stationary state. However, at higher Reynolds numbers ($Re = 12000, 15000$) the behaviour of the motion trajectories is found to be changing substantially at the periodic state, experiencing a combination of linear and circular-type movement. At $Re \in [2000 - 6000]$, the sphere starts to move with a linear trajectory motion with hairpin-type vortex structures shed behind the sphere body Fig. 1(b-middle), however at the stationary state, the sphere motion changes to circular-type trajectory with the vortex shedding mode transforming to spiral mode, Fig. 1(b-bottom). The mode transition for the higher Reynolds number cases however is quite different where the vortex structure modes

(c) Wake structures, stream-wise x-vorticity (ω_x) contour, and qualitative comparison of the free-surface deformation for the piercing sphere case with the experimental observation in [2], at $Re \approx 15,000$. (d) Time histories of the amplitude response and the lift coefficient and the corresponding power spectrum analysis versus the normalized frequency f^*.

transform with a mode shift frequency at the periodic state. The mode shift transforms the linear motion (due to the harpin mode), to circular-type motion (due to the spiral mode) and *vice versa* with the specific frequency. In addition, the sphere linear trajectory motion response is tilted at each mode shift.

The existence of hairpin wake modes even when the sphere is piercing the free-surface is found in our numerical analysis. We find that the vortex loop patterns that were observed for the submerged case (Fig. 1 (c-top-right)) are slightly stretched to elliptical loops for the piercing case (Fig. 1 (c-top-left)). In addition, Fig. 1(c-middle) qualitatively compares the wake dynamics of the fully-submerged sphere at ($h^* = 1$) and piercing sphere at ($h^* = -0.25$). As it can be seen the x-vorticity contour for the piercing case is quite similar with the submerged case except some added stretched vorticity formation at the top. Fig. 1d shows the time histories of the amplitude response at $h^* = -0.25$. For the case of the piercing sphere, the maximum peak-to-peak amplitude response of $\sim 2D$ is observed at the stationary state which is larger than all the submerged cases studied. Further analysis of the power spectrum is shown in Fig. 1d, where two dominant frequencies of the vortex shedding at $St_1 = 0.1$ and $St_2 = 0.29$ are found for the piercing sphere case. The existence of a higher-harmonic behaviour due to the non-symmetric geometry of the piercing sphere at the air-water interface is expected to be a major cause for the large amplitude response for the case of the piercing sphere.

CONCLUSIONS

In the present study, we have successfully employed our in-house coupled multifield solver to simulate two-phase fluid-structure interaction of a spherical body. We found that the effect of Reynolds number on the wake mode transitions and motion trajectories for a freely vibrating sphere at VIV regime is substantial. Despite the circular-type motion at stationary state at $Re \in [2000 - 6000]$ for the 3-DOF sphere, the trajectories for higher Reynolds numbers showed a combination of linear and circular motions with a tilt frequency at the periodic state. The insight gained is used to identify the wake modes and coupled dynamical interactions of the sphere piercing the free-surface. We observed that stretched hairpin-type wake loops are formed behind the sphere when it pierces the free-surface at VIV regime. The wake structures induce large amplitude oscillations ($A_{\max} \sim 2D$) that are greater than the fully submerged cases studied. The existence of higher-harmonic behaviour is observed due to non-symmetric geometry of the piercing case. It can be deduced that the geometry change at the discontinuous air-water interface has a significant impact on the synchronization of the vortex shedding and the vibration frequency, and could be the major cause of the large amplitude response.

EFFECTS OF LUBRICATION AND OSMOTIC PRESSURE ON SOLVENT PERMEATION THROUGH A MEMBRANE AT LOW PECLET NUMBER

Shuji Yamada * [1], Asahi Tazaki[1], Tomohiko Sakamoto[1], Shintaro Takeuchi[1], and Takeo Kajishima[1]
[1]Department of Mechanical Engineering, Osaka University, Osaka, Japan

Summary To understand the lubrication-dominated solvent permeation through a membrane in mass transfer, numerical simulation of permeation through a moving semi-permeable membrane of corrugated geometry is carried out with a fully validated numerical method. In mass transfer under the lubrication, the solvent permeation is induced by the discontinuities in hydrostatic pressure and osmotic pressure, which are respectively caused by the lubrication and concentration jump of solute at the membrane. An analytical model of asymptotic permeate flux of solvent (under an infinitesimal permeability condition) is presented by solving the Reynolds lubrication equation and the convection–diffusion equation of the solute. Through comparisons between the numerical and the asymptotic analytical results, the effect of permeation on lubrication in mass transfer is discussed and the significance of considering osmotic pressure in mass transfer under the lubrication is highlighted.

GOVERNING EQUATIONS, PROBLEM STATEMENT AND ASSUMPTIONS

The fluid is an incompressible Newtonian fluid with a constant density (ρ) and constant viscosity (μ). The governing equations of the fluid are the equation of continuity and Navier-Stokes equation, and the concentration obeys the convection-diffusion equation:

$$\nabla \cdot \boldsymbol{u} = 0, \qquad \frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} = -\frac{\nabla p}{\rho} + \frac{\mu}{\rho}\nabla^2 \boldsymbol{u}, \qquad \frac{\partial c}{\partial t} + \boldsymbol{u} \cdot \nabla c = \nabla \cdot (D \nabla c),$$

where $\boldsymbol{u}$ is the velocity, t is the time, p is the pressure, μ is the viscosity, c is the concentration and D is the diffusivity.

The volumetric flux of the fluid across the membrane is modelled by the following equation: $\boldsymbol{J}_n = L_p([\![p]\!] - [\![\Pi]\!])\boldsymbol{n}$, where $\boldsymbol{n}$ is unit normal vector pointing from the rear side of the membrane Ω_1 to the front side Ω_2, L_p is the permeability for pure fluid, and $[\![p]\!]$ is the hydrostatic pressure jump (i.e., discontinuity) across the membrane calculated with the limiting pressure values at the interface, p_1 and p_2, on the respective sides of the membrane as $[\![p]\!] = p_1 - p_2$. Assuming that the solution is a dilute solution, the osmotic pressure Π is given by van't Hoff's law: $\Pi = cRT$, where R is the ideal gas constant and T is the temperature. Note that the concentration represents the molar concentration. Then, the volumetric flux is described by following equation:

$$\boldsymbol{J}_n = L_p([\![p]\!] - RT\,[\![c]\!])\boldsymbol{n}. \tag{1}$$

We study the permeation across a corrugated semi-permeable rigid membrane in a parallel channel moving at a constant velocity (U_0), as schematically shown in Fig.1. The membrane has an infinitesimal thickness. The geometry of the corrugation and its prescribed motion are given by the following function: $h(x,t) = h_0(1 + \delta\cos[k(x - U_0 t)]$, where $k(= 2\pi/l)$ is the wave-number and δ is a parameter between 0 and 1. The corrugation has an infinite extension in the x direction. We assume that the amplitude of corrugation δh_0 is sufficiently small with respect to the half-channel width h_0 (i.e., $\delta \ll 1$) and that h_0 is much smaller than the wavelength of the corrugation (i.e., $h_0 \ll 2\pi/k$) which is equivalent to aspect ratio $\varepsilon(= h_0/l)$ being sufficiently small, i.e.,$\varepsilon \ll 1$. We solve the concentration field under the prescribed Dirichlet conditions on the top and bottom walls: $c_{\mathrm{top}}(x) = c_0(1 + \sin(kx))$ and $c_{\mathrm{bot}}(x) = c_0(1 - \sin(kx))$.

In the present study, the permeation is solved by transforming the frame to that attached on the membrane for simplicity. When ε and the Reynolds number $\mathrm{Re} = \rho U_0 H/\mu$ satisfy $\varepsilon \ll 1$ and $\varepsilon\mathrm{Re} \ll 1$, the flow can be described by the Reynolds lubrication equation in both Ω_1 and Ω_2 regions. In addition, when ε and the Peclet number $\mathrm{Pe} = U_0 H/D$ satisfy $\varepsilon \ll 1$ and $\varepsilon\mathrm{Pe} \ll 1$, the concentration filed is determined by the diffusion in the y direction.

ASYMPTOTIC PERMEATION FLUX AND OUTLINE OF NUMERICAL METHOD

With a membrane of infinitesimal permeability ($L_p \to 0$, and therefore $J_y \to 0$), the pressures in Ω_1 and Ω_2 regions, $p_1(x)$ and $p_2(x)$, follow separate Reynolds lubrication equations. By solving the Reynolds lubrication equation, the pressure in Ω_1 is given as follows:

$$p_1(x,t) = -6\mu U_0 \frac{h(x,t)+h_0}{(2\pi\varepsilon)^2(2+\delta^2)} \frac{\partial h^{-1}(x,t)}{\partial x}. \tag{2}$$

From the geometric symmetry of Ω_1 and Ω_2 (see Fig.1) and the one-dimensional nature of the lubrication pressures, the pressure in Ω_2 is given as $p_2(x,t) = p_1(x+\pi/k,t)$, and then $[\![p]\!]$ can be calculated. On the other hand, the concentrations in Ω_1 and Ω_2, $c_1(x,y)$ and $c_2(x,y)$, follow the respective diffusion equations. Under $\varepsilon \ll 1$ and $\varepsilon \mathrm{Pe} \ll 1$, c_1 and c_2 become independent of y, and the values are homogeneous in the y direction being fixed at the respective boundary values, $c_{\mathrm{bot}}(x)$ and $c_{\mathrm{top}}(x)$. Finally, under an infinitesimal L_p, the permeate flux is given by the sum of the permeations due to the discontinuities in the hydrostatic and osmotic pressures: $J_y(x,t) = L_p([\![p]\!] - RT\,[\![c]\!])$. By substituting Eq.(2) and $c_{\mathrm{top/bot}}$ into this J_y, the asymptotic permeate flux is obtained as

$$\frac{J_y(x,t)}{U_0} = -\frac{96L}{4\pi\varepsilon}\frac{\delta}{2+\delta^2}\frac{\sin\left[k(x-U_0t)\right]}{\left(1-\delta^2\cos^2\left[k(x-U_0t)\right]\right)^2} - \omega L\mathrm{Re}\sin(kx), \tag{3}$$

where L is the non-dimensional permeability defined as $L_p\mu/H$ and ω is the ratio of osmotic pressure to hydrostatic pressure defined as $2RTc_0/\mu U_0 H^{-1}$. Hereafter, we refer J_y under an infinitesimal L_p as asymptotic permeate flux.

For comparison, the fluid motion is numerically solved on a Cartesian fixed mesh system with a uniform mesh size (Δ). The membrane is represented by connected Lagrangian marker points. For coupling the fluid and object motions, an original discrete-forcing immersed boundary method [2] is employed, which is characterised by (i) the direct discretisation of the governing equations even at the grid points adjacent to the interface and (ii) the consistent coupling of the incompressible velocity and pressure fields. The same strategy is applied for discretising the concentration field near the interface. The above two features of the method enable capturing the sharp discontinuity of the pressure and concentration. For more details on the numerical method, refer to Ref. [2].

RESULTS AND DISCUSSION

In the present study, the domain length l is fixed at $5H$ $(= 10h_0)$; the aspect ratio of each flow region is sufficiently small, $\varepsilon = 0.1$. The amplitude parameter δ is fixed at 0.1. The Reynolds and Peclet numbers are set at $\rho U_0 h_0/\mu = 0.5$ and $U_0 h_0/D = 0.5$, and the reference concentration and the pressure ratio are fixed at $c_0 = 0.5$ and $\omega = 1$, respectively. Numerical simulation is carried out at the spatial resolution $h_0/\Delta = 20$ and the time increment $\Delta t/(H/U_0) = 5\times10^{-5}$. To see the asymptotic trend of J_y as $L \to 0$, the permeability is varied in the following range: $10^{-2}, 10^{-3}, 10^{-4}$ and 10^{-5}. Note that, depending on the phase difference between the corrugation and the boundary profiles of c, the above solvent fluxes $J_y(x,t)$ will encounter the weakening and strengthening instants. Figure 2 compares the longitudinal distributions of $J_y/(U_0L)$ at three different cases: (a) steady solvent flux induced only by $[\![p]\!]$ (i.e., $\omega = 0$), and the two cases of $\omega = 1$ in (b) the weakening configuration at $t/(H/U_0) = 7.5$ and (c) the strengthening configuration at $t/(H/U_0) = 10.0$. The figure highlights the effects of osmotic pressure on permeation under the lubrication. The asymptotic analytical prediction, Eq.(3), reasonably approximates the asymptotic permeate flux distributions, and, in the presentation, the difference from the numerical result will be discussed with the induced flux due to the effect not described by the Reynolds equation. A NEW MECHANISM OF TRANSITION TO AEROELASTIC DIVERGENCE

Vasily Vedeneev *
Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary There are two types of aeroelastic instabilities: flutter, which is an oscillatory loss of stability, and divergence, which is a static instability. A general divergence mechanism described in textbooks consists of decrease of one of natural frequencies down to zero due to negative aerodynamic stiffness, coalescence with its paired frequency, and transformation to one damped and one growing frequency. Most examples of this mechanism use quasi-steady aerodynamics. In this study we show that when using unsteady aerodynamics, analytical structure of eigenfrequencies essentially changes; namely, no frequency coalescence occurs; instead, structural eigenfrequencies stay damped. The divergence mode is not a continuation of a structural mode, but separates from a continuous spectrum that exists in the aeroelastic system when unsteady aerodynamics is used, but is absent in quasi-steady case.

INTRODUCTION

In most of aeroelasticity textbooks [1–3], divergence and flutter are considered separately: divergence as static instability, where steady aerodynamics is employed, and flutter as dynamic instability, where the use of unsteady aerodynamics is crucial for flutter prediction. Even when divergence is considered within the framework of a dynamic system, still, at best, quasi-steady aerodynamics is used. In this study we re-analyse the classical problem of instability of two-degree-of-freedom (bending and torsional) system, focusing on divergence, but using fully unsteady Theodorsen aerodynamics.

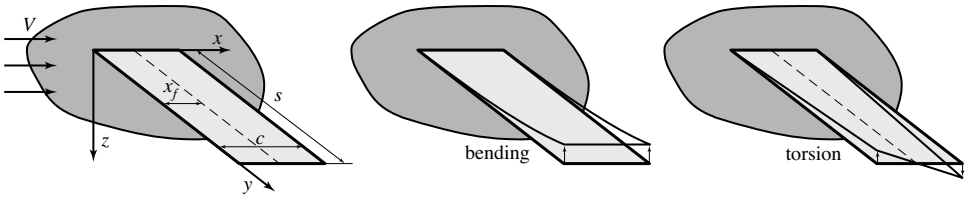

Figure 1: Rectangular wing and its bending and torsional degrees of freedom.

PROBLEM FORMULATION AND RESULTS

Wing model

We consider a classical two-degree-of-freedom aeroelastic model of a thin rectangular wing (Fig. 1) in incompressible fluid flow. To derive equations of motion, we follow a standard procedure, applying Largange equation as done in [3, §10.2.1]. To calculate unsteady aerodynamic lift and moment, we use a strip theory, assuming that aerodynamic forces produced by each cross-section can be taken from corresponding two-dimensional problem. We will restrict ourselves to harmonic motion of the wing, which is sufficient for both divergence and flutter analyses. Taking time dependence in the form $e^{i\omega t}$, the two-dimensional aerodynamic forces are readily given by Theodorsen theory [1, §5-6], [2, §6.9], [3, §9.3]. After standard algebra, we obtain aeroelastic equations of motion that yield the following eigenvalue problem:

$$\mathcal{F}(\omega) = \det(-\omega^2\mathbf{M} + i\omega\mathbf{D}_a(k) + (\mathbf{K}_a(k) + \mathbf{K})) = 0, \tag{1}$$

where $\mathbf{M}$ and $\mathbf{K}$ are structural mass and stiffness matrices, $\mathbf{D}_a(k)$ and $\mathbf{K}_a(k)$ are aerodynamic damping and stiffness matrices. While structural matrices are constant, aerodynamic matrices are expressed through the Theodorsen function $C(k) = K_1(ik)/(K_0(ik) + K_1(ik))$, where K_n are modified Bessel functions of the second kind, and $k = \omega c/(2V)$ is the reduced frequency.

Numerical results

The eigenvalue problem (1) is solved numerically by an iterative method. Calculations are started at sufficiently small flow speed V, where each solution is associated with a wing eigenmode in still air. Next, V is gradually increased so that continuous branch of eigenfrequencies is obtained. Parameters used in [3, §10.8] are considered here as an example.

Figure 2a shows the eigenfrequency loci when using quasi-steady aerodynamics. It is seen that when the flow speed is increasing, bending frequencies ω_2 and ω_4 move just slightly, while torsional frequencies ω_1 and ω_3 move toward each other, coalesce at the imaginary axis, and transform to damped and divergence modes. This behaviour represents classical divergence mechanism [1–3]. However, the use of full unsteady aerodynamics yields completely different eigenfrequency loci shown in Figure 2b. Torsional frequencies do not approach each other and do not interact, but become highly damped. The divergence mode also exists for $V \geq V_{div}$, being the fifth mode. But for $V < V_{div}$ no divergence root is found. Hence, at subcritical flow speed only structural modes are present. Note that the eigenvalue problem (1) is not algebraic, because eigenfrequency ω is not only explicitly present in the equation, but is also implicitly present in aerodynamic matrices, which are functions of the reduced frequency k. That is why constant number of roots cannot be guaranteed.

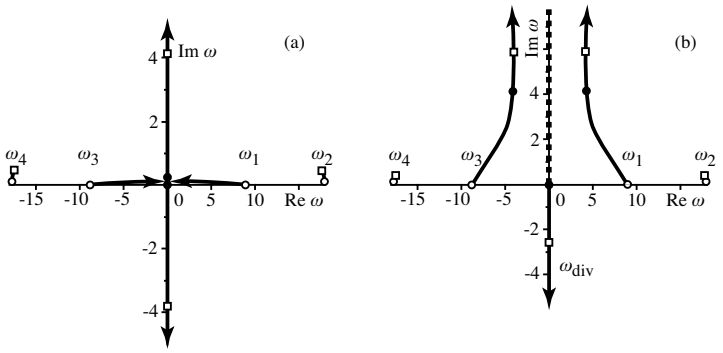

Figure 2: Eigenfrequency loci when changing the flow speed V from $V = 10$ m/s (○) to $V = V_{div} = 54.9$ m/s (●) and further to $V = V_{div} + 5 = 59.9$ m/s (□). Quasi-steady aerodynamics (a), full unsteady aerodynamics (b).

Proof of the non-existence of the divergence mode and subcritical flow speeds

To avoid numerical issues, a rigorous analysis of (1) in the vicinity of the divergence speed has been conducted. Let us have the solution $\omega = k = 0$ at $V = V_{div}$. We take a small velocity deviation $V = V_{div} + V'$ and find a solution of (1) that tends to zero as $V' \to 0$, i.e. find the divergence mode frequency in the vicinity of the divergence boundary. Neglecting ω^2 term as infinitesimal, and considering the asymptotic expansion of Theodorsen function at small k, we find simplified eigenfrequency equation (1) near the divergence boundary. Its rigourous analysis yields the following: the divergence root exists at $V \geq V_{div}$, but no root exists at $V < V_{div}$. In other words, the divergence mode is not a continuation of a natural mode of the wing but is an additional eigenmode that exists only for $V \geq V_{div}$.

Mathematically, this phenomenon is due to logarithmic singularity of Theodorsen function at $k = 0$, and it does not manifest itself if simplified quasi-steady aerodynamics is used.

Initial-value problem and the continuous spectrum

To understand the origin of the divergence mode, we solve the initial-value problem by using Laplace transformation technique. The general solution ($q_{b,t}$ are generalised coordinates corresponding to bending and torsion) has the form

$$q_{b,t}(t) = \frac{1}{2\pi}\int_0^{+i\infty} [\xi]_{b,t}(\omega) e^{i\omega t} d\omega + \sum_{n=1}^{p} i \frac{C_{b,t}(q^n_{b,t}, \omega_n)}{\partial \mathcal{F}(\omega_n)/\partial \omega} e^{i\omega_n t}, \tag{2}$$

where $[\xi]_{b,t}$ and $q^n_{b,t}$ are expressed through the initial conditions. It is seen that the solution is the linear combination of two terms: eigenmodes that form discrete spectrum of the problem (p is the number of eigenfrequencies), and the integral over pure imaginary damped frequencies that form continuous spectrum. Mathematically, the continuous spectrum is present due to the branch cut of the Theodorsen function. Its physical nature originates from the wake behind the oscillating wing: the wake is convected downstream but 'remembers' the wing motion in the past and affects the aerodynamic loading.

It is now clear that the divergence eigenmode that exists only at $V \geq V_{div}$ (Fig. 2b) does not come from "nowhere" but separates from the continuous spectrum at $V = V_{div}$. If quasi-steady aerodynamics is used, then aerodynamic matrices are constant, and no continuous spectrum is present. This reflects the fact that, physically, quasi-steady aerodynamics ignores the wake behind the wing and, consequently, the wake influence on the aerodynamic loads.

CONCLUSIONS

We have proved that when using fully unsteady aerodynamics for aeroelastic calculations, first, in addition to discrete spectrum of eigenfrequencies, there exists a continuous spectrum consisting of monotonically damped frequencies, which originates from the wake behind the oscillating wing. Second, the growing divergence eigenfrequency is not a smooth continuation of 'structural' natural frequency. Instead, all structural frequencies become damped at postcritical flow velocity, whereas the divergence mode is an additional mode which exists only at post-critical speeds and separates at the divergence speed out the continuous spectrum at $\omega = 0$.

Present results are compared with other studies that used unsteady aerodynamics for the divergence analysis [4–6] and with experimental divergence study [6], where divergence not originating from structural modes was observed. 'Practical' methods of aeroelastic analysis, such as k, p-k, g methods, are discussed.

SUPERSONIC FLUTTER OF ELASTIC PANEL UNDER DIFFERENT DISTURBANCES

A.S. Shishaeva[1,2], V.V. Vedeneev[1], G.B.Sushko[2], A.A. Aksenov[2]
[1]Lomonosov Moscow State University, Moscow, Russia

Summary We investigate elastic panel behavior under different external disturbances in a constant, accelerated and decelerated supersonic flow. We obtain that the most dangerous disturbance is the third mode disturbance in gas flow with Mach number $1.45 < M < 1.6$.

INTRODUCTION

Aeroelastic instability of skin panels in supersonic gas flow, known as panel flutter, can be either single mode or coupled mode flutter. The coupled-mode panel flutter occurs at high supersonic gas speed [1], while at low supersonic speed the single-mode flutter is dominating [2]. A single-mode flutter regime is more energy-intensive and, thus, more dangerous. In our study [3] we considered instability of a skin panel in a constant subsonic and supersonic gas flow under a small external disturbance. Gas speed was varying from M=0.7 to M=1.7. We obtained that there are different types of single-mode flutter at small supersonic gas speeds: simple first mode flutter ($1 < M < 1.12$, $1.41 < M < 1.7$), 1:2 resonant flutter ($1.12 < M < 1.33$), high-frequency non-periodic flutter ($1.33 < M < 1.41$). Resonant flutter includes first and second natural modes and internal resonance between them. High-frequency non-periodic flutter includes two, three or more natural modes and an internal resonance between them. In our study [4] we considered instability of a skin panel in accelerating and decelerating gas flow under a small external disturbance. We obtained that there is a strong effect of the acceleration or deceleration on the panel. For example, high acceleration of deceleration eliminates high-frequency non-periodic flutter. Different limit cycles can realize at the same flow conditions in dependence of a form and power of external disturbance. Moreover, in that case one limit cycle can be transformed to another by applying a single disturbance to the plate. In this work we study an effect of a disturbance applied to the plate.

STATEMENT OF THE PROBLEM

We consider an interaction of an elastic plate with an external supersonic flow of air considered as inviscid perfect gas. The gas flows over one side of the plate with Mach number varied in the range $1<M<1.7$. At the other side of the plate, a pressure equal to the undisturbed flow pressure is specified, such that the undisturbed pressure difference along the plate is zero. The elastic plate of length $L_p = 0.3$ m and thickness $h_p = 0.001$ m is mounted into a rigid plane (see Figure 1). The plate is made of steel with Young's modulus $E = 2 \cdot 10^{11}$ Pa, Poison coefficient $\nu = 0.3$ and density $\rho_m = 7800$ kg/m^3. In dimensionless terms, the plate stiffness and length are: $D = D_p/(a^2 \rho_m h^3) = 21.4$, $L = L_p / h_p = 300$, where $D_p = Eh^3/(12(1-\nu^2))$ is the dimensional plate stiffness, and $a = 331$ m/s is the speed of sound in the air. The plate is described by the nonlinear Mindlin plate model, where elastic strains are calculated through Koiter–Sanders shell theory. During small initial period of time, disturbance is applied to the panel, and its evolution is analysed.

The subsequent plate-flow interaction is calculated using two coupled solvers: Abaqus for simulating the plate deformation and FlowVision for simulating the gas flow. The interaction between the programs is organized through the direct coupling mechanism along the surface of the deformed plate. Investigation of grid, time and domain convergence, testing of the model on coupled and single mode flutter at constant flow speed are described in [3].

Figure 1. Statement of the problem.

RESULTS

We consider two statements: panel behavior in a constant flow and in an accelerated or decelerated flow. In the first statement an effect of the first, second and third mode disturbance with significant load applied to the panel is considered. We compare these results with the behavior under disturbance with small load [3]. We analyze shape of the plate oscillations and dimensionless total energy. Dimensionless total energy is calculated as $W = (W_{kinetic}+W_{strain})/0.5\rho V^2 Ldz$. We obtain that there is a significant effect of initial disturbance for $M > 1.2$. If we apply second mode disturbance with significant amplitude to the panel in Mach number range $1.2 < M < 1.5$, than a second mode flutter is realized. Total energy of the second form flutter of the panel in Mach number range $1.4 < M < 1.48$ is two times larger than for small amplitude (see Figure 2, blue marker). If we apply third mode disturbance with significant initial amplitude to the panel in Mach number range $1.33 < M < 1.6$, a third mode flutter is realized. The total

energy of the panel under the third mode disturbance with large amplitude is two times larger than for a small amplitude in Mach number range $1.33 < M < 1.45$ (see Figure 2, green marker), and ten times larger in Mach number range $1.45 < M < 1.6$ than the largest energy of flutter realized under the small load in all investigated Mach numbers.

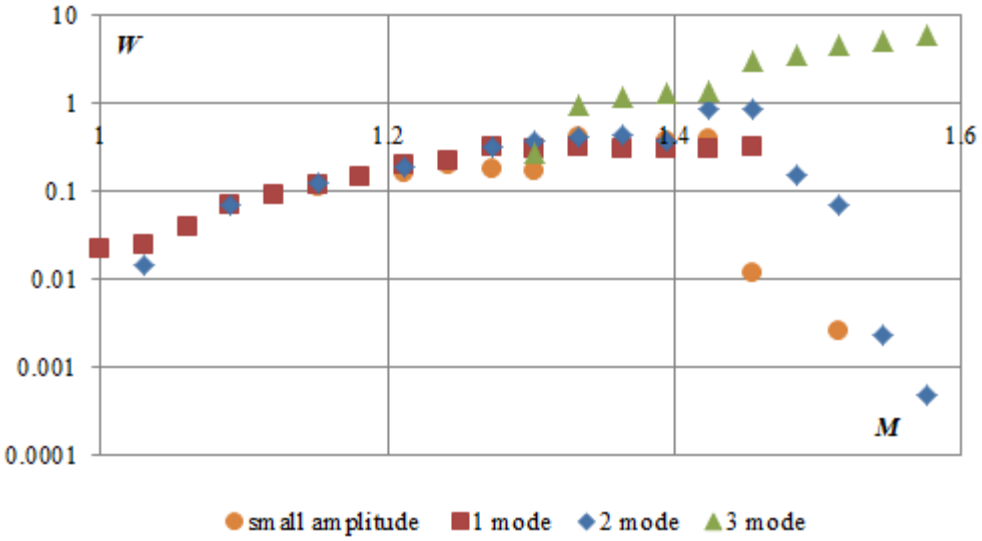

Figure 2. Dimensionless vibration energy of the panel (W) via Mach number (M).

In the second problem statement we investigate the evolution of the disturbance in the accelerated and decelerated supersonic flow. We obtain that the most significant effect takes place for the third mode disturbance with large amplitude at $1.4 < M < 1.7$.

CONCLUSIONS

The investigation shows that disturbances of higher modes (second and third) with large initial amplitude may induce single mode high-frequency vibrations with high energy. That vibrations are more energetic and dangerous than others so that it is important to avoid such kind of disturbances or flow conditions.

INTERMITTENCY IN FLOW FIELD OF PLUNGING TEARDROP FOIL

Chhote Lal Shah* [1], Dipanjan Majumdar[1], and Sunetra Sarkar[1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Madras, Chennai-600036, Tamilnadu, India.

Summary Flapping wings with suitable wing kinematics, wing shapes, and flexible structures can enhance lift as well as thrust by exploiting large-scale vortical flow structures under various conditions. However, it is also necessary to understand the dynamics of the flow field, which may influence the flyers. In the present study, an elliptic foil with an attached tail at the trailing edge is considered for studying the dynamics of the flow field. The present work focuses on analysing the dynamics with an increase in the flexibility of the tail structure. Although a perfectly rigid tail enhances the aerodynamic performance, it can also take the system to aperiodicity. However, a flexible tail has the ability to stabilize the system.

INTRODUCTION

Biologically inspired insect flight mechanisms have recently become a primary research subject, mainly to use in micro air vehicles (MAVs) for defense surveillance and environmental monitoring. The prime source of inspiration in this regard with the reliance on natural selection comes from the natural flyers due to the similar Reynolds number regime in which they fly. Natural flyers utilize the unsteady aerodynamics around their flapping wings to generate the lift and thrust. These aerodynamic loads are related to the formation and shedding of the vortices into the flow which are again dependent on different wing shapes, structural flexibility and wing kinematics. A rigid elliptic foil plunging in uniform stream results in a drag producing von-Karmann wake, thrust producing reverse Karmann wake and deflected reverse Karmann wake with the increase in plunge velocity kh (where $k = \frac{2\pi fc}{U_\infty}$ is reduced frequency, f is frequency, c is chord length of elliptic foil, U_∞ is free stream velocity, and h is nondimensional plunge amplitude) [1]. With further increase in kh the flow field transitions into the aperiodic regime and eventually to chaos [2]. However, a more realistic design of a bio-inspired wing would consist of a flexible trailing part attached to the stiff leading portion. Such models are typically called a teardrop model [3]. Heathcote and Gursul [3] reported that the enhancement in mean thrust is possible by using such a teardrop model. Likewise, Mia and Ho [4] noted that a flexible foil with a pre-defined deformation could increase the propulsive efficiency. Further, Heathcote et al. [5] showed that the thrust/input-power ratio was significantly high for flexible airfoils than rigid airfoils. Also, they observed that at high plunging frequencies, moderately flexible airfoil generates the largest thrust, while highly flexible systems show larger thrusts at low frequencies.

Most of the literature mentioned above focused on enhancing the aerodynamic performance. However, the dynamical transitions in the flow field of such a teardrop model have not been investigated earlier. The focus of this study is to explore the dynamics associated with the flow field for different levels of flexibility for the teardrop model. This study is of importance from the MAVs design point of view as one must avoid the system from entering into an aperiodic state in a broad sense.

COMPUTATIONAL METHODOLOGY

A teardrop airfoil with a rigid elliptic part (with major axis length as c) and a flexible tail of length $0.3c$ is considered here. A sinusoidal plunge motion is provided at the center of the elliptic foil. The trailing part of the teardrop is modeled as an inextensible flexible filament [6] and is allowed to oscillate passively. The flow around the oscillating body is governed by the incompressible Navier-Stokes equations. An in-house flow solver has been developed following the discrete forcing Immersed Boundary Method (IBM) proposed by Kim et al. [7]. In the present Fluid-Structure Interaction (FSI) framework, the structural solver and the IBM solver are coupled in a weak coupling approach where both flow and structural solvers exchange information explicitly at every time-step. The Reynolds number is kept constant at 300 throughout the study. The simulations are run after performing domain and grid convergence studies. A time step of 0.0004 has been considered after performing a time convergence test and has been used for the rest of the simulations.

RESULTS AND DISCUSSIONS

Simulations have been performed for a wide range of kh values. In order to study the effect of tail flexibility on the flow dynamics, different levels of rigidity with γ (nondimensional bending rigidity) = ∞ (rigid case), 1.0 and 0.1 have been considered. It is observed that the inclusion of a tail at the trailing edge of the elliptic foil enhanced the aerodynamic performance. At lower kh, the flow field, as well as aerodynamic loads, remain periodic for all the cases. However, the present study focuses on $kh = 1.5$, which is in the aperiodic regime. Time history of drag coefficient (C_D) and corresponding Morlet wavelet spectra [8] in terms of scalogram plots are presented in Figure 1. The scalograms are the visual representation of the wavelet transforms in which the x-axis represents time, and the y-axis represents the time-evolution of the frequency content of a signal.

*Corresponding author. E-mail: lal.chhote.shah@gmail.com

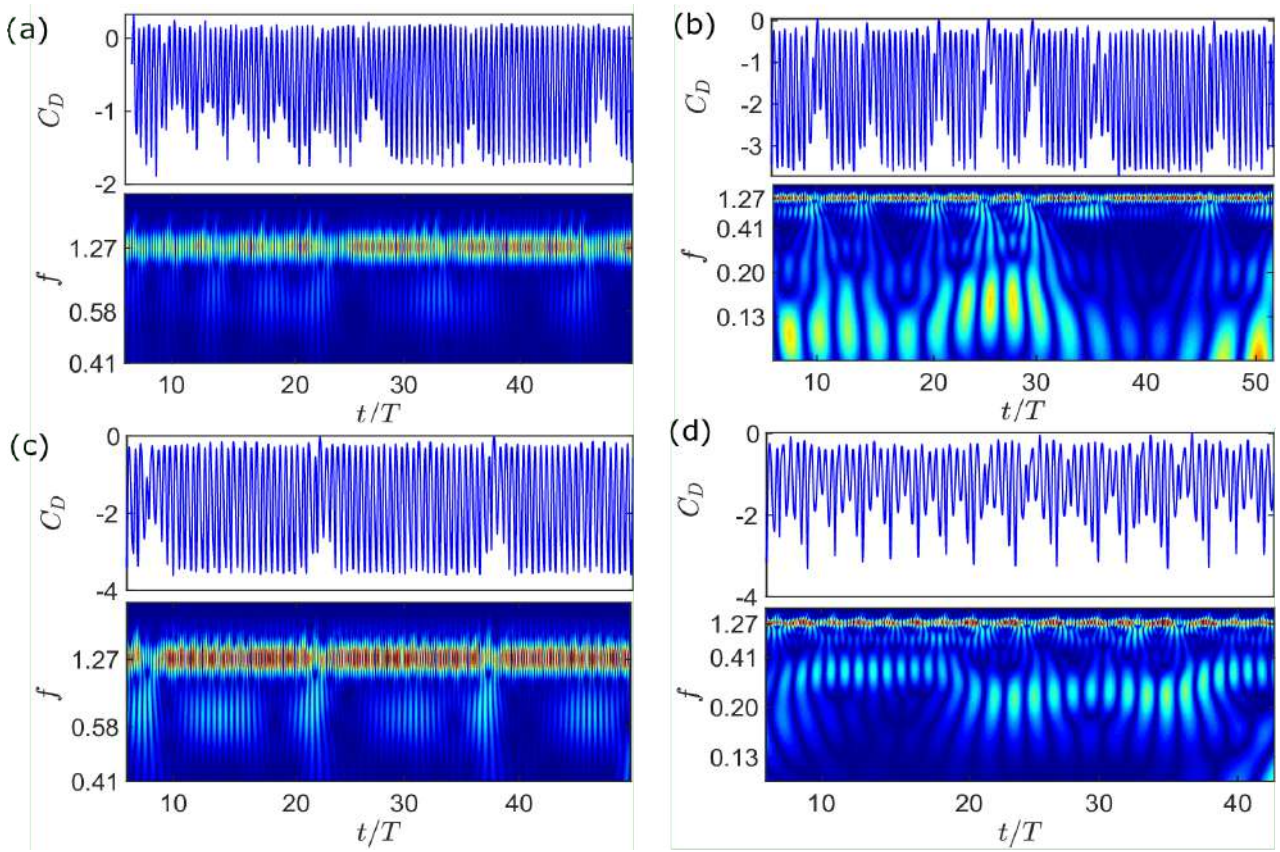

Figure 1: C_D time histories and corresponding scalogram of the wavelet coefficients for $kh = 1.5$; (a) elliptic foil without aft tail, (b) elliptic foil with rigid aft tail, (c) elliptic foil with flexible aft tail of $\gamma = 1.0$, and (d) elliptic foil with flexible aft tail of $\gamma = 0.1$.

The C_D time history for the rigid foil without tail exhibits an intermittent behavior that shows quasiperiodic time windows interspersed by chaotic windows (Figure 1 (a)). With the addition of a rigid tail, the mean thrust also increases notably. However, the system also enters into sustained aperiodicity (chaos) as is strongly suggested by the broad banded frequency spectrum in the scalograms in Figure 1 (b). As the rigidity of the tail is reduced, at $\gamma = 1.0$, the leading edge separation behavior again shows intermittency, which is clearly reflected in the C_D time history and corresponding wavelet spectra (Figure 1 (c)). With further decrease in the rigidity, for $\gamma = 0.1$, the flow field, and hence the C_D, becomes quasiperiodic. The quasiperiodic nature is confirmed from the modulation in the C_D time history caused by incommensurate frequency bands shown in the scalogram plot in Figure 1 (d).

CONCLUSIONS

In this study, the transition in flow dynamics of a sinusoidally plunging teardrop airfoil has been investigated. The existence of intermittency has been observed at $kh = 1.5$. Scalogram is used to characterise the dynamics associated with the time histories. The inclusion of a rigid tail at the trailing edge of the foil gives better aerodynamic performance, but the system also enters into a chaotic regime. However, with an increase in flexibility, the system no longer exhibits chaos, and the dynamics gets stabilized. Further time series analyses on the characterization of different dynamic states and the details of the flow field could not be shown here for the sake of brevity but will be shared during the presentation. The present study contributes towards the design of flexible flapping wings for the development of micro-air vehicles.

ON DYNAMICS OF AN AEROELASTIC SYSTEM WITH TWO TRANSLATIONAL DEGREES OF FREEDOM

Yury D. Selyutskiy[1]
[1]Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary An aeroelastic system is considered which consists of two bodies that can move translationally in the direction transversal to the incoming flow. It is assumed that one of these bodies is bluff, and the aerodynamic load upon the other body is negligible. It is shown that if parameters of the system meet certain conditions then the trivial equilibrium can be destabilized by increasing of stiffness of one of the mounting springs. Dependence of amplitudes of limit cycles arising in the system on the mounting stiffness is studied.

INTRODUCTION

Aeroelastic systems consisting of a bluff body that can move translationally across the incoming flow (which means that the system has one translational degree of freedom) are intensively studied for many years. It is known that the so called galloping can arise in such systems, when the "natural" (or "trivial") equilibrium becomes unstable if the flow speed gets large enough, which results in the onset of self-sustained oscillations. This effect is of great interest from the point of view of engineering: on the one hand, it can lead to the fatigue and break of structures; on the other hand, such oscillations can be used for power generation purposes.

Different aspects of the influence of various parameters on the galloping behaviour of rectangular cylinders were investigated numerically and experimentally, in particular, in [1], [2].

Questions of using this phenomenon for energy harvesting were discussed, e.g., in [3], where the influence of electric load on the onset and characteristics of galloping oscillations were analysed.

In the present work, we consider an aeroelastic system with two translational degrees of freedom.

PROBLEM STATEMENT

Consider an aeroelastic system consisting of rigid bodies M_1 and M_2 connected with springs and able to move translationally along the axis OY (see Fig. 1). The body M_2 has a shape of rectangular cylinder.

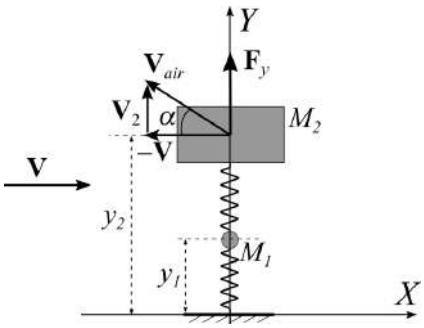

Figure 1. Aeroelastic system with two translational degrees of freedom.

This system is placed in the airflow; the air speed V is constant and perpendicular to the line of motion of bodies. We assume that the body M_2 interacts with the flow, while the aerodynamic load upon the body M_1 is negligible.

Here, we consider a modification of the conventional system, which comprises two bodies instead of one. Taking into account the above mentioned, the equations of motion can be written as follows:

$$m_1 y_1 + k_1 y_1 + h_1 y_1 + k_2(y_1 - y_2) + h_2(y_1 - y_2) = 0,$$
$$m_2 y_2 + k_2(y_2 - y_1) + h_2(y_2 - y_1) = F_y.$$

Here $y_{1,2}$ are coordinates of bodies; $k_{1,2}$ and $h_{1,2}$ are coefficients of stiffness and damping of springs; F_y is aerodynamic force acting upon the body M_2 and directed along the OY axis:

$$F_y = \frac{\rho S}{2} V_{air}^2 C_y(\alpha), \quad V_{air} = \sqrt{V^2 + V_2^2} = \sqrt{V^2 + y_2^2}, \quad \alpha = -\arctan\frac{y_2}{V},$$

where ρ is the air density, S is the cross-section area of the body M_2, V_{air} is the speed of this body with respect to the incoming flow, C_y is a non-dimensional coefficient.

From symmetry considerations, it is clear that $C_y(0) = 0$, and the system has the trivial equilibrium: $y_1 = y_2 = 0$.

RESULTS AND DISCUSSION

For simplicity sake, we normalize equations using characteristic length $L_c = b$ (the width of the body M_2), characteristic time $T_c = b/V$, and characteristic mass $m_c = \mu\rho Sb/2$ (where μ is a non-dimensional coefficient characterizing the ratio of average density of the body M_2 to the air density).

In order to illustrate the behaviour of the system for different values of parameter k_1 changes, numerical simulations were performed. Data for C_y are from [1]. The following values of parameters were used: $m_1 = m_2 = 1$, $k_2 = 1.5$, $u = 1$, $h_1 = -C_y^\alpha + 0.3$, $h_2 = -C_y^\alpha + 0.5$ (here $C_y^\alpha = \left(dC_y/d\alpha\right)\Big|_{\alpha=0}$).

From the point of view of flow energy harvesting, it is important that an attracting limit cycle exists in the system. We denote the amplitude of oscillations of the second body in limit cycle (when it exists) with X_2.

Evolution of X_2 with the change of k_1 is shown in Fig. 2. The solid line corresponds to attracting cycles, and the dashed line, to repelling ones. Plus signs show the intervals of k_1 where the trivial equilibrium is asymptotically stable.

It should be noted that the trivial equilibrium is asymptotically stable for sufficiently small and sufficiently large values of the stiffness of the first spring. For $k_1 \approx 0.86$ and $k_1 \approx 3.6$, subcritical Hopf bifurcations occur, when a repelling limit cycle merges with stable fixed point. For "moderate" values of k_1, the equilibrium is unstable.

It is interesting to note that making the system more "stiff" doesn't necessarily make it stable. Such effect is illustrated in Fig. 3, where the instability area is shown in plane (k_1, k_2). In some cases, simultaneous increase in stiffness coefficients of both springs results in destabilization. Moreover, in some situations it is sufficient to decrease stiffness coefficient of one spring to ensure the stabilization. Such effect of change in stiffness looks somewhat unconventional. Similar phenomenon was reported for an aeroelastic system with one translational and one rotational degrees of freedom in [4].

Thus, increase in stiffness can result in stability loss. In order to make the equilibrium stable again, it is necessary to increase k_1 considerably.

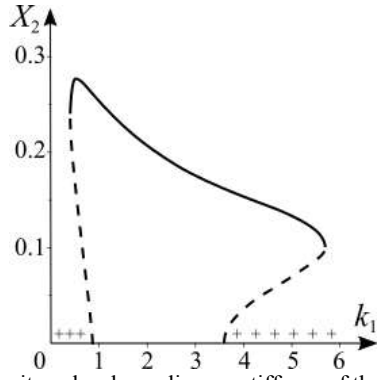

Figure 2. Limit cycles depending on stiffness of the first spring.

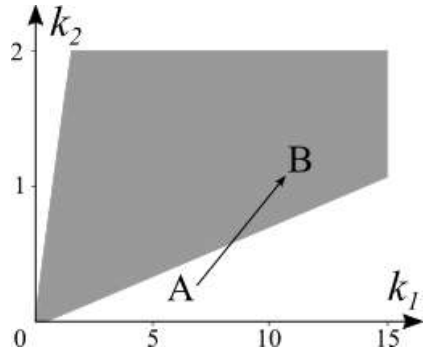

Figure 3. Domain of instability (grey colored): effect of stability loss induced by increase in stiffness

An attracting limit cycle exists in the system in wide enough range of parameters. Its amplitude decreases as k_1 increases. For sufficiently small and sufficiently large values of stiffness of the first spring, no limit cycle was found.

CONCLUSIONS

The discussed aeroelastic system with two translational degrees of freedom is subject to flow-induced vibrations. Proper choice of parameters (such as mounting stiffness) can ensure large enough amplitudes of oscillations. So, this system has the potential to be used as an element of oscillatory-type wind power harvesting devices.

FLUID-STRUCTURE INTERACTION ANALYSIS OF CORRUGATED DACRON GRAFT USED FOR AORTIC REPLACEMENT

Raja Jayendiran[1], Bakr Nour[2] and Annie Ruimi*[1]
[1] Mechanical Engineering Program, Texas A&M University at Qatar, Doha, Qatar
[2]Weill Cornell Medicine-Qatar, Doha, Qatar

Summary Aortic dissection (AD) is a serious medical condition characterized by a tear in the intima, the inner layer of the aortic walls. In such occurrence, blood is diverted to the media layer and may result in patient death if not quickly attended. Treatment involves replacing the diseased portion of the aorta with a graft made of Dacron, a synthetic fabric. Dacron has corrugation folds, with a distinctive accordion-like structure. Here we use the GHO anistropic hyperelastic model combined to a fluid-structure interaction analysis to understand how the blood flow affects the graft-aorta mechanical behaviour. The results show that the model is able to predict the graft nonlinear behavior and its progressive increase in rigidity due to Dacron stretching in the radial direction. This study allows to predict the graft-aorta mechanical response when subjected to realistic conditions.

INTRODUCTION

The aorta is the largest artery in the human body. Its primary function is to distribute oxygenated cells to other parts of the body. Among complications, aortic dissection (AD) is a very serious although not common condition, in which blood is being diverted to other parts of the aorta as a result of a tear in the intima, the inner layer of the aortic walls. The tear can occur in any of the aortic segments and treatments vary depending on the location. Among surgical techniques, one involves resecting (removing) and replacing the damaged portion of the aorta with a polyester graft [1]. The Food & Drug Administration (FDA) qualifies the aortic graft as a cardiovascular prosthetic device (CPD). Graft materials used in aortic replacement procedures include Dacron, which possesses a distinctive accordion-like structure due to corrugations. It is popular for its superior biocompatibility and its low incidence of rejection. It is also strong, flexible and durable. However, differences in the mechanical response of the Dacron fabric and the aorta can result in non-optimal conditions and affect the heart functions [2]. Clinical observations also report a radial stretching of the Dacron caused by internal pressure after being placed in the aorta [3]. This affects the overall rigidity of the structure. Here, we employ a three-dimensional fluid-structure interaction (FSI) analysis to understand how the blood flow affects the mechanical response of the Dacron/aorta taking into account the graft evolving geometry.

METHODOLOGY

For this study, the FSI simulations are performed on the commercial software package Abaqus/Simulia (2013), running on a desktop (i7-4790 CPU). Solidworks is used to generate the graft and the aorta geometry. The graft is modeled as a cylindrical structure 62 mm long, 32 mm diameter and 0.328 mm thickness with 31 corrugation folds. Figure 1 shows the graft straight configuration and the 90 ^{0} (i.e. 2θ) configuration. Other curvatures have been studied. The aorta is idealized as a cylindrical shell 31 mm long and 16 mm radius. It is made of three concentric layers (of total thickness 2.61 mm) which account for the intima, media and adventitia layers. The graft is attached to the aorta at its ends. The graft is modeled as an anisotropic structure due to the corrugations, which will cause its response to depend on the directions. Similarly, it is well established that human tissues exhibit anisotropic properties due to the presence of fibers with various orientations. Both the Dacron graft and the aortic segment have been modeled with the Gasser-Ogden-Holzapfel (GHO) model [4], a sophisticated anisotropic hyperelastic formulation. To obtain parameters representing the anisotropy of the Dacron fabric, we used experimental stress-strain curves generated by Amabili et al. (2018) [5] on a corrugated Dacron woven graft specimen. We used a generic algorithm available on MathWorks (2015) to obtain the material property for the hyperelastic model. The algorithm involves minimizing the error of an R-squared function where σ_{exp} is the value of the stress obtained experimentally and σ is the value of the theoretical Cauchy stress.

$$R - Squared = \frac{\sum_{i=1}^{n}(\sigma_{exp}(i) - \sigma(i))^2}{\sum_{i=1}^{n}(\sigma_{exp}(i) - (\sigma_{exp}^{mean}))^2} - 1$$

Blood is modeled as a Newtonian medium, incompressible and turbulent. The no-slip condition is enforced on the walls of the fluid domain. At the interface of the fluid and the solid domains, the components of the displacement and velocity are equal and the tractions are equal.

RESULTS

The anisotropy parameters obtained from the minimisation function were given as input to the hyperelastic material model. Figure 2 indicates good agreement between the stress-strain curves obtained experimentally and with the hyperelastic GHO material model. Using these parameters, we were able to launch a FSI analysis on a Dacron/aorta structure subjected to blood flow. Stress, strain and wall-shear stress contours on straight as well as curved configurations were obtained (Figure 3). We found that the maximum circumferential strain on the Dacron-graft was 1.9%, comparable to the experimental measurement obtained by Bustos et al. [2] at 110 mmHg. The Dacron is sutured onto the adventitia

layer and stress exceeding its ultimate strength may cause rupture. Results indicate that for all the cases, the von Mises stress computed at the junction between the Dacron and aorta was 1.13 MPa (for curved geometry), below the ultimate strength of the adventitia layer (1.4 MPa [6]). In the literature [7], WSS under 0.4 Pa are reported to generate endothelial proliferation and dysfunction accompanied by apoptosis (cell death). As WSS decreases, the walls weaken further and may also rupture. The WSS values obtained here ranged between 2.2 Pa and 5.2 Pa. We also found that the graft curvature had a noticeable effect on the computed quantities.

CONCLUSION

We conducted a FSI analysis to understand the mechanical response of a Dacron graft used for aortic replacement when subjected to a hemodynamic load. The accordion-like structure of the Dacron fabric was responsible for its anisotropic response. Straight as well as curved configurations of the aorta/graft assembly were studied. Strains and WSS decreased for the curved geometry while stress concentrations appeared at the junction Dacron/aorta. This study can help us predict the graft-aorta mechanical response when subjected to realistic blood flow conditions.

NONLINEAR DYNAMICS OF TUBE-DEBRIS INTERACTION AND TUBE WEAR

Njuki Mureithi*[1], Loay Alyaldin[1], Abdallah Hadji[1] , Huy Peter Pham[1], James Benson [2] and Sean Kil [2]
[1]Department of Mechanical Engineering, Polytechnique Montreal, Canada
[2]Electric Power Research Institute (EPRI), Palo Alto, CA, USA

Summary The flow induced dynamics of foreign objects (debris) in tube arrays of nuclear steam generators is addressed in the present work. Objects undergoing flow-induced motion while in constant contact with neighboring tubes can cause tube wear and compromise tube integrity. In cases where the debris cannot be removed, an analysis to estimate expected tube wear rate is imperative. This paper presents work done to develop and test a quasi-steady nonlinear theoretical model for debris dynamics and tube wear estimation.

INTRODUCTION

Much remains unknown regarding the flow-induced dynamics of small objects (debris) located within tube arrays subjected to transverse (cross-) flow. In particular, the characteristics of fluid forces acting on such objects located within tube arrays remain poorly understood.
Debris found in tube-and-shell heat exchangers, and in particular nuclear steam generators, poses a problem due to the risk of tube wear induced by loose debris moving in contact with the tubes due to flow turbulence-induced motion. Fig.1 shows an example of debris (a screw) found in a nuclear steam generator. Such debris stays permanently in the SG, unless manually removed during a plant shutdown. For operating plants, the practical engineering problem, when the debris cannot be removed (e.g. due to inaccessibility), is the estimation of the limiting debris residence time beyond which tube integrity is compromised.

Fig.1 Screw debris object in steam generator

DYNAMICAL MODEL

The work reported here investigates the dynamics of small rigid or flexibly lodged objects (debris) within a tube array subjected to high turbulence flow and undergoing nonlinear interaction with tubes. Fig.2 shows the typical configuration of a debris object in contact with two tubes. Debris-tube contact is maintained by the flow drag. The object is also subjected to turbulence lift and drag forces. The resulting problem is a nonlinear turbulence-induced 'vibration' problem.

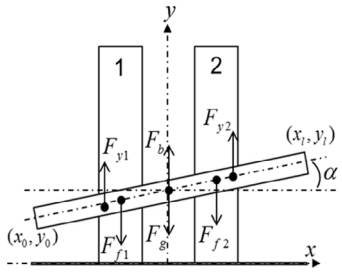
(b)



(c)

Fig.2(a) Object-tube configuration, (b) flow and fluid forces, (c) 2 *d.o.f.* dynamic model.

Due to the presence of the surrounding tubes, the array generated turbulence intensity may be up to 30% or higher. Fig.3 shows an example of the computed flow structure within a tube array relative to the size of a typical debris object. The primary source of nonlinearity is the friction contact between the object and the tubes. The second important nonlinearity is the lift force generated when the objects approaches the bottom wall (tube-sheet region of the steam generator). In the more general case, impacting should also be considered; impact occurs between the object and tubes as well as the object and the bottom wall.

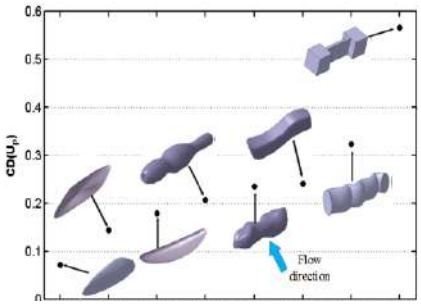

Fig.4 Drag coefficients for typical debris

Fig.2(b) shows the local flow velocity vectors and the fluid forces acting on the object. In the model developed here, a quasi-steady approach is taken in order to account for object-motion dependent forces. Motion independent fluid forces include the turbulence-induced lift ($F_L'(t)$) and turbulence-induced drag ($F_D'(t)$)forces as well as the steady drag ($\overline{F}_D$) and the fluid buoyancy force (F_b). Motion-dependent unsteady fluid forces are generated when the object moves. In a linear quasi-steady formulation, the resulting motion dependent forces are considered to be proportional to FO acceleration, velocity and displacement. The motion independent forces (in Fig.2) are obtained by CFD analysis (e.g. Fig.3) and directly from experimental measurements, Fig.4. To cover a wide class of general object geometries (e.g. Fig.4), pertinent geometry parameters must be obtained to allow the definition of drag force coefficients and dimensionless turbulence spectra. In the quasi-steady approximation, the change in the effective angle of attack of the flow relative to the moving object is also taken into consideration. This introduces a velocity dependent (damping) force component which slightly reduces the energy available for tube wear.

FLOW-INDUCED OBJECT DYNAMICS AND TUBE WEAR

The debris object flow-induced motion is obtained by solving the nonlinear governing equations for the model of Fig.2. In addition to the object motion, the debris-tube contact force histories are also obtained. To estimate the tube wear, the debris normal wear work-rate is computed as the product of the normal contact force and the object velocity, $\dot{W}(t) = F_N(t)|\dot{y}(t)|$. The curved plate debris shown in Fig.5 caused tube through-wall wear in approximately 3 months. The model predicted wear work-rate is presented in the same figure. This corresponds to the energy transfer rate to the tube wear process.

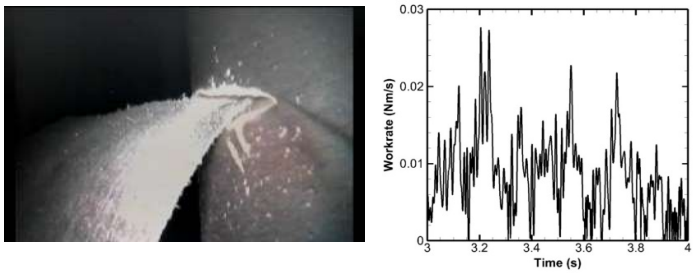

Fig.5 Plate debris in tube contact and model predicted wear work rate

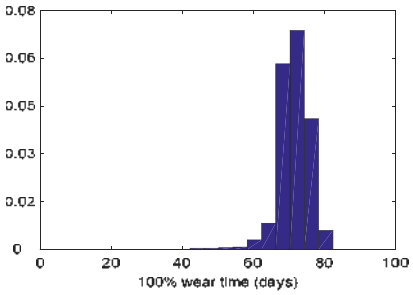

Fig.6 Monte Carlo analysis results

Using the work-rate, and the tube wear scar geometry, the wear time to a given tube wall depth can be estimated in a Monte Carlo analysis. Fig.6 shows the estimated probability distribution of wear times for 100% wall-wear time; analysis results yield 71 days, versus the maximum wear time of 115 days estimated by the plant operator. The Monte Carlo analysis accounts for the uncertainties in the various parameters governing the object dynamics. For practical plant operations, wear time estimates within days are considered quite acceptable and realistic. The analysis results obtained in this work raise some important fundamental questions on the effect of friction nonlinearities on the turbulence induced excitation of arbitrary geometry objects. The effect of turbulence on flutter instability also arises. While turbulence effect on bluff body flutter has been studied (e.g. for bridge decks), the governing mechanisms here are quite different. For bridge decks, for instance, turbulence affects flutter via reduced correlation of the fluidelastic forces along the bridge span. For debris in tube arrays, the flutter derivatives themselves (in particular the fluid force phases) are strongly affected by turbulence. As a result, the instability can potentially be altogether eliminated by high turbulence.

IN SITU MEASUREMENTS OF A HARP FOG COLLECTOR

[2]LMSSC, Conservatoire National des Arts et Métiers, Paris, France

Summary Experimental measurements on a fog collector in real-life conditions are considered here. Full-scale tests are conducted for future comparison with wind tunnel measurements and literature. The collector is made of parallel nylon fibers, its porosity is around 60%. Three force sensors are fixed between the collector and the main structure in order to investigate the drag on this porous elevated panel. Furthermore, the collector is placed within a measurement site, the SIRTA-ReOBS, where fog episodes due to radiative cooling and stratus lowering are frequent. Fog water collection can then be relied to visibility and wind speed, during fog events.

INTRODUCTION

Fog collection using fibrous nets has been used since the 50's, mostly for chemical analysis and to collect drinkable water. They're used in arid location with frequent fog events, with a collection of up to ten litres of water per day per square meter [1]. Fog water collection is mainly due to the inertial impaction mechanism, i.e the deviation of the droplets from the stream lines toward the collector's fibers [2]. The Wind flow is modified when it passes around and through the porous panel, which modifies the collection efficiency. Moreover the net is deformable and get charged in water. The geometrical characteristics are changed and thus the wind loads. There are few experimental studies on the wind effects on collectors of this porosity. We present here a specifically designed fog collector made of parallel fibers (see figure.1). It is installed in the atmospheric observatory SIRTA-ReOBS located in the south of Paris. The collector instrumentation consists of a rain gauge, four anemometers and three force sensors to respectively measure collection efficiency, wind reduction across the collector and the panel drag. Force measurements are compared to previous studies on permeable cladding, with equivalent porosity (i.e its degree by which the net is penetrable by the air), reviewed in 2012 in - [3]. We also aim to relate collection efficiency to measured wind speeds and, thanks to IRTA-ReObs data base - [4], visibility, precipitation and drop sizes measurements.

ENVIRONMENT AND FOG COLLECTION

The collector is set on a plain located 20km southwest of Paris (France). On this site, fog appears because of radiative cooling, when the air get saturated in water vapor because of infrared cooling near the ground surface, and when lowering stratus i.e descent of a cloud [5].The collector is aligned with the North ($\equiv 0°$) and face the dominant wind coming from the West ($\equiv 270°$). In the following we keep the meteorological definition of the wind direction.

(a)  (b)  (c) 

Figure 1: Set-up for fog collection measurement with vertical fibers on the SIRTA. (a) Complete set-up : The fog collector, 2m long, 1m high, on a supporting structure ; One rain gauge of 0.1mm resolution ; Four wind sensors : two on the West side, two on the East side; Three force sensors: two on each upper corners of the frame, one on the bottom side, in the center. (b) Water flowing in the gutter to the rain gauge at the bottom of the collector. (c) Zoom on the pairs of nylon fibers stitched to PVC plates.

The net parameters are chosen to optimize the collection efficiency and to avoid blockage effect. Nylon fibers of diameter $d = 0.3mm$, are placed in pairs in order to form liquid columns [2]. They are separated by $e = 2.2d$ along a length $L = 2m$ leading to a porosity $p = 59\%$. Efforts have been made in order to manually ensure homogeneous tension and spacing throughout the net (see figure.1(c)).

Four cup-anemometers are installed by pairs to measure the wind profiles (figure 1(a)). The first pair is located 4 meters upstream (with respect to the dominant wind coming from the $West$). They measure the wind speed at the center of the mesh (1m90 from the ground), to reach higher wind speeds. and 1m above. The second set is located 3 meters downstream. Finally, custom made force sensors are clamped between the frame and the support structure.

RESULTS

Fog is defined as a visibility reduction below $1km$. A SIRTA's measurement of visibility for December 16^{th} 2019 is reported on figure.2 (a)-(black curve), with our water collection (discrete line blue lines). Fog appears around 8:30 pm, the first water collection appears one hour later. Associated wind speed and direction are reported on figure.2 (b). The winds come from North-East ($\equiv 45°$), to South-Est ($\equiv 140°$), (black dashed line in 2 (b)), its speed is below $1m/s$ (blue pointed line and orange full line). The low collection rate can be explained by low wind speeds ($< 0.6m/s$), and deviation from the collector surface's normal, (90°- red line 2 (b)). Finally a wind reduction is visible when the wind direction is around $90°$. Gathering data for several fog events during the fog season, we aim at linking the collection trend to the visibility, wind speeds and drop sizes measurements. Results will also be compared to empirical model made in the Canary Islands, Spain -[6].

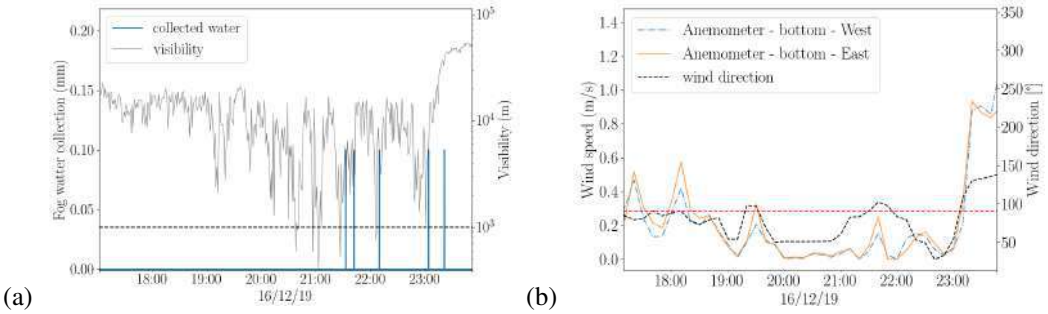

Figure 2: (a) Fog water collection (vertical lines) and visibility as a function of the hour. The horizontal line represent a visibility of $1km$, meaning the presence of fog. (b) Wind speed measurements downstream and upstream the collector at 1m94 high (clear lines), and wind direction measurements (black, dashed line) averaged over 5min. The Net is aligned with the North (see red, horizontal line)

The force acting on the panel, in the direction normal to the net's surface, as a function of the wind speed measured 3m upstream, at mid-height of the panel, is plotted in figure.3. The points correspond to all the measurements made from December 11^{th} to Decmber 25^{th} 2019. Following the work of Richards and Robinsons (1999), the wind velocity has been corrected by a wind direction factor, $cos(\frac{\pi}{2} - \beta)$ where β is the wind direction in radians. Measurements for wind coming from both sides of the net follow the expected trend given by the empirical formula $D = \frac{1}{2}\rho(U * cos(\frac{\pi}{2} - \beta))^2 S(1 - p)Cd_{pe}$, where ρ is the mass density of the air and $Cd_{pe} = 1.15$ is the drag coefficient of a solid (in opposition to porous), elevated panel, of this aspect ratio - [3]. However, some discrepancies can be observed, that can be due to the effect of water collection on drag and measurements uncertainties increased when $\beta \neq \pi[\pi]$. Works are ongoing to clarify that point with the help of additional wind tunnel tests.

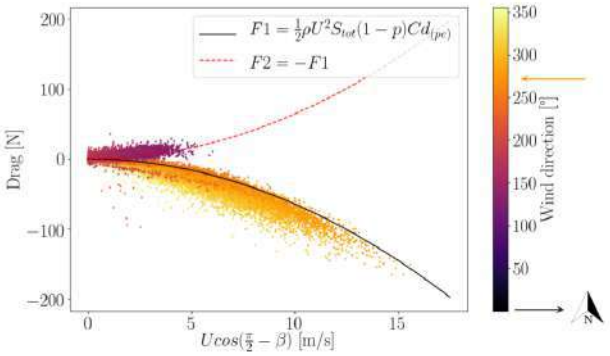

Figure 3: (a) Force measurements for different wind directions, as a function of the corrected wind speed. Positive force is a traction of the captor, negative force is a compression. Solid and dashed lines correspond to the empirical formula cited in [3]. Orange arrow corresponds to the direction normal to the collector, black one is the North.

RESPONSE OF A PLATE TO SUPERSONIC WIND TUNNEL START INCLUDING INTERACTION WITH CAVITY AND THE FREE STREAM FLOW

Maxim Freydin * [1] and Earl H. Dowell[1]
[1]Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina, US

Summary A theoretical/computational model is proposed to analyze the linear stability and the nonlinear time response of a plate with supersonic (or hypersonic) flow on one side and a cavity with stationary fluid on the other. The plate's dynamic coupling with the fluid in the cavity, as well as aerodynamic heating and static deformation due to static pressure differential, are shown to affect the linear stability envelope and the limit cycle oscillation (LCO) amplitude and frequency (in post flutter condition). The coupled plate-cavity-flow model is linearized at a nonlinear deformation of the plate (due to static pressure and temperature differentials) and an eigenvalue problem is formulated to obtain the system's natural frequencies, mode shapes and determine its stability. Direct time integration is also performed and the results are correlated with wind tunnel tests.

THEORETICAL MODEL

The structural model derivation consists of formulating the elastic and kinetic energies of a flat plate with general in-plane stiffness distribution at the edges in terms of three displacement components (in contrast to previous literature where the Airy stress function and a single transverse displacement are employed). Then, the Rayleigh-Ritz approach is applied with Lagrange's Equations to obtain the equations of motion. The full derivation is provided by Freydin and Dowell in [1], including first order Piston Theory (PT) aerodynamics and a simplified cavity model which only includes the added stiffness effect and neglects added mass. The simplified cavity model is an approximation used when the first natural frequency of the cavity is much greater than that of the plate. In this work, the model is improved by replacing the simplified cavity model by the wave equation for the acoustic pressure perturbation and then coupling the equations as outlined in [2]. Figures 1 and 2 show schematic views of the problem. Equation 1a describes the system of structural

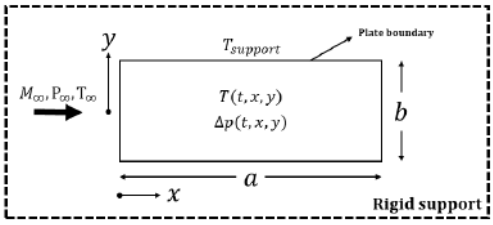

Figure 1: Plate top view with free stream flow

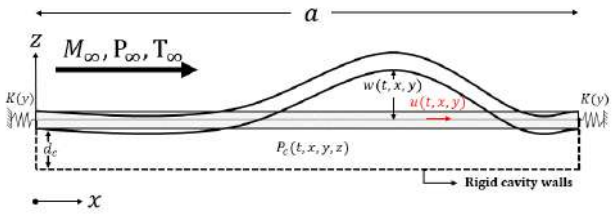

Figure 2: Plate, cavity and free stream flow side view, cross section at $-b/2 < y < b/2$

equations of motion in modal coordinates with important terms underlined. Equation 1b describes the system of cavity dynamical equations in modal coordinates. The coupled system in Equation 1 is solved as an eigenvalue problem for dynamic linearization about a nonlinear statically deformed plate and by direct time integration for the full dynamically nonlinear model. Each approach has advantages and provides different information about the fluid-structure system. Fast computation times make the eigenvalue approach suitable for design while direct time integration provides insight into nonlinear behavior of the system in post flutter conditions that lead to LCO.

pressure and plate temperature transient measurements are plotted on the p_∞ vs ΔT stability maps of static nonlinear/dynamical linear plates loaded with a uniform static pressure differential. Figures 3 and 4 show results without and with the effect of a cavity, respectively. Regions of instability are highlighted in red color and show that the location of these zones is sensitive to whether a cavity is present or not. An additional important difference is the flutter frequency in each zone changes drastically due to coupling with cavity natural modes (which are usually much greater in frequency than the plate's several first natural modes). Figure 5 shows how the natural frequencies of the full coupled system vary with ΔT on a single slice of Figure 4 at $p_\infty = 30kPa$. The three flutter regions are characterized by different frequencies and rates of exponential growth in time (quantified by the positive damping, not presented here). It can be shown (using either eigenvalue analysis or time integration) that the first and third flutter branches will reach a steady limit cycle much slower than the second branch.

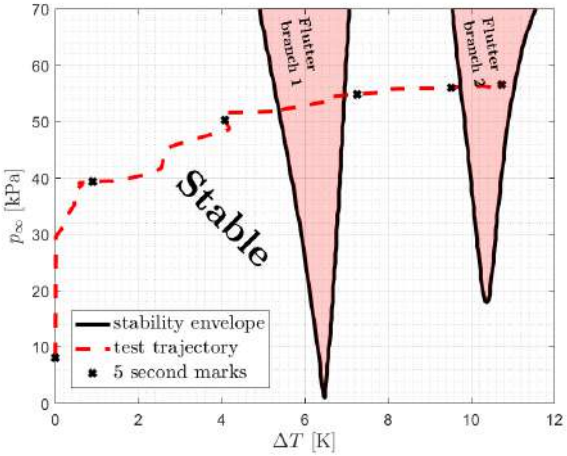

Figure 3: Nonlinear static/linear dynamic stability envelope for $\Delta p = 3kPa$ **without** cavity effect

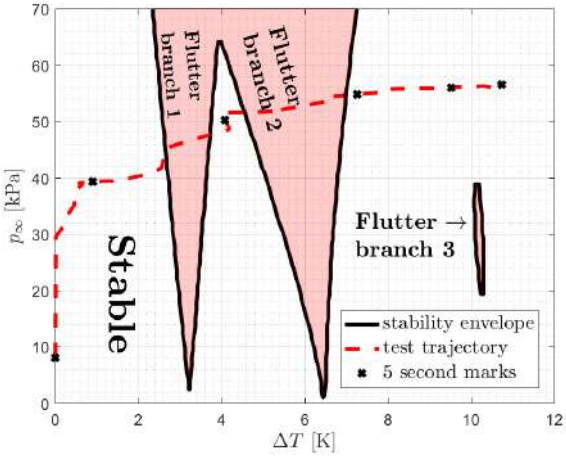

Figure 4: Nonlinear static/linear dynamic stability envelope for $\Delta p = 3kPa$ **with** cavity effect, $p_c = p_\infty - \Delta p$

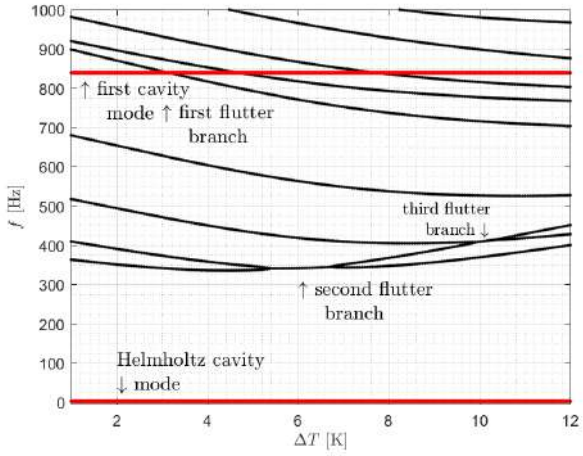

Figure 5: Plate-cavity-flow system's natural frequencies variation vs ΔT for $p_\infty = 30kPa$, $\Delta p = 3kPa$, $p_c = p_\infty - \Delta p$

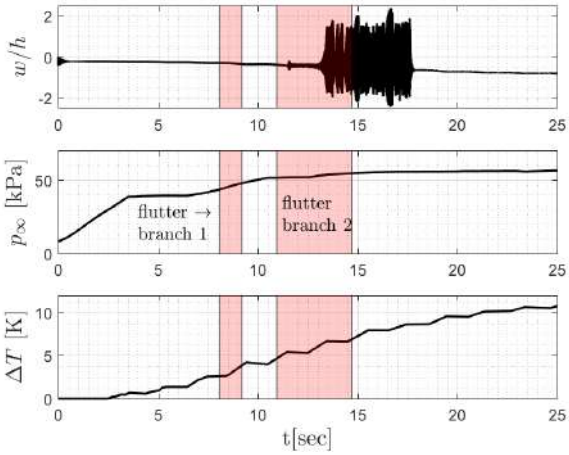

Figure 6: Direct time integration, $\Delta p = 3kPa$, $x/a = 1/4$

Figure 6 shows time series obtained using the direct time integration approach. The $p_\infty(t)$ and $\Delta T(t)$ functions were extracted from [3] and represent the "test trajectory" curve in previous figures. It is clear that while crossing the first and second flutter branches the plate does not have enough time to reach a steady LCO. On the 15th second, the plate has exited the 2nd flutter branch but has yet to stabilize. This suggests that a region of hysteresis exists and can be explored using this model. The presented analysis and results agree well with the qualitative behavior observed in [3].

THE ADDED MASS EFFECT IN FLUID STRUCTURE INTERACTION PROBLEMS

Galina Dynnikova*[1], Sergey Guvernyuk[1]
[1]Lomonosov Moscow State University, Research Institute of Mechanics, Moscow, Russia

Summary The fundamental property of the added masses tensor in a viscous incompressible fluid is discussed and demonstrated by numerical simulation of bodies' movement in a viscous liquid based on Navies-Stokes equations. It is confirmed that the tensor of the added masses is independent of viscosity and is the same as in potential flows of an ideal fluid. The stable numerical scheme is proposed for solving the tasks of fluid structure interaction in the case of light bodies with great added masses.

Added or virtual mass is an unsteady fluid dynamic effect that has been discussed in the literature for over a century beginning with [1] up to the present time (see for example [2]). Most researchers are of the opinion that the added masses are independent of viscosity, based on experimental observations and some theoretical considerations. At the same time, in some recent works the values of the added masses are used as dependent on viscosity (see for example [3]).

In work [4], a theorem is strictly proved, which states that the hydrodynamic force acting on a body in a viscous incompressible fluid of constant density is the sum of two forces $\mathbf{F}_H = \mathbf{F}_{stat} + \mathbf{F}_{add}$, where the force $\mathbf{F}_{stat}$ corresponds to motion without acceleration for a given distribution of vorticity, and $\mathbf{F}_{add}$ is the force of the added mass which depends only on acceleration and geometry but not on viscosity, hence it is the same as in potential flows of an ideal fluid.
In this work the mentioned theorem is illustrated by numerical simulation of an unsteady body motion.

In Figure 1 the numerical results are presented for the following task.
Airfoil NACA0015 moves at an angle of attack of 5 degrees with a speed $\mathbf{U} = -U\mathbf{e}_x$, where time dependence of U is following (see Fig.1b)

$$U = \begin{cases} 2t, & 0 < t < 0.25 \\ 0.5, & 0.25 < t < 0.5 \\ 2t - 0.5, & 0.5 < t < 0.75 \\ 1, & 0.75 < t < 1 \end{cases}$$

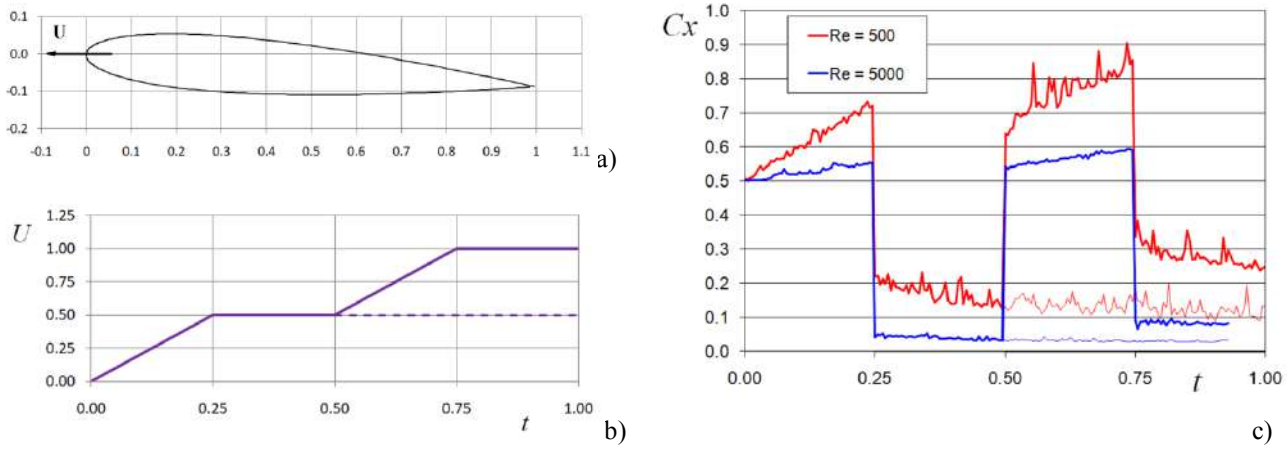

Figure 1. Movement of airfoil NACA0015 with the piecewise constant acceleration. a) airfoil NACA0015; b) time dependence of velocity U; c) time dependences of drag coefficient at Re = 500 and Re = 5000

Dimensionless acceleration is equal to 2 at time intervals $0 < t < 0.25$ and $0.5 < t < 0.75$, and the rest of the time, acceleration is equal to zero. In Fig. 1c, time dependences of drag coefficient are shown at Re = 500 and Re = 5000. The Reynolds numbers are based on the velocity at $t = 1$. The calculations were performed by a meshless Lagrangian method VVD [5]. One can see from Figure 1 that in the moments when acceleration is switched, the drag coefficients changes abruptly. The jump value is constant and does not depend on Re, $|\Delta C_x| = 0.5 \div 0.52$ that corresponds to the added mass $M_{add} = (0.125 \div 0.13)\rho C^2$ (here ρ is fluid density, C is chord length). The theoretical value of the added mass in potential flow for this case is equal to $0.127\rho C^2$. That confirms the theorem mentioned above. Similar calculations with the same results were performed for flat plate, cylinder, sphere, and disk.

Accurate knowledge of the attached masses is useful in solving the flow structure interaction problems, especially in the case of light bodies. It is known that numerical schemes with splitting are unstable in this case. Therefore the monolithic schemes have to be used. But they are more complicated. The use of attached masses allows

*Corresponding author. E-mail: dyn@imec.msu.ru

us to apply the schemes with splitting for light bodies up to bodies with zero mass. For this purpose, at each time step, a force $\mathbf{F}_{stat}$ corresponding to the movement without acceleration should be calculated. After that, the acceleration vector $\mathbf{a}$ is calculated from the equation $m\mathbf{a} = \mathbf{F}_{stat} - \mathbf{M}\mathbf{a} + \mathbf{F}_{ex}$, where m is body's mass, $\mathbf{M}$ is tensor of added mass, $\mathbf{F}_{ex}$ is external force if it exists.

Such method was applied for simulation of oscillation of the cylinder elastically fixed in the fluid with one degree of freedom. Movement of the cylinder is described by the equation $mY = F_H - kY$. Calculation has been performed in dimensionless variables, where the linear sizes are related to the cylinder diameter D, time is related to $t_0 = 2\pi\sqrt{\frac{m}{k}}$, density of the cylinder ρ is related to the fluid density, forces are related to $m_0 D/t_0^2$, where m_0 is displaced mass of fluid. In Fig. 2 the numerical results are presented for the case ρ = 2, Re = $D^2/(\nu t_0)$ = 50. Calculations were performed by the method VVD with modification developed especially for a flow around a cylinder [6]. The scheme with splitting was applied. In fig 2b, the components of the hydrodynamic force F_{stat} and F_{add} are shown. One can see that the force F_{stat} is mainly opposite to speed U that provides the damping. The force F_{add} is co-directed with the deflection of the cylinder, and therefore directed opposite to the force of the spring action. This leads to a change in the oscillation period. In this case, it is 1.29, which is approximately equals to value $\sqrt{(m+M)/m} = \sqrt{3/2} = 1.22$. This task has been solved also with use of the monolithic scheme, described in [7]. The results coincided with high precision.

MIXING AND THERMAL ENHANCEMENTS THROUGH FLOW-INDUCED OSCILLATIONS OF A THIN ELASTIC PLATE ATTACHED TO A BLUFF BODY

Mayank Verma[1] and Ashoke De*[1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Kanpur, Kanpur, India

Summary: The flow-induced oscillations of the thin, flexible plate after a bluff body have several promising engineering applications. In the present study, we have compared the characteristics of the flow induced by the motion of the thin plate with two different bluff bodies, i.e. a circular and a square cylinder, respectively. A partitioned approach is employed to solve the fluid-structure coupled problem. The Reynolds number based on the hydraulic diameter is 200. The results suggest that the flexible plate sweeps almost the same pattern for both the cylinders. Although, the square cylinder produces higher amplitude of the plate oscillations with a lesser frequency as compared to the circular cylinder at the same Reynolds number, resulting in the enhanced mixing and strong vorticity field in the domain. Also, the settling time for the oscillations of the square cylinder is observed to be lesser than that of the circular cylinder. Further, the square cylinder with a flexible plate indicates more convection resulting in the reduced thermal boundary layer.

INTRODUCTION

Many researchers have extensively studied control of the flow over bluff bodies with a thin plate due to its prominent practical applications and interesting fluid-dynamic phenomena associated with it. The rigid thin plates are commonly used for controlling vortex shedding, while the flexible plates are utilized to enhance the vortex shedding behind the bluff bodies. Recently, researchers have studied the effect of the oscillations of the flexible plate, with [1] or without [2] a bluff body, on the mixing and thermal augmentation. However, the literature lacks the comparative study of the flow-induced motion of the plate attached to circular and square cylinders. In the present study, we have attempted to compare the effect of the bluff bodies on the flow-induced motion of the plate. Further, based on the analysis of the mixing and thermal enhancement due to the shed vortices, the authors recommend the square cylinder over the circular cylinder for mixing and thermal enhancements.

PROBLEM DESCRIPTION

The geometry of the fluid-structure domain is shown in Fig. 1a. The analysis is restricted to 2D only. Two different types of bluff bodies, viz. a circular cylinder and a square cylinder is placed before the thin plate. One end of the thin plate is fixed to the rear side of the bluff body and the length of the plate is kept the same for both the bodies. The bluff bodies are rigid and the plate is flexible with the properties: density of plate, $\rho_s = 1000\ kg/m^3$, Young's modulus of the plate, $E = 5.6 \times 10^6\ N/m^2$, and Poisson's ratio, $\mu_s = 0.4$. The uniform velocity of 2 m/s is prescribed at the inflow boundary of the domain. The flow properties considered for the simulation are: temperature of the fluid at the inlet, $T_{inlet} = 300\ K$, density of the fluid, $\rho_f = 1000\ kg/m^3$, kinematic viscosity, $\vartheta_f = 0.001\ m^2/s$, thermal diffusivity, $\alpha_f = 0.001\ m^2/s$. The channel walls are at a constant temperature of 360 K. The mesh used for discretization of the flow domain consists of 96,498 finite volume cells while the thin plate is discretized with 1232 finite element cells. The coupled simulation is steered with a time-step of 0.001 s.

NUMERICAL METHODOLOGY

Solvers:

Fluid Solver: An open-source incompressible flow solver *thermoPimpleFOAM* of OpenFOAM [3], a modified version of *pimpleFOAM*, is used to solve the temperature scalar equation along with the governing equations of the fluid.

$$\frac{\partial T}{\partial t} + \nabla \cdot T = \alpha_f \cdot \nabla^2 T \tag{1}$$

where T is the temperature and α_f is the thermal diffusivity constant.

Solid Solver: CalculiX [4], an open-source Finite Element based solver, is used to solve the governing equations of the solid.

Fluid-Solid System Coupling: In order to facilitate the exchange of data between the Fluid and Solid solvers at the interface, we have employed preCICE [5], an open-source coupling library for partitioned multi-physics simulation.

Numerical Validation:

In order to confirm the validity of the numerical setup, a benchmark problem proposed by Turek and Hron [6] is attempted. The x and y displacement of the flexible plate at $Re = 100$, are compared with the benchmarked results. The results are found to be in good agreement and are shown in Fig. 1 b.

RESULTS AND DISCUSSION

Flow-Induced Motion of the Plate:

The vortex shedding is the most common phenomenon associated with bluff bodies. The vortices force the attached thin plate to oscillate. At the initial time, the amplitude of the oscillations is small but increases with the time as can be seen in Fig. 2 a), and c). Further, after a certain time, the plate oscillates with the fixed amplitude. The settling time of the oscillations for the square cylinder with a flexible plate is found to be less. The square cylinder generates higher amplitude and lesser frequency vortices. The plate sweeps almost the same pattern during its operation for both the cylinders as depicted in Fig. 2 b).

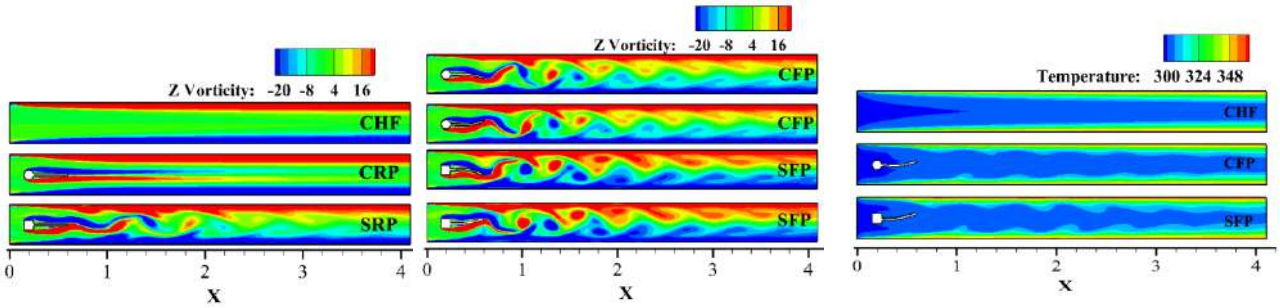
Vorticity magnitude and enhancement of fluid mixing due to FSI:

Fig. 3 a) and b) shows the vorticity contours for the rigid plate and the flexible plate, respectively. From Fig. 3 a), we observed no vortex shedding for the case CHF and CRP, while for SRP, the vortex shedding frequency was found to be 3.66 Hz, as shown in Fig. 2 d). Introducing flexibility in the plate enables the circular cylinder to shed vortices at the frequency 4.63 Hz (case CFP), while for the square cylinder (case SFP), it increases the vortex shed frequency to 4.39 Hz. The vorticity magnitude of SFP is found to be more than that of CFP. Thus, the wake vortices of SFP sweeps higher vorticity regions which further aids in the enhanced mixing of the fluid. Further, Fig. 3 c) depicts the reduction in the thermal boundary layer thickness at the locations of the convected vortices due to the enhanced convection caused by the swept vortices.



a) **b)** **c)**

CONCLUSIONS

The comparative study has been performed on the flow-induced motion of the thin plate attached to two different bluff bodies, i.e., a circular and a square cylinder, respectively. The square cylinder with the flexible plate sweeps the higher amplitude and lesser frequency vortices. The settling time of the oscillations is found to be less for the square cylinder. Further, the square cylinder with the flexible plate imparts the higher vorticity magnitude in the domain resulting in the enhancement of the mixing of the fluid. The enhanced mixing promotes improved convection and indicates the reduction in the thermal boundary layer at the locations of the swept vortices. Thus, the authors recommend the use of a square cylinder with a flexible plate over the circular cylinder arrangement for the effective cooling of the electronics contained in enclosures through the flow-induced motion of the plate.

EVALUATION OF A QUADRATIC ELASTICITY FORMULATION FOR FLUID-STRUCTURE INTERACTION

Ridhwaan Suliman* [1]
[1]Advanced Mathematical Modelling, CSIR, Pretoria, South Africa

Summary The deformation of slender elastic structures due to the motion of fluid around it is a common multi-physics problem encountered in many applications. This work details the development and implementation of a numerical model capable of solving such strongly-coupled fluid-structure interaction problems. A thorough stability analysis of finite elastic plates in uniform flow is conducted, and validation of the results with those from analytical methods is done. An analysis of the dynamic interactions between multiple finite plates in various configurations is also conducted.

INTRODUCTION

In most fluid-structure interaction problems the deformation of the slender elastic bodies is significant and cannot be described by a purely linear analysis. We present a new formulation to model these larger displacements. Examples of such FSI systems include wing flutter on aircraft, aeroelasticity of turbomachinery blades, flows in elastic pipes and blood vessels, heart valve dynamics, swimming of fish and in the processing of paper. In this work, we make use of a blend of mathematical and computational approaches to study strongly-coupled fluid-structure interaction problems involving long thin structures.

STRONGLY-COUPLED FLUID STRUCTURE INTERACTION

Two computational fluid-structure interaction approaches are implemented in a partitioned manner: a finite volume method for discretisation of both the fluid and solid domains and the quadratic modal formulation for the structure coupled with a finite volume fluid solver. Strong-coupling is achieved by means of a fixed-point solver with dynamic relaxation. The fluid-structure interaction approaches are validated and compared on benchmark problems of increasing complexity and strength of coupling between the fluid and solid domains.

Governing Equations

The equations governing viscous incompressible isothermal fluid flow in an arbitrary-Lagrangian-Eulerian (ALE) reference frame [1] are given by the continuity and Navier-Stokes equations. To close the governing equations, a constitutive relation for stress is required. We assume a Newtonian fluid to relate the stress to strain. The partial differential equations that describe a homogeneous isotropic elastic solid undergoing large, non-linear deformation are given by Cauchy's first equation of motion [2]. Assuming an isotropic hyperelastic St. Venant–Kirchhoff material model, the stress-strain relationship is given in terms of the second Piola–Kirchhoff stress. The first Piola–Kirchhoff stress is related to the second Piola–Kirchhoff stress by the deformation gradient, which relates quantities in the undeformed configuration to their counterparts in the deformed configuration. The constitutive stress-strain relationship is given in terms of the Green–Lagrange strain, which is related to the displacement field through the gradients of displacement.

Modal FSI Analysis

Tangential to the full finite volume FSI approach, a reduced-order modal approach to solving the structural equations has been implemented and coupled with an incompressible finite volume fluid solver in OpenFOAM. For a modal structural analysis, Lagrange's equations of motion in the general case are used, which provides an expression for the eigenvalues or natural frequencies and eigenvectors or mode shapes. By extending the standard modal analysis technique for linear structural analysis, the governing equations and boundary conditions are updated to account for the leading-order non-linear terms and a new modal formulation with quadratic modes is derived. Strong-coupling of the fluid and solid domains is achieved by means of a fixed-point solver using a dynamic relaxation parameter based on Aitken's method.

Fluid-Solid Coupling

The coupling between the fluid and solid is done once at the beginning of every time-step when movement of the mesh occurs. The fluid flow provides a traction onto the structure. This results in a deformation of the structure which in turn affects the fluid flow. Coupling conditions for the traction, displacement and velocity are applied to ensure momentum conservation or force equilibrium at the interface, as well as to enforce the kinematic or geometric continuity and no-slip conditions respectively. The above conditions require an iterative procedure such that a strongly-coupled solution is obtained. A strongly-coupled fixed-point solver with dynamic relaxation, has been implemented in this work. It is the most basic of the above approaches yet is highly robust and efficient. The fixed point solver uses a relaxation parameter based on Aitken's method. The solver was modified to call the mesh movement algorithm after every iteration, thus allowing a re-calculation of interface forces, displacements and velocities with every iteration hence resulting in a fully-coupled scheme upon convergence.

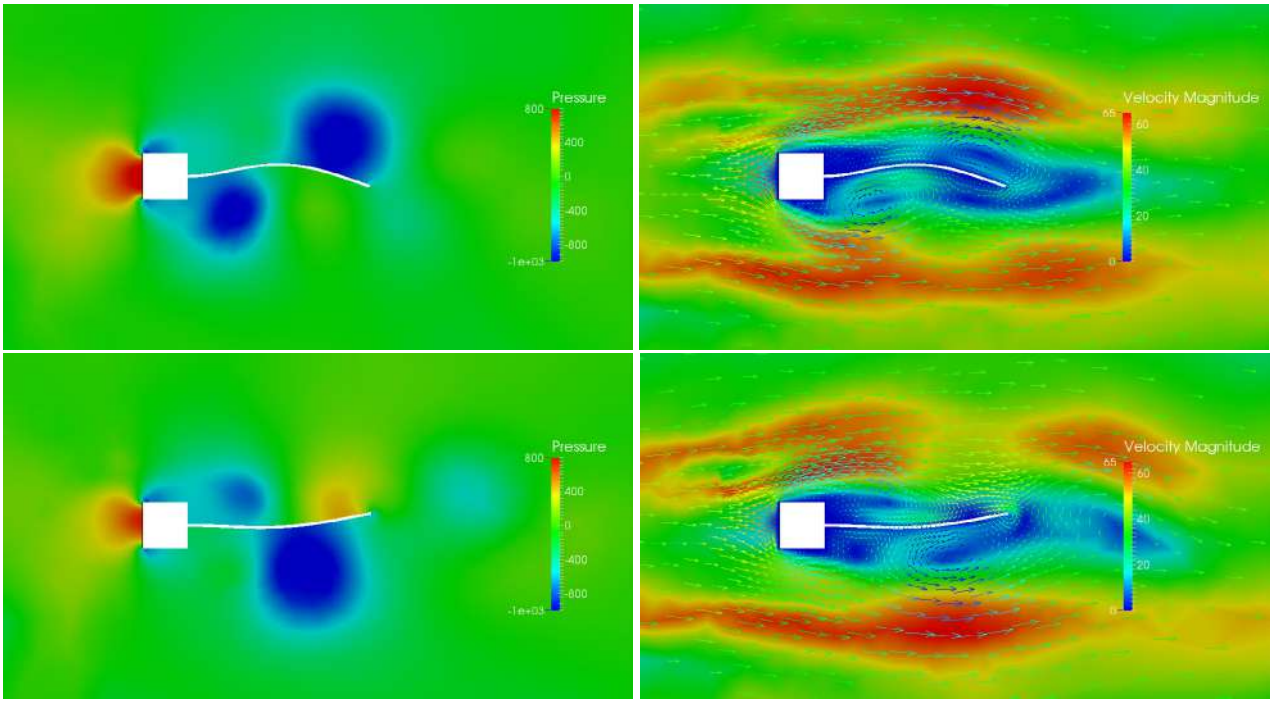

Figure 1: Pressure (left) and velocity contours (right) for the block-tail test-case with the beam oscillating in its second mode of vibration

Two-dimensional Flapping Beam

Both FSI approaches have been successfully validated and compared on benchmark cases and the results for a common FSI benchmark problem, proposed by Turek and Hron [3], of an elastic beam in the wake of a cylinder undergoing vortex-induced vibration are included here. The properties of the fluid and solid are as described by Turek and Hron [3]. A uniform constant fluid velocity, Reynolds number, Re = 100, was applied at the inlet while at the exit pressure was set to zero. Flow is assumed to be laminar. Snapshots of the beam deflection and velocity contours at various times are shown in Figure 1, showing large oscillations of the beam in its second mode of vibration as vortices are shed periodically from either side of it. The finite volume FSI results, however, required a very fine mesh for the solid domain and consequently a long run-time. Upon further investigation of just a cantilever beam under a tip load it was found that the finite volume method for structural mechanics suffered from a phenomenon of shear locking. When the aspect ratio of the elements (ratio of element width to height) is large, a numerical shear strain component is produced in addition to a bending strain. This absorbs strain energy and results in a decrease in displacement or stiffening. In addition, an evaluation of the accuracy of the finite volume scheme shows that the scheme is only first-order accurate, which also explains the slow convergence in the result.

CONCLUSIONS

Two computational fluid-structure interaction approaches have been successfully implemented and validated on benchmark problems. Whilst the partitioned finite volume FSI method displayed accurate results, fine meshes and hence long computational times were required. It was shown that the finite volume method for modelling solid mechanics has a number of deficiencies, especially with regards to long thin structures where locking occurs. The modal FSI solver was successfully validated on a wide range of test-cases. Strong-coupling and the handling of the mesh movement showed promising results. The linear and quadratic modal solutions converged to the same result when the structure undergoes small linear displacement, while the quadratic approach showed substantial improvement in predicting the transient response of FSI systems where the structure undergoes significant deflections. The prediction of the frequency and dynamic behaviour of strongly-coupled fluid-loaded structures compared well with those from full FSI solutions.

STABILISING THE FLOW-FIELD OF A HEAVING FOIL USING A FLEXIBLE AFT TAIL ATTACHED AT THE TRAILING EDGE

Chhote Lal Shah* [1], Dipanjan Majumdar[1], and Sunetra Sarkar[1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Madras, Chennai-600036, Tamilnadu, India.

Summary Flapping wings with suitable wing kinematics, wing shapes, and flexible structures can enhance lift as well as thrust by exploiting large-scale vortical flow structures under various conditions. However, it is also necessary to understand the dynamics of the flow-field, which may influence the flying performance. In the present study, an elliptic foil with an attached tail at the trailing edge is considered for studying the dynamics of the flow-field. The current work focuses on analysing the dynamics with an increase in the flexibility of the tail structure. Although a perfectly rigid tail enhances the aerodynamic performance, it can also take the system to aperiodicity. However, a flexible tail has the ability to change the dynamics and stabilise the system.

INTRODUCTION

Biologically inspired insect flight mechanisms have recently become a primary research subject, mainly to design efficient micro air vehicles (MAVs) used for defence surveillance and environmental monitoring. The prime source of inspiration in this regard with the reliance on natural selection comes from the natural flyers due to the similar Reynolds number regime in which they fly. Natural flyers utilise the unsteady aerodynamics around their flapping wings to generate the lift and thrust. These aerodynamic loads are related to the formation and shedding of the vortices into the flow which are again dependent on different wing shapes, structural flexibility and wing kinematics. A rigid elliptic foil plunging in uniform stream results in a drag producing von-Karmann wake, thrust producing reverse Karmann wake and deflected reverse Karmann wake with the increase in plunge velocity κh (where $\kappa = \frac{2\pi f c}{U_\infty}$ is reduced frequency, f is frequency, c is chord length of elliptic foil, U_∞ is free stream velocity, and h is nondimensional plunge amplitude) [1]. With further increase in κh, the flow-field transitions into the aperiodic regime and eventually to chaos [2]. However, a more realistic design of a bio-inspired wing would consist of a flexible trailing part attached to the stiff leading portion. Heathcote and Gursul [3] reported that the enhancement in mean thrust is possible by inclusions of an aft tail attached to the foil. Likewise, Mia and Ho [4] noted that a flexible foil with a pre-defined deformation could increase the propulsive efficiency. Further, Heathcote et al. [5] showed that the thrust/input-power ratio was significantly high for flexible airfoils than rigid airfoils. Also, they observed that at high plunging frequencies, moderately flexible airfoil generates the largest thrust, while highly flexible systems show larger thrusts at low frequencies. Most of the literature mentioned above focused on enhancing the aerodynamic performance. However, the dynamical transitions in the flow-field of a heaving foil with an attached tail at the trailing edge have not been investigated earlier. The focus of this study is to explore the dynamics associated with the flow-field for different levels of flexibility of the aft tail structure. This study is of importance from the MAVs design point of view as one must avoid the system from entering into an aperiodic state in a broad sense.

COMPUTATIONAL METHODOLOGY

A foil with a rigid elliptic part (with major axis length as c) and a flexible tail of length $0.3c$ is considered here. A sinusoidal plunge motion is provided at the center of the elliptic foil. The trailing part of the foil is modelled as an inextensible flexible filament [6] and is allowed to oscillate passively. The flow around the oscillating body is governed by the incompressible Navier-Stokes equations which are numerically solved using an in-house solver [2] developed based on the discrete forcing type imersed boundary method (IBM). In the present Fluid-Structure Interaction (FSI) framework, the structural solver and the IBM solver are coupled in a weak coupling approach where both flow and structural solvers exchange information explicitly at every time-step [7]. The Reynolds number is kept constant at 300 throughout the study. The simulations are run after performing domain and grid convergence studies. A time step of 0.0004 has been considered after performing a time convergence test and has been used for the rest of the simulations.

RESULTS AND DISCUSSIONS

Simulations have been performed for a wide range of κh values. In order to study the effect of tail flexibility on the flow dynamics, different levels of rigidity with γ (non-dimensional bending rigidity) $\approx \infty$ (rigid case), 1.0 and 0.1 have been considered. It is observed that the inclusion of a tail at the trailing edge of the elliptic foil enhanced the aerodynamic performance. At lower κh, the flow-field, as well as aerodynamic loads, remain periodic for all the cases. However, the present study focuses on $\kappa h = 1.5$, which is in the aperiodic regime. Time history of drag coefficient (C_D) and corresponding Morlet wavelet spectra [8] in terms of scalogram plots are presented in Figure 1. The scalograms are the visual representation of the wavelet transforms in which the x-axis represents time, and the y-axis represents the time-evolution of the frequency content of a signal. The C_D time history for the rigid foil without tail exhibits quasi-periodic

*Corresponding author. E-mail: lal.chhote.shah@gmail.com

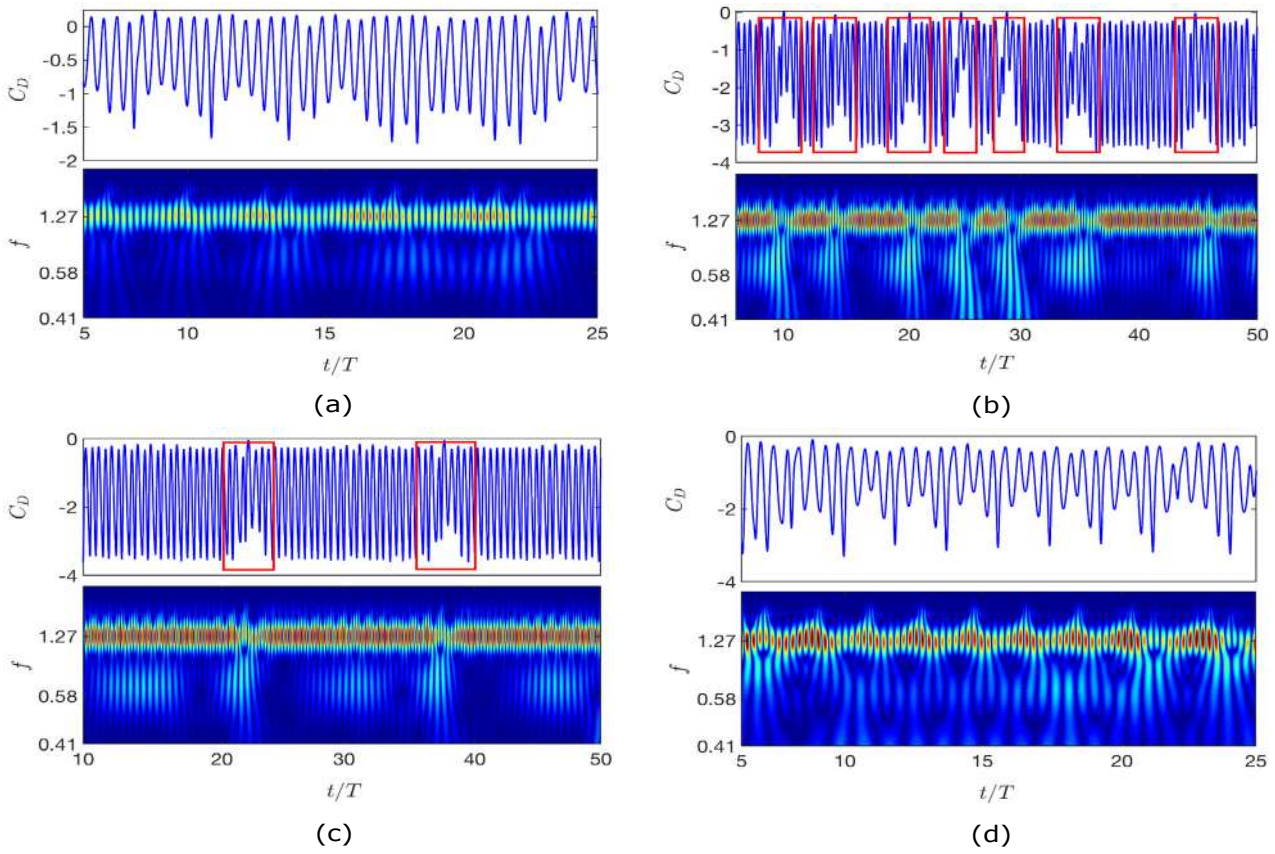

Figure 1: C_D time histories and corresponding scalogram of the wavelet coefficients for $\kappa h = 1.5$; (a) elliptic foil without aft tail, (b) elliptic foil with rigid aft tail, (c) elliptic foil with flexible aft tail of $\gamma = 1.0$, and (d) elliptic foil with flexible aft tail of $\gamma = 0.1$.

behavior which is evident by the presence of incommensurate frequency bands shown in the scalogram plot (Figure 1 (a)). With the addition of a rigid tail, the mean thrust increases notably. However, the system manifests intermittency as evident by the presence of quasi-periodic windows interspersed by the chaotic windows shown in Figure 1 (b). As the rigidity of the tail is reduced, at $\gamma = 1.0$, the leading edge separation behavior still remain intermittent. However, the system behaviour has now become regularised compared to the rigid tail case; see Figure 1 (c). In this case, the length of the quasi-periodic windows has increased and the aperiodic windows has reduced. With further decrease in the rigidity, for $\gamma = 0.1$, the flow-field, and hence the C_D, returns back to the quasi-periodic dynamics which is confirmed from the modulation in the C_D time history caused by incommensurate frequency bands (Figure 1 (d)).

CONCLUSIONS

In this study, the transition in flow dynamics of a sinusoidally heaving foil with flexible aft tail has been investigated. The existence of intermittency has been observed at $\kappa h = 1.5$. Scalogram is used to characterise the dynamics associated with the time histories. The inclusion of a rigid tail at the trailing edge of the foil gives better aerodynamic performance, but the system also shows intermittency. However, with an increase in flexibility, the system no longer exhibits intermittency, and the dynamics gets stabilised. Further time series analyses on the characterisation of different dynamic states and the details of the flow-field could not be shown here for the sake of brevity but will be shared during the presentation. The present study contributes towards the design of flexible flapping wings for the development of micro-air vehicles.

LAMINAR SEPARATION FLUTTER OF A NACA0012 AIRFOIL AS A GLOBAL INSTABILITY

Summary The onset of pitch-oscillations of a NACA0012 airfoil mounted on a torsion-spring is investigated by the means of a global stability analysis. Experimental studies from literature have shown this configuration undergoing on a flutter behaviour for a close range of Reynolds. This phenomenon is attributed to the laminar character of the boundary layer and to its detachment, transition and subsequent reattachment on the airfoil surface. In this regard, we carried out a linear stability analysis of the mean flow field, issued from a RANS simulation, using a Spalart–Allmaras model. A careful choice of the inlet conditions revealed to be necessary to capture a laminar separation and, as the incidence increases, a laminar separation bubble (LSB).

INTRODUCTION

The first investigation of the aeroelastic behaviour of a NACA0012 airfoil was conducted by Poirel *et al.* (2008), with an experimental set up on a Reynolds number range of $4.5 \times 10^4 < Re < 1.35 \times 10^5$. The airfoil was free to rotate in the pitch degree of freedom, presenting a self-sustained behaviour around a mean angle of attack of zero degrees and an amplitude around $5.5°$. The primary driver for this behaviour was associated to the laminar boundary layer separation on the second half of the airfoil surface, with a subsequent flow transition to a turbulent state an reattachment, forming a Laminar Separation Bubble (LSB).

Subsequent works have reproduced the same phenomenon, performing large-eddy simulations of forced pitch oscillations (Poirel & Yuan 2010) or numerical time-marching fluid-structure-interaction simulations using turbulence modelling for the Navier–Stokes equations (Poirel *et al.* 2011), to name a few. In continuation of these works, Poirel & Mendes (2014) performed experiments in the same transitional Reynolds range, but with both pitch and heave degrees of freedom, obtaining both small and large amplitude oscillations.

More recently, an aeroelastic linear stability using a mean flow from 3D DNS simulations was investigated by Negi (2019), showing a static eigenvalue that indicates a divergent behaviour of the airfoil from its equilibrium position at $\alpha = 0°$. Further, they associated the subsequent non-linear oscillation to a sub-critical mode, which is non-linearly excited.

The present study aims to understanding of the laminar separation flutter, by highlighting this divergent onset that leads the airfoil to a new equilibrium point where an unstable eigenvalue is then responsible for the non-linear onset dynamics.

MEAN FLOW ANALYSIS

We consider a flow described by the incompressible Reynolds-Averaged Navier–Stokes equations (RANS) with a closure obtained from the Spalart–Allmaras model. This model was intended to be used in a fully turbulent configuration where no laminar separation was able to appear. This turbulent behaviour is commanded by the inlet condition on the eddy viscosity which is recommended to be $\nu_t^\infty = 3\nu$.

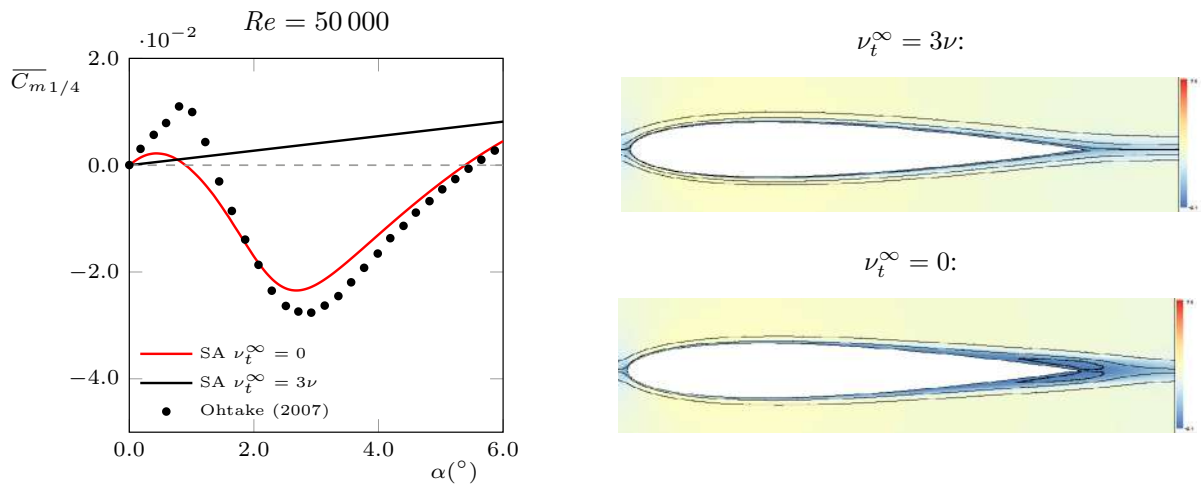

Figure 1: At right, the evolution of the mean flow moment coefficient with the incidence. At left, the streawise velocity for $Re = 50\,000$ for $\alpha = 0°$ and $\alpha = 4°$, showing a detached flow and a laminar separation bubble, respectively.

THEMATIC SESSION FS

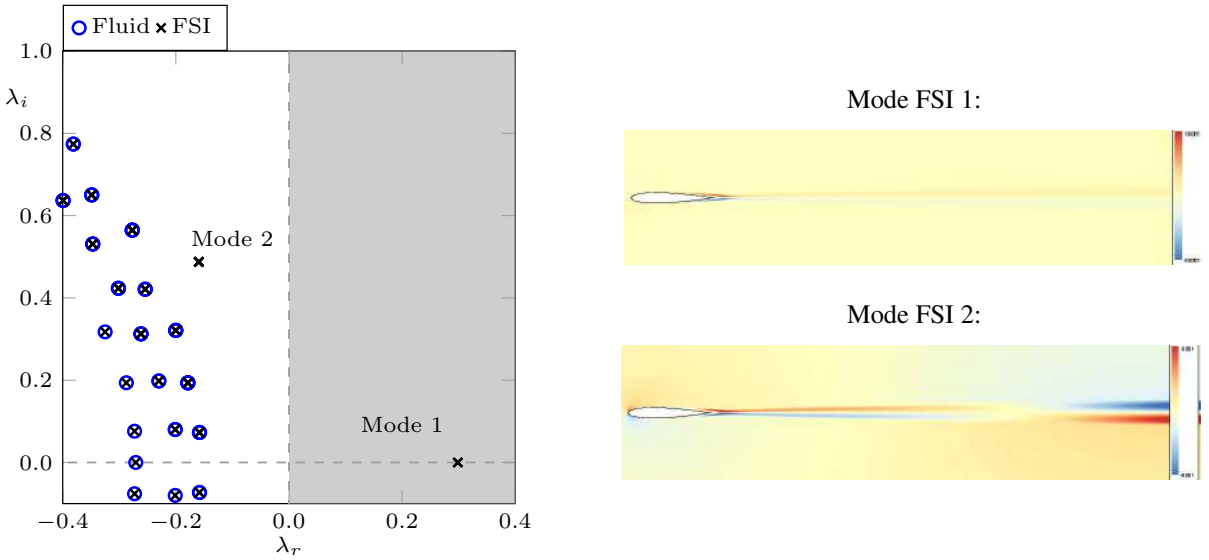

Figure 2: At left, a comparison between the fluid and a fluid structure spectra, the latter presenting a static unstable eigenvalue. At right, the streamwise velocity field for the two FSI modes.

However, recent studies have used this model to describe laminar separation flow, being able to capture the transition triggered by a separated flow (Crivillini & D'Alessandro 2014). The key ingredient of this procedure was the use of very small turbulent variable free-stream conditions, ideally at $\nu_t^\infty = 0$.

Following this idea, we carried out several RANS simulations for different airfoil incidences. The evolution of the mean flow moment coefficient is depicted in figure 1, for two different values of ν_t^∞.

It can be observed that the nonlinear behaviour of the flow field at low incidences cannot be captured by a fully turbulent simulation ($\nu_t^\infty = 3\nu$), whereas a laminar approach was able to capture it, when comparing with the experimental data from Ohtake (2007). The comparison between the flow fields is depicted at the left of figure 1, where a recirculation bubble can be observed for the laminar separated case.

FLUID STRUCTURE LINEAR STABILITY ANALYSIS

In a second time, a global stability analysis was carried out at $\alpha = 0°$ for the case where $\nu_t^\infty = 0$. The FSI stability analysis revealed two additional eigenvalues, associated to the pitching degree of freedom, that are not present when studying a pure hydrodynamic case. This comparison is detailed in figure 2, at left. The FSI stability analysis was carried out with a stiffness, damping and inertia coefficients of $K_s = 0$, $D_s = 0.0$ and $I_s = 0.00135$, respectively. The mode 1 is associated to the divergent linear departure from the equilibrium position. The correspondent spatial structure is depicted at right of figure 2. The second mode, although stable, and can be responsible for the onset of the pitching oscillation, by a non-linear excitation for large enough oscillation amplitudes.

CONCLUSIONS

A global linear stability analysis is performed for a torsion-spring airfoil configuration at the Reynolds number of 50 000. The mean flow field is obtained solving the RANS equations coupled to the Spalart–Allmaras turbulence model, with $\nu_t^\infty = 0$. The stability analysis around $\alpha = 0°$ shows a divergent eigenmode responsible for the departure of the airfoil from this equilibrium position. The subsequent the onset of the pitching oscillation could be explained by a non-linear excitation of a second structure mode.

EXTENDED KINETIC THEORY FOR A DENSE, COLLISIONAL, SHEARING FLOW ABOVE AN INCLINED PARTICLE BED

James T. Jenkins*[1] and Diego Berzi [2]
[1]School of Civil and Environmental Engineering, Cornell University, Ithaca, NY, USA
[2] Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary We outline the physics and provide the equations and boundary conditions that govern the behavior of steady, dense, collisional sharing flows above an inclined particle bed. These may be employed to formulate and solve the boundary problem that gives profiles of particle concentration, average velocity, and the strength of the velocity fluctuations through the depth of the flow.

INTRODUCTION

Balance laws and constitutive relations based on kinetic theory [1] form the basis for the description of many shearing flows of inelastic spheres. However, when flows are sufficiently dense, such kinetic theories fail. For example, in flows down inclines, they predict increases in average density with inclination, significant variation in density across the flow, and limited increases in depth with volume flow rates than are different from those observed in numerical simulations [2,3]. The problem is that they fail to incorporate velocity correlations that develop [4] at particle concentrations above 0.49, at which a transition to an ordered collisional gas is possible in an equilibrated system of elastic spheres [5].

An attempt to correct kinetic theory in order to incorporate the influence of the velocity correlations involves the introduction of an additional length scale in the rate of collisional dissipation of energy [6-8]. The length scale is determined by a phenomenological balance between the orienting influence of the mean shearing and the randomizing influence of collisions. Its presence permits realistic predictions of the behavior seen in dense inclined flows [9,10]; it also allows the resulting theory to be related to simpler phenomenological descriptions of dense flows [11-14] that have recently become popular.

Often, dense collisional shearing flows occur over a particle bed. In this case, particle collisions persist within the bed, but are accompanied by ephemeral chains of contacting particles that transmit force within the bed. The resulting elasticity associated with the existence of force chains and the collisional transfer of momentum associated with their breaking may be incorporated into the stress [10].

Here, we focus on the collisional flow above the bed and collect the elements of the extended kinetic theory that describe the flow. These include balance laws for particle momentum and fluctuation energy, constitutive relations for stress, energy flux, and the rate of energy dissipation, and the associated boundary conditions.

THEORY

We consider steady, two-dimensional shearing flows of a dense aggregate of identical spheres of diameter d, mass density ρ_s, and solid volume fraction, or concentration, ν over an inclined particle bed in the absence of side walls. The spheres have a coefficient of sliding friction μ, and a restitution coefficient e. The x-axis is taken to be in the direction of flow and at an angle of ϕ to the horizontal, the y-axis is perpendicular to it and directed upward. The gravitational acceleration is g, the average particle flow velocity is u, the granular temperature T is one-third the square of the magnitude of the particle velocity fluctuations, and a prime denotes a derivative with respect to y.

Momentum Balance

The particle shear stress s and particle pressure p satisfy familiar forms of the balance of momentum. In flow and normal directions, $s' = \rho_s \nu g \sin\phi$ and $p' = -\rho_s \nu g \cos\phi$. With a free surface at $y = h$, these integrate to $s/p = \tan\phi$; and, when ν does not vary much from a typical value $\overline{\nu}$, as is often the case, $p = \rho_s \overline{\nu} g (h - y)\cos\phi$.

We consider only flows in which $\nu \geq 0.49$ and, in the constitutive relations [1] retain only terms that result from collisions. In this case, $s = 8\hat{J} d \rho_s \nu (1+e) G T^{1/2} u' / (5\pi^{1/2})$, where [1] $\hat{J} = 1/2 + (\pi/4)(3e-1)(1+e)/[24-(1-e)(11-e)]$; and $p = 2\rho_s \nu (1+e) G T$, where [15] $G = 5.69\nu(\nu_c - 0.49)/(\nu_c - \nu)$, with ν_c the value of the solid fraction at which spheres first touch along the axis of compression and the formation of a bed becomes possible. The value of this concentration depends on μ [8,16]: $\nu_c = 0.58 + (0.64 - 0.58)\exp(-4.5\mu)$. The common dependence of the pressure and shear stress upon ν and G allows the shear stress to be expressed as a function of p, rather than ν: $s = 4\hat{J} d (p/T^{1/2}) u' / (5\pi^{1/2})$. This is an advantage, because the distribution of pressure is often known. Inverting the relation for the shear stress results in an equation to be integrated for the average velocity: $u' = 5\pi^{1/2}(T^{1/2}/d)\tan\phi/(4\hat{J})$, once T is determined.

Energy balance

The temperature is determined by an energy balance associated with the particle velocity fluctuations. It involves the divergence of a flux of fluctuation energy Q, the working of the shear stress through the velocity gradients, and a rate of dissipation Γ of fluctuation energy in collisions: $-Q' + su' - \Gamma = 0$. Here, $Q = -4\hat{M}d\rho(1+e)GT^{1/2}T'/\pi^{1/2}$, where [1] $\hat{M} = 1/2 + (9\pi/8)(2e-1)(1+e)/[16-7(1-e)]$, or $Q = -2\hat{M}d(p/T^{1/2})T'/\pi^{1/2}$; and $\Gamma = (12/\pi^{1/2})\left(1-\varepsilon^2\right)\rho GT^{3/2}/L$, or $\Gamma = (6/\pi^{1/2})(1-\varepsilon)pT^{1/2}/L$, where ε is an effective coefficient of restitution, $\varepsilon = e - \left(3/2\right)\mu\exp(-3\mu)$, that incorporates both restitution and friction [17-19], and L is the correlation length, given in a balance between the mean shearing and the temperature as $L/d = fdu'/T^{1/2} = f5\pi^{1/2}\tan\phi/(4\hat{J})$, in which the dependence on ν and ε enter through f, determined in numerical simulations [8] to be $f^2 \equiv 2\hat{J}/[15\left(1-\varepsilon\right)]\left[1+(26/15)(1-\varepsilon)(\nu-0.49)/(0.64-\nu)\right]^3$. When the constitutive relations for Q, s, and Γ are employed in the energy balance and the result expressed in terms of $w \equiv T^{1/2}$, the fluctuation velocity, a linear equation for w results: $d^2w'' + d^2(p'/p)w' + \left[5\pi\tan^2\phi/(8\hat{J}) - 3\left(1-\varepsilon\right)/L\right]w/(2\hat{M}) = 0$. However, in this equation, the pressure and the correlation vary with concentration through the depth of the flow.

In any case, the normal component of the momentum balance, used with the constitutive relation for the pressure, provides a first-order differential equation equation that involves both ν and w. This may be used with the linear equation for the fluctuation velocity and appropriate boundary conditions to determine the variation of both fields through the flow. Then, given w, the inversion of the constitutive relation for the stress may be integrated for the average particle velocity, subject again to an appropriate boundary condition.

Boundary conditions

Here, we assume that at the surface of the bed the concentration is very near ν_c, the average particle velocity is small enough to be neglected, and that particle velocity fluctuations persist into the bed [20]. Then, in the bed, we assume there is a rough balance between the first and last terms in the equation for the fluctuation velocity: $d^2w'' - \lambda^2 w = 0$, where $\lambda^2 = 3d\left(1-\varepsilon\right)/(2\hat{M}L_0)$ and the subscript indicates that L is evaluated at the surface of the bed. Integrating this give a condition on the energy flux at the surface of the bed: $Q = -4\hat{M}p\lambda w/\pi^{1/2}$, or $w'\big|_0 = \lambda w_0/d$. At the free surface, we take $\nu = 0.49$, $s = p\tan\phi$, $w' = 0$. These conditions permit the determination of the profiles of ν, u, and w and the thickness, h, of the flow.

CONCLUSIONS

We have outlined the physics and provided the equations and boundary conditions that govern the behavior of a steady, dense, collisional, sharing flow above an inclined particle bed. The resulting relatively simple system of equations may be employed in, for example, the Matlab solver bvp4c to determine the profiles of particle concentration, average velocity, and fluctuation velocity through the depth of the flow.

FLOW AND PACKING BEHAVIOR OF COHESIVE AND ASPHERICAL PARTICLES IN HOPPERS

Jennifer Sinclair Curtis[1], Yu Guo[2], and Henna Tangri[3]
[1]Department of Chemical Engineering, UC Davis, Davis, CA, USA
[2]School of Aeronautics and Astronautics, Zhejiang University, Hangzhou, China
[3]Chemical Engineering Department, University of Florida, Gainesville, FL, USA

Summary This presentation outlines advances in DEM to simulate the motion of cohesive and/or aspherical particles. Aspherical grains are described either as perfect cylinders or disks of varying aspect ratio or described using a linked and overlapping sphere approach. Using this linked approach, the flow of flexible aspherical particles can also be treated via a bonded particle model which incorporates normal and shear forces as well as bending and torsional moments. The bonded particle model also allows for breakage of aspherical particles during impact. Cohesion between particles is described as originating from surface moisture, described by a liquid bridge force model in the case of pendular liquid bridges. DEM simulations of wet, aspherical particles are validated via experiments of hopper discharge and measurements of particle-phase stress in a ring shear cell.

RESULTS: Hopper Discharge of Dry, Aspherical Particles

DEM has been shown to be a powerful simulation tool to predict the flow behaviour of spherical particles in hoppers – both in wet and dry states ([1],[2],[3]). Here, the discharge of non-spherical particles, specifically cylindrical particles, from a rectangular hopper is investigated. The behavior of both steel and plastic cylindrical particles with varying aspect ratio (same diameter, different lengths) is simulated via DEM and validated via corresponding experimental measurements. In addition, the effects of fill height, particle-particle friction, and hopper cone angle (90 and 55 degrees) are explored and compared with previously published results for spherical particles. A representative computational set up is shown in Figure 1, along with the detailed information regarding particle velocities for various heights in the hopper. The cylindrical particles are simulated using the contact detection as outlined in [4].

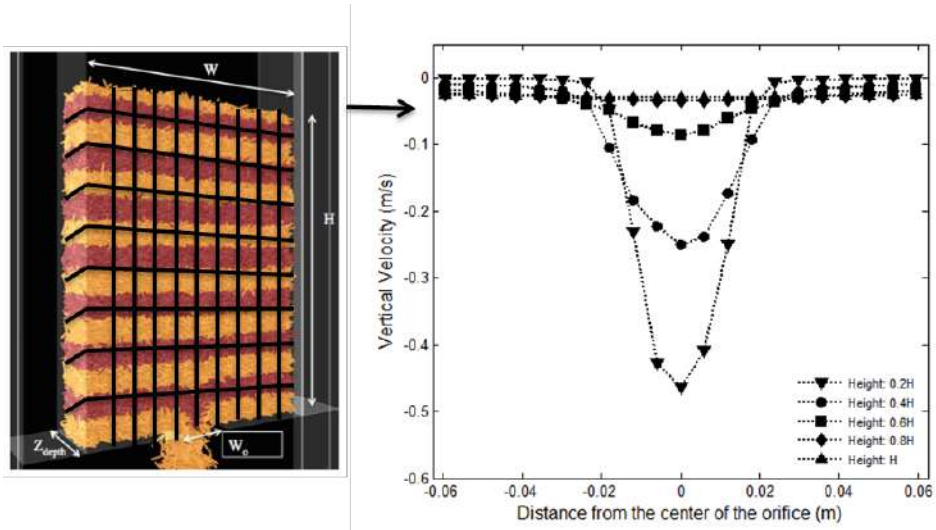

Figure 1. DEM simulation and representative grid (left) used to compute local particle velocities with the hopper (right)

The DEM simulations show that the discharge rate of aspherical particles are drastically different from their spherical counterpart, with the discharge rate decreasing with increasing aspect ratio or decreasing sphericity. This trend is valid even taking into account the increase in equivalent diameter of the aspherical particle. This is shown in Figure 2 by a comparison of the discharge rate of spherical particles, based on the Myers and Sellers hopper discharge rate correlation ([5]), with the discharge rate of aspherical particles with the same equivalent volume diameter. Also, Figure 2 shows that the DEM simulations are fully capable of predicting the discharge rate of the aspherical particles. The coefficient of friction also strongly affects the discharge rate – increasing friction significantly decreases the discharge rate. The critical value of friction coefficient in which the discharge becomes independent of friction is 0.1. The DEM simulations also show that discharge rate of cylindrical particles varies with the orifice width raised to the power 3/2, similar to the case with spherical particles. In addition, decreasing the hopper angle from 90 degree to 55 degrees decreases the discharge rate and further decreases in hopper angle increase the discharge rate. Based on a wide range of simulation and experimental data, a new hopper discharge rate correlation is proposed which incorporates the particle sphericity and longest particle dimension and is applicable to both spherical and aspherical particles.

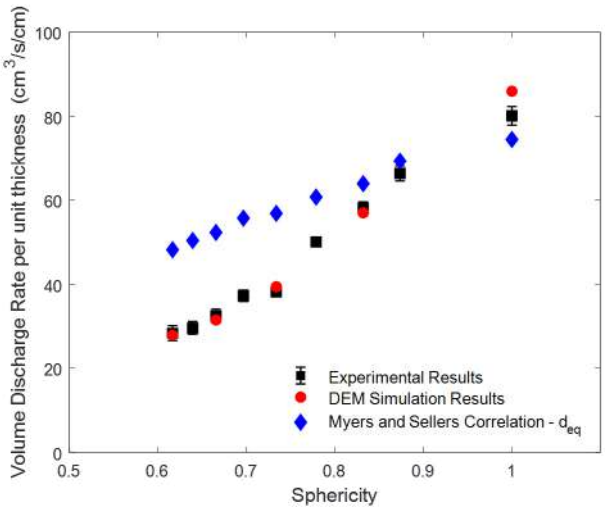

Figure 2. Hopper discharge for particles of varying sphericity from [6]

RESULTS: Hopper Discharge of Wet, Aspherical Particles

When aspherical particles are wet, the cohesive forces associate with the liquid bridges that form between particles affect the discharge rate. As the amount of liquid on the particle surface increases, the rupture distance of the pendular bonds that form between particles increases. A premeasured amount of liquid is added to the particles, and the particle-liquid mixture is thoroughly mixed for uniform distribution of liquid before charging the hopper. The discharge rate of wet steel spheres and wet cylindrical steel particles were measured at varying liquid quantities. Figure 3 shows the effect of silicon oil content on the discharge rate of steel particles. The discharge rate decreases upon the addition of a small amount of surface liquid but further increases in surface liquid do not affect the discharge rate.

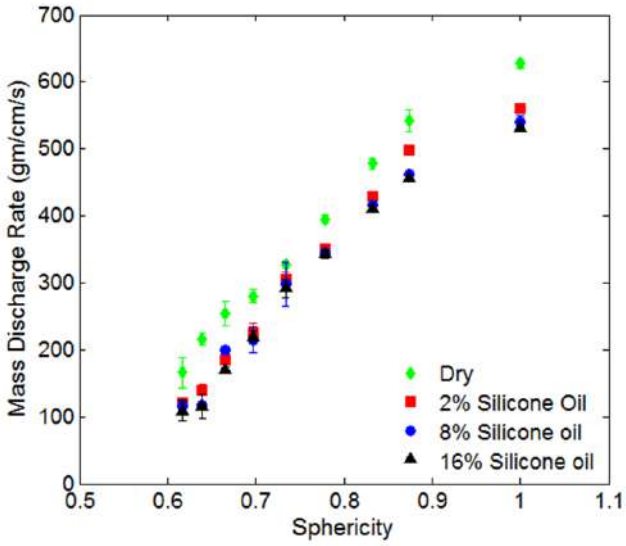

Figure 3. Hopper discharge for varying levels of surface liquid on aspherical particles

LATERAL BOUNDARY INFLUENCE ON TURBULENT BED-LOAD FLOWS FROM REFRACTIVE-INDEX-MATCHED EXPERIMENTS

Hervé Capart *[1] and Wei-Jay Ni [1]
[1]Department of Civil Engineering and Hydrotech Research Institute,National Taiwan University, Taipei, Taiwan

Summary We report experiments aimed at characterizing the influence of lateral boundaries on turbulent bed-load flows. Three types of lateral boundaries are examined: symmetric smooth walls, symmetric rough walls, and an asymmetric half-channel configuration featuring an erodible bank on one side and a smooth wall on the other. In all cases, an erodible loose bed is considered. To image the internal structure of the resulting flows, refractive-index-matching and laser scanning are used, making it possible to measure both the liquid and granular flux distributions over the flow cross-section.

INTRODUCTION

For simplicity, most detailed experiments on turbulent bed-load flows conducted so far have focused on the vertical flow structure. In particular, such experiments have documented the transition from a liquid-dominated upper flow layer to the loose static bed, across a bed-load layer featuring strong concentration and velocity gradients (Sumer et al. 1996; Capart and Fraccarollo, 2011; Revil-Baudard et al., 2015). To achieve quasi-two-dimensional flows, symmetric channels with smooth sidewalls are typically used, and measurements acquired either near the wall, or inside the flow using optical or acoustic methods.

In industrial and natural flows, however, lateral boundaries are typically more complex, and may produce strong gradients in both the lateral and vertical directions. For rigid walls, this will occur if the lateral boundaries are sufficiently rough. Many natural channels, moreover, feature erodible banks that will likewise produce lateral flow variations over the channel width. To investigate such effects, we conducted experiments with different lateral boundaries, examining how they influence the cross-sectional flow and transport distributions.

EXPERIMENTAL METHODS

As illustrated in Fig. 1, we conduct experiments in a sloping open channel, alimented with constant liquid and granular discharges. To gain optical access to the interior of the three-dimensional flows, we use transparent liquid and granular materials with closely matched refractive indexes. The mixture then becomes optically homogeneous, making it possible to observe the undistorted shapes, positions and motions of grains or tracer particles inside the medium. For the present experiments, we adopt the refractive index matched liquid-solid pair proposed by Haam et al. (2000), which we used successfully in previous work (Ni and Capart, 2015, 2018). The transparent liquid is the specialty organic liquid para-cymene, while the solid grains are spheres made from transparent PMMA (polymethyl metacrylate).

To measure the resulting flows, laser scanning is conducted using different orientations of the laser sheet, respectively parallel to the (x,y), (x,z), and (y,z) planes (see Fig. 1 for the axis directions), slowly translating the laser sheet in the normal direction. The (x,z) and (x,y) laser scans make it possible to capture the different components of the liquid and granular velocities, using particle tracking velocimetry. The (y,z) laser scans, on the other hand, capture grain crossing events from which both the granular concentration and granular flux can be estimated. Averaged over the channel cross-section, the resulting measurements produce maps of velocities, concentration and flux intensity at sub-grain diameter resolution (for details regarding the imaging algorithms and averaging methods, see Ni and Capart, 2015 and Ni, 2018).

EXPERIMENTAL RESULTS

Results will be compared for three types of lateral boundaries: symmetric smooth walls, symmetric rough walls, and an asymmetric half-channel configuration featuring an erodible bank on one side and a smooth wall on the other. In all cases, an erodible loose bed is considered. Results for symmetric smooth walls have been reported previously (Ni and Capart 2018), and correspond to quasi-two-dimensional flows with limited near-wall effects.

For symmetric rough walls, however (see Fig. 1), both the granular and liquid flux intensity become strongly non-uniform over the width. The bed-load transport layer acquires a lenticular shape, with a thickness that grows with distance from the wall. The liquid flux distribution, likewise, is strongly affected, with maximas occurring below the free surface near the rough walls. Near the walls, similar intensities are observed for the lateral and vertical gradients.

For the asymmetric half-channel configuration, experiments are more complex because erosional bank migration produces unsteady flows. The granular flux, moreover, appears to play a significant role in destabilizing the bank. At different stages during the resulting evolution, the liquid and granular fluxes again exhibit strong lateral variations. Although ideally the smooth sidewall would represent a symmetry plane of an equivalent full channel configuration, some wall effect are present, hence the effective symmetry plane is displaced into the channel some distance away from the wall.

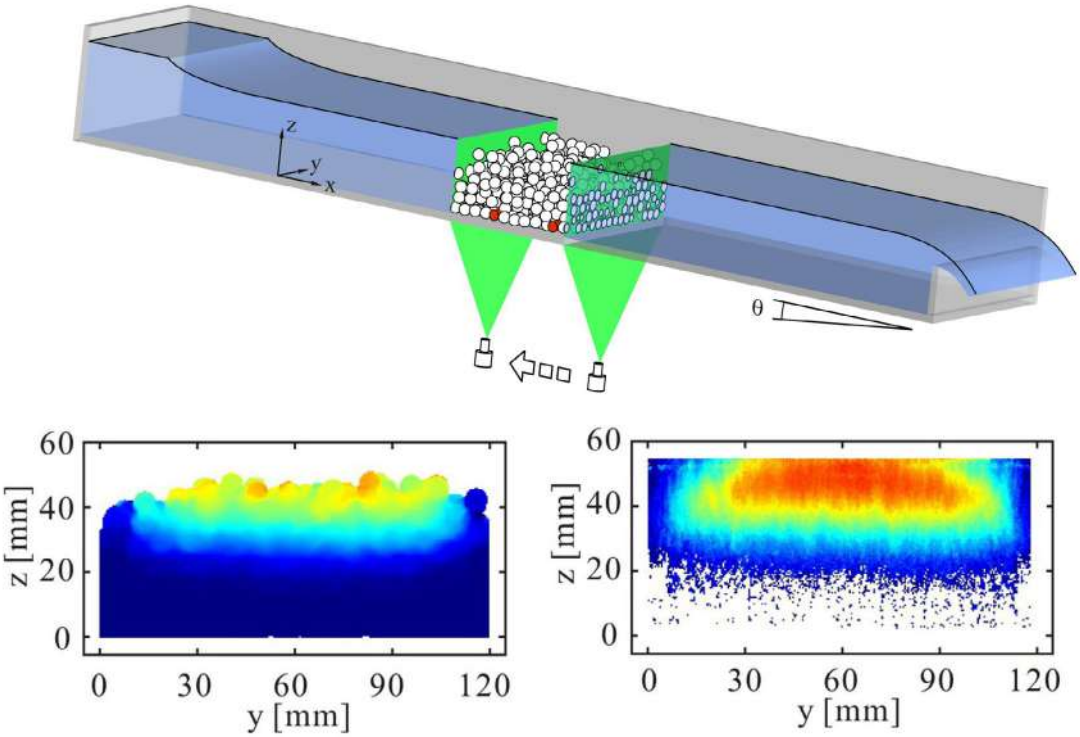

Figure 1: Principle and capabilities of the experimental approach. Top: laser scanning across a three-dimensional flow volume made transparent by using refractive-index-matched liquid and solid materials. Bottom: measurements of the granular (left) and liquid flux distribution (right) over the flow cross section (here for symmetric rough walls).

CONCLUSIONS

Using refractive-index-matching and laser scanning, we obtain detailed cross-sectional maps of liquid and granular fluxes in turbulent bed-load flows with different lateral boundaries. The results show that lateral boundaries exert a very significant influence on the flow and transport distributions. Unlike smooth rigid walls, rough rigid and erodible boundaries produce lateral and vertical gradients of similar strengths.

SPONTANEOUS CLUSTERING IN A SUBMONOLAYER OF GRAINS UNDER HORIZONTAL SHAKING

Song-Chuan Zhao* [1] and Thorsten Pöschel[2]
[1]State Key Laboratory for Strength and Vibration of Mechanical Structures, School of Aerospace Engineering, Xi'an Jiaotong University, Xi'an 710049, China
[2]Institute for Multiscale Simulation, Friedrich-Alexander-Universität, Caustra e [3], 91058 Erlangen,Germany

Summary Granular matters often display clustering instability, a signature of its non-equilibrium state. Nevertheless, the mechanism leading to clustering varies. We study here the spontaneous clustering of a submonolayer of beads under horizontal circular shaking. The clustering is triggered by increasing the oscillation amplitude. It turns out that the observed clustering is due to the formation of density wave, which travels along with the oscillation at the same frequency. The key ingredient of its formation is a type of multiplicative driving resulting from the interplay between the friction between grains and the the frictional driving of the substrate. A phenomenological model shows that the instability arises by increasing the oscillation amplitude and further captures the non-monotonic dependence of the transition amplitude of the clustering on the global density of the system.

BACKGROUND

Owing to the non-equilibrium nature granular materials exhibit self-organization across orders of magnitude, from gold panning to astrophysics. Those phenomena are largely represented by the clustering instability, non-uniform density distribution developing out of an initially homogeneous state. Clustering has been observed both in freely cooling granular gas and in driven systems. Such a collective behavior leads to pattern formation, segregation and phase separation. Though clustering of granular matter exhibits some generic features across various systems, there are peculiarities in any particular system that need to be taken into account, *e.g.,* the type of energy input. In this paper we studied a submonolayer of beads under horizontal oscillations. The constant frictional driving of the substrate distinguishes it from the vertical vibrated system. Strip-like pattern was reported in such a system subjected to one-dimensional oscillation [1]. Under two-dimensional oscillation liquid-solid transition was found, and the solid phase is reached by increasing the oscillation amplitude [2], an example of 'freezing by heating'. However, the mechanism of the spontaneous clustering in such a system is still unknown. Here, we untangle this issue by combining experiments, a phenomenological model and molecular-dynamic simulations.

EXPERIMENTS AND PHENOMENOLOGY

For the system studied here, there are at least three aspects of experimental parameters: the oscillation strength, the global packing density and the ratio of the grain size to that of the container. For simplicity, we first constraint the parameter as follows, and in the end we will expand the parameter space and discuss the consequences. The submonolayer consists of $N_{tot} = 6930$ polydisperse ceramic beads of which the range of diameter is between 0.6 mm to 0.8 mm. The mean diameter is used to denote the grain size $d_g = 0.7\mathrm{mm}$. The grains sitting on a bottom plate are confined by a circular side wall with diameter $D = 82\mathrm{mm}$. The global packing density is given by the area ratio $\phi_0 = N_{tot}(d_g/D)^2$. The inclination of the bottom plate is smaller than 0.02 mm/m. The container is subjected to anti-clockwise circular oscillation in the x-y plane. The oscillation frequency is fixed at 5 Hz. The oscillation amplitude A is varied in the range between 5 mm and 13 mm. Note that here the amplitude represents the diameter of the circular oscillation path (figure 1c). In this range of agitation grains rarely jump over each other, and thus the packing remains two-dimensional. The system is illuminated by a LED panel from bottom, and the dynamics are captured by a high speed camera at the top. The camera is fixed in the laboratory frame of reference. Without specifications the analysis in the following is done in this frame for reference.

In figure 1 snapshots of the packing at two oscillation amplitudes are shown. For $A = 5\mathrm{mm}$ the packing is homogeneous (figure 1a). By increasing A to 11 mm a cluster of grains can be seen at the center (figure 1c). The observed clustering is very sensitive to the oscillation amplitude. The dense area is destroyed within 10 cycles after decreasing A from 11mm to 10mm. This transition is thus second-order like. This highlights the uniqueness of the clustering in the current work with respect to that in a vertically vibrated monolayer [3]. There, the clustering is triggered by decreasing the oscillation strength after fluidization, and the cluster consists of low-velocity particles. Furthermore, in our experiments the dense area appears to move anti-clockwisely, the same direction as the oscillation, and seems to be in phase with the oscillation.

In figure 1b there are dense areas also along periphery of the packing. Those dense boundary layers may be sustained over cycles and moves in a counter-intuitive way, opposite to the oscillation (not shown here). Nevertheless, its formation is not surprising. The rotational degree of freedom of grains reduces the linear momentum transfer from the substrate. Therefore, grains move more slowly than the container, and those close to the side wall is condensed during certain oscillation phases. In contrast, the spontaneous clustering at the center of the packing can not be explained by the same reason, as there are no obvious condensers at the center.

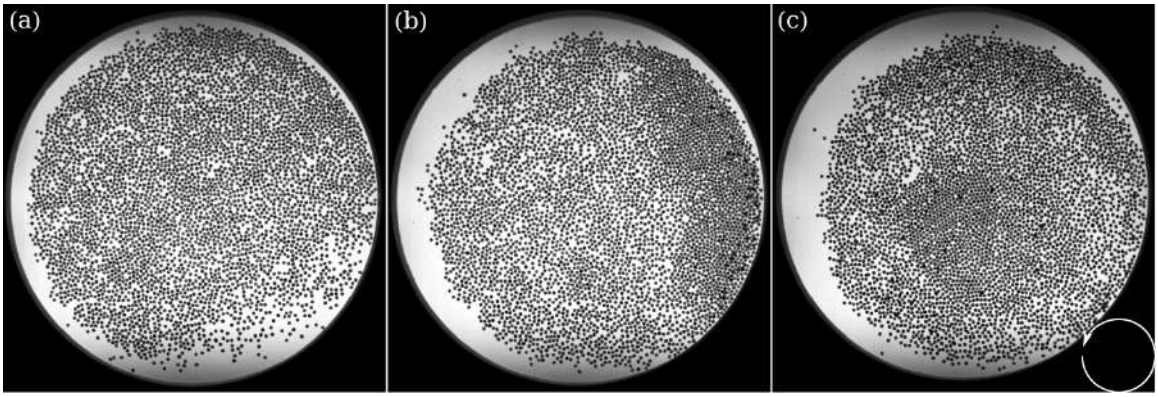

Figure 1: Snapshots of the packing for two oscillation amplitudes: (a) $A = 5\mathrm{mm}$, (b) $A = 8\mathrm{mm}$ and (c) $A = 11\mathrm{mm}$. A dense area can be seen at the center for (c). The white circle at the bottom right indicates the anti-clockwise oscillation path in scale.

THE UNDERLYING MECHANISM OF THE CLUSTERING

To unravel its formation mechanism we perform particle tracking and look into the dynamics for clues. We follow the motion of one grain in the central region. Its neighborhood experiences periodic compression and dilation. It is remarkable that the speed of the grain v_g follows the same periodic pattern and shows a positive correlation with ϕ_{loc}, *i.e.*, a grain in a denser neighborhood tends to move faster. This feature, the dependence of the speed of individual particles on the local density of the local neighborhood remains for $A < 11\mathrm{mm}$ as well, though clustering is not observed.

Considering the continuity equation, it is readily to show that as an increasing function of ϕ_{loc} the velocity $v(\phi_{loc})$, the advection term, promotes the formation of density shocks, similar to Burgers' equation. On the other hand, the finite transition amplitude of the clustering ($A \geq 11\mathrm{mm}$) suggests that the collisions between grains introduce an equivalent term of pressure and competes with the advection term. In addition to the continuity equation, we introduce a phenomenological equation of the velocity field incorporating these two aspects. The stability analysis of the model shows that the uniform flow state becomes unstable against density fluctuations when increasing A beyond the transition amplitude A_c, and the density wave develops into the clustering. This corresponds to the observed 'freezing by heating'. Furthermore, according to the model the transition amplitude is expected to be non-monotonic which is indeed observed in experiments.

The key ingredient promoting the clustering is the dependence of the speed of grains on the the local density. Why such a dependence exists? We believe that it is a consequence of the interplay between the friction between grains and that between grain and the substrate. μ_{gg} and μ_{gs} denote the friction coefficients of the former and the latter respectively, and F_{gg} and F_{gs} are the corresponding frictional forces. Upon agitation F_{gs} accelerates not only the linear momentum but also the angular momentum of individual grains. It has been shown that the faster a grain rolls, the slower its linear speed is [1]. On the other hand, during collisions F_{gg} counteracts the rolling of grains which in turn increases the moment of the inertia with respect to F_{gs} and effectively enhances the linear momentum transfer. F_{gg} is expected to increase with ϕ_{loc} and A. Therefore, grains tend to move faster in denser areas and/or under stronger agitations. This results into the observation where v_g increases with ϕ_{loc} and A. To examine this speculation molecular-dynamic simulations are performed. For a given μ_{gs} and A, the clustering is suppressed by decreasing μ_{gg}.

DYNAMICS OF A HORIZONTALLY WIGGLING INTRUDER IN A DENSE GRANULAR MEDIUM

Bitang Kwrung Tripura[1], Sonu Kumar[1], and Katha Anki Reddy * [1]
[1]Department of Chemical Engineering, Indian Institute of Technology Guwahati, Guwahati 781039, India

Summary We have investigated the effect of an intruder object(IO) shape, and its orientation has on the rise or sink when oscillated horizontally within a granular medium. For the simulations, the discrete element method (DEM)[1] has been used. We have considered six different shapes in our study: a square, two rectangle with different aspect ratio , a disc, an equilateral triangle, and an inverted equilateral triangle. The intruders were oscillated at a varying range of oscillating amplitude(A) and frequency(f). With time the oscillating IO settles down at a specific position within the granular media depending upon the A and f. The rise is seen from its initial position for the intruders at higher oscillating frequencies and the opposite at lower frequency for most of the IO for a given A. It is observed that there is a minimum amplitude(A_{min}) below which the position of the IO remains unaltered even after varying the f. The maximum amount of positive rise is observed for square and inverted triangle shapes. The orientation of the IO plays a significant role in its rise or sink within the media. The two triangles having different orientations have shown to have completely opposite rise behavior to each other. With the equilateral triangle showing negative lift at higher amplitude($A > 1d$) for all the f, while the inverted equilateral triangle has shown to have a positive lift at higher amplitude($A > 1d$) in all the cases. The average drag force calculated is seen to remain the same for all the shapes at the same phase angle.

INTRODUCTION

Granular material is a collection of discrete solid particles that show the property of both solid and fluid depending upon its volume fraction[2]. They can be seen in various forms in nature, ranging from sand particles in the desert to a group of floating iceberg in the ocean. It is one of the most manipulated materials in the industry after water. In recent years studies were performed to understand the dynamics of granular material in various configurations [3, 4, 5]. Many of these studies were aimed at understanding the organizational dynamics of granular material when a disturbance is applied in the system. In our work, we have highlighted one such problem where the movement of a self-energized intruder object oscillating horizontally within the granular media is studied. Such dynamics can be helpful to understand problems such as the brazil nut effect[6] and the use of wave like motion by the sand lizard[7] for its movement when under the surface in desert.

SIMULATION METHODOLOGY

A two-dimensional simulation system is considered for the study with dimensions of 300d×200d along x and y-axis, as shown in Fig. 1, where d is the mean particle diameter. The intruder object(IO) is placed at a depth of h=105d from the top free surface and then oscillated at varying A and f. We have employed Discrete element method(DEM)[1] for the

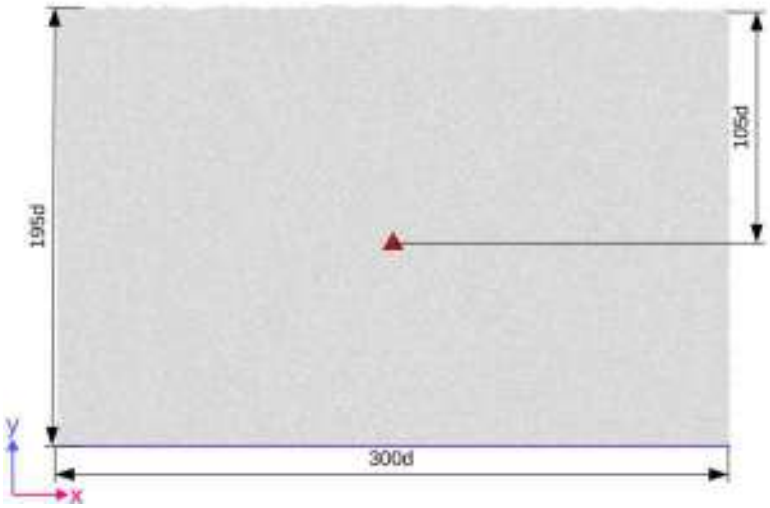

Figure 1: Initial configuration for one of the shapes (equilateral triangle) at a depth $h = 105d$. The x-direction is periodic while y-direction is confined by a wall at $y = 0$ made of particles of size $1d$(blue particles) while the top surface is free to move

simulation i.e used widely to simulate granular materials. While for particle interaction contact force model[8] is applied. The normal and tangential forces experienced by the interacting particles are given from the force model:

$$F_n = \sqrt{(R_{eff}\delta)}(K_n\delta - m_{eff}\gamma_n v_n) \quad (1)$$

*Corresponding author. E-mail: anki.katha@iitg.ac.in

$$F_t = -min(\mu F_n, \sqrt{(R_{eff}\delta)}(K_t\Delta)s_t + m_{eff}\gamma_t v_t) \quad (2)$$

RESULTS

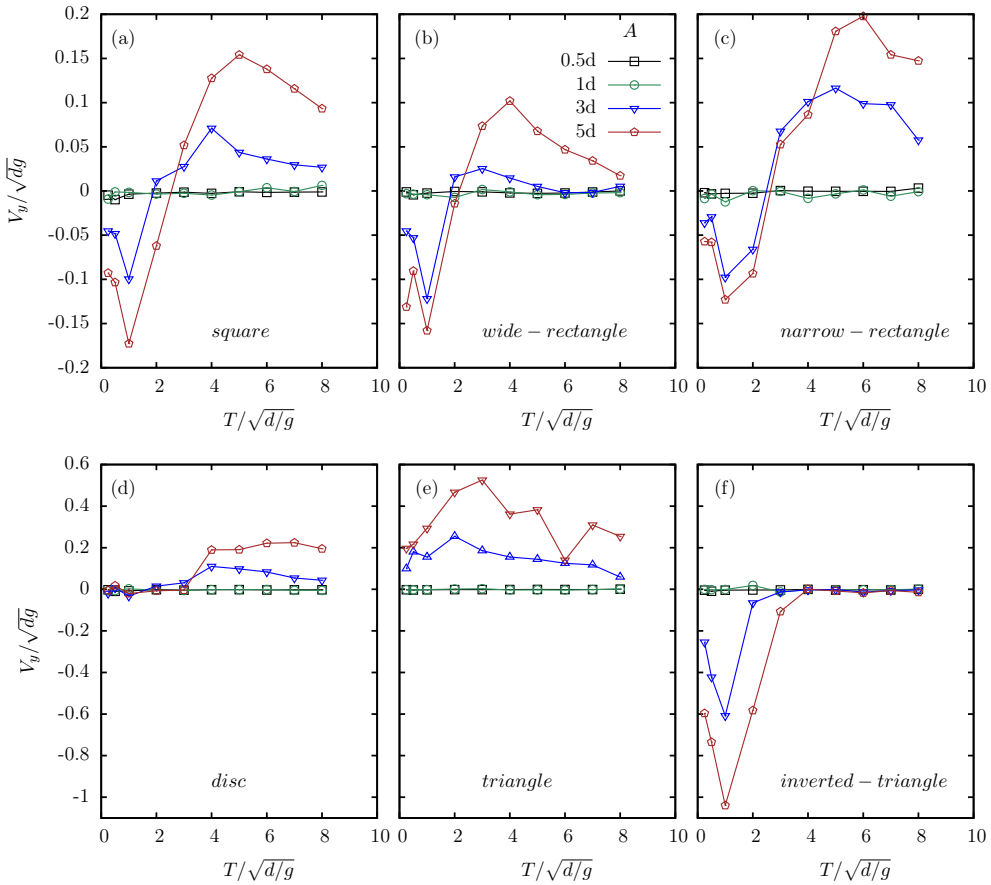

Figure 2: The rise rate(V_y) of the intruder object has been shown as a function of its oscillating time-period(T) for all the amplitude for (a) square (b) wide-rectangle and (c) narrow-rectangle(d) disc (e) triangle and (f) inverted triangle shaped intruder object.

CONCLUSIONS

Due to its continues oscillation, there was a rise or sink observed for the IO from its initial position within the granular medium for all the shapes. It was observed that for oscillation amplitude of 1d or less than it there was negligible change from its initial position of oscillation for all the IO. The maximum amount of rise from its initial position was observed for square and inverted triangular shapes. Some interesting outcome was also seen for the two triangular shapes used. With the equilateral triangle showing negative lift at higher amplitude($A > 1d$) for all the oscillated frequencies, while the inverted triangle has shown completely opposite result showing positive lift at higher amplitude($A > 1d$) in all the cases. The shape and orientation of the intruder object is seen to have an important role in the rising and sinking.

QUASISTATIC BEHAVIOUR OF LOOSE COHESIVE GRANULAR MATERIALS: A NUMERICAL STUDY

Walid Lammali[1], Vinh-Du Than[1], Anh-Minh Tang[1], and Jean-Noël Roux * [1]
[1]Lab. Navier, Univ. Gustave Eiffel, Ecole Nationale des Ponts et Chaussées, CNRS, Champs-sur-Marne, France

Summary The quasistatic mechanical behaviour of model cohesive granular materials is studied by discrete, grain-level (DEM) simulations. Representative (periodic) samples of 4000-9000 spherical beads of diameter d, for which elastic-frictional contacts are endowed with capillary or van der Waals cohesion, are assembled in loose states (solid fraction Φ down to 0.3). The mechanical response is largely determined by the reduced pressure $P^* = Pd^2/F_0$ comparing applied stress P to tensile strength F_0 in adhesive contacts. In isotropic or oedometric compression, Φ irreversibly increases with P^* in range $0.01 \leq P^* \leq 10$, while the apparent internal friction in triaxial compression is strongly enhanced, compared to the cohesionless case. Relations of such macroscopic behaviours to initial state, mechanical parameters and microstructure are discussed.

INTRODUCTION

While discrete-element (DEM) simulations have repeatedly been applied to investigate the quasistatic mechanical properties of assemblies of cohesionless grains [1], the behaviour of cohesive granular materials, which may form very loose structures [2] remains virtually unexplored. We present a DEM study of such a model material, made of cohesive spherical beads, initially assembled at low density.

MODEL AND SAMPLE PREPARATION

We consider spherical beads of diameter d, interacting in their contacts by elastic-frictional forces. We use the elasticity of glass and friction coefficient $\mu = 0.3$ in the contacts. Attractive forces press contacting particles against one another, which we model with a force law approximating the capillary attraction in pairs joined by a bridge formed by a wetting liquid, taking maximum value $F_0 = \pi\Gamma d$ at contact (Γ being the liquid surface tension). A meniscus of volume V_m is assumed to form as soon as grains touch, and a decreasing force subsists in receding pairs as long as the separation distance does not exceed $V_m^{1/3}$. The V_m-independent F_0 value given above holds for small V_m. The limit of very small V_m, then devoid of hysteresis, might be regarded as a simplified model for van der Waals attraction (Γ now representing a solid surface tension). The contact laws are described in detail in Refs. [3, 2]. Despite the simplifications, quantitative agreement was obtained with some experiments on polystyrene beads in simple shear flow [4, 5]. All results are presented in dimensionless form and are therefore valid for arbitrary materials. An essential dimensionless control parameter in these cohesive systems is the reduced pressure $P^* = Pd^2/F_0$: cohesive forces dominate and stabilize loose structures at small P^* and become negligible for large P^*. Reproducible and consistent results are obtained for samples of N beads, with $N = 4000$ or $N = 8788$, with periodic boundary conditions. Loose solid aggregates form by ballistic aggregation at constant solid fraction Φ_0, their structure depending on initial velocities (Fig. 1): better coordinated structures form with larger velocities, but with larger density inhomogeneities.

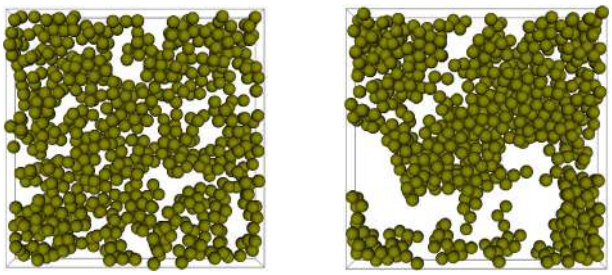

Figure 1: Aspect of aggregated structures formed at solid fraction $\Phi_0 = 0.3$ (front views of slabs of thickness $3d$), with small (left) and large (right) initial agitation velocity.

RESPONSE TO ISOTROPIC OR OEDOMETRIC COMPRESSION

Upon increasing P^* in quasistatic compression, such loose structures irreversibly collapse, and a quasilinear variation of void ratio $e = -1 + \frac{1}{\Phi}$ with $\log P^*$ is observed in some range. As shown in Fig. 2 this behaviour is influenced by the initial structure. We also investigated its dependence on Φ_0 and possible rolling resistance at contacts (also affecting the initial structure).

*Corresponding author. E-mail:jean-noel.roux@univ-eiffel.fr

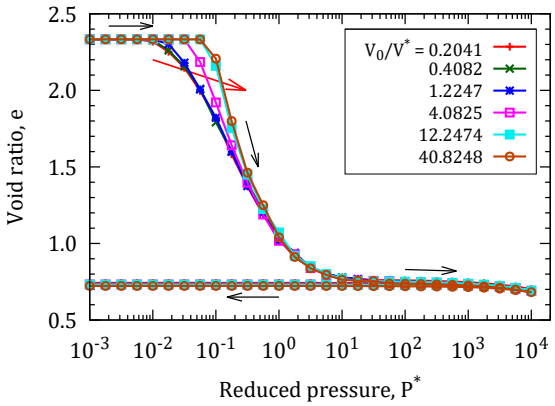

Figure 2: Compression curves showing void index versus $\log P^*$ in isotropic compression for different values of initial agitation velocity V_0. Note irreversibility (arrows) in pressure cycle.

TRIAXIAL COMPRESSION TESTS

Fig. 3 shows how the cohesion increases the deviator stress to lateral stress ratio (the cohesionless value being retrieved for the larger P^* values). The approach to the critical state plateau is delayed for small P^* while the density increases through a large contractance interval of strain.

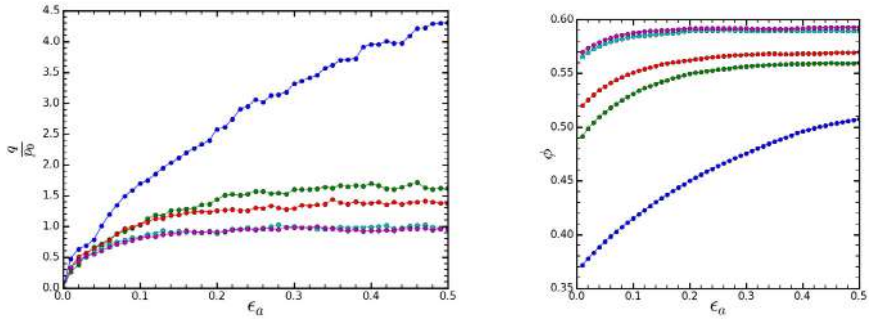

Figure 3: Results of triaxial compression tests: deviator normalized by constant lateral stress (left), and solid fraction (right) versus axial strain. Different initial P^* values: 0.1 (dark blue), 0.62 (green), 1 (red), 6.23 (light blue), 10 (pink).

PERSPECTIVES

We are currently systematically investigating the triaxial response of the model material. In parallel, the considerably greater wealth of microstructures available to cohesive systems is being characterized. Generic features should emerge at both scales, applying to a variety of materials, from clays to powders and colloidal gels.

EULERIAN MULTI-PHASE FLOW MODELING FOR GRAIN-SIZE SEGREGATION IN BEDLOAD TRANSPORT

Hugo Rousseau* [1], Remi Chassagne[1], Julien Chauchat[2], and Philippe Frey[1]
[1]University of Grenoble Alpes, INRAE, UR ETNA, 38000 Grenoble, France
[2]University of Grenoble Alpes, LEGI, G-INP, CNRS, Grenoble, France

Summary In this contribution we develop a Eulerian multi-phase flow model for bidisperse grain size-segregation in bedload transport. The closures used for the particle-particle drag and buoyancy forces are improved using recent advancement in the understanding of particle-particle interaction forces for a large particle in a bath of small. The two-phase flow model is then validated against recent DEM simulations of bidisperse grain-size segregation in bedload transport ([1]). The new model reproduces accurately the segregation dynamics in bedload transport and provides a better understanding of the segregation and remixing fluxes.

Rivers carry sediments that have a wide grain size distribution. This can lead to the grain size segregation phenomenon which has huge consequences on sediment fluxes. Among the various segregation processes, kinetic sieving is a key mechanism in bedload transport: the moving particles on top of the granular layer act as a random fluctuating sieve in which small particles are more likely to percolate down under the action of gravity than coarse particles. Accurate modeling of this phenomenon with continuous equations is a key step to upscale in sediment transport models.
Using the mixture theory, [4] and [2] developed continuous equations for bidisperse segregation. Based on the momentum balance of small particles, a simple advection-diffusion equation for the segregation of small particles was derived which makes it possible to explicit an advection and a diffusion coefficients. However they do not depend immediately on physical parameters of the granular flow.

Recently, Chassagne and co-workers [1] investigated grain-size segregation in bedload sediment transport using a coupled fluid-Discrete Element Method (DEM). The authors results showed that the small particles, initially at the bed surface, percolates through the bed made of large particles as the logarithm of time as a layer with a constant thickness. They developed an analytical solution for the space-time evolution of the concentration depth profile of small particles which shows that the advection and diffusion coefficients of the advection-diffusion model are power laws of the inertial number. However the link with the grain-scale physics and the actual formulation of the particle-particle forces is still lacking.

Using DEM simulations Guillard and co-workers [3] showed that the segregation force applied on a large intruder in a bath of small particles can be seen as a buoyancy force proportional to the pressure and the shear stress gradient. Also using DEM, [5] demonstrated that the drag force experienced by a denser particle in a sheared granular flow can be recasted as a Stokesian drag force proportional to the granular viscosity with a linear dependency to the relative velocity. However, the proportionality coefficient might not be 3 as in the classical Stokes drag law. Based one these new results a force balance for a single large particle in a dense granular flow made of small particles is infered in figure 1.

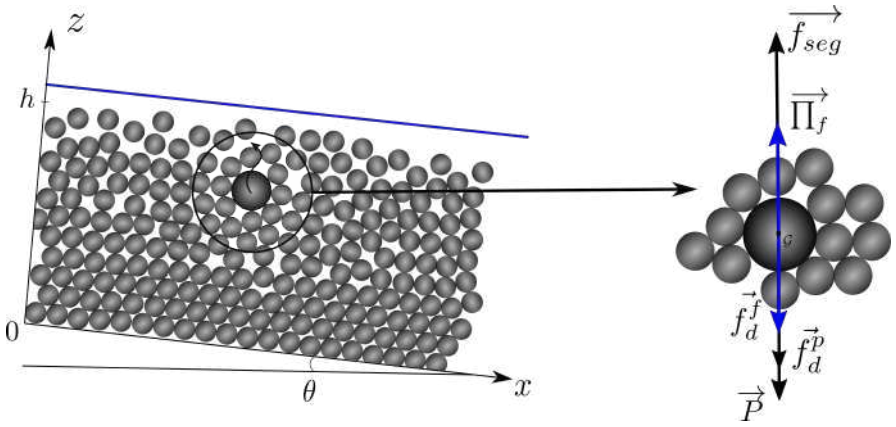

Figure 1: Forces acting on a large particle embedded in small ones. $\vec{\Pi_f}$ is the buoyancy due to the fluid and $\vec{f_{seg}}$ is the segregation force from [3]. The drag forces $\vec{f}_d^p$ and $\vec{f}_d^f$ are respectively due to the interaction with small particles [5] and the fluid.

Using the formulation of the forces presented above, a Eulerian multi-class model is developed to describe grain-size segregation in bed-load transport. The system of partial differential equation in the vertical direction is solved using a 1D Finite Volume Method for the concentration and the velocity of the fluid and of the large and small particles. The

*Corresponding author. E-mail: hugo.rousseau@inrae.fr

numerical results for the small particles are compared with the coupled-fluid DEM simulations from [1] in terms of space-time diagram for the concentration of small particles (see figure 2). It appears that the multi-class model based on the forces proposed by [3] and [5] reproduced accurately the logarithmic layer descent of small particles with time. However figure 2 shows that the thickness of the layer is different from DEM. Possible origins are the calibration of the segregation force because [3] developed it for disks or the calibration of the proportionality coefficient in the solid drag force of [5]. A complete sensitivity analysis on these parameters will be presented. Then, using the advection diffusion equation, an improved formulation inspired from DEM will be proposed.

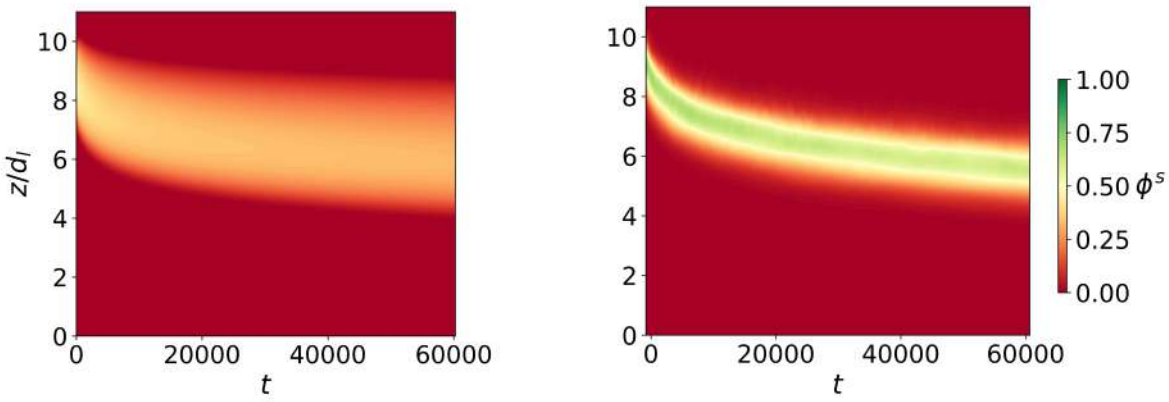

Figure 2: Concentration of small particles ϕ^s with the time in the bed. Left figure is the concentration obtained with the multi-phase model. Right figure shows the DEM results of [1].

Summary Despite many usual geological or industrial processes include erosion of sediments by a superficial fluid flow, there is still a lack of fundamental knowledge about erosional processes, notably as regards the impact of internal cohesive or adhesive stresses. This contribution focuses on the surface erosion by a submerged impinging jet flow and investigates more specifically the influence of cohesion by solid bonding between grains, i.e. cemented granular soils. The methodology relies on both laboratory tests with artificially bonded granular materials and numerical simulation through DEM-LBM calculations. The critical erosion onset condition obtained from our experimental and numerical results is proved to be satisfactorily accounted for through a new generalized form of the usual Shields criterion based on a common definition of a cohesion number from yield tensile values.

MOTIVATION

The ubiquitous occurrence of sediment erosional processes in natural or industrial contexts calls for an accurate prediction of soils resistance to surface erosion by a fluid flow. Following the pioneering work of A. F. Shields [1], erosion of strictly non-cohesive materials (sand, small pebbles, etc…) is interpreted as an individual process whose onset can be deduced from a critical value of the dimensionless Shields number Sh_0, defined as the ratio between the fluid shear stress exerted by the fluid flow at the sediment bed and the buoyant weight of a particle. This critical value varies by less than one order of magnitude according to the particle shear Reynolds number Re_τ and lies approximately along the so-called Shields curve. The complexity grows substantially for cohesive materials, such as benthic sediments, clayey soils or cemented calcareous sands. Indeed, internal attractive forces between particles induce more collective processes during erosion that preclude the previous scheme and consequently discard the related Shields approach.

However, for rather weakly cohesive soils, several attempts to generalize the Shields number have been proposed in the literature and rely notably on a comparison between a characteristic cohesive force and the particle's buoyant weight, thus defining a dimensionless cohesion number often denoted granular Bond number Bo_g [2]. The present contribution continues this approach by extending the applicability of the Shields criterion for the case of weakly cemented granular materials based on both experimental and numerical results in the specific situation of soil's erosion by a submerged impinging jet flow.

METHODOLOGY

In this study, we specifically address surface erosion of soil samples caused by a submerged impinging jet which is a standard experimental test, called Jet Erosion Test (JET), and enables quantifying soil's resistance to erosion either in the lab or in situ. Here, a micro-scale investigation is implemented by means of both numerical simulation and experiments. On the one hand, our numerical modelling uses a bi-dimensional coupled fluid-particle flow scheme, based on the Lattice Boltzmann Method (LBM) for the fluid phase combined with the Discrete Element Method (DEM) for the mechanical description of the solid grains interacting by contacts [3]. On the other hand, our experiments are performed on artificially bonded granular materials in an optically adapted device that permits a direct visualisation of the scouring process at the jet apex by means of the refractive index matching technique [4]. More precisely, our artificial soils are constituted of spherical glass beads bonded by solid bridges made of polyurethane resin.

Both investigations aim at assessing and modelling the effect on the resistance to erosion of a granular sample when additional internal stresses exist between the soil's particles. In our artificial cemented soils, this inter-granular cohesion induced by solid bonds, to be further used through the granular Bond number, is either quantified by traction tests or given by a specific model of the solid bond rheology [3].

RESULTS FOR EROSION ONSET CONDITIONS

We implemented similar protocols in the numerical simulations and in the experiments: the mean jet velocity at injection is progressively increased until first detachment of grains at the upper surface of the artificial soil. The critical injection velocity at erosion onset is thus measured with reasonable accuracy. A recent study based on our 2D LBM-DEM modelling in laminar flow regime [5] can provide the maximal bed shear-stress value in 2D and is extended to 3D in the experiments. Then, the bed shear-stress at erosion onset τ_s^* for both our numerical simulations and our experiments can

*Corresponding author. E-mail: pierre.philippe@inrae.fr.

be deduced from the critical injection velocity based on these 2D and 3D expressions, respectively. Figure 1 shows the Shields diagrams obtained during the numerical, where the critical values of the usual Shields number $Sh_0{}^* = \frac{\tau_s{}^*}{\Delta\rho g d}$ (with d the mean grain diameter and $\Delta\rho = \rho_g - \rho_f$ the difference of density between the grains and the fluid) are plotted versus the particle shear Reynolds number $Re_\tau{}^* = \sqrt{\frac{\tau_s{}^*}{\rho_f}}\frac{d}{\nu_f}$ (with ν_f the fluid dynamic viscosity). A very similar graph is obtained with the experimental data.

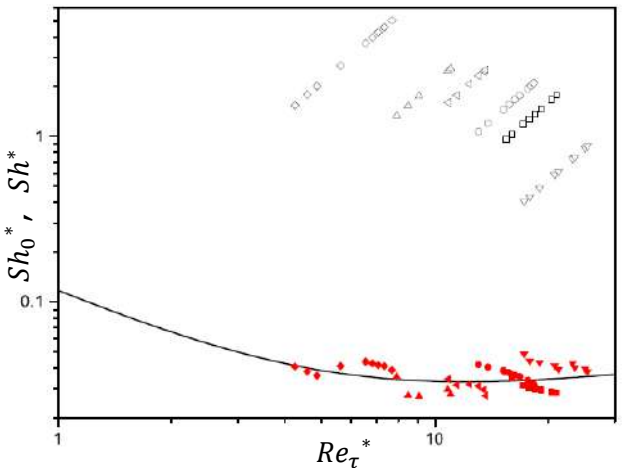

Figure 1. Critical values of the usual Shields number $Sh_0{}^*$ (black open symbols) and generalized Shields number Sh^* (red closed symbols) versus critical friction particular Reynolds number $Re_\tau{}^*$ obtained in the 2D numerical simulations.

As can be seen on these diagrams, the critical values of the usual Shields number $Sh_0{}^*$ increasingly deviate from the Shields curve as $Re_\tau{}^*$ increases, or equivalently as adhesion gets higher. Obviously, the usual Shields number Sh_0 is no more relevant to account for the erosion onset of our cemented granular soils and adhesive stresses must be included in addition to friction and gravitational contributions.

PROPOSAL OF A GENERALIZED SHIELDS CRITERION

We propose here to extend the definition of Sh_0 in a straightforward way by simply adding the adhesive stress, assumed to be directly proportional to the macroscopic yield tensile stress τ_Y, to the buoyant weight. By the end, the following expression is obtained for the generalized Shields number: $Sh = \frac{\tau_s}{\Delta\rho g d + \alpha\tau_Y} = \frac{Sh_0}{1+\alpha Bo_g}$, with introduction of the granular Bond number $Bo_g = \frac{\tau_Y}{\Delta\rho g d}$ and where the empirical coefficient α, expectedly of order 1, can be more precisely determined by linear regression. We found $\alpha_{2D} = 2.69 \pm 0.06$ and $\alpha_{3D} = 2.26 \pm 0.27$ from the numerical and experimental results, respectively. With these values of α, the critical values of the generalized Shields number Sh^* are found to lie approximately on the Shields curve and can consequently advantageously replace the usual $Sh_0{}^*$ in the Shields diagrams of Figure 1. It also manages to reconcile the data for cohesive and cohesion-less materials.

CONCLUSIONS

By means of both a 2D numerical modelling and real 3D experiments of erosion induced by submerged impinging jets on artificial weakly cemented materials, the present study has investigated the critical flow condition at erosion onset and proposed a generalization Sh of the Shields number through addition of cohesion by solid bonding between grains to buoyant weight with the dimensionless granular Bond number Bo_g. This approach is in rather satisfactory agreement with the usual Shields curve and offers a general framework for both cohesion-less (i.e. $Bo_g \sim 0$) and cohesive samples (i.e. $Bo_g > 1$), at least for weakly cemented soils as tested here ($Bo_g < 300$).

VISUALIZATION AND COMPUTATION ANALYSIS OF GRANULAR FLOW CAUSED BY EMBEDDED RIGID BODY MOTION

Hideto Nonoyama[1], and Yoshihisa Miyata [1]
[1]Department of Civil and Environmental Engineering, National Defense Academy, Yokosuka, Japan

Summary The visualization and computation analysis of granular flow caused by embedded rigid body motion are discussed. The outline of model test apparatus and observation system by using transparent granular for the granular flow are introduced. In a series of model tests, effects of the density of granular media and the position of the embedded rigid body were investigated. The observed granular flows were simulated by finite element analysis with four different constitutive models for granular materials.

INTRODUCTION

The granular flow induced by the embedded rigid body is an important research subject in civil engineering and chemical engineering. Since the actual internal behaviour of granular flow cannot be seen from the outside, only the relationship between the force-displacement relationships acting on the rigid body in the granular media has been discussed in previous researches. The authors have developed an observation system to visualize the granular flow. In the system, transparent granular is used. By applying the refractive index matching, the three-dimensional behaviour of the granular flow can be visualized time-successively. This paper introduces the outline of the observation system, results of the visualization and computation analysis for model tests are shown.

MODEL TEST AND VISUALIZATION TECHNIQUE

Granular materials are opaque to visible light, so the classical way to visualize internal granular flow is utilizing methods with X-rays, computerized tomography, or magnetic resonance imaging cameras. Those are very expensive and difficult to use. Visualization technique with transparent granular has been developed as a means of overcoming these difficulties. Transparent granular are two-phase media made by refractive index matching of granular materials and the fluids to saturate the void of granular. By using this technique and recent computational visualization techniques such as PIV and PTV, internal granular flow can be visualized [Inskander et al., 2015]. The authors applied this technique in this study.

Fig. 1 shows the outline of the model test apparatus in this study. Size of the testing box is 195mm in width, 600mm in height, and 195mm in depth. Two side of the testing box is made from acrylic plates and digital cameras were set at each observation windows. In a series of tests, a fan-shaped steel plate (radius B=50mm) was embedded in the granular media. The plate was pulled out at constant speed as 1mm/min. Quartz glass particles (particle density=2.214 g/cm^3, average diameter=1.0 mm, refractive index 1.4585) were used as transparent granular to made model media. The liquid paraffin was used to fill the void of the granular materials, whose refractive index is the same as quartz glass particles. As shown in Fig.2, tracer particles in granular media can be observed.

Model tests were performed in dense condition (relative density, Dr=80%) and loose condition (Dr=40%) of granular media. For each granular density condition, effect of steel plate depth was investigated. Investigated depth condition was D/B=2 and D/B=4, where D is depth of steel plate from the surface of granular media and B=radius of steel plate.

RESULTS OF MODEL TESTS, VISUALIZATION AND COMPUTATION ANALYSIS

Observed pull-out loads-D/B relationships are shown in Fig.3(a) (b) respectively. As is well known, the higher the density of the granular material and the deeper the embedded rigid body (steel plate), the greater the pull-out resistance of the plate. Observed granular flow in D/B=2 and Dr=40% is shown in Fig.4(a). In this figure, the slip line proposed by Clemnce and Veesaert (1977) is also shown. The granular flow occurs around the plate and does not reach the upper part of the granular media.

The authors analysed the observed granular flow by finite element method. Four kinds of constitutive models were used for a series of analysis such as 1) linear elastic model, 2) nonlinear elastic model, 3) classical elasto-plastic constitutive model based on Drucker-Prager yield function, and 4) subloading model proposed by Hashiguchi (2014), respectively. Model parameters were determined by triaxial compression tests for transparent granular sample in Dr=40, 80% under confining pressures: 50, 75, and 100kPa. Computed pull-out loads-D/B relationships are shown in Fig.3. Analysis using linear, non-linear and classical elasto-plastic model overestimates the observed load. Only analysis using subloading model can capture observed load behaviour. A comparison between observe granular flow and analysed results are shown in Fig.4. In D/B=2 and Dr=40%, analysed granular flow is similar to the observed one. In the case of simple and classical constitutive models, analysed granular flow is not local and top of the flow reaches to the surface of granular media. Non-linear plastic deformation should be considered for analysis of the granular flow.

CONCLUSION

Visualization technique using transparent granular is useful for investigating of granular flow. Especially, visualization using multi-camera is very powerful. Complicated granular flow can be simulated by finite element method considering non-linear plastic deformation. Combing the visualization technique with the computational analysis may contribute develop simple engineering solution.

Summary Flow of ellipsoidal grains shows a complex macro-scale response that raises from the micro-scale alignment and relative slipping and collisions of the grains. This complex response is associate with the anisotropy induced by the micro-scale grains' orientation and alignment with respect to each other and the flow. In addition, the grains orientation is governed by the grains shape, the flow, the grain orientation in their surrounding and the interaction with the boundary. Observations from experiments and micro-scale simulations are used to construct a complete continuum model. The proposed model includes a constitutive law for the stresses, evolution law of the micro-scale grain rearrangement and the associate boundary conditions. The model shows good agreement with experimental and micro-scale numerical simulations.

ABSTRACT

Ellipsoidal grains show a complex macro-scale behavior associate with their ability to orient, align and slip with respect to each other. These additional micro-scale degrees of freedom are an evolving property that gives rise to a complex macro-scale anisotropic rheological response associate with micro-scale arrangement of the grains with respect to each other and the flow. Available continuum constitutive models of dense granular materials typically only consider grain size while ignoring grain shape, orientation and alignment and their effect on the rheological response.

Here a simple generalization of the inertia rheology [1] of spherical grains to ellipsoidal grains is proposed. The developed continuum model explicitly accounts for the grain shape and the micro-scale arrangement, while, the construction of the mathematical model is motivated by physical observations. The continuum model consists of a constitutive law that accounts for the grain shape, micro-scale arrangement and their role in the development of stresses when subjected to flow as well as an evolution law for the micro-scale arrangement.

Limited meaningful experimental and micro-scale simulation data on the rheology of ellipsoidal grain is available in the literature, which mainly consists of Discrete Element Method simulations of simple shear (Couette) flow [2, 3]. The response of the ellipsoidal grains subjected to simple shear flow shows nonmonotonic response with respect to the grains' aspect ratio, that is, ellipsoidal grains with small deviation from spheres, show higher resistant to shear flow than spherical grains. However ellipsoidal grains with high aspect ratio show much lower resistance to shear than spherical grains. It is proposed that this complex response is attributed to the arrangement of the grains in the micro-scale. Additionally, it was observed that grains subjected to simple shear tend to partially align with the stream lines which is enhanced with the aspect ratio. As a result, as grains becomes more aligned with respect to the flow the resistant to slip with respect to each other is reduced yielding a lower flow resistance.

The available experimental and micro-scale simulation data is used to determine the model parameters and to investigate its performance. Comparison of the model predictions with micro-scale simulations of simple shear flow shows that the model captures the complex mechanical response that is induced by the grain shape and the micro-scale arrangement as depicted in figure below.

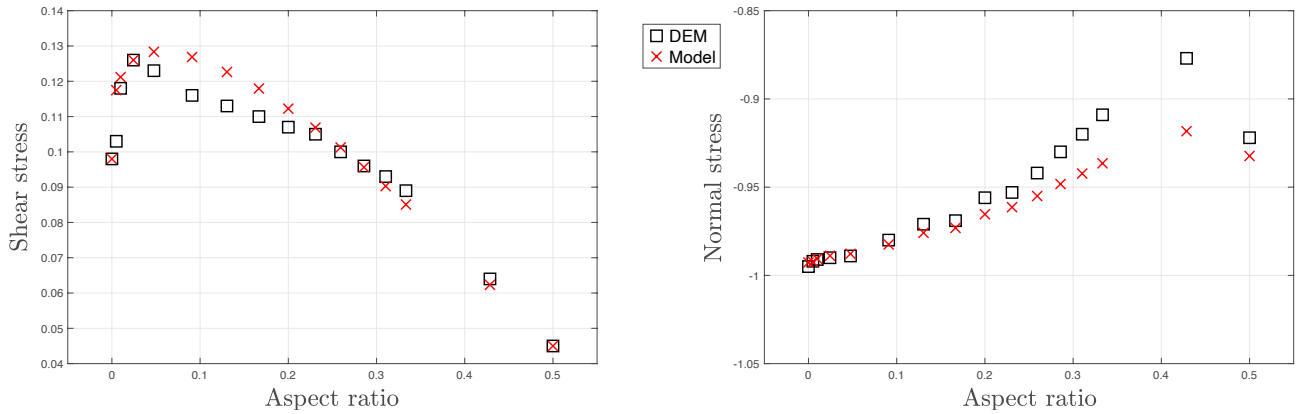

Figure 1. The macro-scale stress response as a function of the aspect ratio for frictionless grains subjected to simple shear

The main limitation of the available experiment and micro-scale simulations of simple shear data is that it is homogenous field and does not provide insight into the influence of inhomogeneity of the grain's alignment and flow. Experiments and Discrete Element Method simulations of flow of elongated grains down an incline plane [4] yields inhomogeneous flow and micro-scale grains arrangement, and hence provides some valuable insights. These observations suggest that the micro-scale

*Corresponding author. E-mail: bnadler@uvic.ca.

alignment diffuses spatially as the grains alignment at a point influence the orientation of its surrounding. This is induced by the characteristic of the collisions between grains that is sensitive to the gains' relative orientation. In addition, the interaction of the grains with the boundaries drives grains toward alignment with the boundary's topography. These observations motivative the introduction of a diffusion-like term in the evolution law of the micro-scale arrangement and treatment of the associate boundary conditions. Such a diffusion term and boundary conditions are proposed in the modified model. The modified continuum model is used to simulate flow down incline plan and it shows agreement with the experimental and micro-scale simulations observation.

CONCLUSIONS

The complex mechanical response of ellipsoidal grains is attributed to the micro-scale arrangement of the grains that is governed by the grain shape, flow and boundary conditions. An intuitive (and simple) continuum model is proposed to rational and predict, their mechanical response by an explicit consideration of the macro-scale arrangement. The model shows good agreement with experimental and micro-scale numerical simulations.

EXPERIMENTAL STUDY OF CYLINDRICAL PARTICLES ORIENTATION IN RANDOM PACKED BEDS

Maciej Marek[1], Paweł Niegodajew[1], Przemysław Rajca[2] and Konrad Gruszka[3]
[1]Czestochowa University of Technology, Department of Thermal Machinery, Częstochowa, Poland

Summary The present work employs a new experimental method to investigate cylindrical particles' orientation in cylindrical columns of different diameters. The idea of the method is to employ as particles cylindrical transparent capsules filled with water and paraffin. The capsules are dumped into the container after they are heated so that the paraffin is in liquid state, then can be freely removed when the paraffin cools down and turns back into solid. The original orientation of the particle can be assessed by the inclination of the liquid-solid interface within a capsule. Sample results on orientation distribution of particles of various aspect ratios are presented.

INTRODUCTION

Random packed beds of particles in a cylindrical container (column) are widely employed in many areas of process engineering as a medium enhancing the contact surface between reacting substances – e.g. in absorbers and strippers [1]. As the information about the bed structure is essential for proper design of the system, substantial effort has been put into experimental and numerical investigations of random packed beds. Detailed studies of a random packed bed structure typically require complex and expensive experimental methods e.g. computer tomography in various forms (X-ray or gamma-ray). To face that problem, a number of numerical methods allowing to reconstruct 3-dimensional geometries of packed beds have been developed. Most of works employing such models focuses on estimation of void fraction distributions which is an important parameter, however, as the beds typically consist of randomly oriented particles, more detailed information about the bed structure, in particular the orientation of particles in various regions of a bed, is of high interest. While the simulation may successfully reproduce void fraction distribution, it may fail in prediction of the particles orientation distribution [2]. As a lot of works deal with numerical generation of non-spherical packings like cylinders [3], spherocylinders [4], frustums and full cones [5], octahedrons [6], tetrahedrons [7], rodlike [8], elliptical particles [9] and rings [10], more experimental data concerning orientation of particles in random packed beds should facilitate the validation of these models. In the present work a new experimental method is used for studies of orientation of cylindrical particles randomly dumped in a cylindrical column.

EXPERIMENTAL PROCEDURE

The experimental stand consists of a cylindrical column of a diameter D_c, an industrial stove for heating of the particles and a large number of transparent particles-capsules. The particles should have only one axis of symmetry (e.g. cylinders or spherocylinders), so that their orientation can be defined by only one angle – between particle's axis and the container's axis. In the initial stage, the capsules must be filled with two substances, denoted here as "*L*" and "*S*", both of approximately the same volume equal to the half of the capsule volume. The substances should have the following properties: a) they should be immiscible (a distinct interface must be formed between *L* and *S*), b) *S* should solidify at temperature T_S above ambient temperature T_0, c) T_S should be lower than T_{max} – the maximum temperature permitted for the material of the capsules, d) shrinkage of *S* cannot be too large and the substance cannot adhere too much to the walls of a capsule – the interface should be essentially flat in both liquid and solid state in order to measure the inclination angle with sufficient accuracy, e) there should be only a slight difference between densities of *L* and *S* in the liquid state.

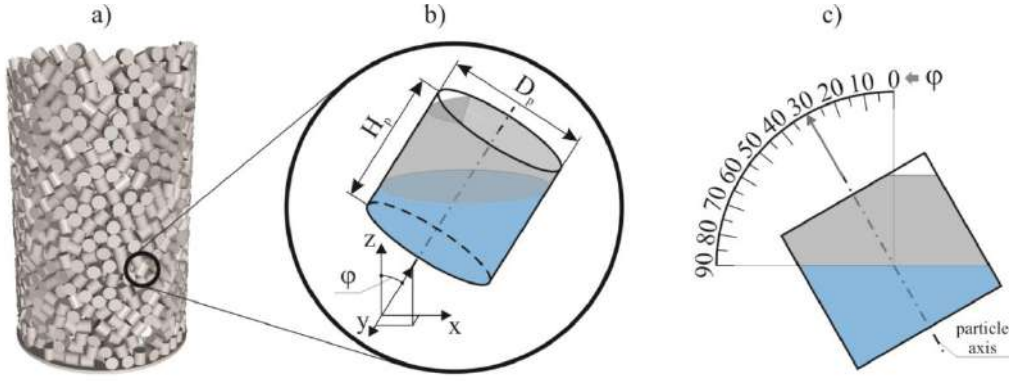

Figure 1. Experimental procedure: a) random packed bed, b) transparent particle-capsule with two immiscible fluids inside *L* and *S* at ambient temperature, c) measurement of the orientation angle

The experiment is performed in three main stages: (1) the capsules are heated in the stove to temperature *T* higher than T_S but lower than T_{max}. Both substances should turn into liquid state. (2) the capsules are randomly dumped into the

container and form a fixed structure. Then, the bed is left until ambient temperature T_0 is attained by all capsules. Additional cooling or ventilation can be considered for acceleration of this process. (3) at ambient conditions S solidifies and the interface between L and S remains at a fixed position related to the original particle-capsule orientation within the bed. Thus, the inclination of the interface can be easily measured (see Fig. 1c). If we are only interested in a global orientation distribution, the capsules may be removed freely but the method offers also possibility of local investigations (e.g. core of the bed, near wall or near bottom region). In such a case, the capsules should be removed with care in order not to alter their original position (not necessarily the orientation) of the remaining capsules within the bed.

SAMPLE RESULTS

In order to test the proposed method, two series of the experiment have been performed: one with 1100 polycarbonate cylindrical screw capsules of diameter D_p=25.6 mm and height H_p=28.5 mm (H_p/D_p=1.11) filled with water (L) and paraffin (S) and then dumped into a column of diameter D_c=387 mm (D_c/D_p=15.1); the second one with 900 capsules of diameter D_p=38 mm and height H_p=32 mm (H_p/D_p=0.84) in a column of diameter D_c=250 mm (D_c/D_p=6.6) . The capsules were sealed with silicone gel sealant and heated in a stove to 80°C. The probability distribution of the measured orientation angles are shown in Fig. 2. The capsules were removed from the container layer by layer, thus the results could be obtained not only for the bed as a whole (global distribution in Fig. 2) but also for the bed with the bottom region removed ("bottom excluded" in Fig. 2, representing the particles positioned higher than $3D_p$ over the bottom). A characteristic feature of the global distribution is the presence of two distinct peaks at 0 and 90° significantly reduced with the bottom section excluded, which means that the main contribution to these peaks comes from the bottom layers. The probability distributions for the case of the narrow column show a strong contribution of the so called "wall effect" – a pronounced peak in the central part of the graph (see also [10]).

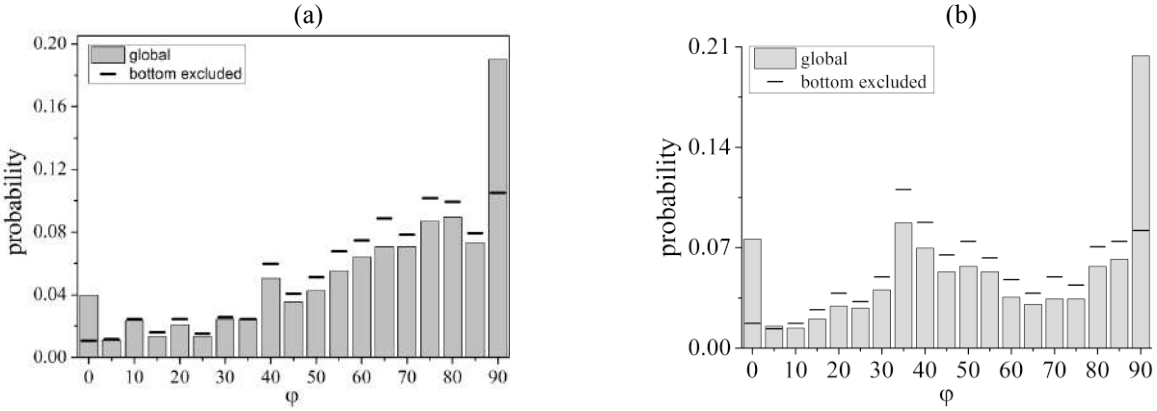

Figure 2. Probability distribution of the orientation angle of cylindrical particles with and H_p/D_p=0.84 (D_c/D_p=6.6) (a) and H_p/D_p=1.11 (D_c/D_p=15.1) (b).

CONCLUSIONS

This work demonstrates a new low-cost method alternative to tomographic techniques that can be used in examination of orientation distribution in random packed beds. This method can be used to analyse the orientation of particles of wide range axisymmetric shapes and sizes. A preliminary results showed that distribution of particles is strongly influenced by bottom region as the global probability distribution of the angle φ differs significantly from the one obtained for the upper part of the bed. The future work will cover the experiments with considerably larger number of particles-capsules, local analysis concerning orientation distribution in various bed zones and wider range of column sizes.

RATE EFFECTS AND SHEAR BANDING DURING ORTHOGONAL CUTTING OF SAND

Abhijit Hegde *[1], and Tejas Murthy [1]
[1]Department of Civil Engineering, Indian Institute of Science, Bengaluru, India, 560012

Summary We report an extensive experimental study on the orthogonal cutting of a cohesionless soil (a model granular material) under plane strain conditions. Experiments have been carried out over a range of cutting speeds. High resolution images of the region of cutting were captured and analyzed using Particle Image Velocimetry(PIV) that allowed quantification of the deformation fields. We make detailed observations on the regions of velocity discontinuities (shear bands) in our ensemble as the tool ploughs through the pile of glass ballotini. The shear band initiates from the tip of the tool and propagates towards the free surface, akin to metal cutting. Consequently, the effective depth of cut increases as the glass ballotini start to rise along the tool face and begin to repose under gravity. As we continue to cut, the system reaches a steady state of deformation.

INTRODUCTION

Ploughing/trenching of soil is an earthmoving process generally carried out with the help of blades or ploughs. Every year humans move trillions of kilograms of earth and soil for various purposes like mining, excavation for road works, dredging, and therefore the problem deserves a proper scientific treatment to get a better physical understanding of the process and hence design more efficient tools for ploughing. The ploughing process in general can be modelled as an orthogonal cutting problem, a framework well established in the field of metal cutting, wherein a preset depth of soil is removed by moving the tool/blade in a direction normal to the embedment of the tool. Hettiaratchi and Reece (1974), McKyes and Ali (1977) have come up with analytical models to theoretically predict the forces on the tool. Further efforts have been made to numerically model the ploughing process using FEM by Szymanski et al.(2011) and using DEM(Discrete Element Method) by Gravish et al. (2010) while Coetzee (2014) has performed a detailed numerical analysis of the soil cutting problem using a meshless Material Point Method(MPM). Palmer (1999) has performed extensive cutting experiments on submerged sand and have studied the effect of pore water pressure on the draft/cutting forces.

EXPERIMENTS

For studying the deformations encountered during the cutting process, we have performed orthogonal, plane strain cutting experiments with dry glass beads-as a model granular material. The cutting operation was carried out on a CNC machine and to capture the images for analysis we use a PCO 1200HS camera. A rectangular box of dimensions 55.5cm x 16cm x 1.5cm, made of high-speed steel was used to contain the glass beads. The dimension of the box was intentionally made small in one of the directions-perpendicular to front face of the cutting box- to ensure plane strain conditions during cutting. The cutting box is first mounted onto the translation stage of the CNC. The motion of the tool is restricted to the vertical direction while the box can only move in a horizontal plane. A glass plate is then carefully attached to the front face of the box. Glass beads are then poured into the box through the open top face with the help of a funnel till the desired depth of cut is reached. A camera is then setup in front of the cutting box to capture the images of the ploughing process. A light source was used to illuminate the region of interest around the tool. A PIV algorithm was used to analyze the images captured through the ploughing process. PIV is an indirect, non-intrusive, whole field velocity measurement technique used extensively in the study of fluid flows and also has been used to study deformation fields in soil.

RESULTS

A series of cutting experiments at different cutting speeds was carried out in this research programme. A preset depth of cut equal to $5d_p$, d_p being the size of glass beads(2.5mm), and a rake angle of 0^0 degrees was used in our experiments. In Figure1(a), we show a sample image of the cutting process captured after a tool displacement of $34d_p$. The material undergoes large deformations and with prolonged ploughing the system seems to reach a steady state. This can be verified by either measuring the angle of repose of the pile formed in front of the tool during ploughing or by looking at the evolution of the effective strain rate in a region surrounding the tool (Figure1(c)). In Figure1(b), we show the corresponding velocity field obtained from our PIV analysis. The direction of motion of the glass beads are apparent from the quiver plots overlaid on top of a contour map which shows the magnitude of the velocity. The bulk velocity of the material, till the tip of the tool, moves at a constant velocity prescribed by the cutting speed. At the tool tip, we observe a bifurcation in the velocity field, i.e. the velocity changes direction, leading to the formation of a shear band, which extends from the tool tip to the material surface. As the ploughing progresses, the material removed from the surface, after undergoing a change in the direction at the tool tip, rises along the surface of the tool, begins to repose and forms a pile in front of the tool. This effectively increases the depth of cut during the ploughing. With prolonged ploughing, the surface angle of the pile remains constant while the height of the pile keeps increasing. In figure1(d) we show the effective shear strain rate field corresponding to the velocity field map shown in Figure1(b). In this figure, we observe the formation of a distinct shear band, a region of very high strain rate, at the tool tip and extending through the thickness of the pile and

*Corresponding author. E-mail: abhijithegde@iisc.ac.in

reaching the free surface. This clearly indicates that the material undergoes strain localization across which a change in the velocity of glass beads is observed, when subjected to severe plastic deformation due to cutting. We also observe shear bands along the free surface of the pile and shearing occurring at the interface between the material and the rake face. We observe formation of a dead zone next to the tool face, the size of which increases as we continue to plough through the material and hence increases the effective rake angle of tool. The effective strain rate is maximum along the shear plane originating at the tool, with a magnitude of $0.0015s^{-1}$ and increased with the speed of cut. The shear strain map also allowed us to accurately measure the thickness and inclination angle of the shear bands. We find that at steady state, the thickness of the shear band was around $7d_p$ and the inclination angle was 42^0. Both the thickness and inclination angle of the shear bands was found to be insensitive to the speed of cut, over the range of speeds tested in our experiments.

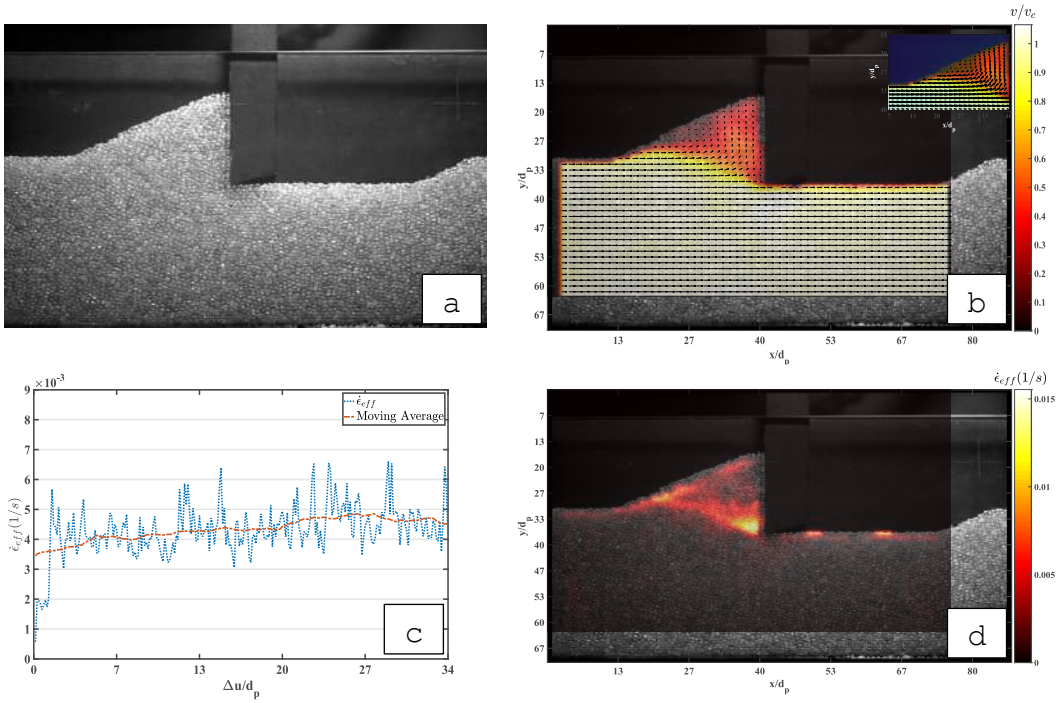

Figure 1(a)-Sample image corresponding to a tool displacement of $34d_p$. Figure1(b)- Velocity field contour map obtained from PIV. Figure1(c)-Evolution of shear strain averaged over the entire ensemble. Figure1(d)- Shear strain contour map.

CONCLUSIONS

Forces exerted on the tool/blade during cutting of soil has been well studied but the deformation undergone by the material itself has often been overlooked. Using PIV, we. have been able to obtain the deformation and velocity fields observed during the ploughing process. We observe formation of shear bands in the material as a result of large plastic deformations imparted on the material during ploughing. With prolonged ploughing, the system reaches a steady state of deformation, as indicated by the slope of the pile formed in front of the tool which also results in an increase in the depth of cut. The problem of orthogonal cutting allows an in-depth examination of the formation and propagation of shear bands in granular materials.

COMPACTION DYNAMICS OF GRANULAR COLUMNS FROM FLUIDIZATION BURSTS

Georges Gauthier* and Philippe Gondret
Université Paris-Saclay, CNRS, Laboratoire FAST, 91405, Orsay, France

Summary How to arrange a packing of spheres is a scientific question that aroused many fundamental works since a long time from Kepler's conjecture to Edward's theory [1], where the role traditionally played by the energy in statistical problems is replaced by the volume for athermal grains. In a recent study [2] we have shown that compaction of a liquid immersered granular pile can be achieved by small upward continuous or bursting flow at low Reynolds number. We now focus on the influence of different flow parameters such as the amount of fluid during each burst, the Reynolds and Stokes numbers, and on the detail mechanism of compaction at the grain scale.

INTRODUCTION

Though the solid fraction in the tetrahedral arrangement of four equal spheres in contact is 0.78, the highest solid fraction that can be achieved in a large packing is 0.74 and corresponds to the densest periodic arrangement of equal spheres. Any other ordered or disordered packing has lower solid fractions. Random packings of equal spheres have a solid fraction $\phi = 0.6 \pm 0.04$ with a Random Loose Packing limit (RLP) $\phi_{RLP} \simeq 0.56$ and a Random Close Packing (RCP) $\phi_{RCP} \simeq 0.64$. For granular systems that are athermal and dissipative, the exploration of the different possible arrangements cannot be driven by temperature but some external energy must be injected continuously. The most classical way of compaction is the mechanical shaking of the container by successive taps [3, 4]. The compaction time dynamics displays a first quick increase of the solid fraction followed by a much slower increase. For rather confined systems with non negligible wall effects, a logarithmic law is often used to describe the evolution of the solid fraction ϕ from the initial packing value ϕ_0 to the final one ϕ_∞ as a function of the number of taps $\mathcal{N}$ [3]:

$$\frac{\phi(\mathcal{N}) - \phi_0}{\phi_\infty - \phi_0} = 1 - \frac{1}{1 + B \ln\left(1 + \mathcal{N}/\mathcal{N}_c\right)}, \tag{1}$$

where $\mathcal{N}_c$ is a characteristic number of taps and the parameter B is related to the compaction efficiency. In the tapping experiments of monodisperse spheres, the solid packing fraction increases from typically $\phi_0 \simeq 0.58$ to $0.61 \lesssim \phi_\infty \lesssim 0.63$. As for dry packings, compaction of liquid immersed granular packings can be achieved by taps with a maximum solid volume fraction $\phi_\infty \simeq 0.64$. A more efficient process consists in shearing the granular packing (*e.g.* [6, 7]) which may lead to solid fraction up to $\phi_\infty \simeq 0.69$ after a few 10^4 cycles, with thus some local ordering. We here present experiments in which liquid immersed piles can be efficiently compacted using small burst upward flows.

EXPERIMENTAL SET-UP

The experimental set-up is sketched in figure 1a. The suspension consists in glass beads of radius $a = 1\,\mathrm{mm}$ and density $\rho_p = 2.3 \times 10^3\,\mathrm{kg/m^3}$ dispersed in a water-glycerol mixture of density $\rho = 1235\,\mathrm{kg/m^3}$ and viscosity $\eta = 0.156\,\mathrm{Pa \cdot s}$ at $T = 24\,^\circ\mathrm{C}$, characterized by a low particulate Reynolds number ($Re_p \simeq 10^{-1}$ when based on the settling velocity of an isolated particle) and low Stokes number ($St \simeq 10^{-1}$).

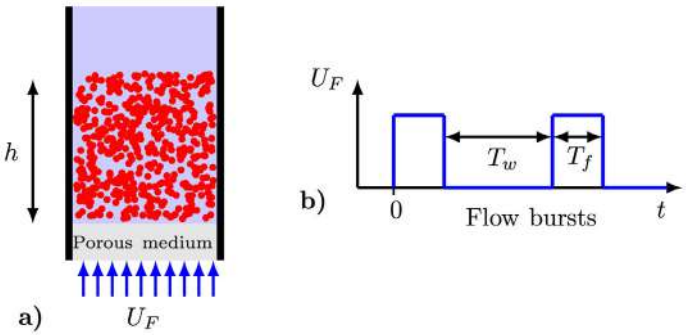

Figure 1: (a) Sketch of the experimental set-up with upward flow U_F across a bed of height h. (b) Burst flow with the time period $T = T_w + T_f$ made of successive flow bursts of time duration T_f with $U_F \neq 0$ sepatated by rest time T_w without flow ($U_F = 0$).

*Corresponding author. E-mail:gauthier@fast.u-psud.fr

The granular pile is contained in a vertical parallelepipedic cell of 50 cm high and of rectangular cross-section $S = 8 \times 2\,\mathrm{cm}^2$. The fluid is injected through a porous media located at the bottom of the cell, with a permeability which is two orders of magnitude lower than the permeability of the granular bed to minimize any possible effect from the evolution the granular bed on the flow injection. The upward flow rate is fixed using a gear pump, controlled with a wave generator, allowing bursting flow with short flow time period T_f at constant flow rate $U_F \neq 0$ followed by a long resting T_w time period without flow ($U_F = 0$) before the next flow time, as sketched in figure 1b. The waiting time has been chosen long enough for the grains to settle before the next flow burst. Images of the cell are taken by a video camera at the maximum rate of 15 images per second. From each image, the bed surface is tracked and averaged spatially to obtain the mean instantaneous height $h(t)$ of the bed. The mean solid volume fraction ϕ of the bed after each burst $\mathcal{N}$ is then deduced from $h(t)$ as $\phi(t) = M_p/\rho_p S h(t)$, where M_p is the total mass of particles.

RESULTS

Figure 2a presents the evolution of the height of the pile during the three first bursts, for two different flow rates. At a burst flow rate U_F above the fluidization threshold $U_{Fc} \simeq 0.32$ mm/s (—), one can see a small increase of the height of the pile followed by a larger decrease down to a lower value before same at the next burst. More surprisingly, below the fluidization threshold ($U_F < U_{Fc}$) (– –), the pile still compacts even though no expansion can be seen. In both

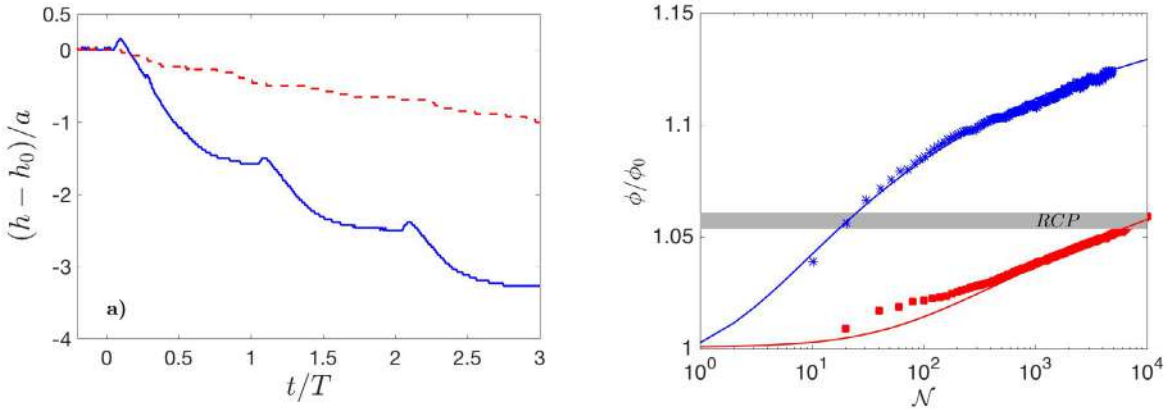

Figure 2: (a) Time evolution of the relative normalized pile height $(h(t) - h_0)/a$ for two burst flow rates U_F : (– –) $U_F = 0.6U_{Fc}$ ($T_f = 0.26T$) and (—) $U_F = 2.6U_{Fc}$ ($T_f = 0.08T$). (b) Evolution of the normalized solid fraction ϕ/ϕ_0 with the number $\mathcal{N}$ of bursts at two flow rates : (■) $U_F = 0.4U_{Fc}$ and (*) $U_F = 2.6U_{Fc}$, together with (—) best fits by eq. (1) with $\phi_\infty = 0.74$ and with (*) $B = 0.07$ and $\mathcal{N}_c = 63$, or (×) $B = 0.21$ and $\mathcal{N}_c = 3$.

cases the evolution of the solid volume fraction ϕ with the number of bursts reasonably follows a logarithmic law of eq. (1) as shown in figure 2b. For $U_F > U_{Fc}$, the final solid volume fraction is observed to exceed ϕ_{RCP} with thus some local ordering. When increasing the flow rate by keeping constant the injected fluid during each burst (fluid displacement $U_F T_f = cte$), we observe a sharp transition in the compaction efficiency across the fluidization threshold U_{Fc}: the parameter B increases from $B \simeq 0.1$ up to $B \simeq 0.2$ and the characteristic number of taps decreases from $\mathcal{N}_c \simeq 60$ down to $\mathcal{N}_c \simeq 3$ [2].

CONCLUSIONS

We have shown that efficient compaction of immersed granular pile can be achieved from bursting upward flow at low particulate Reynolds number. Additional experiments are ongoing to understand the effects of the injected fluid amount, together with the effect of the Reynolds and Stokes numbers. We are also investigating the particle motions that lead to the observed progressive compaction.

Summary We present an experimental investigation of the collapse of a cohesive granular column. The granular material is made of glass beads coated with a thin polymer layer, which controls the cohesion. As observed for cohesionless granular material by previous studies, the front velocity and the run-out length L_f are mainly controlled by the aspect ratio a. The effect of the cohesion on the dynamics and the final deposit of the collapse is also compared with numerical simulations.

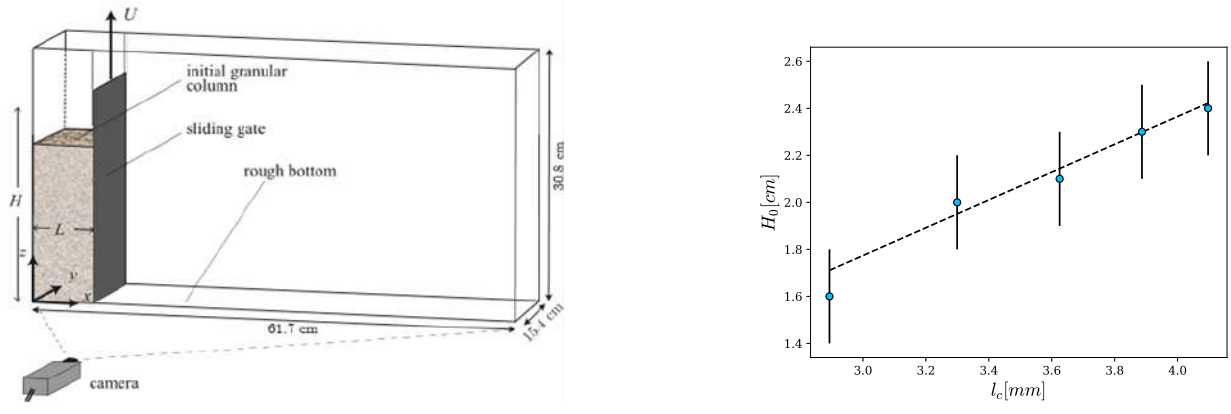
INTRODUCTION

Cohesive granular media are encountered in many geophysical and industrial applications: cement, pharmaceutical powders, and flours among other examples. Whereas many progresses have been made in the description of dry granular flows, the behavior of cohesive powders remains elusive. In particular, one difficulty lies in the cohesion force between the particles. Using our recently developed method to create a cohesion-controlled granular material [1], we experimentally consider the collapse of a column made of cohesive spherical grains. This configuration has been extensively studied in the case of dry granular material: when the grains are released, the granular mass spreads and stops at a finite distance [2]. The morphology of the deposit is mainly controlled by the initial aspect ratio and is independent of the material properties. Yet, for cohesive powders, the inter-particle forces strongly affect the collapse. In this study, we characterize the effects of the cohesion on the collapse dynamics, the run-out length, and the final morphology of the deposit. These experiments illustrate that cohesive forces between particles introduce an additional complexity in this system through a new parameter. Our experiments are compared with numerical simulations performed by A. Abramian and P.-Y. Lagrée at d'Alembert Institute, Paris, in the framework of the COPRINT project (ANR-17-CE08-0017). These simulations are based on a Navier-Stokes solver with a cohesive $\mu(I)$ granular rheology.

EXPERIMENTS

The cohesive granular material is made of glass beads (diameter $d = 800$ μm), coated with polyborosyloxane (PBS) made from a -OH terminated Polydimethylsiloxane (PDMS) cross-linked with H_3BO_3 boric acid [4]. The thickness b of the PBS layer coating the glass beads is the control parameter of the inter-particle cohesion. From our previous study [1], inter-particle force is captured by the expression $F_c = 1.5\pi\gamma d\left(1 - \mathrm{e}^{-b/B}\right)$ where $B \approx 230$ nm and γ is the surface tension of the PDMS. We have also shown that the cohesive stress of the bulk material τ_c is linearly related to the microscopic inter-particle force F_c. Changing the PBS thickness b is a convenient way to control the bulk cohesion of the granular material. To describe the flow under gravity, we define the cohesion length $l_c = \tau_c/(\phi\rho g)$, which represents the characteristic length where gravity effects are balanced by cohesion effects.

The experimental set-up is made of a rectangular channel [Fig. 1(a)], with a removable door sliding upwards, allowing us to build a column of cohesive grains with an aspect ratio $a = H_i/L_i$ where H_i is the initial height and L_i the initial width of the granular column. We investigate the role of the cohesion on the collapse dynamics and the final morphology of the deposit. The experiments are performed using three batches of particles: dry granular beads and cohesive beads with coatings $b = 200$ nm and $b = 300$ nm, respectively.



(a) (b)

Figure 1: (a) Experimental setup. (b) Maximum height of a stable cohesive granular column.

*Corresponding author. E-mail: adrien.gans@univ-amu.fr

RESULTS

We first investigate the maximum height for a stable column i.e. the maximum height for which the cohesion allows the column to support its own weight. A Mohr-Coulomb criterion predicts a linear expression between this maximum height and the cohesion parameter:

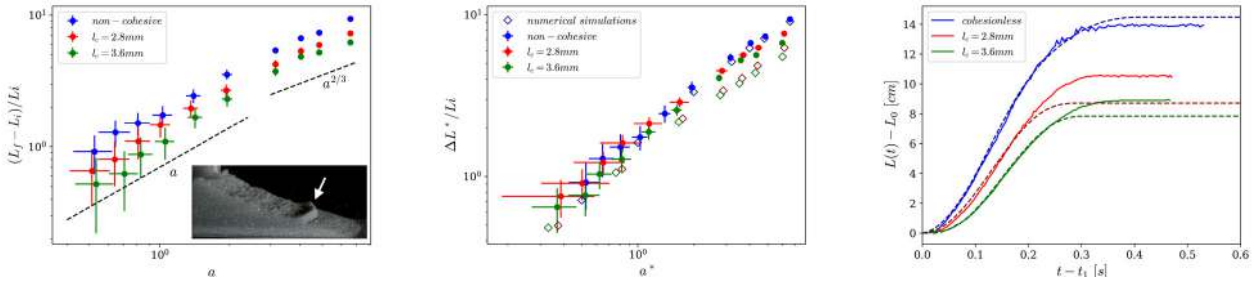
$$H_0 = \frac{2l_c}{\cos\delta(\sin\delta - \mu\cos\delta)}. \tag{1}$$

The experimental results shown in Fig. 1(b) confirm that prediction with a fracture angle $\delta = 53°$. An equivalent numerical configuration has already been studied by Abramian *et al.* [3]

When the collapse occurs, we measure the shape of the final deposit and the final run-out length $L_f = L_i + \Delta L$. As shown by Lajeunesse *et al.* [2], the run-out length ΔL and the final height H_f of a dry granular material are power laws of the aspect ratio a:

$$\frac{\Delta L}{L_i} \propto \begin{cases} a & \text{for } a \leq 3 \\ a^{2/3} & \text{for } a \geq 3 \end{cases} \quad \text{and} \quad \frac{H_f}{L_i} \propto \begin{cases} a & \text{for } a \leq 0.7 \\ a^{1/3} & \text{for } a \geq 0.7 \end{cases} \tag{2}$$

Fig.2 (a) shows that for the non-cohesive case, our results still match the observations of Lajeunesse *et al.* [2]. For the cohesive materials, the power laws are still valid but the pre-factor is affected by the cohesion force. We first propose to introduce a new definition of the aspect ratio $a^* = (H_i - H_0)/L_i$ to account for the the fact that a cohesive column does not fall below a critical height H_0. We also introduce a modified run-out length $L^* = L_f - L_i + H_0 \tan\delta$. This scaling accounts for the observation of a "dead wedge volume" [emphasized by the white arrow on the picture insert of Fig. 2(b)] which does not contribute to the run-out length for an aspect ratio lower than 3. With these new definitions, all the experimental and numerical data follow the same curve governed by a^* as shown in Fig. 2(b). For an aspect ratio larger than 3, the shape of the "dead wedge volume" changes and the influence of the cohesion has not been investigated.



(a) (b) (c)

Figure 2: (a) Run-out length as a function of the aspect ratio for dry and cohesive beads. The power law is the same, but the cohesion changes the pre-factor. (b) Rescaled run-out ΔL^* as a function of the rescaled aspect ratio a^* (c) Position of the front of the falling column over time. The numerical model seems to capture quite well the dynamic of the column

We also investigate the time-evolution of the spreading of the column during the collapse [Fig. 2(c)], and we compare it with numerical simulations. We observe that despite a difference on the final run-out, it seems that the numerical model is able to capture the essential features of the collapse. Further results and explanations will be presented at the conference.

CONCLUSION

Using a cohesion-controlled granular material [1], we investigated the effect of cohesion on the granular collapse of a 2D column. We reported a critical height under which a column will not collapse because of cohesion between grains. This height can be related to the cohesive stress in the media through the cohesive length l_c. We observed that the run-out length of the final deposit depends on the cohesion, and we suggest to use a new definition for the aspect ratio involving the critical height. These experiments provide a first description of the flowing dynamics of cohesion-controlled granular materials.

COLLISIONS IN NARROW FLUIDIZED BEDS: EXPERIMENTS AND SIMULATIONS

Fernando David Cúñez* [1], Karlo Fernandes Rocha[1,2], and Erick de Moraes Franklin[1]
[1]School of Mechanical Engineering, University of Campinas - UNICAMP, Campinas, Brazil
[2]Federal Institute of Espirito Santo, Cachoeiro de Itapemirim, Brazil

Summary In this work, we investigate experimentally and numerically the behavior of particle collisions in narrow fluidized beds (NFB). For the experiments, the fluidized beds were formed in a 25.4 mm-ID tube and consisted of alumina beads with a diameter of 6mm and a specific gravity of 3.69; thus, the ratio between the tube and the particles was 4.23. We used 3 different arrangements of beds and imposed 2 water flows rates at the bottom of the tube. The fluidized beds were filmed with a high-speed camera and the sound of collisions was recorded using a microphone placed on the tube wall. The numerical simulations were performed using an Eulerian-Lagrangian approach (CFD-DEM). From both the acoustic signal (experiments) and the acceleration of particles (numerical computations), we obtained the characteristic frequencies of different types of collisions.

INTRODUCTION

A narrow fluidized bed (NFB) is a suspension of solid particles (grains) in a vertical tube submitted to an ascending flow, where the ratio between the tube and the particles is less than 10. In this narrow case, the formation of regions of high and low compactness is expected [1]. This kind of fluidized bed is gaining interest in many industrial applications, being found, for example, in bioreactors for biological wastewater treatment, which are employed for both large-scale and domestic treatment of wastewater [2]. For the NFB, the dynamics and instabilities are different because of high confinement effects; therefore, this case is still to be understood. When the fluid is a viscous liquid, the Stokes number, comparing particle inertia to viscous forces, allows to determine if the collisional effects can be considered dominant. Del Pozo et al. [3] made particle collisions measurements in gas and liquid fluidized beds, and observed that the collision frequency is an increasing function of the particle fraction, reaching its maximum at minimum fluidization. Zenit et al. [4] measured the collisional particle pressure in liquid fluidized beds and gravity-driven flows. They quantified the granular pressure and found that it is related to the particle fraction in a non-monotonic way. Following the techniques used in [3, 4], Buffière and Moletta [5], analyzed the effects of the particle fraction and gas velocity in three-dimensional fluidized beds. The authors found that there is an increasing evolution of the collision frequency as a function of the solid fraction with a maximum at about 20%. Finally, Aguilar et al. [6] measured the collision frequency and the coefficient of restitution based on the use of a threshold in the peak of the acceleration of the particles, obtained from experiments using a high-speed camera and optical index matching between the grains and the fluid. They showed that the collision frequency is an increasing function of the particle fraction, and follows a law derived from the kinetic theory for granular flow. For a particle fraction of 0.5, [3, 5, 6], they found that the collision frequency is O (100) Hz.

In this work, we investigate particle-particle and particle-wall collisions in narrow fluidized beds experimentally and numerically, when the fluid is a liquid. From Ref.[1], the formation of granular plugs and liquid bubbles is expected, where particle collisions are usually found inside the plugs, i.e., where the particle fraction is around 0.5, but also outside the plugs, where free-falling particles collide with the tube wall or the top of the next plug, with stronger amplitudes but much smaller frequencies. Therefore, we recorded the sound of collisions in the experiments and tracked every single particle in the numerical simulations in order to obtain the collision frequencies for NFB.

EXPERIMENTAL AND NUMERICAL SETUPS

The experimental setup consisted of a water reservoir, a heat exchanger, a centrifugal pump, a flow meter, a flow homogenizer, a 25.4 mm-ID tube with vertical and horizontal sections, and a return line, being the same of Ref. [1]. Thus, the water flowed in a closed loop in the order described above. The vertical section was a 1.2 m-long, 25.4 mm-ID transparent PMMA (Polymethyl methacrylate) tube, vertically aligned within $\pm 3°$. A visualization box filled with water was mounted around the test section to ensure proper photographic images. The water temperature was maintained at 25°C $\pm$ 3°C by the heat exchanger placed in the water reservoir. Alumina beads with d = 6 mm and ρ_p = 3690 kg/m^3 were used as the solid phase, and three different beds were arranged, each one consisting of 250, 400, 500 particles. Two water flow rates were imposed, Q = 250 and 300 l/h, corresponding to superficial velocities of $\overline{U}$ = 0.137 and 0.164 m/s. The Stokes and Reynolds numbers based on terminal velocities were $St_t = v_t d\rho_p/(9\mu_f)$ = 1650 and $Re_t = \rho_f v_t d/\mu_f$ = 4026, respectively. The NFB was filmed with a high-speed camera with a resolution of 1600 px $\times$ 2560 px at frequencies up to 1400 Hz. LED (low emission diode) lamps were used to provide the necessary light. In all the experiments, the camera frequency was set to between 100 Hz and 200 Hz, and a microphone placed on the tube's wall was used to record the sound of particle collisions. The numerical investigation was conducted with the CFD-DEM method, i.e., the fluid motion is computed with an Eulerian approach, and the granular dynamics with a Lagrangian approach. We considered a 0.45 m long and 25.4 mm-ID vertical tube, filled with alumina beads and water. The bed arrangements and the flow rates were as in the experiments. The simulations were performed with the open source code CFDEM [7], that couples OpenFOAM(CFD) to LIGGGHTS(DEM).

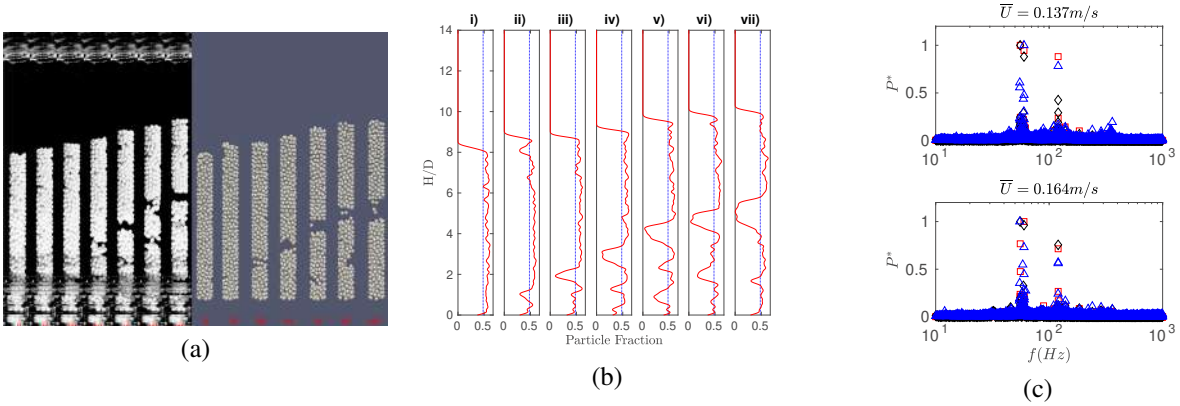
RESULTS

We found the formation of granular plugs and liquid bubbles inside the NFB. These patterns result from a competition between the mechanisms that tend to displace the particles upwards, namely the fluid drag and buoyancy, and downwards, namely the gravity and solid friction between the grains and the wall (this latter being enhanced by the redirection of forces when a granular cluster or plug is pushed upwards). From Fig.1(a), it is possible to observe the good agreement between the experiments and the numerical simulations. Therefore, we tracked every single particle in the simulations to obtain the motion of each particle. We also computed the particle fraction inside the NFB over time and determined that the mean value in the granular plugs is approximately 0.5 [Fig.1(b)]. For all the cases, we found that at least 60% of the particles are exchanged between granular plugs during a period of 5s. To determine the collision frequency from the acoustic signals, we evaluated the energy of the signals applying Fast Fourier Transforms in the time domain; afterwards, by using a high-pass filter, we obtained 2 characteristic frequencies that appear for all cases $f \approx 60$ Hz and $f \approx 120$ Hz [Fig.1(c)]. For the numerical simulations, we computed the instantaneous acceleration of the particles along time and then we used the same technique as Ref.[6], setting a threshold for the peaks of the acceleration and counting the number of peaks above that value. The magnitude of the acceleration is normalized by the acceleration of gravity g and the threshold was $2g$, meaning that we neglected free falling grains between the granular plugs, since they have an acceleration of $\approx 1g$. We observed that the collision frequency of the particles is $f \approx 200$ Hz. The frequencies of particle-wall and particle-plug were identified, and we are currently working on their values and interactions with the different plug regimes.



(a) (b) (c)

Figure 1: (a) Instantaneous snapshots for experiments and numerical simulations [1]; (b) Particle fraction; the time step is 0.5s; (c) Dimensionless pressure vs. Characteristic frequencies. Diamonds, squares and triangles correspond to arrangements of 250, 400 and 500 particles, respectively.

CONCLUSIONS

We presented preliminary and novel results about particle collisions in narrow fluidized beds (NFB). The collision frequency was measured in two ways: by obtaining the characteristic frequencies of recorded sounds from the NFB experiments, and analyzing the acceleration of the particles from the numerical simulations. From the results, we could observe that the total frequency has an order of magnitude of 100 Hz. We also noticed that inside the plugs the particle fraction is ≈ 0.5 and does not depend on the fluid velocity, and, in addition, we could identified from the acceleration signal different types of collision (particle-particle, particle-wall and particle-plug).

EXTENDED KINETIC THEORY FOR GRANULAR FLOW OVER AND WITHIN AN INCLINED, ERODIBLE BED

Diego Berzi [1], James T. Jenkins [2], and Patrick Richard [3]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
[2]School of Civil and Environmental Engineering, Cornell University, Ithaca, USA
[3]IFSTTAR, site de Nantes, GPEM/MAST, Bouguenais, France

Summary We employ kinetic theory, extended to incorporate the influence of velocity correlations, friction and particle stiffness, and a model for rate-independent, elastic components of the stresses at volume fractions larger than a critical, in an attempt to reproduce the results of discrete-element numerical simulations of steady, fully developed, dissipative, collisional shearing flows over and within inclined, erodible, fragile beds. Numerical solutions of the span-wise averaged differential equations of the theory and the associated boundary conditions are seen to be capable of reproducing profiles of stresses, solid volume fraction, average velocity, and the strength of the particle velocity fluctuations, both in the rapid collisional flow above the bed and in the slower creeping flow within the bed.

INTRODUCTION

Particle flows in nature, such as rock avalanches, occur at length scales that are so large that continuum descriptions must be employed to predict their initiation, flow, and run out. In the search for constitutive relations for the closure of such continuum models in the last fifteen years, two approaches have emerged. One is based on kinetic theory of granular gases [1, 2], extended to include the role of significant contact inelasticity [3], surface friction [4], velocity correlations [5], and particle stiffness [6]; the other is based on a phenomenological relation, the inertial rheology, between the particle shear stress and the shear rate, both made dimensionless using the particle pressure, mass density and diameter [7, 8].

The two approaches offer advantages and disadvantages. Extended Kinetic Theory (EKT) requires as inputs four microscopic, well-defined, parameters, at least in the case of linear contacts, that are also the inputs of discrete element numerical simulations of compliant spheres: the normal and tangential coefficients of restitution, the negative of the ratios of post- to pre-collisional normal and tangential relative velocities between two colliding spheres; the coefficient of sliding friction; and the particle stiffness. On the other hand, EKT introduces a measure of the intensity of the particle velocity fluctuations, the granular temperature, that enters the constitutive relations for the stresses. This additional hydrodynamic variable is governed by a partial differential equation, the balance of fluctuation kinetic energy, that must be solved in addition to the classical mass and momentum balances.

In its simplest incompressible form, the inertial rheology requires three model parameters obtained as fits to experiments or numerical simulations. The rather large number of fitting parameters seems justified, given the simplicity of the approach and its straightforward implementation in already existing mathematical models that employ only mass and momentum balances. However, there are several nonlocal effects that cannot be predicted by the inertial rheology, such as the influence of the boundaries on steady, inclined flows over rigid, rough bases [9] and creep in regions where the stress ratio is less than yield [10]. To deal with this nonlocality, Kamrin and Koval [11] recently suggested the introduction of an additional hydrodynamic field, the granular fluidity, governed by a second-order partial differential equation. This nonlocal model has been successfully employed in a number of flow configurations[12, 13], but at least one additional fitting parameter is necessary. Also, distributions of solid volume fraction and stresses cannot be predicted by the nonlocal model: they have to be known in advanced and treated as inputs.

GOAL

The goal of the present paper is to apply Extended Kinetic Theory to steady, inhomogeneous shearing flows in which the solid volume fraction exceeds the critical value for the development of rate-independent components of the stresses. The flow that we consider is the steady, gravity-driven, free surface flow of frictional, soft spheres over a rigid, bumpy base between flat, frictional sidewalls. When a sufficient number of particles is fed to the system, the flow develops an erodible bed above the rigid base. Above the bed, the spheres interact through collisions, with uncorrelated, binary collisions occurring near the top of the flow and correlated collisions taking place nearer to the bed. Within the bed, the particles creep [14], collisions continue to occur, but ephemeral force chains develop and transfer forces from the bed to the rigid base.

Here, we use EKT for modelling the flow above the bed and propose a model for flow in the bed that combines the rate-dependent mechanism of collisional momentum transfer with the rate-independent elastic transfer of force through a continuous evolving network of chains of particles. The surface of the bed is at the same critical volume fraction at which rate-independent components of the stresses develop in steady, homogeneous shearing flows. However, the force chains that begin at the surface the bed are much weaker that those that span the homogeneous flows [15].

RESULTS

We compare the distributions of various quantities obtained from the solution to the two-point boundary value problem with those measured in DEM simulations of inclined flows of inelastic, frictional spheres between frictional sidewalls. The discrete element method is based on the soft-sphere approach.

EKT can qualitatively and quantitatively reproduce the profiles of velocity (figure 1), both in the collisional flow and in the erodible bed. The well-known exponential decay of the velocity in the erodible bed is notably predicted.

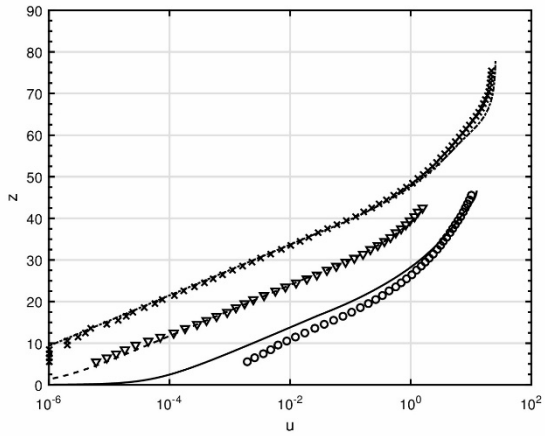

Figure 1. Measured (symbols) and predicted (lines) profiles of velocity for different mass hold-ups, angles of inclination and channel widths.

CONCLUSIONS

We have focused on steady and fully developed, inclined, collisional shearing flows of frictional spheres confined between flat, frictional sidewalls in situations in which the amount of particles in the system is sufficient to develop erodible beds. The bed is the region in which the solid volume fraction exceeds the critical value for the development of rate-independent components of the stresses. Existing results of Discrete Element simulations demonstrate that the flow above the erodible bed is inherently collisional: interactions are essentially binary and stresses originate from momentum exchange in collisions. We have employed the constitutive relations of Extended Kinetic Theory, which accounts for strong collisional inelasticity, friction, velocity correlation at volume fraction larger than the freezing point, and finite duration of particle contacts, to close the balances of momentum and fluctuation energy in the collisional flow.

In the bed, rate-independent stresses proportional to the particle stiffness develop, although much weaker than the rate-independent stresses that would characterize steady and fully developed, homogeneous shearing flows at the same volume fraction.

The comparisons between the numerical solution of the present model and the results of discrete numerical simulations for different values of particle mass per unit basal area, channel widths and inclinations are remarkable. The limited number of physically accessible parameters of the model and its capability of reproducing distributions of stresses, volume fractions, velocity and granular temperature, ranging from dilute to extremely dense conditions, are strong arguments in favor of EKT when dealing with granular flows.

GRANULAR DISCHARGE FLOW FROM A CORNER

Pascale Aussillous* [1], Samira Laidaoui [1,2], and Blanche Dalloz1

Summary In this work, we study the discharge flow of a granular material from a rectangular silo with an orifice at the corner. We performed experiments where we measure independently the mass flow rate and the velocity profiles, together with continuum simulations with a frictional rheology described by a $\mu(I)$ constitutive law and taking into account the wall friction. We study monolayer flows and 3D flows and we aim to propose an analytical model that predicts the discharge flow rate of particles taking into account the outlet horizontal and vertical size and the silo thickness.

INTRODUCTION

Silos are widely used in the industry. While empirical predictions of the flow rate, based on scaling law, exist for more than a century [1, 2], recently advances have been made on the understanding of the control parameters of the flow. In particular using continuum modelling together with the so-called $\mu(I)$ visco-plastic frictional rheology seem to be successful in predicting the flow rate [3, 4]. Recently Zhou et al [5] have shown experimentally and using continuum simulation that if the outlet, of size D, is located at a lateral position the silo thickness, W, plays a role due to the confinement of the geometry. Indeed they have shown that the parietal friction tends to rotate the streamlines to align them toward the gravity with an angle toward the vertical at the outlet $sin\theta_0 \propto (1+\gamma D/W)^{-1/2}$, whereas the norm of the velocity scales with the aperture size, $U_0 \propto \sqrt{gD}$. Then they predicted that the flow rate follows

$$Q = C_l \rho_p \phi_b W D \frac{\sqrt{gD}}{\sqrt{1+\gamma D/W}} \tag{1}$$

where ϕ_b is the bulk volume fraction, ρ_p the particle density, C_l and γ are fitting parameters. For outlet situated at the bottom of the silo, the central streamline is align with the gravity and the confinement does not play a role leading to the classical Hagen law where $Q \propto WD^{3/2}$. The aim of this study is to predict the discharge flow rate when the outlet is situated both at a lateral and at a bottom position, i.e. a corner, and to identify the role of the confinement.

EXPERIMENTS

As shown in Figure 1a, the experimental setup consists on a rectangular silo (of height $H = 1$ m, width $L = 10$ cm and thickness W which can be varied between 5 and 20 mm) made of two thin vertical glass plates separated on the sides by Plexiglas plates. The outlet is located at the right corner and is defined by its horizontal and vertical size, respectively D_x and D_y. The granular material consists of smooth spherical ceramic beads (density $\rho_p = 6000$ kg.m^{-3}) with different diameters d_p from 190 to 4350 μm (with a dispersion of $\pm 10\%$). Once the silo filled with a mass m_p of particles, the column height h_p is measured, giving the initial bulk particle volume fraction ϕ_b. Then the outlet is quickly opened manually and the grains falling out of the silo are collected in a vessel whose temporal evolution of the mass is recorded using an electronic scale. Each experiment is repeated twice to validate the reproducibility of the process. We observe rapidly a steady-state regime of discharge for all the configurations explored and the steady flow rate Q is obtained by time averaging the instantaneous flow rate during this stationary state. The motion of particles at the front plate is recorded using a high-Speed camera with a spatial resolution of 1024×1024 at a rate higher than 500 frames per second. The test section is located at the bottom of the silo and is ≈ 6 cm wide to permit both good visualisation of the flow around the outlet and good resolution of the particle imaging. Particle velocities are measured by particle image velocimetry (PIV).

CONTINUUM MODELLING

Following [5] we simulate the discharge flow of a granular medium from a rectangular silo with an orifice at the corner considering a non-Newtonian incompressible Navier–Stokes system, averaged across the thickness of the silo:

$$\begin{aligned} \frac{\partial u_i^p}{\partial x_i} &= 0 \\ \rho\left[\frac{\partial u_i^p}{\partial t} + u_j^p \frac{\partial u_i^p}{\partial x_j}\right] &= \frac{\partial \sigma_{ij}^p}{\partial x_j} + \rho g_i + f_{wi}, \end{aligned} \tag{2}$$

where $f_{wi} = -2\frac{\mu_w p^p}{W}\frac{u_i^p}{|u_i^p|}$ represents the depth averaged Coulomb friction on the front and back wall, with a coefficient of friction $\mu_w = 0.1$. The stress tensor of the particle phase $\sigma_{ij}^p = -p^p\delta_{ij} + \tau_{ij}^p$ comes only from direct particle-particle

(a) (b) (c)

Figure 1: (a) Experimental set-up. (b) Snapshot of the discharge flow for $d_p = 500\mu$m and $W = 5$mm. (c) Normalised flow rate versus the outlet aspect ratio.

interactions and can be described by a shear-dependant frictional rheology [6], $\tau^p_{ij} = \eta_p(|\dot{\gamma}|, p^p)\dot{\gamma}_{ij}$ with $\eta_p(|\dot{\gamma}|, p^p) = \frac{\mu(I)p^p}{|\dot{\gamma}|}$. We define $I = |\dot{\gamma}|d/\sqrt{p^p/\rho_p}$ where $\dot{\gamma}_{ij} = \partial u^p_i/\partial x_j + \partial u^p_j/\partial x_i$ is the strain-rate tensor and $|\dot{\gamma}| = (0.5\dot{\gamma}_{ij}\dot{\gamma}_{ij})^{0.5}$ its second invariant. For the shear-dependant friction coefficient, we take $\mu(I) = \mu_s + \Delta\mu/(I_0/I + 1)$ with the constant $I_0 = 0.4$, $\mu_1 = 0.4$, and $\mu_2 = 0.68$ [7]. The Navier–Stokes simulations are performed with the free software *Basilisk* which uses a finite-volume projection method and we use a regularisation technique to avoid the divergence of the viscosity.

RESULTS AND DISCUSSION

As shown in Figure 1b, for an aperture at the corner controlled by its horizontal and vertical size we can define the outlet length D_{newc} given by:

$$D_{newc} = (D_x^2 + D_y^2)^{1/2} \tag{3}$$

Figure 1c shows the normalised flow rate $Q/(\rho_p\phi_b\sqrt{gW^5})$ versus the aperture aspect ratio D_{newc}/W for $d_p = 190$ μm and $W = 5$mm. We observe that for an orifice at the bottom, $D_y = 0$, the flow rate is maximum and scales with $(D_{newc}/W)^{3/2}$ corresponding to the classical Hagen law (see the full line). Considering now the case of a lateral orifice with $D_x = 0$, we observe that the flow rate is linear with D_{newc}/W (see the dashed line), corresponding to the asymptotic limit of equation 1 for large D_{newc}/W in good agreement with the experimental and numerical results of Zhou et al. [5]. This shows that D_x and D_y do not play the same role and that the silo thickness is also an important parameter of control of the discharge flow from a corner, due to the friction on the front and rear wall. When D_x and D_y are non-zero values, we observe that all the data are in between these two regimes which suggests that D_{newc}/W is not the correct parameter to describe the discharge flow rate from a corner. To better understand the physical process and the relevant parameters we have performed particle image velocimetry to obtain the velocity fields and in particular the central streamline orientation and the magnitude of the velocity at the outlet. We compare the results with the continuum simulations and propose an empirical law for the discharge flow rate of a granular media from a corner.

FLOW OF WET GRANULAR MATERIALS: EXPERIMENTS AND SIMULATIONS

Abdoulaye Fall[1] and Jean-Noël Roux* [1]
[1]Lab. Navier, Univ. Gustave Eiffel, Ecole Nationale des Ponts et Chaussées, CNRS, Champs-sur-Marne, France

Summary Shear flows of assemblies of wet grains (diameter d) at small liquid saturation (as liquid bridges form near contacts) are investigated with laboratory rheometric experiments and numerical simulations (DEM). Constitutive laws are conveniently expressed in terms of two dimensionless parameters: inertial number I (dimensionless shear rate) and reduced pressure $P^* = \sigma_{22} d^2/F_0$, comparing normal stress σ_{22} in the gradient direction to capillary force F_0. Once the intergranular friction coefficient μ is identified, from the I-dependent rheology of *dry* grains, the simulations quantitatively agree with experiments for $P^* \geq 2$. X-ray tomography is used to probe the 3-phase microstructure. A Mohr-Coulomb cohesion c may be defined in the quasistatic limit, and its microscopic origins are identified. Effects of the liquid viscosity are investigated.

INTRODUCTION

Wet granular materials [1] at small liquid saturations (as liquid menisci join neighboring grains) are interesting both as a particular regime of grain-fluid mixture and as a case of a cohesive granular material for which a quantitative description of interactions is available and numerical simulations can be carried out with well identified models and parameters. We show here that the rheology in shear flow can be measured and its microscopic origins investigated thanks to a combination of rheometry and X-ray visualization in the laboratory, on the one hand, and DEM-type numerical simulations, on the other hand.

MODEL MATERIAL AND RHEOLOGICAL TESTING PROCEDURE

Polystyrene beads of diameter 0.5 mm are mixed with silicone oil, with surface tension $\Gamma \simeq 20.6$ mJ.m^{-2} and contact angle below 5°, varying liquid content $\epsilon = V_l/V_s$ (defined as the liquid to solid volume ratio) in range $0.015 \leq \epsilon \leq 0.075$. The material is tested in normal force-controlled shear flow in a rheometer [2] as sketched in Fig. 1. The top and bottom

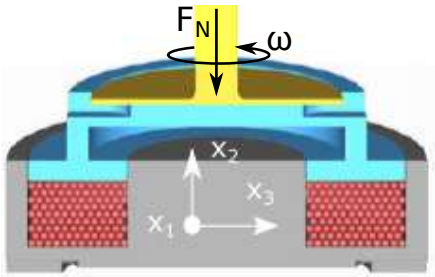

Figure 1: Annular cell (cut by plane containing rotation axis), with controlled normal force F_N on upper wall and varying height h, used in rotatory rheometer.

plates are rough and lateral walls are smooth to enforce as accurately as possible a uniform velocity gradient in the vertical direction. Normal stress σ_{22} and strain rate $\dot{\gamma}$ are respectively deduced from the imposed values of the angular velocity and the normal force, while cell height h in steady flow fixes solid fraction Φ_S and the shear stress is deduced from the measured torque.

Simulations [3] are carried out with standard discrete element modeling of elastic-frictional beads, supplemented by a capillary force model, suitable for small liquid bridges, with contact value $F_0 = \pi \Gamma d$. Elastic properties are irrelevant in flow under ordinary pressure, and the intergranular friction coefficient μ is chosen in order to reproduce the behavior of dry grains in shear flow, as $\mu = 0.09$. The contact laws are described in detail in Refs. [3, 4]. Shear flows are simulated with, typically 4000 beads in a fully periodic cell of variable height [5]. As in experiments, the main macroscopic measurements are those of shear stress σ_{12}, from which the effective macroscopic friction coefficient $\mu^* = |\sigma_{12}/\sigma_{22}|$ is deduced, and of the solid fraction Φ_S.

The material behaviour depends on two dimensionless control parameters: reduced normal stress $P^* = \sigma_{22} d^2/F_0$, comparing cohesive to confining forces, and inertial number $I = \dot{\gamma} d \sqrt{\frac{\rho_S}{\sigma_{22}}}$ (ρ_S denoting the mass density of the solid grains).

MICROTOMOGRAPHIC OBSERVATIONS

A similar rheometric cell was used for microtomographic measurements, consisting of a rotatory plate above a cylindrical cup. This geometry is more favourable for the absorption signal analysis. Images of the corresponding 3-phase morphologies are obtained on assuming they do not change during the necessary time of exposure, and we extract regions where the shear rate is nearly constant during flow. Fig. 2 shows how, for the larger liquid contents, the pendular regime crosses over to a different kind of morphology with menisci merging into larger clusters. Such measurements were also

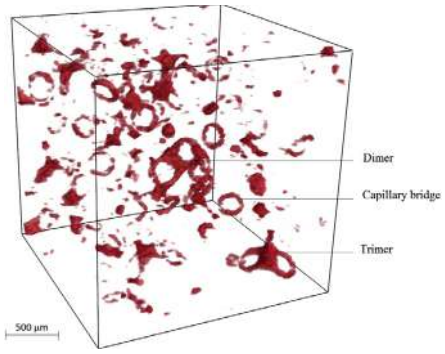

Figure 2: View of liquid menisci within flow, apparent as rings (the liquid layer is too small in meniscus center to be detected). Some are connected to their neighbours, concerning the same grain, forming "clusters" of 3 to 7 rings.

used to check for the absence of global liquid migration – as could be induced by the appearance of narrow shear bands.

MATERIAL RHEOLOGY

Laboratory results for μ^* and Φ_S were shown to be independent of the sample thickness h, ranging from $10d$ to $40d$. Fig. 3 shows the agreement of μ^* and Φ_S, achieved without fitting parameters (once dry quasistatic results are adjusted with $\mu = 0.09$), between simulations and experiments – save perhaps for a somewhat faster increase of μ^* with I at low P^*. We are thus in a good position to exploit the numerical results in the investigation of the microscopic origins of the

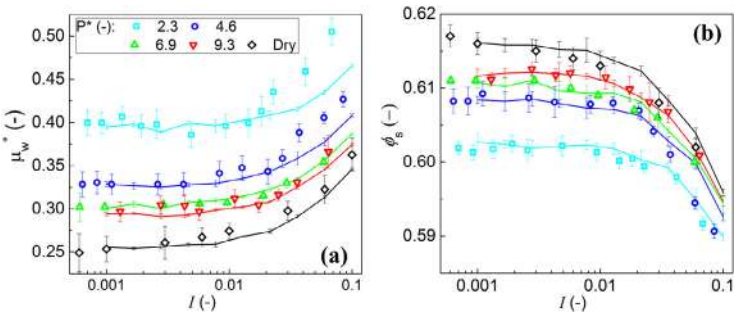

Figure 3: (a) Macroscopic friction coefficient and (b) solid fraction, versus I for different values of P^*. Experimental results are shown as dots, numerical ones as continuous lines.

observed rheology. This was done, e.g., for the observed values of the macroscopic Mohr-Coulomb cohesion [5].

PERSPECTIVES

Some results were obtained for the effects of the liquid viscosity, which causes some increase of μ^*, a decrease of Φ_S and introduced a third influential dimensionless parameters. The influence of liquid content ϵ, quite small in he explored range, will be investigated beyond the pendular regime.

NUMERICAL INVESTIGATION OF STATISTICAL VARIATION OF RANDOM PACKED BED CHARACTERISTICS

K. Gruszka[1], P. Niegodajew[2] and M. Marek[2]
[2]Czestochowa University of Technology, Department of Physics, Częstochowa, Poland
[1]Czestochowa University of Technology, Department of Thermal Machinery, Częstochowa, Poland

Summary Packings of particles have recently become an object of extensive research. A large number of works is devoted to studies of packed beds characteristics including for instance global and local porosity or orientation distribution of particles. However, despite the random nature of the considered packings, very little attention is devoted to examination whether the number of particles adopted in experiments/simulations is sufficient to get reproducible results. When filling the same container with particles twice, one may expect that the characteristics of the packing structure will not be the same. The reproducibility of packing parameters will depend on a number of factors, in particular, the number of particles (sample size) and ordering effects induced by the confining walls. The purpose of the present study was to analyse the influence of the sample size on the statistical variation of the packed bed characteristics in different realisations of the packing process.

INTRODUCTION

Particles packing is a common problem in a number of engineering applications. One of its applications lies in power industry where the random packing is used in boilers equipped with fluidised beds. The size of particles and their packing density is crucial in particle and heat transport within the boiler. When concerning the pebble bed reactor in nuclear engineering, the graphite reflector life-time is dependent on its efficient cooling, which in turn depends on liquid flow maldistribution within the packed bed. The packing of particles is widely used in chemical industry where heat and mass transfer processes are very common – absorption and stripping may serve as examples.

Mentioned above processes can be improved by intervening, in particular, into the packing geometry. Therefore, a number of works can be found in the literature which focuses on study of such properties as local and global porosity distributions [1], orientation of particles [2] and tortuosity [3] of the pore channels within a packed bed interior. However, very little attention is devoted to study whether the number of particles employed in experiments and simulations is sufficient to get reproducible statistics of packed beds like orientation distribution of particles or local void fraction profiles.

When randomly filling the same space with particles twice, it can be expected that the properties of the resulting packing structure will not be the same. The repeatability of key packaging parameters will depend on many factors, in particular on the size of the population of particles and the ordering effects caused by the bounding walls. In a previous study [4] it was shown that for a very large sample the orientation distribution is almost independent of the packaging procedure. Therefore it is necessary to verify such reproducibility for smaller samples, much more adequate from the point of view of typical experiments [5] or simulations [6]. It is possible that some of the available experimental/numerical results on particle orientation distributions are questionable because of insufficiently large number of particles' used. Hence, the aim of the present work is to analyse the influence of the sample size on the statistical variation of the packed bed characteristics, including particle orientation and porosity (not shown here) in different realisations of the packing process.

NUMERICAL MODEL

In this work, packed bed geometries were generated numerically using of the discrete element method described in detail in the works [7,8]. Such an approach is based on sequentially added particles to the bed. In this procedure, firstly, a single particle is placed above the bed with random location and random orientation. Secondly, the particle motion is due to the gravity force and reaction forces resulting from contact with other particles until reaching the mechanical equilibrium. After this step the particle is incorporated into the bed structure at fixed position until the deposition process is completed. To detect the overlap of particles, each of them is covered with a uniform grid of marker points. Such an approach reduces the problem of calculating the overlap to obtain the immersion distance of the point (marker) in the particle. The direction of reaction force is set to push the marker out of the other particle. An additional force acting in the direction normal to the container axis is included in order increase the packing density and to achieve a more realistic structure with inherent ordering.

SAMPLE RESULTS

From the practical point of view it is preferable to define the sample of interest in the form of its physical dimensions, e.g. the packing height h_B, hence, the results will be presented employing these parameters as independent variables. The number of particles in the sample of a packed bed of height h_B should obviously depend on diameter D_p of the particle and diameter D_c of the column (or ratio D_c/D_p). We obtained results for numerically generated random packed beds of equilateral ($H_p/D_p = 1$) Raschig rings (hollow cylinders, which are commonly used as a packing material in trickle bed reactors) in columns with different aspect ratios D_c/D_p equal to 7, 15 and 30. The inner particle diameter

was set to be $0.8D_p$. Single particle orientation is defined as angle φ ($0 \le \varphi \le 90$ deg) between a column's and particle's symmetry axis. Due to an axisymmetric shape of the container the remaining angles necessary to specify the exact orientation of a particle are not concerned as their probability distribution is uniform.

The first study concerned the evolution of PDF(φ) (Probability Density Function) with increasing distance from the column bottom h_B for D_c/D_p=7 – see Fig. 1a. It can be observed that the PDF(φ) is characterised by relatively large irregularities. These fluctuations are reduced as both the packing height d_B and column particle diameter ratio D_c/D_p increases. This can be expected given that for larger D_c/D_p each layer of particles is more numerous, and therefore the sample size increases faster with h_B.

In order to take a closer look at the reproducibility of the orientation distribution, 10 independent simulations for each considered D_c/D_p ratio were performed. Similarly to the study of PDF(φ), this one was aimed at analysing the impact of packed bed height on variations of PDFs. Figure 1b presents the complementary quantitative results showing the evolution of averaged variability of PDF(φ) defined as:

$$\overline{C_v}^{or} = \frac{1}{n}\sum_{i\in B}\frac{\sigma_i^{or}}{\mu_i^{or}} \tag{2}$$

In the above relation σ_i^{or} and μ_i^{or} are the standard deviation and the mean value of probability determined for i^{th} class (bin) $[\varphi_i, \varphi_{i+1}]$ of orientation angles (the size of each bin was taken as $\varphi_{i+1} - \varphi_i = 5^\circ$, except for the first and last bin of size 2.5°), while n represents number of classes. Figure 1b shows the dependence of the averaged variability of PDF(φ) on the packing height. As can be seen, in general, the averaged variability decreases with the increasing h_B because the number of particles also increases. One should note that with increasing D_c/D_p and h_B the averaged variability decreases, again as the result of increasing sample size.

Regarding the maximum variability it may be of interest to study the contribution of each orientation class to the variability coefficient. For this purpose PDFs of orientations with standard deviation σ_i^{or} of probability marked with bars for D_c/D_p=7 is presented in Fig. 1c for h_B=10. As can be seen different classes of PDF(φ) are characterized by different σ_i^{or}. The most reproducible classes of angles are 0° and 10° whereas the class centred at 50° which is the least reproducible.

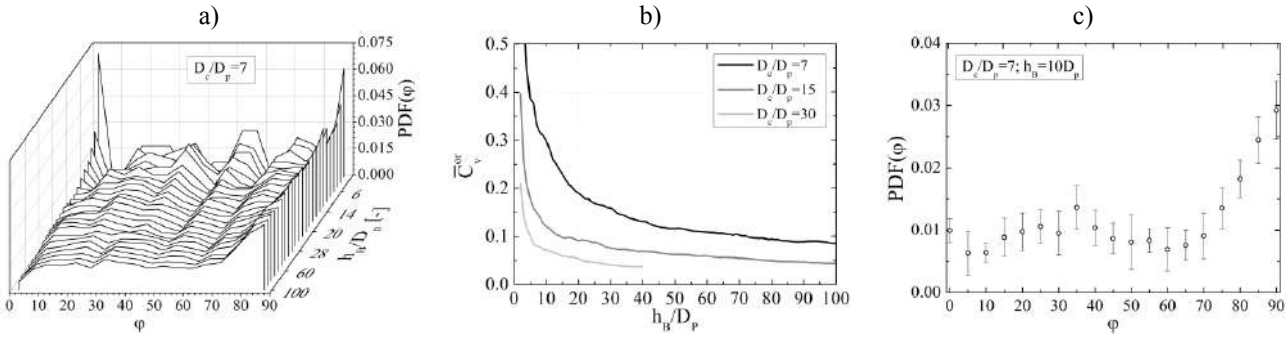

Figure 1. PDFs of orientation distribution – evolution with respect to the increasing h_B for D_c/D_p=7 (a), averaged variability of PDF(φ) as a function of the packing height for D_c/D_p=7, D_c/D_p=15 and D_c/D_p=30 (b) and PDF of orientation with standard deviation bars for D_c/D_p = 7 and h_B = 10 (c)

CONCLUSIONS

We showed that the PDF(φ) strongly depends on the sample size. In particular for slender columns the relative variation of the probability of specific angles can be as high as 50% when the number of layers of the packing is smaller than 10. The statistical variation of orientation angles is influenced not only by the sample size but also by the ordering effects introduced by the column walls or its bottom. The averaged variability of PDF(φ) is not as severe as for single angle classes but can be significant even for larger number of particles in slender columns.

TRANSPORT COEFFICIENTS IN MODERATELY DENSE MULTICOMPONENT GRANULAR SUSPENSIONS

Rubén Gómez González * [1] and Vicente Garzó[1]
[1]Departamento de Física, Universidad de Extremadura, E-06006 Badajoz, Spain

Summary The Enskog kinetic equation for binary granular mixtures in the presence of a bath is considered as a model for multicomponent granular suspensions at moderate densities. As usual, the bath is modeled as a combination of a viscous drag force plus a stochastic Langevin-like term defined in terms of a background temperature. The Enskog equation for the suspension model is solved by means of the Chapman–Enskog method conveniently adapted to dissipative dynamics. To first-order in spatial gradients, the Navier–Stokes transport coefficients are explicitly determined in terms of the parameter space of the problem (masses and sizes, composition, coefficients of restitution, density, and background temperature). A comparison with previous results derived in the dry granular case (no gas phase) shows that in general the impact of the interstitial gas on grains is significant, specially for strong inelasticity.

INTRODUCTION

Kinetic theory tools have been employed in the last few years to get the transport properties of granular matter under rapid flow conditions [1]. Studies have covered not only monodisperse (dry) granular gases but also polydisperse systems where grains have different masses, sizes, and coefficients of restitution. In particular, the Enskog theory has been considered as a reliable model for describing transport at moderate densities. However, although granular matter in nature is generally immersed in a a fluid (like air or water), most of the theoretical and computational works have ignored the influence of the interstitial fluid on the dynamics of grains. Thus, the studies on the application of kinetic theory to gas-solid flows (granular suspensions) are scarcer than those performed so far for dry granular gases.

As usual [2], to model the granular suspension one assumes that the state of the surrounding gas is not affected by the solid particles while the influence of the gas phase on grains is accounted for by means of an external force. This external force is composed by two terms: (i) a viscous drag force proportional to the velocity of the particles and a stochastic force acting on the granular particles. In addition, in the case of a binary system, the drift coefficients γ_i ($i = 1, 2$) appearing in the fluid-solid external forces depend on both partial and global volume fractions and the mechanical properties of grains (masses and sizes).

The objective of this contribution is to determine the Navier–Stokes transport coefficients of the above suspension model. This task is accomplished in two steps. First, in the absence of spatial gradients, the steady state achieved when the energy lost by inelastic collisions and viscous friction is compensated for by the energy injected by the stochastic force is studied. In particular, the partial temperatures T_1 and T_2 (measuring the mean kinetic energy of each component) are explicitly obtained in terms of the parameter space of the problem. The theoretical predictions of these quantities are also shown to be in good agreement with molecular dynamics (MD) simulations. Once the homogeneous steady state is characterized, the set of Enskog equations for the binary mixture is solved by means of the Chapman–Enskog (CE) method. To first-order in spatial gradients, the constitutive equations for the mass, momentum, and heat fluxes are derived with explicit forms for the complete set of relevant Navier–Stokes (NS) transport coefficients.

ENSKOG EQUATION FOR POLIDISPERSE GRANULAR SUSPENSIONS

We consider a granular binary mixture of inelastic smooth hard disks ($d = 2$) or spheres ($d = 3$) immersed in a molecular gas of viscosity η_g. Inelasticity in collisions between particles of the component i with particles of the component j is only characterized by the constant (positive) coefficients of restitution $\alpha_{ij} \leq 1$. In the presence of the gravitational field $\mathbf{g}$, the one-particle velocity distribution function $f_i(\mathbf{r}, \mathbf{v}, t)$ of the component i obeys the Enskog equation

$$\frac{\partial f_i}{\partial t} + \mathbf{v}\cdot\nabla f_i + \mathbf{g}\cdot\frac{\partial f_i}{\partial \mathbf{v}} - \gamma_i \Delta\mathbf{U}\cdot\frac{\partial f_i}{\partial \mathbf{v}} - \gamma_i \frac{\partial}{\partial \mathbf{v}}\cdot\mathbf{V} f_i - \frac{\gamma_i T_{\text{ex}}}{m_i}\frac{\partial^2 f_i}{\partial v^2} = \sum_{j=1}^{2} J_{ij}[f_i, f_j], \quad (i = 1, 2), \tag{1}$$

where $\mathbf{V} = \mathbf{v} - \mathbf{U}$, $\Delta\mathbf{U} = \mathbf{U} - \mathbf{U}_g$, $\mathbf{U}$ and $\mathbf{U}_g$ being the mean flow velocities of the solid and gas phases, respectively. In addition, T_{ex} is the background temperature and $J_{ij}[f_i, f_j]$ is the (inelastic) Enskog collision operator [1]. The drift coefficients γ_i are considered to be proportional to η_g. In such a way, they can be written as $\gamma_i = \gamma_0 R_i$ where $\gamma_0 \propto \eta_g \propto \sqrt{T_{\text{ex}}}$ and the dimensionless quantities R_i are functions of the partial volume fractions ϕ_i, the total volume fraction $\phi = \phi_1 + \phi_2$, and the mass m_1/m_2 and size σ_1/σ_2 ratios. Explicit forms for R_i can be found in the literature for polydisperse gas-solid flows [3].

The balance equations for the densities of mass, momentum, and kinetic energy can be derived exactly from the Enskog equations. These equations are expressed in terms of the mass flux $\mathbf{j}_i$, the pressure tensor P, the heat flux $\mathbf{q}$, and

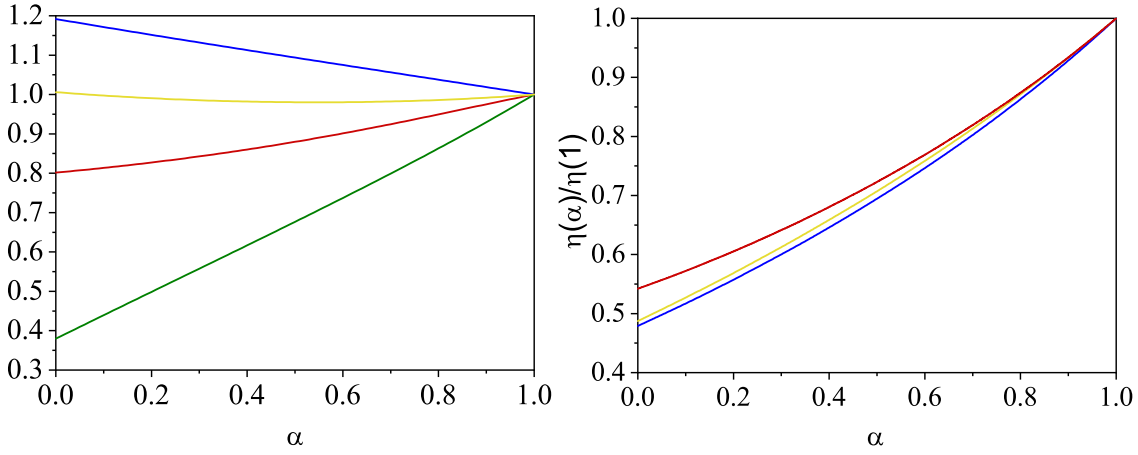

Figure 1: Left panel: Plot of the (reduced) diffusion coefficients $D_{11}(\alpha)/D_{11}(1)$ (green line), $D_{12}(\alpha)/D_{12}(1)$ (yellow line), $D_1^T(\alpha)/D_1^T(1)$ (red line), and $D_1^U(\alpha)/D_1^U(1)$ (blue line) for $m_1/m_2 = 8$. Right panel: Plot of the (reduced) shear viscosity coefficient $\eta(\alpha)/\eta(1)$ for $m_1/m_2 = 0.5$ (red line), $m_1/m_2 = 4$ (blue line), and $m_1/m_2 = 10$ (yellow line). The remaining parameters in both panels are $d = 3$, $T_{\text{ex}}^* \equiv T_{\text{ex}}/(\overline{m}\gamma_0^2\overline{\sigma}) = 0.01$, $x_1 = 0.5$, $\sigma_1/\sigma_2 = 2$, and $\phi = 0.2$. Here, $\overline{m} = \sum_i m_i/2$ and $\overline{\sigma} = \sum_i \sigma_i/2$.

the so-called cooling rate ζ. This latter quantity measures the rate of energy change due to collisions. While the mass flux only contains kinetic contributions, the pressure tensor and the heat flux contain kinetic and collisional contributions.

A simplest situation corresponds to homogeneous steady states where the granular temperature T is obtained from the condition $2\sum_i x_i\gamma_i(T_{\text{ex}} - T_i) - \zeta T = 0$, x_i being the mole fraction of species i. The above equation is coupled to the steady equation for the partial temperature T_i: $2x_i\gamma_i(T_{\text{ex}} - T_i) - \zeta_i T_i = 0$, where ζ_i is the partial cooling rate for the component i. Given that ζ and ζ_i are defined in terms of the distributions f_i, one needs to consider approximate forms for the above distributions. Here, we have considered Maxwellian distributions at different temperatures. In spite of this simplification the theoretical results for the temperature ratio T_1/T_2 compare quite well with MD simulations.

NAVIER–STOKES TRANSPORT COEFFICIENTS

We assume that we slightly perturb the homogenous steady state by small spatial gradients. In this case, we solve the Enskog equation (1) by means of the CE method. For time longer than the mean free time and distance larger than the mean free path, the suspension reaches a hydrodynamic regime where all the space and time dependence of f_i only occurs via a functional dependence on the hydrodynamic fields (*normal* solution). In these conditions, f_i can be expanded in powers of the spatial gradients as $f_i = f_i^{(0)} + f_i^{(1)} + \cdots$ where the approximation $f_i^{(k)}$ is of order k in gradients.

The application of the CE expansion to first-order allows us to obtain the constitutive equations for the fluxes. In particular, the mass flux $\mathbf{j}_i^{(1)}$ and the pressure tensor $P_{\lambda\beta}^{(1)}$ are given by

$$\mathbf{j}_i^{(1)} = -\sum_{j=1}^{2} \frac{m_i\rho_j}{\rho} D_{ij}\nabla \ln n_j - \rho D_i^T \nabla \ln T - D_i^U \Delta \mathbf{U}, \quad P_{\lambda\beta}^{(1)} = -\eta\left(\partial_\lambda U_\beta + \partial_\beta U_\lambda - \frac{2}{d}\delta_{\lambda\beta}\nabla\cdot\mathbf{U}\right) - \delta_{\lambda\beta}\eta_{\text{b}}\nabla\cdot\mathbf{U}, \tag{2}$$

where n_i is the number density of the component i, $\rho_i = m_i n_i$, and $\rho = \sum_i \rho_i$. In addition, in Eq. (2) we have introduced the diffusion transport coefficients D_{ij}, D_i^T, and D_i^U as well as the shear η and bulk η_{b} viscosities. As for molecular hard-sphere mixtures, the above transport coefficients are given in terms of the solution of a set of coupled linear integral equations that can be approximately solved by considering the leading terms in a Sonine (or Laguerre) polynomial expansion. Here, we have obtained explicit forms for these coefficients in terms of the parameters of the system [4]. As an illustration, Fig. 1 shows the dependence of the (reduced) diffusion coefficients (left panel) and the shear viscosity coefficient (right panel) on the (common) coefficient of restitution $\alpha_{ij} = \alpha$ and several systems. Figure 1 highlights the strong influence of inelasticity on the mass and momentum transport, specially in the case of the diffusion coefficients. In addition, a comparison with the results derived for (dry) granular mixtures [1] shows significant differences between both systems (granular suspensions and granular gases). This is clearly indicative that the impact of gas phase on transport properties of solid particles cannot be in general neglected. A more exhaustive discussion on this issue will be developed during the presentation of this work.

Summary A bidisperse medium of large glass beads and small sand particles is mixed in a cylindrical vessel that is put in rotational motion around an eccentric static rod. The subsequent segregation occurring in the system is investigated primarily at the free-surface. In order to gain deeper understanding of the intrinsic forces causing the segregation, we also explore the dynamics in the bulk. Average residual bulk displacements fields both vertically and orthoradially could then be measured and show a secondary flow that counteracts the segregation process.

INTRODUCTION

A common problem in mixing granular materials is segregation, mainly size-segregation [1, 2] that often leads to structural mal-performance in industrial products such as glass, abrasives, pills just to name a few.

Even though the dedication of the particles community has allowed to establish theoretical [3], phenomenological [4] and recently numerical laws [5] describing the phenomenon, it has to be noticed that these findings remain solely applicable to classical configurations (rotating drum, heap flow, Couette-flow, etc...) The generalization to complex flows remains an open question. In this paper we experimentally investigate segregation in one of these complex flows generated by the rotation of a cylindrical vessel around a fixed eccentric rod.

EXPERIMENTAL SETUP

The setup (**Fig1.a**) consists in a cylindrical vessel of diameter $D = 14cm$ in which a bidisperse medium of particles is mixed: large glass particles of average diameter $d_l = 600\mu m$ colored in green and white small sand particles ($d_s = 250\mu m$). For the mixing, we use a rod in steel of diameter $d_{rod} = 2cm$ whose center is positioned at $5cm$ from the center of the vessel and whose end-base was kept at $2cm$ from the bottom of the vessel. To mix, the vessel is put in rotational motion at $\omega \approx 1{,}5\ rpm$ while the rod is kept fixed (quasi-static flow regime).

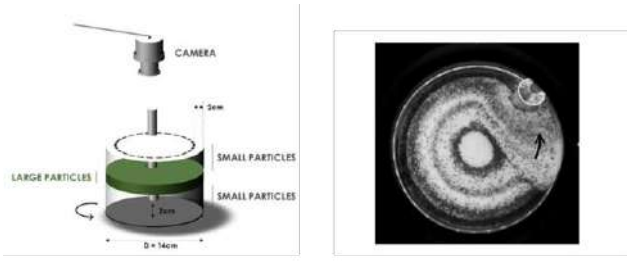

Fig 1: (a) Experimental setup (b) Typical picture of the free-surface after 15 turns with large particles appearing black

We started with a stratified arrangement in which a 4mm layer of large particles is encapsulated between 2 layers of small particles, 3cm at the bottom and 2cm at the top. Once the mixing starts, we use a camera affixed at the top of the vessel to capture 8 bit grayscale images of the free-surface showing how the large particles rise to the surface (**Fig1.b**).

ANALYSIS OF THE SURFACE TO QUANTIFY SEGREGATION

We investigate segregation by processing the successive images that were captured by the camera through time. we define a coverage-ratio $C(t) = \frac{I_0 - I(t)}{I_0 - I_\infty}$ where $I(t)$ is the average grayscale of the surface at time t, I_0 the grayscale at the beginning of the experiment and I_∞ is the grayscale of the free-surface in a hypothetical scenario where the whole surface is covered in black large particles. $C(t)$ is this way, bound between 0 (no large particles at surface) and 1 (full surface saturation with large particles).

RESULTS

Segregation: accumulation at the free-surface

The plotting of $C(t)$ against time shows an overall increase with an exponential relaxation towards a stable regime modulated by repetitive oscillations which represent the successive disappearances and appearances of particles at the

*Corresponding author: kwami.mayeden@saint-gobain.com.

surface (**Fig2.a)**. This rise-and-plunge motion points to the existence a strong recirculation motion that becomes less visible when an equilibrium state is reached in which the repartition of large particles at the surface and the exchanges between bulk and free-surface could be considered as stable. The dynamics observed in the medium through $C(t)$ can then be viewed as a competition between segregation and recirculation currents.

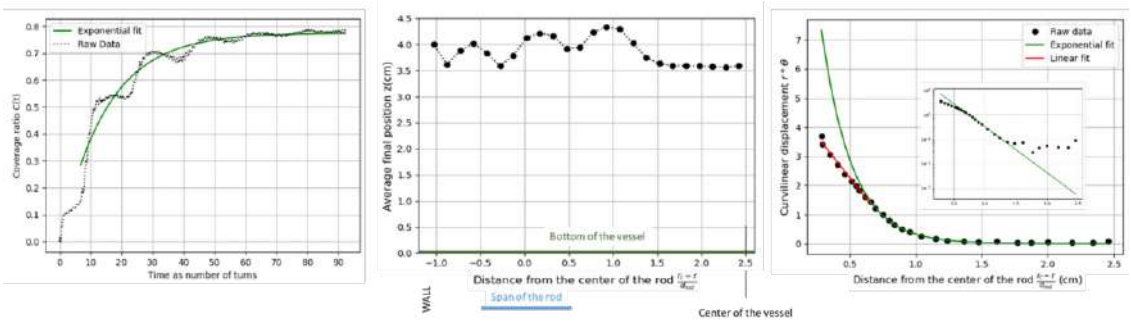
Segregation in the bulk against the normalized distance from the center of the rod

In order to better understand the segregation dynamics in the bulk, a vacuum cleaner is used to remove particles layer by layer after mixing. Pictures of the inside could then be retrieved that show the repartition of particles radially given the depth. From those pictures an average vertical rise could be computed and plotted against the distance from the center of the rod **(Fig 2.b)**. The minimal rise is obtained as expected far away from the rod in the central area of the vessel. The maximal rise on the other hand is obtained at a distance of $\frac{d_{rod}}{2}$ from the outer surface of the rod. If this rise was only due to the amplitude of the shear, one would have expected it to occur close to the rod surface. This result supports the fact that the segregation is not the only mechanism responsible for the movement of the grains. On the wall side, a similar behavior can be observed only with a lower amplitude.

Orthoradial displacement in the bulk against the normalized distance from the center of the rod

As segregation is due to shear which itself stems from displacement, we set up an experiment to retrieve the orthoradial displacement generated by the passage of the rod in the depth of the medium. We encapsulated a thin bar in between the 2 layers of small particles. Vacuuming after mixing allows to retrieve the deformation of the bar stemmed from the passing of the rod. Assuming only an orthoradial displacement we plot the curvilinear displacement $r * \theta$ against the distance from the center of the rod (**Fig2.c**).

On the center-side part of the rod, 2 main regions could be discriminated. A linear model fits the data in the first region whereas an exponential decay satisfyingly fits the curvilinear displacement in the second region (inset **Fig 2.c**). The shear corresponding to this displacement profile should be linked to the segregation and thus to the rise of the grains. Since the curve is monotonous, contrary to the rise curve, this tends to confirm again the existence of another force in the medium that intervenes in the uplifting of the particles: the recirculation current which itself still has to be characterized.



(a) (b) (c)

Fig 2: (a) Evolution of segregation (C(t)) against time for the same parameters as in Fig 1 (b) Average vertical displacement field against normalized distance from the center of the rod after 4 revolutions - the layer of larges particles was initially located at 3cm from the bottom of the vessel (c) Curvilinear displacement against normalized distance from the center of the rod with graph in log space in the inset - r_c being the radial coordinate of the center of the rod

CONCLUSIONS

We investigated segregation dynamics occurring in a bidisperse medium mixed in a cylindrical vessel with an eccentric rod. We showed that the law describing such dynamics has an exponential baseline that is modulated by periodic oscillations which point to the existence of a recirculation current. In the bulk, we studied the rise of particles according to their radial positions. Last, we explored orthoradial displacement field inside the medium generated by the passing of the rod and showed that it follows an exponential law far from the rod. More investigation has to be done especially to understand the downward movement behind the rod and the coupling of recirculation currents with the segregation force.

A MULTI-BODY CONTACT MECHANICS FEM METHOD AND ITS APPLICATION TO GRANULAR PHYSICS

Liuchi Li *[1], Mengsu Hu[1], and Jonny Rutqvist[1]
[1]Earth and Environmental Sciences Area, Lawrence Berkeley National Laboratory, Berkeley, California94720, USA

Summary Inter-particle forces in a granular media form spatially heterogeneous force chains. Understanding them is of fundamental significance to various applications in engineering and physics. However, most studies to date have been focusing on granular media composed of mechanically homogeneous grains, leaving the aspect of heterogeneity a rather uncharted area. Here, we specifically investigate how the mechanical property of a constituent grain can alter the amount of force it obtains in a granular media. In pursuit of such knowledge, we first briefly introduce a multi-body contact mechanics FEM implementation and show several verifications. Next, we take this method to simulate stackings of ordered elastic disks. We discuss how the force distribution deviates from the initial homogeneous one under quasi-static uniaxial compression and what role does mechanical property play in this regard.

INTRODUCTION

Any collection of macroscopic solid frictional particles with size greater than 1 μm belong to the family of granular media. They are ubiquitous on earth and are the second most manipulated industrial material. Despite such a unified and simple definition, at the macro-scale, different granular materials can exhibit drastically different mechanical properties and can behave like solids, liquids, gases or even with the aforementioned phases coexisting under different external loading and boundary settings. Such complex macro-scale behavior is closely tied to the heterogeneously distributed filamentary force chains formed by inter-particles forces [1]. Understanding these force chains is therefore of fundamental significance to various applications in engineering [2] and physics [3].Despite the various characteristics a granular media can exhibit, most studies to date have been focusing on granular materials composed of grains with homogeneous mechanical properties [4, 5, 6], leaving the aspect of heterogeneity a rather uncharted area. Here, we specifically investigate an interesting fundamental question inspired by making an analogy to income inequality studied in economics: How the mechanical property of a constituent grain can alter the amount of force it obtains through its collective interactions with neighboring grains? In pursuit of such knowledge, we will first briefly introduce the implementation of a 2D multi-body contact mechanics FEM method and show several verifications and validations [4]. Next, we will take this method to simulate a model granular media as a starting point: collections of ordered mono-disperse disks. By systematically varying the mechanical properties of each disk, we discuss how the force distribution deviates from the initial homogeneous one under quasi-static uniaxial compression and what role does mechanical property play in this regard. In closure, we will briefly outline several inspired future research directions.

A MULTI-BODY CONTACT MECHANICS FEM IMPLEMENTATION

For simplicity, we consider small deformation and assume each grain is made of linear elastic and isotropic materials. In the absence of body force and acceleration, the problem reduces to finding the displacement field that vanishes the divergence of Cauchy stress within each grain under the boundary condition of boundary displacements and tractions (if present), and contact tractions between neighboring grains. This boundary value problem (BVP), under the condition of small deformation and linear elasticity, is linear in the displacement field and can be solved by standard FEM treatment without iteration. However, with the presence of inter-grain contacts, such BVP becomes nonlinear in the displacement field, since contact tractions depend on the displacement field around the contact region (which is unknown *a-priori*).

To solve this non-linear BVP, we implement a Newton-Raphson solver to find the displacement field under the classical penalty formulation accompanied by a regularized Coulomb friction law. At each Newton-Raphson iteration, the inter-grain contact contribution to the Jacobian is computed numerically via finite difference. Considering scenarios with multiple loading steps, at each load step we solve the BVP using the total displacement field, which allows for convenient realization of loading-unloading simulation and future extension to finite deformation. We note that, although certainly feasible, we choose not to augment the penalty formulation with an encapsulating iteration loop for the ease of contact detection, especially in simulating scenarios with continuous loading. Lastly, as a point of departure, we focus on 2D and use the constant strain triangle (CST) elements.

Due to the limitation of length, here we only demonstrate one verification in the case of Hertzian contact where the analytical solution is obtainable [7]. In this example (Figure. 1a), the top surface of the top grain is subjected to a displacement boundary condition in both the x and y direction, while the bottom surface of the bottom grain is fixed. We show the simulated spatial distribution of the normal stress along the y direction (Figure. 1b) with a friction coefficient equaling 0.5. As expected, the stress distributions in two grains are not symmetric with respect to the x direction with

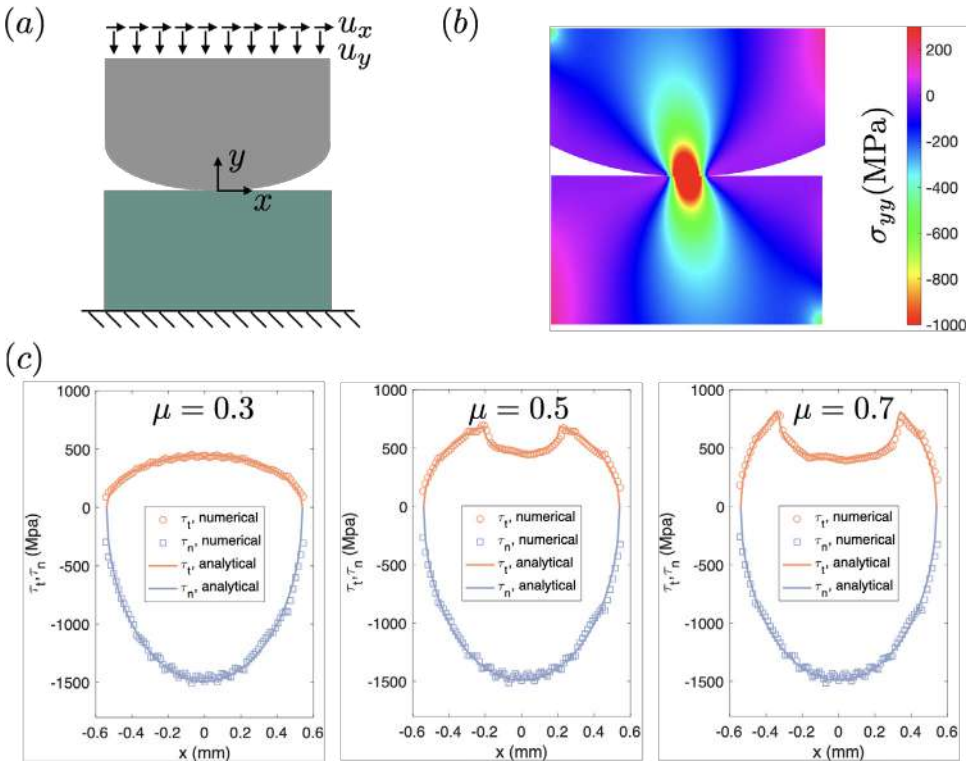

Figure 1: The adopted Hertzian contact example.

mismatched edges, due to the presence of tangent displacement and frictional slip. Further, our implementation also accurately predicts the distributions of both normal and tangent tractions along the contact surface (Figure. 1c) and identifies the slip and stick region for different friction coefficients.

APPLICATIONS TO GRANULAR PHYSICS

We next take this method to analyze the effect of mechanical properties on force chain distributions. Studies are currently under the way, and at the point of the poster presentation, we will discuss, for stackings of ordered disks, how the force distribution deviates from the initial homogeneous one under quasi-static uniaxial compression and what role does mechanical property play in this regard. Besides the fundamental relevance to granular physics, our work can also have practical implications in designing wave-tailoring acoustic devices [8] and tunable mechanical meta-materials [2].

WET ROLLING STONES: GROWTH OF A GRANULAR AGGREGATE

Pierre Jop* [1], Guillaume Saingier[1], and Alban Sauret[2]
[1]Surface du Verre et Interfaces, UMR 125, CNRS/Saint-Gobain, Aubervilliers, France
[2]Department of Mechanical Engineering, University of California, Santa Barbara, CA, USA

Summary Wet granulation processes can be driven from low to high water content. In this study, we consider the model situation of the growth of a single wet aggregate rolling in a dry granular flow inside a rotating drum. We measure the time evolution of its diameter for different grains and liquids, as well as various rotation rates of the drum. Using X-ray tomography, we are able to characterize the internal structure of the granular aggregate at different times during the process. We show that the growth rate of the aggregate can be related to the transport of the liquid inside the granule and the capture of grains. We propose a model to rationalize the maximum size of the aggregate and its growth rate.

INTRODUCTION

Blending dry grains and liquid is a common step of many industrial processes. When the volume of liquid is small compared to the volume of grains, wet aggregates are created. The capillary forces hold the wet grains together, bringing strength to this object. This phenomenon is, for instance, at the base of the wet granulation processes [1]. The wet aggregates interact with the surrounding medium and can collide, break, and exchange grains. In high shear granulators, the kinetic energy of the aggregates is essential. However, in industrial granulation dishes or in rotating drums, the granulation is done at low shear and allows the individual aggregates to preserve their shape and roundness. Depending on the liquid content of the aggregate, different mechanisms can occur. At very low water content, the grains at the surface of the aggregate can be eroded due to the friction of the granular media and to the impact of the dry grains [2]. At very large water content, the flowing dry grains can be captured if they touch a capillary meniscus [3]. In this study, we focus on an isolated wet aggregate during all of its evolution and describe the role of the kinematic and physical properties of the material on its growth.

GROWTH DYNAMICS OF AN AGGREGATE IN A ROTATING DRUM

We use a rotating drum to measure the growth of a single aggregate in a gentle granular flow. The drum is partially filled with sand of diameter $d_g = 60 - 300\ \mu$m and rotates from 3 rpm to 36 rpm. An aggregate is prepared by depositing a drop of aqueous solution of ZnI_2 or glycerol on the surface of the sand before starting the rotation. This method allows us to create an initial aggregate fully saturated with liquid. As shown in Fig. 1(a), the aggregate is then carried by the flow, partially sunk. It can easily be collected after several rotations to characterize its properties, such as its mass.

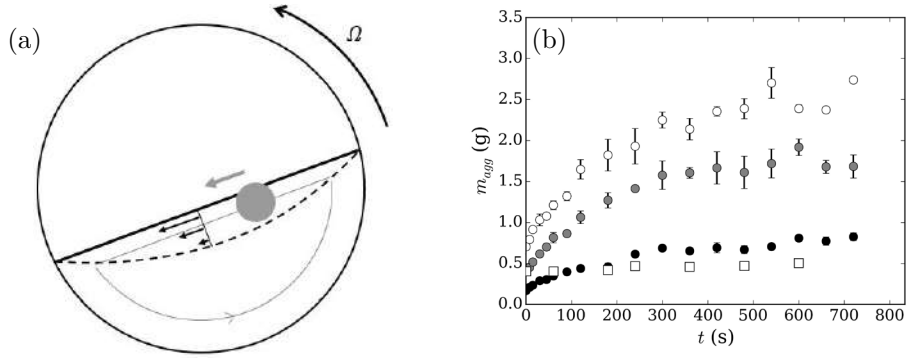

Figure 1: (a) Schematic of the aggregate rolling inside the surface flow of the granular media in a drum. (b) Time evolution of the mass of the aggregates of sand for increasing volumes of the initial droplet of ZnI_2 solution (circles from dark to light) 20 μL, 50 μL, 100 μL and comparison with a buried aggregate in a static media from a 20 μL droplet (squares).

Fig. 1(b) shows the temporal evolution of the mass of the aggregates for different initial volumes of a water solution of ZnI_2. The mass increases with time t, and the growth rate slows down until reaching a saturation. The increase in mass results from the capture of dry grains by the air/liquid menisci at the surface of the aggregate. We do not usually observe clusters of grains detaching from the aggregates. However, at the end of the experiment, a large aggregate can break into several parts. The aggregate then grows by gluing new sand grains on its surface, without releasing them contrary to a recent numerical study [4]. To test if the spontaneous capillary spreading of the liquid toward new dry grains plays a key role, we also report the time evolution of the mass of the same initial aggregate buried in the sand but without flow. We

*Corresponding author. E-mail: pierre.jop@saint-gobain.com

observe that the mass grows by less than 25%. Therefore the capture mechanism of dry grains requires a granular flow and is reminiscent of the growth of wet granular towers [3]. Moreover, as we increase the initial volume of liquid, the mass ratio between the initial and the final aggregate is of the order of 4. This behavior suggests that the evolution of the aggregate can be rescaled by the initial volume of liquid, and the transport of the liquid may be the key parameter.

MODELING OF THE GROWTH DYNAMICS: TRANSPORT OF THE LIQUID

We collect some aggregates at different times and characterize their structure through X-ray tomography, as illustrated in Fig. 2(a)-(d). The solution of ZnI_2 provides a good contrast to observe the liquid distribution in the aggregate. While the pores at the center of the initial aggregate are fully saturated, the local amount of liquid decreases in the outer part. We observe a shell of captured sand grains that are smaller than the initial ones. Moreover, only a fraction of those pores is filled with the liquid. This behavior likely occurs because of the larger probability for the smaller grains, continuously brought to the aggregate by the flow, to get captured. The pore size in the shell is then smaller, and the capillary pressure drops when the liquid starts invading them. As a result, the liquid is pumped out from the core consisting of large pores until it is empty. This hypothesis also explains why the aggregate at rest does not grow: the size distribution of the dry grains in contact with the wet aggregate is the same as the ones inside.

Based on this physical argument and using geometrical assumptions, we can propose a model for the growth rate of this aggregate. We first assume that the core of the aggregate is composed of large grains [inset of Fig. 2(e)] with a shell consisting of smaller grains. Secondly, the volume fraction of the pores is assumed to be constant everywhere. Thirdly, the growth stops when the liquid volume fraction drops below a value that does not allow a continuous path of liquid. The value of this percolation threshold was estimated by Schell *et al* [5] to be of the order of $W = 0.05$, while the initial value for this sand is $W_0 = (1-\phi)/\phi \simeq 0.43$. Finally, the transport of the liquid is governed by a Darcy flow whose pressure gradient is given by the capillary pressure inside the two types of pores. We validate this model using glycerol, which makes stronger aggregates and which wets well the sand grains. We observe a growth of the mass by a factor 10, in quantitative agreement with the prediction of a factor 8.6. Moreover, the model described here provides a growth rate that captures the experimental results, as shown in Fig. 2(e).

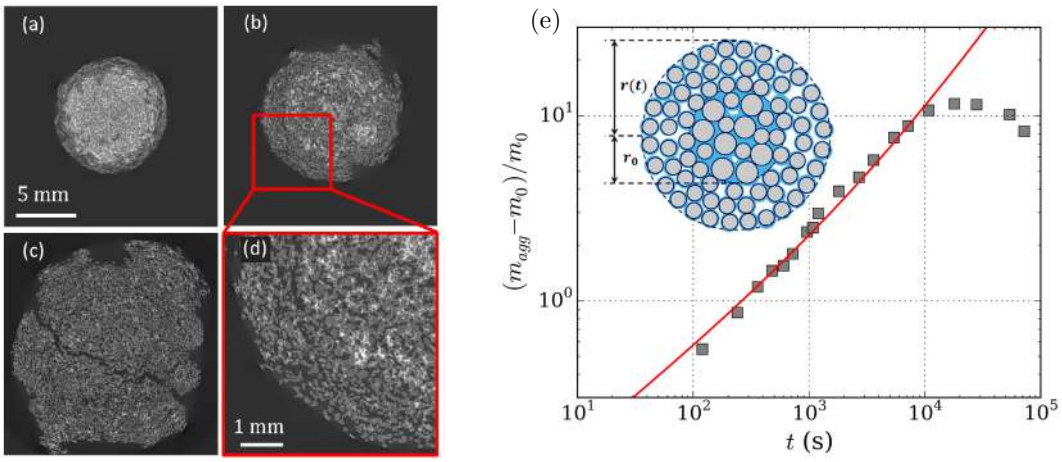

Figure 2: Section of X-ray tomography of aggregates of sand grains at (a) $t = 0$ s, (b) $t = 100$, s, (c) $t = 360$, s and (d) magnification showing the spreading of the liquid. The light area corresponds to the liquid. (e) Time evolution of the mass of the glycerol/sand aggregate (square) and the prediction of the model (line).

CONCLUSIONS

In this study, we characterized the growth of an aggregate, initially saturated in liquid, in a gentle granular flow. We have shown that a shell of smaller grains develops around the core made of larger grains and drives the liquid outside under the effect of capillary pressure. We also presented a model capturing the growth dynamics.

Summary Periodic porous plates are a particular type of phononic crystals with structural periodicity, featuring interesting bandgap properties due to the Bragg scattering mechanism. Such porous plates will be further endowed with mechanical tunability when they are made from soft materials. In this work, we focus on two geometric configurations, and show the feasibility to manipulate waves propagating in the periodic porous plate by different means. The first one we examine is a soft plate with arrays of criss-crossed elliptical holes, which takes the buckled configuration of the plate with arrays of circular holes as its initial configuration. We show numerically and experimentally that the wave propagation behaviour can be robustly tuned by tension. The other one is a soft plate with arrays of circular holes, for which we propose to insert hard inclusions into the holes to tune the deformation and wave propagation. Through numerical simulation and experimental study, it is firmly demonstrated that, inserting inclusions into the holes could be a very convenient and also powerful way for manipulating waves in the soft porous plate.

INTRODUCTION

Phononic crystals (PCs) have been a common hot topic in different disciplines including physics, mechanics, materials, devices, etc. for almost 30 years. The particular bandgap properties in PCs induced by Bragg scattering associated with structural periodicity make them perfect candidates for many novel and useful acoustic devices. Bandgap, a frequency range in which waves are prohibited to propagate through the medium, can also be generated by another mechanism, i.e. the local resonance. Materials with local resonant units, which may be arranged in an aperiodic way, are now called metamaterials (MMs). Most of the earlier studies focus on PCs/MMs with a fixed geometry, attempting to find a wide bandgap with a low mid frequency [1].

In 2001, Goffaux and Vigneron suggested to rotate the solid scatterers in an air/solid PC system to tune the bandgaps [2]. Since then, many different ways have been proposed to acquire tunable PnCs/MMs, such as making use of the multifield coupling effects. As regards mechanical means, either prestress or large deformation has been adopted to tune the bandgaps. In particular, Bertoldi and Boyce [3] showed that a soft porous plate with arrays of circular holes in a square pattern will buckle under compression, and the following large postbuckling deformation will greatly affect the bandgap properties.

In this study, we pay our attention to two cases of soft porous plate. In the first case, the soft plate is perforated with arrays of criss-crossed elliptical holes. This topology is identical to the buckled configuration of a soft plate with arrays of circular holes in Ref. [3]. In the second case, we simply consider the same soft porous plate as in Ref. [3], with its holes however possibly inlayed with hard inclusions in a particular filling pattern. Both numerical and experimental investigations are carried out to explore the tunability of wave propagation in these two soft porous plates.

LARGE DEFORMATION AND WAVE PROPAGATION ANALYSES

The soft materials, which can undergo reversible large deformation, are assumed to obey a hyperelastic constitutive law. In this case, the first Piola-Kirchhoff stress tensor $\mathbf{T}$ can be calculated from a strain energy density function $\Omega(\mathbf{F})$ as $\mathbf{T}=\partial\Omega(\mathbf{F})/\partial\mathbf{F}$, with $\mathbf{F}$ being the deformation gradient. We need to carry out the large deformation analysis within the general framework of nonlinear elasticity [4]. For the infinitesimal wave motion superimposed on the pre-deformation, we shall linearize all the governing equations and perform the analysis based on the following linear incremental equations:

$$\mathrm{div}\,\dot{\mathbf{T}}_0 = \rho\partial^2\boldsymbol{u}/\partial t^2 \tag{1}$$

where $\boldsymbol{u}$ is the incremental displacement vector, and the incremental Piola-Kirchhoff stress tensor $\dot{\mathbf{T}}_0 = \boldsymbol{\mathcal{A}}_0 : \mathrm{grad}(\boldsymbol{u})$, with $\boldsymbol{\mathcal{A}}_0$ being the fourth-order effective or instantaneous elastic moduli tensor, which depends on the pre-deformation [4]. Hence, the pre-deformation not only changes the geometry of the structure, but also alters the effective material properties.

For the problems of static large deformation and linear wave propagation, we carry out the finite element modeling based on ABAQUS with respect to either a unit cell or a porous plate of finite size. When a unit cell is employed, we shall impose the Bloch conditions on the boundaries of the unit cell in the wave propagation analysis.

EXPERIMENTS

Shown in Figure 1 is the experimental setup for the soft porous plate with criss-crossed elliptical holes. The plate is first subjected to a uniaxial tension using a very simple machine, and then the wave propagation test is conducted using an electrodynamic shaker to input a plane-wave harmonic force.

Figure 2 indicates the experimental setup for wave propagation test of the soft porous plate with inserted hard inclusions. To reduce the effects of gravity on the in-plane deformation and the in-plane wave propagation, the sample is laid on the metal block. To increase the contact area between the shaker and the sample so as to generate a uniform in-plane wave as far as possible, a PLA (Polylactic acid) block is placed between the shaker and the sample. On the receiving end of the sample, a thin PTFE (Polytetrafluorethylene) block is stuck onto the sample.

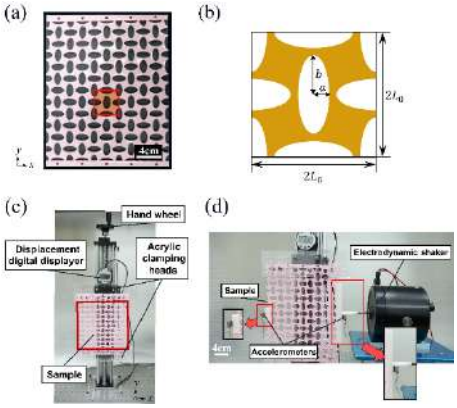

Figure 1. (a) Sample; (b) RVE of (a); (c) Uniaxial tension test; (d) Wave propagation test.

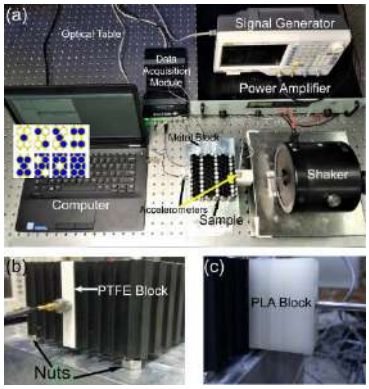

Figure 2. (a) Picture of the experiment; (b) PTFE block; (c) PLA block.

RESULTS

Typical results are given in Figures 2 and 3 for the soft porous plate with criss-crossed elliptical holes subjected to uniaxial tension [5] and for the soft porous plate with its circular holes inserted by hard inclusions in one row in a unit cell (see the specimen in Figure 2(a); different filling patterns are also shown there) [6]. It is seen that both tension and inserting hard inclusions can tune the wave propagation behaviour in soft porous plates effectively. Also, if the theoretical model is appropriate, then the numerical results agree quite well with the experimental observations.

TRANSITION FROM BENDING-DOMINATED TO STRETCHING-DOMINATED BEHAVIOUR IN TWO-DIMENSIONAL NETWORKS

Harika C. Tankasala * [1], Vikram S. Deshpande[1], and Norman A. Fleck[1]
[1]Department of Engineering, University of Cambridge, Cambridge CB2 1PZ, United Kingdom

Summary The transition in macroscopic response from a compliant, bending-dominated mode to that of a stiff, stretching-dominated mode is explored numerically for two choices of two-dimensional networks: (i) a two-phase regular hexagonal network in-filled with a soft matrix and (ii) a random long fibre network. The effective elastic modulus of these networks is probed under uniaxial tension. It is found that the presence of an infill promotes stretching of the cell walls of the otherwise bending-dominated hexagonal network. In the case of random fibre network, it is the relative depth of the boundary layer to the specimen size that dictates the network stiffness.

INTRODUCTION

It is commonly argued that the existence of a continuous force chain in discrete networks ensures that the macroscopic response is affine. This assumption has formed the basis of several analytical models of biological short fibre networks (such as the actin microstructure in cytosketelon [1]) and long fibre engineering composites [2]. Here, we show that a switch from non-affine to affine response can be achieved by suitable choice of material properties and network geometry.

PROBLEM STATEMENT

A regular hexagonal network and a typical realization of a long fibre random network are both shown in Table 1; the relevant geometric parameters are identified for each case. Boundary conditions to simulate uniaxial tensile loading (in the x_2 direction) of the two networks are summarized in Table 1, along with the choices of material properties and constraints for the overlapping fibres (for the random network).

	Regular hexagonal network	**Random long fibre network**
Geometry		Material properties	Elastic cell wall and elastic infill	Elastic fibres
Fibre-to-fibre constraint	Rigid joint	Two sets of constraints assumed: (i) Rotating joint, $k_u = \infty, k_\theta = 0$ (ii) Rigid joint, $k_u = k_\theta = \infty$
Boundary conditions	Periodic displacements imposed on the boundary of the unit cell: $\Delta u_i = \varepsilon_{ij}^{\infty} \Delta x_j$ with only $\varepsilon_{22}^{\infty}$ specified. (Here $\varepsilon_{ij}^{\infty}$ is the macroscopic nominal strain tensor.)	Three classes considered: **A** Affine displacements prescribed on the boundary: $u_i = \varepsilon_{ij}^{\infty} x_j$ with only $\varepsilon_{22}^{\infty}$ specified. **B** Simple tension test with $u_2 = \varepsilon_{22}^{\infty} w$ prescribed on the top edge; sliding of the top and bottom edges, and lateral contraction of the specimen allowed. **C** Tractions prescribed on the top and bottom edges.

Table 1: Geometry of the networks, assumed material properties, and boundary conditions to simulate uniaxial tensile loading.

The elastic modulus of the cell walls (and fibres) is denoted by E_S. For the hexagonal network, the modulus E_I of the infill is varied between $10^{-4} E_S$ and $0.1 E_S$. Realizations with different number of fibres n are considered for the random network. The effective network modulus E is predicted for varying cell wall (or fibre) volume fraction $\overline{\rho}$ expressed as

$$\overline{\rho} = \frac{2}{\sqrt{3}} \frac{t}{\ell} - \frac{1}{3} \left(\frac{t}{\ell} \right)^2 \text{ for the hexagonal network, and } \overline{\rho} = \frac{t \sum_{i=1}^{n} \ell^{(i)}}{w^2} \text{ for the random network}$$

The relative extent of stretching versus bending in the stiff phase is quantified by the ratio $\phi := W_S / (W_S + W_B)$ where W_S and W_B are the elastic strain energy contributions from axial stretching and bending of the cell walls, respectively. For the random network, we define ϕ for each Gauss point along the fibres. For the hexagonal network, W_S and W_B are the quantities summed over all Gauss points of the lattice phase.

RESULTS AND CONCLUSIONS

Infill promotes cell wall stretching in a regular hexagonal network

A transition from non-affine (i.e. bending-dominated) response to an affine (i.e. stretching-dominated) response of the honeycomb composite is observed with (i) increasing cell wall volume fraction $\overline{\rho}$ for a given infill-to-solid modulus ratio $E_\mathrm{I}/E_\mathrm{S}$, and with (ii) increasing $E_\mathrm{I}/E_\mathrm{S}$ for a given $\overline{\rho}$, see Fig. 1. The mechanical constraint provided by the stiff infill promotes stretching of the cell walls, as seen from the evolution of ϕ with $E_\mathrm{I}/E_\mathrm{S}$ in Fig. 1(a). Likewise, a larger cell wall volume fraction (and thereby a larger t/ℓ) results in an affine response even when the infill is of extremely low stiffness such as $E_\mathrm{I}/E_\mathrm{S} = 10^{-4}$, as shown in Fig. 1(b).

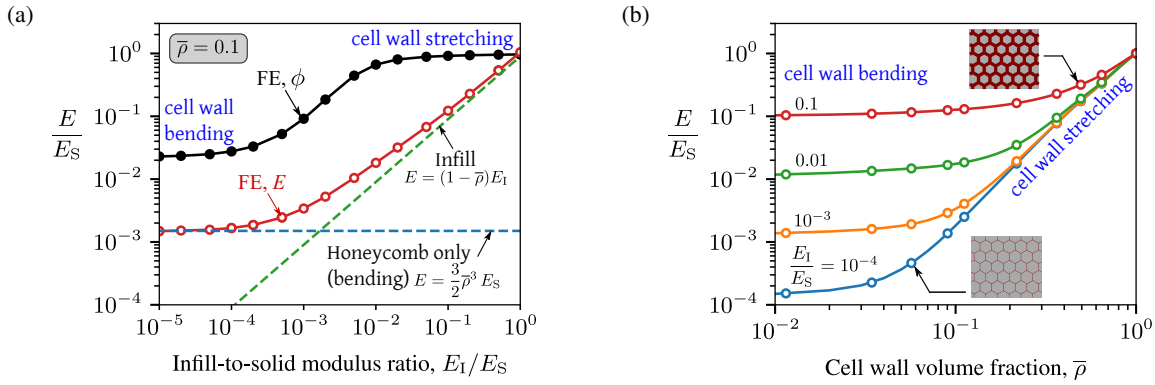

Figure 1: Modulus of the honeycomb composite E as a function of **(a)** infill-to-solid modulus ratio, and **(b)** cell wall volume fraction.

'Structural' non-affine response versus 'material' affine response of a random network

Boundary condition (BC) A gives the Voigt upper bound of the network modulus as $E = (1/3)\overline{\rho}E_\mathrm{S}$, consistent with uniform stretching of all the fibres in the network. BC C corresponds to the Reuss lower bound and is characterised by the bending of fibres such that $E \propto \overline{\rho}^3 E_\mathrm{S}$, see Fig. 2(a). Under simple tension, BC B, the network response switches from a non-affine mode at low $\overline{\rho}$ to an affine mode at high $\overline{\rho}$. This transition correlates with the depth of the compliant boundary layer at the free edges, λ. Denote $\overline{\rho}_\mathrm{T}$ as the transition value of $\overline{\rho}$ such that $E/E_\mathrm{S} = c_1(n)\overline{\rho}_\mathrm{T}^3 = c_2(n)\overline{\rho}_\mathrm{T}$, and $\overline{\ell}_C$ as the mean cross-link spacing of a network. We find from Fig. 2(b)-(d) that at transition, $\lambda \approx w/4 \approx \overline{\ell}_\mathrm{C}/\sqrt{\overline{\rho}_\mathrm{T}}$. The network modulus thus asymptotes between the boundary layer-governed non-affine value and the affine material response.

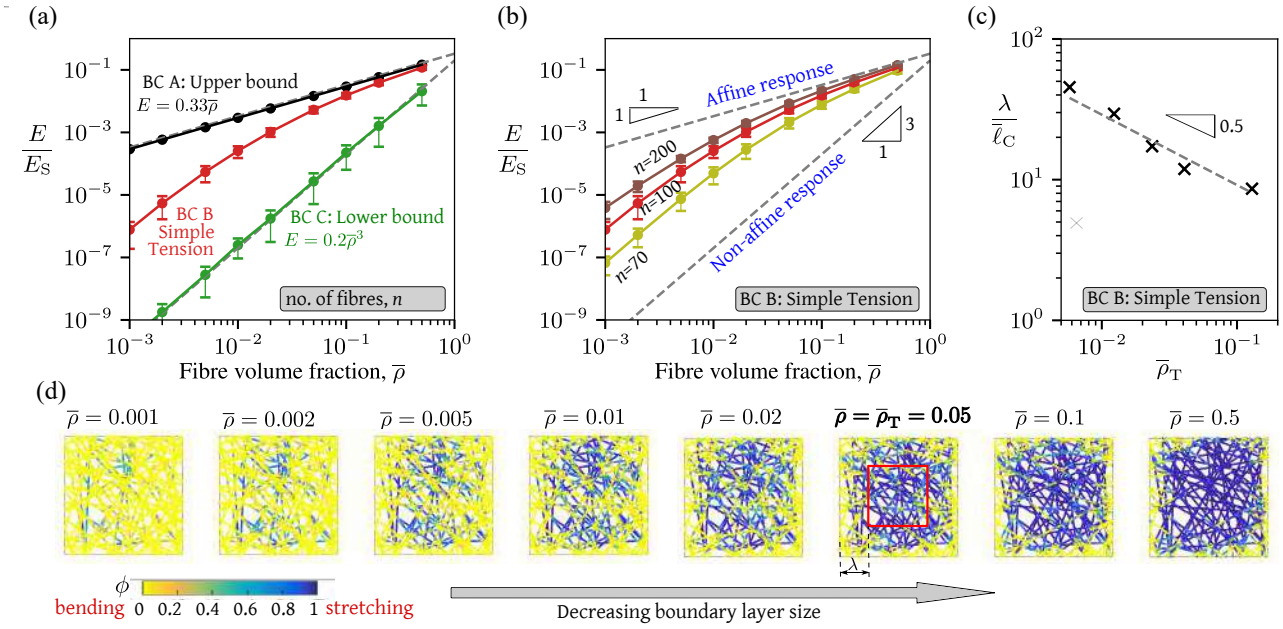

Figure 2: Network modulus E as a function of fibre volume fraction (assuming rotating joints) for **(a)** $n = 100$ and all BCs and **(b)** simple tension BC. The error bars show scatter in E over 20 realizations. **(c)** Depth of the boundary layer λ at transition volume fraction $\overline{\rho}_\mathrm{T}$, and **(d)** contours of ϕ for one realization of $n = 70$: $\phi = 0$ indicates pure bending while $\phi = 1$ indicates pure stretching.

A NEW PARAMETER TO CONTROL THE ANISOTROPY OF PRISMATIC LATTICES

Anastasia Markou and Luc St-Pierre *
Department of Mechanical Engineering, Aalto University, Espoo, Finland

Summary Prismatic lattices, such as the triangular and kagome topologies, have a high specific stiffness and strength. Their in-plane properties are, however, nearly isotropic, which is suboptimal when loading is orientated along a specific direction. Here, we introduce a new parameter to control the degree of anisotropy of a prismatic lattice. This new parameter is the thickness ratio $\bar{t} = t_1/t_2$, where t_1 and t_2 are the thicknesses of bars along different directions. Using the triangular lattice as an example, we have developed new analytical expressions to capture how the elastic modulus and compressive strength vary as a function of this new parameter $\bar{t}$. These equations were then verified by finite element simulations, and found to be in good agreement with experiments performed on 3D printed polymeric lattices.

INTRODUCTION

Lattice materials are among the stiffest and strongest lightweight materials available today. They also possess a unique advantage over fully-dense materials: their mechanical properties can be adjusted by changing their relative density (for a given choice of topology and parent material) [1, 2]. This level of customisation has, however, certain limitations: changing the relative density modifies the density of the lattice and it does not allow to vary the properties along specific loading directions. We propose to alleviate these issues by varying the thickness of the bars along the two in-plane directions of a prismatic lattice, see Fig. 1a. This introduces a new parameter, $\bar{t} = t_1/t_2$, that can be used to control the degree of anisotropy. Considering the triangular lattice as an example, we first derive analytical equations to capture the effect of this new parameter $\bar{t}$ on the elastic modulus and strength of the lattice. These analytical expressions are then verified using finite element simulations and experiments.

ANALYTICAL MODELLING

Consider the triangular lattice shown in Fig. 1a, where the horizontal bars have a thickness t_1 and the diagonal bars, a thickness t_2. All bars have a length l, and are assumed to be made from an elastic perfectly plastic material with a Young's modulus E_s and a yield strength σ_{ys}. Following the same approach used in [1, 2], the elastic modulus of the lattice along x_1 and x_2 can be expressed as:

$$E_1 = \left[\frac{\bar{t}}{\bar{t}+2}\right]\bar{\rho}E_s \qquad \text{and} \qquad E_2 = \frac{9\bar{t}}{(8\bar{t}+1)(\bar{t}+2)}\bar{\rho}E_s, \tag{1}$$

respectively, where the bar thickness ratio $\bar{t} = t_1/t_2$, and the relative density $\bar{\rho} = 2\sqrt{3}(t_1+2t_2)/(3l)$.

When the lattice is compressed, two collapse modes are possible: (i) elastic buckling or (ii) yielding. Elastic buckling occurs when the internal force in a bar reaches the Euler buckling load. With this condition, we find that the elastic buckling strength of the lattice for uniaxial compression along x_1 or x_2 is given by:

$$\sigma_{1,el} = \frac{n^2\pi^2}{16}\left[\frac{\bar{t}}{\bar{t}+2}\right]^3\bar{\rho}^3E_s \qquad \text{and} \qquad \sigma_{2,el} = \frac{3n^2\pi^2}{32}\left[\frac{1}{\bar{t}+2}\right]^3\bar{\rho}^3E_s, \tag{2}$$

respectively. Note that the end constraint factor n varies between 1 and 2 depending on the value of $\bar{t}$. We found the value of n with the method presented in [3, 4], but the procedure is not given here for the sake of brevity.

For high values of relative density, the lattice is expected to collapse by yielding (when the stress in a bar reaches the yield strength of the parent material σ_{ys}). The yield strength of the lattice along x_1 and x_2 directions can be expressed as:

$$\sigma_{1,pl} = \left[\frac{\bar{t}}{\bar{t}+2}\right]\bar{\rho}\sigma_{ys} \qquad \text{and} \qquad \sigma_{2,pl} = \min\left[\frac{3\bar{t}}{(\bar{t}+2)}\bar{\rho}\sigma_{ys}\ ;\ \frac{3}{2(\bar{t}+2)}\bar{\rho}\sigma_{ys}\right], \tag{3}$$

respectively. The expression for $\sigma_{2,pl}$ includes the minimum function because yielding may occur in the horizontal or diagonal bar depending on the value of $\bar{t}$.

RESULTS

The elastic modulus, elastic buckling strength, and yield strength of the lattice are plotted as a function of $\bar{t}$ in Fig. 1b, c, and d, respectively. In all cases, results are given in a non-dimensional form and for both x_1 and x_2 directions.

The results show clearly how $\bar{t}$ can be used to control the degree of anisotropy of the lattice; increasing $\bar{t}$ increases the elastic modulus and strength along x_1, but reduces these properties along x_2. Note, however, that E_1 increases more rapidly than E_2 decreases for $\bar{t} > 0.5$. For example, compare the elastic moduli of a lattice with $\bar{t} = 3$ to those of a conventional lattice with $\bar{t} = 1$. The topology with $\bar{t} = 3$ has a modulus E_1 80% higher than that with $\bar{t} = 1$, whereas the reduction in E_2 is of only 35%. Therefore, the trade-off between E_1 and E_2 can be advantageous. Similar arguments can be made for the elastic buckling and yield strength.

*Corresponding author. E-mail: luc.st-pierre@aalto.fi.

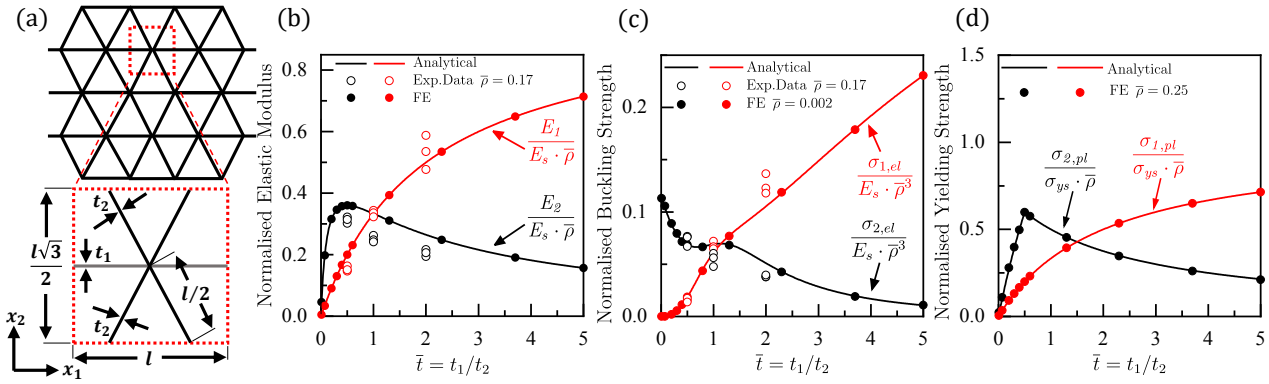

Figure 1: (a) Geometry of the triangular lattice, and its in-plane properties: (b) elastic modulus, (c) elastic buckling strength and (d) yield strength. All properties are given in non-dimensional form, for uniaxial compression along x_1 and x_2 directions, and as a function of the bar thickness ratio $\bar{t}$.

Comparison with finite element simulations

Finite element (FE) simulations were performed to validate the analytical expressions presented above. All simulations were conducted with the implicit solver of the commercial software Abaqus. The calculations were done on a representative unit cell with periodic boundary conditions, and a compressive displacement was prescribed in either x_1 or x_2. Each bar was discretised using 30 beam elements and a geometric imperfection (in the shape of the first eigenvalue and with an amplitude equal to 5% of the bar thickness expected to buckle) was used in all simulations. The material was linear elastic and perfectly plastic, with $E_s = 200\,\text{GPa}$ and $\sigma_{ys} = 250\,\text{MPa}$. Simulations were performed for selected values of $\bar{t}$ ranging from 0.01 to 5, and for two values of relative density $\bar{\rho} = 0.002$ and 0.25. These were selected such that lattices with $\bar{\rho} = 0.002$ collapse by elastic buckling, and those with $\bar{\rho} = 0.25$ fail by yielding.

The elastic modulus, elastic buckling strength and yield strength obtained from FE simulations are compared to our analytical equations in Fig. 1 for both loading directions. In all cases, there is an excellent agreement between FE and analytical results, and this holds true for all values of $\bar{t}$ considered here.

Comparison with experiments

Polymer lattices were produced by additive manufacturing. All samples were made using a Form 2 machine and Clear resin, both provided by Formlabs. Tensile tests, performed on standard dogbone specimens, revealed that the parent material has a Young's modulus $E_s = 2.4\,\text{GPa}$ and a yield strength $\sigma_{ys} = 41\,\text{MPa}$. The lattices manufactured had a bar length $l = 10\,\text{mm}$ with 15 cells along the x_1 direction and 8 cells along x_2 (see Fig. 1a). The relative density was kept constant at $\bar{\rho} = 0.17$, whereas t_1 and t_2 were varied to produce samples with $\bar{t} = 0.5$, 1, and 2.

Compression tests were conducted in both x_1 and x_2 directions. The measured elastic moduli E_1 and E_2 were found to be in reasonable agreement with our analytical predictions as shown in Fig. 1b. For this choice of material and relative density, all specimens collapsed by elastic buckling. The measured compressive strength, along both directions, were also in good agreement with our analytical predictions, see Fig. 1c.

CONCLUDING REMARKS

Prismatic lattices with different bar thicknesses have a significant advantage over those with uniform cell walls: their mechanical properties do not depend only upon their relative density $\bar{\rho}$, but also upon the bar thickness ratio $\bar{t}$. This new parameter $\bar{t}$ allows to control the degree of anisotropy, giving more flexibility to create new materials by design. This concept, demonstrated here with the triangular lattice, is applicable to other topologies and we have extended our investigation to kagome and hexagonal lattices.

Summary Here we report a combined experimental and numerical study for the fracture of micro-architected cellular solids and develop rules for fracture limited design. We investigated embedded crack geometries resembling penny shape cracks fabricated into specimens with millions of unit cells. Multi-axial loading experiments were conducted in an in-situ X-Ray CT visualisation procedure to monitor the crack tip conditions. These investigations reveal two distinct crack-tip failure modes that are also predicted in full scale FE analysis. Remarkably, fracture for both modes is found to be only function of the remote applied K and T fields. Thus, a simple two-parameter fracture model (K+T) can be adopted for fracture limited engineering design of this emerging class of materials.

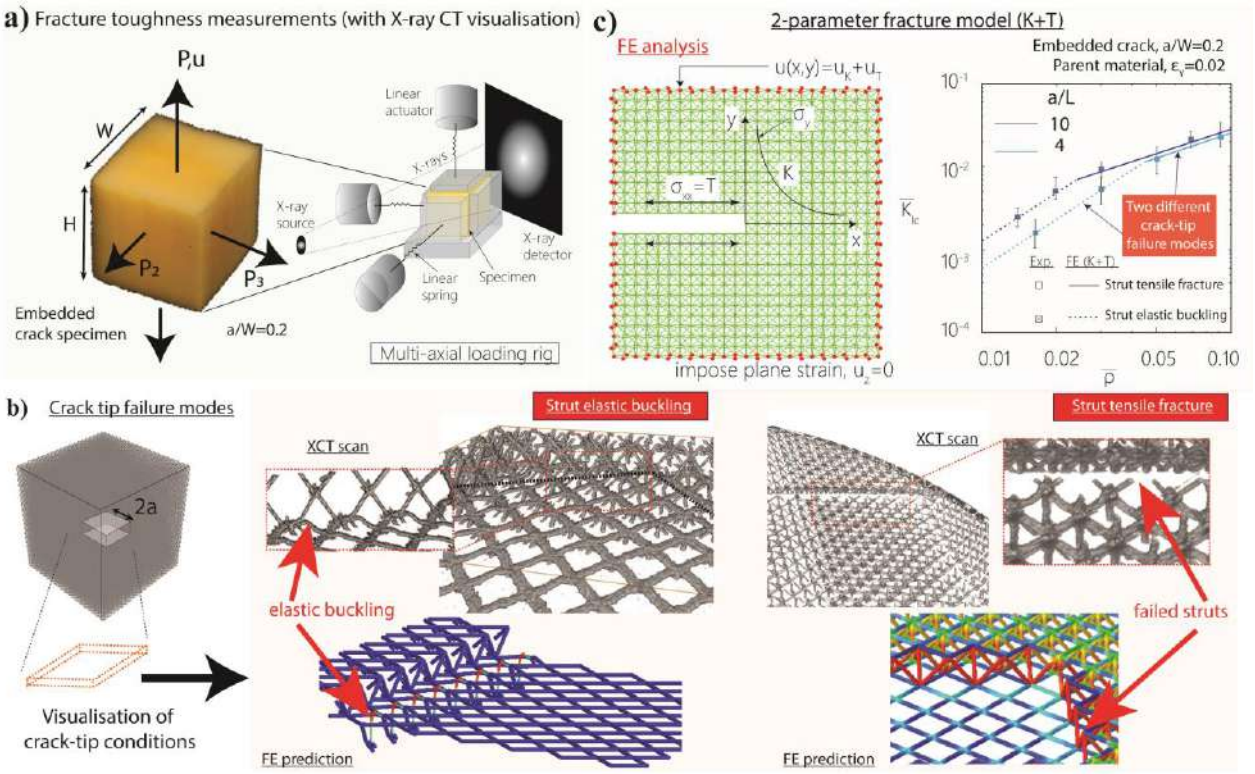

Fig. 1. Fracture toughness of micro-architected cellular solids. (a) Measurement of mode I fracture toughness of the octet truss lattice specimens with an embedded crack (akin to penny shaped crack). The number of unit cells in our specimens ranged from tens of thousands to one million. Specimens with different relative densities (between 0.02 to 0.15) and crack sizes (a/L varied between 4 to 10, where 'a' is crack length and 'L' is unit cell size) were tested in triaxial loadings to understand the significance of crack size effect on toughness. **(b)** Two distinct crack-tip failure modes set the definition of toughness- "elastic buckling" or "tensile yielding" of the crack tip struts. These are captured in FE predictions as well as observed in X-ray CT scans. **(c)** Measured fracture toughness values are in excellent agreement with that predicted from linear elastic FE calculations. Toughness for low density lattices made from soft polymeric materials are knocked down by nearly an order of magnitude in the elastic buckling failure regime. An asymptotic K+T field can generate the same results to show that a simple two parameter (K+T) fracture model can be used to predict failure.

INTRODUCTION

Designing materials as multiscale architected structures has resulted in creation of metamaterials whose properties can be optimised for a plethora of engineering applications. In particular, nano and micro-scale architected cellular materials exhibit properties like enhanced strength, ductility and fracture tolerance [1]. With recent advancements in additive manufacturing techniques such as projection micro-stereolithography [2-4], 3-D micro-architected solids can now be manufactured with 100s of millions of unit cells facilitating a wide spectrum of applications like biomedical implants, nanophotonic devices, energy

*Corresponding author. E-mail:ajds3@cam.ac.uk

storages and even textiles. It is thus important to understand their failure behaviour, or more precisely prescribe failure limits in the presence of flaws. There is a paucity of fracture data in the literature for these materials with data limited to specimens with a few cells [5]. It remains unclear whether traditional fracture mechanics can be applied to this new class of materials. Here we address the question- 'Is fracture toughness a material property for micro-architected solids?'

METHODOLOGY

We began our investigation with a series of mode I fracture toughness measurements on the embedded crack geometry **(Fig. 1a, left)**. To perform valid fracture toughness measurements, the number of unit cells in the truss was increased from a few hundreds of thousands to an excess of one million. To monitor the crack tip condition, experiments were conducted on a custom-built multiaxial loading setup placed inside the X-Ray CT machine **(Fig. 1a, right)**. We developed a procedure to perform in-situ experiments and continuously observed the crack tip conditions in 3D tomographic images while simultaneously measuring the applied loads. Measurements were performed over a wide range of lattice relative densities and loading biaxiality ratios. On the computation side, full scale linear elastic FE calculations were performed to predict the crack-tip failure modes and fracture toughness values**.**

RESULTS

- We found that two modes of failure dictate toughness: (i) tensile strut fracture (ii) strut elastic buckling, even though the remote loading is tensile **(Fig. 1b)**.
- For a given material, these failure modes and toughness values are shown to depend on lattice relative density, biaxiality and normalised crack size (a/L). Thus, toughness can't be defined as a material property using a single parameter K. **(Fig.1c)**
- Interestingly, crack size and loading triaxiality can collapse into a single parameter that is uniquely captured by the "T-stress". Experiments to validate such claim required complicated testing in triaxial loadings and the experimental results are seen to agree with our FE calculations. Thus, a two-parameter (K+T) model can accurately predict toughness values and crack-tip failure modes. This leads to the path for development of failure maps for the fracture limited design of micro-architected cellular solids **(Fig. 2)**.

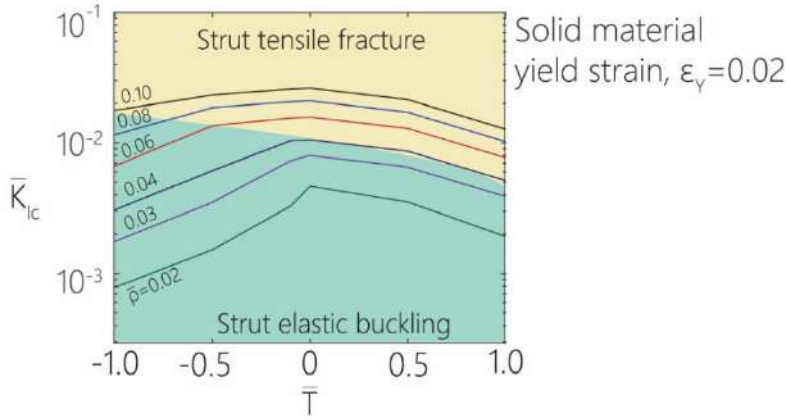

Fig. 2. Design map of failure for the Octet-truss lattice. Contours of the octet truss relative density are shown using axes of normalised toughness, $\overline{K_{Ic}}$ and normalised T-stress, $\bar{T}$.

CONCLUSIONS

In the present study we conclude that fracture toughness can be defined as a material property for micro-architected solids when represented as a 2-parameter (K+T) fracture model. The combined experimental and numerical investigation shows presence of two distinct crack-tip failure modes (strut elastic buckling and strut tensile fracture) across a range of relative densities and applied loading triaxialities. Thus, classical fracture mechanics developed for continuum solids can now be extended to micro-architected solids with the exception that "T-stress" is significant in these solids. Failure maps are generated to aid designing with micro-architected solids.

GAS MARBLES: STRENGTH AND GAS PERMEABILITY

Yousra TIMOUNAY[1], Elise LORENCEAU[2], Olivier PITOIS[1], and Florence ROUYER *[1]
[1] Lab Navier, Univ Gustave Eiffel, ENPC, CNRS, F-77454 Marne-la-Vallée, France
[2]Univ. Grenoble Alpes, CNRS, LIPhy, F-38000 Grenoble, France

Summary Introducing solid particles into liquid films drastically changes their properties. Here we demonstrate that the concept of liquid marbles (liquid droplets enwrapped with hydrophobic particles) can be successfully applied for encapsulating and protecting small gas pockets within an air environment. Similarly, to their liquid counterparts, those new soft-matter objects, that we call "gas marbles" can sustain underpressure but the collapse pressure is ten times larger. Moreover, they can resist overpressure. This magnified strength is shown to originate from the strong cohesive nature of the shell. Yet, gas marbles can undergo gas transfer. Our results show that particulate films are less permeable to gas than their pure liquid counterparts because presence of the particles reduces the surface area through which gas diffuses.

INTRODUCTION

In line with the pioneer work of Pickering, we succeeded to produce new objects which can be described as gas pockets in air and are named gas marbles [1]. They are made of gas surrounded by a layer of grains constrained by thin liquid film in gas environment. The exceptional mechanical strength of their granular shell promise them to many applications [2] as the generation of materials with hierarchical porosity as well as gas encapsulation.

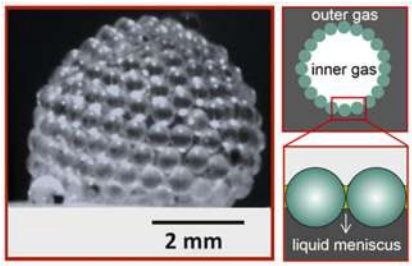

Figure 1. The so-called gas marble elaborated and studied in this work. (a) Image of a gas marble (D_p=590µm and D_b=5mm). (b) Sketch of the cross section revealing the structure of the cohesive granular shell.

MATERIAL and EXPERIMENTAL SET-UP

Gas marbles are created from a granular film by closing over itself after detachment under gravity. The granular film is created by dipping and removing a solid horizontal frame through a particle raft at the interface of a soap solution. The particles are monodisperse polystyrene beads which diameter D_p varies from 140 to 590 µm. The soap solution is a SDS solution at the cmc.

Inserting a needle, connected to a syringe and a pressure sensor, inside the gas marble allows us to study its behaviour during inflation and deflation. The inner pressure P_b is measured by the pressure sensor, and, thanks to a syringe pump, the volume of the syringe is controlled. Increasing the syringe volume results in a decrease of the gas marble inner pressure P_b, and vice versa. Volume variations are performed at a constant flow rate equal to 0.06ml/min during all of our experiments. The inner pressure relative to atmospheric pressure $\Delta P = P_b - P_{atm}$, as a function of the variation of the syringe volume ΔV is recorded while two cameras placed above and on the side allow us to follow the evolution of the shape of gas marbles.

STRENGTH of GAS MARBLES

The strength of gas marbles is characterized by the critical $\Delta P+$ at which the shell fractures (figure 2 top right) and the critical $\Delta P-$ at which the gas marble collapses (figure 2 bottom right). As shown in figure 2 (left), in absolute values these critical pressures are of one order of magnitude larger than the capillary pressure of particle free bubbles. Moreover, $\Delta P-$ and $\Delta P+$ are independent of particle and gas marble size in the range of study. This magnified strength is shown to originate from the strong cohesive nature of the shell.

AIR PERMEABILITY of GAS MARBLES MEMBRANES

To characterize the permeability of gas marble shell, we first increase the inner pressure of gas marbles by a few millibars ($\Delta P < \Delta P+$). Then, we follow the spontaneous evolution of the inner pressure. Figure 3 shows an example of the pressure inside a gas marble relative to the atmospheric pressure $\Delta P = P - Patm$ as a function of time. Considering

*Corresponding author. E-mail: florence.rouyer@u-pem.fr

ideal gas law and gas diffusion though the membrane, one can model the exponential decay of the inner pressure with a characteristic time $\tau = {}^{V}/_{kA}$ where V is the volume of gas inside the marbles, and A and k are respectively the surface and gas permeability of the shell. Experiments with gas marbles of different size and particle sizes show that k is of the order of 0.7 mm/s. One order of magnitude smaller the permeability of a soap bubble. The reduction of gas flow is associated to the area of liquid film reduction due to the hexagonal packing of the spherical particles forming the shell.

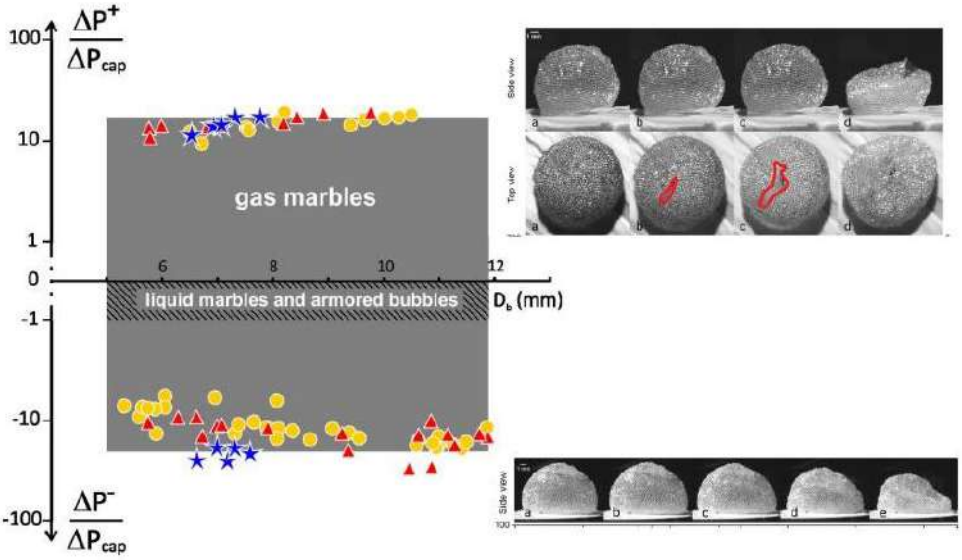

Figure 2. Normalized critical overpressures (ΔP+/ΔPcap) and underpressures (ΔP-/ΔPcap) measured for gas marbles within both inflation and deflation conditions, respectively, as a function of bubble diameter Db. Triangles, stars and circles are data respectively obtained for particles D_p= 250 µm, 315 µm and 590 µm. Laplace pressure ΔPcap= 8γ/D_b is the pressure at equilibrium of the corresponding particle-free bubbles with two interfaces. The stability range of gas marbles is between the two horizontal dashed lines. The images on the right, are successive side and top views during fracturing its granular shell ΔP> ΔP+ (top) and side view of a gas marble after collapsing ΔP< ΔP- (bottom).

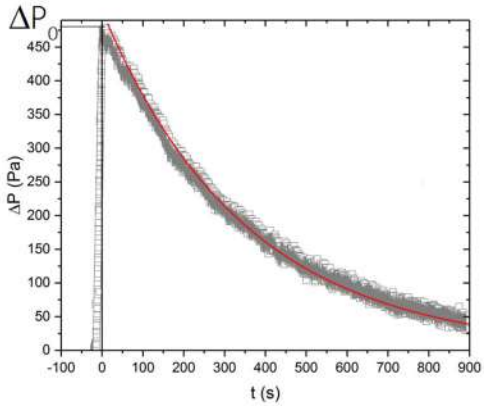

Figure 3. Relative pressure inside a gas marble as a function of time with D_P = 250 µm. The red curve is as fit of the form$\Delta P = \Delta P_0 e^{-t/\tau}$ to the experimental data.

CONCLUSIONS

The strength and low permeability of gas marbles compared to pickering or bare bubbles could be exploited for imprisoning valuable or polluted gases or for designing new aerated materials. Indeed, encapsulation via a liquid membrane - always partially permeable to gases - is metastable and limited by osmotic or capillary gas flows entering or leaving the bubble. The low permeability of the particulate membranes, which ensures slower inflation or deflation of the particle-laden containers, as well as the remarkable strength of the gas marbles' membranes compared to those of pickering bubbles, both ensure a longer lifetime to the gas marbles compared to bare and pickering bubbles. It is therefore the combination of these two properties that makes gas marble an ideal candidate for gas encapsulation.

LIGHTWEIGHT AND ULTRA-STRONG PYROLYTIC CARBON NANOLATTICES AND MICROPILLARS

Xuan Zhang[1], Huajian Gao[2], Julia R. Greer[3] and Xiaoyan L*[1]
[1]Centre for Advanced Mechanics and Materials, Applied Mechanic Laboratory, Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China
[2]School of Mechanical and Aerospace Engineering, College of Engineering, Nanyang Technological University, 70 Nanyang Drive, Singapore 639798, Singapore
[3]Division of Engineering and Applied Science, California Institute of Technology, Pasadena, CA, USA

Summary Designing and synthesizing materials that are simultaneously strong and stiff, substantially deformable, and lightweight remains a long-standing and unsolved challenge. Here we fabricated pyrolytic carbon nanolattices and micropillars by a two-step procedure: 3D printing and high-temperature pyrolysis. The pyrolytic carbon nanolattices have a compressive strength of 1.90 GPa at a density of 1.0 g/cm^3, and an average fracture strain of 14.0%-16.7%. The pyrolytic carbon micropillars have an average tensile strength of 1.60 GPa, a compressive strength approaching the theoretical limit of ~13.7 GPa, a substantial elastic limit of 20-30% and a low density of ~1.4 g/cm^3. These unique mechanical properties are attributed to the controlling of characteristic size of materials, and the optimization of structural topology and the selection of constitute materials.

INTRODUCTION

For nearly all structural materials, the trade-offs between high strength and large deformability/ductility and high strength and low density have been recognized as two pairs of inevitable conflicts. For example, metals and alloys are ductile, but their strengths are usually about several hundred MPa. The ceramics have higher strength (up to about several GPa), but their fracture strains are below 5%. Polymers and porous materials like foams are lightweight and deformable, but their strengths are only on the order of ~10 MPa. Existing materials that come close to "optimizing" all three of these properties are Mg alloys, but their ductility is still lower than the requirements of applications for forming and performance of structural components. Designing and synthesizing materials that are simultaneously strong and stiff, substantially deformable (i.e. >10%), and lightweight represents the Holy Grail of materials sciences, and remains a long-standing and unsolved challenge.

PYROLYTIC CARBON NANOLATTICES

We first fabricated pyrolytic carbon nanolattices with stretching-dominated octet- and iso-truss topologies by a two-step procedure: direct laser writing and pyrolysis at high temperature [1]. The unit cells of these nanolattices had the same dimensions of approximately 2 μm, and the diameters of the individual struts in the lattices varied from 261 nm to 679 nm. The smallest characteristic size of the struts approached the limits of resolution of the available three-dimensional lithograph technologies. In situ scanning electron microscopy (SEM) and ex situ compressive testing revealed that these pyrolytic carbon nanolattices have a compressive strength of up to 1.90 GPa at a density below 1.0 g/cm^3. As a result, the pyrolytic carbon nanolattices achieved an exceptional specific strength (i.e., ratio of strength to density) of 1.90 GPa g^{-1} cm3, which is 1-3 orders of magnitude higher than those of nearly all micro/nanolattices reported so far [2,3]. Such specific strength of our nanolattice is about 35% of that (5.60 GPa g^{-1} cm^3) of diamond, which has the highest specific strength of all bulk materials.

Our compression experiments also showed that these octet- and iso-truss nanolattices have the average fracture strains of 14.0% and 16.7%, respectively, which are larger than those of various brittle nanolattices reported previously [1,2]. More remarkably, these nanolattices become insensitive to fabrication-induced defects, allowing them to attain nearly theoretical strength of the constituent material. The combination of ultra-low density, ultra-high strength and specific strength, large fracture strain and flaw insensitivity of these pyrolytic carbon nanolattices are attributed to the miniaturization (nanosized beams) of the overall structure and the optimization of the lattice topology.

PYROLYTIC CARBON MICROPILLARS

We further fabricated a series of pyrolytic carbon micropillars with diameter from 700 nm to 10 μm by using the two-step procedure mentioned above [4]. The atomic-level microstructural characterization showed that these pyrolytic carbon specimens consist of 1-1.5 nm curved graphene layers. The experimental measurements showed the overall density of micro-sized pyrolytic carbon to be 1.4 g/cm^3, which is close to those of some polymers. In-situ SEM nanomechanical experiments revealed an average tensile strength of up to ~1.6 GPa and a compressive strength approaching theoretical limit of 13.7 GPa, with an ultra-large elastic limit of 20-30%. The combination of close-to-theoretical strength and low density of these micron-sized pyrolytic carbon samples points to their ultra-high specific strength of 9.79 GPa cm^3/g, which surpasses the specific strengths of all existing structural materials, including polycrystalline diamond, which has the highest specific strength of ~5.61 GPa cm^3/g in bulk materials reported to date.

*Corresponding author. E-mail: xiaoyanlithu@tsinghua.edu.cn.

Further, pyrolytic carbon samples with diameters below 2.3 μm sustained compressive strains that exceed 50% without catastrophic fracture, deforming like rubber. Large-scale atomistic simulations uncovered the underlying deformation mechanisms, i.e. the compressive deformation is dominated by slipping/shear of the graphene layers and densification of the structure, while the tensile deformation is governed by the nucleation, growth and coalescence of nanoscale cavities or by the extension of initial flaws. These mechanisms enable the unexpected combination of low density, substantial deformability, high elastic limit and high strength of micro-sized pyrolytic carbon samples.

CONCLUSIONS

The excellent mechanical properties of pyrolytic carbon nanolattices and micropillars are attributed to the controlling of characteristic size of materials, and the optimization of structural topology and the selection of constitute materials. The results from our current studies provide potential routes for designing and synthesizing new high-performance carbon materials.

CELLULOSE-BASED HIGH-PERFORMANCE FOAM FOR SUSTAINABLE PACKAGING

Teng Li*[1], Shuze Zhu[1], Jian Cheng[1], Liangbing Hu[2], Chaoji Chen[2], Jianwei Song[2]
[1]Department of Mechanical Engineering, University of Maryland, College Park, USA

Summary Most packaging materials are made of plastics, which take 100s years to degrade, leading to severe global pollution. Here, we report a degradable, recyclable, and cost-effective solution to packaging materials based on foam fabricated from graphite and cellulose nanofibers (CNFs) via advanced 3D printing. The CNFs can directly disperse the graphite under the physical sonication without the need for any chemical reaction. The interaction of the CNFs with graphite through the function of the hydrophilic and hydrophobic faces in CNFs renders the dispersion polymer-like rheological properties and a good processability with tunable viscosity for 3D printing. A robust 3D graphite-CNF foam can be printed in large scale, demonstrating a higher mechanical strength, better fire resistance and degradability than commercial packaging foam, representing a sustainable solution to packaging.

BACKGROUND

Packaging materials are in great demand (about 100 million tons per year) in modern society, which are widely used in the food and electronics industries for shock-absorption, storage and heat preservation [1-3]. Most commercial packaging materials are made of plastics such as polystyrene and polyvinyl chloride. These plastics are usually environmentally unfriendly, high-energy consumption, nonrecyclable, and undegradable in the processes of synthesis, molding and disposal, leading to severe environmental issues. Developing environmentally friendly, recyclable, and degradable packaging materials is in urgent need toward a sustainable society.

Natural products are from the nature and most of them are environmentally friendly [4]. Graphite, for example, can be produced from coal formed underground and widely used to produce graphene or as anode materials in rechargeable lithium-ion batteries [5]. Cellulose, as the most abundant natural polymer on earth, has been widely used in a range of applications including energy storage, electronics, structural materials, and water treatment [6].

RESULTS

Here we demonstrate the scalable fabrication of a three-dimensional (3D) graphite-cellulose nanofibers (G-CNF) aerogel as a new generation of cost-effective, environmentally friendly, recyclable, and degradable packaging material via a 3D printing method.

Natural cellulose and graphite are earth abundant, low-cost and accessible, promising large-scale manufacturing. In addition, the G-CNF aerogel can be re-dissolved by water, which makes it recyclable and degradable, representing a sustainable solution to the challenge of white pollution (Figure 1a-c).

As illustrated in Figure 1d, the 3D G-CNF foam with various shapes are 3D printed from the slurry containing graphite and CNF. Note that cellulose can be reused or naturally decomposed into glucose via enzyme-assisted hydrolysis [7], while the chemically inert graphite can be recycled and go back to the carbon cycle, which is naturally environment friendly [8], in sharp comparison with the non-degradable petroleum-based plastics.

(b) Digital images of plastic foam and G-CNF foam. (c) Schematic of the recyclability and degradability of the printed G-CNF aerogel made from the plants and graphite mine in nature.

*Corresponding author. E-mail: lit@umd.edu

The resulting G-CNF foam is lightweight and can be supported by a dandelion (Figure 2a). Owing to highly porous structure, the G-CNF foam has an ultra-low density of 0.05 g/cm^3, similar to the density of the commercial plastic foam (Figure 2b). The mechanical properties are important for practical packaging applications. We evaluated these properties of the G-CNF foam and compared with those of the commercial plastic foam, which are shown in Figure 2. The G-CNF foam exhibited an ultimate tensile strength of 3.72 MPa, which is 13 times stronger than the commercial plastic PS foam (Figure 2c). The G-CNF foam also demonstrates a substantially 9 times higher tensile stiffness than the commercial plastic PS foam (27.9 MPa vs. 3.58 MPa). The hydrogen bonding between the graphite and CNF offers the high tensile strength, while there is the weak connection among the PS microspheres of the commercial plastic PS foam. Compressive property is also important for packaging materials. Figure 2d compared the compressive test results of the G-CNF foam and the commercial plastic PS foam. The G-CNF foam showed a higher compressive stiffness of 2.34 MPa than the commercial plastic PS foam. Due to its low density, the specific tensile stiffness and compressive stiffness of the G-CNF foam are as high as 396.8 MPa • cm^3/g and 42.23 MPa • cm^3/g, respectively, both of which are higher than the commercial PS foam.
.

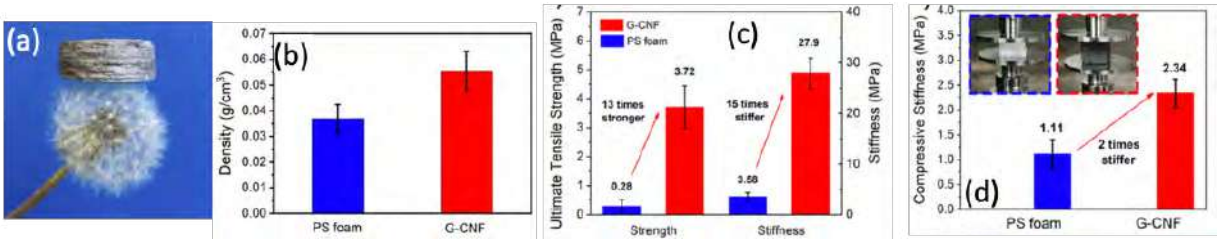

Figure 2. (a) The G-CNF foam supported by a very light dandelion. (b) The density comparison between the G-CNF foam and the commercial plastic foam. (c) The comparison of the ultimate tensile strength and the tensile stiffness between the G-CNF foam and commercial plastic foam. (b) The comparison of the compressive stiffness between the G-CNF foam and commercial plastic foam.

CONCLUSIONS

In conclusion, we develop a degradable, recyclable, and lightweight 3D graphite-cellulose foam as an advanced packaging material via 3D printing method. The graphite powder can be directly dispersed into a uniform and stable slurry by CNF without the need of surfactant or harsh chemicals. The graphite/CNF slurry maintains high apparent viscosity as well as good storage and loss moduli stability, which enables the production of the continuous filaments from slurry to construct 3D architectures. The printed CNF/graphite foam exhibits a 15-times stronger than commercial plastic foam with a high tensile stiffness of 54.9 MPa and 2-times stronger with a high compressive stiffness of 2.34 MPa.

MEDIATION OF DEFECTS IN LATTICE MATERIALS BY STRUT TOPOLOGY

Kan Li*[1], Philipp E. Seiler[1], Vikram Deshpande[1], and Norman A. Fleck[1]
[1]Department of Engineering, University of Cambridge, Cambridge, United Kingdom

Summary We make use of the local modification of a lattice in the vicinity of a stress-raiser such as a notch in order to increase the macroscopic strength. Specifically, a spatially non-uniform waviness distribution of sinusoidal shaped struts is assumed in the vicinity of a notch in a hexagonal lattice or a triangular lattice, and the macroscopic tensile response is determined by finite element analysis. Optimal lattice structures are determined that maximise (or minimise) the macroscopic tensile strength. Hexagonal and triangular lattices are studied as they are representative of bending-dominated and stretching-dominated lattices, respectively.

INTRODUCTION

Spatially periodic networks of struts, called lattice materials, are increasingly used in engineering applications, e.g. tower structures in civil engineering, the cores of lightweight sandwich panels, microscopic mechanical filters [1], and soft network materials utilised in bio-integrated electronics [2]. Existing studies mostly focused on the design, fabrication and modelling of spatially uniform lattice materials. However, in practical applications, lattice materials may contain as-designed defects such as holes [3], notches and solid inclusions [4]. In order to modulate the lattice material in the vicinity of the stress-raiser, we ascribe a spatially non-uniform waviness distribution of the struts in the lattice.

METHODS

Parameter study and optimisation of waviness distribution

A periodic representative volume element (RVE) of lattice is studied, as shown in Figure 1(a). The non-uniform distribution of strut waviness of RVE is demonstrated in Figure 1(b). The wavy struts are in sinusoidal shape and their waviness A is defined by a Gaussian distribution

$$A(r) = A_\infty + (A_m - A_\infty) \cdot \exp\left(-\frac{r^2}{R^2}\right)$$

where r is the distance from the centroid of a strut to the centre of RVE, such that $r^2 = x^2 + y^2$. This Gaussian distribution makes use of the 3 parameters A_∞/ℓ, A_m/ℓ and R/ℓ. The dependence of the macroscopic strength and ductility of the lattice upon these 3 parameters was determined by Optimal Latin Hypercube sampling method, using software ISIGHT v2018, in a representatively large design region (A_∞/ℓ, $A_m/\ell \in [0, 0.2]$ and $R/\ell \in [0, 20]$). A Gaussian approximation was employed to assemble these results and to build a design map. Further optimisation is done by choosing the maximum (or minimum) points on the design map.

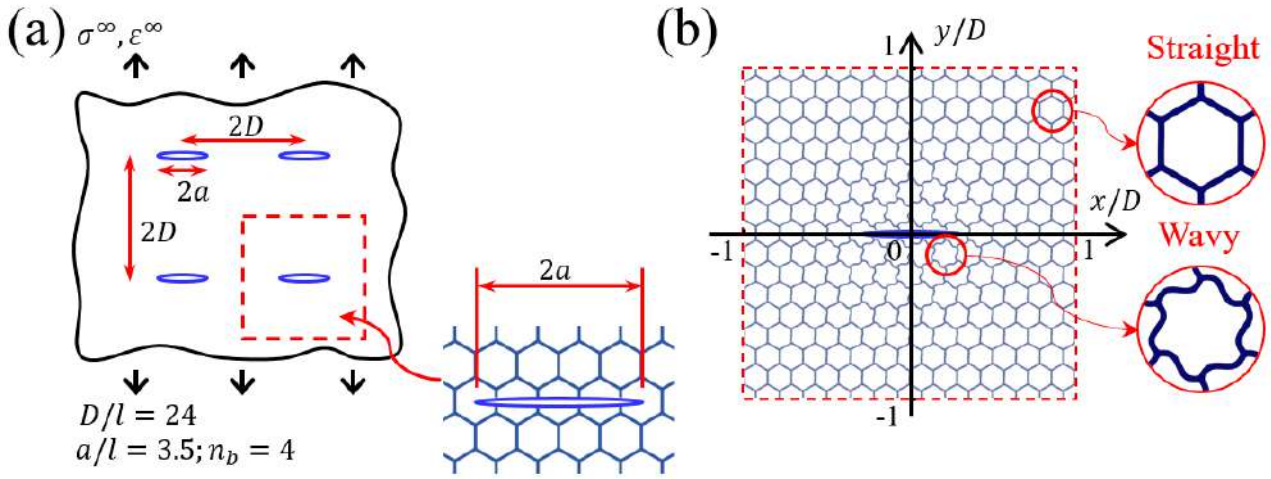

Figure 1. (a) A flaw of length $2a$, consisting of missing cell walls, exists in a periodic RVE of size $D \times D$. (b) A periodic RVE with non-uniform strut waviness distribution.

Finite element modelling

Static finite element simulations are performed using ABAQUS/Standard v2018 to simulate the tensile response of the lattice under uniaxial tension. Periodic boundaries are set by node-to-node equation constraints using a python script

*Corresponding author. E-mail: kl513@cam.ac.uk

interface. Uniaxial loading of the periodic RVE is simulated by imposing a relative displacement between top-most and bottom-most nodes at the boundaries in the y-direction. The finite element mesh of the lattice comprises rectangular elements and quadratic shape functions in plane strain (type CPE8). The elements are of uniform size and each strut has at least 4 elements across its thickness. The material properties are representative of a low carbon steel of Young's modulus $E_S = 210\text{GPa}$, yield strength $\sigma_{YS} = 338\text{MPa}$ and ultimate tensile strength $\text{UTS} = 500\text{MPa}$, as measured from a tensile test on a dog-bone specimen. The macroscopic failure of the lattice is defined by the onset of necking in any strut of the lattice.

RESULTS

Based on the simulations, we plot contours of macroscopic tensile strength of the hexagonal lattice as a function of strut waviness distributions, as shown in Figure 2(a) for the case of a slit with 4 missing cell walls. The normalised tensile strength $\hat{\sigma}$ is defined by

$$\hat{\sigma} = \frac{\sigma_{\text{UTS}}}{\sigma_{\text{UTS}}\left(a; \frac{A_\infty}{\ell} = \frac{A_m}{\ell} = 0\right)}$$

(Similar calculations have been performed for a triangular lattice.) The choice $\frac{A_\infty}{\ell} = \frac{A_m}{\ell} = 0$ corresponds to a lattice with straight struts. The strength of the notched hexagonal lattice is maximised by making the struts wavy within a zone of radius $R = 8\ell$ (Region I), but straight remotely (Region II), as listed in Table 1. Alternatively, the strength is minimised by employing straight struts near the notch (Region I) but wavy remotely (Region II).

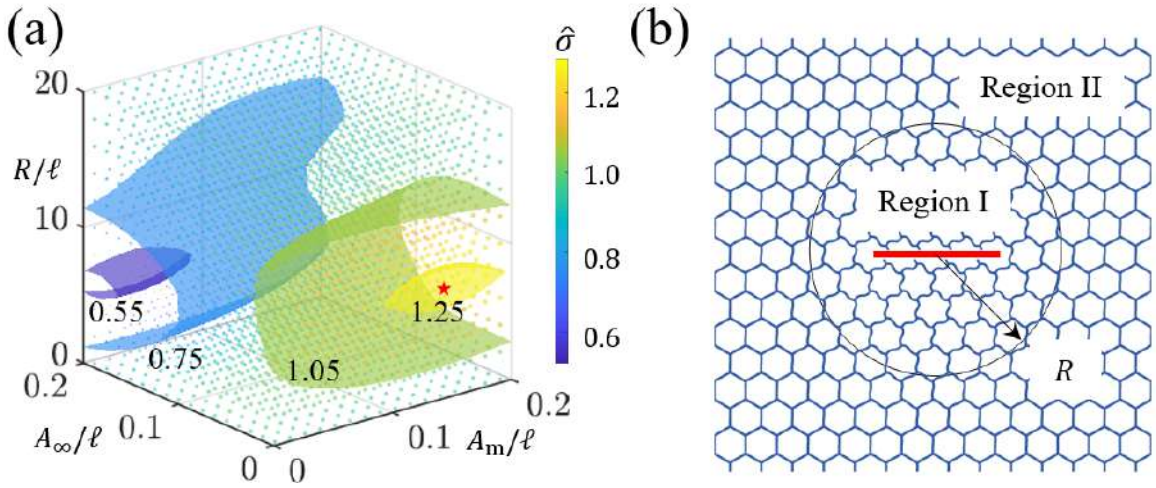

Figure 2. Contours of normalised tensile strength as a function of the strut waviness distributions for a periodic RVE of hexagonal lattice with 4 missing cells. (a) Scattered 3D plot and isosurfaces of normalised tensile strength. (b) Schematic diagram of strut waviness distribution, separating the RVE into two regions by radius R.

	Region I	Region II	$\hat{\sigma}$
$A_\infty/\ell = A_m/\ell = 0$	Straight	Straight	1.00
$A_\infty/\ell = 0, A_m/\ell = 0.15, \quad R/\ell = 8$	Wavy	Straight	Max =1.26
$A_\infty/\ell = 0.2, A_m/\ell = 0, \ R/\ell = 8$	Straight	Wavy	Min = 0.52

MULTIAXIAL CRUSHING OF OPEN-CELL FOAMS

Chenglin Yang[1] and Stelios Kyriakides *[1]
[1]Research Center for Mechanics of Solids, Structures & Materials, University of Texas at Austin, Austin, Texas, USA

Summary A true triaxial numerical apparatus is used to crush micromechanically accurate Al-alloy random open-cell foams along radial displacement paths to volume reductions of 70%. For all loading paths the foam traces an initial stiff and stable branch with the foam deforming uniformly. This branch terminates into a stress maximum followed by localized crushing in narrow bands of cells that tend to spread with limited additional effort, while crushed and relatively undeformed cells coexist. The deformation becomes uniform again once the crushing has spread to the whole domain. This work demonstrates that this three-regime behavior can be simulated at the continuum level using a Drucker-Prager type compressible constitutive model calibrated to a stress-strain response with a softening branch over part of the strain history.

INTRODUCTION

It is widely accepted that under uniaxial compression relatively low density foams exhibit a fairly stiff linearly elastic regime that terminates into a load maximum. It is followed by an extended load plateau during which localized cell crushing initiates and gradually spreads throughout the specimen. When most of the cells are crushed, the densified material stiffens again [1]. Uniaxial crushing has been successfully reproduced numerically using micromechanically accurate random foam models [2]. In a recent study a true triaxial apparatus shown in Fig. 1 has been used to crush such foam models under triaxial loading histories [3]. Cubical random foam models with 10^3 cells are crushed between three pairs of rigid orthogonal planes under radial displacement paths in the x-y-z space. It is demonstrated that multiaxial crushing exhibits the same three deformation regimes observed in uniaxial compression. In a first effort to capture this behavior at the continuum setting, a compressible yield function coupled with a material stress-strain response with a softening branch has been proposed. The constitutive model is incorporated in a cubical finite element model with an irregular mesh of solid elements and used to simulate the triaxial crushing loading histories of the random foam. The performance of the homogenized model is evaluated by comparing the calculated responses with those of the random foam.

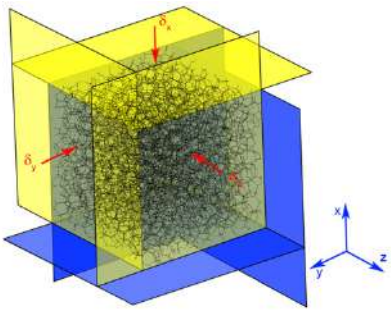

Figure 1. A true triaxial apparatus used to crush random foams under triaxial loadings.

TRIAXIAL CRUSHING OF RANDOM AND HOMOGENIZED MODELS

The true triaxial apparatus shown in Fig. 1 has been used in [3] to crush Al-alloy open-cell foam models with relative density of 0.08 to volume reductions of 70%. The foams start as skeletal versions of monodisperse random foams generated using the Surface Evolver software. They are subsequently assigned the appropriate material distribution along the straight edges of their polyhedral cells, and discretized with shear deformable beam elements as described in [2,3]. Cubical foam models are placed in the triaxial apparatus and crushed along three families of radial displacement paths in the x-y-z space. Here we will outline the results of a representative case crushed along the path $\delta(3,0.5,1)^T$ defined in the inset of Fig. 2. The three recorded true stress-displacement responses are plotted with dashed lines in Fig. 2, and Fig. 3 shows four deformed z-x plane sections from the middle of the domain, which correspond to the numbered bullets on the σ_x - δ_x response. The responses exhibit stiff initial elastic branches that terminate in stress maxima caused by plastic bending of foam ligaments. Descending branches follow during which localizes cell crushing commences starting at the moving platens (e.g., see top of image ①). The crushing continues inwards as shown in images ② and ③, but at different rates and extents in each direction. In the process the stresses trace plateaus (~380 psi–2.62 MPa), an extended one in the x-direction, a shorter one in the z-direction, and an even shorter one in the y-direction. Most importantly, crushed and uncrushed domains coexist up to a volume change of about 60%. For δ_x/H larger than about 0.5, the three stresses trace increasing trajectories that become steeper as the material densifies as shown in image ④ at $\delta_x/H \approx 0.59$. Ref. [3] demonstrates that this three-regime response with two stable branches separated by stress plateaus during which localized crushing spreads was observed in all 18 radial displacements paths considered.

This partially inhomogeneous behavior has been simulated at the continuum level in [4] by adopting a Drucker-Prager type compressible yield function (see also [5]) combined with the partially unstable stress-strain response shown in Fig. 4. A cubical finite element model with an irregular mesh of solid elements is used to simulate the random foam crushing responses of [3]. Included in Fig. 2 are the responses calculated with the continuum model for the $\delta(3,0.5,1)^T$ loading path, and Fig. 5 shows four deformed images of the domain with strain contours superimposed. The responses

*Corresponding author. E-mail: skk@mail.utexas.edu

reproduce the initial stable regime and the limit stresses, and track the subsequent stress plateaus quite well, while the stresses in the densification regime are somewhat underestimated. Since the solid model lacks the microstructure of the random foam, localization is initiated from geometric depressions placed along three of the planes (image [1]). Planar bands of higher deformation then propagate, in this case mainly along two directions, while the stresses remain relatively unchanged. When the whole domain is so deformed the block returns to essentially homogenous deformation. The continuum model performs similarly for the rest of the crushing paths, confirming its veracity.

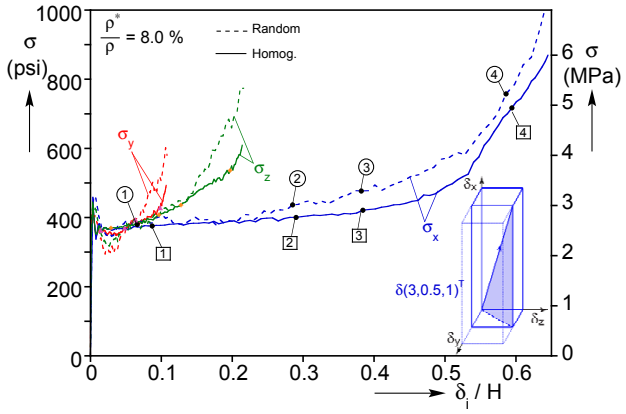

Figure 2. Random and homogenized stress-displacement responses in three directions for a radial triaxial loading.

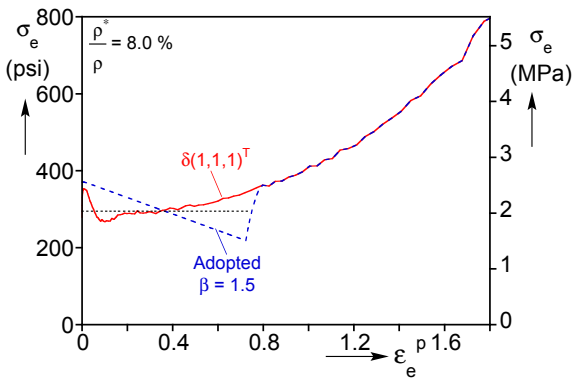

Figure 4. Partially unstable stress-strain response adopted in the homogenized model.

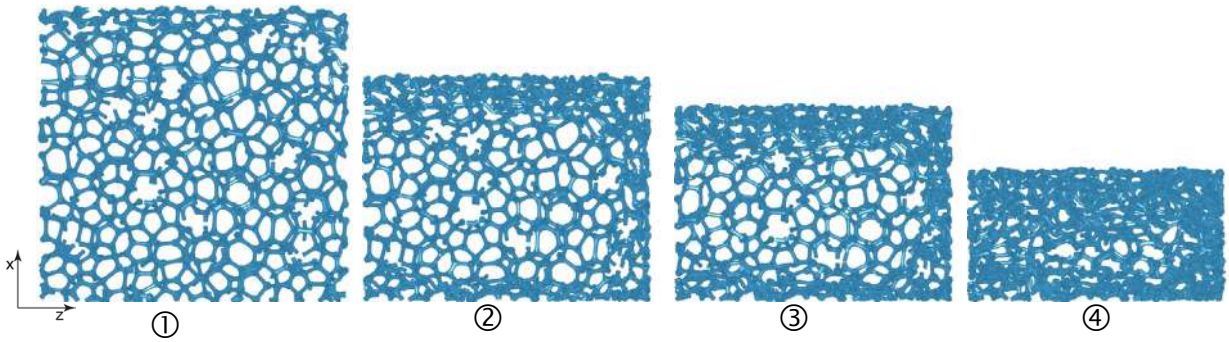

Figure 3. Random foam deformed configurations corresponding to dash line responses in Fig. 2 showing coexisting crushed and uncrushed cells until densification sets in at an increasing stress at ④.

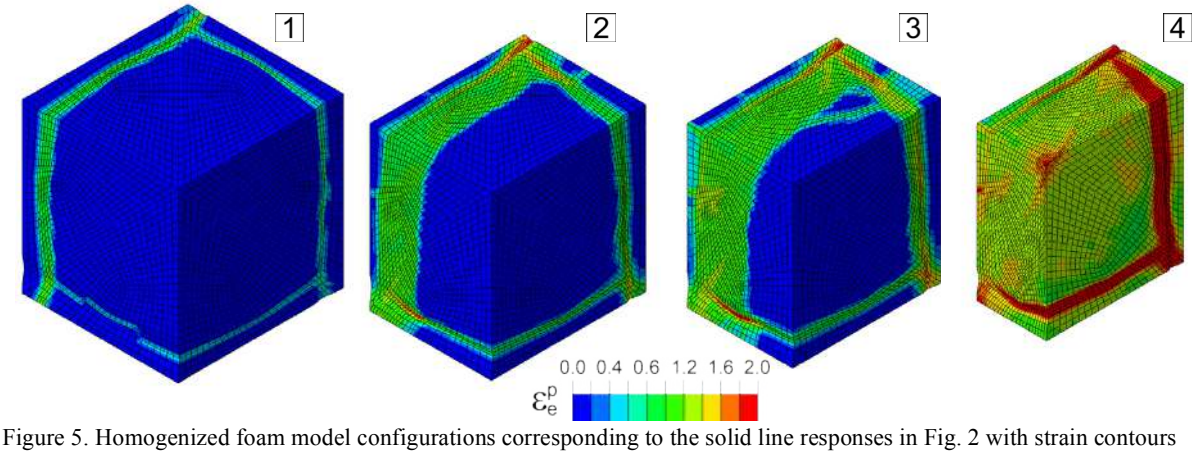

Figure 5. Homogenized foam model configurations corresponding to the solid line responses in Fig. 2 with strain contours superimposed. Observed are zones of high deformation that propagate until the whole domain is affected.

ELASTICITY OF TWO-DIMENSIONAL SOFT CELLULAR SYSTEMS WITH WEAK DISORDER

Marc Durand* and François Villemot
Matière et Systèmes Complexes (MSC), UMR 7057 CNRS & Université de Paris, Paris, France.

Summary Under small strains, soft cellular matter behaves elastically. We investigate how moderate disorder affects this elastic response. Unlike perfectly regular structure or highly disordered structure, for weakly disordered structures the elastic response depends on the spacial arrangement of topological defects (non hexagonal cells). When defects are generated by large amplitude oscillatory strain, we modelize it as an effective temperature whose impact on the population of defects is numerically investigated. We then relate the effective elastic moduli to the population and spatial arrangement of defects using two independent methods: by direct measurement of the strain energy on one hand, and by studying the interaction between defects on the other hand.

INTRODUCTION

Liquid foams, emulsions, and confluent biological tissues are examples of *soft cellular matter*: They are constituted of highly deformable – yet almost incompressible – units (bubbles, drops, cells,...). When highly compacted, they tile the available space (3D) or plane (2D) perfectly (i.e.; without gaps or overlaps). Interface energy is key to the cohesion and the rigidity of these systems, sometimes constituted solely of fluids. Under small strains, soft cellular matter behaves elastically, with stress proportional to strain and no rearrangements. Above the yield strain, local rearrangements occur and the system deforms plastically. Structural disorder strongly affects the elastic response as well as the yield strain value. We call T1 the elementary neighbor switching event. In a regular (hexagonal) structure, a T1 event corresponds to the creation of paired dislocations (where a dislocation itself is composed of one 5-sided and one 7-sided cells). When the applied shear strain increases, the number of dislocations keeps increasing, and the cellular structure gets more and more disordered. This behavior is reminiscent of that of a two-dimensional crystal submitted to an increasing temperature. This comparison suggests that strain acts as an effective temperature for the cellular structure. To probe further this hypothesis, we study numerically the order-disorder transition driven by an effective temperature.

We then investigate how moderate disorder affects the elastic response of soft cellular matter: under small strain, the displacement field is affine on bubble length scale for both ordered (hexagonal) [1] and highly disordered structures. The mechanical behavior can then be inferred from information on the distribution of size and number of sides in these two limit cases [2]. For moderate disorder however, mechanical response may also depend on the specific spatial arrangement of the topological defects.

NUMERICAL SIMULATIONS

Our simulations are based on the Cellular Potts Model (CPM), which is widely used for simulating cellular systems in various fields of physics or biology. The CPM is a lattice based modeling technique: each cell is represented as a subset of lattice sites sharing the same cell ID. Cellular domains can adopt any shape on the lattice. The system evolves using a recently modified Metropolis algorithm that preserves the integrity of the cellular domains and satisfies the detailed balance equation [3]. This algorithm has also been proved to be more efficient that the standard algorithm used in CPM for a same simulation temperature, allowing us to simulate much larger systems. Energy of a monodisperse cellular system is modeled by the discretized version of the following Hamiltonian:

$$\mathcal{H} = \gamma \sum_{\langle i,j \rangle} L_{ij} + \frac{B}{2A_0} \sum_i \left(A_i - A_0\right)^2 . \tag{1}$$

The first term in Eq. (1) accounts for interfacial effects: the sum is carried over neighboring cells $\langle i,j \rangle$ and L_{ij} is the boundary length between cells i and j. The second term accounts for an effective area elasticity which results from a combination of three-dimensional cell incompressibility and cell bulk elasticity. B is the effective 2D bulk modulus, A_i is the actual area of cell i, and A_0 the preferred cell area. To include shear strain, we extend the Hamiltonian as:

$$\mathcal{H}' = \mathcal{H} + k \sum_{i \in boundaries} \left(x_i - x_i^c(t)\right)^2 , \tag{2}$$

where $x_i^c(t) = \Gamma(t) y_i$ is a slowly varying function of time (compared with the equilibration time), while x_i and y_i are the center coordinates of cell i. The new term corresponds to applying shear strain at the top and bottom boundaries, with Γ corresponding to the applied strain.

RESULTS

Order-disorder transition

We perform extensive numerical simulations of systems of $N = 40,000$ cells with periodic boundary conditions. Figs. 1(a)–1(c) show the equilibrated system at three different temperatures, with non-hexagonal cells that are color-coded. At low temperature [1(a)], the only topological defects are bound dislocation pairs. At intermediate temperature [1(b)], paired and single dislocations coexist. At high temperature [1(c)], most of topological defects are assembled into aggregates.

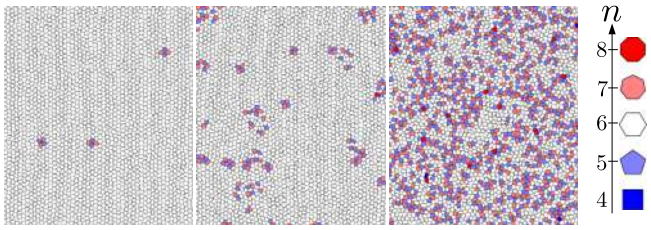

Figure 1: Evolution of defect populations with effective temperature. Only a small portion of the system is shown. Columns from left to right: solid, hexatic, and liquid phases.

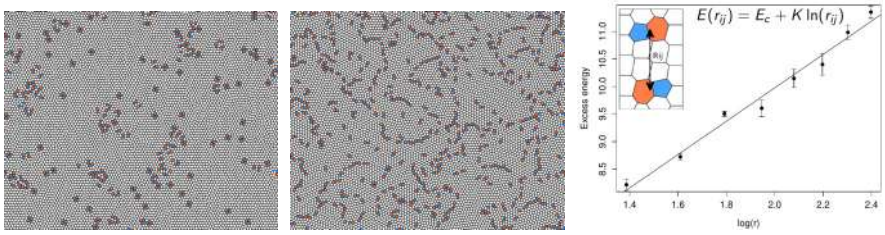
By analyzing the evolution of various quantities, including positional and orientational order parameters and the population of defects, we show that the transition follows most of the predictions of Kosterlitz-Thouless-Halperin-Nelson-Young (KTHNY) theory developed for melting of 2D solids. In particular, we show the existence of an intermediate hexatic phase, which preserves the orientational order of the regular hexagonal tiling, but looses its positional order [4].

Elastic behavior of foam with moderate disorder

Our numerical method allows for rigourous simulation of quasistatic shear of cellular systems. After testing its validity with a regular hexagonal foam [1], we show that the spatial distribution of defects deeply affects the small strain response of soft cellular matter. When they are uniformly distributed [Fig. 2a], strain is homogeneous down to the cellular scale and elastic moduli can be evaluated. Their values are recovered independently by analyzing the interaction energy between defects [Fig. 2c]. On the other hand, when defects self-associate into long chains (generated by quenching) the strain is inhomogeneous on length scale comparable with the sample size [Fig. 2b].



(a) (b) (c)

Figure 2: (a) Cellular system with defects distributed uniformly. (b) Cellular system with defects self-organized into long chains. (c) Semi-log plot of the interaction energy of two dislocations as a function of their distance. Slope allows to extract the effective Young modulus of the medium.

CONCLUSIONS

In summary, we have shown that soft cellular materials under effective thermal agitation follow closely the KTHNY melting scenario, with in particular the existence of an intermediate hexatic phase. Moreover, we have shown that the proportion of n-sided cells within the system, $p(n)$, is not sufficient to capture the mechanical properties of a system with moderated disorder. Spatial correlations of defects must also be accounted for.

WATER INDUCED BLISTERING OF CELLULOSE FOAM

Ratul Das *[1], Vikram Deshpande [1], and Norman Fleck [1]
[1]Engineering Department, Cambridge University, Trumpington Street, Cambridge CB2 1PZ, UK

Summary Dry pre-compressed cellulose foam, a biological lattice material, can swell by up to 1500% along one direction when immersed in water. The kinetics of infiltration and swelling are explored by a series of experiments. Specifically, we add a small droplet of water onto the surface of the foam to form a blister. Two successive stages are observed. In Stage I (over the first 0.1s), water infiltrates the foam due to capillary forces, but does not swell the foam. In Stage II, moisture activates swelling of the form and a blister is established within 2s. This study is the first step in developing a micromechanical model for the actuation of foams by moisture uptake.

INTRODUCTION

Dry cellulose swells when moisture is absorbed: this is the underlying mechanism in the swelling of wet wood. Sheets of dry pre-compressed foam (of relative density $\bar{\rho} = 0.45$, with respect to fully dense cellulose) have been obtained from a commercial supplier: the manufacturing route entails the hot compression of wet cellulose foam from an initial state of relative density $\bar{\rho} = 0.03$. The dry as-received foam has structural memory and swells back to its initial state within 2 s upon the addition of water [1]; we shall refer to the swelling direction as the Rise Direction (RD), and note that it is aligned with the compression direction during manufacture of the foam. The swelling occurs in two stages (see Fig. 1(a)). In Stage I, capillary forces [2] suck liquid water into the micron-scale and millimetre-scale pre-existing voids, but initially the water does not swell the foam. Then in Stage II, moisture swells the cellulose cell walls and the millimetre-scale voids open [1,3,4]. Define the moisture content of the damp foam by m_w/m_f where m_w is the mass of water and m_f is the mass of dry compressed foam. Then, a moisture content of at least 50% is needed to fully actuate the dry foam [1]. In our current study, we add a small droplet of water (volume: V_w) onto the surface of pre-compressed foam and form a blister. We then observe the kinetics of liquid absorption and blister growth.

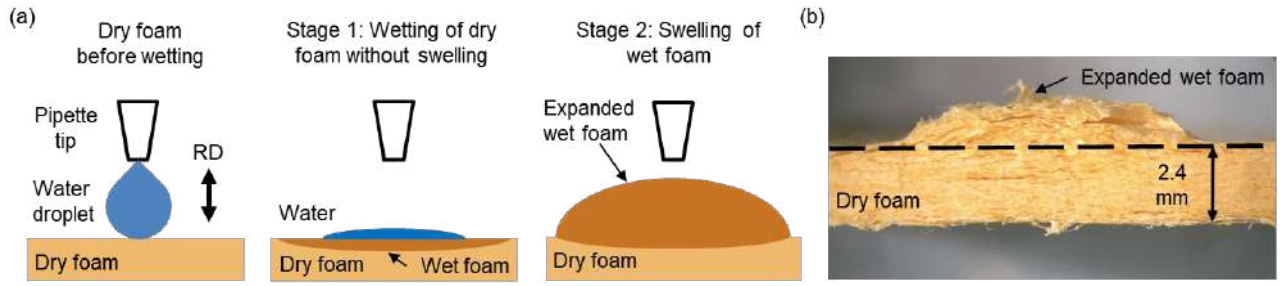

Figure 1. **Wetting of pre-compressed cellulose foam by water and blister formation due to swelling.** (a) Stages of water induced swelling in a pre-compressed foam. RD: Rise Direction (b) Cross-section of a fully formed blister (sectioned along thickness direction of the foam) showing wet expanded foam inside the blister and dry compressed foam underneath it.

MATERIAL AND EXPERIMENT

A droplet of distilled water ($V_w = 0.024$ ml) is added on the surface of a sheet of dry pre-compressed cellulose foam (thickness 2.4 mm). The dry compressed foam has a density of 675 kg/m^3 and can expand approximately 15 times along its thickness direction when wet. Once the droplet touches the surface, the consequent rapid absorption of the water into the sheet and blistering of the foam surface are imaged at a high speed (1000 frames / s) for 19 s; see some of these optical shadowgraphy images in Fig. 2(a). Volumes of the blisters are estimated from the series of high speed images and plotted against time in Fig. 2(b).

OBSERVATIONS

We observe two distinct stages in the experiment:

- In **Stage I** (< 0.1 s), liquid water imbibes into the foam driven by capillary pressure, but does not swell the wet material (see images (i) and (ii) in Fig. 2(a)). Water infiltrates the foam along thickness direction and also spreads radially inside the foam (compare the width of water droplet (ii) and blister (v) in Fig 2(a)). However, the wet foam starts to expand to form a blister before the entire volume of water is absorbed at the end of Stage I. It was

*Corresponding author. E-mail: rd608@cam.ac.uk

not possible to distinguish the liquid water from the wet expanded cellulose foam at the transition from Stage I to Stage II (0.1 s - 0.25 s; see image (iii) in Fig. 2(a)).

- In **Stage II** (> 0.25 s), absorbed water expands the foam and a blister forms on the surface (see images (iv) - (vi) in Fig. 2(a)). The blister volume grows rapidly at a rate of 0.1 ml/s until 1 s, then slows down at times between 1 s and 2 s (see Fig. 2(b)). After 2 s, the blister grows at a slower rate of 0.001 ml/s until the end of experiment.

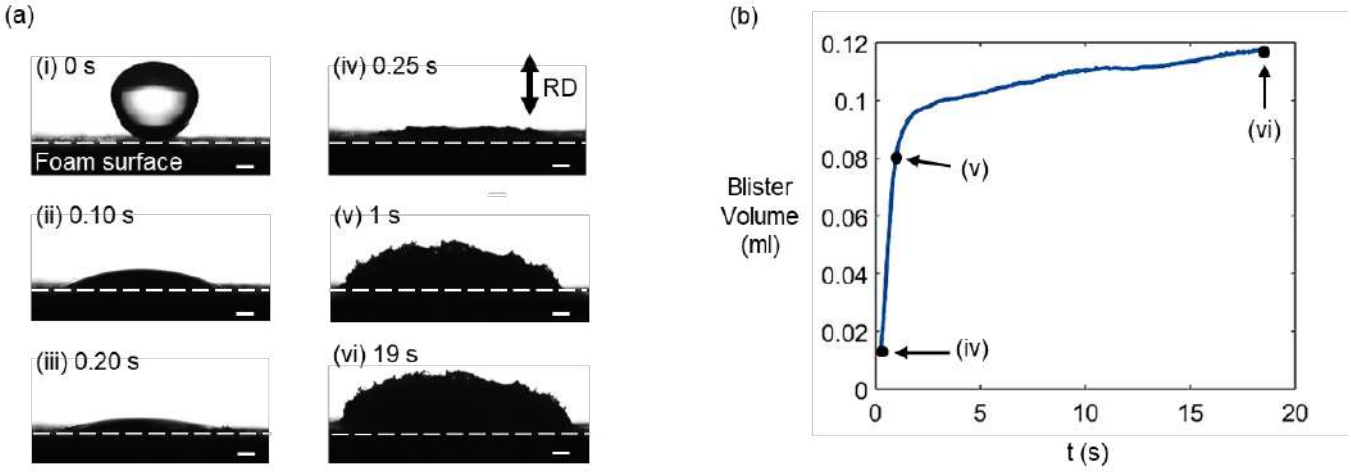

Figure 2. **Kinetics of water induced swelling in a pre-compressed foam** (a) Optical shadowgraphy images of water droplets (i-ii) water mixed with swollen foam (iii), and blisters (iv-vi) during the experiment; scale bars, 1 mm (b) Time evolution of blister volume. Black dots indicate the time and volume of the blister images in (a).

CONCLUDING REMARKS

Controlled actuation of pre-compressed foam is studied by adding a finite volume of water to a pre-compressed foam surface. We observe an initial stage I of water absorption without foam swelling for 0.1 s, and then a second stage of foam swelling between 0.25 s and 19 s. Water infiltration in Stage I is by capillarity action with little to no swelling of foam. In Stage II, moisture activates swelling in foam and forms a blister within 2 s. There is minor additional blistering over 19 s. Further work is needed to determine the mechanism of water transport in the foam in Stage II, and to determine the sensitivity of swelling to a reduced moisture content.

CFD-MODELLING OF NATURALLY OCCURRING DECAY MECHANISMS AND DESTRUCTION MEASURES IN FOAMS USING THE EULER-EULER APPROACH

Thomas Bernstein *[1], Christoph Gerstenberg[1], Eric Morelle[1], Christopher McHardy[1], and Cornelia Rauh[1]
[1]Institute of Food Technology and Chemistry, Department of Food Biotechnology and Food Process Engineering, Technische Universität Berlin, Berlin, Germany

Summary Foams are complex multiphase systems and experience several dynamically coupled phenomena during its lifetime from formation to decay. This paper deals with the numerical simulation of foam dynamics by the specific adaptation of transport terms in the energy, momentum and mass balance equations. This is done in accordance with current concepts for generalized two-phase flows (GENTOP), using the inhomogeneous Multiple Size Group (iMUSIG) model in the Euler-Euler formulation. The influence of thermal radiation on the superimposed effects of foam decay is shown by the simulation.

INTRODUCTION

Undesired foaming is a frequently observed problem occurring in plants used for the processing and packaging of foods or the refinement of chemicals. During the bottling of non-carbonated beverages, for example, there is a high risk of microbial contamination due to foam reaching systems components, entailing a frequent cleaning procedure of the machines and thus resulting in downtimes and economic losses [1]. Furthermore, severe foaming during distillation of fermented mashes results in additional pressure loss within the distillation column and thus in reduced separation efficiency [2]. So far, foam management measures are limited to (i) usage of anti-foaming agents or (ii) the reduction of throughput.

Spatial extent of foam is the critical variable for process control, resulting from the dynamic balance of foam formation and decay rates [3]. Initially, emergence of foam is driven by volume of entrained gas or gas released by evaporation within the fluid linked to the general foaming capacity of the medium, when gas reaches the surface. Foam decay takes place through the natural ageing processes of drainage, Ostwald ripening and coalescence. These coupled processes extend over different time scales and are of decisive importance for the stability of foams [4]. Design limitations in plants as well as the influence of invasive measurement methods on foam dynamics mostly prevent a complete and realistic process analysis. In order to analyse foam stability, it is therefore necessary to be able to represent different foam formation and decay mechanisms as a function of physical fluid properties and process parameters.

FOAM MODELLING

Due to the continuous increase of available computing power and the drastic price reduction of hardware components, CFD simulations are becoming more and more popular for process analysis and optimization in the engineering sciences. They provide local process information with high resolution, can be flexibly transferred to other plants or material systems and therefore proved to be a useful tool for the analysis of foam formation.

The model approach at hand is able to depict the numerous mechanisms in foam on a macroscopic scale by adapting the terms in the energy, momentum and mass balance equation of the gas and liquid phases [Fig.1]. This is done in accordance with current concepts for generalized two-phase flows (GENTOP), using the inhomogeneous Multiple Size Group (iMUSIG) model in the Euler-Euler formulation [5]. Using this methodology foam modelling and numerical simulation is possible without the need to resolve interfaces of bubbly flows or within foams, but rather by treating the bubble size distribution as a concentration field. Centrepiece of the subsequent model is the definition of a range for the dispersed gas volume fraction from $\alpha_{dg,foam\,min}$ to $\alpha_{dg,foam\,max}$ in which foam is detected by an additional morphological function. This function is denoted by

$$\phi_{foam} = (0.5\tanh(a_l[\alpha_{dg} - \alpha_{dg,foam\,min}] + 0.5) - 0.5\tanh(a_h[\alpha_{dg} - \alpha_{dg,foam\,max}] + 0.5)) \quad (1)$$

wherein a_l and a_h are calibration factors. Source terms within the balance equations are multiplied by the morphological function. Thereby, momentum terms are adapted for specific phases and i.e. capillary forces $\vec{M}_{cap}$ or permeabilities $\vec{M}_{perm}$ are used to describe drainage rates within foams analogous to Darcy's law expressing the liquid flow through porous media. Mass transfer terms between the various bubble size groups can also be adapted when foam is detected. The model switches between well-established models for coalescence by Prince and Blanch [6] or break-up by Luo and Svendsen [7] in bubbly flows and new formulations for changes in bubble size distribution within foams, incorporating coarsening and coalescence rates. Furthermore, experimentally determined thermal conductivities for foams k_{foam}, as well as the absorption and scattering coefficients μ_a and μ_s are available for multiphase-multicomponent radiation transfer within the energy equation. By doing this, natural foam ripening mechanisms as well as the influences of foam destruction measures can be investigated in the simulation. Thermal radiation on the superimposed effects of foam decay is the currently studied destruction measure.

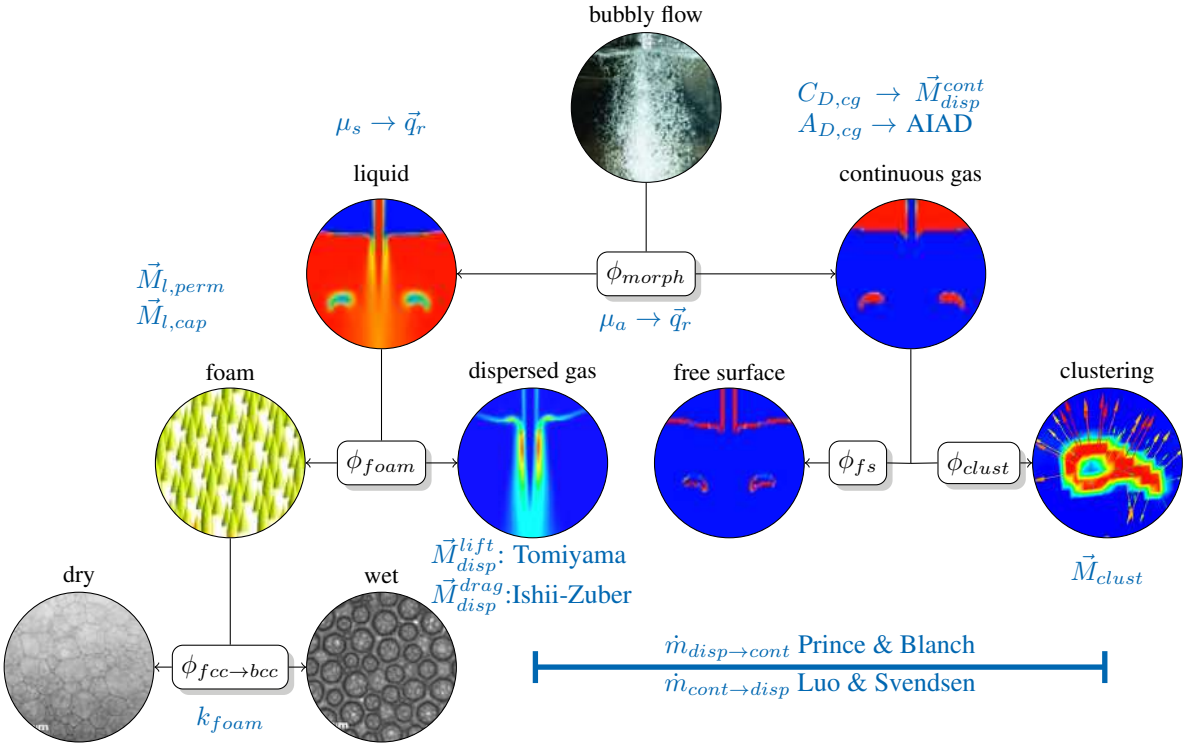

Figure 1: Extension of the GENTOP concept [5] by a foam phase with adapted mass, momentum and energy transfer terms.

EXPERIMENTAL VALIDATION

The main parameters to characterize foams resulting from the simulations are compared with experiments in a test rigs on a laboratory scale. Spatial extent of foam is measured within a Kruess DFA 100. The liquid volume fraction distribution over foam height is measured by electrical conductivity within a specifically designed and constructed foaming device. Bubble size distribution is detected optically and evaluation takes place by convolutional neural networks.

CONCLUSIONS

In the future, the presented model shall offer the possibility to simulate effects of the micro-scale foam dynamics on the macroscopic length scale of production processes. On this basis, characterization of critical plant areas and optimized process windows takes place. If it should emerge, that foam extent can only be controlled by its process parameters entailing performance losses, ideal positioning and operation of thermal actors within process plants can be optimized by the model.

PREDICTION OF EFFECTIVE ELASTIC MODULUS IN ANY DIRECTIONS OF PERIODIC TRUSS STRUCTURES

Shuheng Wang[1,2], Yongbin Ma[1,2], Zichen Deng[1,2]*
[1]School of Mechanics, Civil Engineering and Architecture, Northwestern Polytechnical University, Xi'an, 710072, PR China
[2]MIIT Key Laboratory of Dynamics and Control of Complex Systems, Northwestern Polytechnical University, Xi'an 710072, PR China

Summary This study develops an analytical formula for the effective elastic modulus of periodic truss structure in any directions. Based on the traditional Representative Volume Element (RVE) method, a displacement matrix equivalent to the strain field is applied as the boundary condition of the unit cell. By expressing the displacement boundary condition as a function of direction, the analytical formula of the effective elastic modulus as a function of direction are obtained by strain energy equivalence. The method presented here can easily optimize the size of the structure to adjust the elastic modulus of the structure. This study takes a simple binary compound truss structure as an example, and utilizes this method to make a reasonable size distribution, so that the optimized structure becomes an elastically-isotropic structure.
Keywords: Periodic truss structures; Effective elastic modulus; Analytical formula.

Introduction

With the rapid development of additive manufacturing technology, lightweight, complex periodic cellular structures with special mechanical properties can be fabricated at a low and declining cost [1]. The microstructure characteristics of the cellular structure govern its macroscopic behaviour, and the cellular structure can obtain unprecedented mechanical properties by designing its microstructure. In the meantime, combining two or more plate- or truss- like structures that exhibit high stiffness in different directions to obtain a compound structure with a higher degree of isotropy in effective elastic modulus has been demonstrated [2-4]. At present, researchers have proposed many homogenization methods to predict the effective mechanical properties of periodic truss structures [5-7]. However, the effective elastic modulus of periodic structure in any directions is not easy to obtain in one calculation, and usually obtained through ABAQUS-Python scripts [7].

In this study, a simple method based on the traditional RVE method is developed to obtained an analytical formula for the effective elastic modulus of periodic truss structure in any directions. The analytical formula can be expressed as a function of the effective elastic modulus of the periodic truss structure with respect to its size and the material property, so the effective elastic modulus of the truss structure can be easily optimized.

Method

The RVE method is to take out some unit cells that can completely contain the material microstructure information from the periodic truss material, and apply the boundary conditions on the boundary of the unit cells, and then obtain the effective elastic modulus of the material based on the strain energy equivalence. The Dirichlet Boundary conditions can be represented by a displacement field $\mathbf{u}(\theta)$ corresponding to the strain field $\boldsymbol{\varepsilon}(\theta)$ as follows:

$$\mathbf{u}(\theta) = \boldsymbol{\varepsilon}(\theta)x, \ \forall x \in \partial\Omega \tag{1}$$

where θ represents the specified direction and $\partial\Omega$ represents the boundary of the unit cell. Then, the strain energy of the unit cell can be obtained as $U_{\text{cell}} = \frac{1}{2}\mathbf{u}(\theta)^{\mathrm{T}}\mathbf{K}\mathbf{u}(\theta)$, where $\mathbf{K}$ is the global stiffness matrix of the unit cell. Regarding the unit cell as an effective homogeneous continuum, and the strain energy of the effective homogeneous continuum can be obtained as $U_{\text{hom}} = \frac{1}{2}\boldsymbol{\varepsilon}(\theta)^2 E(\theta)V$, where $E(\theta)$ is the effective elastic modulus in the specified direction and V is the volume of the unit cell. By considering $U_{\text{cell}} = U_{\text{hom}}$, the analytical formula of the effective elastic modulus with respect to the direction can be obtained as follows:

$$E(\theta) = \mathbf{u}(\theta)^{\mathrm{T}}\mathbf{K}\mathbf{u}(\theta)/\boldsymbol{\varepsilon}(\theta)^2 V \tag{2}$$

Example and results

This study takes a simple binary compound periodic truss structure as an example, the unit cell is taken out from the truss structure and shown in Fig.1(a). The unit cell is composed of two square truss and the corner of the smaller truss is at the midpoint of the edges of the larger truss. Square truss stiff along the edges but highly compliant in other loading directions, e.g. along the diagonal. Therefore, the compound truss structure has a higher degree of isotropy than the square truss. Displacement matrix corresponding to the Dirichlet boundary conditions can be expressed as:

$$\mathbf{u}(\theta) = [u_1\ v_1\ u_2\ v_2\ u_3\ v_3\ u_4\ v_4\ u_5\ v_5\ u_6\ v_6\ u_7\ v_7\ u_8\ v_8]^T \tag{3}$$

where u_i and v_i are the displacement components of the node displacements in the u and v directions after θ is determined, e.g. $u_8 = \varepsilon L\cos\theta\cos\theta$ and $v_8 = \varepsilon L\cos\theta\sin\theta$. Substituting $A = A_1 = \frac{1}{20}$, $L = 1$ and $E = 1$ into Eq.

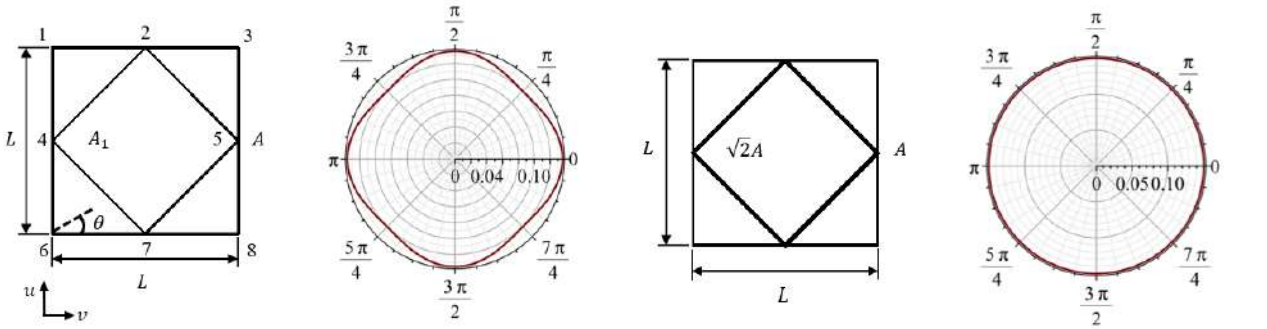
*Corresponding author: Zichen Deng; E-Mail address: (dweifan@nwpu.edu.cn);

(2), the effective elastic modulus is only determined by θ. Fig. 1 (b) is the polar plot of the effective elastic modulus in different directions.

Fig. 1 (b) shows that the elastic modulus is largest along the edges of the larger square and smallest along its diagonal. When θ is determined, the effective elastic modulus can be optimized by changing the size of the unit cell and the material properties. Due to the symmetry existent in the unit cell, only one-eighth direction needs to be considered. From Eqs. (2,3), $E(0)$ and $E\left(\frac{\pi}{4}\right)$ can be obtained:

$$E(0) = E(\sqrt{2}A_1 + 4A)/2L,\ E\left(\frac{\pi}{4}\right) = E(\sqrt{2}A_1 + A)/L \tag{4}$$

In order to increase the degree of elastic isotropy of the structure, consider leting $E(0) = E\left(\frac{\pi}{4}\right)$ and obtain $A_1 = \sqrt{2}A$. Substituting $A_1 = \sqrt{2}A$ into $E(\theta)$ and it can be find that $E(\theta) = 3EA/2L$, which have nothing to do with θ. Therefore, when $A_1 = \sqrt{2}A$, that is, when the proportions of two square truss structures are equal, the compound structure is elastically isotropic. The optimized structure and its effective elastic modulus in drfferents in shown in Fig. 1 (c, d).



(a) (b) (c) (d)

Figure 1. The size of the unit cells and their effective modulus in different directions.

Conclusion

This study develops an analytical formula for the effective elastic modulus of periodic truss structure in any directions. By using this formula, effective elastic modulus of the truss structure can be easily obtained and optimized through changing the size of the unit cell and material properties. A two-dimensional binary compound periodic truss structure composed of two square trusses is taken as an example to show how the method is implemented and used to optimize the effective elastic modulus of the structure. The method presented in this study can also be used in three-dimensional periodic truss structures.

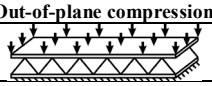
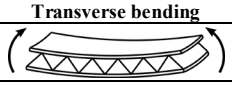
Summary Sandwich panels with web core (namely I core) have recently been found to exhibit superior heat dissipation performance than traditional corrugated sandwich panels [1], and hence it is of significant practical interest to compare their load capacity under different loading conditions. This paper presents a new variegated prismatic core (namely N core) which can be degenerated into the corrugated or web core geometrically, and investigated its compression, bending and shear properties by theoretical modeling and numerical simulation. Results show that under out-of-plane compression and transverse bending, the web core is the best, while under transverse shearing, the corrugated core outperforms the rest. The performance of the three cores is similar under longitudinal bending and shearing.

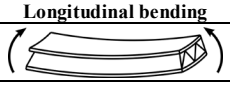
CORE TOPOLOGIES AND LOAD TYPES

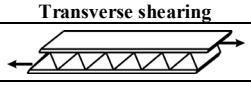
Corrugated cores are extensively used in the packaging and transportation industry [2], while web cores (including I girders or H beams) are widely used in road and bridge construction [3]. In addition to bearing structural load, both corrugated and web cores have fluid through topologies for active cooling applications. Five load types (out-of-plane compression, transverse bending, longitudinal bending, transverse shearing and longitudinal shearing; Table 1) covering almost all the engineering application scenarios are selected to compare the static mechanical properties of corrugated and web cores. A novel variegated corrugated core (namely N core, Table 2) is proposed here by adding ribs at the top angle of corrugated cores. In extreme cases, analytical solutions obtained for the N core under different loading conditions can degenerate into solutions for either corrugated or web core.

Table 1 Load types considered

Out-of-plane compression	Transverse bending	Longitudinal bending	Transverse shearing	Longitudinal shearing
				








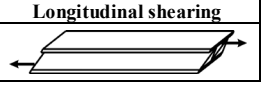


Table 2 Core topologies considered for multifunctional sandwich construction

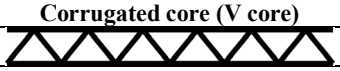
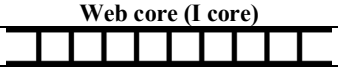
Corrugated core (V core)	Web core (I core)	N core
		





OUT-OF-PLANE COMPRESSION

A unit cell model (Fig. 1(a)) is used assuming that the stiffness of the facesheet is much greater than that of the core, so that the facesheet only transmits the load, while the core bears axial force, shear force and bending moment [4]. The stress of each strut in the unit cell is obtained by solving their strain energy. The failure modes include elastic buckling and plastic yielding. Corresponding load capacity p of each core can be determined as a function of relative density [5]:

$$p = \min\left\{\sigma_{cb}, \sigma_{cy}, \sigma_{ub}, \sigma_{uy}, \sigma_{db}, \sigma_{dy}\right\} \quad (1)$$

where the first subscript c, u, d indicate the inclined and straight struts, and the second subscript b, y indicate the failure modes. A finite element (FE) model is employed to validate the analysis model, with excellent agreement achieved. The results of Fig. 1(b) demonstrate that the web core is superior to the corrugated core, while the N core is between the two.

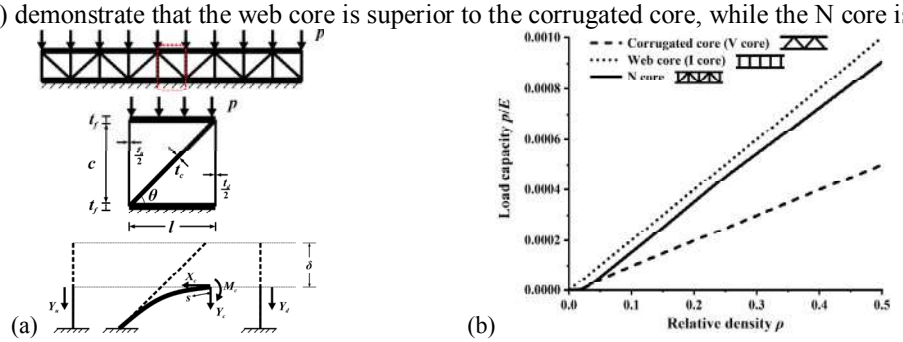


Figure 1. (a) Unit cell analysis of out-of-plane compression for N core; (b) load capacity plotted as a function of relative density under the out-of-plane compression

BENDING

When subjected to bending, one facesheet of the sandwich is in tension while the other is in compression. The core transmits the shear load and bears normal stress to support the facesheet. The maximum bending moment and shear force of the sandwich beam are expressed as M and V, so $\Psi=V/(EM)^{0.5}$ defines a dimensionless load index, and $\chi=M/V$ means the load form (Fig. 2(a)). The failure criterion of elastic buckling is [6]:

* E-mail addresses: shangshengfeng@xjtu.edu.cn (S. Feng), tjlu@nuaa.edu.cn (T. J. Lu)

$$\left(\sigma_i / \sigma_{cr}\right)^2 + \left(\tau_i / \tau_{cr}\right)^2 \le 1 \qquad i = f, c \tag{2}$$

and the failure criterion of plastic yielding is [6]:

$$\sigma_i^2 + 3\tau_i^2 \le \sigma_Y^2 \qquad i = f, c \tag{3}$$

where subscripts f and c denote facesheet and core. It can be seen from Fig. 2(b-c) that under transverse three-point bending, the web core is always the best, while the N core and corrugated core are the weakest at lower (ρ<0.1) and higher (ρ>0.1) relative density, respectively. Under longitudinal three-point bending, the corrugated core and N core outperform the web core, albeit by a small margin.

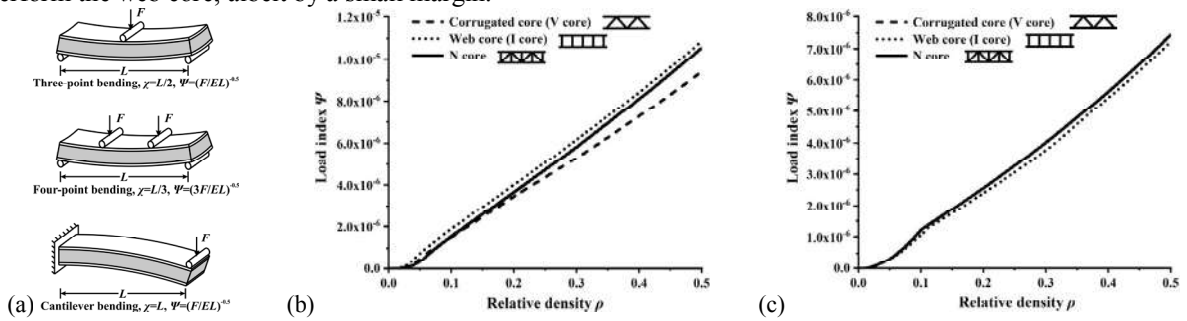

Figure 2. (a) Various bending types of sandwich beams and their corresponding load indices; (b) load capacity plotted as a function of relative density under transverse bending; (c) load capacity plotted as a function of relative density under longitudinal bending

SHEARING

The shearing capacity of corrugated core in its transverse orientation is inferior to its longitudinal orientation [7]. It is assumed that the facesheet is rigid enough and the shear force is distributed to the core. As shown in Fig. 3(a), the compression stress of each strut can also be obtained using a unit cell model. With elastic buckling and plastic yielding assumed as strut failure modes, the corresponding bearing capacity is:

$$\tau = \min\left\{\tau_{cb}, \tau_{cy}, \tau_{ub}, \tau_{uy}, \tau_{db}, \tau_{dy}\right\} \tag{4}$$

It can be seen from Fig. 3(b-c) that under transverse shearing, the performance of the corrugated core is very close to the N core, both better than the web core. Under longitudinal shearing, however, core topology has little influence on the load capacity of the sandwich structure.

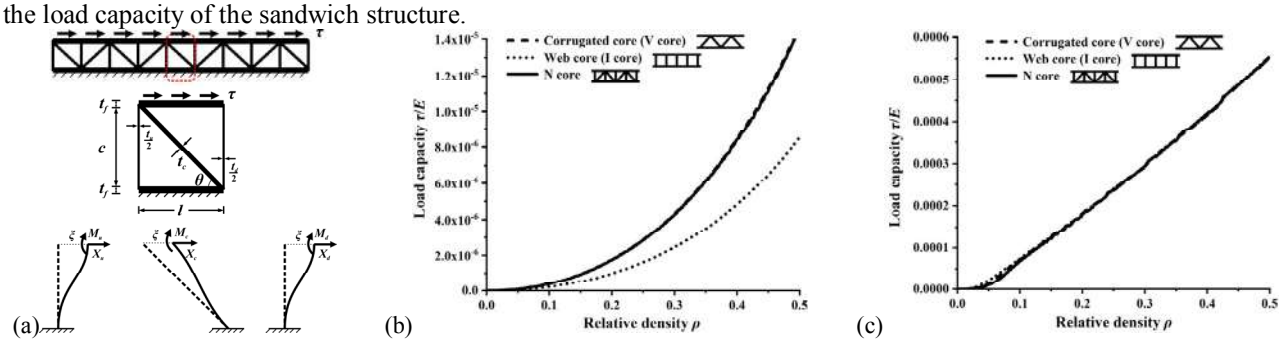

Figure 3. (a) Unit cell analysis of transverse shearing of N core; (b) load capacity plotted as a function of relative density under transverse shearing; (c) load capacity plotted as a function of relative density under longitudinal shearing

CONCLUSIONS

A novel variegated, fluid-through prismatic core topology (namely N core) is presented for sandwich construction for applications requiring simultaneous load-bearing and heat dissipation. Its static load capacity under typical loading conditions is compared with corrugated and web cores by analytical modeling and numerical simulation. It is found that under out-of-plane compression and transverse bending the web core is the best, while under transverse shearing the corrugated core outperforms the rest. The performance of the three cores is similar under longitudinal bending and shearing. Therefore, the thermo-mechanical synergy design of corrugated and web cores needs to be considered comprehensively.

Summary: This work reports a combined experimental and computational study on the fracture of micro-architected lattices composed of interpenetrating multi-material networks. The double gyroid lattice is an example of such a multi-material lattice. A detailed study on the effective elasto-plastic responses of the double gyroid lattice is conducted as a function of its constituent network properties, such that, one of the networks is elastic-brittle, whereas, the surrounding network possesses high ductility. To probe its effective fracture properties, we first perform boundary layer analysis of cracks subjected to plane strain loading, and secondly, we investigate embedded crack geometries with a surrounding resolution of millions of unit cells. In-situ X-Ray CT visualisation procedure is deployed to monitor crack tip conditions. Our investigations reveal that the network constitutive properties of such multi-material lattices, like the double gyroid, can be efficiently tuned to independently harness both its effective strength and its fracture toughness. Extended investigations into such multi-material lattices will guide the development of lightweight solids concurrently optimized and architected for high-strength and fracture-resistant applications.

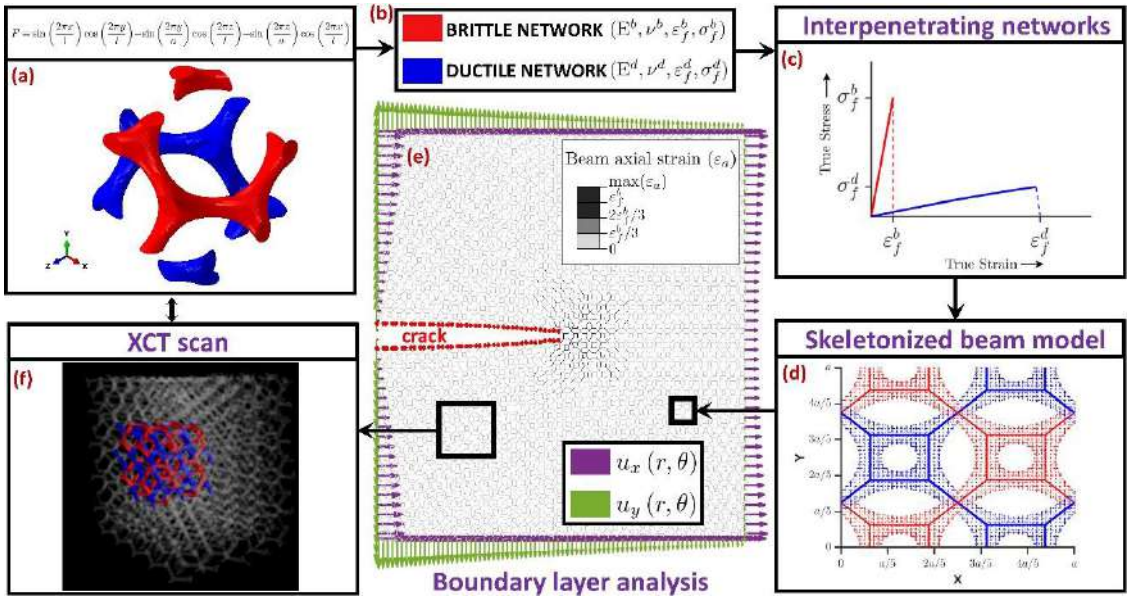

Fig. 1. Methodology for boundary layer analysis of double gyroids. (a) 3D double gyroid comprising of two interpenetrating single gyroids of opposite chirality (coloured red and blue). It is obtained by infilling the space bound by implicit inequalities, $F(x,y,z) - t_0 \leq 0$ and $F(x,y,z) - t_0 \geq 0$ in a cubic domain of edge l, such that t_0 can be tuned to control the total relative density, i.e. $\bar{\rho}$ (volume fraction of the solid material). **(b)** The parameters controlling the constitutive behaviour of the two single gyroids, shown schematically in **(c)**. **(d)** An effective beam skeleton is extracted from the 3D double gyroid in **(a)**, and is discretised in ABAQUS® using 3D Timoshenko beam elements (B31). **(e)** Remote asymptotic boundary displacement fields are applied on the discretized model comprising of ~50X50 unit cells with a central crack (length a) to conduct boundary layer analysis [1]. INTRODUCTION

The mechanical properties of cellular architected materials depend on the topology of the architecture and the constituent materials in the solid phase. Designing such cellular materials with optimised stiffness, strength and ductility is beneficial for a variety of engineering applications like biomedical implants, nanophotonic devices, ballistic armours, energy harnessing, textiles, among many others. The stiffness (E^{lat}) and strength (σ_Y^{lat}) properties of such nano- and micro-scale architected cellular materials have been extensively studied over the past two decades [2]. With recent advancements in additive manufacturing techniques such as projection micro-stereolithography [3-4], 3-D micro-architected solids can now be manufactured with millions of unit cells facilitating their employment in the aforementioned applications. Upper bounds exist on the strength of such solids, e.g. the Hashin-Shtrikman bound [5]. However, the fracture toughness (K_{IC}^{lat}) of such cellular materials is theoretically unbounded, and has been much less investigated. Furthermore, as is the case with continuum solids, it is usually assumed that K_{IC}^{lat} scales inversely with σ_Y^{lat}. This work aims to develop a computational approach to study the fracture toughness of 3D multi-material networked cellular lattices, e.g. the double gyroids, and more importantly, demonstrates that the properties of its constituent networks can be tuned to independently harness the desired K_{IC}^{lat} and σ_Y^{lat}.

METHODOLOGY

We begin by creating a beam based topology of the multi-material double gyroid lattices skeletonised from its triply periodic level surface definition **(Figs. 1a-d)**. The red coloured gyroid has elastic-brittle properties (high strength) followed by damage evolution, modelled within ABAQUS®/Explicit using the Johnson-Cook model. The blue coloured gyroid has low strength (10% of the red gyroid), but high strain to failure (ductility), modelled using von Mises plasticity. We first conduct plane-strain boundary layer analysis to map K_{IC}^{lat} as a function of crack growth for different $\bar{\rho}$ and the constituent gyroid properties. Next, we conduct FE calculations of cracks embedded in a 3D RVE with a surrounding resolution of thousands of unit cells. Similar experimental specimens with different material network properties and thousands of unit cells were manufactured **(**a XCT image is shown in **Fig. 1f)**, and the crack tip conditions were monitored using in-situ XCT method.

RESULTS

Fig. 2 briefly reports the results from the boundary layer analysis (**Fig. 1**) for one particular case of $\bar{\rho}$ and gyroid properties.

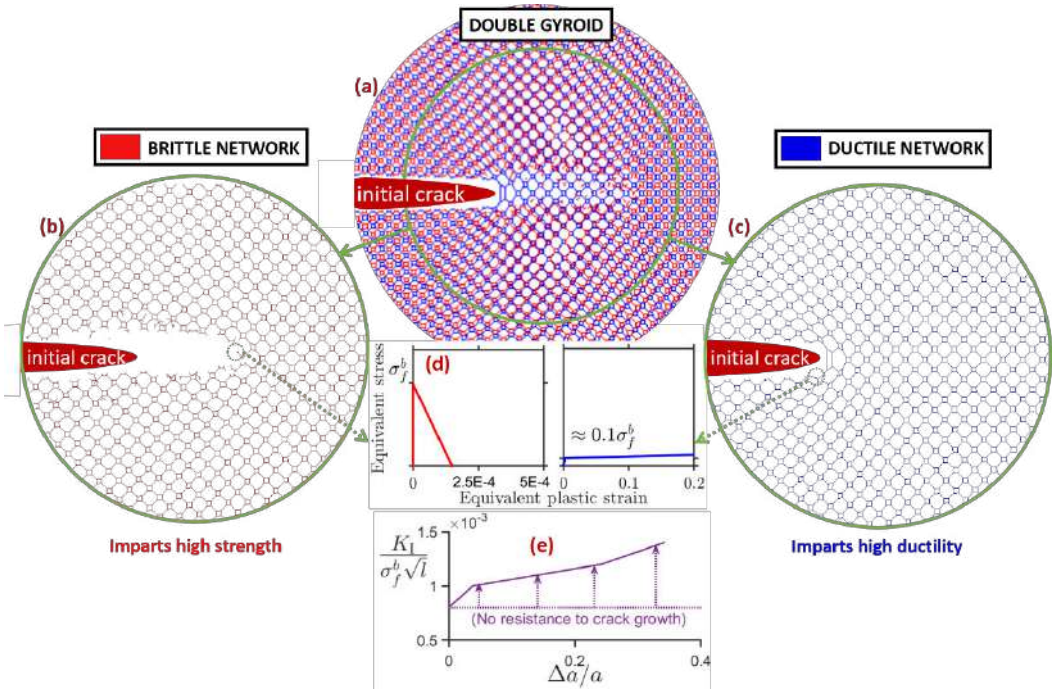

Fig. 2. Results from boundary layer analysis of double gyroids. (a) Crack growth under plane strain asymptotic conditions in double gyroid comprising of two interpenetrating single gyroids (red and blue). **(b)** The brittle network imparts high strength (i.e. σ_f^b), but damage accrued in its struts allows crack growth. **(c)** The ductile network resists crack growth by allowing high plasticity in the crack vicinity, therefore simultaneously allowing the high strength double gyroid structure to attain high strains to failure. **(d)** The equivalent stress-strain curves for the struts that fracture (and are deleted from the FE simulations), and the ones that get highly stretched in the ductile network. **(e)** The evolution of $K_{IC}^{lat}=K_I/(\sigma_f^b\sqrt{l})$ (where K_I is the Mode I stress intensity factor) as a function of crack growth (quantified using $\Delta a/a$). This shows the role played by the ductile gyroid network in prolonging crack growth within such a multi-material networked lattice.

CONCLUSIONS

In this work we present a computational approach to calculate the fracture toughness of multi-material 3D lattices which is then validated with experiments involving thousands of unit cells. We perform boundary layer analysis to map the plastic zone in the vicinity of sharp cracks embedded within these lattices, and measure K_{IC}^{lat} due to a remote crack displacement field. The experimental and numerical investigation of these bending dominated lattices concludes that strength and fracture toughness can be concurrently optimized by tuning the properties of the constituent solid phases, one of which is brittle, while other is highly ductile. This characteristic of such lattices enables us to navigate seamlessly across different domains of the characteristic strength-toughness plot, therefore providing highly optimized cellular architectures for pertinent applications.

CONTROLLING FOAM AGEING IN VISCOELASTIC MEDIA

Chiara Guidolin *[1], Emmanuelle Rio [1], and Anniina Salonen [1]
[1]Laboratoire de Physique des Solides - UMR8502, Université Paris-Saclay, 91405 Orsay, France

Summary Foams are dispersions of gas bubbles in a continuous medium. Thanks to their mechanical properties, such systems find application in many industrial fields. However, liquid foams are not stable, as different mechanisms can alter their structure over time, leading to an irreversible foam damage. We probe how the mechanical properties of the continuous phase affect the foam coarsening process. For this purpose, we study foams made of oil-in-water emulsions: at high droplet concentrations, emulsions are elastic and we can vary the elasticity of the foam continuous phase by simply adjusting the emulsion oil fraction. We show that the elasticity of the foam continuous phase strongly slows down the ripening process, but also affects the foam structure, with the appearance of unrelaxed bubble patterns.

INTRODUCTION

Foams are concentrated dispersions of gas bubbles in a continuous medium. Their typical cellular structure lends them lightness and peculiar mechanical properties that are exploited in many different fields, from food industry to cosmetics or even building materials. However, liquid foams are only meta-stable systems, as they usually undergo a competition between different mechanisms which alter their internal structure over time. Gravitational drainage, bubble coalescence and coarsening eventually lead to an irreversible foam damage and thus can be a strong limitation in many industrial processes, such as the design of solid foams with a well-controlled morphology. The desired longevity of a foam clearly depends on the specific applications, which still call for a thorough understanding of foam stability.

We experimentally study how changing the mechanical properties of the foam continuous phase impacts on the coarsening process, in conditions where drainage and coalescence can both be neglected. It has been theoretically shown that the build up of elastic stresses among the bubbles can arrest coarsening and elastically stabilize the entire foam [1] while a halt of coarsening has been experimentally observed in foams made of elastic polymer gels combined with insoluble gas species [2]. But how the rheological properties of the foam continuous phase affect the coarsening rates is still an open question.

We control the mechanical properties of the liquid by using highly concentrated oil-in-water emulsions as the continuous phase of foams, getting what is called a *foamed emulsion*. In fact, at sufficiently high droplet concentrations, emulsions show an elastic behavior, thanks to the storage of interfacial energy from droplet deformations. As this elasticity increases with droplet concentration [3], we can vary the elasticity of the foam continuous phase by simply adjusting the oil volume fraction ϕ of the emulsion. The scale separation between the foam bubbles and the emulsion oil droplets allows us to consider the emulsion as a continuous viscoelastic medium between the gas bubbles, making foamed emulsions a good system for our purpose. We study foamed emulsion coarsening in quasi-2D foam systems, where the bubble pattern evolution can be followed over time through imaging experiments.

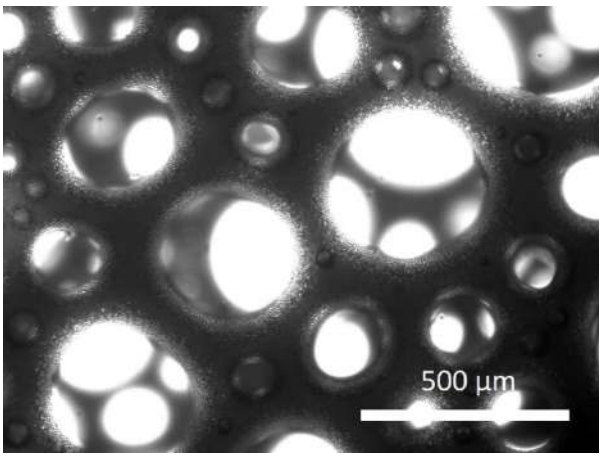

Figure 1. Example of a freshly generated foamed emulsion seen under the microscope.

*Corresponding author. E-mail: chiara.guidolin@universite-paris-saclay.fr.

FOAMED EMULSION COARSENING

Oil-in-water emulsions are prepared by mechanically mixing rapeseed oil and a surfactant solution with the so-called double-syringe method, which ensures a good control of the oil volume fraction ϕ. Emulsions are then foamed with the aid of a planetary kitchen mixer, which allows to incorporate air up to 90% of gas volume fraction. Figure 1 shows how the foams look like under the microscope right after their generation. We then sandwich the freshly generated foamed emulsion between two glass plates and wait for it to coarsen until we get a single layer of bubbles, so that we can visualise and follow the bubble pattern evolution by taking pictures of the quasi-2D foam from the top with a camera. We monitor the coarsening of foamed emulsions having oil fractions ϕ ranging from 65% to 85%. Our experiments show that such systems age very slowly, and that the higher the oil fraction, the lower the mean bubble growth rate. An example of what we observe after several days is shown in figure 2. The picture shows three different samples of foamed emulsions having the same age but increasing oil fraction ϕ from left to right, which means increasing elasticity of the foam continuous phase. One can see how the foam aspect strongly changes as we increase the emulsion oil fraction. While in the first sample on the left at ϕ=70% one can still recognize the typical structure of an aqueous pseudo-2D foam, with approximately polygonal bubbles, as we increase the emulsion elasticity the bubbles are no longer free to rearrange during coarsening, and unrelaxed bubble shapes eventually appear at very high ϕ.

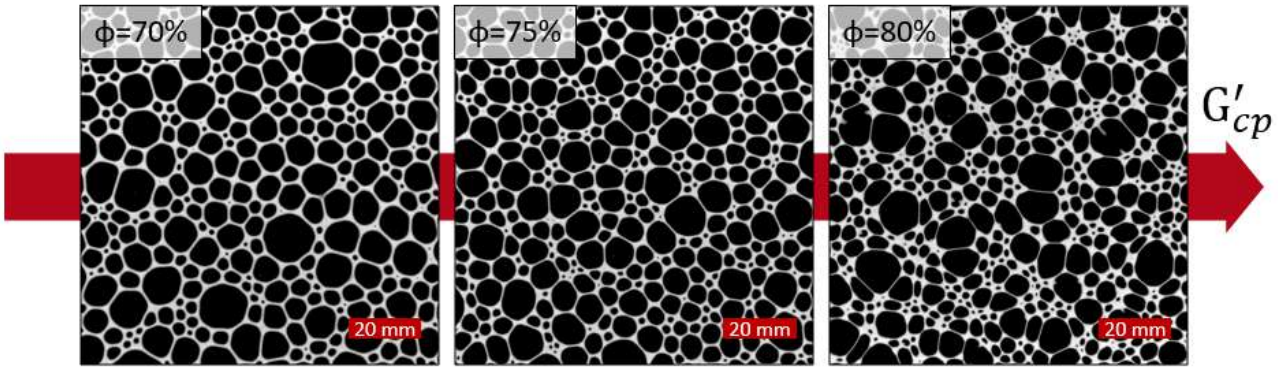

Figure 2. Quasi-2D foamed emulsions at different oil fraction ϕ after 150 hours.

CONCLUSIONS

We show that increasing the elasticity of the foam continuous phase strongly influences the ripening of foamed emulsions, making the coarsening process very slow, with reduced bubble growth rates. Moreover, we show that emulsion viscoelasticity dramatically affects the foam structure, with the appearance of unrelaxed bubble patterns at high oil fractions. The results can lead to a more efficient control of the foam structure and stability.

EMERGING CONCEPTS FOR SMART STRUCTURES IN ADAPTIVE FACADES AND THEIR OPTIMAL DESIGN

Robert J. Zupan[1], Rodrigo Arauz[2], Dale T. Clifford[3], Richard V. Beblo[4], and John C. Brigham *[2,1]
[1]Department of Civil and Environmental Engineering, University of Pittsburgh, Pittsburgh, PA, USA
[2]Department of Engineering, Durham University, Durham, UK
[3]College of Architecture and Environmental Design, California Polytechnic State University, San Luis Obispo, CA, USA
[4]Air Force Research Laboratory, Dayton, OH, USA

Summary Concepts based on both smart materials and emerging smart structural systems for shape-changing façade components for environmentally responsive building facades will be presented. The primary concept considered is a building surface tile fully comprised of a smart material, which can therefore have its intrinsic properties changed on command to facilitate actuating the tile into a variety of different shapes. A numerical representation was experimentally validated and implemented into a computational approach to explore the design space for this adaptive tile to have an effect on the solar irradiance on a building surface. Along with conclusions on this smart material tile concept, present efforts to develop new and complementary strategies incorporating origami and kirigami structural components to achieve adaptivity will be discussed.

BACKGROUND AND MOTIVATION

Energy consumption in the United States is dominated by the commercial building sector at 40% of total energy, and within the commercial building sector the main consumers are lighting and HVAC systems [1]. Due to this, there has been a considerable effort in recent research to reduce energy demand in commercial buildings. Specifically, many of these efforts focus on allowing the building to adapt to internal and external stimuli. Examples of interior building technologies include reducing energy consumption with occupancy sensors for light control [2], or predictive control for ventilation and HVAC systems [3]. Recently, focus has begun to switch to external building technologies, and an example of which is responsive building skins, which change configuration based on an environmental stimulus [4–7].

Responsive building skins have been recently developed to reduce the energy consumption of all main energy consumers within commercial buildings. In an effort to reduce HVAC demand within Media-TIC building in Barcelona an inflatable skin was implemented that inflates portions of the skins based on light sensors to increase insulation [4]. Alternatively the Heliotrace system [4] and the responsive building skin of the Al Bahard towers [5] utilized a series of mechanical apertures to control the flow of light into their respective buildings. Even more recent work has been considering the possibility of including a variety of smart material technologies to further expand the potential capabilities of responsive building skin technologies. The use of smart materials has several potential benefits, due to their controllable (i.e., programmable) intrinsic property changes and the ability to use naturally occurring stimulus (e.g., heat or solar radiation) or minimal supplied energy to elicit these property changes. Utilizing one or both of these smart material capabilities can lead to smart components that have more adaptivity and/or require less energy to achieve the same level of adaptivity, while also potentially eliminating overall system complexity (e.g., removing the need for hinges, etc.).

There are several smart material technologies that have been implemented into external building structures in order to mechanically change the façade to allow the building to positively interact with environmental stimuli. A specific example of a façade component comprised of a smart material was explored in [6] which utilizes hygromorphic materials, which behave similarly to a conifer cone in nature when the relative humidity changes [6]. This allows the façade component to “close” and provide shelter during high moisture loads (i.e., rain) and “open” to allow solar exposure during low moisture loads. Alternatively, Barrett et al. developed a building skin that used bimetal sheet layers that had differing coefficients of thermal expansion in order to curl towards or away from the structure based on the thermal loading in the surrounding environment [7]. The curling behavior of the façade component reduced solar gains by providing shading during high thermal loading and increased insulation during periods of low thermal loading. Alternatively, there has been some focus on creating morphing structures that similarly use intrinsic mechanisms (rather than hinges or multiple mechanical components) to achieve adaptivity, but rather than using smart material, they use structural responses, such as through origami (e.g., bi-stable folding components) or kirigami (e.g., cuts/holes in a component to control deformation). For example, kirigami (i.e., methods based on cutting/removing material) mechanisms have been investigated that can utilize an out-of-plane buckling response to allow portions of the surface to rotate as desired due to in-plane tension or compression [8]. A range of kirigami approaches have been investigated to achieve various structural responses, including parallel cuts, notches, and square cuts.

ADAPTIVE SMART MATERIAL TILE DESIGN CONCEPT

The primary design concept considered herein is an adaptive shape changing “wrinkled” surface tile based upon the prior work developing building surface “cactus tiles” by Clifford [9]. The original cactus tile objective from the previous work was to have static “wrinkled” surface tiles that were both aesthetically pleasing and had functional benefits in terms of self-shading. However, it is envisioned that adding the capability of such tiles to change between

wrinkle patterns, would further enhance the original benefits and potentially include many other functional behaviors. The proposed mechanism to produce a tile that can morph between different wrinkle patterns (i.e., shape changing cactus tile) is envisioned to be controllable localized activation of the smart material comprising the tile (e.g., softening) and mechanical actuation to deform the tile into a desired shape. Localized material activation has been shown to improve the efficiency of a shape-changing structure and is utilized as an additional control variable to increase functionality of the shape-changing building surface tile. Figure 1 shows the apparatus for the benchtop prototype used to test the smart material tiles, validate the numerical representation, and evaluate their morphing capability, including a breakdown of the apparatus components and dimensions.

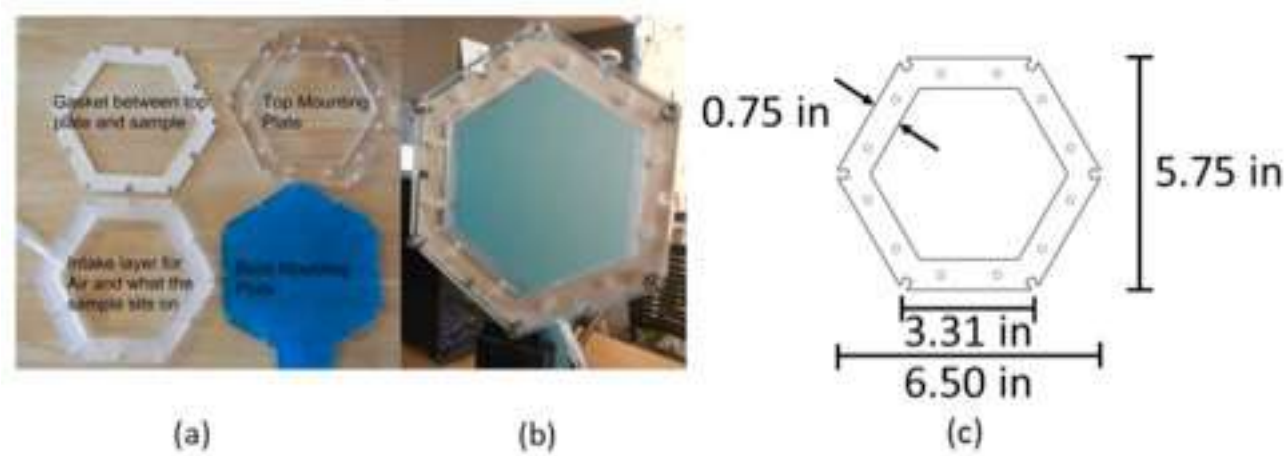

Figure 1. (a) The layers of the apparatus, (b) the fully assembled apparatus, and (c) the dimensions of the apparatus.

RESULTS AND CONCLUSIONS

Several concepts using smart material and smart structural components for creating building surfaces that respond to their environmental conditions have been considered in this work. The particular focus so far has been on a building surface tile entirely composed of a smart material that can be activated and actuated into configurations to reduce solar irradiance on the building surface. The results indicated that the design of the physical tile can be accurately represented by the computational approach and the adaptive tile can change the surface of a structure to considerably improve the structure's interaction with solar irradiance. It was also found that the morphing frequency (i.e., hourly, daily, monthly, etc.) has a significant effect on the area of the tile exposed to solar irradiance. Finally, it was determined that if the tiles are arranged in an array configuration controlling the tiles independently from one another not only leads to less tile area being exposed to solar irradiance but also requires less tile area to be activated. Going forward, concepts utilizing origami and kirigami structural components are being investigated to further enhance energy efficient adaptive façades that can favorably respond to a range of environmental conditions.

TOPOLOGY OPTIMIZATION WITH INEXACT DESIGN SENSITIVITIES

Oded Amir * [1]
[1]Faculty of Civil and Environmental Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary We present recent developments of structural topology optimization procedures with inexact design sensitivities. In the nested approach to structural optimization, the vast majority of computational cost is invested in repeated solutions of the state and adjoint equations. These are used in intermediate design iterations solely for computing the design sensitivities that are subsequently used to generate an updated design by solving an approximate convex subproblem. We hereby explore the possibility of relaxing the accuracy requirement in the iterative solution of the state and adjoint problems, based on the predicted accuracy of the sensitivities. Implementation and results for linear-elastic static problems involving compliance and stress functionals are discussed.

INTRODUCTION

Topology optimization is nowadays a mature and widely accepted computational design approach. Manufacturing processes have also progressed and can realize optimized designs with complex geometries. Consequently, topology optimization is pushed towards very high computational resolution so that novel design concepts can be found that bring significant weight reduction and excellent structural performance. Hence there is a growing interest in efficient computational schemes that can generate high-resolution optimized designs using reasonable computational cost.

One evident consequence of the need for high-resolution topology optimization is the increasing popularity of parallel computing where iterative methods are utilized for solving the state and adjoint equations. But top-class hardware and iterative solvers alone are not enough: algorithmic developments are necessary as well in order to achieve significant reduction in computational time. Recent studies demonstrated considerable computational savings by reusing preconditioners and by relaxing the convergence requirements for the iterative solvers [1, 2, 3]. In some cases, up to 80% savings in computational effort were achieved in comparison to a standard implementation.

INEXACT DESIGN SENSITVITIES

Iterative solution of the state and adjoint problems can be terminated prematurely, yielding an approximation of the displacement or adjoint vector at a reduced computational cost. Various criteria for early termination have been investigated in the context of topology optimization, including: naively relaxing the tolerance of the relative force residual; measuring the convergence of the objective or constraint value; relating the tolerance to the accuracy of the finite element approximation [3]; and monitoring the predicted accuracy of the design sensitivities, that are the first-order gradients used for optimization [1, 2].

The aforementioned studies treat the relatively simple case of optimizing compliance versus volume. For the compliance functional, all design sensitivities are negative and their spatial distribution does not change significantly between design iterations. This makes the compliance functional an ideal platform for reusing preconditioners and for relaxing the convergence of the iterative state solver. The more challenging stress functional, that is also more relevant from an industrial perspective, has not been examined so far in the context of efficient computational procedures. Hence the main purpose of the current contribution is to build upon the idea of monitoring the design sensitivities as discussed in [1, 2] and extend its applicability to stress-based problems.

The approximate maximum stress functional $\tilde{\sigma}$ is formulated using a p-norm approximation of the true maximum stress over the entire domain. In the context of approximate procedures, it is more challenging than compliance due to the following aspects: 1) Dominant local contributions; 2) Dependence on two separate (state and adjoint) iterative solves; and 3) Accumulation of errors from the state solve into the assembly of the right-hand-side vector in the adjoint system.

We suggest that termination of the iterative solvers will be determined according to an acceptable convergence of the design sensitivities, rather than based on residual forces. Accordingly, the iterative solution of the state system $\mathbf{K}\left(\overline{\boldsymbol{\rho}}\right)\mathbf{u}=\mathbf{f}$ is terminated based on the evaluation of $\frac{\partial\tilde{\sigma}}{\partial\overline{\boldsymbol{\rho}}}$ and the iterative solution of the adjoint system $\mathbf{K}^T\boldsymbol{\lambda}=-\frac{\partial\tilde{\sigma}}{\partial\mathbf{u}}$ is terminated based on the evaluation of $\boldsymbol{\lambda}^T\frac{\partial\mathbf{K}}{\partial\overline{\boldsymbol{\rho}}}\mathbf{u}$. In each optimization cycle, given the current vector of design variables $\overline{\boldsymbol{\rho}}$ we call a multigrid-preconditioned conjugate gradient (MGCG) solver to approximate the solution of $\mathbf{K}\left(\overline{\boldsymbol{\rho}}\right)\mathbf{u}=\mathbf{f}$. Compared to a standard MGCG solver, the difference is in the stopping criterion, that is based on the evolution (along CG iterations) of the sensitivity term $\frac{\partial\tilde{\sigma}}{\partial\overline{\boldsymbol{\rho}}}$. Once the approximate solve of the displacements has terminated, the right-hand-side vector of the adjoint equation can be evaluated using the approximate stress vector $\boldsymbol{\sigma}_{k+1}$. Then the solution of the adjoint system $\mathbf{K}^T\boldsymbol{\lambda}=-\frac{\partial\tilde{\sigma}}{\partial\mathbf{u}}$ is approximated in another MGCG procedure, that is terminated based on the evolution (along CG iterations) of the sensitivity term $\boldsymbol{\lambda}^T\frac{\partial\mathbf{K}}{\partial\overline{\boldsymbol{\rho}}}\mathbf{u}$.

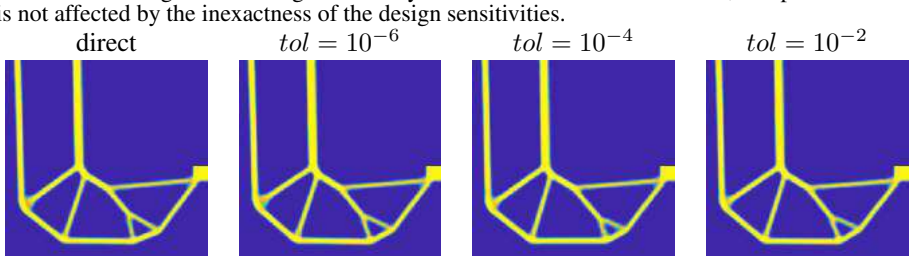
RESULTS

As a demonstrative example, we present the minimum volume optimization of an L-bracket domain, subject to an aggregated p-norm stress constraint. As can be seen in Table 1, the optimized designs are practically identical to the one obtained with exact direct solves. Moreover, the design is not influenced by the value of the convergence tolerance, in the range of $tol = 10^{-2}$ to $tol = 10^{-6}$. Even though the problem is highly nonlinear and non-convex, we obtain very similar convergence curves of the objective and stress constraint, see Figure 1. Remarkably, the first 22 design iterations are practically identical, regardless of the accuracy of the state and adjoint solves. Then parameters are modified according to a continuation scheme and some differences appear. Nevertheless all procedures converge to very similar volumes and satisfy the stress constraint. Computational results are summarized in Table 2. Relaxing the convergence tolerance leads to a reduction of more than 60% in the number of CG iterations performed during the state and adjoint solves. It is important to note that imposing the same tolerances on standard convergence criteria, such as relative residual forces, would not yield the same success. The direct control over the accuracy of the first-order gradients is key to an accurate and efficient optimization outcome.

Table 1: Optimized L-brackets using various design sensitivity tolerances of the iterative solver, compared to the solution with a direct solver. The design is not affected by the inexactness of the design sensitivities.



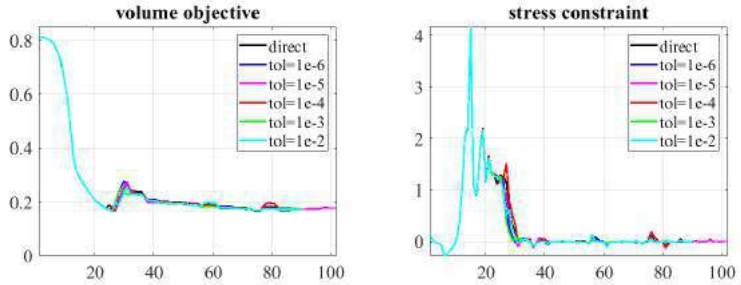


Figure 1: Convergence of the volume objective and stress constraint, for various convergence tolerances of the design sensitivities.

Table 2: L-bracket stress optimization with 31488 finite elements.

tolerance	direct	10^{-6}	10^{-5}	10^{-4}	10^{-3}	10^{-2}
volume	5186	5271	5366	5262	5278	5142
σ_{max}	0.4857	0.4991	0.4949	0.4859	0.4955	0.4906
CG iters., state		1108	1033	695	483	430
CG iters., adjoint		823	682	427	331	295

CONCLUSIONS

A convergence criterion for iterative solves of state and adjoint systems in stress-constrained topology optimization was proposed, based on the predicted accuracy of the design sensitivities. Results show that with this criterion, the number of MGCG iterations—hence the computational cost—is reduced significantly, without compromise on the volume-to-stress trade-off.

NUMERICAL INVESTIGATION OF STIFFNESS AND BUCKLING RESPONSE OF INFILLED STRUCTURES

Fengwen Wang * [1], Jeroen Peter Groen[1], and Ole Sigmund[1]
[1]Department of Mechanical Engineering, Technical University of Denmark, Kongens Lyngby, Denmark

Summary This study investigates the stiffness and buckling responses of 2D coated MBB beams with orthotropic infills obtained using homogenization-based stiffness optimization and de-homogenization. The considered infills are a reference truss lattice microstructure, and a topology optimized one with enhanced buckling strength. Both linear buckling and post-buckling analyses are employed to predict the structure buckling strength. Numerical results show that 2D coated MBB beams with different infills exhibit close stiffness and that the one with the optimized microstructure possesses higher buckling strength. However, buckling strength enhancement of the optimized microstructure significantly degrades in the 2D coated MBB beam compared with the material prediction.

INTRODUCTION

Additive manufacturing brings a tremendous interest in designing hierarchical structures [1]. Topology optimization methods have been employed to design structures with enhanced stiffness considering 3D printing infill or mapped rank-N laminates [2]. Even though coated structures with infill or de-homogenized rank-2 microstructures do not outperform their solid counterparts regarding stiffness, they may possess an advantage from the buckling strength perspective [3]. Recently, materials with enhanced buckling strength [4] have been systematically designed using topology optimization for different macro-level stress situations. It has been shown that material buckling strength can be significantly enhanced at the cost of decreased stiffness. More recently, the material buckling strength has been further studied when considering the material and geometric nonlinearities and geometrical imperfections [5]. Moreover, stiffness and buckling responses of the simple and optimized periodic infill structures have been numerically investigated for uniaxial compression by the authors [6]. Both studies have shown that the optimized microstructures significantly outperform the reference ones in terms of buckling response at the cost of stiffness.

Until now, however it is an open question, how structures with optimized microstructures as infill perform compared to regular infill structures in terms of stiffness and buckling responses. Based on the work in [6], this study further investigates the stiffness and buckling responses of 2D coated MBB beams with orthotropic infills obtained using homogenization-based stiffness optimization and projection [2]. The considered infills are the reference microstructure (RMS) and the optimized microstructure (OMS) as in [6], see Fig. 1.

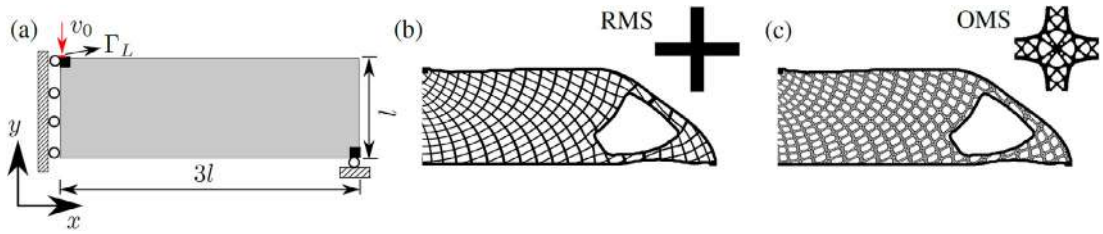

Figure 1: (a) Geometric boundary conditions of the MBB beam. (b) 2D coated MBB beam with RMS. (c) 2D coated MBB beam with OMS.

COMPUTATIONAL METHODS AND NUMERICAL RESULTS

The coated MBB beam is modeled under the plane strain assumptions with a height of $l = 1$ and a thickness of $t = 0.25$. As shown in Fig. 1 (a), the coated MBB beam is subjected to prescribed vertical displacement v_0 on the left upper corner. The length of the loading region Γ_L is 2.4% of the beam height.

Both linear buckling (LB) and post-buckling (PB) analyses are employed to investigate structural performance based on the finite element method. The LB analysis follows the standard linear buckling analysis as described in [7]. In the PB analysis, the total Lagrangian approach is used, and the static equilibrium is solved using the arc-length method for each displacement increment step. The detailed equations for the LB and PB analyses are stated in [6] and will not be repeated here.

The Young's modulus and Poisson's ratio of the base material (in black) are $E_0 = 1$ and $\nu = 0.3$. A modified compressible Neo-Hookean material law [7] is used to describe the material behavior under finite deformations. The corresponding material stored energy density is written as $W = \frac{1}{2}\lambda_0 (J-1)^2 + \frac{\mu_0}{2}(I-3) - \mu_0 \ln(J)$. $\boldsymbol{F}$ is the deformation gradient and $J = \det(\boldsymbol{F})$, $I = \mathrm{trace}(\mathrm{C})$ with $\boldsymbol{C} = \boldsymbol{F}^T\boldsymbol{F}$ being the right Cauchy-Green deformation tensor, and λ_0 and μ_0 are the Lamé parameters of the base material.

*Corresponding author. E-mail: fwan@mek.dtu.dk

In the PB evaluation, the considered geometric imperfections are the equal-weighted first four buckling modes for the LB analysis (see Fig. 2 (a) and (b)), with a maximum perturbation amplitude, $\varphi = 0.0005$. At each equilibrium state, the total reaction force on the displacement loading edge is calculated using $f^{\text{rect}} = \sum_{i \in \Gamma_L} f^{\text{int}}_{y,i}$, where i refers to the nodal number and $f^{\text{int}}_{y,i}$ is the corresponding internal load in the y direction. The buckling point is defined by the state where the structure looses significant stiffness. Here it is defined as the state where the stiffness has decreased to 20% of the initial one.

Fig. 2 shows the structure evaluations using the LB and PB analyses. Fig. 2 (a) and (b) present the first four linear buckling modes with τ_i indicating the ith mode. The LB evaluations show that the 2D coated MBB beam with OMS exhibits 33% higher buckling strength than the one with RMS. Fig. 2 (c) shows the reaction force versus displacement response in the PB analysis with the square symbols indicating buckling points, and final structure deformations. It is seen that the 2D coated MBB beam with OMS exhibits very close stiffness with the one with RMS. Meanwhile, the 2D coated MBB beam with OMS possesses 68% higher buckling strength. Moreover, the buckling strength of both considered structures from the PB analyses is smaller than the corresponding one from the LB analysis due to material and geometric nonlinearity.

Both LB and PB evaluations show that, in the 2D coated MBB beam, buckling strength enhancement of OMS degrades compared with the material prediction in [4, 5] and the evaluations of finite periodic structures under the uniaxial compression in [6].

TOPOLOGY OPTIMIZATION OF A SUBWOOFER

Ahmad H. Bokhari1, Martin Berggren1, Daniel Noreland1,2, and Eddie Wadbro*1
[1]Department of Computing Science, Umeå University, SE–901 87 Umeå, Sweden.
[2]The Forestry Research Institute of Sweden (Skogforsk), Uppsala Science Park, SE–751 83 Uppsala, Sweden.

Summary Subwoofers generate the lowest frequency range in loudspeaker systems. Here, we study a so-called band-pass subwoofer enclosure, in which a transducer is mounted in a closed back chamber located inside the subwoofer cabinet, and an output port is placed in the front chamber. To reduce the computational time of simulating the average response for a given subwoofer design, we present a hybrid 3D/2D model that efficiently models the subwoofer's performance. The results of the hybrid model are validated against a full 3D model over a frequency band of interest; the validation confirms that the hybrid model is computationally efficient as well as accurate. We formulate and solve a material distribution based topology optimization problem, to design of the subwoofer's interior cabinet to provide obtain desired transmission properties.

INTRODUCTION

The classical topology optimization problem is to minimize the compliance of a statically loaded elastic structure subject to constraints on the amount of available material. There are well-established techniques to solve this problem [1]. However, techniques for acoustic design optimization are still maturing. Current methods in acoustics focus on optimizing individual components, such as loudspeaker horns and sound mufflers, under idealized conditions. However, real-life acoustic systems consist of many components that affect each other's performance. In this study, we aim to optimize the interior layout of a subwoofer.

HYBRID MODEL

We study a so-called band-pass subwoofer enclosure, in which a transducer is mounted in a closed back chamber located inside the subwoofer cabinet, and an output port is placed in the front chamber. If we discretize the whole system uniformly and consider 3D effects, we obtain a large-scale problem that is computationally intractable. We propose a mathematical model that describes the interaction between the different subwoofer components as interacting modules whose acoustic properties can partly be precomputed. The model is based on time-harmonic linear wave propagation and includes a 3D model of the transducer, an electromechanical circuit model, a 2D model for the subwoofer cabinet's front chamber, whose interior layout is described by a material indicator function, and a 3D model for the exterior wave propagation. The use of a 2D model in planar symmetry for the front chamber drastically reduces the computational cost. The resulting planar design will also be easier to manufacture compared to full 3D design. Due to the long wavelength, it is reasonable with a restriction to 2D wave propagation within the chamber, but not for the transducer or for the exterior, where we rely on 3D models. The results of the hybrid model are validated against a full 3D model over a frequency band of interest. We numerically verify that the hybrid 3D/2D model produces reliable results and that it significantly reduces the computational time compared to a full 3D model. Figure 1 shows two subwoofers with different internal layouts as well as their performance over the interval 20–160 Hz.

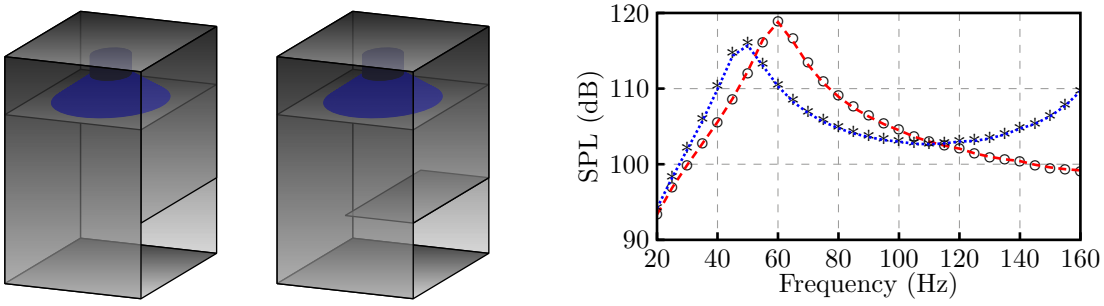

Figure 1: Two subwoofer layouts and their performance evaluated by a full 3D model as well as our proposed hybrid 2D/3D model. The dashed line (hybrid model) and the circles (full 3D model) shows the computed performance of the left subwoofer layout. The right layout has an added internal wall, and its performance is illustrated by the dotted line (hybrid model) and the asterisks (full 3D model).

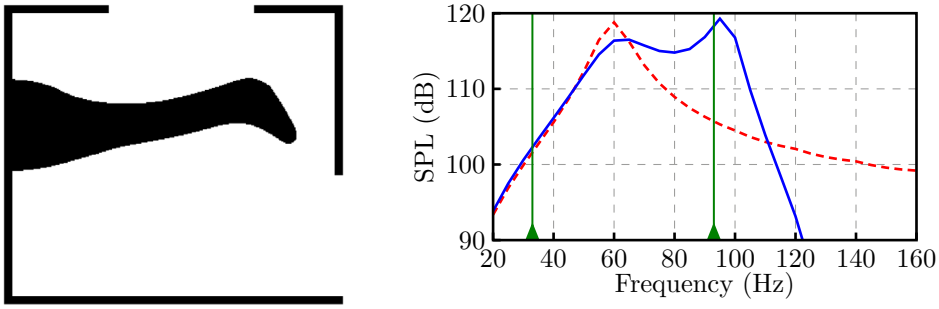

Figure 2: Left: subwoofer optimized for the frequency interval 33–93 Hz, marked by the solid vertical lines. The solid line shows the performance of the optimized subwoofer and the dashed line shows the performance of the of the left subwoofer in Figure 1.

OPTIMIZATION FORMULATION AND RESULTS

We formulate a material distribution topology optimization problem to determine the interior layout of the subwoofer. We use a material indicator function α to determine whether each point in the interior of the subwoofer should be occupied by fluid ($\alpha = 1$) or solid ($\alpha = 0$). To ensure that the resulting interior design (the solid part) has a minimum size, we define α by applying a harmonic-mean based morphology mimicking filter to another function η, which is the function that we optimize over [2, 3, 5].

We mesh the region below the baffle by N elements and in each element, we approximate the material indicator function α and the design η by element-wise constant functions α_h and η_h, respectively. The relation between the vectors $\boldsymbol{\alpha}$ and $\boldsymbol{\eta}$ that hold the element values of α_h and η_h, respectively, can in after discretization be written $\boldsymbol{\alpha} = \mathcal{F}_h(\boldsymbol{\eta})$, where $\mathcal{F}_h$ is a filter operator. The objective of our optimization problem is to find a design so that the output power P is above a certain target P_{target} at given freuencies f_m, $m = 1, \ldots, M$. The topology optimization problem is solved by Svanberg's MMA algorithm, and the adjoint variable method is used to obtain gradients of the objective function with respect to the design variables. Figure 2 shows the cross-sectional internal layout of an optimized subwoofer and its performance together with the performance of the left subwoofer in Figure 1.

[4]Department of Civil Engineering and Architecture, University of Pavia, Pavia, Italy

Summary An innovative method for structural and topology optimization of dynamic systems is presented. The objective function to be minimized is the H_∞–norm of the input/output transfer function that allows to handle single input-single output as well as multi input-multi output systems. The focus of the paper is twofold: on the one side numerical issues concerning the fast computation of the H_∞–norm and its gradient are addressed; on the other side results of structural and practical interest in broad sense are presented to validate the numerical framework. Ongoing and future extensions are eventually highlighted at the end of the paper.

GENERAL REMARKS

A general dynamic system is considered that depends on a vector of structural parameteres, say $\boldsymbol{p}$, that should be determined so as to satisfy some design requirement. The general *descriptor state–space* form is adopted that encompasses several dynamic systems including structural frames and bi–dimensional plane and plate structures. By doing so, the dynamic equilibrium and output equations respectively read

$$\left\{\begin{array}{rcl} \boldsymbol{E}(\boldsymbol{p})\dot{\boldsymbol{x}} &=& \boldsymbol{A}(\boldsymbol{p})\boldsymbol{x} + \boldsymbol{B}\boldsymbol{w} \\ \boldsymbol{y} &=& \boldsymbol{C}\boldsymbol{x} \end{array}\right., \tag{1}$$

wherein matrices and vectors are defined as

$$\boldsymbol{E}(\boldsymbol{p}) = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{M}(\boldsymbol{p}) \end{bmatrix}, \quad \boldsymbol{A}(\boldsymbol{p}) = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{I} \\ -\boldsymbol{K}(\boldsymbol{p}) & -\boldsymbol{D}(\boldsymbol{p}) \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} \boldsymbol{0} \\ \tilde{\boldsymbol{B}} \end{bmatrix}, \ \boldsymbol{x} = \begin{bmatrix} d & \boldsymbol{u} \\ & \dot{\boldsymbol{u}} \end{bmatrix}, \tag{2}$$

in which $\boldsymbol{x}$ and $\boldsymbol{y}$ are the state and output vector, respectively, $\boldsymbol{E}$ is the *descriptor* matrix, $\boldsymbol{A}$ is the *state* matrix, $\boldsymbol{B}$ is the *load* matrix that distributes the external action $\boldsymbol{w}$ to the degrees–of–freedom and $\boldsymbol{C}$ is a matrix that allows to specify the entries of the output vector $\boldsymbol{y}$ as linear combinations of the state vector components. Furthermore the state vector $\boldsymbol{x}$ is obtained by piling displacements $\boldsymbol{u}$ and velocities $\dot{\boldsymbol{u}}$ whereas $\boldsymbol{M}(\boldsymbol{p})$, $\boldsymbol{D}(\boldsymbol{p})$ and $\boldsymbol{K}(\boldsymbol{p})$ are the mass, damping and stiffness matrices and $\boldsymbol{0}$ and $\boldsymbol{I}$ are zero and identity matrices of appropriate dimensions. Based on Equation (1), dynamic optimization could be pursued in the time domain (where the problem is differential) for example along the path set in [1]. It is herein preferred to switch to the Laplace domain (eventually to the Fourier domain) taking advantage of algebraic nature of the resulting problem. By taking the Laplace transform of Equation $(1)_1$, plugging the result into the Laplace transform of Equation $(1)_2$ one gets the input/output relation

$$\boldsymbol{Y} = \boldsymbol{G}(s;\boldsymbol{p})\boldsymbol{W}, \tag{3}$$

that is ruled by the transfer function

$$\boldsymbol{G}(s;\boldsymbol{p}) = \boldsymbol{C}(s\boldsymbol{E}(\boldsymbol{p}) - \boldsymbol{A}(\boldsymbol{p}))^{-1}\boldsymbol{B}. \tag{4}$$

If one now recalls that the H_∞–norm of a system transfer function is the peak response computed over all possible input/output channels, the following optimal design problem arises naturally:

$$\left\{\begin{array}{lll} \min\limits_{\boldsymbol{p}} F(\boldsymbol{p}) & = & ||\boldsymbol{G}(i\omega;\boldsymbol{p})||_\infty \\ \text{s.t.} & & \boldsymbol{G}(i\omega;\boldsymbol{p}) = \boldsymbol{C}(\boldsymbol{p})(i\omega\boldsymbol{E}(\boldsymbol{p}) - \boldsymbol{A}(\boldsymbol{p}))^{-1}\boldsymbol{B}(\boldsymbol{p}) \\ & & V(\boldsymbol{p}) \le V_{\max} \\ & & p_{\min} \le \boldsymbol{p} \le p_{\max} \end{array}\right., \tag{5}$$

where the transfer function definition $(5)_2$ is an equality constraint to the overall optimization problem, $(5)_3$ is a *limited resources* constraint and $(5)_4$ is an elementwise size-constraint.

*Corresponding author. E-mail: paolo.venini@unipv.it.

NUMERICAL ISSUES

On the computation of the H_∞-norm

A key for the solution of Problem 5 is the availability of a reliable and possibly fast numerical scheme for the computation of the H_∞–norm of the system transfer function. This is true for a single norm computation but even more for tackling an optimization problem that calls for several (possibly thousands) successive norm computations. A few methods made available in the literature for computing the H_∞–norm of a complex dynamic system, see e.g. [2] and [3], shall be exploited and relevant performances assessed, at least with respect to the structural problems solved numerically. A few heuristic considerations shall also be given concerning possible improvements that may lead to an even faster H_∞-norm computation.

Using reduced–order models

The number of states entering the formulation, i.e. the dimension N of the state-vector $\boldsymbol{x}$, may be extremely large even for systems of moderate complexity. On the other side, using the H_∞-norm as merit function allows to neglect most of the system poles that are located at a remarkable distance from the frequency $\overline{\omega}$ where the peak response is actually attained, i.e. where the H_∞-norm is realized. It may then be convenient to replace the actual system with a reduced-order one that is capable to accurately replicate the system dynamics in the vicinity of $\overline{\omega}$ without caring about high-frequency (numerically expensive) dynamics that are in fact left unmodelled. The time invested in computing the reduced-order model is likely to be largely paid back as time saved in the computation of the H_∞–norm using a system governed by very few states. All these issues shall be investigated in the paper.

STRUCTURAL AND TOPOLOGY OPTIMIZATION

The above approach shall first be applied to the optimization of the dynamic response of steel plane frames undergoing a dynamic load such as earthquakes or strong winds. The scenario is different form the one recently proposed in [4] in that the design variables grouped in vector $\boldsymbol{p}$ are continuous in the case of reinforced-concrete structures (since they typically represent a cross-section size or the like) whereas they are discrete in the case of steel profiles that are allowed to be of commercial type and therefore belong to a finite-dimensional set. This calls for the adoption of "*non-gradient*" numerical optimization methods such as genetic ones that shall be exploited in this investigation.

Bidimensional problems shall also be considered using classical displacement finite elements but also mixed ones. The latter choice allows an easier and more accurate imposition of the stress constraint especially within a truly-mixed setting wherein the stresses are the primary variables. Furthermore the approach may be extended to a time-dependent viscoelastic response that is of considerable importance when base-isoltaed systems are to be modeled.

CONCLUSIONS

A promising approach for structural and topology optimization of dynamic systems has been presented that is based on the H_∞–norm of the input/output transfer function. Numerical and structural issues have been addressed and shall be reported in much detail. Ongoing extensions include applications to 3D systems as well as to structures affected by uncertainties in the apllied loads and/or in structural properties such as the elastic moduli and the mass density.

EFFICIENT AND ROBUST TOPOLOGY OPTIMIZATION OF NONLINEAR FLEXTURES

Fred van Keulen* and Lidan Zhang
Department of Precision and Microsystems Engineering, Delft University of technology, Delft, The Netherlands

Summary Computationally efficient and robust topology optimization schemes are proposed for the design of nonlinear flexure-based mechanisms (flextures). Advanced layouts of flextures can eliminate crosstalk caused by nonlinearities and may lead to compact designs for precision applications. Special attention is on computational efficiency using adaptive reduced-order models and the elimination of spurious instabilities. Different optimization formulations will be demonstrated to address crosstalk phenomena typical for precision applications.

INTRODUCTION

In precision instruments and tools, alignment and positioning components are key system ingredients. To avoid negative effects caused by play, compliant mechanisms are often preferred for precision settings. These compliant systems are either designed as compliant mechanisms, *i.e.* the elastic deformation is mainly concentrated at the elastic hinges, or as leaf-spring-based systems. In both cases, geometric nonlinearities may cause severe difficulties, for example, leading to crosstalk. To avoid geometrically nonlinear side effects, one could restrict the kinematics to very small rotations, leading to systems which are relatively large as compared to the stroke they are designed for. Alternatively, nonlinear effects may be used to counteract each other. Clearly, the latter adds to the complexity of the design process. As an alternative, leaf-spring type components may be designed in such a manner that certain crosstalk effects are eliminated by advanced layout of flexible components. Such a complex layout can be realized using cost-effective laser cutting on thin-walled sheet materials, see, as an example, Figure 1.

Manual design of flextures with complex layout and manufactured from flat or curved sheets is extremely hard because of the geometric nonlinearities. Topology optimization could potentially address this complex design challenge, provided it can handle the nonlinearities and ill-conditioning caused by the thin-walled setting efficiently. In this contribution we propose and evaluate topology optimization schemes which rely on reduced-order modeling and are geared towards thin-walled finite rotation shell problems.

FINITE ROTATION SHELL MODELING

As mentioned above, advanced sheet-based flexture design should take place in a geometrically nonlinear setting, involving finite rotations and deflections but small deformations. We therefore rely on the triangular thin shell element described in [1]. This simple but robust element is based on a combination of the constant strain and the Morley triangle. For the finite rotation formulation, the bending deformations are evaluated using a co-rotational formulation. The very nature of finite rotations requires internal reference vectors to be updated at every step of an incremental-iterative nonlinear analysis. Although the resulting finite-rotation solution is path independent, the internal reference vectors are path dependent.

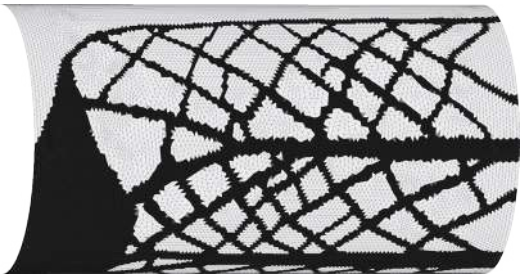

Figure 1: Geometrically nonlinear topology optimization based flexture design on a cylindrical surface. The design is suited for laser cutting.

REDUCED-ORDER MODELING

Topology optimization of geometrically nonlinear structures becomes computationally involved due to the incremental-iterative analyzes involved. For this reason we proposed [2] to use a reduced-order model (ROM), forwhich the degrees of freedom of the finite element model ($\mathbf{u}$) are approximated by $\mathbf{u} \approx \mathbf{R}\mathbf{y}$. Here $\mathbf{y}$ represents a very small set of generalized coordinates and the matrix $\mathbf{R}$ is constructed from a series of carefully selected base vectors Φ_i, *i.e.* $\mathbf{R} = [\Phi_1, \Phi_2, \ldots]$. The base vectors are primarily based on solutions of the full-order model. By measuring the imbalance of a ROM-based solution on the full-order model, an automatic switching between the reduced-order and the full-order model is realized. Moreover, information on the base vectors is used after a design adaptation. Consequently, during an optimization a new analysis may benefit from the ROM basis as developed during previous optimization steps. It was demonstrated that the number of full system solves in a geometrically nonlinear topology optimization could potentially be reduced by one to two orders of magnitude. This ROM formulation is fully compatible with the finite rotation formulation summarized above.

NEARLY INEXTENSIONAL BENDING

Flextures effectively rely on compliant bending modes, whereas extensional modes can be associated with relatively high stiffness. In other words, flexure-based mechanisms exploit nearly inextensional bending. In particularly, for extremely slender structures the correct representation of the bending modes is therefore paramount. Modeling nearly inextensional bending modes incorrectly, may lead to spurious extensions and, consequently, the compliance of the bending modes will be severely underestimated. A careful study of the aforementioned reduced-order model reveals that it suffers from this defect and, therefore is unsuited for the topology optimization of flextures.

To realize a proper ROM-based topology optimization of flexible structures, the ROM basis can be augmented with path-derivative information. A straightforward and inexpensive method to generate path-derivative information is to impose small perturbations of the load level after each full system solve in combination with a modified Newton scheme.

SPURIOUS INSTABILITIES

Geometrically nonlinear topology optimization faces the problems of elements which may, due to severe distortions, "flip" and appearance of spurious instabilities. The latter is especially prominent for thin-walled structures. For flexture design problems, flipping of elements is less prominent. Given the thin-walled nature of flexture designs, spurious instabilities may be anticipated in low density areas.

Different remedies have been proposed to circumvent the above complications. Bruns and Tortorelli [3] proposed to remove the void elements from the model. Yoon and Kim [4] used an element connectivity formulation. Van Dijk *et al.* [5] suggested a scaling of the deformations. Unfortunately, none of these formulations is easy to combine with the co-rotation formulation and/or the ROM scheme being used. Compatible with the ROM scheme at hand is the technique proposed by Wang *et al.* [6], who scale the nonlinearity. In fact, nonlinear elements are converted into linear elements in void areas. A one-to-one application of this method to the co-rotation formulation is not possible. However, given the fact that spurious instabilities are primarily caused by the contributions involving the tangential stress resultants and the membrane deformations are still evaluated via a total-Lagrangian formulation, we opt for a scaling in the spirit of [6], but for the membrane deformations only.

TOPOLOGY OPTIMIZATION OF FLEXTURES

In this presentation, the proposed ROM-based topology optimization schemes with avoidance of spurious instabilities are tested and demonstrated on flexture design problems. The tests are restricted to flextures which can be manufactured from thin sheets (flat or curved) using laser cutting. Different optimization formulations are tested which include crosstalk requirements typical for precision applications. Robustness and efficiency of the proposed methods are demonstrated.

[3]Materialise, Leuven, Belgium

Summary This paper focuses on the design of lattice support structures for 3D printed parts produced by selective laser melting. These support structures are needed to counteract thermal deformations during the printing process, so preventing print failure due to recoater collisions. A method is proposed to minimize the amount of material needed for the lattice support structure. The design is subdivided in a number of printing stages (each combining multiple printed layers), and for each printing stage, constraints are imposed on the upward displacements of the upper side to avoid recoater collisions. In order to predict these displacements, the lattice is modeled as a homogenized medium, and the temperature load is taken into account by means of the inherent strain method. The approach is successfully applied to a number of test problems, both in 2D and in 3D.

INTRODUCTION

Many additive manufacturing techniques involve the generation of heat. This may result in thermal deformations, leading to inaccuracies in the printed part compared to the blueprint design. In the case of selective laser melting, it may also result in complete print failure, as upward displacements due to thermal deformations can give rise to collisions between the recoater (the printer component that deposits new layers of metal powder) and the printed part. Additional support structures that can counteract the thermal deformations are usually foreseen to prevent such recoater collisions. However, these support structures come at a cost, as they involve an increase in material and energy consumption, printing time, and pre- and postprocessing work (to design and to remove the support structure). In this paper, we propose a method to minimize the amount of support structure needed to avoid recoater collisions due to thermal deformations in selective laser melting.

SIMULATION OF THERMAL DEFORMATIONS

Support structures with a lattice layout are often used as they are relatively easy to remove from the printed part. We therefore focus on lattice support structures, and we consider a lattice with the isotruss architecture [1], see figure 1. The isotruss unit cell consists of horizontal and vertical bars with a diameter d and diagonal bars with a diameter $4d/3\sqrt{3}$. This diameter ratio results in isotropic macroscale behavior.

Figure 1: Unit cell of a lattice with the isotruss architecture.

Watts et al. [3] determined approximate polynomial expressions for the homogenized Young's modulus E, Poisson's ratio ν, and bar diameter d of an isotruss lattice in terms of its density ρ. We use these expressions to model the lattice structure as a homogeneous isotropic material.

In order to predict thermal deformations during the printing process, a simulation should be performed for each additional layer. As this is computationally way too expensive due to the large number of layers, a smaller number of printing stages (each consisting of multiple additional layers) is considered instead. For each stage, the inherent strain method is used to model the temperature load. In this method, which has originally been developed for welding [2], initial strains are imposed in the so-called activated layer, or the top layer of the printing stage. The thickness of the activated layer can be chosen freely (e.g. $1\,\mathrm{mm}$); the initial strains must determined from test prints on the same machine where the actual part will be produced, with the same settings, assuming the same activated layer thickness.

The thermal deformations are calculated by means of the finite element method: the design (consisting of the part and the homogenized support structure) is subdivided into finite elements. Each element e of the support structure is assigned a density ρ_e (ranging from 0 for a void element to 1 for a solid element), which determines its elastic properties E_e and ν_e. The element densities ρ_e are collected in a vector $\boldsymbol{\rho}$. Next, the stiffness matrix $\mathbf{K}_i(\boldsymbol{\rho})$ is assembled for each printing stage i, as well as the nodal force vector $\mathbf{f}_i$ that represents the temperature load. Finally, the nodal displacements $\mathbf{u}_i$ for each printing stage i are determined as the solution of the discretized state equation $\mathbf{K}_i\mathbf{u}_i = \mathbf{f}_i$.

FORMULATION OF THE OPTIMIZATION PROBLEM

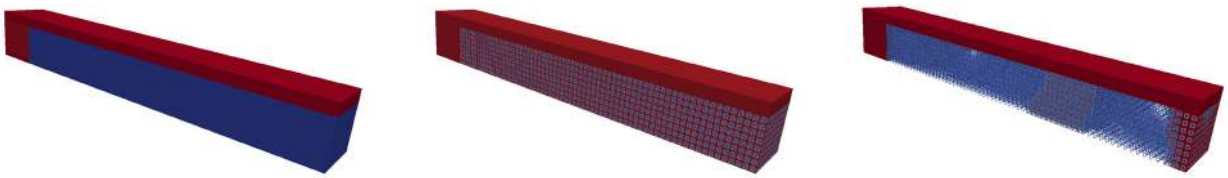
The support structure design optimization problem is formulated as follows:

$$\begin{aligned} \min_{\boldsymbol{\rho}} : \quad & V = \sum_e v_e \rho_e \\ \text{s.t.} : \quad & u_{i,j} \leq u_{\max} \quad \forall i,j \\ & \rho_{\min} \leq \rho_e \leq \rho_{\max} \end{aligned} \tag{1}$$

The element densities ρ_e are used as design variables; they are bounded by a minimum value $\rho_{\min}$ and a maximum value $\rho_{\max}$ that depend on the minimum and maximum allowable bar diameter, respectively. The objective is to minimize the total material volume V of the support structure, which depends on the element volumes v_e and densities ρ_e. For each printing stage i, a number of critical nodes on the upper side of the design printed so far is selected, and the vertical displacements of these nodes (denoted by $u_{i,j}$) are restricted to a maximum allowable value $u_{\max}$.

RESULTS

The optimization problem is solved to determine the support structure for a cantilevering part as shown in figure 2a. Two cases are considered: in the first case, a spatially uniform density distribution is adopted for the support structure; i.e. all unit cells of the lattice are identical. In this case, there is only a single design variable, and the optimization problem is solved by means of a bisection algorithm. This leads to the design shown in figure 2b. For this design, $64.3\,\%$ of the material required to produce the component is used to print the support structure.



(a) (b) (c)

Figure 2: (a) Part (red) and support structure (blue), (b) minimal support structure with a spatially uniform density distribution, and (c) minimal support structure with a spatially varying density distribution.

In the second case, a spatially varying density distribution is adopted for the support structure; i.e. all unit cells are allowed to vary. In order to ensure manufacturability, the spatial variation of the densities (and hence the bar diameters) is limited by means of a density filter. The optimization problem is solved by means of the method of moving asymptotes. The resulting design is shown in figure 2c. The support structure now concentrates where the largest upward displacements are expected: a vertical strut emerges at the tip of the cantilever. In addition, a shear-resisting structure develops at about two-thirds of the length of the cantilever. This can probably be explained as follows: due to shrinkage of the cantilever, the vertical strut is subjected to bending, resulting in an elongation of its right hand side. This causes an upward displacement of the tip of the cantilever. The shear-resisting structure reduces the shrinkage of the cantilever and thus the upward displacement of the tip. For this design, only $11.6\,\%$ of the material needed is used to print the support structure, which is considerably less than for the spatially uniform design.

CONCLUSION

This paper presents a method for the optimal design of lattice support structures used in selective laser melting to reduce thermal deformations, and so to prevent recoater collisions. The lattice is modeled as a homogenized medium, and the temperature load by means of the inherent strain method. The optimization method leads to considerable material savings compared to a simple spatially uniform design. Future work will focus on the use of bar or beam elements to improve the accuracy of the lattice model and to allow for more design freedom, and on the design of support structures to prevent excessive thermal deformations in parts produced by stereolithography.

Summary Structural materials that can be healed enable new approaches, and remove old constraints, for engineering design and optimization. It has, however, been difficult to heal metal effectively, especially at room temperature and in geometrically complex parts where welding is not possible. This work explains how new advances in electrochemical healing of metal enables new design strategies, as demonstrated by the repair of complex 3-D printed metal parts whose internal geometry prevents repair using conventional technologies.

INTRODUCTION

Modern engineering design follows an approach where a part is optimized to withstand all future loading cases in the part's projected lifetime. This approach has been highly effective, but results in concepts like safety factors, which increase the weight and volume of the part beyond what's necessary in normal loading conditions. Most of this excess material is wasted in a part's lifetime. Additionally, this design approach makes it difficult to transfer parts between different use cases as defects and environmental changes can lead to premature failure. An alternative strategy, however, can be found in biology, such as in bone, where parts are efficiently produced to withstand most loading cases and, when an extreme case is encountered, the parts can be repaired without being replaced. Manmade structural materials that could heal like bone would have several advantages, including increased sustainability by reducing the part mass, which reduces associated CO_2 emissions and environmental pollutants, and by extending part service life, which reduces the need for complex recycling processes [1]. A major challenge, however, has been realizing structural metals that can be effectively healed without an expert (in the case of welding) or without high temperatures which consume lots of energy and degrade nearby materials.

Recently, we have demonstrated a new rapid, effective, low-energy, and room-temperature approach for healing cellular metals using electrochemistry and polymer-coated cellular nickel to mimic the transport-mediated healing of bone (Fig. 1) [2]. The polymer coating enabled selective healing only at the fracture site, electrochemical reactions transported metal ions from a metal source to fractured areas, and the open-cell structure of the metal allowed rapid ion transport to healing sites and effective recovery of strength and toughness when the cellular metal was subjected to scission fracture, tensile failure, and plastic deformation. Using this strategy, fractured samples recovered 100% of their tensile strength in as little as 10 and 4 hours of healing. This electrochemistry-based approach enabled the first demonstration of room-temperature healing of structural metallic materials and required several orders of magnitude less energy than many previously-reported metal healing techniques.

In this work, we will discuss the advantages of electrochemical healing of metals, new design strategies that emerge through the combined optimization of mechanics and electrochemical transport, and how this approach enables the repair of complex metal parts realized from 3-D printing whose internal geometry prevents repair using current technologies.

RESULTS AND DISCUSSION

Figure 1b illustrates our approach for healing cellular nickel at room temperature. First, we conformally coated 5 to 9 µm-thick films of Parylene D (an insulating polymer with excellent barrier properties and chemical stability) onto cellular nickel. The cellular nickel had 250 µm average diameter pores and 3% relative density. Figure 1c shows a fractured nickel strut after straining the cellular nickel in tension. The 10% failure strain of Parylene D was large enough so that only severely damaged nickel was exposed, but lower than the 23% failure strain of the nickel so that fractured nickel was not covered by polymer. Applying a negative potential (-1.8 V) to the fractured cellular nickel, relative to a nickel counter electrode, healed the sample by driving electrons through the conductive nickel to the fracture location and reducing nickel ions in the electrolyte to solid nickel. The open-cell pores enabled rapid ion transport to the fracture site. Nickel electrodeposited on both sides of the fractured strut grew until the growth fronts merged, forming a continuous strut (Figure 1d). Figure 1e shows the typical stress-strain data of Parylene-coated cellular nickel.

This healing strategy is especially effective for geometrically complex parts where conventional repair techniques, such as welding, are impossible due to the difficulty of accessing internal geometric components. Welding also requires high temperatures (~104 K) and consumes large amounts of energy (103 to 106 kJ per mm of crack length healed), which makes it difficult to use in composites with low melting point materials. Figure 2 shows a shellular part [3] designed using 3D optimization to only deform in tension and fabricated with an aluminum alloy using selective laser sintering (SLS). This part has internal surfaces that, if fractured, would be impossible to repair with welding. By applying our electrochemical healing approach to this material, we can repair internal and external fractured surfaces to 100% of their initial strength at room temperature and with low energy. Additionally, we demonstrate that tuning the fracture strain in the polymer coating can optimization healing efficiency.

CONCLUSIONS

This work is a step forward in optimizing the efficiency of electrochemical healing, as well as demonstrating its superiority over welding in healing geometrically complex metals. Future work will explore the intersection of structural design and electrochemical transport, so that parts can be optimized to achieve both high strength or modulus and fast transport properties so that the healing time and energy can be minimized.

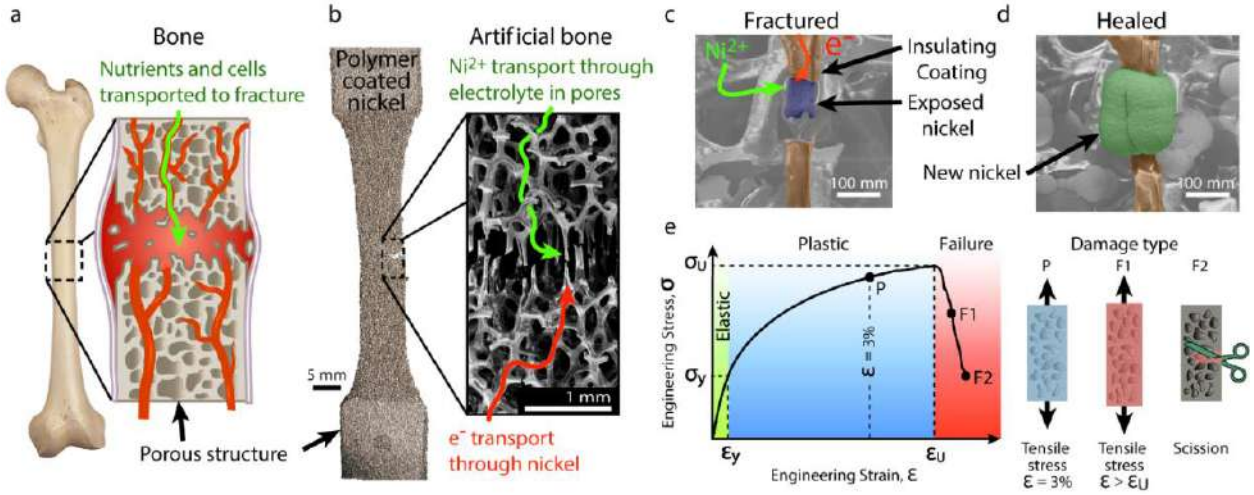

Figure 1. Transport-mediated healing in cellular metals inspired by bone. a) Illustration of hematoma formation during bone fracture. Healing occurs by transporting cells and nutrients through the cellular bone to the fracture location. b) Illustration of our transport-mediated approach for healing polymer-coated cellular nickel. Healing occurs by transporting electrons through the nickel and nickel ions through the electrolyte in the pores to the healing location. The nickel ions electrochemically reduce and new nickel is electrodeposited. c) SEM image of a fractured nickel strut. Exposed nickel and the plastic coating are false-colored with blue and brown, and the background brightened to highlight the strut. d) The same strut in (c) after healing. Electrodeposited nickel is false-colored green. e) Stress-strain data of a cellular nickel sample. We characterized the healing effectiveness of cellular nickel subjected to three damage types: plastic deformation at 3% strain (P), failure beyond the ultimate strain (F1), and local failure by scission (F2).

TOPOLOGY OPTIMIZATION OF IMPERFECT LATTICE MATERIALS ADDITIVELY BUILT

Ahmed Moussa, David Melancon, Asma El Elmi, and Damiano Pasini*
Department of Mechanical Engineering, McGill University, Montreal, Canada

Summary Lattice materials built with current additive technology feature process-induced defects that impact their mechanical properties and optimum design. This work presents a methodology to integrate geometric defects in a gradient-based formulation for topology optimization of additively built lattice materials. The method is of general application, and it is here demonstrated through the application to the Octet-truss unit cell, called to satisfy specific geometric constraints. Validation is performed through the solution of the fixed-beam benchmark problem, assumed to consist of either defect-free or imperfect lattice materials. The results highlight the significance of accounting for geometric defects in topology optimization of additively built lattice materials.

INTRODUCTION

Lattice materials can be designed to feature a range of optimally tuned physical properties, such as stiffness to mass ratio, and mechanical biocompatibility, often superior to those of other existing solids. Once manufactured additively, however, their architecture can deviate from their nominal counterpart due to process-induced defects appearing in both the base material and geometry. The outcome is an undesired shift in mechanical properties [1, 2] and functional performance [3]. To date, however, the impact of additive manufacturing (AM) induced defects on the mechanics and optimized porosity gradient of porous materials has not been studied. This work unveils the role of a set of manufacturing defects and cell orientation on the elastic anisotropy of the unit cell, the optimized gradients of relative density, and the global compliance of optimally graded 3D lattices.

METHODOLOGY

We formulate a gradient-based topology optimization problem that integrates the homogenised properties of imperfect lattice materials. Additively manufactured lattice samples are μCT-reconstructed and morphologically characterized to attain the dispersion of a set of process-induced geometric defects including strut thickness variation and center axis deviation. Their probabilistic distribution is integrated into imperfect-architecture models that can parallel the behavior of as-manufactured lattices.

RESULTS

The geometric discrepancy as well as specific symmetry in elastic properties of the cell have a directional impact on the unit cell response, which also influences the optimized density distribution throughout the entire cellular domain. To capture the moduli dependency on cell orientation with respect to the building direction, Figure 1 illustrates three-dimensional and planar polar plots of the elastic modulus of an illustrative unit cell, the Octet-truss. The responses are given at a representative value of $\rho = 0.4$ (i.e. 60% porosity). Manufacturing defects lead to a shift in symmetry and reduction in elastic moduli of as-built architectures. In the planar plot of the Young's modulus, the maximum discrepancy in the x direction, $\Delta\left(E_{xx}/E_s\right)_{\max}$ between as-designed (nominal) and imperfect models is 25% at 45 degrees rotation angle around z-axis. The impact of these defects can be now integrated into the topology optimization of lattice materials in a benchmark problem.

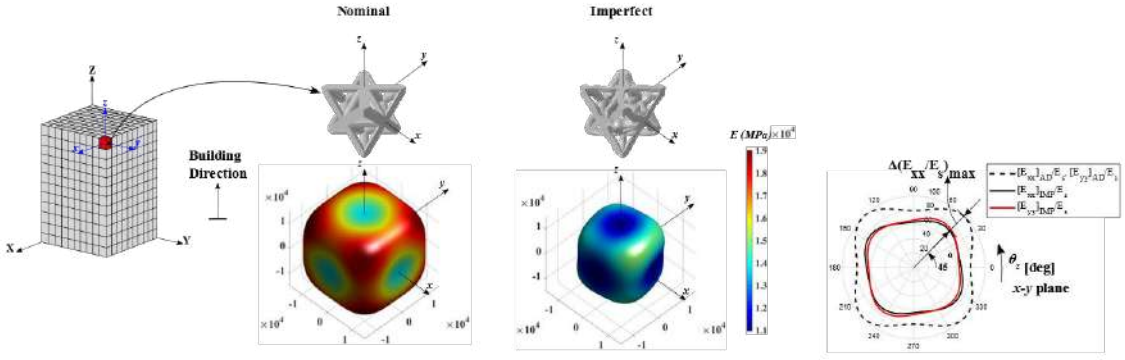

Figure 1. 3D polar plots of Young's moduli, and 2D polar plot of the normalized Young's moduli along *x* and *y* axes at different unit cell orientations, of as-designed and imperfect models, at relative density $\rho = 0.4$.

Figure 2a shows the design domain (L= 6 mm), boundary conditions, and external loads (vertical distributed load F= 1500 N). Heat treated Ti6Al4V alloy (E_s=114 GPa, Poisson's ratio υ_s= 0.342) is used as base material. A design variable filter is applied with a filter radius of 1.5 times the element size. The optimization problem is solved for minimum compliance until convergence is reached for prescribed volume fraction V^*=39% of the solid material. The upper and

*Corresponding author. E-mail: damiano.pasini@mcgill.ca.

lower bounds of the design variable, ρ, are selected as $0.28 \le \rho \le 0.5$, to satisfy manufacturing and pore size constraints here selected in continuity with a previous work [4]. To reduce the computational cost, the effective properties (Figure 1) for both the defect-free and imperfect geometries are used during the optimization process.

Two cell orientations are examined, at rotation angles 0 (top) along the build direction and 45 degrees (bottom) around z-axis. The latter is chosen as a representative value to show the sensitivity to imperfections; in this case it represents the maximum discrepancy in Young's modulus (Figure 1) along the *x* direction ($\Delta\left(E_{xx}/E_s\right)_{\max} = 25\%$). The discrepancy in elastic properties appears in all orientations and along given directions. For example, along the building direction there is approximately 14% difference in Young's modulus E_{xx}, between as-designed (Figure 2b) and imperfect (Figure 2c) models. At both cell orientations, dissimilar relative density distributions are found. For the imperfect models, lower porosity is noticed in the middle region of the fixed beams. In terms of compliance, the imperfect models are typically less stiff than their as-designed counterparts. Their compliance is 32% and 52% higher at unit cell orientations of 0 and 45 degrees respectively. By analyzing the as-designed models at the two cell orientations, we can notice that the density distribution is equivalent with compliance 15% higher at 0 degrees. This result is due to the stiffness of the unit cells at 45 degrees, which is 20% higher than those oriented along the build direction. For the imperfect models, the change in compliance and density distribution is mild. This can be attributed to the small discrepancy present in the elastic modulus between the two orientations ($\Delta\left(E_{xx}/E_s\right) = 6\%$). Process-induced defects also influence the optimized material distribution. Manufacturing defects, which are strongly dependent on the strut orientation [5], are different for both rotation angles. Hence, they alter the density distribution over the fixed beam.

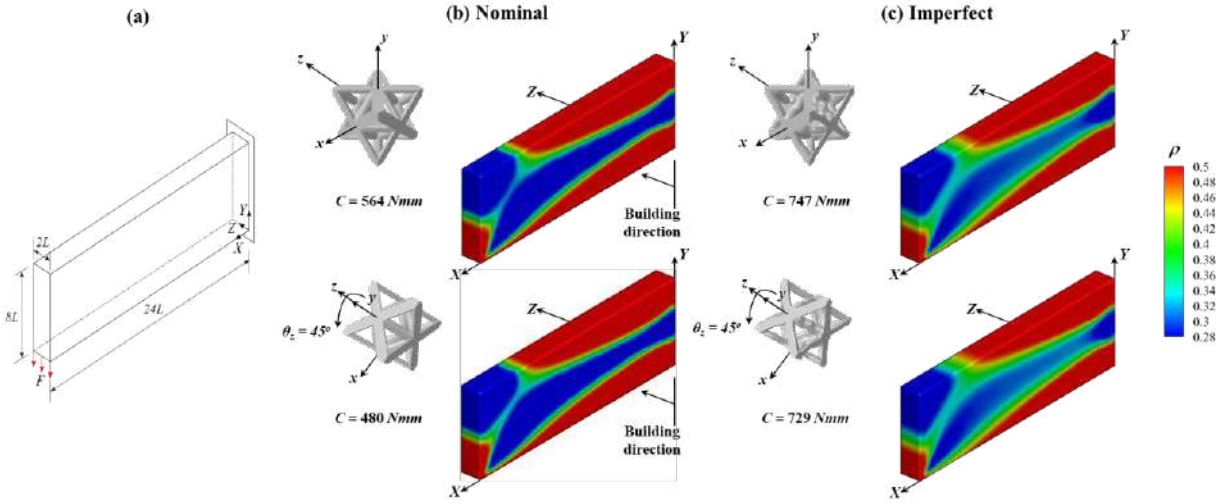

Figure 2. Design domain, boundary conditions, and external loads (a); and optimized relative density distribution for the fixed-beam benchmark problem, of nominal (b) versus imperfect (c) models using the Octet-truss topology. Top: unit cells rotated with an angle 0º, and bottom: unit cells rotated with an angle 45º around the z-axis.

CONCLUSIONS

This work has presented a general framework to assess the role of geometric imperfections on the mechanics and topology optimization of additively built lattice materials. The results have shown the role of cell orientation and manufacturing defects, which impart unit cell anisotropy and impact mechanical properties. As per the influence on the compliance and optimized relative density distribution, the difference within the design domain is shown to be proportional to the discrepancy in elastic properties between as-built and defect-free microarchitecture. The results emphasize the importance of including process-induced defects during the design process, since doing so gives a more realistic assessment of their structural performance.

BIONIAMOTO – THE EFFICIENT NUMERICAL PLATFORM FOR SHAPE AND TOPOLOGY OPTIMIZATION

Michał Nowak *[1], Jan Polak [1]
[1]Department of Virtual Engineering, Poznan University of Technology, Poznan, Poland

Summary The BioniAMoto project based on ideas proven to work in Cosmoprojector software will be presented. It utilizes biomimetic structural optimization algorithm based on trabecular bone remodeling phenomenon. Instead of imposing volume constraint the shapes can be parametrized by the assumed value of the strain energy density. The functional configurations during the process of optimization allows to include size, shape and topology optimization in one numerical procedure. Technically BioniAMoto platform is .Net/C# project designed with Inversion of Control design pattern that provides numerical environment for efficient shape and topology optimization for industrial problems.

INTRODUCTION

The BioniAMoto project is based on ideas proven to work in Cosmoprojector software. It utilizes biomimetic structural optimization algorithm based on trabecular bone remodeling phenomenon. The stiffest design is obtained by adding or removal of material on the structural surface. The assumed value of the strain energy density on the part of the boundary subjected to modification, unlike other topology optimization systems, could be related to the material properties. Change in the assumed value of the strain energy density results in change of the structural form. Instead of imposing volume constraint the shapes can be parametrized by the assumed value of the strain energy density [1].

SHAPE AND TOPOLOGY OPTIMIZATION METHOD BASED ON STRUCTURAL SURFACE MODIFICATION

Due to unique approach to the shape and topology optimization problem, the application has unique features, exceeding existing software on the commercial market. Such features – see Fig.1. - include independence from the design domain, different optimization results for different materials, possible solution of multiple load problem or simultaneous optimisation of size, shape and topology [3].

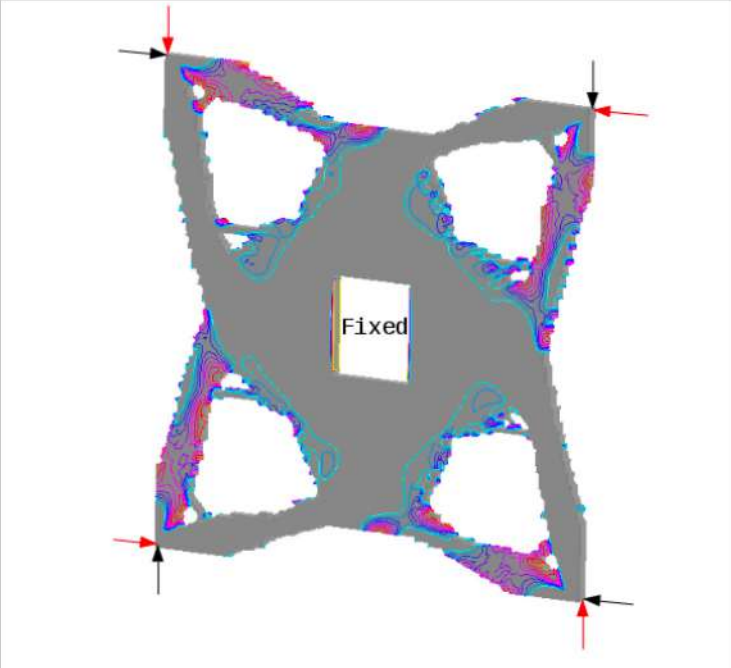

Figure 1. Example of the simultaneous optimization of the shape and topology with use of the presented biomimetic method for multiple load problem. Results are identical to analytical solution [3] (black and red arrows – two different load cases – all loads are of the same magnitude).

Actually BioniAMoto is both growth simulation tool and topological optimization system - the system is based on ideas proven to work in Cosmoprojector software (http://www.cosmoprojector.eu/). It utilizes biomimetic algorithm to optimize shape of input structure using the principles based on bone remodeling phenomenon. Also the bone remodeling process can be simulated for real trabecular structures.

THE EFFICIENT NUMERICAL PLATFORM FOR SHAPE AND TOPOLOGY OPTIMIZATION

In this proven to work approach each iteration of Finite Element Method engine is used to calculate structural strain energy distribution, remodeling (structural evolution) rule is applied and new mesh is constructed. The presented implementation of the BioniAMoto structural optimization system exploits Message Passing Interface support for massive computation. Internally system operates on slices – stack of equally spaced cross-sections of analysed geometry. Application analyzes each slice independently and applies the remodeling rule. Such approach allows to analyze single slice and its neighborhood using small scale and high accuracy approach and then move back to large scale with less details to run structural strain energy distribution calculation. Technically BioniAMoto is .Net/C# project designed with Inversion of Control paradigm design pattern that provides pluggable and extensible platform for both industrial and R&D multi-scale shape and topology optimization. All steps of algorithm are executed by separate components and each can be replaced by custom implementation – see Fig.2. The code uses reactive data flow and is optimized for multithreaded operations.

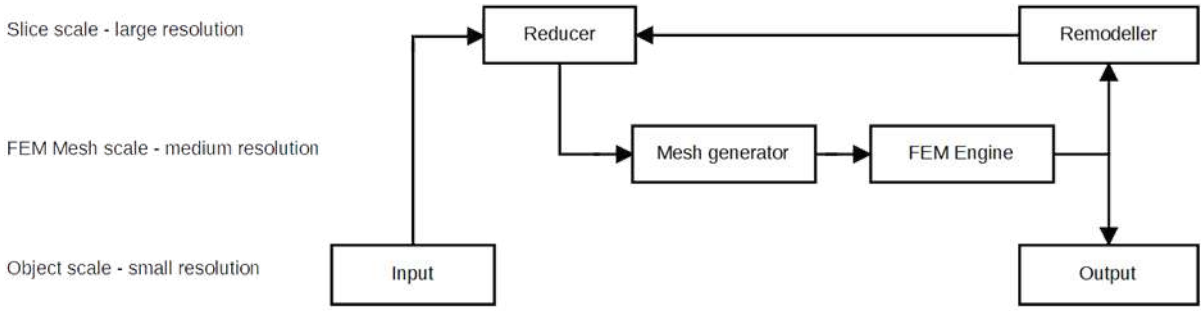

Figure 2. Components of BioniAMoto processing pipeline.

The structural evolution is separated from the Finite Element Method computations and modeled with slices, 2-dimensional images. Each iteration FEM engine is used to calculate stress, remodeling is applied on large resolution model, scale is reduced and new mesh is constructed. FEM engine used for stress calculation is external application, called by BioniAMoto system. Baseline mesh generator creates mesh consisting of tetrahedral elements. Generator was designed to create smooth surfaces to avoid introducing artefacts such as stress concentration at sharp edges. It generates both volume and surface data. Mappings between slices and mesh are maintained so it is possible to find pixels in slices corresponding to mesh points and vice-versa. Multi-scale approach combines precise remodeling on high resolution model with fast structural strain energy distribution calculations with reduced resolution.

CONCLUSIONS

The assumed value of the strain energy density on the part of the boundary subject to modification could be related to the material properties. Change in the assumed value of the strain energy density results in change of the structural form - topology and volume. In this way, the final structural volume results from the optimization procedure. Instead of imposing volume constraint shapes are parametrize by the assumed energy density, which may be quite accurately predicted from the yield criteria. Due to the use of the specific biomimetic approach, the system is particularly suitable for effectively solving the multiple load problem optimization tasks. Project is based on .Net/C# framework, uses multi-scale approach and is optimized for multi-threaded operations. Therefore the structural optimization system is suitable for large problems.

[3]Structural Engineering Department, University of California San Diego, CA 92093, USA

Summary Topology optimization in a multiphysics environment, e.g. fluid-structure interactions (FSI), poses significant numerical challenges. In this work a level set topology optimization (LSTO) approach is combined with a minimally-intrusive FSI algorithm, the modified immersed finite element method (mIFEM). For the analysis of the solid domain the reproducing kernel particle method (RKPM) is used with the naturally stabilized nodal integration technique (NSNI) for the domain integration. Test cases for flows with a range of Reynolds numbers will be presented in both linear and non-linear problems.

LEVEL SET TOPOLOGY OPTIMIZATION

In the level set topology optimization (LSTO), the structural boundary is defined as the zero level set of an implicit function:

$$\begin{cases} \phi(\mathbf{x}) \geq 0 & \mathbf{x} \in \Omega \\ \phi(\mathbf{x}) = 0 & \mathbf{x} \in \Gamma \\ \phi(\mathbf{x}) < 0 & \mathbf{x} \notin \Omega \end{cases} \tag{1}$$

where ϕ is the level set function, Ω is the structural domain and Γ is the structural boundary. Conventionally, the implicit function is initialized as a signed distance function.

The structural boundary is optimized by iteratively solving the following Hamilton-Jacobi equation

$$\frac{\partial \phi(\mathbf{x}, t)}{\partial t} + |\nabla \phi(\mathbf{x})| \, V_n(\mathbf{x}) = 0 \tag{2}$$

where t is a fictitious time domain for the level set evolution and V_n is the normal velocity.

The velocities required for the level set update are obtained by solving the linearized optimization problem. Details of the level set method can be found in [1]. Key features of the methodology proposed in this paper include the ability to handle multiple constraints in the Hamilton-Jacobi equation based level-set topology optimization method, discretized boundary integrals to estimate function changes and the formulation of an optimization sub-problem to attain the velocity function. This velocity function sub-problem is formulated as a linear program (LP). This level set topology optimization method has been used in the past to solve a variety of problems including stress constraints, aero-elasticity considerations, non-linear thermoelasticity and multiscale material modelling.

REPRODUCING KERNEL PARTICLE METHOD

For the solid domain, the Reproducing Kernel Particle Method (RKPM) [2], is used due to its ability to handle the geometrical changes during the optimization procedure and also large structural deformations without the problems caused by re-meshing as in the finite element method. RKPM is a Galerkin type meshfree method based on the reproducing kernel approximation. For the construction of the approximation no mesh is required. The RK shape function can be expressed as:

$$\Psi = \mathbf{H}^{\mathrm{T}}(\mathbf{0})\mathbf{M}^{-1}(\mathbf{x})\mathbf{H}(\mathbf{x} - \mathbf{x}_I)\mathbf{\Phi}_\alpha(\mathbf{x} - \mathbf{x}_I) \tag{3}$$

where $\mathbf{M}(\mathbf{x}) = \sum_{I=1}^{NP} \mathbf{H}(\mathbf{x} - \mathbf{x_I})\mathbf{H^T}(\mathbf{x} - \mathbf{x_I})\mathbf{\Phi}_\alpha(\mathbf{x} - \mathbf{x_I})$ is the moment matrix and NP is the number of points used in the discretization of the problem domain. $\mathbf{H}(\mathbf{x} - \mathbf{x_I})$ is the vector of monomial basis functions. $\Phi_\alpha(\mathbf{x} - \mathbf{x}_I)$ is the kernel function centered $\mathrm{x_I}$ with support size α. The kernel function controls the locality and smoothness of the approximation, and it is chosen to be the cubic spline function in this work.

*Corresponding author. E-mail: NeofytouA@Cardiff.ac.uk

For a Galerkin type meshfree method domain integration is required. Such a domain integration can be performed either using Gauss quadrature on a background mesh or using nodal integration. In this work, the later approach is adopted. Specifically, the naturally stabilized nodal integration (NSNI) is employed here since it has been shown to overcome the problems associated with direct nodal integration has good computational efficiency and accuracy. An illustration of the capability of RKPM to handle the topological changes within the level set topology optimization framework is shown in Fig. 1 where the objective is to minimize compliance under a volume constraint. In this example a beam is placed within a pressure field governed by the Laplace equation. One-way coupling is achieved by first solving for the pressure and then applying the resulting pressure field on the structural surface to solve for the structure.

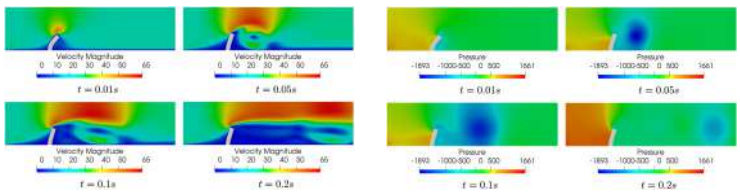
(a) (b)

Figure 1: Compliance minimization for leaflet example: (a) Problem definition and (b) Optimum solution

This paper extends this idea into viscous flow, by combining LSTO-RKPM with the modified immersed finite element method.

MODIFIED IMMERSED FINITE ELEMENT METHOD

In conventional immersed methods including the immersed finite element method, the solid displacement is imposed from the fluid velocity rather than being solved from its own governing equations. This may lead to severe solid mesh distortion resulting in the overestimation of the solid deformation especially for high Reynolds number flows. The modified immersed finite element method (mIFEM) [3] changes the formulation so that the imposition of the velocity is reversed. The solid dynamics is solved using its own governing equations and its velocity is imposed onto its overlapping fluid domain. This preserves the solid dynamics and provides more accurate and realistic coupled solutions. An important advantage of the mIFEM is that it allows modularity in the solvers. The interactions between the solid and the fluid are reflected as tractions on the solid boundary, body force and no-slip boundary conditions in the artificial fluid region making the information exchange between the fluid and the solid rather straightforward because the fluid/solid solvers are interfaced to apply Neumann and Dirichlet boundary conditions. The open-source, high performance software OpenIFEM [4] is used in this work for mIFEM.



(a) (b)

Figure 2: Leaflet example with OpenIFEM (No optimization): (a) Velocity magnitude in cm/s with contours at different time and (b) Pressure field in $dyne/cm^2$ at different time.

One of the main challenges in topology optimization for FSI is to track the interface. The implicit boundary representation in LSTO can be advantageous for this class of problems. The immersed finite element formulation employs an Eulerian background fluid and in combination with LSTO can provide a framework for solving FSI problems without remeshing for the fluid and the difficulties associated with it. The Lagrangian solid domain sits on top of the fluid. Since the structure continuously changes throughout the optimization process, remeshing for the solid becomes a cumbersome task and the difficulty grows if large deformation problems are to be considered. RKPM is used for the solid in this work, to straightforwardly handle the topological changes. The proposed bridging of the LSTO, mIFEM and RKPM enables the accurate topology optimization in a multiphysics environment and sets the framework for structural topology designs in various multiphysics environments.

STRUCTURAL OPTIMIZATION OF ELASTO-PLASTIC FRICTIONAL CONTACT PROBLEMS

Andrzej Myśliński * [1]
[1]Systems Research Institute, Warsaw, Poland

Summary The paper is concerned with the analysis and solution of the shape optimization problems for elasto–plastic rather than elastic structures in bilateral frictional contact with a rigid foundation. The small strain plasticity model with linear hardening and a von Mises effective stress is used. The displacement and stress of this structure are governed by the system of coupled variational inequalities. Using the regularization this original contact problem is replaced by the system of nonlinear equations. The structural optimization problem consists in finding such shape of the domain occupied by the body in contact or its material distribution to minimize the contact stress. The material derivative framework is used to calculate the shape derivative of the cost functional. Generalized Newton as well as the level set method are used to solve numerically the structural optimization problem. The results of computations indicate that the proposed approach generates minimal contact stress topologies.

STRUCTURAL OPTIMIZATION PROBLEM

Consider deformations of an elastic body occupying two–dimensional domain Ω with the smooth boundary Γ [9]. The body is subject to body forces $\mathbf{f}_1(x) = (f_1^1(x), f_2^1(x))$, $x \in \Omega$. The boundary Γ of domain Ω is split into three mutually disjoint parts such that $\Gamma = \bar{\Gamma}_1 \cup \bar{\Gamma}_2 \cup \bar{\Gamma}_3$, $\Gamma_i \cap \Gamma_j = \emptyset$, $i \neq j$, $i,j = 1,2,3$. The body is clamped along the portion Γ_1 of the boundary Γ. The surface tractions $\mathbf{f}_2(x) = (f_1^2(x), f_2^2(x))$, $x \in \Gamma$, are applied on a portion Γ_2 of the boundary Γ. The contact conditions with Tresca friction are prescribed on the portion Γ_3 of the boundary Γ. The domain Ω is filled with a material undergoing elasto-plastic deformation. In the elastic range it obeys Hooke's law [1] governed by a fourth-order tensor $C = (C_{ijkl}(x))$, $i,j,k,l = 1,...2$, $C_{ijkl}(x)$ such that, for any symmetric matrix ζ, $C : \zeta = 2\lambda\zeta + \mu tr(\zeta)\mathbf{I}_d$, where λ and μ are the Lamé constants. Let us also introduce the Cauchy stress tensor σ and the linearized strain tensor $\epsilon(\mathbf{u})$ [1], respectively: $\sigma = \sigma(\mathbf{u}) = \{\sigma_{ij}\}_{i,j=1}^2$ and $\epsilon = \epsilon(\mathbf{u}) = \frac{1}{2}(u_{i,j} + u_{j,i})$ $u_{i,j} = \frac{\partial u_i}{\partial x_j}$, $i,j = 1,...,2$. The summation convention over repeated indices [1] is used throughout the paper. We assume the plastic deformation of the material is governed by the additive small strain plasticity model [1]. In this model the material strain ϵ is sum of the elastic strain ϵ^e and the plastic strain ϵ^p, i.e., $\epsilon(\mathbf{u}) = \epsilon^e(\mathbf{u}) + \epsilon^p(\mathbf{u})$, and the stress tensor satisfies $\sigma(\mathbf{u}) = C : \epsilon^e(\mathbf{u}) = C : (\epsilon(\mathbf{u}) - \epsilon^p(\mathbf{u}))$, and $\epsilon(\mathbf{u}) = C^{-1} : \sigma(\mathbf{u}) + \epsilon^p(\mathbf{u})$.

Under the loading of volume or boundary forces $\mathbf{f}_1$ and $\mathbf{f}_2$ the body material undergoes the deformation. The plastic deformation with the hardening phenomenon is governed by the generalized plastic strain (ϵ^p, ξ) and the generalized stresses (σ, χ). The back stress χ and the internal variable ξ are related in Ω by [1] $\chi = -H : \xi$ where H denotes the hardening tensor. The generalized plastic stress may take values only in a nonempty closed convex set $\mathcal{K}$ of admissible generalized stresses. For a given yield function φ this set is defined as [1] $\mathcal{K} = \{(\sigma, \chi) : \varphi(\sigma, \chi) \leq 0\}$ The evolution of the plastic strain ϵ^p and the internal variable ξ is governed by the associative flow rule [1] stating that the increments $d\epsilon^p$ and $d\xi$ of the plastic strain and the internal variable, respectively, belong to the normal cone N_K to the set K at a point (σ, χ). For the smooth yield function φ it implies the existence of the nonnegative scalar γ and the Kuhn-Tucker complementarity conditions relating γ and the function φ [1]

$$(d\epsilon^p, d\xi) = \gamma \nabla \varphi(\sigma, \chi), \quad \text{and} \quad \gamma \geq 0, \quad \varphi(\sigma, \chi) \leq 0, \quad \gamma\varphi(\sigma, \chi) = 0. \tag{1}$$

The flow rule can also be described using maximal plastic work principle for the generalized stresses [1]. We shall consider the following contact problem: find the generalized stress field (σ, χ), the displacement field $\mathbf{u}$, the generalized strain field (ϵ^p, ξ) satisfying the plasticity condition (1) as well as

$$\text{div}\sigma + \mathbf{f}_1 = 0 \ \text{ in } \ \Omega, \quad \text{div}(\sigma) = \{\sigma_{ij,j}\}, \quad \sigma_{ij,j} = \frac{\partial \sigma_{ij}}{\partial x_j}, \quad i,j = 1,...,2, \tag{2}$$

$$\mathbf{u} = 0 \ \text{ on } \ \Gamma_1 \ \text{ and } \ \sigma_\nu = \mathbf{f}_2 \ \text{ on } \ \Gamma_2, \mathbf{u}_\nu = 0, \ \mid \sigma_\tau \mid \leq \mu_f \tilde{p} \ \text{ on } \ \Gamma_3, \tag{3}$$

$$\mid \sigma_\tau \mid \ < \ \mu_f \tilde{p} \ \Rightarrow \ d\mathbf{u}_\tau = 0 \quad \mid \sigma_\tau \mid \ = \ \mu_f \tilde{p} \ \Rightarrow \ \exists \lambda \geq 0, \ d\mathbf{u}_\tau = -\lambda \sigma_\tau \ \text{ on } \ \Gamma_3. \tag{4}$$

For the unit outward normal vector ν to the boundary Γ normal and tangential components of the displacement field $\mathbf{u}$ (stress σ) are denoted by $\mathbf{u}_\nu$ (σ_ν), and by $\mathbf{u}_\tau$ (σ_τ), respectively. A real constant $\mu_f > 0$ and $\mid \cdot \mid$ denote the friction coefficient and the Euclidean norm, respectively. For a given $\tilde{p} \geq 0$ system (1)-(4) governs the elasto - plastic bilateral contact problem with Tresca friction. Let us introduce the set U_{ad} of admissible domains. This set has the form: $U_{ad} = \{\Omega \ : \Omega \subset D \subset R^2 \ : \ \Omega \text{ is suitable regular, } Vol(\Omega) - Vol^{giv} \leq 0, \ P_D(\Omega) \leq const_1\}$ where $Vol(\Omega) = \int_\Omega dx$ and $P_D(\Omega) = \int_\Gamma dx$. The subset D as well as constants $Vol^{giv}, const_1 > 0$ are given. The set U_{ad} is assumed to be nonempty. Consider the following structural optimization problem: *for a given function* $\eta \in M^{st}$, *find a domain* $\Omega^\star \in U_{ad}$ *such that*

$$J_\eta(\mathbf{u}(\Omega^\star)) = \min_{\Omega \in U_{ad}} J_\eta(\mathbf{u}(\Omega)) \ \text{ where } \ J_\eta(\mathbf{u}(\Omega)) = \int_{\Gamma_2} \sigma_\nu(u)\eta_\nu(x)ds. \tag{5}$$

*Corresponding author. E-mail: myslinsk@ibspan.waw.pl

The set $M^{st} = \{\eta = (\eta_1, \eta_2) : \eta_i \leq 0 \text{ on } D,\ i = 1, 2\}$ and the functional $J_\eta(\cdot)$ approximates the normal contact stress [2, 3]. Structural optimization of elasto-plastic structures has been investigated among others in [4, 5]. Here this approach is extended for elasto-plastic contact problems with friction. For topology optimization of elastic contact problems see [2, 6].

PROBLEM REGULARIZATION

The contact problem (1)–(4) is reformulated in terms of (u, σ, χ) only as a system of two coupled nonlinear equations using von Mises yield function, the regularization of the generalized stress projection on the set of admissible stresses as well as the regularization of friction functional [2, 6, 7]. Shape derivative of the functional (5) with respect to domain perturbation is calculated and the necessary optimality condition is formulated [2, 7].

NUMERICAL IMPLEMENTATION AND RESULTS

Both the state and the adjoint boundary value problems are discretized using bilinear quadrangular finite elements. Ersatz material approach [7] is used to avoid meshing problems with the shapes of domains Ω and singularity of the stiffness matrix. This approach consists in filling the domain $D \setminus \Omega$ with a weak material characterized by law value of Young modulus and mimicking void. The discretized state and adjoint equations are solved numerically using generalized Newton method [2, 7]. Level set method [2, 7, 8, 9] is used to track the domain evolution and find the optimal topology. Fig. 1 presents the optimal domain obtained by solving structural optimization problem (5) in the computational domain D. In a case of elasto-plastic materials the mass of the structure is larger than in a case of elastic model. The algorithm tries to avoid the generation of plastic zones which are less rigid and induce larger displacements. Von Mises effective stress concentration areas appear close to the contact zone (Fig. 2). The obtained normal contact stress is almost constant along the optimal shape boundary and has been significantly reduced comparing to the initial one. The distribution of stresses in elastic and elasto-plastic cases is provided and discussed.

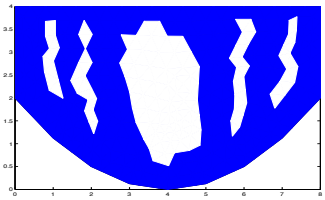

Figure 1: Optimal topology domain $\Omega^\star$.

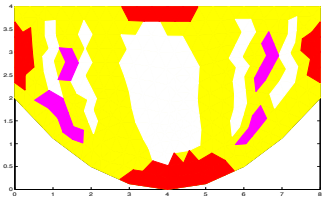

Figure 2: von Mises stress distribution.

CONCLUSION

The obtained results indicate that presented approach based on the application of the level set technique can be applied to solve numerically a topology optimization problem for bodies in bilateral frictional contact where nonlinear small strain elasto-plastic with linear kinematic hardening material model rather than elastic material model is used. It allows to formulate necessary optimality conditions for this type of nonlinear problems and it is capable of finding topologies that generates minimum contact stress. This approach is flexible and can be extended to solve other shape or topology optimization problems for structures governed by nonlinear equations.

RELIABILITY-BASED APPROCHES FOR TOPOLOGY OPTIMIZATION OF ELASTOPLASTIC STRUCTURES

János Lógó *[1], Piotr Tauzowski [2], Bartlomiej Blachowski [2] and Hussien Ismail[1]
[1]Department of Structural Mechanics, Budapest University of Technology and Economics, Hungary
[2]Institute of Fundamental Technological Research, Polish Academy of Sciences, Poland

Summary Plasticity in topology optimization is almost forgotten direction in this popular research area. This paper presents a recently developed elasto-plastic topology optimization procedure extended with reliability constraint. It recalls fundamental concepts from reliability analysis and introduces an algorithm for topology optimization of elasto-plastic structures. In addition to the elasto-plastic constitutive law of the applied material the optimization algorithm includes stress constraints, as well. The presented numerical examples show dependence of the volume fraction on probability of failure.

INTRODUCTION

An important aspect of any optimization process is robustness to variability of structural parameters, either structural (geometry, material) or boundary condition (loading, support location) dependent. The more the structure becomes optimal, the lower the resistance to its parameter changes. One of the possible ways to tackle this issue is to add to the optimization formulation an additional constraint for the probability of failure [2, 5]. The designer will then assure that the optimized structure does not go below the assumed safety level. Since the probability of failure of engineering structures must be small (approximately 0.0001 or smaller), it is possible to obtain a relatively fast estimation of reliability by using first or second order methods [4, 9] or different simulation procedures. Most often, several iterations (finite element solutions) are enough to obtain convergence. Recent advances in probability/reliability based topology problems have been presented in papers by Guest et al. [3] Luo et al. [7], Xia et al. [11], da Silva et al. [8]. The authors of this paper have also several papers in this topic for more than a decade (Logo et al. [5, 6], Blachowski et al. [2]).

Topology optimization is a rather time consuming and discretization dependent computational problem. Due to the complexity of the task it is fundamental to use appropriate topology optimization procedure (Antonietti et al. [1]). In the present paper an iterative topology optimization algorithm together with elasto-plastic material formulation and reliability approach will be shortly described. The formulation based on a recently developed functor-oriented optimization procedure (Tauzowski et al. [10]). Analysis of elasto-plastic structure will be presented on numerical example. All aspects of numerical analysis, finite element formulation, topology optimization as well as reliability analysis library are performed by our own software implemented in MATLAB and C++.

RELIABILITY BASED TOPOLOGY OPTIMIZATION APPROACH

In the case of probabilistic topology optimization random variables vector $\mathbf{r}$ can represent loads or material constants. Shape of the structure is a result of topology optimization therefore random nature of shape parameter is not taken into consideration. In the following the formulation of the elasto-plastic problem of structural analysis as well as the detailed description of the algorithm for topology optimization under reliability constraint is presented briefly. The proposed approach utilizes elastoplastic finite element analysis together with optimality criteria based on sequential removal of the least stressed elements. The whole problem is a standard stress limited topology optimization method extended by a reliability constraint which here is based on a first order reliability method. The stress constrained topology optimization works with an objective function representing the volume of the material required to safely carry the applied loading. The density of the material at a given point in three dimensional space is described by an indicator function $\chi(\mathbf{x})$, taking values 0 or 1. We are looking for a solution to the above problem within a set of kinematically admissible displacement fields V. Additionally, constraints are imposed on stresses $\sigma(\mathbf{x})$ at any the given point of the design domain Ω.

$$\begin{aligned} &\min_{\chi,\mathbf{u}\in V} \quad \int_{\Omega} \chi(\mathbf{x})\mathrm{d}\Omega \\ &\text{s.t.} \quad \int_{\Omega} \chi\boldsymbol{\varepsilon}(\mathbf{u}):\mathbf{D}:\boldsymbol{\varepsilon}(\mathbf{v})\mathrm{d}\Omega - \int_{\Gamma_n} \bar{\mathbf{t}}\cdot\mathbf{v}\mathrm{d}\Gamma = 0\,, \quad \mathbf{v}\in V \\ &\frac{|\sigma(\mathbf{x})|}{\sigma_0} - 1 \le 0, \quad \mathbf{x}\in\Omega_{\mathrm{mat}} \\ &\chi(\mathbf{x}) = \begin{cases} 1, & \mathbf{x}\in\Omega_{\mathrm{mat}} \\ 0, & \mathbf{x}\in\Omega\backslash\Omega_{\mathrm{mat}} \end{cases} \end{aligned} \tag{1}$$

where $\mathbf{u}(\mathbf{x})$, $\mathbf{v}(\mathbf{x})$, $\boldsymbol{\varepsilon}(\mathbf{u})$ represent displacement, virtual displacement and strain fields, respectively. $\mathbf{D}$ is the elasto-plastic material matrix, $\bar{\mathbf{t}}$ is the traction on the boundary, σ_0 is the stress limit and finally Ω_{mat} represents the material domain defined as $\Omega_{\mathrm{mat}} := \{\mathbf{x}\in\Omega \mid \chi(\mathbf{x}) = 1\}$.

*Corresponding author. E-mail: logo@eik.bme.hu

For sake of simplicity the reliability problem is based on a first order reliability method. Probabilistic task is transformed to standard normal space $\mathbf{r} \rightarrow \mathbf{w}$. The most probable point is the closest point to the centre of the coordinate system of this space, which lies on the limit state surface. Therefore determination of this point is optimization problem formulated as follow:

$$\begin{aligned} &\min \quad \|\mathbf{w}^2\| = \mathbf{w} \cdot \mathbf{w}^{\mathrm{T}}, \\ &\text{s. t.} \quad g(\mathbf{w}) = 0. \end{aligned} \tag{2}$$

To tackle this problem Rackwitz and Fiesler [9] proposed the following gradient-based iterative scheme:

$$\mathbf{w}^{(\mathrm{n}+1)} = \frac{1}{\|\nabla g(\mathbf{w}^{(\mathrm{n})})\|^2}\left(\nabla \mathrm{g}\left(\mathbf{w}^{(\mathrm{n})}\right)^{\mathrm{T}}\mathbf{w}^{(\mathrm{n})} - \mathrm{g}\left(\mathbf{w}^{(\mathrm{n})}\right)\right)\nabla \mathrm{g}(\mathbf{w}^{(\mathrm{n})}). \tag{3}$$

In addition to the above formulation the load carrying capacity (P_{Limit}) of the elastoplastic structures is integrated as a first order reliability constraint. The constraint inequality is:

$$P_{\mathrm{FORM}} > P_{\mathrm{Limit}} \tag{4}$$

where $P_{\mathrm{FORM}} = \Phi(-\beta)$ is cumulative distribution function. The reliability procedure above can be interchanged any appropriate formulation (second order reliability method or different simulation techniques).

NUMERICAL RESULTS

To demonstrate the above proposed algorithm the reliability assessment in topological optimization will be illustrated on a simple example shown in Figure 1. The reliability problem is based on a FORM. Regular rectangular mesh composed with four-node Lagrange finite elements is used in the example. The following parameters are used: Young's modulus $E = 71$ GPa, Poisson's ratio $\upsilon = 0.11$, yield stress $\sigma_0 = 260$MPa, thickness $t = 0.22$ units. 10% standard variation is used in case of the Poisson's ratio while the Young's modulus and the yield stress can vary by 5%. Limit state function reflects displacement condition. Unsafe state means the displacement u_c at point c (see Fig. 1.) exceeds permissible value = 0.1 units (l/200). The optimal stress distribution and the topology is shown at right.

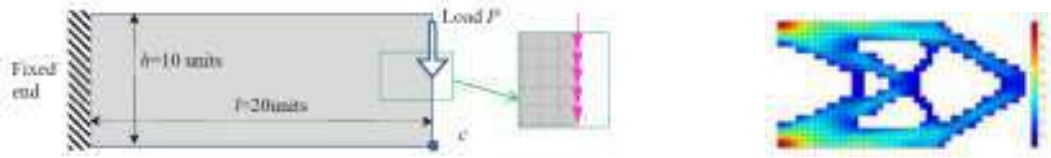

Figure 1. Test problem and the optimal topology with reliability constraint $\mathrm{P_f} = 0.005$.

CONCLUSIONS

In this paper a plasticity based topology optimization procedure with reliability constraint is presented. In the example optimal topology under reliability constraint is shown. Detailed analysis of the results will be discussed and it will be shown that the probability of failure rapidly grows above certain level of volume fraction.

Summary Information on external forces and boundary forces on structures is essential for their damage evaluation and health monitoring. In this paper, we resort to an inverse measurement technique for simultaneous reconstruction of external forces and shock absorber supporting forces on a plate. To solve the inherit ill-posedness in inverse force estimation, a new regularization method, named Element-wise Bayesian regularization, is proposed. A numerical test with two kinds of force profile shows that the proposed method can reconstruct both external forces and shock absorber forces more accurately compared to other existing methods.

INTRODUCTION

Information on external and boundary forces of structures is valuable for response prediction and structural health monitoring. In practice, directly measuring the unknown forces with force transducers is not a reasonable choice due to physical and economic constraints. Inverse methods, i.e., estimating forces based on structural responses, can reconstruct forces at different locations with the same set of sensors, thus offering more flexibility than direct measurements. The inverse problem (force identification) is typically ill-posed and many techniques have been developed to deal with it. The most classic one is Tikhonov regularization which adds a ℓ_2-norm penalty term to stabilize the naive solution (least square method). Another attractive method is ℓ_1 regularzation which produces sparse solutions. However, these methods require precise prior information on the force profile, which is not guaranteed available in practice. The hierarchical Bayesian framework is a promising tool to deal with this problem. It allows a data-driven determination of all unknown variables, relaxing the reliance on prior knowledge of these variables. Aucejo et al. 1 proposed a full Bayesian method to identify multiple forces in frequency domain. Li et al. 2 investigated the influence of shape parameter based on a hierarchical Bayesian formulation with the Markov chain Monte Carlo algorithm. Li et al. 3 proposed an adaptive ℓ_q regularization method to find the appropriate value of shape parameter q. Although promising progress has been continuously made, a stable and accurate method for identification of forces with different types of profile is still strongly demanded. This paper proposes an adaptive method called Element-wise Bayesian Regularization (EWBR) to solve the problem. The method is validated on simultaneous identification of external forces and shock absorber supporting forces on a plate.

HIERARCHICAL BAYESIAN FORMULATION

In Fig. 1, the plate supported by four shock absorbers is assumed as a linear elastic and time invariant system. A response calculation model is established to calculate responses $\mathbf{X}$. Another identification model, i.e., a free plate, is used to calculate the impulse response matrix $\mathbf{H}$ between the external/supporting forces and the response sensors. Denote the excitations as $\mathbf{F}$, and measurement noise as $\mathbf{N}$, we have the following relationship,

$$\mathbf{X}=\mathbf{HF}+\mathbf{N},\quad p\left(\mathbf{F}\left|\mathbf{X}\right.\right)\propto p\left(\mathbf{X}\left|\mathbf{F}\right.\right)p\left(\mathbf{F}\right),\quad p\left(\mathbf{X}\left|\mathbf{F},\tau_n\right.\right)=\left(\frac{\tau_n}{\pi}\right)^{n_s n_t/2}\exp\left(-\tau_n\left\|\mathbf{HF}-\mathbf{X}\right\|_2^2\right) \tag{1}$$

According to Bayes' theorem, the posterior probability distribution function (PDF), which evaluates the distribution of forces given a certain response measurement, is propotional to the product of likelihood function and prior PDF. The likelihood function is equal to the prior PDF of measurement noise which is assumed as a zero-mean Gaussian distribution with precision parameter τ_n. The prior PDF of f_i, i-th element of $\mathbf{F}$, is chosen as a zero-mean Gaussian distribution with the parameter α_i. The components of $\mathbf{F}$ are independent and identically distributed. The proposed method has the ability to deal with multiple forces with different force profile in one reconstruction problem which is very common in engineering condition. Since each element is controlled by their own parameter, no compromise wil be made between the force elements. In the numerical example, the supporting forces are continous profile while the external force (hammer test) is sparse profile.

$$p\left(\mathbf{F}\left|\boldsymbol{\alpha}\right.\right)=\prod_{i=1}^{n_t}\mathcal{N}\left(f_i\left|0,\alpha_i^{-1}\right.\right),\quad p\left(\tau_n\left|a_n,b_n\right.\right)=\frac{{b_n}^{a_n}}{\Gamma\left(a_n\right)}\tau_n^{a_n-1}\exp\left(-b_n\tau_n\right) \tag{2}$$

n_s and n_t are the number of accelerometers and the length of one force history respectively. The precision parameters τ_n and $\boldsymbol{\alpha}$ are also considered as random variables to infer. The prior PDFs of them are assumed as Gamma distribution with small value parameters setting as 1×10^{-16}.

$$p\left(\boldsymbol{\alpha}\right)=\prod_{i=1}^{n_t}p\left(\alpha_i\left|a_f,b_f\right.\right)=\prod_{i=1}^{n_t}\Gamma\left(\alpha_i\left|a_f,b_f\right.\right),\quad \mathbf{F}_{JPM}=\underset{(\mathbf{F},\tau_n,\boldsymbol{\alpha})}{\arg\max}\log p\left(\mathbf{F},\tau_n,\alpha\left|\mathbf{X}\right.\right) \tag{3}$$

*Corresponding author. E-mail: liqiaofeng1990@vt.edu

The hierarchical Bayesian structure is established by repeating Bayes' theorem. The joint posterior mode (JPM) is proposed to estimate $\mathbf{F}$ and all the other unknown variables. The conditional maxmization (CM) algorithm is proposed to solve the JPM.

VALIDATION

A steel plate with four shock absorbers shown in Fig. 1 is used to validate the proposed method. The effect of the four shock absorbers is equivalent to four external forces applying on the free plate. A real external force is exerted vertically on the plate and 7 accelerometers are adopted to measure the responses. Tikhonov regularization with L-curve criterion, ℓ_1 regularization with GIRLS algorithm and Relevance Vector Machine (RVM) are compared with the proposed method. Two cases, sparse-profile and continous-profile for external force, are considered here to validate the proposed method. The reconstructed forces (impact, continous force, and supporting forces of shock absorbers) are illustrated in Fig. 2 and Fig. 3. The measurement noise level is 40dB.

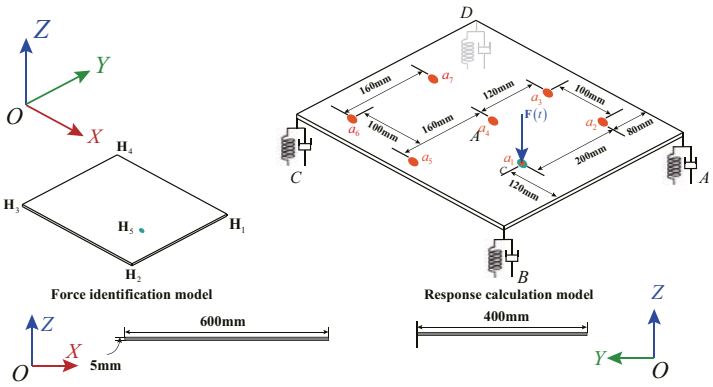

Figure 1: The schematic of the simulated plate.

The result shows that Tikhonov and ℓ_1 regularization can reconstruct the supporting forces successfully in impact case. However, some oscillations appear on the non-force part of the impact with these two methods. RVM is considered as a failure for this reconstruction. EWBR has a great performance in reconstruction of all types of force in both cases compared with other methods. In the continuous force case (Fig. 3), ℓ_1 regularization is invalid since it is sparsity-promoting method.

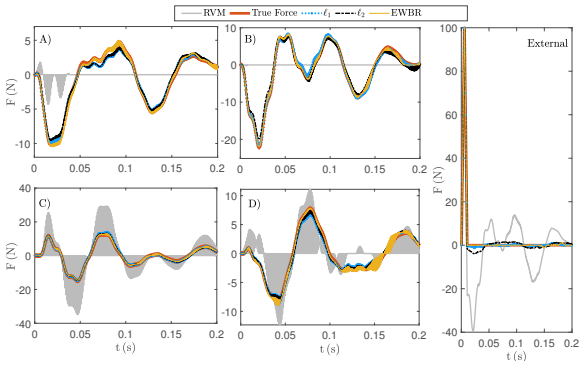

Figure 2: Reconstructed force histories of impact case.

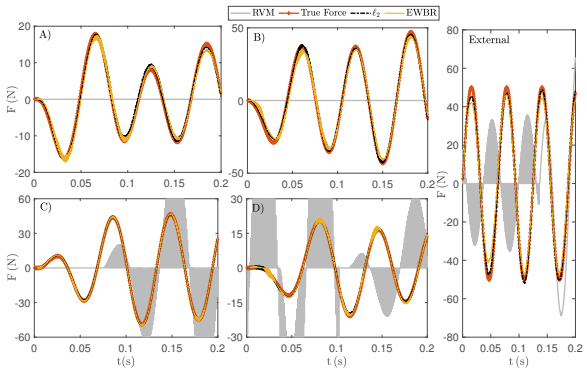

Figure 3: The force histories of continous force case.

CONCLUSIONS

Traditional force identification methods can estimate forces with one type of profile such as sparse or continous. However, forces with different profiles often occur in one reconstruction problem. This paper proposed an Element-wise Bayesian Regularization method based on hierarchical Bayesian formulation for reconstruction of multiple forces with possibly different types of profiles. CM algorithm is adopted for the solution. A numerical validation of a plate is performed to validate the proposed method. The external hammer force, continous sine force, and the supporting forces induced by shock absorbers are identified successfully. Tikhonov regularization, ℓ_1 regularization, and RVM are also applied for this problem. Compared with the traditional methods, EWBR enjoys a more accurate and adaptive merit.

Summary A novel approach based on funicular analysis is investigated to cope with the design of spatial truss networks fabricated by Wire-and-Arc Additive Manufacturing (WAAM). The minimization of the horizontal thrusts of networks with fixed plan geometry is stated both in terms of any independent subset of the force densities and in terms of the height of the restrained nodes. Local enforcements are formulated to prescribe lower and upper bounds for the vertical coordinates of the nodes, and to control the stress regime in the branches. Constraints are such that sequential convex programming can be conveniently exploited to handle grids with general topology and boundary conditions. Optimal networks for WAAM are investigated accounting for self-weight, a design-dependent load case.

WIRE-AND-ARC ADDITIVELY MANUFACTURED STRUCTURAL ELEMENTS

Among different Additive Manufacturing (AM) processes, Wire-and-Arc Additive Manufacturing (WAAM) results to be the most suitable for Structural Engineering applications [1]. Indeed, the first demonstrator of the possibilities given by this innovative technology is the MX3D Bridge (Fig.1a) [2], the first metal 3D-printed bridge ever realized, which will be placed in Amsterdam city center by 2020. The WAAM process, which consists of off-the-shelf welding equipment mounted on top of a numerically controlled robotic arm, allows realizing large-scale structural elements up to few meters, without in principle any geometrical constraints in terms of forms and shapes. However, the high velocity required to print real-scale elements induces some non-negligible irregularities in the geometry of the outcome. Moreover, previous studies have confirmed that WAAM-produced metals differ both in the microstructure and in the mechanical response with respect to those traditionally manufactured. Intense research effort has been devoted to the assessment of the main mechanical parameters of WAAM-produced stainless steel elements for structural purposes. The results from the experimental campaign point out high anisotropic response, depending upon the orientation of specimens with respect to the deposition layer of the printing process. Yielding and tensile strength values are comparable to those commonly adopted for stainless steel members, whereas Young's modulus values are highly influenced by the anisotropy of the material, and are on average 40% lower than the standard value for stainless steel adopted in construction. The results are partially presented in [3,4]. Among the available techniques for WAAM, that employing "dot-by-dot" printed stainless steel rods to build spatial truss-like structures is herein considered.

DESIGN OF TRUSS NETWORKS FOR WAAM USING A CONSTRAINED FORCE DENSITY METHOD

Within the above framework, a design approach for WAAM is investigated, by searching among spatial truss networks that fulfil equilibrium. Funicular analysis is extensively adopted to cope with the assessment and design of arcuated structures such as vaults and domes, see in particular [5, 6, 7]. Following this approach, spatial structures such as three-dimensional trusses and shells are modelled as statically indeterminate networks of vertices and edges of given topology. Boundary supports are prescribed at the restrained nodes of the network, whereas unrestrained ones are in equilibrium with the applied vertical and horizontal loads. To assess the safety of an existing structure in the spirit of the lower bound theorem of limit analysis, a funicular network must be found whose vertices lie within its envelope. To design a new one, optimal networks may be sought prescribing lower and upper bounds for the nodal heights. The equilibrium of funicular networks can be conveniently handled through the force density method, i.e. writing the problem in terms of the ratio of force to length in each branch of the network [8]. As investigated in the literature for the case of

vertical loads, independent sets of branches can be detected for networks with fixed plan geometry [9, 10]. However, enforcing the nodes to lie within a prescribed range of heights is not a trivial task from a numerical point of view.

In this contribution an optimization problem is formulated for networks of general shape having fixed plan geometry and loading conditions that may include self-weight. At first, the equations that link dependent and independent branches of the network are found by solving the horizontal equilibrium through the reduced row echelon form of its augmented matrix. A suitable norm of the horizontal thrusts is adopted as objective function of the minimization problem, whereas both the independent force densities and the coordinates of the restrained nodes play as minimization unknowns. A multi-constrained problem is formulated to enforce bounds for the vertical coordinates of the vertices of the network. Constraints on the sign / magnitude of the force density in each branch of the network may be considered as well. Due to its peculiar form, this problem can be efficiently solved through techniques of sequential convex programming that were originally conceived to handle large scale multi-constrained formulations of size optimization for elastic structures [11].

Preliminary numerical simulations are shown investigating the equilibrium of spatial network of trusses to be fabricated by WAAM. Networks that are fully feasible with respect to the local enforcements on the height of the vertices are retrieved in a limited number of iterations, with no need to initialize the procedure with a feasible starting guess. The same algorithm applies to general networks with any type of geometry, loads and restraints. Self-weight, i.e. a design-depend load case, is considered in the optimization, taking full advantage of the direct analytical method to compute sensitivities.

Figure 1b shows the result of a preliminary assessment of the proposed procedure. The design of a spatial truss network for minimum horizontal reactions is investigated. Self-weight is considered, along with constraints enforcing the nodes of the network to lie within a prescribe range of vertical coordinates and all the force densities to be negative. The four corners and the central point of the bay are supported in the vertical direction, whereas symmetry conditions are enforced along each external side of the grid. Restrained nodes are not coplanar. Crosses and circles stand for nodes whose heights match the prescribed upper and lower bounds, respectively. The number of branches in the network is 1248. The independent ones are only 52, meaning that the number of unknowns for the optimization procedure is limited to 57, being 5 the restrained nodes where supports are given.

Constraints prescribing a minimum difference between the height of the nodes of each branch may be additionally considered to account for possible restrictions on the allowable range of truss inclinations. This depends on the features of the adopted WAAM process.

CONCLUSIONS

Wire-and-Arc Additive Manufacturing (WAAM) technology allows realizing metal-based free forms and shapes, introducing very few fabrication constraints. The “dot-by-dot” technique employs stainless steel rods to build spatial truss-like structures with high strength performances, although experimental results point out a more complex mechanical response with respect to those that are traditionally manufactured.

A design approach for “dot-by-dot” WAAM is proposed in this contribution that searches among spatial truss networks fulfilling equilibrium using funicular analysis. The minimization of the horizontal thrusts of a spatial network with given plan geometry is formulated not only in terms of an independent set of force densities, but also in the height of the restrained nodes. Constraints are enforced on the height of the vertical coordinates of the nodes, and on the stress regime in each truss. The former set of enforcements also allows for a straightforward control of the inclination of each branch, as requested by some fabrication processes. Multi-constrained solutions are achieved at a low computational cost using sequential convex programming.

The ongoing research is devoted to endowing the design formulation with local and global buckling constraints.

DATA-DRIVEN RELIABILITY-BASED DESIGN OPTIMIZATION WITH DIMENSIONALITY REDUCTION

Yoshihiro Kanno* [1]
[1]Mathematics and Informatics Center, The University of Tokyo, Tokyo, Japan

Summary A recently proposed approach to reliability-based design optimization with lack of probabilistic information of uncertain parameters constructs, by using a data sat of samples, a sufficient condition that guarantees the specified target confidence level of structural reliability. This data-driven method, however, often yields a vary overly-conservative structural design, because in general there exists a gap between the constructed sufficient condition and the original confidence-level constraint. By using a dimensionality reduction technique, this paper presents a method that mitigates this gap, especially for a problem involving a large number of uncertain parameters. Numerical experiments demonstrate that the proposed method can drastically reduce over-conservativeness.

INTRODUCTION

Considering uncertainty in design process is indispensable for designing structures with high quality. In structural optimization, *reliability-based design optimization* (RBDO) is one of representative methods handling this issue.

Conventionally, in RBDO we suppose that a probability distribution of uncertain parameters in a structural system is known. However, it is pointed out that, in diverse situations, the input probability distribution is known only imprecisely, due to, e.g., limitation of knowledge, insufficiency of data, etc. Therefore, recent attention has been drawn to RBDO methods addressing uncertainty in the input distribution [1, 2]. Typically, such a method handles the *confidence level*, which is a lower bound for the probability that the structural reliability is no smaller than the target reliability.

As a data-driven approach to RBDO, the method in [3] assumes that a data set of some random samples of uncertain parameters is available, and constructs a robust optimization problem the solution which has the required target confidence level. In this procedure, no information of the input distribution is presumed, and only a given data set is used to guarantee the target confidence level. On the other hand, in general there exists a gap between a sufficient condition used in [3] and the original confidence-level constraint, and this gap often yields an overly-conservative structural design. This paper presents a dimensionality reduction technique to reduce this gap. In other words, the presented method provides an improved approximation. Numerical experiments demonstrate that the proposed method can drastically reduce over-conservativeness of method in [3].

MAIN RESULT

Consider performance constraints $g_i(\boldsymbol{x};\boldsymbol{q}) \le 0$ $(i = 1,\ldots,m)$ in a design optimization problem, where $\boldsymbol{x}$ is a design variable vector and $\boldsymbol{q} \in \mathbb{R}^n$ is a random vector following the joint distribution F. In RBDO, we consider the lower-bound constraint on the probability that the performance constraint is satisfied:

$$\mathrm{P}\{g_i(\boldsymbol{x};\boldsymbol{q}) \le 0\} \ge 1-\epsilon. \tag{1}$$

Here, ϵ $(0 < \epsilon < 1)$ is a constant, and $1-\epsilon$ is the *target reliability*.

When F is known only imprecisely, then the left side of (1) is considered a random variable. Therefore, the inequality (1) is understood only in a probabilistic manner, which leads to a constrain in the form [1, 2]

$$\mathrm{P}_F\left\{\mathrm{P}\{g_i(\boldsymbol{x};\boldsymbol{q}) \le 0\} \ge 1-\epsilon\right\} \ge 1-\delta, \tag{2}$$

where δ $(0 < \delta < 1)$ is a constant, and $1-\delta$ is the *target confidence level*. For instance, if $\epsilon = 0.05$ and $\delta = 0.1$, then (2) means that, with probability at leat 90%, the reliability of design $\boldsymbol{x}$ is no smaller than 95%.

In [3], a sufficient condition for (2) is considered, provided that some independent and identically distributed samples drawn from F are available. For a parameter $\alpha > 0$, define $Q(\alpha) \subset \mathbb{R}^n$ by

$$Q(\alpha) = \{\boldsymbol{q} \in \mathbb{R}^n \mid (\boldsymbol{q}-\bar{\boldsymbol{q}})^\top \Omega (\boldsymbol{q}-\bar{\boldsymbol{q}}) \le \alpha\},$$

where Ω is a positive definite symmetric matrix. For sufficient large α (determined by using the samples), constraint

$$g_i(\boldsymbol{x};\boldsymbol{q}) \le 0, \quad \forall \boldsymbol{q} \in Q(\alpha) \tag{3}$$

serves as a sufficient condition for (2). In the framework of robust optimization, various techniques, e.g., [4, 5], are available to handle the constraint in the form of (3).

*Corresponding author. E-mail: kanno@mist.i.u-tokyo.ac.jp.

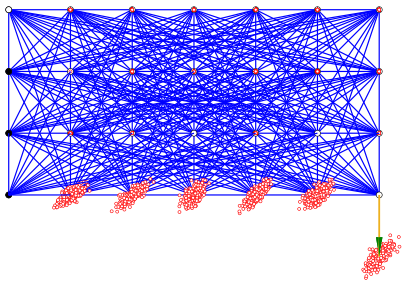

Figure 1: Ground structure and data of external loads.

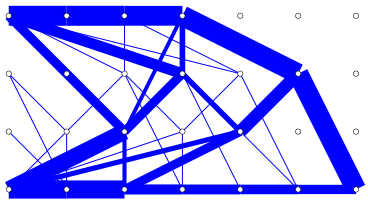

Figure 2: Nominal optimal solution for the mean load.

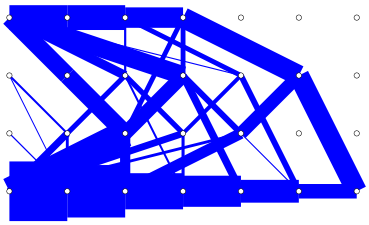

Figure 3: Optimal solution of data-driven RBDO method.

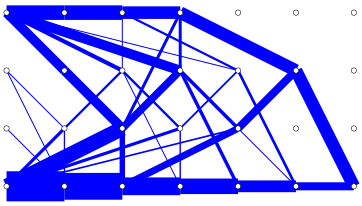

Figure 4: Optimal solution of data-driven RBDO method with dimensionality reduction.

In this paper, we define $Q(\alpha)$ by

$$Q(\alpha) = \{\bar{\boldsymbol{q}} + L\boldsymbol{\theta} \mid \|\boldsymbol{\theta}\| \leq \alpha\}, \tag{4}$$

where $L \in \mathbb{R}^{n\times r}$ $(n > r)$ is a constant matrix obtained by applying the principal component analysis to the given samples. Thus, the dimension of uncertainty parameter is reduced from n to r. If we choose α satisfying

$$\mathrm{P}_F\left\{\mathrm{P}\{\boldsymbol{q} \in Q(\alpha)\} \geq 1-\epsilon\right\} \geq 1-\delta, \tag{5}$$

then a constraint in the form of (3) corresponds to a sufficient condition for (2). To check (5) we use the order statistics of the given samples, in a manner similar to [3]. It is expected that the dimensionality reduction introduced in this paper can mitigate, somewhat, the over-conservativeness of the method in [3].

NUMERICAL EXAMPLES

Consider a truss topology optimization problem outlined in Figure 1. Suppose that the external load vector, denoted $\boldsymbol{f} \in \mathbb{R}^n$, is a random vector, where $n = 48$ is the number of the degrees of the nodal displacements of the ground structure. As a performance requirement, we consider a compliance constraint, $\pi(\boldsymbol{x}; \boldsymbol{f}) \leq \pi^{\mathrm{c}}$, where π^{c} is a specified upper bound.

Small circles in Figure 1 show given samples of $\boldsymbol{f}$, where we suppose that uncertain external forces are applied only at the bottom nodes. For the mean of the samples, denoted $\mathrm{E}(\boldsymbol{f})$, a constraint without considering uncertainty is written as $\pi(\boldsymbol{x}; \mathrm{E}(\boldsymbol{f})) \leq \pi^{\mathrm{c}}$. Under this constraint we minimize the structural volume, which results in the optimal solution shown in Figure 2. Here, the width of each member in the figure is proportional to the member cross-sectional area.

We next consider RBDO with target reliability $1 - \epsilon = 0.95$ and target confidence level $1 - \delta = 0.9$. If the number of available samples is, e.g., 200, then the order statistics guarantees that $Q(\alpha)$ containing 195 samples satisfies (5). Figure 3 shows the optimal solution obtained by the method in [3], i.e., the dimension of uncertainty parameters is $n = 48$. The objective value is 5.588×10^8 mm^3. Figure 4 shows the optimal solution obtained by the method presented in this paper. By using the principal component analysis, the dimension of uncertain parameter is reduced to $r = 5$. The objective value of the solution in Figure 4 is 2.996×10^8 mm^3. Thus, the over-conservativeness of the solution in Figure 3 is drastically mitigated by the presented method.

TOPOLOGY OPTIMIZATION CONSIDERING MANUFACTURING CONSTRAINTS: NEW CAPABILITIES IN PROJECTION METHODS

Mikhail Osanov[1], Hak Yong Lee[1], Julia Carroll[1], and James K. Guest*[1]
[1]Department of Civil and Systems Engineering, Johns Hopkins University, Baltimore, Maryland, USA

Summary Recent advances in manufacturing have provided tremendous opportunities to re-think design and create novel solutions to complex design problems. Topology optimization offers a systematic computational framework for addressing this new design challenge. This work discusses the integration of topology optimization and manufacturing to create designs that are optimized accounting for the manufacturing process. The approach is based on projection methods, which provide a flexible framework for handling a multitude of manufacturing constraints. Recent advancements in projection methods will be discussed, including new constraint and cost function capabilities, as well as new improvements in computational efficiency. Various examples will be considered, including structural components and architected materials fabricated by additive manufacturing or subtractive processes.

INTRODUCTION

Recent advancements in manufacturing have provided unprecedented opportunities to create complex structures and components, as well as produce materials with defined architecture. Although this has rapidly expanded the design space for engineers, each process, hardware and software has its own restrictions as to what can actually be fabricated, fabricated reliably, and what features tend to add cost and time to the manufacturing process. If these considerations are not accounted for during the design process, proposed designs may go through a re-design where geometric modifications are proposed to address these issues. Subsequent design modifications based on manufacturability then require re-analysis to ensure part performance satisfies design specifications. This re-design process not only increases design cycle time and cost, but also reduces part performance and degrades optimality which was initially sought. These issues strongly motivate the incorporation of manufacturing constraints and metrics within the design process.

This talk will discuss the design tool of topology optimization, a systematic approach to distributing material in a design domain, and explore recent advancements related to the incorporation of manufacturing constraints and metrics into the topology optimization framework. We will focus on projection methods, a class of algorithms that represent design through assembly of manufacturing primitives. These methods have been successful at implementing a number of manufacturing constraints, including minimum feature size for [1], maximum feature sizes [2], machining constraints [3], overhang constraints [4,5], insertion of objects of fixed (or variable) size and shape [6], including those from textile manufacturing [7]. Herein we will focus on recent advancements, including extensions and improvements to existing constraints and development of new functions that enable imposition of strict constraints on features but also relax these features and express them in cost functions.

FORMULATION

The key idea behind projection methods is that physical design variables, typically the relative density of elements ρ^e, are expressed as a function of independent design variables that are related to manufacturing actions. This relation is dictated by the manufacturing process and specifically the manufacturing primitive of a process, defined as the smallest building block that can be deposited in (or removed from) the domain. This is expressed mathematically as:

$$\rho^e = 1 - e^{-\beta \mu^e(\phi)} + \frac{\mu^e(\phi)}{\mu_{max}} e^{-\beta \mu_{max}}$$

where β is the curvature parameter dictating the aggressiveness of the mapping and μ^e is the filtered variables in the neighborhood of element e, the simplest of which is radial with the radius r_{min} dictating the minimum feature size associated with a process [1]. This neighborhood set, when used with the Heaviside projection function above, can be termed the manufacturing primitive, defined as the minimum building block of a manufacturing process.

Different manufacturing constraints can be imposed by changing this primitive shape and size and/or by performing multiple independent or dependent projections. Examples of the former include moving from spherical to short disk-like primitives in three dimensions to mimic the layer-by-layer deposition process or tall cylindrical to mimic the machining process. Examples of multiple projections include building structures

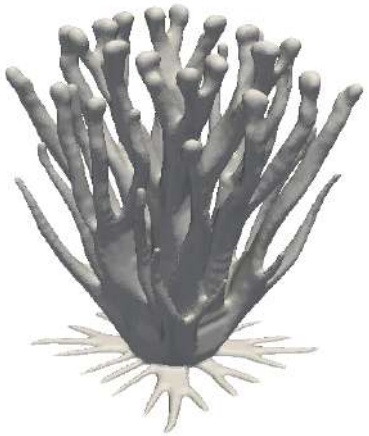

Figure 1. Design of conduction-driven heat sink considering a minimum feature size and overhang constraints of 45 degrees, with the build direction from the bottom up.

*Corresponding author. E-mail: jkguest@jhu.edu.

composed of off-the-shelf inclusions or implementing overhang constraints, defined as a requirement for features to rise at a minimum angle from the build platform, typically associated with the minimum self-supporting angle of a process (e.g., see Figure 1).

In this work we will discuss advancements to the projection approach that include new numerical implementations that provide additional functionality in terms of manufacturing constraints as well as general improvements in computational efficiency. These will include adjustments to existing overhang implementations for topology optimization in additive manufacturing to eliminate enclosed pores and provide specific anchor points for support structures, thereby allowing more convenient access to support structures if they are desired to exist. New cost metrics related to support structures and post-processing costs will also be presenting, culminating in a clear trade-off between material costs (material volume) and post-processing costs of fabricated components. Advancements in topology optimization of subtractive processes will also be presented, including demonstration of an existing machining projection method [3] implemented in a parallel computing framework PETSc for large scale toology optimization [8] (Figure 2). Commonalities between these new methods and future expansions will also be discuss

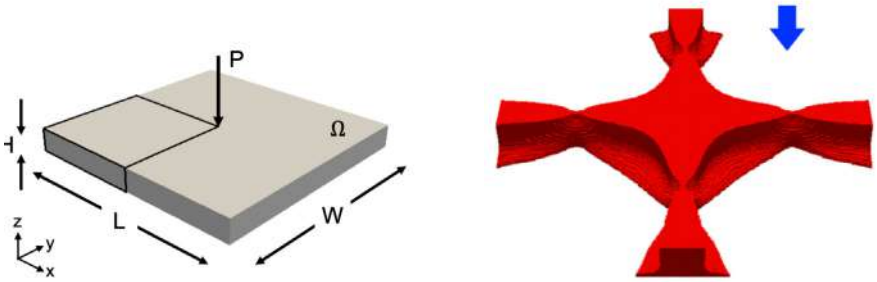

Figure 2. Design of a clamped plate for maximum stiffness using the 2.5 dimension machining projection method from [3].

CONCLUSIONS

Projection methods offer a flexible framework for implementation of manufacturing constraints and considerations in topology optimization. This work demonstrates that with simple modifications to the projection primitives and/or projection functions, that one can implement a wide range of manufacturing constraints and cost functions, including with respect to additive manufacturing (overhang constraints, enclosed pores, feature sizes) and subtractive processes such as machining. These algorithms are demonstrated on structural component design problems as well as for the design of architected materials with optimized combinations of properties.

NEW EFFICIENT MATLAB IMPLEMENTATION OF 2D/3D TOPOLOGY OPTIMIZATION ACCOUNTING FOR BUCKLING

Federico Ferrari * [1], Ole Sigmund[2], and James K. Guest[1]
[1]Department of Civil and Systems Engineering, Johns Hopkins University, Baltimore, MD 21218, USA
[2]Department of Mechanical Engineering, Technical University of Denmark, Lyngby 2400, DK

Summary We present a compact Matlab implementation allowing for the solution of buckling topology optimization problems of an interesting size on a laptop. The code builds on the `top99neo` code [1], and inherits all its basic speedups. The computational burden associated with the setup of the buckling eigenvalue problem and the sensitivity analysis of buckling load factors, which would rapidly become prohibitive when using classical programming approaches in Matlab, is substantially cut by an *ad hoc*, fully vectorized implementation. Some advanced topics, such as the cure of artificial buckling modes and the use of an acceleration strategy are discussed, stressing their easy integration in the basic code.

MOTIVATION

Topology optimization (TO) is rapidly spreading among engineers and researchers from various fields. Its sound mechanical ground and its tendency to highlight mechanical principles and design rules are making it more and more popular among graduate, and even undergraduate engineering students also.

Because TO involves an iterative, redesign procedure containing several ingredients: a finite element analysis, regularization and penalization of the design variables, sensitivity computation and gradient-based variable updates, its programming might be a hurdle to people new to the field. Thus, the well-known `top99` code [2] has certainly the merit of having wrapped up all these procedures in a sharp and short implementation. Then, the `top88` code [3] upgraded the computational efficiency of `top99` exploiting vectorization, allowing users to solve compliance TO problems of an interesting size on a laptop. Recently, Ferrari and Sigmund have shown that also the `top88` had much room left for improvements, and published the new `top99neo`, and its extension to 3D, named `top3D125` [1]. By rethinking some operations and by exploting new routines and functionalities available in Matlab, or developed by independent researchers, the `top99neo` shows speedups ranging from 2 to beyond 6 times compared to the `top88`, on meshes with $3 \cdot 10^4$-$4.8 \cdot 10^5$ elements, and the `top3D125` is the most efficient Matlab implementation for 3D compliance problems to date.

Here we extend the basic codes in [1] to account for buckling, that is a fundamental feature in realistic structural design problems. Our work has been motivated by the lack of any public educational software considering buckling TO and by the fact that both the set up of the buckling analysis and the sensitivity calculation can be potentially highly time consuming operations within a Matlab environment, due to the local nature of the stress stiffness operator.

The new code, named `topBuck250` [4] shares the same neatness and flexibility of the `top99neo` and inherits all its basic speedups: the efficient matrix assembly procedures, the fast implementation of filters and shortcuts in the design update step. Furthermore, by a careful inspection of the stress stiffness operator, we can implement its construction performing extremely cheap matrix operations only, and the same applies for the sensitivity analysis of the buckling load factors (BLFs), introducing major speedups specific for buckling problems. As a result, the proposed code allows the solution of buckling TO problems of a remarkable size ($\approx 10^5$ elements) with a reasonable CPU time.

STATEMENT OF THE OPTIMIZATION PROBLEM

In the standard setting of density-based TO [2] we consider a 2D/3D discretization Ω_h, consisting of m equi-sized elements, and the following single-objective and single-constraint optimization problem

$$\begin{cases} \min\limits_{\mathbf{x}\in[0,1]^m} g_0\left(\hat{\mathbf{x}}\right) \\ \text{s.t.} \quad g_1\left(\hat{\mathbf{x}}\right) \leq 0 \end{cases} \tag{1}$$

The physical densities $\hat{\mathbf{x}}$ are linked to the design variables $\mathbf{x}$ by the relationship $\hat{\mathbf{x}} = \mathcal{H}(H\mathbf{x})$, where H represents the linear density filter and $\mathcal{H}$ the relaxed Heaviside projection.

Either g_0 and g_1 may represent one of the following physical quantities (or the corresponding constraint): volume $V\left(\hat{\mathbf{x}}\right) = \hat{\mathbf{x}}^T \mathbf{1}_m$, compliance $\mathbf{f}^T K^{-1}(\hat{\mathbf{x}})\mathbf{f}$, where $\mathbf{f}$ is a given load vector and $K(\hat{\mathbf{x}})$ is the elastic stiffness matrix, or the buckling load factor $\lambda_1(\hat{\mathbf{x}})$. For this latter we adopt the aggregated measure [5]

$$g_{KS}\left(\lambda_i^{-1}\right) = \lambda_1^{-1} + \frac{1}{\rho} \ln\left(\sum_{i=1}^{q} e^{\rho\left(\lambda_i^{-1} - \lambda_1^{-1}\right)}\right) \tag{2}$$

where λ_i, $1 \ldots q$ are computed by a linearised buckling analysis.

(c) example of Topology Optimization for maximising the fundamental buckling load of a 2D simply supported beam

IMPLEMENTATIONS AND SPEEDUPS

The overall structure of the new code follows that of `top99neo`; Problem (1) is dealt with an iterative, nested analysis and design process and the "basic" speedups are due to

- A new assembly strategy for the $K(\hat{\mathbf{x}})$ matrix, taking advantage of the symmetry of the local and global matrices and exploiting the external routine by [6]. Memory requirements are sensibly cut, and the assembly speed improves up to 15 times on large discretizations (see Figure 1(a));
- Implementation of volume-preserving filters and of a bracketing procedure for the Lagrange multiplier, substantially increasing the speed of the redesign step;

Other speedups are more specific to the buckling problem. In particular, the setup of the stress stiffness operator $G(\hat{\mathbf{x}}, \boldsymbol{\sigma})$ could potentially become very expensive since each local matrix ($G^{(e)}$) depends on the elemental stress distribution, and therefore cannot be obtained as a scaling of a constant, pre-computed matrix. However, upon acknowledging the pattern of the independent coefficients $G_{ij}^{(e)}$ and their explicit expression in terms of the elemental stresses, the global stress stiffness matrix can be computed with an efficiency approaching that of the elastic stiffness matrix (see Figure 1(b)), only performing vectorized operations. The same concept is exploited when computing the buckling loads gradients, and we obtain a code for buckling optimizaton which, apart from the eigenvalue solution step [7], is about as efficient as the one for compliance optimization.

Finally, an extension of the Optimality Criterion, working with rather general MMA-like approximations [8], is implemented in a few lines of code and keeping the same efficiency of the basic OC scheme.

CONCLUSIONS

We extend the recent, highly efficient `top99neo` code to account for buckling, keeping the same readability of the basic compliance code and bringing major computational savings to a potentially time-consuming analysis. Several examples that are easily replicable on a laptop will be shown (see Figure 1(c)). Moreover, discussing around some more advanced topics, such as possible remedies to the phenomenon of artificial buckling modes or the use of alternative optimizers and of advanced convergence acceleration strategies, we prove the `topBuck250` to be a helpful and easily extendable tool for spreading the research on buckling TO.

BAYESIAN INFERENCE OF THE SPATIAL DISTRIBUTIONS OF MATERIAL PROPERTIES

Andrea Vigliotti[1,2], Gábor Csányi[2], and Vikram S. Deshpande * [2]
[1]Innovative Materials Laboratory, Italian Aerospace Research Centre, Capua 81043, Italy
[2]Department of Engineering, University of Cambridge, Trumpington Street, Cambridge CB2 1PZ, UK

Summary The problem of estimating the spatial distributions of material properties from noisy strain measurements is ill-posed and is typically solved by optimisation. Here we employ Bayesian inference and Nested Sampling to identifying the appropriate basis function set and estimate the uncertainty. Complex models generate high likelihood solutions that nevertheless give poor predictions, however, the Bayes' factor peaks for a relatively simple model despite its lower likelihood. Intriguingly, the corresponding maximum likelihood solution still has large errors, but the *mean* of the posterior probability distribution predicts the material properties with significantly higher fidelity. The likelihood landscape is non-Gaussian and can have multiple modes that hinder optimisation methods in such inverse problems.

PROBLEM INTRODUCTION

Estimating the spatial distributions of mechanical properties in a heterogeneous solid body from the measurements of strains or displacements fields has wide ranging applications, including material characterisation, medical diagnosis and civil infrastructure monitoring. For example, there has been a recent burst of activity in the development of smart civil infrastructure and this includes application of strain measurement technologies like fibre optic sensing to monitor the structural health of tunnels (Gue et al., 2015), bridges (Ko and Ni, 2005) and concrete sleepers (Butler et al., 2017), to name a few. In these applications strains are measured at a small number of discrete locations. In some other applications full field measurements of the displacement fields within specimens are available. For example, a technique known as "displacements under applied loading by Magnetic Resonance Imaging" (dualMRI) has been developed to perform in vivo measurements of displacements and strain in musculoskeletal tissues (Chan et al., 2012). In all these cases the spatial distributions of material properties is the information of primary interest but displacement and strain information does not directly describe these material property distributions. The reconstruction of material property maps from noisy (and sometimes sparsely spaced) strain measurements is an ill-posed inverse problem that requires complex modelling approaches.

SOLUTION STRATEGIES

A number of methods have been proposed to identify constitutive parameters from strain/displacement measurements; readers are referred to Avril et al. (2008) for an overview. The most common is the the finite element model updating (FEMU) approach is an optimisation method and involves adjusting the model parameters in order to minimise the difference between computed and measured strains as measured by a likelihood function (Rouger et al., 1991). Various types of regularisations have been proposed to reduce the intrinsic instability of the solutions, but the reconstructed results are inevitably strongly dependent on the choice of the regularisation parameters (Richards et al., 2009). Moreover, the instabilities are aggravated by the presence of measurement noise.

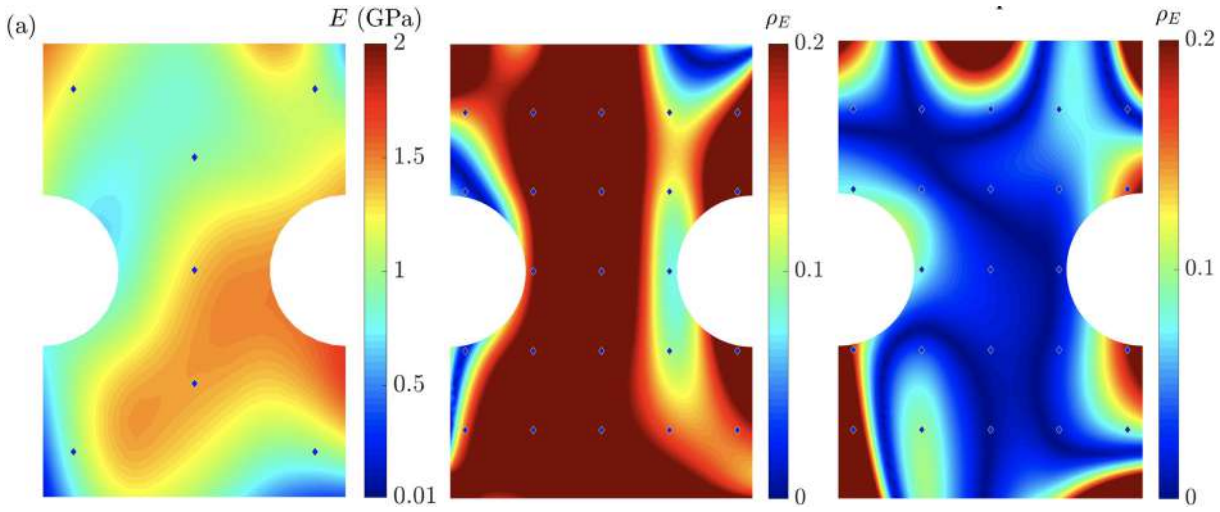

Figure 1: The Young's modulus of our (synthetic) specimen (left), with the error in its prediction by optimisation (middle) and Bayesian inference (right, mean of the posterior).

*Corresponding author. E-mail: vsd20@cam.ac.uk.

Statistical and probabilistic methods are in fact being increasingly used for solutions of ill-posed inverse problems. In particular, the Bayesian approach allows for a full characterisation of all possible solutions, and their relative probabilities, whilst simultaneously addressing the problems associated with the ill-posed problem in a clear and precise fashion. Readers are referred to Stuart (2010) for a detailed discussion of the mathematical basis of Bayesian inference methods. In this study we follow such a Bayesian approach, and in particular we do not use Laplacian or other such approximations for the posterior as in the majority of previous studies, but estimate the entire posterior probability distribution of the material properties using the Nested Sampling method (Skilling, 2006). We quantify the Bayesian evidence in support of particular choices of basis functions, and compare our solutions to those obtained by optimisation.

EXAMPLE

In order to illustrate the method we numerically generated a synthetic specimen with a random spatial distribution of isotropic elastic constants using NURBS functions with grid of 5×5 control weights, the Young's modulus is shown in the left panel of Figure 1. The synthetic strain data was then calculated via the finite element (FE) method. These strains, with and without added measurement noise, were then used as the only available data from which to estimate the spatial distribution of material properties using models with a grid of $p \times p$ control weights. In the presence of measurement noise, the maximum likelihoods increased with increasing p (i.e. increasing model complexity). However, this was a consequence of the complex models overfitting the experimental data, which ultimately resulted in poor predictions of the actual spatial distributions of the material properties. On the other hand, Bayes' factor correctly estimated that a model with a grid of 5×5 control weights best describes the spatial distribution of elastic constants within the specimen and with the lowest uncertainty. Moreover, inference based on Bayes' factor appropriately indicates an increasing uncertainty in model selection with decreasing data and increasing measurement noise. By contrast, inference based purely on likelihood is misleading with the maximum likelihood increasing as the amount of available data decreases. Simpler model selection criteria such as Bayesian information criterion (BIC) were shown to fail for the inverse elasticity problem investigated here and this makes accurate evaluation of the posterior distribution and the associated Bayesian evidence integral (by Nested Sampling or other means) imperative for this class of problems.

Figure 1 also shows the errors in the reconstruction of the spatial distribution of the Young's modulus by optimisation and Bayesian inference. For our parameter settings (number of strain gauges, simulated measurement noise), which are not atypical with respect to a real world scenario, the error in the former is substantial, exceeding 10% over most of the specimen. By contrast, the mean of the posterior obtained by Nested Sampling shows less that 2% error over most of the specimen, except at the edges.

CONCLUSIONS

The numerical results presented above suggest clear advantages of the Bayesian approach over traditional optimisation methods based on maximum likelihood. However, these gains come at the price of considerably higher computational costs and finding ways to reduce these costs is of interest. While Bayesian inference using Nested Sampling has been demonstrated here with the focus on an inverse elasticity problem, the ideas are general and can be readily used for a wide range of high dimensionality problems in mechanics. This includes selection of constitutive models given available (noisy) material data as well as the corresponding estimation of parameters and the associated uncertainty. The key advantages of Bayesian inference over optimisation procedures typically used in these problems include: (i) an in-built Occam's razor that aids in avoiding overfitting both for model selection and parameter estimation; (ii) increased accuracy in predicting material properties for data-poor and high noise regimes; and (iii) a quantification of the uncertainty associated with the estimated parameter values.

TOPOLOGY OPTIMIZATION WITH 3D PRINTING NOZZLE SIZE RESTRICTIONS

Josephine V. Carstensen *
Department of Civil and Environmental Engineering, MIT, Cambridge MA, USA

Summary This paper presents a density-based topology optimization algorithm that implicitly incorporates the discrete nozzle size constraint associated with material extrusion 3D printing processes. The algorithm uses a projection-based approach such that a discrete number of nozzle passes is enforced on the resulting designs by altering the filtering operation. A standard intermediate density penalization scheme is used and the optimization problem is solved using a mathematical program. The algorithm is demonstrated on 2D benchmark examples.

INTRODUCTION

Recent years has seen a rapid development in manufacturing technologies, including 3D printing. This has raised a need for re-thinking conventional design. Topology optimization offers a means to leverage the new new manufacturing possibilities as it is a free-form design method that does not require a preconceived notion of the final layout. It has been known to achieve new, often complex, solutions that typically outperform conventional low-weight design. It is based on formulating a formal optimization problem and most rigorously solved using a mathematical program.

Although the advances in manufacturing technologies have made it possible to realize increasingly complex designs, there are still constraints associated with fabrication. Most recent research on topology optimization that embeds the constraint and/or possibilities associated with 3D printing has focused on eliminating overhang and designing with multiple base materials (see e.g. overview in [1]). In contrast, this work seeks to address the discrete nozzle size constraint that exists in material extrusion 3D printing processes.

Material extrusion 3D printing processes will in this work refer to manufacturing technologies that use Fused Deposition Modeling (FDM) or a similar fabrication procedure. In most FDM technologies, a 3D object is sliced and printed layer by layer by moving a nozzle that deposits material as illustrated in Fig. 1a. The solid parts of a realized design therefore consists of an integer number of nozzle passes. For example, if a nozzle that deposits material has size $d_{min,c} = 2$ units and is printing along the length of a member, then this member can have thickness $t_{member} = 2$ units, $t_{member} = 4$ units, $t_{member} = 6$ units and so on. It is not possible for the member to have a thickness of e.g. 3 units, since the nozzle cannot pass the member and deposit 1 unit thickness. This constraint is relevant for all FDM processes, but especially important to consider for large scale printing technologies such as concrete 3D printing.

To describe the nozzle constraint, the following assumptions are made about FDM processes; (i) the center part of the extruded material has a discrete member size that cannot be altered or overlap with other nozzle passes, and (ii) a bonding region is present on each side of the non-overlapping center. The bonding region is allowed to overlap with bonding regions created from other passes. The center and bonding regions within the nozzle passes are illustrated in Fig. 1b where the red refers to the non-overlapping part of a nozzle pass whereas green illustrates the bonding regions.

PROJECTION BASED NOZZLE SIZE RESTRICTIONS

This work suggests to implicitly embed discrete nozzle size restrictions in density-based topology optimization using a projection-based approach [2]. The proposed algorithm therefore embeds the manufacturability constraint in the filtering

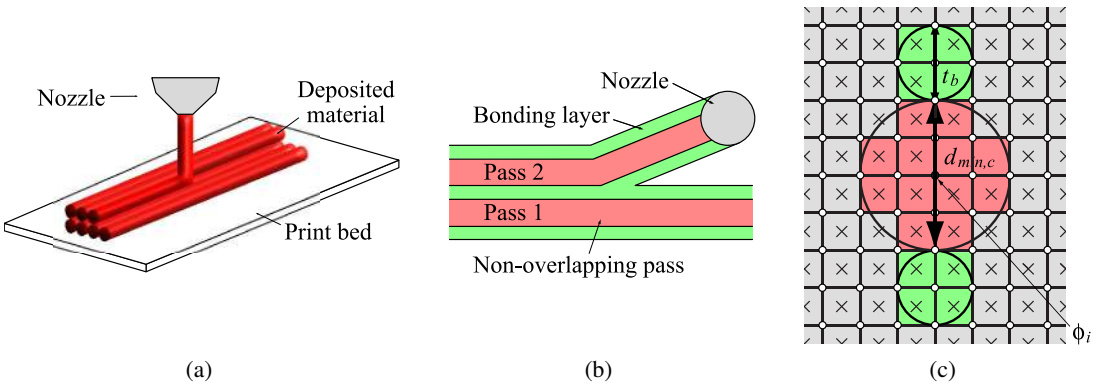

Figure 1: (a) schematic showing the FDM printing process, (b) the two regions herein assumed to be associated with a nozzle pass, and (c) the suggested projection domain that embeds the nozzle size restrictions.

*Corresponding author. E-mail: jvcar@mit.edu.

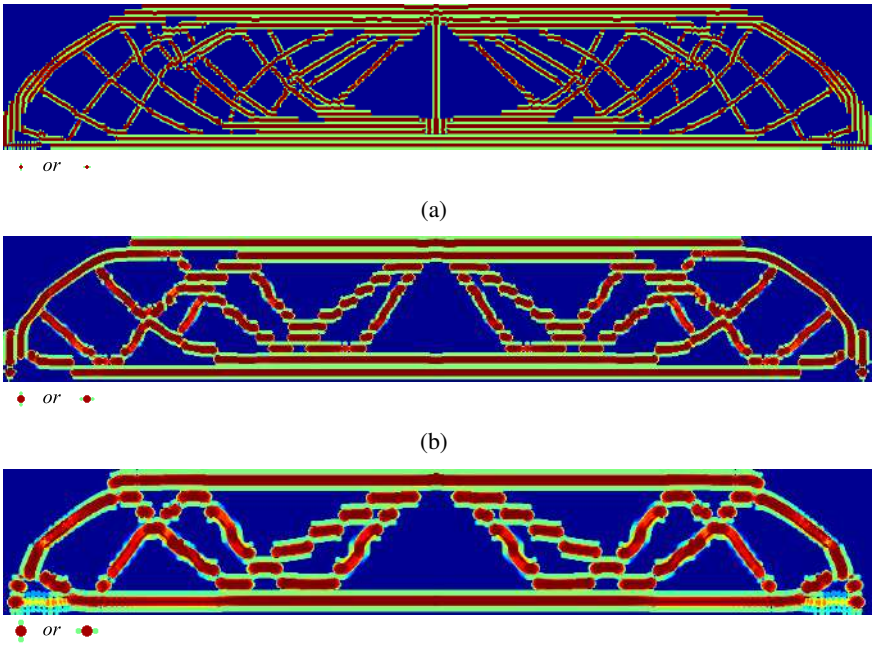

Figure 2: MMB beams designed for minimum compliance with volume constraints of 50% material and nozzle specifications of (a) $d_{min,c} = 0.50$ and $t_b = 0.25$, (b) $d_{min,c} = 1.00$ and $t_b = 0.50$, and (c) $r_{min,c} = 1.50$ and $t_b = 0.75$.

operation and uses a standard intermediate density penalization scheme. In this work, the Solid Isotropic Material with Penalization (SIMP) method [3] is used and the Method of Moving Asymptotes (MMA) [4] is taken as the gradient based optimizer.

To enforce the nozzle size restrictions an altered form of Discrete Object projection [5] is used to create the center and bonding zones. If the printing process is primarily associated with the nozzle moving along a single direction, the bonding layer is placed on each side of the non-overlapping feature along this direction. Figure 1c shows the new projection features for printing processes where the nozzle moves primarily horizontally. Here, the diameter of the circular features $d_{min,c}$ describes the non-overlapping size printed by the nozzle and t_b gives the bonding thickness allowed on each side. To allow horizontally and vertically dominated nozzle movement, an extension is suggested that use nonlinear weighting functions to determine the print direction at each point. The nonlinear weighting functions are taken as in [6].

Benchmark Results

The proposed algorithm is used to solve the standard topology optimization problem of minimum compliance on a range 2D benchmark problems. Figure 2 shows the results obtained for the MBB beam with different nozzle size restrictions and a total material constraint of 50%. As can be seen, the obtained designs depends highly upon the user specified constraints and all designs fulfill the discrete nozzle size requirements.

CONCLUSIONS

A projection based approach can implicitly embed the discrete nozzle size restrictions associated with material extrusion 3D printing processes in topology optimization. The herein suggested algorithm has been demonstrated on 2D examples and is in principal extendable to 3D.

GENERATING MULTI-MATERIAL TRUSS-LIKE CELLULAR STRUCTURE DESIGN BASED ON CONTINUOUS/DISCRETE DENSITY MAPPING STRATEGY

Yingchun Bai *, Siqi Li
National Engineering Laboratory for Electric Vehicles, School of Mechanical Engineering, Beijing Institute of Technology, Beijing, China

Summary Multi-material truss-like cellular design can generate high-performance and light-weight structures, however, the design complexities arise from the necessities of material selection and truss cellular design simultaneously. In this work, a continuous/discrete density mapping strategy is proposed in combination with AAP multi-material topology optimizer. A numerical example is tested to demonstrate its effectiveness.

Introduction

With the increasing usage of additive manufacturing (AM), feasibility of fabricating light-weight and high-performance complicated structures makes it extremely urgent to design multi-material truss-like structures. The classical truss-like cellular structure can be designed by using the Ground Structure Approach (GSA) or Size Matching and Scaling (SMS) method, which will bring computational burden when involving multi-material problems. To accelerate the design efficiency, a continuous/discrete density mapping strategy is developed following the continuous multi-material topology optimization solution to generate the truss-like cellular structure, which will balance the computational cost and expected design feature.

Multi-material Relative Density Mapping Strategy (MM-RDM)

Similar as single-material relative density mapping approach, multi-material truss-like cellular structures can be generated by using multi-material relative density mapping strategy (MM-RDM) in combination with multi-material topology optimizer such as alternative active phase (AAP). When multi-material involved, the arising challenges are material selection and geometry size calculation for each member of the background truss structures. Inappropriate mapping strategy may lead to manufactural unfavourable material interface, in which specific material member are isolated within other material members. To handle this issue, we proposed two mapping strategies, namely continuous and discrete mapping strategy, based on which the multi-material truss-like structures can be obtained. The framework of the proposed approach is shown in Fig. 1. The remarkable difference between the continuous and discrete mapping strategies is the material selection method, which will be detailed explained hereafter.

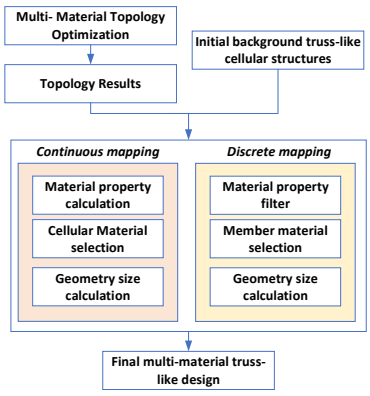

Fig. 1. Framework of the proposed approach

(1) Continuous mapping strategy

Based on the topology optimization results by AAP, a modified projection weight is developed as

$$w_{jm} = \frac{\sum_{i=1}^{n} \rho_{im} SE_i e^{-\frac{r_{ij}}{0.1L}}}{\sum_{i=1}^{n} e^{-\frac{r_{ij}}{0.1L}}} \tag{1}$$

where w_{jm} is the projection weight of mth material for jth truss member; ρ_{im} is the material density of mth material for ith element; SE_i is the strain energy of the ith element of final topology by AAP; r_{ij} is distance between the centroid of ith element and jth truss member; L is the length of the jth truss.

*Corresponding author. E-mail: baiyc@bit.edu.cn.

With the above projection weight, the Young's Modulus E_j of the jth truss member can be calculated by

$$E_j = \frac{\sum_{m=1} E_m w_{jm}}{\sum_{m=1} w_{jm}} \tag{2}$$

where E_m is the Young's Modulus of the mth material. It should be noted that the Young's Modulus E_j may have difference with the actual Young's Modulus of the candidate materials, and it can be further filtered into the Young's Modulus of the candidate materials.

(2) Discrete mapping strategy

Discrete mapping strategy employ a brute-force method to directly compare the projection weight to select the corresponding projection weight. The Young's Modulus E_j of the jth truss member can be calculated by

$$E_j = E_{k \in \max(w_{jm}), m=1,2,\ldots,M_{total}} \tag{3}$$

where $E_{jk \in \max(w_{jm})}$ means assigning the Young's Modulus with the maximal projection weight to jth truss member, and M_{total} is the total number of the candidate materials.

(3) Geometry size calculation

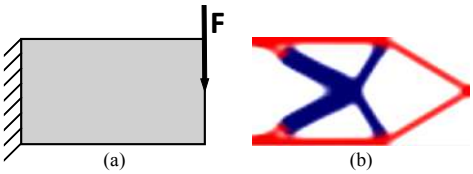
For the above two material selection strategies, the geometry size calculation can be performed using the following formulation

$$Ar_j = \frac{\sum_{m=1} w_{jm} E_m}{E_j} \tag{3}$$

where Ar_j is the cross-section area of jth truss member.

A Demonstrated Numerical Example

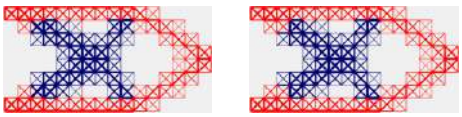
A cantilever beam as shown in Fig. 2(a) is provided to demonstrate the effectiveness of the proposed method. The design domain is $80\text{mm} \times 40\text{mm}$. An external force F=1N is applied at the middle point of the right boundary. The Young's Modulus are 3000 Mpa (red material) and 1000Mpa (blue material) for candidate materials, respectively. For the design problem, the target truss volume of each material are 300mm^3 and 300mm^3, respectively.



(a) Cantilever example (b) MMTO results

Fig. 2 Design space and MMTO results

The optimization result of the AAP algorithm is shown in Fig.2(b). The result of the continuous mapping method is shown in Fig.3(a), whose displacement of force apply point is 0.21 mm, which costs 47.55s. While the result of the discrete mapping method is shown in Fig.3(b), whose displacement of force apply point is 0.17mm, which costs 44.97s. It can be observed that the proposed strategies can generate manufacturing favourable multi-material truss-like cellular structure.



(a) Result of continuous mapping method; (b) Result of discrete mapping method

Fig. 3 Generation of multi-material truss-like structures

CONCLUSIONS

A modified continuous/discrete mapping strategy is proposed for multi-material truss-like structure generation. The numerical example demonstrates that both mapping strategy can generate the manufacturing favourable structures effectively and efficiently. Compared with the continuous approach, the discrete approach shows its advantages in terms of structural performance and computation efficiency.

It has been suggested that optimal designs for structures undergoing unsteady, transient loading can be achieved using equivalent static loads [1-4]. However, this approach does not incorporate the structure's force-time history into the optimization process. Consequently, the approach may be suboptimal and, in some cases, may produce designs with decreased performance [5]. A topology optimization (TO) software integrated with a time-resolved, finite element (FE) solver is needed to determine whether the current static TO process is a reasonable cost-effective approach, or whether a more computationally-intensive, time-resolved, TO process is required.

In order to clearly demonstrate this need, Materials Sciences LLC (MSC), Lawrence Livermore National laboratory (LLNL), and the Air Force Research Laboratory (AFRL) are conducting research on the transient topology optimization of structures subjected to dynamic loads and boundary conditions. In particular, the team has focused on the development of a simple benchmark problem that clearly demonstrates that topology optimization via equivalent static loads not only produces a sub-optimal design, but instead produces designs that will fail under the intended transient loading. The presented research will include theoretical analysis of the benchmark problem, development of the static and transient optimizations of the benchmark problem, and experimental verification of the findings. It is believed that the results of this research clearly demonstrate the need for transient topology optimization and provide an experimentally verified benchmark problem to support future algorithm development.

CNN - DRIVEN APPROXIMATE ALGORITHM OF TOPOLOGY OPTIMISATION BASED ON INITIAL STRESS LEARNING

Jun Yan*[1], Qi Zhang[1], Qi Xu[1] , Kun Yan[1]
[1] State Key Laboratory of Structural Analysis for Industrial Equipment, Department of Engineering Mechanics, Dalian University of Technology, Dalian, 116024, China

Summary A new approximate algorithm for topology optimisation is proposed by learning the initial stress, (ISL), which is the principal stress matrix obtained from the finite element analysis in the first iteration of classical topology optimisation. And a new algorithm evaluation method is proposed to optimize the prediction performance by selecting training samples and CNN models. By the established approximate algorithm based on both above, topological prediction results with high prediction accuracy can be produced with no iterations based on a relatively small sample set training. The algorithm is evaluated on cases, obtaining good prediction results.

INTRODUCTION

Recently, machine learning algorithms have developed rapidly. Because the machine learning algorithm requires high calculation costs in its offline training process and the use of trained model requires almost no complex calculations, it is used to achieve the accelerated or instant calculation of complex calculation processes. Currently, scholars have combined topology optimisation with the machine learning algorithm to improve the real-time computing efficiency of topology optimisation. However, existing results primarily include the following drawbacks: (1) The acceleration is incomplete, and the iterative process needs to be performed during online topology optimisation[1]; (2) The optimisation results are not ideal, and a clear load-transferred path cannot be obtained[2]; (3) An extremely large training set is required to train the model to achieve an acceptable approximate accuracy[3], which results in an exorbitant computing cost for training.

Hence, based on the CNN (Convolutional Neural Networks), a new approximate algorithm for topology optimisation is proposed by learning the initial stress, which is the principal stress matrix obtained from the finite element analysis in the first iteration of classical topology optimisation. By learning the relationship between the principal stress matrix of the initial (first iteration) optimisation structure and the final optimisation topology, this algorithm can provide approximate results of topology optimisation with a small number of training samples. Furthermore, a new algorithm evaluation method is proposed herein. Using this evaluation method, a CNN model is set up and trained to verify the feasibility of the algorithm proposed.

FLOW OF TOPOLOGY OPTIMISATION APPROXIMATE ALGORITHM

The flow of the algorithm proposed herein can be divided into three steps: generating dataset, CNN model training, and CNN-based prediction.

In step 1, the algorithm will generate loads according to the given boundary conditions based on certain rules and load types to perform topology optimisation. The specific rules and their effects are introduced in section 4. Based on the data generated using the SIMP method[4] and the optimised topology, the algorithm obtains the principal stress matrix from the finite element analysis in the first iteration of the topology optimisation. Additionally, the final topology optimisation results are required as the labels. These data will be used in step 2 to train the CNN model.

In step 2, the algorithm will train the CNN model according to the data obtained in step 1. The initial principal stress matrix serves as a variable, and the topology optimisation result is the label. To balance the effect of each sample on the training results, the initial principal stress matrix must be normalised (the matrix divided by the largest element) before being imported into the CNN model.

In step 3, the algorithm will predict the topology optimisation results under other load cases according to the trained CNN model obtained in step 2. The prediction requires a finite element calculation based on the topology optimisation problem to be predicted, and the extracted principal stress matrix is input into the trained CNN model. After obtaining the input, the CNN model can output the probability distribution of the final predicted results of topology optimisation of the structure rapidly and convert the distribution into the predicted topology optimisation results.

EVALUATION OF TOPOLOGY OPTIMISATION APPROXIAMATE ALGORTHM

For the algorithm herein, the optimisation formulation of the model optimisation process in traditional concept is as follows:

$$\min \ \frac{\sum_{i=1}^{S} d(\boldsymbol{\rho}^p)}{S}$$
$$d(\boldsymbol{\rho}^p) = \sqrt{\frac{\sum_{i=1}^{m}\sum_{j=1}^{n}(\rho_{ij}^t - \rho_{ij}^p)^2}{N}}, \qquad (1)$$

where m and n are the length and width of the design domain, respectively; $\boldsymbol{\rho}^t$ is the optimised topology matrix composed of ρ_{ij}^t based on the SIMP method; $\boldsymbol{\rho}^p$ is the predicted topology matrix composed of ρ_{ij}^p based on the algorithm; S is the total number of samples in the training set; d is the difference coefficient, which is introduced to represent the effectiveness of the prediction results of the algorithm for a sample. The smaller the $d(\boldsymbol{\rho}^p)$ is, the more similar the predicted topology is to the results obtained by the standard SIMP topology optimisation.

* Corresponding author. Email: yanjun@dlut.edu.cn

The performance evaluation method above is highly effective for most algorithms. However, because the optimisation goal is to minimise the overall difference between the optimised and predicted results, the predicted results of the deep learning model adjusted according to the evaluation method above may exhibit a phenomenon that the deep learning model stops predicting some samples that are difficult to master and only provides ideal or the same predicted results for samples that are easy to master. This may result in algorithm instability. Hence, a prediction accuracy parameter D and a new evaluation method is proposed based on (9):

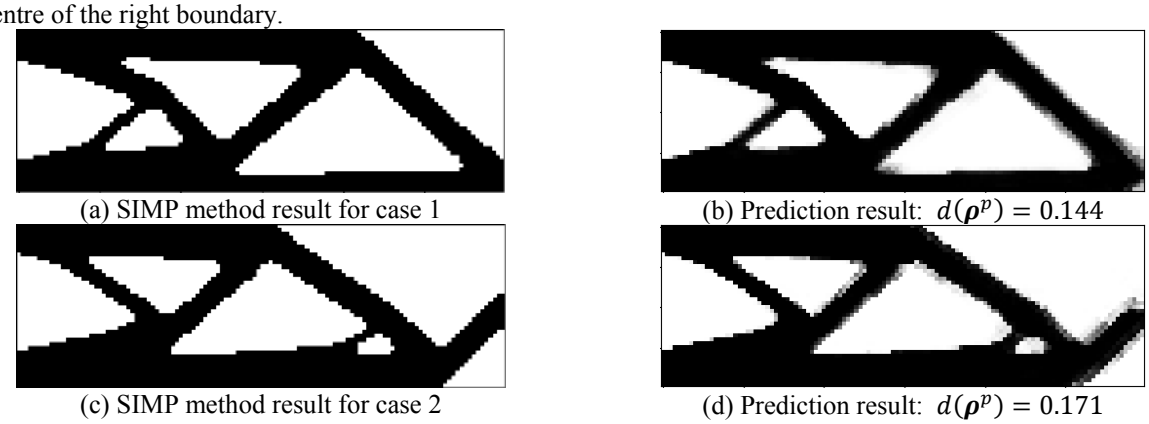
$$f(\boldsymbol{\rho}_p) = \begin{cases} 0 & if\ \ d(\boldsymbol{\rho}_p) > \alpha \\ 1 & otherwise \end{cases}$$
$$D(\boldsymbol{\rho}_p) = \frac{\sum_{i=1}^{S} f_i(\boldsymbol{\rho}_p)}{S}, \qquad (2)$$

where $f(\boldsymbol{\rho}_p)$ is the similarity discriminant function, which is used to judge whether two structures are similar; α is the critical difference threshold. If the difference coefficient between the optimised and predicted results is greater than this threshold, then the predicted result is not similar to the optimised result; otherwise, it is similar. The smaller the α, the larger is D, and the better is the prediction performance of the model.

THE SINGLE-LOAD EXAMPLE

To verify the validity of the algorithm, a model was designed and trained with 1000 samples in this study. These samples were produced based on load cases in which equidistant sample points were selected and single vertical, horizontal, or 45° unit force was applied to the sample point. Also, a test set with 1000 samples in were set up in which load location and direction are both given randomly. The trained model gives validation accuracy D_v=0.892 on the test set while the critical difference threshold was set as $\alpha = 0.25$. That proves the algorithm proposed herein can effectively predict most single load cases after only 1000 samples of training and provide reasonable approximate results of topology optimisation.

Two load cases are chosen to show the specific prediction result, as shown in **Fig.1**. In case 1, a vertical downward unit load to the lower right corner of the cantilever was applied. In case 2, the load is applied at an upper 45° direction at the centre of the right boundary.



(a) SIMP method result for case 1 (b) Prediction result: $d(\boldsymbol{\rho}^p) = 0.144$

(c) SIMP method result for case 2 (d) Prediction result: $d(\boldsymbol{\rho}^p) = 0.171$

Figure 1 Comparison between topology optimisation and CNN-predicted results of load

CONCLUSIONS

An approximate topology optimisation method with high prediction performance and improved real-time calculation efficiency was proposed. Compared with the published approximate algorithm for machine learning topology optimisation, the algorithm proposed herein reduced the number of learning samples significantly and simultaneously yielded approximate results that were highly similar to those of the standard topology optimisation algorithm. Based on the new algorithm evaluation method proposed herein, a set of CNN model structure and sample selection method are proposed.

Summary Labyrinth seals are the most popular and the oldest mechanical sealing solution in the industry and play a vital role in the prevention and reduction of fluid emission. In the last decades, the improvement of the Labyrinth seal in multi-stage pumps and compressors attracts a great attention. Due to the very high number of geometrical parameters (e.g., seal cavity depth, seal tooth thickness and tooth tip clearance) and difficulties related to determining their effects on labyrinth seal performance, the Topology Optimization is a feasible approach to achieve the best design with the highest efficiency. Thus, this paper presents a Topology Optimization formulation for design the labyrinth seal by using a 2D swirl flow model. The model is developed based on the Navier-Stokes equation to consider an axisymmetric flow with flow rotation around the shaft (fluid flow in labyrinth seal), and an objective function is defined in order to maximize the Diodicity of dissipation energy. Then, the Topology Optimization formulation with a 2D swirl flow model is coupled and implemented in COMSOL Multiphysics (based on the finite element method) and solved using Sparse nonlinear OPTimizer (SNOPT) solver. Post-processed results, e.g. Topology optimization design, fluid flow, and pressure contour, is presented. The results show the improvement in the performance of the labyrinth seal.

INTRODUCTION

Labyrinth seals are the most popular and the oldest mechanical sealing solution in the industry and play a key role in the prevention and reduction of fluid emission. The labyrinth seals have several layouts and because of convenient installation and reasonable efficiency have a wide range of applications in compressors, pneumatic turbines, sodium-cooled fast reactor (SFR), and very high-temperature reactors (VHTR). The fundamental of labyrinth seal mechanism commonly is based on a series of extended surfaces forming chambers between an axis and a fixed part that cause recirculation in the fluid which reduces leakage. The fluid flow through a labyrinth seal can be considered as a flow through a series of mechanical restriction and this fluid is driven by the total pressure gradient between two sides ofthe labyrinth seal. For many years, improving the design and performance of the labyrinth seals attracts great attention and has been a challenge in engineering. Due to the complexity of the labyrinth seal, a few experimental works were conducted to investigate and study the labyrinth seal and stablish an understanding of the flow mechanism in the labyrinth seal

Labyrinth seals being studied with different structures. However, in the context of labyrinth seals optimization, works in literature are limited to parametric assessments, shape optimization, regression optimization, and genetic algorithms. Due to the very high number of geometrical parameters (e.g., seal cavity depth, seal tooth thickness and tooth tip clearance) and difficulties related to determining their effects on labyrinth seal performance, the Topology Optimization is a suitable approach to achieve the best design with the highest efficiency. In recent years, topology optimization has been considered as a powerful computational tool for fluid and structural design. Topology optimization is a mathematical formulation to optimize and distribute the material in the design domain with predefined boundary conditions and constraint.

In order to enhance the performance and efficiency of labyrinth seal, this paper presents a Topology Optimization formulation for design the labyrinth seal by using a 2D swirl flow model. The model is developed based on the Navier-Stokes equation to consider an axisymmetric flow with flow rotation around the shaft (fluid flow in labyrinth seal), and an objective function is defined in order to maximize the energy dissipation. The rotation of the rotor is also taken into consideration in the 2D-Swirl domain to evaluate the shaft rotattion speed influence on the labyrinth seal design. Due to working details of labyrinth seal, it is necessary to keep a gap between labyrinth seal and shaft. Here, we use the diodicity behavior to minimize the leakage in main flow (forward flow) of labyrinth seal using an auxiliary reverse flow to maintain the necessary gap. Then, the Topology Optimization formulation with a 2D swirl flow model with predefined boundary conditions is implemented in COMSOL Multiphysics (based on the finite element method) and optimization was performed using Sparse nonlinear OPTimizer (SNOPT) solver. First, the fluid simulation needs to be performed in both direction, then the output velocities need to be supplied to the sensitivity analysis together with the solution of the adjoint system. Finally, the optimization can take place, calculating the objective function and its gradients, obtaining possible new geometries for the labyrinth seals. The problem constraint is the volume of fluid. To the author's best knowledge, this is the first work that used the topology optimization formulation to improve the labyrinth seal design.

NUMERICAL IMPLEMENTATION

The theoretical Multiphysics model has been implemented and subsequently solved numerically in the finite-element software COMSOL Multiphysics. Briefly, the mathematical model consists of the fully coupled fluid and Topology Optimization Method. Fluid implemented with the incompressible Navier-Stokes equations, density model implemented using Darcy model and finally coupled equations solved by Sparse Nonlinear OPTimizaer (SNOPT) solver. The general idea is maximizing diodicity to catch minimum leakage possible at the outlet of labyrinth seal. Figure 1 illustrates the domain and related boundary conditions which is implemented in COMSOL. Here, velocity was chosen at the inlet, ambient pressure (100 kPa) at the outlet and no slip condition applied to the walls. Specified velocity of rotating shaft employed in 2D swirl flow topology optimization simulation.

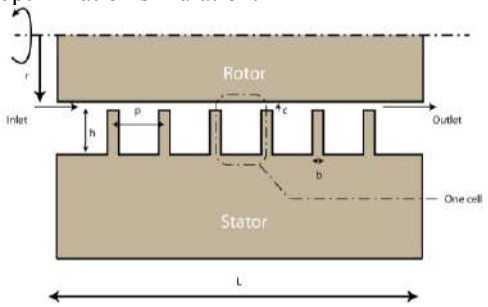

Figure 1. Schematic design of a full labyrinth seal with shaft rotation and key parameters.

PRELIMINARY RESULTS

In this section simulations are performed with focus on full labyrinth seal and topology optimization applied to typical geometry of labyrinth seal consist of inlet, topology domain and the outlet. A labyrinth seal with aspect ratio of 20:3, 40 mm shaft radius, fixed velocity (0.25 m/s) at the inlet and fixed pressure (100 kPa) at the outlet imposed. Simulations here are performed with real properties of CH_4 and 1500 to 6000 rpm rotation. Topology optimized geometry and related fluid velocity profile are demonstrated in figure 2.

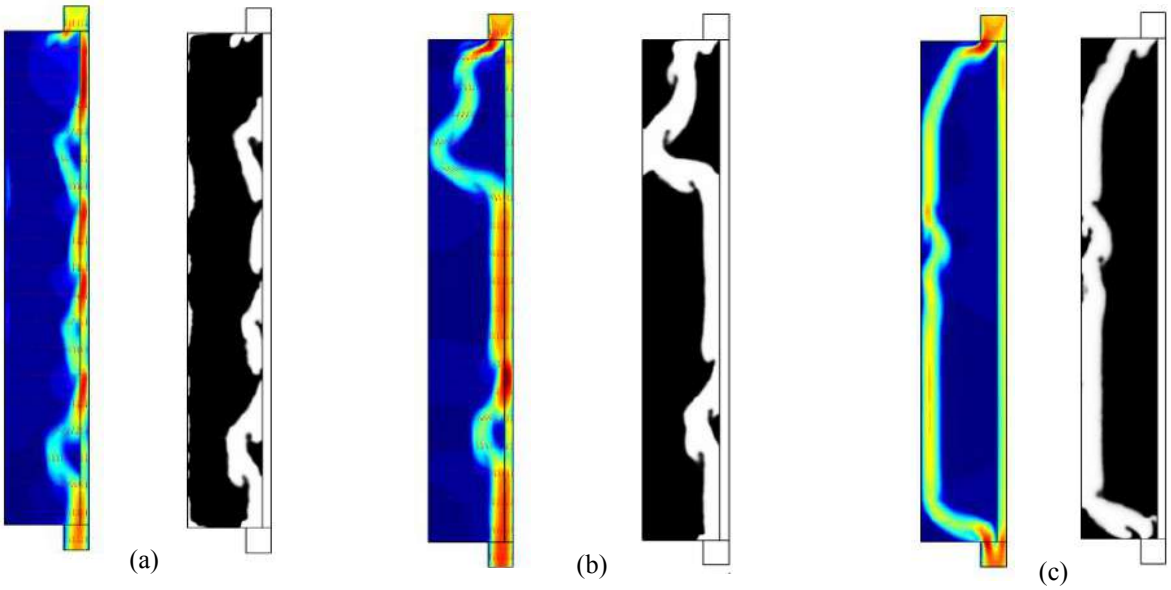

Figure 2. Topology optimized design and related fluid velocity profile obtained for full labyrinth seal with aspect ratio of 20:3, volume constraint < 0.3 and (a)1500 rpm (config. 4), (b) 3000 rpm, and (c) 6000 rpm (config. 5) rotation speed.

DISCOVERY OF HIGH-PERFORMANCE CU ALLOYS FROM DISCARDED EXPERIMENTS AND PHYSICAL FEATURES: A DATA-DRIVEN METHOD

Qingkun Zhao[1], and Haofei Zhou*[1]
[1]Center for X-mechanics, Department of Engineering Mechanics Zhejiang University, Hangzhou, Zhejiang, PR China

Summary: Copper alloys with high strength and electrical conductivity are ideal candidates for a wide range of civilian and engineering applications. Traditional experiments are costly and time-consuming, leading to the "discarded" experimental data with unsatisfied properties. Herein, an accelerated multi-objective design strategy from the application of machine learning, experimental characterization, genetic algorithm is proposed. The predicted Cu alloys were experimentally characterized, exhibiting superior hardness or electrical conductivity. The physical features of Cu alloys are employed to train effective models, and the impact the features on prediction model is evaluated by a genetic algorithm. Our findings suggest that the data-driven method holds great potential for solving complex optimum problems owing to its ability to consolidate information from multiple sources.

INTRODUCTION

The engineering applications require enhanced mechanical properties of Cu materials such as high strength and hardness while maintaining excellent electrical conductivity. Unfortunately, universal strengthening approaches may cause impurity scattering, leading to the undesirable degradation of electrical conductivity. Conventional "trial-error" exploration of Cu alloys based on a priori knowledge or intuition are lacking robustness, leading to experimental data with undesirable hardness or conductivity. Benefiting from its ability to abstract knowledge from data, the machine learning (ML) tools are used to study the mechanical properties of materials and structures [Wen et al., 2019; Chen et al., 2019; Wang et al., 2019]. Our recent work [Zhao et al., 2021] presents a data-driven method to guide the design of high-performance Cu alloys by learning from the discarded experimental data. The physical features including extra information of the alloys are applied to the small sample training ML models. We successfully synthesized and characterized these optimized alloys, confirming the feasibility of our data mining method in the discovery of high-performance Cu alloys.

MACHINE-LEARNING RESULTS

The discarded experimental data and the physical features are normalized as the inputs of the ML model (Figure 1a). We select the ML algorithms and use the correlation-based feature selection to build an accurate and concise ML model (Figure 1b). The best combination of the experimental data and physical features is selected from all 6.92×10^{18} possible models. Experimental validation and iteration are performed (Figure 1c). In comparison with the original training dataset, the predicted Cu alloys exhibit a maximum of 7% and 12% increases for hardness and electrical conductivity, respectively. Finally, five Cu alloys showing superior overall performance are predicted. The increase of hardness is due to precipitation of second-phase Co-Ti and Fe-Ti compounds during aging, while the rise of electrical conductivity is caused by a purification effect of the precipitates on Cu matrix.

EFFECT OF THE PHYSICAL FEATURES ON ML MODELS

A genetic algorithm is used to quantitively describe the importance of physical features for the ML prediction by counting the survival rate, which is the possibility for a feature to be retained by the algorithm. A feature with survival rate equal to 1 indicates that it is retained in all repeated calculations. Interestingly, the feature named local size mismatch,$D.r = \sum_{i=1}^{n}\sum_{j=1,i\neq j}^{n} C_iC_j * |r_i - r_j|$(where C_i is the molar fraction of compositional element *i* (Cu, Co, Ti, Fe), and r_i is the atomic radius),is reserved in every GA calculation for electrical conductivity prediction. It is generally accepted [Qu et al., 2013] that the contribution of solid solution scattering to electrical resistivity ($\Delta\rho_S$) can be calculated as $\Delta\rho_S = \left(\frac{\Delta\rho}{\Delta x}\right)x$, where x is the element solubility (in Cu), and the coefficient ($\Delta\rho/\Delta x$) depends on the type of element. One possible explanation is that the atomic size bears influence to the coefficient ($\Delta\rho/\Delta x$). The feature related to the modulus mismatch shows the highest survival rate for hardness prediction, can also be explained by solid solution strengthening effect [Wang et al., 2018]. We note that the discovery of these interesting results does not rely on prior knowledge.

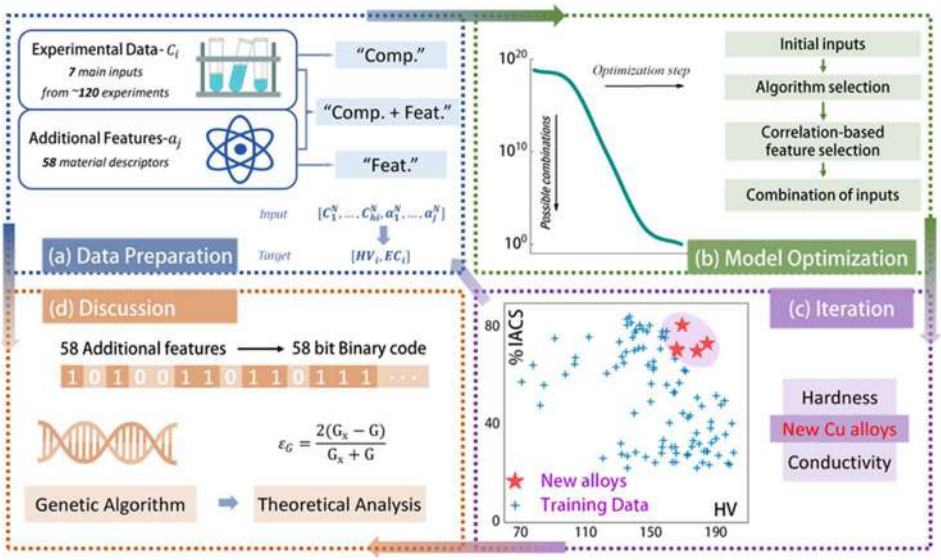

Figure 1. Schematics of the discovery process in high strength and high conductivity Cu alloys.

CONCLUSIONS

In the present study, we proposed a data-driven method to identify the relationship between chemical composition, aging time and target properties (hardness and electrical conductivity) of Cu alloys. The machine learning models were trained by "discarded" experimental data with unsatisfactory properties produced by "trial and error" experiments. The additional features calculated by physical equations were introduced and combined by correlation-based analysis and genetic algorithm, further minimizing the error of prediction and reducing the complexity of the ML models. Through employing the optimized ML model with iteration and experimental validation, better properties of hardness (with an increment of 7%) and electrical conductivity (with an increment of 12%), which are higher than the maximum value in the original training data, were developed in the Cu alloys. Among the five selected Cu alloys showing both high hardness and electrical conductivity, Cu-0.45Co-0.23Ti and Cu-0.44Fe-0.23Ti are chosen for microstructure characterization and property testing. In addition, the impact of additional features on the ML models was analysed by a genetic algorithm and the importance of each feature in the model is quantitatively described. The results indicate that the ML model can predict the hardness and electrical conductivity of Cu alloys with reasonable accuracy, even if the compositional information is removed. Our findings suggest the ML-based method holds great potential for creating high-performance Cu alloys with both high strength and electrical conductivity.

FILTERING BASED MILLING CONSTRAINTS FOR TOPOLOGY OPTIMIZATION

Lukas C. Høghøj* and Erik A. Träff
Department of Mechanical Engineering, Technical University of Denmark, Kongens Lyngby, Denmark

Summary A PDE-based filtering technique for topology optimization ensuring manufacturability by milling is introduced. The filter is based on the advection-diffusion equation. With the advection term dominating, the equation mimics a cumulative sum in the advection direction. Performing the mapping as a filtering step instead of a cumulative sum allows for a parallel implementation on unstructured grids, using the finite volume method with an upwind difference scheme. Results are obtained on unstructured meshes of up to 64 million elements.

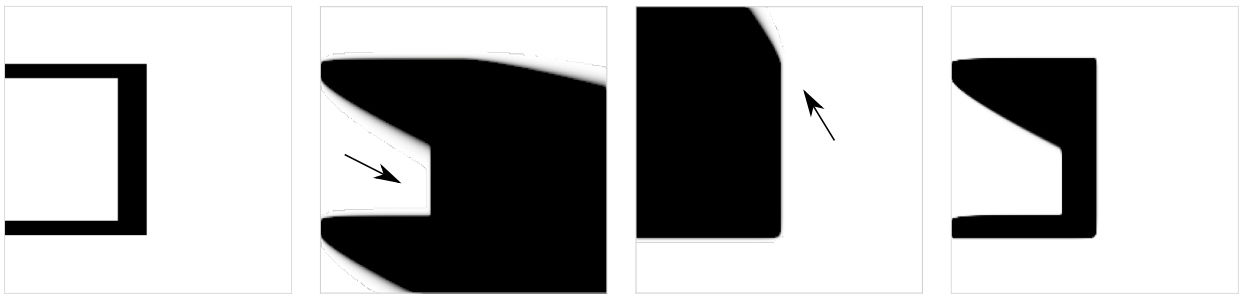
INTRODUCTION

Topology optimization with milling and casting constraints was first introduced by [1], where rows or columns in a structured grid were characterized by a single design variable. The methodology was extended by use of cumulative sums in the milling directions [2]. Arbitrary milling directions were made possible with the approach introduced [3] using cumulative sums and a mapping technique. The mapping technique requires the storage of memory intensive transformation matrices, which also are expensive to assemble. The presented PDE filtering approach mimics the cumulative sum in arbitrary directions, allowing for an efficient implementation on large-scale problems.

FILTER FORMULATION

The milling filter is separated into one shadowing step (mimicking the cumulative sum) for each milling direction. This is seen in Figure 1, where the design field from Figure 1a is shaddowed in two directions, as seen in Figures 1b and 1c, respectively. In the shaddowing process, the density filtered variable is used as source term in the advection-diffusion equation, solved for the respective milling direction. The advection direction is set to the corresponding milling direction, combined with a high Peclet number, ensuring low diffusive effects. The advection-diffusion equation is solved using the Finite Volume Method, implemented with an upstream difference scheme on the advection term, which guarantees numerical stability of the solution. Robin boundary conditions are imposed on free boundaries, which allows for material to be placed adjacent to them. Dirichlet boundary conditions are placed on the boundaries next to passive domains, to ensure the manufacturability of those.

The shadowed fields are agglomerated using a smooth p-norm elementwise minimum function. The agglomerated field is then projected to the physical bounds of the design variable using a smooth Heaviside projection, which yields the final physical field, as seen in Figure 1d.



(a) (b) (c) (d)

Figure 1: Example of filtering process for a design field (a). Two shaddowing steps are performed by solving the advection-diffusion PDE (b-c) in the respective milling directions (indicated by the arrows) and are then agglomerated using the soft min and Heaviside projection (d).

The smooth Heaviside projection is performed with a constant projection sharpness to bound the physical field throughout the optimization process. Combined with the general nature of the milling filter, this makes the problem very sensitive. Hence, the Method of Moving Asymptotes (MMA) is used with a tightened initial asymptote setting [4], which alleviates oscilatory behavior.

*Corresponding author. E-mail: luch@mek.dtu.dk.

EXAMPLE

The milling filter is implemented in an in-house parallel three dimensional topology optimization framework [5], operating on unstructured meshes. To illustrate the methodology, the GE aircraft engine bracket [6] is optimized with a single milling direction from the top. The supporting and loaded rings are fixed to be solid, Dirichlet boundary conditions are enforced on the adjacent surfaces of the design domain.

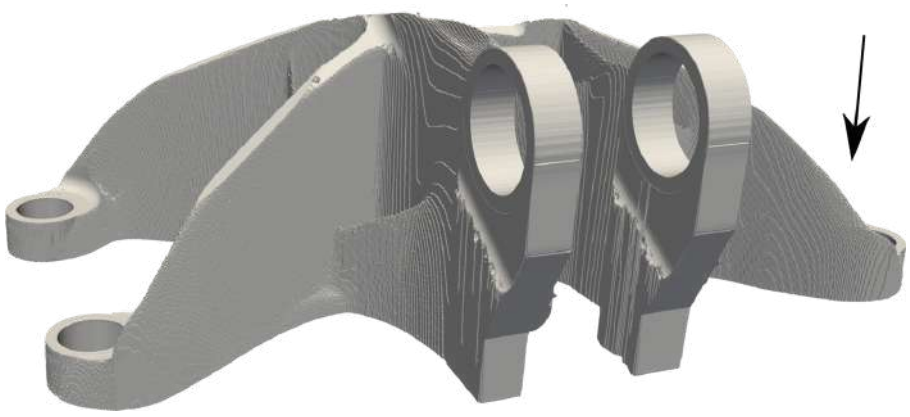


Figure 2: Optimized GE engine bracket, manufacturable with a single milling direction from the top, indicated by the arrow.

The design optimized with the single, from top, milling direction is seen in Figure 2. It is seen that no overhangs, except for the two passive loading rings, are present in the obtained design. The design is hence realizable by milling. The computational effort of the milling filter on the unstructured mesh with 64 million elements on 640 CPU cores is 25s per design iteration (including the projection and two adjoint solutions). In contrast, solving the four linear elasticity loadcases varies from 200s to 600s per design iteration (depending on the change and the contrast of the design).

CONCLUSION

A filtering technique based on the advection-diffusion equation, which ensures manufacturability by milling of the designs, is introduced. Contrary to previous work, the presented methodology allows arbitrary milling directions to be enforced in a parallel setting on unstructured meshes, omitting the need to assemble and store large transformation matrices.

OPTIMIZATION FOR VIBRATING COMPOSITE PLATE BY DISCRETE-CONTINUOUS MODEL AND RESONANT PEAK LIMITATION

Haoqing Ding*[1], Bin Xu[1]
[1]School of Mechanics, Civil Engineering and Architecture, Northwestern Polytechnical University, Xi'an, China

Summary Discrete material model includes many design variables, which cause intensive computational and storage burdens in both frequency response and sensitivity analysis. Even the continuous optimal model can be expected to solve the above problems, local optimal solution is more likely to be obtained due to the model's high non-convex character. Further, resonant peak limitation is also highly significant because of its dominant role in structural vibration. Based on above starting points, this paper develops an efficient optimal model for minimizing composite plate's frequency response by the combination of discrete-continuous parameterization model and the solid isotropic material with penalization scheme. The optimization problem is solved by the method of moving asymptotes and several numerical examples are employed to verify the effectiveness of the proposed model.

INTRODUCTION

Structural vibration suppression gains much attention because many structures in engineering are exposed to dynamic environments and the excessive vibration could have detrimental effects on structural functionality and safety. Integrated optimal design of the damping layer and the host layer is more likely to achieve the best performance of structural vibration reduction. For the optimal design of composite structures, the Discrete Material Optimization (DMO) formulation is considered as one of the effective methods and it has shown its effectiveness in solving both static and dynamic problem [1-3]. However, for complex optimal problems, such DMO technique can also cause heavy computational cost and storage burdens. One effective method to solve this issue is to consider the continuous orientation design. However, the continuous orientation design technique has been proven to be easily obtain a local optimal solution [4-6]. Therefore, the combination of DMO and continuous orientation design may provide a better way to handle the local optimal solution as well as reduce the computational and storage burdens. Besides, using the integration of frequency response as the objective function does not mean the peak value must be reduced. The peak value plays a dominant role in low-frequency vibration. Without limitation of the resonant peak, the structure would vibrate more excessively. Inspired by dynamic topology optimization from other scholars, this paper builds an integrated optimal model for minimizing composite plate's frequency response over a given frequency band and simultaneously considering low-order resonant peak limitation.

OPTIMAL PROBLEM STATEMENT

The optimization model for the laminated plate is formulated as:

$$\begin{aligned}
&\min_{y_i,x_i^l}: && J_d=\int_{\omega_l}^{\omega_u} J(\omega,\mathrm{y}_i,x_i^l,\theta_i^e)d\omega \\
&s.t.: && -\omega^2\mathbf{MU}+\mathbf{KU}=\mathbf{F} \\
&: && G_1=\sum_{i=1}^{N} y_i v_i \,/\sum_{i=1}^{N} v_i - V\le 0 \\
&: && 20\log 10(\left|\mathbf{U}\right|_{\omega=\mathrm{Re}(\omega_i)})\le P_{\lim} \\
&: && 0.001\le y_i\le 1 \\
&: && 0.001\le x_i^l\le 1 \\
&: && \theta_i^e\in[-\frac{\pi}{2n^l},\frac{\pi}{2n^l}]
\end{aligned} \tag{1}$$

where $J(\omega,\mathrm{y}_i,x_i^l,\theta_i^e)=\left|\mathbf{F}^T\mathbf{U}\right|$ represents the dynamic compliance under the excited frequency ω; ω_l and ω_u are the lower and upper bounds of the frequency interval, respectively; V is the maximum allowable volume fraction for the damping material 1; v_i is the volume of the i th finite element; θ_i^e, y_i and x_i^l are the design variables; **M** and **K** are the global mass and stiffness matrix, respectively; $P_{\lim}$ is the resonant peak limitation.

The discrete-continuous model (DCP) is used to obtain the element elastic matrix $\mathbf{Q}_{\theta_i^e}^l$ for the stiffness matrix (i.e. **K**) calculation. It can be stated as:

$$\mathbf{Q}^l=\sum_{i=1}^{n^l}\xi_i\mathbf{Q}_i=\xi_1\mathbf{Q}_1+\xi_2\mathbf{Q}_2+\ldots+\xi_{n^l}\mathbf{Q}_{n^l} \tag{2}$$

$$\mathbf{Q}_{\theta_i^e}^l=\mathbf{T}(\theta_i^e)\ \mathbf{Q}^l(\xi_1,\xi_2,\cdots,\xi_{n^l})\mathbf{T}(\theta_i^e)^T \tag{3}$$

NUMERICAL EXAMPLES

In this numerical example, a three-layer laminated plate with four edges clamped subjected to a harmonic mechanical load is investigated. The amplitude of the load is 100N and it is applied at the central point of the top of the plate. The length, width of the plate and the thickness of each layer are 1 m, 0.5m and 2 mm, respectively. The plate is meshed by 800 (40 × 20) four-node Mindlin laminated plate elements. The material prosperities are shown in **Table 1**. And the optimized results are shown in **Figure 1** and **2**.

Table 1. Material properties

Material	Density(kg/m^3)	Elastic modulus (Gpa)	Poisson's ration	Loss factor
Fiber	1559	$E_x = 165Gpa, E_y = 9Gpa,\ G_{yz} = 4.3Gpa\ , G_{xy} = G_{zx} = 6Gpa,$	$v_{xy} = 0.25$	-
Damping material	1000	2	0.4	0.5
`	200	0.065	0.47	-

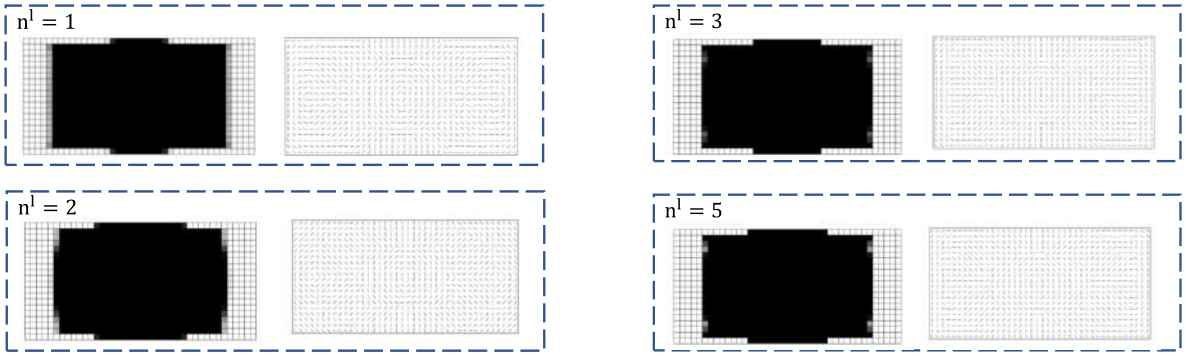

Figure 1 The optimized results for damping layer and fibre layer for different frequency intervals.

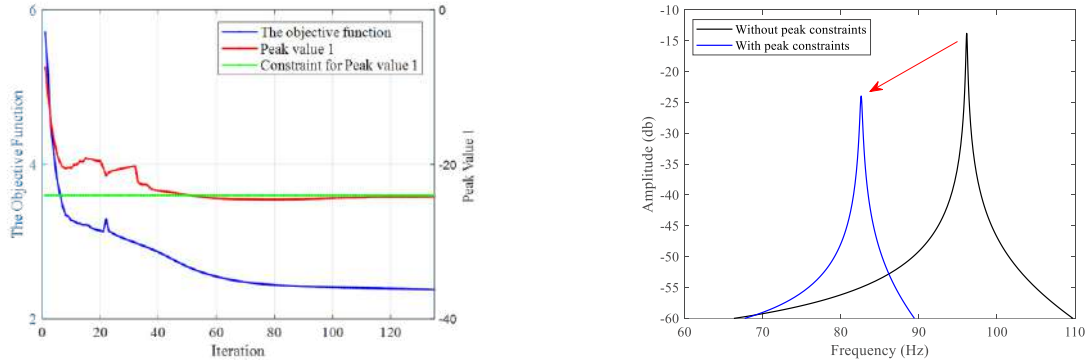

Figure 2. The iteration process and the change of the peak after optimization

CONCLUSIONS

Based on the optimized results in numerical example, a couple of conclusions can be drawn: (1) the DCP model provides a wide and flexible design space and reduces the number of the discrete design variables. Thus, it reduces the computational and storage burdens; (2) the DCP model efficiently reduces the risks of falling into local optimum solution; (3) 2 or 3 subintervals are suggested to efficiently reduce the possibility of falling into local optimum solution;(4) the proposed optimal model with resonant peak limitation is efficient and feasible.

A NOVEL USE OF THE GROUND STRUCTURE TOPOLOGY OPTIMIZATION FOR THE DESIGN OF PRESSURIZED STIFFENED PANELS

Mario Capo, JF Gamache, T. Rochefort-Beaudoin, Aurelian Vadean, Sofiane Achiche
Department of Mechanical Engineering, Polytechnique Montréal, Montréal QC, CANADA

Summary: The Ground Structure method is well-known in the literature for trusses and frames Topology Optimization, but its use in the design of stiffened panel has not been explored. In this work, an original reformulation of the method is proposed. Since beam elements are directly used as the set of candidate reinforcements, this approach ensures an explicit description of the final stiffener's geometry. This eliminates the need for interpreting the resultant material distribution or for imposing any geometric constraint to force the optimization towards manufacturability. The proposed reformulation has been implemented in MATLAB, tested on a benchmark problem and its potential as a design tool is demonstrated on the compliance-based topology optimization of the stiffeners layout of a simplified pressure bulkhead. The optimized design complies with those obtained by using SIMP and MMC methods.

INTRODUCTION

Stiffened panels are commonly used in aircraft structures for their high performance/weight ratio. The design process of such assemblies starts with an a priori choice on the reinforcement configuration (e.g. ortho-grid), mainly based on industrial experience. The use of Topology Optimization (TO) [1] can support this starting phase using a mathematical approach to enhance mechanical properties of stiffened panels from a global point of view.

Early research works proposed to roughly identify rib position optimizing thickness distribution of plates elements [2]. Methodologies based on the use of the SIMP method [3,4], propose to identify the stiffeners layout from the interpretation of high-density regions resulting from the TO. These approaches need the addition of geometric constraints to obtain manufacturable stiffener-like components, and post-processing procedures for the interpretation task [5]. To overcome these issues, new formulations based on the use of topological variables that explicitly control the geometry of the final structure rather than the mechanical properties of the starting mesh have been proposed. Belonging to this category, the MMC approach [6] has been recently applied to composite stiffened panels, where stiffeners are embedded in the plate model using equivalent stiffness method [7]. A major drawback of this method is the need of a very fine mesh to describe the stringers' features. The mesh size has to be at least smaller than the stringer's section width. This renders the use of such a model computationally expensive for large-scale applications.

The idea of a Ground Structure TO, which uses a mesh made of plates and beams comes from two basic considerations:
(1) This modelling strategy is computationally inexpensive and is commonly used in the industry for FEM analysis of large structures composed of stiffened plates, as well as for preliminary sizing of wingbox components. [8]
(2) The Ground Structure method is an easy-to-implement formulation which can deal with the structural members of interest in aircraft constructions. After the removal of vanishing members, the output of the TO contains explicit information on the final geometry without the need for interpretation.

METHODOLOGY

For the proposed formulation, a simple model made of Euler-Bernoulli beams coupled with discrete quadrilateral Kirchhoff plates with isotropic linear elastic material properties is used. In first approximation, one can consider that the two structural elements lie in the same plane and are connected to same nodal grid. Alternatively, to increase the accuracy of the analysis, the nodal points defining the beams must be offset and connected to the plate using rigid connections. Mechanical deformation of the stiffened panel under lateral loads is obtained from a linear static analysis.

An adaptation of the ground structure generation algorithm proposed by [9] is used to automatically superimpose a dense mesh of beam elements on a plate model, with an arbitrary level of connectivity. In the proposed method the topological design variables are the cross-sectional area of each beam elements composing the stiffeners, while the plates properties are kept constant.

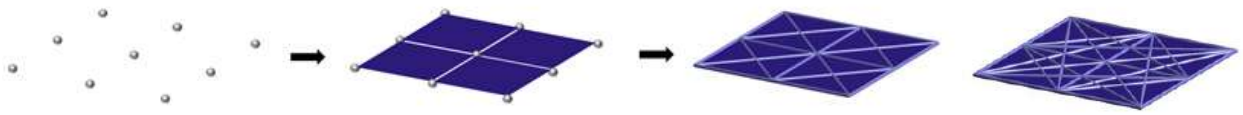

Figure 1. Ground Structure generation with arbitrary level of connectivity.

The formulation of the minimum compliance problem and the pseudo code of the algorithm are summarized in fig.2(a) and fig.2(b). The optimization problem is solved using the Interior Point Method implemented in the MATLAB Optimization Toolbox [10]. Load and nodal displacement vectors $\boldsymbol{f}, \boldsymbol{u}$ are expressed in the global reference system. Vector $\boldsymbol{l}$ contains all beam lengths and v_{max} is the maximum volume allowed for the reinforcement. A benchmark problem faced to test the algorithm is also shown in fig.2(c).

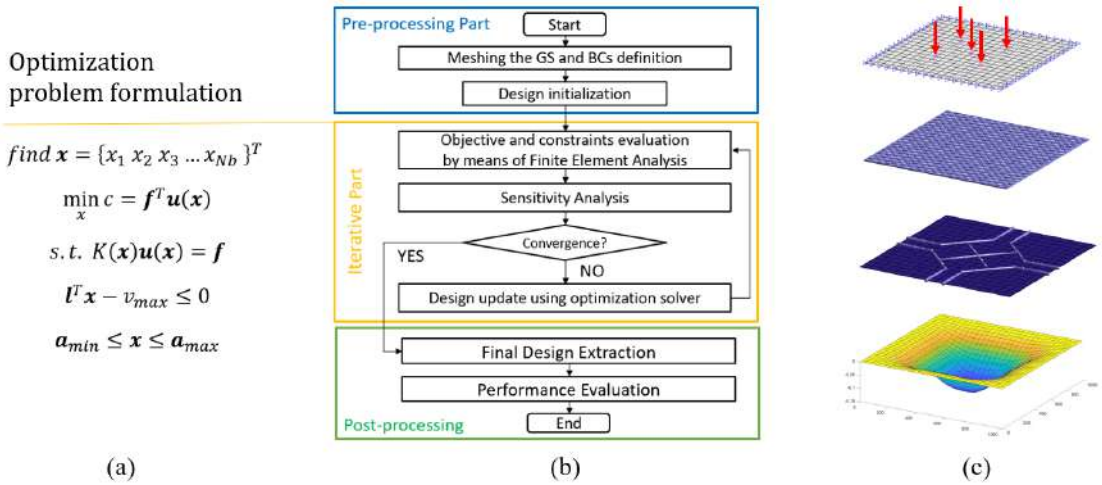

Figure 2. Overview of the method: (a) optimization formulation; (b) pseudo code implemented in MATLAB; (c) a benchmark problem test

A PRACTICAL ENGINEERING APPLICATION

A practical engineering problem is addressed to validate the procedure: the design of a flat pressure bulkhead subject to differential pressure ($0.1\ MPA$). Contour supports are located at equispaced points and simulate a riveting connection. The mechanical properties of Al2024-T4 are used, and geometric parameters are given as follows. A mesh of 40x24 rectangular element discretizes the design domain where $L = 2500\ mm$. This leads to an initial GS of 1984 members. The skin thickness is $1.25mm$, the interval for cross-sectional areas is $a_i \in [10^{-5}, 10^3]mm$, and v_{max} cannot exceed $5.625 \cdot 10^6\ mm^3$. The obtained optimized layout in fig.3 can be compared to those in [4,7].

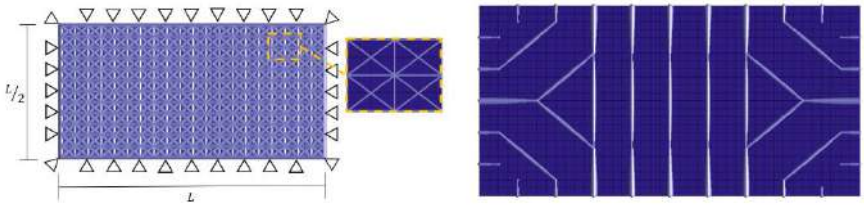

Figure 3. Starting GS and the optimized Stiffeners layout for a flat pressurized bulkhead.

CONCLUSIONS

In this work, a novel reformulation of the ground structure topology optimization is applied to the design of stiffeners layout for pressurized panels. The novelty of the method lies in the hybrid use of plates and beams elements to construct the ground structure, and in the context of application, never explored by the traditional method according to the authors' knowledge [11]. Numerical results indicate that the method can provide a clear stiffener layout for the compliance problem with volume constraints. The structure obtained is sound and one note the lesser involvement of designer during the post-processing procedure and particularly the TO interpretation. Inclusion of stress and buckling criteria, as well as a more complete finite element formulation are promising to be considered in future works.

TEACHING APPARATUSES FOR MECHANICAL VIBRATIONS

Masato Saeki *[1]
[1]Department of Mechanical Engineering, Shibaura Institute of Technology, Tokyo, Japan

Summary Various apparatuses used in a classroom lecture on mechanical vibrations are presented. In my laboratory, 15 types of apparatus have been developed to reproduce various vibration phenomena such as mechanical resonance and vibration modes. They are used to teach students how to forecast the type of motion that could occur before determining equations of motion for mechanical systems. Their use seems to have a positive educational impact on students.

INTRODUCTION

In a classroom lecture on mechanical vibrations, showing various vibration phenomena in mechanical systems can stimulate the interest of students. Although animated images obtained by numerical simulations are often used in classroom lectures, the use of vibration apparatuses has a positive educational impact on students compared with numerical simulations, because it is more impressive to see live performances. Various demonstrations of physics [1], [2] and structural mechanics [3] have been presented. However, there are not many apparatuses for use in lectures on mechanical vibrations.

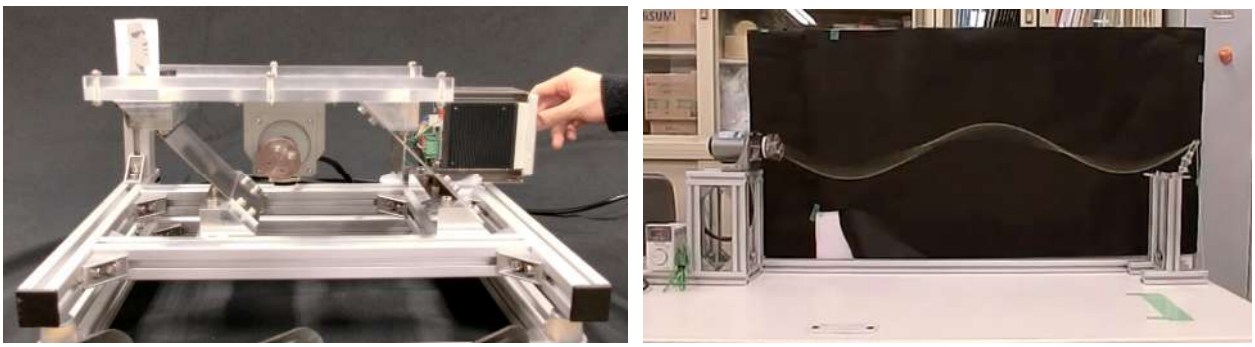
In my laboratory, various apparatuses have been developed to reproduce vibration phenomena such as mechanical resonance and vibration modes. They are used to teach students how to forecast the type of motion that could occur before determining equations of motion for mechanical systems. According to the responses to a questionnaire, most students said that the lecture in which teaching apparatuses were used was interesting. All teaching apparatuses have been evaluated by researchers belonging to enterprises and universities and have been improved.

VARIOUS TEACHING APPARATUSES

Figures 1(a) and (b) show two examples of various teaching apparatuses, a vibration conveyor and a device generating transverse vibration of a string, respectively. Although vibration conveyors are widely used in various industries such as food processing and pharmaceuticals, the mechanism of vibration feeding is not well known. Also, most students are not able to move an eraser on a notebook in the horizontal direction by vibration. Therefore, the vibration conveyor shown in Figure 1(a) was developed. In this apparatus, a conveying plate is supported by two leaf springs that are inclined toward the horizontal plane. An eccentric rotating mass vibration motor is attached to the underside of the conveying plate. When the conveying plate is excited by an eccentric rotating mass vibration motor, an object placed on the conveying plate can be conveyed owing to the inertia force acting on the object. Also, the behaviour of the object and the conveying plate can be clearly observed in the images captured by a high-speed camera. As a result, students can understand the mechanism of the vibration conveyor and the purpose of the two inclined leaf springs.

The apparatus shown in Figure 1(b) consists of a motor and a string. The string is fixed at both ends, one of which is excited sinusoidally via a slider-crank mechanism and a motor. When the frequency of the end of the string excited sinusoidally is increased, the first four modes of vibration of the string can be observed.

Figures 2(a) and (b) show a tuned mass damper and a sloshing damper, respectively. In Figure 2(a), apparatus A at the front consists of a primary mass supported by two leaf springs whose ends are located on a linear guideway. The ends of the springs are excited sinusoidally via a slider-crank mechanism. Apparatus B behind A has the same structure as A but a mass-spring system is attached to the primary mass as an auxiliary system. As shown in Figure 2(a), the damping performance of the tuned mass damper can be observed since the amplitude for A is much greater than that for B.



(a) Vibration conveyor (b) Transverse vibration of a string

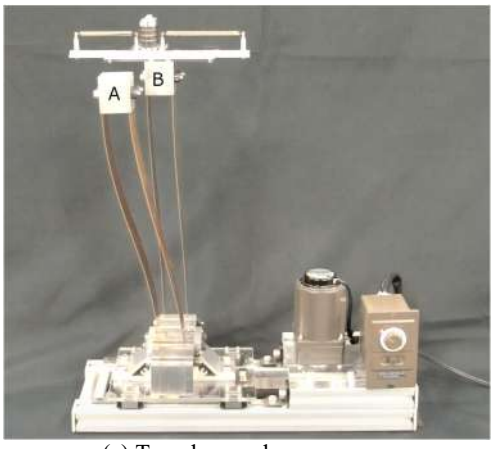
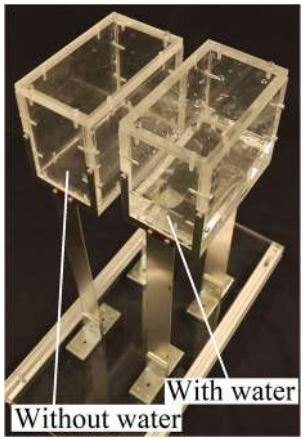
*Corresponding author. E-mail: saeki@sic.shibaura-it.ac.jp



(a) Tuned mass damper



(b) Sloshing damper

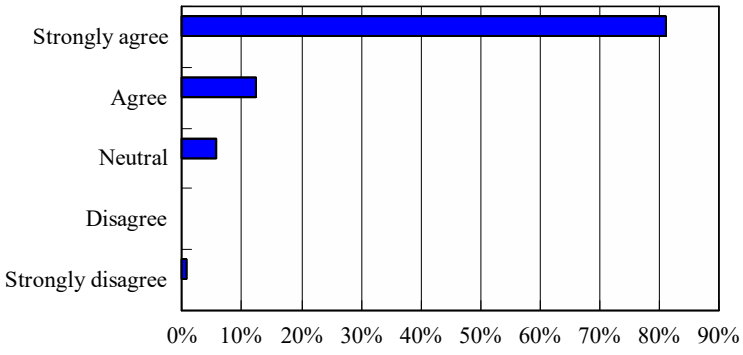
Figure 2. Various dampers.

In Figure 2(b), there are two of the same apparatus consisting of a primary mass supported by two leaf springs. As the ends of the springs are fixed to a horizontal plate, two primary masses act as a single-degree-of-freedom system. The primary masses made of acrylic resin are boxlike and a proper amount of water is filled in the primary mass on the right. When the two primary masses are given the same initial displacements and then released suddenly, the primary masses vibrate freely. Since the vibration of the primary mass filled with water stops earlier than that without water, the damping performance of the sloshing damper can be observed.

All of the vibration apparatuses were constructed by the fourth-year students in our laboratory.

EVALUATION AND IMPROVEMENT ACTIVITIES

Figure 3 shows an example of the evaluation of the lecture using teaching apparatuses by the students. As shown in this figure, more than 90% of the students said that the lecture in which the teaching apparatuses were used was interesting. To improve these apparatuses, all teaching apparatuses have also been evaluated by researchers belonging to enterprises and universities.



How much do you agree with the following statement?
This lecture using vibration apparatuses was interesting.

Figure 3. Evaluation by students.

CONCLUSIONS

Various apparatuses used in a classroom lecture on mechanical vibrations were presented. The use of vibration apparatuses seemed to have a positive educational impact on students compared with numerical simulations since it is more impressive to see live performances. I would like to develop some apparatuses that reproduce nonlinear phenomena in the future.

VARIATION OF NATURAL FREQUENCIES OF AXIALLY CONNECTED WOODEN BLOCKS

Vikram Pakrashi[1,2], Eolann Sheehan[3], Jake O'Callaghan[3], Paul Cahill[1,2], Darragh Noble[4], Maria Nogal[5] & Alan O'Connor[4]

Summary: The change of natural frequency of a prestressed beam with increasing prestress has come under significant scrutiny in recent times. Experimental data on both concrete and steel beams tend to indicate that the variation of natural frequency does not monotonically decrease for prestressed beams, despite an intuitive expectation for this to happen. This paper investigates this problem using a desktop experiment with small wooden blocks connected with a central axial force to form a beam and carried out a range of experiments to understand this change. The variation of natural frequencies indicates how the changes are not obvious. Additionally, the experiments raise an important challenge of separating effects of noise from information, when the order of both are similar.

INTRODUCTION

An intuitive estimate of change in natural frequency of a prestressed beam indicates that the natural frequency should monotonically decrease with increased prestressing force on the beam due to reduction in stiffness [1]. However, experimental results on steel and concrete (uncracked and cracked) [2,3,4] indicate that in reality, this answer is more complicated. The changes are not necessarily monotonic with increasing prestressing. While there are several models trying to address this [5,6], none are adequate. This paper presents a simple desk study, with extensive experimental results to present this complex issue in an undergraduate teaching setting. The experiments demonstrate that how even for wooden blocks connected with an axial force, this complex variation exists.

EXPERIMENTAL SETUP

Experimental Design

A tower of individual wooden blocks was connected centrally to form a simple experiment in this regard. The simplicity of the experiment makes it easy to replicate it, especially in an undergraduate framework of Teaching and Learning. Wooden blocks of different geometry were created, and the beam was instrumented with 5 no. LORD Microstrain G-Link LXRS Accelerometers. This can be replaced with any cheaper accelerometer and even by smartphone accelerometers. The data was recorded by a LORD Mircostrain WSDA- Base-LXRS and with Node Commander Software. The accelerometers were attached to the same face of five out of the ten wooden blocks. This was done using a drill and two screws per accelerometer. The base section was bolted firmly to the frame of a table. A cable in then attached to a weight holder by looping one end of the cable through the eye nut and securing it with a bull clip. The threaded bar was then attached to the eye nut and secured with two nuts. A 100x100mm balancing plate was then attached to the other end of the threaded bar and secured with a nut and a 50mm washer either side to keep the plate from tilting. The 'tower' of wooden blocks was placed on top of the bolted down base section, making sure that the accelerometers were on every second block. The 100x100mm steel plate was then placed on the top block. The end of the cable with nothing on it was then passed through the holes in the centre of the beam and secured on top of the steel plate with another bull clip. The base of the system was fixed. Several experiments to estimate the natural frequency were subsequently carried out for varied axial force. Figure 1 presents a setup of this experiment.

Figure 1. *Connected wooden blocks with varying axial force.*

Experimental Procedure

To determine the variations of natural frequencies of the setup, responses due to impulse forces were with 5 accelerometers. A baseline case was initially established for the system in this regard. A wide range of experiments established the experimental variation of estimated natural frequencies of the system.

EXPERIMENTAL RESULTS

The main thought processes currently surrounding the relationship between natural bending frequency and prestress force are as follows:

- Frequency increases with increasing prestress force.
- Frequency decreases with increasing prestress force.
- There is no monotonic relationship between frequency and prestress force.

In the set of experiments carried out it appears that the natural bending frequency overall increased with increasing prestress force. The estimated natural frequency increases with an increase in prestress, but the rate of change of frequency gets smaller and with equal increase in prestressing force. Whether this leads to a limit or if it eventually changes to a decrease (as observed in larger beams in some cases, where the natural frequency decreases after increasing for some time) cannot be established from these experiments. However, the study clearly demonstrates, from a simple desktop experimental study that the answer to this seemingly simply problem is significantly more complex than it appears.

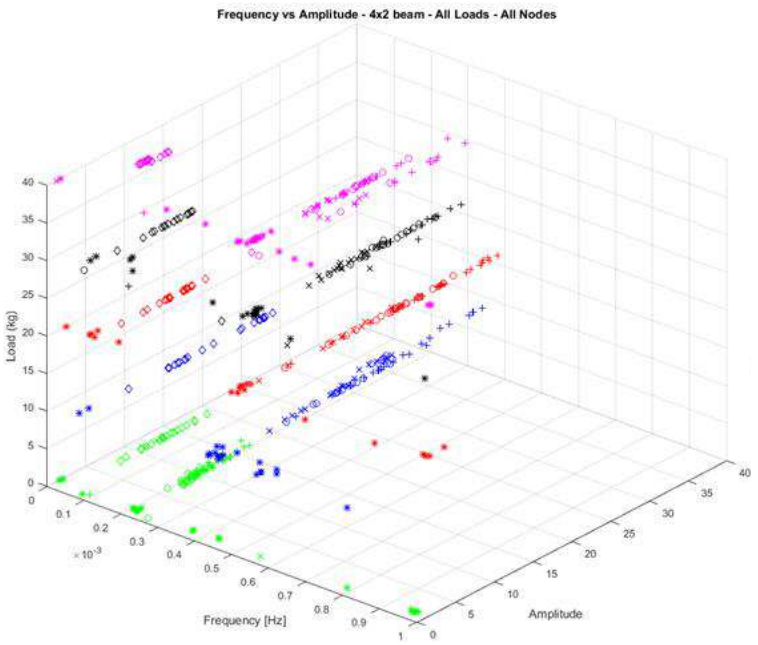

Figure 2. *Variation of Natural Frequencies of the connected wooden blocks for varied axial forces.*

CONCLUSIONS

This paper presents a study on the variation of natural frequency for wooden blocks connected by varied levels of axial forces. In this regard, a simple desktop experiment was created that can be replicated easily in any learning environment. Estimates of natural frequencies for various axial forces provided the variation of such frequencies from extensive experimental study. It was observed that the changes in such frequency are not intuitive, as evidenced by larger experiments in the past. The experiments also indicated the uncertainty due to possible noise and inaccuracies is a challenging problem and extensive work may be required to isolate information from noise, thereby making a obvious interpretation of the variations difficult.

AN INTERACTIVE APPROACH TO LEARNING FLUID MECHANICS

Kevin Nolan * [1]
[1]School of Mechanical & Materials Engineering, University College Dublin, Belfield, Dublin 4, Ireland

Summary A new approach to fluid mechanics teaching incorporating interactive and visually engaging media is discussed. A common approach to teaching is via the use of slideware whereby students are required to take notes by filling in gaps in printouts of slides. A challenge in this arrangement is the that students note taking may be interrupted when the next slide is advanced and so they cannot contunue to engage with the material. The use of visually engaging materials and scrolling lecture notes is investigated as a means to build intuition and engagement.

INTRODUCTION

It has been reported that students undertaking introductory fluid mechanics often experience conceptual difficulties when considering ideal fluids. Suarez et al. [9] reports four key observations, (i) students continue to apply hydrostatic reasoning to purely hydrodynamic systems, (ii) students neglect the principe of the conservation of mass when considering flows in vertical pipe configurations (iii) students frequently do not understand the role of pressure and the forces exerted on a fluid element and (iv) that students do not understand the range of validity of Bernoulli's equation.

The literature reports a number of educator interventions to improve student learning in subjects such as fluid mechanics. Of note Fraser et al. [5] eschewed traditional CFD tools in favour of more accessible Excel based computer simulations designed using phenomenographic learning theory to facilitate conceptual understanding. Two of the three simulations evaluated showed good improvement in the student test scores. More recently Barba and Forsyth [1] details an accessible approach to introductory Navier-Stokes using the *Python* programming language and the *Jupyter Notebook* environment with a similar approach used for aerodynamics [2].

The Jupyter (Julia Python Terminal) Notebook environment [8] has a number of advantages that make it useful in engineering education. Jupyter Notebooks are rendered in a web browser and can be navigated in much the same way as a webpage. A typical notebook contains a series of cells that comprise either text (written in the Markdown format with LaTeX equation rendering) or code (in the Julia or Python languages) which can be run interactively. Any generated output such as charts or graphics are displayed inline. Kernels supporting other languages such as Matlab are also available. Notebooks can be run locally on a host machine, or hosted on web server. Hosting can be provided by services such as Nbviewer, Binder and Google CoLab. These services make the notebooks available on any device with a web browser. Jupyter is also extensible and many third-party libraries can be used to increase functionality.

In the field of visual effects, various approaches to fluid flow simulation are employed for a wide range of artistic intent. These methods often lack the accuracy of traditional computational fluid dynamics codes, many methods are not conservative [3], but can visually capture the physical behaviour of complex flows [6] and fluid interactions with objects [4] to a degree suitable for general audiences. Indeed the visual representations of fluids simulated with these methods is often superficiality superior to the visualisations typically produced in CFD studies. The codes also tend to be fast with simulation times on consumer hardware ranging from minutes to several hours.

While Jupyter Notebooks are popular in higher education, the use of sophisticated visual effects tools as a teaching aid has not been explored in the literature to date to the best of the author's knowledge. This work details the use of Jupyter Notebooks and 3D animation of fluid flow to improve engineering student learning and engagement with *Mechanics of Fluids 1* at University College Dublin[7].

INPLEMENTATION

A series of notebooks were compiled on approximately half the course content. The topics included: fluid properties, pressure, hydrostatics, flow kinematics, Bernoulli's equation and control volume analysis. The remainder of the course which comprised the conservation laws, dimensional analysis and internal viscous flow were unchanged. Student feedback and year on year changes in exam performance will be collected and reported.

Each notebook was written in a conversational style with Jupyter cells carefully arranged so that text is broken up with videos and code blocks. This allowed the notebooks to be presented directly to the students with a persistence of content displayed via the scrolling nature of content presented in a web browser avoiding the abrupt nature of slide changes typical of slide ware. This approach was used to directly address prior student feedback.

3D models and animations were created using Blender, an open source 3D content creation suite. Fluid simulations were performed within Blender using a Particle in Cell/Fluid-Implicit Particle (PIC/FLIP) solver. Rendering was performed using the Cycles path tracer in conjunction with the FreeStyle non-photorealistic (NPR) rendering engine to provide emphasis to particular elements. Figure 1 shows snapshots from a number of the videos presented. The blackout line of the manometer tube and the geometry in figure 1(c) and (d) show show the Freestyle result. Videos were exported at 1920×1080 pixels as h.264 in mp4 format which is supported on a wide range of devices.

Shown in figure 1(a) are four streams of fluid each of increasing viscosity. The number indicates the magnitude of the viscosity but no unit is provided. Once the video (and others) are shown and discussed in an attempt to build intuition, the units of viscosity are introduced. In figure 1(b) a similar arrangement of fluids is presented however now only the surface

*Corresponding author. E-mail: kevin.nolan@ucd.ie

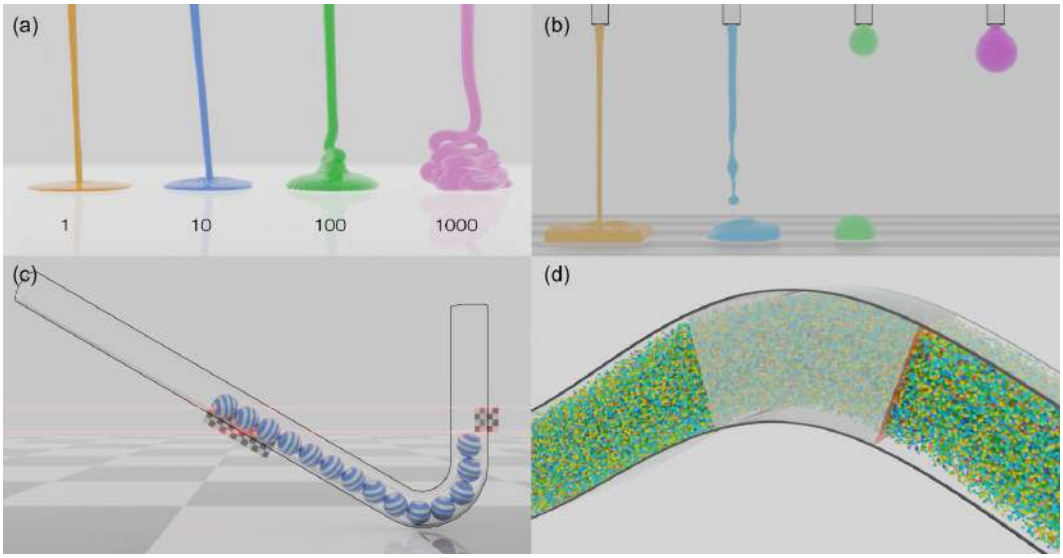

Figure 1: Snapshots of some of the animations used. (a) A demonstration of the effect of increasing viscosity on falling streams of fluid. (b) Demonstration of the effect of increasing surface tension. (c) A simplification of the operation of an inclined manometer with a ball bearing analogy. (d) A colourful introduction to control volume analysis and the difficulties of the Lagrangian frame of reference.

tension of each fluid is varied from zero on the left to some arbitrarily large value on the right. Again this is followed by further examples and a deeper more traditional analysis and discussion of units. Figure 1(c) represents an analogy that was developed to introduce the operation of a manometer whereby a chain of ball bearing represent the gauge fluid. By considering the distribution of ball bearings students can confirm the observed behaviour. This approach also fosters an understanding of role of the fluid weight in this type of problem. Finally in figure 1(d) the flow of a large number of Lagrangian particles is observed to flow through a curved duct. The students are asked to consider the difficulty of tracking each particle in contrast to measuring the amount entering and exiting the translucent control volume.

In addition to the videos, static 3D models depicting concepts such as differential elements were imported as interactive elements into the Jupyter Notebooks. Students are able to rotate, zoom and pan the model as they desire preventing any misintrepretation that may result from a 2D sketch.

Formal student feedback on this new approach is forthcoming and will be presented, however informal feedback from students has been positive. Students report that the visualisations are helpful and the Jupyter approach is gennerall preferred to the slideware approach.

CONCLUSIONS

An approach to teaching fluid mechanics that employs high-quality videos created using visual effects tools is reported. By using the popular Jupyter Notebook environment various types of media can be combined in an easy to use manner. Informal student feedback has been overwhelmingly positive and a statistical analysis of student performance will be performed and formal feedback is forthcoming. The tools used for this work are all open source and straightforward to use with excellent documentation. The teaching materials are available online [7] under an MIT license.

TEACHING MECHANICS WITH STRUCTURAL MODELS

Davide Bigoni[1], Francesco Dal Corso[1], Diego Misseroni[1]
[1]Department of Civil, Environmental and Mechanical Engineering, Università di Trento, Trento, Italy

Summary Several models are presented to help teaching solid and structural mechanics, at all levels, to engineering and physics students. The simpler models have been developed to explain the concepts of elastic beam, segmental arch, truss structure, elastic frame, and Euler buckling. More sophisticated models have been designed to introduce advanced concepts such as flutter instability under nonconservative loads, configurational forces generated through bending, and snake locomotion.

INTRODUCTION

In the last fifteen years we have developed physical teaching models to improve the presentation and understanding of scientific results, especially for engineering and physics students (frequenting undergraduate and graduate courses), but also for audiences at all levels, ranging from untrained people to peers in the scientific community.

Digital technology has indisputable merits and is of crucial importance in teaching. However, it tends to reduce physical intuition in students, while for students used to an intuitive approach (such as those involved in engineering studies) it can be difficult to understand how principles are applied in the real world. This is particularly true in mechanical engineering, probably the hardest discipline in engineering studies.

Several mechanical models developed in our laboratory have been shown to be of primary importance (i) as proof-of-concepts of newly discovered phenomena; (ii) as teaching models at different levels, including PhD programs; (iii) as demonstrators at public exhibitions, even for untrained public.

Our models have been conceived, designed, and realized to give tangible, vivid evidence of non-intuitive mechanical phenomena. Some of them have been invented for illustrating results obtained within EU financial schemes, others have been addressed to scientific presentations, and others have been designed to help students in understanding basic and advanced concepts of mechanics.

Our results and findings provide a breakthrough innovation in engineering education, through a simplification in the teaching of mechanics. We will continue developing our methods, thus contributing, through engineering education, to a sustainable and equal opportunities human development.

MODELS FOR STRUCTURAL ANALYSIS

Cross and Morgan wrote in 1932: 'the ability of a designer of continuous structures is measured chiefly by his ability to visualize the deformation of the structure under load. If he cannot form a rough picture of these deformations when he begins the analysis he will probably analyse the structure in some very awkward and difficult way; if he cannot picture these deformations after he has made the analysis, he doesn't know what he is talking about'. This statement remains valid today. However, the visualization of the deformation of a structure is more complex than it may appear and for this reason, teaching models are fundamental to stimulate students' interest and to simplify learning. We have developed several structural models for Civil engineering students, for elastic beam, segmental arch, truss structure [1], elastic frame [2], and Euler's buckling, Fig. 1.

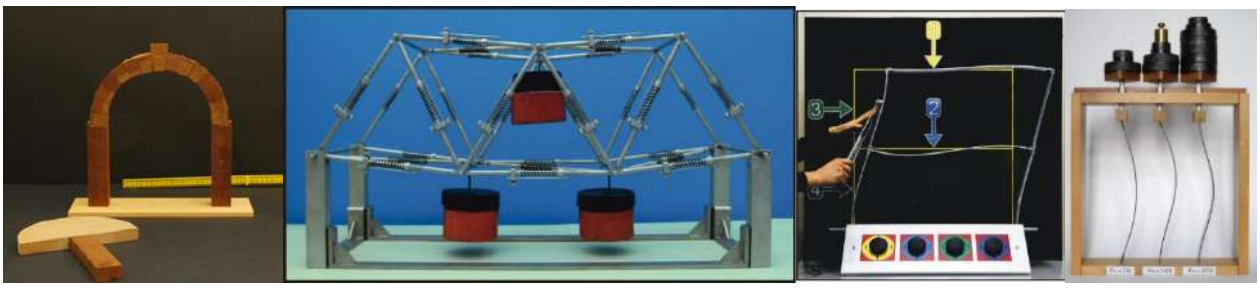

Fig. 1 from left to right, models for: Segmental arch; Truss structure; Elastic frame and Euler's buckling

MODELS FOR NEW PHENOMENA: FLUTTER INSTABILITY & CONFIGURATIONAL FORCES

Proof-of-concept-models have been designed by us to give evidence to previously unknown mechanical phenomena. These include: buckling of an elastic rod under tensile dead load [3], flutter instability induced by dry friction [4], effects of curvature constraint on instability [5], existence of configurational forces [6], effects of configurational forces on instability [7], the elastica arm scale [8], the torsional gun [9], snake locomotion [10], Fig. 2. All these phenomena are so innovative that it is hard to imagine their real-world implications without a working physical model.

Fig. 2 From left to right, models for: Flutter instability; The elastica arm scale; The torsional gun; Snake locomotion

CONCLUSIONS

Usually engineers face the problem of characterizing new materials of unknown properties and this is done using standard testing machines. Our models originate from an 'inverted approach' in which we first develop a theory to describe a phenomenon and then we build a model intended to validate the theory. In this sense, our laboratory is unique: we use our testing machines to fully define the behaviour of our physical models and to see how well it fits the theoretical predictions. We have thus been able to show complex nonlinear instabilities, such as flutter and Hopf bifurcations, which were previously only mathematically demonstrated. We have discovered buckling instability of a bar in tension and the existence of configurational forces. We have invented a new type of elastically deformable arm balance and a torsional actuator, each one with its associated model. We have for the first time tested a model for snake locomotion. These models have been used to engage both our peers and the public in our discoveries. Teaching models of truss structures and frame structures have been developed to enhance teaching at the undergraduate level.

ELASTICA CATASTROPHE MACHINE FOR TEACHING SNAP INSTABILITIES IN STRUCTURAL MECHANICS

Francesco Dal Corso* , Alessandro Cazzolli, and Diego Misseroni
Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy

Summary A new catastrophe machine is proposed to illustrate concepts of snap instabilities in structural mechanics. Differently from the classical catastrophe machines, the present machine is based for the first time on the snapping of a continuous flexible element, namely an elastic rod. In addition to opening new perspectives in the mechanical design for advanced technologies, the developed *elastica catastrophe machine* finds application as a tool for teaching mechanics at different levels, ranging from public exhibitions for untrained public to PhD programs.

René Thom initiated in 1969 the celebrated framework of catastrophe theory [3] to provide interpretation to sudden large changes in the configuration of complex systems as the result of a small variation in the boundary conditions. Over the years, concepts of this theory have been exploited to explain instability phenomena in the mechanics of fluids, solids, and structures, but also in optics, physical chemistry, economics, biology and sociology.

Few years later, Erik Christopher Zeeman invented and realized in 1972 a simple but intriguing mechanical device [4] to illustrate for the first time concepts of catastrophe theory, Fig. 1 (left). The 'Zeeman's catastrophe machine' is a two-spring system composed by two elastic rubber bands tied together through a knot pinned on a disk that can only rotate around its center. The other end of the first elastic band is pinned to a fixed point while that of the second elastic band is held by hand, controlling its position within the plane. The number of equilibrium configurations for the system varies by changing the hand position. More specifically, the physical plane is found to be split in a bistable region inside a closed diamond-shaped curve and a complementary monostable region outside it. The closed curve represents the *catastrophe locus*, because when crossed by the hand position from inside to outside the system may snap.

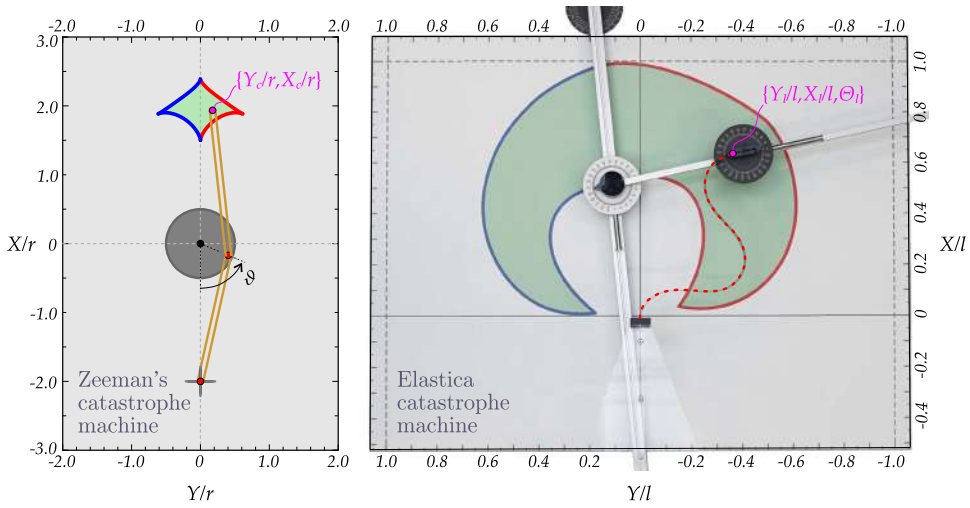

Figure 1: (Left) Sketch of the Zeeman's catastrophe machine and (right) the prototype of the developed *elastica catastrophe machine*. One of the two stable configurations available within the bistable green region is shown for the two rubber bands (left) and for the elastic rod (right).

Based on the recent concept of universal snap surface disclosed for planar elasticae with kinematically controlled ends [1], a catastrophe machine based on an elastic continuous element has been designed and realized for the first time [2], Fig. 1 (right). A general theoretical framework has been developed by extending that of the classical catastrophe machines made up of discrete elastic systems. Similarly to the classical system, the *elastica catastrophe machine* splits the plane in monostable and bistable regions, but now it is a flexible continuous element that displays a snapping mechanism when the controlled end properly crosses the catastrophe locus from inside to outside, Fig. 2. Furthermore, substantial changes in the catastrophe locus properties, such as convexity and number of bifurcation points, are achievable by tuning the design parameters.

In addition to opening new perspectives in the design of cycle mechanisms for actuation and dissipation devices towards energy harvesting, locomotion and wave mitigation, the proposed model finds obvious pedagogical application with reference to catastrophe theory in combination with snapping mechanisms in structural mechanics.

SMART PIV – FLOW VISUALIZATION WITH SMARTPHONES FOR EDUCATION IN FLUID MECHANICS

Christian Cierpka*[1], Constanze Poll[2], Jonas Hüther[2], Sebastian Jeschke[2], Henning Otto[1] and Patrick Mäder[2]
[1]Institute of Thermodynamics and Fluid Mechanics, Technische Universität Ilmenau, Germany
[2] Group for Software Engineering for Safety-Critical Systems, Technische Universität Ilmenau, Germany

Summary Flow visualization is important to understand the underlying non-linearity in fluid mechanics. Students are often astonished encountering surprising effects for example by increasing the Reynolds number in a flow around a cylinder. The SmartPIV app allows them to use their smartphones for the determination of velocity fields on-line in class and export the results for later analysis in lab reports.

INTRODUCTION

Flow visualization is important to understand the underlying non-linearity in fluid mechanics. Students are often astonished encountering surprising effects for example by increasing the Reynolds number in a flow around a cylinder. An advanced optical method to determine the vector field of a flow is particle image velocimetry [1]. In the basic configuration the flow of interest is seeded with so called tracer particles. These tracer particles are illuminated by a thin laser light sheet and their images are recorded by a digital camera. Two images within a very short time span enables to follow the particle displacement, for example by cross correlation or optical flow analysis. With known magnification the velocity can be determined and allows to characterize the instantaneous flow field. However, commercial PIV systems for scientific purposes with double pulse lasers and scientific cameras are very expensive (~100.000 Euro) and very complex. Thus these systems are only seldom used for teaching. Another problem arises that students are very often afraid of using complex and expensive systems.
On the other hand, nowadays students use their smartphones in daily live very intuitively without any reservation. Modern devices incorporate a multitude of sensors and large computational power and are therefore already used for education in physics classes [2,3], as well as for flow visualization by Schlieren techniques [4,5] or for the determination of surface tension [6] and other mechanical properties of fluids [7]. Most smartphones also contain very powerful cameras allowing frame rates of up to 920 Hz and thus very short time distances between images. Therefore these systems are suited for recording PIV images and the comparison with scientific equipment shows that smartphone videos are principally suited for the determination of the velocity field using low cost continuous lasers or LEDs [8]. Aguirre-Pablo et al. [9] even showed the successful application of smartphones for the tomographic reconstruction using pulsed colored LEDs and several smartphones imaging a scene from different angles. However, all these systems use off-line processing of the videos recorded by the smartphone. The aim of the current study was therefore to develop a smartphone app that allows for the on-line evaluation of the images to give a direct feedback for the students in course and to be able to process videos and export the corresponding results for reports of practical lab sessions.

SMART PIV

The app was developed within a student software project in close collaboration between students of engineering and computer science. It is available for Android and IOS in the app stores and can be downloaded and used free of charge. Since the ability for on-line flow visualization was most crucial concerning computer performance also optical flow algorithms were implemented as these request much less resources. On current smartphone the data evaluation time is in the order of ~200 ms for the correlation based algorithm and about ~30 ms for optical flow, which is fast enough for smooth visualization. After choosing the processing parameters (Fig. 1 left) the user can directly process the images from the live preview (Fig. 1, right), record videos or process already stored videos.

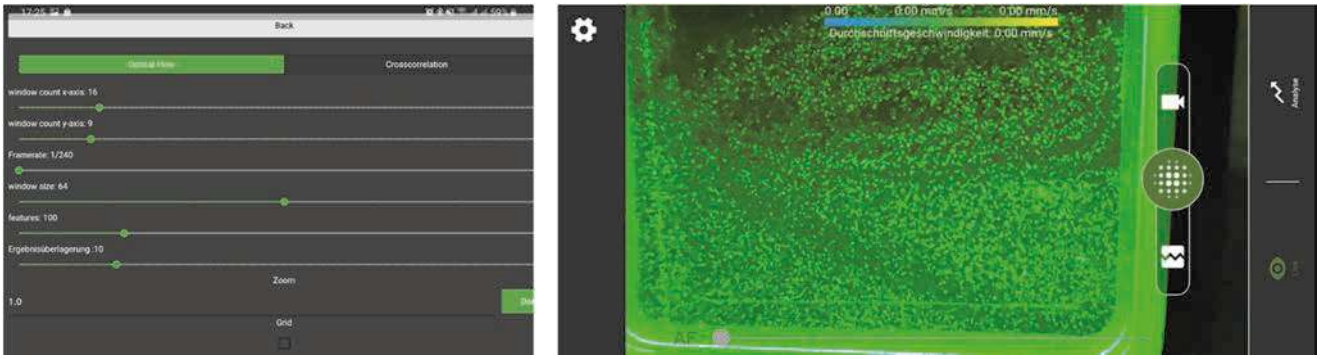

Figure 1. Menu for parameter settings (left) and main preview screen of the smartPIV app (right).

*Corresponding author. E-mail: christian.cierpka@tu-ilmenau.de.

Images as well as videos can also be stored for later export for lab reports. In addition to the images a text file and a csv file will be created that can be used for later analyses for example to test different mean estimators and outlier detection methods that will typically be taught in lab classes. Since for the conversion of the particle image displacement to physical coordinates the knowledge of the optical magnification is necessary a module that allows for a quick calibration using a square white paper with known side length was also included. Since typical fields of view are in the range of 1-20 cm the side length of the calibration target can be adopted to these values. The app can be intuitively controlled by users that are familiar with the video or photo function of their smartphones as the menus are designed very similar. A photograph of the application of smrtPIV for a test flow using a low power continuous laser diode and a fluidic actuator based on surface acoustic waves are shown in Fig. 2.

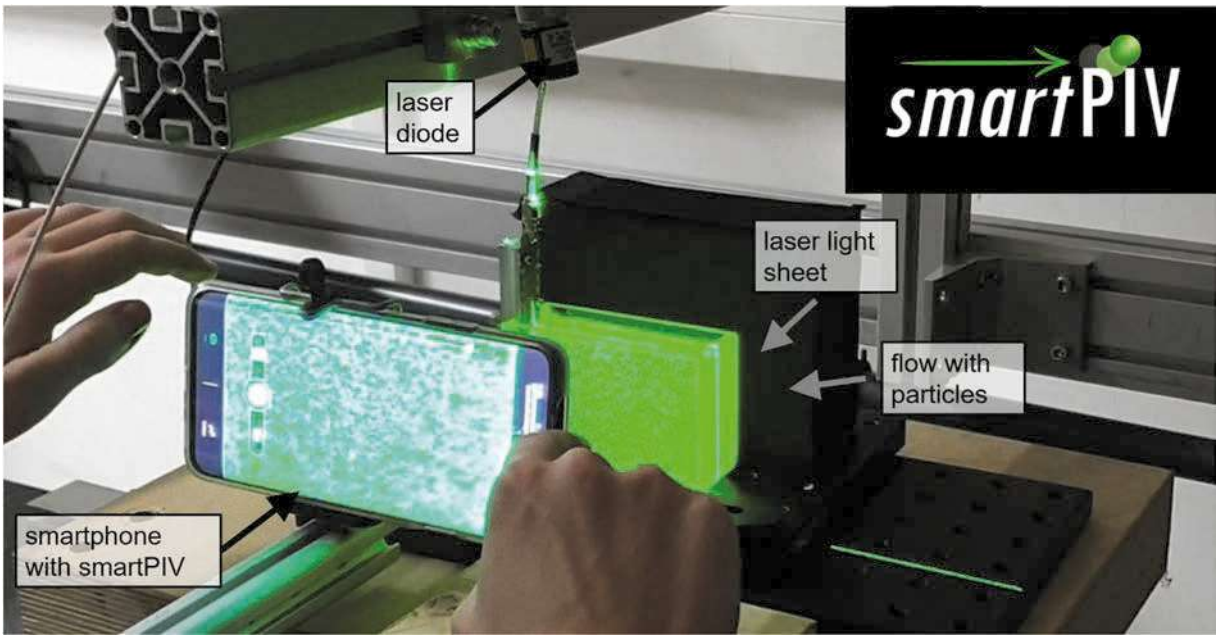

Figure 2. Experimental setup including a continuous laser diode and the smartphone with the preview screen of the smartPIV app.

CONCLUSIONS

The app smartPIV was developed for the velocity determination within lab session based on cross-correlation or optical flow. The app uses the fast camera and computational resources of modern smartphones and can be used in conjunction with a continuous laser to build a low-cost PIV system for educational use. The app also allows for a simple calibration and the storage and export of processed videos for later lab reports. Other than for teaching the app also might be helpful to get a first glimpse on flow velocities in nature or other technical processes even in harsh environments.

ACKNOWLEDGEMENTS

VIDEO ANALYSIS OF A ROWING KINEMATICS: A CASE STUDY USING OPEN SOURCE TRACKING SOFTWARE AS A TEACHING TOOL

David McKeown[1]
[1]School of Mechanical and Materials Engineering, University College Dublin, Dublin, Ireland

Summary The use of real-life examples in mechanics education can greatly help embed difficult concepts into the minds of students, but a lecture theatre is not real life. Examples from textbooks are generally contrived and limited to sketches capturing only a snapshot in time. Three dimensional animations overcome some of these limitations allowing a time varying representation, but still lack the realism and relatability of real-world examples. Demonstrations in class can be impactful but suffer from reliability, maintainability and are limited due to portability. This paper explores the uses of video analysis of mechanical systems as a teaching aid. The set up required to achieve the automated tracking of features is examined using the case study of a rower's motion captured using a bespoke low-cost tracking system and open source analysis software.

Introduction

The motivation for the cased study was the design of a wrist prosthesis for a 16 year old male rower with a transradial upper limb deficiency. Information about this natural rowing stroke was required implement limits on the range of motion of prosthetic wrist. The project lacked funding or access to a high-end commercial motion tracking system, so I bespoke low cost system was developed. Coloured markers were manufactured from toy rubber balls sliced in half and covered in coloured electrical tape, as shown in Figure 1. These were placed on the body of the rower's joints using double sided adhesive tape. The rower's motion was recorded in a rowing tank. This an indoor training setup where the rower remains stationery and water is pumped around the rower, as shown in Figure 2. This allowed for recording of the rowing stroke using stationary cameras. Four go-pro cameras were set up to record the rower from the left and right sides, from in front and above.

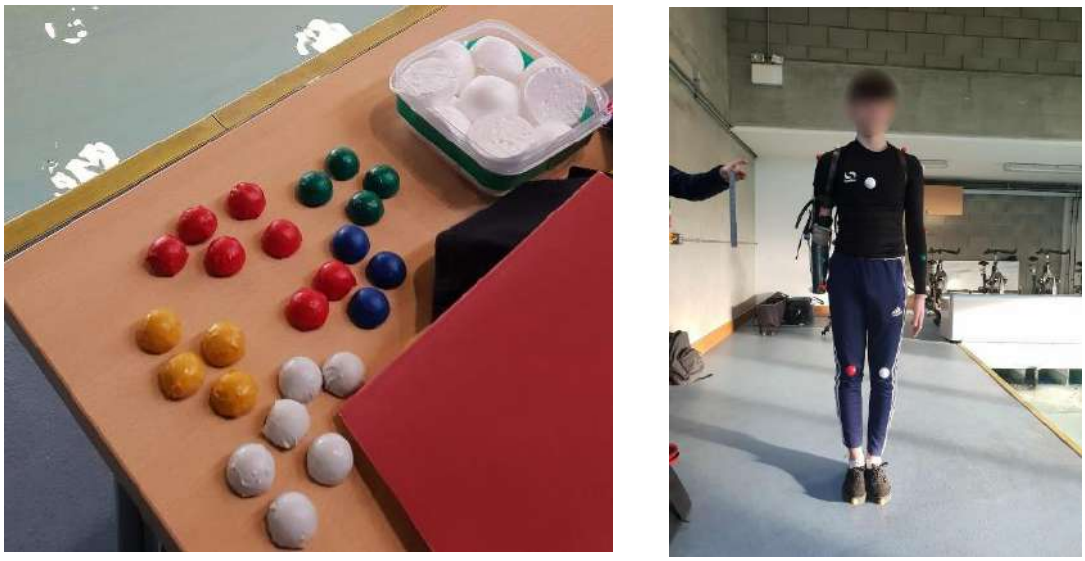

Figure 1. Markers for tracking (left). Rower wearing markers (right)

Software

The ability of track features from one video frame to next is using an automated or semi-automated method is available in a number of software packages. The author found 3 open source software packages, Tracker [1], Kinovea [2] and Mokka [3], which provided this feature. For this study the analysis Tracker was used. It provides automated and manual tracking of features based on matching an updating reference template. The success of this depends on the light conditions and the contrast of the markers with the surroundings. Another limitation is that some markers can become hidden to the camera during parts of the stroke. The video can be annotated with the result of the feature tracking and graphs of the kinematic data automatically produced. If mass and moment of inertia data is assigned to features of force vectors can also be annotated on to the video.

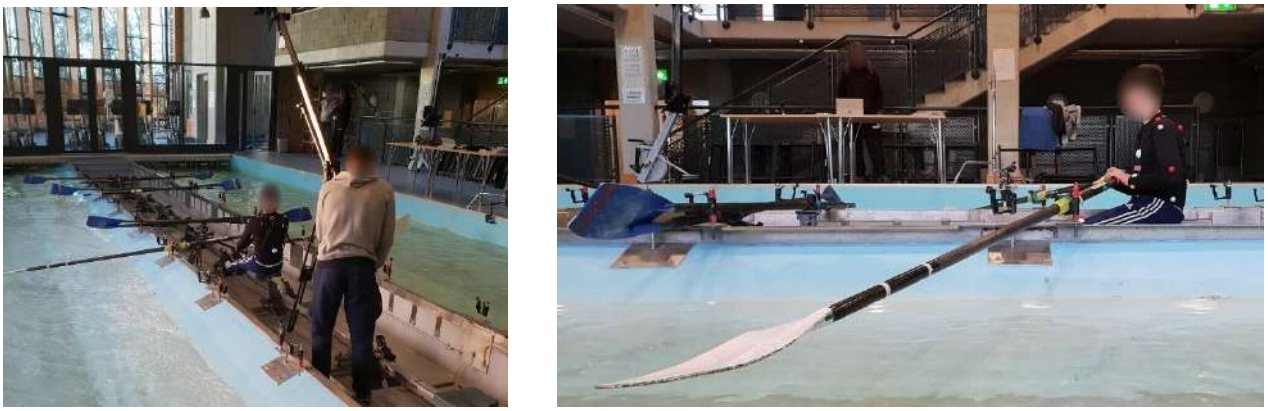

Figure 2. Overhead camera rigging (left). Side on camera (right)

Results.

Figure 3 shows Tracker software sample annotations from the overhead camera. In the figure two joints have been tracked, the left wrist in yellow and the left elbow in cyan. To the right of the video a time series plot of the vertical displacement of the wrist is shown as an output of the automatic marker tracking. Plots of velocity and acceleration (not shown) are also auto generated. The axes (magenta lines) can be aligned to in the direction of motion. The bottom right shows an exportable table of the same data.

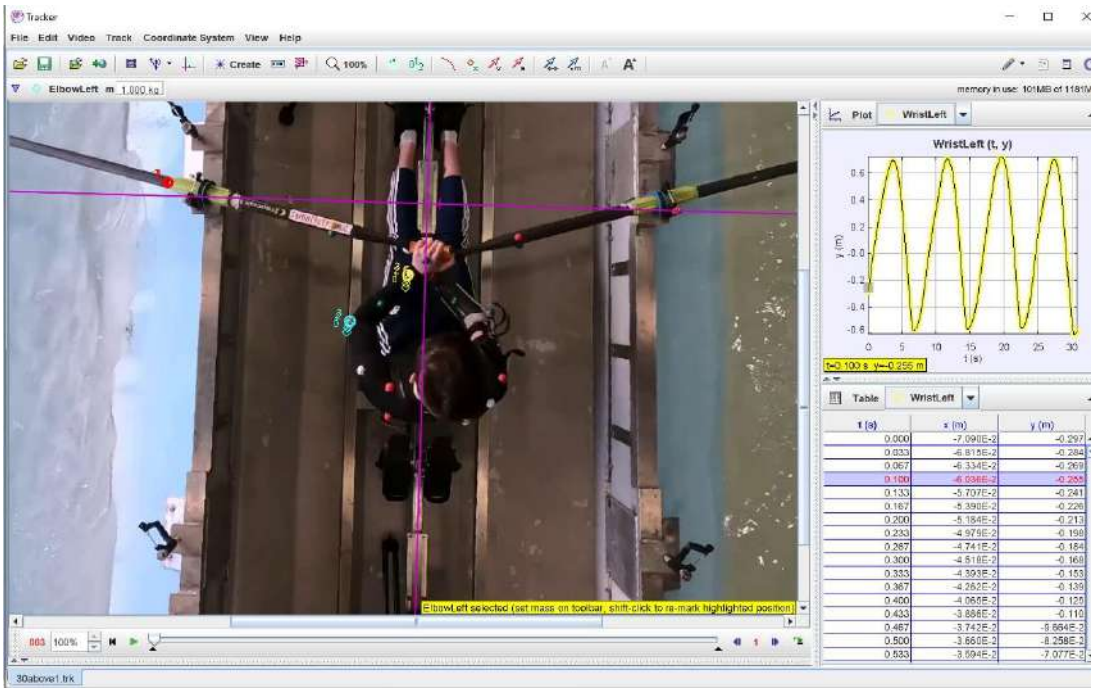

Figure 1. Screenshot of Tracker software. The graphs show the vertical (y-axis) motion of the left wrist marker.

CONCLUSIONS

Software to extract kinematic parameters from videos is powerful and can be relatively simple. It shows good promise as a useable teaching aid especially for reinforcing learning in combination with problem solving through more traditional approaches.

METHOD OF ANALOGY FOR A WALKING ROBOT AND A GRIP

Yury Golubev[12] and Elena Melkumova*[1]
[1]Moscow State University, Moscow, Russia
[2]Keldysh Institute of Applied Mathematics, RAS, Moscow, Russia

Summary Theoretical mechanics and mechatronics methods help to solve the walking robot with a grasp problem. We teach our students in Moscow State University by lectures and seminars. These methods are used in statics and dynamics. We consider the problem of a fragile cylinder grasping by the manipulator fingers. Each finger contacts the cylinder in a single supporting point. Using numerical simulations and analytically, possible locations of the contact points on the cylinder, for which there is a kinetostatics problem solution when the cylinder is moved by four fingers, are received. As V.V. Kozlov said, aerobatics are analogies. We use an analogy of the equilibrium of a four-legged robot on a cylinder for the problem of transfer by a manipulator with a four-finger grasp of a fragile rough cylinder. The work was supported by the Russian Foundation for Basic Research (grant No. 19-01-00123 A).

INTRODUCTION

During the teaching we use the book [1] for the lectures and seminars in the Theoretical Mechanics and Mechatronic Chair of the Faculty of Mechanics and Mathematics of Lomonosov Moscow State University. In [2] we continue the series of the manuals devoted to the Theoretical Mechanics methods, issued by our chair. The book is addressed in addition to the students of the Optimal Control, Nonlinear Dynamics System and Control Processes, System Analysis Chairs of the Faculty of Computational Mathematics and Cybernetics of Lomonosov Moscow State University. Basic types of the problems for the first part of the Theoretical Mechanics Course: Kinematics, with expanded solutions are given in the manual. This book is for students and postgraduate students and also for Theoretical Mechanics teachers. The full program of lectures for the Faculty of Computational Mathematics is in our book [2] which is for seminars too.

FORMULATION OF THE PROBLEM

If during driving the car you see the turtle on the road, you save it. But how one robot with a manipulator can help to another. Let the corpus is cylinder. How to hold it. The analytical and the numerical parameter diagrams for two fields of supporting points are shown. A man's hand has five fingers. It is shown in [3-10] that when the number of support points of a walking robot inside a smooth horizontal cylinder increases to two, the support set is divided into two subsets. Similarly in fig. 1. The capture of a tortoise shell by a human hand is shown. One finger on one side and two on the other. In fact, two would have been enough. However, for a more comfortable and confident grip, it is desirable to use four fingers. For more complex surfaces or when changing the capture points are not superfluous, as practice shows, all five fingers.

Figure 1. Division of a reference set into two subsets.

*Corresponding author. E-mail: elena_v_m@mail.ru.

It is assumed that the arms, fingers, and legs of the robot make a predetermined movement relative to the robot body. The kinetic moment of the robot relative to the point is considered. In order for the given motion to be realized, reactions at the fulcrum must satisfy the kinetostatic equations. The first vector equation is responsible for changing the amount of movement of the robot. It is equivalent to the three scalar equations in projection onto the selected axes. The second equation of the system determines a given change in the kinetic moment.

We restrict ourselves to the case when active force $\tilde{\mathbf{\Phi}} \neq 0$ and perpendicular to momentum $\tilde{\mathbf{M}}$. We give the system $\{\tilde{\mathbf{\Phi}}, \tilde{\mathbf{M}}\}$ to the resultant at the point C [11 – 16]. Point C will also be the point of application of the resultant reactions. For example, point C may be the center of mass of the transferred object.

CONCLUSIONS

During the robot motion, one, two and three supporting point phases are changed. And for example the humanoid robot with five arm fingers can hold the object by one and grasp by two, three or four fingers. The reaction distribution problem have a solution in following cases. Let we give some examples. For one-supporting point phase. So the motion existing condition is reaction is equal to force and supporting point and the point C are on the line along the force. And the angle between the force and the normal not exceed friction angle. As for two-supporting point phases. The grasp can be in the cylinder. The point C and the reactions have to be in the plane parallel to the force. If supporting points are on one diameter. When coefficient $E < 0$ [16]. And in some fields with connected set of points, when $E \geq 0$ [17]. Robot can hold the cylinder by two fingers on one diameter. Robot can hold the horizontal cylinder by three fingers. Let one of the points is in vertical plane containing cylinder axis and another are in the plane orthogonal to the axis. Without friction, the cylinder center of mass has to be in the vertical plane that contain the cylinder axis. The supporting points are on the external surface of the lower semi-cylinder and the center mass of the cylinder is in the footholds triangle. If the first supporting point is in the lower semi-cylinder and two another are on the upper, the center of mass has to be out of the footholds triangle. Four fingers can hold the cylinder in two pars symmetric points about the cylinder axis. Or two pairs of points in the rectangular planes. The supporting set is divided into two subsets. For example thumb and the rest except for the little finger. So the robot can transfer the cylinder by one, two, three or four fingers.

STRUCTURAL APPROACH TO TEACHING BASIC COURSES OF MECHANICS OF DEFORMED SOLID

Ekaterina Korovaytseva
Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary The work represents methodology of teaching disciplines of mechanics of solids which is based on defining types of problems solved and developing algorithms of solution for each type. Special attention is payed to such disciplines as strength of materials and structural mechanics. Classification of problems considered in mentioned courses is carried out on the basis of unity of mathematical formulations or structural models. The following algorithmization of problems solution includes step-by-step description of doings which reflect either methodical side of solution process or the process of drawing different structural models. Such an approach to teaching leads to significant reducing of content knowledge to be learnt, and at the same time rises generalizing level of knowledge.

In Russia specialty "Dynamics and strength of machines" provides the most complex training of specialists in the field of mechanics of solids. The specialty program supposes, besides humanities, studying of more than thirty general engineering and special disciplines. Instruction is provided mainly on the basis of textbooks of 70^{th}-80^{th} years of the last century, which seems quite reasonable, as mechanics of solids theory hasn't changed through the past 40 years. But in this period computing technology and its role in work of mechanic changed significantly. That's why, in our opinion, the problem of forming contemporary methodology of teaching mechanics of solids courses is still actual. This methodology should connect theoretical disciplines, such as elasticity theory, plasticity theory, plates and shells theory etc. with computing technology using, including both individual programming and using commercial software. Along with this, the most important goal of education process is, besides knowledge transmission, forming a way of thinking which will be required in future work of a specialist.

We distinguish two types of specialists trained in specialty "Dynamics and strength of machines" – scientists (mechanicians) and mechanical engineers. Both types of specialists are taught the same courses by the same methodology, but their purposes in future work are different. The scientists should provide engineering calculations by algorithms, methodology and programs of a high quality, while engineers should be able to use the results of the scientists' work consciously, understanding features of real structures calculation – both properties of the resolving equation systems and properties of calculation process realizing various methodologies or algorithms.

As it is known, "computer multiple times rises level of incompetency of a user". That is why general engineering courses, teaching analytical solution of mechanics of solids problems, are of important value. We developed methodology of strength of materials teaching, the purpose of which is not only knowledge transmission, but also developing skills of finding common patterns, cause-and-effect relations, which allows in future successfully working with large amounts of information when studying individually or in working practice.

Within the framework of this methodology problems of strength of materials are accumulated into 22 types, for each of which solution algorithms are formulated [1]. Problems classification is carried out by the following characteristics:
- type of stress-strain state considered (tension-compression, torsion, bending, combined stress state);
- structure type (rod, beam, plane frame, space frame, shell);
- calculation type (strength, stability, impact).

Also we emphasize unity of different stress-strain types calculation problems from the point of view of mathematical formulation of corresponding problems. For example, structural notation of the rod infinitely small element equilibrium differential equations has the form

$$\frac{dR}{dx} = G(x),$$

where

$$R = \begin{cases} N & \text{for tension-compression} \\ M_к & \text{for torsion} \\ Q_y & \text{for straight transverse bending} \\ M_z & \text{for pure and straight transverse bending} \end{cases} ; \quad G(x) = \begin{cases} q_x(x) & \text{for tension-compression} \\ m_к(x) & \text{for torsion} \\ q_y(x) & \text{for straight transverse bending} \\ Q_y(x) & \text{for pure and straight transverse bending} \end{cases}$$

Structural formulae for calculating maximum stresses, generalized strains and displacements, single for any of four types of elementary stress-strain state, are constructed similarly.

In such a way we develop an ability to find unity or logical connection of problems which seem different at the first site. The students are encouraged to form logic and structural properties of thinking, to be sure in their ability of solving any problems with given structural models.

Using structural approach in strength of materials course allows simply passing to teaching structural mechanics as the most important course for developing skills of carrying out calculations of real structures. We suggest, after introducing the students to theoretical basis of the course, demonstration of unity of the problems considered both in structural mechanics and real calculation practice – unity from the point of view of mathematical formulation. For example, for the course of structural mechanics we suggest introducing three canonical forms of linear boundary

problems of mechanics of deformed solid. These forms can describe behavior of the simplest and complex branched structures as well [2]:
1) two-point boundary value well-posed problems without additional relations (canonical form I);
2) multi-point unbranched boundary value well-posed problems without additional relations (canonical form II);
3) multi-point branched boundary value well-posed problems without additional relations (canonical form III).

Suggested forms can be used for structuring notation of equations of any structure elements deforming. For example, canonical form I includes differential equations

$$\frac{dy}{dx} = \mathbf{A}(x,\mu)y + a(x,\mu), \tag{1}$$

and boundary conditions

$$\mathbf{B}_i(x_i,\mu_i)y_i + b_i(x_i,\mu_i) = 0; \quad i \leftrightarrow e. \tag{2}$$

Here $y(x,\mu)$, $y_i(x_i,\mu_i)$ are vectors of resolving variables, $\mathbf{A}(x,\mu)$, $\mathbf{B}_i(x_i,\mu_i)$ are coefficient matrices, $\mu(x)$, μ_i are vector-function and vector of initial values of the problem parameters, $a(x,\mu)$, $b_i(x_i,\mu_i)$ are vectors of external distributed and concentrated loads correspondingly, i and e are indices denoting values of variables and argument at the initial and end point of integration interval correspondingly. For example, vector of resolving variables y can have the form

$$y = \begin{cases} \{w;\ \vartheta;\ Q_y;\ M_z\}^T & \text{for the beam} \\ \{w;\ \vartheta;\ Qr;\ M_1 r\}^T & \text{for symmetrically loaded round plate} \\ \{u;\ w;\ \vartheta_1;\ T_1;\ Q_1;\ M_1\}^T & \text{for symmetrically loaded shell of revolution} \end{cases}$$

Similar to strength of materials course, for each canonical form we represent an algorithm of corresponding problem solution. Special attention is payed to teaching skills of analyzing considered equation system properties, taking into account features of using this or that numerical method, developing skills of individual constructing problem solution algorithms and further structural programming.

The results of this teaching method are both complex structural way of thinking forming and developing culture of scientific work. This culture is precondition for protecting computer-aided scientific and engineering research from the mistakes of the computer man.

EFFECTIVE TEACHING OF VECTOR TO MITIGATE TENSOR-PHOBIA IN MECHANICS AND APPLICATION OF EXTERIOR FORM

Ade Akinola * [1], Bolanle Olokuntoye[1], Adebowale Borokinni[1], Odunayo Fadodun[1], and Olawanle Layeni[1]
[1]Department of Mathematics, Obafemi Awolowo University, Ile-Ife, Nigeria

Summary We interrogate the observed proclivity of students of mechanics and engineering and some scientists to nursing phobia towards *Tensor*, known as "*tensor-phobia*" [1-3]. An effective cognitive teaching approach needs urgent attention: to let students see the connection between tensors and vectors, as common invariants. Students are made to carry out simple operations using *invariant/rank* concept. Here, we reveal how the familiar vector operations form synergy with isotropic tensors; and demonsrtate how the *exterior form* behaves as "skew-symmetric tensor". Invoking Poincare's theorem on *differential forms* we reduce the equations of state for plane elasticity to a differential form and show the source of *Airy's Function* deduction. The application of this cognitive principle is used in deriving effective moduli for composites; and on strain-gradient plasticity problem [4].[0]

INTRODUCTION

It is of utmost necessity that most basic engineering designs make ample use of vector concepts [2,3]; and a proper grasp of this is quite imperative [1-3]. But more, any significant modern designs and engineering analysis is unfathomable without proper comprehension of the basics of tensor analysis [3]; particularly so, where it is a *fait accompli* to invoke the concept of continuum mechanics. In fact, in continuum mechanics, without being well grounded in tensor it could be practically quite strenuous interrogating some vital engineering concepts that include: invariants of objects such as stress, strain, material characteristics and others that copiously make use of the Hamilton-Cayley theory; energy function and its tensor derivatives; homogenization theory that enables the delicate navigation through complex relations involved in heterogeneous media and the deduction of effective characteristics of composites.

Observation over the years revealed that while students and researchers in mechanics show some degree of understanding of vector concepts they depict tendency to nurse phobia for tensor, in what is often known to as "*tensor-phobia*" [1]. If this is not properly addressed, it could have a ramifying implication on the development of continuum mechanics and related subject at a later stage. However, the adoption of an appropriate cognitive teaching approach would help mitigate the situation. A potent approach is to let students see early enough the connection between tensor and vectors, for which they already had acquaintance from the secondary or high school. This makes them carry out simple operations, which they were used to, such as *scalar product*, *vector product* and others on vectors, using *invariant/rank* concept. As an illustration, we demonstrate how the already familiar primary vector operations (the *dot* and *cross* products) form synergy with the so-called isotropic tensors. Also, we show how the *exterior form* behaves as skew-symmetric tensor defined on basis, as multiple vector products (now known as *exterior products* or *wedge products*). Then, using the Poincare's theorem on *differential forms* we reduce the equations of state for plane elasticity to a differential form and hence show the basis of *Airy's Function* deduction.

VECTOR OPERATIONS, ISOTROPIC TENSOR, EXTERIOR FORMS

Dot and Cross Vector Product Operations and Isotropic Tensor

Consider, without loss of generality, vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$ and what we call the rank-2 *isotropic tensor* $\underset{\sim}{\mathbf{I}} = g^{ij}\mathbf{e}_i\mathbf{e}_j = \mathbf{e}^j\mathbf{e}_j$ and rank-3 *isotropic tensor* $\underset{\sim}{\epsilon} = \epsilon^{ijk}\mathbf{e}_i\mathbf{e}_j\mathbf{e}_k$ in the three dimension Euclidean space E^3, $i, j, k = 1, 2, 3$; $\mathbf{e}_i$ and $\mathbf{e}^i$ are the orthogonal covariant and contravariant base vectors respectively. Then recalling from the elementary vector theory, *dot product* is $\mathbf{a}\cdot\mathbf{b} = \mathbf{b}\cdot\mathbf{a}$, *cross product* is $\mathbf{b}\times\mathbf{a} = -\mathbf{a}\times\mathbf{b}$, while the *scalar triple product* is $\mathbf{a}\cdot(\mathbf{b}\times\mathbf{c}) = (\mathbf{a}\times\mathbf{b})\cdot\mathbf{c}$. Now, the cross product of vectors $\mathbf{a}$ and $\mathbf{b}$ can be given with the aid of $\underset{\sim}{\epsilon}$, such that $\mathbf{a}\times\mathbf{b} = \underset{\sim}{\epsilon}\cdot\cdot\,\mathbf{a}\,\mathbf{b}$. In fact,

$$\mathbf{a}\times\mathbf{b} \equiv \begin{vmatrix} \mathbf{k}_1 & \mathbf{k}_2 & \mathbf{k}_3 \\ a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \end{vmatrix} = \begin{vmatrix} a_2 & a_3 \\ b_2 & b_3 \end{vmatrix}\mathbf{k}_1 + \begin{vmatrix} a_3 & a_1 \\ b_3 & b_1 \end{vmatrix}\mathbf{k}_2 + \begin{vmatrix} a_1 & a_2 \\ b_1 & b_2 \end{vmatrix}\mathbf{k}_3 = c_m\mathbf{k}_m \equiv \mathbf{c} = \epsilon^{ijk}a_ib_j\mathbf{e}_k = \underset{\sim}{\epsilon}\cdot\cdot\,\mathbf{a}\,\mathbf{b}, \tag{1.1.1}$$

where $m = 1, 2, 3$, c_1, c_2, c_3 are the minor to the orthonormal base vectors $\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3$ respectively; and for simplicity, in the cartesian coordinates, the components of $\underset{\sim}{\epsilon}$ become the *Levi Chivita symbols* $e^{ijk} = e_{ijk}$.

[0]**Prologue:** *Perhaps the best evidence of the remarkable effectiveness of the tensor apparatus in the study of Nature is in the fact that it was possible to include, between the covers of one small volume a large amount of material that is of interest to mathematicians, physicists and engineers. – Sokolnikoff, I. S.*

Cofactor

Further, given any rank-2 tensor $\underset{\sim}{\mathbf{T}}$, its *cofactor tensor* $\underset{\sim}{\mathbf{T}}^c$ can be obtained simply as the *dyad* of vector $\mathbf{e}_i \times \mathbf{e}_j$ and vector $(\underset{\sim}{\mathbf{T}} \cdot \mathbf{e}^i) \times (\underset{\sim}{\mathbf{T}} \cdot \mathbf{e}^j)$ such that

$$\underset{\sim}{\mathbf{T}}^c = [(\underset{\sim}{\mathbf{T}} \cdot \mathbf{e}^i) \times (\underset{\sim}{\mathbf{T}} \cdot \mathbf{e}^j)][\mathbf{e}_i \times \mathbf{e}_j] = \frac{1}{2}\epsilon_{skq}\epsilon^{mnp} T_n{}^k T_p{}^q \mathbf{e}^s \mathbf{e}_m. \tag{1.1.4}$$

Thus, the *1st invariant* $I_1(\underset{\sim}{\mathbf{T}})$ and *2nd invariant* $I_2(\underset{\sim}{\mathbf{T}})$ of tensor $\underset{\sim}{\mathbf{T}}$ can be given through the double dot product:

$$I_1(\underset{\sim}{\mathbf{T}}) = \underset{\sim}{\mathbf{I}} \cdot \cdot \, \underset{\sim}{\mathbf{T}}, \; I_2(\underset{\sim}{\mathbf{T}}) = I_1(\underset{\sim}{\mathbf{T}}^c) = \underset{\sim}{\mathbf{I}} \cdot \cdot \, \underset{\sim}{\mathbf{T}}^c = \frac{1}{2}[I_1^2(\underset{\sim}{\mathbf{T}}) - I_1(\underset{\sim}{\mathbf{T}}^2)]. \tag{1.1.5}$$

This process can be followed to, compute other invariants, obtain the Hamilton-Cayley relation and other tensor functions.

Exterior Form, Differential Form

An *exterior form* $\Phi = \varphi_{i_1 i_2 \ldots i_{m-1} i_m} \mathbf{e}^{i_1} \Lambda \mathbf{e}^{i_2} \cdots \Lambda \mathbf{e}^{i_{m-1}} \Lambda \mathbf{e}^{i_m}, \quad m = 1, 2, 3, \ldots,$ becomes a *differential form* $\omega = a_{i_1 i_2 \ldots i_{m-1} i_m}(x^1, x^2, \ldots, x^{n-1}, x^n) dx^{i_1} \Lambda dx^{i_2} \ldots \Lambda dx^{i_{m-1}} \Lambda dx^{i_m}$ by replacing **(i.)** the base elements *covectors* $\mathbf{e}^{i_k}, k = 1, 2, 3, \ldots$ with the *differentials* dx^k, where **(i.)** the object $\varphi_{i_1 i_2 \ldots i_{m-1} i_m}(x^1, x^2, \ldots, x^{n-1}, x^n)$ in an n-dimensional Euclidean space E^n with the function $a_{i_1 i_2 \ldots i_{m-1} i_m}(x^1, x^2, \ldots, x^{n-1}, x^n) \in C^m(\Omega), \quad m \geq 1, \quad \Omega \subset E^n$, often referred to as the *Cartan's ring of coefficients* and **(ii.)** the base elements *covectors* $\mathbf{e}^{i_k}, k = 1, 2, 3, \ldots$ with the *differentials* dx^k.

Poincare's Theorem:

The second exterior differential of an exterior form is zero,

$$\mathcal{D}\mathcal{D}\omega = 0,$$

where $\mathcal{D}\mathcal{D}\omega = \dfrac{\partial^2 a_{i_1 i_2 \ldots i_{m-1} i_m}}{\partial x^j \partial x^k} dx^k \Lambda dx^j \Lambda dx^{i_1} \Lambda dx^{i_2} \ldots \Lambda dx^{i_{m-1}} \Lambda dx^{i_m}$.

Application of Poincare's Theorem in Plane Elasticity

Theorem: The Airy's function $\phi(x_1, x_2)$ constitutes a *form* describing the state of stress $\sigma_{ij}, i, j = 1, 2,$ equivalent to the elastostatic equations of *plane elasticity* $\frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{12}}{\partial x_2} = 0; \; \frac{\partial \sigma_{12}}{\partial x_1} + \frac{\partial \sigma_{22}}{\partial x_2} = 0$ only and only if $\sigma_{11} dx_2 - \sigma_{12} dx_1$ and $\sigma_{22} dx_1 - \sigma_{12} dx_2$ respectively is an exact differential - *a form.*

Proof: By Poincare's theorem, ω is an exact differential if $d\omega = 0$. Thus, $\sigma_{11} dx_2 - \sigma_{12} dx_1$ is an exact differential $\Longrightarrow$ $D(\sigma_{11} dx_2 - \sigma_{12} dx_1) = 0$. In deed, we have

$$D(\sigma_{11} dx_2 - \sigma_{12} dx_1) = \frac{\partial}{\partial x_1}(\sigma_{11} dx_2 - \sigma_{12} dx_1) dx_1 + \frac{\partial}{\partial x_2}(\sigma_{11} dx_2 - \sigma_{12} dx_1) dx_2$$

$$= \left(\frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{12}}{\partial x_2}\right) dx_2 \Lambda dx_1 = 0; \; \text{since } dx_1 \Lambda dx_1 = dx_2 \Lambda dx_2 = 0. \implies \left(\frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{12}}{\partial x_2}\right) = 0.$$

Conversely: Let $(\frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{12}}{\partial x_2}) = 0. \implies d(\sigma_{11} dx_2 - \sigma_{12} dx_1) = 0$. Then, $\sigma_{11} dx_2 - \sigma_{12} dx_1$ is an exact differential. $\Longrightarrow \; \exists$ function $P(x_1, x_2)$;

$$\sigma_{11} dx_2 - \sigma_{12} dx_1 = dP(x_1, x_2) = \frac{\partial P}{\partial x_1} dx_1 + \frac{\partial P}{\partial x_2} dx_2; \implies \sigma_{11} = \frac{\partial P}{\partial x_2}, \; \sigma_{12} = -\frac{\partial P}{\partial x_1}.$$

$$\text{Similarly, } \exists\, Q(x_1, x_2); \; \sigma_{22} dx_1 - \sigma_{12} dx_2 = \frac{\partial Q}{\partial x_1} dx_1 + \frac{\partial Q}{\partial x_2} dx_2; \implies \sigma_{22} = \frac{\partial Q}{\partial x_i}, \; \sigma_{12} = -\frac{\partial Q}{\partial x_2}.$$

$$\text{By Poincare}'\text{s theorem } \exists\, \phi; \; \sigma_{11} = \frac{\partial^2 \phi}{\partial {x_2}^2}; \quad \sigma_{22} = \frac{\partial^2 \phi}{\partial {x_1}^2}; \quad \sigma_{12} = -\frac{\partial^2 \phi}{\partial x_2} \partial x_1.$$

CONCLUSIONS

Deep understanding of vector, vector operations and their physical implications, as well as early introduction as a *lower-level invariant* assists to demystify key concepts of tensor, geometry, exterior forms and their applications; which are vital tools for navigating the complex labyrinths of mechanics, application to technology and nature in general.
